tion ships in terms of electrostatic principles and for head on-alignment of ion and dipole, the equation becomes

$$E_s = E_\mu - \frac{N_Z \mu}{D_r^2} \qquad (5)$$

According to this equation, when the energy of activation is plotted against the dipole moment of dipolar molecules reacting with ions, the plot should be linear with a negative slope if the reacting ion is positive in charge, and with a positive slope if the ion is negative in charge.

In the present case, though the difference of dipole moments of alcohols is less, energy of activation has been plotted against 'μ'. It can be seen from that the plot is a straight line with a negative slope (Fig. 2), which means in this case the reacting ion is a positively charged I^+ ion reacting with a dipolar molecule like alcohol ($CH_3OH \rightleftharpoons CH_3O^- + H^+$). This also proves that in the case $ICl \rightleftharpoons I^+ + Cl^-$, a product like CH_3OI is expected not to be a chloride derivative. This has also been confirmed by the estimation of Cl^- ions, as AgCl, that no Cl^- ions are consumed during the course of the reaction.

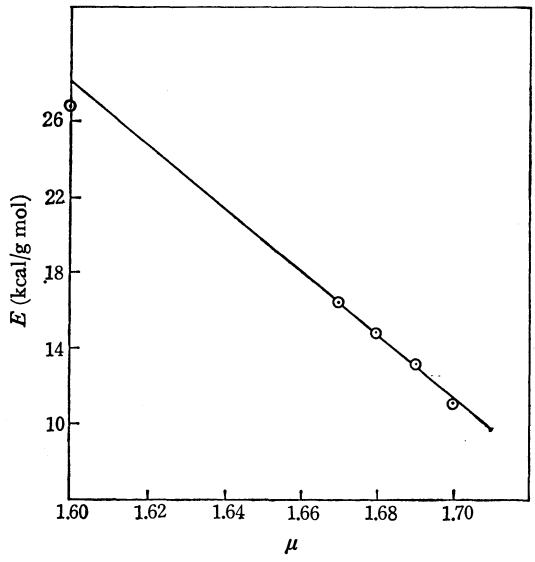

Fig. 2. Plot of E *vs.* μ for the reaction of ICl with alcohols.

Product Identification. The product in each case has been identified by IR spectrum (Fig. 3). A sharp peak at 1620 cm^{-1} confirms a (O–I) bond stretching[21] in the product. This confirms that iodo derivative of the type R–O–I is formed.

Mechanism. ICl being a highly reactive species and a polar compound, it is easily ionized in a medium of alcohols having high dielectric constants according to either of the following equations.

$$ICl \longrightarrow I^+ + Cl^- \qquad (1)$$

$$I_2Cl_2 \longrightarrow I^+ + ICl_2^- \qquad (2)$$

The interpretation will be the same whether ionization takes place according to Eq. (1) or (2). The iododichloride ion (ICl_2^-) has been ruled out, since the iodinating agent with the iodine in the middle of the structure of (ICl_2^-) has an unfavourable geometry for substitution.[22] Ionization (1) is favoured at high dielectric constants, as has been observed by Bearcraft and Nachtrich.[23]

Alcohols are also polar compounds and it is quite reasonable to predict that alcohols combine with highly reacting species like I^+ ions according to the reaction

$$CH_3OH + I^+ = CH_3OI + H^+ \qquad (3)$$

showing that this is an ion-dipole type of reaction.

If step (1) were the rate determining step of the present reaction, then the rate of the reaction would have increased with the increase of dielectric constant of the medium. In the present case (Table 2), however it was observed that as the dielectric constant decrease, from methanol to butanol, the rate of the reaction

increases. This has also been confirmed from the straight line plot of $\log k$ against $100/D$.

It is also seen that addition of HCl does not change the specific reaction rate constant in these cases. Thus a reaction of the type $ICl+HCl=HICl_2$ is ruled out in this case, or if such a reaction takes place at all, the rate of reaction is extremely slow and indistinguishable kinetically.

The proposed mechanism is thus

$$ICl \xrightarrow{\text{fast}} I^+ + Cl^- \quad (1)$$

$$CH_3OH + I^+ \xrightarrow{\text{slow}} CH_3OI + H^+ \quad (2)$$

Step (2) is the rate determining step of the reaction as step (1) is an ionization process and very fast. A similar mechanism can be given for other alcohols.

The authors are grateful to Prof. E. Pickett, University of Missouri, U.S.A. and Prof. C. R. Kanekar of TIFR, Bombay, India for their kind help in carrying our IR analysis and supplying the pure ICl sample.

Electronic Structures and Spectra of Pyridinyl Hetero Diradicals. Charge-transfer Interaction between Two Different Radicals

Michiya Itoh

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo

(Received October 14, 1972)

Pyridinyl hetero diradicals, Py(Ac)·$(CH_2)_n$ Py(Car)·, (in which Py(Ac)· and Py(Car)· are 4-$CH_3OCC_5H_4N$· and 4-$CH_3OOCC_5H_4N$·, respectively, and $n=3$, 4, and 5) were obtained. Equilibrium between the open and closed forms in the hetero diradical $n=3$ was directly observed by temperature dependence of absorption spectra ($-\Delta H=5.6$ kcal and $\Delta S=-10.5$ e.u.). Electronic absorption spectroscopy and SCF–CI molecular orbital calculation reveal that the closed form shows a strong charge-transfer band from Py(Car)· to Py(Ac)· moieties. The electronic structure of the hetero diradical was discussed in relation to the electronic interaction between two different radicals.

Molecular complexes between two different free radicals, the hetero radical dimers may be considered to be a special case of the electron-donor-acceptor complex, both components of which are electron excess systems. From the viewpoint of the electronic structure, the hetero radical dimers may be isoelectronic with hetero nuclear diatomic molecule, although the hetero dimer involves no covalent bond between radical moieties.

While numerous investigations of the radical dimers[1-3] have been carried out, only few spectroscopic studies of the electronic interaction between two different radicals have been reported.[4,5] Recently, Yamazaki and Kimura[5,6] have demonstrated the complex formation of tetracene and perylene cation radicals in concentrated sulfuric acid at low temperature, where the cation dimers of each component were also observed.[7] In the previous papers, Itoh and Kosower[8] reported a strong intramolecular interaction of two pyridinyl moieties in the 1,3-dipyridinylpropane, Py(Car)·$(CH_2)_3$Py(Car)·. Subsequently, Itoh[9] demonstrated that the closed form of the pyridinyl cation radical, Py(Car)$^+(CH_2)_3$Py(Car)· was regarded to be the dimer cation which could not be observed in the mixed solution of the pyridinyl and pyridinium salt without tri- or tetramethylenes. On the other hand, importance and efficiency of the trimethylene group for the intramolecular interaction have been also emphasised in the excimer formation,[10,11] energy transfer[12] and fluorescence quenching.[13]

This paper presents a study of a new series of pyridinyl hetero diradicals; CH_3OOC-  -$(CH_2)_n$-  -C-

OCH_3, $n=3$, 4, and 5 which exhibit intramolecular charge-transfer interaction between two different pyridinyl radicals in solution at room temperature. Electronic structure of the closed form of the hetero diradical which is considered to be a hetero radical dimer was calculated by the aid of the SCF-CI method. Spectroscopic and theoretical results for the hetero diradical were compared with those for the diradicals, Py(Car)·$(CH_2)_3$Py(Car)·[8] and Py(Ac)·$(CH_2)_3$Py(Ac)··[14] (abbreviated to Car-3-Car, and Ac-3-Ac, respectively.).

Results and Discussion

Electronic Absorption Spectra. The pyridinyl hetero diradicals (**3** for $n=3$, **4** for 4, and **5** for 5) were prepared by reduction of the corresponding diiodides or bromides in the manner previously described.[8,9] The electronic absorption spectra of the 2-methyltetrahydrofuran (abbreviated to MTHF) solutions of **3**, **4**, and **5** were determined at room temperature (27—28°C), as shown in Fig. 1. While the spectra of **4** and **5** are very much

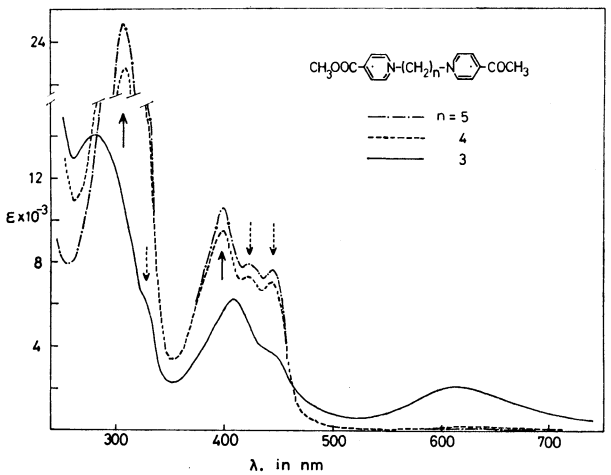

Fig. 1. The absorption spectra of the hetero diradical, **3**, **4**, and **5** in MTHF at room temperature (27—28°C); ←— and ←— show absorption bands due to 4-carbomethoxy- and 4-acetylpyridinyl moieties, respectively.

similar to the sum of the spectra of 1-methyl-4-carbomethoxy-[2,15] and 1-methyl-4-acetylpyridinyls,[15] **3** shows a remarkable absorption band in 600—650 nm region. Concentration independence of the spectrum of **3** at room temperature (1×10^{-3}—5×10^{-5}M) suggests that the spectrum of **3** may be ascribed to an intramolecular interaction. From spectroscopic behavior of **3** in comparison with that of the diradical, Car-3-Car reported in the previous paper, the visible absorption band at 615 nm may be a charge-transfer band between two kinds of pyridinyl moieties. This assignment is supported by the theoretical consideration based on the SCF-CI calculation, as will be mentioned later. Yamazaki and Kimura[6] reported two charge-transfer bands between tetracene and perylene cations at 800—950 nm region. In this paper, theoretical study suggests that a strong charge-transfer band from Py(Car)· to Py(Ac)· moieties and another very weak charge-transfer band in the reverse direction may appear by the electronic interaction between two different pyridinyl radicals. However, only one strong absorption band was observed as mentioned above.

An absorption maximum at 400—420 nm region appears in the MTHF solution of **3**, and a band at 300—340 nm region due to the pyridinyl moiety shifts to the shorter wavelength region compared to **4** and **5**, as shown in Fig. 1. These two absorption bands in the UV region which seem to be due to shifted local excitations decrease in intensity compared with those of the hetero diradicals **4** and **5**. Similar decrease of intensity at UV region was also observed in the diradicals, Car-**3**-Car and Ac-**3**-Ac. Leonard *et al.*[16] demonstrated the hypochromism in the absorption spectra of a series of dinucleotide analogs in which the bases are connected by a trimethylene; B-C_3-B or B-C_3-B′. It seems that the decrease of the intensity in the UV region in the diradicals is attributed to the hypochromism, and/or intensity borrowing by the charge-transfer band.[17]

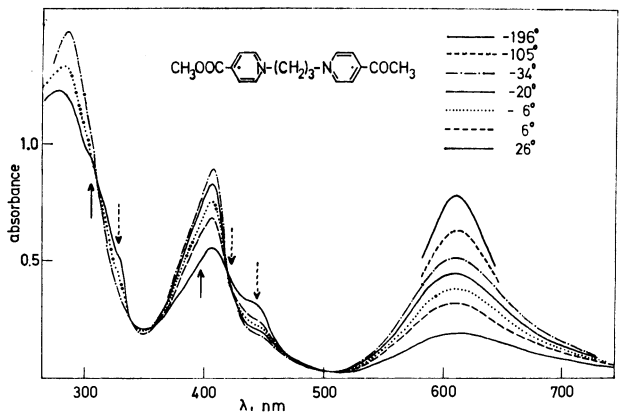

Fig. 2. Temperature dependence of the spectrum of **3** in MTHF. Concentration is 0.85×10^{-4}M: ←— and ←--- show absorption bands due to 4-carbomethoxy- and 4-acetylpyridinyl moieties, respectively. A visible absorption band at −196°C is shown as an extreme case of the equilibrium.

As mentioned in the previous communication,[18] the spectrum of the MTHF solution of **3** shows a remarkable temperature dependence (Fig. 2). The intensities of the 615 and 319 nm bands increased with decreasing temperature, while the absorption due to the each pyridinyl moiety decreased. This temperature dependence of the spectrum was ascribed to an equilibrium of the open and closed forms in **3** (an analog of the monomer dimer equilibrium). The thermodynamic data ($-\Delta H=5.6$ kcal and $\Delta S=-10.5$ e.u.) are compared with those on the complex formation of tetracene and perylene cations ($-\Delta H=7.7$ kcal and $\Delta S=-1.6$ e.u. at 20°C.[6] The complex formation of two different pyridinyls in **3** (the closed form) seems to be more

efficient than that without any methylene chain of which the open form may be more predominant on the energetic ground. Similar equilibrium between the open and closed forms was observed in the diradical, Ac–**3**–Ac.[14] In the diradical Car–**3**–Car reported in the previous paper, a strong charge-transfer interaction of two moieties seems to make the diradical to be in the closed form, and to prevent direct observation of the equilibrium mentioned above.

Electronic Structure of Pyridinyl Hetero Diradical. In the previous paper,[2] Itoh and Nagakura reported molecular orbital calculation of the pyridinyl radical, and semiquantitatively estimated the transition energy of the charge-transfer band in the pyridinyl dimer. In order to bear out the quantitative discussion on the charge-transfer interaction between two different radicals in the hetero diradical, the SCF–CI calculations were made. Most of the calculations of the radical dimers[7,19,20] and/or dimer radical[21] have been made with the method of "composite molecule", which consists of configuration interaction including the charge-transfer configuration between two SCF MO's of the radical monomers. In this paper, molecular orbitals (closed shell) were considered to be delocalized over two different radicals (open shell).[22]

The standard program for restricted SCF–CI procedures was used in the diradicals as well as in the hetero diradical.[23,24] Interatomic overlap integrals between two pyridinyl moieties were calculated by the aid of the data in Clementi's Table.[25] Both intra- and intermolecular electron-electron repulsions were approximated by the Nishimoto-Mataga formula. The calculated results of the electronic transitions in the hetero diradical are summarized in Table 1, in comparison with the spectral data of **3**, where the molecular

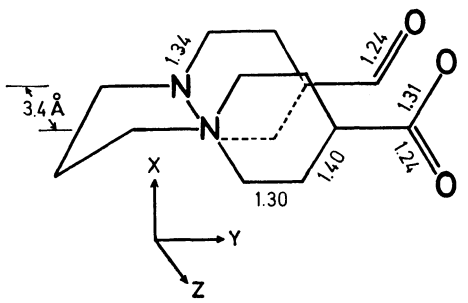

Fig. 3. Molecular geometry of the hetero diradical, **3** assumed in the calculation. A molecular model says that two pyridinyls are non-parallel in the spacing of ~3.4 Å.[2,14]

geometry was assumed to be a sandwich structure as shown in Fig. 3. Several other sandwich structures such as a twisted model[26] and a slided model along x axis were assumed for calculation. However, the results suggested that the structure shown in Fig. 3 was the most reasonable both in their transition energies and intensities. For the sake of simplicity, the results calculated based on the structure shown in Fig. 3 are discussed in this paper. The transition energies show fairly good agreement with the spectral data of the hetero diradical **3**, although no parameterization in SCF–CI calculation was made for adjusting the theoretical results to the spectral data. Similar molecular orbital calculations were done for the diradicals, Car–**3**–Car and Ac–**3**–Ac. These calculated results are shown in Fig. 4, together with the absorption spectra.

Comparison of both theoretical and spectral results in the hetero diradical with those in two diradicals, Ac–**3**–Ac and Car–**3**–Car, suggests that the electronic interaction between two different radicals seems to be rather similar to that in the same radical species. This argument may be justified by the following consideration from the results in SCF–CI calculation of the pyridinyl mono radicals, Py(Ac)· and Py(Car)·, which are components of the hetero diradical. Figure 5 demonstrates the energy levels of two pyridinyls and the hetero diradical. Energy difference of half-occupied

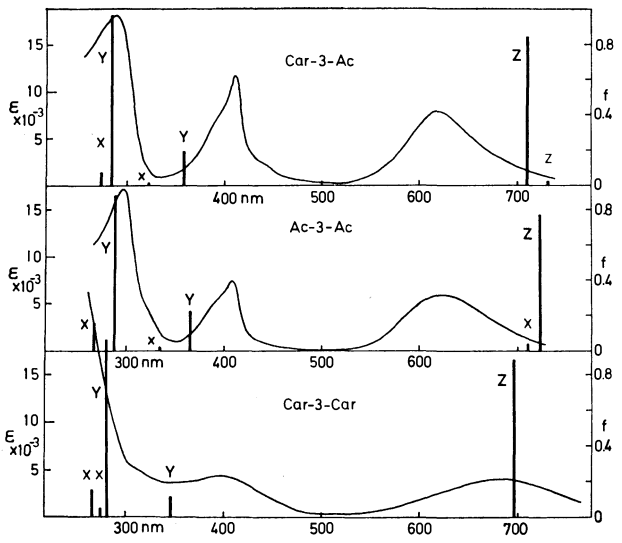

Fig. 4. Electronic absorption spectra of the MTHF solutions of **3** (at 77 K), Ac–**3**–Ac (at 77 K), and Car–**3**–Car (at room temperature), respectively. The sticks represent the calculated transition energies and osscillator strengths.

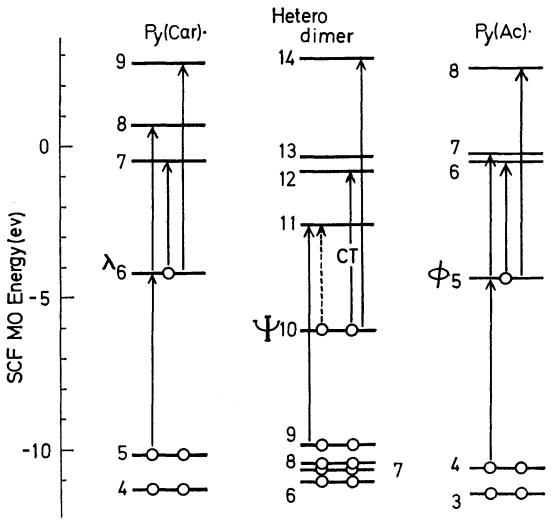

Fig. 5. Energy levels of molecular orbitals in the pyridinyl mono radicals and hetero diradical, respectively. In Py(Car)·, (6→7) is corresponding to ~640 nm (ε:<100) band, (5→6) and (6→7) are ~390 nm (4500), and (6→8) and (6→9) are 295 nm (11000), respectively. Electronic transitions in Py(Ac)• are very much similar to those in Py(Car)•.

molecular orbitals in two pyridinyls (ϕ_5 and λ_6) is unexpectedly only 0.185 eV. In the complex of tetracene$^+$–perylene$^+$ system, the energy difference of two half-occupied MO's was also very small. The half-occupied MO's in both radical components in the diradical (radical dimer) are degenerate, and only one charge-transfer band in the dimer is an allowed transition, which is from the ground state to the antisymmetric combination in the following equations;[1)]

$$\frac{1}{\sqrt{2}}[\Psi(R_1^+, R_2^-) \pm \Psi(R_1^-, R_2^+)]$$

where (R_1^-, R_2^+) is the charge-transfer configuration in the radical pair. Yamazaki and Kimura[6)] estimated two charge-transfer energies in the complex mentioned above from the following conventional equations; $I_I - A_P + C_{TP} = CT_1$ and $I_P - A_T + C_{PT} = CT_2$, where I and A are the ionization potential and electron affinity of the cations, respectively, and C is electrostatic force. However, they did not mention about the intensity of the charge-transfer bands. In this paper, theoretical results which was calculated by assuming electron delocalization over radical moieties show a strong charge-transfer transition from Py(Car)· to Py(Ac)· moieties, and another very weak charge-transfer in the reverse direction. These electronic transitions (energy, f-value and transition moment) and electronic configurations are summarized in Table 1. Then, the strong charge-transfer band observed at 615 nm in the hetero diradical **3** can be ascribed to transition, $\Psi_{10} \rightarrow \Psi_{12}$, of which MO's are shown in Fig. 6. Figure 6 clearly demonstrates a strong charge-transfer mentioned above, while $\Psi_{10} \rightarrow \Psi_{11}$ has a very small f-value with the reverse direction compared with that of $\Psi_{10} \rightarrow \Psi_{12}$.

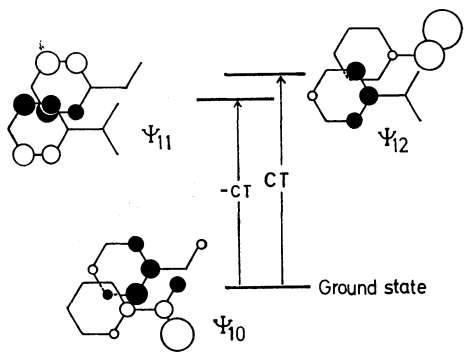

Fig. 6. Highest occupied orbitals of the ground (Ψ_{10}) and two charge-transfer states (Ψ_{11} and Ψ_{12}).

On the other hand, the electron transfer reaction from 1-methyl-4-carbomethoxypyridinyl to 1-methyl-4-acetylpyridinium occurred by adding the latter to an acetonitrile solution of the former. This suggests that Py(Ac)· may be an electron acceptor in the hetero diradical. The argument is successfully consistent with the direction of the charge-transfer mentioned above. Furthermore, total electron density on the each pyridinyl moiety in the diradical **3** demonstrates ~5% charge-transfer structure in the ground state;

$$\text{Py(Car)}^+ - \text{Py(Ac)}^- \sim 5\%$$
$$\text{Py(Car)}\cdot - \text{Py(Ac)}\cdot \sim 95\%.$$

If two different radical species (R_1 and R_2) of which the energy levels of each half-occupied MO are sufficiently different from each other, a complete electron transfer in this radical pair would occur to produce an ion pair (R_1^+,R_2^-) in the ground state. Conclusively, it seems that only two radical species where the half-occupied MO's are nearly degenerate have a possibility to make the molecular complex between them. In this molecular complex, *i.e.*, the hetero radical dimer with a conceivable conformational structure, a strong charge-transfer band and another very weak transition (nearly forbidden) in the reverse direction might be observed in the visible or near IR region.

Experimental

Materials. Three α-(4-carbomethoxypyridinium)-ω-(4-acetylpyridinium) alkane diiodides were prepared from 4-carbomethoxy- and 4-acetylpyridines, and three corresponding alkyl diiodides or bromides. 1-(4-Carbomethoxypyridinium)-3-(4-acetylpyridinium)propane dibromide, mp 150—151°C. Found: C, 43.94; H, 4.77; N, 5.88%. Calcd for $C_{17}H_{20}O_3N_2Br_2$: C, 44.34; H, 4.34; N, 6.08%. 1-(4-Carbomethoxypyridinium)-4-(4-acetylpyridinium)butane diiodide, mp 203°C. Found: C, 38.03; H, 4.00; N, 4.48%. Calcd for $C_{18}H_{22}O_3N_2I_2$: C, 38.05; H, 3.88; N, 4.93%. Non-crystalline products of 1-(4-carbomethoxypyridinium)-5-(4-acetylpyridinium)pentane diiodide and dibromide were used. The structure and purity were checked by IR, UV, and NMR spectroscopies. Purification of the solvents was mentioned in the previous papers.

Preparation of Hetero Diradicals. α,ω-Dipyridinium diiodides (~0.02 g) and 3% sodium amalgam (~0.2 g) were sealed into the reaction tube. After evacuating to 10^{-5} Torr, degassed acetonitrile (~7 ml) was introduced by using a vacuum line. The reaction tube was shaken several times for about 3—5 hr at room temperature. The solvent was removed by using a vacuum line, and the diradical was extracted with MTHF (~10 ml).

Measurements. Electronic absorption spectra were determined with a Cary Model 11 recording spectrophotometer. A quartz dewar with windows was used for low-temperature spectra. ESR measurements were made with JEOLCO P-10 ESR spectrometer with 100 kHz modulation. Determinations of concentration of the diradical and of relative spin concentration were done using the same procedures as described in the previous papers.

The author expresses his sincere thanks to Professor S. Nagakura for permission to use the computer center of the Institute of Physical and Chemical Research, and for reading the manuscript. The author is indebted to Dr. S. Iwata for supplying the computer program.

Spin Trapping by Use of Nitroso-Compounds. VII.[1] β-Fluorine Splitting Constants in Nitroxides

Shigeru TERABE and Ryusei KONAKA

Shionogi Research Laboratory, Shionogi & Co., Ltd. Fukushima-ku, Osaka, 553

(Received November 1, 1972)

Hyperfine splitting constants of β-fluorine atoms in aryl perfluoroalkyl nitroxides, $ArN(R_f)O\cdot$, where Ar= 2,4,6-tri-*t*-butylphenyl, phenyl, pentafluorophenyl, and 2,3,5,6-tetramethylphenyl and R_f=trifluoromethyl, pentafluoroethyl, and heptafluoroisopropyl were explored. The temperature dependence of hyperfine splitting constants was studied in the cases of 2,4,6-tri-*t*-butylphenyl and pentafluorophenyl nitroxides. In the former nitroxides the conformation of β-fluorine atoms are rigid and dihedral angles between the C_β–F bonds and p_z orbitals are 30 and 0° when perfluoroalkyl groups are ethyl and isopropyl, respectively. The conformational dependence of β-fluorine splitting constants are discussed, and it is concluded that the $\cos^2\theta$ law, $a_\beta^F=(B_0+B\cos^2\theta)\rho^\pi$, is also applicable to β-fluorine splitting constants in a series of nitroxides. The values of B_0 and B seem significantly dependent on the compound.

The conformational dependence and the origin of β-hydrogen splitting constants have been well established.[2,3] However, several different proposals[4-13] have recently been advanced concerning those of the β-fluorine atom. It is desirable for the elucidation of the dependence of β-fluorine splitting constants on conformation to investigate the ESR spectra of radicals having β-fluorine atoms in known conformations. Such radicals may include those in single crystals and rigid cyclic radicals. A few studies[9,13-16] along these lines have been reported, although in most of these cases the assumed conformations of the alkyl group containing the β-fluorine atoms have not always been unequivocal.

We have previously found during the spin trapping study[17] of 2,4,6-tri-*t*-butylnitrosobenzene that the ethyl and isopropyl groups in these adducts have substantially rigid conformations wherein the dihedral angles between

the C_β–H bonds and p_z orbitals containing the odd electron on the nitrogen atom are 30 and 0°, respectively. These conformational situations would be expected to remain unchanged if the *N*-alkyl groups are replaced by perfluoroalkyl groups. Hence perfluoroalkyl 2,4,6-tri-*t*-butylphenyl nitroxides were chosen to elucidate the dependence of β-fluorine splitting constants on conformation and a few other substituted phenyl perfluoroalkyl nitroxides were also prepared and studied for comparison.

Results

Substituted phenyl perfluoroalkyl nitroxides were produced by the photolysis of perfluoroalkyl iodides in the presence of substituted nitrosobenzenes.[10]

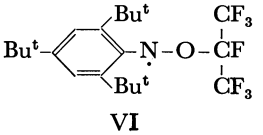
a) Hyperfine splittings were not resolved because of line broadening.

g Values and the temperature dependence of hyperfine splitting constants of the nitroxides Ia, Ib, and Ic are shown in Table 1. The photolysis of 2-iodoheptafluoropropane in the presence of 2,4,6-tri-*t*-butylnitrosobenzene produced *N*-perfluoroisopropoxy-2,4,6-tri-*t*-butylanilino radical (VI) as the major product



VI

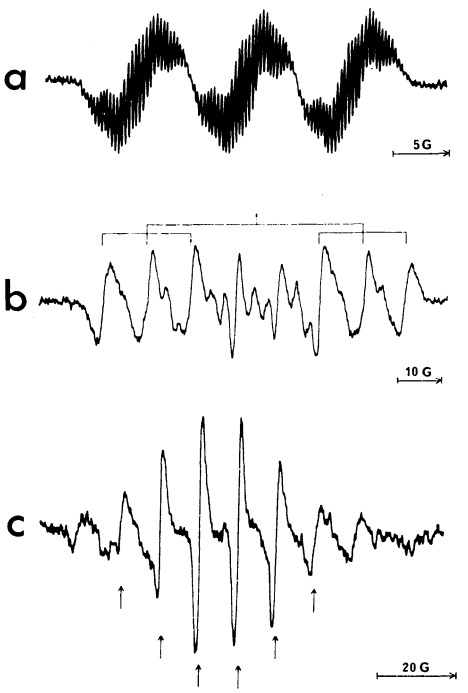


Fig. 1. ESR spectra obtained by the photolysis of 2-iodoheptafluoropropane in the presence of 2,4,6-tri-*t*-butylnitrosobenzene in *n*-hexane at 25°C. Intensities of these three spectra dose not show their relative concentrations because gains of the spectrometer were not equal in each measurement. In b and c, couplings of *meta*-hydrogens and γ-fluorines were not observed because of a high modulation amplitude.

c) Six lines indicated by arrows correspond to the absorption lines due to 2,4,6-tri-*t*-butylphenyl trifluoromethyl nitroxide (Ia). See text also.

whose spectra (g=2.0034) consisted of a triplet (a^N= 9.36 G) of multiplets having 0.30 G spacings (Fig. 1a) and the nitroxide Ic as minor ones together with other unknown radicals whose spectra could not be analyzed because of the superposition of the complex and strong spectrum of VI. However, since the anilino radical VI was less stable than the nitroxide Ic the former VI disappeared completely on standing in solution for a day and permitted the ESR spectra of minor radicals to be obtained (Fig. 1b), and it was inferred that at least three radicals existed in the solution. The main six lines shown in Fig. 1b are considered to be due to the nitroxide Ic because *g* value and the nitrogen splitting constant are very similar to those of Ia and Ib. Further standing of the solution for a total of three days gave the spectrum shown in Fig. 1c which

indicated that trifluoromethyl nitroxide Ia was the major radical and Ic was the minor one. This result implies that a minor radical observed in Fig. 1b is Ia. The concentration of Ic was too low to observe *meta*-hydrogen and γ-fluorine splittings and to study the temperature dependence of β-fluorine splitting.

The ESR spectrum of the pentafluoroethyl nitroxide Ib is shown in Fig. 2. The rather low peak heights of the three central multiplets suggest that the two β-fluorine atoms are not completely equivalent, but they could not be distinguished within this experiment.

Spectral data at room temperature (25°C) of the nitroxides IIa, IIb, and IIc and those of the nitroxides IVa, IVb, and IVc are given in Tables 2 and 4, respectively. The temperature study of the nitroxides IIIa, IIIb, and IIIc and that of the 2,4,6-tri-*t*-butylphenyl alkyl nitroxides (V)[17] are summarized in Tables 3 and 5. The latter study was undertaken for the confirmation of the expected conformation of *N*-alkyl groups.

The ESR spectrum of IIIb is shown in Fig. 3. Some other substituted phenyl perfluoroalkyl nitroxides have been described previously.[1]

Discussion

2,4,6-Tri-t-buthylphenyl Perfluoroalkyl Nitroxides. The nitrogen splitting constant of each 2,4,6-tri-*t*-butylphenyl alkyl nitroxide increases with increase in tem-

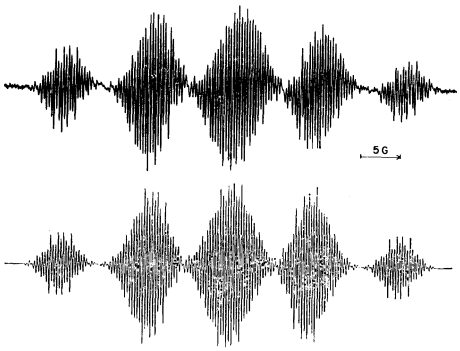

Fig. 3. ESR spectrum of pentafluorophenyl pentafluoroethyl nitroxide (IIIb) in perfluoro(methylcyclohexane) at 25°C. The upper spectrum is experimental and the lower is a simulation based on the splitting constants given in Table 3 and Lorentzian line shapes.

perature as shown in Table 5, and this observation is expected from the results of MO calculations[18] which have shown that the nitrogen splitting constant increases with the torsion of the nitroxide group. The decrease in the β-hydrogen splitting constant of the methyl nitroxide Va with temperature is also consistent with MO calculations[18] which have predicted that the β-hydrogen hyperfine splittings for free rotating hydrogens decrease as the out-of-plane torsion angle of the N–O bond increases. Slightly larger variations of β-hydrogen splitting constants in the nitroxides Vb and Vc with temperature than that in the nitroxide Va would mainly be attributable to the conformational changes of β-hydrogens.

The β-hydrogen splitting constants have been well known to obey the $\cos^2\theta$ law,[2,3,19]

$$a_\beta^{\mathrm{H}} = (B_0 + B\cos^2\theta)\rho^\pi \qquad (1)$$

where B_0 and B are constants, θ is the dihedral angle between the C_β–H bond and the p_z orbital containing an odd electron, and ρ^π is the π electron spin density. The value of B_0 is known to be small and is regarded to be zero in this consideration, and ρ^π is assumed to be constant among the nitroxides Va, Vb, and Vc, although the three nitroxides have slightly different values for nitrogen splitting constants. Then, Eq. (1) becomes

$$a_\beta^{\mathrm{H}} = B\cos^2\theta\rho^\pi_{\mathrm{N}} \qquad (2)$$

The methyl group on the nitrogen in Va is considered as freely rotating which leads to $\cos^2\theta = 1/2$. Taking $a_\beta^{\mathrm{H}} = 12.83$ G for Va at −60°C Eq. (2) gives $B\rho^\pi_{\mathrm{N}} = 24.76$ G. On substituting this value in turn into Eq. (2), dihedral angles at −60°C for Vb and Vc are found to be 30 and 17°, respectively. Examination of molecular models of Vb and Vc has predicted the angles are 30 and 0°, respectively, as described previously.[17] These values are in fair agreement with those obtained above. Although the value (17°) obtained by the above considerations for Vc seems large as compared with the predicted one from a molecular model, the difference between the magnitude of β-hydrogen splitting constants is only 1.4 G.

It will be reasonable to assume that the perfluoroalkyl groups in 2,4,6-tri-*t*-butylphenyl perfluoroalkyl nitroxides have the same conformations as the alkyl groups in 2,4,6-tri-*t*-butylphenyl alkyl nitroxides. A molecular model of the heptafluoroisopropyl nitroxide Ic indicates that steric repulsion between two *t*-butyl groups at the *ortho* positions and two trifluoromethyl groups in the heptafluoroisopropyl group is very large. This is probably the reason why the concentration of the nitroxide Ic formed was very low as mentioned above. The temperature effect on nitrogen splitting constants in the nitroxides Ia and Ib was similar to that in the corresponding alkyl nitroxides Va, Vb, and Vc in the direction and magnitude of variations. Changes of β-fluorine splitting constants with temperature were less than those of β-hydrogen splitting constants in the corresponding alkyl nitroxides.

The applicability of the $\cos^2\theta$ law (Eq. (3)) to the

$$a_\beta^{\mathrm{F}} = (B_0 + B\cos^2\theta)\rho^\pi_{\mathrm{N}} \qquad (3)$$

β-fluorine splitting constant is evaluated on the nitroxides shown in Table 1. Spin densities on nitrogens are assumed to be constant among the three nitroxides, although, in fact, nitrogen splitting constants differ slightly. We can take the values $a_\beta^{\mathrm{F}} = 9.44$ G (25°C) and $\cos^2\theta = 1/2$ for the nitroxide Ia, and $a_\beta^{\mathrm{F}} = 48.4$ G and $\theta = 0°$ for the nitroxide Ic. Hence, Eq. (3) gives $B_0\rho^\pi_{\mathrm{N}} = -29.52$ G and $B\rho^\pi_{\mathrm{N}} = 77.92$ G. On substituting these values and $\theta = 30°$ into Eq. (3), the β-fluorine splitting constant for Ib is found to be 28.92 G, which is close to the observed value (27.21 G). The assumed dihedral angle (0°) for Ic is chosen for convenience, but it must be near to zero-degrees. A change of even 10° does not affect the results seriously. The results obtained reveal that the Eq. (3) can relate β-fluorine splitting constants to dihedral angles at least in the series of nitroxides shown in Table 1. If we assume arbitrarily $\rho^\pi_{\mathrm{N}} = 0.30$, B_0 and B are found to be −98 G and 260 G, respectively. The negative value of B_0 is unequivocal so long as the β-fluorine splitting constant is taken to be positive. The negative value of B_0 has also been deduced by INDO calculations.[11] Large β-fluorine splitting constants have also been found in some other nitroxides where the dihedral angles are assumed to be small by Janzen and co-workers.[20,21]

Phenyl Perfluoroalkyl Nitroxides. Free rotation about the C_β–N bond is possible in the nitroxides shown in Table 2, so that the conformation of the β-fluorine atom is not definite. β-Hydrogen splitting constants decrease in the order methyl>ethyl>isopropyl in phenyl alkyl nitroxides.[19,22] This observation implies that the average dihedral angle θ increases reversely in that order. The conformational analogy between phenyl alkyl nitroxides and *t*-butyl alkyl nitroxides has been known.[19,22] In *t*-butyl perfluoroalkyl nitroxides, however, the conformational preference has been inferred to be somewhat different.[10,11] Trifluoromethyl and heptafluoroisopropyl groups are considered

18) J. Duady, Y. Ellinger, A. Rassat, R. Subra, and G. Berthier, *Mol. Phys.*, **17**, 217 (1969).
19) G. Chaplet-Letourneux, H. Lemaire, R. Lenk, M.-A. Maréchal, and A. Rassat, *Bull. Soc. Chim. Fr.*, **1968**, 3963.

to have similar conformational preference to the corresponding alkyl groups in *t*-butyl nitroxide, but pentafluoroethyl group is assumed to lie in the averaged dihedral angle less than 45°.[10,11]

The conformational analogy between *t*-butyl perfluoroalkyl nitroxides and phenyl perfluoroalkyl nitroxides should be valid. We assume averaged dihedral angles of β-fluorine atoms in the nitroxides IIa, IIb, and IIc to be 45, 35, and 80°, respectively, though the choice of the latter two values is rather arbitrary. Spin densities on nitrogens are assumed constant among IIa, IIb, and IIc. Substitution of β-fluorine splitting constants and dihedral angles for IIa and IIc into Eq. (3) gives $B_0\rho^{\pi}_N=-5.95$ G and $B\rho^{\pi}_N=33.10$ G. These values and $\theta=35°$ are in turn substituted into Eq. (3) to give the β-fluorine splitting constant of 16.26 G, which is fairly close to the observed value for IIb. By taking ρ^{π}_N as 0.30, B_0 and B are found to be −25 and 110 G, respectively. In the above consideration the β-fluorine splitting constant of IIc is assumed to be negative. If we assume it to be positive, we cannot relate the observed results through Eq. (3). Evidently it is possible to apply Eq. (3) to phenyl perfluoroalkyl nitroxides, although the interpretation is not unequivocal.

Pentafluorophenyl Perfluoroalkyl Nitroxides. The temperature dependence of the hyperfine splitting constants shown in Table 3 is small. It will be reasonable to expect that preferred conformations of these nitroxides are similar to those of phenyl perfluoroalkyl nitroxides. Average dihedral angles of IIIa, IIIb, and IIIc are assumed to be the same as in the corresponding phenyl perfluoroalkyl nitroxides. The same treatment utilizing hyperfine splitting constants at −30°C as mentioned above gives $B_0\rho^{\pi}_N=-4.79$ G and $B\rho^{\pi}_N=24.82$ G, thus $a_\beta^F=11.86$ G for $\theta=35°$. The calculated value is close to observed value for IIIb. B_0 and B are found to be −19 and 100 G, respectively, if $\rho^{\pi}_N=0.25$. The β-fluorine splitting constant of IIIc is assumed similarly to be negative.

2,3,5,6-Tetramethylphenyl Perfluoroalkyl Nitroxides. β-Hydrogen splitting constants of corresponding methyl, ethyl, and isopropyl nitroxides are 12.17, 10.97, and 6.92 G, respectively.[1] These values are similar in tendency to phenyl alkyl nitroxides but the magnitude of differences is not large. It is difficult to deduce suitable average dihedral angles for 2,3,5,6-tetramethylphenyl perfluoroalkyl nitroxides because the steric effect of two *ortho*-methyl groups on *N*-substituents is very subtle,[1] so that the validity of Eq. (3) cannot be tested

Conclusion

The conformations of β-fluorine atoms in Ib and Ic are rigid, and related to β-fluorine splitting constants through Eq. (3), where a negative value of B_0 is essential. For phenyl and pentafluorophenyl perfluoroalkyl nitroxides the application of Eq. (3) is possible although some ambiguity exists. Three series of perfluoroalkyl nitroxides studied give different values of B_0 and B. The validity of Eq. (3) is also confirmed concerning *t*-butyl perfluoroalkyl nitroxides[10,11] though the agreement between the calculated and observed values is not so good as in examples described above. The dihedral angle of 90° in perfluoro-2-azopropane radical anion[7] which shows very large β-fluorine splitting constant seems questionable because second order splittings will possibly be observed even at $\theta=0°$.[23] If this interpretation is correct β-fluorine splitting constants in perfluoroazoalkane radical anions can be successfully related to dihedral angles through Eq. (3) to give $B_0\rho^{\pi}_N=-26.93$ G and $B\rho^{\pi}_N=88.38$ G.

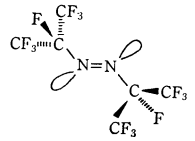
The results concerning B are consistent with SCF-MO calculations by Morokuma[8] which show that B depends on the particular molecule but that B_0 is near zero. Chachaty and co-workers[13] have proposed the values of B_0 and B to be ~-20 and −80 G, respectively for some perfluoroalkyl radicals. The meaning of B_0 is obscure at present.

Experimental

Trifluoromethyl iodide, pentafluoroethyl iodide, and heptafluoroisopropyl iodide were purchased from PCR, Incorp., and used without further purifications. Preparation of nitroso-compounds have been described previously.[1,17] For the preparation of perfluoroalkyl nitroxides,[10] 0.005—0.01 M deoxygenated solution of a nitroso-compound containing a suitable amount of a perfluoroalkyl iodide was irradiated by the light from a high pressure mercury lamp in the cavity of a spectrometer until an appropriate concentration of the nitroxide was attained. All spectra were recorded on a Varian V-4502-15 X-band spectrometer with 100 kHz magnetic field modulation. Temperature study was achieved with a Varian V-4557 variable temperature accessory in a 3 mm o.d. quartz cell, and temperature was calibrated by a thermometer. Hyperfine splitting constants and *g* values listed in Tables are the average values of at least three measurements. Measurements of magnetic field and microwave frequency, and ESR simulation have been given previously.[24]

The authors are grateful to Professor E. G. Janzen and Dr. K. Nishikida for helpful discussions and to Mr. S. Sakata for his assistance in the ESR experiments.

23) Dr. K. Nishikida suggested that two β-fluorine atoms will be almost completely equivalent in the conformation shown below,



where perfluoro-2-azopropane radical anion shows possibly second order splittings.

Effect of Halogens on the Ionization of Alkali Metals in the Hydrogen Flame Ionization Detector for Ultra-Micro Analysis of Alkali and Alkaline Earth Metals

Masaaki YAMADA, Shigetaka SUZUKI, and Shun ARAKI

Department of Industrial Chemistry, Faculty of Engineering, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received March 21, 1972)

Quantitative treatment of alkali metals in a small hydrogen flame in the presence or absence of halogens was studied. The proportionality of the ion current to the concentration of alkali metals was found to depend on the applied potential of the electrodes. On adding halogens, the concentration of free neutral alkali atoms decreased. Addition of bromine and iodine increased the ionization of alkali metals, while fluorine decreased it slightly. Addition of chlorine increased or decreased the ionization. The thermionic detection mechanism of halogen-containing compounds in TID of gas chromatograph was discussed.

Ultra-micro analysis of alkali and alkaline earth metals by the hydrogen flame ionization method was developed by the authors.[1-3] The method, in which an electric current caused by ionization of these metals in the hydrogen flame is measured by applying an electric field, has a high sensitivity. It was observed that the ionization of alkali metals was enhanced or suppressed by the addition of hydrogen chloride gas to the flame. Behavior of alkali metals in the small diffusion hydrogen flame without an electric field, distribution of free neutral atoms and charged particles and the mobility of charged particles were also studied.[4] In investigations carried out on the ionization of alkali metals in the presence of halogens,[5-7] large, flat and pre-mixed flames were used, no electric field being applied.

On the other hand, a high sensitive and selective gas chromatographic detector has been used[8,9] for halogen- and phosphorus-containing compounds, known as a thermionic or alkali flame detector. It is a modification of the flame ionization detector making use of different ionization processes in the flame in the presence of an alkali metal. The mechanism of response was discussed from the point of view that halogens and phosphorus increase the ionization or volatilization of alkali metals.

This paper deals with the quantitative treatment of the ionization of alkali metals when halogens are added or not added to a small diffusion flame to which electric field is applied. The study is also related with the thermionic detection mechanism.

Experimental

A double jet type hydrogen flame ionization detector was used, the flow rates of hydrogen and oxygen and also the instrument being the same as those used previously.[4] The electric field is applied to the ionizing flame by two parallel plane electrodes, 5.5×3.5 cm nickel plates plated with silver and gold. The applied potential and distance between the electrodes are variable. The flame photometric method was applied for studying the effect of halogens on the concentration of free neutral atoms.

Alkali metals were intermittently supplied to the ionizing flame (the upper flame) by inserting the tip of a platinum wire coated with 10^{-9}—10^{-11} mol alkali chloride into the evaporating flame (the lower flame). Halogens were continuously added to the ionizing flame by introducing them into the hydrogen gas stream for the ionizing flame. Chlorine was added as hydrogen chloride from a cylinder. Iodine, bromine, and fluorine were added as methyl iodide, diethyl bromide, and fluorobenzene, respectively, from a heated reservoir.

Results and Discussion

In the Absence of Halogens. Alkali chlorides MCl react with hydrogen atoms in the flame as follows:

$$MCl + H \rightleftarrows M + HCl; \text{ eq. const. } K_1.$$

This gives alkali atoms M which can be readily ionized. Alkali atoms are ionized by collisional process with B, major constituent of the gas products (water molecule in this case):

$$M + B \xrightarrow{k_1} M^+ + e^- + B. \qquad (I)$$

The activation energy of reaction (I) is equal to the ionization potential.[10] Since the concentration of water molecule is constant in a given flame, the reaction is considered to be of first order, depending only on the alkali atom concentration. This indicates that the ionization occurs *via* a thermal rather than a chemical path. If the process completely follows this reaction, then we have

$$\frac{d[M^+]}{dt} = k_1[M][B],$$

where k_1 is the rate constant of reaction (I), [M] and [B] are concentrations of alkali atom and water molecule, respectively. If the recombination in the electric field is neglected, the ion current i which flows into the outer circuit will be proportional to $d[M^+]/dt$:

$$i \propto \frac{d[M^+]}{dt} = k_1[M][B]. \quad (1)$$

If $[M]_0$ and $[Cl]_0$ are total concentrations of metal and chlorine atom, whether combined or free, then

$$[M]_0 = [M] + [MCl] + [MOH], \quad (2)$$

$$[Cl]_0 = [M]_0 = [MCl] + [HCl] + [Cl], \quad (3)$$

where [MCl] is the concentration of undissociated alkali chloride, [MOH], [HCl], and [Cl] are concentrations of alkali hydroxide, hydrogen chloride and chlorine atom, respectively, formed in the flame. Formation of MOH and HCl is governed by the reversible reactions:

$$M + H_2O \rightleftarrows MOH + H,$$

$$Cl + H_2 \rightleftarrows HCl + H.$$

Putting $[MOH]/[M]=\phi$, Eq. (2) becomes

$$[M]_0 = [M]\left(1+\frac{[MCl]}{[M]}+\phi\right)$$

$$= [M]\left(1+\frac{[HCl]}{K_1[H]}+\phi\right). \quad (4)$$

From the previous results, the value of ϕ was 0.1—0.3 for lithium and $\phi \ll 1$ for the other alkali mtals.[4] Equations (2) and (3) give

$$[M](1+\phi) = [HCl]\left(1+\frac{[Cl]}{[HCl]}\right).$$

Since $[Cl]/[HCl] \ll 1$, this becomes

$$[M](1+\phi) = [HCl]. \quad (5)$$

From Eqs. (4) and (5), we obtain

$$[M] = \frac{2[M]_0}{(1+\phi)\{\sqrt{1+4[M]_0/K_1[H](1+\phi)}+1\}}. \quad (6)$$

In our experiment, the amounts of alkali metals added were 10^{-11}—10^{-9} mol. Thus we get for $[M]_0$ 10^{-8}—10^{-6} atm (partial pressure), for $K_1[H](1+\phi)$ about 10^{-2} atm for lithium and 10^{-3} atm for cesium. Equation (6) can therefore be simplified as

$$[M] = \frac{[M]_0}{1+\phi}. \quad (7)$$

This holds also for the other halides of alkali metals. Thus, we have from Eqs. (1) and (7)

$$i \propto \frac{[M]_0}{1+\phi}.$$

This indicates that the ion current is proportional to the total concentration of alkali metals. The experimental results are shown in Fig. 1.

The plot of lithium alone shows a straight line. A deviation from the straight line would be due to the space charge effect caused by insufficient applied potential. The relationship between the saturated ion current i_s and the minimum applied potential V_s at which i_s is obtained is shown in Fig. 2. The slope of straight lines is found to be 2 and i_s-V_s relation is represented by the equation. Since the coefficient a is correlated

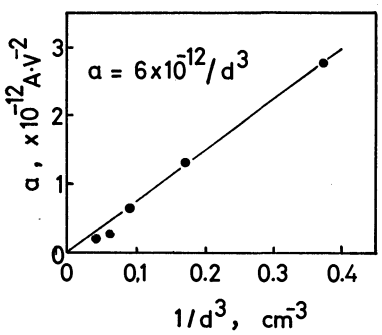

Fig. 3. Relationship between a and $1/d^3$.

with the distance between the electrodes d as shown in Fig. 3, we obtain

$$i_s = 6 \times 10^{-12} \frac{V_s^2}{d^3} (\mathrm{A}). \quad (8)$$

This shows that the saturated ion current depends on the applied potential, if d is kept constant. Under the conditions shown in Fig. 1, where V_s is 1000 V and d 1.8 cm, i_s is calculated to be 1.0×10^{-6} A. This value is represented by a horizontal dotted line. Above this line, linear relation can not be obtained because the applied potential is not sufficient. When the applied potential is larger, the plots should be linear if the secondary ionization do not occur. The working curves became non-linear in the range of large amounts of halide (for example, 10^{-10} mol in sodium chloride).[3] The applied potential was about 300 V, and the linear dynamic ranges of the working curves were not more than 100. These results show that the applied potential was apparently low.

In the Presence of Halogens. On adding halogens, the ionization can be considered to be the following reactions in the electric field:

$$\mathrm{M} + \mathrm{B} \xrightarrow{k_1} \mathrm{M^+} + \mathrm{e^-} + \mathrm{B}, \quad (\mathrm{I})$$

$$\mathrm{M} + \mathrm{X} \xrightarrow{k_2} \mathrm{M^+} + \mathrm{X^-}, \quad (\mathrm{II})$$

and halogens take part in two reversible bimolecular reactions,

$$\mathrm{MX} + \mathrm{H} \rightleftarrows \mathrm{M} + \mathrm{HX}; \text{ eq. const. } K_2, \quad (\mathrm{III})$$

$$\mathrm{H_2} + \mathrm{X} \rightleftarrows \mathrm{H} + \mathrm{HX}; \text{ eq. const. } K_3, \quad (\mathrm{IV})$$

where X is a halogen atom. In reaction (II), it is expected to increase the ion current, and in reaction (III), to decrease the ion current, since ionizable alkali atoms are removed as gaseous alkali halides.

If reaction (II) is of second order, the ion current i' is given by

$$i' \propto \frac{\mathrm{d}[\mathrm{M^+}]'}{\mathrm{d}t} = k_1[\mathrm{M}]'[\mathrm{B}] + k_2[\mathrm{M}]'[\mathrm{X}]', \quad (9)$$

where $[\mathrm{M^+}]'$ and $[\mathrm{M}]'$ are concentrations of the metal ion and the free atom, respectively, in the presence of added halogen, and $[\mathrm{X}]'$ that of atomic halogen. [B] remains constant because of the buffer effect of the flame gases. From Eqs. (1) and (9), the ion current ratio i'/i is obtained:

$$\frac{i'}{i} = \frac{[\mathrm{M}]'}{[\mathrm{M}]}\left(1 + \frac{k_2[\mathrm{X}]'}{k_1[\mathrm{B}]}\right). \quad (10)$$

If $[\mathrm{M}]_0$ and $[\mathrm{X}]'_0$ are the concentrations of total alkali metals and halogens, respectively, the material balance is given by

$$[\mathrm{M}]_0 = [\mathrm{M}]' + [\mathrm{MOH}]' + [\mathrm{MX}]', \quad (11)$$

$$[\mathrm{X}]_0' = [\mathrm{X}]' + [\mathrm{HX}]'. \quad (12)$$

Ions are ignored in the metal balance since the degree of ionization is small. $[\mathrm{MX}]'$ is neglected in the halogen balance since $[\mathrm{X}]'_0 \gg [\mathrm{M}]_0$. Equation (12) is rewritten as

$$[\mathrm{X}]_0' = [\mathrm{X}]'\left(1 + \frac{[\mathrm{HX}]'}{[\mathrm{X}]'}\right) = [\mathrm{X}]'\left(1 + \frac{K_3[\mathrm{H_2}]}{[\mathrm{H}]}\right). \quad (13)$$

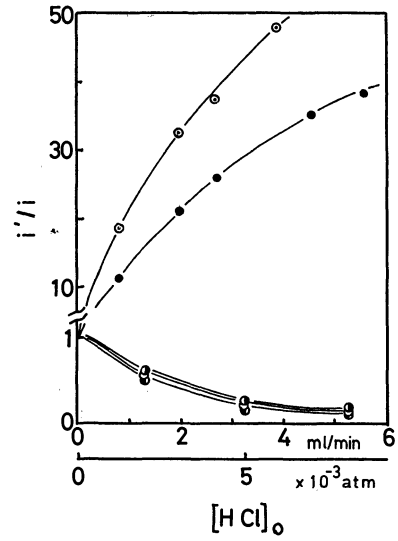

Fig. 4. Plots of i'/i against $[\mathrm{HCl}]_0$.
Applied potential: 1000 V; Distance between the electrodes d(cm): 1.8; Sample (mol): ⊙ LiCl 1×10^{-10}, ● NaCl 1×10^{-11}, ◑ KCl 1×10^{-11}, ○ RbCl 1×10^{-11}, ◐ CsCl 1×10^{-11}

Equation (10) then becomes

$$\frac{i'}{i} = \frac{[\mathrm{M}]'}{[\mathrm{M}]}\left\{1 + \frac{k_2[\mathrm{X}]_0'}{k_1(1 + K_3[\mathrm{H_2}]/[\mathrm{H}])[\mathrm{B}]}\right\}. \quad (14)$$

Change of i'/i, on addition of a few milliliters per minute of hydrogen chloride (an order of 10^{-3} atm in partial pressure), is shown in Fig. 4. We see that the ion currents for lithium and sodium increase, while those for the other alkali metals decrease. This is because $[\mathrm{M}]'/[\mathrm{M}]$ in Eq. (14) decreases the ion current, while the second term in the brace increases it. That is to say, in the case of lithium and sodium, the second term in the brace is much larger than 1, while in the case of other alkali metals, it is much smaller than 1.

Equation (11) is rewritten as

$$[\mathrm{M}]_0 = [\mathrm{M}]'\left(1 + \frac{[\mathrm{MOH}]'}{[\mathrm{M}]'} + \frac{[\mathrm{MX}]'}{[\mathrm{M}]'}\right) = [\mathrm{M}]'\left(1 + \phi + \frac{[\mathrm{HX}]'}{K_2[\mathrm{H}]}\right).$$

We have from Eqs. (12) and (13)

$$[\mathrm{M}]_0 = [\mathrm{M}]'\left\{1 + \phi + \frac{[\mathrm{X}]_0'}{K_2[\mathrm{H}](1 + [\mathrm{H}]/K_3[\mathrm{H_2}])}\right\}. \quad (15)$$

ϕ, [H], and $[\mathrm{H_2}]$ remain constant because of the buffer effect of the flame gases. Since $[\mathrm{Cl}]'/[\mathrm{HCl}]' \ll 1$, Eq. (15) for chlorine becomes

$$[\mathrm{M}]_0 = [\mathrm{M}]'\left(1 + \phi + \frac{[\mathrm{Cl}]_0'}{K_2[\mathrm{H}]}\right). \quad (16)$$

From Eqs. (6) and (16), the concentration ratio of free alkali atoms in the presence or absence of added hydrogen chloride is given by

$$\frac{[\mathrm{M}]}{[\mathrm{M}]'} = \frac{2\{1 + [\mathrm{Cl}]_0'/(1+\phi)K_2[\mathrm{H}]\}}{1 + \sqrt{1 + 4[\mathrm{M}]_0/(1+\phi)K_2[\mathrm{H}]}}. \quad (17)$$

$[\mathrm{M}]/[\mathrm{M}]'$ is equal to I/I', where I and I' are emission intensities of alkali atoms in the absence and presence of added hydrogen chloride. Plots of I/I' against $[\mathrm{Cl}]'$ and of $(I - I')$ against I give straight lines as shown in

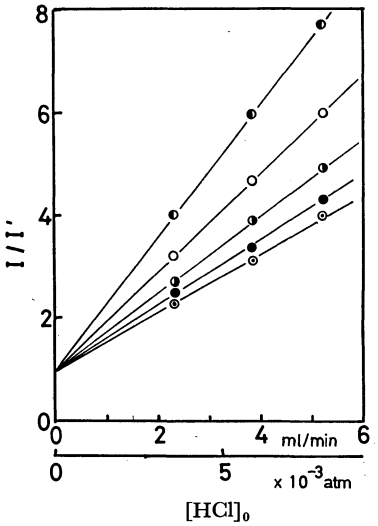

Fig. 5. Plots of I/I' against $[HCl]_0$.
Sample (mol): ⊙ LiCl 1×10^{-9}, ● NaCl 1×10^{-10}, ◑ KCl 1×10^{-8}, ○ RbCl 1×10^{-8}, ◐ CsCl 1×10^{-8}

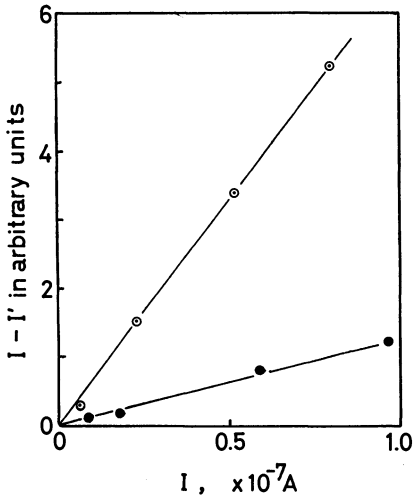

Fig. 6. Plots of $(I-I')$ against I.
Alkali metals were continuously supplied to the flame, while one milliliter of hydrogen chloride was intermittently injected to the hydrogen gas stream. Sample: ⊙ LiCl, ● NaCl

Figs. 5 and 6, respectively. Thus, $4[M]_0/(1+\phi)K_2[H]$ is considered to be negligible compared with 1. Thus Eq. (17) is simplified to

$$\frac{[M]}{[M]'} = 1 + \frac{[Cl]_0'}{(1+\phi)K_2[H]}.$$

Therefore, $(1+\phi)K_2[H]$ can be determined from the slope of straight lines in Fig. 5. They were 10^{-2} atm for lithium and 10^{-3} atm for cesium. The concentration of free alkali atoms was reduced because of the formation of MCl, and $[M]'/[M]$ was in the order of magnitude of 10^{-1}.

The second term in the brace in Eq. (14) should next be considered. The expression for the rate constant k_1 of reaction (I) is

$$k_1 = \pi r_{M-B}^2 \sqrt{\frac{8kT(m_M+m_B)}{m_M m_B}} \exp\left(-\frac{E_M}{RT}\right), \qquad (18)$$

where r_{M-B} is the collision diameter, m_M and m_B are respectively the atomic and molecular weight of the metal and water and E_M is the ionization potential of the metal. The collision cross-sections πr^2_{M-B} are greater than the normal gas kinetic values by several orders of magnitude and were deduced experimentally.[10] The results indicate that, although reaction (I) seems to be of first order with respect to the metal, it can not be a simple single-step process as given by reaction (I). Nevertheless, Eq. (18) with the appropriate values of the collision cross-sections can still be used to estimate the rate at which alkali metals are ionized.

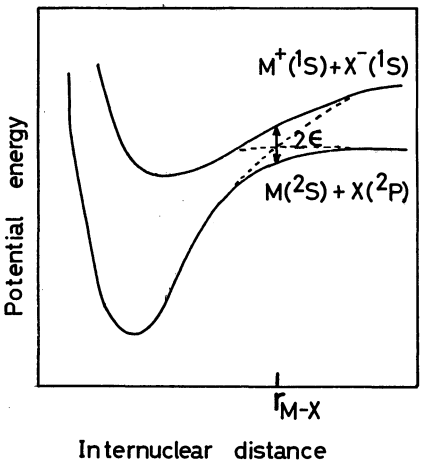

Fig. 7. Potential energy curves for electron transfer reaction.

Electron transfer reaction (II) may be considered with referring to the simple diagram of Fig. 7, which represents the potential curves for the two lowest states of the MX molecule. The rate constant k_2 of reaction (II), with a transition complex in the region of r_{M-X}, is reduced to

$$k_2 = \kappa\pi r_{M-X}^2 \sqrt{\frac{8kT(m_M+m_X)}{m_M m_X}} \exp\left(-\frac{E_M-E_X}{RT}\right), \qquad (19)$$

Where κ is a transmission coefficient, r_{M-X} the distance between the nuclei of alkali metal and halogen at the crossing point and E_X the electron affinity of halogen atom. The potential energy relative to the separated ions is approximately the same as at infinity, *i.e.*, E_M-E_X. Hence we have at the crossing point

$$r_{M-X} = \frac{e^2}{E_M-E_X}, \qquad (20)$$

where e is the electronic charge. The values of r_{M-X} calculated from Eq. (20) give the effective collision diameters for the reaction between the various alkali metals and halogen atoms.

If χ is the probability of crossing from the lower to the upper potential energy surface, then

$$\kappa = 2\chi(1-\chi).$$

The following Landau-Zener formula gives χ in terms of 2ε:

$$\chi = \exp\left(-\frac{4\pi^2\varepsilon^2}{hv|s_i-s_f|}\right),$$

where 2ε is the energy equivalent to the closest distance between the upper and lower curves. Thus ε is the resonance energy in the activated state, v the velocity

with which the system passes through this configuration, and $|s_i-s_f|$ is the absolute magnitude of the difference between the slopes of the two common tangents to the curves. There will be little error in taking v as the classical mean velocity, $\sqrt{kT(m_M+m_X)/2\pi m_M m_X}$, s_i as e^2/r^2_{M-X}, and s_f as zero. Magee[11] calculated ε using the Slater one-electron wave functions. Equations (18) and (19) give the rate constant ratio of reactions (I) and (II) as

$$\frac{k_2}{k_1}=\frac{\kappa r^2_{M-X}}{r^2_{M-B}}\sqrt{\frac{(m_M+m_X)m_B}{(m_M+m_B)m_X}}\exp\frac{E_X}{RT}.$$

The calculated values of k_2/k_1 are given in Table 1.

The equilibrium constant of reaction (IV), K_3, was obtained by statistical calculations (Table 2):

TABLE 2. EQUILIBRIUM CONSTANT K_3

produced in the evaporating (lower) flame. The total concentration of added halogens, $[X]_0'$, was in the order of 10^{-3} atm. Thus the second term in the brace in Eq. (14) was calculated as given in Table 3.

The results shown in Fig. 4 can be easily understood from Table 3 and the values of $[M]'/[M]$ in Fig. 5. The results from the presence of 10^{-3} atm of halogens are given in Table 4. $[M]'/[M]$ was in the order of 10^{-1} for bromine, and was nearly equal to 1 for fluorine and iodine. It can be predicted from the data of Table 3 whether the addition of halogens increases or decreases ion current. The predicted results are compatible with the experimental results as shown in Table 5. The experimental values of i'/i fairly differ from those predicted from the data in Table 3. Exact prediction is difficult in this experiment in which the diffusion flame is used. It is necessary to consider ionization not only from the ground states but also from electronically excited levels.

On TID Response. It has been found that the thermionic detector (TID) has a high sensitivity to halogen-containing compounds in gas chromatography. Karmen[13–15] proposed a TID with two burners placed one above the other and separated by a platinum screen treated with an alkali metal salt. This detector essentially consists of a combination of two self-contained detectors: a flame ionization (lower) detector and a thermionic (upper) detector. It is believed that the TID response depneds on the increase in ionization or volatilization of alkali metals. Karmen explained the sensitivity of the TID to halogen-containing compounds by the increase in volatilization. However, we see from Table 3 that the effect of halogens on ionization can not be neglected. The TID response will be discussed by means of Eq. (14).

Working conditions of the gas chromatographic detector required for the calculations were assumed as follows: the flow rates of hydrogen, air, and carrier gas (nitrogen) are 30, 400, and 40 ml/min, respectively; the flame is a stoichiometric one; mono-halogenated benzenes as halogen-containing compounds are supplied in the rate of 10^{-10}—10^{-7} g/sec (10^{-8}—10^{-5} atm in partial pressure) to the TID. Temperature of the flame used for the TID may be lower than that used for this experiment. It may be about 1000—1200 K.[16] Since $[X]_0'$ is very small, $[M]'/[M]$ is assumed to be nearly equal to 1. Calculated values of i'/i are given in Table 6.

We see that chlorine, bromine, and iodine appear to increase the ionization of all or some alkali metals, while fluorine appears to be ineffective. Karmen showed that the relative sensitivity to butyl bromide, chloride and iodide varied somewhat when screens treated with different alkali metals were used, and that the sensitivity to butyl bromide was greater than that to butyl chloride or butyl iodide for each of the screens. The sensitivity to fluorine-containing compounds was much less, but a definite response was obtained, particularly when a screen treated with a cesium salt was used. These results are consistent with the data in Table 6. However, Karmen also found that when a potassium-treated screen was used, the relative sensitivity to butyl chloride was higher than those treated with any of the other alkalis. This indicates that the increase in the volatilization of alkali metals plays an important role in the increase in sensitivity. It is almost certain that the sensitivity to fluorine-containing compounds and to chlorine-containing compounds when potassium-, rubidium-, and cesium-screens are used is due to the increase in the volatilization of alkali metals. In the case of other combinations of halogen-containing compounds and alkali metals, the response is considered to arise from the increase not only in the volatility, but also in the ionization. The increment of evaporation and ionization should be known in order to study the detection mechanism of TID in detail.

The Ion-exchange Behavior of the Ammonium Ion on Crystalline Zirconium Phosphate

Yoshitsugu HASEGAWA and Hisashi AOKI

Department of Industrial Chemistry, Faculty of Engineering, Tokyo University of Agriculture and Technology, Nakamachi, Koganei, Tokyo 184

(Received May 24, 1972)

The ion-exchange behavior of the ammonium ion on crystalline zirconium phosphate (c-ZrP) was studied by pH titration and X-ray powder diffraction. The ion-exchange capacity of c-ZrP was 4.4 meq/g in an acidic solution and 6.6 meq/g in an alkaline solution. At an exchange of 66% the $Zr(NH_4PO_4)_{1.33}(HPO_4)_{0.67}\cdot H_2O$ phase was present and at an exchange of 100% $Zr(NH_4PO_4)_2\cdot H_2O$ phase was present. The forward and backward titration curves exhibited a hysteresis loop. This results from the presence of the different phases in the titration of each direction. Through the ion-exchange cycle, the crystallinity of c-ZrP was maintained.

Since the crystalline zirconium phosphate ion-exchanger (referred to as c–ZrP hereafter) was prepared by Clearfield and Stynes,[1] the ion-exchange behavior of the compound has been investigated extensively. Especially for alkali-metal cations, the distribution coefficients, (K_d), the dependence of K_d on pH, and the pH titrations have been studied.[2,3] Clearfield and Smith prepared a single crystal of zirconium bis(monohydrogen orthophosphate) monohydrate, $Zr(HPO_4)_2\cdot H_2O$, and suggested a crystal structure for it.[4–6]

However, the ion-exchange behavior of the ammonium ion on c–ZrP has scarcely been studied at all. Only the composition of the ammonium form of c–ZrP, its interplanar spacing, and a simple thermal analysis have been reported.[1,7]

In the present study, the capacity and reversibility of the ion exchange were measured by pH titrations, and the structural change of c–ZrP was examined by means of the X-ray powder diffraction. A chemical analysis of the ammonium forms of c–ZrP was also carried out.

Experimental

Reagents. All the reagents were of a reagent grade and were used without further purification. The c-ZrP was prepared by refluxing a gelatinous zirconium phosphate in 6.7M phosphoric acid for 120 hr.[3]

pH-Titrations. The titrations were carried out by batch as follows: 250 mg of c-ZrP was placed in contact with 25 ml of an NH_4OH+NH_4Cl solution in a thermostat regulated at 25°C. The composition of the solution was chosen so that the total ammonium concentration was equal to 0.1N, and the ratio of OH^-/Cl^- was varied from 0/0.1 to 0.1/0N. The mixtures were shaken continuously until equilibration. After equilibration, the pH values of the supernatants were measured on a Model MG-1 pH meter (Denki Kagaku Keiki Co., Ltd.) with a glass electrode. The equilibrated pH was attained about 2 hr after the start of shaking. Usually the pH's were determined after the reaction mixtures had been shaken for 12—24 hr.

The analysis of the exchanger obtained at the end-point of the pH titration showed that the composition of the compound was $Zr(NH_4PO_4)_2\cdot H_2O$. Taking the difference in molecular weight from c-ZrP into consideration, in the backward titration 278 mg of the ammonium-form exchanger was placed in contact with the solution of $HCl+NH_4OH$. The ammonium hydroxide added was adjusted to 3.29 meq/g c-ZrP, since 6.6 meq NH_4^+/g c-ZrP was already included in the exchanger, and the amount of added hydrochloric acid was varied.

In confirmation of the ion-exchange capacity, the titrations were carried out with NH_4OH alone and with HCl alone in separate runs.

Analytical Procedure. The ammonium forms of the exchanger were analysed as follows. Zr; A weighed sample (*ca.* 100 mg) and 1.5—2.0 g of sodium peroxide powder were mixed. To the mixture 25 ml of water was added in an ice bath. After a few minutes, the slurry was placed on a water bath and the precipitated zirconium hydroxide was aged for 2—3 hr. After filtration, the precipitate was dissolved in 3N HCl. Then the zirconium was re-precipitated as cupferronate and ignited to ZrO_2. PO_4; The phosphorus was determined gravimetrically by the method described by Kolthoff and Sandell.[8] NH_4^+; The ammonium ion was determined gravimetrically to be tetraphenyl borate.[9]

X-Ray Powder Diffraction. X-Ray powder patterns were obtained with Ni filtered copper X-rays using a Geigerflex (Rigaku Denki Co., Ltd.).

Results and Discussion

pH *Titration Curves.* The titration curves obtained for NH_4OH–NH_4Cl solution media are shown in Fig. 1. The forward titration curve can apparently be divided into two regions. The first region of the ion exchange extends from zero exchange to 4.4meq/g c–ZrP ammonium ion uptake. In the second region, the ion-exchange reaction proceeds slowly and the end-point of neutralization is not observed claerly. The titration curve in Fig. 2(a) also shows that the ion-exchange capacity of c–ZrP for the ammonium ion in

an acidic solution is equal to about 4.4 meq/g. As the theoretical ion-exchange capacity of c-ZrP is 6.6 meq/g, the value of 4.4 meq corresponds to a 66% exchange.

In the backward titration (Fig. 1(b)), it was found that the ion-exchange reaction took place in two stages. The first stage extended from an exchange of 100% to 67%, and the second stage, from 66 to 0%. That is, 0—33% of the ammonium ion in the exchanger was re-exchanged with the hydrogen ion at pH 5.5—5.0 and 34—100% over the pH range from 5.0 to 2.0. The second stage might be further divided into two steps if one takes account of the plateau found at an exchange of around 34—50% at pH 4.5. From Figs. 1(b) and 2(b) it turns out that the total ion-exchange capacity for the ammonium ion is equal to 6.6 meq/g c-ZrP experimentally.

The titration curves in Fig. 1 show the irreversibility of the ammonium-hydrogen ion exchange on c-ZrP; it results in a hysteresis loop of the curves. These may be due to the presence of different phases in the forward and backward titrations (the details will be presented later).

The ion exchange of the ammonium ion on c-ZrP resembles that of the lithium ion in some respects. Clearfield and Troup, and Nancollas and Harvie, have reported, respectively, that lithium-ion exchange takes place in two stages and that the ion-exchange capacity of c-ZrP for the lithium ion is 4.4 in an acidic solution and 6.6 meq/g in an alkaline solution.[10,11] This is what was observed for the ammonium ion.

It has already been established that c-ZrP works as a dibasic exchanger to the sodium ion and that the two groups of phosphate protons exist in the ratio of 1 to 1.[12] This can reasonably be expected from the $Zr(HPO_4)_2 \cdot H_2O$ formula. For ammonium exchange, this is not the case; *i.e.*, the two groups of phosphate protons seems to exist in the ratio of 2 to 1. This phenomenon was also observed in the lithium-ion exchange.[10,11]

The compositions of the 66%-exchange phase (Phase I) and 100%-exchange phase (Phase II) are as follows. Phase I, Found: Zr; 28.3, PO_4; 57.6, NH_4; 7.2, ignition loss; 18.0%. Calcd for $Zr(NH_4PO_4)_{1.33}(HPO_4)_{0.67} \cdot H_2O$, Zr; 28.2, PO_4; 58.6, NH_4; 7.43, ignition loss; 18.1%. Phase II, Found: Zr; 27.4, PO_4; 54.9, NH_4; 10.8, ignition loss; 21.1%. This corresponds to $Zr(NH_4PO_4)_2 \cdot H_2O$ (Calcd for Zr; 27.2, PO_4; 56.7, NH_4; 10.8, ignition loss: 20.9%).

X-Ray Diffraction. In Figs. 3 and 4, the X-ray diffraction patterns of the samples taken from the titration experiments are shown schematically. In Table 1, the interplanar spacing (*d* values) of c-ZrP, Phase I and Phase II, are shown. The *d* values of Phase II agreed with that reported by Clearfield and Stynes,[1] but did not agree with that reported by Dyer *et al.*[7]

At the initiation of the forward titration, a new reflection at d=9.49 Å was observed. In the ion-exchange process, the relative strength of this reflection increased and the reflection of 7.60 Å, which is the first one in c-ZrP, decreased. Beyond an exchange of

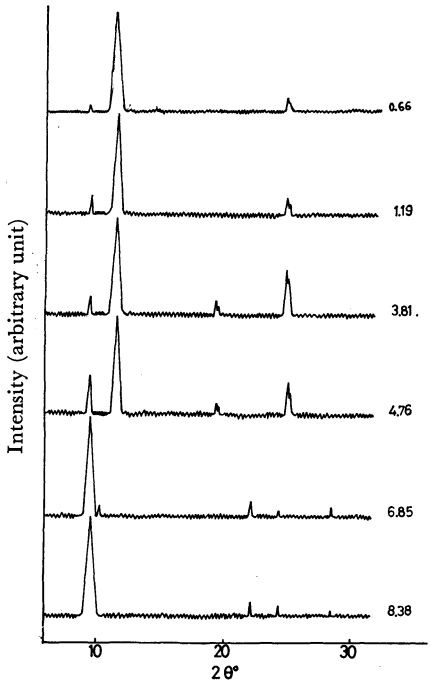

Fig. 3. Schematic diagrams of X-ray diffraction patterns for the ammonium forms of c–ZrP in forward titration. Numerals correspond to that of abscissa in Fig. 1.

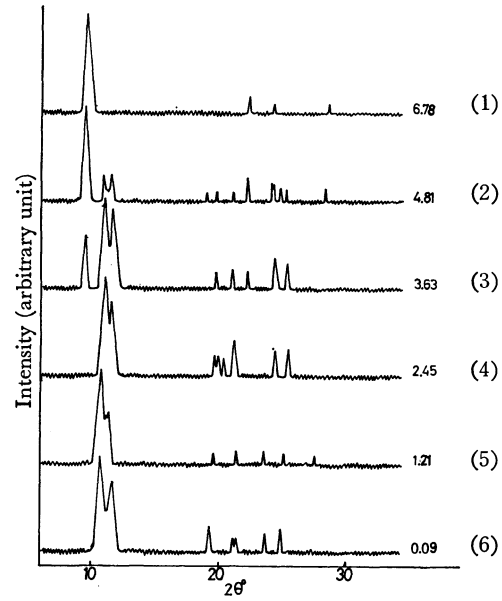

Fig. 4. Schematic diagrams of X-ray diffraction patterns for the ammonium forms of c–ZrP in backward titration. Numerals correspond to that of abscissa in Fig. 1.

66%, these two reflections were both observed. Finally, the latter reflection diminished.

Crystalline zirconium phosphate is known to have a layered structure, the interlayer distance is represented by the first reflection in the X-ray powder pattern. The change in the interplanar distance is found to be shorter than that to be expected from the ionic radius of the ammonium ion. Clearfield and Stynes[1] suggested that the shorter d value for the first reflection of the ammonium form might be due to hydrogen-bond formation between the ammonium ion and the phosphate group.

It is not possible to deduce, from the obtained diffractograms alone, whether the phases accompanied by the ion exchange are entirely different from that of c–ZrP or whether they are a mixture of two phases, c–ZrP and the ammonium-form exchanger. By analogy with the lithium-ion exchange, however, the existence of two phases is very likely, Phase I just at an exchange of 66% and Phase II at 100%.

The X-ray diffraction patterns of the samples which were taken from the backward titration were different from those of the forward titration. On the re-exchange of the ammonium ion with the hydrogen ion, the first reflection (d=9.50 Å) decreased and the second (d=8.20 Å) and third reflections (d=7.60 Å) appeared. The third reflection is identical with the first one of c–ZrP. The first reflection was not observed in Sample (4). It corresponds to the third reflection at 3.3 meq OH^-/g c–ZrP in the titration curve of Fig. 1(b). At the end of the backward titration, the exchanger was no longer identical with the original one, c–ZrP.

As has been stated above, the structural change in the exchanger is irreversible through the whole range of the ion exchange. This is the cause of the hysteresis loop in the titration curves.

In the ion-exchange cycle for the lithium ion, gelatinous zirconium phosphate was formed.[10] When the ammonium ions in the exchanger were replaced by protons, the crystallinity was maintained.

The authors would like to acknowledge the continuous guidance and helpful discussion of Professor Shuji Abe. One of the authors, Y. H., also wishes to thank Professors Kozo Nagashima and Isao Tomita of Tokyo Kyoiku University for their encouragement.

Estimation of the Thermal Yields in the Reaction with Methanes of ^{80}Br Activated by (n, γ) Process

Masakatsu SAEKI and Enzo TACHIKAWA

Division of Reactor Chemistry, Japan Atomic Energy Research Institute, Tokai, Ibaraki

(Received June 26, 1972)

The Estrup-Wolfgang Kinetic theory has been applied to the results obtained from the reactions of ^{80}Br activated by the (n,γ) process with two methanes, CH_4 and CD_4. With suitable assumptions, the most probable kinetic parameters, I's and α's have been obtained. The thermal yields of the products have been estimated as a function of the m.f. of the Kr moderator as the differences between the yields predicted by the kinetic theory with these kinetic parameters and those experimentally obtained. The thermal $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ yields are strongly affected by the m.f. of Kr in such a way that they are not important in the range from zero to around 0.7 m.f. of Kr, but become significant over 0.7 m.f. of Kr. On the other hand, the thermal $CH_2{}^{80}BrBr$ and $CD_2{}^{80}BrBr$ yields are much less sensitive to the m.f. of Kr and are almost constant at 0.5% over the whole moderator range of Kr.

In the recoil chemistry of the gaseous phase, the excess kinetic energy processes are depressed by the addition of an inert gas as a kinetic energy moderator to the reaction system. At 1.0 m.f. of an inert gas moderator, the yields of the energetic processes should be extrapolated to zero. If the extrapolated value is finite, the value is usually considered to be the yield of the kinetic-energy-independent processes in an unmoderated system. In our recent work on the reaction with CH_4 of ^{80}Br activated by the (IT) process, however, we found that the addition of a large excess of inert gases to a reaction system sometimes causes an increase in the yield.[1] In such a case, it is necessary for a detailed analysis of the data to establish how the kinetic energy-independent-processes are affected by the addition of inert gases.

This complex phenomenon is primarily due to the charges imparted to the ^{80}Br atom at the time of the nuclear reaction; it is also due to the relatively low ionization potential of Br. Thus, it could also be anticipated in the reaction of ^{80}Br activated by the (n,γ) process with methane.

Rack and Gordus have examined the above reaction and reached the conclusion that the ^{80}Br atom from the (n,γ) activation reacts with CH_4 principally *via* energetic processes in the whole m.f. range of the moderators.[2] However, a detailed examination of the same reaction system using Kr as the additive has clearly shown that the kinetic-energy-independent process also contributes to the observed organic yields.[3]

In this paper we will apply the Estrup-Wolfgang kinetic theory[4,5] to the data obtained in the reaction of ^{80}Br activated by the (n,γ) process with two methanes, CH_4 and CD_4; with suitable assumptions, the most probable kinetic parameter I's and α's will be determined. The thermal yields of the products have, then, been determined as a function of the m.f. of the Kr moderator as the differences between the yields predicted by the kinetic theory and those experimentally determined.

Experimental and Results

The experimental procedure has been described in detail in a previous paper.[3] Samples were prepared in 18.5 ml silica ampoules. In all cases, the Br_2/CH_4 or CD_4 ratio was 0.02, and the total pressure was kept constant at 500 ± 10 mmHg. Energetic ^{80}Br was formed by irradiating the samples for 5—60 sec in a JRR-4 reactor. The thermal neutron flux at the irradiation port was 2×10^{12} n/cm^2/sec.

The present experimental data, as well as those in Ref. 3, have been used for the present kinetic treatment. The agreements between them are reasonably good. A small difference, however, can be seen in the yield of $CH_3{}^{80}Br$ at a high moderation. All the results are included in Figs. 1 and 2. The most sig-

nificant error in the present data has been introduced in the measurement of the total ^{80}Br activities; it amounts to $\pm 10\%$ in some cases. The uncertainties in the figures indicate the standard deviations among the several measurements.

Application of Kinetic Theory

Estrup and Wolfgang have developed a kinetic theory of hot atom reactions partially based on the mathematics of neutron-cooling processes.[4,5] Although the exact solutions for the kinetic theory must be valid only for highly restricted special cases, they can furnish appropriate forms for the treatment of the experimental data. Three assumptions are involved in this kinetic treatment.[5] The first is that the energy loss occurs by collisions, in which the collision partners can be treated as elastic spheres. The second is that the initial energy of the atom, E_0, is sufficiently large so that the atom has made a number of collisions before reaching the upper limit of the reaction zone, E_2, thus providing a statistically well-defined distribution of energies for the hot atoms in the region of interest. The third is that the minimum energy required for the reaction, E_1, is still large compared to the thermal energies. The validity of these assumptions has been discussed in various systems, and the theory has been successfully applied to the hot atom reactions of halogens[2,6-8] as well as tritium.[5,9]

In the present systems, difficulties arise for at least two reasons. One is related to the initial energy of the ^{80}Br atom, in connection with the second assumption. Since the present knowledge of the spectrum of γ-rays emitted after the neutron capture of ^{79}Br is not sufficient, we only known that the maximum initial kinetic energy of ^{80}Br is 179 eV, which is low compared with those of (n,p)-activated tritium atoms (in the order of 10^5 eV). Thus, it can be considered that an appreciable fraction of the ^{80}Br atoms will be born with a low kinetic energy, in or near the reactive zone.[10] Rack and Gordus applied this theory to the reaction of ^{80}Br with gaseous methane.[2] Later, its application was extended further to the reaction of ^{80}Br[11,12] or ^{82}Br[6] activated by isomeric transition in various systems. These successful applications in both gaseous and liquid phases[8] can be taken as indicating that this assumption is reasonably justified in our present system. The other concerns the fact that no information is available about the Br-to-HBr abstraction reaction probability for the present reaction system, since no experimental procedure can serve for measuring $H^{80}Br$. Because of the low organic yield in the $^{80}Br+CH_4$ system, we could expect the inorganic yield to be comparable, causing no difficulty in the use of the kinetic theory treatment for a case of low reactivity.

According to the developed kinetic theory, the total energetic yields, P, in the moderator experiments have been expressed in terms of two kinetic parameters, I, reactivity integral and, α, average logarithmic energy loss, as follows:

$$-\frac{1}{\ln(1-P)} = \frac{\alpha_{react}}{I} + \frac{\alpha_{mod}}{I}\cdot\frac{1-f}{f} \qquad (1)$$

When the total probability of a hot reaction, P, is low, as in the present case, the developed equation for the yield of individual products from the hot reaction with a reactant in the moderated system, P_i (hot), can be simply expressed as:

$$P_i(\text{hot}) = (I_i/\alpha_{react})(1+\alpha_{mod}/\alpha_{react}(1/f-1))^{-1} \qquad (2)$$

If we know the values of I_i/α_{react} and $\alpha_{react}/\alpha_{mod}$, we can calculate P over the whole range of moderators using Eq. (1).

In the actual application of the kinetic theory to the results shown in Figs. 1 and 2, we have to consider the contribution of the thermal yield involved. It is possible to express the observed yield of individual products as the summation of the yields due to the energetic process and the thermal process at any m.f. of Kr. Thus, the following equation can be derived:

$$P_i = (I_i/\alpha_{CH_4})(1+\alpha_{Kr}/\alpha_{CH_4}(1/f-1))^{-1} + P_{i(\text{thermal})} \qquad (3)$$

The first term is for the energetic yield, and the second, for the thermal yield. It is known only that $P_{i(\text{thermal})}$ is equal to the extrapolated value, $P^{\infty}_{i(\text{thermal})}$, at 1.0 m.f. of Kr. Three cases can be considered, depending upon how the $P_{i(\text{thermal})}$ varies with the m.f. of Kr:

10) Using the random-walk equations, Rack *et al.* tried to calculate the kinetic energy spectra for (n,γ)-activated ^{128}I atoms, which have the maximum initial kinetic energy of 194 eV. The results showed that an appreciable fraction of the ^{128}I species are born with kinetic energy, near the reaction zone. M. Yoog, Y. C. Pao, and E. P. Rack, COO-1617-30 (1971).
11) E. Tachikawa and K. Yanai, *Radiochim. Acta*, **17**, 138 (1972).
12) K. Numakura and E. Tachikawa, This Bulletin, **46**, 346 (1972).

Case 1. $P_{i(thermal)}$ is constant over the whole m.f. range of Kr. In this case, $P_{i(thermal)}$ is simply equal to $P^{\infty}_{i(thermal)}$ and can be experimentally found.

Case 2. $P_{i(thermal)}$ is zero with no additive, but rises with an increase in the m.f. of Kr.

Case 3. This involves both cases, 1 and 2. $P_{i(thermal)}$ increases with the m.f. of Kr from a non-zero value to $P^{\infty}_{i(thermal)}$.

In the first case, the addition of an inert gas simply reduces the average kinetic energy of the ^{80}Br atom, resulting in a reduction of the energetic yiled without influencing the thermal yield. This is the case which is usually expected in recoil chemistry. In the other cases, however, the physical properties other than the kinetic energy of the recoil atom, such as the charge or electronic excitation energy state, are also affected by the addition of an inert gas, and the extrapolated value, $P_{i(thermal)}$, at 1.0 m.f. of Kr does not reflect the true thermal yield in the unmoderated system.

Unfortunately, without any *a priori* basis to know which category the present case belongs to, we can only assume that the thermal yield does not exceed the $P^{\infty}_{i(thermal)}$-value at any m.f. of Kr. Thus, the contribution of the total thermal yield ($P_{thermal}=\sum P_{i(thermal)}$) to the observed yield (P) is probably not significant at low m.f. values of Kr. As a first step to the kinetic treatment, therefore, the total organic yields obtained from zero to about 0.4 m.f. of Kr were subjected to Eq. (1), with the assumptions that, in this range of the m.f. of Kr, the total thermal yield is of only minor importance and that practically all the products are formed *via* energetic processes. The results obtained were shown graphically in Figs. 3 and 4 for the ^{80}Br–CH_4–Kr and ^{80}Br–CD_4–Kr systems. The ratio of the intercept to the slope gives $\alpha_{CH_4}/\alpha_{Kr}=0.33$ in Fig. 3 and $\alpha_{CD_4}/\alpha_{Kr}=0.37$ in Fig. 4.

If the I_i/α_{react} values are obtained by subtracting the thermal yield, $P^0_{i(trermal)}$, from the observed yield, P_i, in an unmoderated system, we can calculate the energetic yield of the individual products at any m.f. of Kr using Eq. (2). Then, the difference (ΔP_i) between the calculated yield and the experimentally-obtained

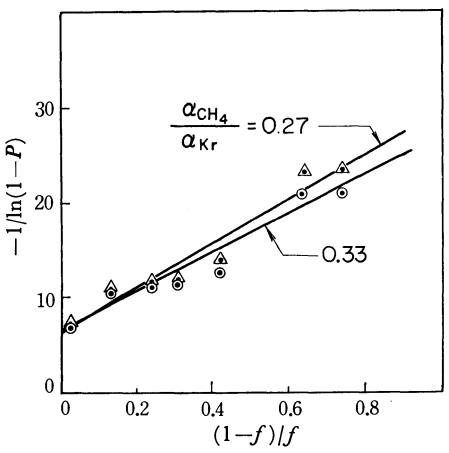

Fig. 3. Plot corresponding to equation 1) for the reaction system, ^{80}Br+CH_4+Kr.

yield can be assumed to be the kinetic-energy-independent yield. Without a knowledge of the true $P^0_{i(thermal)}$ value, however, we can choose any value from zero to the limiting yield at 1.0 m.f. of Kr, $P^{\infty}_{i(thermal)}$. If a proper value is taken for $P^0_{i(thermal)}$, ΔP_i as a function of the m.f. of Kr should belong to one of three classes, depending upon the Cases 1, 2, or 3 discussed above. In Case 1, ΔP_i will be equal to the chosen value at any m.f. of Kr, while in Case 2 or 3 ΔP_i will increase with the m.f. of Kr from zero or a non-zero value to the $P^{\infty}_{i(thermal)}$. A set of calculations with the results for $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ show that when we use a $P^0_{i(thermal)}$ value other than zero the ΔP_i value obtained always shows a concave curve *vs.* the m.f. of Kr and has a minimum around 0.5 m.f. of Kr. Such a behavior of the thermal yield is very unrealistic, since the thermal process yield should not be reduced by the addition of an inert gas. On the other hand, when $P^0_{i(thermal)}$ is set as zero, the ΔP_i converges from around zero up to 0.7 m.f. of Kr. This ΔP_i curve shows a behavior consistent with the Case 2, indicating that the thermal yields of $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ in the present system are not important in the range from zero to around 0.7 m.f. of Kr, but become significant at a higher moderation.

A similar treatment of the results for $CH_2{}^{80}BrBr$ and $CD_2{}^{80}BrBr$ leads to the conclusions that, when $P^0_{i(thermal)}$ is chosen as 0.5%, ΔP_i is almost constant at 0.5 any mole fraction of Kr. This accords with the results expected in Case 1.

Those results were fed back to the recalculation of $\alpha_{react}/\alpha_{mod}$ using Eq. (1). In this feed-back calculation, the total organic yields less 0.5% were used as the P values. The results obtained are also plotted in Figs. 3 and 4 in the $-1/\ln(1-P)$ *vs.* $(1-f)/f$ relation. The ratio of the intercept to the slope of the lines gives $\alpha_{CH_4}/\alpha_{Kr}=0.27$ for the CH_4–Kr system and $\alpha_{CD_4}/\alpha_{Kr}=0.28$ for the CD_4–Kr system. Using new values for $\alpha_{react}/\alpha_{mod}$, the calculation of the energetic yields of the individual products were performed in a manner similar to that described above. The results are summarized in Fig. 5 for methyl bromides, $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$, and in Fig. 6 for methylene bromide, CH_2-

$^{80}BrBr$. The calculated energetic yields are shown by broken lines, in comparison with the experimental data, which are expressed by circles, with the experimental error and are connected by a solid line. The differences between two lines are assumed to be the thermal yields and are shown in the same figures by solid circles for $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ and by open circles for $CD_3{}^{80}Br$. The thermal yields of $CD_2{}^{80}BrBr$ obtained by a similar treatment, which are not included in the figure, were just the same as that obtained for $CH_2{}^{80}BrBr$, showing no significant difference in the contribution of the thermal process to the observed yield between $CH_2{}^{80}BrBr$ and $CD_2{}^{80}BrBr$.

It can be said that the thermal yield of methyl bromide is not significant and that it is substantially zero in the m.f. range of Kr from zero to around 0.7, but it starts to rise with a further increase in the m.f. of Kr and can reach to around 0.8% at 1.0 m.f. of Kr. On the other hand, the thermal yield of methylene bromide, $CH_2{}^{80}BrBr$ or $CD_2{}^{80}BrBr$, is almost constant at 0.5% over the whole m.f. range of Kr and no noticeable effect has been observed upon the addition of Kr.

In order to confirm the above hypotheses, a further investigation has been carried out on the isotope effect in $CH_3{}^{80}Br/CD_3{}^{80}Br$. The following assumptions have been introduced:

1) The thermal yield of the methyl bromide is related to the m.f. of Kr in the form of X_{Kr}^{n} (X_{Kr} is the m.f. of Kr, and n is a constant), and no isotope effect exists in the $CH_3{}^{80}Br/CD_3{}^{80}Br$ system as far as the thermal yields are concerned.
2) The values of the isotope effect in the energetic yield do not vary significantly from 2.7 over the whole moderator range of interest.

The first assumption is primarily based on the findings of the above kinetic treatments of the results. Although any other possible function might be used, it is convenient to use the present simple function, since there is almost no knowledge about the dependence of the thermal yield on the concentration of Kr except the present results. The non-existence of the isotope effect on the thermal processes has also been noticed in the reaction of ^{80}Br activated by the isomeric transition.[11] Thus, this is a reasonable starting assumption for the subsequent considerations. The second assumption is a rather crude one. Strictly speaking, this assumption is well justified only in a situation where the possible reaction energy range is the same for both reactions to form $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ and where the ratio of the probability of a successful reaction per collision for $CH_3{}^{80}Br$ relative to that for $CD_3{}^{80}Br$ is constant over the whole reaction energy range. This situation is a case of the reactivity integral isotope effect. However, the distinction of this situation from the others is not possible, and we can only assume this is the case.

On these assumption, the following equation can be derived for the isotopic variation in the yield of methyl bromide:

$$Y_{(n)} = \frac{(I_i/\alpha_{CH_4})(1+\alpha_{Kr}/\alpha_{CH_4}(1/f-1))^{-1}+X_{Kr}^{n}A}{(I_i/\alpha_{CD_4})(1+\alpha_{Kr}/\alpha_{CD_4}(1/f-1))^{-1}+X_{Kr}^{n}A'} \quad (4)$$

If n=zero, Eq. (4) can be simplified to;

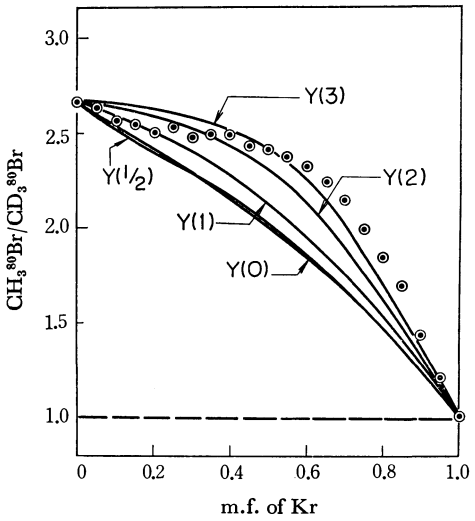

Fig. 7. Plot corresponding to Eqs. (4) and (5) with the experimental values. (details in the text.)

$$Y_{(n)} = \frac{(I_i/\alpha_{CH_4}-A)(1+\alpha_{Kr}/\alpha_{CH_4}(1/f-1))^{-1}+A}{(I_i/\alpha_{CD_4}-A')(1+\alpha_{Kr}/\alpha_{CD_4}(1/f-1))^{-1}+A'} \quad (5)$$

At the limiting condition at 1.0 m.f. of Kr, $A=P^{\infty}_{CH_3{}^{80}Br\,(thermal)}$ and $A'=P^{\infty}_{CD_3{}^{80}Br\,(thermal)}$. Since the limiting yield is roughly equal to 0.85% for both $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$, $A'=A$. On the other hand, at zero m.f. of Kr, I_i/α_{CH_4} and I_i/α_{CD_4} are equal to $P^0_{CH_3{}^{80}Br}$ and $P^0_{CD_3{}^{80}Br}$ and are 12.3 and 4.6% respectively. Figure 7 shows Eq. (4) (for n equal to 1/2, 1, or 2) and Eq. (5) (for n equal to zero). The plots of the $CH_3{}^{80}Br/CD_3{}^{80}Br$ ratio obtained from the interpolated curves in Figs. 1 and 2 for $CH_3{}^{80}Br$ and $CD_3{}^{80}Br$ are also shown in the same figure. It is obvious that the experimental curve is far from the prediction for n=zero, although it does not show a good fit with either of the calculated cruves.

In view of the limits, accuracy of the present experimental results, it is very hard to discuss the results quantitatively and to find a function to fit the experimental results. One conclusion we can draw from the present calculations is that the contribution of the thermal process in producting methyl bromide is affected by the concentration of Kr. This conclusion accords with the finding in the early part of this paper.

Comparison of the Kinetic Parameter. I. Here it is interesting to evaluate the I value in the present reaction system and to compare it with those found in other reaction systems, such as in the reaction with the methane of ^{80}Br activated by isomeric transition.[1] This comparison will provide qualitative information concerning the reactivity of the recoil atom activated by various nuclear reactions.

By expanding Eq. (1), the following can be obtained:

$$P = (f/\alpha)I - (f/\alpha)^2K + (f/\alpha)^3L \cdots \quad (6)$$

In the case of a low reactivity, the total probability, P, may be well approximated by the first two terms, because these series will converge rapidly. A plot of $(\alpha/f)P$ *vs.* f/α should give a straight line, with an intercept of I and a slope of K. The values for I obtained by the plots are tabulated in Table 1, with along the α_{CH_4} and α_{CD_4} values. The I_i values obtained using Eq. (2) were also included. Those are all expressed in units of α_{Kr}.

Nicholas and Rack have also applied the kinetic theory to the total organic yield in the reaction of ^{82}Br activated by the (IT) process with CH_4.[6] In their calculation, the kinetic energy yield was obtained simply by subtracting the limiting yield at 1.0 m.f. of the moderator from the observed yield at various m.f. values of the moderator; $\alpha_{CH_4}=0.098\ \alpha_{Kr}$ and $I_{CH_3{}^{82}Br}=0.004\ \alpha_{Kr}$ were thus obtained.

However, a recent detailed examination of the reaction of ^{80}Br activated by the (IT) process with CH_4[1,14] has revealed that an additional yield due to the kinetic-energy-independent process becomes noticeable at a high moderation. A similar trend can also be expected in Rack's experiment. We consider that these reported values are strongly affected by the kinetic-energy-independent yield.

Although the α value should be an energy-dependent term, it is not conceivable that the value changes drastically in the reaction of the (IT)-induced ^{80}Br or ^{82}Br atom. The treatment of the results in Ref. (1) using the α value obtained in this work, $\alpha_{CH_4}=0.27\ \alpha_{Kr}$, gave $I_{CH_3{}^{80}Br}=0.018\ \alpha_{Kr}$, which is also included in Table 1. The $I_{CH_3{}^{80}Br}$ value in the $(n,\gamma)^{80}Br$–CH_4 system is roughly three times that in the ^{80m}Br–CH_4 system under the present kinetic treatment.

Discussion

The above calculations show that, within the limits of experimental error, the kinetic theory appears to be applicable to the present system as far as the energetic reactions are concerned; it also seems to be an adequate

Table 1. Parameters of kinetic theory
(expressed in units α_{Kr})

framework for the entire range of data. In other words, it appears that the assumptions of the kinetic theory are reasonably satisfied, in that the treatment is sufficiently insensitive to the approximations that are inherent in these assumptions.

However, some question still remains as to the value used as the total energetic yield. The abstraction of hydrogen by the recoil atom is a very common reaction mode; it must also be taken into account in the present system. In the recoil tritium reactions, the ratio of the hydrogen-abstraction yield to the hydrogen-substitution-reaction yield has been well established as 0.79 for CH_4,[15] and it tends to increase with the number of carbon atoms in the reactant molecule.[16] Recently Root *et al.* examined the energetic F-to-HF abstraction yield in the reaction of recoil ^{18}F with CH_3CF_3 and reported the value of 51% for the primary yield.[17]

Without any available experimental data for the Br-to-HBr abstraction reaction, we assigned various yields for this abstraction yield and tried to determine the trend shown by the results drawn from the kinetic treatment. Assuming, for example, that the energetic $H^{80}Br$ yield is equal to the total organic yield, the kinetic treatment gave $\alpha_{CH_4}/\alpha_{Kr}=0.26$, which is quite similar to the value found in the preceeding calculation. Thus, the conclusion reached above is hardly affected by a correction for the total organic yield, considering the energetic $H^{80}Br$ yield.

The identity of the thermal processes is primarily ascribed to the thermal ionic processes, considering the physical state of ^{80}Br at the time of formation from the nuclear reaction. However, when we compared the limiting yield at 1.0 m.f. of Kr between the present case and the ^{80m}Br–CH_4,[1] a similar value was found for $CH_3{}^{80}Br$ but not for $CH_2{}^{80}BrBr$. This can not be easily explained with the presently available knowledge, as has been suggested in an earlier report of this series,[18] the role of interaction between ^{80}Br and Kr might also be considered.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 844—847 (1973)

Synthesis and Metal Chelate Stability of *N,N'*-Ethylenebis(aminomalonic) Acid

Misao MASHIHARA*, Takeshi ANDO, and Ichiro MURASE

Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Fukuoka 810

(Received July 20, 1972)

N,N'-Ethylenebis(aminomalonic) acid (EAMA) has been synthesized, and its acid dissociation constants and the stability constants of its alkaline earth metal complexes were determined potentiometrically at 25°C in a medium of ionic strength of 0.10 (KNO_3) with the following results: $pK_1=2.1$, $pK_2=2.72$, $pK_3=6.56$, $pK_4=9.69$; $\log K_{MY}$ and $\log M_{MHY}$ for Ca(II) respectively, 5.45 and 2.02; for Mg(II) respectively 4.93 and 1.80. The exact stability constants of Cu(II) and Ni(II) chelates of this ligand were not obtained on account of its decomposition in low pH solution, but the order of relative stability has been established. From a comparison of the stability of Ca(II) and Mg(II) chelates with those of the analogous complexane, the function of the malonate group in the chelate formation has been discussed. Zn(II) and Co(II) chelates of this ligand have been obtained and their probable structures are proposed.

Aminomalonic acid investigated by Schwarzenbach[1] as a chelating ligand has three functional groups in metal chelate formation. However, it is sterically impossible for these three groups to coordinate to the metal ion forming two chelate rings. The ligand functions as a bidentate ligand in which the amino nitrogen and one carboxylate participate in chelate formation. This was evidenced by the fact that the stability of the metal chelates of aminomalonic acid is lower than that of iminodiacetic acid which can act as a terdentate ligand to form two chelate rings with the metal ion.

N,N'-Ethylenebis(aminomalonic) acid (EAMA) (I) is a tetrabasic acid having six donor groups including two basic nitrogen atoms.

(I)

However, it is considered to act as a quadridentate ligand in metal chelate formation as in aminomalonic acid, being expected to exhibit behavior analogous to that of ethylenediamine-*N,N'*-diacetic acid.

This paper deals with the synthesis and chemical behavior of EAMA, the potentiometric determination of acid dissociation constants, and metal chelate stability. A discussion is given on the function of the

malonate moieties in metal chelate formation and stability in comparison with analogous ligands such as ethylenediaminetetraacetic acid (EDTA), ethylenediamine-*N,N'*-diacetic acid (EDDA), and ethylenediamine-*N,N'*-di(α-propionic) acid (EDDMA). The structure of the insoluble chelates with Co(II) and Zn(II) ion has been determined by means of infrared spectroscopy.

Experimental

Material. N,N'-*Ethylenebis(aminomalonic) acid (EAMA)*: To a solution of 9.2 g (0.05 M) of bromomalonic acid dissolved in 30 ml of water and neutralized with 30% aqueous sodium hydroxide at 5°C was added 1.5 g (0.025 M) of 98% ethylenediamine and the mixture was heated at 70°C. The pH of the solution was kept at 9—11 for 1 hr by dropwise addition of 30% aqueous sodium hydroxide. On cooling, it was brought to 1—2 by careful addition of dilute hydrochloric acid and the resulting precipitates were filtered and washed with water and methanol. For purification, the crude product was dissolved in aqueous alkali, filtered and precipitated by adjusting the pH of the filtrate at nearly 1 with dilute hydrochloric acid. The procedure was repeated three times and a pure sample was dried over calcium chloride in a vacuum. The acid undergoes decarboxylation at 166—169°C and melts at 202—204°C with decomposition.

Found: C, 33.62; H, 5.33; N, 10.03%. Cacld for $C_8H_{12}N_2O_8 \cdot H_2O$: C, 34.05; H, 5.00; N, 9.93%.

Disodium Salt of EAMA: To a suspension of 6 g of free EAMA in 100 ml of water was added 30% aqueous sodium hydroxide until the pH of the solution reached 8 and the solution was filtered. The filtrate was diluted with 300 ml of ethanol and the resulting precipitates were filtered. The product was dissolved in a minimum amount of water, filtered, and precipitated by the addition of a large amount of ethanol. The procedure was repeated and the product was dried over calcium chloride in a vacuum.

Found: C, 28.14; H, 4.04; N, 8.55%. Calcd for $C_8H_{10}N_2O_8Na_2 \cdot 2H_2O$: C, 27.92; H, 4.10; N, 8.14%.

Decarboxylation of EAMA: A suspension of 6 g of free EAMA in 60 ml of water was refluxed for 2 hr, while the acid gradually dissolved into solution accompanied by evolution of carbon dioxide. The resulting clear solution was concentrated to 20 ml in a vacuum and diluted with 60 ml of ethanol. After being left overnight in a refrigerator, the resulting crystals were filtered. Recrystallization twice from dilute ethanol gave a pure sample of ethylenediamine-*N,N'*-diacetic acid, mp 210—211°C (decomp.).

Found: C, 40.56; H, 7.12; N, 15.84%. Calcd for $C_6H_{12}N_2O_4$: C, 40.91; H, 6.82; N, 15.90%.

The filtrate from which crude EDDA was obtained was evaporated to dryness and the residue was recrystallized three times from methanol. The compound was determined to be ethylenediamine-*N,N'*-diacetic acid lactam. It melts at 222°C with decomposition. IR (KBr) 1645 cm^{-1} (lactam C=O), 1586 cm^{-1} (COO^-).

Found: C, 44.02; H, 6.58; N, 17.29%. Calcd for $C_6H_{10}N_2O_3 \cdot 1/3\ H_2O$: C, 43.90; H, 6.55; N, 17.06%.

Co(II) Complex of EAMA: A 100 ml aqueous solution of 0.01 M disodium salt of EAMA was mixed with 90 ml of 0.01 M $Co(NO_3)_2$ aqueous solution, to which was added 20 ml of 0.1 N HNO_3. After being left overnight, the resulting precipitates were filtered and washed with water and methanol and dried over calcium chloride in a vacuum. Pink crystalline powder, mp>280°C.

Found: C, 25.43; H, 4.24; N, 7.77; Co, 15.85%. Calcd for $C_8H_{10}N_2O_8Co \cdot 3H_2O$: C, 25.61; H, 4.30; N, 7.47; Co, 15.72%.

Zn(II) Complex of EAMA: The procedure was the same as in the preparation of Co(II) complex except that zinc nitrate was used in place of cobalt nitrate. Colorless crystalline powder, mp>280°C.

Found: C, 25.18; H, 4.03; N, 7.48; Zn, 17.20%. Calcd for $C_8H_{10}N_2O_8Zn \cdot 3H_2O$: C, 25.18; H, 4.23; N, 7.34; Zn, 17.13%.

Measurements and Calculation. The method consists of potentiometric titration of the ligand in the absence of the metal ion for the acid dissociation constant and in the presence of the metal ion for the chelate stability. A carbonate free 0.1M KOH was used for the titration. All measurements were carried out at 25±0.1°C in a medium of ionic strength of 0.10 (KNO_3) with a Hitachi Horiba model F-5 pH meter.

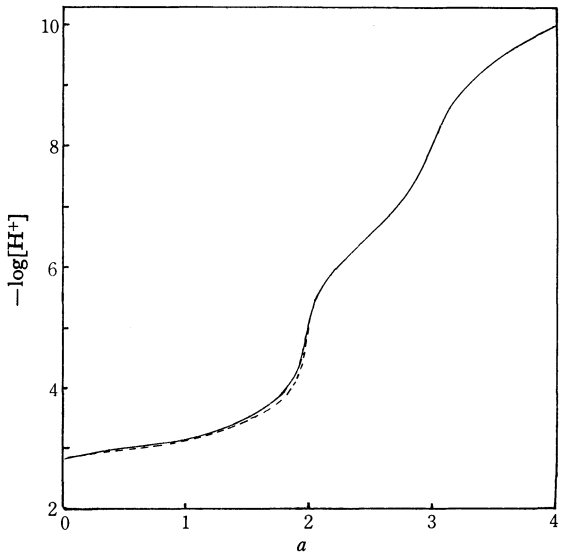

Fig. .1 Titration of EAMA and EAMA–2Na, ------ EAMA–2Na+0.1M HCl; —— EAMA+0.1M KOH (after the neutralization of EAMA–2Na). The concentration of the acid is 0.001 M.

It should be substantiated that no decomposition of the ligand occurs during the course of titration, since EAMA turns to decarboxylate in solution at low pH. Thus the solution of disodium salt of EAMA was titrated with 0.1M HCl until two equivalent of the acid had been added and the solution was retitrated with 0.1M KOH until four equivalent of the base had been added. As seen in Fig. 1, the titration curves coincide with each other within experimental error, provided that the effect of increasing volume is taken into consideration. Therefore, it has been proved that no decomposition occurred.

The acid dissociation constants were calculated by the method of Schwarzenbach and Ackermann.[2] Determination of the stability constants of the Ca(II) and Mg(II) chelates was also accomplished by the same method. For the determination of the stability of Ni(II) and Cu(II) chelates, attempts were made to apply the method of Anderegg used for measuring the stability constants of moderately stable chelates of complexanes.[3] However, the stability constants could not be calculated owing to possible partial decomposition of the ligand. Thus the calculation was made by Bjerrum's

2) G. Schwarzenbach and H. Ackermann, *ibid.*, **31**, 1029 (1947).
3) F. L'Eplattenier and G. Anderegg, *ibid.*, **47**, 1792 (1964).

procedure on the assumption that EAMA would form 1:1 chelates with both metal ions almost exclusively. The procedure was applied by Chaberek and Martell[4] to measure the stability of transition metal chelates of ethylenediamine-*N*,*N*'-diacetic-*N*,*N*'-dipropionic acid. In the present case, the relative precision of the obtained data was very low.

The equilibrium constants are expressed as follows:

Acid dissociation constants,

$$K_n = [H^+][H_{4-n}Y^{n-}]/[H_{4-n+1}Y^{(n-1)-}]$$

Stability constants,

$$K_{MHY} = [MHY^-]/[M^{2+}][HY^{3-}]$$

$$K_{MY} = [MY^{2-}]/[M^{2+}][Y^{4-}]$$

where H_4Y and M represent EAMA and metal ion, respectively.

Results and Discussion

Titration Curves. The titration curve of EAMA (Fig. 2) has buffer regions at about pH 4 and 7 followed by inflections at two equivalents and three equivalents of base respectively per mole of the amino acid. Thus the free acid, the divalent anion and the trivalent anion exist in a relatively pure state in solution, whereas the tetraalkali metal salt is extensively hydrolyzed.

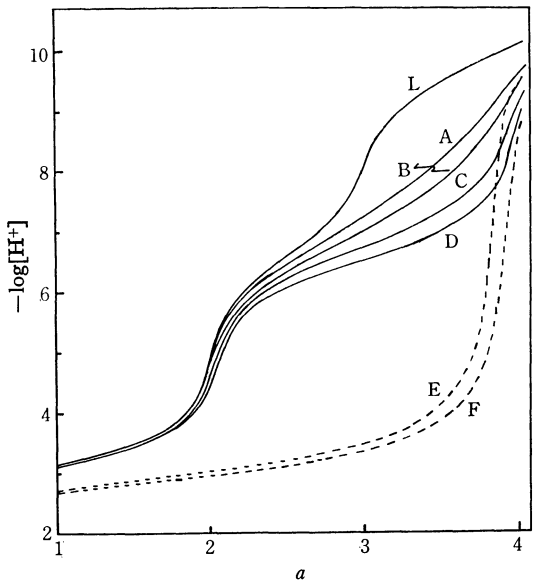

Fig. 2. Titration of EAMA with 0.1M KOH in the presence of metal ions. L, 0.001M free acid; A, B, E, and F, same as L with equimolar Mg(II), Ca(II), Ni(II), and Cu(II) respectively; C and D, with about ten times excess of Mg(II) and Ca(II) respectively. (All metal salts are the nitrate)

The titration curves in the presence of metal ions, shown in Fig. 2, indicate relatively weak chelate formation with alkaline earth metals but strong interaction with transition metals.

The free amino acid tends to decompose in acidic solution due to decarboxylation of the malonic acid moiety to yield ethylenediamine-*N*,*N*'-diacetic acid. In the absence and presence of alkaline earth metal ions, however, such decomposition process could not be observed during the course of titration. On the other hand, in the titration curves with Cu(II) and Ni(II) ions, the inflection deviates from the exact stoichiometry at $a=4$ indicating the decomposition of the ligand.

Table 1. Acid dissociation constants
$t=25°C$; $\mu=0.10$ (KNO_3)

	pK_1	pK_2	pK_3	pK_4
EAMA	2.1	2.72	6.56	9.69

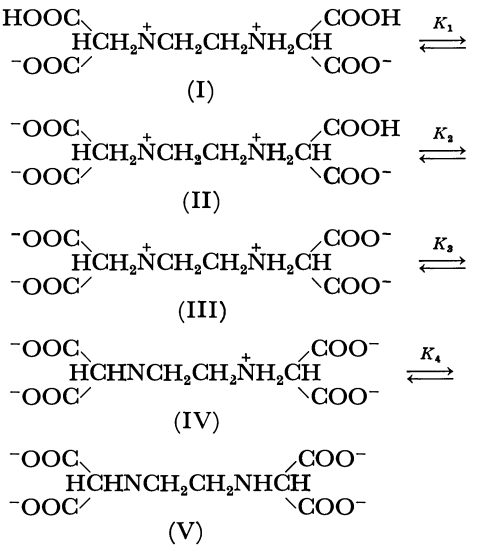
a) These were measured at 20°C, $\mu=0.10$(KCl)

Acid Dissociation and Metal Chelate Stability Constants. The first and second acid dissociation constants (pK_1 and pK_2) of EAMA, listed in Table 1 are almost the same as the corresponding values for EDTA, indicating that they are due to the dissociation of the free carboxylic acid in (I) and (II).



The third dissociation of a proton is the liberation from the $-\overset{+}{N}H_2-$ in (III). It is greatly influenced by positive charge of the adjacent ammonium group. The pK_3 value is higher than that of EDTA by 0.4 log unit and almost comparable to that of EDDA as seen in Table 1.

The difference between the acidity of the last proton to dissociate from (IV) and that of corresponding anion of EDTA may be explained on the basis of the relative electrostatic effects in these anions. The pK_4 value of EAMA is lower than that of EDTA by *ca.* 0.6 log unit. We see that the inductive effect of two carboxylate anions through one $-CH<$ group in EAMA is smaller than that of the two carboxylate anions through each $-CH_2-$ group in EDTA. However, a larger inductive effect of the malonate anion than that of single acetate

group is observed in comparing the pK_4 value with pK_2 value in EDDA.

The stability constants of EAMA with alkaline earth metal ions are much lower than those with EDTA as seen in Table 2. Although EAMA carries six coordination sites in the molecule, it will be sterically impossible for the two carboxylate groups in each malonate moiety to coordinate to the metal ion at the same time. Since the presence of the binuclear chelate is not observed from titration in the presence of large excess of the metal ion (log $K_{M_2Y}\approx 0$), the most probable structure of the alkaline earth metal chelates will be one in which a carboxylate group in each malonate moiety is free and the remaining coordination sites are occupied by water molecules as shown in Fig. 3.

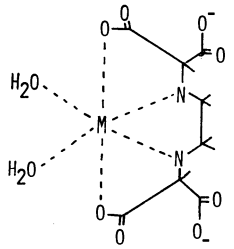

Fig. 3. Probable structure of the alkaline earth metal chelate.

We see from a comparison of log K_{MY} of Mg(II) chelate of EAMA with that of EDDA that the stability for the former is higher by one log unit. This may be partly due to higher basicity of the nitrogen atoms. However, the main contribution lies on the entropy effect of the two malonate groups, which results from an increase of the probability of attaining a spatial orientation required for chelation with the central metal ion. This is also evidenced by the comparison with EDDMA in which one carboxylate of both malonate groups in EAMA is replaced by a methyl group. Although the basicities of the two nitrogen atoms are comparable to those of EAMA (Table 1), the stability of Mg(II) chelate is lower than that of EAMA and even that of EDDA (Table 2). The methyl groups functioned only as a bulky group to exert a steric hindrance to the chelate formation.

A strong interaction of EAMA with Cu(II) and Ni(II) ions is observed from the titration curves. However, the chelate formation with these ions is accompanied by decomposition of the ligand, and the stability constants obtained suggest only a relative order of their magnitude. Considering the above chelate effect the true stability constants might assume any values between those of EDDA and EDTA provided the structures of these chelates are the same as those of the alkaline earth chelates. Decomposition will be due to a lowering of pH by the chelate formation and the metal ion in the chelate also may catalyze the decomposition.

Structure of Co(II) and Zn(II) Chelates. Titration of EAMA with Co(II) and Zn(II) ions was impossible because they formed insoluble precipitates before titration. It was found that the lower pH was favorable for the formation of precipitates. The metal-ligand composition is exactly 1:1 for both compounds as suggested by elementary analysis.

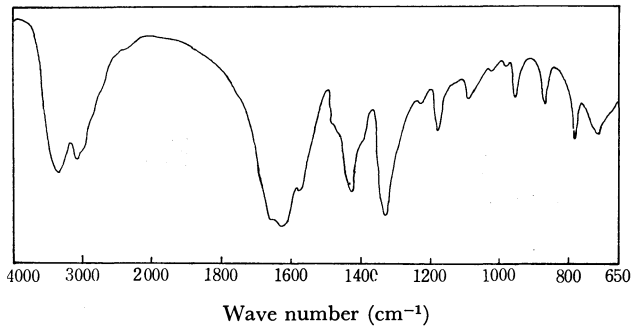

Fig. 4. Infrared spectrum of Zn(II) chelate.

Infrared spectra of both compounds are superimposal (Fig. 4). A very strong and broad band was observed around 1640 cm^{-1}, due to a symmetric stretching vibration of the carboxylate group. A stretching vibration of ammonium group appears around 3000—2500 cm^{-1}. In the free ligand, the carboxylate absorption is at the same position, but the carbonyl vibration of the free carboxylic acid is observed as a sharp absorption at 1754 cm^{-1}. Thus the compound might be a neutral metal chelate polymer in which the ligand molecules are bridged together with the metal ion at the terminal malonate groups and all imino nitrogens are protonated (Fig. 5).

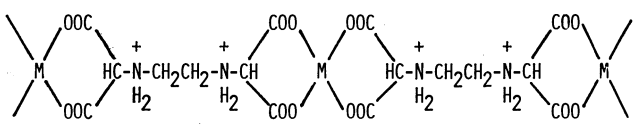

Fig. 5. Structure of Co(II) and Zn(II) chelates.

The chelate polymer is insoluble in water and soluble in alkaline solution. This can be explained by the positive charges on the ammonium nitrogens being neutralized by the hydroxide anion and the unit molecule carring −2 charge.

Photochromism of Thallium Chloride

(Received July 26, 1972)

The ultraviolet-induced darkening and subsequent bleaching of crystalline thallium chloride was investigated in order to study the processes occurring in a photochromic glass containing TlCl crystalline particles. Doping with a small amount of copper, silver or indium ion was found to be effective in promoting darkenability of TlCl crystals. Exposure to visible light causes bleaching of UV-induced coloring of TlCl crystals. Almost no fading occurs, however, when TlCl crystalline pieces are kept in darkness at room temperature or higher temperatures up to about 70°C, where very quick fading in color is observed in the case of TlCl crystals embedded in a glassy matrix.

Much attention has been drawn to photochromic silver halide glass[1,2] since its discovery. The glass darkens when it is exposed to UV light and returns reversibly to the original non-colored state when kept in darkness. The active agents inducing such behavior are silver halide crystalline particles embedded in a glassy matrix. The reversibility of color change was explained by the reasoning that silver halide particles do not lose halogens since they are surrounded by impermeable and inert glassy matrix.[1]

Thallium monohalides are supposed to be similar to silver halides in some respects[3] and it is considered that photochromic glasses could be made with the use of thallium halides as active agents. This was actually found to be the case.[4] Experimental results on the photosensitive and photochromic behavior of TlCl crystalline pieces and a comparison with the behavior of TlCl crystals in glass are given in this paper. The photolytic behavior of silver halide crystal has been extensively investigated, because of its importance in the field of photography, but not that of thallium halide crystal. It is known that the presence of impurity Ag or Pb promotes the photosensitivity of TlCl,[5] although, according to Renz,[6] even very pure TlCl becomes dark by prolonged UV irradiation. Optical absorption measurements[7,8] show that TlCl has a few large absorption bands with the absorption edge reaching 400 mμ and a broad visible absorption band peaking at 535 mμ before and after UV irradiation, respectively. The crystal shows selective bleaching, to which Hilsch and Pohl attributed the presence of colloids.

Christy and Dimock[9] suggested that no color centers were formed by X-ray irradiation in a pure large crystal of TlCl. This is also the case for AgCl crystal. A large AgCl crystal showed almost no coloration upon irradiation when it was very pure, the addition of copper being necessary to give the UV coloration.

A small amount of chalcogen impurities such as S^{2-} and Se^{2-} produced an absorption peak near 400 mμ when a TlCl crystal is quenched from high temperatures without irradiation. The peak disappeared and another band (colloidal band) appeared near 600 mμ when the crystal was kept at room temperature. The study made by Christy and Dimock[9] and other previous works[5-8] would imply that a large TlCl crystal should contain some kind of impurity if it is colored by UV irradiation and that there is a possibility for the formation of Tl colloids in TlCl crystal.

Experimental

Preparation of TlCl Crystal. TlCl crystals were prepared by melting TlCl powder (Alfa Inorganics, Inc., U.S.A.). The powder was heated in a small pyrex beaker in an electrically heated furnace in air at 500°C. The molten mass of TlCl was slowly cooled down in the furnace. From the clear but slightly greyish solidified mass of TlCl crystal, rectangular pieces, about $20 \times 10 \times 1$ mm^3, were cut off with a razor blade, and, to make the surface smooth, were remelted between two thin sheets of glass which were easily peeled off after cooling. The thickness of plate samples was 1.0—1.4 mm. To incorporate a given impurity cation into "pure" TlCl, a given amount of the corresponding metal chloride was mixed with TlCl powder before the first melting.

Preparation of Glass. Composition, preparation, and properties of photochromic glasses containing TlCl crystallites were described in detail in a separate paper.[4]

For the present suty, a batch mixture consisting of KPO_3 25, $Ba(PO_3)_2$ 25, $Al(PO_3)_3$ 50, TlCl 12, NaCl 6, Cu_2O 0.03 parts by weight was melted in a platinum crucible at 1200°C for 20 min. A glass plate 8 mm × 20 mm × 1 mm was heated at 420°C for 10 hr to precipitate TlCl crystallites, and then subjected to measurement.

Light Exposure and Transimission Measurement. A black ray lamp with main emission peak at 3660 Å (General Electric Model F6T5) was used as UV-light source. The sample plate was placed at a distance of 4 cm from the lamp. An infrared heating lamp of 250 watts was used as a visible light source to cause bleaching of darkened samples. The sample was placed at a distance of 36 cm from the lamp, with filters which permitted light of wavelengths 530—680 mμ. To avoid possible temperature rise in the sample during exposure air was blown to the sample by an electric fan. Transmission measurements were made with a recording spectrophotometer Model Spectronic 505 of Bausch and Lomb Company. For the sake of simplicity "absorption"

or "absorbance" will be used throughout this paper to indicate the increment of absorption or absorbance over that of the samples before UV irradiation. Throughout the experiments, the samples were kept in darkness in a dessicator to avoid possible effects of room lights and diffuse sunlight.

Results

Preliminary Results for the Effect of Impurity on Darkenability. A small amount (0.05 mol%) of various chlorides was incorporated into TlCl by melting powder mixture and the resultant doped TlCl mass was exposed to UV light. The chlorides tried were $CaCl_2$, VCl_3, $MnCl_2$, $FeCl_2$, $NiCl_2$, CuCl, $CuCl_2$, $SrCl_2$, AgCl, $CdCl_2$, $PbCl_2$, $BiCl_3$, InCl, $CeCl_3$, and $SmCl_2$. Some of these chlorides gave grey, yellow, or brown color to the TlCl mass before irradiation. In spite of this original discoloration, it was possible to tell the effect of impurity on UV darkenability qualitatively. It was found that Cu, Ag, and In have a remarkable effect in promoting the coloring of the TlCl crystal induced by UV irradiation. "Pure" TlCl and Cu-doped TlCl crystalline pieces will be used for further experiments.

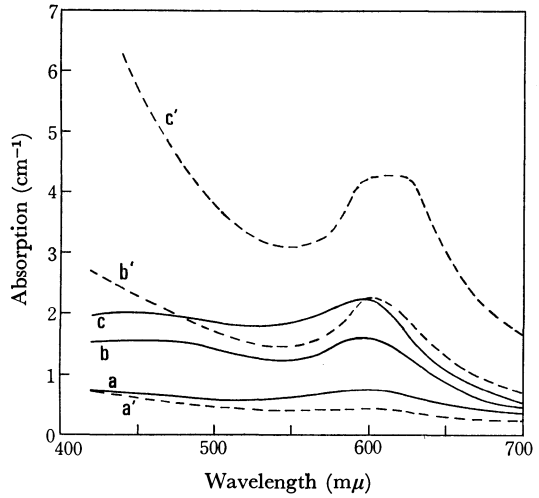

Fig. 1. Absorption spectra of TlCl crystals darkened by UV exposure. Solid lines (a′, b′, c′): "Pure" TlCl. Broken lines (a′, b′, c′): Cu-doped TlCl. Time of exposure: a 6 min, a′ 1 min, b and b′ 30 min, c and c′ 60 min.

Darkening by UV Irradiation. TlCl samples were exposed to UV light for different periods of time ranging from one to 60 min. Some examples of the absorption curves are shown in Fig. 1. The increase in absorption coefficient due to irradiation is plotted as a function of wavelength. In TlCl: Cu sample, darkening was quite remarkable on the surface facing the UV light source. In the "pure" TlCl sample, no particularly dark surface layer was detected. In spite of the difference, plots were given with the use of nominal absorption coefficient for a comparison of the darkenabilities.

We see that an absorption band is developed with a peak around 600 mμ and, at the same time, the absorption increases in the range of wavelengths shorter than 500 mμ. The increase in the latter absorption is particularly remarkable in Cu-doped sample.

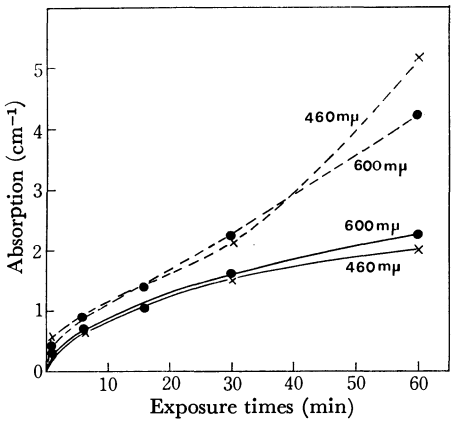

Fig. 2. Absorption change of TlCl crystals with increasing time of exposure to UV. Solid lines: "Pure" TlCl. Broken lines: Cu-doped TlCl.

Figure 2 shows the growth of a peak near 600 mμ and a band less than 500 mμ as a function of exposure time. The absorption coefficient at 600 mμ was chosen as a measure of absorption for the former and that at 460 mμ for the latter. We see that TlCl: Cu darkens at a faster rate than "pure" TlCl. The growth of the absorption at 460 mμ is almost parallel to that at 600 mμ, although the former grows slightly faster in Cu-doped TlCl when exposure time is long (30—60 min).

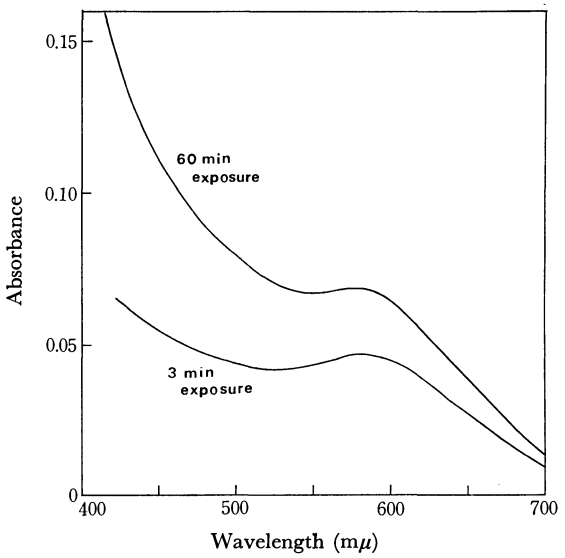

Fig. 3. Absorption spectra of glass darkened by UV exposure. Thickness of the sample: 0.67 mm.

Figure 3 shows the absorption in the TlCl-containing photochromic glass caused by UV irradiation. It can be seen that the general shape of the absorption curve is similar to that of TlCl crystals, especially TlCl: Cu sample. There is an absorption band with a peak at 580 mμ, which is a little shorter than those (600—610 mμ) for TlCl crystals, but pretty close. In the range of the wavelengths smaller than 500 mμ, there is another band.

Exposure of Darkened Samples to a Longer Wavelength Light. Irradiation of UV colored samples by a visible light causes the bleaching in color. Absorption

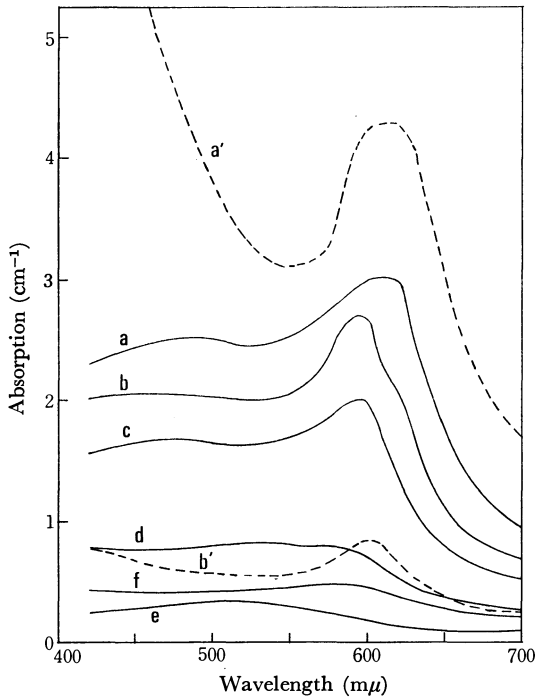

Fig. 4. Fading of color by visible light exposure. a: "Pure" TlCl after UV exposure of 2 hr (before bleaching). b: 1 min bleaching by visible light through filters. c: 2 min bleaching. d: 16 min bleaching. e: 26 min bleaching. f: 1 min bleaching by visible light without filters. a': Cu-doped TlCl after UV exposure of 1 hr. b': 20 min bleaching by visible light through filters.

curves obtained in the process of bleaching by a visible light containing rays ranging from 530 to 680 mμ are shown in Fig. 4.

From a series of cruves for "pure" TlCl (solid line), it can be seen that the band with a peak at 600 mμ becomes weak at a greater rate than in the absorption at shorter wavelengths. Thus the curves d and e have no distinct absorption peak around 600 mμ, while there is some absorption left around 500 mμ. It is true, however, that all absorption is decreased by irradiation and disappears eventually. When the sample is exposed to light without filters which permit only 530—580 mμ, the 600 mμ peak is found to remain more or less noticeable (see curve f). On the other hand, no preferential decrease in absorption is found in the case of TlCl: Cu from the curve b' which has a distinct 600 mμ-band.

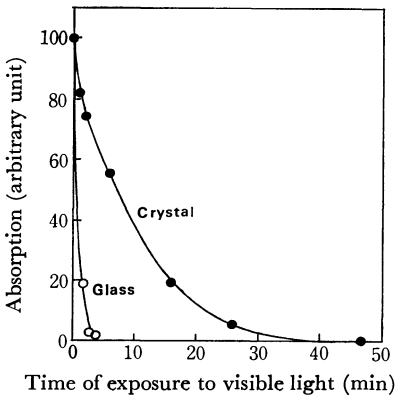

Fig. 5. Fading of UV-colored TlCl crystal and TlCl-containing glass upon visible light exposure.

Figure 5 shows the absorption change at 600 mμ with time of exposure to the bleaching light for "pure" TlCl crystal and the TlCl-containing glass. Both the crystal and glass are bleached, the rate being larger for the glass.

Heating of Darkened Samples. Fading is accelerated by heating the darkened samples. "Pure" TlCl and Cu-doped TlCl samples were heated at 40, 55, and 66°C for 30 to 60 min, but no fading occurred. The absorption spectra remained the same.

On the other hand, it was found that the darkened TlCl glass was bleached slowly at room temperature and rapidly at higher temperatures.

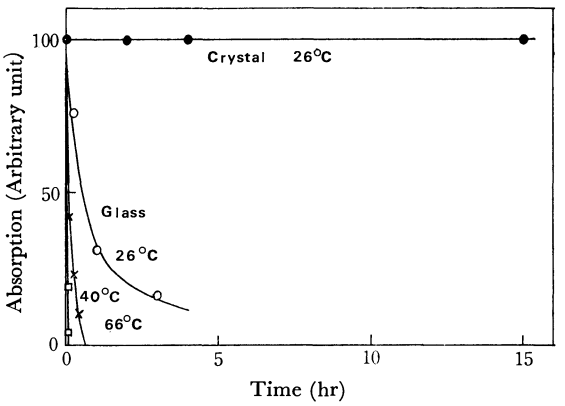

Fig. 6. Fading of UV-colored TlCl crystal and TlCl-containing glass in darkness.

Figure 6 shows the change in absorption at 600 mμ with time for the UV-colored crystalline TlCl plate and TlCl-glass sample kept at room temperature (26°C) in darkness. It is seen that with the TlCl plate sample no change in absorption is observed in 15 hr, while the darkened glass sample loses 50% of its absorption in about half an hour (b). Other curves show that the rate of fading of the glass increases sharply as the temperature rises.

Discussion

Effect of Impurity. Some impurity ions promote the darkenability of a TlCl crystal remarkably. For an explanation of the effect of copper ion the results obtained by Moser *et al.*[10] on silver chloride might be useful. They found that the presence of a small amount of cuprous ions promotes the darkenability of a silver chloride crystal noticeably and suggested that the cuprous ion might act as a trap for a positive hole produced by UV irradiation, changing into a cupric ion. If there is no cuprous ion, positive holes may be easily recombined with electrons and, as a result,the darkenability of a silver chloride crystal will be low. They also suggested that it is possible to interpret the photolytic absorption curve of a copper containing AgCl crystal as the sum of the absorptions due to dissolved cupric ions and photolytic silver. The absorption of cupric ions in an AgCl crystal can be described by a

10) F. Moser, N.R. Nail, and, F. Urbach, *J. Phys. Chem. Solids*, **9**, 217 (1959).

curve which is high in intensity at 400—450 mμ, becoming low rather rapidly with increasing wavelength toward 600—700 mμ.

A similar mechanism seems to be applied to the action of copper ion in a TlCl crystal. The absorption of TlCl: Cu increased remarkably in the wavelength range of 420—500 mμ upon UV irradiation compared with "pure" TlCl (Fig. 1). This can be attributed to the formation of Cu^{2+} ions from Cu^{+} ions in the TlCl: Cu crystal. The non-irradiated TlCl: Cu crystal had a little higher absorption in this wavelength region than the non-irradiated "pure" TlCl crystal, which can be attributed to possible presence of Cu^{2+} ions even before irradiation. It will be reasonable to assume that there are Cu^{+} ions as well as Cu^{2+} ions in the non-irradiated TlCl: Cu crystal, the Cu^{+} ions working as trapping centers for positive holes and promoting darkenability of the TlCl crystal.

Fading of Darkened Crystals by Visible Light. Darkened TlCl crystals are bleached by visible light (530—680 mμ), restoring then to their original state. A process reverse to the darkening by UV irradiation is believed to occur. Thallium atoms or their small aggregates (colloids) will absorb the light quanta and release electrons, which will be recombined with positive holes.

It should be noted, however, that the change in absorption spectra with increasing exposure of the crystal to the bleaching light is not monotonic (Fig. 4). Namely, the absorption near 600 mμ disappears faster than the absorption at shorter wavelength region. This is interpreted in terms of preferential (selective) bleaching.[8)]

For bleaching, the visible light of wavelengths 530—680 mμ was used. The centers which absorb this light must have been destroyed preferentially. It was found that bleaching by light covering the whole visible region was less preferential (Fig. 4, curve f).

In contrast to "pure" TlCl, Cu-doped TlCl crystal showed no such preferential bleaching. The cause of the difference has not been clarified. A possible explanation may be that some of the light quanta are absorbed by Cu^{2+} ion sites because these ions have absorption also in the range 530—680 mμ, and the light energy is transferred to the centers responsible for the absorption at shorter wavelength region, destroying the centers. This will give relatively less preferential bleaching.

Comparison of the Behavior of a TlCl Crystal with TlCl-Containing Glass. From Figs. 3, 5, and 6 it is clear that the darkening behavior of a glass can be explained on the basis of that of a TlCl crystal. Like the TlCl crystal the TlCl-containing glass becomes dark upon UV irradiation, giving an absorption curve with a peak near 600 mμ. The increase of absorption in the region 420—500 mμ will be explained by the presence of copper ion since a TlCl crystal shows the same tendency when doped with copper ion.

The quick bleaching of a darkened glass by visible light exposure would also be explained by a similar behavior of a TlCl crystal, although the rate appears different, the glass being bleached much faster. It is interesting to note that there is a great difference in thermal fading behavior. The darkened TlCl crystals show almost no thermal fading under the experimental conditions, 15 hr at room temperature and 2 hr at 66°C, while the darkened TlCl-containing glass is bleached by 50% in 30 min at room temperature and by 100% in 5 min at 66°C (Fig. 6).

If we assume that thermal fading and optical bleaching is initiated by the release and migration of positive holes (Cl°) which have been produced as a result of UV irradiation in darkening process and trapped somewhere in the TlCl crystal and TlCl-containing glass, trapping sites would be crystalline defects or crystal grain boundaries in the case of TlCl crystals and crystal-glass interfaces in the case of the photochromic glass. In the glass the size is too small for the crystallites to have dislocation or grain boundaries. There is no reason for considering that the bonding of the UV-induced reaction products (electrons, holes, Ag and Cl atoms) with crystalline defects is stronger than that with crystal-glass interfaces. Such a situation may be justified, however, if it is considered that glass is generally chemically inert near room temperature and its composition is quite different from that of the TlCl crystal or possible reaction products.

Our results indicate that the above view is reasonable, *viz.*, the effect of the presence of glassy matrix is shown.

Detosylation of *N*-Tosyl Amino Acids and Peptides by Electrolytic Reduction[1,2]

Tameo Iwasaki,[3] Kazuo MATSUMOTO,[4] Manabu MATSUOKA, Takeo TAKAHASHI, and Kentaro OKUMURA

Department of Synthetic Chemistry, Research Laboratory of Applied Biochemistry Tanabe Seiyaku Co., Ltd. Kashima-cho, Higashiyodogawa-ku, Osaka

(Received March 4, 1972)

An electrolytic reductive cleavage of tosyl group in *N*-tosyl amino acids was carried out by the use of 2 mol equivalent of NaCl or KCl as an electrolyte to the tosyl amino acids and of lead as a cathode in methanol–water. The procedure was applicable to the cleavage of *N*-tosyl peptides with preservation of the peptide bond, and with retention of their optical activity. No cleavage of the other protecting groups such as urethane type group and benzyl group was observed. The optimum conditions for reductive cleavage were found to be pH 11, lead being preferable to other cathode metals.

N-*p*-Toluenesulfonyl (tosyl) amino acids are easily prepared from the reaction of *p*-toluenesulfonyl chloride with amino acids in good yields and with retention of their optical activity.

Removal of the *N*-tosyl group with a warm phosphonium iodide–hydroiodic acid mixture was first reported by Fischer[5] in 1915. This drastic method was subsequently applied by Schönheimer[6] to obtain a free peptide from the tosyl peptide.

Since du Vigneaud[7] demonstrated in 1937 that the tosyl group was readily cleaved by reduction in sodium-liquid ammonia, the tosyl group has been employed for peptide synthesis, and is especially useful for the protection of the ω-amino groups in lysine and ornithine peptides.

The *N*-tosyl group was also removed by heating with 48% hydrobromic acid in the presence of phenol[8] and with 30% hydrobromic acid in acetic acid.[9] However, these methods have not been accepted for amino acid and peptide syntheses, since they involve drastic conditions for the cleavage of tosyl amino acids and peptides. Actually they seem to involve a side reaction in the case of hydrolysis of unstable amino acids such as hydroxy amino acid, the concomitant cleavage of peptide bond being often observed. Most of them were not applicable to the detosylation of *N*-tosyl serine because of a partial decompsoition of the resulting serine.

Recently, Horner and Neumann[10] reported a method of electrolytic reductive cleavage of the *N*-tosyl group by the use of tetramethylammonium (TMA) amalgam. The method was new for organic synthesis on a laboratory scale, but the use of TMA and mercury did not make it practicable for carrying out the procedure on a large scale. They stated that cleavage of the tosyl group had not been observed with the use of electrolyte and cathode materials other than TMA and mercury respectively. If a real convenient method with milder conditions could be developed, the tosyl group would serve as a useful protecting group of amino acids and peptides.

We previously reported a method for the cleavage of the tosyl group in various amino acids and peptides by an electrolytic reduction.[11] In the present paper, we wish to report in detail on the electrolytic reduction of tosyl amino acids and peptides.

The reductive cleavage of *N*-tosyl-L-serine under various conditions in particular was investigated. We chose tosyl serine for preparing L-serine practically, the latter being an unstable amino acid under drastic conditions such as heat and strong acid or alkali. Satisfactory results for the preparation of L-serine from tosyl serine readily prepared from *N*-tosyl-L-aspargine[12] have not been obtained.

Results and Discussion

Cathode Material. Experiments on the tosyl serine were carried out with the electrode materials given in Table 1. A lead cathode gave the highest yield of serine under the same conditions, and was used in the investigations.

Table 2. Effect of electrolyte on the elecrolysis of tosyl serine at pH 11 in 20% MeOH

Electrolyte	Yield(%)
NaCl	88.0
KCl	87.4
LiCl	67.3
NH_4Cl	0
$CH_3NH_2 \cdot HCl$	19.8
$(CH_3)_2NH \cdot HCl$	8.2
$(CH_3)_3N \cdot HCl$	12.0
$(CH_3)_4N \cdot Cl$	62.3

Cathodic solution: tosyl serine (0.1 mol) and NaCl (0.2 mol) dissolved in 20% MeOH (500 ml); Cathode: Pb; Anodic solution: 20% HCl; Anode: Carbon; Current density: 3.2 A/dm²; Current concentration: 8A/L; Temp.: 25°C; Time: 5 hr.

was performed with the electrolytes shown in Table 2. NaCl and KCl gave high yields in methanol–water solvent.

Ammonium chloride, monomethylamine hydrochloride, dimethylamine hydrochloride, and trimethylamine hydrochloride did not give good results, but reduction with tetramethylammonium chloride afforded a relatively good yield.

The electrolytic reduction was carried out with the use of 1.2 mol equivalent of the electrolyte to the tosyl serine. It was found that reaction temperature rose since resistance of the cathodic solution increased. In the case of a large amount of the electrolyte, treatment after the reaction was troublesome.

Reaction was achieved successfully with 2 mol equivalent of the electrolyte such as NaCl or KCl.

Effect of pH in the Cathodic Solution. The electrolytic reduction of various organic compounds such as ketone,[13,14] alkyl halide[15] *etc.* is often observed to a great extent depend on the pH of the cathodic solution. We found this to be strongly so in our electrolytic reduction of the tosyl serine.

The reduction at pH 11 gave the best result (Fig. 1); a considerably lower yield being obtained in either higher or lower pH regions. In a higher pH region the resulting serine was partially decomposed and racemization took place, whereas in a lower one unreacted tosyl serine markedly appeared on the membrane. In curve E, the pH was adjusted to 11.0 before electrolytic reduction, and was not controlled during the course of the reduction. The pH gradually shifted to alkaline region with the lapse of time, and the final concentration of sodium hydroxide in cathodic compartment was about 0.5 N after 5 hr. Hardly any reaction took place during last one hour. The results suggest that cleavage of the tosyl group cannot be performed in a higher pH region than 13.

In the water–methanol system, an adequate amount of methanol was needed to dissolve the tosyl amino

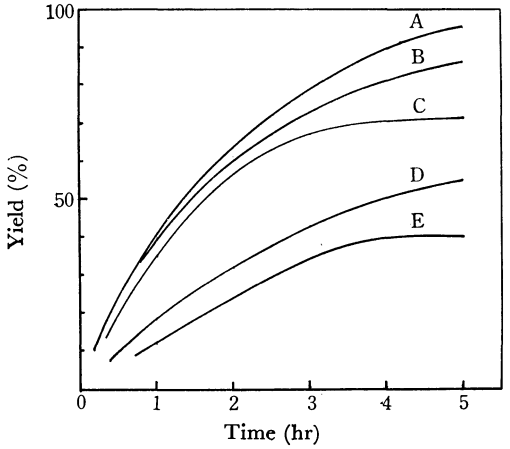

Fig. 1. Effect of pH on the electrolysis of tosyl serine. Cathodic solution: tosyl serine (0.1 mol) and NaCl (0.38 mol) dissolved in 20% MeOH (500 ml); Cathode: Pb; Anodic solution: 20% HCl; Anode: C; Current density: 3.2 A/dm²; Current concentration: 8 A/L; Yield: Analytical value. A: pH 10.8—11.2; B: pH 9.6—10.0; C: pH 12.6—13.0; D: pH 7.0—9.0; E: No controlled pH.

acid deposited on a membrane during the course of electrolysis. In the case of tosyl serine, 20% methanol was required.

Cathodic Erosion of Lead. The reductive cleavage of 0.1 mol of L-tosyl serine was carried out by the use of 0.2 mol of NaCl and lead cathode in 20% methanol. After 5 hr, L-serine was obtained in 88% yield. However, the cleavage of 0.2 mol of the tosyl serine in the presence of 0.4 mol of NaCl did not proceed sufficiently. The yield of L-serine was only 45%, even when the reaction was allowed to continue for 10 hr. This might be attributed to incorporation of alkali metal into the lead cathode.[16–19] It can also be understood from the fact that use of the lead cathode renewed by washing with 5% nitric acid after 5 hr resulted again in a high yield of the cleavage of the tosyl serine.

In these experiments the electrode potential of the lead cathode showed −2.08 V *vs.* SCE in the initial stage of reaction. After 5 hr, the potential shifted to −1.95 V *vs.* SCE. When the electrode was washed with 5% nitric acid, the potential returned to −2.08 V *vs.* SCE. This result is in line with that of Chernomorskii.[20]

Thus a potential of −2.0 V *vs.* SCE would be required at least in the reductive cleavage of the tosyl serine.

The current density was 3.2 A/dm² at 25°C. A current density greater than 5 A/dm² was not needed, since intensive erosion of lead took place by the incorporation of Na^+ into the cathode and temperature rose markedly in the cathodic solution.

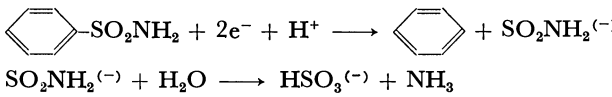
a) Amino acids obtained were paper-chromatographically pure and agreed with authentic specimens.
b) Amino acids (run 1–9, and run 15): "Chemistry of Proteins," Vol. 1, ed. S. Akabori and S. Mizushima, Kyoritsu Shuppan Co. Ltd., (1954) p. 112.
c) L. Zervas, I. Photaki, and N. Ghllis, *J. Amer. Chem. Soc.*, **85**, 1337 (1963).
d), e), f) J. P. Greenstein and M. Winitz, "Chemistry of the Amino Acids," Vol. 2, John Wiley & Son, Inc, (1961) p. 893, p. 1203, p. 1228, respectively.
g) Alanine was obtained.

In the case of tosyl-L-β-chloroalanine,[12] simultaneous fission of sulfur-nitrogen bond and carbon-chlorine bond occurred to give L-alanine.

Urethane type protecting groups such as benzyloxycarbonyl (Z), *t*-amyloxycarbonyl, and *t*-butyloxycarbonyl and *S*-benzyl (S–Bzl) group were not cleaved under the above conditions, but the benzoyl group was attacked.[21] Z and Bzl groups could be cleaved in the electrolytic reduction under basic conditions using other electrode material.[21] Thus, N^{ε}–Z–L-lysine and *S*–Bzl-L-cysteine were obtained by the selective electrolytic reduction of N^{α}-tosyl-N^{ε}-Z-L-lysine and *N*-tosyl-*S*-Bzl-L-cysteine, respectively. *N*-Tosyl-*S*-Bzl-glutathione was treated to give *S*-Bzl-glutathione without cleavage of the *S*-Bzl group.

Reaction Mechanism. In connection with cleavage of the tosyl group in the TMA–mercury–methanol system, Horner and Neumann[22] stated that the radical (stable in the presence of mercury) obtained by reducing TMA cation on the mercury cathode cleaved the tosyl group, and that other electrolytes such as Na or K formed the corresponding amalgam without appreciable cleavage of this group.

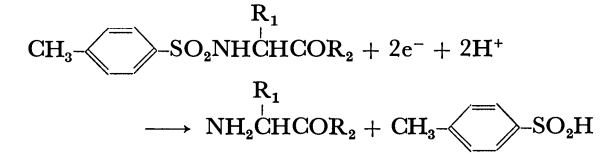
In the polarographic reduction of benzenesulfonylamide, Manousék *et al.*[23] stated that benzene and sulfurous acid monoamide resulting from carbon-sulfur bond cleavage were produced in the initial stage of the reaction, and that the reaction mechanism as represented in the following Scheme was very similar to that of the reduction with sodium-liquid ammonia as reported by Kovacs Ghatak.[24,25]



$$SO_2NH_2^{(-)} + H_2O \longrightarrow HSO_3^{(-)} + NH_3$$

However, in our electrolytic reductive cleavage of tosyl amino acids, *p*-toluenesulfinic acid was isolated from the reaction mixture in a good yield. *p*-Thiocresol was not detected at all even by iodometric titration of the cathodic solution after electrolytic reduction. The electrolytic reduction of *p*-toluenesulfinic acid was not observed under the same conditions as for tosyl amino acids and peptides, although it was reported that *p*-toluenesulfinic acid was reduced to *p*-thiocresol.[26]

The reaction in the electrolytic reduction of tosyl amino acids and peptides under our conditions should proceed *via* two electrons transfer to give sulfur-nitrogen bond cleavage as shown in the following Scheme;



R_1=Amino acid side chains
R_2=OH or amino acid residues

Experimental

Apparatus. A Yanagimoto controlled potential electrolyser was used as a D.C. source. A 600 ml electrolysis cell with a cathode, anode, cellular membrane, thermometer, and a pH autocontroller was used (Fig. 2). Commercial metal plates sufficiently polished before use were used as electrode.

A glass electrode of pH meter was rounded with platinum

wire to prevent disturbance on accurate pH value from the electric current for the anode and cathode.

The pH of the cathodic solution was controlled to the desired value within ± 0.1 using a Toa Denpa pH autocontroller equipped with a buret.

Temperature in the cathodic compartment was maintained at 25°C with circulating water cooled by a Yamato cool line model BL-11 around the electrolysis cell. Current, voltage and temperature were recorded on the same chart by a Yokogawa multipoint model ERB, and the pH by a Toa Denpa multipoint pH recorder model HMR-3.

The anodic compartment, in which the anolyte was exchanged at a constant velocity with a fresh solution with a Mitsui Kagaku model SJ-1200, was clamped in position so that the anolyte and catholyte were on the same level. All optical rotations were measured with a Perkin-Elmer 141 polarimeter.

Method. Typical cases *A* and *B* are shown. *A*. Experiments on the effect of pH, electrolyte and cathode material were carried out by the following procedure. After a mixture of 26 g tosyl-L-serine and 12 g of sodium chloride dissolved in 500 ml of 20% methanol was placed in a cathodic compartment, pH of the cathodic solution was adjusted to the desired value with 1N sodium hydroxide solution. On the other hand, 20% hydrochloric acid was put in an anodic compartment with a carbon anode. The anode and cathode compartments were separated by a membrane. An electric current 4A (4—6 V), with density 3.2 A/dm^2, was then passed through the solution at 25°C. The pH of the cathodic solution was maintained at the desired value with 5% hydrochloric acid during the course of electrolytic reduction. The anodic solution was exchanged continuously with 20% hydrochloric acid.

The yield of L-serine was determined by the method of formol titration within an error of 3% in the follwoing way. A 10—20 ml sample taken out from the reaction mixture was adjusted to pH 7.0 with 0.1N hydrochloric acid. To this was added 10 ml of 37% formaldehyde, and pH of the solution was then adjusted to 8.3 with 0.1N sodium hydroxide solution. The amount of L-serine was calculated from that of the consumption of 0.1N sodium hydroxide solution.

For the preparation of L-serine, the cathodic solution was acidified with 20% hydrochloric acid. After removal of the unreacted compound and *p*-toluenesulfinic acid by extraction with ethyl acetate, the aqueous solution was treated with Dowex 50×2 column (H^+ form) and non-amino acid acidic components were eluted with distilled water, then amino acid was eluted with 5% ammonia. The solution was evaporated to dryness *in vacuo* to give a crude serine. The product was recrystallized from water to afford paper-chromatographically and optically pure L-serine as shown in Table 3.

B. A mixture of 55.0 g (0.1 mol) of *N*-tosyl-*S*-Bzl-glutathione, 7.0 g of potassium chloride and 500 ml of 20% methanol was placed in a cathodic compartment with a lead cathode, and potassium hydroxide solution was then added to adjust the pH of the cathodic solution at 11. The anodic solution in an anodic compartment with a carbon anode was exchanged continuously with 20% hydrochloric acid. A membrane was used, and electric current 4A (4—6 V), current density 3.2 A/dm^2, was passed through the solution at 25°C for 5 hr. The pH of the cathodic solution was maintained at 11 with 20% hydrochloric acid during the course of reduction. On completion of electrolysis, the cathodic solution was adjusted to pH 3—4 with hydrochloric acid. The precipitated crystals were collected by filtration and the crude product was washed with methanol. After recrystallization from water, 36 g (92%) of *S*-Bzl-glutathione was obtained, mp 204—205°C (decomp.),[27] $[\alpha]_D^{25}$ −9.7° (*c* 0.70, 3N-HCl). The material showed a single spot when subjected to paper chromatography (Toyo filter paper No. 50), R_f 0.58 (*n*-BuOH–AcOH–H_2O=3:1:1). Found: C, 51.24; H, 5.93; N, 10.87; S, 7.81%. Calcd for $C_{17}H_{23}O_6N_3S$: C, 51.36; H, 5.85; N, 10.57; S, 8.06%.

Isolation of p-*Toluenesulfinic Acid.* The cathodic solution subjected to the above treatment was acidified with hydrochloric acid. After removal of methanol under reduce pressure, the hydrochloric acid solution was extracted with ethyl acetate. The ethyl acetate solution was evaporated to dryness under reduced pressure. The residue was recrystallized from water to obtain *p*-toluenesulfinic acid (80% yield). The crystal showed mp 84—85°C, which was consistent with an authentic specimen.

Liquid-phase Oxidation Catalyzed by Cu(II)-Cl System. I. Oxidation of Cyclohexene

Sei-Ichiro IMAMURA, Toshiaki BANBA, and Yoshinobu TAKEGAMI*

Department of Chemistry, Kyoto Institute of Technology, Sakyo-ku, Kyoto

**Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto*

(Received May 4, 1972)

Oxidation of cyclohexene catalyzed by Cu(II)–Cl systems was carried out in glacial acetic acid. The oxidation of cyclohexene with cupric chloride was highly accelerated by addition of various alkali chlorides. The decomposition of cyclohexenyl hydroperoxide, an intermediate product of the oxidation, was also accelerated by this catalyst system. Salts other than alkali chlorides had little effect. It was concluded that the activation of copper catalyst was due to the chloride ions which form a complex with copper. In the course of the reaction the catalyst loses its activity through ligand exchange with solvent molecule, acetic acid.

It is well known that the solubility of cupric salt is increased by the formation of complexes with alkali chlorides in acetic acid or acetonitrile. These catalyst systems are often used in the chlorination of olefines.[1] Tamura used these systems in the synthetic reaction of vinyl acetate and discussed the form of the catalyst and its behaviour.[2]

We have studied the oxidation of cyclohexene in detail to clarify the effect of various alkali chlorides on the catalytic activity of cupric chloride.

Experimental

Cyclohexene was synthesized by the dehydration of cyclohexanol.[3] The crude cyclohexene was washed with 5% aqueous sodium hydroxide, distilled twice and stored under nitrogen. Cyclohexenyl hydroperoxide was obtained by the autooxidation of cyclohexene. Cyclohexenol was obtained by the reduction of cyclohexenyl hydroperoxide with triphenylphosphine and cyclohexenone by the decomposition of cyclohexenyl hydroperoxide with cupric chloride–pyridine system.[4] Acetic acid was purified by the standard method. Cupric chloride and other reagents (anhydrous, GR grade) were used without further purification.

Oxidation was carried out using a reactor equipped with an atmospheric pressure gas burette. Fifteen ml of the mixture of cyclohexene and acetic acid containing a catalyst was warmed to the desired temperature (60°C) in a nitrogen atmosphere. Nitrogen was then replaced with oxygen and the reaction started. The decomposition of cyclohexenyl hydroperoxide was carried out in a nitrogen atmosphere and the rate of reaction was followed by iodometric titration of the remaining hydroperoxide.

Analysis of oxidation products was carried out using a Hitachi gas chromatograph 063 equipped with a flame-ionization detector. The column packing was *n*-decyl phthalate (1 m length) and the column temperature was 70—120°C (5°C/min). Visible spectra were measured by means of a Toshiba-Beckman UV spectrophotometer DBG.

Results and Discussion

Catalytic Activity of Cu(II)–Cl System. The effect of lithium chloride on the catalytic activity of cupric chloride was investigated and the results are shown in Fig. 1 and Table 1. In all cases, retardation of the reaction occurs after some uptake of oxygen. During the constant uptake of oxygen the reacting system is yellowish green or green but a deep blue colour appears

4) Cyclohexenone is obtained exclusively in the decomposition of cyclohexenyl hydroperoxide by cupric chloride in pyridine solution. This was reported by T. Banba, S. I. Imamura, and Y. Takegami at the 5th Oxidation Symposium in Osaka. (December 3, 1971).

after the retardation of oxygen uptake. Though the maximum rate of oxygen absorption (R_m) increases with an increase in the amount of lithium chloride added, a large excess (more than seven parts to one part of copper) results in a decrease in the rate. On the other hand, the maximum quantity of absorbed oxygen defined as the quantity of oxygen absorbed before the retardation occurs, increases linearly with the increase in the concentration of lithium chloride added. It is clear that lithium chloride increases and maintains the activity of the catalyst. As shown in Fig. 1 lithium chloride without copper salt has little activity.

The effects of various alkali metal chlorides and lithium salts on the catalytic activity of the cupric chloride were investigated and the results are shown in Table 2. We see that the addition of magnesium chloride, sodium chloride, or potassium chloride increases the maximum quantity of absorbed oxygen and the maximum rate of oxygen absorption (R_m) as in the case of lithium chloride, but the addition of lithium fluoride, lithium bromide, lithium carbonate, and lithium nitrate has little effect. It has been reported that lithium salts, which have a considerable covalent character, have a catalytic activity for oxidation through the activation of a molecular oxygen[5] or through the homolysis of a peroxide.[6] However, in our experiments no such general effect could be seen with lithium salts except for lithium chloride as mentioned above. The order of the effect is found to be KCl>NaCl>LiCl≒$MgCl_2$. The greater the ionic character of the added chloride, the more effective for the oxidation. It can be said that the effect of the additives on the catalytic activity of copper salt is due to the anionic part, namely chloride ion, the activity of copper salt increasing through complex formation with chloride ions. In Table 3 the activity of various copper compounds–lithium chloride systems is shown together with the visible spectra. All copper salts tested are inactive with the exception of cupric chloride. However, oxidation takes place on addition of lithium chloride to these salts. The visible spectra of the inactive copper salts show an absorption at about 670 mμ, while the active catalyst systems containing lithium chloride have absorption in a wavelength region greater than 710 mμ The absorption seems to indicate the formation of various types of complexes. The effect of chloride ion on the catalytic activity of transition metals other than copper was also studied. In Table 4 the effect of lithium chloride on the catalytic activity of cobalt, nickel, and manganese chlorides is given. Hardly any or no effect can be seen for chlorides of other transition metals.

of 0.136 mol/l. The results are given in Fig. 2. The addition of lithium carbonate or lithium nitrate has no effect upon the hydroperoxide yield, but in the case of various chlorides, the higher the concentration of the chloride, the lower the yield.

Product Distribution. The product distribution of the cyclohexene oxidation catalyzed by cupric chloride-lithium chloride system was investigated. Main products were cyclohexenyl hydroperoxide, cyclohexenol, and cyclohexenone. Two unknown high boiling products, I and II, were detected. Product I showed an infrared absorption at 1730 cm^{-1} due to carbonyl group and the product II at 3450 cm^{-1} due to hydroxyl group.[7] It was found that the product II contained chlorine. The relation between the product distribution at the point where the oxygen uptake amounted to 0.136 mol/l and the quantity of lithium chloride added is shown in Fig. 3. We see that as the concentration of lithium chloride increases, the yield of the hydroperoxide decreases and that of cyclohexenone increases. The higher the concentration of lithium chloride, the lower the total yield of these products and on the contrary, the higher the total yield of the unknown products; which is not shown in the figure. Thus it seems that the chloride ion is consumed by the chlorination of the reaction product.[8]

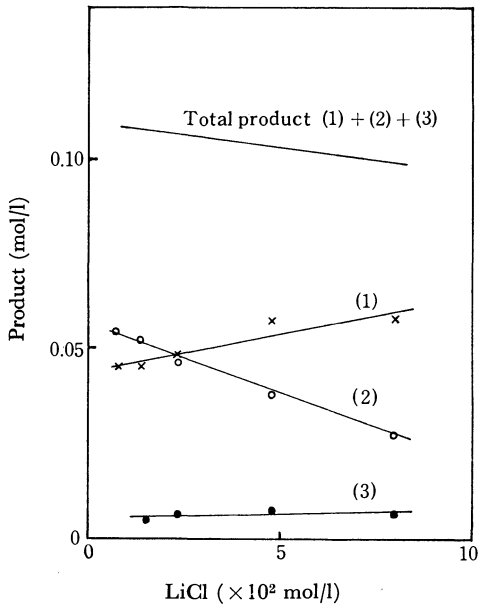

Fig. 3. Effect of LiCl on the product distribution.

Decomposition of Cyclohexenyl Hydroperoxide Catalyzed by Cu(II)–Cl System. It was found that the addition of alkali chlorides decreased the yield of hydroperoxide, and thus the effect of lithium chloride on the decomposition of hydroperoxide catalyzed by copper salt was investigated. The result is given in Fig. 4. In this case also, lithium chloride increases the catalytic activity of the cupric chloride remarkably. Decomposition of hydroperoxide in the presence of lithium chloride alone does not proceed so much. The promotion of the catalytic activity by lithium chloride seems to be caused by the complex formation with copper. The decomposition curves resemble that of the oxidation of cyclohexene, *viz.*, retardation occurs after the decomposition of a certain amount of hydroperoxide, the colour of the solution turning from yellowish green to deep blue. The quantity of the hydroperoxide decomposed by the time retardation occurs is proportional to the concentration of lithium chloride added. It seems that lithium chloride increases the rate of decomposition of hydroperoxide and consequently increases that of oxidation.

7) By comparison with standard sample, substances I and II proved not to be 3-chlorocyclohexanone or 3-chlorocyclohexanol formed by the chlorination of the conjugated cyclohexenone which is one of the oxidation products. Moreover, they both did not correspond to 2-chlorocyclohexanone or cyclohexyl acetate.

8) After the retardation occurred, chloride ion was scarcely detected in the solution with silver nitrate.

Change of the Dissolved State of the Catalyst System. In the oxidation of cyclohexene, the colour of the solution changes from yellowish green to green and finally to deep blue in the course of the reaction. Thus the visible spectra of the reaction system were observed and the effect of lithium chloride upon the change of the state of the catalyst was discussed. At the beginning of the reaction a feeble absorption is observed at 760 mμ which seems to be due to the Cu(II)–Cl complex.[2] Soon after oxidation takes place, the absorption disappears and a new absorption appears at 680 mμ. From a comparison with the standard reagent, the absorption proved to be due to the cupric acetate which seemed to be formed through the ligand exchange of the catalyst with the solvent molecule, acetic acid. The time dependence of absorption is given in Fig. 5.

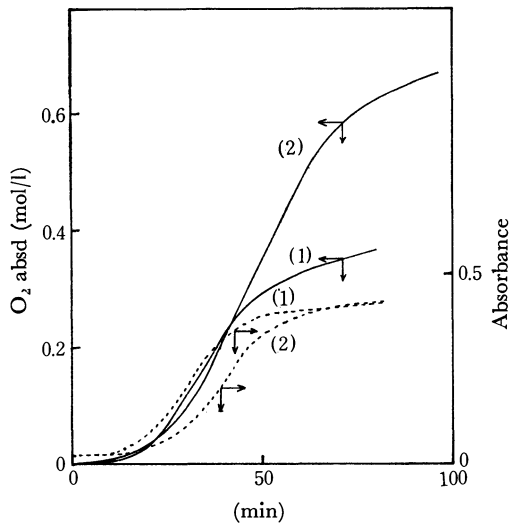

Fig. 5. Time dependence of the visible spectrum (λ_{max}=680mμ)
AcOH: 10 ml. Cyclohexene: 5 ml. $CuCl_2$: 8×10^{-3}mol/l. 60°C LiCl (mol/l) (1) 8×10^{-3}, (2) 4.8×10^{-2}.

We see that the absorbance increases during the reaction until the point where the rate of the oxidation begins to decrease and then remains constant. It seems that all the copper turns to cupric acetate at the end of the reaction. When the quantity of the lithium chloride increases, the time is lengthened at which the absorbance becomes constant [Curve (2), Fig. 5]. At the point where the catalyst became deactivated, addition of more lithium chloride recovered the activity of the system. This shows that the inactive cupric acetate is partly changed to the active Cu(II)–Cl complex. It can thus be concluded that lithium chloride contributes to maintain the activity of the catalyst and deactivation is caused by the consumption of chloride ions and the solvent molecules enter into the ligand site of the copper forming inactive cupric acetate.

Effect of the Catalyst Concentration. Dependence of the oxidation rate on the catalyst concentration was investigated. When the concentration of the copper catalyst is increased at a constant concentration of lithium chloride, R_m increases but reaches its maximum value at the concentration of copper about 2.4×10^{-2} mol/l, then remains constant [Curve (1), Fig. 6]. When

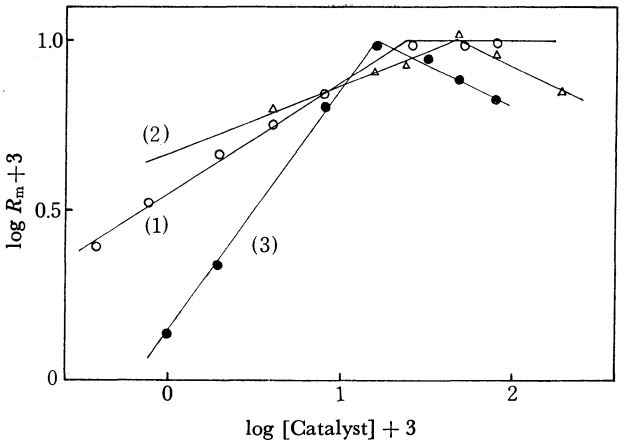

Fig. 6. R_m *vs.* catalyst concentration.
AcOH: 10 ml. Cyclohexene: 5 ml. 60°C.
(1) [$CuCl_2$] Dependence, [LiCl] 8×10^{-3}mol/l.
(2) [LiCl] Dependence, [$CuCl_2$] 8×10^{-3}mol/l.
(3) $\left[\begin{smallmatrix}CuCl_2\text{–}LiCl\\ 1:1\end{smallmatrix}\right]$ Dependence

the concentration of lithium chloride was made to vary at a constant concentration of copper [Curve (2)], R_m reaches the maximum value for a mole ratio of lithium to copper, *ca.* 7: 1, then begins to decrease. The concentration of the Cu(II)–Cl was made to vary at constant lithium to copper concentration of unity. It is shown that R_m also reaches the maximum value at the complex concentration of about 2.0×10^{-2} mol/l and then decreases [Curve (3)]. In all cases the maximum value of R_m is about 1.0×10^{-2} mol/l·min. From curves (2) and (3), it seemes that excess lithium chloride retards the reaction. An explanation for the phenomenon may be that excess lithium chloride blocks the active sites of the copper catalyst and prevents hydroperoxide molecules from approaching them. Another explanation may be that while the active species is $CuCl_3^-$, excess lithium chloride forms a complex of the type $CuCl_4^{2-}$[9] which retards the reaction.

Oxidation Scheme. From the results so far obtained, the oxidation mechanism is schematically drawn as follows.

$$CuCl_2 + Cl^- \rightleftarrows CuCl_3^- (CuCl_4^{2-}) \quad (1)$$

$$RH \longrightarrow R\cdot \quad (2)$$

$$R\cdot + O_2 \longrightarrow ROO\cdot \quad (3)$$

$$ROO\cdot + RH \longrightarrow ROOH + R\cdot \quad (4)$$

$$ROOH + CuCl_3^- (CuCl_4^{2-}) \longrightarrow ROO\cdot \text{ or } RO\cdot \quad (5)$$

$$CuCl_3^- (CuCl_4^{2-}) \xrightarrow[O_2,\,S]{AcOH} Cu(OAc)_2 + \text{Chlorination product} \quad (6)$$

$$\downarrow Cl^-$$

$$Cu(Cl)(OAc),\ CuCl_2,\ CuCl_3^-,\ CuCl_4^{2-} \quad (7)$$

In reaction (1) the copper salt forms a complex with chloride ions. It seems that the complex is not of a single form but a mixture of various forms. In reactions (2)—(4) cyclohexenyl hydroperoxide is formed.

9) C. L. Jenkins and J. K. Kochi, *J. Org. Chem.*, **36**, 3103 (1971).

In reaction (5) the hydroperoxide is decomposed by the Cu(II)–Cl complex. The increase in the rate of oxidation seems to be due to the high activity of the complex to promote the step. As shown in reaction (6), during oxidation, presumably in the decomposition of hydroperoxide, some ligand exchange occurs through the chlorination of a third body (cyclohexene or its oxidation product), represented by S in reaction (6), and cupric acetate is formed causing deactivation of the catalyst system. In reaction (7) addition of alkali metal chlorides to the deactivated system restores the activity of the system.

In conclusion, it can be said that in acetic acid solvent, chloride ion increases and maintains the catalytic activity of the copper salt as its ligand.

The authors are very much indebted to Professor Hiroshi Teranishi for his guidance and encouragement through this work. They also wish to thank Dr. Sakae Uemura for his helpful advice and discussions.

Studies of Organo Sulfur Compounds. II. The Preparation and Reactions of Benzoyl Benzenethiosulfonates

Shinzi KATO and Masateru MIZUTA
Faculty of Engineering, Gifu University, Kagamihara, Gifu

(Received May 31, 1972)

Some mixed sulfonic thiocarboxylic anhydrides (II, R, R′: Aryl) were obtained from the reactions of potassium substituted-thiobenzoate with benzene- or *p*-toluenesulfonyl chlorides. The reactions of benzoyl benzenethiosulfonate were examined in comparison with those of the corresponding mixed sulfonic carboxylic anhydrides.

Although a few reports[1-8] have been recorded on the mixed sulfonic carboxylic anhydride (I), there have been no reports for the mixed sulfonic thiocarboxylic anhydride (II). In this paper an attempt at the syntheses and reactions of mixed sulfonic carboxylic anhydride (II) will be described.

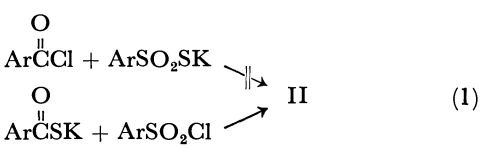
R, R′: Alkyl, Aryl

The reaction of benzoyl chloride with potassium *p*-toluenethiosulfonate gave no benzoyl *p*-toluenethiosulfonate. However, it was found that the reactions of potassium substituted thiobenzoate with benzene- or *p*-toluenesulfonyl chloride gave the corresponding aroyl



(1)

benzenethiosulfonate (Eq. (1)). We attempted to react the mixed sulfonic thiocarboxylic anhydride thus obtained with several reagents (*cf.* Chart 1).

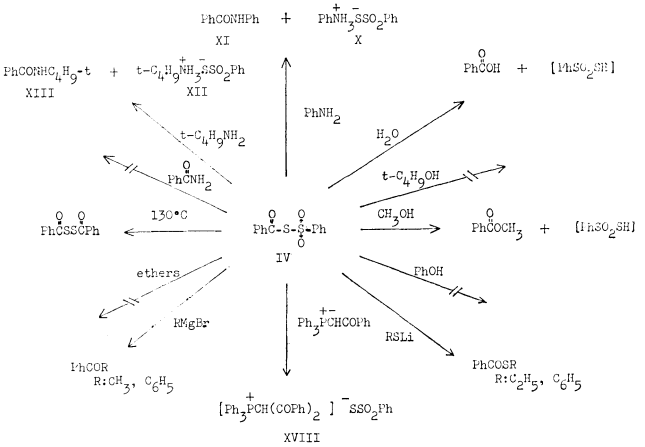


Chart 1. Reactions of benzoyl benzenethiosulfonate.

Results and Discussion

Potassium thiobenzoate and an equimolar amount of benzenesulfonyl chloride in dry acetonitrile (or THF) reacted exothermically. From the reaction mixture, benzoyl benzenethiosulfonate (IV), dibenzoyl disulfide (V), potassium benzenesulfonate (VI), benzoic anhydride, and potassium chloride were isolated in 31, 40, 20, trace, and 65% yields (based on the potassium thiobenzoate used) respectively. The structure IV was confirmed by the result of elemental analyses and by the IR spectrum. On the other hand, V and VI were identified by elemental analyses and by comparisons of the IR spectra with those of authentic samples. By an

analogous treatment of potassium thiobenzoate with *p*-toluenesulfonyl chloride, and of potassium *p*-methylthiobenzoate with benzenesulfonyl chloride, *p*-methylbenzoyl benzenethiosulfonate (IX) and benzoyl *p*-toluenethiosulfonate (XI) were obtained in 22.9 and 20.5% yields respectively.

The thiosulfonates were a slightly yellow oil or a semi-solid which could not be crystallized and which showed a strong carbonyl absorption band at 1690 cm^{-1}. They were fairly stable under anhydrous conditions below 130°C,[9] but were hydrolyzed by moisture when the THF solution was stood in air at room temperature; the absorption at 1690 cm^{-1} disappeared completely after 6 hr. Furthermore, the addition of a few drops of water to IV, IX, and XI accelerated their decomposition.

One of the most interesting reactivities of these anhydrides is their ability as acylating reagents. Benzoyl benzenethiosulfonate (VI) reacted with aniline exothermally in ether to give benzanilide (VIII) and anilinium benzenethiosulfonate (VIII) quantitatively. Furthermore, the reaction of IV with *n*-, or *t*-butylamine gave *N*-*n*(or *t*)-butylbenzamide (XVI or XIII), and *n*(or *t*)-butylammonium benzenethiosulfonate (XV or XIII) in good yields, respectively. However in contrast to benzoyl benzenesulfonate,[3] it did not react with phenol, *t*-butyl alcohol and benzamide. Recently, Karger and Mazur[10] have reported the powerful acylating ability of mixed sulfonic carboxylic anhydrides or the basis of their facile cleavage of ethers (*n*-butyl ether, benzyl ether, THF, *etc*). However, the reactions of IV with propylene oxide, tetrahydrofuran, tetrahydropyran, 1,4-dioxane, dibenzyl ether, and di-*n*-butyl ether did not occur even under more severe conditions than that of Karger.[10]

It has been known that stable phosphoranes[11] and sulforanes[12] are C-acylated by acid anhydrides to give other stable ylides. The anhydride IV reacted with phenacylidenetriphenyl phosphorane at room temperature to give the stable adducts, α,α′-dibenzoylmethyltriphenylphosphonium benzenethiosulfonate (XVIII),

$$\underset{\text{IV}}{PhCOSSO_2Ph} + Ph_3\overset{+}{P}-\overset{-}{C}HCOPh \xrightarrow[CH_2Cl_2]{rt} \left[Ph_3\overset{+}{P}-CH(COPh)_2\right]\overset{-}{S}SO_2Ph \quad (2)$$

XVIII

in a 56% yield (Eq. (2)). The XVIII structure was confirmed by elemental analyses by the IR spectrum, which a strong new peak at 1670 cm^{-1} due to carbonyl stretching, and the formation of α,α′-dibenzoylmethyltriphenyl phosphorane (XIX) through a reaction with 5% aqueous sodium hydroxide (Eq. (3)):

$$\text{XVIII} \xrightarrow{5\%\ NaOH} Ph_3\overset{+}{P}-\overset{-}{C}(COPh)_2 \quad (3)$$

XIX

Moreover, the anhydride (IV) in petroleum ether reacted exothermally with methyl- and phenylmagnesium bromide to give acetophenone (41%), and benzophenone (46%) respectively. In addition, the treatment of the anhydrides (IV) with lithium ethane- and benzenethiolate gave 52% of *S*-ethyl thiobenzoate and 33% of *S*-phenyl thiobenzoate.

Experimental

All the melting points are uncorrected. The IR spectra were measured on a JASCO Grating Infra-red spectrophotometer IR-G.

Materials. Benzene- and *p*-toluenesulfonyl chloride were purified by distillation before use. The potassium substituted thiobenzoate was prepared according to the directions in the literature.[13] The phenacylidenetriphenyl phosphorane was prepared according to the procedure of Ramirez and Dershowitz;[14] mp 185.2—186.5°C. The solvents were rigorously dried and distilled before use.

Reactions and the manipulations of the samples were carried out under dry nitrogen.

Benzoyl Benzenethiosulfonate (IV). A suspended solution of potassium thiobenzoate (8.4 g, 0.05 mol) in acetonitrile (100 ml) was added to a solution of benzenesulfonyl chloride (8.4 g, 0.05 mol) in acetonitrile (50 ml), after which the mixture was stirred for 5 hr at room temperature. After the acetonitrile had been evaporated from the organic layer, the residue was washed with two 20 ml portions of dichloromethane.

The concentration of the washings and subsequent chromatographic separation on silica gel [*n*-hexane–ether (9.5: 0.5)] under dark conditions gave 6.3 g (30.6%) of IV from the second effluent, which showed one spot on thin-layer chromatography. IR (neat): ν C=O 1690 cm^{-1}, ν SO_2 1382 (asym) and 1180 (sym) cm^{-1}, Found: C, 56.01; H, 3.42; S, 22.60%. Calcd for $C_{13}H_{10}O_3S_2$: C, 56.11; H, 3.30; S, 22.90%. An effluent insoluble in the dichloromethane insoluble parts were recrystallized from benzene–*n*-hexane to give 3.6 g of dibenzoyl disulfide (V) as colorless crystals. The melting point, the result of sulfur analysis, and the IR spectrum coincided exactly with those of an authentic sample obtained by the reaction of potassium thiobenzoate with iodine. Mp 134—135°C, IR (KBr): ν C=O 1700 and 1680 cm^{-1}, Found: S, 25.70% (Calcd for $C_{14}H_{10}O_2S_2$: S, 26.06%). On the other hand, the acetonitrile insoluble parts (solid) was extracted with five 30 ml portions of hot methanol. The subsequent evaporation of the methanol from the extracts left 4 g (25% based on the benzenesulfonyl chloride used) of potassium benzenesulfonate (VI). The results of elemental analyses and the spectrum were identical with those of an authentic sample prepared from benzenesulfonic acid and potassium hydroxide. IR (KBr): ν SO_2 1200 and 1190 cm^{-1}. Found: C, 35.62; H, 2.63; S, 14.49% (Calcd for $C_6H_5O_3SK$: C, 35.58; H, 2.50; S, 14.24%). The methanol insoluble part contains 95% KCl, as determined by Standard Volhard potentiometric titration (65%, based on the potassium thio-

9) Heating of IV in glass ampoule at 150°C for 3 hr under nitrogen atmosphere gave a 63% of dibenzoyl disulfide together with intractable oil.

benzoate used).

p-*Methylbenzoyl Benzenethiosulfonate (VII).* Yield, 22.9%: IR (neat) ν C=O 1691 cm^{-1}, ν SO_2 1388 (asym) and 1190 (sym) cm^{-1}. Found: C, 57.44; H, 4.01; S, 21.74%. Calcd for $C_{14}H_{12}O_3S_2$: C, 57.39; H, 4.19; S, 21.90%.

Benzoyl p-*Toluenethiosulfonate (VIII).* Yield 20.5%: IR (neat) ν C=O 1691 cm^{-1}, ν SO_2 1385 (asym) and 1197 (sym) cm^{-1}. Found: C, 57.50; H, 4.20; S, 21.98%. Calcd for $C_{14}H_{12}O_3S_2$: C, 57.39; H, 4.19; S, 21.90%.

Reaction of the Anhydride IV with Methanol. A methanol solution (20 ml) of IV (1.08 g, 0.04 mol) was refluxed for 10 hr. After the evaporation of the excess methanol from the reaction mixture, vacuum distillation of the residue gave 0.3 g (41% based on the IV used) of methyl benzoate (IX): bp 55°C/0.04 mmHg. The IR spectrum was identical with that of an authentic sample. The treatment of the distillation residue with 4 ml of aqueous 5% potassium hydroxide, the evaporation of the water from the reaction mixture, and subsequent recrystallization of the evaporation residue from methanol gave 0.3 g (96%) of potassium benzenesulfonate, which was identified by a comparison of the IR spectrum with that of an authentic sample.

Reaction of Benzoyl Benzenethiosulfonate (IV) with Aniline. When a solution of 0.4 g (0.04 mol) of aniline in 2 ml of ether was added to a solution of 0.56 g (0.002 mol) of IV in 10 ml of ether, the reaction began immediately and gave the precipitates. After the reaction mixture had been stirred at room temperature for 10 min, the insoluble parts were filtered out and washed four times with 3 ml portions of hot ether to give 0.45 g (50.5% based on the IV used) of anilinium benzenethiosulfonate (X), mp 171—172°C. IR (KBr): ν-NH_3 3100 cm^{-1} (strong, broad absorption), 1540 cm^{-1}, ν SO_2 1160 and 1038 cm^{-1}. Found: C, 54.12; H, 4.80; N, 5.11; S, 23.94%. Calcd for $C_{12}H_{13}NO_2S_2$: C, 54.14; H, 4.89; N, 4.89; S, 24.00%. The structure X was comfirmed by elemental analyses and by the IR spectrum. From the ether soluble parts, a 1.3 g portion of benzanilide (XI, mp 162.5—163.5°C) was obtained. The mp and IR spectrum were identical with those of the commercially obtained compound.

Reaction of the Anhydride IV with t-*Butylamine.* A solution of 0.29 g (0.04 mol) of *t*-butylamine in 2 ml of ether was added to a solution of 0.56 g (0.002 mol) of IV in 10 ml of ether and the mixture was stirred at room temperature for 15 min. The precipitates were filtered, washed four times with 3 ml portions of ether, and recrystallized from ethanol to give 0.37 g (79%, based on the IV used) of *t*-butylammonium benzenethiosulfonate (XII) as colorless crystals. Mp 196—197°C, IR (KBr): ν-NH_3 3100 cm^{-1} (strong, broad absorption), ν SO_2 1185 and 1050 cm^{-1}. Found: C, 50.93; H, 7.03; N, 5.48; S, 26.84%. Calcd for $C_{10}H_{17}NO_2S_2$: C, 50.84; H, 7.20; N, 5.51; S, 27.12%. The XII structure was comfirmed by elemental analyses and by the IR spectrum. From the ether-soluble parts, 0.29 g (81%, based on the IV used) of *N*-*t*-butylbenzamide (XIII) was obtained. Mp 128—129°C, IR (KBr), ν NH 3300 cm^{-1}, ν C=O 1630 cm^{-1}. The mp and the IR spectrum were identical with those of an authentic sample prepared from benzoyl chloride and *t*-butylamine.

Reaction of the Anhydride IV with n-*Butylamine.* An analogous treatment of IV (0.002 mol) with *n*-butylamine (0.004 mol) gave 0.32 g (68%, based on the IV used) of *n*-butylammonium benzenethiosulfonate (XV) and 0.3 g (78%, based on the IV used) of *N*-*n*-butylbenzamide (XVI). XV: mp 168—170°C, IR (KBr), ν-NH_3 3100 cm^{-1} (strong-broad absorption), ν SO_2 1170 and 1040 cm^{-1}. Found: C, 50.62; H, 7.12; N, 5.44; S, 27.03%. Calcd for $C_{10}H_{17}NO_2S_2$: C, 50.48; H, 7.20; N, 5.51; S, 27.12%. XVI: mp 69—71°C, IR (KBr), ν NH 3300 cm^{-1}, ν C=O 1630 cm^{-1}. The mp and the IR spectrum were identical with that of an authentic sample prepared from benzoyl chloride and *n*-butylamine.

Reaction of the Anhydride IV with Phenol. A mixture of IV (0.52 g, 0.002 mol) and phenol (0.18 g, 0.002 mol) was heated in a glass ampoule at 100°C for 20 hr. Phenol (0.17 g, 92%) was subsequently recovered from the mixture by distillation.

Reaction of Anhydride IV with Benzamide. A solution of benzamide (0.94 g, 0.008 mol) and IV (1.04 g, 0.004 mol) in ether (30 ml) was refluxed for 24 hr. The subsequent concentration of the reaction mixture gave 0.88 g of colorless crystals; was 94% of the recovered benzamide. The mp and the IR spectrum of the crystal consisted with those of benzamide obtained commercially.

Hydrolysis of the Anhydride IV. A benzene-solution (20 ml) of IV (1.05 g, 0.004 mol) was stirred for 6 hr at room temperature. After the evaporation of the solvent from the reaction mixture, the extraction of the residue with small portions of hot water and the cooling of the extracts gave 0.3 g of benzoic acid (XVII); mp 121—123°C.

On the other hand, the treatment of the hot water insoluble parts with 5 ml of aqueous potassium hydroxide gave 0.6 g of potassium *p*-toluenesulfonate.

Reaction of the Anhydride IV with Phenacylidenetriphenyl Phosphorane. A solution of 1.52 g (0.004 mol) of phenacylidenetriphenyl phosphorane and 1.05 g (0.004 mol) of IV dissolved in 10 ml of dichloromethane (1.05 g, 0.004 mol) was stirred for 12 hr at room temperature. After the subsequent concentration of the reaction mixture, the residue was crystallized from a small portion of acetone, subsequent recrystallization from dichloromethane–acetone containing minimum amount of *n*-hexane gave 1.5 g (56%) of α,α'-dibenzoylphenacyltriphenylphosphonium benzenethiosulfonate (XVIII) as slightly yellow crystals; mp 245—247°C, IR (KBr): ν C=O 1670 cm^{-1}. Found: C, 71.53; H, 4.74; P, 4.60; S, 9.61%. Calcd for $C_{39}H_{31}O_4PS_2$: C, 71.69; H, 4.71; P, 4.58; S, 9.60%.

Treatment of α,α'-*Dibenzoylmethyl Triphenylphosphonium Benzenethiosulfonate (XVIII) with Base.* The treatment of XVIII (1.3 g, 0.02 mol) with an aqueous 5% sodium hydroxide solution according to the usual method gave 0.86 g (85%) of α,α'-dibenzoylmethyl triphenylphosphorane (XIX), which was identified by a comparison of the mp and the IR spectrum with those of an authentic sample prepared according to the literature;[14] mp 191—193°C, IR (KBr) ν C=O 1520 cm^{-1}.

The Reaction of the Anhydride IV with Grignard Reagents.

a) Methylmagnesium Bromide: An ether solution of methylmagnesium bromide (0.01 mol) was added to an equimolar amount (2.8 g) of IV in the same solvent (10 ml) at 0°C, and the mixture was stirred at room temperature for 30 min. After the removal of the insoluble parts from the reaction mixture by filtration, the vacuum evaporation of the solvent from the filtrate and the distillation of the residue gave 0.49 g of acetophenone, bp 201—202°C (lit,[15] 202°C), IR (neat) ν C=O 1680 cm^{-1}. The boiling point and the IR spectrum coincided with those of an authentic sample which had been obtained commercially.

b) Phenylmagnesium Bromide. The similar treatment of the anhydride IV with phenylmagnesium bromide gave 0.83 g of benzophenone, bp 99°C/0.2 mmHg (lit,[16] 108°C/1 mmHg), IR (CCl_4) ν C=O 1664 cm^{-1}. The IR spectrum was quite similar to that of an authentic sample.

15) "The Merck Index" 7 ed. Merck and Co. INC. p. 9 (1960).
16) *ibid.*, p. 134 (1960).

Treatment of the Anhydride IV with Thiolates. *a) Lithium Ethanethiolate*: An ether solution of IV (2.78 g, 0.01 mol) was slowly added to a petroleum ether solution of lithium ethanethiolate (0.01 mol), which had been prepared from *n*-butyllithium and ethanethiol, at 0°C, and the mixture was stirred at room temperature for 1 hr. After filtrating the insoluble parts had been filtered from the reaction mixture, the evaporation of the solvent and vacuum distillation gave 0.85 g of *S*-ethyl thiobenzoate. Bp 79—80°C/2 mmHg (lit,[17] 83—84°C/2.5 mmHg). IR (neat) ν C=O 1669 cm^{-1}. The IR spectrum was identical with that of an authentic sample prepared from benzoyl chloride and lithium ethanethiolate.

b) Lithium Benzenethiolate: A similar treatment of IV (0.01 mol) with lithium benzenethiolate (0.01 mol) in petroleum ether gave *S*-phenyl thiobenzoate (0.69 g), mp 55—58°C (lit,[18] 56°C), IR (KBr) ν C=O 1685 cm^{-1}. The IR spectral data was quite similar to that of an authentic sample prepared from benzoyl chloride and lithium benzenethiolate in petroleum ether.

The authors wish to thank Professor Yoshio Hirabayashi and Mr. Hideharu Ishihara of Gifu University for their discussions, and wish to express also their hearty gratifude to Professor Yoshio Ishii of Nagoya University for his encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 863—871 (1973)

The Crystal and Molecular Structure of Vitamin B_6 Derivatives. I. Pyridoxal Phosphate Hydrate and Pyridoxal Phosphate Methyl Hemiacetal

Takaji FUJIWARA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka

(Received June 2, 1972)

Pyridoxal phosphate hydrate (PLPHYD) was crystallized from an aqueous solution in the form of monoclinic needles; space group $P2_1/c$ with $a=10.503$, $b=13.608$, $c=7.488$ Å, $\beta=93.71°$ and four molecules in the unit cell. Prism-shaped crystal of pyridoxal phosphate methyl hemiacetal (PLPMHA) was obtained by dissolving the pyridoxal phosphate hydrate crystals into 90% methanol; space group $P\bar{1}$, with cell dimensions, $a=9.42$, $b=10.61$, $c=6.20$ Å, $\alpha=105.6°$, $\beta=95.7°$, and $\gamma=99.7°$, and two molecules per cell. Intensity data were collected on an automated diffractometer for PLPHYD and photographically for PLPMHA. Crystal structures have been determined by the symbolic addition method. Refinements were done by the block-diagonal least-squares procedures, the final R value being 0.093 for PLPHYD and 0.112 for PLPMHA. The free aldehyde group of pyridoxal phosphate interacts with water molecule to form *gem-diol* in the crystalline state of PLPHYD and the *gem-diol* group of PLPHYD with methanol to form methyl hemiacetal. One of the two hydrogen atoms on a phosphate group is liberated and protonated to the pyridine ring nitrogen atom, resulting in the zwitterionic structure for both PLPHYD and PLPMHA molecules. All hydrogen bonds in PLPHYD are intermolecular ones, but in PLPMHA there is one OH–O intramolecular hydrogen bond.

Vitamin B_6 is found in natural foods in various forms as pyridoxine, pyridoxamine, pyridoxal, pyridoxamine-5′-phosphate and pyridoxal-5′-phosphate (PLP). Of these, PLP is the most important coenzyme form of vitamin B_6; that is, as the form of 'co-decarboxylase' or 'co-transaminase', it participates in a vast number of enzyme systems associated with nitrogen metabolisms. A great many PLP-dependent enzymes have been isolated in a crystalline state and a number of mechanisms have been proposed as regards substrate-enzyme interactions, but many substantial points are still obscure.[1-2] In order to elucidate the relationship between the structure and function of PLP-dependent enzymes, it is necessary to determine the molecular structure of the coenzyme PLP.

This paper deals with a detailed X-ray diffraction analysis of two forms of PLP; pyridoxal phosphate hydrate (PLPHYD) and pyridoxal phosphate methyl hemiacetal (PLPMHA); a preliminary report has been published.[3]

Experimental

The yellowish needle crystals of PLPHYD were obtained by dissolving the sample (labelled 'Pyridoxal Phosphate Monohydrate', Sigma Chemicals) into ion-exchanged distilled water (pH=6.5) at room temperature, and then by keeping the solution at 7°C in the dark.

PLPMHA was obtained in the form of transparent yellow prism-shaped crystals by dissolving PLPHYD into about 90% methanol aqueous solution by heating up to boiling point, cooling at room temperature and then standing the solution at 5°C.

Unit cell parameters of PLPHYD were obtained with a

D_c(g·cm^{-3})	1.649	1.595
μ(cm^{-1}) for Cu Kα	26.75	24.95

Intensity data of PLPHYD were collected with a crystal of dimensions $0.04\times0.18\times0.07$ mm^3, on a Rigaku Denki four-circle computer-controlled diffractometer using nickel-filtered Cu$K\alpha$ radiation and ω-2θ scanning technique. Scanning speed (2θ) was 2°/min and scanning width was taken as $\Delta\omega=1°+0.015\tan\theta$. Background was counted for ten seconds. 1912 independent reflections with $\sin\theta/\lambda$ less than 0.600 Å^{-1} were measured.

Three-dimensional intensity data for PLPMHA were collected from equi-inclination Weissenberg photographs with nickel-filtered Cu$K\alpha$ radiation. X-ray photographs for layers ($hk0$) to ($hk5$), and ($h0l$) to ($h8l$) were taken with two crystals, $0.31\times0.40\times0.31$ mm^3 and $0.24\times0.31\times0.38$ mm^3, respectively. The intensity was estimated visually by comparison with a standard scale, and corrected for spot size, and Lorentz and polarization factors. Independent 2526 reflections were measured.

The observed structure factors for both compounds were put on an absolute scale by Wilson statistics, and normalized structure factors ($|E_h|$) were computed.[4]

Phase Determination

Both PLPHYD and PLPMHA structures were solved by the symbolic addition method[5] for the centrosymmetric system (program DPD).

With the normalized structure factors for both compounds, the $\sum_2$ listings[4] were made for reflections with $|E_h|\geqq1.5$ and with probability larger than 97%, using a computer program SIGMA.

The starting set for PLPHYD is shown in Table 2,

Table 2. Starting set for the application of $\sum_2$ formula to PLPHYD

where the sign of (002) reflection is uniquely determined by the $\sum_2$ listing. After three cycles of phase determination, the following relations were found to be predominant; A=−, AC=+, AD=+, BC=+, BD=+, CD=+, and ABC=−, which were reduced to A=B=C=D=−. Out of 261 reflections with $|E_h|\geqq1.5$, phases of 140 reflections were determined, and a subsequent E map revealed the appropriate peak height for all seventeen non-hydrogen atoms at proper positions. Two large spurious peaks were thought to come from insufficient number of E_h per atom, when it was compared with that of the empirical criterion by Karle.[4]

Table 3. Starting set for the application of $\sum_2$ formula to PLPMHA

a) Number of $\sum_2$ interaction pairs.

Direct phase determination of PLPMHA was initiated by the starting set of eight reflections as listed in Table 3, where a positive sign of reflection (0−62) was uniquely determined from the $\sum_1$ formula[5] with a probability of 0.99. After three cycles of the symbolic addition procedure, the signs of 253 reflections were determined out of 328 reflections with $|E_h|\geqq1.5$. From relationship occurring between the letters A to D, it seemed probable that A=−, B=+, C=−, and D=−. Three dimensional E map calculated by this combination clearly elucidated the molecular structure of PLPMHA.

Refinement of the Structure

Refinement was done by the successive Fourier synthesis and then by a block-diagonal least-squares method (program BLLS).

PLPHYD. The molecular structure derived from the E map was quite different from the expected one which consists of one pyridoxal phosphate molecule

4) J. Karle and I. L. Karle, *Acta Crystallogr.*, **21**, 849 (1966).
5) H. Hauptman and J. Karle, "Solution of the Phase Problem" I. The Centrosymmetric Crystal. A.C.A. Monography No. 3. Polycrystal Book Service, Pittsburgh (1953).

and one water molecule of crystallization. The peculiar *gem-diol* structure was confirmed by the two Fourier syntheses, one using the phases except for two oxygen atoms of *gem-diol*, and the other the phases of all non-hydrogen atoms (R=0.28). Further refinement of the positional and thermal parameters was carried out by the least-squares calculation wihch minimized $\sum\omega_i(k|F_o|-|F_c|)^2$, where ω_i, the weight of ith reflection, was zero for $|F_o|=0$ and unity for $|F_o|\neq 0$. Several cycles of refinement employing anisotropic temperature factors for all non-hydrogen atoms reduced the R index to 0.11. At this stage, a difference Fourier synthesis was computed, and all of twelve hydrogen atoms were found to occupy the appropriate positions. Final three cycles of refinement including the hydrogen atoms with isotropic thermal factors reduced the R index to 0.106 (R=0.093 with non-zero reflections). The final atomic positional and thermal parameters are listed in Tables 4 and 5, respectively.

PLPMHA. Refinement of the structure by the least-squares method with isotropic thermal parameters brought the R value from 0.21 to 0.16 after five cycles of refinement. A difference Fourier synthesis was calculated at this stage. Out of 14 hydrogen atoms, thirteen could be located at the peak positions in the difference map. Five cycles of refinement were done

with anisotropic temperature factors for non-hydrogen atoms and with isotropic for 13 hydrogen atoms. A subsequent difference Fourier synthesis revealed no plausible peak for the one remaining hydrogen atom attached to the phosphate oxygen atom. This might be due to uncertainty of the hydrogen position; the two P–O bond lengths (P–O5=1.519 Å and P–O7=1.520 Å) were equal within the estimated standard deviation (0.005 Å) and the oxygen-oxygen distances related by a center of symmetry (O5–O5=2.555 Å and O7–O7=2.580 Å) indicated the existence of the symmetrical hydrogen bonding. The final five cycles on the least-squares refinement were carried out by keeping the one hydrogen atom at two centers of symmetry with a half weight, and the R index dropped to 0.112. The final positional and thermal parameters are listed in Tables 6 and 7, respectively.

A list of the observed and calculated structure factors for both crystals is kept as Document No. 7308 at the office of the Chemical Society of Japan.

All the numerical computations were done on an NEAC 2200—500 of the Computing Center of this University, a FACOM 230—60 of the Data Processing Center, Kyoto University and HITAC 5020E of the Computer Centre, the University of Tokyo. Computer programs SIGMA, BLLS, and DAPH were written by

Dr. Tamaichi Ashida and others by the author. The atomic scattering factors were taken from 'International Tables for X-ray Crystallography'.[6]

Discussion

The bond lengths and angles were calculated using the computer program DAPH and are shown in Fig. 1 for PLPHYD and Fig. 2 for PLPMHA.

Phosphate Group. Four P–O bond lengths of 1.587, 1.565, 1.503, and 1.501 Å in PLPHYD are in good agreement with the following average values[7] found in the other known monoanionic phsophates:[7–10] P–OC=1.602, P–OH=1.554, P–O$^-$=1.502, and P=O=1.490 Å, respectively. The P–O4 bond length of 1.600 Å and the P–O6 bond length of 1.487 Å in PLPMHA are very close to the above P–OC and P=O distances, respectively, whereas the P–O5 (1.519 Å) and the P–O7 (1.520 Å) bond lengths associated with the symmetrical hydrogen atom are intermediate to the normal P–OH and P=O bond lengths, similar P–O bond lengths of 1.522 and 1.530 Å being found in DL-*O*-serine phosphate monohydrate.[11] The correla-

tion of each four O–P–O angles of PLPHYD and PLPMHA is explainable by considering the repulsive force between two adjacent oxygen atoms;[9] the larger bond angle is found between the two shorter bonds.

a) Pyridoxine hydrochloride[12]
b) Pyridoxal phosphate oxime[13]

Pyridine Ring. Figures 1 and 2 show the molecular projection on the plane of the pyridine ring for PLPHYD and PLPMHA, respectively. The deviations of the individual atoms from the least-squares plane, together with the corresponding values of similar compounds, pyridoxine hydrochloride[12] and pyridoxal phosphate oxime[13] are listed in Table 8. The pyridine ring is exactly planar and C1, C7, C8, O3, and two hydrogen atoms (C6H and NH) are nearly in the plane of the ring, both in PLPHYD and PLPMHA. The equations of the best plane passing through the ring atoms are as follows:

for PLPHYD, $-0.24677X+0.06189Y-0.96709Z+3.51217=0$,
for PLPMHA, $-0.11690X-0.94425Y+0.30779Z+7.16397=0$.

The bond lengths and the angles in the pyridine ring are listed in Table 9, together with those of the related compounds. In the pyridine ring of PLPHYD and PLPMHA, the average C–C bond length is 1.394 Å and the C–N bond length is 1.330 Å. Three $C(sp^2)$–$C(sp^3)$ bond lengths have a mean value of 1.515± 0.009 Å, which is comparable to a standard value of 1.50 Å for a $C(sp^2)$–$C(sp^3)$ single bond. The bond angles, C2–N–C6 of 125.2 and 124.0° for PLPHYD and PLPMHA indicate that an extra-annular hydrogen atom attaches to the ring nitrogen as suggested by Singh[14] and the position of the attached hydrogen atom is confirmed by the difference Fourier synthesis.

Molecular Conformation. The conformational angles of PLPHYD and PLPMHA molecule are shown in Fig. 3. The torsion angle around the C1–O4 bond (162.2° for PLPHYD and 198.0° for PLPMHA) indicates that the P–O4 bond of the two compounds is almost symmetrical with each other with respect to the plane passing through C5, C1, and O4. The torsion angle around the C1–C5 bond (52.1° for PLPHYD and 13.5° for PLPMHA) means that the O4 atom of PLPHYD deviates appreciably from the plane of the pyridine ring (1.02 Å) but the O4 atom of PLPMHA is roughly in the plane (0.20 Å). As for the O4 atom, it is found that the C1–O4 bond distance of PLPHYD is significantly greater than that of PLPMHA. A large conformational change between PLPHYD and PLPMHA around the C8–C4 bond is probably due to the difference in the type of hydrogen bonding. Both two oxygen atoms (O1 and O2) in the *gem-diol* of PLPHYD are situated symmetrically at both sides of the pyridine ring plane as donors of the intermolecular hydrogen bonds, and the two C–O bonds with nearly equal length of 1.403 and 1.405 Å are in the *gauche-gauche* conformations with regard to the C4–C5 bond. On the other hand, of two oxygen atoms attached to the C8 atom of PLPMHA, O1 is of a methyl hemiacetal group and O2 is of a hydroxyl group, and the formation

of the intramolecular hydrogen bond between O2 and O3 restricts the torsion angle between the C8–O2 and C4–C3 bonds to be 15.6°.

Pyridoxal phosphate has been determined to form a stable *gem-diol* type crystalline hydrate in PLPHYD. The reason for the *gem-diol* formation of the pyridoxal phosphate is ascribable to the electron attracting character of the protonated pyridine ring; the withdrawal of electron from the carbon atom of the carbonyl group causes this atom to have a relatively positive charge and hence to be attacked by hydroxide ion, as in the formation of chloral hydrate[15] by chloral. It is also indicated that the reaction from PLPHYD to PLPMHA is not the addition reaction between an aldehyde and a molecule of methyl alcohol but the dehydration reaction between a *gem-diol* and a molecule of methyl alcohol. On the other hand, from NMR spectra measurement of pyridoxal phosphate in D_2O solution at pD=7.8,[16] the ratio of the hydrated form (*gem-diol*) to the free aldehyde form has been calculated to be 0.86, and a similar ratio of 0.66 was estimated from the ultraviolet absorption measurement of 5-deoxypyridoxal at pH=6.88.[17]

Cystal Structure. The projections of the crystal structure and the hydrogen bondings in PLPHYD viewed along the *c* and *b* axes, respectively, are shown in Figs. 4 and 5, and the crystal structure of PLPMHA projected along the *c* axis in Fig. 6. The hydrogen bond distances and angles are listed in Tables 10 and 11 for PLPHYD and PLPMHA, respectively. All the

hydrogen bonds in PLPHYD are intermolecular ones, whereas in PLPMHA there is one intramolecular hydrogen bond of 2.534 Å between O2 and O3. Phosphate oxygen atoms of both compounds participate in hydrogen bond formation. It is of interest that O5 and O7 atoms of PLPMHA form the symmetrical hydrogen bonds of 2.555 and 2.580 Å, respectively. The shortest OH···O hydrogen bond distance of 2.517 Å found on P–OH···O=P of PLPHYD is comparable to 2.492 Å of L-serine phosphate.[7] The ester oxygen atom O4 in both compounds and O1 in PLPMHA are not involved in the hydrogen bonding. The protonated nitrogen atom in the pyridine ring also takes part in the hydrogen bonding of NH···O type in both compounds. PLPHYD molecules are fixed by three dimensional networks of hydrogen bonding and the large overlaps of the pyridine rings with spacing of 3.7 Å are found among the molecules related by the *c* glide plane symmetry. Molecular arrangement in the PLPMHA crystal can be described as a layered structure parallel to the *ac* plane. The L and D antipodes

of PLPMHA related by a center of symmetry are held together by the network of hydrogen bonds in each layer, whereas between the adjacent layers the methyl group acts mainly as a spacer. As the number of intermolecular short contacts is greater in PLPHYD than in PLPMHA, it can be said that PLPHYD molecules are in closer packing arrangement than PLPMHA, which explains well the larger observed density of the former ($1.635\ g \cdot cm^{-3}$) than that of the latter ($1.587\ g \cdot cm^{-3}$).

Solvolysis of Organic Phosphates. VI. Intramolecular Catalysis in the Hydrolysis of 2-Pyridylalkyl Phosphates[1)]

Yukito MURAKAMI, Junzo SUNAMOTO, and Naomi KANAMOTO

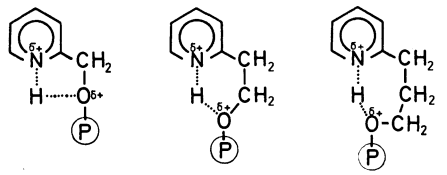
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received June 5, 1972)

The spontaneous hydrolysis of 2-pyridylethyl, 2-pyridylpropyl, and 6-methyl-2-pyridylmethyl phosphates was investigated at 80—95°C in aqueous media with an ionic strength of 0.10. The reactions followed apparent first-order kinetics with respect to the phosphate species, and the maximum rates were observed at $-\log[H^+]$ 2—3 with a shoulder around 5—6. The participation of intramolecular catalysis played by the pyridinium group in the hydrolysis of the above pyridylalkyl phosphates as well as in that of 2-pyridylmethyl phosphate was investigated from the LFER viewpoint. For the evaluation of LFER, the acid dissociation constant was employed as the most reasonable structural parameter. As a result, the intramolecular pyridinium catalysis was found to takes place in the zwitterion hydrolysis for 2-pyridylmethyl, 2-pyridylethyl, and 6-methyl-2-pyridylmethyl phosphates. This indicates the importance of the geometry around the reaction center for the intramolecular catalytic action. The isokinetic relationship was established for the hydrolysis of pyridylalkyl phosphates with the exception of 6-methyl-2-pyridylmethyl phosphate. The anomalous behavior in the hydrolysis of the latter was attributed to the activation entropy effect which may have been caused by defreezing of solvation in the transition state.

We have investigated the extent of intramolecular catalysis in the hydrolysis of aryl and alkyl phosphates containing a hetero-aromatic ring system around the reaction center. An intramolecular general acid catalysis has been confirmed in the spontaneous hydrolysis of 2-pyridylmethyl,[2)] 8-quinolyl,[3)] and 3-hydroxy-2-pyridylmethyl phosphates.[4)] From the results so far obtained a question arose as to whether acidity of the catalytic group or the geometry around the reaction center contributes to the intramolecular catalysis in the hydrolysis.

In this work, we intend to clarify the effect of structural environment on the intramolecular catalysis by studying the hydrolysis of 2-pyridylalkyl phosphates. If both 2-pyridylethyl and 2-pyridylpropyl phosphates secure the rate enhancement in their hydrolyses due to the intramolecular catalysis by the pyridinium group as in the case of 2-pyridylmethyl phosphate **1**, a six-membered ring **2** and a seven-membered one **3**, respectively, would be formed in their transition states.



1 2 3

The stability of these ring conformations yielded in the hydrolysis of the above three phosphates will be discussed in connection with the intramolecular catalysis. The electronic and steric effects due to the methyl-substituent on the intramolecular-proton transfer mechanism were investigated in the hydrolysis of 6-methyl-2-pyridylmethyl phosphate.

Experimental

Materials. 2-Pyridylethyl and 2-pyridylpropyl phosphates were prepared by the phosphorylation of the corresponding alcohols with pyrophosphoric acid.

Pyridylethanol (2-(β-hydroxyethyl)pyridine) (CP grade, Wako Pure Chemical Ind., Ltd., Osaka) was purified by vacuum distillation. Fractions distilled at 66.5°C/0.20—0.25 mmHg were combined and used for the phosphorylation. Pyridylpropanol (2-(γ-hydroxypropyl)pyridine) (Schuchard Chemische Fabrik, München) was purified by distillation, the distillates at 95°C/0.35 mmHg being used for the phos-

phorylation. Phosphorylation of both pyridylalcohols was carried out according to the previous method.[5,6] Phosphorylated products were purified by the cation exchange column-chromatographic technique and further purified by recrystallization from aqueous ethanol.

2-Pyridylethyl Phosphate. Found: C, 40.58; H, 5.11; N, 6.78; P, 14.3%. Calcd for $C_7H_{10}NO_4P$: C, 41.34; H, 4.96; N, 6.90; P, 15.3%. 2-Pyridylpropyl Phosphate. Found: C, 44.01; H, 5.51; N, 6.33%. Calcd for $C_8H_{12}NO_4P$: C, 44.25; H, 5.57; N, 6.45%. IR[7] (KBr disk); ν_{O-H}, ~3400; $\nu_{P=O}$, 1295, 1280, 1175, 1158, and 1080; $\nu_{P-O-C(alk)}$, 1045, 1030, and 920 cm^{-1}. UV (10^{-4}M in water): λ_{max} 263 mμ (ε=7760). Neutralization equivalence; 107.72 (calcd., 108.58).

Preparation and purification of 2-pyridylmethyl[5] and 6-methyl-2-pyridylmethyl phosphates[6] were described previously.

Kinetic and Potentiometric Measurements. The apparatus and experimental procedures were essentially the same as those described previously,[2-4] except for the hydrolysis of 2-pyridylpropyl phosphate at 85, 90, and 95°C, and of 2-pyridylethyl phosphate at 95°C. For the hydrolysis of 2-pyridylpropyl and 2-pyridylethyl phosphates at higher temperatures, a 10 ml Pyrex test tube with a ground Pyrex stopper was used. An aliquot of sample solution containing a substrate, an inorganic salt to maintain the ionic strength constant, and perchloric acid to adjust the hydrogen ion concentration at an appropriate value was placed in the test tube. Several test tubes containing a sample solution of the same constituents were dipped in a water bath regulated to a given temperature. At an appropriate time interval one of them was drawn out and the sample was analyzed for inorganic phosphate liberated during the course of reaction. Since all runs using the Pyrex test tubes were carried out to cover a pH range 1—3 where the phosphate exists predominantly in a neutral zwitterion form, the pH-deviation during the course of hydrolysis reaction did not exceed ±0.02. The observed rate constant in each run was retained within an accuracy of ±2% while the reaction temperature was controlled within ±0.1—0.05°C.

Acid Dissociation Constants and Specific Rate Constants. Acid dissociation constants of the present phosphates at 80°C were obtained by the potentiometric determination[2] and/or by the dynamic (kinetic) method. Specific rate constants assigned to the reactive substrate species were calculated from the apparent first-order rate constants obtained at various pH values. The calculation procedures were described previously.[3,4]

Results

Acid Dissociation Constants. Acid dissociation constants obtained are summarized in Table 1. The acid dissociation constant for the 1-pyridinium proton is represented by K_{H_2A}, and that for the second phosphate proton by K_{HA}.

Table 1. Acid dissociation constants of the pyridylalkyl phosphates at μ=0.10 (KNO_3) as determined by potentiometric titration[a]

Phosphate	pK_{H_2A}		pK_{HA}	
	25°C	80°C	25°C	80°C
6-Methyl-2-pyridylmethyl	4.74[b]	4.50 (4.34)[f]	6.64[b]	6.36 (6.08)[f]
2-Pyridylmethyl	4.42[c]	4.15[d] (4.03)[e,f]	6.29[c]	6.54[d] (6.46)[e,f]

2-Pyridylpropyl	5.60	5.09	6.90	6.75
3-Pyridylmethyl	4.86[c]	4.43[d]	6.23[c]	6.48[d]

a) Estimated error is within 0.02. Values in parentheses were evaluated by kinetic method using Eq. (1).
b) Cited from Ref. 6.
c) Cited from Ref. 5.
d) Cited from Ref. 2.
e) Cited from Ref. 3.
f) At 90°C.

Introduction of a methyl group at the 6-position of 2-pyridylmethyl phosphate resulted in an increase of both pK_{H_2A} and pK_{HA}. Similarly, the extension of the methylene-chain from 2-pyridylmethyl through 2-pyridylpropyl group brought about the lowering of acidity of both groups. Since the temperature dependency of the ionization constant varies according to the nature of the structural environment of the acid, the above trend would not necessarily be the case at a higher temperature.

Specific Rate Constants. All runs followed good first-order kinetics. The pH-rate profile for the hydrolysis of 6-methyl-2-pyridylmethyl phosphate at 90°C is illustrated in Fig. 1 as a typical example. The rate maximum in the pH-rate profile was observed at −log[H+] 2—3. This indicates that the most reactive species is in the neutral zwitterion form followed by the monoanionic one. This holds true also for the cases of 2-pyridylethyl and 2-pyridylpropyl phosphates.

The solid line in Fig. 1 is the theoretical curve calculated from the following equation:

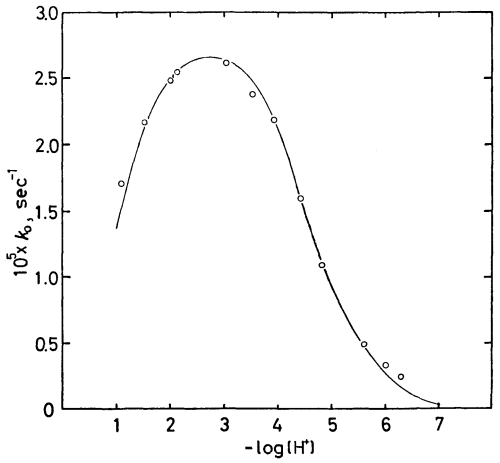

Fig. 1. pH-rate profile for the spontaneous hydrolysis of 6-methyl-2-pyridylmethyl phosphate at 90°C and μ=0.10. Solid line is a theoretical curve calculated from values listed in Tables 1 and 3 by using Eq. (1).

$$k_0 = k_{H_2A}X_{H_2A} + k_{HA}X_{HA} \quad (1)$$

where X_{H_2A} and X_{HA} stand respectively for the mole fractions of neutral zwitterionic and monoanionic species, and k_0, k_{H_2A}, and k_{HA} are the overall first-order rate constant and the specific rate constants, respectively, of the above two reactive phosphate species. The calculation procedures of these parameters were the same as those described previously.[2-4] The agreement between the observed and the calculated rate constants was quite satisfactory.

85.0	0.350	——[b]
2-Pyridylpropyl phosphate		
95.0	0.685	——[b]
90.0	0.374	——[b]
85.0	0.200	——[b]

a) Calculated by Eq. (1) with the aid of the acid dissociation constants listed in Table 1; μ=0.10.
b) Because of the extremely low hydrolysis rate, assignment of the rate constant was not performed.

For the hydrolysis of 6-methyl-2-pyridylmethyl, 2-pyridylethyl, and 2-pyridylpropyl phosphates, the apparent first-order rate constants and the reaction conditions are listed in Table 2. The calculated specific rate constants for the present phosphates are summarized in Table 3. We could not obtain reliable specific rate constants for the hydrolysis of 2-pyridylethyl and 2-pyridylpropyl phosphates in their monoanionic forms, for the reaction was extremely slow even at 90°C. However, participation of the intramolecular catalysis in hydrolysis can be studied for the zwitterionic species. Thus, the above data are not necessarily required for the present purpose.

Activation Parameters. Each specific rate constant satisfactorily followed the Arrhenius law. The activation parameters for the hydrolysis of the neutral zwitterion species, along with the data for 3-pyridylmethyl and 2-pyridylmethyl phosphates,[2] are listed in Table 4.

Table 4. Activation parameters for the hydrolyses of 6-methyl-2-pyridylmethyl, 2-pyridylmethyl, 2-pyridylethyl, and 2-pyridylpropyl phosphates in their zwitterion forms[a]

Phosphate	E_a kcal mol^{-1}	$\Delta H^{\neq}$ kcal mol^{-1}	$\Delta S^{\neq}$ e. u.

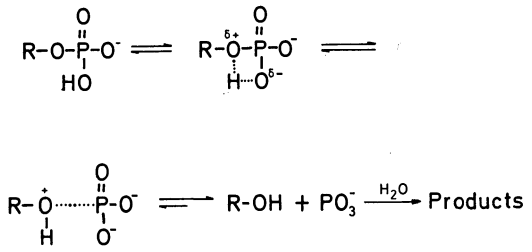
a) Errors for these parameters were calculated from the standard error of rate constant and errors ascribed to the reaction conditions such as reaction temperature and pH-values.

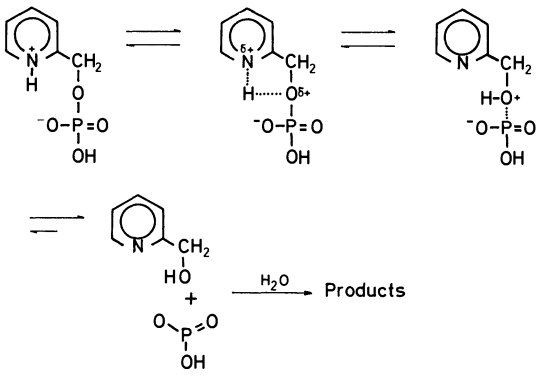
Discussion

Acid Dissociation Constants. The hydrolysis of alkyl and aryl phosphates has been provided with



Scheme 1.

many evidences for an unimolecular P–O bond cleavage upon intramolecular general acid catalysis.[8,9] The state of affairs is shown in Scheme 1 for the monoanionic phosphate species. The extent of intramolecular general acid catalysis can be evaluated by referring to the acid dissociation constant of the corresponding alcohol (the leaving group)[8] and that of the second phosphate proton.[10] The latter, represented by K_{HA}, may reflect the donability of the proton from the phosphate moiety, while the former may be related to the proton acceptability of ester oxygen at the transition state. Both values may refer to the P–O bond strength in the transition state as well.



Scheme 2.

When a nitrogen atom exists in its leaving group as in the hydrolysis of the pyridylalkyl phosphates, the most reactive species is in the neutral zwitterion form and a general acid catalysis occurs intramolecularly with participation of the 1-pyridinium proton[2] as shown in Scheme 2. We understand, therefore, that the acid dissociation constant of ionic substrate is an important structural parameter for a study of the structure-reactivity correlation in its hydrolysis.

Substitution with the electron-donating methyl group at the 6-position of 2-pyridylmethyl phosphate resulted in an increase of pK_{H_2A} and pK_{HA}. The electron donability of the methyl group seems to prevent the dissociation of both protons, on the pyridine nitrogen and on the phosphate oxygen. Similarly, the extension of the methylene-chain in the 2-pyridylalkyl phosphates may result in the increase of basicity of both pyridyl nitrogen and phosphate moiety. These trends on both pK_{H_2A} and pK_{HA} values are obvious from the data given in Table 1.

Intramolecular Catalysis. We have already proposed a mechanism for the intramolecular general acid catalysis in the hydrolysis of 2-pyridylmethyl phosphate[2] and of 8-quinolyl phosphate[3] in their zwitterion forms. The catalysis was played by 1-pyridinium and 8-quinolinium groups, respectively. In the hydrolysis of 3-hydroxy-2-pyridylmethyl phosphate in its monoanion and dianion species, a unique intramolecular general acid catalysis by the 3-hydroxy group has also been clarified.[4] In all cases, the catalytic action has certainly been dependent upon the location of the catalytic site relative to the reaction center. Thus, a functional group of catalytic ability being located sterically in the proximity of ester oxygen, the hydrolysis rate is promoted through intramolecular proton transfer. In order to know whether an intramolecular catalysis takes place also in the hydrolysis of 2-pyridylalkyl phosphates, and to evaluate the extent of catalytic effect if any, we studied LFER on the hydrolysis of pyridylalkyl phosphates in their zwitterion forms. The acid dissociation constant of the second phosphate proton pK_{HA} was considered to be the most reasonable structural parameter for the present LFER study, as obvious from the preceding discussion on this parameter.[10] The linear relationship between pK_{HA} at 80°C and the logarithm of the specific first-order rate constant for the zwitterion hydrolysis at 90°C (log k_{H_2A}) is illustrated in Fig. 2.[11]

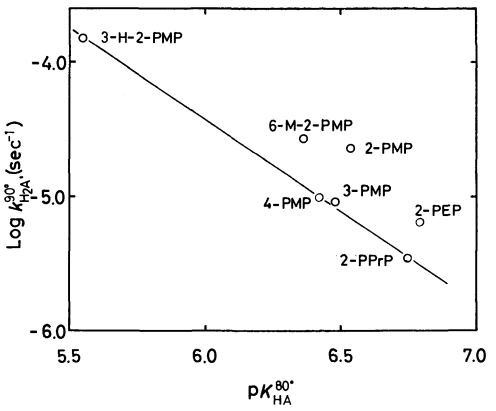


Fig. 2. Correlation between first-order rate constants at 90°C for hydrolyses of pyridylalkyl phosphates in their zwitterion forms and pK_{HA}'s of the phosphates at 80°C. Abbreviations: 3-H-2-PMP, 3-hydroxy-2-pyridylmethyl phosphate; 6-M-2-PMP, 6-methyl-2-pyridylmethyl phosphate; 2-PMP, 2-pyridylmethyl phosphate; 3-PMP, 3-pyridylmethyl phosphate; 4-PMP, 4-pyridylmethyl phosphate; 2-PEP, 2-pyridylethyl phosphate; 2-PPrP, 2-pyridylpropyl phosphate.

Judging from the location of the pyridinium group relative to the ester oxygen, the neutral zwitterions of 3-hydroxy-2-pyridylmethyl,[4] 3-pyridylmethyl, and 4-pyridylmethyl[2] phosphates can not secure an intramolecular catalysis due to the pyridinium group. Thus,

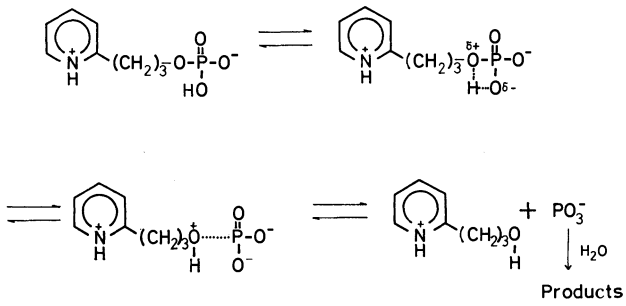
11) Reliabilities of the present linear relationship and of the structural parameters used are scheduled to be discussed in a forthcoming paper along with more extensive investigations.

a straight line can be drawn in Fig. 2 through the plots for these phosphates as a reference for which the reaction proceeds without the pyridinium catalysis. 6-Methyl-2-pyridylmethyl, 2-pyridylmethyl, and 2-pyridylethyl phosphates apparently deviate upward from this line, while 2-pyridylpropyl phosphate lies on it. The significant rate enhancement of the former three phosphates, with reference to those expected from the simple LFER, may be ascribed to some additional catalysis. Thus, it can be seen that the intramolecular general acid catalysis takes place not only in the hydrolysis of 2-pyridylmethyl phosphate but also in that of 2-pyridylethyl and 6-methyl-2-pyridylmethyl phosphates in their zwitterion forms. As a result, we can conclude that formation of either a five-membered (**1**) or a six-membered ring (**2**) at the pre-equilibrium stage of the hydrolysis reaction is in favor of the intramolecular catalysis by the pyridinium group, but that formation of a seven-membered ring (**3**) is no longer favorable for such a catalysis. For the hydrolysis of 2-pyridylpropyl phosphate zwitterion, thus, we may propose a mechanistic pathway *via* an intramolecular proton transfer from the phosphate moiety, not from the pyridinium nitrogen as seen in Scheme 3, analogous to the cases of the usual alkyl phosphates.[8,9]



Scheme 3.

There exists another question as to the extent of their rate enhancement. In a series of 2-pyridylalkyl phosphates, the extents of the rate enhancement are 2.5-fold for $-CH_2-$, 2.0-fold for $-CH_2-CH_2-$, and 1.0-fold for $-CH_2-CH_2-CH_2-$ in their alkyl chains, respectively, relative to the corresponding rates expected from LFER without any additional effect as shown in Fig. 2. In reference to our previous postulate on the reaction mechanism,[2,3] the first energy barrier in this reaction pathway may exist at the stage, where the proton-transfer from the hetero-aromatic nitrogen atom or the terminal phosphate oxygen to the ester oxygen occurs, *viz.*, the pre-equilibrium protonation step. The second barrier may be located in the reaction coordinate at the stage where the P–O bond cleavage takes place to give products; this may most likely correspond to the rate-determining step, as justified by the kinetic solvent isotope effect,[3] and/or by the extent of activation parameters.[2-4,8] This phenomenon is illustrated by a typical schematic representation in Fig. 3. The fact that the linear free energy relationship between pK_{HA} and $\log k_{A_2A}$ was established apparently suggests that the rate-limiting step almost consists of an unimolecular P–O bond fission.

Isokinetic Relationship. The differential thermodynamic activation parameters for the hydrolysis of 2-pyridylalkyl phosphates, with 2-pyridylmethyl phosphate taken as the standard reactant, are plotted in Fig. 4. It is, therefore, most reasonable to assume that these phosphates undergo hydrolysis through essentially the same mechanistic pathway. At first sight, the isokinetic relationship obtained does not appear to be consistent with the mechanistic criteria on the intramolecular proton-transfer path. However, entropy and enthalpy of activation obtained in the present reaction system are mostly concerned with the unimolecular P–O bond fission of the protonated species. It is not necessary to consider from where the proton was transferred at the pre-equilibrium stage. An exception was noticed for the hydrolysis of 6-methyl-2-pyridylmethyl phosphate. The presence of the 6-methyl group seems to perturb the transition state. Contrary to what would be expected, Table 3 and Fig. 2 indicate that the zwitterionic species of 6-methyl-2-pyridylmethyl phosphate is more rapidly hydrolyzed than that of 2-pyridylmethyl phosphate. This was similarly observed in the hydrolysis of monoanionic species; $k_{HA}=5.63\times10^{-3}$

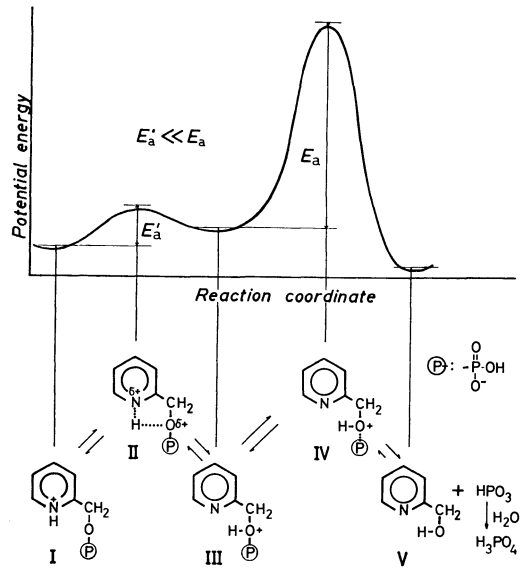


Fig. 3. Schematic representation of unimolecular mechanism in terms of potential energy *vs.* reaction coordinate as a typical intramolecular catalysis acted in the 2-pyridylmethyl phosphate hydrolysis.

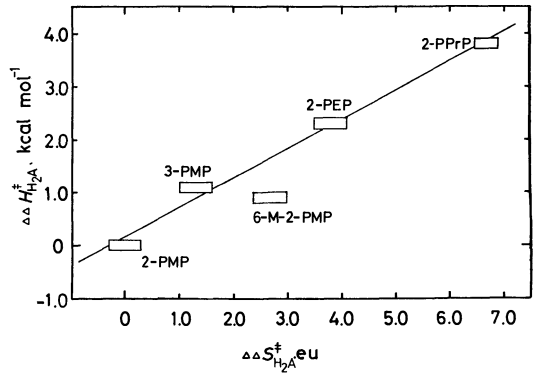

Fig. 4. The isokinetic relationship for the spontaneous hydrolyses of pyridylalkyl phosphate zwitterions. Abbreviations are the same as those used in Fig. 2.

sec^{-1} at 90°C for 6-methyl-2-pyridylmethyl phosphate, and 4.14×10^{-3} sec^{-1} at 90°C for 2-pyridylmethyl phosphate. A question of what is the driving force to bring about the rate enhancement must be solved. A clue can be found in Fig. 4 and Table 4. Only 6-methyl-2-pyridylmethyl phosphate showed deviation downward from the linear relationship of enthalpy-entropy compensation, being different from other pyridylalkyl phosphates. The electron-donating effect of the methyl group must be reflected in terms of activation enthalpy for the hydrolysis of 6-methyl-2-pyridylmethyl phosphate, partially in the pre-equilibrium protonation stage and mostly in the P–O bond cleavage step. The increase of activation enthalpy by 900 cal mol^{-1} was, in fact, observed as an evidence. Thus, the rate-enhancement and deviation in the isokinetic relationship caused by methyl-substitution should be attained from the activation entropy term and therefore the cause of a larger activation entropy ($\Delta\Delta S^{\neq}=2.7$ e.u.) should be considered. It may be most reasonable to postulate that a bulky alkyl-substituent in the neighborhood of the reaction center interferes significantly with the solvation, *viz.*, "defreezing" of solvation, in the transition state.

The Synthesis of 3-Amino-3-deoxy-D-allose and Related Substances[1]

Shinkiti KOTO, Noboru KAWAKATSU, and Shonosuke ZEN
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo

(Received June 15, 1972)

Starting from methyl 2,4,6-tri-*O*-benzyl-α-D-glucopyranoside, a facile synthesis of 3-amino-3-deoxy-D-allose was carried out; some new *O*-benzyl derivatives of 3-amino-3-deoxy-D-allopyranose are also described.

A variety of derivatives of 3-amino-3-deoxy-D-allose has been synthesized by various methods.[2-9] Recently, an alternative method of preparing this sugar has been reported.[10] In a practical sense, the synthesis demonstrated by Coxon and Hough[11] may be most convenient for getting this aminosugar. However, the known methods for the preparation of the derivative of this aminosugar with the pyranose-ring system[5-7] seem to be rather unpromising. This paper will be concerned with another route to 3-amino-3-deoxy-D-allose as well as with the *O*-benzyl derivative of 3-amino-3-deoxy-D-allopyranose. Recently, the *O*-benzyl derivative of aminosugars has frequently been synthesized as an useful synthetic intermediate.[11]

Methyl 2,4,6-tri-*O*-benzyl-α-D-glucopyranoside,[12] obtained by the one-step benzylation of readily-available methyl α-D-glucopyranoside, was treated with *p*-toluenesulfonyl chloride in pyridine to give the corresponding 3-*O*-*p*-toluenesulfonate (I), which, after debenzylation and acetylation, gave known methyl 2,4,6-tri-*O*-acetyl-3-*O*-*p*-toluenesulfonyl-α-D-glucopyranoside[13] (II), which was the starting material for the synthesis of 3-amino-3-deoxy-D-glucose (kanosamine).[14]

The nucleophilic displacement of the sulfonyloxy group of the sulfonate (I) by the azide ion encountered some difficulties. The nucleophilic substitution of the sulfonyloxy group of the benzylated sugar by the azide residue has been investigated by Stevens and his coworkers.[15] They have successfully utilized moist *N*,*N*-dimethylformamide (DMF) as a solvent. More recently, other high basic dipolar aprotic solvents, such as dimethylsulfoxide (DMSO)[16] and hexamethylphosphoric triamide (HMPA),[17] have been used and found to be excellent solvents for nucleophilic displacement reactions in the carbohydrate field. However, in the case of the replacement reaction of the sulfonate (I) with an azide ion, practically no reaction at all took place under those conditions. However, in DMSO or HMPA, the displacement did proceed under rather

compulsive conditions to give methyl 3-azide-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-allopyranoside (III) (Table 1). The reaction was monitored by thin-layer chromatography of the reaction mixture. HMPA gave slightly better results.

The azide (III) was treated with lithium aluminium hydride in dioxane[15] to give methyl 3-amino-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-allopyranoside (IV), which was characterized as a crystalline 2,4-dinitrophenyl derivative (V). The corresponding *N*-acetyl and *N*-carbobenzoxy compound of IV could not be crystallized. The amine (IV) was converted into known methyl 2-acetamido-2,4,6-tri-*O*-acetyl-3-deoxy-α-D-allopyranoside (VI)[7] by catalytic hydrogenolysis, followed by acetylation. The treatment of V with a warm suspension of an anionic resin in moist acetone regenerated the amine (IV), which was then converted into Compound VI. Thus, as might be expected, the substitution of the sulfonyloxy group by the azide ion proceeded with an inversion of the configuration at the reaction center.

The observed lack of reactivity of the sulfonyloxy group in the nucleophilic substitution reaction might be explained, at least, by the idea that the formation of the transition state, which requires the backside approach of the azide anion to C-3, would be interfered with by the 1,3-diaxial interactions by the axial methoxy group at the anomeric center.[18]

We have applied these conditions to another sulfonate, 3-*O*-*p*-toluenesulfonyl-1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranose[19] (Ia), which has been mentioned as having little susceptibility to nucleophilic substitution reactions.[20] The replacement reaction of this sulfonate with sodium azide was recently carried out in moist DMF, in which heating was continued for 15 days a 115°C.[4] When this was treated with sodium azide in hot HMPA, however, the replacement reaction proceeded well above 125°C and was completed after 24 hr. This result showed that the sulfonate was slightly more susceptible to the replacement with the azide anion under those reaction conditions than was the sulfonate I.

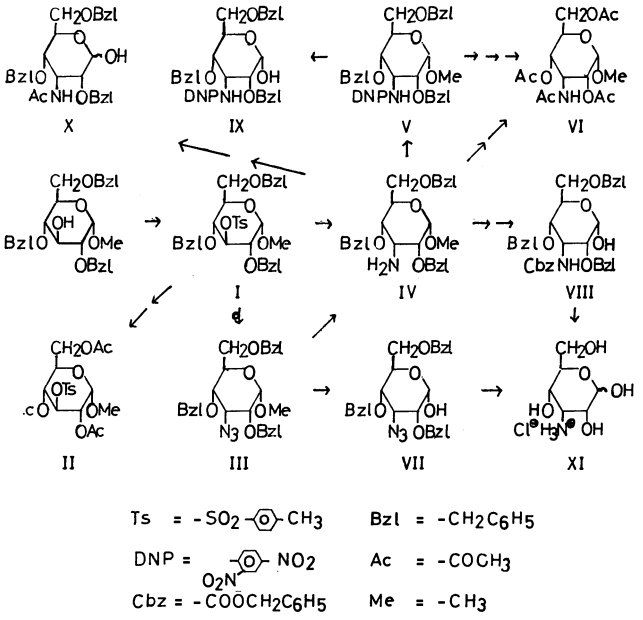

Chart 1.

The difference between the susceptibilities of these sulfonates might be interpreted on the basis of the recent conformational findings[21] that the most stable conformer of methyl α-D-glucopyranoside and its related substances in various solvents is one whose methyl group is oriented to have a *gauche* relationship with the ring oxygen and the C-2 carbon. Therefore, it is conceivable that the access of the azide anion to the reaction center from the opposite side of the leaving sulfonyloxy group would allow the aglycon to rotate to have an unfavorable eclipse relationship to the ring oxygen (Chart 2). On the other hand, the sulfonate (Ia) would not encounter such barriers.

By the way, the nucleophilic replacement of the sulfonyloxy group of syrupy methyl 3-*O*-methanesul-

fonyl-2,4,6-tri-*O*-benzyl-α-D-glucopyranoside by the azide ion was of no practical use.

The amination of the sulfonate (I) was also carried out by ammonolysis in methanol at 150°C for 30 hr; this gave the amine (IV).

The azide compound (III) was hydrolyzed to furnish a fine crystalline reducible compound (VII), which was then smoothly hydrogenolyzed over palladium-black in the presence of hydrochloric acid to gave the hydrochloride of 3-amino-3-deoxy-D-allose. This aminosugar was also obtained *via* the *N*-carbobenzoxy derivative (VIII).

Two other C-1 free compounds, the *N*-acetyl derivative (X) and the *N*-2,4-dinitrophenyl derivative (IX), were also synthesized. All the crystalline hydrolyzed products (VII, VIII, and IX) were assigned the α-configuration on the basis of their mutarotative behavior.[22] It should be noted that the concentration of the strong acid in the mixed acid used in these hydrolyses was lower than that used in the hydrolyses of the *O*-benzyl sugar with the gluco configuration[11] (Table 2).

Table 2. Hydrolyses of *O*-benzyl sugars

Experimental

General Procedures. The solvent systems used for the column chromatography over silica gel (Kanto Chemical Co.) or the tlc (Silica Gel G; Merck) were as follows: A, benzene–2-butanone; B, benzene–acetone. The melting points were determined by means of a Yanagimoto micro-melting point apparatus; uncorrected values are given. The specific rotation was measured in a 1-dm tube by means of an Atago Polux apparatus. The IR spectra were determined by means of a JASCO IRA-1 infrared spectrophotometer. The PMR spectra were measured with a Varian S-60T apparatus in $CDCl_3$, with TMS as the internal standard. The elemental analyses were made by means of a Perkin-Elmer Model 240 Elemental Analyser apparatus.

Methyl 2,4,6-Tri-O-benzyl-3-O-p-toluenesulfonyl-α-D-glucopyranoside (I). A solution of methyl 2,4,6-tri-*O*-benzyl-α-D-glucopyranoside[12] (13 g) and *p*-toluenesulfonyl chloride (15 g) in pyridine (26 ml) was kept standing for 4 days at 28°C. The mixture was then diluted with benzene, and the solution was thoroughly washed by aqueous sodium carbonate and then by water. The yellow syrup thus obtained (18 g) was crystallized with cyclohexane to give crude crystals (14 g, 81%), which were then recrystallized from diisopropyl ether to give colorless crystals (10 g, 58%), mp 96—97°C, $[\alpha]_D^{25}$ +34° (*c* 1.9, $CHCl_3$), ν_{max}^{KBr} (cm^{-1}): 1365 and 1171 (sulfonyl). δ (ppm): 2.29 (3H, singlet; C<u>H</u>$_3$C$_6$H$_4$SO$_2$–), 3.31 (3H, singlet; C<u>H</u>$_3$O–), 7.27 and 7.32 (15H, quasi singlets; C$_6$<u>H</u>$_5$CH$_2$O–).

Found: C, 67.54; H, 6.29%. Calcd for $C_{35}H_{38}O_8S$: C, 67.94; H, 6.19%.

Methyl 2,4,6-Tri-O-acetyl-3-O-p-toluenesulfonyl-α-D-glucopyranoside[13] *(II).* I (0.20 g) was hydrogenolyzed over palladium-on-carbon (5%, 30 mg) in methanol (7 ml) at room temperature under atmospheric pressure. The glass thus obtained was then heated with acetic anhydride (6 ml) and sodium acetate (0.1 g) at 95°C for 3 hr. A crude acetate (0.16 g) was recrystallized from diisopropyl ether to afford colorless crystals (0.10 g, 65%); mp 95—96°C, $[\alpha]_D^{25}$ +91° (*c* 1.7, $CHCl_3$). The mp admixed with an authentic sample showed no depression. The IR spectrum (KBr) of II could be superimposed upon that of the authentic sample.

Methyl 2,4,6-Tri-O-benzyl-3-(2,4-dinitroanilino)-3-deoxy-α-D-allopyranoside (V). *Via the Replacement Reaction in DMSO*: A suspension of I (1.0 g) and sodium azide (4.0 g) in DMSO (10 ml) was vigorously stirred on an oil bath (150°C) under reflux for 15 hr. Another portion (1.0 g) of the azide was then added to the mixture, which was further stirred for 5 hr at the same temperature. The mixture was then diluted with benzene, and the insoluble matters were filtered off. The filtrates were concentrated and then evaporated under reduced pressure (3 mmHg) at 70°C to give a dark brown residue, which was chromatographed over the silica gel, developed with the A solvent system (40: 1). After the elution of some by-products as well as the unchanged starting material, the main product appeared; it gave a homogeneous syrup (0.54 g, 68%) of methyl 3-azido-2,4,6-tri-*O*-benzyl-3-deoxy-α-D-allopyranoside (III); ν_{max}^{film} 2155 cm^{-1}. The oily azide (III) (0.58 g) was immediately refluxed with lithium aluminum hydride (0.08 g) in dioxane (10 ml) for 2 hr.[15] After the decomposition of the excess hydride with water the mixture was extracted with benzene to afford a ninhydrin-positive syrup (0.50 g, 91%) of methyl 3-amino-3-deoxy-2,4,6-tri-*O*-benzyl-α-D-allopyranoside (IV). The traces of the by-products were removed by means of column chromatography over silica gel using B solvent system (1: 1). A mixture of the amine (IV) (0.28 g), 2,4-dinitrofluorobenzene (0.10 ml), and triethylamine (0.10 ml) in DMF (2 ml) was kept standing at room temperature overnight. The red solution was then evaporated at 55°C under reduced pressure to give a dark red residue, which was subsequently chromatographed over silica gel, elution being done with the A solvent system (20: 1). The yellow glass thus obtained was crystallized with diisopropyl ether to give yellow crystals (0.23 g, 60%; mp 120—122°C). Two recrystallizations from the same solvent gave an analytical sample; mp 122—123°C, $[\alpha]_D^{25}$ +124° (*c* 0.9, $CHCl_3$), ν_{max}^{KBr} (cm^{-1}): 1620, 1590, 1528, 1500, and 1333 (NHDNP), 1070 (ether).

Found: C, 64.64; H, 5.66; N, 6.63%. Calcd for $C_{34}H_{35}N_3O_9$: C, 64.85; H, 5.60; N, 6.67%.

Via the Replacement Reaction in HMPA: A suspension of I (1.0 g) and sodium azide (4.0 g) in HMPA (10 ml) was stirred at 145°C for 15 hr. Another portion (1.0 g) of the azide was then added to the mixture, after which it was further stirred at 155°C for 5 hr. The mixture was treated in the manner described in Method A to give an oil (0.58 g, 73%) of III, which was then treated with lithium aluminum hydride (0.13 g) in dioxane (13 ml) to give the amine (IV) (0.49 g, 89%).

The amine (IV) (73 mg) was treated with 2,4-dinitrofluorobenzene (50 mg) and triethylamine (33 mg) in DMF (0.7 ml) to give yellow crystals (55 mg, 55%). The mp of this compound was not depressed by admixture with V.

Via Ammonolysis: I (0.30 g) and a solution of ammonia (12 g, saturated at 0°C) in methanol (30 g) was charged in an autoclave, and then the mixture was heated at 155°C

22) O. T. Schmidt, T. Auer, and H. Schmadel, *Chem. Ber.*, **93**, 556 (1960).

for 30 hr with stirring. The resulting mixture was concentrated, diluted with methanol, and then passed through a column of Amberite IRA-400 (OH type, stored in methanol). The ninhydrin-positive fractions gave an oil (0.15 g, 67%) of IV. The amine (IV) (0.13 g) was treated with 2,4-dinitrofluorobenzene (0.05 ml) and triethylamine (0.05 ml) in DMF. The yellow crystals thus obtained (0.12 g, 68%) were recrystallized from diisopropyl ether to give a pure sample. The mp of this compound was not depressed by admixture with V.

Methyl 2-Acetamido-2,4,6-tri-O-acetyl-3-deoxy-α-D-allopyranoside[7] *(VI).* *From V*: A mixture of V (130 mg) and Dowex 1×2 (OH type, 4 ml) in acetone (40 ml) was stirred at 55°C for 50 hr under reflux, with the occasional addition of water (up to 5 ml). The subsequent evaporation of the solvent afforded a syrup which was diluted with methanol (3 ml) and then treated with acetic anhydride (3 ml). The crude syrup was chromatographed over silica gel and developed with the A solvent system (5: 1) to give a homogeneous syrup which was subsequently hydrogenolyzed in methanol in the presence of palladium-on-carbon (5%, 50 mg) under atmospheric pressure. The hydrogenolyzed product was heated with acetic anhydride (1 ml) in the presence of sodium acetate (0.1 g) to give a crude acetate (mp130—131°C). Recrystallization from diisopropyl ether gave a pure sample (37 mg, 50%); mp 134—135°C $[\alpha]_D^{25}$ +90° (*c* 2.3, $CHCl_3$). The mp of this compound admixed with the authentic specimen showed no depression. The IR and PMR spectra of the two compounds were superimposable.

Via the Catalytic Hydrogenolysis of IV: A sample (100 mg) of oily IV was hydrogenolyzed over palladium-on-carbon (5%, 20 mg) in methanol (6 ml) containing 0.02 ml of concd hydrochloric acid at room temperature under atmospheric pressure. A colorless glass (52 mg) thus obtained was subsequently heated with acetic anhydride (4 ml) in the presence of sodium acetate (0.4 g). A crude acetate (74 mg, 95%) thus obtained was crystallized with diisopropyl ether. The mp of this compound was not depressed by admixture with VI.

Via the N-Acetylation and Reduction of IV: A sample (200 mg) of oily IV was treated with acetic anhydride (1 ml) in methanol (4 ml) for 2 hr at 25°C to give a ninhydrin-negative syrup, which was dissolved in liquid ammonia (30 ml) and then treated with small pieces of sodium at −80°C until a blue color remained. The reduced mixture was acetylated by heating with acetic anhydride (8 ml) and sodium acetate (0.2 g). The crude acetate was chromatographed over silica gel with the A solvent system (1: 1) to give a pure acetate (94 mg; 60%). The mp admixed with VI showed no depression.

3-Azido-2,4,6-tri-O-benzyl-3-deoxy-α-D-allopyranose (VII). A mixture of oily III (0.23 g), acetic acid (4 ml), and dilute sulfuric acid (2N; 0.6 ml) was heated on a boiling-water bath for 2.5 hr. The mixture was then extracted with benzene to give a brown syrup (0.19 g), which was subsequently chromatographed over silica gel irrigated with the A solvent system (20: 1). After the recovery of a small quantity of the unreacted starting material, the main product was eluted. A homogenous colorless syrup was crystallized with *n*-hexane to give long needles (0.12 g; 54%), which were then recrystallized from the same solvent to afford an analytical sample; mp 108—109°C, $[\alpha]_D^{25}$ +26° (*c* 1.0, $CHCl_3$), $[\alpha]_D^{25}$ +30° (*c* 1.1, pyridine)→+25° (90 hr), $[\alpha]_D^{25}$ +29° (*c* 1.1, pyridine-phenol (8: 1, v/v])→+14° (20 hr). ν_{max}^{KBr} (cm^{-1}): 3410 (OH), 2123 (N_3), 1093 (ether), 820, 754, 733, and 692 (phenyl).

Found: C, 68.07; H, 5.97; N, 8.61%. Calcd for $C_{27}H_{29}N_3O_5$: C, 68.19; H, 6.15; N, 8.84%.

2,4,6-Tri-O-benzyl-3-carbobenzoxyamino-3-deoxy-α-D-allopyranose (VIII). To a mixture of III (0.21 g) in pyridine (4 ml), a solution (1.5 g) of carbobenzoxy chloride in toluene (30%) was added in three portions under cooling; after having been stirred for 18 hr at 25°C, the mixture was treated with a little water and extracted with benzene to gave an orange syrup which was subsequently chromatographed over silica gel irrigated with the A solvent system (20: 1). Homogeneous ninhydrin-negative oil (0.20 g, 74%) was immediately hydrolyzed by heating in a mixed acid prepared from acetic acid (6 ml) and dil. sulfuric acid (1N, 1 ml) at 90°C for 8 hr. The tlc of the hydrolyzate showed the presence of at least six products. A crude mixture which was chromatographed over silica gel was developed with the A solvent system (10: 1). After the elution of the unchanged material as well as other by-products, the aniline phthalate-positive main product (R_f 0.32; the A solvent system [5: 1]) was eluted to give a syrup which was subsequently crystallized with diisopropyl ether to afford a colorless solid (0.07 g, 28%). Recrystallization from the same solvent gave a pure sample; mp 152—153°C, $[\alpha]_D^{25}$ +34° (*c* 0.6, $CHCl_3$), $[\alpha]_D^{25}$ +61° (*c* 1.1, pyridine)→+51° (70 hr), $[\alpha]_D^{25}$ +61° (*c* 0.6, pyridine-phenol [8: 1])→+40° (180 min). ν_{max}^{KBr} (cm^{-1}): 3410 (OH), 3326, 1727, 1517 (NH–Cbz), 1052 (ether), 736, 733, and 690 (phenyl).

Found: C, 72.31; H, 7.24; N, 2.48%. Calcd for $C_{35}H_{37}NO_7$: C, 72.02; H, 6.39; N, 2.40%.

2,4,6-Tri-O-benzyl-3-deoxy-3-(2,4-dinitroanilino)-α-D-allopyranose (IX). A mixture of VI (0.30 g), acetic acid (6 ml), and dil sulfuric acid (2N, 1 ml) was heated at 90°C for 11 hr. The mixture was then treated in the manner described for VII to give an yellow syrup which was subsequently, chromatographed on silica gel with the irrigation of the A solvent system (5: 1). After the elution of the unchanged starting material, the hydrolyzed product (IX) (0.14 g, 48%) was obtained; recrystallization from diisopropyl ether furnished a pure sample, mp 164—165°, $[\alpha]_D^{25}$ +89° (*c* 1.1, $CHCl_3$), $[\alpha]_D^{25}$ +103° (*c* 0.4, pyridine–phenol [8: 1], 45 min)→+96° (7 hr), ν_{max}^{KBr} (cm^{-1}): 3290, 1621, 1592, 1505, 1334 (NH–DNP), 1075 (ether).

Found: C, 64.06; H, 5.43; N, 6.91%. Calcd for $C_{33}H_{33}N_3O_9$: C, 64.38; H, 5.40; N, 6.83%.

3-Acetamido-3-deoxy-2,4,6-tri-O-benzyl-D-allopyranose (X). The acetylation of the amine (IV) (0.21 g) with acetic anhydride (1 ml) in dry methanol (4 ml) at 25°C for 1 hr gave quantitatively a ninhydrin-negative syrupy *N*-acetate, to which was added acetic acid (6 ml) containing dil sulfuric acid (1N, 1 ml). After having been heated over a boiling-water bath for 2 hr, the reaction mixture was treated in the same manner as in the case of VII to give a crude syrup, which was then chromatographed over silica gel, with irrigation with the A solvent (5: 1). After the recovery of the unchanged *N*-acetate of IV (0.10 g), the product appeared to be a homogeneous hard syrup (0.06 g, 27%), $[\alpha]_D^{25}$ +19.3° (*c* 2.9, $CHCl_3$), ν_{max}^{film} (cm^{-1}): 1650, 1530 (NH–Ac), δ(ppm): 1.99 (3H, singlet; $\underline{CH_3}COO$).

Found: C, 69.96; H, 6.71; N, 2.83%. Calcd for $C_{29}H_{33}NO_6$: C, 70.86; H, 6.71; N, 2.85%.

3-Amino-3-deoxy-D-allose Hydrochloride[10] *(XI).* *From VII*: VII (60 mg) was hydrogenolyzed over palladium black (20 mg) in methanol (8 ml) containing a calculated amount of hydrochloric acid under the pressure (10 lb/in²) of hydrogen. The colorless glass thus obtained was taken up with a small volume of ethanol and then precipitated by the addition of excess diisopropyl ether to give an amorphous hygroscopic mass; (23 mg; 85%); mp 157—160° (decomp.), $[\alpha]_D^{25}$ +25° (*c* 0.7, water). R_{f3AG}[23]=1.08±0.01 (*n*-butanol: pyridine:

23) 3AG=3-amino-3-deoxy-D-glucose hydrochloride.

water: acetic acid=6: 4: 3: 1), Toyo filter paper No. 50; developed at 20°C for 50 hr in the descending manner and sprayed with ninhydrin in pyridine (0.3%) and aniline hydrogen phthalate in aqueous *n*-butanol (2.5%). The authentic sample[10] had the same value of R_{f3AG}.

From VIII: A small sample was hydrogenolyzed in the manner just described. The paper chromatogram of the hydrogenolyzed solution showed the existence of a single product, detectable by spraying with ninhydrin as well as aniline hydrogenphthalate, which had the same R_{f3AG} value as authentic 3-amino-3-deoxy-D-allose hydrochloride.[10]

3-Acetamido-3-deoxy-1,2: 5,6-di-O-isopropylidene-α-D-allofuranose[3] *(XII)*. A mixture of 3-*O*-*p*-toluenesulfonyl-1,2: 5,6-di-*O*-isopropylidene-α-D-glucofuranose (Ia)[19] (1.0 g) and sodium azide (4.0 g) in HMPA (10 ml) was vigorously stirred at 130°C for 24 hr. The crude mixture was then chromatographed over silica gel using the A solvent system (20: 1) gave a pure oil (0.49 g, 71%), which was subsequently reduced by the treatment with lithium aluminum hydride (0.1 g) in hot dioxane (10 ml). The amine (0.38 g, 85%) thus obtained was acetylated with acetic anhydride (0.15 ml) in methanol (4 ml) at 25°C for 2 hr to furnish Compound XII (0.38 g, 86%); mp 132—134°C, $[\alpha]_D^{25}$ +67° (*c* 1.3, $CHCl_3$). The mp admixed with the authentic sample showed no depression. The IR and PMR spectra of XI were identical with those of an authentic specimen.

Synthetic Photochemistry. I. The Cycloaddition Reaction of Methyl Acetopyruvate with Olefins

Hitoshi TAKESHITA* and Shimaho TANNO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

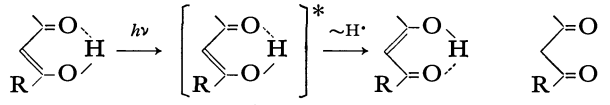
(Received June 15, 1972)

The photochemical cycloaddition reaction of methyl acetopyruvate, an unsymmetrical β-diketone, with olefins afforded the single 1: 1 molar adducts in good yields. A ready method of the cyclization of the adducts to the β-methoxycarbonyl-$\Delta^{\alpha,\beta}$-cyclohexenones has preparative values.

Unsaturated carbonyl compounds with various types of structural modifications have been reported to undergo a cycloaddition reaction with olefins upon ultraviolet light irradiation, and the mechanistic features of this method have been intensively investigated.[1,2] The cycloaddition reaction of acetylacetone (I), a typical enolizable β-diketone, has also been shown to yield aldolic adducts which dealdolyze spontaneously to heptane-2,6-diones.[3,4]

The absence of intermolecular hydrogen abstraction from the olefins or solvents, a distinctive feature of this particular instance, was in sharp contrast with the phenomenon observed in ordinary carbonyl irradiations, and could be interpreted as the intervention of intramolecular γ-hydrogen abstraction. Since I is a symmetrical molecule, one could not distinguish the difference between Ia and Ib; it is thus not possible to ascertain the reactivity of Ib, a species derived after the hydrogen shift, for the photochemical reaction.

In addition, since the photochemical adducts were convertible to cyclohexenone derivatives under very mild conditions, it has been considered that these would be useful as building blocks for the construction of certain types of alicyclic systems. The presence of two orientations of cyclization, however, could reduce the usefulness of the photoadducts.



I: R=Me II: R=COOMe

Chart 1

We have carried out a study of the photochemical cycloaddition reaction of methyl acetopyruvate (II) with various types of olefins in connection with the above points and have obtained some new findings, which will be described herein.

Results and Discussion

The irradiation of an ethereal solution of II in cyclohexene with high-pressure mercury lamp through a Pyrex glass filter smoothly afforded a single photoadduct (III) in a nearly quantitative yield.[5] The presence of an acetyl group as well as a methoxycarbonyl group in III was evident from the NMR[δ 2.03 (3H, s) and 3.82 (3H, s)] and IR[$\nu_{C=O}$ 1730—1710

* Present address: Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka 812.

2) P. de Mayo, *ibid.*, **4**, 41 (1971).

3) P. de Mayo and H. Takeshita, *Can. J. Chem.*, **40**, 440 (1963).

4) Since our early investigation was made, several reports on the photochemical cycloaddition of enolizable β-diketones appeared. Ref. 4a has shown the reaction occurred *via* n–π^* triplet of I by quenching experiment. 4a) H. Nozaki, M. Kurita, T. Mori, and R. Noyori, *Tetrahedron*, **24**, 1821 (1968). 4b) G. Büchi, J. A, Carlson, J. F. Powell, Jr., and L. F. Tietze, *J. Amer. Chem. Soc.*, **92** 2165 (1970).

5) In this case, the formation of 3,3-bi(cyclohexenyl), due to the intermolecular hydrogen abstraction by an n–π^* triplet, was not recognized (gas-liquid chromatogram).

cm^{-1} (strong)] spectra. The former also indicated the composition of II to be that of a 1:1 adduct. The cyclization of III in the presence of catalytic amounts of *p*-toluenesulfonic acid yielded IV, which was shown to be an epimeric mixture of β-methoxycarbonyl-$\Delta^{\alpha,\beta}$-cyclohexenone derivatives by the IR [$\nu_{C=O}$ 1730 and 1667 cm^{-1}, and δ_{CH_2} 1413 cm^{-1}] and NMR[δ 3.76 (s) and 3.78 (s), the total of both the signals integrated for 3H, 6.53 (br. s) and 6.28 (d, J=2.1 Hz), the total of the two signals integrated for 1H] spectra, although a silica-gel, thin-layer chromatogram showed only one spot. These observations permitted us to suggest the structure IVa or IVb for the cyclization product; those structures are analogous to those for the adducts from the reaction with I. The selection of the correct structure from the above two was made on the basis of the following evidence, first, zinc, and acetic acid reduction of IV afforded a dihydro-derivative (V) which subsequently gave a mixture of deuterio-derivatives by the ordinary procedure and by subsequent reesterification. The occurrence of a pentadeuterio-derivative among the products, confirmed by mass-spectral analysis, requires that Va be at least one of the components of V, even when it consists of an undetectable mixture of isomers. Secondly, palladium dehydrogenation after the lithium aluminum hydride reduction of IV yielded α-methylnaphthalene as the sole aromatized compound, which was characterized as the picrate. Since it has been established that the mixture of α- and β-methylnaphthalenes can not be fractionated by this procedure,[6] the absence of β-methylnaphthalene clearly excludes the possibility of the structures of III, IV, and V being IIIb, IVb, and Vb respectively.

A similar reaction of II with cyclohexa-1,4-diene afforded the corresponding photoadduct (VI), which was then catalytically reduced to III. The acid cyclization of VI yielded the corresponding cyclohexenone (VII), parallel to the case of the conversion of III to IV. The spectral data of VI[δ 2.03 (s) and 2.06 (s), the total of these two integrated for 3H, 3.82 (3H, s) and 5.63 (2H, br.), $\nu_{C=O}$ 1735 cm^{-1} (strong)] and VII[δ 3.78 (s) and 3.79 (s), the total of these two signals also integrated for 1H, $\nu_{C=O}$ 1738 and 1675 cm^{-1}, and δ_{CH_2} 1412 cm^{-1}] also supported the respective structures as depicted.

As examples of the unsymmetrical olefins, vinyl acetate and isobutyl vinyl ether were taken for the reaction with II; they again afforded the single adducts, VIII and IX, in each case.[7] Their structures were clearly deduced from the spectral evidence. In particular, the appearance of the triplets at δ 5.63 (1H, J=7 Hz) in VIII and at δ 4.32 (1H, J=7 Hz) in IX excluded the alternative structures. This electronic selectivity in the reaction is remarkable, and it may have a potential usefulness in synthesis.

Now, obvious points of interest in the relation between the structures of the products and the major tautomer of II in the ground state have to be considered.[8]

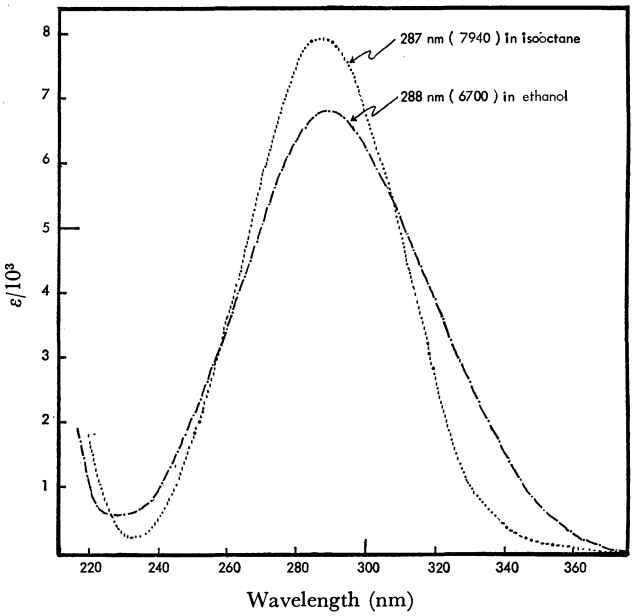

Fig. 1. UV absorption spectrum of II.

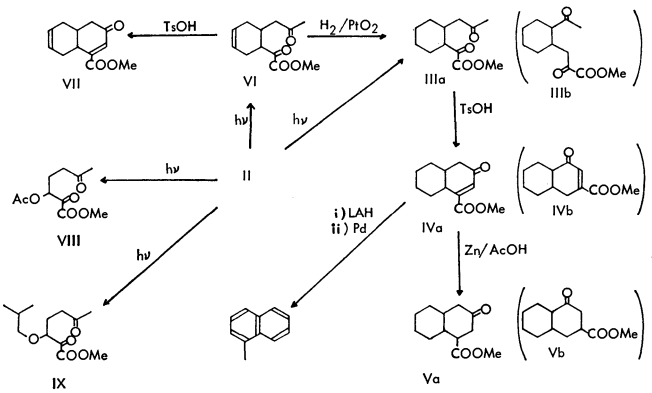

Chart 2.

The NMR spectrum of II [δ 2.22 (3H, s), 3.83 (3H, s), 6.27 (1H, s), and 13.5 (1H, br.)] in a carbon tetrachloride solution indicates that II is at least 95% enolized, showing no signal due to the diketonic tautomer (IIc). In addition to this, the UV spectrum of II (Fig. 1) in an isooctane solution showed an absorption maximum at 287 nm (ε=8000), suggesting that, even in a dilute solution, the enol form is substantial. Since the linearly conjugated tautomer (IIa) should be more stable than the other one (IIb),[9] it can be concluded that all of the above adducts were derived from the reaction of the major tautomer (IIa) in a straightforward manner, and that IIb, produced after a possible intramolecular hydrogen shift through photochemically-excited IIa, was being deactivated and was unreactive. The exclusive formation of VIII and IX from the oxygen-bearing olefins, a result in contrast with the reaction of I and isopropenyl acetate, might, with the reactants, be attributable to a hydrogen-bonding or

6) R. Meyer and H. Fricke, *Ber.*, **47**, 2770 (1914).

7) No indication for the intermolecular hydrogen abstraction. process was obtained in the reaction of II with cyclohexa-1,4-diene, vinyl acetate or isobutyl vinyl ether.

8) The reactive state of the reaction will be a subject of independent studies.

9) There would be no reason to reveal a marked difference in the contents of enolic tautomers between I and II, if II indeed exists as IIb.

a dipole-dipole interaction; II could form a more rigid complex than I leading to photoadducts with the observed orientation.

Finally, it may be mentioned that the yields of the products are quite high; even in the case of cyclohexa-1,4-diene, the 1:1 adduct VI was obtained in satisfactorily high yield. Since these adducts possess only one acetyl group, the cyclization naturally leads to a single product in each case. These two points make this procedure practical for certain alicyclic syntheses.

Experimental

The mps, determined with a Fisher-Jones apparatus, were uncorrected. The UV spectra were measured in a methanol solution unless otherwise stated. The IR spectra were obtained for either KBr disks or a carbon tetrachloride solution. The NMR spectra were determined at 60 MHz for a solution in carbon tetrachloride, with tetramethylsilane as the internal standard, and the chemical shifts were expressed in δ values.

The Reaction of Methyl Acetopyruvate (II) and Cyclohexene; The Formation of Methyl 2-Acetonylcyclohexylglyoxalate (III). II (5.76 g) was dissolved in a mixture of cyclohexene (40 ml) and ether (120 ml) and irradiated by a 450 W high-pressure mercury lamp through a Pyrex glass filter in a nitrogen atmosphere; the reaction was monitored by submitting an aliquot to a color reaction with a ferric chloride solution. After the completion of the reaction, the mixture was evaporated *in vacuo*; the residual oil was purified by distillation to yield a colorless liquid; bp 128°C/2 mmHg; 8.58 g (95%).

Found: C, 63.55; H, 8.21%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%. λ_{max} 232 nm (8700).

The Bis-Semicarbazone of III. Colorless needles; mp 240—242°C (from ethanol).

Found: C, 49.22; H, 6.95; N, 24.23%. Calcd for $C_{14}H_{24}O_4N_6$: C, 49.40; H, 7.11; N, 24.69%.

The Dehydration of III; The Formation of 4-Methoxycarbonyl-Δ^3-octalone-2 (IV). III (800 mg) was heated with *p*-toluenesulfonic acid (10 mg) in a benzene solution for 5 hr; then, the reaction mixture was passed through an alumina column and evaporated. The distillation of the residue on a cold finger yielded a colorless liquid; bp 105°C/0.2 mmHg (bath temp.); 750 mg (86%). This was homogeneous in gas-liquid chromatograms.

Found: C, 68.89; H, 7.58%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

The 2,4-Dinitrophenylhydrazone of IV. Yellow-orange needles; mp 176—177°C (from ethanol).

Found: C, 55.11; H, 6.30; N, 14.09%. Calcd for $C_{18}H_{24}O_6N_4$: C, 55.09; H, 6.17; N, 14.28%. λ_{max} 385 nm (18800).

The Reduction of IV by Zinc and Acetic Acid; The Formation of 4-Methoxycarbonyldecalone-2 (V). IV (200 mg) was reduced by an excess amount of zinc in acetic acid to give a colorless liquid; 140 mg; bp 125°C/0.2 mmHg (bath temp.).

Found: C, 68.41; H, 8.55%. Calcd for $C_{12}H_{18}O_3$: C, 68.54; H, 8.63%.

The 2,4-Dinitrophenylhydrazone of V. Yellow needles; mp 121—123°C (from ethanol).

Found: 55.49; H, 5.77; N, 14.11%. Calcd for $C_{18}H_{22}O_6N_4$: C, 55.38; H, 5.68; N, 14.35%. λ_{max} 363 nm (18100).

The Deuterium Oxide Treatment of V. V (60 mg) was converted to a mixture of deuterio-derivatives by the use of deuterium oxide (0.2 ml) in dioxane (1.2 ml) containing a trace amount of sodium deuteroxide. After the reesterification of the product by diazomethane, a colorless liquid (43 mg) was obtained by cold-finger distillation.

Mass spectrum: M^+/e; 210 (7.7), 211 (13.2), 212 (24.0), 213 (31.2), 214 (19.7), and 215 (4.2%).

The Dehydrogenation of the Lithium Aluminum Hydride Reduction Product of IV. IV (200 mg) was reduced by the use of lithium aluminum hydride (50 mg) in ether. After the usual work-up, the product was placed in a dehydrogenation tube containing 5% palladium carbon (500 mg) and heated at 220°C for 16 hr in a nitrogen atmosphere. Then, the mixture was extracted by ethanol and filtered. A saturated solution of picric acid was poured into the extract to precipitate naphthalenes. The yellow crystals (45 mg) thus obtained were purified by recrystallization from ethanol to give fine yellow needles; mp 141—142°C, which was undepressed on admixture with authentic α-methylnaphthalene picrate. Every fraction of the recrystallizations showed the absence of β-methylnaphthalene on NMR-spectral analysis.

The Photochemical Reaction of II with Cyclohexa-1,4-diene; The Formation of Methyl 2-Acetonylcyclohex-4-enylglyoxalate (VI). II (2.88 g) was dissolved in a mixture of cyclohexa-1,4-diene (50 ml) and ether (70 ml) and irradiated similarly as in the case of cyclohexene. The product was then purified by distillation to yield a colorless liquid (bp 132°C/0.2 mmHg (bath temp.)), whose homogeneity was proved by gas-liquid chromatograms; 4.08 g (91%).

Found: C, 64.55; H, 7.38%. Calcd for $C_{12}H_{16}O_4$: C, 64.26; H, 7.19%.

The Bis-Semicarbazone of VI. Colorless needles; mp 235—237°C (from methanol).

Found: C, 49.81; H, 6.43; N, 24.60%. Calcd for $C_{14}H_{22}O_4N_6$: C, 49.69; H, 6.55; N, 24.84%.

The Catalytic Reduction of VI. a): VI (25 mg) was hydrogenated in an ethyl acetate solution containing 10% palladium carbon (50 mg). After the reaction had ceased, the product was isolated by the filtration of the catalyst and by distillation with a cold finger to give a colorless liquid (15 mg), which was a 50:50 mixture of III and IV, as confirmed by NMR-spectral and gas-liquid-chromatographic analyses.

b): VI (55 mg) was reduced in acetic acid with platinum oxide. The product isolated after the usual work-up afforded a colorless liquid (45 mg) which was found to be homogeneous by gas-liquid-chromatographic determination and which was identified as IV.

The 2,4-Dinitrophenylhydrazone of the Reduction Product of VI. A part of the above sample was converted to 2,4-dinitrophenylhydrazone, which was identified with that of IV by a direct comparison.

The Acid Catalyzed Cyclization of VI; The Formation of 4-Methoxycarbonyl-$\Delta^{3,6}$-hexalone (VII). VI (200 mg) was heated with *p*-toluenesulfonic acid (5 mg) in benzene for 3 hr, and the product purified by cold-finger distillation was a colorless liquid (165 mg) which was gas-liquid chromatographically homogeneous.

Found: C, 70.21; H, 6.55%. Calcd for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84%. λ_{max} 231 nm (7300).

The 2,4-Dinitrophenylhydrazone of VII. Yellow-orange needles; mp 176—177°C (from ethanol).

Found: C, 55.67; H, 4.37; N, 14.82%. Calcd for $C_{18}H_{18}O_6N_4$: C, 55.95; H, 4.70; N, 14.50%. λ_{max} 387 nm (19400).

The Photochemical Reaction of II with Vinyl Acetate; The Formation of Methyl 3-Acetoxy-2,6-dioxoheptanoate (VIII). II (77 mg) was sealed in a Pyrex glass tube with vinyl acetate (7 ml) and placed for an external irradiation. After 3 hr, the mixture was evaporated and the residue was distilled on a cold finger to yield a colorless liquid; 95 mg (82%). This was homogeneous in thin-layer chromatograms and in NMR spectroscopic analysis.

Found: C, 52.22; H, 6.27%. Calcd for $C_{10}H_{14}O_6$: C, 52.17; H, 6.13%.

The Photochemical Reaction of II with Isobutyl Vinyl Ether; *The Formation of Methyl 2,6-Dioxo-3-isobutoxyheptanoate (IX).* II (77 mg) was dissolved in a mixture of isobutyl vinyl ether (2 ml) and ethyl acetate (5 ml) and was externally irradiated in a sealed Pyrex tubing. A colorless liquid; 103 mg (84%), obtained after a cold-finger distillation, was homogeneous in thin-layer chromatograms and in NMR spectral analysis.

Found: C, 58.81; H, 8.33%. Calcd for $C_{12}H_{20}O_5$: C, 59.00; H, 8.25%.

We thank Professor S. Itô for a stimulating discussion, Mrs. H. Arai and Miss M. Suzuki for elemental analyses, and Messrs. K. Sasaki and T. Kondo for NMR measurements. H. T. is also grateful to The Matsunaga Science Foundation for a research grant by which a part of the expense has been defrayed.

The Dimerization of Acrylonitrile to 2-Methyleneglutaronitrile with Metal Halide and Trialkylamine

Yoshihisa WATANABE and Makoto TAKEDA

Central Research Laboratory, Mitsubishi Petrochemical Company Ltd., Ami-machi, Ibaraki

(Received June 19, 1972)

Acrylonitrile is dimerized to 2-methyleneglutaronitrile by the binary catalyst system of metal halide and trialkylamine. The catalytic activities of metals are in this order: Co(II)≥Zn(II)≫Fe(II)>Al(III)≫V(III)> Cd(II)>Ti(IV), while that of halogens is I>Br>Cl. Triethylamine is particularly effective for the reaction. The kinetic features are discussed, and a reaction mechanism for the catalyst system of zinc chloride and triethylamine is proposed.

The catalytic dimerization of acrylonitrile has been extensively investigated. When phosphines are used as the catalysts, 2-methyleneglutaronitrile is selectively obtained; a reaction mechanism has been proposed by Baizer *et al.*[1] It is generally acecpted that Lewis bases can catalyze the reaction; many catalysts such as trialkylstibine, trialkylarsine,[2] triethylenediamine,[3] and phosphine-coordinated metal carbonyls[4] have been reported. Saegusa has also reported metal-isocyanide complexes as a new type of catalyst.[5] These catalysts are, however, effective only in the presence of protic solvents.

We have found that acrylonitrile is readily dimerized to 2-methyleneglutaronitrile under mild conditions by the binary catalysts; metal halide and tertiary amine.[6] With these catalyst systems, a protic solvent is not necessary. On the contrary, its presence hinders the reaction. In the present work, various metal halides and amines have been examined; the kinetic features will be discussed in detail.

Results and Discussion

Catalytic Activity of Metal Halide and Amines. The dimerization reaction of acrylonitrile was investigated using various metal halides and amines. The results are shown in Table 1.

Acrylonitrile was catalytically converted to methyleneglutaronitrile; only a small amount of the trimeric product was formed as a by-product. Gas-chromatographic analysis showed that no other acrylonitrile oligomers were formed. The reaction products were isolated by fractional distillation. Two fractions, with bp's of 97°C/3 mmHg and 202°C/4 mmHg, were identified as 2-methyleneglutaronitrile and 2,4,6-tricyanohexene-1 respectively by the molecular weight measurement, infrared and NMR spectroscopy.

Table 1 shows that the order of the catalytic activity is Co(II)≥Zn(II)≫Fe(II)>Al(III)≫V(III)>Cd(II) >Ti(IV) for metals and I>Br>Cl for halogens. In our investigation, only metal halides could catalyze the reaction; all the other metal compounds, such as acetates, stearates, oxides, carbonates, sulfates and acetylacetonates of zinc, cobalt and iron, did not catalyze the dimerization reaction.

Primary and secondary amines showed no catalytic activity when coupled with various metal halides, but an addition reaction to the double bond of acrylonitrile occurred. Polyamines such as triethylenediamine and hexamethylenetetramine were also found to be undesirable since the chelation to the metal halide proceeded and inhibited the dimerization reaction. From these results, it is quite probable that only tertiary amines can be used as catalyst components. Especially it was found that only three amines, triethylamine, tri-*n*-propylamine, and tri-*n*-butylamine, were effective. Triphenylamine, tribenzylamine, and tricyclohexylamine, when coupled with zinc chloride or cobaltous chloride, did not show any catalytic activity. Also, *N*,*N*-diethylaniline and diethylcyclohexylamine, which are quite

analogous to triethylamine, did not catalyze the dimerization reaction. Many amines form complexes with halides of cobalt or zinc, and it has been reported[7,8] that acrylonitrile also forms complexes with halides of cobalt or zinc. It is probable that zinc halide forms a complex with triethylamine and acrylonitrile and that this complex catalyzes the dimerization reaction.

Catalytic Dimerization of Other Olefinic Compounds by Zinc Chloride and Triethylamine. Many olefinic compounds, such as methacrylonitrile, crotononitrile, various acrylates, styrene, butadiene, and vinyl chloride, were examined, but no dimer was obtained except for acrylates. The rates of the dimerization of acrylates were smaller than that of acrylonitrile. The co-dimerizations of acrylonitrile and various acrylates were also attempted. These results are shown in Table 2.

In all the co-dimerization experiments, the dimer of acrylate was not detected and the dimerization of acrylonitrile was fairly much inhibited. This suggests that acrylates are more strongly coordinated to zinc chloride than to acrylonitrile.

Effect of Acrylonitrile Concentration. The relation of the 2-methyleneglutaronitrile obtained and the reaction time at various acrylonitrile concentrations is shown in Fig. 1.

The rate of 2-methyleneglutaronitrile formation was calculated from the initial gradient of the curves in Fig. 1. The result is plotted against the concentration of acrylonitrile in Fig. 2. A straight line with an inclination of +2 as observed in Fig. 2 suggests a second-order reaction with the acrylonitrile concen-

Temperature: 20°C, $ZnCl_2$: 0.18 mol/l, Triethylamine: 2.40 mol/l, Acrylonitrile concentration: (1) 2.02 mol/l, (2) 4.05 mol/l, (3) 6.07 mol/l, (4) 8.09 mol/l.

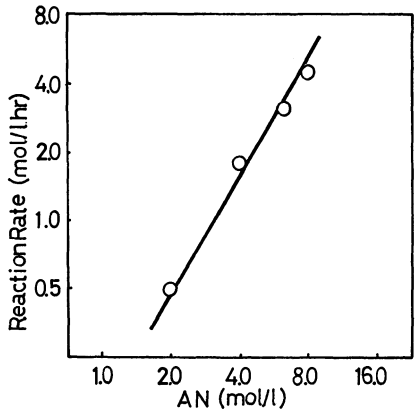

Fig. 2. Dependence of dimerization rate on concentration of acrylonitrile.
Temperature: 20°C, $ZnCl_2$: 0.18 mol/l, triethylamine: 2.40 mol/l.

tration.

The Reaction Paths of the Acrylonitrile Trimer. As is shown in Fig. 3, the trimeric product was found even in the very eary stages and exhibited a pattern of increase similar to that of the dimeric product. If the trimer is formed only from the dimer and the monomer by the consecutive reaction mechanism, its amount will be very small at first, but will show a rapid increase as the dimer increases. Such a pattern was not observed, however, even after more than half of the acrylonitrile was converted to the dimeric product. Therefore, two parallel paths for the trimeric product were postulated: one, a successive reaction of the dimer with the monomer, and the other, a simultaneous reaction from three molecules of acrylonitrile.

In order to confirm the assumption, the simulation of the rate process of the reaction was attempted by means of an analog computer (Melcom Model EA-716). The results of the simulation agree satisfactorily with the experimental results. An example is shown in Fig. 3; the results of the simulation are shown by solid lines, while the experimental values are illustrated symbols.

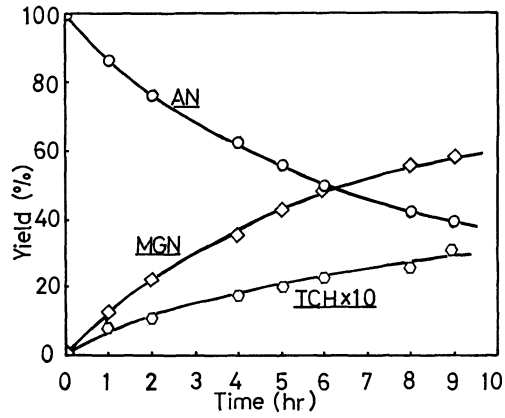

Fig. 3. Comparison of experimental yields with computer simulation. Solid lines are results of simulation (k_1: 0.180, k_2: 0.004, k_3: 0.009) and symbols are experimental values: ○ unreacted acrylonitrile, ◇ yield of methyleneglutaronitrile, ⟨⟩ yield of 2,4,6-tricyanohexene-1. Temperature: 20°C, acrylonitrile: 13.1 mol/l, $ZnCl_2$: 0.18 mol/l, triethylamine: 0.98 mol/l.

We may conclude that the reaction of acrylonitrile catalyzed by zinc chloride and triethylamine is composed of the following reactions:

$$2CH_2{=}CH{-}CN \xrightarrow{k_1} CH_2{=}C(CH_2{-}CH_2{-}CN){-}CN \quad (1)$$

$$CH_2{=}CH{-}CN + NC{-}\overset{CH_2}{\overset{\|}{C}}{-}CH_2{-}CH_2{-}CN \xrightarrow{k_2} CH_2{=}C(CH_2{-}CH(CH_2{-}CH_2{-}CN){-}CN){-}CN \quad (2)$$

$$3CH_2{=}CH{-}CN \xrightarrow{k_3} CH_2{=}C(CH_2{-}CH(CH_2{-}CH_2{-}CN){-}CN){-}CN \quad (3)$$

The rate expression of the above reaction is as follows. The concentration of the dimer and the trimer are reduced to those of the acrylonitrile consumed:

$$-d[A_1]/dt = k_1[A_1]^2 + k_2[A_1][A_2] + k_3[A_1]^3$$
$$d[A_2]/dt = k_1[A_1]^2 - k_2[A_1][A_2]$$
$$d[A_3]/dt = k_1[A_1][A_2] + k_3[A_1]^3$$

A_1=acrylonitrile unreacted, A_2=acrylonitrile converted to 2-methyleneglutaronitrile, A_3=acrylonitrile converted to 2,4,6-tricyanohexene-1.

Temparature Dependence on the Reaction Rate. The rate constants calculated by means of the analog computer will be used hereafter.

Figure 4 shows, the k_1, k_2, and k_3 logarithms *vs.* $1/T$. The apparent activation energies, as calculated from Fig. 4, are 3.4, 2.8, and 2.3 kcal/mol for Reactions (1), (2), and (3) respectively.

These unusually small activation energy values suggest the existence of an exothermal partial equilibrium prior to the rate-determining step. Therefore, it is assumed that the apparent activation energies can be observed as the differences in the real activation energies and the reaction heats of the equilibrium reaction.

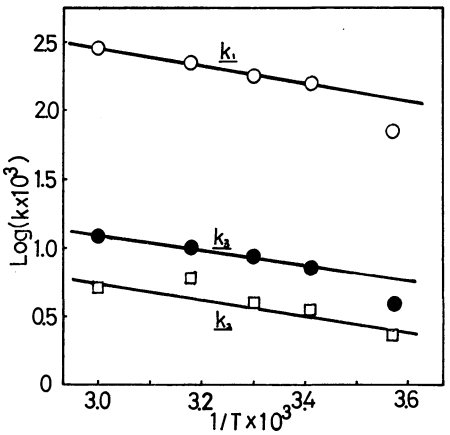

Fig. 4. Dependence of reaction rate on reaction temperature.
Acrylonitrile: 13.1 mol/l, $ZnCl_2$: 0.18 mol/l, triethylamine: 0.98 mol/l.

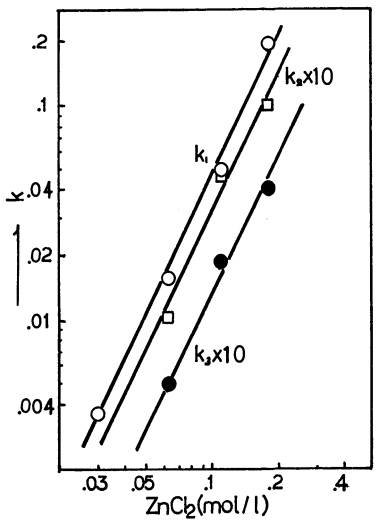

Fig. 5. Reaction rate as a function of $ZnCl_2$ concentration.
Temperature: 20°C, Acrylonitrile: 10.1 mol/l, Triethylamine: 2.40 mol/l.

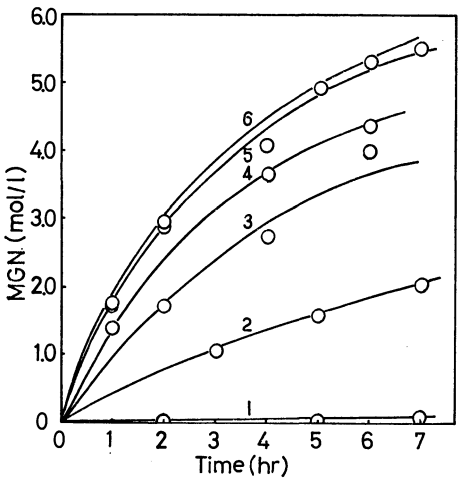

Fig. 6. The relation between amount of 2-methyleneglutaronitrile and reaction time at various triethylamine concentration.
Temperature: 20°C, Acrylonitrile: 10.1 mol/l, $ZnCl_2$: 0.18 mol/l, Triethylamine: (1) 0.19 mol/l, (2) 0.48 mol/l, (3) 0.96 mol/l, (4) 1.46 mol/l, (5) 1.94 mol/l, (6) 2.40 mol/l.

Effect of the Catalyst Concentration. The dependence of the zinc chloride concentration on the rate constants, k_1, k_2, and k_3, is shown in Fig. 5. The straight lines with the gradient of +2 for all the k's suggest that the reaction is of the second order with relation to the concentration of zinc chloride. This suggests that the zinc chloride complex exists in the dimeric form.

The relations of the 2-methyleneglutaronitrile and the reaction time obtained at various triethylamine concentrations are shown in Fig. 6. As is evident from Fig. 6, the catalytic activity is very small when the molar ratio of zinc chloride to triethylamine is less than unity, while it is almost constant when the ratio is over ten.

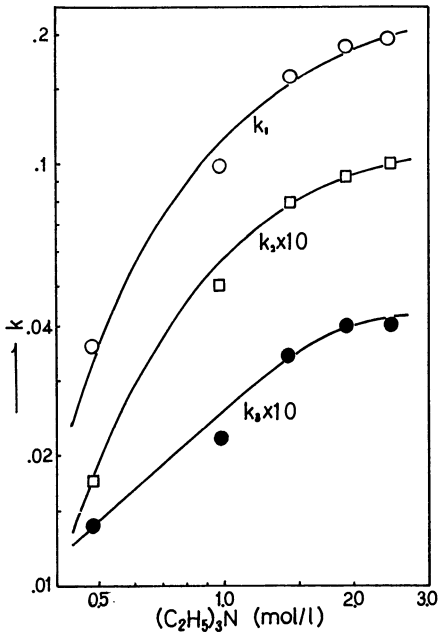

Fig. 7. Plots of reaction rates *vs.* concentration of triethylamine.
Temperature: 20°C, Acrylonitrile: 10.1 mol/l, $ZnCl_2$: 0.18 mol/l.

The logarithms of k_1, k_2, and k_3 are plotted against the logarithm of the triethylamine concentration in Fig. 7. The maximum gradient of each line was calculated as follows: about +2 for k_1 and k_2, and about +1 for k_3. In other words, the concentration of triethylamine influences Reactions (1) and (2) in the second order and Reaction (3) in the first order.

Reaction Mechanism. Summing the experimental results, we get: (1) zinc chloride, triethylamine, and acrylonitrile form a complex, and this complex catalyzes the reaction; (2) the trimer is formed through two different paths; (3) an exothermal partial equilibrium exists prior to the rate-determining step, and (4) the kinetic order of each catalyst component was determined and the product distribution in the co-dimers of acrylonitrile and acrylates was investigated.

The following reaction scheme is proposed on the basis of the experimental results:

i) Formation of methyleneglutaronitrile:

$$2ZnCl_2 + 2Et_3N + AN \rightleftarrows [Zn_2Cl_4(Et_3N)_2(AN)] \quad (4)$$

$$[Zn_2Cl_4(Et_3N)_2(AN)] + AN \xrightarrow{\text{-A-}} [Zn_2Cl_4(Et_3N)_2(MGN)] \quad (5)$$

$$[Zn_2Cl_4(Et_3N)_2(MGN)] + AN \xrightarrow{\text{fast}} [Zn_2Cl_4(Et_3N)_2(AN)] + MGN \quad (6)$$

ii) Formation of 2,4,6-tricyanohexene-1:

a) Successive reaction from methyleneglutaronitrile:

$$2ZnCl_2 + 2Et_3N + AN \rightleftarrows [Zn_2Cl_4(Et_3N)_2(AN)]$$

$$[Zn_2Cl_4(Et_3N)_2(AN)] + MGN \xrightarrow{\text{-A-}} [Zn_2Cl_4(Et_3N)_2(TCH)] \quad (7)$$

$$[Zn_2Cl_4(Et_3N)_2(TCH)] + AN \xrightarrow{\text{fast}} [Zn_2Cl_4(Et_3N)_2(AN)] + TCH \quad (8)$$

b) Direct formation from acrylonitrile:

$$2ZnCl_2 + Et_3N + 2AN \rightleftarrows [Zn_2Cl_4(Et_3N)(AN)_2] \quad (9)$$

$$[Zn_2Cl_4(Et_3N)(AN)_2] \xrightarrow{\text{fast}} [Zn_2Cl_4(Et_3N)(MGN)] \quad (10)$$

$$[Zn_2Cl_4(Et_3N)(MGN)] + AN \xrightarrow{\text{-A-}} [Zn_2Cl_4(Et_3N)(TCH)] \quad (11)$$

$$[Zn_2Cl_4(Et_3N)(TCH)] + 2AN \xrightarrow{\text{fast}} [Zn_2Cl_4(Et_3N)(AN)_2] + TCH \quad (12)$$

or

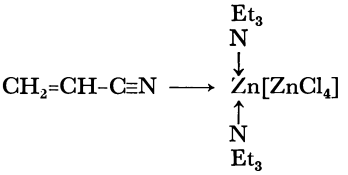
$$[Zn_2Cl_4(Et_3N)(TCH)] + AN + Et_3N \xrightarrow{\text{fast}} [Zn_2Cl_4(Et_3N)_2(AN)] + TCH \quad (13)$$

AN: acrylonitrile, MGN: 2-methyleneglutaronitrile, TCH: 2,4,6-tricyanohexene-1, Et_3N: triethylamine.

The above mechanism requires that zinc chloride be in the dimeric form and that the molar ratios of chlorine, acrylonitrile and triethylamine to zinc in the catalytic complex (Scheme 4) be 2, 1, and 1/2 respectively. We have tried to separate the catalytic complex and have succeeded in obtaining an orange precipitate by adding a small amount of toluene to the reactive solution.

The precipitate was examined by elemental analysis and by IR and NMR spectroscopy, and was shown to contain zinc, chlorine, acrylonitrile, triethylamine, and toluene as components. However, the integral stoichiometry was not determined (except that the ratio of chlorine to zinc is 2), since the complex was rather unstable in the air.

The dimeric form of zinc chloride may be supported by the fact that cadmium chloride forms an autocomplex like $Cd[CdCl_4]$, though the same structure has not been established for zinc chloride. Thus, according to the above mechanism, the structure of the catalytic complex may be postulated to be as follows:



However, the real stoichiometry and the autocomplex structure were not proved in our experiments; these problems are left to further investigations.

Experimental

Materials and Reagents. As the reaction was strikingly hindered by the presence of water, it was carefully removed from all the reagents. The acrylonitrile and amines were dried over molecular sieves (4A) and distilled under nitrogen. The water content of the acrylonitrile after the purification was less than 10 ppm, while that of triethylamine was less than 20 ppm.

All the commercially-obtained metal halides except titanium tetrachloride were dried by heating them under nitrogen or gaseous hydrogen chloride.

The Reaction of Acrylonitrile. The following procedure was carried out under a nitrogen atmosphere.

About 3.6 g of zinc chloride were dissolved in 100 ml of acrylonitrile in a 200 ml three-necked flask provided with a stirrer, and then 16 ml of triethylamine were added. The flask was set in a water bath, and the temperature was controlled by means of a "Coolnics circulator" (Yamato Kagaku Co. Ltd.). The mixture was kept at the prescribed temperature for a certain number of hours. During the reaction, if desired, a portion of the reaction mixture was sampled by operating a micro syringe through the serum cap and was analyzed by gas chromatography.

The Synthesis and Absolute Configuration of Optically Active Tricyclo[4.3.0.0^{3,8}]nonane (Twist-brendane)

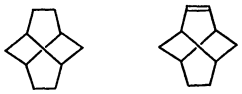
Koichiro NAEMURA and Masao NAKAZAKI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received June 19, 1972)

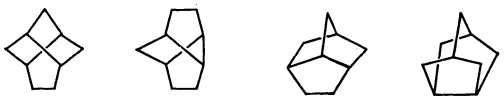
(−)-Tricyclo[4.3.0.0^{3,8}]nonane ("twist-brendane") was synthesized *via* (−)-tricyclo[4.3.0.0^{3,8}]nonan-2-one ("twist-brendan-2-one"). The absolute configuration, (1*R*,3*S*,6*S*,8*R*)-tricyclo[4.3.0.0^{3,8}]nonane was assigned to (−)-twist-brendane by correlating with (−)-*endo*-5-carboxybicyclo[2.2.1]heptane.

Of the hydrocarbons with tricyclodecane skeleton, only tricyclo[4.4.0.0^{3,8}]decane ("twistane") (**1**) and tricyclo[4.4.0.0^{3,8}]dec-4-ene ("twistene") (**2**) are known in optically active modifications, their absolute configurations having been established.[1,2]



(**1**) (**2**)

"Twist-brendane" (**3**), brexane (**4**), brendane (**5**), and noradamantane (**6**) are the members of tricyclononane,[3-8] the next lower homolog of tricyclodecane, and are free from strain. We see from their structure formula that twist-brendane (**3**) and brexane (**4**) may be called "nortwistane" retaining the chiral twist boat cyclohexane moiety of their parent compound.



(**3**) (**4**) (**5**) (**6**)

Having succeeded in the synthesis of optically active twistane (**1**) and establishment of its absolute configuration,[1] we directed our studies toward the syntheses of the chiral hydrocarbons. This paper reports the synthesis and assignment of the absolute configuration of optically active twist-brendane (**3**).

endo-5-Carboxybicyclo[2.2.1]hept-2-ene (**7a**) is convenient as starting material since the absolute configuration and the absolute rotation have been determined by Berson and his co-workers.[9,10]

Pure *endo*-carboxylic acid (**7a**) was obtained from an *endo-exo* mixture of carboxylic acid (**7a**) and **7b** by the known method.[10-12]

Since the Arndt-Eistert reaction of the unsaturated carboxylic acid (**7a**) to give the higher homolog failed, the following stepwise procedure was adopted.

Reduction of carboxylic acid (**7a**) with lithium aluminium hydride in ether afforded *endo*-5-hydroxymethylbicyclo[2.2.1]hept-2-ene (**9**) which was converted into *p*-toluenesulfonate (**10**). *endo*-5-Cyanomethylbicyclo-[2.2.1]hept-2-ene (**11**) prepared from *p*-toluenesulfonate (**10**) was hydrolyzed by heating with potassium hydroxide in ethylene glycol to yield the desired higher homologous carboxylic acid (**12**).

We next spanned the ethano-bridge between 3 and 6 positions of norbornane by using, with a slight modification, the scheme for the synthesis of optically active twistane (**1**).

Iodolactonization of the unsaturated carboxylic acid (**12**) with iodine-iodide in aqueous sodium bicarbonate solution secured iodolactone (**13**), which was heated, without further purification, with 10% aqueous sodium hydroxide to give 3-oxo-5-*endo*-carboxymethylbicyclo-[2.2.1]heptane (**14**), mp 96—97°C.[13]

After esterification of carboxylic acid (**14**) with diazomethane followed by protection of the keto group

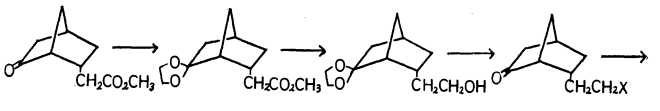
by ketal formation with ethylene glycol, the resulting ketal-ester (**16**) was treated with lithium aluminium hydride in ether to yield ketal-alcohol (**17**), hydrolysis of which with *p*-toluenesulfonic acid in acetone gave 3-oxo-5-*endo*-(2-hydroxy)ethylbicyclo[2.2.1]nonane (**18**) Since the procedure which proved satisfactory in twistane synthesis gave a very poor yield (about 2%) for intramolecular alkylation of ketomethanesulfonate (**19**),[1] the conditions were modified as follows.

Prolonged heating (22 hr) at 60°C with excess sodium hydride in dry dimethylformamide in a nitrogen atmosphere converted the methanesulfonate (**19**) into a mixture from which twist-brendan-2-one, tricyclo-[4.3.0.0^{3,8}]nonan-2-one (**20**), mp 174—175°C was obtained after chromatographic purification and sublimation.

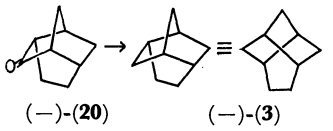
Although various evidences, including elemental analysis, mass spectrum (molecular ion peak, *m/e* 136) and infrared spectrum (1750 cm^{-1}) clearly supported the structure, conclusive proof was obtained by its conversion into the known twist-brendane.

The Wolff-Kishner reduction of the ketone (**20**) gave a product which was purified by column chromatography on neutral alumina followed by sublimation to provide a crystalline hydrocarbon, mp 159—160°C.

Its mass spectrum showed peaks at *m/e* 122, 93, 81, 80, 79, 67, 41, and 39. The NMR spectrum exhibited two broad singlets at τ 7.75 and 8.16 and a poorly resolved multiplet around 8.30—8.90. These spectra are found to be in line with those reported for twist-brendane (**3**) by Vogt.[3]



(+)-(**15**) (+)-(**16**) (**17**) (+)-(**18**) X=OH (**19**) X=OMs

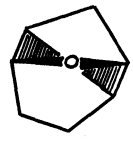


(−)-(**20**) (−)-(**3**)

The same reaction scheme outlined above provided optically active twist-brendan-2-one (**20**), mp 169—171°C, $[\alpha]_D^{21}$ −240° and twist-brendane (**3**), mp 157.5—159°C, $[\alpha]_D^{18}$ −235° from (−)-*endo*-5-carboxybicyclo-[2.2.1]hept-2-ene (**7a**), $[\alpha]_D^{20}$ −119° (82% optical purity), which was obtained by optical resolution of racemate *via* cinchonidine salt.

Since the absolute configuration of (−)-unsaturated carboxylic acid (**7a**) has been established by correlating with (−)-fenchone, (−)-twist-brendan-2-one (**20**) and (−)-twist-brendane (**3**) should be (−)-(1*R*,3*R*,6*S*,8*R*)-tricyclo[4.3.0.0^{3,8}]nonan-2-one and (−)-(1*R*,3*S*,6*S*,8*R*)-tricyclo[4.3.0.0^{3,8}]nonane, respectively.

The cyclohexanone moiety of twist-brendan-2-one which is indicated by the shaded past in the projection formula (**21**) has a "right-handed" twist boat form according to the definition of Djerassi and Klyne who drew the general conclusion that the twist boat form of this type exhibits a strong positive CD curve around 300 mμ.[15]



(**21**)

Contrary to expectation, (−)-twist-brendan-2-one (**20**) shows a negative maximum ([θ] 1.50×10^4) at 289 mμ (Fig. 1).

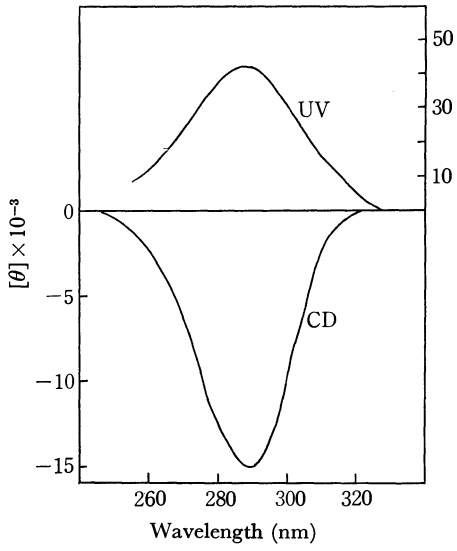


Fig. 6. UV and CD spectra.

This suggests that proper caution should be paid in applying this rule, which has been proved valid in steroid, to this type of cage compound.

Experimental[16]

(±)-endo-5-Hydroxymethylbicyclo[2.2.1]hept-2-ene (9) and Its Tosylate (10). *endo*-5-Carboxybicyclo[2.2.1]hept-2-ene

14) The structure formula indicated refers to the enantiomers which eventually give (−)-twist-brendane.

15) C. Djerassi and W. Klyne, *Proc. Nat. Acad. Sci. U.S.*, **48**, 1093 (1962).

16) Melting points and boiling points are uncorrected. NMR measurements were carried out on a JEOLC-60 H. Optical rotations were measured with a JASCO DIP-SL automatic polarimeter. Mass spectra were measured with a Hitachi RMS-4 spectrometer.

(**7a**) (35.6 g), which was prepared by the method of Berson,[10] was refluxed for 4.5 hr with 9.8 g of lithium aluminium hydride in 300 ml of dry ether. After addition of aqueous sodium sulfate, a separated solid was filtered off and the filtrate was washed with saturated aqueous sodium carbonate, saturated aqueous sodium chloride and dried. After removal of the solvent, the residue was distilled to give 28.3 g of *endo*-5-hydroxymethylbicyclo[2.2.1]hept-2-ene (**9**), bp 100—104°C/18 mmHg, n_D^{18} 1.5000.

IR (neat film): 3320, 1030, and 720 cm^{-1}.

NMR (CCl_4): τ 3.88—4.20 (2H, s), 6.00 (1H, s), 6.55—7.00 (2H, m), 7.05—7.35 (2H, m), 7.50—8.00 (1H, m), 8.00—8.50 (1H, m), 8.55—8.90 (2H, m), 9.40—9.70 (1H, m).[17]

A solution of 25.1 g of unsaturated alcohol (**9**) and 42.4 g of *p*-toluenesulfonyl chloride in 80 ml of dry pyridine was kept at room temperature for 24 hr. The reaction mixture was poured into chilled hydrochloric acid and extracted with ether. The extract was washed with dilute hydrochloric acid, aqueous sodium bicarbonate, saturated aqueous sodium chloride and dried. After removal of the solvent, crude *p*-toluenesulfonate (**10**) was recrystallized from *n*-hexane to give needles (50.4 g), mp 47—48°C.

Found: C, 64.47; H, 6.45; S, 11.64%. Calcd for $C_{15}H_{18}O_3S$: C, 64.73; H, 6.52; S, 11.50%.

(±)-endo-*5-Cyanomethylbicyclo[2.2.1]hept-2-ene (11).* A mixture of 55.9 g of *p*-toluenesulfonate (**10**) and 29.7 g of sodium cyanide in 330 ml of dry dimethylformamide was heated at 110—120°C for 2 hr and then at 130—140°C for further 8 hr. After cooling, a solid was filtered off and the filtrate was concentrated under reduced pressure. The residue was poured into chilled water and extracted with ether. The extract was washed with dilute hydrochloric acid, saturated aqueous sodium bicarbonate, saturated aqueous sodium chloride and dried over magnesium sulfate. After filtration and removal of the solvent, distillation gave *endo*-5-cyanomethylbicyclo[2.2.1]hept-2-ene (**11**) (20.7 g), bp 106—107°C/19 mmHg, n_D^{18} 1.4864.

IR (neat film): 2250 and 720 cm^{-1}.

Found: C, 80.75; H, 8.38; N, 10.32%. Calcd for $C_9H_{11}N$: C, 81.16; H, 8.33; N, 10.52%.

(±)-endo-*5-Carboxymethylbicyclo[2.2.1]hept-2-ene (12).* A mixture of 19.5 g of *endo*-5-cyanomethylbicyclo[2.2.1]hept-2-ene (**11**), 25.0 g of potassium hydroxide and 200 ml of ethylene glycol was heated at 130—140°C for 1 hr and then at 150—160°C for further 6 hr. After cooling, the reaction mixture was diluted with water and washed with ether. The aqueous solution was then acidified and extracted with ether. The extract was washed with saturated aqueous sodium chloride and dried over magnesium sulfate. After removal of the solvent, distillation gave 20.5 g of *endo*-5-carboxymethylbicyclo[2.2.1]hept-2-ene (**12**), bp 118—119°C/3 mmHg, n_D^{18} 1.4970.

IR (neat film): 1700 and 720 cm^{-1}.

Found: C, 70.74; H, 8.01%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

*(±)-3-Oxo-5-*endo-*carboxymethylbicyclo[2.2.1]heptane (14).* To a solution of 19.7 g of *endo*-5-carboxymethylbicyclo[2.2.1]-hept-2-ene (**12**) in 860 ml of 0.5N aqueous sodium bicarbonate was added a solution of 40 g of iodine and 158 g of potassium iodide in 470 ml of water and the mixture was kept for 24 hr in a dark place. A dark oil was separated by decantation and dissolved in chloroform and the water layer was extracted with chloroform. A combined chloroform solution was washed with aqueous sodium thiosulfate, saturated aqueous sodium bicarbonate, saturated aqueous sodium chloride and dried over magnesium sulfate. After filtration, the solvent was removed to give a crystalline iodolactone (**13**), which, without purification, was dissolved in 10% aqueous sodium hydroxide (800 ml). The mixture was heated at 100°C for 1 hr and then washed with ether. The alkaline solution was acidified and extracted with ether. The extract was washed with saturated aqueous sodium chloride and dried over magnesium sulfate. Filtration and removal of the solvent afforded a crystalline substance which was recrystallized from *n*-hexane–benzene to give 16.5 g of 3-oxo-5-*endo*-carboxymethylbicyclo-[2.2.1]heptane (**14**), mp 96—97°C.

IR (nujol): 1730 and 1700 cm^{-1}.

Found: C, 64.62; H, 7.23%. Calcd for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

*(±)-3-Oxo-5-*endo-*methoxycarbonylmethylbicyclo[2.2.1]heptane (15).* To a solution of 8.40 g of 3-oxo-5-*endo*-carboxymethylbicyclo[2.2.1]heptane (**14**) in ether was added a solution of diazomethane in ether at 5—0°C and the mixture was stirred for 2 hr at the same temperature. The solvent and excess diazomethane were then removed under reduced pressure and the residue was distilled to give 8.36 g of the methyl ester (**15**), bp 128—129°C/5 mmHg, n_D^{18} 1.4787.

IR (neat film): 1740 cm^{-1}.

NMR (CCl_4): τ 6.40 (3H, s), 7.3—7.6 (3H, m), 7.7—7.8 (2H, d), 8.0—8.1 (2H, d), 8.2—8.3 (3H, m), 8.85—9.20 (1H, d).

2,4-Dinitrophenylhydrazone: mp 95—96°C.

*(±)-3-Ethylenedioxy-5-*endo-*methoxycarbonylbicyclo[2.2.1]heptane (16).* A mixture of 32.6 g of 3-oxo-5-*endo*-methoxycarbonylmethylbicyclo[2.2.1]heptane (**15**), 560 ml of ethylene glycol, 2.10 g of *p*-toluenesulfonic acid and 2.5 l of benzene was refluxed for 21 hr. During this period the water generated was separated as benzene azeotrope from the reaction mixture. After cooling, the benzene layer was separated from ethylene glycol layer, which was poured into water and extracted with benzene. A combined benzene solution was washed with saturated aqueous sodium bicarbonate, saturated aqueous sodium chloride and dried over magnesium sulfate. After removal of the solvent, distillation gave 30.7 g of 3-ethylenedioxy-5-*endo*-methoxycarbonylmethylbicyclo[2.2.1]heptane (**15**), bp 127—131°C/4 mmHg, n_D^{18} 1.4829.

IR (neat film): 1735, 1175, 1100, and 1020 cm^{-1}.

Found: C, 63.51; H, 7.97%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*(±)-3-Oxo-5-*endo-*(2-hydroxy)ethylbicyclo[2.2.1]heptane (18).* A solution of 30.5 g of 3-ethylenedioxy-5-*endo*-methoxycarbonylbicyclo[2.2.1]heptane (**16**) in 240 ml of dry ether was added to a suspension of 7.6 g of lithium aluminium hydride on 240 ml of dry ether and the mixture was refluxed for 4.5 hr. Saturated aqueous sodium sulfate was added to the chilled reaction mixture and a solid was filtered off. The filtrate was washed with saturated aqueous sodium chloride and dried over magnesium sulfate. After filtration, the solvent was removed to give ketalalcohol (**17**), which was stirred at room temperature for 5 hr with *p*-toluenesulfonic acid (4.4 g) in 1.8 l of acetone. After neutralization with sodium bicarbonate the acetone was removed and then a residue was diluted with ether. The resulting mixture was washed with saturated aqueous sodium chloride and dried over magnesium sulfate. After removal of the solvent, distillation gave 3-oxo-5-*endo*-(2-hydroxy)ethylbicyclo[2.2.1]-heptane (**18**) (14.1 g), bp 118—120°C/1.5 mmHg, n_D^{18} 1.4968.

IR (neat film): 3400, 1735, and 1050 cm^{-1}.

NMR (CCl_4): τ 6.23 (1H, s), 6.51 (2H, m), 7.50 (1H, s),

(±)-Tricyclo[4.3.0.0^{3,8}]nonan-2-one (**20**). To a solution of 4.34 g of 3-oxo-5-*endo*-(2-hydroxy)ethylbicyclo[2.2.1]heptane (**18**) in 16 ml of dry pyridine was added 6.9 g of methanesulfonyl chloride at 5—0°C. After stirring at the same temperature for 2 hr, the reaction mixture was kept at room temperature for 24 hr and then poured into chilled hydrochloric acid. The mixture was extracted with ether and the extract was washed with dilute hydrochloric acid, saturated aqueous sodium bicarbonate, saturated aqueous sodium chloride and dried over magnesium sulfate. After filtration, the solvent was removed to give methanesulfonate (**19**), which, without purification, was dissolved in 50 ml of dry dimethylformamide. The solution was added to a suspension of 4.00 g of sodium hydride on 100 ml of dry dimethylformamide and the mixture was heated at 60°C for 21.5 hr under a nitrogen atmosphere. The reaction mixture was poured into chilled water and extracted with ether. The extract was washed with dilute hydrochloric acid, saturated aqueous sodium bicarbonate, saturated aqueous sodium chloride and dried over magnesium sulfate. After removal of the solvent, the residue was chromatographed on neutral alumina (activity III). An elution with *n*-pentane gave a semisolid which was sublimed to yield 0.89 g of tricyclo[4.3.0.0^{3,8}]nonan-2-one (**20**), mp 174—175°C (in a sealed tube).

IR (CCl_4 solution): 1750 cm^{-1}.

Found: C, 70.69; H, 8.00%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

*(+)-3-Oxo-5-*endo*-methoxycarbonylmethylbicyclo[2.2.1]heptane* (**15**). Iodolactone (**13**) which was prepared from 18.5 g of (−)-*endo*-5-carboxymethylbicyclo[2.2.1]hept-2-ene (**12**) by the same procedure as described for racemate was, without purification, treated with 10% aqueous sodium hydroxide at 100°C for 1 hr to give 32.3 g of 3-oxo-5-*endo*-carboxymethylbicyclo[2.2.1]heptane (**15**). Without purification, the ketocarboxylic acid (**14**) was treated with diazomethane in ether to give 17.9 g of (+)-3-oxo-5-*endo*-methoxycarbonylbicyclo[2.2.1]heptane (**15**), bp 106—108°C/2 mmHg, $[\alpha]_D^{14}$ +16.5° (*c* 1.2, 99% ethanol), n_D^{18} 1.4790.

Found: C, 65.45; H, 7.67%. Calcd for $C_{10}H_{14}O_3$: C, 65.91; H, 7.74%.

*(+)-3-Ethylenedioxy-5-*endo*-methoxycarbonylmethylbicyclo-[2.2.1]heptane* (**16**). Treatment of 17.5 g of (+)-3-oxo-5-*endo*-methoxycarbonylmethylbicyclo[2.2.1]heptane (**15**) with 300 ml of ethylene glycol and 1.38 g of *p*-toluenesulfonic acid in 1.34 l of benzene gave 18.7 g of (+)-3-ethylenedioxy-5-*endo*-methoxycarbonylmethylbicyclo[2.2.1]heptane (**16**), bp 112—115°C/1 mmHg, $[\alpha]_D^{23}$ +22.1° (*c* 1.1, 99% ethanol), n_D^{18} 1.4833.

Found: C, 63.28; H, 7.88%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

*(+)-3-Oxo-5-*endo*-(2-hydroxy)ethylbicyclo[2.2.1]heptane* (**18**). Reduction of 18.6 g of (+)-3-ethylenedioxy-5-*endo*-methoxycarbonylmethylbicyclo[2.2.1]heptane (**16**) with lithium aluminium hydride in ether gave 3-ethylenedioxy-5-*endo*-(2-hydroxy)ethylbicyclo[2.2.1]heptane (**17**), which, without purification, was treated with *p*-toluenesulfonic acid in acetone to

give 8.79 g of (+)-3-oxo-5-*endo*-(2-hydroxy)ethylbicyclo-[2.2.1]heptane (**18**), bp 122—123°C/1.5 mmHg, $[\alpha]_D^{22}$ +17.2° (*c* 1.1, 99% ethanol), n_D^{18} 1.5007. The substance was very hygroscopic.

Found: C, 69.22; H, 8.20%. Calcd for $C_9H_{14}O_2$: C, 70.10; H, 9.15%.

*(−)-Tricyclo[4.3.0.0^{3,8}]nonan-2-one (**20**).* Methanesulfonate (**19**), prepared from 4.26 g of (+)-3-oxo-5-*endo*-(2-hydroxyethyl)bicyclo[2.2.1]heptane (**18**), was heated at 60°C for 25 hr with 4.00 g of sodium hydride in 150 ml of dry dimethylformamide. The product was chromatographed on neutral alumina (activity III) and a semisolid eluted with *n*-pentane was sublimed to yield 789 mg of (−)-tricyclo-[4.3.0.0^{3,8}]nonan-2-one (**20**), mp 169—171°C (in a sealed tube), $[\alpha]_D^{21}$ −240° (*c* 0.58, 99% ethanol).

UV: λ_{max}^{MeOH} 289 mμ (ε 43).

CD (*c* 3.03×10^{-3}, methanol): $[\theta]_{320}$ 0, $[\theta]_{289}$ -150×10^2, $[\theta]_{245}$ 0.

Found: C, 78.72; H, 8.92%. Calcd for $C_9H_{12}O$: C, 79.37; H, 8.88%.

*(−)-Tricyclo[4.3.0.0^{3,8}]nonane (**3**).* The Wolff-Kishner reduction of 450 mg of (−)-tricyclo[4.3.0.0^{3,8}]nonan-2-one (**20**) was carried out by the same procedure as described for racemate. The product was purified by chromatography and sublimation to give 208 mg of (−)-tricyclo[4.3.0.0^{3,8}]-nonane (**3**), mp 157.5—159°C (in a sealed tube), $[\alpha]_D^{18}$ −235°, $[\alpha]_{436}^{20}$ −483° (*c* 0.52, 99% ethanol).

Found: C, 87.76; H, 11.49%. Calcd for C_9H_{14}: C, 88.45; H, 11.55%.

The authors are grateful to Dr. K. Kuriyama for measurement of the CD curve.

Cyclopropanes from Olefins by the Oxygen-accelerated Zinc-carbenoid Reaction

Sotaro MIYANO and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai

(Received June 28, 1972)

Oxygen greatly accelerates the cyclopropanation of olefins by the diethylzinc-chloroiodomethane or -diiodomethane system. Olefins, including cyclohexene, cyclooctene, 1-heptene, 1-octene, 2-heptene, indene, *n*-butyl vinyl ether, styrene, and methyl oleate, gave the corresponding cyclopropanes in yields of *ca.* 70—100%. The methylene addition to *cis*- and *trans*-2-butene proceeded in a stereospecific manner in the presence of oxygen. Methyl methacrylate gave no appreciable amount of cyclopropanated product, but polymerization proceeded. Styrene inhibited the formation of the zinc-carbenoid reagent from diethylzinc and dihalomethanes under a nitrogen atmosphere. AIBN and UV light initiated the cyclopropanation of styrene with diethylzinc and chloroiodomethane. A free-radical-chain mechanism is proposed for the formation of the zinc-carbenoid reagent from diethylzinc and dihalomethanes.

Furukawa *et al.* explored the cyclopropanation of olefins by the zinc-carbenoid reagents obtained from diethylzinc and *gem*-diiodoalkanes.[1] α-Iodoalkylethylzinc and bis(α-iodoalkyl)zinc are said to be active intermediates in the cyclopropanation reactions.[1c] Little attention has been paid to the mechanism of the formation of these carbenoid species from diethylzinc and *gem*-diiodoalkanes.

Since diethylzinc is highly sensitive to oxygen,[2] Furukawa's cyclopropanation reaction was carried out under a nitrogen atmosphere.[1] On the other hand, we ourselves have previously reported that oxygen greatly accelerates the cyclopropanation of olefins with diethylzinc and diiodomethane[3] or chloroiodomethane.[4] In the present paper we will report the details of the synthesis of cyclopropanes from olefins and will propose a plausible mechanism for the accelerating effect of oxygen on the zinc-carbenoid reaction with diethylzinc and dihalomethanes.

Results and Discussion

Accelerating Effect of Oxygen on the Formation of Norcarane from Cyclohexene, Diethylzinc, and Chloroiodomethane. Figure 1 shows that chloroiodomethane reacts with diethylzinc to form norcarane from cyclohexene under a nitrogen atmosphere. After 6 hr, the yield of norcarane was 61% based on the cyclohexene. By passing dry air into the free space above the reaction mixture after the addition of chloroiodomethane, the reaction was completed within only 30 min to give norcarane in a 99% yield (Fig. 2). Thus, oxygen greatly accelerates the formation of norcarane. Product analysis showed that the molar amount of ethyl iodide and propyl iodide formed was almost equal to that of the chloroiodomethane consumed, irrespective of the reaction atmosphere. This suggests that the zinc-carbenoid reagent is formed from chloroiodomethane by the selective cleavage of a carbon–iodine bond. Both

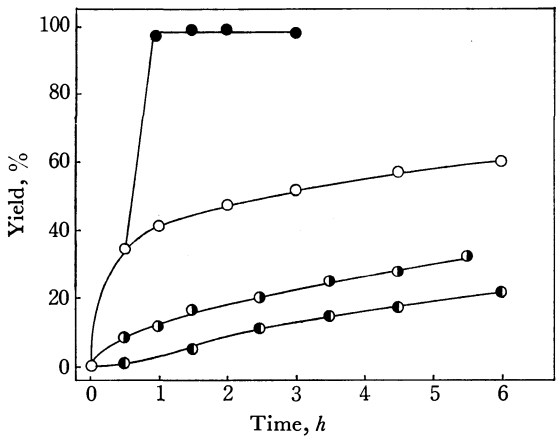

Fig. 2. Accelerating effect of oxygen and inhibiting effect of styrene and diphenylamine on the formation of norcarane from cyclohexene (25 mmol) with diethylzinc (25 mmol) and chloroiodomethane (38 mmol).
Benzene, 20 ml, at 40°C. ○; under a nitrogen atmosphere, ●; air was introduced at a rate of 10 ml/min after 0.5 h, ◐: styrene, 1.3 mmol, ◑: diphenylamine, 1.8 mmol.

zinc-ethyl bonds of diethylzinc seem effective in the zinc-carbenoid formation in the presence of oxygen from the fact that, upon passing air through, more than 1 mol of chloroiodomethane reacted with 1 mol of diethylzinc. However, under a nitrogen atmosphere the second zinc–ethyl bond seems not so reactive as the first one to chloroiodomethane[5] (Fig. 1 and Table 1). Similar results were obtained for the reaction of diethylzinc with diiodomethane.[1]

Dibromomethane gave only 4% of norcarane after air had been passed through for 3 hr, and 83% of the starting halide was recovered (Table 2). Bromochloromethane did not give norcarane under similar reaction conditions, and it was recovered almost quantitatively.

Table 1. Effect of the amount of diethylzinc for the cyclopropanation of cyclohexene[a]

CH_2ClI mmol	Et_2Zn mmol	Cyclohexene mmol	Reacted CH_2ClI mmol	Norcarane Yield (%)
10	8	10	8.2	62

38[b]	25	25	22	61

a) Reactions were carried out under nitrogen atmosphere for 6 h at 35°C in 30 ml of benzene.
b) In 20 ml of benzene at 40°C.

Cyclopropanation of Olefins. The accelerating effect of oxygen in the zinc-carbenoid reaction with diethylzinc and chloroiodomethane was utilized for the cyclopropanation of several olefins (Table 2). While the scope of the reaction has not been fully investigated with respect to the type of olefin and the reaction variables, it can be seen that the procedure described in this paper is useful for the cyclopropane synthesis. In general, chloroiodomethane gave better yields of cyclopropanes than did diiodomethane. This is partly due to the fact that diiodomethane gave more propyl iodide as a side-product than did chloroiodomethane.

Simple olefins gave the corresponding cyclopropanes in very good yields within rather short reaction periods. A satisfactory yield of a cyclopropane was obtained with 1 mol of diethylzinc and 1.2—1.5 mol of a dihalomethane for 1 mol of an olefin. Styrene gave a somewhat poor yield of phenylcyclopropane because of the polymerization of styrene and probably also because of the electron-withdrawing effect of the phenyl substituent on the ethylene bond. *n*-Butyl vinyl ether gave a high yield of *n*-butyl cyclopropyl ether under a nitrogen atmosphere, and the accelerating effect of oxygen was also observed. Methyl methacrylate gave no appreciable amount of a cyclopropanated product, but polymerized products were obtained. The stereospecific nature of the methylene transfer of the oxygen-accelerated zinc-carbenoid reaction was confirmed as follows. From *cis*- and *trans*-2-butene, *cis*- and *trans*-1,2-dimethylcyclopropane were obtained respectively. The NMR spectra of the products are consistent with the assumption that the methyl group linked to the cyclopropane ring shields the *cis* ring proton more than the *trans* proton.[1a,7] The glc analysis of each reaction mixture showed the presence of only unchanged olefin and a single cyclopropane, showing that no isomerization of the olefins and cyclopropanes occurred during the reaction. Methyl *cis*-9,10-methyleneoctadecanoate was obtained in an almost quantitative yield from methyl oleate (Eq. (1)):

5) This implies that the Schlenk equilibrium
$$Et_2Zn + ZnCl_2 \rightleftarrows 2EtZnCl$$
lies substantially in the right hand side. This is the case for ethylzinc iodide, but unambiguous result is not yet obtained for ethylzinc chloride.[6]

Inhibition by Styrene of the Zinc-carbenoid Formation from Diethylzinc and Chloroiodomethane. Styrene was allowed to react with diethylzinc and chloroiodomethane in benzene under a nitrogen atmosphere at 50°C. No phenylcyclopropane was obtained in 3 hr, but the starting styrene and chloroiodomethane were recovered unchanged (Table 3). When oxygen was introduced into the reaction mixture, cyclopropanation was completed within 1.5 hr, giving phenylcyclopropane in a 66% yield. When oxygen was introduced just after the completion of the addition of chloroiodomethane, the reaction was also completed within 1.5 hr, giving phenylcyclopropane in a 70% yield. These facts indicate that the presence of styrene inhibits the formation of the zinc-carbenoid reagent from diethylzinc and chloroiodomethane. When diiodomethane is used as the methylene source, styrene is cyclopropanated under a nitrogen atmosphere, but a higher temperature and a longer reaction period are necessary.[1] The presence of only 5% of styrene (based on cyclohexene) retarded the formation of norcarane from cyclohexene, chloroiodomethane, and diethylzinc (Fig. 2).

The AIBN- and Photochemically-initiated Cyclopropanation of Styrene. The accelerating effect of oxygen and the inhibiting effect of styrene suggest that the zinc-carbenoid formation from diethylzinc and dihalomethanes proceeds by means of a free radical mechanism. This assumption is supported by the facts that AIBN and UV light also initiate the cyclopropanation of styrene (Table 3). Without diethylzinc, chloroiodomethane did not cyclopropanate styrene in the presence of AIBN or UV light, though peroxides or UV light initiate the cyclopropanation of olefins with diiodomethane.[8,9]

The irradiation of a mixture of styrene, chloroiodomethane, and diethylzinc in *n*-hexane with a high-pressure mercury lamp at −70°C gave the zinc-carbenoid reagent under a nitrogen atmosphere, while the styrene remained unchanged. When the light was turned off and the temperature of the reaction mixture was allowed to rise to room temperature, an exothermic reaction took place and phenylcyclopropane was obtained in a 50% yield within 1 hr. On the addition of an ethereal solution of iodine to an irradiated mixture at −70°C, chloroiodomethane (32.3%) and diiodomethane (63.3%) were obtained. This shows that the zinc-carbenoid species[10] in the reaction mixture contained a Cl–CH_2–Zn– unit. Wittig *et al.* reported that diiodomethane was formed preferentially when $(ClCH_2)_2Zn$ was allowed to react with iodine because of the rapid exchange of iodide ions for chlorine atoms in chloromethyl groups.[11,12] The possibility that the zinc-carbenoid species contain the –Zn–CH_2–Zn– unit is excluded by the fact that the "$CH_2(ZnI)_2$" species does not cyclopropanate olefins.[13–15]

Oxygen also initiated the formation of the zinc-carbenoid reagent from diethylzinc and chloroiodomethane in the presence of styrene at −70°C, but the cyclopropanation of styrene did not occur at this temperature. After the reaction vessel had been flushed with nitrogen, the reaction mixture was allowed to stand at room temperature to give phenylcyclopropane in a 66% yield within 1 hr.

Mechanistic Consideration of the Accelerating Effect of Oxygen. Recently Brown *et al.* have shown that the addition of triethylborane to α,β-unsaturated carbonyl compounds proceeds by a radical-chain mechanism and that the reaction is initiated by oxygen, UV light, or peroxides.[16] Davies and Roberts proposed that the autoxidation of diethylzinc involves a radical-chain mechanism[17] rather than an ionic one.[18] It is known that a combination of diethylzinc and oxygen or polyhalometanes initiates the radical polymerization of vinyl monomers even in the presence of conventional radical inhibitors.[19,20] The reactivity order of dihalomethanes towards diethylzinc is: $CH_2I_2 > CH_2ClI > CH_2Br_2 > CH_2BrCl$. This reactivity sequence is in accordance with that of radical halogen-abstraction reactions from dihalomethanes.[21]

These facts suggest that the zinc-carbenoid reagent may be formed from diethylzinc and dihalomethanes *via* radical processes (Eqs. (2)—(4)) (X; Cl or I, R; Et or X):

$$EtZnR \xrightarrow{\text{Initiator}} Et\cdot \quad (2)$$

$$Et\cdot + CH_2IX \longrightarrow EtI + \cdot CH_2X \quad (3)$$

$$\cdot CH_2X + EtZnR \longrightarrow XCH_2ZnR + Et\cdot \quad (4)$$

Styrene or methyl methacrylate may easily react with the ethyl or halomethyl radical and stop the radical

chain. Among the radical inhibitors examined, diphenylamine retarded the formation of norcarane (Fig. 2), but galvinoxyl and hydroquinone were ineffective. Davies and Roberts reported that galvinoxyl did not inhibit the initial step of the autoxidation of diethylzinc.[17] Diphenylamine is almost inactive towards diethylzinc in the absence of a ligand such as bipyridine,[22] and it might retain its activity as a radical inhibitor in the zinc-carbenoid reaction. As the behavior of radical inhibitors has not yet been fully studied in the presence of organometallics, the results with galvinoxyl or hydroquinone do not exclude the proposed above reaction paths.

Though the exact nature of the zinc-carbenoid species formed in the oxygen-accelerated reaction of diethylzinc and CH_2IX (X; Cl or I) is not yet clear, XCH_2ZnEt and $(XCH_2)_2Zn$ seem to be the active methylene transferring reagents to judge from the results of Furukawa *et al.*,[1] Wittig *et al.*,[11,23] and Blanchard and Simmons.[24] Once the zinc-carbenoid species are formed, the methylene-transferring step to olefins seems to be a conventional one-step, three-centered carbenoid reaction in view of the stereospecific methylene addition to olefins, the absence of a C–H insertion product, and the fact that the zinc-carbenoid species formed can cyclopropanate styrene without any free radical initiator.

Experimental

Analytical Instruments. The glc analysis was carried out on a Shimadzu GC 3AF apparatus equipped with hydrogen-flame detectors and two 3 m×3 mm stainless steel columns packed with Diasolid M coated with Silicone DC 550 and Silicone DC 410 respectively. The infrared spectra were obtained with a JASCO Model IR-E spectrophotometer. The NMR data were obtained with a Varian Associates HA-60 instrument. All the chemical shifts are relative to the internal TMS or chloroform reference (*ca.* a 5 wt% solution in CCl_4).

Materials. The chloroiodimethane[25] (bp 108—109°C) and diiodomethane[26] (bp 65—67°C/13 mmHg) were synthesized as has been described before and were stored over tin pellets in the dark. Commercial diethylzinc was distilled under reduced pressure (bp 64°C/111 mmHg—66°C/125 mmHg). The galvinoxyl was obtained according to the method described by Bartlett and Funahashi,[27] and was recrystallized twice from ethanol; mp 152—153°C (lit,[27] 153.2—153.6°C). The AIBN was recrystallized from methanol, dried under reduced pressure, and stored in the dark in a refrigerator (decomp. 101°C). The hydroquinone and diphenylamine were of commercial origin and were used without further purification. The other materials were reagent-grade chemicals and were purified as usual before use. Distillation or recrystallization was carried out under a nitrogen atmosphere. The materials were stored under nitrogen.

Experimental Procedure. The following example is representative. The reaction was carried out in a 100 ml round-bottomed flask equipped with a magnetic stirrer, a reflux condenser, a pressure-equilibrating dropping funnel topped with a gas inlet cock, a thermometer, and an inlet with a rubber septum cap. The flask was flushed with prepurified nitrogen. In the flask, 20 ml of benzene, 25 mmol of cyclohexene, 3.3 g of ethylbenzene, and 2.5 ml of diethylzinc (25 mmol) were placed; the mixture was stirred and then warmed to 40°C. Chloroiodomethane (38 mmol) was added, drop by drop, over a 30 min period at 40°C under a nitrogen atmosphere. Samples (*ca.* 1 ml) were withdrawn at various times through the septum cap by means of a hypodermic syringe, and quenched under a nitrogen atmosphere with 3 ml of a dilute hydrogen chloride solution saturated with nitrogen. After three extractions of the aqueous layer with benzene, the combined organic phase was analysed by glc. The amounts of the products were estimated from the peak areas, using ethylbenzene as the internal standard.

Acceleration of the Formation of Norcarane with Oxygen. After the addition of chloroiodomethane had been completed, dry air was introduced at a rate of 10 ml/min into the space above the reaction mixture through the gas inlet cock and the side arm of the dropping funnel. The subsequent exothermic reaction was observed to be accompanied by fuming and by the precipitation of white solids, but it subsided within about 10 min. The products were then analyzed as above. Norcarane (25.8 mmol), ethyl iodide (33.3 mmol), and propyl iodide (3.2 mmol) were formed from cyclohexene (26 mmol), diethylzinc (25 mmol), and chloroiodimethane (37.8 mmol) after air had been passed through for 1 hr.

In another experiment, after the addition of chloroiodomethane the nitrogen inlet was replaced by a calcium chloride tube. The reaction mixture was then allowed to stand overnight (20 hr) at room temperature (see Table 2).

Zinc-carbenoid Formation at a Low Temperature. By means of a microfeeder, a 140 ml portion of oxygen was bubbled for 5 hr into a mixture of diethylzinc (40 mmol), chloroiodomethane (38 mmol), and styrene (25 mmol) in *n*-hexane (20 ml) at −70°C. Chloroiodomethane was consumed by the formation of ethyl iodide (37 mmol), but the cyclopropanation of styrene did not occur at this temperature. When the temperature of the mixture was then allowed to rise to room temperature, a 16.5 mmol portion of phenylcyclopropane was obtained within 1 hr.

Synthesis of Cyclopropanes. *Norcarane*: For the identification of norcarane, a controlled reaction was carried out according to the above procedure except that reaction scale was 4 times larger and ethylbenzene was not added. After air had been passed through at a rate of 10 ml/min for 1 hr, the reaction mixture was treated as has been described by Furukawa *et al.*[18] Repeated distillation through a Widmer column gave 0.7 g of an analytical sample boiling at 116—117°C (lit,[28] 116.5°C). The spectral data were identical with those of norcarane. IR (liq. film): 3090, 3010, 1020 cm^{-1} for the characteristic absorption of the cyclopropane ring.[29] NMR: δ 2.2—1.5 (4H, broad), 1.5—1.0 (4H, m), 1.0—0.7 (3H, m), 0.9——0.2 (1H, m). Found: C, 87.35; H, 12.90%. Calcd for C_7H_{12}: C, 87.42; H, 12.58%.

A similar procedure gave the following cyclopropanes (see Table 2 for the reaction conditions).

Phenylcyclopropane: Bp 83—83.5°C/38 mmHg (lit,[30] bp 79—80°C/37 mmHg). IR (liq. film): 1025, 1050 cm^{-1}. NMR: δ 7.1 (5H, m), 2.1—1.2 (1H, m), 1.1—0.5 (4H, m). Found: C, 91.16; H, 8.49%. Calcd for C_9H_9: C, 91.47; H, 8.53%. After the distillation of the reaction mixture, a resinous substance was obtained; it was dissolved in a small amount of benzene and precipitated with methanol. The white precipitate gave IR absorption spectra (KBr) apparently identical with those of polystyrene film over the wave range from 650 to 3200 cm^{-1}.

n-*Amylcyclopropane*: Bp 128—129°C (lit,[28] 128—129°C). NMR: δ 3.2—2.8 (8H, broad), 2.8—2.6 (3H, broad), 2.3—1.9 (3H, m), 1.8—0.5 (2H, m). Found: C, 85.76; H, 14.24%. Calcd for C_8H_{16}: C, 85.63; H, 14.37%.

n-*Hexylcyclopropane*: Bp 148—151°C (lit,[28] 148°C). IR (liq. film): 3090, 1045 cm^{-1}. NMR: δ 1.4—1.1 (10H, broad), 1.1—0.6 (3H, broad), 0.6—0. 2(3H, m), 0.2——0.2 (2H, m). Found: C, 85.31; H, 14.64%. Calcd for C_9H_{18}: C, 85.63; H, 14.37%.

1-n-*Butyl-2-methylcyclopropanes*: A mixture of *trans*- (27%) and *cis*-2-heptene (73%) gave a reaction mixture containing 26% of *trans*- and 74% of *cis*-1-*n*-butyl-2-methylcyclopropane. Distillation gave a portion boiling at 123—128°C which consisted of 84% of the *cis* and 16% of the *trans* isomer. In a glc analysis, the *cis* isomer gave the retention time of 7.4 min, while the *trans* isomer gave one of 5.9 min (Silicone DC 550 column, 110°C, nitrogen-carrier flow rate of 35 ml/min). NMR: δ 0.7—0.5, −0.3——0.4 (ring protons of the *cis* isomer), 0.35—0 (ring protons of the *trans* isomer). Found: C, 85.69; H, 14.31%. Calcd for C_8H_{16}: C, 85.63; H, 14.37%.

Benzobicyclo[*3.1.0*]*hex-2-ene*: A portion boiling at 84—88°C/22 mmHg (lit,[31] 104°C/40 mmHg) was finally purified by preparative glc (Shimadzu GC 2B, Apiezon Grease L). IR (liq. film): 3050, 1020 cm^{-1}. NMR: δ 7.3—6.9 (4H, m), 3.1—2.9 (3H, t), 2.5—2.1 (1H, m), 2.0—1.6 (1H, m), 1.2—0.8 (1H, m), 0.2——0.1 (1H, m).

Bicyclo[*6.1.0*]*nonane*: Bp 78°C/42 mmHg (lit,[32] 89°C/66 mmHg). IR (liq. film): 3035, 1030, 1010 cm^{-1}. NMR: δ 2.1—2.0 (1H, broad), 2.0—1.8 (1H, broad), 1.8—1.0 (9H, broad), 0.9—0.4 (4H, broad), −0.2——0.4 (1H, m).

n-*Butyl Cyclopropyl Ether*: Bp 121—121.5°C (lit,[18] 122—123°C). IR (liq. film): 3100, 1025 cm^{-1}. NMR: δ 3.6—3.3 (2H, m), 3.3—2.9 (1H, m), 1.7—1.1 (4H, m), 1.1—0.7 (3H, m), 0.6—0.2 (4H, m). Found: C, 74.01; H, 12.63%. Calcd for $C_7H_{14}O$: C, 73.63; H, 12.36%.

cis- *And* trans-*1,2-Dimethylcyclopropane*: *cis*-2-Butene (7.0 g, 125 mmol) was distilled into a sealed tube. To the cooled liquid, toluene (10 ml), diethylzinc (4 ml, 40 mmol), and chloroiodomethane (60 mmol) were added. The reaction mixture was allowed to stand at room temperature for 1 hr with stirring. Then, 200 ml of oxygen was injected into the reaction mixture. After the fuming had subsided, the reaction mixture was treated as usual. Glc analysis was carried out with a Silicone DC 550 column operated at 51°C with a nitrogen-carrier flow rate of 17 ml/min. The yields of *cis*- and *trans*-1,2-dimethylcyclopropane were not determined because of their volatility. NMR of the *cis* isomer: δ 1.2—1.0 (6H, m), 0.9—0.6 (3H, broad), 0.5——0.2 (1H,m). NMR of the *trans* isomer: δ 1.1—0.9 (6H, d), 0.6—0 (4H, m).

Methyl cis-*9,10-Methyleneoctadecanoate*: Methyl oleate (15 g, 53 mmol), chloroiodomethane (75 mmol), and diethylzinc (50 mmol) were allowed to react in 50 ml of *n*-hexane by passing air through (10 ml/min) for 1 hr at 50°C. Distillation gave two portions, boiling at 160—180°C/2 mmHg (6.2 g) and 180—186°C/2 mmHg (10 g) (lit,[33] bp 188.7—189°C/3 mmHg). Both portion showed NMR spectra identical with those of methyl *cis*-9,10-methyleneoctadecanoate. NMR: δ 3.6 (3H, s), 2.3 (2H, t), 1.7—1.1 (26H, broad), 1—0.8 (3H, t), 0.7—0.5 (3H, broad), −0.3——0.4 (1H, broad). IR (liq. film): 3060, 1020 cm^{-1}. Found: C, 77.68; H, 12.59%. Calcd for $C_{20}H_{38}O_2$: C, 77.37; H, 12.25%. Hydrolysis with methanol–KOH gave a free acid, mp 37.5—39°C (lit,[33] 39.7—40.5°C). Found: C, 76.46; H, 12.90%. Calcd for $C_{19}H_{36}O_2$: C, 76.96; H, 12.24%.

Attempted Cyclopropanation of Methyl Methacrylate: A mixture of methyl methacrylate (0.10 mol) and chloroiodomethane (0.15 mol) was added, drop by drop, to diethylzinc (10 ml) in *n*-hexane (50 ml) over a 30 min period under a nitrogen atmosphere. Oxygen was then passed through at a rate of 10 ml/min at 50°C for 1 hr. The subsequent usual work-up gave 8.9 g of a residue after distillation. From the distillate, ethyl iodide, propyl iodide, and unchanged methyl methacrylate and chloroiodomethane were detected by glc and NMR spectra, but the presence of cyclopropanated product was not detected. The residue was dissolved in acetone and precipitated with methanol. The white precipitate seemed to be polymethyl methacrylate, judging from its NMR spectra and the results of elemental analysis. NMR: δ 3.4 (3H, broad), 2.2—1.9 (2H, broad), 1.5—0.9 (3H, broad). Found: C, 59.55; H, 7.83%. Calcd for $(C_5H_8O_2)_n$: C, 59.98; H, 8.05%. The methanol-soluble part showed NMR spectra similar to the above spectra except for the new signals at 1.3—1.2 and 1.1 ppm, and it seemed to be a oligomerizied product.

This work was partly supported by a grant of the Ministry of Education of Japan. The authors wish to thank Assistant Professor Junzo Yamashita for his valuable discussions, and Professor Kyohei Yamashita and Professor Makoto Imaizumi for their interest.

Oxidation of Diphosphine Dioxides, Disulfides and Phosphinothioite and Photolysis of Diphosphine Disulfides. Formation of Phosphinic and Phosphinothioic Anhydrides

Tateki EMOTO, Renji OKAZAKI, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received July 1, 1972)

Oxidation of tetraphenyldiphosphine dioxide with an equimolar amount of peroxybenzoic acid (III) gave diphenylphosphinic anhydride in a good yield. Similarly, diphosphine disulfides (II) with 1.5—2.0 mol times of III, gave the corresponding phosphinothioic anhydrides (V), together with the corresponding phosphinic acid and sulfur. II gave V in air in refluxing xylene or *o*-dichlorobenzene. The yields of V increased with reaction temperature and with reaction time, indicating a homolytic fission of the P(S)–P(S) bond. Reaction of tetraphenyldiphosphine disulfide with sulfur in refluxing *o*-dichlorobenzene gave bis(diphenylphosphinothioyl) sulfide. Photolysis of II with a low pressure mercury lamp gave phosphinic acid and sulfur under oxygen, and gave phosphine sulfide and *O*-methyl phosphinothioate in methanol. Phenyl diphenylphosphinothioite gave diphenyl disulfide and diphenylphosphinic acid with silver nitrate.

Diphosphine dioxides (I) and disulfides (II) undergo heterolytic cleavage of the P–P bond with various reagents.[1] Phosphinic anhydrides are considered to be the intermediate in the oxidation of diphosphines[2] and the corresponding disulfides (II),[3–5] with oxidizing reagents such as hydrogen peroxide and mercuric oxide to the corresponding phosphinic acids.

It has been reported that II inserts ethylene molecules between their phosphorus atoms.[6] In the course of unsuccessful attempts to insert heterocumulenes into the P(S)–P(S) bond of II, it was found that phosphinothioic anhydrides were always obtained in small yields in refluxing benzene or xylene in air.

We thus carried out oxidation of I and II with peroxybenzoic acid, anticipating the formation of the corresponding anhydrides through Baeyer-Villiger type reaction[7] and the air oxidation of II. This paper describes the results, photolysis of II and also oxidation of phenyl diphenylphosphinothioite with silver nitrate.

Results and Discussion

Oxidation of Diphosphine Dioxide (I) and Disulfides (II) with Peroxybenzoic Acid (III). Tetraphenyldiphosphine dioxide (Ia) was chosen as a sample of diphosphine dioxide, since tetraalkyldiphosphine dioxides are scarcely known.

When Ia was allowed to react with an equimolar amount of peroxybenzoic acid (III) in dichloromethane for 40 min at room temperature, diphenylphosphinic anhydride (IVa) was obtained in 83% yield.

Longer reaction time or use of excess amounts of III gave mainly diphenylphosphinic acid. The low yields of IVa may be attributed to decomposition of IVa by benzoic acid produced during the reaction or by excess of III. Anhydride (IVa) could not be purified by column chromatography or by recrystallization, because of easy hydrolysis with moisture.

$$\underset{\text{I, X=O}\quad\text{II, X=S}}{R_2P(=X)\text{-}P(=X)R_2} + \underset{\text{III}}{PhCO_3H} \longrightarrow R_2P(=X)\text{-}O\text{-}P(=X)R_2 + PhCO_2H$$

IV, X=O; V, X=S

a, R=Ph; b, R=Et

A similar oxidation of diphosphine disulfides (II) gave phosphinothioic anhydrides (V). Typical results are listed in Table 1.

V was obtained in poor yield with an equimolar amount of III, but in fairly good yield with 1.5—2.0 mol times of III. Phosphinic acid and sulfur were always produced in small yields, indicating that the oxygen atom insertion into the P(S)–P(S) bond competes with the oxidative desulfurization of the P=S groups. Therefore, use of the above 3 mol times of III gave no V but the corresponding phosphinic aicd and sulfur.

In order to clarify the oxidative desulfurization of the P=S group, triphenylphosphine sulfide was oxidized with III as a model compound under similar conditions. The reaction products were triphenylphosphine oxide and sulfur. It is known that triphenylphosphine sulfide is oxidized to the corresponding oxide with various oxidizing reagents.[8]

Recently the oxidation of diethyl aroylphosphonates with III has been reported to produce aroyl diethyl phosphates.[9] The present reactions are also explained by the Baeyer-Villiger type reaction.

However, the structures VI and VII may be considered to be the actual structures of so-called "diphosphine dioxides and disulfides", respectively.

$$\underset{\text{VI}}{R_2P(O)\text{-}OPR_2} \qquad \underset{\text{VII}}{R_2P(S)\text{-}SPR_2}$$

Both samples of Ia prepared by air oxidation of tetraphenyldiphosphine[2] and by air oxidation of diphenylphosphinous chloride in the presence of *t*-amine

Table 1. Oxidation of diphosphine disulfides (II) with peroxybenzoic acid (III) in dichloromethane

II	Temp. (°C)	Time (hr)	III/II (mol/mol)	Mol % $[R_2P(S)]_2O$	Mol % $R_2P(O)OH$	Mol % S
IIa R=Ph	18—35	2	1.2	13	22	11
	ca. 2	2	2.0	54	4	3
IIb R=Et	*ca.* 7	24	3.8	0	58	46
	ca. −50	5	1.5	37	25	33
	18—31[a]	14	2.0	40	17	21

a) In benzene.

and water,[10] and those of IIa or IIb prepared by sulfurization of diphosphines[2] and reaction of ethylmagnesium bromide with diphenylphosphinothioyl chloride[11] or phosphorus thioxychloride,[12] were quite the same as each other with respect to melting point, IR spectrum, and reactivity toward III. Uncertainty as to structure was thus eliminated.

Air Oxidation of Diphosphine Disulfides (II). When diphosphine disulfides (II) were refluxed in toluene, xylene or *o*-dichlorobenzene in the air for a longer time, phosphinothioic anhydrides (V) were obtained but not under nitrogen. Typical data are summarized in Table 2.

Table 2. Phosphinothioic anhydrides (V) from diphosphine disulfides (II)

II	R	Solvent	Temp. (°C)	Time (hr)	V (%)
IIa	Ph	PhH	80	24	8
		PhMe	110	64	45
		Xylene	140	72	98
IIb	Et	PhH	80	29	0
		Xylene	140	93	12
		o-$Cl_2C_6H_4$	180	33	35
IIc	*n*-Bu	*o*-$Cl_2C_6H_4$	180	42	48

We see that both higher temperature and longer reaction time favor the formation of V. No V was formed in benzene at room temperature after a longer period even under oxygen stream. These observations suggest the homolytic cleavage of the P(S)–P(S) bond in II.

$$\underset{\text{II}}{R_2P(S)\text{–}P(S)R_2} \xrightarrow{\Delta} 2R_2\dot{P}\text{=}S \xrightarrow{O_2} \underset{\text{V}}{R_2P(S)\text{–}O\text{–}P(S)R_2}$$

a, R=Ph; b, R=Et; c, R=*n*-Bu

IIa reacts at lower temperature because of the formation of more stable $Ph_2P(S)\cdot$ radical.

In the cases of aliphatic diphosphine disulfides, especially IIc, the formation of unidentified decomposition products was observed by tlc.

Thus, ethylene insertion reaction of II[6] is considered to proceed through homolysis of the P(S)–P(S) bond followed by the addition of $R_2P(S)\cdot$ radicals to ethylene, since the reaction is carried out at 275°C for 48 hr.

Similarly the reaction of IIa with sulfur gave bis(diphenylphosphinothioyl) sulfide (VIII) in refluxing *o*-dichlorobenzene under nitrogen.

$$\underset{\text{IIa}}{Ph_2P(S)\text{–}P(S)Ph_2} \longrightarrow 2Ph_2\dot{P}\text{=}S \xrightarrow{S_8} \underset{\text{VIII}}{Ph_2P(S)\text{–}S\text{–}P(S)Ph_2}$$

Photolysis of Diphosphine Disulfides (II). It has been reported that tetraphenyldiphosphine undergoes homolysis on irradiation of light or on heating at above 180°C,[13,14] but there is no report on the homolytic fission of II, except for the above results.

In the photolysis of II, evidences for the homolytic fission of the P(S)–P(S) bond were also obtained.

At room temperature, no Vb could be detected on irradiation of IIb with a high pressure mercury lamp in carbon disulfide or in methanol for 18—28 hr, even in the presence of rose bengal as a sensitizer, and IIb was recovered. On the other hand, irradiation of IIb in benzene with a low pressure (LP) mercury lamp for 19 hr under oxygen gave 59% of sulfur and 18% of diethylphosphinic acid, along with a trace amount of Vb.

The result is explained by a homolytic cleavage of the P(S)–P(S) bond and oxidative desulfurization of the P=S groups.

$$\underset{\text{IIb}}{Et_2P(S)\text{–}P(S)Et_2} \xrightarrow{\text{LP } h\nu} 2Et_2\dot{P}\text{=}S \xrightarrow{O_2} \underset{\text{Vb}}{[Et_2P(S)\text{–}O\text{–}P(S)Et_2]}$$

$$\xrightarrow[O_2]{h\nu} 1/4S_8 + [Et_2P(O)\text{–}O\text{–}P(O)Et_2] \xrightarrow{H_2O} 2Et_2P(O)OH$$

Although IIb did not react with α,α′-azobisisobutyronitrile (AIBN) in refluxing benzene under irradiation with a high pressure mercury lamp, IIb gave a small amount of diethyl-1-cyano-2-methylethylphosphine sulfide (IX) on irradiation with a low pressure mercury lamp. Sulfide (IX) could not be isolated in pure state, but its presence was determined by IR (2240 cm^{-1}) and MS (*m/e* 189, M^+).

$$\underset{\text{IIb}}{Et_2P(S)\text{–}P(S)Et_2} + \left(Me_2C(CN)\text{–}N\text{=}\right)_2 \xrightarrow{\text{LP } h\nu} \underset{\text{IX}}{Et_2P(S)\text{–}CMe_2CN}$$

When IIa was irradiated in methanol under nitrogen for 6 hr with a low pressure mercury lamp, 52% of diphenylphosphine sulfide and 65% of *O*-methyl diphenylphosphinothioate were obtained. This reaction is also explicable in terms of homolysis as follows.

10) L. D. Quin and H. G. Anderson, *J. Org. Chem.*, **31**, 1206 (1966).
11) N. K. Patel and H. J. Harwood, *ibid.*, **32**, 2999 (1967).

$$Ph_2P(S)-P(S)Ph_2 \xrightarrow{LP\ h\nu} 2Ph_2\dot{P}=S$$

$$Ph_2\dot{P}=S + MeOH \longrightarrow \left[\begin{array}{c} Ph_2\dot{P}-\overset{+}{O}-Me \\ {}^{-}\!S\ \ H \end{array}\right]$$

$$\xrightarrow{Ph_2\dot{P}=S} Ph_2P(S)OMe + Ph_2P(S)H$$

A similar reaction has been reported in photolysis or thermolysis of tetraphenyldiphosphine in alcohols.[14]

The above results indicate that II undegoes homolytic cleavage of the P(S)–P(S) bond on irradiation with a low pressure mercury lamp, and are reasonable from the fact that the disulfides (II) in methanol exhibit absorption maximum at 236—248 nm.

Oxidation of Phenyl Diphenylphosphinothioite (X) with Silver Nitrate. When X was allowed to react with silver nitrate in carbon disulfide at room temperature, silver metal (70%), diphenyl disulfide (87%), and diphenylphosphinic acid (60%) were obtained. The reaction might be attributed to electron transfer from X to silver ion.

$$\underset{X}{Ph_2P\text{–}SPh} + AgNO_3 \longrightarrow \underset{XI}{[Ph_2P\text{–}SPh]^{\cdot+}} + Ag + NO_3^-$$

$$[Ph_2P\text{–}SPh]^{\cdot+} \longrightarrow Ph_2P^+ + PhS\cdot$$

$$2PhS\cdot \longrightarrow PhS\text{–}SPh$$

$$Ph_2P^+ + NO_3^- \longrightarrow \underset{XII}{[Ph_2PONO_2]} \xrightarrow[H_2O]{O_2} Ph_2P(O)OH$$

The formation of diphenylphosphinic acid is explained by oxidation of an intermediate XII followed by hydrolysis during isolation.

A similar reaction of trimethylsilyldiphenylphosphine with silver halides has been reported.[15] The reaction is also considered to proceed through a similar mechanism.

$$\underset{XIII}{Ph_2P\text{–}SiMe_3} + AgX \longrightarrow [Ph_2P\text{–}SiMe_3]^{\cdot+} + Ag + X^-$$

$$[Ph_2P\text{–}SiMe_3]^{\cdot+} \longrightarrow [Me_3Si^+] + Ph_2P\cdot$$

$$\downarrow X^- \qquad \downarrow$$

$$Me_3SiX \quad 1/2\ Ph_2P\text{–}PPh_2$$

In the radical cations (XI and XIII), it is shown that more electronegative group generates the free radical.

Experimental

Materials. The following compounds were prepared by the methods given in literature: tetraphenyldiphosphine dioxide[2,10] (mp 164—165°C), tetraethyl-[12,16] (mp 76—76.5°C), tetra-*n*-butyl-[12,16] (mp 71—72°C), tetraphenyldiphosphine disulfides[11] (mp 170—171.5°C), phenyl diphenylphosphinothioite[17] (mp 46—48°C) and peroxybenzoic acid.[18]

Oxidation with Perbenzoic Acid (III). Only typical examples are given.

a) Tetraphenyldiphosphine Dioxide (Ia): To 10 g (25 mmol) of Ia in 100 ml of dichloromethane was added dropwise III (30 mmol) in 150 ml of dichloromethane at room temperature for 40 min under stirring. The reaction was exothermic. When addition was completed, III had been almost consumed. After removal of the solvent, the residual solid was extracted with ether to remove benzoic acid. Crude anhydride thus obtained was dissolved in carbon tetrachloride followed by precipitation with petroleum ether, mp 137—138°C (lit,[19] 142—143°C), *m/e* 418 (M^+); yield 9.2 g (83%).

b) Tetraphenyldiphosphine Disulfide (IIa): To 4.35 g (10 mmol) of IIa in 100 ml of dichloromethane was added dropwise III (20 mmol) in 100 ml of dichloromethane at room temperature over a period of 2 hr. The mixture was stirred for further 30 min and extracted with 5% aqueous sodium carbonate. The organic layer was washed three times with 400 ml of water and dried with anhydrous sodium sulfate. After removal of the solvent, the residual tarry material was dissolved in benzene and the solution was concentrated to give crude anhydride. After removal of the solvent from the filtrate, the residue gave 18.5 mg (3%) of sulfur as the insoluble in dichloromethane. The solution was separated by preparative tlc. In total, 2.4 g (54%) of anhydride (Va), mp 192—194°C (lit,[19] 196—198°C), *m/e* 450 (M^+), was obtained and 0.62 g (14%) of IIa was recovered. The first aqueous layer was acidified with hydrochloric acid to give 0.187 g (4.3%) of diphenylphosphinic acid, mp 190—191°C (lit,[20] 194—196°C).

c) Tetraethyldiphosphine Disulfide (IIb): To 4.85 g (20 mmol) of IIb in 100 ml of dichloromethane was added dropwise III (30 mmol) in 100 ml of dichloromethane at about −50°C over a period of 2 hr under stirring. 5% of III remained after addition was completed. After standing for 3 hr at this temperature, the reaction mixture was extracted with 5% aqueous sodium bicarbonate. The organic layer was dried with anhydrous magnesium sulfate and the solvent was removed. The oily residue was chromatographed on alumina to separate sulfur (0.42 g, 33%), unchanged IIb (1.2 g, 25%) and anhydride (Vb). Crude anhydride thus obtained was again chromatographed on silica gel, and recrystallized repeatedly from petroleum ether, mp 34—36°C (lit,[21] 42.5°C), *m/e* 258 (M^+); yield 1.9 g (37%)(Found: C, 36.92; H, 8.14%). The aqueous alkaline layer was acidified with hydrochloric acid, and extracted with dichloromethane. After removal of dichloromethane the residue was extracted with water, and dried to give viscous liquid (1.2 g, 25%). The IR spectrum was superimposable with that of diethylphosphinic acid.

d) Triphenylphosphine Sulfide: To 1.47 g (5 mmol) of triphenylphosphine sulfide in 10 ml of dichloromethane was added dropwise III (15 mmol) in 15 ml of dichloromethane at room temperature under stirring. After standing for 6 days, the solvent was removed. The residue was washed with ether and then aqueous sodium bicarbonate, and recrystallized from benzene to give triphenylphosphine oxide (0.98 g, 71%), mp 154—155°C (lit,[22] 156°C). The ethereal washings were washed with 10% aqueous sodium bicarbonate to give 98 mg (61%) of sulfur.

Air Oxidation of Diphosphine Disulfides (II). *a) Tetraphenyl Derivative (IIa)*: A solution of IIa (4.4 g, 10 mmol)

in xylene (40 ml) was refluxed for 72 hr. Removal of the solvent under reduced pressure and washing of the residue, with ether gave 4.4 g (98%) of crude anhydride (Va), which was recrystallized from benzene, mp 198—199°C (lit,[19] 197—198°C), 3.9 g (87%).

b) Tetraethyl Derivative (IIb): A solution of IIb (0.72 g 3.0 mmol) in *o*-dichlorobenzene (30 ml) was refluxed for 33 hr. After removal of the solvent *in vacuo*, the residual brown oil (0.96 g) was chromatographed on silica gel. Elution with petroleum ether gave colorless oily material. Recrystallization from petroleum ether gave 0.27 g (35%) of Vb, mp 31—32°C (lit,[21] mp 42.5°C). The IR spectrum and R_f value on tlc were in agreement with those of an authentic sample.

c) Tetra-n-butyl Derivative (IIc): A solution of IIc(0.60g, 1.7 mmol) in *o*-dichloromethane (30 ml) was refluxed for 42 hr. After removal of the solvent *in vacuo*, the residual brown tarry material (0.64 g) was purified by means of preparative tlc (silica gel, with petroleum ether–acetone (8: 2)) to obtain pure Vc (0.30 g, 48%), which was oily. IR (liquid film), ν_{max} 920 (P–O–P) and 520 cm^{-1} (P=S); *m/e* 370 (M^+, 41%), 314 ($M^+-C_4H_8$, 28), 257 ($M^+-C_4H_8-C_4H_9$, 80), 193 ($Bu_2P(S)O^+$, 77), and 177 (Bu_2PS^+, 100).

Found: C, 52.02; H, 9.62%. Calcd for $C_{16}H_{36}OP_2S_2$: C, 51.85; H, 9.81%.

Reaction of IIa with Sulfur. A mixture of IIa (0.55 g, 1.3 mmol) and sulfur (58 mg, 1.8 mg-atom) in *o*-dichlorobenzene (50 ml) was refluxed for 8 hr under nitrogen. After removal of the solvent *in vacuo*, the residual brown solid was purified by preparative tlc (silica gel, with *n*-hexane–benzene (1: 1)). Crude sulfide (VIII) (0.45 g) was recrystallized twice from 2-propanol, mp 120—121°C (lit,[23] 118—121°C), 0.39 g (66%).

Photochemical Oxidation of IIb. The disulfide (IIb) (0.86 g, 3.55 mmol) in benzene (50 ml) was irradiated with a low pressure mercury lamp (10 W) under oxygen at room temperature for 19 hr. After removal of the solvent, a small amount of benzene was added for the purpose of obtaining sulfur. The solution was chromatographed on silica gel to give sulfur (in total, 0.134 g, 59%), a small amount of Vb and diethylphosphinic acid (0.142 g, 18%) with petroleum ether and ether as eluent, respectively. The IR spectrum of diethylphosphinic acid was superimposable with that of an authentic sample.[20]

Photolysis of IIb in the Presence of AIBN. A mixture of IIb (1.2 g, 5 mmol) and AIBN (5.1 g, 31 mmol) in dichloromethane (100 ml) was irradiated for 10 hr with a low pressure mercury lamp (160 W) under nitrogen. After removal of the solvent and sublimation of tetramethylsuccinodinitrile *in vacuo*, the oily residue containing about ten components was separated by silica gel dry column chromatography (with petroleum ether–acetone (3:2)). The fraction of R_f 0.66 exhibited a peak at *m/e* 189, corresponding to the parent peak of diethyl-1-cyano-1-methylethylphosphine sulfide, and a weak band at 2240 cm^{-1} (C≡N). The fraction was also impure and further purification was difficult.

Photolysis of IIa in Methanol. A solution of IIa (0.54 g, 1.2 mmol) in absolute methanol (80 ml) and dichloromethane (40 ml) was irradiated with a low pressure mercury lamp (10 W) for 5 hr with water-cooling under nitrogen. After removal of the solvent, the residual viscous oil was separated into two components by silica gel dry column chromatography (with chloroform). One component was *O*-methyl diphenylphosphinothioate (0.20 g, 65%) mp 82—84°C (from *n*-hexane) (lit,[24] 84.5—85.5°C), and the other was diphenylphosphine sulfide (0.14 g, 52%), mp 93—95°C (lit,[25] 95—97°C).

Oxidation of Phenyl Diphenylphosphinothioite (X) with Silver Nitrate. To a solution of X (0.81 g, 2.76 mmol) in carbon disulfide (20 ml) was added under nitrogen silver nitrate (0.48 g, 2.8 mmol), the surface of which turned yellow at first and then black. After being stirred at room temperature overnight, a black precipitate containing mainly metallic silver and a small amount of silver diphenylphosphinate (by IR), was filtered off and the filtrate was evaporated. The residue was extracted with ether to leave 0.36 g (60%) of diphenylphosphinic acid, mp 190—191°C. The extract gave 0.26 g (87%) of diphenyl disulfide, mp 58—60°C.

A Novel Degradation Pathway of L-Ascorbic Acid under Non-oxidative Conditions[1]

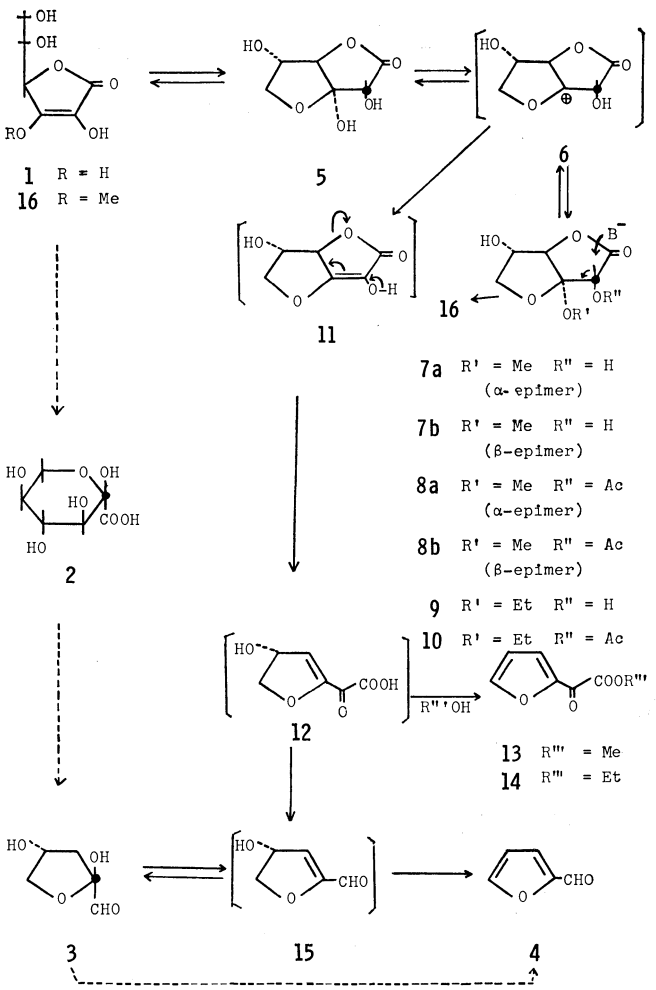
Kazuaki GOSHIMA, Norihide MAEZONO, and Kanji TOKUYAMA
Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553
(Received July 7, 1972)

The degradation of L-ascorbic acid (**1**) in methanol was studied in the presence of boron trifluoride-etherate under non-oxidative conditions. Two epimeric compounds containing an acetal group (**7a** and **7b**) were isolated as the intermediates and 2-methoxalylfuran (**13**) the final product. From the result, the degradation pathway of **1** in methanol was proposed to be **1**→**7**→**13**. By analogy with the proposed pathway, one in an aqueous acid was also presented.

It is well known that L-ascorbic acid (**1**) decomposes to 2-furaldehyde (**4**) and carbon dioxide in aqueous acids under non-oxidative conditions.[2,3] Many extensive studies have been reported on the mechanism of this degradation reaction.[3-9] From the kinetic point of view, Regna and Caldwell[5] and Yamamoto and Yamamoto[3] have concluded that the degradation does not proceed *via* L-xylo-2-hexulosonic acid (**2**),[2] the hydrolyzed product of **1**, as an intermediate. Several pathways have been proposed in which that conclusion was expanded.[6,7] However, no experimental proofs on their proposed pathways have been provided. On the other hand recently, Kurata and Sakurai[9] have succeeded in the first isolation of an intermediate, 3-deoxy-L-2-pentosulose (**3**), and proposed a novel pathway of **1**→**2**→**3**→**4**.

Although the isolation of **3** was very important, their conclusion as to the degradation pathway seemed to be in conflict with the kinetic results from which a possible pathway of the degradation can be presented as (**2**→)**1**→**3**→**4**. This disagreement in the interpretation of the role of **3** prompted us to study the degradation of **1**. For the purpose, the degradation of **1** in methanol containing boron trifluoride-etherate was studied as a model reaction.

When **1** in methanol was refluxed in the presence of boron trifluoride for about 10—15 hr, three spots appeared in the tlc, though some of the starting material, **1**, remained unchanged. From the product, **7a**, **7b**, and 2-methoxalylfuran (**13**)[8] were successfully isolated by means of preparative thin-layer chromatography. Compounds **7a** and **7b** had correct analyses for **1** plus one mole of methanol minus one mole of water.



They showed the characteristic bands due to hydroxyl and γ-lactone groups in the IR spectra. Their acetylation gave diacetates, **8a** from **7a** and **8b** from **7b**, which showed the absence of a hydroxyl group in the IR spectra and a singlet due to one methoxy group in the NMR. By the deacetylation of **8a** with a potassium carbonate solution, **7a** was recovered; further, small amounts of **7b** and 3-*O*-methyl-L-ascorbic acid (**16**)[10] were detected. A similar result was obtained for the deacetylation of **8b**, which gave **7b** as the major product and **7a** and **16** as minor products. Therefore,

10	$CDCl_2$	4.29	5.21	4.78	5.45	6.01					
	C_6D_6	4.29	5.49	5.95	5.75	6.20					

7a and **7b** must be epimers to each other.

The formation of **16** was interesting; it occurred by the further reactions of **7a** and **7b**, initially formed by the deacetylation, with the base employed. The fact that the alkaline treatment of **7a** easily afforded **16** supports this idea and suggests that the position of the methoxy group of **7** corresponds to the C_3-position of **1**. Therefore, the structures of **7a** and **7b** were determined to be the acetal derivatives of **1**, as is shown in the chart.

The structures were confirmed by the NMR spectra, the data of which are reported in Table 1. In the NMR spectrum of **8a** in chloroform-*d* at 60 MHz, three singlets due to one methoxy and two acetoxy groups, a singlet due to H_2 and signals appearing as the pattern of an ABXY system due to H_6, H_6', H_5, and H_4 were observed. The NMR spectrum of **8b** was similarly assigned.

The easy exchange of the methoxy group of **7a** with an ethoxy group also supported the idea of the existence of an acetal group in **7**. When **7a** in ethanol was refluxed in the presence of boron trifluoride, the ethoxy analog of **7a** (**9**) and 2-ethoxalylfuran (**14**) were obtained. The structure of **9** was determined by its conversion into its diacetate (**10**), whose NMR spectrum was assigned in a way similar to that used for **8a** (see Table 1). The structure of **14** was established from the IR and mass spectra, which are quite similar to those of **4**[11] and **13**.[8] Another compound was detected on the tlc. It was considered to be the ethoxy analog of **7b**, but an attempt of its isolation was unsuccessful because of its limited amount.

We will now describe how the epimeric structures of **7a** and **7b** were determined. It is quite natural to consider that the configuration of the 3-methoxy group should be α, since a *cis*-form is more stable in bicyclo-[3.3.0]octanes.[12] Therefore, **7a** should be the C_2-epimer of **7b**. In the acid treatment of **1**, the yield of **7a** was always higher than that of **7b**. Further, in the acid-catalyzed epimerization of **7**, the yield of **7a** was always higher, too. These facts demonstrate that **7a** is a stable epimer. Therefore, the configuartion of the 2-hydroxyl group of **7a** must be α, since the compound with the OH-*exo* configuration to the tetrahydrofuran ring is more stable than that with the OH-*endo* configuration, from the stereochemical point of view.

The CD curves for **7a** and **7b** in UV spectral region have peaks at 236 and 231 nm, respectively. The positive Cotton effect of **7a** suggests that the β-atom of the lactone exists above the lactone plane and the negative one of **7b** suggests the opposite conformation.[13,14] On the other hand, their diacetates, **8a** and **8b**, show a positive Cotton effect. The difference in conformations of the lactone ring between **7b** and the other compounds supported the above-described epimeric structures. The conformation of **7b** must be affected by the presence of a hydrogen bond between the 2-hydroxy group and the oxygen atom of the tetrahydrofuran ring; the presence of the hydrogen bond cannot be considered in the cases of the other compounds. When the hydrogen bond of **7b** disappears upon the acetylation of the 2-hydroxy group, the conformation may be effected to be transformed a conformation similar to the others; that is, the sign of the Cotton effect in **8b** was in accord with those of **7a** and **8a**. The presence of the hydrogen bond in **7b** was also evidenced by the IR spectrum in chloroform.

When **1** was treated in methanol containing boron trifluoride, the spots of **7a** and **7b** appeared on the tlc at the initial stages of the reaction, and then there appeared **13**, which increased at the expense of **7**. Therefore, the reaction was concluded to proceed *via* the pathway of **1**→**7**→**13**. This apthway was further supported by the fact that the acid treatment of **7** afforded **13**. In this treatment, a small amount of **1** was also detected, so the presence of an equilibrium between **1** and **7** was confirmed.

In conclusion, on the basis of the above results, the acid-catalyzed degradation of **1** in methanol may be said to proceed *via* the pathway of **1**→**5**→**6**→**11**→**12**→**13** as is shown in the chart. By analogy with this conclusion, the possible pathway of the degradation of **1** in water can be proposed to be **1**→**5**→**6**→**11**→**12**→**15**→**4**, as is shown in the chart. The interesting intermediate, **3**, reported by Kurata and Sakurai[9] can reasonably be explained as the hydrate of a possible intermediate, **15**.

Experimental

All the melting points were recorded on a Kofler block and have not been corrected. The NMR spectra were taken with a Varian A-60-A spectrometer, using tetramethylsilane as the internal reference; the data are reported in

Table 1. Thin-layer chromatography was performed on a silica-gel plate using acetone and chloroform [5: 5, v/v (Solvent A) and 6: 4, v/v (Solvent B)] as the solvent for both detection and preparation. The separated materials were developed with either iodine vapor or UV light. The R_f-values are shown in Table 2. In the case of preparative thin-layer chromatography (ptc), the developed zones were extracted with acetone. The evaporation of the acetone under reduced pressure gave the materials.

Table 2. R_f-values of products

Compound	Solvent A	Solvent B
1	0.13—0.18	
7a	0.50—0.59	0.48—0.49
7b	0.53—0.63	—0.57
13	0.84—0.91	0.28—0.40
16	—0.20	

Reaction of L-*Ascorbic Acid (1) in the Presence of Boron Trifluoride-etherate.* (i) A solution of **1** (5.0 g) in absolute methanol (100 ml) containing boron trifluoride-etherate (5 ml) was refluxed for 10 hr and neutralized with triethylamine (7.5 ml), and then the solvent was removed. The preparative thin-layer chromatography of the residue with Solvent A afforded a mixture syrup of **7a** and **7b** (1.20 g) and crystals of **13** (0.3 g). The further ptc of the mixture syrup with Solvent B yielded **7a** (449 mg) and **7b** (169 mg) in pure states.

7a: mp 167—169°C. $[\alpha]_D^{26}$ +2.7 (*c* 1.031, methanol). CD (methanol) $[\phi]_{251}$ 0, $[\phi]_{226}$ +1351. $IR_{cm^{-1}}^{Nujol}$ 3480, 3390 (OH), 1790 (γ-lactone). Found: C, 44.24; H, 5.42%. Calcd for $C_7H_{10}O_6$: C, 44.21; H, 5.30%. **7b**: mp 94—95°C. $[\alpha]_D^{21.5}$ +73.9 (*c* 1.016, methanol), CD (methanol) $[\phi]_{257}$ 0, $[\phi]_{231}$ −1698, $IR_{cm^{-1}}^{Nujol}$ 3360, 3160 (OH), 1780 (γ-lactone). $IR_{cm^{-1}}^{CHCl_3}$ 3607 (free OH), 3578 (bonded OH). Found: C, 44.47; H, 5.19%. Calcd for $C_7H_{10}O_6$: C, 44.21; H, 5.30%.

(ii) A solution of **1** (2.0 g) in methanol (40 ml) containing boron trifluoride-etherate (2 ml) was refluxed for 15 hr and neutralized with triethylamine, and then the solvent was removed. The residue was washed with acetone. The remaining crystals (702 mg) were identified as **1**. The repeated preparative thin-layer chromatography of the acetone-soluble part with Solvents A and B afforded **1** (377 mg), **7a** (275 mg), **7b** (82 mg), and **13** (103 mg).

Reaction of **7a**. *1) Acetylation*: To a solution of **7a** (4.0 g) in pyridine (20 ml) we added acetic anhydride (20 ml) under cooling, after which the solution was left in a refrigerator overnight. The solution was evaporated to dryness and the residue was recrystallized from ether and petroleum ether. The acetate of **7a** (**8a**) was thus obtained. The yield was 5.68 g. Mp 105—106°C. $[\alpha]_D^{21}$ +58.9 (*c* 1.025, chloroform). CD (methanol) $[\phi]_{250}$ 0, $[\phi]_{216}$ +9100. $IR_{cm^{-1}}^{Nujol}$ 1806, 1740 (C–O), $IR_{cm^{-1}}^{CCl_4}$ 1820, 1760 (C=O). Found: C, 48.37; H, 5.18%. Calcd for $C_{11}H_{14}O_8$: C, 48.18; H, 5.15%.

2) Deacetylation of **8a**: To a solution of **8a** (600 mg) in methanol (12 ml) we added a solution of potassium carbonate (600 mg) in water (3 ml). The solution was left at room temperature for 1 hr, neutralized with Amberlite IR-120 (H^+) (25 ml), and then evaporated to dryness. The preparative thin-layer chromatography of the residue with Solvent B afforded **7a** (373 mg), **7b** (39 mg), and **16** (44 mg).

3) Base-catalyzed Reaction: A solution of potassium carbonate (700 mg) in water (3.5 ml) was added to a solution of **7a** (700 mg) in methanol (14 mg). The solution was allowed to stand at room temperature for 2.5 hr, neutralized with Amberlite IR 120 (H^+) (25 ml), and then evaporated to dryness. The preparative thin-layer chromatography of the residue with Solvent B afforded **7a** (499 mg), **7b** (57 mg), and **16** (67 mg).

4) Acid-catalyzed Reaction: (i) Methanol as a solvent: A solution of **7a** (700 mg) in absolute methanol (14 ml) containing boron trifluoride-etherate (0.7 ml) was refluxed for 15 hr, neutralized with triethylamine (0.5 ml), and then evaporated to dryness. The preparative thin-layer chromatography of the residue with Solvent A afforded **1** (105 mg), **7a** (349 mg), **7b** (22 mg), and **13** (118 mg).

(ii) Ethanol as a solvent: A solution of **7a** (1.0 g) in absolute alcohol (20 ml) containing boron trifluoride-etherate (1.0 ml) was refluxed for 6 hr. The solution was neutralized with triethylamine (1 ml) and then the solvent was removed. The preparative thin-layer chromatography of the residue with a mixture of acetone and chloroform (6: 4, v/v) afforded **1** (47 mg, R_f 0.06), **9** (493 mg, R_f 0.46), and **7a** (211 mg, R_f 0.85). **9**: Mp 144—145.5°C. $[\alpha]_D^{21}$ −2.5 (*c* 1.021, methanol). $IR_{cm^{-1}}^{Nujol}$ 3570, 3450 (OH), 1815 (C=O). Found: C, 47.33; H, 5.96%. Calcd for $C_8H_{12}O_6$: C, 47.06; H, 5.92%. **14**: Mp 29—29.5°C. $IR_{cm^{-1}}^{CCl_4}$ 1735, 1677 (C=O), C=C), 886 (furan).[15] Found: C, 56.39; H, 4.85%. Calcd for $C_8H_8O_4$: C, 57.14; H, 4.80%.

Compound **9** was acetylated in a way similar to that used in the acetylation of **7a**. The acetate of **9** (**10**): syrup. $[\alpha]_D^{20}$ +48.2 (*c* 0.901, chloroform). IR $_{cm^{-1}}^{CCl_4}$ 1815, 5757. Found: C, 50.00; H, 5.60%. Calcd for $C_{12}H_{12}O_8$: C, 50.02; H, 5.61%.

Reaction of **7b**. *1) Acetylation*: Acetic anhydride (5 ml) was added to a solution of **7b** (1.0 g) in pyridine (5 ml) under cooling. The solution was left overnight in a refrigerator and then evaporated to dryness. The recrystallization of the residue from acetone and ether gave **8b** (1.2 g). Mp 98.5—100°C. $[\alpha]_D^{26}$ +155.8 (*c* 1.053, chloroform). CD (methanol) $[\phi]_{265}$ 0, $[\phi]_{223}$ +4824, $[\phi]_{205}$ +2396. IR $_{cm^{-1}}^{Nujol}$ 1788, 1750 (C=O). IR $_{cm^{-1}}^{CCl_4}$ 1810, 1760 (C=O). Found: C, 47.99; H, 5.34%. Calcd for $C_{11}H_{14}O_8$: C, 48.18; H, 5.15%.

2) Deacetylation of **8b**: A solution of potassium carbonate (1.0 g) in water (5 ml) was added to a solution of **8b** (1.0 g) in methanol (20 ml). The mixture was allowed to stand at room temperature for 1 hr and then neutralized with Amberlite IR 120 (H^+) (40 ml). After the removal of the solvent, the residue was fractionated by ptc (Solvent A) to give 128 mg of **7a**, 261 mg of **7b**, and 20 mg of **16**.

3) Acid-catalyzed Reaction: A solution of **7b** (700 mg) in absolute methanol (14 ml) containing boron trifluoride-etherate (0.7 ml) was refluxed for 15 hr and then worked up in a way similar to that used for **7a** (Reaction of **7a**, *4*). L-Ascorbic acid **1** (157 mg), **7a** (98 mg), **7b** (85 mg, and **13** (74 mg) were thus obtained.

Autoxidation of Aromatic Hydrocarbons Catalyzed with Cobaltic Acetate in Acetic Acid Solution. II. Oxidation of Ethylbenzene and Cumene[1)]

Yoshio KAMIYA and Mikito KASHIMA
Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo
Polymer Research Laboratory, Ube Ind. Ltd., Goi, Ichihara, Chiba

(Received July 12, 1972)

The oxidation of ethylbenzene and cumene catalyzed with cobaltic acetate in acetic acid was studied kinetically in order to elucidate the reaction mechanism and the roles of cobaltic salt. The maximum absorption rate of oxygen as well as the maximum reduction rate of Co(III) in the oxidation of ethylbenzene or cumene were of first order with respect to the initial concentration of hydrocarbon, of inverse first order with respect to the initial concentration of Co(II), and of second order with respect to the initial concentration of Co(III). The kinetic equations are therefore just the same as in the case of toluene, but $d[Co(III)]/d[O_2]$ gave a quite different average value of 3.8, showing that almost no regeneration of Co(III) from Co(II) due to oxidation with peroxidic compounds occurred. Both rates were remarkably accelerated by the addition of sodium acetate and also influenced by a small amount of water. The order of oxygen absorption rate in oxidation was toluene>ethylbenzene>cumene in contrast to the order of hydrogen abstraction rate by peroxy radicals. The apparent activation energy for these hydrocarbons was found to be 10.1 kcal mol^{-1}.

Many papers have appeared on the mechanism of the initiation step in the autoxidation of ethylbenzene[1-3)] and cumene.[4-9)] The main role of transition metal salts established in the autoxidation of hydrocarbons with secondary and primary C–H bond is to decompose hydroperoxide[10-12)] into radicals by the following reactions.

$$M^{n+} + ROOH \longrightarrow M^{n+1} + RO\cdot + OH^-$$
$$M^{n+1} + ROOH \longrightarrow M^{n+} + ROO\cdot + H^+$$

However, another role of transition metal salts has been clarified recently, in which the hydrogen abstraction from hydrocarbon with a higher valence metal ion plays an important role in the reaction of methylbenzenes as follows.

$$M^{n+1} + RH \longrightarrow R\cdot + M^{n+} + H^+$$

We reported on the oxidation of toluene with cobaltic acetate either in the presence and the absence of oxygen and proposed that the reaction was initiated by an electron transfer equilibrium between cobaltic acetate and toluene.[13,14)]

The present kinetic study was undertaken in order to elucidate the reaction mechanism in the oxidation of ethylbenzene and cumene catalyzed with cobaltic acetate in acetic acid solution. The results were compared with those obtained in the oxidation of toluene.

Experimental

Materials. Ethylbenzene, cumene, benzene, and chlorobenzene were repeatedly shaken with concentrated sulphuric acid until no coloration was observed. They were then fractionally distilled after being washed with water and dried over calcium chloride. Acetic acid and cobaltous acetate were of reagent grade. Cobaltic acetate was prepared by the same method as in Part I[14)] and its concentration was determined by potentiometric titration.[13)] The amount of water in the solution was measured by Karl-Fischer titration. Ordinary reaction mixture containing 1.5—2.0M water was prepared unless otherwise stated.

Procedure. The oxidation apparatus and method were the same as in Part I.

Analysis. The solution after oxidation was poured into water of equal volume and extracted with ether. The extract was washed with aqueous sodium hydroxide and analyzed by gas chromatography with a Shimadzu model GC-20 with a 2.2 m column packed with D.O.P. on Celite 545; helium flow rate, 50 ml-min^{-1}, at 140°C. Analysis confirmed the formation of acetophenone and a small amount of α-phenylethanol and α-phenylethyl acetate in the oxidation of ethylbenzene. The main products in the oxidation of cumene were acetophenone, cumylalcohol and α-methylstyrene.

Results and Discussion

Oxidation of Cumene. Cumene can be easily oxidized with oxygen in acetic acid at 60°C, when cobaltic acetate is employed as a catalyst. Oxidation proceeded without induction period, the initial absorption rate of oxygen becoming the maximum rate of oxidation.

The initial oxidation rate and its rate constant in the oxidation of cumene are given in Table 1. The initial rate of oxidation was of first order with respect to the initial concentration of cumene, and of inverse first

order with respect to the initial concentration of cobaltous ion. The initial rate also was of first order with respect to the total cobalt ion, when the molar ratio of cobaltic to total cobalt ions was kept constant. However, when the inverse first order dependence of the initial rate on the initial concentration of cobaltous ion is taken into account, the over-all reaction should be of second order with respect to cobaltic ion concentration. Although the rate constants present good accordance within each set of experiment, they show a considerable discrepancy between individual sets. This may be mainly due to the difference of water concentration in the course of Co(III) preparation, since water remarkably influences the initial rate of oxidation.

The initial absorption rate of oxygen can be expressed as follows.

$$-d[O_2]/dt = k[\phi\text{-}CH(CH_3)_2][Co(III)]^2[Co(II)]^{-1}$$

The initial reduction rate of Co(III) and its rate constant in the typical oxidation of cumene with cobaltic acetate in acetic acid at 60°C are given in Table 2. The result is similar to that in Table 1.

Thus, the initial reduction rate of Co(III) can be expressed as follows.

TABLE 2. CONSUMPTION RATE OF Co(III) AND RATE CONSTANTS IN OXIDATION OF CUMENE, 60°C, O_2: 1 atm

ϕ-$CH(CH_3)_2$ (M)	Co(III) (M)	Co(II) (M)	$-d[Co(III)]/dt$ (M/sec)	$k'\times10^5$ (l/M·sec)

				5.69

$$-d[Co(III)]/dt = k'[\phi\text{-}CH(CH_3)_2][Co(III)]^2[Co(II)]^{-1}$$

The reduction rate takes the value of 4.0×10^{-6} mol·l^{-1}·sec^{-1}, when cumene concentration is extrapolated to zero. This suggests that self-decomposition of Co(III) takes place in the early stage of reaction. Although it is considered that methyl radical ($\cdot CH_3$) or carboxymethyl radical ($\cdot CH_2COOH$) may be produced with self-decomposition of Co(III), they will not significantly contribute to the initial rate of oxidation and the initial reduction rate of Co(III) at higher concentration of cumene. In this case also there is an appreciable difference between rate constants of the two sets of experiment. This may be due to the concentration of water in the solution varies to some extent according to preparation condition of Co(III).

Oxidation of Ethylbenzene. The initial rate of oxidation and its rate constant in the oxidation of ethylbenzene with cobaltic acetate in acetic acid at 60°C are given in Table 3. The absorption rate of oxygen can be expressed by a similar equation to that obtained in the oxidation of toluene and cumene:

$$-d[O_2]/dt = k''[\phi\text{-}CH_2CH_3][Co(III)]^2[Co(II)]^{-1}$$

The initial reduction rate of Co(III) in the oxidation of ethylbenzene can also be expressed by a similar equation to that obtained in the oxidation of toluene and cumene.

$$-d[Co(III)]/dt = k'''[\phi\text{–}CH_2CH_3][Co(III)]^2[Co(II)]^{-1}$$

Reaction Products. When cobaltic acetate was employed as a catalyst, the main products in the oxidation of cumene were acetophenone, cumyl alcohol and α-methylstyrene. The product distribution differs considerably from that obtained in the autoxidation of cumene, *viz.*, the molar ratio of acetophenone to (cumyl alcohol+α-methylstyrene) is about 1.2 (Fig. 1). However, the difference in the ratio of ketone to alcohol can be attributed to the effect of dilution.[12]

Figure 2 shows a comparison of consumption curves of Co(III) under oxygen atmosphere with those under argon atmosphere in the oxidation of toluene, ethylbenzene, and cumene. The regeneration of Co(III)

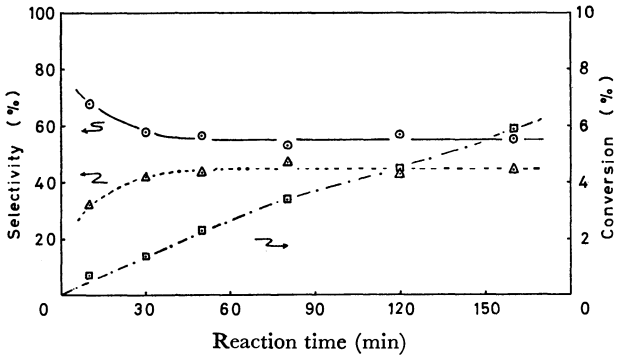

Fig. 1. Products distribution in oxidation of cumene

⊙: Acetophenone, △: Cumyl alcohol + α-Methylstyrene

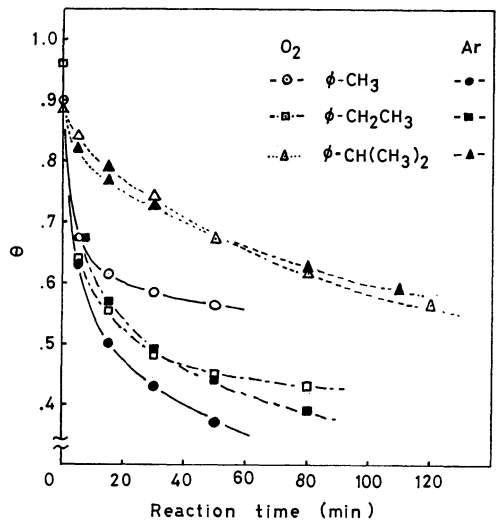

Fig. 2. Consumption curves of Co(III) in oxidn. of ϕ-CH_3, ϕ-CH_2CH_3 and ϕ-$CH(CH_3)_2$ at 60°C.

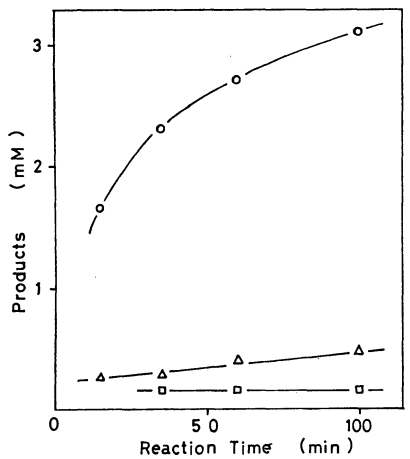

Fig. 3. Products distribution in Co(III) oxidn. of ϕ-CH_2CH_3.
ϕ-CH_2CH_3: 1.36M, Co(III): 0.19M, Co(II): 0.04M, 60°C, O_2: 1 atm.
○: $\phi COCH_3$, △: ϕ-$CH(OH)CH_3$, □: ϕ-$CH(OAc)\ CH_3$

was not observed in the oxidation of ethylbenzene or cumene in contrast to toluene.

The main products in the oxidation of ethylbenzene with Co(III) were acetophenone, α-phenylethanol and α-phenylethyl acetate (Fig. 3). The salient point of product distribution is that the molar ratio of ketone to alcohol is large in comparison to that obtained in the autoxidation of ethylbenzene. This is probably due to the subsequent oxidation of α-phenylethanol and the reaction of peroxy radical with cobaltic acetate.

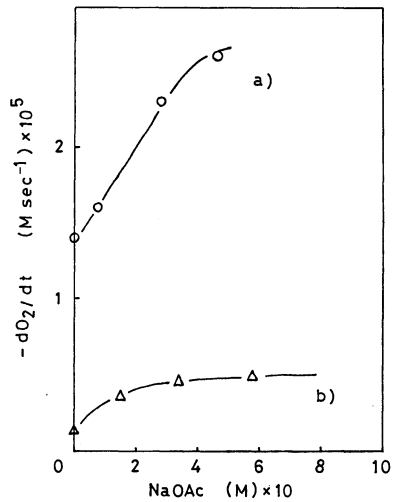

Fig. 4. Effect of NaOAc on initial rate
a) ϕ-CH_2CH_3: 1.26M, Co(III): 0.166M, Co(II): 0.017M.
b) ϕ-$CH(CH_3)_2$: 0.599M, Co(III): 0.153M, Co(II): 0.040M

Effect of Sodium Acetate. In the oxidation of cumene and ethylbenzene with cobaltic acetate in acetic acid, the initial rate of oxidation as well as the initial reduction rate of Co(III) were remarkably accelerated by the addition of sodium acetate (Fig. 4).

Table 4. Solvent effect
Co(III): 0.106M, Co(II): 0.080M, 60°C

ϕ-CH_2CH_3 (ml)	AcOH (ml)	ϕ-Cl (ml)	ϕ-H (ml)	$-dO_2/dt$ ($M \cdot sec^{-1}$)
5.0	60	—	—	1.01×10^{-5}
5.0	45	15	—	1.57
5.0	30	30	—	2.45
5.0	30	—	30	1.78

This can be explained as follows. Since the dissociation constant of sodium acetate in acetic acid is relatively large (1.3×10^{-6}),[15] a cobaltic ion is easily coordinated with an extra acetate anion and forms an active cobalt ion with coordination number greater than three.[16,17]

Solvent Effect. A remarkable positive solvent effect is observed in oxidizing ethylbenzene with cobaltic acetate, when a part of acetic acid is replaced with benzene or chlorobenzene. The initial rate of oxidation increases linearly as the amount of benzene or chlorobenzene is increased (Table 4). This suggests that the solvation of acetic acid around Co(III) is relieved by the addition of neutral solvent and it becomes easy for cobaltic ion to interact with ethylbenzene and the initial rate of oxidation is enhanced

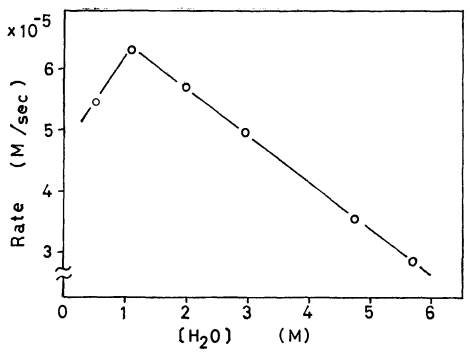

Fig. 5. Plots of initial rate *vs.* $[H_2O]_0$
ϕ-CH_2CH_3: 0.74M, Co(III): 0.21M, Co(II): 0.01M, 60°C, O_2: 1 atm.

by the dilution of acetic acid.

When alkylbenzenes are oxidized with cobaltic acetate in acetic acid, water remarkably influences the initial rate of oxidation. The initial rate in the oxidation of ethylbenzene increases as water concentration increases and reaches the maximum value at water concentration of about 1.0 mol·l^{-1} (Fig. 5). This can be explained as follows. The presence of a small amount of water makes the concentration of monohydroxide of cobaltic acetate increase which is more active than triacetate. When the concentration of water becomes very high, however, the deactivation effect of cobaltic ion with water will overcome the activation effect.

Effect of Reaction Temperature. The Arrhenius plot for the oxidation of toluene, ethylbenzene, and cumene with cobaltic acetate is shown in Fig. 6. The apparent activation energies (10.1 kcal·mol^{-1}) were found to be the same. The order of relative reactivities was toluene>ethylbenzene>cumene, a complete reverse of that expected from the C–H bond energy, *viz.*, the rate constant was profoundly affected in an inverse way to the case of oxidation by free radicals. The results are not explicable in terms of the C–H bond rupture process, but support the view that the electron transfer process is rate-determining.

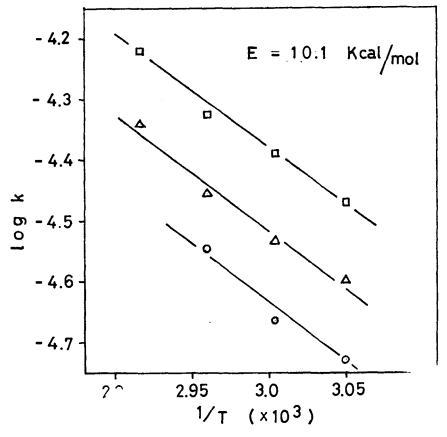

Fig. 6. Effect of reaction temp. on rate of aromatic hydrocarbon oxidn.
RH: 1.0M, Co(III): 0.13M. Co(II): 0.03M, O_2: 1 atm.
(—○—): ϕ-$CH(CH_3)_2$, (—△—): ϕ-CH_2CH_3, (—□—): ϕ-CH_3

Reaction Mechanism. We proposed that the active species of cobalt ion is a dimer of cobaltic ion or quadrivalent cobalt ion because the absorption rate of oxygen is of second order with respect to cobaltic ion and of inverse first order to cobaltous ion concentration.[14] We also postulated the following electron transfer equilibrium in the early stage of reaction.

$$Co(III)_2 + RH \rightleftarrows [RH^+AcO^-Co(III)] + Co(II)$$

$$[RH^+AcO^-Co(III)] \longrightarrow R\cdot + Co(III) + AcOH$$

The electron transfer equilibrium can be applied to the oxidation of ethylbenzene or cumene. The following reactions will mainly contribute to the oxidation of ethylbenzene or cumene with cobaltic acetate in the early stage of reaction.

$$2Co(III) \overset{K_1}{\rightleftarrows} Co(III)_2 \quad (1)$$

$$Co(III)_2 + RH \overset{K_2}{\rightleftarrows} [RH^+AcO^-Co(III)] + Co(II) \quad (2)$$

$$[RH^+AcO^-Co(III)] \overset{k_3}{\longrightarrow} R\cdot + Co(III) + AcOH \quad (3)$$

$$R\cdot + O_2 \overset{k_4}{\longrightarrow} ROO\cdot \quad (4)$$

$$ROO\cdot + Co(III) \overset{k_5}{\longrightarrow} \text{ketone} + H^+(\text{or } CH_3^+) + Co(II) + \frac{1}{2}O_2 \quad (5)$$

where R· is ϕ-$CHCH_3$ or ϕ-$C(CH_3)_2$ and ROO· is the corresponding peroxy radical. The difference in reactivities toward cobaltic acetate may be ascribed to that of the entropy decrease of the hydrocarbon in the transition state. When the rate determining step is reaction (3), the rate of oxygen absorption in the early stage of reaction can be expressed as follows.

$$-d[O_2]/dt = \frac{1}{2}K_1K_2k_3[RH][Co(III)]^2[Co(II)]^{-1}$$

The rate of Co(III) reduction in the early stage of reaction can be calculated as follows.

$$-d[Co(III)]/dt = 2K_1K_2k_3[RH][Co(III)]^2[Co(II)]^{-1}$$

Thus, the ratio of $d[Co(III)]/d[O_2]$ is 4. The value is nearly equal to that obtained from Tables 1 and 2 and would be comparable with the value of 1.7 in the case of toluene, in which the regeneration of Co(III) by oxidation product takes place.

Linear Conjugated Systems Bearing Aromatic Terminal Groups. XI. Syntheses and Electronic Spectra of α,ω-Diphenanthrylpolyenes

Yasuhira TAKEUCHI, Akio YASUHARA, Shuzo AKIYAMA, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received July 21, 1972)

The syntheses of α,ω-di(2-phenanthryl)-, di(3-phenanthryl)-, and di(9-phenanthryl)polyenes (I_n, I_n', and I_n'', $n=1$—6) by means of the Wittig reaction are described. Formylphenanthrenes (II, II′, II″), phenanthrylpropenals (III′, III″), phenanthrylpentadienals (IV, IV′, IV″) and muconaldehyde (VIII) were used as carbonyl components in the reaction. Phenanthrylmethyl-, phenanthrylpropenyl- and phenanthrylpentadienyltriphenylphosphonium bromides and 1,4-bis(triphenylphosphonium)-2-butene dibromide were converted into phosphoranes (V, V′, V″, VI, VI′, VII″, IX, IX′, IX″, VII) by a reaction with phenyllithium. The reaction of carbonyl components with phosphoranes with a proper combination yielded diphenanthrylpolyenes (I_n, I_n', I_n''). 2- and 3-Phenanthryl derivatives (I_n and I_n') exhibited electronic spectra with well-defined vibartional fine structure, whereas 9-phenanthryl derivative (I_n'') showed broad and structureless absorption curves. It was found that the plots of the longest-wavelength maxima (λ_{max}) of I_n and I_n' against $n^{0.6}$ and $n^{0.8}$ give excellent straight lines which can be given by the empirical formulas:

I_n: $\lambda_{max} = 57.9n^{0.6} + 303$ nm (in tetrahydrofuran)

I_n': $\lambda_{max} = 30.3n^{0.8} + 348$ nm (in tetrahydrofuran)

A linear relationship between the square of wavelength of the longest-wavelength absorption maxima (λ_{max}) and the number of ethylenic bond (n) [$\lambda^2_{max} \propto n$, *i.e.*, $\lambda_{max} \propto n^{0.5}$] has been recognized for the electronic spectra of several series of all-*trans*-polyenes.[1] However, the bathochromic shift of λ_{max} of α,ω-di(2-naphthyl)polyenes was found to be linearly proportional to $n^{0.7}$ suggesting a marked influence of the terminal groups on the electronic excitation of polyene chromophore.[2] Thus we considered it desirable to prepare other series of diarylpolyenes to get information on the role of terminal groups on the electronic spectral regularity. The present paper deals with the syntheses of α,ω-di(2-phenanthryl)-(I_n), α,ω-di(3-pehnanthryl)- (I_n'), and α,ω-di(9-phenanthryl)-polyenes (I_n''), and the spectral regularity of the former two series of polyenes (I_n and I_n').

Syntheses. The reaction sequence used in the syntheses of α,ω-diphenanthrylpolyenes (I_n, I_n', I_n'') is outlined in the Scheme. Phosphoranes were prepared by the reaction of phenyllithium with the corresponding triphenylphosphonium bromides. I_1, I_1', and I_1'' were obtained by the reaction of II, II′, and II″ with V, V′, and V″, respectively. III, III′, and III″ were prepared from II, II′, and II″ by a modified Arens and van Dorp method.[3] I_2 could be obtained from II and VI. The reaction of III′ and III″ with V′ and V″ afforded I_2' and I_2'', respectively. Treatment of IV and IV′ with V and V′ yielded I_3 and I_3'. I_3' was also prepared by the reaction of II′ with VII derived from 1,4-dibromo-2-butene.[4] The reaction of III″ with VI″ gave I_3''. The Wittig reaction of muconaldehyde (VIII) with V, V′, and V″ yielded I_4, I_4', and I_4'', respectively. IV, IV′, and IV″ were treated with IX, IX′, and IX″ to yield I_5, I_5', and I_5''. I_6, I_6', and I_6'' were obtained from VI, VI′, and VI″ and VIII.

1. RCHO (II, II′, II″) + $RCH{=}PPh_3$ (V, V′, V″) ⟶ RCH=CHR (I_1, I_1', I_1'')

2. RCHO (II) + $RCH{=}CHCH{=}PPh_3$ (VI) ⟶ $R(CH{=}CH)_2R$ (I_2)

   RCH=CHCHO (III′, III″) + $RCH{=}PPh_3$ (V′, V″) ⟶ $R(CH{=}CH)_2R$ (I_2', I_2'')

3. $R(CH{=}CH)_2CHO$ (IV, IV′) + $RCH{=}PPh_3$ (V, V′) ⟶ $R(CH{=}CH)_3R$ (I_3, I_3')

   RCHO (II′) + $Ph_3P{=}CHCH{=}CHCH{=}PPh_3$ (VII) ⟶ $R(CH{=}CH)_3R$ (I_3')

   RCH=CHCHO (III″) + $RCH{=}CHCH{=}PPh_3$ (VI″) ⟶ $R(CH{=}CH)_3R$ (I_3'')

4. $2RCH{=}PPh_3$ (V, V′, V″) + $OCH(CH{=}CH)_2CHO$ (VIII) ⟶ $R(CH{=}CH)_4R$ (I_4, I_4', I_4'')

5. $R(CH{=}CH)_2CHO$ (IV, IV′, IV″) + $R(CH{=}CH)_2CH{=}PPh_3$ (IX, IX′, IX″) ⟶ $R(CH{=}CH)_5R$ (I_5, I_5', I_5'')

6. $RCH{=}CHCH{=}PPh_3$ (VI, VI′, VI″) + $OCH(CH{=}CH)_2CHO$ (VIII) ⟶ $R(CH{=}CH)_6R$ (I_6, I_6', I_6'')

Roman numerals with no prime, single prime and double prime denote the 2-phenanthryl, 3-phenanthryl and 9-phenanthryl isomers, respectively.

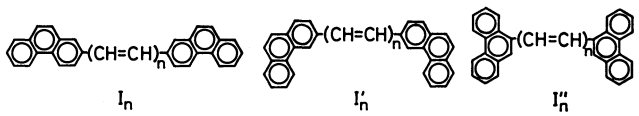
The color of the crystals, melting points and wave number of IR absorption due to C–H out-of-plane deformation (δ) of *trans*-double bond are summarized in Table 1. Regular increase in melting point with increase in the chain length in α,ω-diphenylpolyenes[5] could not be observed in the series of diphenanthrylpolyenes (I_n, I_n', I_n'') as in di(1-anthryl)-[6] and di(2-naphthyl)polyenes.[2] The higher members of I_n were found to be scarcely soluble in usual organic solvents. Shift of δ to a higher wave number with the increase of n was observed in the three series of diphenanthrylpolyenes (I_n, I_n', I_n'') (Table 1). The same trend has been observed in the IR spectra of dianthryl-[6] and dinaphthylpolyenes.[2]



I_n I_n' I_n''

Electronic Spectra. Numerical data of the electronic spectra of I_n and I_n' are summarized in Tables 2 and 3. Absorption curves with well-developed fine structure were obtained for I_n and I_n', but broad and structureless ones for I_n'' (Figs. 1 and 2). The difference can be reasonably attributed to violation of coplanarity of the molecules of I_n'' caused by the steric interference between the hydrogen atoms at 1-, 1'-, 8-, and 8'-positions of the aromatic nuclei and β- and β'-positions of the ethylenic bonds. The same spectral behavior has been observed in other series of sterically hindered diarylpolyenes[2,5,7] and explained in

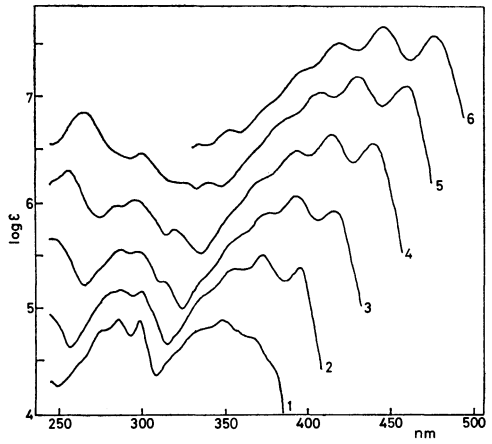

Fig. 1. Electronic spectra of di(2-phenanthryl)polyenes (I_n) in tetrahydrofuran. Each curve, except for the lowest one, has been displaced upward by a 0.5 log ε unit increment from one immediately below.

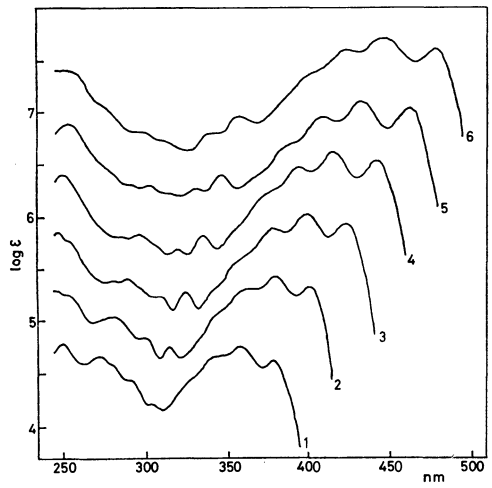

Fig. 2. Electronic spectra of di(3-phenanthryl)polyenes (I_n') in tetrahydrofuran. Each curve, except for the lowest one, has been displaced upward by a 0.5 log ε unit increment from one immediately below.

terms of nonplanarity of molecule.[7] The longest-wavelength absorption band consisting of three vibrational sub-bands seems to arise from an interaction of ^{1}La band of the terminal group with the absorption of polyene chromophore. The difference of wavelength $\Delta\lambda$ of the longest-wavelength sub-bands between a member of I_n or I_n' and the next higher member, I_{n+1} or I'_{n+1} decreases with the increase in the number of n. The same trend of bathochromic shift has been observed in various series of linear polyenes[1,2,5] in contrast with the increase of $\Delta\lambda$ in several series of diarylpoly-ynes.[8] This suggests the possibility that the mode of interaction of aromatic terminal groups with polyene chromophore differs from that with polyyne chromophore.

Discussion on spectral regularity is limited to I_n and I_n', owing to difficulty of estimation of the exact location of longest-wavelength sub-band (λ_I) or next

8) M. Nakagawa, S. Akiyama, K. Nakasuji, and K. Nishimoto, *Tetrahedron*, **27**, 5401 (1971).

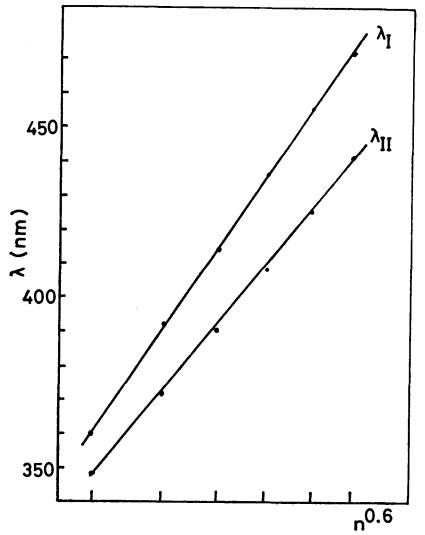

Fig. 3. Plot of λ_{max} *vs.* $n^{0.6}$ for di(2-phenanthryl)polyenes (I_n). λ_I: longest-wavelength maxima λ_{II}: second-longest-wavelength maxima

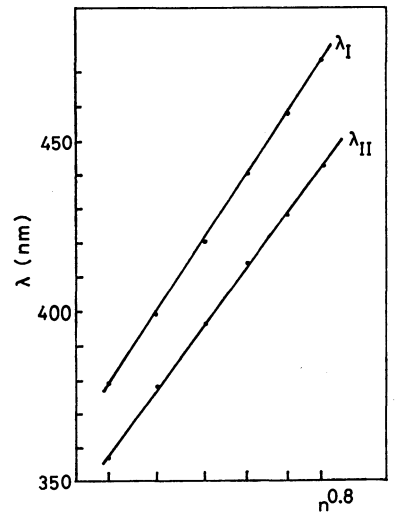

Fig. 4. Plots of λ_{max} *vs.* $n^{0.8}$ for di(3-phenanthryl)polyenes (I_n'). λ_I: longest-wavelength maxima λ_{II}: second-longest-wavelength maxima

longest-wavelength sub-band (λ_{II}) of I_n'' because of the broad and structureless feature of their absorption curves. The longest-wavelength bands of I_n and I_n' are considered to shift linearly with the xth power of the number of ethylenic linkage (n).[2] It was revealed that the plots of λ_I and λ_{II} of I_n *versus* $n^{0.6}$ and those of I_n' *versus* $n^{0.8}$ give good straight lines (Figs. 3 and 4). The linear relationships can be well represented by the following empirical formulas:

$$\lambda = An^x + B$$

I_n: $\lambda_I = 57.9n^{0.6} + 303$ nm (in tetrahydrofuran)

$\lambda_{II} = 48.6n^{0.6} + 298$ nm (in tetrahydrofuran)

I_n': $\lambda_I = 30.3n^{0.8} + 348$ nm (in tetrahydrofuran)

$\lambda_{II} = 27.1n^{0.8} + 330.5$ nm (in tetrahydrofuran)

The spectral regularity of acetylenic analogues of I_n and I_n', 2,2'-diphenanthrylpoly-ynes and 3,3'-diphenan-

thrylpoly-ynes, could be expressed by $\lambda_I = 13.9\ n^{1.3} + 333$ and $\lambda_I = 10.8\ n^{1.4} + 347$, respectively.[9] The value of constant B was found to be similar in both series, but that of coefficient A to be much larger in the polyene series than in poly-yne analogues.

Experimental

All the melting points are not corrected. The electronic spectra were measured with a Hitachi EPS-3T spectrophotometer using a well-matched pair of 1 cm quartz cells. The IR spectra were obtained on a Hitachi EPI-2 spectrophotometer by KBr disk method. Pure and anhydrous solvents were used. Preparation of phosphoranes was carried out under nitrogen atmosphere using ethereal solution of phenyllithium as a base. The Wittig reaction was performed under shielding from light.

1,2-Diphenanthrylethylenes (I_1, I_1', and I_1''). (a) 1,2-Di(2-phenanthryl)ethylene (I_1). To a suspension of 2-phenanthrylmethyltriphenylphosphonium bromide[10] (0.64 g, 1.2 mmol) in benzene (20 ml) was added phenyllithium (0.175N, 6.8 ml). After stirring for 1 hr at room temperature, a solution of II[2] (0.21 g, 1.0 mmol) in benzene (10 ml) was added to the resulting orange red solution of phosphorane (V). The solvent was removed after the mixture had been stirred for 24 hr. The residue was digested with boiling benzene and the solution was passed through a short column of alumina. Pure I_1 was obtained as colorless crystals, mp 315—316°C, 0.109 g (28.7%) by concentration of the filtrate. Further concentration of the filtrate afforded the second crop of I_1, mp 309—312°C, 0.02 g (5.2%).

(b) 1,2-Di(3-phenanthryl)ethylene (I_1'). By a similar method to that used in the preparation of I_1, I_1' (mp 284—287°C, 0.258 g, 67.9%) was obtained from V' [from the corresponding phosphonium bromide[10] (0.65 g, 1.2 mmol) and phenyllithium (0.69N, 1.7 ml)] and II'[9] (0.21 g, 1.0 mmol). Pure I_1', pale yellow needles, mp 288—289°C (from benzene).

(c) 1,2-Di(9-phenanthryl)ethylene (I_1''). The reaction of II'[9] (0.35 g, 1.5 mmol) with V'' [from 9-phenanthrylmethyltriphenylphosphonium bromide[10] (0.80 g, 1.5 mmol) and phenyllithium (0.09N, 16.6 ml)] afforded I_1'', mp 271—273°C (from toluene), $\lambda_{max}^{benzene}$ (log ε): 301 (4.27), 340 (4.30) nm.

Found: I_1, C, 94.58; H, 5.28%. I_1', C, 94.86; H, 5.38%. I_1'', C, 94.35; H, 5.28%. Calcd for $C_{30}H_{20}$: C, 94.70; H, 5.30%.

3-Phenanthryl-2-propenals (III, III', and III''). The preparation of 2-phenanthryl isomer (III) is described as a representative example, III' and III'' being prepared by a similar procedure.

(a) 3-(2-Phenanthryl)-2-propenal (III). To a solution of lithium ethoxyacetylide prepared from 2-chlorovinyl ethyl ether (7.0 g, 0.066 mol) in tetrahydrofuran (20 ml) and lithium amide (from lithium 0.9 g, 0.13 g-atom) in liquid ammonia (130 ml) was added a solution of II[9] (4.0 g, 0.019 mol) in tetrahydrofuran (50 ml). After the mixture had been stirred for 48 hr at the boiling point of liquid ammonia, ammonium chloride (10 g) was added and the ammonia was allowed to evaporate. The residue was mixed with water and extracted with benzene. The extract, after being washed and dried, was concentrated to give crude ethoxyethynylcarbinol as a brown liquid. A solution of the crude carbinol in tetrahydrofuran (40 ml) was added to a suspension of lithium aluminum hydride (2.9 g, 0.078 mol) in the same solvent (50 ml). After being stirred for 2 hr at room temperature, the reaction mixture was treated with ethyl acetate (15 ml), water (10 ml), and 2N sulfuric acid (120 ml), successively. Crude III obtained as a brown liquid was dissolved in benzene-tetrahydrofuran and the solution was shaken with a saturated solution of sodium hydrogen sulfite to precipitate sulfite adduct of III. Decomposition of the adduct with 10% hydrochloric acid afforded pale yellow crystals, mp 118—123°C (1.19 g, 26.4%) which were recrystallized from benzene to give pure III, colorless cubes, mp 132—133°C.

(b) 3-(3-Phenanthryl)-2-propenal (III'). Crude III' (0.87 g, 19.3%) obtained in crystalline state from II'[9] (4.0 g) was recrystallized from ethanol to afford pure III', colorless plates, mp 114—115°C.

(c) 3-(9-Phenanthryl)-2-propenal (III''). Pale yellow needles (5.7 g, 37.2%) obtained from II'[9] (13.6 g) were recrystallized from benzene to yield pure III'', colorless needles, mp 158—159°C.

Found: III, C, 87.63; H, 5.23%. III', C, 87.94; H, 5.06%. III'', C, 87.88; H, 5.70%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.21%.

3-Phenanthryl-2-propen-1-ols. Phenanthrylpropenols were obtained by the sodium borohydride reduction of III, III', and III''. The preparation of 2-phenanthryl isomer is described as a typical example.

(a) 3-(2-Phenanthryl)-2-propen-1-ol. A suspension of sodium borohydride (1.20 g, 3.2 mmol) in methanol (20 ml) was added to a stirred solution of III (1.48 g, 6.4 mmol) in tetrahydrofuran (16 ml) and methanol (8 ml) at room temperature. After being stirred for 1.5 hr, dilute hydrochloric acid was added to the reaction mixture and extracted with benzene. The extract was washed, dried and treated with active charcoal at room temperature. Pale yellow crystals, mp 157—162°C, 1.31 g (87.9%) obtained by concentration of the extract were recrystallized from benzene to yield pure alcohol, pale yellow plates, mp 167—168°C.

(b) 3-(3-Phenanthryl)-2-propen-1-ol. Crude alcohol (0.30 g) obtained from III' (0.30 g) and sodium borohydride (0.30 g) were recrystallized from benzene to give 3-phenanthrylpropenol, colorless plates, mp 130.5—131.1°C.

(c) 3-(9-Phenanthryl)-2-propen-1-ol. Reduction of III'' (2.3 g) with sodium borohydride (2.3 g) yielded 9-phenanthrylpropenol (2.2 g, 96%) which was recrystallized from benzene to give pure material, colorless needles, mp 143—144°C.

Found: 2-isomer, C, 87.08; H, 6.03%. 3-isomer, C, 87.30; H, 5.99%. 9-isomer, C, 86.99; H, 5.96%. Calcd for $C_{17}H_{14}O$: C, 87.15; H, 6.02%.

3-Phenanthryl-2-propenyltriphenylphosphonium Bromides. The synthesis of 2-phenanthryl isomer is described as a representative example, the preparation of phenanthryl-2-propenyltriphenylphosphonium bromides being performed under similar reaction conditions.

(a) 3-(2-Phenanthryl)-2-propenyltriphenylphosphonium Bromide. To a solution of 3-(2-phenanthryl)-2-propen-1-ol (1.0 g, 4.3 mmol) in chloroform (50 ml) containing 4 drops of pyridine was added a solution of phosphorus tribromide (0.8 g, 3.0 mmol) in chloroform (10 ml) under cooling with an ice-salt bath, and the mixture was stirred for 30 min at the same temperature. After being stirred for 30 min at room temperature, the reaction mixture was poured onto ice-water. The organic layer, after being washed and dried, was treated with active charcoal at room temperature. Fine pale

9) S. Akiyama and M. Nakagawa, This Bulletin, **44**, 2237 (1971).

10) S. Akiyama, K. Nakasuji, and M. Nakagawa, *ibid.*, **44**, 2231 (1971).

yellow crystals obtained by evaporation of the solvent were mixed with triphenylphosphine (1.3 g, 5.0 mmol) and benzene (30 ml) and the mixture was refluxed for 19 hr. The phosphonium bromide deposited as colorless plates, mp 235—241°C, 2.12 g (88.7%).

(b) 3-(3-Phenanthryl)-2-propenyltriphenylphosphonium Bromide. 3-Phenanthrylpropenol (0.217 g, 0.93 mmol) was converted into bromide with phosphorus tribromide (0.20 g, 0.73mmol). Treatment of the bromide with triphenylphosphine afforded phosphonium bromide, colorless crystals, mp 223—226°C, 0.309 g (59.4%).

(c) 3-(9-Phenanthryl)-2-propenyltriphenylphosphonium Bromide. The reaction of the bromide obtained from 9-phenanthryl-2-propenol (1.50 g, 6.4 mmol) and phosphorus tribromide (1.2 g, 4.4 mmol) with triphenylphosphine (1.9 g, 7.5 mmol) gave phosphonium bromide, colorless crystals, mp 144—146°C (from ethanol), 3.55 g (93.6%).

Found: C, 74.92; H, 5.11; Br, 14.55%. Calcd for $C_{35}H_{28}BrP$: C, 75.15; H, 5.01; Br, 14.30%.

5-Phenanthryl-2,4-pentadienals (IV, IV', and IV''). As the three isomeric aldehydes were prepared by similar procedures, only IV is described in some detail.

(a) 5-(2-Phenanthryl)-2,4-pentadienal (IV). To a stirred solution of ethylmagnesium bromide in tetrahydrofuran [from ethyl bromide (4.4 g) and magnesium (0.70 g, 28 mg-atom)] was added a solution of 1-methoxy-1-buten-3-yne (3.2 g, 38.9 mmol) in tetrahydrofuran (12 ml). After being stirred for 30 min at 40°C and then for 30 min at room temperature, a solution of II[9] (4.0 g, 19.4 mmol) in the same solvent (20 ml) was added dropwise under cooling. After stirring for 12 hr at room temperature, ethanol (1.3 ml) and lithium aluminum hydride (1.1 g, 29 mmol) were added to the stirred mixture. After 2 hr, water (4 ml) and 4N sulfuric acid (100 ml) were added successively to the reaction mixture and stirring was continued for 2 hr. The reaction mixture was worked up in the usual way. Crude IV (3.89 g, 77.8%, mp 159—161°C) was recrystallized from ethanol to give pure IV, yellow needles, mp 161°C.

(b) 5-(3-Phenanthryl)-2,4-pentadienal (IV'). The reaction product obtained from the Grignard derivative of methoxybutenyne (5.0 g, 61 mmol) and II'[9] (6.2 g, 30 mmol) was reduced with lithium aluminum hydride (1.7 g, 35 mmol) and the reduction product was treated with 4N sulfuric acid. The aqueous layer was extracted with benzene. The combined organic layer was shaken with a saturated sodium hydrogen sulfite solution to precipitate sulfite adduct. Decomposition of the adduct with a dilute hydrochloric acid afforded yellow crystalline powder (5.7 g, 73.5%, mp 90—94°C) which was recrystallized from ethyl acetate to give pure IV', yellow rods, mp 102°C.

(c) 5-(9-Phenanthryl)-2,4-pentadienal (IV''). Crude IV'', yellow crystalline powder, 2.50 g (32.3%), mp 170—173°C obtained from II''[9] (6.20 g, 0.030 mol), the Grignard derivative of methoxybutenyne (6.1 g, 0.074 mol) and lithium aluminum hydride (1.7 g, 0.035 mol) was rcerystallized from benzene to yield pure IV'', yellow rods, mp 177—178°C.

Found: IV, C, 88.03; H, 5.48%. IV', C, 88.34; H, 5.47%. IV'', C, 88.16; H, 5.47%. Calcd for $C_{19}H_{14}O$: C, 88.34; H, 5.46%.

5-Phenanthryl-2,4-pentadien-1-ols. Reduction of IV, IV', and IV'' in tetrahydrofuran-methanol with sodium borohydride followed by treatment of the products with a dilute hydrochloric acid afforded phenanthrylpentadienols.

(a) 5-(2-Phenanthryl)-2,4-pentadien-1-ol. IV (1.50 g, 5.8 mmol) in the mixed solvent (3: 1, 40 ml) and the hydride (0.45 g, 12 mmol) in methanol (10 ml) gave fairly pure 2-phenanthrylpentadienol, colorless crystals, mp 89—100°C, 1.45 g (96.2%) which were used directly in the following reaction.

(b) 5-(3-Phenanthryl)-2,4-pentadien-1-ol. Pale yellow crystalline powder, mp 143—149°C, 0.94 g (quantitative) obtained from IV' (0.90 g, 3.5 mmol), the mixed solvent (2: 1, 12 ml) and the hydride (0.27 g, 6 mmol) in methanol (8 ml) was recrystallized from chloroform, yielding pure alcohol, yellow plates, mp 149—150°C.

(c) 5-(9-Phenanthryl)-2,4-pentadien-1-ol. IV'' (0.394 g, 1.5 mmol), the mixed solvent (2: 1, 30 ml) and the hydride (0.120 g, 3.2 mmol) in methanol (10 ml) gave colorless needles, mp 119—124°C, 0.399 g (quantitative) which were recrystallized from benzene–cyclohexane (1:1) to give pure material, colorless needles, mp 125°C.

Found: 3-isomer, C, 87.30; H, 6.07%. 9-isomer, C, 87.43; H, 6.18%. Calcd for $C_{19}H_{16}O$: C, 87.66; H, 6.19%.

5-Phenanthryl-2,4-pentadienyltriphenylphosphonium Bromides. The preparation of 9-phenanthryl isomer is described as a typical example.

(a) 5-(9-Phenanthryl)-2,4-pentadienyltriphenylphosphonium Bromide. To a solution of 5-(9-phenanthryl)-2,4-pentadien-1-ol (0.60 g, 2.3 mmol) in chloroform (30 ml) containing a drop of pyridine was added a solution of phosphorus tribromide (0.68 g, 2.5 mmol) in chloroform (10 ml) under cooling on an ice-salt bath. After being stirred for 1 hr at room temperature, the reaction mixture was poured onto ice–water. The organic layer, after being washed and dried, was evaporated and the residue was mixed with benzene (52 ml) and triphenylphosphine (0.76 g, 2.9 mmol). Phosphonium bromide, pale yellow crystals, mp *ca.* 117°C, 0.64 g (47.6%) crystallized out on standing the mixture overnight at room temperature. The filtrate was refluxed for 6 hr, giving a second crop of phosphonium bromide, mp 137—143°C, 0.567 g (42.1%). The combined crystals were recrystallized from ethanol to yield pure material, colorless cubes, mp 190—191.5°C.

Found: C, 74.48; H, 5.28; Br, 13.60%. Calcd for $C_{37}H_{30}BrP \cdot 1/2C_2H_5OH$: C, 75.00; H, 5.47; Br, 13.13%.

(b) 5-(2-Phenanthryl)-2,4-pentadienyltriphenylphosphonium Bromide. The reaction of triphenylphosphine (0.36 g, 1.4 mmol) with the bromide derived from 2-phenanthrylpentadienol (0.24 g, 0.92 mmol) and phosphorus tribromide (0.26 g, 0.97 mmol) afforded phosphonium bromide, light yellow crystals, mp 160—164°C, 0.27 g (50%). This was used without purification in the following reaction.

(c) 5-(3-Phenanthryl)-2,4-pentadienyltriphenylphosphonium Bromide. 3-Phenanthrylpentadienol (1.5 g, 5.77 mmol) was converted into the corresponding bromide by the reaction with phosphorus tribromide (1.8 g, 6.68 mmol). The bromide was refluxed with triphenylphosphine (2.3 g, 8.8 mmol) in benzene (40 ml) to give phosphonium bromide (1.27 g) which was used without purification in the subsequent reaction.

1,4-Diphenanthryl-1,3-butadienes (I_2, I_2', and I_2''). (a) 1,4-Di(2-phenanthryl)-1,3-butadiene (I_2). A suspension of 3-(2-phenanthryl)-2-propenyltriphenylphosphonium bromide (0.67 g, 1.2 mmol) in benzene (25 ml) was mixed with phenyllithium (0.73N, 1.6 ml) to give a dark red solution of phosphorane (VI). A solution of II[9] (0.21 g, 1.0 mmol) in benzene (11 ml) was added and the mixture was stirred for 24 hr at room temperature. The residue obtained by evaporating the solvent was extracted with hot benzene and the hot extract was passed through a short column of alumina. Concentration of the filtrate gave pure I_2, greenish yellow crystals, mp 296—297°C, 0.132 g. Further concentration of the filtrate afforded a slightly impure second crop of I_2, mp 288—297°C, 0.020 g (total yield 37.5%).

(b) 1,4-Di(3-phenanthryl)-1,3-butadiene (I_2'). To a yellow solution of V′ prepared from 3-phenanthrylmethyltriphenylphosphonium bromide (1.10 g, 2.07 mmol) in benzene (20 ml) and phenyllithium (0.31N, 6.7 ml) was added a solution of III′ (0.322 g, 1.38 mmol) in the same solvent (15 ml), and the mixture was stirred for 28 hr at room temperature. The residue obtained by evaporating the solvent was extracted with hot benzene. I_2', mp 280—284°C, 0.174 g (31.1%) obtained by concentration of the extract was redissolved in hot benzene, and the hot solution was passed through a short column of alumina to give pure I_2', greenish yellow plates, mp 286°C.

(c) 1,4-Di(9-phenanthryl)-1,3-butadiene (I_2''). To a solution of V″ prepared from 9-phenanthrylmethyltriphenylphosphonium bromide (0.80 g, 1.5 mmol) and phenyllithium (0.15N, 10.0 ml) was added a solution of III″ (0.350 g, 1.5 mmol) in benzene (18 ml). Greenish yellow crystalline powder obtained after stirring the mixture for 6 hr at room temperature was triturated with a small amount of benzene, and the powder was extracted with hot toluene. Greenish yellow needles, mp 269—171°C, 0.557 g (25.8%) deposited on cooling the extract were dissolved in hot toluene and the hot solution was percolated through a thin layer of alumina to give pure I_2'', greenish yellow needles, mp 270—272°C, $\lambda_{max}^{benzene}$ (log ε): 367 (4.56) nm.

Found: I_2, C, 94.67; H, 5.63%. I_2', C, 94.54; H, 5.62%. I_2'', C, 94.33; H, 5.46%. Calcd for $C_{32}H_{22}$: C, 94.54; H, 5.46%.

1,6-Diphenanthryl-1,3,5-hexatrienes (I_3, I_3', and I_3''). (a) 1,6-Di(2-phenanthryl)-1,3,5-hexatriene (I_3). To a solution of V prepared from 2-phenanthrylmethyltriphenylphosphonium bromide (0.80 g, 1.5 mmol) in benzene (25 ml) and phenyllithium (0.38N, 4.0 ml) was added a solution of IV (0.322 g, 1.25 mmol) in the same solvent (25 ml). After the mixture had been stirred for 24 hr at room temperature, the product was extracted with hot benzene and the hot extract was passed through a short column of alumina. Concentration of the filtrate afforded I_3, yellow plates, mp 287—288°C. Further concentration of the filtrate yielded a sceond crop of I_3, mp 276—279°C, total 0.386 g (71.5%).

(b) 1,6-Di(3-phenanthryl)-1,3,5-hexatriene (I_3'). From 3-Phenanthrylmethyltriphenylphosphonium Bromide. A solution of IV′ (0.26 g, 1.0 mmol) in benzene (12 ml) was added to a solution of V′ in the same solvent (20 ml) prepared from 3-phenanthrylmethyltriphenylphosphonium bromide (0.64 g, 1.2 mmol) and phenyllithium (0.69N, 1.7 ml). After being stirred for 72 hr at room temperature, the product was extracted with hot toluene. Fine yellow crystals, mp 295—296°C, 0.15 g (34.9%) obtained by concentrating the extract were dissolved in hot toluene and passed through a short column of alumina to yield I_3', yellow plates, mp 295—296°C.

From 3-Formylphenanthrene (II′) and Bis-phosphorane (VII). To an ice-cooled solution of 1,4-bis(triphenylphosphonium)-2-butene dibromide[4] (0.75 g, 1.0 mmol) in ethanol (26 ml) were added simultaneously over a 12 min period a solution of lithium methoxide (from lithium, 0.14 g, 0.02 g-atom and methanol, 28 ml) and a solution of II′ (0.45 g, 2.2 mmol) in ethanol (42 ml) and the mixture was stirred for 4 hr at 0°C. Fine yellow crystals, mp 285—291°C, 0.068 g (15.8%) deposited after stirring overnight at room temperature were washed with ethanol and recrystallized from benzene to yield pure I_3', yellow plates, mp 294.5°C.

(c) 1,6-Di(9-phenanthryl)-1,3,5-hexatriene (I_3''). To a solution of VI″ in benzene (15 ml) prepared from 3-(9-phenanthryl)-2-propenyltriphenylphosphonium bromide (0.840 g, 1.5 mmol) and phenyllithium (0.17N, 17.6 ml) was added a solution of III″ (0.348 g, 1.5 mmol) in the same solvent (20 ml). After being stirred overnight at room temperature, the product was washed with a small amount of benzene and extracted with hot toluene. The hot extract was percolated through a thin layer of alumina and the filtrate was concentrated to yield pure I_3'', yellow needles, mp 243—244°C, $\lambda_{max}^{benzene}$ (log ε): 384 (4.67) nm.

Found: I_3, C, 94.15; H, 5.57%. I_3' (from IV′), C, 94.15; H, 5.57%. I_3' (from II′), C, 94.04; H, 5.59%. I_3'', C, 94.30; H, 5.55%. Calcd for $C_{34}H_{24}$: C, 94.41; H, 5.60%.

1,8-Diphenanthryl-1,3,5,7-octatetraenes (I_4, I_4', and I_4''). (a) 1,8-Di(2-phenanthryl)-1,3,5,7-octatetraene (I_4). To a solution of V in benzene (20 ml) obtained from 2-phenanthrylmethyltriphenylphosphonium bromide (0.64 g, 1.2 mmol) and phenyllithium (0.18N, 6.8 ml) was added a solution of VIII (0.055 g, 0.50 mmol) in benzene (7 ml). After the mixture had been stirred overnight at room temperature, the product was digested with boiling benzene. Concentration of the extract afforded yellow crystals (0.0935 g). The mother liquor was passed through a short column of alumina and the filtrate was concentrated to yield a second crop of yellow crystals (0.013 g). The combined crude crystals (mp 280—281°C) dissolved in hot benzene were percolated through a short column of alumina to give pure I_4, yellow plates, mp 283°C.

(b) 1,8-Di(3-phenanthryl)-1,3,5,7-octatetraene (I_4'). A mixture of VIII (0.056 g, 0.5 mmol) and V′ derived from 3-phenanthrylmethyltriphenylphosphonium bromide (0.64 g, 1.2 mmol) and phenyllithium (0.69N, 1.7 ml) was stirred for 24 hr at room temperature. The product dissolved in hot toluene was passed through a short column of alumina. Fine yellow crystals, mp 279—285°C, 0.0935 g (20.4%) obtained from the filtrate were dissolved in hot toluene and percolated through a thin layer of alumina to yield pure I_4', yellow plates, mp 284—285°C.

(c) 1,8-Di(9-phenanthryl)-1,3,5,7-octatetraene (I_4''). To a solution of V″ in benzene (15 ml) prepared from 9-phenanthrylmethyltriphenylphosphonium bromide (0.800 g, 1.5 mmol) and phenyllithium (0.14N, 10.7 ml) was added a solution of VIII (0.056 g, 0.5 mmol) in benzene (6 ml). After being stirred for 6 hr at room temperature, crystalline powder deposited was washed with benzene and digested with hot toluene. Concentration of the extract afforded yellow needles, mp 255—257°C, 0.107 g (46.7%). A second crop of yellow needles, mp 236—241°C, 0.065 g (28.3%) was obtained from the filtrate on concentration. A hot toluene solution of the first crop was percolated through a short column of alumina to give pure I_4'', yellow needles, mp 263°C, $\lambda_{max}^{benzene}$ (log ε): 296 (4.52), 403 (4.83) nm.

Found: I_4, C, 94.00; H, 5.69%. I_4', C, 94.33; H, 5.68%. I_4'', C, 94.40; H, 5.67%. Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%.

1,10-Diphenanthryl-1,3,5,7,9-decapentaenes (I_5, I_5', and I_5''). (a) 1,10-Di(2-phenanthryl)-1,3,5,7,9-decapentaenes (I_5). A solution of IV (0.136 g, 0.53 mmol) in benzene (18 ml) was added to a benzene solution (20 ml) of IX prepared from 5-(2-phenanthryl)-2,4-pentadienyltriphenylphosphonium bromide (0.34 g, 0.59 mmol) and phenyllithium (0.97N, 0.6 ml) and the mixture was stirred for 27 hr at room temperature. Yellow solid obtained by evaporation of the solvent was digested with hot toluene. Concentration of the extract afforded yellow plates, mp 284—288°C, 0.086 g (33.7%) which were redissolved in hot toluene and passed through a short column of alumina to give pure I_5, orange yellow plates, mp 300°C.

(b) 1,10-Di(3-phenanthryl)-1,3,5,7,9-decapentaene (I_5'). To a solution of IX′ in benzene (20 ml) prepared from 5-(3-

phenanthryl)-2,4-pentadienyltriphenylphosphonium bromide (0.70 g, 1.2 mmol) and phenyllithium (0.098N, 9.6 ml) was added a solution of IV′ (0.26 g, 1.0 mmol) in benzene (15 ml). After being stirred for 49 hr at room temperature, the reaction product was extracted with hot toluene. Concentration of the extract yielded I_5', orange yellow plates, mp 275—276°C, 10 mg.

(c) 1,10-Di(9-phenanthryl)-1,3,5,7,9-decapentaene (I_5''). A solution of IV″ (0.214 g, 0.83 mmol) in benzene (20 ml) was added to a solution of IX″ in the same solvent (30 ml) obtained from 5-(9-phenanthryl)-2,4-pentadienyltriphenylphosphonium bromide (0.480 g, 0.83 mmol) and phenyllithium (0.16N, 5.2 ml). After being stirred for 19 hr at room temperature, crystalline solid deposited was washed with benzene and extracted with hot toluene. The hot extract was percolated through a short column of alumina. Orange yellow needles, mp 233—236°C, 0.070 g (17.4%) obtained on concentration of the filtrate were redissolved in hot toluene and again passed through a thin layer of alumina to yield pure I_5'', yellow needles, mp 248—249°C, $\lambda_{max}^{benzene}$ (log ε): 305 (4.43), 420 (4.81) nm.

Found: I_5, C, 93.55; H, 5.83%. I_5', C, 93.71; H, 5.82%. I_5'', C, 93.86; H, 5.90%. Calcd for $C_{38}H_{28}$: C, 94.18; H, 5.82%.

1,12-Diphenanthryl-1,3,5,9,11-dodecahexaenes (I_6, I_6', and I_6'').

(a) 1,12-Di(2-phenanthryl)-1,3,5,7,9,11-dodecahexaene (I_6). A solution of VIII (0.052 g, 0.5 mmol) in benzene (10 ml) was added to a solution of VI in the same solvent (25 ml) prepared from 3-(2-phenanthryl)-2-propenyltriphenylphosphonium bromide (0.714 g, 1.3 mmol) and phenyllithium (0.84N, 1.5 ml) and the mixture was stirred for 21 hr at room temperature. The reaction product was extracted with hot toluene. Orange crystals obtained by concentrating the extract were dissolved in hot toluene and percolated through a thin layer of alumina to give pure I_6, orange crystals, mp 293—294°C.

(b) 1,12-Di(3-phenanthryl)-1,3,5,7,9,11-dodecahexaene (I_6'). By a similar procedure to that for I_6, 3-(3-Phenanthryl)-2-propenyltriphenylphosphonium bromide (0.309 g, 0.56 mmol), phenyllithium (0.19N, 2.9 ml) and VIII (0.030 g, 0.28 mmol) afforded I_6', orange rods, mp 286—287°C (from toluene), 11.5 mg (8.2%).

(c) 1,12-Di(9-phenanthryl)-1,3,5,7,9,11-dodecahexaene (I_6''). A solution of VI″ in benzene (15 ml) prepared from 3-(9-phenanthryl)-2-propenyltriphenylphosphonium bromide (0.670 g, 1.2 mmol) and phenyllithium (0.135N, 8.9 ml) was mixed with a solution of VIII (0.044 g, 0.4 mmol) in benzene (7 ml). After being stirred overnight at room temperature, the reaction product was extracted with hot toluene. Orange crystals, mp 217—220°C, 0.117 g (57.4%) obtained by concentrating the extract were redissolved in hot toluene. Percolation of the hot solution through a short column of alumina afforded pure I_6'', orange needles, mp 231—232°C, $\lambda_{max}^{benzene}$ (log ε): 314 (4.35), 434 (5.17) nm.

Found: I_6, C, 93.97; H, 5.88%. I_6', C, 93.89; H, 5.94%. I_6'', C, 93.93; H, 5.97%. Calcd for $C_{40}H_{30}$: C, 94.08; H, 5.92%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 915—920 (1973)

Optically Active 9,10-Dihydro-9,10-etheno and -ethanoanthracenes. I. Syntheses of Optically Active 1,5-Disubstituted-9,10-dihydro-9,10-etheno and -ethanoanthracenes.

(Received July 21, 1972)

1,5-Dimethoxycarbonyl-9,10-dihydro-9,10-ethenoanthracene was synthesized by the reaction of 1,5-dimethoxycarbonylanthracene with dichloroethylene followed by dechlorination with zinc-copper couple. Optical resolution of 1,5-dicarboxy-9,10-dihydro-9,10-ethenoanthracene prepared from the dimethyl ester could be achieved by strychnine to give optically pure (−)-dicarboxylic acid and (+)-diacid with an optical purity of 87.3%. Catalytic reduction of (−)-dicarboxylic acid afforded (−)-ethano-dicarboxylic acid. Transformation of the carboxyl groups in various substituent groups to give optically active C_2-symmetrical etheno- and ethanoanthracene derivatives belonging to the same series of absolute configuration as that of the starting material is described.

The present authors have studied the relation of structure and optical rotatory properties of a number of optically active triptycene derivatives bearing various substituents at various positions of the benzene rings.[1] The absolute configurations of optically active 2,5-dimethoxy-7-substituted- and 2,7-disubstituted-triptycenes have been studied by both X-ray analysis[2] and chemical correlation.[3] It was found that the cautious analyses of CD spectra of these triptycene derivatives lead to antipodal absolute configurations.[4,5]

9,10-Dihydro-9,10-etheno- and ethanoanthracenes (I and II) prepared by Cristol[6] are stable compounds with a fairly rigid cage structure. 9,10-Dihydro-9,10-etheno- and ethanoanthracene derivatives substituted dissymmetrically in the benzene rings should be resolved in the optical antipodes. In fact, optical resolution and CD spectral properties of some etheno- and ethanoanthracene derivatives have been reported.[7] Considering the direction of polarization of transition of benzene chromophores,[8] we have carried out the syntheses and optical resolution of a series of 9,10-dihydro-9,10-etheno- and ethanoanthracenes bearing the same substituent groups at 1,5-positions (III and IV). It is contemplated that systematic studies on the CD spectral properties of series of III and IV with the same absolute configuration may afford valuable information on the relation of structure and rotatory properties.

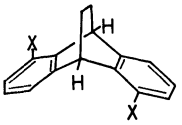
III



IV

The present paper deals with the synthesis and optical resolution of 1,5-dicarboxy-9,10-dihydro-9,10-ethenoanthracene (X) and the transformation of carboxyl groups in optically active X in various substituents to give a series of optically active 1,5-disubstituted derivatives with the same absolute configuration. The reaction sequence of the synthesis of X and ethanoanalogue (XII) starting from 1,5-dichloroanthraquinone is outlined in Fig. 1. The reaction of *cis*- or *trans*-dichloroethylene with 1,5-dimethoxycarbonylanthracene (V) derived from dichloroanthraquinone was carried out in a sealed tube at 180—190°C. As expected, *cis*-dichloroethylene gave an adduct (VI) and the *trans*-isomer afforded two kinds of adducts which could be separated on silica gel column chromatography into crystalline VII and VIII. Treatment of the adduct (VI or VII or VII or a mixture of VII and VIII) with zinc-copper couple in boiling methanol by the reported method[9] yielded the same 1,5-dimethoxycarbonyl-9,10-dihydro-9,10-ethenoanthracene (IX) in a good yield. Hydrolysis of IX gave dicarboxylic acid

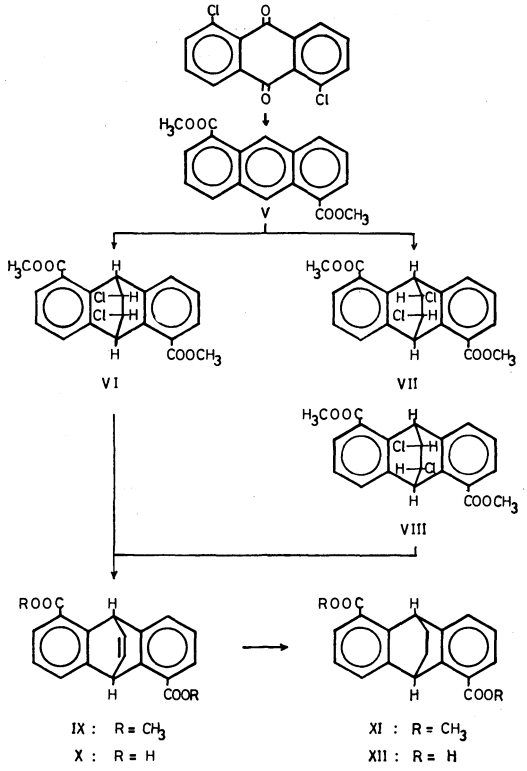


Fig. 1. Synthesis of 1,5-dicarboxy-9,10-dihydro-9,10-etheno- and ethanoanthracenes (X and XII).

(X). Catalytic hydrogenation of IX and X afforded ethano-derivatives (XI and XII), respectively.

The optically resolution of X could b eachieved by strychnine. A solution of X and equimolar strychnine in 99% ethanol was refluxed to give crystalline salt. Optically pure salt obtained by repeated recrystallization of the salt from ethanol was treated with aqueous 50% acetic acid to yield (−)-X. Decomposition of crude salt obtained by concentration of the mother liquor of first recrystallization with aqueous 50% acetic acid afforded (+)-X with an optical purity of 87.3%.[10]

The reaction sequence of the transformation of carboxyl groups in optically active X in various substituents is shown in Fig. 2. X was converted into diamino derivative (XIII) by the Curtius reaction *via* acid chloride, azide, and isocyanate. Hydrogenation of XIII over platinum catalyst gave diamino-ethano derivative (XIV). XIV in chloroform was oxidized with peracetic acid to give dinitro-ethanoanthracene (XVIII). (−)-Diamino derivative (XIII) was converted into (−)-dihydrobromide (XV) and the single crystal of (−)-XV was subjected to X-ray structure analysis by the Bijvoet method to determine the absolute configuration. Diazotization of XIII in acetic acid with sodium nitrite followed by hydrolysis afforded etheno-phenol (XVI) which was converted into etheno-dimethyl ether (XVII) by the reaction with dimethyl sulfate. 1,5-Dimethoxycarbonyl-ethenoanthracene (IX) obtained from dicarboxylic acid (X) was treated with lithium aluminum hydride to give bis-hydroxymethyl deriva-

10) Attempts to resolve (±)-X with cinchonidine resulted in (−)-X with poor optical purity (5.13%).

tive (XIX). The reaction of thionyl chloride with XIX resulted in bis-chloromethyl-etheno derivative (XX). Bis-iodomethyl-etheno compound (XXI) obtained on treatment of XX with sodium iodide in acetone was reduced by lithium aluminum hydride in tetrahydrofuran to give dimethylethenoanthracene (XXII). Catalytic reduction of XXII afforded dimethyl-ethano compound (XXIII).

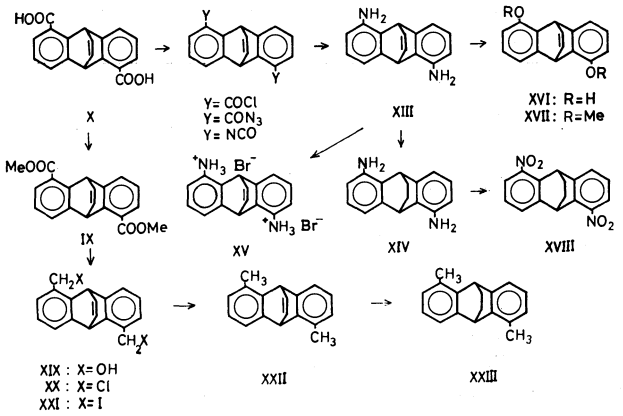

Fig. 2. Transformation of X into 1,5-disubstituted-9,10-dihydro-9,10-etheno- and ethanoanthracenes.

Optically active 1,5-disubstituted-9,10-dihydro-9,10-etheno- and ethanoanthracenes thus prepared clearly belong to a series of the same absolute configuration as that of starting X, because the rigid cage structure of the molecule excludes the possibility of occurrence of the Walden inversion and racemization during the course of transformation.

Experimental

The melting points below 260°C were determined on a Mettler FP2 apparatus and those over 260°C on a Shimadzu Kofler micro hot stage, and are not corrected. Anhydrous pure solvents were used unless otherwise stated. Ligroin with bp 60—80°C was used. The IR and UV spectra were obtained on Hitachi EPI-2, JASCO DS-301 and Hitachi EPS-3T spectrophotometers, respectively. A Yanagimoto ORD-185 and a JASCO J-20 with CD attachment spectropolarimeters were used for the measurements of rotation and CD spectra, respectively. Inflection or shoulder is denoted by an asterisk. Methanol or ethanol containing 10 vol% of 0.1N hydrochloric acid (MeOH–HCl or EtOH–HCl) was used for the measurements of UV, ORD, and CD spectra in an acidic medium. The UV, ORD, and CD spectral data are summarized in Tables 1, 2, and 3. The NMR spectra in deuteriochloroform were measured on a Varian A-60 spectrometer using TMS as an internal standard. Chemical shifts are given in τ-unit.

*1,5-Dimethoxycarbonyl-9,10-dihydro-9,10-(*cis*-11,12-dichloro)-ethanoanthracene (VI).* A mixture of 1,5-dimethoxycarbonylanthracene[1d] (V, 6.54 g, 0.0222 mol) and *cis*-dichloroethylene (18.75 g, 0.2065 mol) in a sealed tube was heated to 180—185°C for 3 days. The crystals deposited on standing the reaction mixture overnight were washed with benzene to give colorless crystals (6.46 g). The residue obtained by evaporating the combined washings and filtrate was dissolved in carbon tetrachloride–benzene (1:1) and the solution was passed through a column of alumina (150 g), yielding an additional amount of crystals, 1.23 g (total 7.69 g, 88.9%). The combined crystals were recrystallized twice from carbon tetrachloride to give pure VI, mp 204.8—205.2°C, IR (KBr-disk): 1718 ($\nu_{C=O}$) cm^{-1}, NMR: 1.98—2.73 (m, 6H, aromatic), 3.83 (m, 1H, bridgehead), 4.09 (m, 1H, bridgehead), 5.50 (t, 2H, bridge), 6.02 (s, 6H, $-COOCH_3$), UV: $\lambda_{max}^{dioxane}$ (ε) 291 (4430), 227* (23000), 211 (39500) nm.

Found: C, 61.23; H, 4.14; Cl, 18.22%. Calcd for $C_{20}H_{16}Cl_2O_4$: C, 61.39; H, 4.12; Cl, 18.13%.

1,5-Dimethoxycarbonylanthracene (V, 0.9 g) was recovered from benzene eluate of the alumina column.

*1,5-Dimethoxycarbonyl-9,10-dihydro-9,10-(*trans*-11,12-dichloro)-ethanoanthracene (VII and VIII).* A mixture of V[1d] (5.0 g, 0.017 mol) and *trans*-dichloroethylene (16.5 g, 0.170 mol) in a sealed tube was heated to 180—190°C for 48 hr. Treatment of the reaction mixture by a similar method to that used for VI afforded pale yellow crystals (6.33 g, 95.2%) along with recovered V (0.02 g). A solution of the crystals (5.364 g) in benzene–carbon tetrachloride (1:1) was passed through a column of silica gel (300 g) and eluted with the same mixed solvent. The eluate was divided into 36 fractions, each fraction being 100 ml. As fractions 10—16 gave a spot at the same R_f on tlc (silica gel), they were combined and evapo-

rated to give crystals (2.733 g) which were recrystallized from benzene–ligroin to afford colorless needles, mp 211.6—211.7°C, 2.136 g. Fractions 17—23 gave two spots on tlc indicating that they contain VII and VIII. Fractions 24—36 gave a spot on tlc and were therefore combined and evaporated, yielding crystals (1.225 g). Recrystallization from benzene–ligroin afforded colorless granulous crystals, mp 256.3—256.4°C 0.925 g.

Lower Melting Isomer: IR (KBr-disk): 1720 ($\nu_{C=O}$) cm^{-1}, NMR: 2.00—2.87 (m, 6H, aromatic), 4.13 (t, 2H, bridgehead), 5.77 (m, 2H, bridge), 6.02 (s, 6H, $-COOCH_3$), UV: $\lambda_{max}^{dioxane}$ (ε) 290 (4260), 228 (24100), 211 (37200) nm.

Found: C, 61.65; H, 4.18; Cl, 18.12%. Calcd for $C_{20}H_{16}Cl_2O_4$: C, 61.39; H, 4.12; Cl, 18.13%.

Higher Melting Isomer: IR (KBr-disk): 1715 ($\nu_{C=O}$) cm^{-1}, UV: $\lambda_{max}^{dioxane}$ (ε) 292 (4200), 287* (4140), 230* (23200), 211.5 (43500) nm.

Found: C, 61.19; H, 4.01; Cl, 18.09%. Calcd for $C_{20}H_{16}Cl_2O_4$: C, 61.39; H, 4.12; Cl, 18.13%.

1,5-Dimethoxycarbonyl-9,10-dihydro-9,10-ethenoanthracene (IX). From cis*-Adduct (VI).* Zinc-copper couple[11] (76 g) was added to a solution of VI (3.00 g, 7.67 mmol) in methanol (400 ml) and benzene (140 ml). The mixture was refluxed for 4 days under stirring. The hot reaction mixture was filtered and the insoluble material was washed successively with hot methanol and hot benzene. The combined filtrate and washings were concentrated and mixed with water (1000 ml) and extracted with benzene. The extract, after washing and drying, was evaporated under reduced pressure to give colorless crystals 2.43 g (95.3%) which were recrystallized from methanol to yield pure IX, mp 150.5—151.0°C, IR (KBr-disk): 1724 ($\nu_{C=O}$) cm^{-1}, NMR: 2.27—3.16 (m, 8H, aromatic and olefinic), 3.30—3.55 (m, 2H, bridgehead), 6.03 (s, 6H, $-COOCH_3$).

Found: C, 75.25; H, 4.99%. Calcd for $C_{20}H_{16}O_4$: C, 74.99; H, 5.03%.

From Lower Melting trans*-Adduct (VII or VIII).* A mixture of lower melting *trans*-adduct (0.301 g, 0.77 mmol), zinc-copper couple[10] (7.6 g), methanol (40 ml) and benzene (15 ml) was refluxed under stirring for 48 hr. The reaction mixture was worked up according to a procedure similar to that used for VI, and the crude IX in benzene was chromatographed on alumina (15 g). Colorless crystals 0.288 g (92.2%) obtained from the first benzene eluate (300 ml) were recrystallized twice from methanol, yielding pure IX as colorless rhomboids, mp 151.4—151.7°C. The IR spectrum was found to be identical with that of IX derived from *cis*-adduct.

Found: C, 74.97; H, 5.13%. Calcd for $C_{20}H_{16}O_4$: C, 74.99; H, 5.03%.

From Higher Melting trans*-Adduct (VII or VIII).* Zinc-copper couple[11] (7.6 g) was added to a mixture of higher melting *trans*-adduct (0.297 g, 0.76 mmol), methanol (40 ml) and benzene (30 ml), and the mixture was refluxed for 77.5 hr under stirring. Crystals obtained on working up the reaction mixture by a similar procedure to that used for *cis*-adduct were found to be contaminated with the starting chloro compound (25% on the basis of NMR spectrum). The crystals in benzene (20 ml) and methanol (60 ml) were treated with zinc-copper couple[10] (8.0 g) for further 28 hr. Working up the reaction mixture yielded colorless crystals, 0.143 g (58.8%), which were recrystallized 3 times from methanol to give pure IX, mp 149.8—151.1°C. The IR spectrum was identical with that of IX obtained from *cis*-adduct.

11) R. D. Smith and H. E. Simmons, "Organic Syntheses," Vol. 41, p. 72 (1961).

Found: C, 74.97; H, 5.03%. Calcd for $C_{20}H_{16}O_4$: C, 74.99; H, 5.03%.

A mixture of VII and VIII gave IX under the same reaction conditions.

1,5-Dicarboxy-9,10-dihydro-9,10-ethenoanthracene (X). A solution of potassium hydroxide (100 g) in water (200 ml) was added to a solution of IX (4.305 g, 13.44 mmol) in methanol (300 ml) and the mixture was refluxed for 5 hr. After the methanol had been removed by distillation, the mixture was made acidic to Congo red with concentrated hydrochloric acid under cooling. Colorless precipitate formed was washed thoroughly with cold water and dried *in vacuo* at 100°C to give X, 3.86 g (98.4%). This material was recrystallized successively from acetic acid and methanol to afford pure X, colorless crystals, mp 303—309°C (decomp.), IR (KBr-disk): 1678, 1691 ($\nu_{C=O}$) cm^{-1}.

Found: C, 73.50; H, 4.21%. Calcd for $C_{18}H_{12}O_4$: C. 73.96; H, 4.14%.

X could be converted into IX on heating with methanol and sulfuric acid.

1,5-Dimethoxycarbonyl-9,10-dihydro-9,10-ethanoanthracene (XI), Dimethyl ester (IX, 0.324 g, 1.011 mmol) in dioxane (50 ml) was reduced over platinum oxide (21.4 mg). The crystals (0.316 g) obtained on evaporation of the solvent were recrystallized twice from methanol to yield pure XI, colorless crystals, mp 140.1—140.3°C, IR (KBr-disk): 1713 ($\nu_{C=O}$) cm^{-1}, NMR: 2.15—3.03 (m, 6H, aromatic), 4.34 (m, 2H, bridgehead), 6.06 (s, 6H, $-COOCH_3$), 8.27 (t, 4H, ethane bridge).

Found: C, 74.36; H, 5.06%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

Hydrolysis of XI under the similar reaction conditions used for IX afforded ethano-dicarboxylic acid (XII).

1,5-Dicarboxy-9,10-dihydro-9,10-ethanoanthracene (XII). Catalytic hydrogenation of X (0.0987 g, 0.338 mmol) in methanol (40 ml) over platinum oxide (14.9 mg) afforded XII as colorless crystals (0.1024 g) which were recrystallized twice from methanol to give pure XII, mp 318—327°C (decomp.), IR (KBr-disk): 1690 ($\nu_{C=O}$) cm^{-1}.

Found: C, 73.30; H, 5.02%. Calcd for $C_{18}H_{14}O_4$: C, 73.46; H, 4.80%.

XII could be converted into XI on treatment with methanol and sulfuric acid.

Optical Resolution of (±)-1,5-Dicarboxy-9,10-dihydro-9,10-ethenoanthracene (X). A solution of equimolar strychnine (4.58 g, 0.0137 mol) in 99% ethanol (600 ml) was added to a solution of (±)-X (4.00 g, 0.0137 mol) in the same solvent (3500 ml). After being refluxed for 3 hr, the mixture was concentrated to *ca.* 1000 ml and allowed to stand overnight. Crystalline salt deposited (3.43 g) was recrystallized 4 times from 99% ethanol to give optically pure salt, mp 322—326°C (decomp.), 1.43 g.

Found: C, 74.41; H, 5.45; N, 4.43%. Calcd for $C_{39}H_{34}N_2O_6$: C, 74.74; H, 5.47; N, 4.47%.

Since the measurement of rotation of the strychnine salt was difficult owing to its poor solubility in organic solvents, the increase in optical purity of the salt was followed by measurements of rotation of dicarboxylic acids obtained from the mother liquors of recrystallization on acidification with acetic acid.

Optically pure salt thus obtained was decomposed with aqueous 50% acetic acid to yield optically pure (−)-X, mp 315—322°C (decomp.), 0.65 g.

Found: C, 73.45; H, 4.24%. Calcd for $C_{18}H_{12}O_4$: C, 73.96; H, 4.14%.

The mother liquor of the first recrystallization was concentrated to give crystalline salt (5.05 g). Decomposition of the salt with aqueous 50% acetic acid afforded (+)-enantiomer, 2.35 g, $[\alpha]_D$ +291.2° (*c*, 0.215, dioxane), optical purity, 87.3%.

(−)-1,5-Dimethoxycarbonyl-9,10-dihydro-9,10-ethenoanthracene (IX). Concentrated sulfuric acid (3 ml) was added to a solution of (−)-X (0.196 g) in methanol (30 ml) and the mixture was refluxed for 16.5 hr. The reaction mixture was worked up by the usual way to afford (−)-etheno-diester (IX), 0.198 g (92.4%). Pure (−)-IX was obtained by recrystallization from methanol, mp 151.5—151.8°C, $[\alpha]_{405}$ −1160° (*c* 0.00546, methanol).

Found: C, 75.22; H, 5.14%. Calcd for $C_{20}H_{16}O_4$: C, 74.99; H, 5.03%.

(−)-1,5-Dimethoxycarbonyl-9,10-dihydro-9,10-ethanoanthracene (XI). Reduction of (−)-IX (22.6 mg) in dioxane (10 ml) over platinum oxide (6.6 mg) yielded colorless liquid which could be crystallized on trituration with methanol. Recrystallization from methanol gave pure (−)-XI, colorless crystals, mp 121.8—122.4°C, 19.4 mg, $[\alpha]_{405}$ −1170° (*c* 0.00600, methanol).

Found: C, 74.21; H, 5.66%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%.

(−)-1,5-Diamino-9,10-dihydro-9,10-ethenoanthracene (XIII). A mixture of (−)-X (0.441 g, 1.508 mmol), thionyl chloride (5 ml) and tetrahydrofuran (40 ml) was refluxed for 3 hr. Crude acid chloride (0.716 g) obtained by evaporation of volatile material under reduced pressure was dissolved in tetrahydrofuran (16 ml), and a solution of sodium azide (0.359 g, 5.521 mmol) in water (8 ml) was added under ice-cooling. After being stirred for 3 hr at the same temperature, the reaction mixture was mixed with ice-water and extracted with benzene. The extract, after washing and drying, was concentrated under reduced pressure to give crystalline acid azide. Thoroughly dried acid azide (0.561 g) in benzene (40 ml) was refluxed for 5 hr. Isocyanate (0.584 g) obtained as a brown liquid on evaporation of the solvent under reduced pressure was mixed with a solution of potassium hydroxide (3 g) in 99% ethanol (35 ml) and water (8 ml). After the mixture had been refluxed for 12 hr, the reaction mixture was poured onto ice-water and extracted with benzene. Concentration of the extract, after washing and drying, afforded crude diamine (XIII, 0.281 g) as a brown solid. A solution of the crude XIII in benzene–ether (9: 1) was passed through a column of silica gel (30 g) and the filtrate was chromatographed on the same adsorbent. Elution with dichloromethane afforded (−)-XIII (0.128 g, 79.1%) which was recrystallized from ether-ligroin to give pure (−)-XIII, mp 188.3—189.6°C (racemate, mp 187.6—189.5°C), IR (Nujol mull): 3320, 3230 (ν_{N-H}), 1627 (δ_{N-H}) cm^{-1}, NMR: 2.72—3.75 (m, 8H, aromatic and olefinic), 4.85 (t, 2H, bridgehead), 6.45 (s, 4H, $-NH_2$).

Found: C, 81.89; H, 6.10; N, 11.81%. Calcd for $C_{16}H_{14}N_2$: C, 82.02; H, 6.02; N, 11.96%.

(−)-1,5-Diamino-9,10-dihydro-9,10-ethanoanthracene (XIV). Hydrogenation of (−)-XIII (0.167 g, 0.712 mmol) in methanol (20 ml) over platinum oxide afforded crude (−)-XIV (0.158 g) which was chromatographed on silica gel and eluted with benzene–ether (9: 1) to yield (−)-XIV (0.146 g, 86.7%). Recrystallization of this material from benzene-ligroin gave pure (−)-XIV, mp 213.3—213.8°C (racemate, mp 188.8—188.9°C), IR (Nujol mull): 3340, 3230 (ν_{N-H}), 1625 (δ_{N-H}) cm^{-1}, NMR: 2.90—3.43 (m, 6H, aromatic), 5.68 (s, 2H, bridgehead), 6.60 (s, 4H, $-NH_2$), 8.30 (t, 4H, bridge).

Found: C, 81.49; H, 6.84; N, 11.73%. Calcd for $C_{16}H_{16}N_2$: C, 81.32; H, 6.83; N, 11.86%.

(−)-1,5-Diamino-9,10-dihydro-9,10-ethenoanthracene Dihydrobro-

mide (XV). A mixture of hydrobromic acid (47%, 2 ml) and water (2 ml) was added to a solution of (−)-XIII (0.0211 g) in 99% ethanol (10 ml). Homogeneous solution obtained on warming the mixture was allowed to stand at room temperature. Fine needles deposited after a week were dissolved on addition of the same solvent (5 ml) under warming. The homogeneous solution in a loosely stoppered flask was kept in a dark place at room temperature. After 3 months, single crystal of (−)-XV was obtained as a rod.

Found: C, 46.54; H, 4.53; Br, 38.22%. Calcd for $C_{16}H_{16}Br_2N_2 \cdot H_2O$: C, 46.40; H, 4.38; Br, 38.59%.

(−)-1,5-Dinitro-9,10-dihydro-9,10-ethanoanthracene (XVIII). To a warm solution of peracetic acid prepared by heating a mixture of chloroform (0.1 ml), 90% hydrogen peroxide (0.15 ml), concentrated sufuric acid (2 drops) and acetic anhydride (0.1 ml) was added dropwise a solution of (−)-XIV (51.7 mg) in chloroform (5 ml). After the mixture had been refluxed for 2.5 hr under stirring, the reaction mixture was poured onto water and extracted with chloroform. The extract, after washing and drying, was concentrated under reduced pressure to afford crystals (37.1 mg, 57.2%). A solution of the crystals in carbon tetrachloride–benzene (1:1) was passed through a column of alumina (7 g). The crystals (23.3 mg) obtained from the early filtrate (150 ml) were recrystallized twice from benzene–methanol to give pure (−)-XVIII, feather-like crystals, 10.7 mg, mp 206.3—207.3°C (racemate, mp 225.1—225.6°C), IR (Nujol mull): 1532 ($\nu_{as\ N-O}$), 1347 ($\nu_{s\ N-O}$) cm^{-1}, NMR: 2.00—2.90 (m, 6H, aromatic), 4.47 (broad s, 2H, bridgehead), 8.15 (broad s, 4H, ethane bridge).

Found: C, 64.71; H, 4.13%. Calcd for $C_{16}H_{12}N_2O_4$: C, 64.86; H, 4.08%.

(+)-1,5-Dimethoxy-9,10-dihydro-9,10-ethenoanthracene (XVII). To a solution of (+)-XIII (0.0573 g, 0.2446 mmol) in acetic acid (2 ml) was added dropwise a solution of sodium nitrite (0.047 g, 0.6812 mmol) in water (1.0 ml) under ice-cooling. After being stirred for further 1.5 hr at the same temperature, the solution of diazonium salt was added dropwise to boiling 6N sulfuric acid (24 ml) and reflux was continued for 1.5 hr. The reaction mixture was repeatedly extracted with ether. The ethereal extract, after washing and drying, was concentrated under reduced pressure. Crude (+)-phenol (XVI, 0.0434 g, 75.1%) obtained as a brown solid was methylated without purification. In the case of racemate, crude XVI was converted into diacetate by the usual method, and treated with lithium aluminum hydride in tetrahydrofuran to give pure (±)-XVI.

(±)-Diacetate: mp 176.7—177.1°C. Found: C, 74.99; H, 5.03%. Calcd for $C_{20}H_{16}O_4$: C, 74.99; H, 5.03%.

(±)-Phenol (XVI): mp 231.4—234.8°C (decomp.). Found: C, 81.05; H, 5.08%. Calcd for $C_{16}H_{12}O_2$: C, 81.34; H, 5.12%.

A mixture of crude (−)-XIV (43.4 mg), dimethyl sulfate (0.15 g), potassium carbonate (0.75 g) and acetone (13 ml) was refluxed for 18.5 hr. The reaction mixture was worked up in the usual way to give crude crystals (46.6 mg, 72% based on (+)-XIII). The crude crystals dissolved in carbon tetrachloride–benzene (1:1) were passed through a column of alumina (20 g). Colorless crystals (15.3 mg) obtained from the early eluate (200 ml) were recrystallized from methanol–benzene to yield pure (+)-XVII, colorless needles, 9.3 mg, mp 206.9—207.3°C (sealed tube) (racemate 210.0—210.4°C), NMR: 3.60—2.77 (m, 8H, aromatic and olefinic), 4.43 (t, 2H, bridgehead), 6.23 (s, 6H, $-OCH_3$).

Found: C, 82.13; H, 6.09%. Calcd for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

(−)-1,5-Bis(hydroxymethyl)-9,10-dihydro-9,10-ethenoanthracene XIX). A solution of (−)-IX (0.158 g, 0.494 mmol) in tetrahydrofuran (10 ml) was added to a suspension of lithium aluminum hydride (0.295 g) in the same solvent. After refluxing for 21 hr, ethyl acetate (5 ml), ice-water (5 ml) and 6N sulfuric acid (60 ml) were added successively to the reaction mixture under ice-cooling, and then extracted with ether. The extract, after washing and drying, afforded yellow liquid (0.143 g) on evaporation under reduced pressure. The liquid was chromatographed on silica gel (10 g) and eluted with benzene–ether (9: 1) to give pale yellow liquid (0.113 g, 86.7%) which could be crystallized from benzene–acetone, yielding pure (−)-XIX, colorless crystals, 0.0454 g, mp 154.5—155.1°C (racemate, mp 204.5—205.5°C), IR (Nujol mull): 3260 (ν_{O-H}) cm^{-1}.

Found: C, 81.72; H, 6.10%. Calcd for $C_{18}H_{16}O_2$: C, 81.79; H, 6.10%.

(−)-1,5-Dimethyl-9,10-dihydro-9,10-ethenoanthracene (XXII). To a solution of (−)-XIX (79.1 mg, 0.2993 mmol) in benzene (20 ml) was added thionyl chloride (2 ml). After the mixture had been refluxed for 10 hr, the volatile material was removed under reduced pressure to give crude XX (84.9 mg). Crude (−)-XX thus prepared was used in the following reaction. (±)-XX was recrystallized from ligroin to give pure material, mp 195.6—197.5°C, NMR: 2.47—3.23 (m, 8H, aromatic and olefinic), 4.41 (t, 2H, bridgehead), 5.23 (s, 4H, $-CH_2Cl$).

Found: C, 71.71; H, 4.78%. Calcd for $C_{18}H_{14}Cl_2$: C, 71.77; H, 4.69%.

Crude (−)-XX (84.9 mg) in acetone (15 ml) was refluxed for 6 hr with sodium iodide (0.2 g) under shielding from light. Crude crystals of (−)-XXI (102.4 mg) obtained by working up the reaction mixture in the usual way were dissolved in tetrahydrofuran (40 ml) and the solution was added to a stirred suspension of lithium aluminum hydride (0.2 g) in the same solvent (40 ml). After being refluxed for 25 hr, the reaction mixture was treated successively with ethyl acetate, water and 6N sulfuric acid and extracted with ether. The extract, after being washed and dried, was concentrated under reduced pressure. The resulting colorless liquid (58.6 mg, 84.3%) was distilled *in vacuo* to give pure (−)-XXII, bp 90—100°C/15 mmHg (bath temp.) which gave a spot on tlc, NMR: 2.72—3.36 (m, 8H, aromatic and olefinic), 4.66 (t, 2H, bridgehead), 7.58 (s, 6H, $-CH_3$).

(±)-XXII was obtained as crystals, mp 159.4—162.9°C (from methanol) which gave an identical UV spectrum in isooctane with that of (−)-XXII.

Found: C, 92.82; H, 7.03%. Calcd for $C_{18}H_{16}$: C, 93.06; H, 6.94%.

(−)-1,5-Dimethyl-9,10-dihydro-9,10-ethanoanthracene (XXIII). (−)-XXII (21.1 mg) in 99% ethanol was reduced over platinum oxide. The product dissolved in carbon tetrachloride was chromatographed on alumina (10 g). Crude crystals obtained from the early eluate (100 ml) were recrystallized from methanol to give pure (−)-XXIII, mp 92.4—94.7°C (racemate, mp 49.0—55.0°C), NMR: 2.79—3.18 (m, 6H, aromatic), 5.46 (s, 2H, bridgehead), 7.59 (s, 6H, $-CH_3$), 8.36 (t, 4H, ethane bridge).

Found: C, 91.99; H, 7.83%. Calcd for $C_{18}H_{18}$: C, 92.26; H, 7.74%.

Stereochemical Studies on the Halogenation of Sulfoxides. I. The Chlorination of Cyclic Sulfoxides[1]

Shinobu IRIUCHIJIMA, Mariko ISHIBASHI, and Gen-ichi TSUCHIHASHI

Sagami Chemical Research Center, Nishiohnuma, Sagamihara, Kanagawa 229

(Received June 5, 1972)

The cyclic sulfoxides, thiane 1-oxide, *cis*- or *trans*-4-chlorothiane 1-oxide, and *cis*- or *trans*-4-phenylthiane 1-oxide, were chlorinated with *t*-butyl hypochlorite, sulfuryl chloride, and chlorine in the presence of potassium acetate or pyridine. The stereoformulas of the products, together with those of the isomers having an inverted sulfoxide configuration, were determined by means of the IR and NMR spectral data and the R_f-values in the tlc. Consequently, it has been found that chlorination occurs when the sulfinyl oxygen is equatorial and that chlorine is always introduced at a *trans*-position to the sulfinyl lone pair to give rise to the *cis*-products. A mechanism accommodating these results is proposed. The conformation of the substituted thiane 1-oxide rings is also discussed.

The configurational stability of sulfoxides has been confirmed by the resolution of three sulfoxides,[2] and examples of geometrical isomerism attributable to the sulfinyl group has been reported.[3] Recently, a simple synthetic method of the optically active sulfoxides has been established,[4] and there has been much interest in the stereochemical aspects of sulfoxides.[5]

The α-halogenation of sulfoxides with halogenating agents in the presence of base is known to be a stereoselective reaction. For example, in the halogenation of benzyl methyl sulfoxide with iodobenzene dichloride or bromine in the presence of pyridine, it has been shown that the proton diastereotopic to the proton which is preferentially exchanged by deuterium in the presence of NaOD in D_2O is replaced with halogen stereospecifically.[6] The stereoselectivity was also observed in the chlorination of benzyl phenyl sulfoxide with *t*-butyl hypochlorite.[7]

In this and the following papers we would like to report on our stereochemical studies of the halogenation of the cyclic sulfoxides, designed to ascertain the stereochemical course of the reaction. The cyclic sulfoxides used were thiane 1-oxide, *cis*- or *trans*-4-chlorothiane 1-oxide,[8] and *cis*- or *trans*-4-phenylthiane 1-oxide.[9] The chlorination with *t*-butyl hypochlorite,[7] sulfuryl chloride,[10] and chlorine[11] in the presence of potassium acetate or pyridine will be described here, while the bromination with bromine/*N*-bromosuccinimide in the presence of pyridine[12] will be reported in the following paper.[13]

Results and Discussion

The Chlorination of Thiane 1-Oxide with t-*Butyl Hypochlorite.* The chlorination of six-membered thiane 1-oxide (**1**) with *t*-butyl hypochlorite in the presence of anhydrous potassium acetate in dichloromethane produced, stereospecifically, *cis*-2-chlorothiane 1-oxide (**2**) (Fig. 1) (mp 65.5—66.5°C) in an 88% yield. The inversion of the sulfoxide configuration of **2** with triethyloxonium tetrafluoroborate(Et_3OBF_4)[14] furnished *trans*-2-chlorothiane 1-oxide (**3**) (mp 43—44 °C) in a 74% yield.

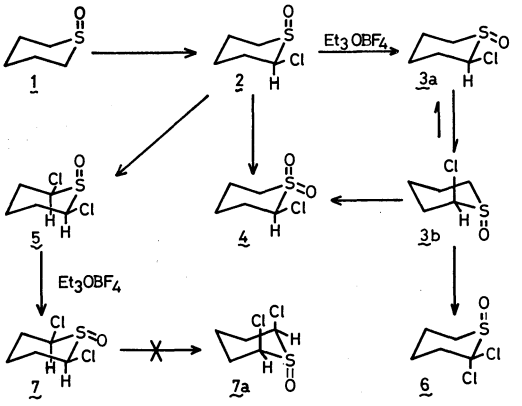

Fig. 1.

The stereoformulas of **2** and **3** were determined as follows. Aromatic solvent-induced shifts(ASIS; $\Delta = \delta_{CCl_4} - \delta_{C_6H_6}$), known as a useful method in deriving stereochemistry, are also applicable to the sulfoxides, as has been shown in the cases of penicillin sulfoxides,[15]

biotin sulfoxides,[16] and thiolane 1-oxide.[17] According to ASIS for the sulfoxides, the proton *trans* to the sulfinyl oxygen is more shielded and has a larger Δ-value than the proton *cis* to the sulfinyl oxygen, because aromatic systems like benzene coordinate at electron-deficient sites, avoiding a strongly negative sulfinyl oxygen atom (and probably a negative halogen atom, also). Therefore, the chlorinated product with a larger Δ-value(Δ=0.65) (Table 1) should possess a *cis*-form(**2**), while the inverted isomer with a smaller Δ-value(Δ=0.43) should possess a *trans*-form(**3**). This assignment is supported by the facts that the IR C–Cl stretching frequency of **2** is observed at 763 cm^{-1}(C-Cl_{eq}) while that of **3** is observed at 696 cm^{-1}(C-Cl_{ax})[18] in carbon disulfide, and that **3** is detected higher than **2** on a thin-layer plate of silica gel, indicating that **3** is a less polar substance than **2**. Moreover, in the polar solvents (CD_3CN, D_2O, and CF_3COOH), the H-C_2 of **3** was observed as axial, while in the non-polar solvents(CCl_4, $CDCl_3$, and C_6H_6), it was observed as equatorial rather than axial, whereas the H-C_2 of **2** was always observed as axial regardless of whether the solvent was polar or not (Table 1). This phenomenon can be well explained by saying that **2** has a stable *cis*-form possessing a preferable axial sulfinyl oxygen[8,19] and equatorial chlorine. On the other hand, since **3** has an unstable *trans*-form, its conformation changes with the solvent polarity; the polar conformation **3a** is favored in the polar solvents, while the less polar conformation **3b** dominates in the non-polar solvents. The possibility that **3**, which might be formed by the chlorination of **1**, was isomerized to the thermodynamically stable isomer(**2**) during the reaction was excluded by the fact that **2** was not produced at all when **3** was kept in the chlorination condition with 0.5 equivalent of *t*-butyl hypochlorite. After treatment with concentrated hydrochloric acid (1 volume) in dioxane (2 volumes), which is known to cause the complete racemization of sulfoxides,[20] **3** was recovered unchanged, whereas *cis*-4-chlorothiane 1-oxide(**10**) or *trans*-isomer(**8**) was equilibrated to a 47.5 : 52.5 mixture of **10** and **8**.[21] Therefore, **3** is a configurationally stable compound, and it is evident that **2** is directly formed by the chlorination of **1**.

The hydrogen peroxide oxidation of both **2** and **3** in acetic acid gave 2-chlorothiane 1,1-dioxide(**4**) (mp 68—69.5°C).

Further chlorination of **2** and **3** gave results which are quite informative of the reaction mechanism. The chlorination of **2** gave a mixture from which 2e,6e-dichlorothiane 1a-oxide(**5**) (mp 134—135°C), was subsequently isolated in a 37% yield as the major product, whereas the chlorination of **3** produced 2,2-dichlorothiane 1-oxide(**6**) (mp 34.5—36°C) in a 67% yield. The transformation of **5** with Et_3OBF_4 afforded 2e,6e-dichlorothiane 1e-oxide(**7**) (mp 129—130°C) in a 60% yield. The stereochemistry of **5** and **7** has been established on the basis of the NMR coupling constants, ASIS(Table 2), and tlc; **5** is detected higher than **7** on a thin-layer plate. According to the general rule which we found in a series of studies, a sulfoxide having an axial sulfinyl oxygen is observed higher on a thin-layer plate than the isomer having an equatorial oxygen if the other parts of the structures are the same.

TABLE 2. NMR SPECTRAL DATA OF H-C_2(AND H-C_6) OF 2,6-DICHLOROTHIANE 1-OXIDES (**5** AND **7**), 2-CHLORO-4-PHENYLTHIANE 1-OXIDES(**17** AND **18**), AND 2,6-DICHLORO-4-PHENYLTHIANE 1-OXIDES(**20** AND **21**). $\Delta=\delta_{CCl_4}-\delta_{C_6H_6}$.

The Chlorination of 4-Chlorothiane 1-Oxides and 4-Phenylthiane 1-Oxides with t-*Butyl Hypochlorite.* The chlorination of *trans*-4-chlorothaine 1-oxide(**8**) gave, stereospecifically, 2e,4a-dichlorothiane 1a-oxide(**9**) (mp 72.5—74°C) in a 70% yield, while *cis*-4-chlorothiane 1-oxide(**10**) furnished, in a 66% yield, a 67 : 33 mixture of **9** and 2e,4e-dichlorothiane 1a-oxide(**11**) (mp 110—111.5°C) (Fig. 2). The inversion of **9** with Et_3OBF_4 gave 2a,4e-dichlorothiane 1a-oxide (**12**) (mp 92—93.5°C) in an 83% yield. The stereochemical structures of **9**, **11**, and **12** were established by means of the NMR coupling constants of H-C_2 and H-C_4, ASIS (Table 3), and by comparison with the corresponding bromo-derivatives.[13]

The oxidation of a mixture of **9** and **12** produced *trans*-2,4-dichlorothiane 1,1-dioxide(**13**) (mp 131.5—

132°C) in a 71% yield.

The chlorination of conformationally rigid *trans*-4-phenylthiane 1-oxide(**15**) and *cis*-4-phenylthiane 1-oxide (**16**) in the presence of potassium acetate gave a single identical product, 2a-chloro-4e-phenylthiane 1e-oxide (**17**) (mp 160—160.5°C), in 83% and 66% yields respectively (Fig. 3). In the presence of pyridine, *cis*-oxide(**16**) gave **17** in a 45% yield. The product (**17**) was converted with Et_3OBF_4 into 2a-chloro-4e-phenylthiane 1a-oxide (**18**) (mp 94.5—95°C) in an 82% yield. The stereoformulas (**17** and **18**)[22] were based on the NMR (Table 2) and tlc; compound **18** possessing an axial oxygen is higher than **17**, which possesses an equatorial one. After treatment with concentrated hydrochloric acid in dioxane, compound

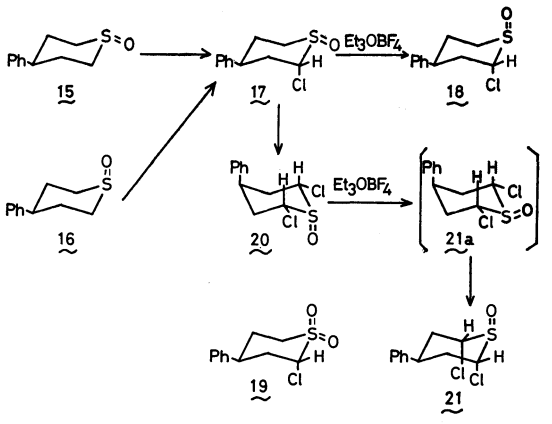

Fig. 3.

22) The stereoformulas of **17** and **18** together with **15** and **16** were unambiguously determined by the use of the shift-reagent, Eu(DPM)$_3$, and the decoupling study in the NMR spectra. M. Fukuyama, K. Sato, M. Fukuyama, S. Iriuchijima, and G. Tsuchihashi, Abstracts of the 26th Meeting of the Chemical Society of Japan: III, Kanagawa, Japan (1972). p. 1438.

17 was recovered quantitatively.

The oxidation of **17** gave *trans*-2-chloro-4-phenylthiane 1,1-dioxide(**19**) (mp 157.5—158.5°C) in a 93% yield.

The chlorination of **17** with 2.4 equivalents of *t*-butyl hypochlorite gave 2e,6e-dichloro-4a-phenylthiane 1a-oxide(**20**) (mp 119—120°C) in an 87% yield; this was then converted with Et_3OBF_4 into 2a,6a-dichloro-4e-phenylthiane 1a-oxide (**21**) (mp 101.5—102°C) in a 34% yield. The structures of **20** and **21** were established by the complete assignments of all their protons in the NMR spectra.

Mechanism of the Chlorination with t-*Butyl Hypochlorite.* The chlorination of the thiane 1-oxides(**1**, **2**, **3**, **8**, **10**, **15**, **16**, and **17**) with *t*-butyl hypochlorite described above gives products in which chlorine was always introduced at a *cis*-position to the sulfinyl oxygen, and it seems to occur when the oxygen is equatorial; compounds **15** and **17**, which possess an equatorial oxygen, are chlorinated at a *cis*-position to the oxygen, as is shown in Fig. 4. Compounds **1** and **8** which can easily take the conformations **1a** and **8a** by the inversion of the ring, are chlorinated at a *cis*-position to the equatorial oxygen in **1a** and **8a**. Compounds **2** and **3** seem to be chlorinated mainly in a manner similar to **1** and **8**. Compound **10**, the ring of which is appreciably fixed by an equatorial chlorine at C_4, is chlorinated partly by passing through the conformation **10a** (Route *a* in Fig. 4) and partly by passing through **8a**, with an inversion of the sulfoxide configuration (Route *b* in Fig. 4) to produce a mixture of **11** and **9**. The possibility of the intermediacy of **8a** is supported by the fact that the isomerization of

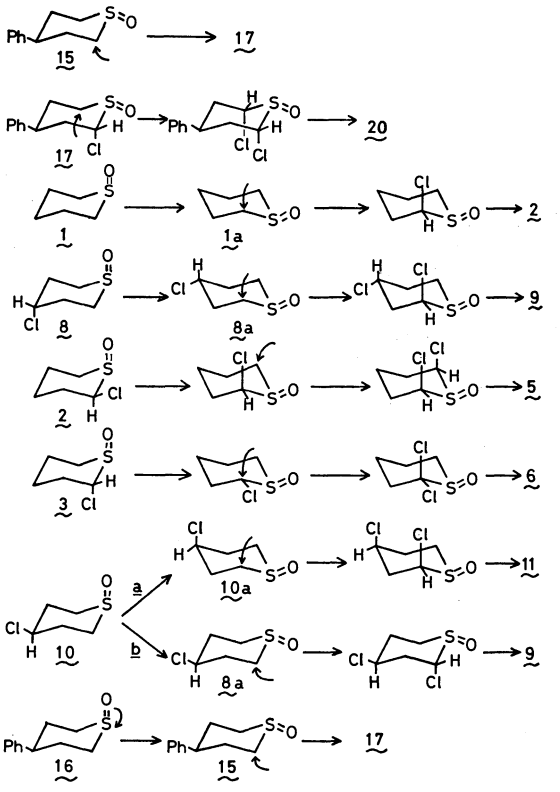

Fig. 4.

10 to **8** was observed in the chlorination of **10** with 0.3 equivalent of *t*-butyl hypochlorite. Compound **16**, the ring of which is rigidly fixed by a phenyl group, gives product **17**, accompanied by a complete sulfoxide inversion. Compound **16** might be chlorinated mainly *via* **15**, because the isomerization of **16** to **15** was observed in the chlorination of **16** with 0.5 equivalent of *t*-butyl hypochlorite.

It has been proposed that α-chlorosulfoxides can be obtained from the chloro-oxosulfonium ions *via* the ylids, either by a concerted rearrangement[23] or by an elimination-addition sequence analogous to a Pummerer-type rearrangement.[24] Our result is not compatible with the concerted rearrangement because the formation of the *trans*-product (**26**) should be expected by the process, as is shown in Fig. 5. Here, we would like to propose the mechanism shown in Fig. 6. The first step is the formation of the chloro-

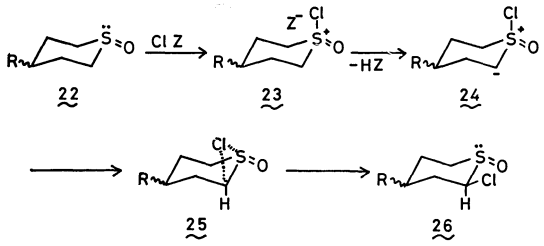

Fig. 5. Z=*t*-BuO, Cl; R=H, Cl, Ph.

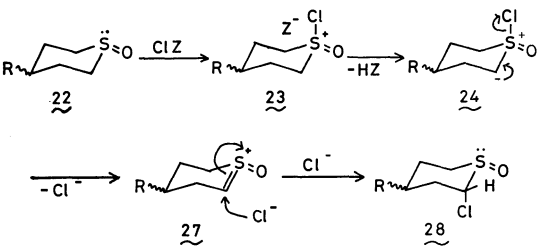

Fig. 6. Z=*t*-BuO, Cl; R=H, Cl, Ph.

oxosulfonium ion(**23**) by the attack of a positive chlorine of *t*-butyl hypochlorite on the sulfinyl lone pair. The second step is the formation of the hypothetical intermediate (**27**); the chloro-oxosulfonium ion (**23**) gives the ylid (**24**) by the action of the counter anion Z^-, which, in the present case, is the *t*-butoxide anion, and then **24** gives rise to **27** by the elimination of the chloride ion. The final step is the addition of the chloride ion to **27**, thus producing the α-chlorosulfoxide(**28**), in which the chlorine atom and sulfinyl lone pair are in the *trans* relationship. Although we do not have any direct evidence of the intervention of the chloride ion, an analogous mechanism has been proposed in the Pummerer rearrangement.[25] We have stated that chlorine is always introduced at a *cis*-position to the sulfinyl oxygen, but according to this mechanism we should say that chlorine is always introduced at a *trans*-position to the sulfinyl lone pair.

The Conformational Stability of the Substituted Thiane 1-Oxides. It is known that thiane 1-oxide(**1**)[19] and *trans*-4-chlorothiane 1-oxide(**8**)[8] exhibit a conformational preference for the forms with the sulfoxide oxygen axial, and that, in 4-substituted thiane 1-oxides such as **15** and **16**, the isomer bearing the axial oxygen is more stable.[26] In addition to this knowledge, we have found that a preferable conformer of **3** is **3a** in the polar solvents and **3b** in the non-polar solvents. Moreover, **7** is a preferable conformer to **7a**, probably because **7a** possesses two axial chlorine atoms which are highly unfavorable because of a 1,3-diaxial relationship, although it possesses a favorable axial oxygen. In **17** an equatorial phenyl group can hold the ring against the unfavorable equatorial sulfinyl oxygen and axial chlorine. In **20**, however, the phenyl group cannot hold the ring against the 1,3-diaxial chlorine atoms and equatorial oxygen; instead, the diequatorial chlorine atoms and axial oxygen keep the ring against the unfavorable axial phenyl group. In compound **21** which was obtained by the inversion of the sulfoxide configuration of **20** with Et_3OBF_4, the equatorial phenyl group and the axial oxygen together keep the ring against the 1,3-diaxial chlorine atoms. Thus, in the thiane 1-oxide ring, (1) an equatorial phenyl group keeps both a sulfinyl oxygen equatorial and a chlorine atom axial (Ph> >S=O+Cl); (2) the combination of 1,3-diequatorial chlorine atoms and an axial sulfinyl oxygen keeps a phenyl group axial(1,3-diCl+ >S=O> Ph), and (3) the combination of an euqatorial phenyl group and an axial sulfinyl oxygen keeps two chlorine atoms diaxial (Ph+ >S=O>1,3-diCl).

The Chlorination with Other Chlorinating Agents. The chlorination of **15** with 0.8 equivalent of sulfuryl chloride in the presence of pyridine produced, stereospecifically, **17**, the same product as was obtained with *t*-butyl hypochlorite, in a 79% yield. The chlorination of **16** with 0.8 equivalent of sulfuryl chloride furnished the same product(**17**) in a 62% yield, while with 1.2 equivalent it gave a mixture of **17** (79% yield) and **20** (16% yield).

The chlorination of **1** with chlorine in the presence of pyridine gave a mixture of **2**(54.5% yield) and **5** (18% yield), though 19% of **1** was also recovered. The chlorination of **8** afforded **9** in a 68% yield, together with **11**(7% yield), while **10** gave, in an 87% yield, a mixture of **9** and **11** in a 3 : 7 ratio, a converse ratio to that obtained in the chlorination with *t*-butyl hypochlorite. In the reaction with *t*-butyl hypochlorite in the presence of potassium acetate, **10** was chlorinated, mainly *via* Route *b*, to produce **9** as the major product, whereas with chlorine in the presence of pyridine **10** was chlorinated, mainly *via* Route *a*, to give **11** as the major component. Compound **15** furnished **17** in a 63% yield, plus small amounts of **20**. **16** also gave **17** in 80% and 62% yields, plus small amounts of **20**.

The chlorination of the cyclic sulfoxides with sul-

furyl chloride or chlorine in the presence of pyridine seems to be nearly the same as the reaction with *t*-butyl hypochlorite, except that dichlorides can be easily obtained and that the ratio of the isomers (if any are obtained) may be different. Accordingly, the mechanism shown in Fig. 6 can also be applied to the reaction with sulfuryl chloride or chlorine (Z=Cl) in the presence of pyridine.

Experimental

Unless otherwise noted, the NMR spectra were measured with a Varian HA-100 spectrometer and/or a Hitachi R-20B spectrometer in a concentration of 40—50 mg in 0.4 ml of $CDCl_3$, while the IR spectra were recorded with a KBr pellet using a Hitachi EPI-G3 spectrometer. HHW in the NMR spectral data means half-height width. In the crystallization solvents, B, C, and H stand for benzene, cyclohexane, and hexane respectively, and B/C/H means that the crystal was dissolved in benzene, followed by the successive addition of cyclohexane and hexane.

*Chlorination of Thiane 1-Oxide(**1**) to* cis*-2-Chlorothiane 1-Oxide(**2**) with* t*-BuOCl.* *(a) In the Presence of Potassium Acetate*: To a stirred mixture of **1**(405 mg, 3.16 mmol) and potassium acetate(0.82 g, 8.4 mmol) in 20 ml of CH_2Cl_2 was added 0.34 ml(3.1 mmol) of *t*-BuOCl at 0°C. After the mixture had then been stirred for 2 hr, 20 ml of water was added. The mixture was extracted with CH_2Cl_2, and the extract was dried over Na_2SO_4 and evaporated to give white crystals. Recrystallization from C/H afforded 423 mg(2.78 mmol; 88%) of **2**, which was then recrystallized to give mp 65.5—66.5°C. IR: 755, 1050(S=O) cm^{-1}. IR(5% in CS_2): 763(C-Cl_{eq}), 1047, 1080(S=O) cm^{-1}. NMR($CDCl_3$): 1.2—3.4(8H), 4.91(1H, octet, J=1, 3, 8). NMR(CCl_4): 1.2—3.3(8H), 4.88(1H, q, J=3.2, 9.3). NMR(C_6H_6): 0.4—2.75(8H), 4.23(1H, q, J=3.1, 9.6). NMR(D_2O): 1.85—3.8(8H), 5.71(1H, octet, J=1, 4, 8.3). NMR(CD_3CN): 1.3—3.1(8H), 4.95(1H, octet, J=1,3.3, 10). NMR(CF_3COOH): 1.5—3.65(8H), 5.33(1H, octet, J=1.5, 2.7, 6.6). Mass: *m/e* 152(M^+), 41 (base peak). Found: C, 39.59; H, 6.13; Cl, 23.34%. Calcd for C_5H_9ClOS: C, 39.35; H, 5.94; Cl, 23.23%.

(b) In the Presence of Pyridine: To a stirred solution of **1**(0.50 g, 3.91 mmol) and pyridine(0.63 ml, 7.82 mmol) in 20 ml of CH_2Cl_2 at 0°C was added *t*-BuOCl(0.43 ml, 3.91 mmol). The solution was stirred for 1.5 hr, and then 25 ml of 0.5 N aqueous sulfuric acid was added and it was extracted with CH_2Cl_2. The subsequent evaporation of the solvent and the crystallization of the residue from B/C gave 407 mg(2.67 mmol; 68.2%) of **2**, identified by means of mp, IR, NMR, and tlc.

*Transformation of **2** to* trans*-2-Chlorothiane 1-Oxide(**3**) with Et_3OBF_4.* 1.2 g(6.3 mmol) of Et_3OBF_4 was added to a solution of 625 mg(4.1 mmol) of **2** in 5 ml of CH_2Cl_2. After the mixture had been stirred at room temperature for 1 hr, 40 ml of anhydrous ether was added at 0°C to give oily ethoxysulfonium salt as a precipitation. After the mixture had been stirred for 2 hr, the solvents were removed by decantation, and to the residue was added 20 ml of a 0.5 N NaOH solution. The mixture was then extracted with CH_2Cl_2. The solvent was dried over Na_2SO_4 and evaporated to give a residue which was subsequently chromatographed on silica gel with benzene. Elution with benzene containing 2% ethyl acetate then furnished 465 mg(3.05 mmol; 74.3%) of **3**. The continuation of the elution gave a small amount of **2**. **3** is eluted faster and is detected higher than **2** on a thin-layer plate. Recrystallization from B/C/H at 0°C gave mp 43—44°C. **3** is hygroscopic. IR(Nujol): 697, 954, 1029, 1059(S=O) cm^{-1}. IR(5% in CS_2): 696 (C-Cl_{ax}), 950, 1030, 1063(S=O) cm^{-1}. NMR($CDCl_3$): 1.45—3.28 (8H), 4.69(1H, m, HHW=11). NMR(CCl_4): 1.43—3.2 (8H), 4.72(1H, m, HHW=10). NMR(C_6H_6): 0.8—2.7 (8H), 4.29(1H, m, HHW=11). NMR(CF_3COOH): 1.5—3.65(8H), 5.02(1H, q, J=3, 7.5). NMR(CD_3OD): 1.42—3.4(8H), 4.84(1H, octet, J=1, 3, 7.5). NMR(D_2O): 1.8—4.03(8H), 5.36(1H, q, J=3.4, 8.7). Mass: *m/e* 152 (M^+). Found: C, 39.60; H, 6.07; Cl, 23.23%. Calcd for C_5H_9ClOS: C, 39.35; H, 5.94; Cl, 23.23%.

*Oxidation of **2** to 2-Chlorothiane 1,1-Dioxide (**4**).* The oxidation of **2** by the usual method with 30% H_2O_2 in acetic acid gave **4**. Recrystallization from B/C/H afforded mp 68—69.5°C. IR(Nujol): 1127, 1161, 1280, 1312 cm^{-1}. NMR: 1.3—3.7(8H), 4.75(1H, octet, J=2, 3.5, 6.5). Mass: *m/e* 168(M^+), 42(base peak). Found: C, 35.95; H, 5.36%. Calcd for $C_5H_9ClO_2S$: C, 35.61; H, 5.38%.

*Chlorination of **2** with* t*-BuOCl.* 153 mg(1 mmol) of **2** was chlorinated with 0.13 ml(1.15 mmol) of *t*-BuOCl in the presence of potassium acetate(0.32 g, 3.26 mmol) in 5 ml of CH_2Cl_2 at room temperature for 2 hr. The NMR spectrum of the crude extract after the usual work-up indicated that 2e,6e-dichlorothiane 1a-oxide (**5**) was obtained as the major product. Crystallization from B/C at 0°C gave 0.70 g(0.374 mmol; 37.4%) of **5**. Recrystallizations from CCl_4 gave mp 134—135°C. IR(Nujol): 752, 1060(S=O) cm^{-1}. NMR: 1.3—2.7(6H), 4.69(2H, q, J=3.8, 12.2). NMR(7 mg in 1 ml of CCl_4): 4.45(q, J=3, 12). NMR(25 mg in 0.3 ml of C_6H_6): 0.45—1.60(4H), 1.80—2.60(2H), 3.82(2H, q, J=3.5, 12). Mass: *m/e* 186(M^+), 75(base peak). Found: C, 32.18; H, 4.27; Cl, 37.89%. Calcd for $C_5H_8Cl_2OS$: C, 32.10; H, 4.31; Cl, 37.90%.

*Chlorination of **3** with* t*-BuOCl.* *(a) With 1.1 equiv of* t*-BuOCl*: 177 mg(1.16 mmol) of **3** was chlorinated with 0.145 ml(12.8 mmol) of *t*-BuOCl in the presence of potassium acetate(0.34 g, 3.48 mmol) in 10 ml of CH_2Cl_2 at room temperature for 1 hr. The NMR of the extract showed the major product to be 2,2-dichlorothiane 1-oxide (**6**). Chromatography with benzene/hexane (7 : 3), followed by elution with a (8 : 2) mixture, afforded 145 mg(0.775 mmol; 66.7%) of **6**, which was then crystallized at −20°C. Recrystallization from hexane at 0°C gave mp 34.5—36°C. IR (Nujol): 776, 945, 958, 1034, 1080, 1411 cm^{-1}. NMR: 1.55—3.37(8H) [1.55—2.6(5H), 2.75—3.37 (3H)]. Mass: *m/e* 186(M^+), 151(base peak). Found: C, 32.24; H, 4.31; Cl, 37.64%. Calcd for $C_5H_8Cl_2OS$: C, 32.10; H, 4.31; Cl, 37.90%.

(b) With 0.5 equiv of t*-BuOCl*: A mixture of **3**(101 mg, 0.665 mmol), potassium acetate(40 mg, 0.41 mmol), and *t*-BuOCl(0.036 ml, 0.33 mmol) in 10 ml of CH_2Cl_2 was stirred at room temperature for 3 hr. The usual work-up gave 98 mg of the white crystals, in which **2** was not detected by studying the NMR spectrum.

*Transformation of **5** to 2e,6e-Dichlorothiane 1e-Oxide (**7**).* A solution of **5**(425 mg, 2.27 mmol) and Et_3OBF_4(0.65 g, 3.4 mmol) in 3 ml of CH_2Cl_2 was stirred at room temperature for 2 hr. The usual work-up gave a residue, which was then crystallized on standing. Recrystallization from B/C/H gave 255 mg(1.36 mmol; 60.0%) of **7**, showing mp 129—130°C(sintered at *ca.* 100°C) on further recrystallization. IR(Nujol): 758, 1071(S=O) cm^{-1}. NMR: 1.5—2.25(4H) 2.35—2.65(2H), 4.72(2H, q, J=3.5, 11). NMR(12 mg in 0.7 ml of CCl_4): 1.7—2.2(4H), 2.3—2.65(2H), 4.97(2H, J=3, 10.5). NMR(12 mg in 0.3 ml of C_6H_6): 0.5—2.0 (6H), 4.49(2H, q, J=4, 10.5). NMR(CF_3COOH): 1.7—

3.0(6H), 5.05(2H, q, J=3.5, 11.5). Found: C, 32.23; H, 4.10%. Calcd for $C_5H_8Cl_2OS$: C, 32.10; H, 4.31%.

Chlorination of **8** *to 2e,4a-Dichlorothiane 1a-Oxide (***9***) with* t-*BuOCl.* To a stirred, suspended solution of **5**(454 mg, 2.98 mmol) and potassium acetate (322 mg, 3.28 mmol) in 15 ml of CH_2Cl_2 at 0°C was added 0.36 ml(3.28 mmol) of *t*-BuOCl. The mixture was stirred at 0°C for 4 hr. The usual work-up gave a residue, which was then chromatographed with benzene. Elution with 1% ethyl acetate in benzene gave 0.39 g(2.09 mmol; 70.0%) of **9**. 80 mg(0.53 mmol) of **8**(containing 10% of **10**) was recovered with benzene–ethyl acetate(85 : 15). The recrystallizations of **9** with B/H gave mp 72.5—74°C. IR: 570, 688, 780, 1000—1090 cm^{-1}. IR(5% in CS_2): 572, 692, 787, 1076 cm^{-1}. NMR($CDCl_3$): 1.80—3.17(6H), 4.51(1H, m, HHW=9), 5.00(1H, q, J=3, 11). NMR(CCl_4): 4.52(1H, m, HHW=8.5), 4.94(1H). NMR(C_6H_6): 3.61(1H, m, HHW=9), 4.40(1H). NMR(CF_3COOH): 4.52(1H, m, HHW=11), 5.27(1H). Mass: *m/e* 186(M^+), 101(base peak). Found: C, 32.06; H, 4.24; Cl, 38.07%. Calcd for C_5H_8ClOS: C, 32.10; H, 4.31; Cl, 37.90%.

Chlorination of **10** *with* t-*BuOCl.* *(a) With 1.1 equiv of* t-*BuOCl*: To a stirred mixture of **10** (465 mg, 3.04 mmol) and potassium acetate (0.33 g, 3.36 mmol) in 15 ml of CH_2Cl_2 was added 0.37 ml (3.36 mmol) of *t*-BuOCl at 0°C. The mixture was stirred at 0°C for 2 hr. The NMR spectrum of the crude extract obtained by the usual work-up showed it to be a 67 : 33 mixture of **9** and 2e, 4e-dichlorothiane 1a-oxide(**11**). Chromatography with benzene, followed by elution with 1% ethyl acetate–benzene, gave 375 mg(2.0 mmol; 65.7%) of a mixture of **9** and **11**, while 108 mg(0.71 mmol) of a 35 : 65 mixture of **8** and **10** was recovered with a 1 : 1 mixture of benzene and ethyl acetate. Since **9** is eluted faster than **11** in silica gel chromatography, **9** was isolated from the first fractions, while **11** was isolated from the last. **9** was identified by mp, IR and NMR(CCl_4). **11** has mp 110—111.5°C from B/H. IR: 730, 792, 1000—1090 cm^{-1}. NMR: 1.80—3.43(6H), 3.96(1H, septet, J=4, 4, 8, 8), 4.62(1H, q, J=4.5, 11). NMR(4 mg in 0.4 ml of CCl_4): 3.76(1H), 4.32(1H). NMR(8 mg in 0.4 ml of of C_6H_6): 0.96—2.99(7H), 3.28(1H). NMR(8 mg in 0.5 ml of CF_3COOH): 3.95(1H), 4.78(1H). Mass: *m/e* 186(M^+), 101(base peak). Found: C, 32.10; H, 4.30; Cl, 38.09%. Calcd for $C_5H_8Cl_2OS$: C, 32.10; H, 4.31; Cl, 37.90%.

(b) With 0.3 equiv of t-*BuOCl*: A solution of **10** (100 mg, 0.655 mmol), potassium acetate (30 mg, 0.33 mmol), and *t*-BuOCl (0.023 ml, 0.204 mmol) in 8 ml of CH_2Cl_2 was stirred for 1.5 hr. The NMR spectrum of the extract showed that **8**, **9**, and **10** were obtained in a ratio of 35 : 89 : 100. A 26.5 : 73.5 mixture (33 mg) of **8** and **10** was recovered by chromatography.

Transformation of **9** *to 2a,4e-Dichlorothiane 1a-Oxide (***12***).* A solution of **9**(185 mg, 0.99 mmol) and Et_3OBF_4 (0.38 g, 1.99 mmol) in 3 ml of CH_2Cl_2 was stirred for 1 hr. The usual work-up gave white crystals at −20°C. Recrystallization from B/H afforded 153 mg(0.82 mmol; 82.7%) of **12**, with mp 92—93.5°C.

IR: 580, 650, 700, 800, 1000—1100 cm^{-1}. NMR(CDCl): 2.00—3.50(6H), 4.25(1H, nonet, J=3.5, 3.5, 11, 11), 4.86 (1H, m, HHW=10). NMR(CCl_4): 4.17(1H), 4.83(1H, m, HHW=7.5). NMR(C_6H_6): 3.64(1H), 4.15(1H, m, HHW=10). NMR(CF_3COOH): 4.38(1H, septet, J=3.5, 3.5, 7, 7), 5.31(1H, q, J=3.5, 8). Mass: *m/e* 186(M^+). Found: C, 32.17; H, 4.41; Cl, 38.02%. Calcd for $C_5H_8Cl_2OS$: C, 32.10; H, 4.31; Cl, 37.90%.

trans-*2,4-Dichlorothiane 1,1-Dioxide (***13***).* A solution of **9** (63 mg), **12**(65 mg), and 30% H_2O_2 (0.11 ml; 1.1 mmol) in 2 ml of acetic acid was kept at 45°C for 15 hr. The subsequent addition of Na_2CO_3, followed by extraction with CH_2Cl_2 and the evaporation of the solvent, gave 0.11 g (0.545 mmol; 71.0%) of **13** as white crystals. Recrystallizations from $CHCl_3$/H gave mp 131.5—132°C. IR: 1150, 1323 cm^{-1}. NMR: 2.66(4H, m), 3.40(2H, t, J=6, 6), 4.51(1H, quintet, J=5—6, 5—6, 5—6, 5—6), 5.00(1H, q, J=5.5, 8). Mass: *m/e* 202(M^+), 75(base peak). Found: C, 29.39; H, 3.98; S, 15.60%. Calcd for $C_5H_8Cl_2O_2S$: C, 29.57; H, 3.97; S, 15.79%.

*2e,4a,6e-Trichlorothiane 1a-Oxide (***14***).* To a stirred mixture of **8**(0.12 g, 0.785 mmol), **10**(0.12 g, 0.785 mmol), and potassium acetate(0.62 g, 6.3 mmol) in 15 ml of CH_2Cl_2 was added 0.69 ml (6.28 mmol) of *t*-BuOCl at 0°C, and the mixture was stirred for 1.5 hr. The usual work-up gave 0.33 g(1.49 mmol; 94.9%) of the white crystals (**14**). Recrystallizations from B/H gave mp 139.5—140.5°C. IR: 1056 cm^{-1}. NMR: 2.35(2H, sextet, J=3.5, 3.5, 15), 2.82(2H, septet, J=3.5, 12, 15), 4.52(1H, quintet, J=*ca.* 3.5, 3.5, 3.5, 3.5), 5.07(2H, q, J=3.5, 12). Mass: *m/e* 220(M^+), 135(base peak). Found: C, 27.33; H, 3.27; S, 14.52%. Calcd for $C_5H_7Cl_3OS$: C, 27.11; H, 3.19; S, 14.47%.

Chlorination of **15** *to 2a-Chloro-4e-phenylthiane 1e-Oxide (***17***) with* t-*BuOCl.* To a stirred mixture of **15**(159 mg, 0.815 mmol) and potassium acetate(0.16 g, 1.63 mmol) in 10 ml of CH_2Cl_2 was added 0.09 ml(0.82 mmol) of *t*-BuOCl at 0°C, and the mixture was stirred at 0°C for 2 hr. The usual work-up gave yellowish white crystals, which were later recrystallized from B/H to give 154 mg(0.675 mmol; 82.8%) of **17**. Further recrystallization from B/H gave mp 160—160.5°C. IR(Nujol): 689, 710, 773, 1072(S=O) cm^{-1}. NMR($CDCl_3$): 1.92—2.20 (2H), 2.30—2.25 (2H), 2.97—3.43 (3H), 5.30(1H, m, HHW=8), 7.23(5H, m). NMR(CCl_4): 5.14 (1H, m, HHW=8). NMR(C_6H_6): 4.65(1H, m, HHW=8.5). NMR(CF_3COOH): 5.64(1H, m, HHW=8). Mass: *m/e* 228(M^+), 117(base peak). Found: C, 57.53; H, 5.84; Cl, 15.77%. Calcd for $C_{11}H_{13}ClOS$: C, 57.76; H, 5.73; Cl, 15.50%.

Chlorination of **16** *to* **17** *with* t-*BuOCl.* *(a) With 1.0 equiv of* t-*BuOCl*: A mixture of **16** (0.15 g, 0.77 mmol), potassium acetate(0.15 g, 1.54 mmol), and *t*-BuOCl(0.085 ml, 0.77 mmol) in 10 ml of CH_2Cl_2 was stirred at 0°C for 3.5 hr. The NMR spectra($CDCl_3$ and C_6H_6) of the crude crystals obtained by the usual work-up revealed that **17** was the sole product. Recrystallization from B/H gave 117 mg(0.51 mmol; 66.4%) of **17**, identified by mp, IR, NMR, and tlc.

(b) With 0.5 *equiv of* t-*BuOCl in the Presence of Potassium Acetate*: A solution of **16** (200 mg, 1.03 mmol), potassium acetate(51 mg, 0.52 mmol), and *t*-BuOCl (0.06 ml, 0.53 mmol in 10 ml of CH_2Cl_2 was stirred for 3 hr. The usual work-up followed by chromatography gave 120 mg (0.53 mmol) of **17** and 73 mg of a 23 : 77 mixture of **15** and **16**.

(c) In the Presence of Pyridine: A mixture of **16** (154 mg, 0.79 mmol), pyridine (0.14 ml, 1.74 mmol), and *t*-BuOCl (0.90 ml, 0.80 mmol) in 10 ml of CH_2Cl_2 was stirred at 0°C for 3 hr. The usual work-up followed by chromatography gave 81 mg (0.356 mmol; 45.0%) of **17**, eluted with 1% ethyl acetate in benzene.

Transformation of **17** *to 2a-Chloro-4e-phenylthiane 1a-Oxide (***18***).* A solution of **17**(148 mg, 0.647 mmol) and Et_3OBF_4 (0.25 g, 1.31 mmol) in 3 ml of CH_2Cl_2 was stirred at room temperature for 1 hr. The usual work-up gave a white solid, which was subsequently crystallized from C/H to afford 121 mg(81.6%) of **18**. Chromatographic purifi-

cation with benzene–ethyl acetate(99 : 1), followed by recrystallization from B/H gave, a pure sample with mp 94.5—95.0°C. IR: 691, 1053, 1497, 1602 cm^{-1}. NMR-($CDCl_3$): 1.65—3.43(7H), 4.89(1H, m, HHW=7), 7.25(5H, s). NMR(CCl_4): 4.75(1H, m, HHW=7). NMR(C_6H_6): 4.20(1H, m, HHW=6.5). Mass: *m/e* 228(M^+). Found: C, 57.51; H, 5.79; Cl, 15.75%. Calcd for $C_{11}H_{13}ClOS$: C, 57.76; H, 5.73; Cl, 15.50%.

*Treatment of Chlorothiane 1-Oxides(**2**, **3**, **8**, **10**, and **17**) with Concentrated Hydrochloric Acid(1 vol) in Dioxane (2 vol).*

*(a) **2***: To a stirred solution of **2** (50 mg) in 6 ml of dioxane was added 3 ml of concentrated HCl at room temperature, after which the mixture was stirred for 1 hr. The addition of water and subsequent extraction with CH_2Cl_2 gave 48 mg of white crystals, the NMR spectrum of which showed that **2** was recovered unchanged.

*(b) **3***: A solution of **3**(92 mg) in a mixture of concentrated HCl(3 ml) and dioxane (6 ml) was stirred at room temperature for 1 hr. The usual work-up gave 89 mg of white crystals, the NMR spectrum of which showed that **3** was recovered quantitatively.

*(c) **8***: A solution of **8** (50 mg) in the same reagent(9 ml) was stirred for 1 hr. The usual work-up gave a 52 : 48 mixture (49 mg) of **8** and **10**.

*(d) **10***: A solution of **10** (52 mg) in 9 ml of the reagent was stirred for 1 hr. A work-up gave a 53 : 47 mixture (47 mg) of **8** and **10**.

*(e) **17***: A solution of **17**(56 mg) in 9 ml of the reagent was stirred for 1 hr. A work-up afforded 52 mg of **17**.

*Oxidation of **17** to trans-2-Chloro-4-phenylthiane 1,1-Dioxide (**19**).* A solution of **17**(0.19 g, 0.83 mmol) and 30% H_2O_2(0.18 ml, 1.76 mmol) in 2 ml of acetic acid was kept at 45°C for 15 hr. The subsequent addition of water furnished white crystals, which were then filtered off, washed with water, and dried under a vacuum to give 188 mg(0.77 mmol; 93%) of **19**. Recrystallizations from B/H gave mp 157.5—158.5°C. IR: 1136, 1330 cm^{-1}. NMR: 2.10—3.97(7H), 4.82(1H, q, J=3.5, 6), 7.28(5H, s). Mass: *m/e* 244(M^+), 117(base peak). Found: C, 53.90; H, 5.42; S, 13.01%. Calcd for $C_{11}H_{13}ClO_2S$: C, 53.98; H, 5.35; S, 13.10%.

*Chlorination of **17** to 2e,6e-Dichloro-4a-phenylthiane 1a-Oxide (**20**) with t-BuOCl.* A mixture of **17**(250 mg, 1.09 mmol), potassium acetate(215 mg, 2.18 mmol), and *t*-BuOCl 0.12 ml, 1.06 mmol) in 15 ml of CH_2Cl_2 was stirred for 1 hr. An additional 0.06 ml(0.53 mmol) of *t*-BuOCl was then added, and after 1 hr's stirring, 0.10 ml(0.885 mmol) of *t*-BuOCl was added. After stirring for 1 more hr, the usual work-up furnished white crystals, which were recrystallized from $CHCl_3$/H to give 252 mg(0.95 mmol; 87.2%) of **21**. Further purification by chromatography and recrystallizations from $CHCl_3$/H gave an analytical sample with mp 119—120°C. IR: 1078, 1495, 1598 cm^{-1}. NMR: 2.25—3.70(5H), 4.73(2H, q, J=4, 10). NMR(15 mg in 0.6 ml of CCl_4): 2.47(H_{eq}–C_3 and –C_5, sextet, J=3—4, 3—4, 14), 2.89(H_{ax}–C_3 and –C_5, octet, J=3—4, 12, 14), 3.41(H_{eq}–C_4, quintet, J=3—4, 3—4, 3—4, 3—4), 4.52(H_{ax}–C_2 and –C_6, q, J=3—4, 12). NMR(25 mg in 0.4 ml of C_6H_6): 1.98(2H), 2.60(2H), 2.64(1H), 3.81(2H). Mass: *m/e* 262(M^+), 115 (base peak). Found: C, 49.97; H, 4.56; S, 12.24%. Calcd for $C_{11}H_{12}Cl_2OS$: C, 50.20; H, 4.60; S, 12.18%.

*Conversion of **20** to 2a,6a-Dichloro-4e-phenylthiane 1a-Oxide (**21**).* A solution of **20**(132 mg, 0.50 mmol) and Et_3O-BF_4(0.20 g, 1.05 mmol) in 4 ml of CH_2Cl_2 was stirred for 1 hr. The subsequent recrystallization from $CHCl_3$/H of the crude crystals obtained by the usual work-up gave 45 mg (0.172 mmol; 34.2%) of **21**, with mp 101.5—102°C. IR: 1052, 1493, 1600 cm^{-1}. NMR(CCl_4): 2.16(H_{eq}–C_3 and –C_5, sextet, J=3, 3, 15.5), 2.93(H_{ax}–C_3 and –C_5, octet, J=3, 11, 15.5), 3.47(H_{ax}–C_4, nonet, J=3, 3, 11, 11), 4.80 (H_{eq}–C_2 and –C_6, m). NMR(C_6H_6): 1.68(2H), 2.60(2H), 3.32 (1H), 4.28(2H). Mass: *m/e* 262(M^+). Found: C, 50.21; H, 4.64; S, 12.15%. Calcd for $C_{11}H_{12}Cl_2OS$: C, 50.20; H, 4.60; S, 12.18%.

*Chlorination of **15** to **17** with SO_2Cl_2.* To a stirred solution of **15** (120 mg, 0.617 mmol) and pyridine (0.15 ml, 1.86 mmol) in 15 ml of CH_2Cl_2 was added 0.04 ml(0.494 mmol) of SO_2Cl_2 at 0°C, after which the mixture was stirred for 1 hr. The usual work-up gave crude white crystals which were subsequently dissolved in 1.0 ml of $CDCl_3$ with 36.0 mg(0.153 mmol) of bromomethyl phenyl sulfone as the standard. The NMR spectrum of the solution showed that **17** was produced, and through the NMR integral of the H–C_2 of **17** and the –CH_2– of bromomethyl phenyl sulfone, the yield of **17** was estimated to be 79%.

*Chlorination of **16** with SO_2Cl_2. (a) With 0.8 equiv of SO_2Cl_2*: A solution of **16** (120 mg, 0.617 mmol), pyridine (0.15 ml, 1.86 mmol), and SO_2Cl_2(0.04 ml, 0.494 mmol) in 15 ml of CH_2Cl_2 was stirred at 0°C for 2 hr. The NMR spectrum of the reddish crystals obtained by the usual work-up showed that **17** was produced in a 61.7% yield, by the same method as has been described above.

(b) With 1.2 equiv of SO_2Cl_2: A solution of **16** (256 mg, 1.32 mmol), pyridine(0.32 ml, 4.0 mmol), and SO_2Cl_2(0.13 ml, 1.61 mmol) in 15 ml of CH_2Cl_2 was stirred at 0°C for 4 hr. The NMR spectrum of the crude crystals obtained by the usual work-up showed that **17** and **20** were produced in a ratio of 8 : 2. The mixture was chromatographed with benzene/hexane(8 : 2). 43 mg(0.162 mmol; 15.7%) of **20** was eluted with benzene, and 187 mg (0.814 mmol; 79.1%) of **17** was eluted benzene–ethyl acetate (98 : 2). **17** and **20** were identified by means of the mp, IR, and NMR spectra.

*Chlorination of **1** with Cl_2.* To a stirred solution of **1** (4.86 g, 41.2 mmol) and pyridine (9.9 ml, 123.6 mmol) in 50 ml of CH_2Cl_2 was added at 0°C a solution of Cl_2(more than 2.48 g; 35 mmol) in 35 ml of CCl_4 over a 0.5-hr period. The mixture was stirred for 1 hr. The usual work-up, followed by chromatography with benzene, gave 1.38 g (7.37 mmol; 17.9%) of **5** with benzene, and 3.43 g (22.5 mmol; 54.3%) of **2** with benzene containing 1—5% ethyl acetate. 0.91 g (7.7 mmol; 18.7%) of **1** was recovered by elution with benzene/ethanol (95 : 5). **2** and **5** were identified by means of mp, IR, and NMR spectra.

*Chlorination of **8** with Cl_2.* To a stirred solution of **8** (50 mg, 0.328 mmol) and pyridine(0.08 ml, 1.0 mmol) in 10 ml of CH_2Cl_2 was added a solution of Cl_2(more than 20.6 mg; 0.29 mmol) in 0.29 ml of CCl_4 at 0°C, after which the mixture was stirred for 2 hr. Further addition of 0.088 mmol of Cl_2 in CCl_4, followed by 2.5 hr's stirring; the usual work-up gave a crude residue which was dissolved in 0.5 ml of $CDCl_3$, with 69.6 mg(0.312 mmol) of dichloromethyl 4-methylphenyl sulfoxide as the standard. The NMR spectrum of the solution showed that a 91 : 9 mixture of **9** and **11** was produced in a 75% yield.

*Chlorination of **10** with Cl_2.* To a stirred solution of **10**(48 mg, 0.314 mmol) and pyridine(0.08 ml, 1.0 mmol) in 10 ml of CH_2Cl_2 was added a solution of Cl_2(ca. 0.29 mmol) in 0.29 ml of CCl_4 at 0°C, after which the mixture was stirred for 3 hr. The usual work-up, followed by NMR spectral measurement with 70.5 mg(0.316 mmol) of dichloromethyl 4-methylphenyl sulfoxide, showed that a 3 : 7 mixture of **9** and **11** was obtained in an 86.6% yield.

*Chlorination of **15** with Cl_2.* To a stirred solution of **15** (122 mg, 0.627 mmol) and pyridine(0.15 ml, 1.87 mmol)

in 15 ml of CH_2Cl_2 was added a solution of 0.55 mmol of Cl_2 in 0.55 ml of CCl_4 at 0°C, after which the mixture was stirred for 1.5 hr. The addition of 0.088 mmol of Cl_2(1.5 hr's stirring) and the further addition of 0.055 mmol of Cl_2 1.5 hr's stirring), followed by the usual work-up, gave 140 mg of white crystals. Their NMR spectrum with 36.2 mg (0.154 mmol) of bromomethyl phenyl sulfone showed that **17** and **20** were produced in 62.7% and 6.3% yields respectively.

Chlorination of ***16*** *with* Cl_2. *(a)*: To a stirred solution of **16** (247 mg, 1.27 mmol) and pyridine(0.3 ml, 3.75 mmol) in 15 ml of CH_2Cl_2 was added a solution of Cl_2(1.27 mmol) in 1.27 ml of CCl_4, after which the mixture was stirred for 2.5 hr. The usual work-up followed by crystallization from $CHCl_3$/H gave 234 mg(1.02 mmol; 80.3%) of **17**.

(b): To a stirred solution of **16** (121 mg, 0.622 mmol) and pyridine(0.15 ml, 1.87 mmol) in 15 ml of CH_2Cl_2 was added a solution of 0.50 mmol of Cl_2 in 0.50 ml of CCl_4 at 0°C, after which the mixture was stirred for 2.5 hr. An additional 0.13 mmol of Cl_2 in CCl_4 was added, and stirring was continued for 1.5 hr. The NMR measurement after the usual work-up showed that **17** was obtained in a 61.8% yield.

Synthesis of trans-*4-Chlorothiane 1-Oxide (8) and* cis-*4-Chlorothiane 1-Oxide (10)*. To a stirred solution of 4-chlorothiane[27] (0.58 g, 4.25 mmol) in 100 ml of methanol was added a solution of $NaIO_4$(955 mg, 4.46 mmol) in 100 ml of water at 0°C. The mixture was stirred at 0°C for 5 hr and then at room temperature for 5 hr. 100 ml of water was added, and the mixture was extracted with CH_2Cl_2. The evaporation of the solvent gave 595 mg(3.9 mmol; 91.7%) of the white crystals which were a 60 : 40 mixture of **8** and **10** on the basis of the NMR spectrum.

4.20 g(30.8 mmol) of 4-chlorothiane was oxidized similarly, followed by chromatography with benzene. Elution with benzene–ethyl acetate(90 : 10) afforded 1.62 g(10.6 mmol; 34.4%) of **8**, 863 mg(5.65 mmol; 18.4%) of a mixture of **8** and **10**, and 1.295 g(8.48 mmol; 27.5%) of **10** containing a very small amount of **8** successively. The solubilities of **8** and **10** in cyclohexane at room temperature were 6 mg/ml and 1 mg/ml respectively. Accordingly, **10** can be easily isolated from a mixture of **8** and **10**. Recrystallization of **8** from B/C/H gave mp 108—109.5°C (sintered at *ca.* 85°C) (lit,[8] mp 104—105°C). IR(3.5% in CS_2): 573, 719, 980, 1055 cm^{-1}. NMR: 1.65—3.2(8H), 4.51(1H, m, HHW=9). Found: C, 39.45; H, 6.08%. Calcd for C_5H_9ClOS: C, 39.35; H, 5.94%. Recrystallization of **10** from C/H gave mp 120—121°C (lit,[8] mp 120—121°C). IR(0.5% in CS_2): 726, 753, 938, 1019, 1066 cm^{-1}. NMR($CDCl_3$): 1.85—3.40(8H), 4.12(1H, m, HHW=16—21.5).

Synthesis of 4-Phenylthiane. 4-Phenylthiane was prepared by a modification of a method previously reported.[28] A solution of 4-hydroxy-4-phenylthiane(2.32 g, 12 mmol) and *p*-toluenesulfonic acid monohydrate(0.30 g) in 15 ml of isopropyl acetate was refluxed for 10 hr, while being monitored by tlc. The subsequent evaporation of the solvent gave 2.11 g (12 mmol; 100%) of a crystalline residue, which was then treated with charcoal in cyclohexane.

A solution of dehydrated product(1.58 g, 8.96 mmol) in 30 ml of 99.5% ethanol was stirred with 2.37 g of 5% Pd-charcoal under H_2 for 40 hr at 100—120 atm/40—50°C. The mixture was filtered, and the filtrate was concentrated to a residue which was treated with charcoal in cyclohexane. The crystallization of the product from hexane at 0°C gave 0.95 g of 4-phenylthiane. The mother liquor was cooled to −20°C to furnish 0.32 g of the product. The total yield was 1.27 g(7.13 mmol; 79.5%). Recrystallization from methanol at −20°C gave mp 52—53°C (lit,[28] mp 55°C).

Synthesis of trans-*4-Phenylthiane 1-Oxide (15) and* cis-*4-Phenylthiane 1-Oxide (16)*. To a stirred solution of $NaIO_4$(2.79 g, 13.0 mmol) in 300 ml of water was added a solution of 4-phenylthiane(2.07 g, 11.6 mmol) in 900 ml of methanol at 0°C; the mixture was stirred at 0°C for 5 hr and then at room temperature for 14 hr. It was then filtered, and the filtrate was concentrated to 400 ml which was subsequently extracted with CH_2Cl_2. The usual work-up gave 2.122 g(10.93 mmol; 94.2%) of white crystals, which were a 26 : 74 mixture of **15** and **16**, as determined by means of the 100 MHz NMR spectrum.[9] Fractional crystallization from cyclohexane gave 0.89 g (39.6%) of **16** with mp 148.5—149°C(lit,[9] mp 150—151°C).

A 2.82-g portion of a 1 : 1 mixture of **15** and **16** was chromatographed with benzene. After successive elutions with 1, 2, 4, 6, 8, 10, and 15% of ethyl acetate in benzene, elution with 15—20% of ethyl acetate, followed by fractional crystallizations from cyclohexane, afforded 867 mg(30.8%) of **16**, 834 mg(29.6%) of **15** with mp 121—123°C(lit,[9] mp 137—138.5°C), and 1.11 g(39.3%) of a 1.1 : 1 mixture of **15** and **16**.

The authors wish to thank the Kawakami Memorial Foundation for its partial financial support of this work. They are also grateful to the members of the Analytical Laboratory of this research center for the microanalyses and for the NMR and mass spectra measurements.

Stereochemical Studies on the Halogenation of Sulfoxides. II. The Bromination of Cyclic Sulfoxides[1]

Shinobu IRIUCHIJIMA and Gen-ichi TSUCHIHASHI

Sagami Chemical Research Center, Nishiohnuma, Sagamihara, Kanagawa 229

(Received July 26, 1972)

The cyclic sulfoxides, thiane 1-oxide, 4-chlorothiane 1-oxides, and 4-phenylthiane 1-oxides, were brominated with a mixture of bromine and *N*-bromosuccinimide in the presence of pyridine. The stereoformulas of the products, together with those of the isomers with an inverted sulfoxide configuration, were determined by means of the IR and NMR spectral data and by a comparison of the R_f-values in the tlc. As a result, it has been revealed that the bromination reaction gives products in which a bromine atom is introduced stereospecifically at a *trans*-position to the sulfinyl lone pair, in a manner similar to that of the chlorination reaction reported previously. The same mechanism as in the chlorination is proposed for the main reaction course.

The α-halogenation of sulfoxides with the halogenating agents in the presence of base is known to be a stereoselective reaction.[2,3] In the preceding paper[4] we have reported on the chlorination of the cyclic sulfoxides with *t*-butyl hypochlorite, sulfuryl chloride, and chlorine in the presence of potassium acetate or pyridine. In the present paper we would like to describe our stereochemical study on the bromination of the cyclic sulfoxides,[4] thiane 1-oxide, *cis*- or *trans*-4-chlorothiane 1-oxide, and *cis*- or *trans*-4-phenylthiane 1-oxide, with a mixture of bromine and *N*-bromosuccinimide[5] in the presence of pyridine.

Results and Discussion

Bromination of Thiane 1-Oxide. The bromination of six-membered thiane 1-oxide (**1**) with a mixture of 0.5 equiv of bromine and 1.0 equiv of *N*-bromosuccinimide[5] in the presence of pyridine in dichloromethane produced, stereospecifically, *cis*-2-bromothiane 1-oxide(**2**) (mp 61—62°C) (Fig. 1) in an 80% yield. The inversion of the sulfoxide configuration of **2** with triethyloxonium tetrafluoroborate (Et_3OBF_4)[6] furnished *trans*-2-bromothiane 1-oxide(**3**) (mp 59.5—60°C) in a 68% yield.

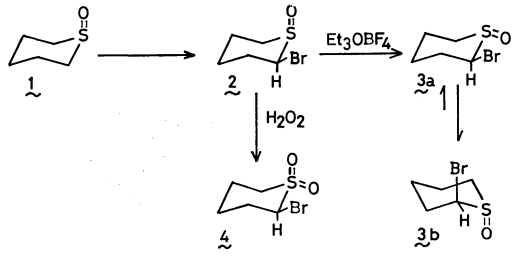

Fig 1.

The stereoformulas of **2** and **3** were determined in the same way as the corresponding chloro-derivatives described in the preceding paper:[4] the aromatic solvent-induced shifts (ASIS; $\Delta=\delta_{CCl_4}-\delta_{C_6H_6}$) are also a useful method in determining the stereoformulas of sulfoxides. Since a proton *trans* to the sulfinyl oxygen is more shielded and has a larger Δ-value than a proton *cis* to the sulfinyl oxygen, the product obtained by bromination, which has a larger Δ-value ($\Delta=0.64$)(Table 1), should possess a *cis*-form (**2**), while the inverted isomer, with a smaller Δ-value ($\Delta=0.43$), should possess a *trans*-form (**3**). This assignment was supported by the following facts: the H-C_2 of **3** was observed as axial in the polar solvents (CD_3OD, D_2O, CF_3COOH, and CD_3SOCD_3) and as equatorial rather than axial in the nonpolar solvents (CCl_4, $CDCl_3$, and C_6H_6), whereas the H-C_2 of **2** was always observed as axial, regardless of whether the solvent was polar or not(Table 1). This observation can be explained as follows. The product (**2**) has a thermodynamically stable *cis*-form possessing a preferable axial sulfinyl oxygen and equatorial bromine. On the other hand, since **3** has an unstable *trans*-form, its conformation changes with the solvent polarity;

Table 1. NMR spectral data of H-C_2 of 2-bromothiane 1-oxides(**2** and **3**). $\Delta=\delta_{CCl_4}-\delta_{C_6H_6}$

TABLE 2. NMR SPECTRAL DATA OF H-C_2 AND H-C_4 OF 2-BROMO-4-CHLOROTHIANE 1-OXIDES(**6**, **7**, **9**, AND **10**)

	6		**7**		**9**		**10**	
	H-C_2	H-C_4	H-C_2	H-C_4	H-C_2	H-C_4	H-C_2	H-C_4
δ_{CCl_4}	5.10 ax	4.47 eq	4.87 eq	4.17 ax	4.51 ax	3.80 ax	4.90 ax	4.16 ax
$\delta_{C_6H_6}$	4.57	3.63	4.17	—	3.56	—	4.20	3.28
Δ	0.53	—	0.70	—	0.95	—	0.70	—

the polar conformation, **3a**, is favored in the polar solvents, while the less polar conformation, **3b**, dominates in the non-polar solvents. Moreover, the fact that, in thin-layer chromatography, **3** was found at a higher position than **2** indicates that **3** has a less polar structure than **2**. The possibility that **3**, which might be formed by the bromination of **1**, was isomerized to the stable isomer (**2**) during the reaction was excluded by the fact that **2** was not produced when **3** was kept under the bromination conditions for 3 hr.

The halogenation of **1** in the presence of base[7] proved to give, stereospecifically, the *cis*-halogenated product in both chlorination[4] and bromination.

The hydrogen peroxide oxidation of **2** in acetic acid gave 2-bromothiane 1,1-dioxide (**4**) (mp 89—90°C), in a 95% yield.

Bromination of 4-Chlorothiane 1-Oxide. The bromination of *trans*-4-chlorothiane 1-oxide(**5**) afforded, stereospecifically, 2e-bromo-4a-chlorothiane 1a-oxide(**6**) (Fig. 2) (mp 48—49°C) in an 81% yield. The bromination of *cis*-4-chlorothiane 1-oxide (**8**), however, furnished, in an 85% yield, a 20 : 80 mixture of **6** and 2e-bromo-4e-chlorothiane 1a-oxide (**9**) (mp 102—103°C). This fact indicates that **8** is brominated, mainly, not *via* **5** but *via* the ring inversion, unlike as in the chlorination with *t*-butyl hypochlorite in the presence of potassium acetate.[4] The competitive bromination of **5** and **8** showed that **8** is brominated approximately five times faster than **5**. This is a somewhat unexpected result, which remains unexplained.

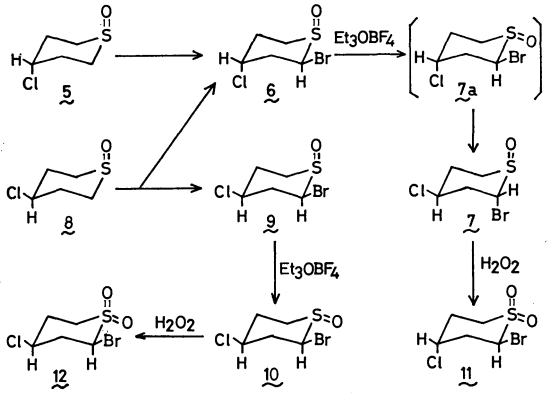

Fig. 2.

The products, **6** and **9**, were transformed with Et_3OBF_4 to 2a-bromo-4e-chlorothiane 1a-oxide (**7**) (mp 73.5—75°C) in an 86% yield and 2e-bromo-4e-chlorothiane 1e-oxide (**10**) (mp 93—94.5°C) in an 85% yield respectively.

The stereochemical structures of **6**, **7**, **9**, and **10** were established by means of the NMR coupling constants of H-C_2 and H-C_4, ASIS shown in Table 2 (the isomer **9** is expected to have the largest Δ-value), and the behavior on a thin-layer plate; the compound **7** was observed higher, than **6** and **9** which were themselves higher than **10**. According to the axial-equatorial sulfinyl oxygen rule,[8] the compound **9**, which possesses an axial oxygen, is expected to be higher on a thin-layer plate than **10**, which possesses an equatorial one.

The oxidation of **7** and **10** with hydrogen peroxide in acetic acid yielded *trans*-2-bromo-4-chlorothiane 1,1-dioxide (**11**) (mp 105—108°C) in a 93% yield and *cis*-2-bromo-4-chlorothiane 1,1-dioxide (**12**) (mp 124—125°C) in a 93.5% yield respectively.

Bromination of 4-Phenylthiane 1-Oxides. The bromination of conformationally rigid *trans*-4-phenylthiane 1-oxide (**13**) with a mixture of bromine (0.5 equiv) and NBS(1.0 equiv) for 0.5 hr furnished, in an 86% yield, a 63 : 37 mixture of 2a-bromo-4e-phenylthiane 1e-oxide (**14**) (mp 143—144°C) and 2e-bromo-4e-phenylthiane 1a-oxide (**15**) (mp 132—133°C), while *cis*-4-phenylthiane 1-oxide (**18**) with bromine (0.5 equiv) and NBS (2.2 equiv) for 23 hr afforded, in only a 48.5% yield, a 81 : 19 mixture of **14** and **15** (Fig. 3), with a 44% recovery of **18**. This fact, indicating that **13** is much more easily brominated than **18**, is in agreement with the result of the competitive bromination that **13** is brominated approximately five times faster than **18**. The bromination of both **13** and **18** produced an all-*cis* product

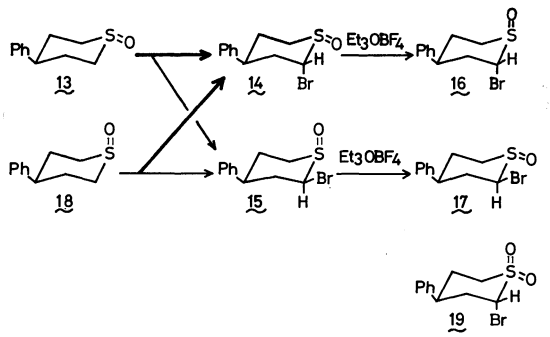

Fig. 3.

7) In the absence of base, non-stereoselectivity was observed. K.-C. Tin and T. Durst, *Tetrahedron Lett.*, **1970**, 4643.

8) A sulfoxide which possesses an axial oxygen is observed higher on a thin-layer plate than a sulfoxide which possesses an equatorial one, when the other part of their structures is the same.[4]

Table 3. NMR spectral data of H-C_2 of 2-bromo-4-phenylthiane 1-oxides(**14**, **15**, **16**, and **17**)

	14	**15**	**16**	**17**
δ_{CCl_4}	5.23 eq	4.71 ax	4.86 ex	4.61 ax
$\delta_{C_6H_6}$	4.80	4.16	4.42	4.30
Δ	0.43	0.55	0.44	0.31

(**15**) as a minor component, while the corresponding chloro-derivative was never detected in the chlorination.[4]

The products, **14** and **15**, were isomerized with Et_3OBF_4 to 2a-bromo-4e-phenylthiane 1a-oxide (**16**) (mp 93°C) in an 83% yield and 2e-bromo-4e-phenylthiane 1e-oxide (**17**) (mp 133—143°C) in a 59% yield respectively. The assignment of the stereoformulas of **14**, **15**, **16**, and **17**, is based on the NMR spectral data shown in Table 3 (the isomer **15** is expected to have the largest Δ-value) and the comparison of the R_f-values in the tlc: the isomer **16** was observed higher than **15**, which was itself higher than **14** and **17** on a thin-layer plate; according to the rule (see above), the isomer **16** which possesses an axial sulfinyl oxygen is expected to be higher than **14** which possesses an equatorial oxygen, and **15** is expected to be higher than **17** as well.

The inverted isomer **16** was not isomerized to **14** when it was placed in the bromination condition. Moreover, since the both compounds **14** and **16** were recovered unchanged after treatment with concentrated hydrochloric acid(1 vol) in dioxane(2 vol),[9] they are configurationally-stable compounds.

The oxidation of **14** gave *trans*-2-bromo-4-phenylthiane 1,1-dioxide(**19**) (mp 149—151°C) in an 82.5% yield.

Mechanism of the Bromination with Bromine/N-Bromosuccinimide in the Presence of Pyridine. The bromination of the thiane 1-oxides(**1**, **5**, **8**, **13**, and **18**) with bromine/NBS in the presence of pyridine proved to give products in which bromine was introduced at a *trans*-position to the sulfinyl lone pair, mainly in the same manner as in the chlorination.[4] Consequently, the mechanism postulated for the chlorination[4] is also applicable to the bromination reaction as shown in Fig. 4; the bromo-oxosulfonium ion (**21**), which is formed by the attack of a positive bromine of a bromine molecule on the sulfinyl lone pair, gives the ylid (**22**) by the action of the bromide ion, and then **22** gives rise to the hypothetical intermediate (**23**) by the elimination of the bromide ion. The final step is the addition of the bromide ion to **23**, producing the α-bromosulfoxides (**24**), in which the bromine atom and sulfinyl lone pair are in a *trans* relationship.

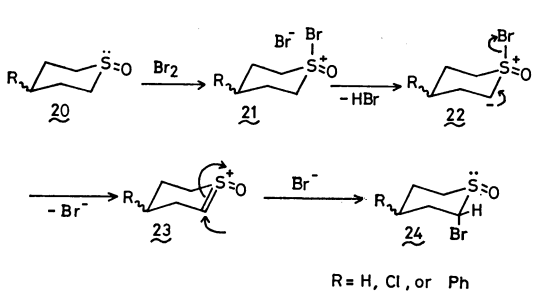

Fig. 4.

Experimental

Unless otherwise stated, the NMR spectra were measured with a Varian HA-100 spectrometer (100 MHz) and/or a Hitachi R/20B spectrometer (60 MHz) in a concentration of 40—50 mg in 0.4 ml of $CDCl_3$, while the IR spectra were recorded with Nujol mull using a Hitachi EPI-G3 spectrometer. In the NMR spectral data, J(coupling constant) is expressed in Hz, and HHW means a half-height width or the sum of the coupling constants. In the crystallization solvents, B, C, and H stand for benzene, cyclohexane, and hexane respectively, and the expressions B/C/H, *etc.* mean that the crystallization was carried out by dissolution in benzene, followed by the successive addition of cyclohexane and hexane.

*Bromination of Thiane 1-Oxide (**1**) to* cis*-2-Bromothiane 1-Oxide (**2**).* A solution of Br_2(0.6 g, 3.75 mmol) in 5 ml of CH_2Cl_2 and *N*-Bromosuccinimide (NBS) (1.34 g, 7.5 mmol) was added to a stirred solution of **1** (0.89 g, 7.55 mmol) and pyridine (0.61 ml, 7.6 mmol) in 30 ml of CH_2Cl_2. After stirring at room temperature for 1 hr, 30 ml of water, 10 ml of a 1M aqueous Na_2CO_3 solution, and 10 ml of a 1M Na_2SO_3 solution were added; the mixture was then extracted with CH_2Cl_2. The organic phase was dried over anhydrous Na_2SO_4 and then concentrated to an oily residue which was subsequently chromatographed on silica gel with benzene. Elution with benzene containing 2—5% ethyl acetate afforded 1.20 g (0.608 mmol; 80.5%) of the white crystals (**2**). Recrystallization from B/C/H gave mp 61—62°C. IR: 697, 946, 953, 1002, 1040 (S=O), 1058, 1068 cm^{-1}. IR (5% in CS_2): 700, 1078 (S=O) cm^{-1}. NMR: 1.2—3.4(8H), 5.09 (1H, octet, J=1, 3.5, 8). NMR (CCl_4): 1.3—3.1 (8H), 5.14(1H, q, J=3.5, 9). NMR(C_6H_6): 0.6—2.8 (8H), 4.50(1H, octet, J=1, 3, 9.5). NMR(CD_3CN): 5.13 (1H, octet, J=1, 3.5, 9.5). NMR(HCOOH): 1.5—3.5(8H), 5.40(1H, octet, J=1, 3.8, 8). NMR(D_2O): 2.0—3.7(8H), 5.84(1H, octet, J=0.5, 4, 8.5). NMR(CF_3COOH): 1.5—3.55(8H), 5.37(1H, octet, J=1.6, 3.4, 7). Mass: *m/e* 196(M^+), 117(base peak). Found: C, 30.59; H, 4.58; Br, 40.49%. Calcd for C_5H_9BrOS: C, 30.47; H, 4.60; Br, 40.54%.

*Transformation of **2** to* trans*-2-Bromothiane 1-Oxide(**3**).* To a stirred solution of **2** (0.885 g; 4.5 mmol) in CH_2Cl_2 (5 ml) *ca.* 1.5 g (7.9 mmol) of triethyloxonium tetrafluoroborate (Et_3OBF_4) was added. After the mixture had been stirred at room temperature for 1 hr, 40 ml of anhydrous ether was added at 0°C to give the oily ethoxysulfonium salt as a precipitation. After standing for 2 hr, the solvents were removed by decantation, and to the residue was added 20 ml of a 0.5M NaOH solution. The mixture was then extracted with CH_2Cl_2. The solvent was dried over Na_2SO_4 and evaporated to the residue, which was then chromatographed on silica gel with benzene. Elution with benzene containing 2% ethyl acetate yielded 0.60 g (3.06 mmol; 67.8 %) of a colorless oil (**3**) which was crystallized on standing. Recrystallizations from B/C/H at 0°C gave mp 59.5—60°C. **3** was detected with iodine higher than **2** on a thin-layer plate, using ethyl acetate: 95% ethanol (95 : 5). IR: 1016, 1023, 1050(S=O) cm^{-1}. IR(2% in CS_2): 1059 cm^{-1}.

IR(CCl_4): 1058 cm^{-1}. NMR: 1.4—3.6(8H), 4.76(1H, m, HHW=10.5). NMR(CCl_4): 1.4—3.45(8H), 4.78(1H, m, HHW=9). NMR(CS_2): 1.35—3.45(8H), 4.70(1H, m, HHW=9). NMR(C_6H_6): 0.7—2.95(8H), 4.35(1H, m, HHW=10). NMR(Et_3N): 4.98 (1H, m, HHW=10). NMR(Et_2O): 4.88(1H, m, HHW=8.5). NMR(pyridine): 1.1—3.5(8H), 5.08(1H, octet, J=1, 3.2, 6.3). NMR(CF_3COOH): 1.5—4.0(8H), 5.09(1H, q, J=3, 7.2). NMR (CD_3SOCD_3): 1.3—3.5, 5.12(1H, q, J=3.5, 7.5). NMR-(CD_3OD): 1.4—3.5, 4.93(1H, octet, J=1, 3.2, 7.4). NMR(CD_3COCD_3): 1.45—3.4, 4.91(1H, octet, J=1.2, 3, 7). NMR(D_2O): 1.9—4.12, 5.43 (1H, q, J=3.5, 8.3). Mass: *m/e* 196(M^+), 117(base peak). Found: C, 30.48; H, 4.59; Br, 40.27%. Calcd for C_5H_9BrOS: C, 30.47; H, 4.60; Br, 40.54%.

Oxidation of ***2*** *to 2-Bromothiane 1,1-Dioxide (****4****).* A solution of **2** (0.89 g; 4.51 mmol) and 30% H_2O_2(1 ml; 10 mmol) in acetic acid (10 ml) was kept at 45°C for 15 hr. The subsequent addition of water (40 ml) gave crystals which were then filtered off and recrystallized from B/C/H to yield 0.92 g (4.3 mmol; 95%) of **4**. Recrystallization from the same solvents gave mp 89—90°C. IR: 1122, 1155, 1279, 1309 cm^{-1}. NMR: 1.3—3.8 (8H), 4.82(1H, octet, J=2, 4, 8). Mass: *m/e* 212 (M^+), 41(base peak). Found: C, 28.19; H, 4.28; Br, 37.46%. Calcd for $C_5H_9BrO_2S$: C, 28.18; H, 4.26; Br, 37.50%.

Bromination of trans*-4-Chlorothiane 1-Oxide(****5****) to 2e-Bromo-4e-chlorothiane 1a-Oxide (****6****).* To a stirred solution of **5** (347 mg; 2.28 mmol) and pyridine (0.2 ml; 2.5 mmol) in CH_2Cl_2 (20 ml) were added NBS (405 mg; 2.28 mmol) and a solution of Br_2(0.18 g; 1.14 mmol) in CH_2Cl_2 (5 ml). The mixture was then stirred at room temperature for 22 hr. The usual work-up gave a residue, which was subsequently chromatographed on silica gel with benzene. Elution with benzene containing 4% ethyl acetate afforded 0.43 g (1.86 mmol; 81.5%) of the white crystals (**6**), which were then recrystallized from B/C at 0°C to give mp 48—49°C. IR: 965, 1031(S=O) cm^{-1}. IR (2% in CS_2): 982, 1073 (S=O) cm^{-1}. NMR: 1.7—3.35 (6H), 4.48 (1H, m, HHW=9), 5.13 (1H, q, J=3.6, 11). NMR (CCl_4): 1.82—3.40 (6H), 4.47 (1H, m, HHW=9), 5.10 (1H, q, J=3.3, 11.5). NMR (C_6H_6): 1.03—1.45 (1H), 1.78—2.4 (4H), 2.54—2.85 (1H), 3.63 (1H, m, HHW=9), 4.57 (1H, q, J=3.2, 11.2). NMR (CF_3COOH): 1.92—3.67 (6H), 4.53 (1H, m, HHW=9.5), 5.38 (1H, m, HHW=19). Mass: *m/e* 230 (M^+), 151 (base peak). Found: C, 26.43; H, 3.59; S, 13.76%. Calcd for $C_5H_8BrClOS$: C, 25.94; H, 3.48; S, 13.85%.

45 mg (13.0%) of **5** was recovered by elution with benzene: ethyl acetate (9 : 1).

Transformation of ***6*** *to 2a-Bromo-4e-chlorothiane 1a-Oxide (****7****).* To a stirred solution of **6** (365 mg; 1.58 mmol) in CH_2Cl_2 (5 ml) was added 0.45 g (2.37 mmol) of Et_3OBF_4, and the mixture was then stirred at room temperature for 1 hr. The addition of anhydrous ether (40 ml) gave rise to a white solid as a precipitation. The solvent was removed by decantation, and to the residue a 0.2M NaOH solution (25 ml) was added. The mixture was extracted with CH_2Cl_2. The evaporation of the solvent afforded an oil which was subsequently crystallized from B/C/H at −20°C to give 315 mg (86.6%) of **7**. Recrystallizations gave mp 73.5—75°C. IR: 762, 832, 870, 921, 1012, 1023, 1054 (S=O) cm^{-1}. IR (5% in CS_2): 970, 1022, 1064 (S=O) cm^{-1}. NMR: 2.0—3.44 (6H), 4.24 (1H, nonet, J=4, 4, 10, 10), 4.88 (1H, m, HHW=10). NMR (CCl_4): 1.95—3.38 (6H), 4.17 (1H, nonet, J=4, 4, 11, 11), 4.87 (1H, m, HHW=9.5). NMR (C_6H_6): 3.66 (1H, m, HHW=29.5), 4.17 (1H, m, HHW=9.5). NMR (CF_3COOH): 2.1—3.77 (6H), 4.33 (1H, septet, J=*ca.* 4, 4, 8, 8), 5.29 (1H, q, J=3.4, 7.4). NMR (CD_3OD): 2.0—3.72 (6H), 4.39 (1H, septet, J=*ca.* 4.3, 4.3, 8.6, 8.6), 5.19 (1H, m, HHW=10). NMR (CD_3CN): 1.85—3.60 (6H), 4.37 (1H, septet, J=4.3, 4.3, 8.6, 8.6), 5.02 (1H, m, HHW=10.5). Mass: *m/e* 230 (M^+). Found: C, 25.93; H, 3.56; S, 13.95%. Calcd for $C_5H_8BrClOS$: C, 25.94; H, 3.48; S, 13.85%.

Bromination of cis*-4-Chlorothiane 1-Oxide (****8****).* To a stirred solution of **8** (0.42 g, 2.75 mmol) and pyridine (0.33 ml, 4.1 mmol) in CH_2Cl_2 (10 ml) were added bromine (0.22 g, 1.38 mmol) and *N*-bromosuccinimide (0.49 g, 2.75 mmol). The mixture was stirred at room temperature for 6 hr. The NMR spectrum of the extract after the usual work-up showed it to be a 80 : 20 mixture of 2e-bromo-4e-chlorothiane 1a-oxide (**9**) and **6**. Crystallization from $CHCl_3$/B/C/H at 0°C gave 0.39 g (1.684 mmol; 61.2%) of **9**. The chromatography of the mother liquor gave 46 mg of **6** and 104 mg of a mixture of **6** and **9**, by elution with benzene containing 2% ethyl acetate. **6** was identified by mp, IR, and NMR. The total yield of **6** and **9** became 84.7%. Recrystallization of **9** from B/C gave mp 102—103°C (decompn.). IR: 681, 925, 1010, 1042, 1059 (S=O) cm^{-1}. IR (0.6% in CS_2): 917, 1079, 1086 (S=O) cm^{-1}. NMR: 1.95—3.38 (6H), 3.91 (1H, m, axial H), 4.68 (1H, q, J=4, 12). NMR (15 mg in 0.4 ml C_6H_6): 3.56 (1H, q, J=3, 12), NMR (CF_3COOH): 2.25—3.35 (5H), 3.61 (1H, sextet, J=3.5, 3.5, 15), 4.01 (1H, m, HHW=30, axial H), 4.90 (1H, q, J=7.2, 8.8). NMR (5 mg in 0.4 ml CCl_4+0.1 ml $CDCl_3$): 3.80 (1H, m, axial H), 4.51 (1H, q, J=4, 12). Mass: *m/e* 230 (M^+), 151 (base peak). Found: C, 26.04; H, 3.64; S, 13.74%. Calcd for $C_5H_8BrClOS$: C, 25.94; H, 3.48; S, 13.85%.

Transformation of ***9*** *to 2e-Bromo-4e-chlorothiane 1e-Oxide (****10****).* A solution of **9** (0.33 g, 1.43 mmol) and 0.42 g (2.2 mmol) of Et_3OBF_4 in CH_2Cl_2 (5 ml) was stirred at room temperature for 1 hr. The usual work-up and chromatography gave 282 mg (85.5%) of **10**, eluted with benzene containing 2% ethyl acetate. Recrystallization from B/C/H gave mp 93—94.5°C. IR: 490, 643, 674, 850, 931, 1051 (S=O) cm^{-1}. IR (1% in CS_2): 988, 1063 (S=O), 1078 cm^{-1}. NMR: 1.87—3.19 (5H), 3.53 (1H, octet, J=3, 7, 13), 4.12 (1H, nonet, J=4, 4, 9.5, 9.5), 4.65 (1H, q, J=3.6, 10). NMR (25 mg in CCl_4 0.4 ml): 1.82—3.14 (5H), 3.40 (1H, octet, J=3, 7, 12.5), 4.16 (1H, nonet, J=4, 4, 9.5, 9.5), 4.90 (1H, q, J=4, 10.5). NMR (C_6H_6): 1.11—2.52 (5H), 2.71 (1H, octet, J=3, 6, 13), 3.28 (1H, nonet, J=4, 4, 10, 10), 4.20 (1H, q, J=4, 11). NMR (CF_3COOH): 1.95—3.40 (5H), 3.80 (1H, octet, J=3, 5.7, 13), 4.11 (1H, nonet, J=4, 4, 10.5, 10.5), 5.02 (1H, q, J=3.8, 11.5). Mass: *m/e* 230 (M^+). Found: C, 26.12; H, 3.56; S, 13.84%. Calcd for $C_5H_8BrClOS$: C, 25.94; H, 3.48; S, 13.85%.

Oxidation of ***7*** *to* trans*-2-Bromo-4-chlorothiane 1,1-Dioxide(****11****).* A solution of **7** (0.26 g, 1.12 mmol) and 30% hydrogen peroxide (0.3 ml, 2.94 mmol) in 3 ml of acetic acid was kept at 45°C for 15 hr. The subsequent evaporation and crystallization from B/C gave 257 mg (1.04 mmol; 92.7%) of **11**. Recrystallization from B/C gave mp 105—108°C. IR: 485, 718, 1004, 1119, 1143, 1155, 1288, 1313 cm^{-1}. NMR: 2.1—3.1 (4H), 3.15—3.85 (2H), 4.47 (1H, quintet, J=*ca.* 4, 4, 4, 4), 5.08 (1H, q, J=6, 8.2). Mass: *m/e* 246 (M^+), 131 (base peak). Found: C, 24.32; H, 3.50; S, 13.10%. Calcd for $C_5H_8BrClO_2S$: C, 24.26; H, 3.26; S, 12.95%.

Oxidation of ***10*** *to* cis*-2-Bromo-4-chlorothiane 1,1-Dioxide(****12****).* A solution of **10** (83 mg, 0.354 mmol) and 30% H_2O_2 (0.1 ml, 1 mmol) in 3 ml of acetic acid was kept at 45°C for 15 hr. The subsequent evaporation of the solvent afforded white

crystals, which were recrystallized from B/C/H to give 82 mg (0.33 mmol; 93%) of **12**. The recrystallization gave mp 124—125°C. IR: 1139, 1280, 1320 cm^{-1}. NMR: 2.05—3.70 (6H), 4.14 (1H, m, HHW=30.5), 4.83 (1H, q, J=5.1, 11.1). Mass: *m/e* 246 (M^+). Found: C, 24.23; H, 3.29; S, 12.89%. Calcd for $C_5H_8BrClO_2S$: C, 24.26; H, 3.26; S, 12.95%.

Bromination of trans-*4-Phenylthiane 1-Oxide (**13**).* To a stirred solution of **13** (0.36 g, 1.85 mmol) and pyridine (0.23 ml, 2.8 mmol) in 10 ml of CH_2Cl_2 were added Br_2 (0.15 g, 0.94 mmol) and NBS (0.48 g, 2.7 mmol). The mixture was stirred at room temperature for 30 min. The NMR spectrum of the crystalline residue, obtained by the usual work-up, showed it to be 63 : 37 mixture of 2a-bromo-4e-phenylthiane 1e-oxide (**14**) and 2e-bromo-4e-phenylthiane 1a-oxide (**15**). Crystallization from B/CCl_4 followed by recrystallization from B/C/H gave 0.12 g (0.44 mmol; 23.7%) of **14**. Recrystallizations from B/C/H gave mp 143—144°C. IR: 710, 771, 1065 cm^{-1}. NMR: 1.7—3.4 (7H), 5.39 (1H, m, HHW=9), 7.20 (5H, m). NMR (C_6H_6): 1.0—3.2 (7H), 4.80 (1H, m, HHW=9). NMR (3 mg in 0.4 ml CCl_4): 5.23 (1H, m, HHW=8). Mass: *m/e* 272 (M^+), 193 (base peak). Found: C, 48.30; H, 4.77; S, 11.78%. Calcd for $C_{11}H_{13}BrOS$: C, 48.36; H, 4.80; S, 11.74%.

The combined mother liquors were chromatographed with benzene. Elution with benzene containing 1% ethyl acetate furnished 0.157 g (0.574 mmol; 31%) of **15**, and then 0.158 g (0.578 mmol; 31.2%) of **14**. Recrystallizations of the former (**15**) from B/C gave mp 132—133.5°C. IR: 699, 751, 921, 1011, 1037, 1055 cm^{-1}. NMR: 1.7—3.35 (7H), 4.77 (1H, q, J=3.5, 12.2), 7.20 (5H, m). NMR (C_6H_6): 0.8—3.4 (7H), 4.16 (1H, q, J=3.2, 12). NMR (6 mg in 0.4 ml CCl_4): 4.71 (1H, q, J=3.5, 12). Mass: *m/e* 272 (M^+). Found: C, 47.84; H, 4.84; S, 11.75%. Calcd for $C_{11}H_{13}BrOS$: C, 48.36; H, 4.80; S, 11.74%.

Bromination of cis-*4-Phenylthiane 1-Oxide (**18**).* *(a) With 1.0 equiv of NBS*: A solution of **18** (0.25 g, 1.29 mmol), pyridine (0.21 ml, 2.6 mmol), Br_2 (0.1 g, 0.64 mmol), and NBS (0.23 g, 1.29 mmol) in 10 ml of CH_2Cl_2 was stirred for 3 hr at room temperature. Chromatography after the usual work-up gave 128 mg (0.47 mmol; 36.0%) of a 77 : 23 mixture of **14** and **15**, eluted with benzene containing 1—2% ethyl acetate, and 0.15 g (60%) of **18** containing *ca.* 5% of **13** eluted with benzene–ethyl acetate (1 : 1).

(b) With 2.2 equiv of NBS: To a stirred solution of **18** (0.42 g, 2.16 mmol) and pyridine (0.26 ml, 3.24 mmol) in 10 ml of CH_2Cl_2, were added Br_2(0.17 g, 1.06 mmol) and NBS (0.46 g, 2.58 mmol). After the mixture had then been stirred at room temperature for 18 hr, more NBS (385 mg, 2.16 mmol) and pyridine (0.26 ml, 3.24 mmol) were added and the reaction was continued for 5 hr. The NMR spectrum of the extract from the usual work-up showed that a 81 : 19 mixture of **14** and **15** was obtained. Chromatography gave 45 mg (0.165 mmol; 7.6%) of **15**, with benzene containing 1% ethyl acetate, and then 0.245 g (0.90 mmol; 41.5%) of **14**, with 1—4% ethyl acetate. **14** and **15** were identified by mp, IR, NMR, and tlc. 185 mg (44.0%) of **18** was recovered by the elution of benzene containing 5% methanol.

*Transformation of **14** to 2a-Bromo-4e-phenylthiane 1a-Oxide (**16**).* A solution of **14** (0.38 g, 1.39 mmol) and 0.53 g (2.8 mmol) of Et_3OBF_4 in 5 ml of CH_2Cl_2 was stirred at room temperature for 30 min. The addition of ether at 0°C gave a crystalline ethoxysulfonium salt, which was decomposed with 20 ml of a 0.2M NaOH solution and extracted with CH_2Cl_2. The chromatography of the extract afforded 315 mg (1.15 mmol; 82.8%) of **16** with 1% ethyl acetate in benzene. Recrystallizations from B/H gave mp 93°C. IR: 703, 750, 1016, 1049 cm^{-1} (S=O) cm^{-1}. NMR: 1.65—3.50 (7H), 4.91 (1H,m, HHW=7), 7.23 (5H, m). NMR (C_6H_6): 0.95—3.15 (7H), 4.42 (1H, m, HHW=7.5). NMR (CCl_4): 1.55—3.41 (7H), 4.86 (1H, m, HHW=7), 7.18 (5H, s), NMR (CF_3COOH): 1.7—4.0 (7H), 5.29 (1H, m, HHW=7). Found: C, 48.51; H, 4.92; S, 11.67%. Calcd for $C_{11}H_{13}BrOS$: C, 48.36; H, 4.80; S, 11.74%.

*Transformation of **15** to 2e-Bromo-4e-phenylthiane 1e-Oxide (**17**).* A solution of **15** (205 mg, 0.75 mmol) and Et_3O-BF_4 (285 mg, 1.5 mmol) in 3 ml of CH_2Cl_2 was stirred at room temperature for 1 hr. The usual work-up furnished a crystalline extract, which was subsequently recrystallized from B/H to give 0.12 g (59%) of **17**. Several recrystallizations from B/H gave mp 133—143°C (decompn.). IR: 703, 750, 1016, 1049 (S=O) cm^{-1}. NMR: 1.8—3.2 (6H), 3.60 (1H, sextet, J=3.6, 3.6, 13), 4.74 (1H, q, J=4, 11.3), NMR (3 mg in 0.4 ml CCl_4+0.05 ml $CDCl_3$): 4.61 (1H, q, J=4, 12). NMR (5 mg in 0.4 ml C_6H_6): 4.30 (1H, q, J=4, 12). Found: C, 47.76; H, 4.87; S, 11.66%. Calcd for $C_{11}H_{13}BrOS$: C, 48.36; H, 4.80; S, 11.74%.

*Oxidation of **14** to* trans-*2-Bromo-4-phenylthiane 1,1-Dioxide (**19**).* A solution of **14** (0.24 g, 0.88 mmol) and 0.2 ml (2.0 mmol) of 30% H_2O_2 in 5 ml of acetic acid was kept at 50°C for 15 hr. The subsequent evaporation of the solvent followed by passage through silica gel with benzene, gave 0.21 g (0.725 mmol; 82.5%) of **19**. Recrystallization from B/H gave mp 149—151°C (sintered at 144°C). IR: 1110, 1287, 1314 cm^{-1}. NMR: 1.93—3.87 (7H), 4.85 (1H, q, J=3.2, 6.4), 7.22 (5H, m). Mass: *m/e* 288 (M^+), 209 (base peak). Found: C, 45.80; H, 4.60; S, 11.14%. Calcd for $C_{11}H_{13}BrO_2S$: C, 45.68; H, 4.53; S, 11.09%.

*Competitive Bromination of **13** and **18**.* A solution of **13** (197 mg), **18** (180 mg), pyridine (0.12 ml, 1.5 mmol), Br_2 (80 mg, 0.5 mmol), and NBS (0.18 g, 1 mmol) in 10 ml of CH_2Cl_2 was stirred at room temperature for 40 min. The NMR spectrum of the residue, which had been obtained by the usual work-up, showed that **14** and **15** were obtained in a 65 : 35 ratio. Chromatography gave 53 mg of **15** and 125 mg of **14**, together with 243 mg of a 37 : 63 mixture of **13** and **18**. Accordingly, in this bromination reaction, 107 mg of **13** was consumed, while only 27 mg of **18** was used, showing that **13** is brominated approximately five times faster than **18**.

*Treatment of 2-Bromo-4-phenylthiane 1-Oxides (**14** and **16**) with Concentrated Hydrochloric Acid (1 vol) in Dioxane (**2** vol).*

*(a) **14***: To a stirred solution of **14** (117 mg) in 4 ml of dioxane, 2 ml of concentrated HCl were added. The mixture was then stirred at room temperature for 24 hr. After the usual work-up, **14** was recovered unchanged, as was confirmed by the NMR and mass spectra and by tlc.

*(b) **16***: A solution of **16** (53 mg) in 6 ml of the reagent was stirred at room temperature for 2 hr. After the usual work-up, **16** was recovered quantitatively, as estimated by means of the NMR spectrum and tlc.

Kinetics and Mechanism of Aziridine Synthesis from Ketoxime with Lithium Aluminum Hydride[1]

Hiroshi TANIDA, Tetsuo OKADA, and Katsumi KOTERA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553

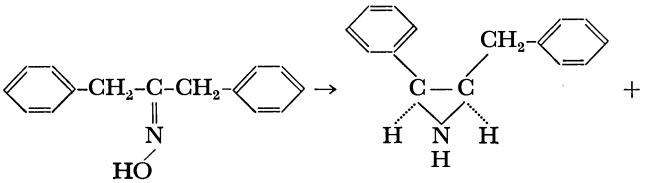
(Received July 29, 1972)

The stoichiometry and rate of the reaction of dibenzyl ketoxime (**1**) with lithium aluminum hydride in tetrahydrofuran leading to *cis*-2-benzyl-3-phenylaziridine (**2**, 92%) and 2-amino-1,3-diphenylpropane (**3**, 8%) were determined by gas meter and vpc. It was found that the aziridine formation proceeds with an immediate evolution of 1 mole of hydrogen followed by a slow liberation of a second mole of hydrogen and an accommodation of 1 equiv. of hydride into the molecule. Also, the formation has an induction period and there is a catalytic acceleration effect by the concurrently-formed minor product **3**. Combination of the previously-reported results and the present findings leads us to propose a mechanism by which an aluminum derivative rapidly obtained on addition of **1** to the solution of lithium aluminum hydride undergoes slow hydrogen elimination to afford an azirine intermediate, followed by reduction to the aziridine. Making use of the catalytic effect discovered, the reaction rate and yield of aziridine were increased by the addition to the reaction mixture of an amine, particularly a secondary amine such as *n*-butylmethylamine.

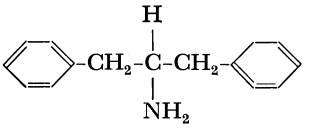
Although the principal products from the reductions of ketoximes with lithium aluminum hydride (LAH) had been reported to be the corresponding primary amines,[2] we observed some years ago that the reactions of certain aryl ketoximes and bridged benzocyclene oximes mainly yielded the aziridine derivatives.[3] Since then, this reaction has been considerably developed as a simple and convenient method for aziridine synthesis.[4-6] During this development, some characteristic features of the reaction have been revealed. First, the reaction produces only *cis* aziridine. For example, dibenzyl ketoxime (**1**) leads to *cis*-2-benzyl-3-phenylaziridine. Secondly, aziridine ring-closure takes place on the side syn to the oxime configuration preferably to the side anti to it.[7] This is entirely different from the Neber rearrangement, which has been reported to proceed independently of oxime configuration.[8] Thirdly, aziridine ring-closure at a benzylic position is favored over that at an aliphatic position.[6,7] Fourthly, when lithium aluminum deuteride (LAD) is used, one deuterium atom is incorporated into the carbon originally carrying the oximino function, but not at all into other carbons.[3,4d,6] Fifthly, no aziridine is formed from *N*-(α-methylphenethyl)hydroxylamine so that it is very unlikely that the reaction proceeds through a hydroxylamine intermediate.[9] With these findings in mind, we undertook a kinetic investigation in order to get further insight into the mechanism of this reaction and also to improve the reaction from a synthetic viewpoint.

Results and Discussion

As reported earlier,[4,5] dibenzyl ketoxime (**1**) undergoes the reaction affording *cis*-2-benzyl-3-phenylaziridine (**1**) and 2-amino-1,3-diphenylpropane (**3**) in the isolated yields of 71—78% and about 8%, respectively. The present procedure was essentially the same as that reported, but it involved the use of a reaction mixture of LAH (0.25 M, 1.00 M in hydride) and **1** (0.167 M) in tetrahydrofuran.[10] When reaction was complete, the mixture was treated with water to destroy the excess hydride and analyzed by vpc, showing the formation of **2** in 92% yield and **3** in 8% yield.



1 **2**



3

The rate and stoichiometry were determined by measurement of evolving hydrogen with a gas meter and the results obtained are presented in Table 1 and Fig. 1. It is noted that about 1 mol (the amount actually found was 1.13 mol) of hydrogen is evolved very rapidly on mixing **1** with the LAH solution, the reaction then proceeding with slow evolution of a second

10) It is convenient to discuss the utilization of the reagent in terms of moles of hydride consumed per mole of compound.

Table 1. Kinetic analysis by gas meter[a)]

Reaction time hr	Hydrogen evolved	Hydride consumed	Hydride utilized for reduction
0	1.13	1.21	0.08
0.5	1.14	1.27	0.13
1.0	1.19	1.51	0.32
3.0	1.75	2.53	0.78
6.0	2.10	3.17	1.07
12.0	2.12	3.36	1.24

a) Units: mol for hydrogen and mol equiv for hydride.

1 mol of hydrogen (in total, 2.12 mol were evolved before cessation of reaction). At appropriate time intervals, the reaction mixture was hydrolyzed by addition of dilute sulfuric acid and the hydrogen evolved was determined to calculate the hydride consumed; this is shown in the second column of Table 1. The difference between the hydride consumed and the hydrogen evolved corresponds to the hydride taken up by the molecule of **1** for reduction; this is 1.24 mol equiv. at 100% reaction. It has been reported that the reduction of cyclohexanone oxime to cyclohexylamine requires 4 equiv of hydride, 2 for reaction and 2 for hydrogen evolution, and also that the reaction proceeds with a rapid evolution of 1 equiv. of hydrogen followed by a slow utilization of 2 equiv. of hydride for reduction and slow liberation of a second mole of hydrogen.[11] In this connection, 100% formation of aziridine would require, after an immediate evolution of 1 mol of hydrogen, a slow utilization of 1 equiv of hydride for reduction and a slow liberation of a second mole of hydrogen. It is obvious that the first step in both the reactions with **1** and cyclohexanone oxime is the formation of an O–Al bond, as evidenced by the immediate evolution of hydrogen corresponding to the active hydrogen on the oxime function.[2,12] If an aziridine is then formed as the only product, since the molecular formula is equal to that of an imine, the stoichiometry

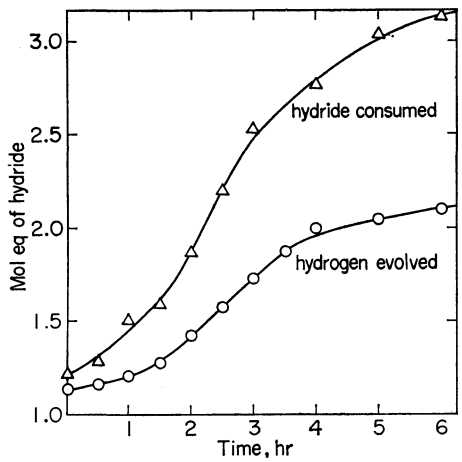

Fig. 1. Kinetic analysis by gas meter. At $t=0$, [**1**]=0.167 M and [LAH]=0.25 M in THF; reaction temp., 25°C.

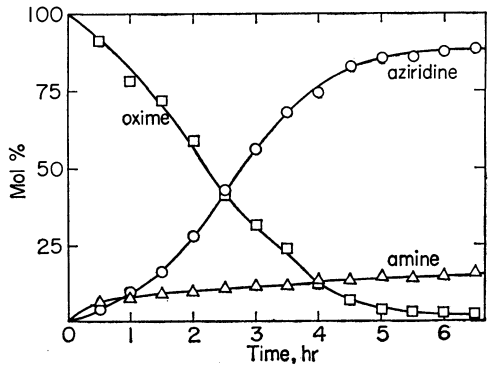

Fig. 2. Kinetic analysis by vapor phase chromatography. At $t=0$, [**1**]=0.167 M and [LAH]=0.25 M in THF; reaction temp., 26°C.

will involve utilization of 1 equiv. of hydride for reduction and the liberation of a second mole of hydrogen. Therefore, the stoichiometric difference between the formation of amine and that of aziridine will be indicated by the amount of hydride utilized for reduction; 2 equiv. or 1 equiv. In this connection, the results in Table 1 (1.24 mol equiv were utilized at the completion of reaction) are understood if one considers the formation of a mixture consisting of mostly **2** with a minor amount of **3**.

The results obtained by monitoring the reactant and products by vpc are shown in Fig. 2. Of note are the existence of an induction period in the reaction and the close resemblance between the curve for the slow evolution of hydrogen in Fig. 1 and that for the production of aziridine in Fig. 2. The vpc data were analyzed in our laboratory[13] by a Melcom EA-7410 analog computer and it was found possible to accommodate the data by the following kinetic equations. An important implication of these equations

$$\text{Oxime} + \text{LAH} \xrightarrow{\text{very fast}} I_1 + H_2$$

$$I_1 \xrightarrow{k_1} \text{Amine} \qquad I_1\text{: Intermediate}$$

$$I_1 \xrightarrow{k_2 C_{\text{Amine}}} \text{Aziridine}$$

is that the amine formed by k_1 has a catalytic acceleration effect upon the formation of aziridine with

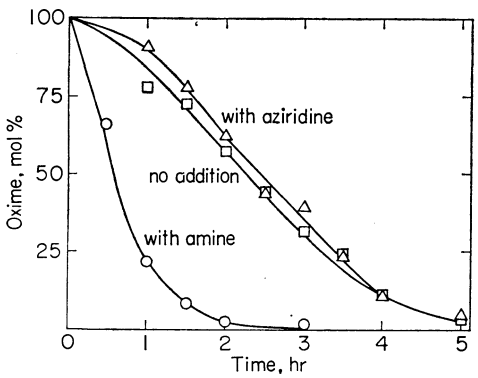

Fig. 3. Demonstration of catalytic effect by the amine. At $t=0$, [1]=0.167 M and [LAH]=0.34 M in THF; reaction temp., 26°C. The concentrations of **2** and **3** added were 0.167 M.

13) We thank Dr. T. Takahashi and Mr. M. Shudo for the aid.

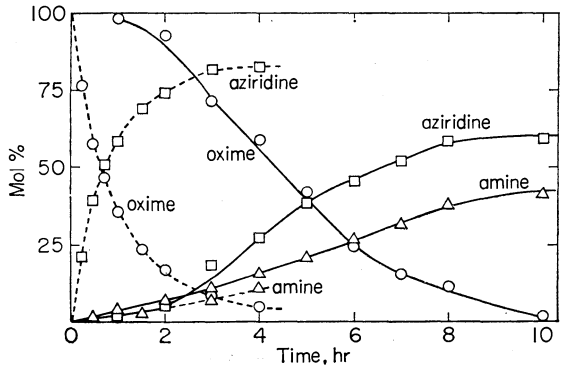

Fig. 4. Reaction of acetophenone oxime; solid lines for results without addition of *n*-butylmethylamine, dotted lines for those with addition. At $t=0$, [oxime]=0.167 M and [LAH]=0.30 M in THF; reaction temp., 40°C.

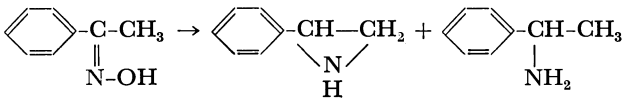
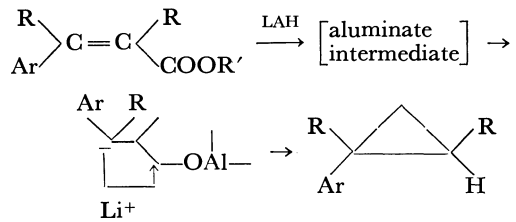
the rate coefficient $k_2\ C_{\text{Amine}}$. Indeed, it was confirmed that addition of **3** to the reaction mixture enhances the reaction rate and shortens the induction period though the addition of **2** has no effect; these experiments are shown in Fig. 3.

Similar experiments were carried out for the reaction of *anti*-acetophenone oxime.[14] Figure 4 shows



the results monitored by vpc. Again, treatment by the computer yielded equations of the same type as the above and suggested a positive catalytic effect by the by-product amine. The yield of 2-phenylaziridine was raised to 80% by addition of an amine, *n*-butylmethylamine, although it had been reported as 60% without the addition.

In the reaction with **1**, variation of the concentration of LAH did not affect the reaction rate or the aziridine yield. Therefore, the transition state in the rate-determining step must be of an intramolecular nature. Transformation of certain α,β-unsaturated carboxylic acids or esters into the corresponding cyclopropanes by reduction with LAH may be a related reaction. The ring-closing steps in these reactions have been suggested as intramolecular nucleophilic displacement reactions.[17,18]



(or concerted displacement)

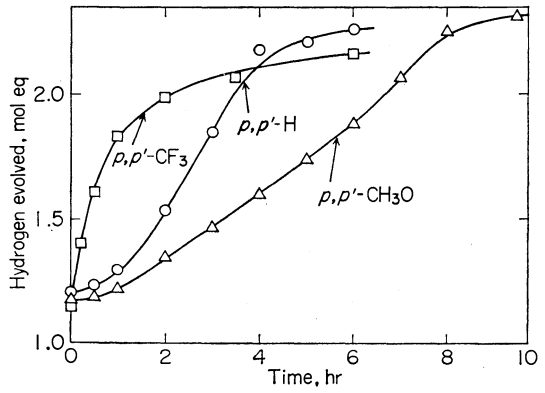


Fig. 5. Substituent effects. At $t=0$, [oxime]=0.167 M and [LAH]=0.25 M in THF; reaction temp., 26°C.

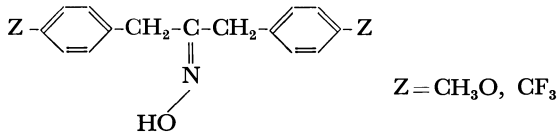
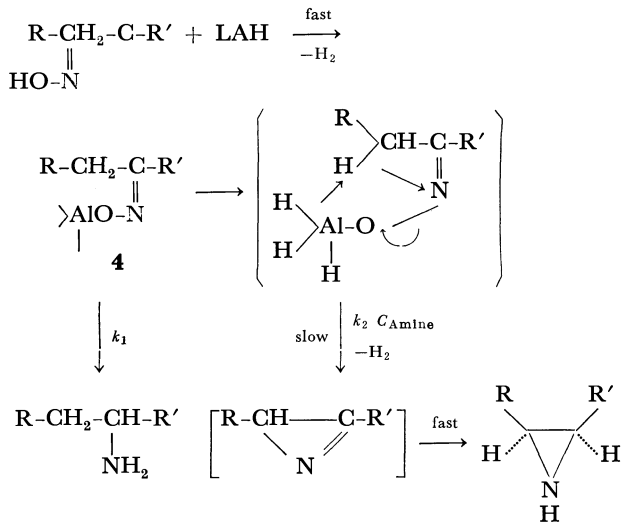
Studies of substituent effects were carried out with *p,p'*-di-(trifluoromethyl) and *p,p'*-dimethoxyl derivatives of **1** and the results obtained are shown in Fig. 5.



Shortening of the induction period and enhancement of the rate are noted with introduction of the electron-withdrawing trifluoromethyl substituents and a rate decrease is noted with that of the electron-donating methoxy substituents. Therefore, increasing capability of the proton α to the aryl group for elimination increases the overall rate.

On the basis of the present data and previous findings (see Introduction) we propose that the aziridine formation proceeds by the rapid formation of an aluminate intermediate **4** on addition of the oxime to the LAH solution, followed by a concerted intramolecular displacement to give an azirine and, finally, saturation to the aziridine. This may be depicted as follows.



14) The anti configuration has been reported by Karabatsos and Taller.[15] We have determined by NMR that the aluminate of this oxime has the same configuration and no alternation of it at the reaction temperature.[16]

Table 3. Effects of added *n*-butylmethylamine[a]

Ketoxime	With addition		Without addition	
	Aziridine, %	Amine, %	Aziridine, %	Amine, %
	75	15	30	60
	82	11	57	47
	50	20	12	60
	51		10	
	30		2	
	60	35	20	75

a) One mol of the amine was added per mol of lithium aluminum hydride.

The by-product amine is considered to activate one of the aluminate hydrogens in **4** thereby facilitating proton elimination. Reduction of the azirine with LAH will take place from a sterically less hindered side resulting in the *cis* aziridine.[2-6,19] Since according to the proposed mechanism hydrogen is incorporated in the steps from the azirine to the aziridine and from **4** to the amine, the results obtained with LAD (Introduction)[3,4d,6] are reasonably accommodated.

Solvent Effects. Various solvents were tested in the reaction with **1**. Yields of products and half-lives of the reaction were as shown in Table 2. Relatively high yields of **2** were found in solvents having high solvation ability such as tetrahydrofuran and dimethoxyethane, while a low yield was found in ether, which has a low solvation ability.

Influence of Added Amine on Yield. Several kinds of amine were added to the reaction mixture to improve the reaction; the results obtained are shown in Fig. 6. Of the amines tested, secondary *n*-butylmethylamine gave the best result. Reactions with

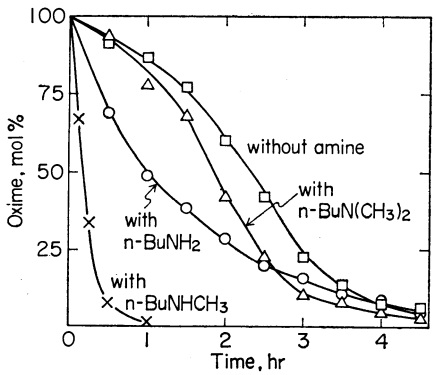

Fig. 6. Catalytic effects by various amines. At $t=0$, [**1**]= 0.167 M, [LAH]=0.70 M, and [amine catalyst]=0.30 M in THF; reaction temp., 26°C.

19) A Hassner and W. Fowlen, *J. Amer. Chem. Soc.*, **90**, 2869 (1968).

and without added *n*-butylmethylamine were carried out with the oximes listed in Table 3. It is clearly seen that the addition increases the yield of aziridine and decreases the yield of amine; with benzylmethyl ketoxime, for example, aziridine increases from 30% to 75% and amine decreases from 60% to 15%.

None of the experimental results so far obtained are inconsistent with the above-proposed mechanism.

Experimental

Materials. Purification of lithium aluminum hydride was carried out by the method of Davis *et al.*[20] Forty grams of LAH purchased from Metal Hydrides Inc. was added to 500 ml of anhydrous ether, refluxed for several days under argon atmosphere, and filtered. The filtrate was concentrated to a volume of 50 ml under reduced argon atmosphere, mixed with anhydrous benzene which had been distilled over LAH, and stored for several hours in an ice bath to deposit 23 g of prismatic crystals. LAH thus purified was completely soluble in THF. Commercially available THF was refluxed for three days over LAH under argon atmosphere and distilled. Two further distillations over LAH then provided THF suitable for the present use.

Dibenzyl Ketoxime. A solution of 50 g of dibenzyl ketone (Tokyo Kasei, GR. grade) in 100 ml of pyridine was added to a solution of 10 g of hydroxylamine hydrochloride in 30 ml of water and 30 ml of alcohol. After being stirred for 2 hr at room temperature, the reaction mixture was poured into water and extracted with ether. The ether layer was washed with dilute hydrochloric acid, dilute sodium carbonate, and water, and dried over sodium sulfate. Evaporation of the solvent followed by recrystallization from a mixture of hexane and ether yielded 50 g of dibenzyl ketoxime, mp 123—124°C.

Vapor Phase Chromatography. Concentrations of the reactants and reaction temperatures in the reactions analyzed by vpc are indicated in the captions of the figures. The analyses were carried out on a Hitachi gaschromato Model K-53 equipped with a hydrogen flame ionization detector using a 1 m × 3 mm stainless steel column.

Procedure-A: A column packed with 4% KF-54 on 60—80 mesh Chromosorb W was used for analysis of **1**, **2**, and **3**; benzyl *p*-methylbenzyl ether was used as an internal reference. The retention times of benzyl *p*-methylbenzyl ether, **3**, **2**, and **1** were 6.8, 9.0, 13.0, and 16.5 min, respectively, at 170°C with 1.0 kg/cm^2 of N_2.

Procedure-B: A column packed with 10% KF-54 on 80—100 mesh Chromosorb W was used for analysis of acetophenone oxime, 2-phenylaziridine, and 1-phenylethylamine, using pentamethyl benzene as an internal reference. The retention times of the amine, the aziridine, pentamethylbenzene, and the oxime were 7.0, 16.2, 26.0, and 41.3 min, respectively, at 70°C with 1.4 kg/cm^2 of N_2.

Kinetic Analysis by Gas Meter. Hydrogen Evolved. A 100 ml three-necked flask equipped with a magnetic stirrer was kept in a constant temperature bath. A glass tube connected one neck of the flask to a trap which was kept at −50°C in a dry ice-acetone bath, and an exit to the trap was connected to a buret adjusted by a water level. The flask was flushed with argon and stoppered with a gum cap. When the water level of buret became constant, 15.0 ml of the LAH solution was injected into the flask through the gum cap, then the oxime solution was added over a period of 2 min under stirring. A control experiment was performed by addition of the reaction solvent containing no oxime to the LAH solution. Concentrations of the reactants and reaction temperatures are shown in the captions of the figures. Hydrogen evolved was measured at appropriate time intervals with the buret.

Hydride Consumed. A known volume of the reaction mixture was injected through the gum cap and decomposed by 5% sulfuric acid with ice-water cooling. Hydrogen liberated was measured with the buret. Subtraction of the amount of hydrogen thus-liberated at a given reaction time from the amount liberated at zero reaction time corresponds to the amount of hydride consumed.

We are indebted to Dr. K. Kitahonoki for his encouragement.

The Structures of the Reoxidation Products of 7,8-Dihydroneopterin

Katsura SUGIURA and Miki GOTO

Department of Chemistry, Gakushuin University, Toshima-ku, Tokyo

(Received August 3, 1972)

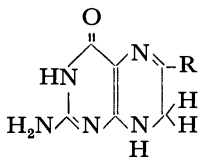
On the reduction of D-*erythro*-neopterin with sodium dithionite, after which it was let stand in neutral pH, three colorless compounds, I, II, and III, and two yellow compounds, I and II, were obtained. On the reduction of D-*erythro*-neopterin with Fe dust in 25% acetic acid, after which it was let stand at a neutral pH, two yellow compounds, II and III, were obtained. From UV and NMR spectral data as well as from the chemical reactions, the structures for these compounds were identified, Colorless Compound I is 2-amino-4-hydroxy-6-(1′,3′-dihydroxypropyl)pteridine; Colorless Compound II, 2-amino-4-hydroxy-6-(D-*erythro*-1′,2′,3′-trihydroxypropyl)-pteridine; Colorless Compound III, 2-amino-4-hydroxy-6-(D-*threo*-1′,2′,3′-trihydroxypropyl)pteridine; Yellow Compound I, 2-amino-4-hydroxy-6-(1′-oxo-3′-sulfopropyl)-7,8-dihydropteridine; Yellow Compound II, 2-amino-4-hydroxy-6-(1′-oxo-3′-hydroxypropyl)-7,8-dihydropteridine, and Yellow Compound III, 2-amino-4-hydroxy-6-(1′-oxo-2′,3′-dihydroxypropyl)-7,8-dihydropteridine.

The biological function of a phosphate of 2-amino-4-hydroxy-6-(D-*erythro*-1′,2′,3′-trihydroxypropyl)-7,8-dihydropteridine (7,8-dihydro-D-*erythro*-neopterin) was proved to serve as a key compound for the biosynthesis of folic acid and the biopterin group of co-factors.[1-3] Recently, the enzymic transformation of 7,8-dihydro-D-*erythro*-neopterin to D-*threo*-neopterin has been demonstrated.[4] Kaufman has reported that 7,8-dihydrobiopterin is obtained from biopterin by treatment with Fe dust in an acidic solution, and the synthetic 7,8-dihydrobiopterin has been demonstrated by using purified rat liver extract to be the phenylalanine-hydroxylation co-factor.[5] Fukushima and Akino have reported that neopterin and biopterin give 7,8-dihydroneopterin and 7,8-dihydrobiopterin respectively by treatment with sodium dithionite.[6]

For the study of the biosynthesis of pteridines, we prepared 7,8-dihydro-D-*erythro*-neopterin by treating it with sodium dithionite or Fe dust in 25% acetic acid, as has been described by the above authors. On the reduction of D-*erythro*-neopterin, followed by its purification on a Sephadex column, we did not get pure 7,8-dihydro-D-*erythro*-neopterin, but some unknown compounds were always produced together with 7,8-dihydro-D-*erythro*-neopterin.[2] The yields of these unknown compounds were increased when the reduced solutions were kept standing in a neutral pH for a longer time. The present paper will report on the structures of these compounds.

On the reduction of D-*erythro*-neopterin by treatment with sodium dithionite, after which it was let stand in a nuetral pH, three colorless and two yellow substances were obtained, *i.e.*, colorless Compounds I, II, and III, and Yellow Compounds I and II. On the reduction of D-*erythro*-neopterin by treatment with Fe dust in 25% acetic acid, after which it was let stand in a neutral pH, the products were two yellow substances, Yellow Compounds II and III.

On the basis of UV and NMR spectral data as well as the chemical reactions, the structures for these compounds were deduced to be as follows:



R; $-CO-CH_2-CH_2SO_3H$
Yellow Compound I

R; $-CO-CH_2-CH_2OH$
Yellow Compound II

R; $-CO-\underset{\displaystyle OH}{\underset{|}{CH}}-CH_2OH$
Yellow Compound III

Experimental

Reduction of D-erythro-*Neopterin by Treatment with Sodium Dithionite and the Isolation of the Products.* D-*erythro*-Neopterin (140 mg) was suspended in 2 ml of water, and then 2M sodium hydroxide was added until a clear solution was obtained. After the addition of sodium dithionite (400 mg), the solution was left at 90—95°C for 15 min, then, after the addition of 6M hydrochloric acid (1 ml), the solution was heated at 90—95°C. The solution was neutralized with ammonia, and the excess sodium dithionite was removed by means of a Sephadex G-25 (fine) column (3×25 cm, developer; water) and the eluate was concentrated to 200 ml by means of a rotary evaporator below 40°C. The solution was left standing for 48 hr at room temperature in the dark. The solution was acidified with acetic acid, and then it was placed on a 3×25 cm column of Florisil; the column was subsequently washed with 0.001M acetic acid, and 20% aqueous acetone successively. Colorless matters were eluted by the first solvent, and yellow matters by the second solvent. The colorless substances were separated into two fluoresent bands by means of a cellulose column (4×25 cm, developer; 2-propanol—1% ammonia; 2 : 1). The eluate of the

first was concentrated and the residue was recrystallized from water to give colorless needles; 12 mg (8.6%); this was Colorless Compound I. The eluate of the second was purified by chromatographic method using six sheets of paper (40×40 cm, Toyo Roshi Co. Ltd., No. 54, developer; 2-propanol—1% ammonia: 2 : 1). The fluorescent bands were then cut out, and the materials were eluted from it with water. The eluates were subsequently evaporated to dryness. There was a trace of the (R_f, 0.21) fraction; this was Colorless Compound III. The residue of the (R_f, 0.31) fraction was recrystallized from water to give colorless needles; 29 mg (21%); this was Colorless Compound II. The yellow substances were separated into two fluorescent bands by means of a cellulose column (3×20 cm, developer; 0.05% ammonia). The eluate of the first was concentrated, the residue was purified by means of a Sephadex G-25 (fine) column (3×25 cm, developer; water), the eluate was concentrated to dryness *in vacuo*, and the residue was recrystallized from 50% ethanol to give yellow needles; 48 mg (25%); this was Yellow Compound I. The eluate of the second such substance was concentrated, the residue was purified by means of a DEAE-cellulose column (3×25 cm, developer; water), the eluate was concentrated to dryness *in vacuo*, and the residue was recrystallized from water to give yellow needles; 25 mg (18%); this was Yellow Compound II. The samples were dried at 70—80°C/0.01 mmHg for 12 hr over P_2O_5 for analysis.

Colorless Compound I:

Found: C, 44.02; H, 4.50; N, 29.55%. Calcd for $C_9H_{11}O_3N_5 \cdot 0.5H_2O$: C, 43.90; H, 4.88; N, 28.46%.

NMR (CF_3COOD): δ 3.33 (t, J=5.8 Hz, 2H), 4.14 (t, J=5.8 Hz, 2H), 4.56 (s, 2H).

Bromine Oxidation of Yellow Compound I. A suspension of Yellow Compound I (40 mg) in 2M hydrochloric acid (20 ml) was treated with bromine (*ca.* 1 g) for a few minutes at room temperature. The mixture was then concentrated to 10 ml by means of a rotary evaporator and the solution was treated with charcoal (1 g). The adsorbed fluorescent compound was eluted with a mixture of 3% aqueous ammonia and ethanol (3 : 1). The eluate was purified by the chromatographic method, using a cellulose column (3×25 cm, developer; 50% ethanol). The eluate was evaporated to dryness, and the residue was crystallized from 50% ethanol (yellow powder, 36 mg, 74%; this was Yellow Compound I·Br_2). The sample was dried at 70—80°C/0.01 mmHg for 3 hr over P_2O_5 for analysis.

Found: C, 29.26; H, 3.11; N, 19.86; S, 8.46%. Calcd for $C_9H_9O_5N_5S \cdot 3.5H_2O$: C, 29.83; H, 4.41; N, 19.33; S, 8.83%.

UV: $\lambda_{max}^{0.1M\ NaOH}$ mμ (ε), 277 (16.2×10³), 316 (7.4×10³), 372 (11.5×10³); $\lambda_{min}^{0.1M\ NaOH}$ mμ (ε), 240 (4.58×10³), 308 (7.3×10³), 332 (6.8×10³); $\lambda_{max}^{0.1M\ HCl}$ mμ (ε), 234 (9.72×10³), 270 (11.7×10³), 318 (10.6×10³); $\lambda_{min}^{0.1M\ HCl}$ mμ (ε), 230 (9.70×10³), 250 (8.8×10³), 291 (7.12×10³).

NMR (CF_3COOD): δ 4.00 (m, 4H), 9.16 (s, 1H).

2,4-Dinitrophenylhydrazone of Yellow Compound II. An aqueous solution of Yellow Compound II reacted immediately with 2,4-dinitrophenylhydrazine in 2M hydrochloric acid to give a dark-red precipitate. This was collected, washed with water, and dried at 70—80°C/0.01 mmHg for 12 hr over P_2O_5 for analysis.

Found: C, 42.99; H, 3.48; N, 29.64%. Calcd for $C_{15}H_{15}O_6N_9$: C, 43.17; H, 3.60; N, 30.22%.

The Reduction of D-erythro-*Neopterin by Treatment with Fe Dust in* 25% *Acetic Acid and the Isolation of the Products.* To a solution of D-*erythro*-neopterin (2 g) in 200 ml of 25% acetic acid, Fe dust was added. The mixture was shaken for 30 min at 50—60°C. The Fe dust was then removed, and the solution was neutralized with ammonia and left standing for 12 hr at room temperature in the dark. The solution was subsequently acidified with acetic acid, and then the solution was placed on a 3×25 cm column of Florisil; the yellow substances were adsorbed at the top of the column. The column was washed well with 0.01% acetic acid, and the yellow substances were eluted with 20% aqueous acetone. The eluate was concentrated. The yellow substances were purified by means of a chromatographic method, using a cellulose column (7.5×35 cm, developer; water) and a DEAE-cellulose column (2.5×25 cm, developer; water). For the exclusion of Yellow Compound II, the eluate was placed on a 7.5×25.0 cm column of cellulose and the column was eluted with *n*-butanol–ethanol–water (2 : 1 : 1). The eluate of the second substance was concentrated to dryness, and the residue was recrystallized from water to give a yellow powder; 453 mg (23%); this was Yellow Compound III. The sample was dried at 70—80°C/0.01 mmHg for 2 hr over P_2O_5 for analysis.

Found: C, 41.23; H, 4.54; N, 27.06%. Calcd for $C_9H_{11}O_4N_5.0 \cdot 5H_2O$: C, 41.22; H, 4.96; N, 26.71%.

UV: $\lambda_{max}^{0.1M\ NaOH}$ mμ (ε), 270 (17.5×10³), 446 (12.8×10³); $\lambda_{min}^{0.1M\ NaOH}$ mμ (ε), 240 (6.2×10³), 350 (1.4×10³); $\lambda_{max}^{H_2O}$ mμ (ε), 268 (17.9×10³), 424 (10.3×10³); $\lambda_{min}^{H_2O}$ mμ (ε), 236 (6.4×10³), 340 (1.4×10³); $\lambda_{max}^{0.1M\ HCl}$ mμ (ε), 273 (12.8×10³), 416 (8.4×10³); $\lambda_{min}^{0.1M\ HCl}$ mμ (ε), 254 (8.2×10³), 340 (1.6×10³).

NMR: (CF_3COOD): δ 4.55 (bs, 2H), 4.73 (s, 2H), 5.70 (bs, 1H). ($(CD_3)_2SO$-D_2O): δ 3.68 (d, J=5.2 Hz, 2H), 4.15 (s, 2H), 5.00 (t, J=5.2 Hz, 1H).

The R_f values of the pteridines are given in Table 1.

Results and Discussion

Yellow Compound II gives ultraviolet spectra similar to those of isosepiapterin.[7] The analytical data indicate that the empirical formula for the compound is

7) H. S. Forrest, C. Van Baalen and J. Myers, *Arch. Biochem. Biophys.*, **83**, 508 (1959).

$C_9H_{11}O_5N_5$. The yellow compound contains a keto group on the side chain, since the compound forms a 2,4-dinitrophenylhydrazone. The NMR spectrum of the compound in CF_3COOD has two triplets, at 3.33 ppm and 4.14 ppm, and a singlet at 4.56 ppm, the proton ratio of the signals being 2 : 2 : 2. The two triplet signals (4.56 ppm and 3.33 ppm) showed that this compound has a $-CH_2-CH_2-$group. The signal at 4.56 ppm was assigned to the methylene protons at the 7 position. The triplet signal at 3.33 ppm was assigned to the methylene protons adjacent to a keto group, and the triplet signal at 4.14 ppm, to the methylene protons adjacent to a hydroxyl group; this couples with the signal (3.33 ppm) of the neighboring methylene protons (J=5.8 Hz), and *vice versa* (J= 5.8 Hz). Therefore, the structure of Yellow Compound II was determined to be 2-amino-4-hydroxy-6-(1′-oxo-3′-hydroxypropyl)-7,8-dihydropteridine.

When Yellow Compound II was reduced with sodium borohydride after treatment with bromine in an acidic solution, Colorless Compound I was obtained in an almost quantitative yield. Thus, Colorless Compound I is 2-amino-4-hydroxy-6-(1′,3′-dihydroxypropyl)pteridine.

Colorless Compound II was indistinguishable from authentic *erythro*-neopterin,[8] and Colorless Compound III was identical with authentic *threo*-neopterin,[8] as determined by a study of the ultraviolet spectra and R_f values. It remains to be decided which configurations the products have, although it is most probable that Colorless Compound II and III are D-isomers.

Yellow Compound I gives ultraviolet spectra similar to those of isosepiapterin, and it has an acidic group. The permanganate oxidation to 2-amino-4-hydroxy-6-carboxypteridine shows that the compound is a 6-substituted pteridine. On treatment with bromine in acidic solution, Yellow Compound I yielded a new compound, Yellow Compound I·Br_2, which gives ultraviolet spectra similar to those of 2-amino-4-hydroxy-6-acetyl-7-methylpteridine.[9] Accordingly, Yellow Compound I has the keto group on carbon 1′ of the side chain, and its ring system has the 7,8-dihydro structure. Yellow Compound I contains a $-CH_2SO_3H$ group, but does not contain a $-CH_2OSO_3H$ group, since the compound remained unchanged by the acidic hydrolysis. The NMR spectrum of Yellow Compound I in CF_3COOD has a broad singlet at 3.56 ppm and a singlet at 4.61 ppm; the proton ratio of the signals is 4 : 2. The NMR spectrum of Yellow Compound I·Br_2 in CF_3COOD has a broad singlet at 3.5—4.0 ppm and a singlet at 9.16 ppm; the proton ratio of the signals is 4 : 1. The signal of Yellow Compound I at 4.16 ppm was assigned to the methylene protons at the 7 position, while in the spectrum of Yellow Compound I·Br_2 its signal (4.16 ppm) was transferred to 9.16 ppm as a vinyl proton. The signal of Yellow Compound I at 3.56 ppm and that of Yellow Compound I·Br_2 at 3.5—4.0 ppm were assigned to the protons of a $-CH_2-CH_2-$ group on the side chain, because their spectra could be explained by the A_2B_2 spin system and the slight chemical-shift difference between the methylene adjacent to a keto group and the methylene adjacent to a sulfonic acid group. These findings suggest that Yellow Compound I is 2-amino-4-hydroxy-6-(1′-oxo-3′-sulfopropyl)-7,8-dihydropteridine.

Table 1. Paper chromatography and electrophoresis of pteridines

Compounds	R_f in Solvents[a]

Isosepiapterin	0.52	0.49	0.58	0.24	0

a) Solvents: A, 2-Propanol-2% ammonium acetate (1:1); B, 2-Propanol-1% ammonia (2:1); C, *n*-Butanol-acetic acid-water (4:1:1); D, 3% Ammonium chloride; E, Distance to anode in electrophoresis; buffer: 0.05 M acetic acid-sodium acetate (pH 4.25); 30 min and 500 V/25 cm.

Yellow Compound III gives ultraviolet spectra similar to those of sepiapterin.[10] The analytical data indicate that the empirical formula for the compound is $C_9H_{11}O_4N_5$. The reduction of the compound with sodium borohydride, followed by oxidation with manganese oxide to *erythro*-neopterin and *threo*-neopterin, shows that Yellow Compound III has a side chain of a $-CO-CHOH-CH_2OH$ or $-CHOH-CO-CH_2OH$ group. The NMR spectrum of Yellow Compound III in $(CD_3)_2SO-D_2O$ has a doublet at 3.68 ppm, a singlet at 4.15 ppm, and a triplet at 5.00 ppm, the proton ratio of the signals being 2 : 2 : 1. The signals (a doublet signal at 3.18 ppm (J=5.2 Hz) and a triplet signal at 5.00 ppm (J=5.2 Hz)) show that Yellow Compound III has a $=CH-CH_2-$ group. The signal at 3.68 ppm was assigned to the methylene protons adjacent to a hydroxyl group; the signal at 5.00 ppm, to the methylene group adjacent to a hydroxyl group and a keto group, and the signal at 4.15 ppm, to the methylene protons at the 7 position. Accordingly, the structure of Yellow Compound III is determined to be 2-amino-4-hydroxy-6-(1′-oxo-2′,3′-dihydroxypropyl)-7,8-dihydropteridine.

It may be concluded that these compounds are not produced by the process of the reduction of D-*erythro*-neopterin, but by the process of the reoxidation of 7,8-dihydro-D-*erythro*-neopterin. When the reaction mixture of sepiapterin and the sepiapterin reductase was

8) K. Sugiura, H. Yamashita, and M. Goto, This Bulletin, **45**, 3564 (1972).

10) S. Nawa, *ibid.*, **33**, 1555 (1960).

treated with diluted acid after an almost complete reduction of the pteridine, biopterin was produced together with isosepiapterin.[11] This fact is not inconsistent with the above observation. This type of reaction including epimerization, oxidation, and reduction, is similar to certain reactions of carbohydrates. The relation of the C=N bond at 5 and 6 positions to the polyhydroxyalkyl group at the 6 position of 7,8-dihydroneopterin is similar to that in a keto and polyhydroxyalkyl group in carbohydrates.

The Photochemistry of 2-Quinolinecarbonitriles. I. The Photochemical Reactions of 2-Quinolinecarbonitriles with Alcohols, Ethers, or Carboxylic Acids

Norisuke HATA, Isao ONO, Satoru MATONO, and Harutoshi HIROSE

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo

(Received August 19, 1972)

The photochemical reactions of 2-quinolinecarbonitriles with alcohols, diethyl ether, or aliphatic carboxylic acids in an atmosphere of oxygen or nitrogen were found to result in the replacement of the cyano group by 1-hydroxyalkyl, 1-ethoxyethyl, or alkyl group. However, the irradiation of 2-quinolinecarbonitrile in an alcoholic solvent except for the case of *tert*-butyl alcohol under a nitrogen atmosphere gave an unidentified substance (probably, a certain triazapentaphene) in addition to the photosubstitution product. The photoinduced substitution reaction found in the present experiment was revealed to proceed through the excited singlet state of 2-quinolinecarbonitrile, whereas the lowest triplet state was responsible for the formation of an unidentified substance in a deaerated alcohol.

Photoalkylation reactions of *N*-heterocyclic compounds have been extensively studied from both a synthetic and mechanistic point of view during the past few years.[1] In order to investigate the effect of an electron-withdrawing group on such photoinduced reactions, the present authors have started photochemical studies of cyano-substituted N-heteroaromatics. As has been briefly reported in a preliminary communication,[2] 2-quinolinecarbonitrile in an alcoholic solvent has been found, interestingly, to be converted into 2-(1-hydroxyalkyl)quinoline upon irradiation by ultraviolet light longer than 300 nm under an oxygen atmosphere. The purpose of the present paper is to present the experimental data on the photochemical reactions of 2-quinolinecarbonitriles with alcohols, ethers, or carboxylic acids.

Photochemical Reactions of 2-Quinolinecarbonitriles with Alcohols. A 2×10^{-2} M solution of 2-quinolinecarbonitrile (I) in an alcoholic solvent (II) (350 ml of ethanol, 1-propanol, 2-propanol, or *tert*-butyl alcohol was irradiated with ultraviolet light longer than 300 nm in an atmosphere of oxygen at room temperature. As a result, white, crystalline solids (III) depending on the reaction medium were isolated as the main product. The UV absorption spectra of the photoproducts (III) were quite similar to that of quinaldine. The IR spectra of III in KBr showed absorptions at about 3250 cm^{-1} (O–H stretching) and ~2900 cm^{-1} (aliphatic C–H stretching), while the peak at 2230 cm^{-1} characteristic of the C≡N group was completely missing. The NMR spectra in $CDCl_3$ indicated the presence of a 1-hydroxyalkyl group, which corresponds to the alcohol used as a reaction medium, at the 2-position of a quinoline. In addition to the UV, IR, and NMR spectra, the structural determinations of the products (III) were made on the basis of the mass spectra as well as by means of elemental analysis; the results are summarized in Table 1. It was concluded from these results that the 2-quinolinecarbonitrile (I) changed photochemically in an alcoholic solvent (IIa—d) to yield 2-(1-hydroxyalkyl)quinoline (IIIa—d). In the case of 4-methylquinoline-2-carbonitrile, also a similar photosubstitution reaction was found to take place to afford 2-(1-hydroxyalkyl)-4-methylquinoline in a good yield; the analytical data for 2-(1-hydroxyethyl)-4-methylquinoline (III'a) are listed in Table 1.

a) Represents the yield in an oxygen atmosphere. b) Measured in $CDCl_3$ solution using a TMS as an internal standard. c) The value in bracket represents the yield in HCl acidified solution. d) Mp of the picrate: 141—142°C. e) The picrate.

Such a photochemical hydroxyalkylation of 2-quinolinecarbonitrile was demonstrated to take place in an HCl-acidified alcoholic solution as well, although the yield of III was appreciably different from that in the solution without acid. On the other hand, Stermitz *et al.*[1d] have reported that the irradiation of quinoline in HCl-acidified ethanol resulted in the ethylation of the 2- or 4-position of a quinoline, indicating that there exists a striking difference in the photoreactivity between 2-quinolinecarbonitrile and quinoline in an acidified alcohol.

When the irradiation of 2-quinolinecarbonitrile in alcohols different from *tert*-butyl alcohol was carried out, with nitrogen being bubbled in instead of oxygen, the solution became reddish-violet[3] and two products were separated; one was the product (III) depending on the reacting solvent, while the other was a compound (IV) with a mp of 215°C (decomp), irrespective of the alcohol used as a reaction medium. The yields of III and IV in various alcohols are as follows: 36% and 17% in ethanol, 30% and 25% in 1-propanol, and 26% and 20% in 2-propanol. However, the product (IV) was not formed in an acidified alcohol, nor was it in the case of 4-methylquinoline-2-carbonitrile. When the *tert*-butyl alcohol was used as a reaction medium, only the product (IIId) was isolated as the major product in a 14% yield, while the formation of the product (IV) was not observed. The IR spectrum of the photoproduct (IV) in KBr indicated that the peak at 2230 cm^{-1} characteristic of a C≡N group was absent, whereas absorptions around 3060 cm^{-1} (aromatic C–H stretching), 1505, 1590 cm^{-1} (ring vibration), and 830, 755 cm^{-1} (aromatoc C–H out-of-plane) were observed. The NMR spectrum showed only multiplet signals due to aromatic protons around 7.5—8.5 ppm ($CDCl_3$, TMS); also, the predominantly strong peaks corresponding to M^+= 281 and $(M-1)^+$=280 were observed in the mass spectrum. Figure 1 shows the UV absorption spectrum of the product (IV), which is interestingly very similar to that of pentaphene in maximum wavelength and in molar extinction coefficient.[4] In addition to these data, the elemental analysis led to a conclusion that the product (IV) might be a certain triazapentaphene; Found, C 80.22, H 3.96; N 14.99%, Calcd for $C_{19}H_{11}N_3$, C 81.22, H 3.92, N 14.95%.

3) The reddish-violet color disappeared rapidly by the introduction of air (or oxygen) or the addition of DPPH into the irradiated solution.

4) H. H. Jaffé and M. Orchin, "Theory and Applications of Ultraviolet Spectroscopy", John Wiley & Sons Inc., London, (1962) Chapter 13.

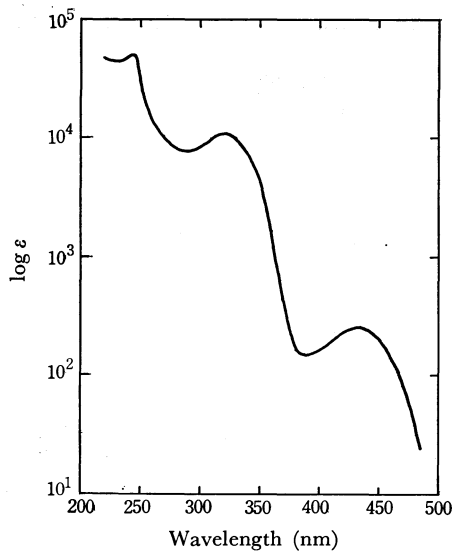

Fig. 1. The UV absorption spectrum of photoproduct (IV) in ethanol.

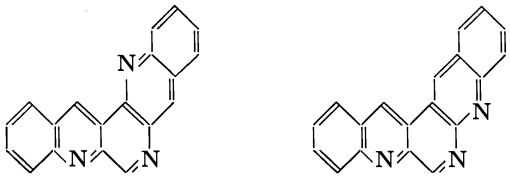
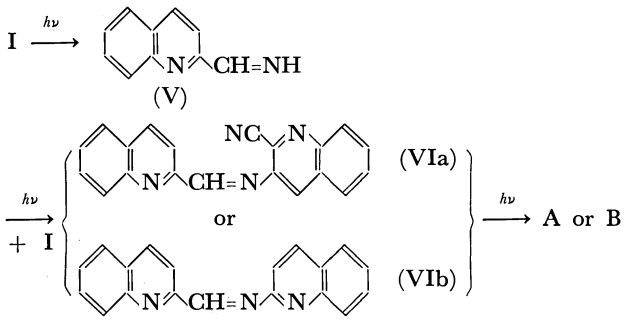
Although the location of nitrogen atoms on the pentaphene nucleus is entirely ambiguous at present, (A) or (B) seems to be a plausible structure for the reason to be discussed below.



Judging from the fact that the photochemical conversion I→IV did not occur in *tert*-butyl alcohol or benzene, the light absorption of 2-quinolinecarbonitrile (I) appears first to cause a hydrogen-atom abstraction from an alcohol to give V. If V thus formed reacts photochemically with I to yield an azomethine compound (VIa) or (VIb), followed by photochemical cyclization, A or B may be expected to be formed.



As has been described above, the product (III) was formed under an oxygen or nitrogen atmosphere, while the product (IV) resulted only in an atmosphere of nitrogen. This implies that the reactive state responsible for the formation of the product (III) is probably the excited singlet state of 2-quinolinecarbonitrile, whereas the triplet state is involved in the formation of the product (IV). In order to make this clear, a quenching experiment on the lowest triplet state of 2-quinolinecarbonitrile was thus undertaken

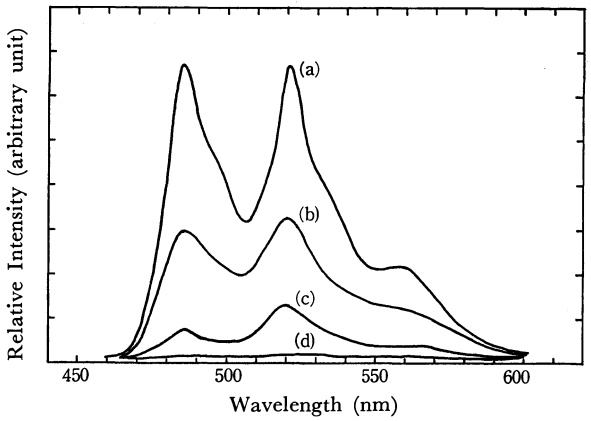


Fig. 2. The phosphorescence spectrum of 2-quinolinecarbonitrile in ethanol at 77K (concentration of 2-quinolinecarbonitrile: 5.0×10^{-4} M).
(a) [Piperylene]: 0 M, (b) [Piperylene]: 5.0×10^{-2} M, (c) [Piperylene]: 4.0×10^{-1} M, (d) [Piperylene]: 1.0 M

in deaerated ethanol. Figure 2 shows the phosphorescence spectrum of 2-quinolinecarbonitrile in ethanol at 77K. It was estimated, from the first maximum of the phosphorescence spectrum (484 nm), that the lowest triplet state of 2-quinolinecarbonitrile has an excitation energy of about 59 kcal·mol^{-1}. Accordingly, the piperylene (E_T=57 kcal·mol^{-1}) may be expected to be usable as a triplet quencher for 2-quinolinecarbonitrile. As is shown in Fig. 2, the addition of piperylene to an ethanol solution of 2-quinolinecarbonitrile in amounts much greater than the molar equivalence led to the complete disappearance of the phosphorescence of 2-quinolinecarbonitrile. The photochemical reaction of 2-quinolinecarbonitrile in deaerated ethanol at room temperature was, therefore, carried out in the presence of varying amounts of piperylene. As can be seen from Fig. 3, the photochemical conversion from I to IIIa was not affected by the addition of piperylene, while the formation of the product (IV) decreased linearly with the in-

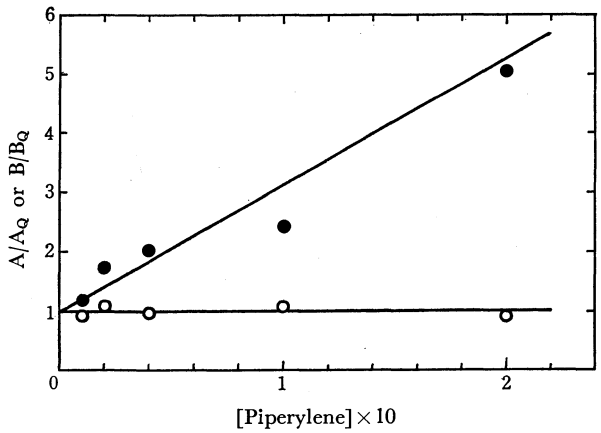

Fig. 3. The Effect of piperylene on the photochemical reaction of 2-quinolinecarbonitrile in ethanol under nitrogen atmosphere at 20°C. A (or B) and A_Q (or B_Q) represent, respectively, the amounts of the product (IIIa) (or (IV)) in the absence and in the presence piperylene.
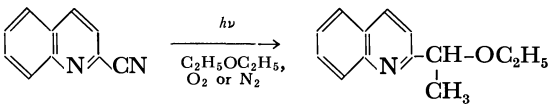
Initial amount of 2-quinolinecarbonitrile: 100 mg (in 70 ml ethanol). Irradiation time: 60 min. A: 25 mg. B: 16 mg. ○: product (IIIa). ●: product (IV).

creased concentration of piperylene. These results indicate that the photochemical substitution reaction I→III proceeds through the excited singlet state of 2-quinolinecarbonitrile, whereas the photochemical formation of IV involves the lowest triplet state.

Photochemical Reactions of 2-Quinolinecarbonitriles with Diethyl Ethers. In the same manner as in the case of an alcoholic solution, the ultraviolet irradiation of 2-quinolinecarbonitrile was carried out in diethyl ether under an oxygen or nitrogen atmosphere. As a result, an oily, colorless substance (VIII) was obtained as the main product; the yield was 32% in an oxygen atmosphere, while it was only 21% in a nitrogen atmosphere. The UV absorption spectrum of the product (VIII) was very similar to that of quinaldine. The IR spectrum in liquid showed peaks at about 3050 cm^{-1} (aromatic C–H stretching), 2960, 2930, 2850 cm^{-1} (aliphatic C–H stretching), 1100 cm^{-1} (C–O–C stretching), and 828 and 705 cm^{-1} (aromatic C–H out-of-plane), while a peak due to the C≡N group (2230 cm^{-1}) was missing. The analytical data of the product (VIII) are listed in Table 1. Consequently, the C≡N group of 2-quinolinecarbonitrile was revealed to be replaced by an 1-ethoxyethyl group as follows:



(I) (VII) (VIII)

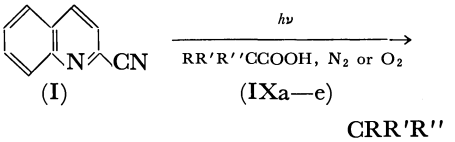
Differing from the case of an alcoholic solution, neither a deep coloration of the solution nor the formation of a triazapentaphene-like substance was detected in an atmosphere of nitrogen. The photosubstitution reaction also took place in the solution saturated with HCl gas; the yield was good (59%).

Photochemical Reactions of 2-Quinolinecarbonitriles with Aliphatic Carboxylic Acids. 2-Quinolinecarbonitriles (0.5 g) dissolved in 70 ml of benzene containing carboxylic acid (IX) (2 g of acetic acid, propionic acid, butyric acid, isobutyric acid, or trimethylacetic acid) in a Pyrex vessel were irradiated with ultraviolet light under a nitrogen or oxygen atmosphere. As a result, two products, X and XI, were separated as the main products; the yields of these products in an atmosphere of nitrogen are shown in Table 2. On the basis of the UV, IR, and NMR spectra as well as the melting points of the picrates, the products (X) were identified as known 2-alkylquinolines[1b] corresponding to the carboxylic acid used in the photoreaction. The UV absorption spectra of the products (XI) closely resembled that of 2-quinolinecarbonitrile (I), and the IR spectra in KBr showed peaks at about 3050 cm^{-1} (aromatic C–H stretching), 2220 cm^{-1} (C≡N stretching), and ~2900 cm^{-1} (aliphatic C–H stretching). Table 3 summarizes the analytical data for the products (XI).

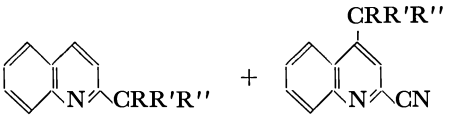
Table 2. Yields of the photoproducts X and XI

Products	Yield (%)				
	a	b	c	d	e
X	4	11	18	17	13
XI	trace	9	15	14	5

It was concluded from these results that the 2- or 4-alkylquinolines were formed as a result of the photochemical reaction of 2-quinolinecarbonitrile with an aliphatic carboxylic acid in benzene as follows:



(I) (IXa—e)



(Xa—e) (XIa—e)

IXa, Xa and XIa: R=H, R'=H, R''=H
IXb, Xb and XIb: R=CH_3, R'=H, R''=H
IXc, Xc and XIc: R=C_2H_5, R'=H, R''=H
IXd, Xd and XId: R=CH_3, R'=CH_3, R''=H
IXe, Xe and XIe: R=CH_3, R'=CH_3, R''=CH_3

a) Measured in $CDCl_3$ solution using a TMS as an internal standard. b) Estimated from the result of the mass analysis performed with a JEOL JMS-OISG-2 mass spectrometer.

Such a photochemical alkylation was not inhibited by the addition of piperylene.

Further studies for the elucidation of the primary photochemical process as well as the reaction mechanism are now in progress and will be reported soon.

Experimental

The UV absorption and the phosphorescence spectra were respectively, measured with a Hitachi recording spectrophotometer EPS–3T and a Hitachi fluorescence spectrophotometer MPF–2A with a phosphorescence accessory attached. The IR spectra were determined with a JASCO infrared spectrophotometer IR–G. The NMR spectra were taken in deuteriochloroform with a Hitachi-Perkin Elmer NMR spectrometer R–20 at 60 MHz, using a TMS as the internal standard. The mass spectra were obtained with a Hitachi RMU–6L or a JEOL JMS–O1SG–2 mass spectrometer.

Materials. The 2-quinolinecarbonitrile and 4-methylquinoline-2-carbonitrile used in this experiment were prepared according to the method given in the literature;[5] these compounds were purified by recrystallization from ethanol several times. The aliphatic carboxylic acids and all the solvents for the irradiation experiments were reagent-grade products of Wako Pure Chemical Industries, all of which were used without further purification. Reagent-grade piperylene was purified by distillation several times.

Photochemical Reactions of 2-Quinolinecarbonitriles with Alcohols under an Oxygen Atmosphere. 2-Quinolinecarbonitrile (1.0 g) dissolved in 350 ml of alcohol (ethanol, 1-propanol, 2-propanol or *tert*-butyl alcohol in a Pyrex vessel was irradiated with a 100 W high-pressure immersion mercury lamp (Riko Kagaku Sangyo Co.) for 10 hr while oxygen was being bubbled in. After the removal of the solvent under reduced pressure, the residue was chromatographed on a silica-gel column by elution with a mixture of *n*-hexane and diethyl ether (1 : 1). A white, crystalline solid (III) was isolated as the main product. When the HCl-acidified alcohol was used as the reaction medium, a 350–ml alcoholic solution with 2-quinolinecarbonitrile (1.0 g), dissolved in it, to which 3.0 ml of concentrated HCl had been added, was irradiated for 10 hr under an oxygen atmosphere. The irradiated solution was concentrated *in vacuo*, and the concentrate was neutralized with a sodium carbonate aqueous solution. The aqueous solution was then extracted with chloroform, dried with anhydrous sodium sulfate, and the inorganic salts were removed by filtration. The chloroform solution was then concentrated under reduced pressure to afford a crystalline mass, which was subsequently chromatographed over silica gel to isolate the product (III).

Photochemical Reactions of 2-Quinolinecarbonitriles with Alcohols under a Nitrogen Atmosphere. A solution of 1.0 g 2-quinolinecarbonitrile in 350 ml of alcohol (ethanol, 1-propanol, or 2-propanol) was irradiated with a 100W high-pressure immersion mercury lamp, where half an hour before the irradiation was started nitrogen had been bubbled through the solution; this was continued constantly during the irradiation. When the irradiation was performed for *ca.* 15 min, the solution became reddish-violet. After the solution had been irradiated for 5 hr, the solvent was evaporated to dryness *in vacuo*. The residue was subjected to silica-gel chromatography (with dichloromethane used as the eluent) to afford the starting material, the products (III) and (IV). III or IV was purified by silica-gel chromatography using a mixture of *n*-hexane and diethyl ether (1 : 1) or a mixture of dichloromethane, *n*-hexane, and diethyl ether (10 : 1 : 1) as the eluent. The product (IV) thus obtained was further purified for the analysis by recrystallization from ethanol several times.

Photochemical Reactions of 2-Quinolinecarbonitriles with Diethyl Ether under a Nitrogen or Oxygen Atmosphere. A solution of 1.0 g of 2-quinolinecarbonitrile in 350 ml of diethyl ether was irradiated in a Pyrex vessel under cooling at 5—10°C in an ice-bath, and with a 100W high-pressure immersion mercury lamp in an atmosphere of oxygen or nitrogen. After having been irradiated for 10 hr, the solution was concentrated under reduced pressure; the residue was chromatographed on a silica-gel column by elution with dichloromethane to isolate the product (VIII). The product (VIII) thus obtained was further purified by using a mixture of *n*-hexane and diethyl ether (1 : 1) as the eluent.

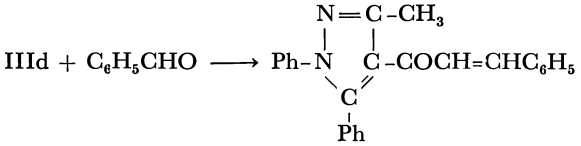
Photochemical Reactions of 2-Quinolinecarbonitriles with Aliphatic Carboxylic Acids in Benzene under a Nitrogen or Oxygen Atmosphere. A solution of 2-quinolinecarbonitrile (0.5 g) and carboxylic acid (2 g of acetic acid, propionic acid, butyric acid, isobutyric acid, or trimethylacetic acid) in 70 ml of benzene was irradiated in a Pyrex vessel with a 100W high-pressure immersion mercury lamp for 6 hrs while nitrogen or oxygen was being bubbled in. After the removal of the solvent under reduced pressure, a 30-ml portion of water was added to the residue; the solution was then neutralized with sodium carbonate. After the extraction with chloroform or dichloromethane, the solution was concentrated *in vacuo*. The concentrate was chromatographed on a silica-gel column by elution with a mixture of *n*-hexane and ethyl acetate (9 : 1) to separate the starting material, the products (X) and (XI). These products were then further purified by alumina chromatography using the same eluent as before.

In conclusion, the authors wish to thank Professor Juji Yoshimura of Tokyo Institute of Technology for his kind discussions and Dr. Teiki Iwaoka of Sankyo Co. for his mass-spectral measurement of the photoproduct (IV).

5) H. Menze, *Ber.*, **69**, 1566 (1936).

When VII was subjected to thermal decarboxylation, it gave a compound which was found to be identical with Va. Esterification of dicarboxylic acid with ethanol and hydrogen chloride afforded half ester (VIII), which is isomeric with VII. When the esterification of VI was carried out by refluxing ethanol–benzene solution of VI in the presence of *p*-toluenesulfonic acid with continuous removal of water, a mixture of both esters (Va and VIII) was obtained.

Condensation of I with acetylacetone could be accomplished by heating the reaction mixture at 120°C in the absence of condensing agent, an intermediate hydrazone (IIId) being obtained. The hydrazone, when treated with alcoholic sodium hydroxide, gave a new compound, 4-acetyl-3-methyl-1,5-diphenylpyrazole (Vd). Compound Vd readily condensed with benzaldehyde in the presence of sodium hydroxide to give 4-cinnamoyl-3-methyl-1,5-diphenylpyrazole (IX).



IX

The procedures for preparation of 4-carboxyl-1,5-diphenylpyrazol-3-ylacetic acid and all its possible esters were found to be satisfactory and compounds with interesting synthetical possibilities are now available.

Experimental

Preparation of Hydrazone (IIIa). To a solution of 4.25 g (0.02 mol) of I in 100 ml of benzene was added 2.6 g (0.02 mol) of ethyl acetoacetate and 2 g of phosphorus pentoxide. The mixture was refluxed on a water bath for 5 hr. The hot benzene solution was separated by decantation and the solvent was removed under reduced pressure. The residual oily product was triturated with a small amount of ethanol and the resulting solid was recrystallized from ethanol to afford colorless crystals, mp 142°C. 5.8 g (90%).

Found: C, 70.20; H, 5.98; N, 8.55%. Calcd for $C_{19}H_{20}O_3N_2$: C, 70.53; H, 6.09; N, 8.64%.

Cyclization of IIIa to Pyrazole (Va). Two milliliters of 2M sodium hydroxide was added dropwise at room temperature with vigorous stirring to a solution of IIIa (1 g) in 50 ml of ethanol. Stirring was continued until the yellow color disappeared completely. Fifty milliliters of water was then added. The precipitate was collected by filtration and recrystallized from ethanol to give colorless crystals, mp 121°C (lit. mp 122°C). Yield 95%.

Found: C, 74.35; H, 5.77; N, 9.28%. Calcd for $C_{19}H_{18}O_2N_2$: C, 74.49; H, 5.92; N, 9.15%.

4-Carbethoxy-1,3,5-triphenylpyrazole (Vb). Hydrazone (IIIb) was prepared from 1-benzoyl-1-phenylhydrazine (4.2 g) and ethyl benzoylacetate (3.8 g) by the same method as for the preparation of IIIa. The hydrazone (6.2 g), obtained as an oily product, was dissolved in 100 ml of ethanol, to which 5 ml of 2 M sodium hydroxide solution was gradually added. The solution was then stirred for 10 min, diluted with water and the precipitate formed was collected to give 4.8 g of Vb which was recrystallized from ethanol to give colorless crystals, mp 143—144°C (lit. mp 145—146.5°C).

Found: C, 77.97; H, 5.60; N, 7.58%. Calcd for $C_{24}H_{20}O_2N_2$: C, 78.24; H, 5.42; N, 7.60%.

Ethyl 4-Carbethoxy-1,5-diphenylpyrazol-3-ylacetate (Vc). To a solution of 1-benzoyl-1-phenylhydrazine (4.2 g) and diethyl acetonedicarboxylate (4.1 g) in 100 ml of benzene was added 2 g of phosphorus pentoxide and the mixture was refluxed on a water bath for 5 hr. The hot benzene solution was separated by decantation and concentrated *in vacuo*. The residual oil (6.8 g) was dissolved in 100 ml of ethanol and to the resulting solution was added gradually 5 ml of 2 M sodium hydroxide solution at 10—15°C with stirring. Stirring was continued for 30 min at room temperature, after which water was added to precipitate Vc which was recrystallized from dilute ethanol to give colorless crystals (4.5 g), mp 67.5—68°C.

Found: C, 69.50; H, 5.65; N, 7.51%. Calcd for $C_{22}H_{22}O_4N_2$: C, 69.82; H, 5.86; N, 7.40%. IR: 1743, 1693 cm^{-1}.

Preparation of Hydrazone (IIId). A mixture of acetylacetone (1 g) and 1-benzoyl-1-phenylhydrazine (2.1 g) was heated in an oil bath at 120°C for about 30 min. After cooling, the solid product was recrystallized from ethanol to afford IIId as colorless crystals, mp 147—148°C.

Found: C, 73.35; H, 5.91; N, 9.70%. Calcd for $C_{18}H_{18}O_2N_2$: C, 73.45; H, 6.16; N, 9.52%.

4-Acetyl-3-methyl-1,5-diphenylpyrazole (Vd). To a solution of 2 g of the hydrazone (IIId) in 50 ml of ethanol was added 5 ml of 2 M sodium hydroxide solution. This was left to stand at room temperature for 1 hr and then diluted with water. The precipitates were collected, washed with water, and recrystallized from dilute ethanol to give Vd, colorless crystals, mp 93—95°C.

Found: C, 77.94; H, 5.98; N, 10.21%. Calcd for $C_{18}H_{16}ON_2$: C, 78.23; H, 5.84; N, 10.14%, IR: 1660 cm^{-1}.

4-Cinnamoyl-3-methyl-1,5-diphenylpyrazole (IX). To a solution of 2.8 g of Vd and 1.1 g of benzaldehyde in 50 ml of ethanol was added gradually with stirring 10 ml of aqueous sodium hydroxide solution (40%). The reaction mixture was left to stand for 2 hr at room temperature and then diluted with water. Precipitates were collected, washed thoroughly with water and recrystallized from ethanol to give IX, pale yellow crystals, mp 157—158°C. 3.2 g.

Found: C, 82.10; H, 5.65; N, 7.73%. Calcd for $C_{25}H_{20}ON_2$: C, 82.39; H, 5.53; N, 7.68%. IR: 1650 cm^{-1}.

4-Carboxy-1,5-diphenylpyrazol-3-ylacetic Acid (VI). A solution of the diethyl ester (Vc, 3 g) in ethanol (25 ml) containing potassium hydroxide (2.5 g) and water (5 ml) was refluxed at 100°C for 30 min and concentrated, cooled, and acidified with dilute hydrochloric acid. The product was collected and washed with water, and then crystallized from dilute acetic acid (80%) to give dicarboxylic acid (VI) in colorless prisms, mp 251—252°C with decomposition.

Found: C, 66.85; H, 4.37; N, 8.57%. Calcd for $C_{18}H_{14}O_4N_2$: C, 67.07; H, 4.38; N, 8.69%. IR: 3500—2500, 1710, 1665 cm^{-1}.

4-Carbethoxy-1,5-diphenylpyrazol-3-ylacetic Acid (VII). Ethyl 4-carbethoxy-1,5-diphenylpyrazol-3-ylacetat (4 g) was dissolved at room temperature in ethanol (30 ml) containing potassium hydroxide (3.5 g) and water (2 ml). After 30 min dipotassium salt of the dicarboxylic acid (0.5 g) was separated by filtration and the filtrate was diluted with water and acidified with dilute hydrochloric acid to precipitate VII which was recrystallized from ethanol to give 2.6 g of colorless plates, mp 195—196°C.

Found: C, 68.65; H, 5.04; N, 8.16%. Calcd for $C_{20}H_{18}O_4N_2$: C, 68.56; H, 5.18; N, 8.00%. IR: 3300—

2500, 1743, 1715 cm^{-1}.

The above half ester (2 g) was heated at 190—200°C in an oil bath until evolution of carbon dioxide was over. The residue solidified on treating with ethanol, and by recrystallization from ethanol, the compound Va (1 g) was obtained in colorless crystals, mp 120—121°C.

Ethyl 4-Carboxy-1,5-diphenylpyrazol-3-ylacetate (VIII). (i) Dry hydrogen chloride was passed into a suspension of 2 g of VI in 20 ml of absolute ethanol until VI dissolved completely (15 min). The reaction mixture was allowed to stand at room temperature for 2 hr. Crystals separated out were collected and washed to give 1.2 g of the crude half ester VIII. Recrystallization from benzene gave colorless prisms, mp 185—186°C.

Found: C, 68.30; H, 4.93; N, 7.97%. Calcd for $C_{20}H_{18}O_4N_2$: C, 68.56; H, 5.18; N, 8.00%. IR: 3200—2500, 1740, 1665 cm^{-1}.

(ii) To a suspension of 2 g of VI in anhydrous benzene (50 ml) and absolute ethanol (1 ml) was added 0.5 g of *p*-toluenesulfonic acid. The mixture was refluxed for 5 hr using a water separator. Benzene was removed and the oily residue was boiled in petroleum ether (bp 40—60°C) and cooled, and the precipitates were collected and recrystallized from benzene to give 0.7 g of VIII. Mixed melting point measurement with an authentic sample showed no depression.

Evaporation of the petroleum ether filtrate and recrystallization of the residue from dilute ethanol gave 0.6 g of diester (Vc), mp 67—68°C.

(Received September 26, 1972)

Tuberactidine (III) is a guanidino amino acid component of antitubercular peptides, tuberactinomycin A and B, while the known guanidino amino acid capreomycidine (V) is involved in tuberactinomycin N and O. The structure of tuberactidine was assigned to be α-(4-hydroxy-2-iminohexahydro-6-pyrimidinyl)glycine and its stereochemistry was also established. During isolation of tuberactidine from an eluate in the column chromatography of tuberactinomycin hydrolyzate, it was converted to N^{α}-formyltuberactidine dimer (I). In this dimer, structural alternation between a carbinolamine form of cyclol type and an amide lactone form was noticed depending to a pH of the solution. I was hydrolyzed to tuberactidine and viomycidine (IV) with hydrobromic acid. In addition, a plausible pathway for the formation of viocidic acid (VII), one of the artifacts formed during hydrolysis of tuberactinomycin, was proposed.

Tuberactinomycins are antitubercular peptides isolated from the broth filtrate of *Streptomyces griseoverticillatus* var. *tuberacticus*[3] and its mutant.[4] A family of this antibiotic comprises four congeners, A, B, N and O. Among them, tuberactinomycin B was found to be the same to the one known as viomycin.[4] Amino acid compositions of these four peptides were listed in Table 1.

Acid hydrolyzate of tuberactinomycin A was separated by ion-exchange column chromatography, using a buffer solution of pyridine and formic acid as an eluent. Serine, α,β-diaminopropionic acid, a mixture of guanidino amino acids, *i.e.*, viomycidine, tuberactidine and viocidic acid, and finally γ-hydroxy-β-lysine[1] were eluted in this order. In the case of viomycin, a similar elution pattern was obtained except a replacement of γ-hydroxy-β-lysine with β-lysine. As a guanidino amino acid in viomycin, viomycidine (IV) has already been isolated from its hydrolyzate by many workers,[5] and its structure was determined by Büchi and Raleigh as shown in Fig. 1.[6] From hydrolyzates of tuberactinomycin N and O, capreomycidine (V) was obtained as a guanidino amino acid component. First isolation of this amino acid from the known

Table 1. Amino acid compositions of tuberactinomycins (TUM)

TUM	Molecular Formula	Ser	Dpr	Uda	Tbd	Cpd	γ-Hy-β-lys	β-Lys
A	$C_{25}H_{43}O_{11}N_{13}$	2	1	1	1	—	1	—
B	$C_{25}H_{43}O_{10}N_{13}$	2	1	1	1	—	—	1
N	$C_{25}H_{43}O_{10}N_{13}$	2	1	1	—	1	1	—
O	$C_{25}H_{43}O_9N_{13}$	2	1	1	—	1	—	1

Ser: L-serine, Dpr: L-α,β-diaminopropionic acid, Tbd: L-tuberactidine, Cpd: L-capreomycidine, γ-Hy-β-lys: γ-hydroxy-L-β-lysine, β-Lys: L-β-lysine, Uda: 3-ureidodehydroalanine

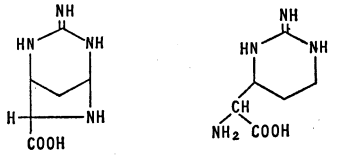

Fig. 1. Structures of viomycidine(IV) and capreomycidine(V).

antibiotic capreomycin had been reported by Herr and its structure was decided as above (Fig. 1).[7]

The existence of 3-ureidodehydroalanine as a composite amino acid in the antibiotics was confirmed not only by X-ray analysis in the case of tuberactinomycin O,[8] but also by the chemical evidences and NMR data[9] which were coincided with those reported in the studies of viomycin by Bycroft and his colleagues.[10] However, this moiety could not be isolated from the hydrolyzate because of ease of decomposition to NH_3 and CO_2 during acid hydrolysis.

For the isolation of tuberactidine (III), fractions of a positive Sakaguchi reaction in the eluates of column chromatography were combined and evaporated to give colorless prisms. Although the original eluate containing tuberactidine gave positive reactions both for ninhydrin and Sakaguchi reactions, the crystals obtained above were found to be negative for both reactions. Molecular formula of $C_{14}H_{20}O_6N_8$ (I) was deduced to the compound from the results of elemental analysis and molecular peak (396) in the mass spectrum. This molecular weight was supported by the results of mass spectrum of its diacetyl derivative $C_{18}H_{24}O_8N_8$ (480) (II).

When I was treated with 15% hydrobromic acid at 50°C, it was degradated to tuberactidine (III) and viomycidine (IV), in almost equal amounts, both of which were isolated separately by fractional crystallization from aqueous ethanol. As reported in the preliminary form, we decided the structure of tuberactidine on the basis of NMR (Fig. 2) and ORD spectrum (Fig. 3) to α-(4-hydroxy-2-iminohexahydro-6-pyrimidinyl)glycine (4S, 6R, 7S) (Fig. 4).[2] The signals of the NMR spectrum in D_2O could be assigned as follows: a triplet at δ 5.26 (1H, J=3.0 Hz) is ascribed to C-4 equatorial proton: a multiplet at δ 4.40 (1H, J=3.0, 3.45, 6.9 Hz) to C-6 axial proton; a doublet at δ 3.91 (1H, J=3.0 Hz) to C-7 proton; a multiplet at δ 2.45 (1H, J=3.45, 6.9, 14.7 Hz) to C-5 axial proton; a multiplet at δ 2.12 (1H, J=3.45, 3.45, 14.7 Hz) to C-5 equatorial proton.

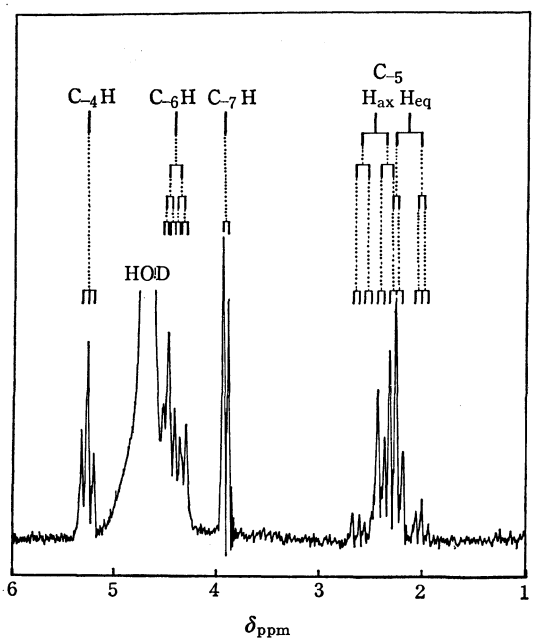

Fig. 2. NMR spectrum of tuberactidine in D_2O.

The ORD spectrum of tuberactidine showed a positive Cotton effect at 221 nm ([Φ]+807 pk, 0.1 M hydrochloric acid) which is characteristic of L-α-amino acid. In connection with this observation, ORD curves of a series of guanidino amino acids obtained from tuberactinomycins were measured (Fig. 3). Tuberactidine, capreomycidine and dihydroviomycidine showed a positive Cotton effect characteristic of L-α-amino acids whereas viomycidine a negative effect characteristic of L-α-imino acids as proline or hydroxy proline.

The structure of viomycidine was determined by X-ray analysis as shown in Fig. 4. The unit cell of crystalline hydrobromide was orthorhombic with a=9.37, b=12.49, c=15.41Å, Z=8, ρ_c=1.865, and

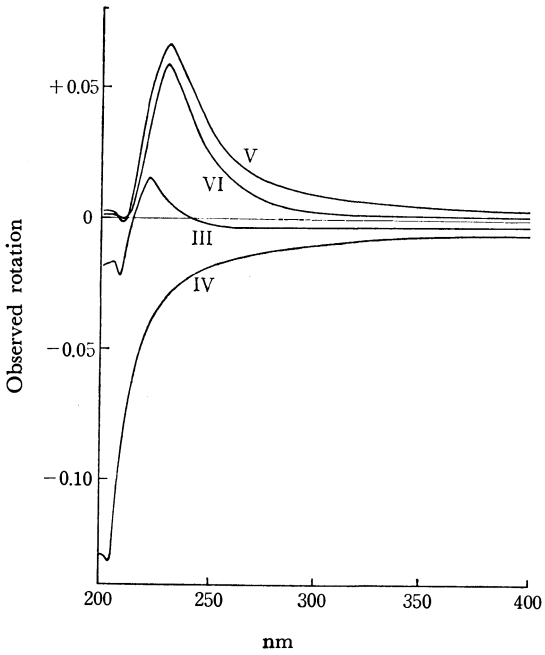

Fig. 3. Observed ORD curves of guanidino amino acids, *i.e.* tuberactidine (III), viomycidine (IV), capreomycidine (V) and dihydroviomycidine (VI). Molecular rotations [Φ] were calculated to +807° (III, 221 nm), −5373° (IV, 204 nm), +3992° (V, 229 nm), and +3926° (VI, 229 nm) respectively.

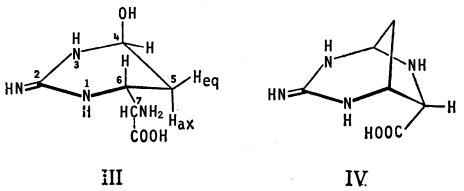

Fig. 4. The absolute structure of tuberactidine(III) and viomycidine(IV).

space group $C222_1$. The result was consistent with that reported by other investigators.[11]

The facts obtained above indicated that I could be a condensed product of two molecules of formyl derivative of tuberactidine or viomicidine. From the measurement of pK_a', it was shown that free amino group is not present in the molecule of I. In the NMR spectrum of I as shown in Fig. 7, two signals ascribed to formyl protons were recognized at the position centered at δ 8.5. However, no more useful data for the structural determination of I were obtained from I itself at the stage of the investigation. In the meantime, hydrobromide (II), $C_{14}H_{20}O_6N_8 \cdot 2HBr$, of I was readily prepared. It showed the absorption of carbonyl of either ester or lactone at 1740 cm^{-1} and 1760 cm^{-1} in IR spectrum, while no absorption was recognized in I between 1700 cm^{-1} to 1800 cm^{-1} (Fig. 5). Moreover, when an aqueous solution of II was neutralized with pyridine, it was reconverted to I.

The peculiar interconversion between I and II reminded us of lactone-lactal equilibrium in tetrodotoxin,[12] cyclol-amide lactone carbonyl interaction in ergotamine[13] or depsipeptides,[14] and amide-ortho-amide transannular interaction in cyclic peptides,[15] all of which were realized rather recently in the field of chemistry of natural compounds. By an application of the above concept to our observation, the reversible structural alternation between I and its hydrobromide II was concluded to be interconversion of cyclic carbinolamine form of cyclol type and amide lactone form (Fig. 6).

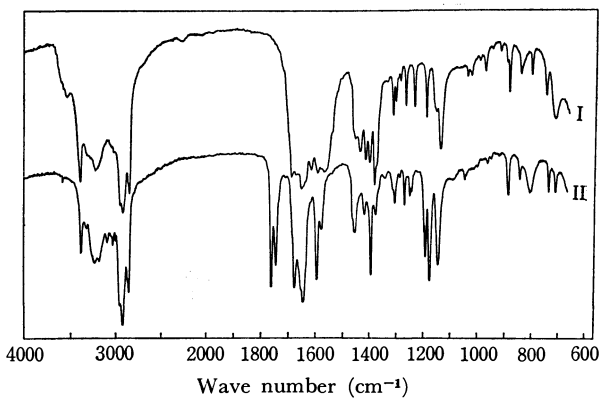

Fig. 5. IR Spectra of I and its hydrobromide II.

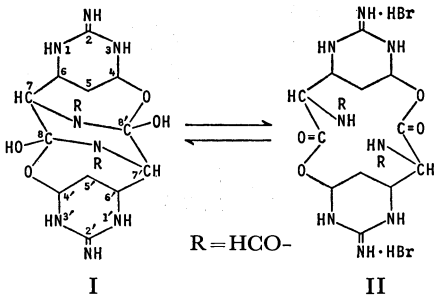

Fig. 6. Structures and interconversion of I and II.

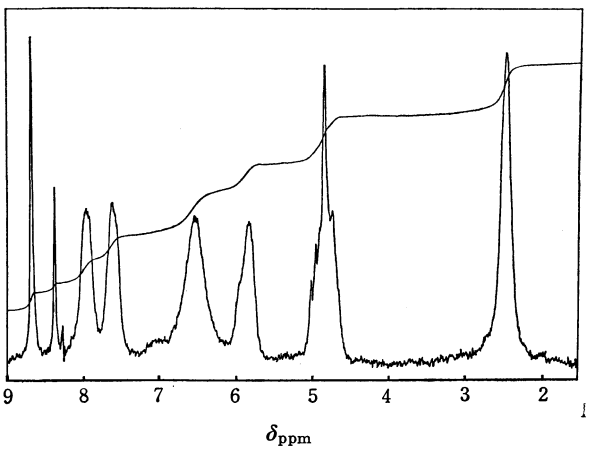

Fig. 7. NMR spectrum of I in TFA.

15) A. Prox, J. Schmid, and H. Ottenheym, *Ann. Chem.*, **722**, 179 (1969).

On the basis of the proposed structure, the signals of the NMR spectrum of I in TFA (Fig. 7) could be now assigned as follows: 4H protons at δ 2.5 were ascribed to C-5 and C-5′ methylene; 4H at δ 4.85 to C-6, C-6′, C-7 and C-7′ methine; 2H at δ 5.8 to C-4 and C-4′ methine; 4H at δ 6.5 to =NH bearing on C-2 and C-2′, and -OH on C-8 and C-8′; 2H at δ 7.6 to N-1 and N-1′ protons; 2H at δ 7.95 to N-3 and N-3′ protons; 2H centered at δ 8.5 to two formyl protons.

Splitting of the formyl protons at δ 8.36 and 8.66 could be presumably accounted for by the equilibrium of two types of hydrogen bonding between two formyl groups as shown in Fig. 8. Thus the upfield signal may be due to non-hydrogen bonded proton and the lowfield to hydrogen bonded one. In fact, the latter is relatively stronger than the former.

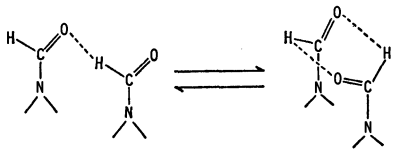

Fig. 8. Hydrogen bonding in formyl groups.

A mechanism for the formation of I was assumed from its structure as follows. Tuberactidine was first formylated with formic acid and pyridine in the eluate during concentration and then two molecules of them were condensed each other by dehydration followed by cyclization. However, a possibility of the formation of I through N^{α}-formylviomycidine could not be excluded, because I was actually obtained when the solution of viomycidine alone in the above buffer solution was evaporated. In addition to this, tuberactidine was easily converted to viomycidine with dehydration in the aqueous solution. Therefore, it is not clear at this stage whether N^{α}-formyltuberactidine or N^{α}-formylviomycidine is the real intermediate in the formation of I.

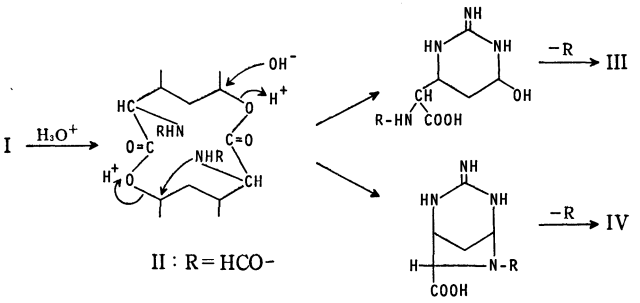

Fig. 9. Degradation of I to tuberactidine(III) and viomycidine(IV).

On the other hand, degradation of I to tuberactidine and viomycidine could be explained by concerted hydrolysis mechanism through II as shown in Fig. 9.

As mentioned previously,[2] it was contended that tuberactidine is a true constituent of tuberactinomycin A and viomycin, and viomycidine is possibly an artifact derived from tuberactidine during the isolation process. This assumption was supported by the following facts. First, tuberactidine as well as tuberactinomycin A and viomycin showed a positive Sakaguchi reaction whereas viomycidine gave a negative one. Secondly, when tuberactinomycin A was reduced with sodium borohydride in alkaline medium followed by acid hydrolysis, a hydroxy compound VI was obtained (Fig. 10). Physical properties such as mp, $[\alpha]_D$ and NMR spectrum in D_2O of monohydrochloride of VI were virtually identical with those of dihydroviomycidine hydrochloride which was obtained by reduction of viomycin in similar manner by Maeda *et al.*[16] The formation of VI can be elucidated by the interconversion between tuberactidine and its amino-aldehyde form in alkaline solution.

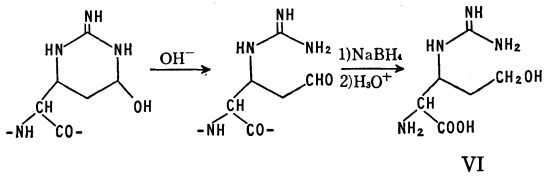

Fig. 10. Isolation of dihydroviomycidine(VI) from tuberactinomycin A.

The presence of the amino-aldehyde form in alkaline solution of tuberactidine can also explain a positive Sakaguchi reaction of tuberactidine, since this reaction should work on mono substituted guanidino compound like amino-aldehyde form derived from tuberactidine but not on disubstituted derivative like tuberactidine itself. Thus, it may be reasonable that VI gave a positive Sakaguchi reaction while viomycidine and capreomycidine were negative.

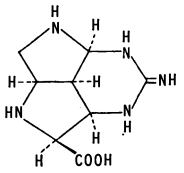

Fig. 11. Structure of viocidic acid(VII)

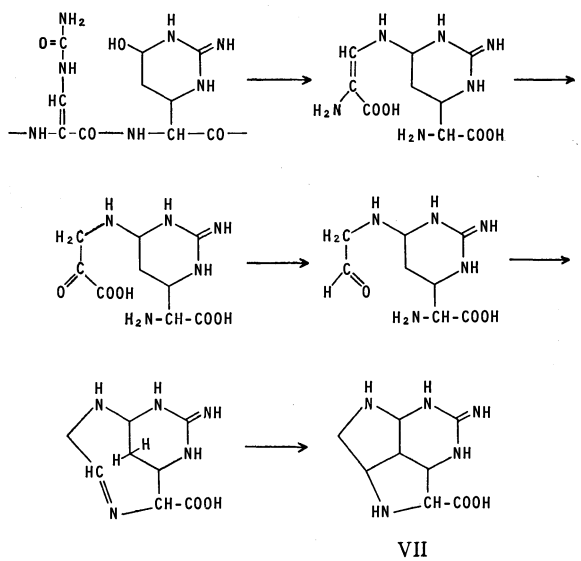

Fig. 12. Presumed formation pathway of viocidic acid(VII)

16) T. Takita and K. Maeda, *J. Antibiotics*, **22**, 39 (1969).

In several runs of column chromatography of the hydrolyzate of tuberactinomycin A, viocidic acid (VII), the other artifact formed during the hydrolysis, was eluted after viomycidine and tuberactidine. Viocidic acid had been also isolated from the hydrolyzate of viomycin, and the structure was determined using X-ray analysis by Bycroft *et al.* (Fig. 11).[17]

Pathway for the formation of viocidic acid remains unexplained as yet. However, it may be possibly interpreted by assuming the participation of 3-ureidodehydroalanine moiety as shown in Fig. 12, although the clarification of this problem must be left to a future investigation.

Experimental

All melting points are uncorrected. The infrared spectra were obtained in Nujol mull with a Hitachi EPI-G3 spectrophotometer. The NMR spectra were obtained with a Hitachi NMR R-20 spectrometer at 60 MHz in trifluoroacetic acid and deuterium oxide. Tetramethylsilane (TMS) was used as an internal reference in trifluoroacetic acid solution, and sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) in the case of deuterium oxide solution. The ORD curves were obtained with a Yanagimoto ORD-185 spectropolarimeter in 0.1 M hydrochloric acid. The specific rotations were obtained with a Perkin-Elmer 141 polarimeter in water and 1 M hydrochloric acid. Amino acids were analyzed with a JEOL-JLC-5AH amino acid analyzer. Thin-layer chromatography was carried out by the ascending method on silica gel G using developing solvents of phenol–water–28% ammonium hydroxide (30 : 10 : 0.6) and *n*-butanol–acetic acid–water (4 : 1 : 2). Paper electrophoresis was carried out at 750 volt and 10 mA for 1.5 hr on Toyo Roshi No. 51 paper using a buffer solution of pyridine–acetic acid–water (30:4:966).

Isolation of Viomycidine (IV). A solution of 20 g of tuberactinomycin A hydrochloride or viomycin hydrochloride in 180 ml of 6 M hydrochloric acid was heated at 135—140°C under reflux for 20 hr. Hydrochloric acid was evaporated *in vacuo* and the residue was dissolved in water. The evaporation was repeated three times after addition of water. The solution of the residue obtained in a small amount of water was applied on a column (2.5×65 cm) of Dowex 50W×2 ion exchange resin which was previously equilibrated with buffer solution of 0.2 M pyridine and formic acid (pH 3.1). Fractions of a positive Sakaguchi reaction were collected and evaporated *in vacuo*. The residue was dissolved in diluted hydrochloric acid and evaporated again. Ethanol and ether were added and a powder thus obtained was recrystallized from water and ethanol two times. Colorless prisms of viomycidine (IV) hydrochloride were obtained, yield 500 mg, mp 215—219°C (decomp.), Lit, mp 200—208°C (decomp.)[5c], $[\alpha]_D^{13}$ −89° (*c* 0.5, H_2O), Lit, $[\alpha]_D^{22}$ −85° (*c* 0.11, H_2O).[18]

Found: C, 34.89; H, 5.61; N, 26.84; Cl, 16.97%. Calcd for $C_6H_{10}O_2N_4 \cdot HCl$: C, 34.87; H, 5.37; N, 27.12; Cl, 17.16%.

Isolation of N^{α}*-Formyltuberactidine Dimer (I).* The same fraction of a positive Sakaguchi reaction in the eluate at another run of the above column chromatography was concentrated without acidification. Ethanol was added to the residue to make it powder. It was filtered off and crystallized from water. Colorless prisms of N^{α}-formyltuberactidine dimer (I) were obtained, yield 540 mg, mp 230°C (darkened) −245°C (decomp.). For analysis sample was dried *in vacuo* at 100°C.

Found: C, 42.19; H, 5.41; N, 28.09%. Calcd for $C_{14}H_{20}O_6N_8$: C, 42.42; H, 5.09; N, 28.27%.

Isolation of Viocidic Acid (VII). Mother liquor of I was evaporated *in vacuo* and the residue was dissolved in diluted hydrobromic acid. The acidic solution was concentrated and the residue was treated with ethanol to make it powder. It was recrystallized from aqueous ethanol several times to give colorless needles of viocidic acid (VII) dihydrobromide in a low yield, mp 208—210°C (decomp.), Lit. mp of trihydrate 222—225°C,[18] $[\alpha]_D^{25}$ −27° (*c* 0.5, H_2O).

Found: C, 25.70; H, 4.16; N, 18.64; Br, 42.71%. Calcd for $C_8H_{13}O_2N_5 \cdot 2HBr$: C, 25.70; H, 4.05; N, 18.77; Br, 42.84%.

N^{α}*-Formyltuberactidine Dimer from Viomycidine.* In a buffer solution of 0.2 M pyridine and formic acid (pH 3.1), 90 mg of viomycidine hydrochloride was dissolved. The solution was evaporated *in vacuo* at 50—60°C. The oily residue was treated with ethanol to make it powder. It was recrystallized from water to give colorless prisms. Melting point and infrared spectrum were virtualy identical with I obtained above.

Capreomycidine (V) from Tuberactinomycin N and O. A solution of 7 g of tuberactinomycin N hydrochloride in 21 ml of 6 M hydrochloric acid was heated at 100—110°C in a sealed tube for 24 hr. Hydrolyzate treated as mentioned above was column chromatographed on Dowex 50W×2 ion exchange resin (200—400 mesh, 2.5×25 cm) with a buffer solution of 0.2 M pyridine and acetic acid (pH 3.6). Fractions containing capreomycidine were evaporated and the residue was purified by column chromatography again with the same buffer solution. Crude capreomycidine hydrochloride was recrystallized from water and ethanol, yield 666 mg, mp 242—248°C (decomp.), Lit. mp 241°C (decomp.),[5] $[\alpha]_D^{25}$ +21° (*c* 1, H_2O), Lit, $[\alpha]_D$ +16.1° (*c* 1, H_2O).[7]

Found: C, 34.21; H, 6.17; N, 26.40; Cl, 17.17%. Calcd for $C_6H_{12}O_2N_4 \cdot HCl$: C, 34.54; H, 6.28; N, 26.85; Cl, 16.99%.

Detection of capreomycidine in a hydrolyzate of tuberactinomycin O was carried out by comparison with authentic sample chromatographically. Amino acid analysis, thinlayer chromatography and paper electrophoresis also characterized this guanidino amino acid in the hydrolyzate of tuberactinomycin O.

Hydrobromide of N^{α}*-Formyltuberactidine Dimer.* Crystals of 210 mg of I were dissolved in 1 ml of 25% hydrobromic acid, and then immediately 10 ml of ethanol and 20 ml of ether were added. After allowing to stand at room temperature until some crystals precipitated, it was stored in refrigerator overnight. Colorless needles were filtered off and washed with ethanol and ether thoroughly, yield 190 mg, mp 227°C (decomp.).

Found: C, 30.10; H, 4.04; N, 19.92; Br, 28.49%. Calcd for $C_{14}H_{20}O_6N_8 \cdot 2HBr$: C, 30.12; H, 3.97; N, 20.08; Br, 28.63%.

To the solution of the hydrobromide in a small amount of water, enough pyridine was added. Excess of pyridine was neutralized with formic acid. When it was allowed to stand for some time, I was recovered as a precipitate

17) a) B. W. Bycroft, D. Cameron, L. R. Croft, A. W. Johnson, T. Webb, and P. Coggon, *Tetrahedron Lett.*, **1968**, 2925. b) P. Coggon, *J. Chem. Soc., B*, **1970**, 838.

Acetyl Derivative of N^{α}*-Formyltuberactidine Dimer.* In 25 ml of pyridine, 470 mg of I was suspended and 13 ml of acetic anhydride was added. After stirring overnight at room temperature, a clear solution obtained was poured on ice and concentrated *in vacuo*. The residue was dissolved in water and evaporation was repeated. Residual oil was dissolved in ethanol and allowed to stand, yield of crystals 390 mg. Analytical sample was obtained by recrystallization from water, mp 217—220°C (decomp.).

Found: 42.07; H, 5.26; N, 22.06%. Calcd for $C_{18}H_{24}O_8N_8 \cdot 2H_2O$: C, 41.86; H, 5.46; N, 21.70%.

Recrystallization from water and ethanol gave fine plates, mp 194—196°C (decomp.).

Found: C, 44.00; H, 5.68; N, 20.84%. Calcd for $C_{18}H_{24}O_8N_8 \cdot H_2O \cdot C_2H_5OH$: C, 44.11; H, 5.92; N, 20.58%

Degradation of I to Viomycidine and Tuberactidine. Crystals of 1.1 g of I were dissolved in 4.5 ml of 15% hydrobromic acid and evaporated *in vacuo* at about 50°C. The residue was dissolved in water and evaporation was repeated several times. The oily residue was dissolved in ethanol and allowed to stand in refrigerator overnight. Precipitate was filtered off and crystallized from water and ethanol to give colorless prisms of viomicidine hydrobromide, yield 350 mg, mp about 210°C (decomp.), Lit, mp 202—204°C (decomp.),[11b] $[\alpha]_D^{25}$ −63° (*c* 0.5, H_2O).

Found: C, 28.63; H, 4.61; N, 22.24; Br, 31.77%. Calcd for $C_6H_{10}O_2N_4 \cdot HBr$: C, 28.70; H, 4.42; N, 22.31; Br, 31.83%.

Mother liquor from viomycidine was evaporated. The residue was dissolved in ethanol and stored in refrigerator for a long time. Tuberactidine hydrobromide was obtained and recrystallized from aqueous ethanol repeatedly, if necessary, with addition of ether, yield 100 mg, mp about 182°C (decomp.), $[\alpha]_D^{13}$ −25.8° (*c* 0.5, H_2O).

Found: C, 26.98; H, 4.81; N, 20.94; Br, 29.65%. Calcd for $C_6H_{12}O_3N_4 \cdot HBr$: C, 26.78; H, 4.87; N, 20.82; Br, 29.70%.

Dihydroviomycidine (VI). In 100 ml of 0.3 M sodium hydroxide, 20 g of tuberactinomycin A hydrochloride was dissolved and 5 g of sodium borohydride in 70 ml of 0.3 M sodium hydroxide was added dropwise with stirring magnetically at 45°C for 8 hr. After stirring for 24 hr, 5 g of sodium borohydride was added by portions for 10 hr. Reaction mixture was acidified with hydrochloric acid and concentrated *in vacuo*. The residue was dissolved in 100 ml of concentrated hydrochloric acid and insoluble inorganic substance was filtered off. Filtrate was diluted with 100 ml of water and heated under reflux at 135°C for 8 hr. Hydrolyzate was column chromatographed as mentioned above. Next fraction to that of diaminopropionic acid showed a positive Sakaguchi reaction but was differentiated from those of viomycidine or tuberactidine. It was concentrated *in vacuo*, and the residue was dissolved in water. Evaporation was repeated and residual oil obtained was allowed to stand overnight. Crystalline product thus obtained was dissolved in a small amount of diluted hydrochloric acid, and then ethanol and ether were added. After allowing to stand overnight in a refrigerator, colorless needles were obtained. Recrystallization from water and ethanol gave 93 mg of hydroxy compound as hydrochloride, mp 180°C (decomp.), Lit, mp 182°C (decomp.),[5d] $[\alpha]_D^{15}$ +33° (*c* 0.5, 1 M HCl), Lit. $[\alpha]_D^{25}$ +25° (*c* 0.7, 6 M HCl).

Found: C, 30.90; H, 7.06; N, 23.59%. Calcd for $C_6H_{14}O_3N_4 \cdot HCl \cdot 1/2H_2O$: C, 30.58; H, 6.84; N, 23.77%.

S_N2 Reactions in Dipolar Aprotic Solvents. III. Chlorine Isotopic Exchange Reactions of Cinnamyl Chlorides and 3-Aryl-2-propynyl Chlorides. Effect of the Unsaturated Group Adjacent to the Reaction Center

Jun-ichi HAYAMI,[1] Nobuo TANAKA, and Aritsune KAJI
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto

(Received October 6, 1972)

Chlorine isotopic exchange reactions of substituted cinnamyl chlorides and 3-aryl-2-propynyl chlorides with tetraethylammonium chloride-^{36}Cl were studied in acetonitrile. In both cases, the electron-donating groups accelerated the reaction. An acceptable linear Hammett relationship was found for the propynyl chlorides. Cinnamyl chlorides gave a linear relationship for the *m*-substituted compounds superposed by a concaved U-shaped relationship of *p*-substituted compounds. Both classes of compounds showed 10^{2-3} times of rate enhancement, compared with 2-arylethyl chlorides in the similar isotopic exchange reaction. Features of these S_N2 reactions are discussed.

Many works have been carried out to further our understanding of the bimolecular nucleophilic substitution at a saturated carbon atom,[2] an important reaction in organic chemistry.

Of the bimolecular nucleophilic substitutions at a saturated carbon atom, the Finkelstein reaction is one of the most thoroughly studied.[3] However, not many works have been carried out dealing with the Hammett type analysis to reveal the electronic requirement of the reaction center in a transition state.

The authors presented an example of a Hammett analysis in which the heteroatom adjacent to the S_N2

reaction center accelerates the reaction by a conjugative stabilization of the transition state.[4] The authors also showed that, in the Finkelstein reaction with benzyl chloride, chloride and fluoride anions behave similarly and the substituent effect can be rationalized in terms of the importance of the approach of a nucleophile superposed by the stabilization of the transition state.[5]

The rate enhancing effect of the unsaturated bond in an S_N2 reaction is well-known.[6] However, a further advance can be anticipated from systematic studies of the symmetrical exchange reaction of these classes of compounds.

The authors studied the chlorine-chlorine isotopic exchange reactions of the nuclear substituted cinnamyl chlorides and 3-aryl-2-propynyl chlorides in solvent acetonitrile to examine the effect of the carbon to carbon multiple bond adjacent to the S_N2 reaction center. Comparison was made with the results obtained for the other modified methyl chlorides to reveal the dominating factors of these reactions.

Results and Discussion

Nine kinds of nuclear substituted cinnamyl chlorides and eight kinds of 3-aryl-2-propynyl chlorides were treated with tetraethylammonium chloride-^{36}Cl in dry acetonitrile, as shown in the following scheme.

$$X\text{-}Ph\text{-}Y\text{-}CH_2Cl + (C_2H_5)_4N\overset{*}{Cl} \rightleftharpoons X\text{-}Ph\text{-}Y\text{-}CH_2\overset{*}{Cl} + (C_2H_5)_4NCl$$

I Y: $CH^{t}{=}CH$, X: a) p-NO_2, b) m-NO_2, c) m-CF_3, d) m-Cl, e) p-Cl, f) H, g) m-CH_3, h) p-CH_3, i) p-OCH_3

II Y: C≡C, X: a) p-NO_2, b) m-CF_3, c) m-Cl, d) p-Cl, e) H, f) m-CH_3, g) p-CH_3, h) p-OCH_3

The advantage of using the dipolar aprotic solvent has been reported.[7] In the present cases, a good second-order kinetics holds, the second-order rate coefficients remaining virtually constant in varying concentration of nucleophile and also on addition of an inert salt, tetraethylammonium perchlorate (Table 1).

The results are given in Table 2 together with the rate coefficients for the Finkelstein reaction of benzyl chloride with chloride ion and fluoride ion.

The rate data for the unsubstituted modified methyl chlorides are collected in Table 3 to show the relative effectiveness of the group adjacent to the S_N2 reaction center.

A significant rate enhancement as compared with the chlorine-chlorine isotopic exchange reaction of 2-arylethyl chloride was observed for the three classes of compounds in Table 2. Thus benzyl chloride, cinnamyl chloride, and 3-aryl-2-propynyl chloride showed fairly similar reactivity, and all reacted about 10^2 times more rapidly in the S_N2 isotopic exchange reaction than 2-arylethyl chloride. However, the double bond in cinnamyl chloride seemed to exert a more pronounced effect than the triple bond and direct linkage in other classes. Sulfur atom in the chloromethyl aryl sulfides seemed to be more effective than the unsaturated groups in Table 3 in accelerating the Finkelstein reaction.

Electron-donating groups on the phenyl ring faciliated the chlorine-chlorine exchange reaction of cinnamyl chlorides as well as the same reaction of 3-aryl-2-propynyl chlorides. The rate data are plotted against Hammett σ to give the relationships given in Figs. 1 and 2.

As is shown in Fig. 2, the Hammett plot for the 3-aryl-2-propynyl chlorides gives an acceptable linear relation ($\rho=-0.19$, $r=0.919$[8]). Similarly, the m-substituted cinnamyl chloride gives a straight line ($\rho=-0.19$, $r=0.962$[8]) superposed by a concaved U-

shaped line for *p*-substituted compounds.

In discussing the results, three factors are conceivable in determining the rate of the S_N2 reactions. Besides the solute-solvent interactions and steric effects, which are similar or essentially similar to those of all the reaction systems studied, the following factors have been proposed and successfully applied to rationalize the S_N2 reactions:[10] a) approach of the nucleophile; b) stabilization of the transition state by the electron-donating conjugation with the incipient pseudo-p-orbital; and c) the "neighboring orbital overlap," an interaction which involves both the substrate and nucleophile.

The rate determining approach of a nucleophile is a characteristic feature of the S_N2 reaction, a dominating factor when there is no group that stabilizes the transition state of such a reaction. An example was presented for the Finkelstein reaction of 2-arylethyl chlorides where a good linear Hammett relationship with positive value of ρ was obtained.[4] For modified methyl chlorides, at least for the examples studied in the present paper, the nucleophilic approach may be rather a common factor while the other two effects should be discriminating. The polar effect alone cannot account for the rate differences between 2-

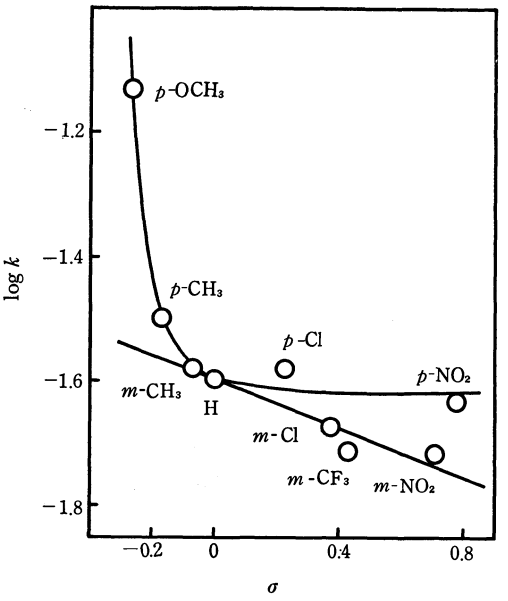

Fig. 1. Hammett plot for the chlorine exchange of substituted cinnamyl chlorides (I) at 20°C.
$\rho = -0.19$, $r = 0.962$

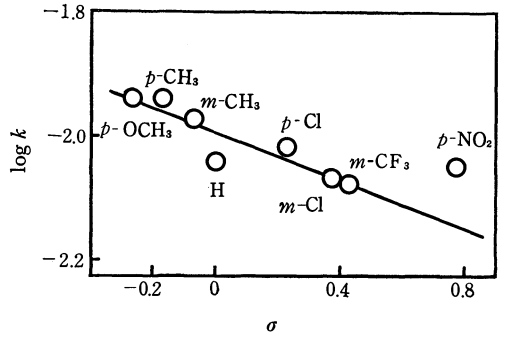

Fig. 2. Hammett plot for the chlorine exchange of 3-aryl-2-propynyl chlorides (II) at 20°C. $\rho = -0.19$, $r = 0.919$

phenylethyl chloride and benzyl chloride.[11] Thus the rate enhancement should be attributed to the conjugative interaction involving the reaction center.

Negative ρ values found for the cinnamyl and 3-aryl-2-propynyl chlorides indicate that an electron-donating effect is dominant in these reactions. Stabilization would be attributed to an electron-donating conjugation. The cinnamyl system seems to exert a somewhat larger effect than the 3-aryl-2-propynyl system does. Taking into account the fact that an acceptable linear Hammett relationship holds for both of the *p*- and *m*-substituted 3-aryl-2-propynyl chlorides and that the ethynylic linkage is a rather poor transmitter of the conjugative effect but a good transmitter of the polar effect,[12] the effect in this system should be ascribed to the electron-donating conjugation of the triple bond itself with the reaction center.

10) Ref. 2c. pp. 26—29.

11) The difference in $\sigma^*(\sigma^*_{Ph} - \sigma^*_{PhCH_2} = 0.4)$ predicts a rate enhancement not more than several times for a conceivable reaction parameter ($\rho = 1$—2) for such a reaction.

12) For a reaction involving the rate determining approach of an anion, a triple bond exerts an almost similar effect as a double bond as long as there is no pronounced effect of conjugation. Thus for the base catalyzed hydrolysis of ethyl cinnamate, ρ was reported to be 1.3 while the same reaction with ethyl 3-arylpropiolate gave $\rho = 1.1$. (cf. R. M. O'Ferrall and S. I. Miller, *J. Amer. Chem. Soc.*, **85**, 2440 (1963), and I. J. Solomon and R. Filler, *ibid.*, **85**, 3492 (1963).)

Table 4. Comparison of the rate of Finkelstein reaction of benzyl chlorides with chloride and fluoride[a)]

	p-OCH_3	p-CH_3	m-CH_3	H	p-Cl	m-CF_3	m-NO_2	p-NO_2
k_{Cl^-}/k_{F^-}	1.39	0.80	0.84	0.77	0.79	0.60	0.43	<0.60[b)]

a) Ref. 5. b) $k_{Cl^-}(p\text{-}NO_2)/k_{F^-}(m\text{-}NO_2)$

The U-shaped Hammett plot for the p-substituted cinnamyl chlorides suggests an operation of an additional conjugation through the double bond, an effect not operative in the present instance of the ethynylic linkage. This additional rate enhancement definitely shows that the cinnamyl system is a good transmitter of a conjugative effect even in the S_N2 transition state. A similar observation for the benzyl chloride is common, an example having been given[13] (Table 2).

The increment of the rate constant from the value predicted by the ρ-σ relationship for m-substituted compounds is a measure of the perturbing effect of a p-substituent. Such increments for the benzyl chlorides[14] are plotted against a similar increment observed in the cinnamyl chlorides, and shown in Fig. 3.

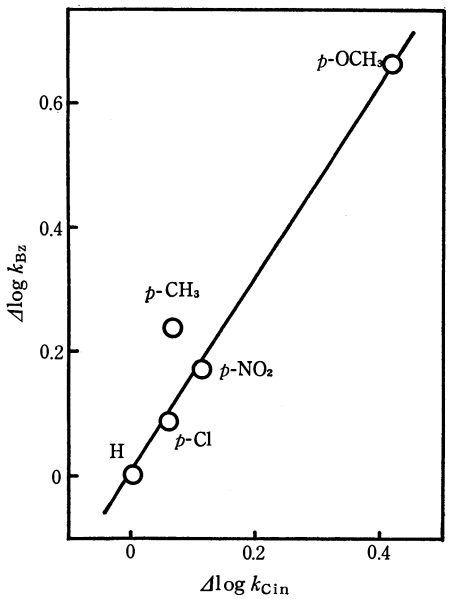

Fig. 3. Rate increment by p-substituents. Comparison of benzyl chlorides ($\Delta\log k_{Bz}$) with cinnamyl chlorides ($\Delta\log k_{Cin}$).

A fairly good linear relationship was obtained which implies the common nature of the reactivity of two classes of compounds. A most interesting observation is that the linear relationship also includes p-nitro substituent which shows a rate enhancement hardly interpreted.

The concept of "neighboring orbital overlap" is quite attractive to rationalize the rate accelerating effect by p-cyano and p-nitro substituents.[10] The trend has often been reported and is also observed in the present cases (Figs. 1 and 2).

In a trial to reveal the contribution of the effect, the reaction of benzyl chlorides with fluoride anion in acetonitrile[5] has quite an important bearing.

If the "neighboring orbital overlap" is operative in the present instances of chlorine-chlorine isotopic exchange reaction, the overlap should serve as a retarding factor for the organic halides with an electron-donating substituent, while the S_N2 reaction with fluoride anion should be essentially free of this overlap.[15]

Thus the ratio of the second-order rate coefficients of these two Finkelstein reactions, k_{Cl^-}/k_{F^-}, should be lower for benzyl chlorides with effective electron-donating substituent and higher for benzyl chlorides with strongly electron-attracting substituent whose rate enhancement due to the overlap is expected. This is not the case with the two Finkelstein reactions of the substituted benzyl chlorides (Table 4). The finding would be an indication against the operation of the "neighboring orbital overlap."

However, there can be another explanation for the rate ratio in Table 4. Tightening of the transition state, which is possibly brought about by the involvement of a very "hard" nucleophile (fluoride anion), should result in a lower k_{F^-} for compounds with electron-donating substituent and a higher k_{F^-} for compounds with electron-attracting substituent. Thus, the effect of "neighboring orbital overlap" can be counteracted, or could be apparently counterbalanced depending upon the degree of tightening. In an extreme case, in which tightening is overwhelming, importance of the approach of a nucleophile becomes dominating and the contribution of conjugative stabilization plays only a minor role. The effect of the overlap can thus easily be masked.

13) G. M. Bennett and B. Jones, *J. Chem. Soc.*, **1935**, 1815.

14) A linear relationship ($\rho=0.36$, $r=0.905$) was tentatively given from the data for the benzyl chlorides with m-substituent (m-NO_2, m-CF_3, m-Cl, and H, m-CH_3).

15) It is commonly accepted that the rate-controlling effect of this nature is more pronounced in cases in which the entering and leaving groups are not first row elements. (*cf.* Ref. 2c, p. 28).

a) Ref. 20. b) Ref. 21. c) Ref. 6b. d) Ref. 22. e) Ref. 19.

However, the use of the fluoride anion failed to substantiate the tight transition state as is proved by the U-shaped Hammett plot concave upward of the reaction with benzyl chlorides.[16]

As to the relative effectiveness of the group adjacent to the S_N2 reaction center in promoting the reactions of the modified methyl chlorides, the present work furnishes the order O≫S>CH=CH>None (benzyl)≳C≡C≫CH_2. This can be rationalized in terms of the relative effectiveness of the conjugative stabilization of the transition state, oxygen and sulfur atom being more effective than the unsaturated group. The data of activation energy support this explanation (Table 5).

As the rate enhancement due to the effective conjugation implies loose transition state,[17] a study of the secondary deuterium isotope effect should be quite interesting. The work is now in progress and the results will be the subject of the forthcoming paper.[18]

Experimental

Preparation of Materials. Cinnamyl chloride (If) and *p*-nitrocinnamyl chloride (Ia) were prepared from the corresponding cinnamyl alcohols by the standard method with thionyl chloride in dry benzene. Other cinnamyl chlorides (Ib, c, d, e, g, h) were prepared from the corresponding 1-arylallyl alcohols[19] by passing gaseous hydrogen chloride through their ethereal solutions. After being passed through a short column of alumina with *n*-hexane-benzene mixture as an eluent, cinnamyl chlorides were purified by distillation under reduced pressure or by recrystallization from the solvent listed in Table 6.

TABLE 7. PHYSICAL CONSTANTS OF 3-ARYL-2-PROPYNYL DERIVATIVES

	X	Chloride bp°C/mmHg (mp°C)	Alcohol bp°C/mmHg (mp°C)

3-Aryl-2-propynyl chlorides. 3-Aryl-2-propynyl alcohols were prepared from the corresponding arylacetylenes. As an example, phenylacetylene (20 g, 0.20 mol) in 50 ml of ether was added to ethereal solution of 0.22 mol of ethyl magnesium bromide in 150 ml of ether. The resulting solution was stirred overnight at room temperature. Powdered paraformaldehyde (10 g, 0.33 mol as CH_2O), dried in a vacuum dessicator for a few days, was added to this solution in small portions. After being refluxed for three hours, the solution was worked up as usual. Distillation gave 16.5 g (63%) of 3-phenyl-2-propynyl alcohol. 3-Aryl-2-propynyl chlorides (IIb—IIh) were obtained from the corresponding alcohols by the reaction with thionyl chloride.

3-*p*-Nitrophenyl-2-propynyl chloride (IIa) was prepared by nitration of 3-aryl-2-propynyl chloride (IIe). Under vigorous stirring 1g of IIe was added slowly into 20 ml of fuming nitric acid (d. 1.50) at −30°C. After the addition was complete, the solution was stirred for another minute,

16) The observed trend that the rate ratio is slightly larger for the strongly electron-donating substituent and smaller for the strongly electron-attracting substituent was pointed out previously.[5] This can be a reflection of the tightening of the transition state, although it is not overwhelming.

17) A. J. Parker, *Chem. Rev.*, **69**, 1 (1969).

18) Normal isotope effects were found; 5% for *p*-methyl and *p*-methoxy benzyl chloride, about 10% for chloromethyl aryl ethers and sulfides. Cinnamyl chloride also exhibited about 5% isotope effect. The positive effect definitely supports the concept of loose transition state and a conjugative interaction. cf. Preprint p. 21, 23rd Symposium on Organic Reaction Mechanism, Kobe, October 1972 and also N. Tanaka, A. Kaji, and J. Hayami, *Chem. Lett.*, **1972**, 1223.

and the mixture was poured into ice water. The organic compounds were extracted with benzene. The benzene extract was dried with anhydrous magnesium sulfate and the solution was concentrated under reduced pressure. The residue was chromatographed on silica gel with *n*-hexane–benzene as an eluent. Recrystallization from methanol gave pure IIa.

These chlorides decomposed gradually on standing. Fresh samples were therefore used for the kinetic experiment immediately after purification. Purification was affected by column chromatography on alumina followed by distillation or recrystallization.

The structures of these unsaturated chlorides were confirmed by their NMR and IR spectra. Physical constants are summarized in Tables 6 and 7.

Preparation and purification of tetraethylammonium salts and acetonitrile were undertaken as described previously.[4]

Kinetic Measurements. Batch method was utilized. A modification was made by use of toluene as an extracting solvent instead of benzene.

Tracer experiments were carried out at Radioisotope Research Center of Kyoto University. Sincere thanks are due to the staff of this institution. The work was supported by the Ministry of Education and Saneyoshi Shogakkai.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 959—963 (1973)

4-Epifriedelin and 4-Epishionone. Structure and Reflex Effect[1]

Reiko AOYAGI, Shūzō YAMADA, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received October 13, 1972)

4-Epifriedelin (III) and 4-epishionone (VII) were prepared by photoepimerization of friedelin (I) and shionone (VI), respectively. On base treatment, III and VII were completely isomerized into I and VI, respectively; this observation was discussed based on reflex effect.

Friedelin (I), a pentacylic triterpene bearing 3-oxo-4-methyl substituents in A-ring, is widely distributed in the plant kingdom.[2] Especially it is well-known as one of the major constituents of cork.

Biosynthetic pathway of friedelin from squalene has been described.[3] Friedelin in enol form (II) may be derived from the protonated β-amyrin type intermediate by a sequence of 1,2-shifts of methyl groups and hydrogen atoms, followed by deprotonation in the last step.[3] It is, therefore, reasonable that the formation of 4α(axial)-methyl epimer (III, 4-epifriedelin) as well as that of friedelin (I) would be expected. Friedelin and several friedelin derivatives have been isolated from a large number of plants. However, isolation of 4-epifriedelin (III) from natural source has never been reported.

Ramirez and Stafiej described that D-homosteroid (IV) and its 17aα-methyl epimer (V) existed in a ratio of 70 : 30 under equilibrating conditions.[4] On the other hand, Ourisson *et al.* showed that friedelin (I) did not contain 4-epifriedelin (III) at equilibrium and this observation was explained by reflex effect.[5] The deformation of ring B caused by 1,3-diaxial interaction between the 5β- and 9β-methyl groups of III produces reflex effect which brings the 4α-methyl group nearer to the 10α-hydrogen atom, resulting in destabilization of III.[5] In the 17aα-methyl epimer (V), the corresponding 1,3-diaxial interaction (between 13β-methyl and 8β-hydrogen) should cause the reflex effect less severe.[5] These considerations were also supported by the equilibrating experiment on shionan-3-one (VI, with saturated side chain) with alkali; the 4α-epimer (VII, with saturated side chain) was not detectable at equi-

librium.[6a] This seems, therefore, to be the reason why neither the preparation of III[7] (and VII) nor the isolation of III (and VII) from natural source has yet been described.

In order to verify the exertion of the reflex effect in 4-epifriedelin (III) and 4-epishionone (VII), equilibration of these two compounds, as well as that of 17aβ- and 17aα-D-homo-5α-androstan-17-ones (VIII and IX) as comparative compounds, was examined.

We have briefly reported a photochemical reaction of I in ethanol, in which III has been isolated together with A-norfriedelane, ethyl 3,4-seco-friedelan-3-oate, friedelin and 3β- and 3α-friedelanols.[8] Friedelin (I) in ethanol, *n*-hexane or diethyl ether was irradiated with a high pressure mercury lamp under a nitrogen atmosphere at room temperature. The reaction products were subjected to silica gel column chromatographic separation and a ketone fraction was collected. The ketone fraction consisted of two components; the tlc examination showed two spots. A ketone with R_f 0.52 was shown to be identical with I. The other ketone (R_f 0.45), recrystallized from petroleum ether, showed mp 257.5°C, IR ν_{max} (Nujol) 1706 cm^{-1}. The molecular formula of $C_{30}H_{50}O$ was determined by the appearance of M^+ peak at *m/e* 426 in the mass spectrum, whose fragmentation pattern was very similar to that of I. These observations suggest that the photoepimerized ketone would be 4-epifriedelin (III). IR spectrum of III together with that of I is given in Fig. 1.

Further confirmation of the structure (III) was given by isomerization reaction of III. 4-Epifriedelin (III) in benzene was adsorbed on alumina overnight and then eluted with benzene to afford an isomerized product which was found to be identical (mp, mixed mp, IR, tlc and glc) with I, and no original ketone (III) was detectable by tlc examination. When silica gel was used no isomerization occurred. When III was treated with sodium methoxide in methanol–dioxane under reflux, it was completely isomerized to I. 4-Epifriedelin (III) was also thermally isomerized; on glc (Diasolid H-523, at 250°C) it gave two peaks at 36.6 and 41.1 min, due to III and I, respectively. These observations firmly confirm the Ourisson's reflex effect and lead to assignment of 4α(axial)-methyl configuration (X) for 4-epifriedelin (III).

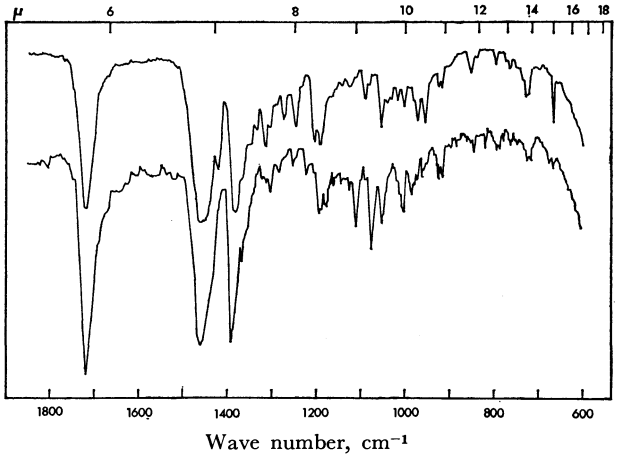

Fig. 1. IR spectra of friedelin (I, lower) and 4-epifriedelin (III, upper).

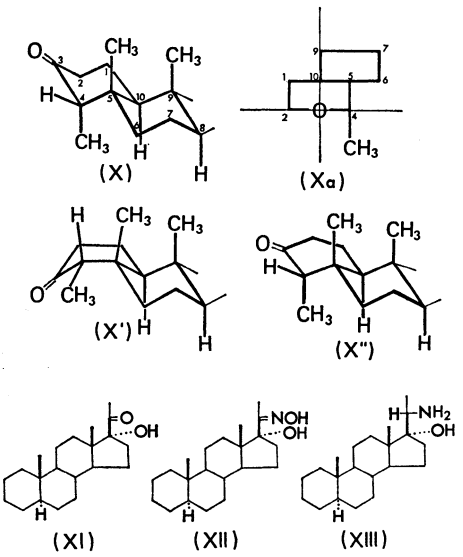
This assignment for III is compatible with optical rotatory dispersion (ORD) curve of III when compared with that of I(Fig. 2a). Both ORD curves show negative Cotton effect and the amplitude[9] of III ($a=-43$) is smaller than that of I($a=-126$). If one assumes a chair comformation such as X for both rings A and B, this evidence could be interpreted as that, while 4β-methyl group of I lies on octant plane, 4α-methyl group of III contributes to the positive octant (Xa), resulting in reduction of absolute value of the amplitude for III. As positive Cotton effect is expected for conformations (X′ and X″) with ring A in boat form, these conformations can be excluded for III.



4-Epishionone (VII) was prepared by photoepimerization of shionone (VI).[1] The same observations were obtained for VII as in the case of 4-epifriedelin (III), except the isomerization with alumina; VII was not isomerized with alumina. ORD curves of VI and VII are shown in Fig. 2b.

17aβ- and 17aα-methyl-D-homo-5α-androstan-17-one (VIII and IX) were prepared as follows. Oximation of 17α-hydroxy-5α-pregnan-20-one (XI)[10] gave an oxime (XII), which on hydrogenation yielded 17α-

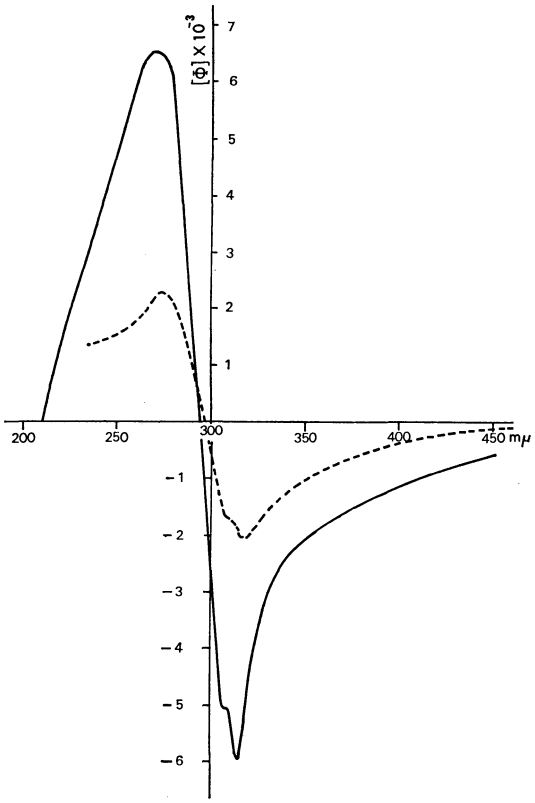

Fig. 2a. ORD curves of friedelin (I, solid line) and 4-epifriedelin (III, dotted line).

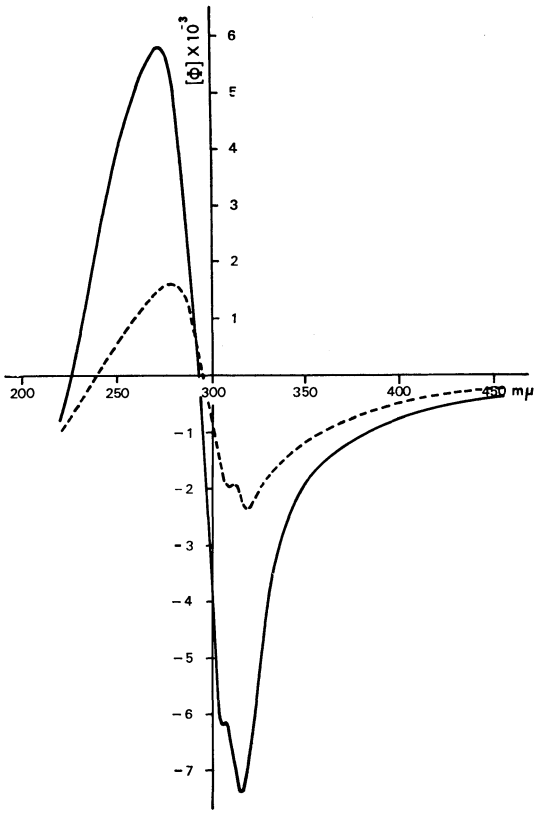

Fig. 2b. ORD curves of shionone (VI, solid line) and 4-epishionone (VII, dotted line).

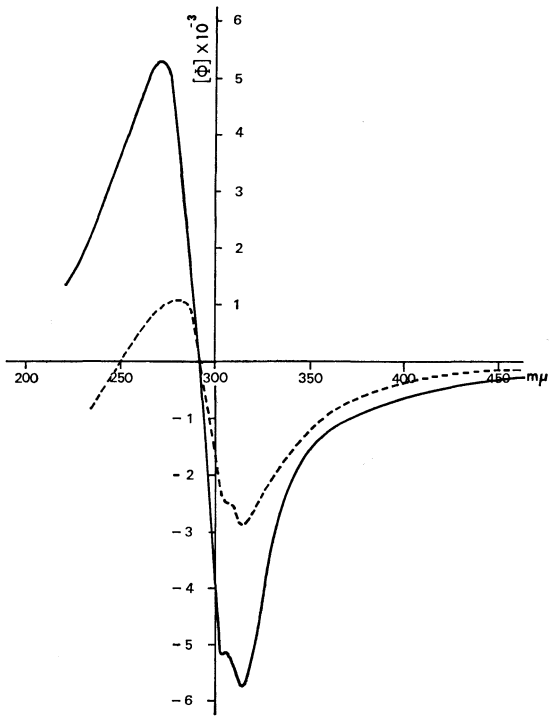

Fig. 2c. ORD curves of 17aβ-methyl-D-homo-5α-androstan-17-one (VIII, solid line) and 17aα-methyl epimer (IX, dotted line).

hydroxy-20α-amino-5α-pregnane (XIII).[11] As in the case of the corresponding 3α-hydroxy derivative[4] of XIII, when treated with nitrous acid XIII underwent the Demjanov ring enlargement to give 17aα(axial)-methyl-D-homo-5α-androstan-17-one (IX).[13] This ketone (IX) was treated with potassium hydroxide in ethanol under reflux to afford a mixture of 17aα- and 17aβ-methyl-D-homo-5α-androstan-17-ones (IX and VIII). The same equilibrating mixture was also obtained by treatment of 17aβ-methyl-D-homo-5α-androstan-17-one (VIII) with alkali. The equilibrating mixture was separated into each component. ORD curves of VIII and IX are

11) The configuration at C-20 of XIII was deduced from the formation of 17aα-methyl-D-homosteroid (IX) on nitrosation of XIII (*cf.* Ref. 4 and 12).

12) D. N. Kirk and M. P. Hartshorn, "Steroid Reaction Mechanisms," Elsevier, Amsterdam (1968), p. 304.

13) The location of ketone group on C-17 (not on C-17a) for IX was shown as follows. The mass spectrum of the ethylene ketal (XIV) of 17aβ-methyl epimer (VIII) showed the presence of a characteristic peak at *m/e* 99 due to fragmentation "a" and absence of peak at *m/e* 113 due to fragmentation "b", which would be responsible for an alternative structure (XV). The 17aα-(axial)-methyl configuration of IX was deduced from equilibration experiments.

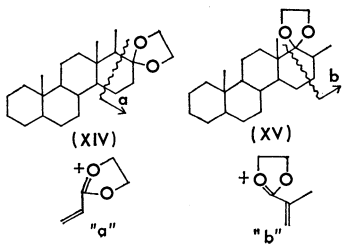

Table 1. PMR spectral data[a)]

		δ_{CDCl_3}	$\delta_{C_6D_6}$	Δ		δ_{CDCl_3}	$\delta_{C_6D_6}$	Δ		δ_{CDCl_3}	$\delta_{C_6D_6}$	Δ
I	4β-CH_3	0.87	0.97	−0.10	5β-CH_3	0.72	0.63	+0.09	9β-CH_3	0.87	0.74	+0.13
III	4α-CH_3	1.11	0.86	+0.25	5β-CH_3	0.87	0.69	+0.18	9β-CH_3	0.92	0.85	+0.07
VI	4β-CH_3	0.87	0.92	−0.05	5β-CH_3	0.71	0.60	+0.11	9β-CH_3	0.88	0.74	+0.14
VII	4α-CH_3	1.11	0.86	+0.25	5β-CH_3	0.90	0.74	+0.16	9β-CH_3	0.90	0.83	+0.07
VIII	17aβ-CH_3	0.87	0.98	−0.11	13β-CH_3	0.60	0.51	+0.09	10β-CH_3	0.72	0.66	+0.06
IX	17aα-CH_3	1.08	0.85	+0.23	13β-CH_3	0.81	0.70	+0.11	10β-CH_3	0.77	0.66	+0.11

a) Chemical shifts are expressed in δ_{ppm} downfield from TMS; $\Delta = \delta_{CDCl_3} - \delta_{C_6D_6}$.

given in Fig. 2c. The equilibrating mixture was shown to consist of 28% of 17aα- and 72% of 17aβ-isomers from ORD data. The fact that the amplitude of 17aα-methyl isomer (IX, $a=-40$) is smaller than that of 17aβ-methyl isomer (VIII, $a=-108$), indicates that 17aα(axial)-methyl group of IX contributes to the positive octant and 17aβ(equatorial)-methyl group of VIII lies on octant plane just as same as in the cases of friedelin and shionone series.

PMR spectral data of I, III, VI, VII, VIII, and IX are given in the Table. The solvent shift for a signal due to methyl group adjacent to carbonyl is well documented.[14] Each of 4α-, 4α- and 17aα-methyl resonances of III, VII and IX, respectively, suffers an appreciable upfield shift ($\Delta=\delta_{CDCl_3}-\delta_{C_6D_6}=+0.23\sim+0.25$ ppm) on passing from deuteriochloroform to deuteriobenzene solution, showing that these methyl groups are in axial conformation. However, in I, VI and VIII, 4β-, 4β- and 17aβ-methyl resonances, respectively, suffer a small downfield shift ($\Delta=-0.05\sim-0.11$ ppm), suggesting an equatorial nature for these methyl groups. As to the other methyl signals, the solvent shifts (Δ) of 5β- or 13β-methyl resonances are within $+0.09\sim+0.11$ ppm for I, VI or VIII, and within $+0.11\sim+0.18$ ppm for III, VII or IX. An upfield shift ($\Delta=+0.06\sim+0.14$ ppm) is observed for 9β- or 10β-methyl resonances of I, III, VI, VII, VIII or IX.

These observations exclude boat conformations of ring A for these six compounds, in agreement with the results obtained from ORD data. In conclusion, the most probable conformation of ring A of III and VII, and that of ring D of IX should be a deformed chair conformation.

Experimental[15]

1. Friedelin Series. Isolation of 4-Epifriedelin (III). Friedelin[2] (I, 2.01 g) in ethanol (750 ml) was heated under reflux with introduction of nitrogen for 30 min and the resulting solution was irradiated with a high pressure mercury lamp under a nitrogen atmosphere at reflux temperature. After evaporation of the solvent under reduced pressure, the residue was dissolved in petroleum ether–benzene (1 : 1) and passed through a column (silica gel, 60 g). The elution with the same solvent gave hydrocarbons, ethyl 3,4-seco-friedelan-3-oate, ketones, and 3β- and 3α-friedelanols. The ketone fraction consisted of two components. A ketone (R_f 0.52) which was eluted from the column, was collected and recrystallized from ethyl acetate to give 788 mg of white crystals which were shown to be identical with friedelin (I) in every respect. Further elution with the same solvent gave another ketone (R_f 0.45), which was recrystallized from petroleum ether to afford 4-epifriedelin (III, 53.7 mg, 2.7%); IR (Nujol): $\nu_{C=O}$ 1706 cm^{-1}; Found: C, 84.31; H, 11.97%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%. MS: *m/e* 426 (M^+), 341 [$(M-85)^+$] and 302 [$(M-124)^+$]; PMR ($CDCl_3$): δ 0.87, 0.92, 0.95, 0.99, 1.00, 1.04, 1.17 (each singlet due to *t*-CH_3), 1.11 ppm (d, $J=7.0$ Hz, *sec*-CH_3); PMR (C_6D_6): δ 0.69, 0.85, 0.94, 1.01, 1.03, 1.09, 1.22 (each singlet due to *t*-CH_3), 0.86 ppm (d, $J=6.0$ Hz, *sec*-CH_3), ORD: $[\Phi]_{589}$ 0°, $[\Phi]_{318}^{trough}$ −2070°, $[\Phi]_{309}$ −1680° (sh), $[\Phi]_{275}^{peak}$ +2280° and $[\Phi]_{214}$ +1180°. Friedelin (I, 1.00 g) in *n*-hexane (500 ml) was irradiated under the same conditions. By the same separation procedure, 4-epifriedelin (III, 47 mg, 4.7%) was isolated from the photoreaction mixture.

Isomerization of 4-Epifriedelin (III) into Friedelin (I).

a) With Sodium Methoxide: 4-Epifriedelin (III, 5 mg) in dioxane (5 ml) and methanol (5 ml) was heated under reflux with sodium methoxide under a nitrogen atmosphere for 5.5 hr. The residue, after removal of the solvent, was extracted with ether. The ethereal extract was dried over sodium sulfate. Tlc (SiO_2) examination showed only one spot with R_f 0.52, which corresponded to that of friedelin. The presence of 4-epifriedelin (III) was not detectable.

The isomerized product was isolated by SiO_2 preparative tlc to give friedelin (I), which was identified with an authentic sample by mp, IR and glc.

b) With Alumina: 4-Epifriedelin (III) was dissolved in benzene and the solution was divided into two portions. Each portion was poured into alumina (Showa Chemical, neutral) and silica gel columns, respectively, and adsorbed overnight. On elution with benzene, friedelin (I) was isolated from the eluent from the alumina-packed column. In the benzene eluent from the silica gel column, no friedelin (I) was detected; 4-epifriedelin (III) was recovered unchanged.

c) Thermal Isomerization in Gas Chromatography: 4-Epifriedelin (III) in acetone was injected into a column packed with Diasolid H-523 at 250°C. There appeared two peaks; one peak at t_R 36.6 min due to III was exceedingly weak compared with the other one at t_R 41.1 min due to friedelin

14) N. S. Bhacca and D. H. Williams, "Applications of NMR Spectroscopy in Organic Chemistry," Holden-Day (1964), pp. 164—169.

15) IR and mass spectra were measured using Hitachi EPI-G2 and Hitachi RMU-6 spectrometers, respectively. PMR spectra were taken on a JEOL-JNM-C-60 spectrometer at 60MHz using TMS as an internal standard. ORD measurement was carried out on a JASCO ORD/UV-5 spectrometer in dioxane solution (*c*: 2 mg/ml). All melting points were determined on a hot block and reported uncorrected. Silica gel column and thin layer chromatographies were carried out on Wakogel C-200 (Wako Pure Chem.) and Kieselgel G nach Stahl (E. Merck), respectively.

(I).

2. Shionone Series. Isolation of 4-Epishionone (VII) A solution of shionone[6] (VI, 1.00 g) in *n*-hexane (500 ml) was irradiated under the same conditions (*cf.* friedelin series) for 7 hr. This procedure was repeated and the combined residue, after the solvent had been removed, was chromatographed on silica gel. By the same procedures described for friedelin series, shionone (VI, R_f 0.52) and 4-epishionone (VII, R_f 0.45) were isolated. The latter (VII) was purified by recrystallization from ethyl acetate to give 93.1 mg of 4-epishionone (4.7%), mp 153.5—154°C; IR (Nujol): $\nu_{C=O}$ 1706 cm^{-1}; Found: C, 84.63; H, 11.61%. Calcd for $C_{30}H_{50}O$: C, 84.44; H, 11.81%. MS: *m/e* 426 (M^+); PMR ($CDCl_3$): δ 0.90, 0.92 (each singlet due to $2\times t$-CH_3), 1.15 (s, *t*-CH_3), 1.11 (d, J=7.0 Hz, *sec*-CH_3), 1.60, 1.67 ppm (each singlet, $C{=}C\langle^{CH_3}_{CH_3}$); PMR ($C_6D_6$): δ 0.74, 0.98, 1.10 (each singlet, *t*-CH_3), 0.83 (s, $2\times t$-CH_3), 0.86 (d, J=6.5 Hz, *sec*-CH_3), 1.62, 1.70 ppm (each singlet, $C{=}C\langle^{CH_3}_{CH_3}$); ORD: $[\Phi]_{589}$ −130°, $[\Phi]^{trough}_{319}$ −2370°, $[\Phi]_{310}$ −1990° (sh), $[\Phi]^{peak}_{278}$ +1620° and $[\Phi]_{220}$ −1010°.

Isomerization of 4-Epishionone (VII) into Shionone (VI).

a) With Sodium Methoxide: 4-Epishionone (VII, 5 mg) was dissolved in a mixture of dioxane (5 ml) and methanol (5 ml) and the solution was heated with sodium methoxide under a nitrogen atmosphere for 5.5 hr. The reaction products were worked up as usual and examined by silica gel tlc. The presence of VII was not detectable and the spot due to VI appeared on tlc.

b) With Alumina: 4-Epishionone (VII) in benzene was adsorbed on alumina and silica gel, respectively, for 24 hr. The compound eluted with benzene from each column was shown to be identical with the starting material (VII), by tlc. In the case of 4-epishionone (VII), it was shown that alumina did not bring about isomerization of VII.

3. D-Homosteroid Series. 17α-Hydroxy-20-hydroxyimino-5α-pregnane (XII). A mixture of 17α-hydroxy-5α-pregnan-20-one[10] (X, 1.69 g), ethanol (60 ml), hydroxylamine hydrochloride (4.0 g) sodium acetate (4.7 g) and water (20 ml) was heated under reflux for 6 hr. On evaporation of some amount of solvent followed by cooling, crystals precipitated from the concentrated solution. Recrystallization from ethanol gave the oxime (XII, 1.59 g), mp 212.0—212.5°C; IR (Nujol): 3450 cm^{-1} (broad). Found: C, 75.55; H, 10.67; N, 3.94%. Calcd for $C_{21}H_{35}O_2N$: C, 75.63; H, 10.58; N, 4.20%.

17α-Hydroxy-20α-amino-5α-pregnane (XIII). 17α-Hydroxy-20-hydroxyimino-5α-pregnane (XII, 1.59 g) in acetic acid (180 ml) was hydrogenated in the presence of platinum oxide with addition of two drops of concentrated hydrochloric acid (*cf.* Ref. 4). After the acetic acid had been removed under reduced pressure, the residue was washed with chloroform and recrystallized from methanol. The product XIII gave one spot on tlc, mp 290°C (with decomposition), IR (Nujol): 3300 and 3260 cm^{-1}. From the chloroform washings, the starting material (XII, 50 mg) was recovered.

17aα-Methyl-D-homo-5α-androstan-17-one (IX). A solution of 17α-hydroxy-20α-amino-5α-pregnane (XIII, 318 mg) in acetic acid (15 ml) and water (13 ml) was kept at 0°C. To this solution was added dropwise, with stirring, a solution of sodium nitrite (1.0 g) in water (5 ml). The mixture was stirred for 4 hr at 0°C and allowed to stand at room temperature for 10 hr. The reaction mixture was filtered and the precipitate was washed with chloroform. The filtrate and the washings were combined and neutralized with aqueous sodium hydrogen carbonate solution (*cf.* Ref. 4). After an usual work-up, recrystallization from acetone yielded 181 mg of a ketone (IX), mp 138.0—138.5°C; IR (Nujol): 1710 cm^{-1}; Found: C, 83.26; H, 11.49%. Calcd for $C_{21}H_{34}O$: C, 83.38; H, 11.33%. MS: *m/e* 302 (M^+) and 230 [$(M-72)^+$; base peak]; PMR ($CDCl_3$): δ 0.77, 0.81 (s, *t*-CH_3), 1.08 ppm (d, J=7.0 Hz, *sec*-CH_3); PMR (C_6D_6): δ 0.66. 0.70 (s, *t*-CH_3), 0.85 ppm (d, J=7.5 Hz, *sec*-CH_3); ORD: $[\Phi]_{589}$ −170°, $[\Phi]^{trough}_{318}$ −2870°, $[\Phi]_{308}$ −2410° (sh), $[\Phi]^{peak}_{280}$ +1120°, and $[\Phi]_{234}$ −420°.

17aβ-Methyl-D-homo-5α-androstan-17-one (VIII). A solution of 17aα-methyl-D-homo-5α-androstan-17-one (XI, 91.6 mg) and potassium hydroxide (400 mg) in ethanol (47 ml) was refluxed under nitrogen for 16 hr. The solution was concentrated, treated with 1 M-hydrochloric acid and diluted with water. The precipitate was extracted with ether and the ethereal extract was washed with water, dried over sodium sulfate and evaporated to dryness giving rise to 88 mg of product. This showed two spots (R_f 0.5 and 0.4) on silica gel tlc developed with benzene and the lower spot was found to be identical with that of the starting material (IX). The mixture was separated by silica gel column chromatography into 17aα-methyl epimer (IX, 16.8 mg) and 17aβ-methyl epimer (VIII, 69 mg). The 17aβ-methyl epimer (VIII) showed mp 143.5°C; Found: C, 83.51; 11.44%. Calcd for $C_{21}H_{34}O$: C, 83.38; H, 11.33%. MS: *m/e* 302 (M^+) and 230 [$(M-72)^+$; base peak]; PMR ($CDCl_3$): δ 0.62, 0.72 (s, *t*-CH_3), 0.87 ppm (d, J=6.0 Hz, *sec*-CH_3); PMR (C_6D_6): δ 0.51, 0.66 (s, *t*-CH_3), 0.98 ppm (d, J=7.0 Hz, *sec*-CH_3); ORD: $[\Phi]_{589}$ −180°, $[\Phi]^{trough}_{312}$ −5740°, $[\Phi]_{304}$ −4980° (sh), $[\Phi]^{peak}_{270}$ +5010° and $[\Phi]_{222}$ +1660°.

Equilibration of 17aβ-Methyl-D-homo-5α-androstan-17-one (VIII) with Alkali. 17aβ-Methyl-D-homo-5α-androstan-17-one (VIII, 11.3 mg) was treated with potassium hydroxide (100 mg) in ethanol (2 ml) and subjected to equilibration for 17 hr. The equilibrating products were extracted and the ketone fraction was washed with water, dried and used for ORD measurement. ORD: $[\Phi]_{589}$ −175°, $[\Phi]^{trough}_{314}$ −4980°, $[\Phi]_{303}$ −3930° (sh), $[\Phi]^{peak}_{270}$ +3930° and $[\Phi]_{230}$ +1130°. These data show that the equilibrated ketone mixture consisted of 28% of 17aα- and 72% of 17aβ-epimers. On preparative tlc separation, the equilibrating mixture gave 17aα-methyl epimer (IX, 2.6 mg) and 17aβ-methyl epimer (VIII, 7.4 mg).

Ethylene Ketal (XIV) of 17aβ-Methyl-D-homo-5α-androstan-17-one (IX). 17aβ-Methyl-D-homo-5α-androstan-17-one (VIII, 10 mg) was dissolved in benzene (10 ml) and heated under reflux with ethylene glycol (4 ml) and *p*-toluenesulfonic acid (150 mg) for 13.5 hr under a nitrogen atmosphere. The reaction products were subjected to silica gel column chromatography and the ethylene ketal (XIV, 6.7 mg, recrystallized from acetone), mp 163°C; MS: *m/e* 346 (M^+) and 99 (fragment "a", base peak), was obtained.

Mesoionic 5-Acylimino-2-methylthiothiazoles

Toshie SHIBA and Hiroshi KATO*

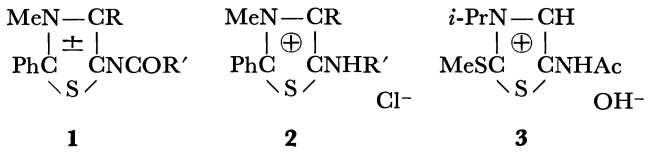
Okaya Works, Kyorin Pharmaceutical Co., Okaya 394

**Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390*

(Received October 27, 1972)

Treatment of 5-acylamino-4-thiazoline-2-thiones (**6**) with methyl iodide followed by treatment with an alkali gave the corresponding mesoionic 5-acylimino-2-methylthiothiazoles (**8**) instead of the corresponding thiazolium salts. The reactions of 2-methylthiothiazoles (**8**) with nucleophiles gave 2-substituted 5-acylamino-4-thiazolines.

We reported[1] on the preparation of mesoionic 5-acyliminothiazoles (**1**) by treatment of 3-substituted 5-acylaminothiazolium chlorides (**2**) with an alkali. Cook and Cox[2] claimed the preparation of 5-acetamido-2-methylthio-3-isopropylthiazolium hydroxide (**3**) by the reaction of 5-acetamido-3-isopropyl-4-thiazoline-2-thione and methyl iodide in the presence of sodium hydroxide. Although their results of elemental analyses agreed with those of thiazolium hydroxide structure, the substance might be assumed to actually have the corresponding anhydro-base or mesoionic structure, since the method of preparation is similar in principle to the one we employed for the preparation of mesoionic 5-iminothiazoles. The present study was initiated with the view of establishing the structure of the product obtained by Cook and Cox.



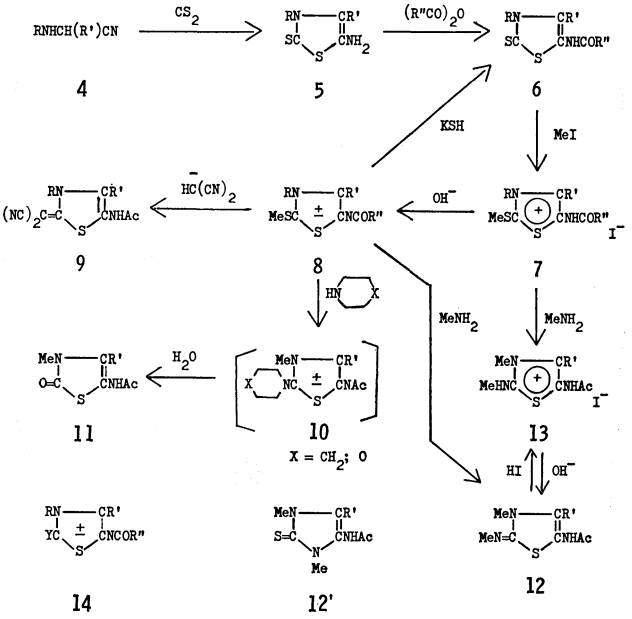
1 **2** **3**

The reactions between aminoacetonitriles (**4a—c**) and carbon disulfide gave 5-amino-4-thiazoline-2-thiones (**5a—c**), which, on treatment with acetic anhydride or benzoic anhydride, gave the corresponding acylamino-4-thiazoline-2-thiones (**6a—d**). Treatment of **6a—d** with methyl iodide gave the corresponding 5-acylamino-2-methylthiothiazolium iodides (**7a—d**), which gave the free bases **8a—d** on treatment with aqueous alkali.

The elemental analyses of the final products agreed with the anhydro-bases **8** but not with the thiazolium hydroxides of type **3**. A considerable bathochromic shift of the ultraviolet absorption maxima is observed with **8** in comparison with iodides **7**. The infrared spectra of **7** show an amide carbonyl band at 1650—1675 cm^{-1} whereas the free bases **8** show no carbonyl band above 1600 cm^{-1}.

From the results including spectral data (Table 2), we might conclude that the compounds obtained by treatment of iodides **7** with alkali are mesoionic 5-acylimino-2-methylthiothiazoles (**8**).

The same **8a** was isolated when **6a** was treated with methyl iodide in aqueous sodium hydroxide as described by Cook and Cox.[2] Treatment of **8a** with water did not afford hydroxide **3**. The melting points of **8a** (178—179°C) and its hydriodide **7a** (159—160°C) did not agree with the reported values (83°C and 182—183°C respectively).



a: R=*i*-Pr, R′=H, R″=Me
b: R=Me, R′=Me, R″=Me
c: R=Me, R′=Ph, R″=Me
d: R=Me, R′=Ph, R″=Ph

The NMR chemical shifts of the substituents of **8** (Table 2) appear at a region close to the values of the corresponding thiazolium salts **7**. The signal for the methylthio group of **8** is also shifted downfield in comparison with thioanisole (δ 2.47) and 2-methylthiopyrimidines (δ around 2.5).[3] These spectral values are very close to those of mesoionic 2-phenyl-5-acyliminothiazoles.[1] For the sake of comparison, 5-acetylimino- and 5-benzoylimino-3,4-dimethyl-2-phenylthiazole (**1b**: R=R′=Me; **1c**: R=Me, R′=Ph) were prepared by the method reported,[1] and the results are shown in Tables 1 and 2. The NMR data, together with the solvent dependent electronic spectra (See Table 2) and the lack of infrared carbonyl absorption in the normal infrared region suggest that the ring bears a considerable positive charge, and the acylimino group is strongly polarized; *i.e.*, there is a large contribution from resonance structures such as **8′** and **8″**.

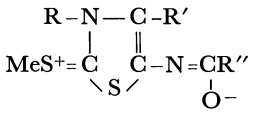
8′



8″

The mass spectra (see Experimental) of **8b** and **8c** show, besides the molecular ion peak, prominent fragmentation peaks corresponding to $(MeSCS)^+$, $(MeNCSMe)^+$, and $(MeNCR')^+$ as well as peaks of fragmentation at the ring substituents. It is to be noted that both **8b** and **8c** give fragment ion peaks corresponding to (M—133) with a considerable relative intensity.[4]

Since the spectral study suggested that the thiazole ring is positively charged, it was expected that the methylthio group of **8** would be readily replaced by nucleophiles.

Mesoionic 5-acylimino-2-methylthiothiazoles (**8a**—**c**) readily reacted with potassium hydrosulfide at room temperature to give the corresponding 5-acetamido-4-thiazoline-2-thiones (**6a**—**c**). The reaction between **8a**—**c** and dicyanomethide ion also gave the corresponding 2-dicyanomethylene derivatives **9a**—**c**. Methylthiothiazoles **8b** and **c** and their hydriodides **7b** and **c** reacted with piperidine and morpholine on heating in ethanol. However, the expected mesoionic 2-piperidino and 2-morpholino derivatives **10b** and **c** were not isolated, which apparently underwent hydrolysis to give the corresponding 5-acetamido-4-thiazolin-2-ones (**11b** and **c**) as the final products.

Although **8b** and **8c** did not react with aniline even on heating, they reacted with methylamine to give substitution products, the elemental analyses of which agreed with 2-methylimino derivatives (**12b** and **c**). However, an imidazoline-2-thione structure **12′** should also be considered as a possible structure of the reaction products since a similar skeletal rearrangement has been observed by the reactions of 5-methylthiothiazolium[5] and 5-methylthiothiadiazolium[6] salts and methylamine.

4) The high resolution mass spectrum of **8c** measured by Prof. Fukiko Yamada, Kansai University, gave the composition $C_9H_9N_2$ for this fragment.

5) T. Shiba and H. Kato, This Bulletin, **43**, 3491 (1970); P. B. Talukdar, S. K. Sengupta, and A. K. Datta, *Chem. Commun.*, **1972**, 696.

6) M. Ohta, H. Kato, and T. Kaneko, This Bulletin, **40**, 579 (1967).

Comparison of the NMR spectra of the reaction products and their hydriodides, formed either by the treatment of **12b** and **c** with hydriodic acid or directly by the reaction of methylthiothiazolium iodides **7b** and **c** and methylamine, shows that one methyl signal is shifted to a considerably lower magnetic field in going from the free base to the hydriodide, but the other remains almost unchanged. This suggests that one methyl group is substituted on a ring nitrogen atom while the other is substituted on an exocyclic nitrogen atom. This, together with the lack of infrared bands often observed with an N-C=S group,[6,7] supports the view that the reaction products have a 2-methyliminothiazoline structure **12b** and **c**. Although the mass spectra of **12b** and **c** do not provide information as to the choice of structure between **12** and **12'**, they show a strong peak corresponding to (M−116) which probably has the same composition as the (M−133) peak of **8**.

That the products of nucleophilic displacement reactions have 5-acetamido-4-thiazoline structures (**6**, **9**, **11**, **12**) rather than the corresponding mesoionic 2-substituted 5-acetyliminothiazole structures (**14**) was supported, *inter alia*, by the presence of the amide carbonyl band at a normal infrared region and the presence of an NH stretching frequency band. This shows that 4-thiazoline structures are thermodynamically more stable than the corresponding mesoionic thiazole structures.

Experimental[8]

*5-Amino-4-thiazoline-2-thiones (**5**).* A solution of 0.21 mol of aminoacetonitriles (**4**) and 16 g (0.21 mol) of carbon disulfide in 150 ml of ethyl acetate was allowed to stand at room temperature for two days. The solvent was concentrated and the residue was recrystallized. IR: **5b**: ~3300 (NH), 1620 (C=C), 1092, 1300 (C=S); **5c**: 3380—3300 (NH), 1620 (C=C), 1105, 1295 (C=S).

*5-Acylamino-4-thiazoline-2-thiones (**6**).* One part of 5-aminothiazolinethione (**5**) was dissolved in 20 parts of acetic anhydride and the resulting precipitate was collected. Benzoylation of **5c** was effected by heating equimolar amounts of **5c** and benzoic anhydride in benzene for twenty minutes. IR: **6a**: 3200—3100 (NH), 1665 (C=O), 1595 (C=C) 1075, 1290 (C=S); **6b**: ~3280 (NH), 1670 (C=O), 1630 (C=C), 1105, 1275 (C=S); **6c**: ~3320 (NH), 1650 (C=O), 1610 (C=C), 1120, 1294 (C=S); **6d**: ~3210 (NH), 1660 (C=O), 1610 (C=C), 1105, 1294 (C=S).

*5-Acylamino-5-methylthiothiazolium Iodides (**8**).* A solution of 5-acylamino-4-thiazoline-2-thione (**6**) and two molar equivalents of methyl iodide in methanol was heated under reflux; the solvent was concentrated and the residue was recrystallized.

*Mesoionic 5-Acylimino-2-methylthiothiazoles (**8**).* An aqueous solution (or suspension) of 5-acylamino-2-methylthiothiazolium iodide (**7**) was made alkaline with potassium carbonate and the crystals which separated out were collected and recrystallized. MS: **8b**: 216 (30) M, 201 (41) [M-Me], 91 (73) MeSCS, 88 (21) MeNCSMe, 83 (30) [M−MeSCS−Ac+H], 56 (88) MeNCMe, 43 (100) Ac. **8c**: 278 (41) M, 263 (38) [M−Me], 145 (19) [M−MeSCS−Ac+H], 118 (80) MeNCPh, 91 (97) MeSCS, 88 (32) MeNCSMe, 77 (48) Ph, 43 (100) Ac.

*Mesoionic 5-Acylimino-3,4-dimethyl-2-phenylthiazoles (**1**).* The compounds were prepared by methods similar to those described earlier.[1]

*Reactions of **8a–c** with Potassium Hydrosulfide.* To a solution of 0.5 g of **8** in 15 ml of ethanol was added a solution of two molar equivalents of potassium hydrosulfide in 10 ml of ethanol, and the resulting solution was stirred at room temperature for one hour. The reaction mixture was poured into water and the precipitate was collected, recrystallized and identified to be 5-acetamido-4-thiazoline-2-thiones (**6**) by mixed mp and comparison of their infrared spectra. Yields: 99, 96, and 87% from **8a**, **b**, and **c** respectively.

*5-Acetamido-2-dicyanomethylene-4-thiazolines (**9**).* One gram of **8a–c** was added under an atmosphere of nitrogen to a solution of dicyanomethide anion in 20 ml of dimethyl sulfoxide prepared from an equimolar amount of malononitrile and sodium hydride. The resulting solution was stirred at room temperature for two hours, and poured into 20 ml of water. The precipitate was collected and recrystallized. IR: **9a**: 3300—2700 (NH), 2200, 2175 (CN), 1670 (C=O), 1625 (C=C); **9b**: 3260—2840 (NH), 2200, 2165 (CN), 1680 (C=O), 1640 (C=C); **9c**: 3700—2900 (NH), 2200, 2170 (CN), 1665 (C=O), 1630 (C=C).

*5-Acetamido-4-thiazolin-2-ones (**11**).* A solution of **8** or **7** and an equimolar amount of piperidine or morpholine was heated under reflux for ten hours. The solvent was concentrated and the crystals which separated out were collected.

*5-Acetamido-2-methylimino-4-thiazolines (**12**).* A solution of 0.5 g of **8** and 1.5 ml of 30% ethanolic methylamine in 10 ml of ethanol was stirred at room temperature for ten hours. The reaction mixture was concentrated and the crystals which separated out were collected and recrystallized. MS: **12b**: 199 (56) M, 156 (29) [M−Ac], 83 (78) [M−MeNCS−Ac], 56 (100) MeNCMe, 43 (60) Ac; **12c**: 261 (49) M, 219 (15) [M−Ac+H], 218 (10) [M−Ac], 145 (36) [M−MeNCS−Ac], 118 (100) MeNCPh, 77 (42) Ph, 43 (29) Ac.

*5-Acetamido-2-methylaminothiazolium Iodides (**13**).* The compounds were prepared either by the action of hydroiodic acid on **12**, or by treatment of **7** with an excess of ethanolic methylamine at room temperature for ten hours. The yields given in Table 1 refer to those from **7**. The free bases **12** were formed by treatment of **13** with potassium carbonate.

We are indebted to the staff of Kyorin Chemical Laboratories for elemental analyses and mass spectral measurements.

7) T. G. Stewart and L. B. Kier, *J. Pharm. Sci.*, **54**, 731 (1965); P. B. Talukdar and S. K. Sengupta, *J. Indian Chem. Soc.*, **47**, 49 (1970); and references cited therein.

8) The melting points were determined on a micro hot stage and are not corrected. The ultraviolet spectra were recorded on a Hitachi model ESP-2U spectrophotometer, and the infrared spectra were recorded as KBr disks on a Hitachi model EPI-SII spectrophotometer. Unless otherwise stated, the NMR spectra were obtained on a JEOLCO JNM-4H-100 (100 MHz) spectrometer in deuteriochloroform, and the chemical shifts are recorded (ppm) downfield from internal TMS. The mass spectra were measured on a Hitachi RMU-6 spectrometer at 75 eV using a direct inlet technique. The yields, properties and elemental analyses are given in Table 1, and the spectral data of some compounds in Table 2.

Synthesis of a Gramicidin S Analog Containing δ-Aminovaleric Acid, [4–5-δ-Aminovaleric Acid]-Gramicidin S

Shōsuke SŌFUKU

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Tokyo, Japan

(Received July 6, 1972)

In order to investigate the contribution of amide bond in peptide to its activity and conformation, a new type of analog of gramicidin S, [4–5-δ-aminovaleric acid]-gramicidin S, was synthesized, in which one of the D-phenylalanyl-L-proline residues of gramicidin S was replaced with δ-aminovaleric acid residue. The analog peptide has antimicrobial activity and shows similar ORD and CD spectra to those of gramicidin S. The linear peptide (Val-Orn-Leu-δAva-Val-Orn-Leu-D-Phe-Pro) has no activity and its ORD and CD spectra are nearly the same as those of random coil of polypeptide.

Since the primary structure of antibiotic cyclodecapeptide gramicidin S (GS) from *Bacillus brevis* was confirmed by means of successful total synthesis by Schwyzer and Sieber,[1] a number of investigations have been undertaken to determine the higher structure of the antibiotic. Hodgkin and Oughton[2] proposed some possible models for GS from X-ray diffraction analysis. One of them, an antiparallel β-pleated sheet model, was favored by Schwyzer,[3] and supported by the results of nuclear magnetic resonance by Stern *et al.*[4] and others.[5,6] Several studies on optical rotatory dispersion (ORD)[7–9] and circular dichroism (CD)[7,10,11] of GS have also been undertaken to reveal the conformation in solution. A considerable number of analogs of GS have been prepared by Izumiya *et al.* in an effort to elucidate the relationship between structure and antimicrobial activity. In almost all cases, each amino acid residue of the natural peptide was replaced with a residue having a different side chain. Their results[12] suggested some fundamental significance of the presence of side chains of constituent amino acids, especially basic amino acid.[13] It was found that the analogs formed by replacing the L-proline residues of GS with glycine[14] or sarcosine[15] residues had an activity similar to that of GS. For determining the relation between ring-size of cyclic peptide and activity, cyclic pentapeptide (half-size compounds of GS[16] and some analogs[12,17]), cyclo-(Val-Orn-Leu-D-Phe-Pro-Gly),[18,19] cyclo (Val-Orn-Leu-D-Phe-Pro-Gly-Gly),[19,20] and [5,5′-βAla]-GS[21] were synthesized by Izumiya and his co-workers,but found to show no activity. It is consequently presumed that the ring-size of such an analog is an important factor in determining whether or not the analog possesses activity.

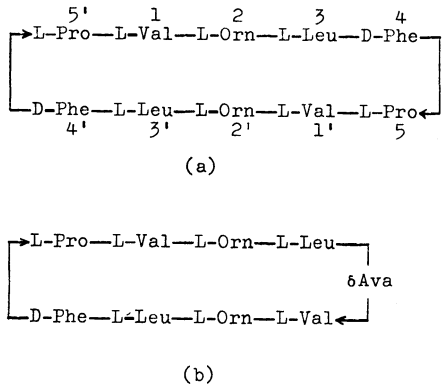


Fig. 1. Structure of GS (a) and [δAva$^{4-5}$]−GS (b).

Participation of amide bonds through hydrogen bonds between L-valine and L-leucine residues in holding the rigid ring structure of the peptide was confirmed by nmr studies.[4,5] However, it has not been ascertained whether all the amide bonds are indispensable for the function and conformation of the antibiotic. In order to determine this, we synthesized a new type of GS analog containing δ-aminovaleric acid residue (δAva). In this peptide, one of the D-phenylalanyl-L-proline residues of GS is replaced with δAva and, consequently, one amide group is displaced with an ethylene group (–CH_2–CH_2–) which has almost the same length as –CO–NH– but does not participate in the hydrogen bond. Since this analog and the

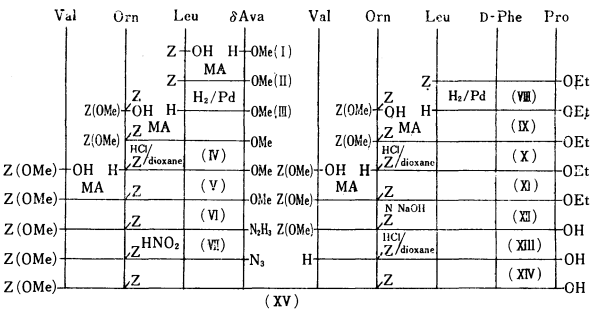
natural peptide have the same number of members in the ring although the side chains inevitably differ, it is expected that the analog peptide may have a similar ring structure and antimicrobial activity as those of the natural peptide if the amide group between phenylalanine and proline is not involved in any intramolecular hydrogen bond. We recently reported on the antimicrobial activity of this analog toward certain microorganisms,[22] giving details of the syntheses of the cyclic analog peptide and the related linear nonapeptide (Val-Orn-Leu-δAva-Val-Orn-Leu-D-Phe-Pro)[19] and their properties in comparison with GS.

Results and Discussion

Synthesis. The synthesis of the GS analog is shown in Schemes 1 and 2. The conventional coupling methods could be applied to the synthesis of peptide containing δAva as well as α-amino acid. Two fragments VI and XII were synthesized without racemization by using the procedure of stepwise elongation with the mixed anhydride method improved by Anderson *et al.*[24] The latter was saponified to XIII. After the removal of the *N*-protecting group of XIII, the resulting peptide XIV was coupled with VII to the linear nonapeptide XV by the Rudinger modification[25] of the azide method. Preparation of XV by hydrolyzing the ethyl ester (XX) of the peptide was unsuccessful under various of conditions. Cyclization of XV was carried out following the method of Schwyzer *et al.*[1,16] for the synthesis of GS. The cyclic peptide XVI was obtained in a good yield (70%) regardless of the presence of δAva in the middle of the linear peptide. This result might indicate that the conformation of the active ester of XV is so arranged as to be favorable for the cyclization as well as the synthesis of GS.[3] The desired [4-5-δAva]-GS XVII was obtained as a crystalline dihydrochloride by means of hydrogenolysis of benzyloxycarbonyl groups on ornithine residues of the cyclic peptide XVI in the presence of hydrogen chloride, followed by lyophilization in water.



Scheme 1.[19,23]

The linear nonapeptide trihydrochloride XVIII was prepared from peptide XV. *N*-Protecting groups of XV were removed with hydrogen bromide in acetic acid, and the hydrobromide of the product was transformed into trihydrochloride XVIII.

Characterization. Thin layer chromatography of each of the synthetic peptides XVII and XVIII gave one ninhydrin-positive spot. The chromatogram of paper electrophoresis is shown in Fig. 2. The linear peptide XVIII has three amino groups and hence moves faster than the others.

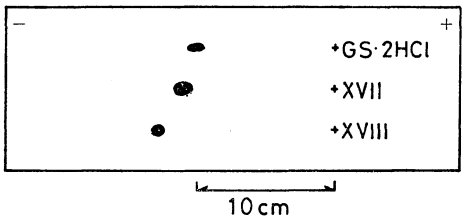


Fig. 2. Paper electrophoresis of cyclic analog (XVII), linear peptide (XVIII), and gramicidin S dihydrochloride (GS) (HCOOH-AcOH-H_2O; 4 : 15 : 180 v/v, pH 1.9, Toyo No. 50 15×40 cm, 600 v, 2 hours).

The free amino groups of the analog peptide XVII were detected by the DNS method in the usual manner.[26] After coupling the peptide with 1-dimethylamino-naphthalene-5-sulphonyl chloride (DNS-chloride) and hydrolyzing the DNS derivative, only the

N^{δ}-DNS-ornithine was detected on thin layer chromatograms,[27] which proves that the analog has a cyclic form. The IR spectrum of XVII was measured as a KBr disk and the absorption bands of amide I (1640 cm^{-1}) and II (1530 cm^{-1}) were in good agreement with those of GS. The IR spectrum of XVIII had a band at 1727 cm^{-1} (-COOH) besides bands I and II.

On the Structure and Biological Activity. Analog XVII has an antimicrobial activity in the range from the same to half that of GS toward certain microorganisms, and about one third of the acute toxicity of GS in mice when given intravenously.[22] Linear nonapeptide XVIII has no activity toward the same microorganisms. To obtain information on the conformation of this biological active analog, ORD and CD were measured. ORD studies on GS and several other GS analogs had been carried out by Craig,[8] Balasuburamanian,[7] and Kato *et al.*[9] Kato *et al.* pointed out that GS and biological active analogs showed negative Cotton effect at 232 mμ and inactive analogs gave curves differing from that of GS. The ORD of the new analog has a trough similar to GS at 232 mμ in both ethanol and water (Fig. 3). In the case of XVIII, a trough is found at 210 mμ with hypsochromic shift. The trough corresponded to that of random structure of polypeptide.[28] The CD spectra of XVII and XVIII are shown in Fig. 4. The minimum value of XVII appears at 203 mμ and a shoulder at 216 mμ. This band is observed at a wavelength slightly shorter than that of the band of GS (at 206 mμ). Laiken *et al.*[11] found that the CD of modified GS, in which D-phenylalanine residues were hydrogenated, showed two minima in the same region as that of GS. They supposed that the two minima are attributable to the common backbone conformation of both peptides. The CD of XVIII is regarded as that of random structure[29,30] in the same manner as ORD. Thus, the CD band of XVII in the region of 203—216 mμ seems to be attributable to the backbone conformation. The CD spectrum resembles one typical of the α-helix conformation of polypeptide but the wavelength of the minimum differs from that of α-helix and also β-structure.[29,30] It seems reasonable to assume that the CD of GS or its analog is characteristic for such cyclic oligopeptides. The CD spectra in the region near 260 mμ were measured and the bands[31] caused by phenylalanine residue were found. We might conclude that the analog XVII has a conformation similar to that of GS both from the results of ORD and CD measurements and from a valuation of the biological activity. The results also support the antiparallel β-pleated sheet structure of GS proposed by Stern *et al.* and Schwyzer, in which amide groups of phenylalanylproline residues do not take part in any intramolecular hydrogen bond.

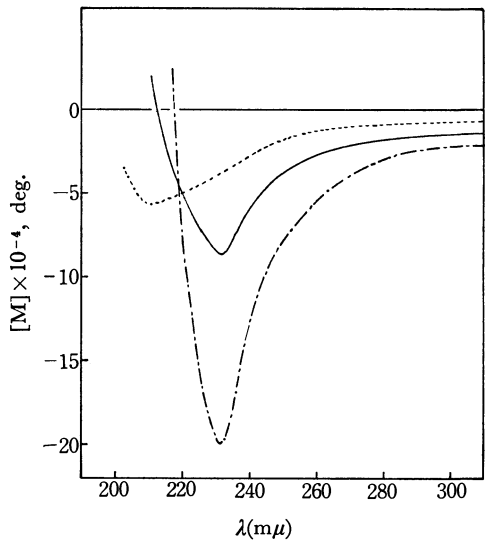

Fig. 3. Optical rotatory dispersions of cyclic analog (XVII), linear peptide (XVIII), and gramicidin S dihydrochloride (GS) in water, XVII (—), XVIII (·····), and GS (—·—). Measurments were made using a 1 mm quartz cell at room temperature.

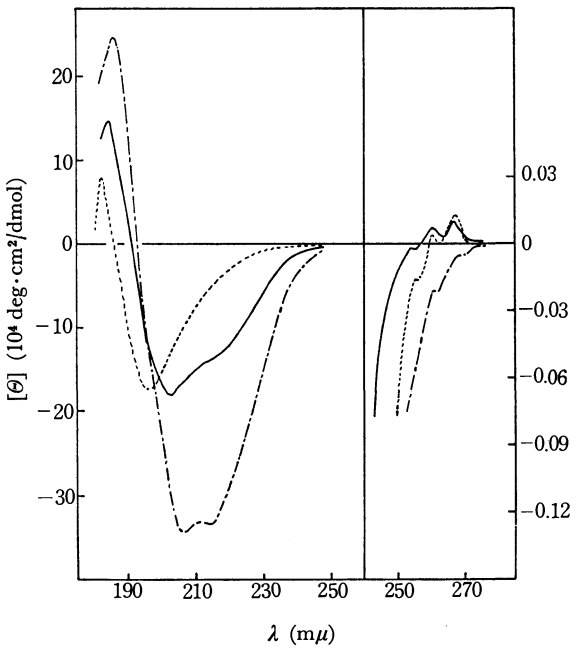

Fig. 4. Circular dichroism spectra of cyclic analog (XVII), linear peptide (XVIII), and gramicidin S dihydrochloride (GS) in water, XVII (——), XVIII (·····), and GS(———). Measurments were made using 0.5 mm (<250 mμ) and 10 cm (>240 mμ) quartz cells at room temperature.

Experimental

All melting points are uncorrected. ORD measurements were performed with a JASCO model UV/ORD-5 and the results were expressed in terms of molar optical rotations.

27) DNS-amino acid was detected as a green spot under UV (254 mμ). R_f values of δ-DNS-ornithine were 0.5 on silica gel plate with *n*-butanol-acetic acid-water (10 : 1 : 1, v/v) and 0.3 on polyamide plate with benzene-acetic acid-*n*-butanol (9 : 2 : 1, v/v).

CD spectra were measured with a JASCO model J-20 and represented by molar ellipticity values. IR spectra were recorded on a Hitachi grating infrared spectrophotometer model 215. The molecular weight of XVI was determined with a Hitachi-Perkin-Elmer vapor pressure osmometer model 115, using methanol. Amino acid analyses were carried out with an automatic amino acid analyzer,[32] after hydrolysis of XVII and XVIII in 6 N hydrochloric acid for 19 hours at 110°C. The purity of the peptide derivatives at each step was confirmed by thin layer chromatography on a silica gel plate with the following solvent systems (v/v): Solv. 1, chloroform–methanol–acetic acid (95 : 5 : 3); Solv. 2, chloroform–methanol (9 : 1); Solv. 3, chloroform–methanol–acetic acid–pyridine (95 : 5 : 3 : 4); Solv. 4, chloroform-methanol–acetic acid (12 : 1 : 1); Solv. 5, *n*-butanol–acetic acid–water (4 : 1 : 1); Solv. 6, *n*-butanol –acetic acid–pyridine–water (4 : 1 : 1 : 2). Compounds possessing free amino groups were detected by spraying ninhydrin reagent. *N*-Protected compounds were also detected with ninhydrin after deblocking with concd. hydrobromic acid.

Methyl δ-Aminovalerate Hydrochloride (I). A solution of δ-valerolactam (45.0 g) in 500 ml of methanol was saturated with dry hydrogen chloride and refluxed for 3 hours. The reaction mixture was concentrated *in vacuo* to an oily residue which was dissolved in methanol. The colorless product was crystallized by the addition of ethyl ether, and collected by filtration; yield, 58.0 g (76.2%). This ester was also obtained by Fischer's esterification from δ-aminovaleric acid in a 95% yield. Mp 145—146°C (lit,[33] mp 145—146°C); Tlc: 0.75 (Solv. 6). (Found: C, 42.94; H, 8.32; N, 8.65%).

Methyl Benzyloxycarbonyl-L-leucyl-δ-aminovalerate (II). Benzyloxycarbonyl-L-leucine obtained from the corresponding dicyclohexylammonium salt[34] (9.0 g, 20.0 mmol) was dissolved in 100 ml of tetrahydrofuran, and 1.74 ml of *N*-methylmorpholine and 2.68 ml of isobutyl chloroformate were added at −15°C. After 5 min, a chilled mixture of 3.34 g (21.5 mmol) of I and 2.8 ml of triethylamine in 15 ml of chloroform was added at −15° to a solution of the mixed anhydride prepared in the preceding step. The reaction mixture was stirred at 5°C for one hour and then at room temperature for one hour. After removal of insoluble materials by filtration, the filtrate was concentrated *in vacuo*. The residue was dissolved in ethyl acetate, and the solution was washed successively with 5% sodium bicarbonate, water, 0.5 N hydrochloric acid and water, and then dried over sodium sulfate. After the solvent was evaporated *in vacuo*, the product was recrystallized from ethyl acetate and petroleum ether. Yield, 5.40 g (71.4%); mp 89—90°C; $[\alpha]_D^{22}$ −15.3° (*c* 1.5, ethanol); Tlc: R_f 0.7 (Slolv. 1).

Found: C, 63.37; H, 8.27; N, 7.64%. Calcd for $C_{20}H_{30}N_2O_5$: C, 63.47; H, 7.99; N, 7.40%.

Methyl L-Leucyl-δ-aminovalerate Hydrochloride (III). II (4.5 g, 11.9 mmol) was hydrogenolyzed in the usual manner over 0.2 g of palladium black in a mixture of 40 ml of ethanol and 6 ml of 2 N hydrochloric acid. After 4 hours, the filtrate from the catalyst was concentrated to dryness *in vacuo*. The oily product was obtained in a theoretical yield. Tlc: R_f 0.1 (Solv. 1).

Methyl N^{α}-p-*Methoxybenzyloxycarbonyl-*N^{δ}*-benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovalerate (IV).* This was prepared from N^{α}-*p*-methoxybenzyloxycarbonyl-N^{δ}-benzyloxycarbonyl-L-ornithine[35] (30.0 mmol) and III (30.0 mmol) by a method similar to that for the synthesis of II. The product was recrystallized from ethanol. Yield, 14.56 g (73.9%); mp 154—157°C; $[\alpha]_D^{20}$ −7.7°C (*c* 1, dimethylformamide); Tlc: R_f 0.6 (Solv. 1).

Found: C, 62.42; H, 7.44; N, 8.40%. Calcd for $C_{34}H_{48}N_4O_9$: C, 62.17; H, 7.37; N, 8.53%.

Methyl N^{α}*-Benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovalerate Hydrochloride (V).* To a solution of IV (5.5 g, 8.4 mmol) in 33 ml of chloroform were added 3.73 N hydrogen chloride in dioxane (11.3 ml) and 2.5 ml of anisole. The solution was stirred at room temperature for 10 min and then concentrated *in vacuo*. The residue was washed several times with ethyl ether and dried *in vacuo*. The product was obtained in a theoretical yield. Tlc: R_f 0.65 (Solv. 5).

Methyl p-*Methoxybenzyloxycarbonyl-L-valyl-*N^{δ}*-benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovalerate (VI).* *p*-Methoxybenzyloxycarbonyl-L-valine[35] (12.0 mmol) was coupled with V (8.4 mmol) by the mixed anhydride method. After removal of the precipitate in the reaction mixture by filtration, the filtrate was concentrated to dryness *in vacuo*. The residue washed with petroleum ether by decantation was combined with the above precipitate. The solids were washed on a filter funnel successively with water, 5% sodium bicarbonate, water, 10% citric acid and water, and dried under reduced pressure. The product was recrystallized from methanol and ethyl ether. Yield, 4.93 g (77.2%); mp 204—205°C; $[\alpha]_D^{20}$ −8.5° (*c* 2, dimethylformamide); Tlc: R_f 0.9 (Solv. 6).

Found: C, 61.82; H, 7.56; N, 9.21%. Calcd for $C_{39}H_{57}N_5O_{10}$: C, 61.97; H, 7.60; N, 9.27%.

p-*Methoxybenzyloxycarbonyl-L-valyl-*N^{δ}*-benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovaleryl Hydrazine (VII).* To a solution of 2.27 g (3.0 mmol) of VI in 18 ml of dimethylformamide was added 5.63 g (90 mmol) of 80% hydrazine hydrate and the solution was stirred for 2 days at room temperature. The hydrazide, precipitated by the addition of 340 ml of water, was filtered and washed with water. A white product dried under reduced pressure was obtained in a yield of 2.26 g (99.6%). Mp 215—217.5°C; $[\alpha]_D^{18}$ −9.0° (*c* 1, hexamethylphosphoramide); Tlc: R_f 0.7 (Solv. 1).

Found: C, 60.17; H, 7.84; N, 12.92%. Calcd for $C_{38}H_{57}N_7O_9$: C, 60.38; H, 7.60; N, 12.97%.

Ethyl N^{α}-p-*Methoxybenzyloxycarbonyl-*N^{δ}*-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolinate (X).* Ethyl L-leucyl-D-phenylalanyl-L-prolinate hydrochloride (IX)[36] obtained from VIII (31.0 mmol) by hydrogenolysis was coupled with N^{α}-*p*-methoxybenzyloxycarbonyl-N^{δ}-benzyloxycarbonyl-L-ornithine[35] (31.5 mmol) by the mixed anhydride method. The product was purified in a manner similar to that for II and weighed 19.47 g (77.0%). Mp 135—138°C; $[\alpha]_D^{30}$ −52.4° (*c* 1, methanol); Tlc: R_f 0.55 (Solv. 1).

Found: C, 64.59; H, 7.17; N, 8.58%. Calcd for $C_{44}H_{57}N_5O_{10}$: C, 64.77; H, 7.04; N, 8.58%.

Ethyl N^{δ}*-Benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolinate Hydrochloride (XI).* To a solution of X (12.24 g, 15 mmol) in 120 ml of dioxane was added 5.5 M hydrogen chloride in dioxane (68.2 ml) in an ice bath, and the solution was stirred at room temperature. After 45 min a white precipitate appeared and the reaction was completed in

4 hours. The product, a white hygroscopic precipitate, was obtained in a reasonable yield after evaporation of the solvent *in vacuo* and washing with ethyl ether by decantation. Mp 126—130°C; Tlc: R_f 0.05 (Solv. 1).

Ethyl p-*Methoxybenzyloxycarbonyl*-L-*valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-D-*phenylalanyl*-L-*prolinate (XII).* This was obtained from *p*-methoxybenzyloxycarbonyl-L-valine[35] (15.0 mmol) and XI (15.0 mmol) by the method for VI. The crude product was recrystallized from ethyl acetate. Yield 12.27 g (89.4%); mp 153—156°C; $[\alpha]_D^{23}$ −29.5° (*c* 1, dimethylformamide), (lit,[16] mp 149—150°C; $[\alpha]_D^{24}$ −26.8° (*c* 2, dimethylformamide)), Tlc: R_f 0.65 (Solv. 3). (Found: C, 64.33; H, 7.38; N, 9.02%).

p-*Methoxybenzyloxycarbonyl*-L-*valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-D-*phenylalanyl*-L-*proline (XIII).*[16] XII (2.29 g, 2.5 mmol) was saponified according to Ref. 16. The reaction mixture was acidified to pH 4.2 with 25 ml of 2.2% citric acid on cooling, and concentrated *in vacuo*. The residue was washed with 5% citric acid and water, and dried under reduced pressure. Recrystallization from methanol and ethyl ether gave 1.75 g (78.8%) of the product. Mp 149—150.5°C; $[\alpha]_D^{21}$ −31.9° (*c* 1, dimethylformamide); Tlc: R_f 0.5 (Solv. 3).

Found: C, 62.68; H, 7.19; N, 9.54%. Calcd for $C_{47}H_{62}N_6O_{11}\cdot H_2O$: C, 62.36; H, 7.13; N, 9.29%.

L-*Valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-D-*phenylalanyl*-L-*proline Hydrochloride (XIV).* When XIII (1.24 g, 1.6 mmol) was subjected to the same treatment as for V, the product was obtained in a theoretical yield. Mp 153—157°; Tlc: R_f 0.1 (Solv. 1).

p-Methoxybenzyloxycarbonyl-L-*valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-δ-*aminovaleryl*-L-*valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-D-*phenylalanyl*-L-*proline (XV).* To a suspension of 1.21 g (1.6 mmol) of VII in 26 ml of dimethylformamide were added 5.5 N hydrogen chloride in dioxane (1.12ml) and 0.43 ml of *n*-butyl nitrite.[37] To this mixture a solution of 1.6 mmol of XIV and 0.44 ml of triethylamine in 38 ml of dimethylformamide was added dropwise at −20——30°C, and the stirring was continued at this temperature for 15 min and at 0°C for 2 days. The crude product precipitated on pouring the reaction mixture into 500 ml of cold water was filtered and washed with cold 5% citric acid and water and dried. It was dissolved in 130 ml of dimethylformamide and the insoluble material was removed by filtration. The product was precipitated by addition of ethyl ether into the filtrate. After filtering off and drying it weighed 1.614 g (69.7%). Mp 225—227°C (decomp.). It was then recrystallized from a large quantity of methanol. Yield, 1.354 g (58.5%); mp 226°C (decomp.); $[\alpha]_D^{21}$ −34.4° (*c* 0.5, dimethylformamide); Tlc: R_f 0.55 (Solv. 4).

Found: C, 63.19; H, 7.73; N, 10.69%. Calcd for $C_{76}H_{107}N_{11}O_{17}$: C, 63.09; H, 7.46; N, 10.65%.

Cyclo-L-*valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-δ-*aminovaleryl*-L-*valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-D-*phenylalanyl*-L-*prolyl (XVI).* The reaction of XV (723 mg, 0.5 mmol) and dinitrophenylsulfite[38] (1.62 g, 5 mmol) in a mixture of pyridine (6 ml) and dimethylformamide (20 ml) at room temperature for 41 hours gave the *p*-nitrophenyl ester of XV. After evaporation of the reaction mixture *in vacuo* and treatment of the residue with a mixture of *n*-hexane and ethyl ether (1 : 1), the dried colorless product was dissolved in trifluoroacetic acid (5 ml) containing anisole (0.8 ml) in an ice-salt bath. After 20 min, the reaction mixture was concentrated *in vacuo* at 0°C. The residue was triturated with ethyl ether and the supernatant liquid removed by decantation. A solution of the residue in dimethylformamide (10 ml) containing acetic acid (0.13 ml) was added dropwise into 330 ml of anhydrous pyridine with stirring at 58—60°C over 2.5 hours. The reaction mixture was further stirred for 5 hr at this temperature and then evaporated to dryness *in vacuo*. The yellow residue was dissolved in a mixture of methanol and water (7 : 1) and this solution was passed successively through columns of Dowex-1 (OH^- form) and Dowex-50 (H^+ form) which had been washed with the same solvent. The effluent (total 300 ml) was concentrated to dryness *in vacuo* and a white crystalline product was obtained in a 81% yield, mp 212—215°C. It was recrystallized from 90% methanol. Yield, 446.7 mg (70.6%); mp 221—223°C; $[\alpha]_D^{27}$ −207.0° (*c* 0.5, methanol); Tlc: R_f 0.6 (Solv. 1), 0.65 (Solv. 4), 0.95 (Solv. 6); MW, Found: 1224.5 (Calcd for $C_{67}H_{97}N_{11}O_{13}$: 1264.6).

Found: C, 63.43; H, 7.87; N, 11.93%. Calcd for $C_{67}H_{97}N_{11}O_{13}$: C, 63.64; H, 7.73; N, 12.18%.

Cyclo-L-*valyl*-L-*ornithyl*-L-*leucyl*-δ-*aminovaleryl*-L-*valyl*-L-*ornithyl*-L-*leucyl*-D-*phenylalanyl*-L-*prolyl Dihydrochloride (XVII).* XVI (252.9 mg, 0.2 mmol) in *ca.* 8 ml of methanol containing 0.89 N methanolic hydrogen chloride (0.68 ml) was hydrogenolyzed in the presence of palladium black (30 mg) for 8 hours. After removal of the catalyst, the filtrate was concentrated to dryness *in vacuo*. The residue was dissolved in water and the solution was filtered through active charcoal. A white crystalline product was obtained by lyophilization of the filtrate which was dried in a desiccator over calcium chloride. Yield, 192.9 mg (90.2%); mp 251—252 °C (decomp.); $[\alpha]_D^{28}$ −204.0° (*c* 0.1, ethanol); Tlc: R_f 0.75 (Solv. 6); IR: 1530, 1640 cm^{-1} (KBr). Amino acid ratios: Val, 2.09; Orn, 1.90; Leu, 2.09; Phe, 1.00; δAva, 0.83. When the sample dried in a vacuum over phosphorous pentoxide at 105°C for 6 hours was left standing in the air, it rapidly absorbed moisture. The increase in weight was 9.6%, which was in good agreement with one (10.5%) calculated from change of the anhydrous form to the heptahydrate.

Found: C, 51.16; H, 8.59; N, 12.71; Cl, 6.38%. Calcd for $C_{51}H_{87}N_{11}O_9Cl_2\cdot 7H_2O$: C, 51.24; H, 8.52; N, 12.89; Cl, 5.93%.

L-*Valyl*-L-*ornithyl*-L-*leucyl*-δ-*aminovaleryl*-L-*valyl*-L-*ornithyl*-L-*leucyl*-D-*phenylalanyl*-L-*proline Trihydrochloride (XVIII).* XV (434 mg, 0.3 mmol) was added into 25% hydrogen bromide in acetic acid (2.5 ml) in an ice bath. The solution was shaken at room temperature for one hour and concentrated *in vacuo*. Treatment of the oily residue with cold ethyl ether afforded a hygroscopic solid, which was collected by filtration and dried rapidly under reduced pressure. An aqueous solution of the product was charged to a column (1.5 × 13 cm) of Dowex-50 (H^+ form) and the column was washed with water. Pyridine-acetate buffer was used for elution and the effluent was collected in *ca.* 7 ml fractions, each of which was tested by thin layer chromatography with ninhydrin. Buffers[39] of pH 4.87, 4.96, and 5.13 were used for fraction numbers 1—37, 38—50, 51—65, respectively. Fraction nos. 21—65 were combined and concentrated *in vacuo*. Addition of water to the residue and evaporation were repeated several times to remove pyridine and acetic acid completely. The product was dissolved in a small amount of methanol. Hydrogen chloride in tetrahydrofuran (4.09 N, 3 ml) was added to it. The solution was

Found: C, 50.43; H, 8.27; N, 12.69; Calcd for $C_{51}H_{90}N_{11}O_{10}Cl_3 \cdot 5H_2O$: C, 50.47; H, 8.30; N, 12.96%.

Antimicrobial activity of XVIII for some microorganisms (*Bacilus subtilis*, *Staphylococcus aureous*, *Micrococcus flavus*, *Sarcina lutea*, *Proteus vulgaris etc.*) was examined by the agar dilution method, but no inhibition was observed in concentrations below 100 μg/ml.

Ethyl L-*Valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-D-*phenylanalyl*-L-*prolinate Hydrochloride (XIX).* To a solution of XII (2.29 g, 2.5 mmol) in 20 ml of dioxane was added 3.73 N hydrogen chloride in dioxane (20 ml). The solution was stirred at room temperature for 3 hours and then concentrated to dryness *in vacuo*. The product was obtained as oil in a theoretical yield. Tlc: R_f 0.35 (Solv. 2).

Ethyl p-*Methoxybenzyloxycarbonyl*-L-*valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-δ-*aminovaleryl*-L-*valyl*-N$^{\delta}$-*benzyloxycarbonyl*-L-*ornithyl*-L-*leucyl*-D-*phenylalanyl*-L-*prolinate (XX).* VII (1.89 g, 2.5 mmol) was dissolved in 60 ml of dimethylformamide containing 10 ml of acetic acid; 190 mg of sodium nitrite in 4 ml of water and 7.5 ml of 1 N hydrochloric acid were then added at 0—5°C under vigorous stirring. After 15 min, the reaction mixture was poured into cold water (700 ml). In a cold room the white precipitate was filtered and washed on a funnel successively with cold water, 5% sodium bicarbonate, and water. This peptide azide was dried in a desiccator over phosphorous pentoxide. The azide was added to a solution of XIX (2.5 mmol) and 0.35 ml of triethylamine in 85 ml of dimethylformamide, and the mixture was stirred for 7 days at 0°C. The insoluble substance was removed by filtration and the filtrate was poured into water. The precipitate was collected, and washed with 5% citric acid, water, 5% sodium bicarbonate, and water. After drying, the product was purified from dimethylformamide and ethyl ether. Yield, 2.18 g (59.2%); mp 218—225°C (decomp.); $[\alpha]_D^{21}$ −32.4° (*c* 0.5, dimethylformamide); Tlc: R_f 0.6 (Solv. 2).

Found: C, 63.52; H, 7.59; N, 10.45%. Calcd for $C_{78}H_{111}N_{11}O_{17}$: C, 63.64; H, 7.85 N, 11.29%.

The author wishes to express his sincere gratitude to Professor I. Muramatsu for his suggestions and support in this work, and to Professor A. Hagitani for his encouragement. He also wishes to thank Mr. T. Takakuwa, Applied Research Laboratory of the Japan Spectroscopic Co., for the measurements of CD and ORD, and the members of the Research Laboratories of Toyo Jozo Co., for elementary and amino acid analyses and microbiological assays.

The Syntheses of Heterocyclic Compounds by the Ternary Condensation of Malononitrile, Salicylaldehyde, and Aliphatic Ketones in the Presence of Ammonium Acetate

Akio SAKURAI, Yoshito MOTOMURA,* and Hiroshi MIDORIKAWA

The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received July 28, 1972)

Various 2-amino-6-alkyl (or 5,6-dialkyl)-4-aryl-4,5-dihydronicotinonitriles (**1**) were readily prepared by the ternary condensation of malononitrile, salicylaldehyde (or 3-methoxysalicylaldehyde), and aliphatic ketones in the presence of ammonium acetate. The resulting **1** was transformed into the corresponding 3-carbamoyl derivatives (**3**) *via* their 2-acetamino derivatives (**2**). In addition, the reaction of **3** with acetic anhydride led to [2,3-*d*]pyridopyrimidine derivatives (**4**).

In a previous paper,[1] the syntheses of benzopyranopyrido-pyrimidine and benzopyranopyridine derivatives by the ternary condensation of malononitrile, salicylaldehyde, and aromatic ketones in the presence of ammonium acetate were reported.

The present paper will deal with the syntheses of substituted 4,5-dihydronicotinonitriles (**1**), 1,4,5,6-tetrahydro-[2,3-*d*] pyridopyrimidines (**4**), and 4,4a,5,6,7,8-hexahydroquinolines (**8**) by the ternary condensation of malononitrile, salicylaldehyde (or 3-methoxysalicylaldehyde), and aliphatic ketones, *e. g.*, acetone, methyl ethyl-, methyl *n*-propyl, and diethyl ketone, and cyclohexanone in the presence of ammonium acetate.

The reaction of malononitrile, 3-methoxysalicylaldehyde, and the *n*-alkyl ketone (molar ratio of 1 : 1 : 1) in the presence of ammonium acetate (1 mol or a slight excess) gave 2-amino-6-alkyl (or 5,6-dialkyl)-4-(2-hydroxy-3-methoxyphenyl)-4,5-dihydronicotinonitriles (**1**) in 13—23% yields. The subsequent treatment of the resulting **1** with acetic anhydride led to the corresponding 2-acetamino derivatives (**2**), which were then further transformed into 3-carbamoyl derivatives (**3**) by the action of acetic acid in refluxing ethanol. The further treatment of **3** with boiling acetic anhydride afforded cyclization products, such as 5-(2-hydroxy-3-methoxyphenyl)-2,7-dimethyl (or 2,6,7-trimethyl)-4-oxo-1,4,5,6-tetrahydro[2,3-*d*]pyridopyrimidines (**4**), as is indicated in Scheme 1. On the other hand, **2b** (**2**, R_1=OCH_3, R_2=H, R_3=CH_3) was converted directly to **4a** (**4**, R_1=OCH_3, R_2=H,

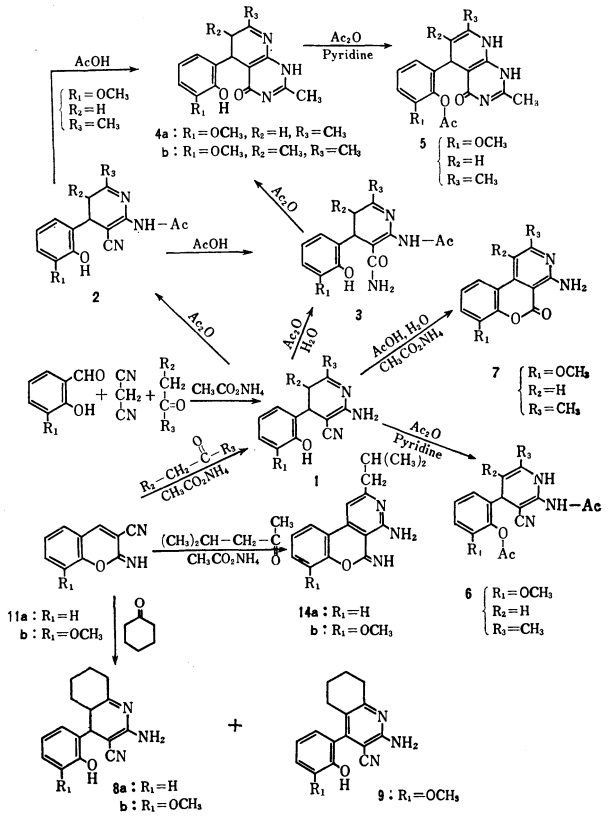

Scheme 1.

$R_3=CH_3$) by treatment with acetic acid in boiling ethanol. The acetylation of **4a** with acetic anhydride in boiling pyridine afforded 5-(2-acetoxy-3-methoxyphenyl)-2,7-dimethyl-4-oxo-1,4,5,8-tetrahydro[2,3-*d*]pyridopyrimidine (**5**). The acetylation of **1b** with acetic anhydride gave **2b**, while the same reaction of **1b** with acetic anhydride-pyridine gave 2-acetamino-4-(2-acetoxy-3-methoxyphenyl)-6-methyl-1,4-dihydronicotinonitrile (**6**). On the other hand, when heated with acetic acid containing a few drops of water in the presence of ammonium acetate, **1b** was cyclized to 4-amino-7-methoxy-2-methyl-5-oxo-[1]benzopyrano-[3,4-*c*]pyridine (**7**),[2] which was proved, on the basis of the spectral studies, to be identical with that previously-reported substance obtained by the condensation of ethyl cyanoacetate, 3-methoxysalicylaldehyde, and acetone. Type 1 compounds were also obtained in 13—33% yields by the condensation of 3-cyanocoumarinimide (**11**) with *n*-alkyl ketones. The reaction of cyclohexanone with **11a** afforded 16% of 2-amino-3-cyano-4-(2-hydroxyphenyl)-4,4*a*,5,6,7,8-hexahydroquinoline (**8a**), while the same reaction with 11b gave a mixture of **8b** (27%) and its 5,6,7,8-tetrahydro derivative **9** (7%) under the same reaction conditions (Scheme 1). When a methyl isoalkyl ketone such as the methyl isobutyl ketone was employed as the ketone reactant, ring-opening did not occur. For example, the condensation of **11b** with methyl isobutyl ketone afforded 4-amino-5-imino-2-isobutyl-7-methoxy-[1]-benzopyrano[3,4-*c*]pyridine (**14b**), which was then hydrolyzed to the corresponding 5-oxo compound.[2]

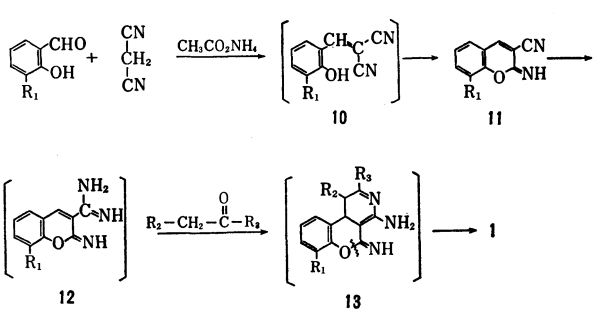

Scheme 2.

It seems reasonable to assume that the formation of 1 may be achieved by the following process. Malononitrile is first condensed with salicylaldehyde in the presence of ammonium acetate to give **10**, which is then readily converted to **11**. This is further transformed into amidine-type **12**. Then, **12** condenses with the *n*-alkyl ketone to form **13**, which immediately undergoes ring-opening to yield **1** (Scheme 2).

In the IR spectra of **1**, **2**, and **8**, C≡N stretching bands were shifted to lower frequencies at 2160—2150 cm^{-1} (**1**), 2170 cm^{-1} (**2**), and 2170—2140 cm^{-1} (**8**) respectively, whereas the stretching bands of **6** and **9** appeared at 2200 cm^{-1}. The NMR spectra of **1a-e** in $(CD_3)_2SO$ showed a methyl singlet due to three protons in the 1.5—1.7 ppm region. In addition, **1c** (from methyl ethyl ketone) gave a methyl doublet, centered at 0.98 ppm, due to three protons. These NMR data suggest that the methylene group adjacent to the carbonyl group of the ketones, such as the methyl ethyl-, methyl *n*-propyl-, and diethyl ketone, is involved in this cyclization. The structural assignment of **1**, therefore, was based on the above spectral data and the fact that **1b** gave the expected compound, **7**. The IR spectrum of **3a** (obtained when **2b** was heated with acetic acid in ethanol) gave no absorption band due to a C≡N stretching, but new bands appeared at 3440, 3350, 3320, and 3180 cm^{-1}. In the spectrum of **4a**, however, the primary amino stretching bands disappeared and only the absorption at 3310 cm^{-1} was observed in this region. The NMR spectrum in CF_3CO_2H revealed two singlets, at 2.0 and 2.8 ppm, due to three protons. The former was assigned to a methyl proton at the 7-position by means of a NMR comparison of the methyl protons in **1b**, **2b**, and **3a** (Tables 1, 2, and 3). The latter signal, therefore, was assigned to a methyl proton of the 2-position. The NMR spectrum in $(CD_3)_2SO$ of **5** (derived from **4a**) gave a new methyl singlet at 2.24 ppm, and the IR spectrum showed a new absorption band at 1755 cm^{-1} attributable to acetoxy carbonyl. These observations show that the hydroxy group of **3a** is independent of the cyclization to **4a**. The NMR spectrum of **5** exhibited signals of methine doublets at 4.24 and 4.62 ppm, each corresponding to one proton, but no signal for the methylene group was observed in Compound **4a**. This suggests that compound **5** is predominantly in the 1,4,5,8-tetrahydro form rather than in the 1,4,5,6-tetrahydro form of [2,3-*d*]pyridopyrimidine. Similarly, **6** (derived from **1b**) is predominantly in the 1,4-dihydro form of ni-

a) Yield based on **1**. b) Parts per million downfield from tetramethylsilane in $(CD_3)_2SO$; s, singlet; d, doublet; t, triplet; br, broad. In **3a** spectrum, δCH_2 1.8—2.1 ppm, overlapped with CH_3 (δ 1.98), 5H.

cotinonitrile, judging from the NMR spectrum, which has methine doublets at 4.27 and 4.43 ppm, each corresponding to one proton. On the other hand, the IR spectra of the compound, **14**, obtained by the condensation of **11** with methyl isobutyl ketone gave no absorption attributable to a C≡N group, and the NMR spectra showed no signal for the methyl singlet observed in Compound **1**—**6**, as has been mentioned above. This shows that the methyl group adjacent to the ketone carbonyl was involved in this cyclization.

Experimental

All the melting points are uncorrected. The IR spectra were determined by means of potassium bromide pellets. The NMR spectra were determined in deuterodimethylsulfoxide or trifluoroacetic acid at 100 MHz, using tetramethylsilane as the internal standard. The chemical shifts are reported as parts per million downfield from TMS.

Reaction of Malononitrile, 3-Methoxysalicylaldehyde (or Salicylaldehyde), and n-*Alkyl Ketones.* A mixture of malononitrile (0.06 mol), aldehyde (0.06 mol), ketone (0.06 mol), and ammonium acetate (0.06—0.07 mol) in ethanol (30 ml) was refluxed for 1 hr. The pale yellow crystals which precipitated during the reaction were collected and washed with hot ethanol. Recrystallization from dimethyl sulfoxide–ethanol gave **1a**–**c** and **1f**. The experimental results and spectral data are summarized in Table 1.

Found: C, 66.74; H, 5.59; N, 15.65%. Calcd for $C_{15}H_{15}N_3O_2$ (**2a**): C, 66.90; H, 5.61; N, 15.61%. Found: C, 64.08; H, 5.73; N, 14.15%. Calcd for $C_{16}H_{17}N_3O_3$ (**2b**): C, 64.20; H, 5.72; N, 14.04%. Found: C, 66.04; H, 6.51; N, 12.72%. Calcd for $C_{18}H_{21}O_3N_3$ (**2c**): C, 66.03; H, 6.47; N, 12.84%.

*Formation of **3** by the Reaction of **1** with Acetic Anhydride and Water.* Acetic anhydride (5—8 ml) was added to **1** (4 mmol), and the mixture was heated for a few minutes. After cooling, a few drops of water were added to the reaction mixture; a crystalline precipitate was thus formed. Recrystallization from acetic acid–ethanol afforded colorless crystals (Table 3).

Found: C, 60.41; H, 5.96; N, 13.15%. Calcd for $C_{16}H_{19}N_3O_4$ (**3a**): C, 60.55; H, 6.04; N, 13.24%. Found: C, 61.62; H, 6.39; N, 12.55%. Calcd for $C_{17}H_{21}N_3O_4$ (**3b**) C, 61.62; H, 6.39; N, 12.68%. Found: C, 62.81; H, 6.47; N, 12.26%. Calcd for $C_{18}H_{23}N_3O_4$ (**3c**): C, 62.59; H, 6.71; N, 12.17%. Found: C, 62.36; H, 6.68; N, 12.04%. Calcd for $C_{18}H_{23}N_3O_4$ (**3d**): C, 62.59; H, 6.71; N, 12.17%.

*Formation of **4a** by the Reaction of **3a** and Acetic Anhydride.* Acetic anhydride (3 ml) was added to **3a** (1 mmol) and heated for 0.5 hr. After the mixture had cooled, the deposited crystals were collected and recrystallized from dimethyl sulfoxide–ethanol to afford white crystals (mp 276—278°C (decomp.)) in a 63% yield; ν_{max}^{KBr} 3310 (NH), 1650 cm^{-1} (C=O); NMR (CF_3CO_2H) 2.0, 2.8 (CH_3, singlet, 3H each), 3.97 (OCH_3, singlet, 3H), 2.35 (CH_2, doublet, 2H), 4.55 (CH, triplet, 1H), 7.7—8.2 ppm (NH, broad, 1H).

Found: C, 64.21; H, 5.86; N, 13.89%. Calcd for $C_{16}H_{17}N_3O_3$: C, 64.20; H, 5.72; N, 14.04%.

Similarly, the same reaction with **3b** gave **4b** (mp 273—274°C (decomp.)) in a 72% yield; NMR (CF_3CO_2H) peaks at 1.15 (CH_3, doublet, 3H), 1.92, 2.8 (CH_3, singlet, 3H each), 3.97 (OCH_3, singlet, 3H), 2.4—2.7 (CH, multiplet, 1H), 4.25 (CH, doublet, 1H), 7.5—8.2 ppm (NH, broad, 1H).

Found: C, 64.99; H, 6.11; N, 13.09%. Calcd for $C_{17}H_{19}N_3O_3$: C, 65.16; H, 6.11; N, 13.41%.

*5-(2-Acetoxy-3-methoxyphenyl)-2,7-dimethyl-4-oxo-1,4,5,8-tetrahydro[2,3-d]pyridopyrimidine (**5**).* A mixture of **4a** (1.1 g) and acetic anhydride (5 ml) in pyridine (4 ml) was heated for 2 hr. When the reaction mixture was then left to stand overnight, pale yellow crystals were obtained. Recrystallization from ethanol gave 0.7 g of colorless needles (mp 225—227°C); ν_{max}^{KBr} 3360 (NH), 1755, 1660 cm^{-1} (C=O); NMR spectrum (DMSO-d_6) gave signals at 1.64, 2.16 (CH_3, singlet, 3H each), 2.24 (O–Ac, singlet, 3H), 3.72 (OCH_3, singlet, 3H), 4.24, 4.62 (CH, doublet, 1H each), 8.5, 11.59 ppm (NH, singlet, 1H each).

Found: C, 63.20; H, 5.73; N, 12.42%. Calcd for $C_{18}H_{19}N_3O_4$: C, 63.33; H, 5.61; N, 12.31%.

*2-Acetamino-4-(2-acetoxy-3-methoxyphenyl)-6-methyl-1,4-dihydronicotinonitrile (**6**).* To a solution of **1b** (0.8 g) dissolved in pyridine (3 ml), acetic anhydride (3 ml) was added, after which the mixture was heated for 5 min. After the mixture had then been allowed to stand at room temperature, the resulting precipitate was washed with dilute methanol and recrystallized from ethanol–dimethyl sulfoxide to afford 0.5 g of colorless crystals (mp 224—227°C); NMR (DMSO-d_6) 1.66 (6-CH_3, singlet, 3H), 2.0 (NH–Ac, singlet, 3H), 2.28 (O–Ac, singlet, 3H), 3.76 (OCH_3, singlet, 3H), 4.27, 4.43 (CH, doublet, 1H each), 8.68, 9.9 ppm (NH, singlet, 1H each); ν_{max}^{KBr} 3260, 3220(NH), 2200 (C≡N), 1760 (O–Ac), 1690 cm^{-1} (NH–Ac).

Found: C, 63.13; H, 5.62; N, 12.22%. Calcd for $C_{18}H_{19}N_3O_4$: C, 63.33; H, 5.61; N, 12.31%.

*Reaction of **1b** and Acetic Acid.* A mixture of **1b** (0.4 g), acetic acid (5 ml), water (1 ml), and ammonium acetate (1 g) was refluxed for 1 hr. The pale yellow crystals which were thus precipitated were collected and recrystallized from ethanol–dimethyl sulfoxide to give 0.2 g of 4-amino-7-methoxy-2-methyl-5-oxo-[1]benzopyrano[3,4-*c*]pyridine (**7**) (mp 230—232°C).[2] This compound was proved by IR spectral studies to be identical with that obtained by the condensation of ethyl cyanoacetate, 3-methoxysalicylaldehyde, and acetone in the presence of ammonium acetate.

*Reaction of **11** and Cyclohexanone.* To a mixture of **11a**[1] (2.38 g, 0.014 mol) and cyclohexanone (1.37 g, 0.014 mol) in ethanol (10 ml), ammonium acetate (2 g, 0.026 mol) was added. After having been refluxed for 1 hr, the reaction mixture afforded 0.6 g (16%) of 2-amino-3-cyano-4-(2-hydroxyphenyl)-4,4a,5,6,7,8-hexahydroquinoline (**8a**).

(mp 223—225°C (decomp.)); ν_{max}^{KBr} 3440, 3350, 3220 (NH_2, OH), 2140 cm^{-1} (C≡N).

Found: C, 71.89; H, 6.26; N, 15.98%. Calcd for $C_{16}H_{17}N_3O$: C, 71.88; H, 6.41; N, 15.72%.

When **11b** was used instead of **11a**, the condensation afforded 27% of **8b** (mp 230—233°C (decomp.)) and 7% of 2-amino-3-cyano-4-(2-hydroxy-3-methoxyphenyl)-5,6,7,8-tetrahydroquinoline (**9**) (mp 241—244°C); ν_{max}^{KBr} 3470, 3370, 3220 (NH_2, OH), 2200 cm^{-1} (C≡N).

Found: C, 68.99; H, 5.46; N, 14.58%. Calcd for $C_{17}H_{17}N_3O_2$: C, 69.13; H, 5.80; N, 14.23%.

The IR spectrum (KBr) of **8b** gave bands at 3440, 3340, 3220 (NH_2, OH), and 2170 cm^{-1} (C≡N).

Found: C, 68.53; H, 6.42; N, 14.19%. Calcd for $C_{17}H_{19}N_3O_2$: C, 68.66; H, 6.44; N, 14.13%.

*Reaction of **11** and Methyl Isobutyl Ketone.* To a mixture of **11b** (3 g, 0.015 mol) and methyl isobutyl ketone (1.8 g, 0.018 mol) in ethanol (10 ml), ammonium acetate (2.31 g, 0.03 mol) was added, and the mixture was refluxed for 1 hr. This mixture afforded 1 g (22%) of **14b** (mp 180—182°C); ν_{max}^{KBr} 3300, 3130 (NH_2, NH), 1645 cm^{-1} (C=N); NMR (CF_3CO_2H) peaks at 1.15 (CH_3, doublet, 6H), 2.05—2.55 (CH, multiplet, 1H), 2.95 (CH_2, doublet, 2H), 4.13 (OCH_3, singlet, 3H).

Found: C, 68.90; H, 6.48; N, 14.02%. Calcd for $C_{17}H_{19}N_3O_2$: C, 68.66; H, 6.44; N, 14.13%.

When **11a** was used instead of **11b**, the condensation afforded 18% of **14a** (mp 184—186°C); ν_{max}^{KBr} 3295; 3125 (NH_2, NH), 1645 cm^{-1} (C=N).

Found: C, 71.84; H, 6.35; N, 15 44%. Calcd for $C_{16}H_{17}N_3O$: C, 71.88; H, 6.41; N, 15.72%.

*Reaction of **14b** and Hydrochloric Acid.* To a solution of **14b** (0.2 g) suspended in ethanol (7 ml), hydrochloric acid (3 ml) was added. After the reaction mixture has then been refluxed for 1 hr, a crystalline precipitate was yielded. Recrystallization from ethanol gave 0.1 g of 4-amino-2-isobutyl-7-methoxy-5-oxo-[1]benzopyrano[3,4-*c*]pyridine(mp 196—197°C).[2] This compound was identified with that obtained by the reaction of ethyl cyanoacetate, 3-methoxysalicylaldehyde, and methyl isobutyl ketone by a study of their IR spectra.

The authors wish to express their thanks to Dr. Taro Hayashi and Dr. Tatsuo Takeshima for their kind advice. Thanks are also due to Dr. Haruo Homma and his staff for their microanalyses, to Mr. Jun Uzawa for his measurements of the NMR spectra, and to Mr. Hironori Ogawa for his measurements of the IR spectra.

Studies of Peptide Antibiotics. XXVIII.[1] Syntheses of Sesquigramicidin S and Digramicidin S[2,3]

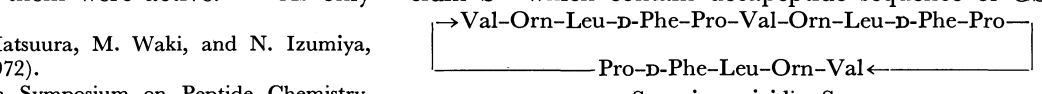
Shuji MATSUURA, Michinori WAKI, Tetsuo KATO, and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received September 6, 1972)

Two macro-ring analogs of gramicidin S, namely *cyclo*(–L-Val–L-Orn–L-Leu–D-Phe–L-Pro–)$_3$ (sesquigramicidin S) and *cyclo*(–L-Val–L-Orn–L-Leu–D-Phe–L-Pro–)$_4$ (digramicidin S), were prepared to investigate the influence of the ring size of gramicidin S for antibacterial activity. Several linear analogs such as H–(L-Val–L-Orn–L-Leu–D-Phe–L-Pro)$_n$–OH (n=2, 3 and 4) were also prepared as reference compounds. All these macro-ring and linear analogs showed weaker activity than gramicidin S and synergistic property when each of the analogs is mixed with gramicidin S. Measurements of optical rotatory dispersion were made with these analogs and gramicidin S in solvents of ethanol and 8 M aqueous urea. From these experiments, it was suggested that the mode of antibacterial action of the macro-ring analogs and their conformations are similar to those of the linear analogs.

In studies of the relationship between chemical structure and antibacterial activity of gramicidin S (GS), various analogs have been synthesized.[5] Particularly in regard to the ring size, several cyclic peptides with smaller ring size than that of GS were prepared, but none of them were active.[4,6] As only one analog with a larger ring size than GS, [β-Ala$^{5,5'}$]-GS was synthesized, but this compound was also inactive.[7] In order to determine further the influence of larger ring size on the activity, we have designed the syntheses of sesquigramicidin S[3] and digramicidin S[3] which contain decapeptide sequence of GS.



Sesquigramicidin S

1) Part XXVII: S. Matsuura, M. Waki, and N. Izumiya, This Bulletin, **45**, 863 (1972).

2) Presented at the 9th Symposium on Peptide Chemistry, Shizuoka, November, 1971. Part of this work has been briefly communicated: S. Matsuura and N. Izumiya, *Experientia*, **28**, 1402 (1972).

3) We introduced the naming of cyclosemigramicidin S for *cyclo*(-Val-Orn-Leu-D-Phe-Pro-) primarily,[4] but changed this naming as semigramicidin S in the recent review.[5] Therefore, we employ the namings of sesquigramicidin S and digramicidin S for *cyclo*(-Val-Orn-Leu-D-Phe-Pro-)$_3$ and *cyclo*(-Val-Orn-Leu-D-Phe-Pro-)$_4$, respectively.

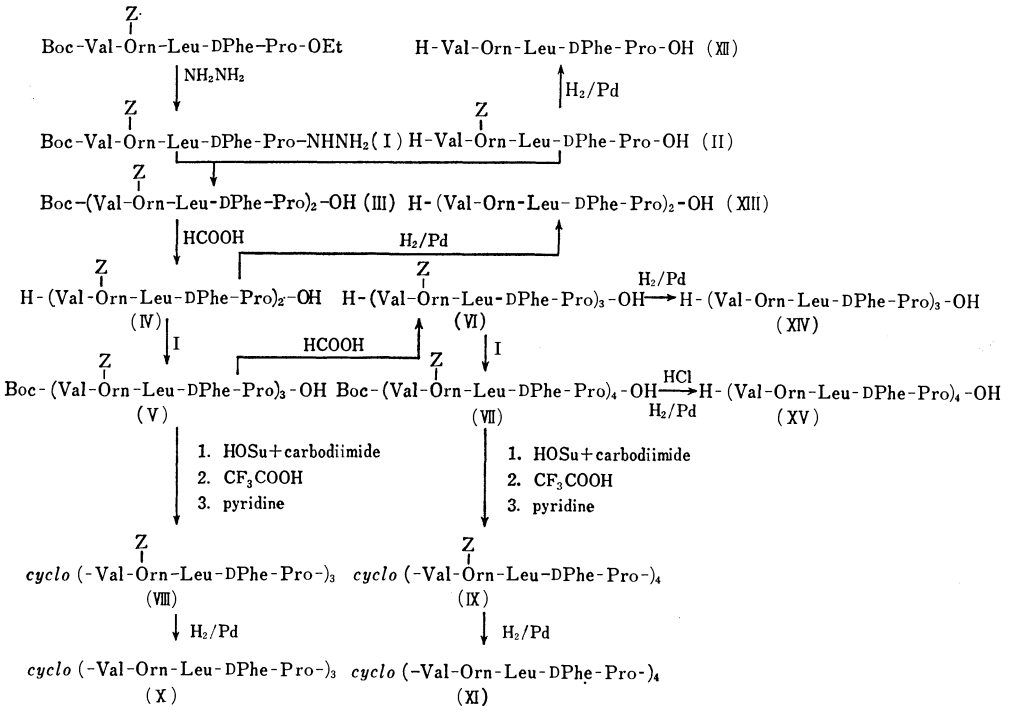
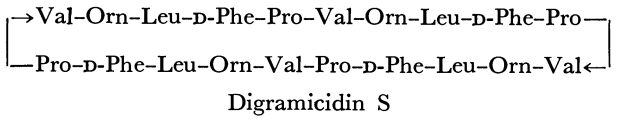


Scheme 1.



Digramicidin S

This paper describes the syntheses, antibacterial properties and ORD[8] measurements of two macro-ring analogs of GS besides those of several linear analogs.

Scheme 1 indicates the routes for syntheses of the macro-ring and linear analogs. The azide derived from Boc–pentapeptide hydrazide (I) was condensed with a neutral pentapeptide (II), and the resulting acyl-decapeptide acid (III) was converted to a neutral decapeptide (IV) by the action of formic acid. The azide derived from I was again condensed with VI, the resulting Boc–pentadecapeptide acid (V) was transformed to Boc–pentadecapeptide *N*-hydroxysuccinimide ester by the action of HOSu and water soluble carbodiimide, and its Boc group was removed with trifluoroacetic acid. Pentadecapeptide ester trifluoroacetate thus obtained was treated with pyridine for the cyclization reaction.[9] The reaction mixture yielded a pure Z-substituted cyclic pentadecapeptide (VIII) with a fairly good yield. The hydrogenolysis of VIII afforded the desired sesquigramicidin S (X) as a crystalline trihydrochloride. In a similar manner, the desired digramicidin S (XI) was prepared as a crystalline tetrahydrochloride as shown in Scheme 1.

The linear penta- (XII), deca- (XIII), and pentadecapeptide (XIV) were prepared from the corresponding Z-substituted peptides by hydrogenolysis.

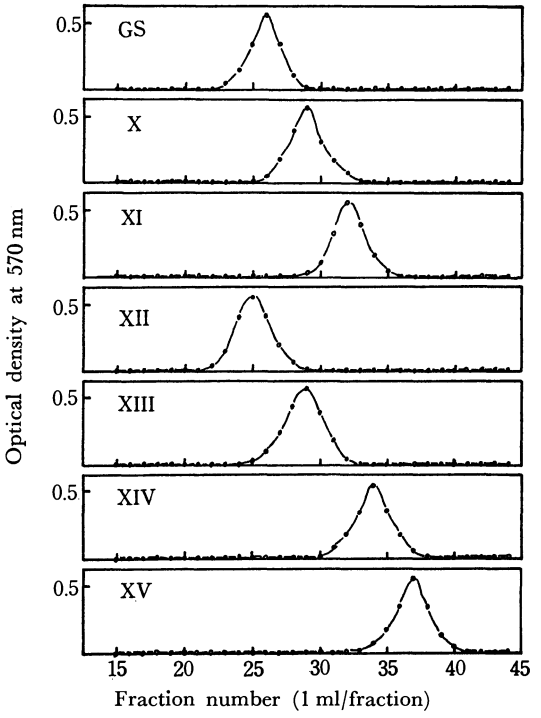


Fig. 1. CMC column chromatography of macro-ring and linear analogs of GS.

8) Abbreviations according to IUPAC-IUB Commission on Biochemical Nomenclature, *J. Biol. Chem.*, **247**, 977 (1972), are used. Additional abbreviations are as follows: ORD, optical rotatory dispersion; CMC, carboxymethyl cellulose; HOSu, *N*-hydroxysuccinimide; TEA, triethylamine; DMF, dimethylformamide. Amino acid symbols except D-Phe denote the L-configuration.

9) For the cyclization reaction we have used very often linear peptide *p*-nitrophenyl esters. However, we recognized recently that the cyclization of linear peptide *N*-hydroxysuccinimide ester gives better yield than that of *p*-nitrophenyl ester in many cases. Some features using *N*-hydroxysuccinimide ester for the cyclization were presented at the 24th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1971.

Table 1. Antibacterial activity of the compounds (Minimum inhibitory concentration, μg/ml)

Compound[a,b]	Medium for assay[c]	*Staphylococcus aureus*	*Bacillus subtilis*
semiGS	B, S	>100	>100
GS	B	5	2
	S	5	5
X (sesquiGS)	B	50	20
	S	50	50
XI (diGS)	B	20	10
	S	20	10

	S	100	20
XV (eicosa)	B	20	10
	S	20	20
GS+X[d]	B	10	2
	S	5	5
GS+XI[d]	B	5	2
	S	5	2
GS+XIII[d]	B	5	5
	S	5	5
GS+XIV[d]	B	5	5
	S	5	5
GS+XV[d]	B	5	5
	S	5	5

a) The μg in the minimum inhibitory concentration refers net weight of a peptide without either HCl or H_2O in the compound. b) All compounds showed no activity for *Echerichia coli*. c) B, usual bouillon agar medium of pH 7.0. S, synthetic Stephensen-Whetham's medium of pH 7.0. d) A mixture was prepared with 1 : 1 weight ratio of GS and an analog.

The eicosapeptide (XV) was derived from α-Boc-δ-Z-substituted eicosapeptide (VII) by successive treatments of hydrogen chloride in ethyl acetate and hydrogenolysis. The purities of these macro-ring and linear analogs were ascertained by CMC column chromatography (Fig. 1) besides other experiments such as elemental analysis.

The antibacterial activities of the macro-ring and linear analogs toward microorganisms were tested (Table 1). As like that semigramicidin S was inactive,[4] the corresponding linear pentapeptide (XII) was also inactive. The linear decapeptide (XIII) showed weak activity as reported previously.[10,11] It is interesting to note that a level of the activity of sesquigramicidin S and digramicidin S was approximately same with that of the corresponding linear peptides, XIV, and XV, respectively. Furthermore, it seems that level of the specific activity increased with an increase of molecular size in both the macro-ring and linear analogs. Erlanger and Goode observed that some linear decapeptides such as XIII reveal synergistic activity with GS against microorganism, and noted that the mode of antibacterial action by XIII may differ from that of GS.[12] As shown in Table 1, a mixture of GS and each of macro-ring and some linear analogs showed the same activity as GS itself; these analogs revealed synergistic activity with GS. We thus assumed that the mode of antibacterial action of the macro-ring analogs is similar to that of the linear analogs, and differ from that of GS.

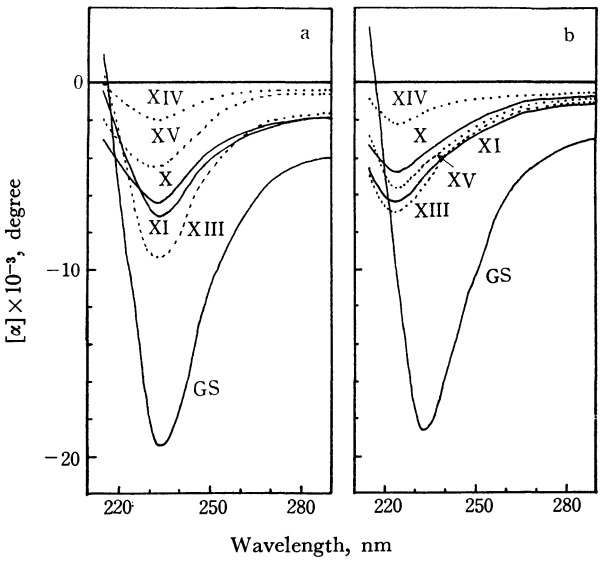

Fig. 2. ORD curves of macro-ring and linear analogs of GS. Solvent; a, ethanol; b, 8 M urea.

The assumption mentioned is favored by the experiments of ORD. The ORD curves measured in a solvent of ethanol are shown in Fig. 2-a. The macro-ring and linear analogs have similar shaped curves with a negative trough at 232 nm as GS possesses the same. In a solvent of 8 M aqueous urea which causes denaturation of some polypeptides,[13] the troughs of the peptides except GS were moved to 225 nm whereas that of GS remained constant (Fig. 2-b). The results may indicate that a conformation of the macro-ring analogs is similar to that of the linear analogs, whereas that of GS is very stable even in 8 M aqueous urea. In this connection, it would be noteworthy that GS has the rigid β-pleated sheet structure having an antiparallel tripeptide sequence with four hydrogen bondings.[14] In conclusion, the presented data suggest that a cyclic character in a pentadeca- or eicosapeptide which contains a sequence of GS is not essential to exhibit the activity, whereas in a linear decapeptide sequence in GS, the cyclic character is important to form the rigid structure and consequently to exhibit a strong and characteristic antibacterial activity.

Experimental

Thin layer chromatography was carried out on Merck silica gel G with the following solvent systems: R_f^1, *n*-butanol–acetic acid–pyridine–water (4 : 1 : 1 : 2, v/v); R_f^2, chloroform–methanol (5 : 1, v/v); R_f^3, *sec*-butanol–formic acid–water (4 : 1 : 1, v/v).

Boc–Val–Orn(Z)–Leu–D-Phe–Pro–NHNH$_2$ (I). A solution of Boc–Val–Orn(Z)–Leu–D-Phe–Pho–OEt[15] (8.72 g, 10.3 mmol) and hydrazine hydrate (9.9 ml, 205 mmol) in DMF (35 ml) was allowed to stand at room temperature for 7 days. The solution was evaporated *in vacuo*, and then water (150 ml) was added to the residue. The resulting crystals were collected by filtration and recrystallized from methanol–ether; yield, 7.73 g (90%); mp 183—185°C; $[\alpha]_D^{15}$ −19.2° (*c* 0.5, DMF); R_f^1 0.67, R_f^2 0.60.

Found: C, 60.75; H, 7.88; N, 13.53%. Calcd for $C_{43}H_{64}O_9N_8 \cdot 1/2H_2O$: C, 61.04; H, 7.74; N, 13.25%.

Boc–(Val–Orn(Z)–Leu–D-Phe–Pro)$_2$–OH (III). I (2.23 g, 2.66 mmol) was dissolved in DMF (10 ml) and 2 N hydrogen chloride in dioxane (2.7 ml). To the solution at −30°C was added isoamyl nitrite (0.45 ml, 3.2 mmol). After some 10 min, disappearance of the hydrazide was ascertained by the detection method for hydrazide.[16] To the reaction mixture was added TEA (0.74 ml, 5.3 mmol). After 5 min at 0°C, a solution of H–Val–Orn(Z)–Leu–D-Phe–Pro–OH·HCOOH (II·HCOOH)[11] (2.46 g, 3.2 mmol) in DMF containing TEA (0.9 ml) was added to the mixture. After 3 days at 4°C, the reaction mixture was added to cold 0.2 M citric acid (1000 ml). The resulting solid was recrystallized from methanol–ether–petroleum ether; yield, 3.49 g (86%); mp 173—175°C; $[\alpha]_D^{25}$ −105° (*c* 1, MeOH). The same compound was prepared already from Boc–Val–Orn(Z)–Leu–D-Phe–Pro–OH and II by the method of HOSu plus DCC; $[\alpha]_D^{23}$ −109° (MeOH).[11] No depression of melting point was observed on a mixture of III with the previous product.[11]

H–(Val–Orn(Z)–Leu–D-Phe–Pro)$_2$–OH (IV). A solution of III (2.57 g, 1.68 mmol) in 99% formic acid (30 ml) was allowed to stand for 5 hr at room temperature. The solvent was removed by evaporation, and the residue was dissolved in a mixture of TEA (12 ml) and methanol (70 ml). The solution was evaporated, and the resulting crystals were collected by filtration with the aid of water;[17] yield, 2.19 g (87%); mp 155—157°C; $[\alpha]_D^{25}$ −21.8° (*c* 0.3, DMF); R_f^1 0.80, R_f^2 0.70. Hygroscopic monohydrochloride of IV was prepared previously.[11]

Found: C, 60.86; H, 7.51; N, 11.17%. Calcd for $C_{76}H_{106}O_{15}N_{12} \cdot 4H_2O$: C, 60.86; H, 7.66; N, 11.20%.

Boc–(Val–Orn(Z)–Leu–D-Phe–Pro)$_3$–OH (V). I (515 mg, 0.62 mmol) in DMF (5 ml) was treated with isoamyl nitrite (0.1 ml, 0.74 mmol) as in the case of III. To the azide solution was added a solution of IV (1.02 g, 0.68 mmol) in DMF (4 ml) containing TEA (0.095 ml). After being stirred for 5 days at 4°C, the reaction mixture was added to 0.2 M citric acid (300 ml). The resulting solid was collected and recrystallized from methanol–ether–petroleum ether; yield, 1.13 g (80%); mp 150—152°C; $[\alpha]_D^{25}$ −22.8° (*c* 0.5, DMF); R_f^1 0.98, R_f^2 0.64.

Found: C, 62.64; H, 7.54; N, 11.22%. Calcd for $C_{119}H_{166}O_{24}N_{18} \cdot 3H_2O$: C, 62.49; H, 7.58; N, 11.03%.

H–(Val–Orn(Z)–Leu–D-Phe–Pro)$_3$–OH (VI). This was prepared from V (2.26 g, 0.99 mmol) with 99% formic acid (60 ml) as in the case of IV: yield, 1.96 g (90%); mp 158—160°C; $[\alpha]_D^{25}$ −77.4° (*c* 0.5, DMF); R_f^1 0.90, R_f^2 0.65.

Found: C, 61.85; H, 7.52; N, 11.37%. Calcd for $C_{114}H_{158}O_{22}N_{18} \cdot 4H_2O$: C, 62.10; H, 7.50; N, 11.44%.

Boc–(Val–Orn(Z)–Leu–D-Phe–Pro)$_4$–OH (VII). The azide solution was prepared from I (1.04 g, 1.24 mmol) as in the case of III. To this was added a solution of VI (2.11 g, 0.96 mmol) in DMF (15 ml) containing TEA (0.13 ml). The solid was obtained as in the case of V and recrystallized from methanol–ether–petroleum ether; yield, 2.38 g (82%); mp 151—154°C; $[\alpha]_D^{25}$ −47.6° (*c* 1.0, DMF); R_f^1 0.90, R_f^2 0.70.

Found: C, 62.40; H, 7.67; N, 11.09%. Calcd for $C_{157}H_{218}O_{31}N_{24} \cdot 5H_2O$: C, 62.28; H, 7.59; N, 11.10%.

cyclo*(–Val–Orn(Z)–Leu–D-Phe–Pro–)$_3$ (VIII).* To a solution of V (320 mg, 0.14 mmol) in dichloromethane (2 ml) and DMF (1 ml) at 0°C, *N*-hydroxysuccinimide (32 mg, 0.28 mmol) and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride[18] (54 mg, 0.28 mmol) was added. After 12 hr at 4°C, the mixture was evaporated. The residual solid was collected by filtration with the aid of cold water; yield, 314 mg. To Boc–pentadecapeptide *N*-hydroxysuccinimide ester obtained, trifluoroacetic acid (3 ml) was added at 0°C. After 20 min, the solution was evaporated, and the residual powder was collected by filtration with the aid of ether. Pentadecapeptide *N*-hydroxysuccinimide ester trifluoroacetate obtained was dissolved in DMF (5 ml), and the solution was added into pyridine (50 ml) at room temperature. The stirring was continued for 2 hr. The solvent was removed, and the residue was dissolved in a mixture of methanol (50 ml) and water (10 ml). The solution was passed through columns (1.9×20 cm, each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (200 ml), the combined effluent was evaporated, and the product was collected by filtration with the aid of water. The product was further purified by a column (2.4×115 cm) with Sephadex LH-20; the product dissolved in methanol (3 ml) was applied to the column, and developed with methanol. Main fractions were evaporated, and the residual solid was recrystallized from methanol-ether-petroleum ether; yield, 144 mg (47% from V); mp 128—130°C; $[\alpha]_D^{25}$ −15.6° (*c* 0.3, DMF); R_f^1 0.90, R_f^2 0.75.

Found: C, 62.39; H, 7.49; N, 11.34%; mol wt 2110.[19] Calcd for $C_{114}H_{156}O_{21}N_{18} \cdot 4H_2O$: C, 62.61; H, 7.56; N, 11.53%; mol wt 2186.

cyclo*(–Val–Orn(Z)–Leu–D-Phe–Pro–)$_4$ (IX).* VII (1.91 g, 0.63 mmol) was converted to IX as described for the preparation of VII; yield, 911 mg (50% from VII); mp 153—155°C; $[\alpha]_D^{25}$ −23.0° (*c* 0.5, DMF); R_f^1 0.98, R_f^2 0.75.

Found: C, 63.00; H, 7.32; N, 11.37%; mol wt 2900.[19] Calcd for $C_{152}H_{208}O_{28}N_{24} \cdot 4H_2O$: C, 63.13; H, 7.53; N, 11.63%; mol wt 2891.

cyclo*(–Val–Orn–Leu–D-Phe–Pro–)$_3$ (Sesquigramicidin S) (X).* A solution of VIII (39 mg, 0.018 mmol) in 0.01 N methanolic hydrogen chloride (6 ml) was subjected to hydrogenolysis in the presence of palladium black, and the filtrate was evaporated. The product was recrystallized from methanol-ether–petroleum ether; yield of air-dried product (X·3HCl·

(Received September 16, 1972)

A comparative study of the relative reactivity of bisglycinatocopper(II) and *N*-pyruvylideneglycinatoaquocopper(II) in a base-catalyzed condensation reaction with aldehydo sugar derivatives concluded that the latter complex is much more reactive than the former. This reaction was found to proceed with a considerably high stereoselectivity to afford blocked 2-amino-2-deoxyaldonic acids with a *threo* configurational relationship between *C*–2 and *C*–3, and between *C*–3 and *C*–4. The resultant products were converted to the corresponding free 2-amino-2-deoxyaldonic acids in good yields by deblocking them with Amberlite IR–120B(H form).

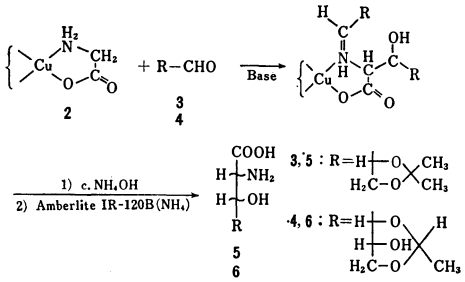
In the preceding papers,[1] a new procedure for synthesizing β-hydroxy amino acids and 2-amino-2-deoxyaldonic acids involving the base-catalyzed condensation reaction of *N*-pyruvylideneglycinatocopper(II) complexes with a variety of aldehyde species has been reported. An investigation of the syntheses of some 2-amino-2-deoxyaldonic acids by the above

Ishido, *Tetrahedron Lett.*, **1971**, 79; c) T. Ichikawa, S. Maeda, T. Okamoto, Y. Araki, and Y. Ishido, This Bulletin, **44**, 2779 (1971).

procedure was undertaken on the basis of the fact that the reaction is applicable to aldehydes susceptible to isomerization or polymerization under strongly basic conditions,[1] and the discovery of polyoxins,[2] which have been demonstrated to involve 2-amino-2-deoxy-L-xylonic acid and 5-amino-5-deoxy-D-alluronic acid as their constituents.

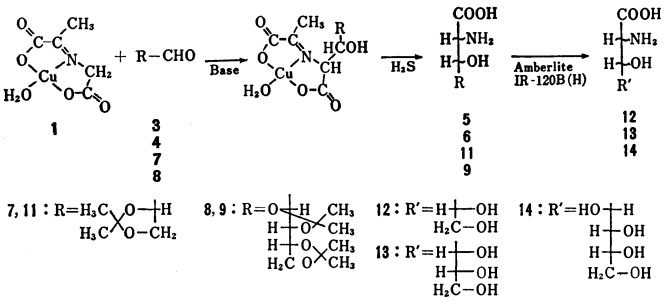
Results and Discussion

The Condensation Reaction with Bisglycinatocopper(II). To elucidate the excellence of the procedure utilizing *N*-pyruvylideneglycinatoaquocopper(II)[1] (**1**) in comparison with that utilizing bisglycinatocopper(II)[3] (**2**), the base-catalyzed condensation reactions of **2** with 2,3-*O*-isopropylidene-D-glyceraldehyde (**3**) and with 2,4-*O*-ethylidene-*al*-D-erythrose (**4**) were examined first.



The reaction of **2** (10 mmol) with **3** (80 mmol) was carried out at 48—50°C, keeping the pH of the mixture at 10.7 by the drop-by-drop addition of an aqueous sodium hydroxide solution during the reaction; this gave 2-amino-2-deoxy-4,5-*O*-isopropylidene-D-aldopentonic acid (**5**) in a 31% yield. Similarly, 2-amino-2-deoxy-4,6-*O*-ethylidene-D-aldohexonic acid (**6**) was obtained in a 22% yield from the reaction of **2** with **4**. The application of **2** to the reaction involving such aldehydo sugars was abandoned since the reaction requires an excess amount of the aldehyde species because of the formation of a Schiff-base-type intermediate in the course of the reaction, and since the yields of the reactions are not very good.

The Condensation Reaction with N-*Pyruvylideneglycinatoaquocopper(II).* On the basis of the above results, the syntheses of 2-amino-2-deoxyaldonic acids were scrutinized by the base-catalyzed condensation reaction of **1** with almost equimolar amounts of **3**, **4**, 2,3-*O*-isopropylidene-L-glyceraldehyde (**7**), and 2,3;4,5-di-*O*-isopropylidene-*al*-D-arabinose (**8**) respectively. In contrast with the reaction of **2**, in which an excess amount of aldehyde species have been utilized, the reaction of **1** with all these aldehydes was completed within 60 min, even at pH 9.5, at room temperature to afford the corresponding 2-amino-2-deoxyaldonic acids with blocking groups in good yields. These results are summarized in Table 1. **3** (Run 1), **4** (Run 2) and **8**(Run 4) gave **5**, **6**, and 2-amino-2-deoxy-4,5;6,7-di-*O*-isopropylidene-D-aldoheptonic acid (**9**) in 70, 70, and 60% yields respectively. On the other hand, the reaction of **1** with **7**(Run 3) assumed a different aspect in contrast with those with other aldehydro sugars. Raw **7**, which was prepared by the lead-tetraacetate oxidation of 4,5-*O*-isopropylidene-L-arabinose dibenzyl dithio acetal,[4] followed by the condensation of the solution *in vacuo*, gave no product. This fact was deduced to arise from the decomposition of **1** by interaction with glyoxal 1,1-dibenzyl dithio acetal (**10**), which was co-produced in the course of the oxidation. On the basis of this fact, a variety of attempts at the separation of **7** from **10** were made. 2-Amino-2-deoxy-4,5-*O*-isopropylidene-L-aldopentonic acid(**11**) was obtained in a 36% yield by the use of a raw sirup of **7** which had been prepared by the concentration of a lead diacetate-free benzene solution of **7**, followed by repeatedly removing the viscous precipitates produced during the evaporation of methanol from the methanolic aqueous solution of the above residual sirup. No more effective procedure was evolved in spite of further attempts at the purification of **7**. The purification by high-vacuum distillation or by chromatography on a column of silica gel gave a material no longer reactive in the condensation reaction. An attempt at the removal of **10** by treating the oxidation mixture with such metal halides as cupric chloride or mercuric bromide was unsuccessful, and the extraction of **7** from the raw sirup with methylene chloride or benzene also resulted in failure. Fortunately, no such trouble accompanied the reactions of **4** or **8** with **1** since they were easily separated from the co-produced sodium formate by repeating the treatment of the raw sirup with ethanol followed by filtration and concentration, or were easily separated from formaldehyde by extraction with methylene chloride from the periodate oxidation mixture.



Subsequently, we attempted to remove blocking groups of the above 2-amino-2-deoxyaldonic acid derivatives by the use of Amberlite IR-120B(H form) in water. By the treatment of **5**, **6**, and **9** with the resin, 2-amino-2-deoxy-D-aldopentonic acid(**12**), -D-aldohexonic acid(**13**), and -D-aldoheptonic acid(**14**) were obtained in 87, 85, and 76% yields respectively. **12**, **13**, and **14** were prepared similarly from **3**, **4**, and **8** without the isolation of **5**, **6**, and **9** by the base-catalyzed condensation reaction, followed by this deblocking procedure; this resulted in 22, 60, and 65% yields respectively. In the first case, the filtrate of crystallization was found by tlc examination still to contain a considerable amount of **12**;

Table 3. Stereoisomeric composition in the reaction products calculated from the area of chromatograms obtained by the amino acid analysis

Observed Peaks[a]	*aldehydo*-Sugar Derivative Used for the Reaction					
	3[b]	**3**[c]	**4**[b]	**4**[c]	**8**[b]	**8**[c]
A	0.03	0.02	0.02	0.01	0.15	—
B	0.17	0.17	0.12	0.02	0.20	0.05
C	1 (**5**)	1 (**12**)	1 (**6**)	1 (**13**)	1 (**9**)	1 (**14**)
D	0.13	0.14	—	—	0.09	0.07

a) The terms of A, B, C, and D are arbitrary given to the peaks in the chromatograms in the order of their appearence, and C always stands for the main peaks.
b) These mixtures were obtained by the condensation reaction of **1** with *aldehydo*-sugar derivatives.
c) These mixtures were obtained by the condensation reaction followed by the deblocking procedure.

however, no more crystalline product could be obtained. These results are summarized in Table 2.

Subsequently, the stereoisomeric composition of each product was examined by amino-acid analysis in order to examine the possibility that the potential four stereoisomers, which are expected to be formed in this reaction, might be detected easily. These results are summarized in Table 3. Three or four peaks were obviously detected in every chromatogram; the ratios demonstrated in the table were calculated from the ratios of area in the corresponding chromatogram of amino-acid analysis. In view of these data, and supposing that these ratios stand for the actual compositions in each product, it is very interesting that all the reactions proceed with a considerably high stereoselectivity; hence, an important clue for the elucidation of the steric course of the reaction may be obtained by determining the configuration at *C*-2 and *C*-3 in each main product. **12** was confirmed to be 2-amino-2-deoxy-D-xylonic acid on the basis of its behavior in the amino-acid analysis (it behaved just like 2-amino-2-deoxy-L-xylonic acid),[2] and **13** was identified with 2-amino-2-deoxy-D-gluconic acid[5] by a mixed-melting-point determination and by IR spectroscopy. On the basis of these facts, the stereochemistry in **12** and **13** among *C*-2, *C*-3, and *C*-4 were confirmed; they are all *threo* to each other.[6] The stereochemistry in **9** or **14**, in analogy with the above facts, was thought to have the same relation, although there is no decisive evidence at present.[7] These products were found by amino-acid analysis to be identical with the main products observed in each chromatogram.

5) M. L. Wolfrom and M. J. Cron, *ibid.*, **74**, 1715 (1952).
6) Further investigations with close attention to some potential factors were required to elucidate the steric course of the reaction mechanism involving a variety of aldehydes which are variously substituted. A tentative proposal on the mechanism has been made in Dr. Thesis of T. Ichikawa, Tokyo Institute of Technology (1971, March).
7) The stereochemistry of this compound will be confirmed by deriving into the corresponding 2-amino-2-deoxy-D-aldoheptose. The investigation is now in progress along with **12** and **13**.

Experimental

All the melting points are uncorrected. Amino-acid analyses were carried out by means of a Hitachi KLA-3B Amino-acid Analyzer. The specific rotations were determined by means of a Carl-Zeiss Photoelectric Precision Polarimeter (0.005°) at 546 and 578 nm, and the $[\alpha]_D$ values were calculated by the use of Drude's equation.

The Condensation Reaction with Bisglycinatocopper(II). *The Reaction of Bisglycinatocopper(II) (**2**) with 2,3-O-Isopropylidene-D-glyceraldehyde (**3**).* To a solution of 1,2;5,6-di-*O*-isopropylidene-D-mannitol[8] (10.4 g, 40 mmol) in water (120 ml), we added, portion by portion, sodium metaperiodate (8.8 g, 40 mmol), keeping the temperature at 25°C; the solution was then stirred at room temperature for 30 min. The precipitated sodium iodate was filtered off, and the filtrate was concentrated *in vacuo* below 40°C almost to a sirup. When the sirup was treated with ethanol (20 ml), the sodium iodate further precipitated was removed by filtration. This operation was repeatedly carried out in order to remove the small amount of sodium iodate remaining in the sirup. To a solution of the resultant sirup in water (total volume: 60 ml), we added **2**[3] (2.30 g, 10 mmol); the resultant mixture was stirred for 1 hr at room temperature, keeping the pH at 10.7 by the drop-by-drop addition of a 1 M aqueous sodium hydroxide solution. Then, the resultant mixture was treated with a concentrated aqueous ammoniacal solution to decompose the complex of 2-amino-2-deoxy-4,5-*O*-isopropylidene-D-xylonic acid (**5**), after which the solution was treated on a column (2.5×7 cm) of Amberlite IR-120B (NH_4 form). The column was then washed with water (500 ml). The light yellow effluent was evaporated *in vacuo* to a volume of *ca.* 20 ml, and the concentrate was extracted with methylene chloride (10 ml×3). The aqueous layer was further concentrated *in vacuo* to a volume of *ca.* 5 ml, and the concentrate was treated with several milliliters of methanol to afford **5** (1.27 g, 31%). Mp 201—202°C (decomp.) [lit.[1c] 198°C (decomp.)].

*The Reaction of **2** with 2,4-O-Ethylidene-al-D-erythrose (**4**).* To a solution of 4,6-*O*-ethylidene-D-glucopyranose[9] (8.4 g, 40 mmol) in water (100 ml), sodium metaperiodate (17.6 g, 80 mmol) was portion by portion added, under cooling with ice water. During this operation, the pH of the mixture was kept at 4—5 by the addition of crystalline sodium bicarbonate. After the removal of the resultant salts in the same way as above, the solution of **4** was similarly subjected to the reaction with **2**. When the resultant mixture was treated in a similar manner, 2-amino-2-deoxy-4,6-*O*-ethylidene-D-gluconic acid (**6**) (0.96 g, 22%) was obtained. Mp 209°C (decomp.). Found: C, 43.54; H, 6.97; N, 6.54%. Calcd for $C_8H_{15}NO_6$: C, 43.43; H, 6.84; N, 6.33%.

*The Condensation Reaction with N-Pyruvylideneglycinatoaquocopper(II). The Reaction of N-Pyruvylideneglycinatoaquocopper(II) (**1**) with 2,3-O-Isopropylidene-L-glyceraldehyde (**7**):* To a solution of 4,5-*O*-isopropylidene-L-arabinose dibenzyl dithio acetal[4] (4.2 g, 10 mmol) in benzene (80 ml), we added lead tetraacetate (4.7 g, 11 mmol); the solution was then stirred at room temperature for about 30 min. The precipitate was filtered off, and the filtrate was concentrated *in vacuo* below 40°C to a sirup. After the dissolution of the sirup in methanol (20 ml), distilled water (20 ml) was added. The solution was concentrated again *in vacuo* below 40°C to a volume of *ca.* 20 ml. The resultant sirupy precipitate was filtered off, and the filtrate was concentrated to a volume of 10 ml. To a solution of L-glyceraldehyde thus prepared, **1** (2.30 g, 9 mmol) was added together with water (30 ml); the pH of the resultant mixture was adjusted to 9.5 by the addition of a 2 M aqueous sodium hydroxide solution. Then, the mixture was stirred at room temperature for 1 hr, keeping its pH at 9.5. After the reaction, the resultant solution was adjusted at pH 4.5 with a 2 M aqueous hydrochloric acid solution and treated with hydrogen sulfide gas; the resultant precipitate was filtered off. The filtrate was immediately treated on a column (2.5×9 cm) of Amberlite IR-45 (OH form), and the column was washed with water (100 ml). The effluent was concentrated to a volume of *ca.* 50 ml, and the concentrate was treated on a column (2.5×9 cm) of Amberlite IR-120B (NH_4 form). Then, the column was washed with water (100 ml). The effluent was concentrated to a volume of *ca.* 50 ml, and the concentrate was washed with methylene chloride (10 ml×3). The aqueous layer was then concentrated *in vacuo* to a volume of *ca.* 10 ml. The treatment of the concentrate with several milliliters of ethanol gave raw crystals, which were subsequently recrystallized from aqueous ethanol to give 2-amino-2-deoxy-4,5-*O*-isopropylidene-L-aldopentonic acid (**11**) (0.65 g, 36%).

Mp 198°C (decomp.). $[\alpha]_D^{20}$ −0.2° (*c* 1.0, H_2O). Found: C, 46.61; H, 7.51; N, 6.66%. Calcd for $C_8H_{15}NO_5$: C, 46.82; H, 7.37; N, 6.83%.

*The Reaction of **1** with 2,4-O-Ethylidene-al-D-erythrose (**4**):* To a solution of **4**, which had been prepared from 4,6-*O*-ethylidene-D-glucopyranose (2.1 g, 10 mmol) in the way described previously, in water (50 ml), we added **1** (2.30 g, 9 mmol) together with water (30 ml); the mixture was then stirred at room temperature for 40 min, keeping the pH at 9.5 by the drop-by-drop addition of a 1 M sodium hydroxide solution. After the reaction, the resultant mixture was treated in the same way described in the previous experiment, and the resultant raw crystals were recrystallized from aqueous ethanol to give **6** (1.40 g, 67%). Mp 209°C (decomp.).

*The Reaction of **1** with 2,3;4,5-Di-O-isopropylidene-al-D-arabinose (**8**):* To a solution of 1,2;3,4-di-*O*-isopropylidene-D-mannitol (2.6 g, 10 mmol)[10] in water (50 ml) we added sodium metaperiodate (2.2 g, 10 mmol); the solution was then stirred at room temperature for 30 min, keeping the pH at 4—4.5 by the addition of sodium bicarbonate. The solution was then extracted with methylene chloride (50 ml×10), and the extract was concentrated *in vacuo* below 40°C almost to a sirup. The resultant sirup was subjected to a reaction with **1** (2.30 g, 9 mmol) (reaction time: 40 min) and treated in the same way as above to give 2-amino-2-deoxy-4,5;6,7-di-*O*-isopropylidene-D-aldoheptonic acid (**14**) (1.85 g, 60%).

Mp 212°C (decomp.) (recrystallized from aqueous ethanol). Found: C, 50.86; H, 7.56; N, 4.78%. Calcd for $C_{13}H_{23}NO_7$: C, 51.14; H, 7.59; N, 4.59%.

*Deblocking of **5**:* An aqueous solution of **5** (2.83 g, 13.7 mmol) in water (200 ml) was treated on a column of Amberlite IR-120B (H form) (3×9 cm), after which the column was washed with water (2000 ml). Then, the column was eluted with a 0.5 M aqueous ammoniacal solution (2000 ml), and the effluent was concentrated *in vacuo* to a volume of *ca.* 10 ml. The concentrate was treated with methanol (10 ml) to give crystals of 2-amino-2-deoxy-D-xylonic acid (**12**) (1.98 g, 87%). Mp 160°C (decomp.). $[\alpha]_D^{25}$ −3.4° (*c* 1.9, H_2O).

Found: C, 36.41; H, 6.95; N, 8.48%. Calcd for $C_5H_{11}NO_5$: C, 36.36; H, 6.71; N, 8.48%.

Deblocking of ***6***: To a solution of **6** (10g, 45 mmol) in water (300 ml), we added Amberlite IR-120B (H form) (200 ml); the mixture was then stirred at room temperature for 24 hr.[11] The complete adsorption of **6** to the resin was examined by means of the ninhydrin test. The resin was then packed in a column (d: 2.5 cm), and the column was washed with water (1000 ml) and subsequently eluted with a 1 M aqueous ammoniacal solution (500 ml). The effluent was concentrated *in vacuo* to a volume of about 10 ml, and the concentrate was treated with several milliliters of ethanol to give 2-amino-2-deoxy-D-gluconic acid (**13**) (7.5 g, 85%). Mp 245°C (decomp.). This sample showed no depression on admixture with an authentic specimen.[5] $[\alpha]_D^{20}$ +3.7° (*c* 1.0, H_2O). The IR spectrum of this sample was also in complete agreement with that of the specimen.[5] Found: C, 36.64; H, 6.82; N, 7.17%. Calcd for $C_6H_{13}NO_6$: C, 36.92; H, 6.71; N, 7.18%.

Deblocking of ***9***: A solution of **9** (3.0 g, 10 mmol) in water (200 ml) was treated in the same way as has been described for the deblocking of **5** to give 2-amino-2-deoxy-D-aldopentonic acid (**14**) (1.7 g, 76%). Mp 180°C (decomp.). $[\alpha]_{546}^{22}$ +0.2° and $[\alpha]_{578}^{22} \simeq 0°$ (*c* 2.0, H_2O). Found: C, 37.21; H, 6.49; N, 6.36%. Calcd for $C_7H_{15}NO_7$: C, 37.33; H, 6.71; N, 6.22%.

Preparation of ***12***, ***13***, *and* ***14*** *without the Isolation of* ***5***, ***6***, *and* ***9*** *Respectively.* *Preparation of* ***12***: The mixture resulting from the base-catalyzed condensation reaction of **1** with **3**, which has been described in a previous paper,[1c] was adjusted at pH 4.5 with a 5 M aqueous acetic acid solution and then treated with hydrogen sulfide gas. The precipitated cupric sulfide was removed by filtration, and the filtrate was treated on a column of Amberlite IR-120B (H form) (3×9 cm). The column was washed with water (1000 ml) and then eluted with a 0.5 M aqueous ammoniacal solution (1000 ml). The effluent was concentrated *in vacuo* to a volume of *ca.* 10 ml, and the concentrate was treated as has been described previously to give **12** in a 22% yield.

Preparation of ***13***: The mixture resulting from the reaction of **1** with **4**, which has been described as the fourth example in this section, was treated in the same way as above, except that the washing procedure after the adsorption of **6** on the resin was done with 5000 ml of water. Yield, 60%.

Preparation of ***14***: The mixture resulting from the reaction of **1** with **8**, which has been described as the fifth example in this section, was treated in the same way as that used in the preparation of **12**. Yield, 65%.

11) Unless this operation is done under possibly gentle stirring, the resin was ground into small particles, and the washing and the elution procedures got into difficulties. Moreover, these operations came to need much voluminous solvents, and the yield of **13** was considerably lowered.

The authors are grateful to Professor Juji Yoshimura, Tokyo Institute of Technology, and Dr. Kiyoshi Isono, the Institute of Physical and Chemical Research, for their kind gifts of 2-amino-2-deoxy-D-gluconic acid and 2-amino-2-deoxy-L-xylonic acid respectively for the identification. They also wish to express their thanks to the members of the Laboratory of Elemental Analysis, Tokyo Institute of Technology, and Dr. Tadatoshi Seino and Miss Yoshimi Koike, Central Research Laboratories, Ajinomoto Co., Inc., for their assistance in the elemental and amino acid analyses respectively. Moreover, they are grateful to the Ministry of Education, Japanese Government, for a Scientific Research Grant-in-aid.

Stereospecific Syntheses and Acid Dissociations of 2,3-Diaminotetralins and 2,3-Diamino-*trans*-decalins[1)]

Tairoku YANO, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering Kyushu University, Fukuoka, Japan 812

(Received September 29, 1972)

cis- and *trans*-2,3-Diaminotetralins and 2(*e*),3(*e*)-, 2(*e*),3(*a*)-, and 2(*a*),3(*a*)-diamino-*trans*-decalins were stereospecifically synthesized from 1,4-dihydronaphthalene and *trans*-Δ^2-octalin, respectively. The stepwise acid dissociation constants of the decalin derivatives were determined by potentiometric method and discussed in relation to their configurations.

In the course of investigations into steric effect on the chelate formation equilibria of complexane type ligands,[2,3)] we required stereochemically pure samples of three kinds of 2,3-diamino-*trans*-perhydronaphthalenes. Since reasonable separation of the isomers was unlikely, we were obliged to synthesize each diamine separately *via* a stereospecific route, using a starting material of known stereochemistry. This paper deals with such routes and their applications to the synthesis of related *cis*- and *trans*-2,3-diamino-1,2,3,4-tetrahydronaphthalenes, as well as their proton dissociation behaviors in aqueous solutions.

2,3-Diamino-trans-*perhydronaphthalenes.* The three kinds of configurational isomers are denoted as *trans*-2(*a*),3(*a*)-,*cis*-2(*a*),3(*e*), and *trans*-2(*e*),3(*e*)-diamines. The sequences of their preparations are outlined in Scheme 1. Of the three routes, the first two are essentially the same as those reported by Swift and Swern.[4)] The last one, however, required some modifications in order to control the number of inversions

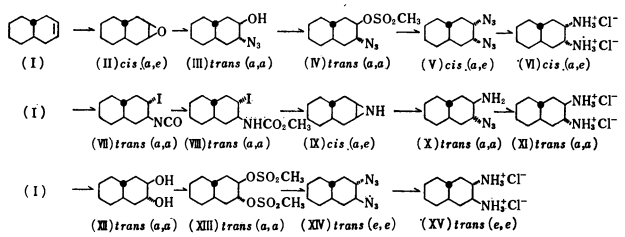


Scheme 1.

in the synthetic route. Our starting material for each synthesis was *trans*-octahydronaphthalene (I). Epoxidation of olefin (I) with perbenzoic acid gave *cis*-epoxide (II), which was ring-opened, with inversion, to *trans*-3(*a*)-azido-2(*a*)-ol(III) in a quantitative yield by the reaction with sodium azide in aqueous ethanol. Hydroxy function of the resulting azido-alcohol (III) was mesylated with methanesulfonyl chloride in pyridine to yield 3(*a*)-azido-*trans*-2(*a*)-perhydronaphthyl methanesulfonate (IV) in 86% yield. Sulfonate (IV) was treated with sodium azide in aqueous dimethylformamide to displace the methanesulfonate function, with inversion, to give oily *cis*-2(*e*), 3(*a*)-diazide (V) in 79% yield. It was then hydrogenated at room temperature over Adam's catalyst to yield the *cis*-diamine, which was immediately converted into *cis*-2(*e*),3(*a*)-diamino-*trans*-perhydronaphthalene dihydrochloride (VI) in 77% yield, melting above 250°C. Acetylation of the *cis*-diamine gave the bisacetyl derivative melting at 245—255°C.

On the other hand, iodine isocyanate, generated *in situ* from silver cyanate and iodine, was added olefin (I), and the resulting *trans*-iodoisocyanate (VII) was converted, without isolation, into *trans*-2(*a*)-iodo-3(*a*)-carbamate (VIII) in 32% yield. Highly purified carbamate (VIII) was ring-closed, with inversion, to *cis*-aziridine (IX) in 72% yield by warming with alcoholic potassium hydroxide. Aziridine (IX) was then converted into *trans*-2(*a*)-amino-3(*a*)-azide (X) in 72% yield by ring cleavage accompanied by inversion, with sodium azide in aqueous ethanol. Aminoazide (X) gave *trans*-2(*a*),3(*a*)-diamino-*trans*-perhydronaphthalene dihydrochloride (XI) in 27% yield by hydrogenation over Adam's catalyst at room temperature, followed by treatment with ethanolic hydrochloric acid. Dihydrochloride (XI) melted with decomposition above 200°C, while the bisacetyl derivative of the *trans*-diamine showed melting point at 245—250°C, which was very close to that of bisacetyl-*cis*-diamine. A mixed melting point test of both bisacetyl derivatives, however, showed considerable depression, mp 213—220°C.

trans-2(*e*),3(*e*)-Diamine was prepared through a sequence involving simultaneous two inversions in contrast to the sequences leading to the other two isomers, which involved successive two inversions *via* three-membered ring intermediates. Olefin (I) was oxidized with performic acid to *trans*-2(*a*),3(*a*)-diol (XII) in 42% yield, followed by mesylating with methanesulfonyl chloride in pyridine to afford *trans*-2(*a*),3(*a*)-bismethanesulfonate (XIII) in 54% yield. Bissulfonate (XIII) was then treated with sodium azide in aqueous dimethylformamide to displace both sulfonate functions at the same time, with inversions. Resulting 2(*e*),3(*e*)-diazide (XIV) was, without further purification, hydrogenated over Adam's catalyst at room temperature, followed by treatment with ethanolic hydrochloric acid to give *trans*-2(*e*),3(*e*)-diamino-*trans*-perhydronaphthalene dihydrochloride (XV) in 29% yield.

TABLE 1. ACID DISSOCIATION CONSTANTS OF 1,2-DIAMINES

Diamine	pK_{a_1}	pK_{a_2}
(VI) (*a*, *e*)[a]	6.36±0.01	9.93±0.01
(XV) (*e*, *e*)[a]	6.68±0.01	10.08±0.01
(XI) (*a*, *a*)[a]	6.97±0.01	9.97±0.01
cis-Cyclohexane-1,2-diamine[b]	6.41	9.99
trans-Cyclohexane-1,2-diamine[b]	6.72	9.89
Ethylenediamine[b]	7.48	10.18
Propane-1,2-diamine[c]	7.13	10.00
dl-Butane-2,3-diamine[d]	6.91	10.00

a) Measured at 25.0±0.1°C and μ=0.10 (KNO_3).
b) Measured at 20°C and μ=0.1 (KCl), G. Schwarzenbach and R. Bauer, *Helv. Chim. Acta*, **39**, 722 (1956).
c) Measured at 25°C and μ=0.5 (KNO_3), F. Basolo, R. K. Murmann, and Y. T. Chen, *J. Amer. Chem. Soc.*, **75**, 1478 (1953).
d) Measured at 25°C and μ=0.5 (KNO_3), F. Basolo, Y. T. Chen, and R. K. Murmann, *ibid.*, **76**, 956 (1954).

The apparent pK_a values of the conjugate acids (VI), (XI), and (XV) were measured potentiometrically in water at 25°C under an ionic strength of μ=0.1 (KNO_3). The obtained values are summarized in Table 1 along with those of some related diamine hydrochlorides.

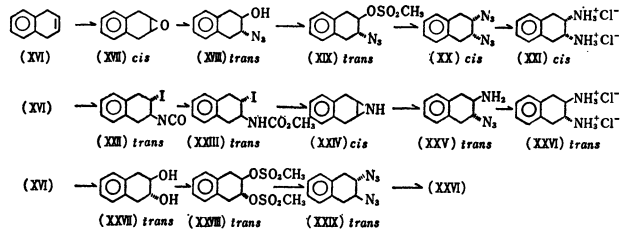
At the first dissociation step, the mutual field effect between the vicinal di-cation seems to be predominant in affecting the pK_{a_1} values of the three conjugate acids, since the inductive effect is considered to be equal among such isomeric systems to a first approximation. As expected from the order of the distance between the vicinal di-cation,[5] the isomer which shows the highest pK_{a_1} value is assigned to be the *trans*-(*a*,*a*)-diamine. The difference in pK_{a_1} values of the remaining two is of a similar extent, as observed between *cis*- and *trans*-cyclohexanediamine, and may be rationalized by steric hindrance among the axial ammonium and the axial hydrogens on the same six-memberes ring.[6] If this is the case, the isomer of the lowest

5) Studies with Dreiding molecular models show that the nitrogen atoms in the *trans*-(*a*,*a*)-diamine are separated by approximately 3.7 Å, and those of *trans*-(*e*,*e*)- and *cis*-(*a*,*e*)-isomers by 2.8 Å.

6) The steric effect might act as a direct steric repulsion between ammonium hydrogen and the adjacent axial hydrogens, or as a buttressing effect of the axial hydrogens upon the axial ammonium group, causing a much shorter distance and consequently an increased field effect between the vicinal ammonium group in the *cis*-(*a*,*e*)-diamine than that of the *trans*-(*e*,*e*)-homologue. Alternately, such congestion around the axial ammonium function causes steric hindrance preventing solvation by polar solvent molecules which, otherwise, would stabilize the charged site by dielectric shielding: G. Schwarzenbach and R. Bauer, *Helv. Chim. Acta*, **39**, 722 (1956). Other workers also recognized and increased acidity of protonated amines in overcrowded steric environments: T. Sasaki, S. Eguchi, and T. Kiriyama, This Bulletin, **44**, 3410 (1971).

pK_{a_1} should be assigned to the *cis*-(*a*,*e*)-homologue. Assignations of the three conformational isomers are consistent with the consequences considered from their respective synthetic routes. Of the two conjugate cations in the *cis*-(*a*,*e*)-isomer, the axial ammonium dissociates preferentially to the equatorial function, and the assignment is compatible with the fact that the pK_{a_1} values of axial conjugate acids are smaller than those of the corresponding equatorial ones.[7] It seems also ascribable to the 1,3-diaxial steric hindrance that the *trans*-(*a*,*a*)-diamine shows a much lower pK_{a_1} value than ethylene diamine, the value being rather close to that of *dl*-butane-2,3-diamine in which the ammonium group is under considerable steric hindrance of the methyl group in the *guache* position.

In the second acid dissociation constants pK_{a_2} we expected rather large differences among the three isomeric diamines, depending upon the relative easiness of forming an intramolecular hydrogen bonding between the ammonium and the vicinal amino group. However, differences in the observed pK_{a_2}'s are very small as shown in Table 1. Each IR spectrum of the diamines measured at high dilution exhibits a sharp peak at 3380—3385 cm^{-1} and a broad peak at 3300 cm^{-1}, which are ascribable to a free amino group. Similarity of the spectra of the diamines, as shown in Fig. 2, indicates that intramolecular hydrogen bonding on the *trans*-(*e*,*e*)-diamine, though stereochemically quite possible, is unlikely to be formed even in a non-polar solvent such as tetrachloroethylene.[8] Thus, the absence of intramolecular hydrogen bonding in the three isomeric diamine mono-cations, may be partly responsible for the resemblance in their second dissociation constants. However, the cause for their rather similar pK_{a_2} values, which were determined in aqueous media and found to be contrary to ones expected from a stereochemical standpoint, can be rationalized only with additional experimental data such as an equilibrium study in aqueous organic solvents.



Scheme 2.

2,3-Diamino-1,2,3,4-tetrahydronaphthalenes. The reaction sequences shown in Scheme 1 were then applied to the preparation of vicinal diamines having a tetralin skeleton as outlined in Scheme 2. Dihydrochloride (XXVI) of the *trans* isomer obtained from 1,4-dihydronaphthalene (XVI) *via* the aziridine (XXIV), was identical with the diamine dihydrochloride obtained from the same starting material (XVI) *via* the *trans*-diazide (XXIX). Two possible configurations of the *trans* vicinal diamine would be readily equilibrated on the flexible tetralin skeleton, so that they cannot be isolated separately, whereas the vicinal diamine groups on the rigid *trans*-decalin framework retain their configurations, two *trans* diamino isomers (XI) and (XV) being individually isolated. This also provides an evidence for the simultaneous displacement of the vicinal two sulfonate functions with azide groups, with inversions.

It should be noted that in the route leading to *trans*-diamine (XXVI), aziridine (XXIV) could be obtained only from the extremely purified iodocarbamate (XXII), otherwise the carbamate gave only naphthalene.

Experimental

trans-Δ^2-Octalin(I),[9] 2,3-epoxy-*trans*-decalin(II),[9] 2(*a*),3(*a*)-dihydroxy-*trans*-decalin(XII),[10] 1,4-dihydronaphthalene (XVI),[10] 2,3-epoxytetralin(XVII),[11] and *trans*-2,3-dihydroxytetralin(XXVII)[12] were prepared according to literature. Melting and boiling points were not corrected. Infrared spectra were determined with JASCO DS-301 and DS-403G spectrophotometers. NMR spectra were recorded with a Varian A-60 and JOEL JNM-PS-100[13] in heavy water solutions using *t*-butanol as an internal reference (at 72 Hz downfield from TMS) unless otherwise stated.

2(a)-Hydroxy-3(a)-azido-trans-*decalin (III).* 2,3-Epoxy-*trans*-decalin(II) (14 g, 0.092 mol) was refluxed for 24 hr in 80% aqueous ethanol(200 ml) with sodium azide (7.4 g, 0.114 mol) and ammonium chloride (5.65 g, 0.114 mol). The reaction mixture was poured into water and extracted with ether. The ether layer was evaporated to give an oil which solidified gradually on cooling. Yield: 18.0 g, almost quantitative. Analytical sample was purified by sublimation under reduced pressure. Mp 36—38°C. IR: ν_{OH} 3310 cm^{-1}, ν_{N_3} 2120 cm^{-1}. Found: C, 62.14; H, 8.63; N, 20.69%. Calcd for $C_{10}H_{17}ON_3$: C, 61.59; H, 8.72; N, 21.54%.

3(a)-Azido-2(a)-trans-*decahydronaphthyl Methanesulfonate (IV).* Methanesulfonyl chloride (18 g, 0.158 mol) was gradually added to a solution of *trans*-azidohydrine(III) (18.0 g, 0.092 mol) in pyridine (100 ml) at 0—5°C with stirring for 3 hr. Stirring was continued for 1.5 hr without cooling. The reaction mixture was allowed to stand overnight at room temperature(14—25°C). The resulting solution was poured into water (1 liter) and the crystalline precipitate was recrystallized from methanol to give colorless needles(22 g, 86%). An analytical sample was purified by sublimation. Mp 56—58°C. IR: ν_{N_3} 2120 cm^{-1}, $\nu_{OSO_2CH_3}$ 800—1000 cm^{-1}. Found: C, 48.21; H, 6.97; N, 14.62%. Calcd for $C_{11}H_{19}N_3O_3S$: C, 48.35; H, 6.96;

7) J. Sicher, M. Tichý, F. Šipoš, M. Svoboda, and J. Jonáš, *Collection Czechoslov. Chem. Commun.*, **29**, 1561 (1964).

8) The result is in line with the conclusion that in a series of monoprotonated diamines $(H_2N(CH_2)_nN^+H_3)$ in acetonitrile, the intramolecular hydrogen bonding contributes very little to the increase of pK_a value of the diamines with $n=2$ or $n>5$. 13) Measured by Mr A. Kito at the Government Industrial Research Institute, Osaka, to whom the authors are very grateful.

N, 15.38%.

2(e),3(a)-Diamino-trans-*decalin Dihydrochloride (VI).* A mixture of the azidomethanesulfonate (IV) (35 g, 0.13 mol) and sodium azide (17 g, 0.26 mol) in 85% aqueous dimethylformamide (420 ml) was refluxed for 6 hr. The resulting solution was poured into water (1 l) and extracted with ether. Evaporation of the ethereal extract gave an oily diazide (23 g, 79%). Diazide (V) (23 g, 0.1 mol) was dissolved in absolute ethanol (150 ml) and hydrogenated in an autoclave, under 80 kg/cm² over Adam's catalyst (0.43 g) for 90 hr at room temperature. The resulting solution was acidfied with hydrochloric acid (100 ml) and the solvent was evaporated off. The residue was dissolved in water (200 ml) and washed with ether. The aqueous solution was treated with activated charcoal and evaporated off. The residual solid was recrystallized from water–ethanol to yield diamine dihydrochloride(19.3 g, 76.5%). Mp above 254°C. NMR(in D_2O):[14] 1.2—2.4 ppm(14H), 3.8—4.2 ppm(2H). Found: C, 49.66; H, 9.26; N, 11.62%. Calcd for $C_{10}H_{22}N_2Cl_2$: C, 49.79; H, 9.12; N, 11.62%. The bisacetyl derivative of (VI) had mp 246—250°C. Found: C, 66.60; H, 9.53; N, 10.94%. Calcd for $C_{14}H_{24}N_2O_2$: C, 66.67; H, 9.52; N, 11.11%.

Methyl-2(a)-iodo-trans-*decalin-3(a)-carbamate (VIII).* *trans*-Δ^2-Octalin (I) (7 g, 0.05 mol) and iodine (12.7 g, 0.05 mol) were dissolved in dry ether (120 ml) at 0—5°C and silver cyanate[15] (12 g, 0.075 mol) was added in one portion with stirring. After continuous stirring for 2 hr, an additional silver cyanate (6 g) was added. The resulting light yellow mixture was then kept under stirring for further 15 hr with cooling at 0—5°C. It was filtered and the filtrate was evaporated to dryness. The residue, dissolved in absolute methanol (100 ml), was refluxed for 3 hr and kept standing overnight to give colorless needles (5.4 g, 32%), which were recrystallized from methanol. Mp 134.5°C. IR: ν_{NH} 3280 cm^{-1}, $\nu_{C=O}$ 1690 cm^{-1}. Found: C, 42.67; H, 6.11; N, 4.05%. Calcd for $C_{12}H_{20}NO_2I$: C, 42.73; H, 5.93; N, 4.15%.

2,3-Imino-trans-*decalin (IX).* A solution of potassium hydroxide (7 g) in water (15 ml) was added into a solution of the methylcarbamate (VIII) (8 g, 0.024 mol) in ethanol (60 ml). After being refluxed for 2 hr, the reaction mixture was poured into water (700 ml). The aqueous mixture was extracted with ether and the ethereal extract was evaporated off to give (IX) (2.6 g, 72%). An analytical sample was purified by sublimation. Mp 42—47°C. IR: ν_{NH} 3170 cm^{-1}. Found: C, 78.40; H, 11.06; N, 8.65% Calcd for $C_{10}H_{17}N$: C, 79.54; H, 11.26; N, 9.27%.

2(a)-Amino-3(a)-azido-trans-*decalin Hydrochloride (X).* A solution of (IX) (10 g, 0.07 mol), sodium azide (9.15 g, 0.14 mol), and ammonium chloride (7.56 g, 0.14 mol), in ethanol (160 ml) and water (40 ml) was refluxed for 24 hr, and then poured into water. The aqueous mixture was adjusted to be slightly alkaline and extracted with ether. The ethereal extract was evaporated off to give an oil (10.8 g, 84%) which was subjected to hydrochlorination to yield (X). Hydrochloride (X) was recrystallized from ethanol–ether for an analytical sample. Mp 190—197°C. IR: (free HCl) ν_{NH_2} 3320 cm^{-1}, ν_{N_3} 2120 cm^{-1}. Found: C, 52.11; H, 8.27; N, 24.04%. Calcd for $C_{10}H_{19}N_4Cl$: C, 52.06; H, 8.24; N, 24.30%.

2(a)-3(a)-Diamino-trans-*decaline Dihydrochloride (XI).* Aminoazide compound (X) (10.8 g, 0.055 mol) was hydrogenated in a similar manner to that described for VI. Yield, 5.2 g (39%). Mp 197—230°C (decomp.). NMR (in D_2O):[14] 1.2—2.2 ppm (14H), 4.00 ppm (2H). Found: C, 47.55; H, 9.15; N, 11.03%. Calcd for $C_{10}H_{22}N_2Cl_2 \cdot 0.7H_2O$: C, 47.30; H, 9.24; N, 11.05%.

The bisacetyl derivative of XI had mp 245—250°C. Found: C, 66.37; H, 9.40; N, 10.86%. Calcd for $C_{14}H_{24}N_2O_2$: C, 66.67; H, 9.52; N, 11.11%.

2(a),3(a)-Dihydroxy-trans-*decalin(XII).* Into a mixture of 99% formic acid(110 g) and 30% hydrogen peroxide (13 g), was gradually added *trans*-Δ^2-octalin (I) (13.6 g, 0.1 mol) at 40—45°C with stirring and the stirring was continued for 9 hr. After the remaining performic acid was decomposed with sodium sulfite, formic acid was removed by evaporation and the residue was refluxed together with ethanol (50 ml) and sodium hydroxide (15 g) in water (30 ml) for 5 hr. The resulting mixture was acidified and again evaporated under reduced pressure. The residual precipitate was washed with water and recrystallized from benzene. Yield was 15.7 g. Mp 164—165.5°C. (lit,[9] 163—164°C). IR: ν_{OH} 3280 cm^{-1}. Found: C, 70.62; H, 10.56%. Calcd for $C_{10}H_{18}O_2$: C, 70.58; H, 10.58%.

trans-*Decahydro-2(a),3(a)-naphthalene Bismethanesulfonate (XIII)* was prepared from XII (12.8 g, 0.076 mol) in a similar manner to that for IV. Methanesulfonate (XIII) was purified by repeated recrystallization from methanol. Yield, 23 g (93%). Mp 129—130°C. IR: $\nu_{OSO_2CH_3}$ 800—1000 cm^{-1}. Found: C, 43.85; H, 6.86%. Calcd for $C_{12}H_{22}O_6S_2$: C, 44.17; H, 6.75%.

2(e),3(e)-Diamino-trans-*decalin Dihydrochloride (XV).* Methanesulfonate (XIII) (19.7 g, 0.06 mol) dissolved in 85% aqueous dimethylformamide (210 ml) was refluxed for 5.5 hr together with sodium azide (16.0 g, 0.25 mol). Reaction mixture was treated subsequently in a similar manner to that for VI. The oily diazidodecalin was separated as a fraction soluble in petroleum ether (100 ml, boiling region 38—43°C). Yield, 8.6 g (64%). Without further purification, the product (XIV) was hydrogenated over Adam's catalyst in absolute ethanol (100 ml) at room temperature under 100 Kg/cm² for 72 hr. The resulting ethanol solution was acidified with hydrochloric acid, ethanol being removed by evaporation. The residue was dissolved in water and washed with ether. The final aqueous solution was evaporated and the residue was recrystallized from water–ethanol to yield diamine dihydrochloride(XV) (2.7 g, 28.5%). Mp 265—270°C. NMR(in D_2O):[14] 1.2—2.4 ppm (14H), 3.6—3.8 ppm (2H). Found: C, 49.44; H, 9.10; N, 11.20%. Calcd for $C_{10}H_{22}N_2Cl_2$: C, 49.79; H, 9.10; N, 11.62%.

The bisacetyl derivative of XV had mp above 290°C. Found: C, 66.49; H, 9.55; N, 11.08%. Calcd for $C_{14}H_{24}N_2O_2$: C, 66.67; H, 9.52; N, 11.11%.

trans-*3-Azido-2-hydroxytetralin (XVIII).* 2,3-Epoxytetralin (XVII) (27.3 g, 0.187 mol) dissolved in 80% aqueous ethanol (380 ml), was refluxed for 24 hr together with sodium azide (15 g, 0.23 mol) and ammonium chloride (12.3 g, 0.23 mol). The reaction mixture was poured into water (1 liter) and a cystalline precipitate was recrystallized from benzene–petroleum ether. The yield was nearly quantitative. Mp 66—67°C. IR: ν_{OH} 3300 cm^{-1}, ν_{N_3} 2124 cm^{-1}. Found: C, 63.58; H, 5.83; N, 22.08%. Calcd for $C_{10}H_{11}N_2O$: C, 63.49; H, 5.82; N, 22.02%.

trans-*3-Azido-2-tetrahydronaphthyl Methanesulfonate (XIX).* *trans*-Azidohydrin (XVIII) (40.8 g, 0.217 mol), dissolved in pyridine (155 ml) was treated with methanesulfonyl chloride in a similar manner to that for III. The yield was nearly quantitative. An analytical sample was recrystallized from methanol. Mp 76—76.5°C. IR: ν_{N_3} 2120 cm^{-1}, $\nu_{OSO_2CH_3}$

14) The proton signal in D_2O was used as a reference and set at 5.0 ppm downfield from TMS.

15) R. G. Neville and J. J. McGee, "Inorganic Syntheses" Vol. 8, p. 23 (1966) McGraw-Hill, New York.

820—980 cm^{-1}. Found: C, 49.14; H, 4.94; N, 15.42%. Calcd for $C_{11}H_{13}N_3O_3S$: C, 49.43; H, 4.87; N, 15.73%.

cis-*2,3-Diazidotetralin (XX).* A mixture of azidomethanesulfonate (XIX) (17 g, 0.064 mol) and sodium azide (8.5 g, 0.13 mol) was treated in a similar manner to that for V, to give the oily product (XX) (7.5 g, 54.5%). IR: ν_{N_3} 2120 cm^{-1}.

cis-*2,3-Diaminotetralin Dihydrochloride (XXI).* Diazide (XX) (7.5 g, 0.035 mol) in absolute ethanol (100 ml) was hydrogenated in a similar manner to that for VI. Dry hydrogen chloride was passed into the resulting ethanol solution at 0—5°C to give a colorless precipitate, which was recrystallized from water–ethanol to yield diamine dihydrochloride (XXI) (7 g, 85%). Mp 243°C. NMR(in D_2O): 2.05 ppm (4H), 2.97 ppm (2H), 6.06 ppm (4H). Found: C, 51.17; H, 6.93; N, 11.73; Cl, 29.4%. Calcd for $C_{10}H_{16}N_2Cl_2$: C, 51.06; H, 6.83; N, 11.90; Cl, 30.2%.

trans-*Methyl-2-iodo-3-tetrahydronaphthylcarbamate (XXIII).* 1,4-Dihydronaphthalene (XVII) (13 g, 0.1 mol) and iodine (25.4 g, 0.1 mol) were dissolved in dry ether (170 ml) at 0—5°C. To this solution was added silver cyanate (15 g, 0.1 mol) in one portion. The mixture was stirred for 24 hr and filtered. The filtrate was evaporated to dryness. The solid residue was dissolved in absolute methanol (300 ml), and refluxed for 3 hr. The solution was treated with sodium thiosulfate in order to remove the remaining iodine and then evaporated to about 100 ml. The concentrated solution was poured into water (3 l) to give precipitate which was recrystallized from methanol. Mp 138—140°C. IR: ν_{NH} 3320 cm^{-1}, $\nu_{C=O}$ 1700 cm^{-1}. Found: C, 43.23; H, 4.33; N, 4.12%. Calcd for $C_{12}H_{14}NO_2I$: C, 43.50; H, 4.23; N, 4.23%.

cis-*2,3-Iminotetralin (XXIV).* A solution of potassium hydroxide (18 g) in water (35 ml) was added into a solution of methanesulufonate (XXIII) (20 g, 0.06 mol) in ethanol (170 ml). After being refluxed for 2 hr, the reaction mixture was concentrated to about 100 ml and poured into water (300 ml). The aqueous mixture was extracted with ether and the ethereal extract was evaporated and distilled to give an oil (5 g, 57%) boiling at 70—80°C/0.17 mmHg, which solidified immediately. Mp 72°C. IR: ν_{NH} 3238 cm^{-1}. Found: C, 81.81; H, 7.52; N, 9.12%. Calcd for $C_{10}H_{11}N$: C, 82.75; H, 7.59; N, 9.66%.

trans-*3-Azido-2-aminoteralin Hydroazide (XXV).* A mixture of imine (XXIV) (5 g, 0.036 mol), sodium azide (11.5 g, 0.174 mol) and ammonium chloride (9.5 g, 0.147 mol) in 80% aqueous ethanol (220 ml) was refluxed for 17 hr, and then poured into water. A solid product was obtained by extraction of the aqueous mixture with ether, followed by evaporation to dryness. Recrystallization from methanol gave the product melting at 88°C. Yield, 5.5 g (68%). IR: ν_{N_3} 2040 and 2140 cm^{-1}, (free HN_3) ν_{N_3} 2110 cm^{-1}, ν_{NH_2} 3320 and 3380 cm^{-1}. Found: C, 52.21; H, 5.70; N, 42.36%. Calcd for $C_{10}H_{13}N_7$: C, 51.94; H, 5.63; N, 42.42%.

trans-*2,3-Diaminoteralin Dihydrochloride (XXVI).* *trans*-3-Azido-2-aminotetralin (XXV) (4.5 g, 0.025 mol) was hydrogenated and was worked up in a similar manner to that for *cis*-diamine (XXI). Yield, 3.2 g (57%). Mp 270°C. NMR(in D_2O): 2.00 ppm (4H), 2.75 ppm (2H), and 6.07 ppm (4H). Found: C, 51.11; H, 6.93; N, 11.67%. Calcd for $C_{10}H_{16}N_2Cl_2$: C, 51.06; H, 6.83; N, 11.90%.

1,2,3,4-Tetrahydro-trans-*2,3-naphthalene Bismethanesulfonate (XXVIII).* *trans*-Glycol (XXVII) (21.1 g, 0.13 mol) was mesylated in a similar manner to that for III and XIII, to give the bismethanesulfonate (XXVIII) (39.4 g, 95%) which was recrystallized from methanol. Mp 138°C. IR: $\nu_{OSO_2CH_3}$ 825—1000 cm^{-1}. Found: C, 44.65; H, 5.05%. Calcd for $C_{12}H_{16}O_7S_2$: C, 44.95; H, 5.02%.

trans-*2,3-Diazidotetralin (XXIX).* Bismethanesulfonate (7.4 g, 0.023 mol) was refluxed in a mixture of dimethylformamide (60 ml) and water (10 ml) for 5 hr together with sodium azide (5.1 g, 0.091 mol), to afford diazide (XXIX) (2 g, 40%), which was recrystallized from methanol. Mp 55°C. IR: ν_{N_3} 2120 cm^{-1}. Found: C, 56.49; H, 4.75; N, 39.20%. Calcd for $C_{10}H_{10}N_6$: C, 56.07; H, 4.67; N, 39.25%. Hydrogenation of the diazide (6 g, 0.03 mol) followed by subsequent working up yielded diaminodihydrochloride (XXVI) (4.5 g, 68%).

Determination of Acid Dissociation Constants. The potentiometric measurements were carried out at 25°C and under a constant ionic strength (μ=0.100) with potassium nitrate, using a Horiba pH meter model P equipped with 1026 glass and 2010 calomel electrodes. The pH-meter reading was calibrated under the same titration conditions by referring to the hydrogen ion concentration cal-

culated from the acetic acid–potassium hydroxide titration system.

Calculation. The titration curves of diamine dihydrochlorides are shown in Fig. 1, from which the dissociation constants were calculated according to the standard procedure by Schwarzenbach *et al.*[16] as typical dibasic acids. The result for the present diamines are summarized in Table 1 along with the values of related compounds.

Infrared Spectra in Highly Diluted Solutions. Sample solutions were prepared as follows. To a solution of 20 mg of diamine hydrochloride in 0.5 ml of water were added three drops of 50% aqueous potassium hydroxide. The resulting alkaline solution was extracted with two 1.5 ml portions of tetrachloroethylene which had been purified by passing through a column of activated alumina. The combined extract was dried over anhydrous sodium sulfate. IR spectra were measured with matched pairs of 1.0, 5.0, and 10.0 cm quartz cells using a JASCO-DS-403G spectrophotometer at room temperature. Concentrations of the solutions were in the range 2×10^{-2}—6×10^{-4} M, where intermolecular association of these compounds can be neglected. The results are shown in Fig. 2.

The Peroxide-induced Addition of Acetic Acid to Olefins

Yasuo SUHARA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo

(Received May 20, 1972)

The peroxide-induced addition of acetic acid to ethylene gave straight-chain fatty acids, such as butyric, hexanoic, octanoic, decanoic, lauric, myristic, and palmitic acids. Some α-branched-chain fatty acids were also formed. Di-*t*-butyl peroxide (DTBP) was an effective initiator in forming fatty acids. To obtain the 1 : 1-telomer acids, it was preferable that a 20—10 : 1 : 0.25 (mol) mixture of acetic acid, ethylene, and DTBP be heated at 150°C for 6 hr. Straight-chain fatty acids were also obtained by the reaction of acetic acid to 1-olefins under similar conditions.

The radical addition to 1-olefins gives anti-Markownikoff's products,[1] and α-branched-chain fatty acids are generally formed by the addition of fatty acids to 1-olefins.[2-4] It is expected that straight-chain fatty acids can be obtained by the radical addition of acetic acid to ethylene or 1-olefins. However, the removal of a hydrogen atom from the α-position of acetic acid is much more difficult than that of other fatty acids.[2,3,5,6] Consequently, the yields of the addition products of acetic acid to olefins are generally poor.[5,6] A few papers[3,5,7,8] have reported on the addition of acetic acid to olefins. However, the addition of acetic acid to ethylene has been considered in only two patents.[6,9] Therefore, the details of the reaction have not been made clear.

In the present study, in order to find preferable conditions for the formation of fatty acids, the acidic products of the radical addition of acetic acid to ethylene and 1-olefins under various conditions were investigated. The peroxides used were di-*t*-butyl peroxide (DTBP), *t*-butyl hydroperoxide (TBHP), benzoyl peroxide (BZPO), and dilauroyl peroxide (DLPO). The reaction was carried out in an autoclave, and the products were identified by GLC, GC–MS, and IR, and determined by GLC.

When BZPO or DLPO was used in the reaction temperature range of 60—180°C, no fatty acids were formed. When DTBP or TBHP was employed, however, the addition product was a mixture of acidic and neutral substances, and DTBP was the best initiator for the reaction forming fatty acids. No succinic acid formed by the radical dimerization of acetic acid was found in any products, although a small amount of succinic acid was obtained by heating acetic acid with DTBP in the absence of an olefin.

In the case of the addition of acetic acid to ethylene, no acidic product was separated from the reaction mixture, because butyric acid formed by the reaction is easily soluble in water. However, the compositions of the acidic products could be determined by GLC. The addition product contained acetic, butyric (1 : 1-telomer), 2-ethylbutyric, hexanoic, (2 : 1-telomer), 2-ethylhexanoic, octanoic (3 : 1-telomer) 2-ethyloctanoic, decanoic (4 : 1-telomer), lauric (5 : 1-telomer), myristic (6 : 1-telomer), and palmitic (7 : 1-telomer) acids, various hydrocarbons, and a small amount of an ester

a) Small amounts of palmitic acid were detected except Runs 3, 5, and 9.

of acetic acid. 2-Ethylbutyric, 2-ethylhexanoic, and 2-ethyloctanoic acids are presumably formed by the adition of butyric, hexanoic, and octanoic acids respectively to ethylene. 2-Ethylhexanoic acid may also be formed by the addition of ethylene to a radical formed by the addition of butyric acid to ethylene. The ester of acetic acid may be formed by the ionic addition of acetic acid to ethylene.[10]

The reaction conditions and the yields of the addition products of acetic acid to ethylene are shown in Table 1. The best yield of straight-chain fatty acids was given by Run 11 (the conversion of ethylene to straight-chain fatty acid: 7.0%), but very large amounts of neutral substances were also formed in this case. On the other hand, the autoclave was a little injured at reaction temperatures above 70°C. Judging from the conversions of ethylene, the yields of the products, and the reaction time and the temperature, the conditions of Runs 1 and 6 are preferable (the conversions of ethylene to straight-chain fatty acids were 35.2% in Run 1 and 17.2% in Run 6).

The telomerization for the formation of fatty acids with reasonable yields required 20—25 mol % of a peroxide to olefin; the amount of the peroxide was much larger than the amount employed usually as an initiator. This fact shows that the kinetic chain lengths are rather short.

The addition of acetic acid to 1-olefins was carried out under conditions similar to those in the case of Run 6, and the acidic and neutral products were separated from each other. The acidic addition product of acetic acid to 1-octene was a mixture of hexanoic, heptanoic, 3-methylnonanoic (Markownikoff's product), decanoic (1 : 1-telomer), 4-hexyldodecanoic 2 : 1-telomer), and 4,6-dihexyltetradecanoic (3 : 1-telomer) acids. It is noteworthy that Markownikoff's product[11] and lower fatty acids were also formed, although their yields were quite low.

Gas chromatograms of the acidic addition products of acetic acid to other 1-olefins resembled that of the acidic addition product of acetic acid to 1-octene. Thus, the formations of 1 : 1-, 2 : 1-, and 3 : 1-telomers, and of small amounts of lower fatty acids and Markownikoff's products, were observed. The following acids (1 : 1-telomers) with purities of more than 95% could be obtained from the acidic products of the addition of acetic acid to the corresponding 1-olefins by distillation or recrystallization: octanoic (from 1-hexene), decanoic (from 1-octene), lauric (from 1-decene), myristic (from 1-dodecene), palmitic (from 1-tetradecene), stearic (from 1-hexadecene),

Table 2. Conversion of 1-olefin in addition of acetic acid to 1-olefin

Acetic acid : 1-olefin : DTBP=10 : 1 : 0.25 (mol)
Reaction temperature : 150°C. Reaction time: 6 hr.

and eicosanoic (from 1-octadecene) acids.

The conversions of 1-olefins are shown in Table 2. Allen *et al.* obtained decanoic acid in a 70% yield from a 300 : 1 : 0.15 (mol) mixture of acetic acid, 1-octene, and DTBP.[3] Although the yield based on the moles of 1-octene employed was very high, only 6.7 g of decanoic acid were obtained from 1 kg of acetic acid under the above conditions. According to the conditions shown in Table 2, however, 81.2 g of decanoic acid were obtained from the same amount of acetic acid. Therefore, the present conditions were preferable practically.

Dimers and trimers of the 1-olefins employed and esters of acetic acid were found in the neutral products.

Experimental

GLC was carried out with a Hitachi Gas Chromatogram 063 equipped with dual columns (3 mm × 2 m) packed with 15% SE 30-Chromosorb WAW (70→300°C, 10°C/min) or 20% DEGS-Chromosorb WAW (50→220°C, 10°C/min).

GC-MS was carried out with a Shimadzu LKB-9000 Gas Chromatograph-Mass Spectrometer with a column packed with 15% SE 30-Chromosorb WAW, and the ionization intensity was 70 eV.

The IR spectra were measured in a liquid film with a Hitachi EPI-S2 Infarared Spectrophotometer, a sodium chloride cell being used.

Identification of Products. The acidic products were identified by deriving them into their butyl esters, and by comparing the retention times of the esters in GLC with those of authentic esters using two columns packed with SE 30 and DEGS. In the cases of the addition products of acetic acid to ethylene, both butyl and amyl esters of the products were used in order to distinguish between acidic and neutral substances. In addition, the correction factor for GLC and mass spectrum of each butyl ester were measured.

The derivation into butyl and amyl esters was done as follows: Ten milliliters of 1-butanol or 1-pentanol containing 0.2 ml of sulfuric acid was added to 1 g of a sample, and the solution was warmed for 1 hr on a water bath. Then, a solution saturated with both sodium carbonate and sodium chloride was added to the reaction mixture until the mixture was free from sulfuric acid; the upper layer of the mixture was then ready to submit to GLC.

The neutral products were analyzed by means of GLC and IR without pretreatment.

Materials. The purity of ethylene was more than 99%. Each gas chromatogram of acetic acid and 1-olefins showed a single peak. The 1-olefins used were 1-hexene, 1-octene, 1-decene, 1-dodecene, 1-tetradecene, 1-hexadecene, and 1-octadecene. The peroxides were all commercial products.

Addition of Acetic Acid to Ethylene. A typical procedure (Run 6) was as follows: Ninety milliliters of acetic acid and 5.70 g of DTBP were put in a 200-ml autoclave, after which ethylene was fed into the autoclave until the pressure gauge showed 36 kg/cm² at 20°C (the pressure was calculated by presuing that ethylene was an ideal gas and that it was insoluble in acetic acid). When stirring was begun, the pressure quickly dropped to 13.5 kg/cm². The reaction mixture was heated at 150°C under stirring. The pressure rose to 26 kg/cm² with an increase in the temperature, and then it gradually decreased to 18 kg/cm². After 6 hr, the reaction mixture was cooled and distilled to remove most of the unreacted acetic acid.

A part of the residue was esterified for identification. Most of the residue was dissolved in ether, and the ethereal solution was washed successively with water, a 5% aqueous potassium carbonate solution, and water. The ethereal solution was dried over anhydrous sodium sulfate, and the ether was distilled off to obtain neutral substances.

The conversions of ethylene and the yields of fatty acids were calculated from the results of GLC, and the amounts of the residue and neutral substances.

Addition of Acetic Acid to 1-Olefins. A mixture of acetic acid (2.0—1.5 mol), and 1-olefin, and DTBP (molar ratio, 10 : 1 : 0.25) was stirred in a 200-ml autoclave at 150°C for 6 hr. Then, unreacted acetic acid was distilled off from the reaction mixture, and the residue was dissolved in ether. The ethereal solution was washed successively with water, a 5% aqueous potassium carbonate solution, and water. After being dried over anhydrous sodium sulfate, the ether was distilled off to obtain neutral product. The washings obtained above were combined and then acidified with hydrochloric acid. The acidic product separated from the washings was extracted with ether. The ethereal solution was washed with water and dried over anhydrous sodium sulfate. The ether was distilled off, and acidic product was thus obtained. A part of the acidic product was esterified to make identification possible.

The isolation of 1 : 1-telomer acids from the acidic products was carried out by distillation (C_8—C_{12} acids) or by three recrystallizations (C_{14}—C_{20} acids) from petroleum benzin (bp 60—85°C).

The author is grateful to Mr. Yasuhiko Kubota for recording the GC-MS, and to Mr. Yutaka Inoue and Mr. Mitsuru Tanaka for their assistance in the experimental work.

Further Study on the Course of Olefin Dimerization Catalyzed by σ-Aryl Nickel(II) Compound-Boron Trifluoride Etherate

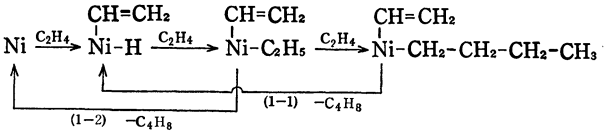
Ken-ichi MARUYA, Tsutomu MIZOROKI, and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received September 22, 1972)

The codimerization of ethylene with propylene catalyzed by the catalyst systems composed of bis(triphenylphosphine)bromo(σ-aryl)nickel(II) and boron trifluoride etherate was investigated to know the course of the reaction from the product distribution. 2-Pentene and 2-methyl-1-butene are mainly formed in the first stage of the codimerization. Their formations are in consistent with the process of the insertion of propylene into ethyl-nickel bond to form 1-methylbutyl- and 2-methylbutyl-nickel complexes followed by elimination of β-hydrogen to give 2-pentene and 2-methyl-1-butene respectively.

It was reported that a new catalyst system composed of a σ-aryl nickel(II) compound and boron trifluoride etherate is highly active and selective for ethylene dimerization[1] and the codimerization of ethylene with styrene[2] to give butene and 3-phenyl-1-butene respectively. From the study on the isotopic exchange between C_2H_4 and C_2D_4 and the dimerization of C_2D_4 using this catalyst system, it has been concluded that a nickel hydride is responsible for dimerization of ethylene and that the hydrogen is supplied by dissociative addition of ethylene.[3] In the previous paper,[4] two possible processes(1-1 and 1-2) were left undiscriminated on the course of dimerization of ethylene with the same catalyst.



The isomer distribution of pentene obtained from the codimerization of ethylene with propylene, however, is helpful to discriminate them, because the isomer distribution of pentene formed depends on the processes expected for 1-1 and 1-2.

The present work was undertaken to clarify the course of olefin dimerization catalyzed by bis(triphenylphosphine) bromo(1-naphthyl)nickel(II) in the presence of boron trifluoride etherate by investigating the product distribution of the codimerization of ethylene with propylene.

Experimental

Dried bis(triphenylphosphine)bromo(1-naphthyl)nickel (II) (1 mmol) prepared according to the method described in the literature[5] was dissolved in a dried methylene dichloride (30 ml) at 0°C under nitrogen atmosphere, using a two necked flask (50 ml), followed by adding a given amount of benzene solution of purified boron trifluoride etherate (10% in volume) with vigorous stirring. The nitrogen in the flask was, then, evacuated before propylene (300 ml at S. T. P.) was introduced into the flask at 0°C and the pressure was kept constant at 40 cmHg for a given period of time by supplying ethylene during the run. The codimerization was terminated by cooling the flask with liquid nitrogen. All volatile materials such as ethylene, propylene, butenes, pentenes, solvent *etc.* in the flask were transferred into another flask cooled with liquid nitrogen and their amounts were determined by a gas chromatograph equipped with VZ-7 columun (8 m).

Results and Discussion

The mole ratio of propylene to ethylene in the solution was separately estimated from their solubilities in methylene dichloride under the same condition. On addition of propylene (300 ml S. T. P.) to the methylene dichloride solution(30 ml) of 1-$C_{10}H_7Ni(P\phi_3)_2Br$ in the absence of boron trifluoride etherate, 249 ml of propylene was dissolved leaving a 20 cmHg of propylene in the gas phase. On a further addition of ethylene to this solution up to a total pressure of 40 cmHg including 20 cmHg of propylene and 15 cmHg of the solvent vaper, 13 ml (S. T. P.) of ethylene was dissolved. Thus the mole ratio, C_3H_6/C_2H_4, in the solution is calculated to be about 23, a fairly large excess of propylene. This ratio could be assumed to be unchanged during the early period of the reaction time. Since ethylene was absorbed almost linearly with respect to the reaction time, the rate of ethylene absorption was obtained from its amount consumed within a given reaction time. This rate can be regarded as the rate of reaction of ethylene under large excess of propylene dissolved. The rate increases linearly with increasing the mole ratio as was observed in the dimerization of ethylene.[4] In Fig. 1, the product distribution at the same temperature and concentrations of ethylene and propylene are plotted against the amount of ethylene consumed, which depends on the reaction time and the mole ratio of $BF_3 \cdot OEt_2$ to 1-$C_{10}H_7Ni(P\phi_3)_2Br$. This indicates that the product distribution neither depends on the amount of ethylene consumed, nor on the mole ratio of the catalyst. Accordingly, both butene and pentene are catalytically formed by the same active species and its amount increases almost

linearly with increasing the amount of boron trifluoride etherate as was discussed in the previous paper.[4] The isomer distribution of pentene is shown in Fig. 2 as a function of the amount of ethylene consumed. The initial products of the codimerization are mainly 2-pentene and 2-methyl-1-butene. The fraction of isopentene in total pentene is nearly 54±1%, independent of the amount of ethylene consumed and the mole fraction of the catalyst. Since the sum of the selectivities to butene and pentene reaches near 100%, a secondary reaction of butene and pentene with ethylene is negligible. The coordination equilibrium between olefin and the active species is evidently more favorable for ethylene than for propylene, because butene is preferably formed even in the presence of a large excess of propylene. This is also supported by the strong inhibition of the dimerization of propylene caused by ethylene.

If pentene is formed through the following processes (2-1～4) expected for 1-1, four isomers of pentene, 2-methyl-1-butene, 1-pentene and 3-methyl-1-butene, will be initially formed. If it does through the other processes expected for 1-2, neither 2-pentene, nor 2-methyl-1-butene will be initially formed. Figure 2 indicates that pentene should be formed predominantly through the processes of 2-1～4, since 2-pentene (d and e) and 2-methyl-1-butene(a) are main products, where the formation of small amounts of 1-pentene and 3-methyl-1-butene can be attributed to the disadvantage of propylene for its coordination to the active species of the catalyst. Thus this results supports that butene is formed through the process of 1-1. At present, there is no evidence to support the existence of vinyl ligand on nickel atom during the reaction. All attempts to detect the vinyl and its coupling compounds were unsuccessful.

The Distribution of Benzene and Its Monosubstituted Derivatives between Hexane and Water

Tatsuya SEKINE, Yasuo SUZUKI, and Naohiko IHARA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 14, 1972)

The liquid-liquid distribution equilibria of benzene and its eight monosubstituted derivatives have been investigated in order to study the effect of the substituted atom or atom group on the distribution behavior. The results are compared with the solubilities of the materials in water.

Experimental

All of the reagents used were of a reagent grade. The purity was checked by spectrometry and, in some cases, by gas chromatography. All of the procedures were carried out in a thermostatted room at 25±0.3°C. A weighed portion of the material was dissolved in hexane. The concentration of aniline was further checked by titration with a standard acid solution.

The distribution experiments were done as follows. A portion of a hexane solution of the material and a portion of water (in the case of benzoic acid, 0.03M perchloric acid in order to prevent dissociation) were placed in a stoppered glass vessel. The two phases were shaken vigorously by hand for three minutes, and then the hexane phase was transferred into a stoppered glass tube and centrifuged. When the distribution ratio was too high, a portion of this aqueous phase was also shaken with a portion of hexane, and then this hexane phase was transferred into another glass tube and centrifuged. The concentration of the material in the hexane phase was determined by spectrometry.

Results and Discussion

The distribution ratio of the material, M, was defined as follows:

$$D = \frac{[M]_{org,total}}{[M]_{total}} \quad (1)$$

The subscript "org" denotes the species in the organic phase, while the absence of a subscript denotes that in the aqueous phase.

The distribution ratios of all these materials except benzoic acid were independent of their concentrations. Thus, it was concluded that these materials undergo no dissociation in the aqueous phase and that there is no association in the organic phase under these experimental conditions.

For this reason, the distribution constant;

$$M \rightleftharpoons M_{(org)}, \quad K_D = \frac{[M]_{org}}{[M]} \quad (2)$$

for these materials is identical with the distribution ratio. The constants obtained are listed in Table 1.

The distribution ratio of benzoic acid is given in Fig. 1 as a function of its concentration in the aqueous phase. Since the aqueous phase is 0.03M perchloric acid, the dissociation of benzoic acid (pK_a=4.0[1] μ=0.1 25°C)) is negligible. Furthermore, this distribution ratio was unaffected by perchloric acid within the concentration range from 0.003M to 0.03 M.

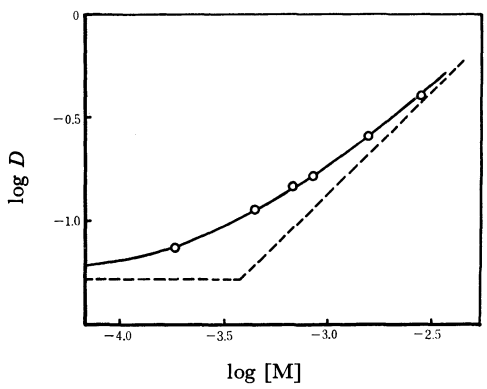

Fig. 1. Distribution ratio of benzoic acid which is denoted by M, between hexane and 0.03 M $HClO_4$ as a function of the solute concentration in the aqueous phase. The solid curve represents:
$\log D = \log(K_D + 2K_{dim(org)}K_D^2[M])$
$= \log(5.13\times10^{-2} + 1.32\times10^{2}[M])$
The two dotted lines represent the asymptotes for the extraction curve.

Thus, the distribution ratio of benzoic acid can be written as;

$$D = \frac{[M]_{org} + 2[(M)_2]_{org}}{[M]} \quad (3)$$

The dimerization constant in the organic phase can be written as;

$$2M_{(org)} \rightleftharpoons (M)_{2(org)}, \quad K_{dim(org)} = [(M)_2]_{org}/[M]^2_{org} \quad (4)$$

By introducing the distribution constant and this dimerization constant, Eq. (3) can be rewritten as;

$$D = K_D + 2K_{dim(org)}K_D^2[M] \quad (5)$$

The K_D and $2K_{dim(org)}K_D^2$ values can be determined by a curve-fitting method.[2] The value of $K_{dim(org)}$ obtained from these values is listed in Table 1. The table also lists the solubilities of these materials reported in the literature.[3]

The solubility in water has sometimes been employed as an index of the aquophilic tendency of molecular substances; when a molecule has an aquophilic group, it is usually estimated to be more soluble in water than those which have no such group. However, this is only a rough approximation, because the introduction of such a group into a nonpolar molecule increases

TABLE 1. DISTRIBUTION CONSTANTS BETWEEN HEXANE AND WATER (25°C) AND OTHER PROPERTIES OF BENZENE AND ITS MONOSUBSTITUTED DERIVATIVES

Material	Distribution (25°C)		Solubility (30°C)	
	K_D[a]	$K_D/K_D(C_6H_6)$	S[b] (M)	$S(C_6H_6)/S$
Benzene	2.8×10^{2}	1	2.4×10^{-2}	1
Toluene	9.7×10^{2}	3.5	6.2×10^{-3}	3.9
Fluorobenzene	3.0×10^{2}	1.1	1.6×10^{-2}	1.5
Chlorobenzene	9.5×10^{2}	3.4	4.3×10^{-3}	5.6
Bromobenzene	1.2×10^{3}	4.5	2.8×10^{-3}	8.6
Nitrobenzene	3.1×10	1.1×10^{-1}	1.7×10^{-2}	1.4
Aniline	9.0×10^{-1}	3.3×10^{-3}	4.1×10^{-1}	5.9×10^{-2}
Phenol	1.3×10^{-1}	4.9×10^{-4}	9.8×10^{-1}	2.4×10^{-2}
Benzoic acid[c]	5.1×10^{-2}	1.9×10^{-4}	3.4×10^{-1}	7.1×10^{-2}

a) The values for benzoic acid, *cf.* Fig. 1. b) The values of solubility by wt% are summarized in Ref. 3. They are converted into molarity assuming that the density of the solution at this temperature is 1.0. c) The dimerization constant in Eq. (4) was obtained to be 2.5×10^{4} in hexane.

not only the interaction between the solute and water molecules in the solution, but also the interaction among the molecules in the pure solute phase. For example, as can be seen from Table 1, the solubility of nitrobenzene in water in the molar units is even lower than that of benzene; this is probably caused by the strong interaction among the molecules in the water-saturated nitrobenzene phase.

The increase in the distribution ratio of toluene may mainly be attributed to the increase in the molecular volume. It was reported by Collander[4] that the distribution ratio of organic compounds between diethyl ether and water increases by a factor of from two to four for each new CH_2 group introduced into the molecule in a homologous series. The solubility of normal aliphatic alcohols in water was found by Kinoshita, Ishikawa, and Shinoda[5] to decrease by a factor of four when a CH_2 group is added to the hydrocarbon chain; an increase in the distribution ratio of aliphatic alcohols between benzene and the aqueous phase by a factor of around four was also reported by Tanaka and Kojima.[6] The increase in the distribution ratio by a factor of 3.5 by the replacement of a hydrogen atom of benzene with a methyl group in the present study is quite similar to these previous results.

The effect on the distribution of the replacement of a hydrogen atom with a halogen atom is not very clear. However, the effect of the replacement with one of the four aquophilic atom groups, $-NO_2$, $-NH_2$, -OH, and -COOH, seems to be very clear. The replacement increases the molecular volume, but it also increases the interaction with water very much, and the distribution ratio is very much decreased by the latter.

Since the interaction between the solute molecules in the pure solute phase has no effect on the distribution ratio, the effect of the replacement on the distribution is not parallel with that on the solubility, as may be seen from Table 1; the introduction of an aquophilic group does not so increase the solubility into water as it increases the distribution into the aqueous phase.

The dimerization of benzoic acid in the organic phase is very important for its distribution. As can be seen from Fig. 1 and from the value of K_D, the effect of the dimerization becomes negligible only when the concentration is very low.

Rise Times of Triplet-Triplet Absorptions of Some Aromatic Hydrocarbons

Naohiko MIKAMI, Yasuo UDAGAWA, Ikuo HAYASHI, Koji KAYA, and Mitsuo ITO

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai

(Received July 4, 1972)

Recent development of lasers has given the chemist short-lived sources of excitation which are powerful enough to observe excited singlet species by absorption spectroscopy.[1-5] This technique has been called "laser photolysis" and applied to know higher excited singlet levels. Analyses of the growth rate of triplet state and the decay process of singlet state which occur during scores of nanoseconds are possible by the similar technique and give informations about dynamic behavior of energy relaxation. Especially, if the rate constant of the growth of the triplet state is determined, it provides information on the initial state of the relaxation process to the triplet state. In this note we report the rise times of the triplet states of phenanthrene, 3,4-benzpyrene and 1,2,3,4-dibenzanthracene in 2-methyltetrahydrofuran at room temperature. The transient spectra and the decay times of the singlet states of these compounds were already reported by Porter and Topp.[4] In order to make a comparison, we also measured the decay times of their excited singlet states on the same experimental condition for the triplet states.

A coaxial type pulsed N_2 laser constructed in our laboratory was used as a pumping source. A 12 nsec, 0.2 mJ. pulse of light of wavelength of 3371 Å is produced with a repetition rate of *ca.* 30 Hz. In spite of the small peak power of our N_2 laser used here, sufficient amount of excited singlet molecules for observation of the transient process can be accumulated by focusing the laser beam on a very small area.

A probe light must be intense on account of the low sensitivity of wide band detection system. When fluorescence overlaps S–S or T–T absorption region, monitoring light has to be more intense than the fluorescence by the order of two or more. A CRL 52B cw Ar ion laser which has total output power of 4 W was used for this purpose. This laser has eight lasing lines between 4579 Å and 5145 Å and the molecules studied here have both S–S and T–T absorptions in this region.[4] The two laser beams were made to coincide strictly by employing the experimental setup shown in Fig. 1. The greater part of the light from N_2 laser passed through a quartz plate Q, while a portion

of the Ar ion laser beam was reflected and the two beams were adjusted to coincide exactly. Although the reflectivity of the quartz plate is low, reflected Ar ion laser beam was still intense enough. After adequate diaphragms the two beams were focused through the sample cell and refocused onto the entrance slit of a Nalumi 0.3-m double monochromator.

The repeated pulsed N_2 laser enabled us to employ sampling technique which is suitable for high speed phenomena. A probe beam emerging from the exit slit of the monochromator was detected by a 1P28 photomultiplier with a load resistance of 50 Ω. The output of the photomultiplier at a centain time after triggering was displayed on a Tektronix 564A sampling oscilloscope.

Fig. 2 shows the rise curve of the T–T absorption of 5×10^{-3} mol/l deaerated solution of phenanthrene in 2-methyltetrahydrofuran taken at 4880 Å and decay curve of the S–S absorption at 5145 Å. Upper traces are with the monitoring light off and lower traces are with the exciting light off. Assuming first order processes, triplet rise time and singlet decay time are determined by plotting log $((O.D.)^{T-T}_{max}-(O.D.)^{T-T})$ and log $(O.D.)^{S-S}$ *vs.* time, respectively. Fig. 3 shows that they are described well as first order processes and the results are tabulated in Table 1. The rise times of the T–T absorption and the decay times of the S–S absorption coincide with each other within experimental errors and also agree well with the fluorescence lifetimes. These agreements apparently show that the initial states of the energy relaxation process of these molecules to their triplet states are the fluorescent states. In this table, the rate times obtained in this work are somewhat different from those of the literatures.[4,6] It is probably due to the difference of the solvent used.

The method described here is considered to be of wide applicability to the study of the dynamic behaviors of the excited state molecules. For example, intermediate species formed after the photolysis can be detected, and the rate of formation can be determined. Recently it has been suggested that intersystem crossing of electron-donor-acceptor complex[7] or photoionization of organic molecules[8] may occur from excited Franck-Condon state, not from fluorescent state. Such problems can be dissolved by the comparison of the rise time of triplet state or ionized molecules with the decay time of singlet state, both of which are determined with high accuracy by this technique.

Charge-transfer and Proton-transfer in the Formation of Molecular Complexes. V.[1] Tryptophan Picrate

Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 11, 1972)

In connection with our work on molecular complexes in which charge-transfer and proton-transfer interactions operate simultaneously between the component molecules, and also in connection with a recent report on the crystal and molecular structures of red-colored serotonin picrate monohydrate by Thewalt and Bugg,[1-3] a spectroscopic examination of the tryptophan picrate has been undertaken. The preparation of this picrate was reported by Mayeda as early as 1907.[4] He noted also that the color is similar to that of the indole picrate.

The tryptophan picrate was crystallized from water following the procedure described by Mayeda, and

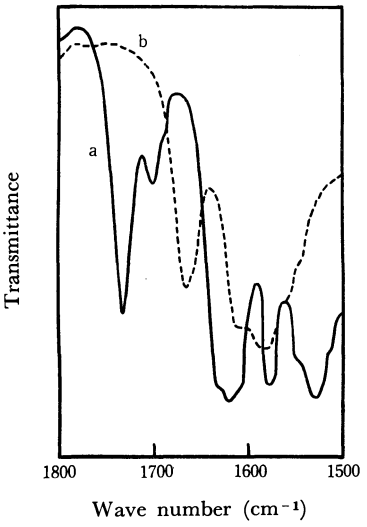

Fig. 1. Vibrational spectra of a) the tryptophan picrate and b) tryptophan.

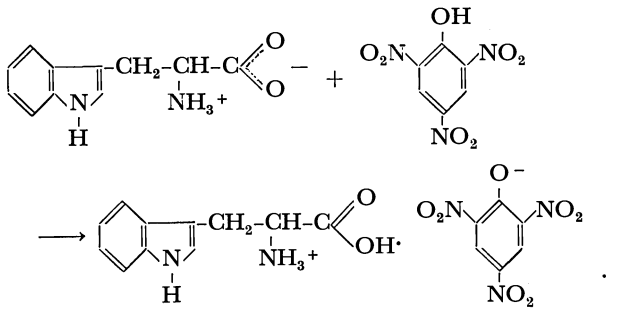
the indole picrate, from chloroform. As was pointed out by Briegleb and Delle,[5] the infrared spectrum of the latter complex, well approximated by the superposition of the spectra of the component compounds, clearly indicates the absence of proton transfer.

Tryptophan is in the form of the zwitter ion; therefore, the vibrational spectrum in the region from 2000 to 4000 cm^{-1} is dominated by the pattern due to the NH_3^+ group. Although this pattern remains through the picrate formation, a big change is observed in the region from 1500 to 1800 cm^{-1} (see Fig. 1). A strong band located at 1740 cm^{-1} in the picrate should be assigned to the carbonyl stretching vibration. These pieces of evidence indicate that the proton-transfer from picric acid to tryptophan occurs in the following way:



Both of the complexes are reddish orange. Their visible spectra, measured by the diffuse reflectance method, are plotted using the Kubelka-Munk function in Fig. 2. Indole and its derivatives have been shown to be electron donors.[6] The charge-transfer absorption in the indole-*s*-trinitrobenzene complex in carbon tetrachloride is expected to appear around 26 kK by the extrapolation of the plot of the energies corresponding to the band maxima of indole with each of a series of acceptors against the energy maxima

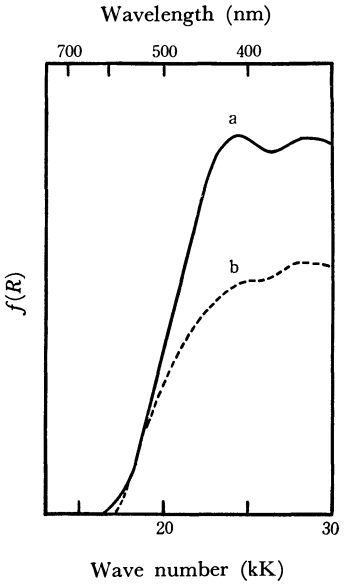


Fig. 2. Diffuse reflection spectra of a) the tryptophan picrate and b) the indole picrate.

of the spectra of the corresponding hexamethylbenzene-electron-acceptor complexes. As the electron-acceptor strength of picric acid is comparable with that of *s*-trinitrobenzene, the absorption maximum observed at about 25 kK in the solid indole picrate may be attributed to the charge-transfer interaction. The intense maximum located at 24.4 kK in the tryptophan picrate is possibly due to the picrate ion; however, the contribution from this yellow-colored anion must end by 21 kK.[7] No absorption beyond this limit is present in either component species alone. As the indole nucleus and the functional groups in protonated tryptophan are separated by the $-CH_2-CH-$ group, the electron-donating ability is expected to be essentially determined by that of the indole nucleus. Moreover, we have shown that the picrate anion is as strong as picric acid itself as an electron-acceptor.[1,2,7] Because of the intense absorption due to the picrate ion, the maximum of the charge-transfer absorption band in the tryptophan picrate cannot be located. Nevertheless, the similarity in the spectrum below 20 kK between the indole and tryptophan complexes strongly supports the assumption that the color of the tryptophan complex arises from the charge-transfer interaction between the indole nucleus and the picrate anion.

Thewalt and Bugg have found that protonated serotonin cation, which is very closely related to the protonated tryptophan cation, and the picrate anion are arranged in alternatingly stacked arrays to form continuous columns in the red-colored crystal. On the basis of its color and those crystallographic observations, they have concluded that the picrate is a complex of the electron donor-acceptor type.[3] The results of the present spectroscopic study of the tryptophan picrate seem to be in conformity with their conclusion.

(Received July 14, 1972)

The fractionation of tritiated water (HTO) on the crystallization of various hydrated sulfates from their aqueous solutions has been reported in our recent papers.[1,2] It may also be worthwhile to examine such a fractionation in other hydrated salts, because more data seem to be necessary in order for us to study the fractionation in a systematic way. In the present investigation, hydrated chlorides of cobalt, strontium, and barium have been chosen for study.

The results have been discussed on the basis of the crystal-growth mechanism and an ionic process in the solution in a way similar to that described in a previous paper.[1] Furthermore, other factors such as the dehydration temperature of the chloride have been taken into account. For this purpose, thermal analyses, *i.e.*, the DTA and TGA of the hydrated chlorides, were studied, since no exact dehydration temperatures have yet been determined, as far as we know.

Experimental

Crystal Growth. The chlorides, of commercial origin, were purified by recrystallization. The purified salts were put into the solvent, which consisted of twice-distilled water containing a trace of tritiated water (HTO). The well-developed single crystal of the hydrated chloride was grown from a very slightly super saturated aqueous solution by evaporating the solvent gradually. At the same time, the temperature of the solution was lowered in a narrow range in order to suppress the formation of stray crystals. The temperature ranges were 38.3—37.9°C for $CoCl_2 \cdot 6H_2O$, 40.3—39.7°C for $SrCl_2 \cdot 6H_2O$, and 37.7—37.3°C for $BaCl_2 \cdot 2H_2O$.

Recovery of Water and Analysis of the β-Activity. Water from both the mother liquor and the hydrated single crystal was recovered by heating them under identical conditions. The β-activity of the sample water was measured with a liquid scintillation counter, as has been described in a previous paper.[1]

Thermal Analysis. TGA and DTA were carried out simultaneously with a thermal analyzer, Model 8002 TG-DTA, of the Rigaku Denki Co., Ltd., using a sample of *ca.* 20 mg and heating it at the rate of 5°C/min.

Results and Discussion

The separation factor of HTO, S, on the crystal growth of a hydrated salt from a slightly supersaturated aqueous solution is given as follows:

$$S = N_s/N_l, \quad (1)$$

where N_s and N_l are the mole fractions of HTO in the water of crystallization and in the mother liquor respectively. Table 1 gives the S values for the hydrated chlorides, together with the net cpm due to HTO in the water. It can be seen that an appreciable dilution of HTO occurs in the crystalline water of the chlorides. The dilution in $SrCl_2 \cdot 6H_2O$ may be compared with the S value of deuterated water (mostly HDO), which has been determined to be 0.977± 0.005 by Barrer and Denny.[3]

TABLE 1. THE SEPARATION FACTOR, S, OF HTO FOR HYDRATED CHLORIDES

Crystal	Net cpm of HTO[a]		S_{obsd}
	N_s	N_l	
$CoCl_2 \cdot 6H_2O$	23688±188	24244±229	0.977±0.008
$SrCl_2 \cdot 6H_2O$	20328± 88	21472± 83	0.947±0.004
$BaCl_2 \cdot 2H_2O$	17929±191	19311±115	0.928±0.008

a) Averaged for several measurements using 0.1 g of the sample water recovered from the hydrated crystal of 2—3 g.

It was reported in a previous paper that the appreciable dilution of HTO in the hydrated crystal might be attributed to the surface-diffusion model of the crystal growth and to an ionic process in an aqueous solution.[1] The S value of the free water can thus be approximately calculated as 0.949 ($= (18/20)^{1/2}$) for the surface diffusion, provided that a possible fractionation of HTO in the hydration water of an ion from bulk water is disregarded.[4]

According to this treatment, the S value for $CoCl_2 \cdot 6H_2O$ can be derived as *ca.* 0.975, assuming that half of the hydration water of $Co(OH_2)_6^{2+}$ in the solution becomes free to integrate into the crystal.[1] On the other hand, it can be assumed in the cases of $SrCl_2 \cdot 6H_2O$ and $BaCl_2 \cdot 2H_2O$ that practically all of the water of crystallization comes from free water in the solution, because the half-lives, τ, of $Sr(OH_2)_6^{2+}$ and $Ba(OH_2)_6^{2+}$ in the solution[6] are much smaller than the relaxation times of these ions needed to integrate themselves into the crystal from the solution.[7] Accordingly, the S values for $SrCl_2 \cdot 6H_2O$ and $BaCl_2 \cdot 2H_2O$ are

Table 2. The calculated S value together with the τ, r_c, and T_d values

Crystal	S_{calc}	τ (sec)[a]	r_c (Å)	T_d (°C)
$CoCl_2 \cdot 6H_2O$	0.975	10^{-6}	0.72	185
$SrCl_2 \cdot 6H_2O$	0.949	10^{-9}	1.13	145
$BaCl_2 \cdot 2H_2O$	0.949	$10^{-9.5}$	1.35	120

a) Taken from Ref. 4.

derived as *ca.* 0.949 by means of the surface-diffusion model. Table 2 gives the estimated S values, together with the half-lives of the hydrated cations, τ.

It may be noticed here that the observed S values are in good agreement with the estimated ones for $CoCl_2 \cdot 6H_2O$ and $SrCl_2 \cdot 6H_2O$, but not for $BaCl_2 \cdot 2H_2O$. Although the cause of the discrepancy can not be ascertained at this stage, it is interesting to note that the observed S value decreases with an increase in the cationic radius, r_c, of the chloride (*cf.* the fourth column of Table 2). The increase in the radius leads to a hydrated ion with a shorter half-life in the solution,[8] which in turn gives more free water in the process of diffusion onto the crystal surface.[9] The S value should thus decrease with an increase in the mole fraction of free water in the solution according to the present assumption that free water is largely responsible for the dilution of HTO in the crystal.

The too small S value for $BaCl_2 \cdot 2H_2O$ seems likely to be caused by the following factors of (1) and/or (2):

(1) As has been pointed out in Ref. 1, the minimum S value estimated should be regarded as an approximate one, because some approximation and assumption are included in the derivation. A small deviation of the estimated value from the observed one seems to be inevitable, as was the case with the few other inorganic hydrates.[1,10] From the viewpoints of the crystal-growth mechanism and the ionic process, however, the direction of the dilution may be significant in our study.

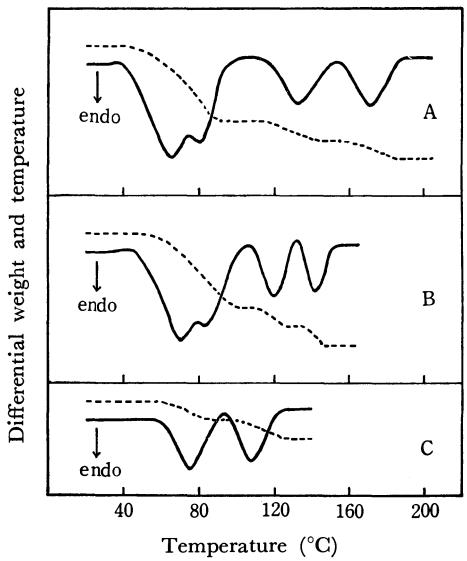

Fig. 1. Curves of the simultaneous DTA and TGA for the dehydration of the hydrated chlorides of cobalt (A), strontium (B), and barium (C).
——: DTA, ----: TGA, and endo: endothermic

(2) The dehydration temperature, T_d, of the barium chloride dihydrate is considerably lower than those of the other chlorides (*cf.* the last column of Table 2), as may be seen from the DTA and TGA curves in Fig. 1. This fact shows that the bonding of the crystalline water is relatively weak; this might be related to the too small S value, since the content of a heavier isotope in a given chemical species is known to decrease as the bonding becomes weaker in the case of an exchange reaction of isotopes.

We still believe that the major cause of the observed dilution in the chloride is the surface-diffusion mechanism of the crystal growth, since the possible enrichment, if any, of HTO in the hydration water of the Ba^{2+} ion in the solution seems to be negligible.[5]

The authors wish to express their thanks to Dr. Osamu Yamamoto for his help in analyzing the activity of tritium.

A CNDO Treatment of the Strucures of the Grignard Reagents

Hiroshi KATO and Shigeru TSURUYA*

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

** Department of Chemical Engineering, Faculty of Engineering, Kobe Univrsity, Nada-ku, Kobe*

(Recieved August 18, 1972)

Although many experimental studies of the structures of Grignard reagents have been accumulated[1], there have been few approaches from the point of view of the molecular orbital consideration of the structures of these organomagnesium compounds.[2]

The purpose of this note is to examine the plausible

1) E. C. Ashby, *Quart. Revs.* (London), **21**, 259 (1967); G. E. Parris and E. C. Ashby, *J. Amer. Chem. Soc.*, **93**, 1206 (1971).

structures of Grignard reagents on the basis of their energies obtained by the CNDO/2 method[3], which does not consider the outer d-AO of the Mg atom. The following monomer-dimer equilibrium has been observed as the composition of Grignard reagents in diethyl ether[1]:

$$\underset{\text{(III)}}{R\text{-}Mg\langle^{X}_{X}\rangle Mg\text{-}R} \rightleftharpoons \underset{\text{(I)}}{2RMgX} \rightleftharpoons \underset{\text{(IV)}}{R\text{-}Mg\langle^{X}_{R}\rangle Mg\text{-}X}$$

$$\underset{\text{(VI)}}{\left(X\text{-}Mg\langle^{R}_{R}\rangle Mg\text{-}X\right)}$$

$$\rightleftharpoons \underset{\text{(II)}}{R_2Mg} + \underset{}{MgX_2} \rightleftharpoons \underset{\text{(V)}}{^{R}_{R}\rangle Mg\langle^{X}_{X}\rangle Mg}$$

$$\underset{\text{(VII)}}{\left(^{R}_{R}\rangle Mg\text{-}X\text{-}Mg\text{-}X\right)}$$

$$\underset{\text{(VIII)}}{\left(^{R}_{R}\rangle Mg\text{-}Mg\langle^{X}_{X}\right)}$$

For the sake of simplicity, the smallest molecules showing the essential properties are chosen that is $R=CH_3$ and $X=Cl$. The geometries of the above compounds are taken to be Mg–Cl=2.5 Å, Mg–C=2.2 Å, and Mg–Mg=2.8 Å(bridge type)[6] through all the compounds considered (the adopted valence angle for R–Mg–R, R–Mg–X, and X–Mg–X in dimers and bent monomers are determined by the use of the above atomic distances).

The relative energies of various compounds appearing in the above equilibrium are illustrated graphically in Fig. 1, in which the total energies of linear and bent CH_3–Mg–Cl monomers are doubled for the sake of comparison with those of the dimeric species, and in which the sum of the energies of the linear $Mg(CH_3)_2$ and $MgCl_2$ is taken as a reference for the energy di-

4) The SCF procedures for many solvated compounds did not converge.

5) Some results for the energy differences in solvated species which are calculated to be considerably unstabilized by the coordinated water molecules, are given as as follows:

$$\left[^{R}_{R}\rangle Mg\langle^{OH_2}_{OH_2} + {}^{H_2O}_{H_2O}\rangle Mg\langle^{X}_{X}\right]\left[{}^{H_2O}_{X}\rangle Mg\langle^{X}_{R}\rangle Mg\langle^{R}_{OH_2}\right]$$

ΔE 0.0 −0.068

$$\left[{}^{H_2O}_{R}\rangle Mg\langle^{X}_{X}\rangle Mg\langle^{R}_{OH_2}\right]$$

−0.081 (a. u.)

where the energy reference is the one-half of the sum of the total energies of the two monomers in the first bracket. From the above results, the solvated states seem to be situated in the narrower energy region than the isolated state as in Fig. 1.

6) These distances are taken as the sum of the covalent radius estimated by Prithard and Skinner (*Chem. Rev.*, **55**, 177 (1955)).

agram (in atomic units). The dimer types are energetically more favored than the monomer types, as is indicated in Fig. 1. The calculated results for the net charge of the atoms are presented in Table 1, together with their energy differences. It seems in this table that the net charges of Mg atoms coordinated by three or four atoms in dimers are generally smaller than in monomers, and that these excess charges are transferred from the bridge-head atoms or groups. That is, the stability of the dimer forms, especially of the bridge structures, is mainly dependent on the electro-dificient character of the magnesium atom as well as on the electron-rich character of the bridge-head atoms and the methyl groups which act as the electron donor. The exchange of alkyl groups can be explained by the existence of an intermediate mixed alkyl-halogen bridge structure(IV), as has suggested earlier.[1] Figure 1 indicates that the stability of this mixed bridged dimer is considerably larger than those of monomers; this is in accordance with the above experimental considerations. It should be noted, however, that our results are obtained by neglecting the solvent effects,[4] and also that the experiment shows that the dimer forms are present in equilibrium states in "weak" solvents such as diethyl ether, and not in "strong" solvents such as tetrahydrofuran. Thus, it may be said that both the experimental and calculated results prove that the mixed structure is favored at the monomer-dimer equibrium in the case of weak interaction with solvent molecules;[5] also, there is no doubt that the solvent strongly influences the structures of Grignard reagents.

For the solvated state in these compounds, further treatments are desired.

We wish to acknowlege the help of Mr. Ishida in these CNDO calculations, and also that of the Computer Center of Kyoto University and of Nagoya University.

The Formation of β-Glycine in the Thermal Decomposition of a Solid Complex of Aminomalonic Acid with Glycine

Jujiro NISHIJO and Toshio KINUGASA*

Kobe Women's College of Pharmacy, Higashinada-ku, Kobe

** Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe*

(Recived September 5, 1972)

In a previous paper,[1] we reported that aminomalonic acid reacted with glycine to form a solid complex with a 1 : 1 molar ratio on crystallization from an aqueous solution, and that the solid complex decarboxylated at a higher temperature and at a slower rate than did aminomalonic acid, as was established by means of the DTA–TGA of the solid complex at a heating rate of 1°C/min in air. Moreover, it was found, by the aid of X-ray analysis, that an unstable unknown substance was formed, together with α- and γ-glycine, in the course of the thermal decomposition of the solid complex, and that this substance changed to either α- or γ-glycine above 150°C. At the stage where this substance is formed, however, the coexistence of a remaining solid complex and the α- and γ-glycine produced made it difficult for us to study the unstable substance. Here, an investigation was carried out into the conditions for the formation of the unstable unknown substance and on its formation mechanism.

Experimental

To a mixture of 1.19 g of a recrystallized aminomalonic acid and 0.75 g of glycine of a reagent grade, was added 30 ml of pure water and then 30 ml of methanol. The resulting solution was kept overnight in a refrigerator (7—8°C) to yield scaly crystals. The yield was 1.90 g (90%).

Found: C, 30.86%; H, 5.36%. Calcd for $C_5H_{10}O_6N_2$ (aminomalonic acid : glycine=1 : 1) : C, 30.93%; H, 5.15%. The X-ray diffraction pattern, the infrared spectrum, and the DTA-TGA of this substance agreed well with those of the crystalline powder[1] obtained by the concentration of an aqueous solution.

The solid complex was decomposed in a Riken-type sample dryer. The infrared spectra were observed with a Nihon Bunko Grating Infrared Spectrometer, type DS-402G, by means of the Nujol-mull method. X-ray analysis was carried out with the same apparatus as had previously been reported.[1] In order to represent the amount of the decomposition products semi-quantitatively, the ratio of the height of diffraction peak was used. Also, a sample holder was used throughout this work.

Results and Discussion

The unstable unknown substance changed either α- or γ-glycine at temperatures above 150°C.[1] On the assumption that the unknown substance may be formed in a large amount at a lower temperature, thermal decomposition was carried out at a temperature in the neighborhood of 122°C.

The decarboxylation proceeded extremely slowly and required about 45 hours for completion. The product in this period was only an unknown sudstance in many cases, but in some cases a small amount of α- and γ-glycine was also formed at the completion of the reaction. On further heating, the intensity of the dif-

fraction peak of the unknown substance decreased and γ-glycine was formed in a large amount, accompanied by the formation of a small amount of α-glycine. The infrared spectrum of the unknown substance differs slightly from that of α- or γ-glycine. These properties resemble those of β-glycine. The X-ray diffraction pattern of the unknown substance was compared with that of β-glycine which had been prepared according to Iitaka method[2] (Fig. 1). Although different in the relative intensities of the diffraction peaks, they agree with each other in the angles of the diffraction peaks. It was thus proved that the unknown substance produced in the thermal decomposition of the solid complex was β-glycine. The difference between them in the relative intensities of the diffraction peaks may result from the difference in the orientation of the crystals which is caused according to the method of preparation.

The formation mechanism of β-glycine, the most unstable among three polymorphic forms of glycine, will be discussed below. When aminomalonic acid decomposed slowly at the temperature in the neighborhood of 115°C, not β- but γ-glycine was detected in the decomposition product (Table 1). This is consistent with the findings that, as was reported previously,[3] aminomalonic acid decarboxylates, with the disintegration of the crystal lattice to amorphous glycine, and that the amorphous glycine crystallizes to γ-glycine, which is the most stable against the thermal processes.

On the other hand, scarcely no thermal change due to the crystallization of the decomposition products was in the decarboxylation of the solid complex.[1] This fact suggests that the decarboxylation of the complex occurs with no disintegration, but with only a slight displacement of the crystal lattice. Moreover, the observation that the crystal lattice is not disintegrated may be explained as follows. Since each stretching vibration of NH_3^+ in the aminomalonic acid and α-glycine is observed near 3165 cm^{-1} and 3154 cm^{-1} respectively and near 3233 cm^{-1} in the complex, the intermolecular hydrogen bond has been formed between aminomalonic acid and glycine by forming the solid complex (Fig. 2). Hence, when the solid complex decarboxylates at a low temperature and at a very slow rate, the intermolecular hydrogen bond may remain to some extent, and the disintegration of the crystal lattice of the complex may not occur. Therefore, the formation of an unstable compound such as β-glycine may be possible.

The authors wish to thank Professor Isamu Imanishi and Dr. Genzo Hashizume for their advice and interest.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1005—1006 (1973)

Ion-exchange Equilibria on a Crystalline Zirconium Phosphate Exchanger

Hiroko SEKINO and Isao TOMITA

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Tokyo

(Received August 25, 1972)

Ahrland and Albertsson have suggested that the zirconium phosphate gels contain, besides the ordinary phosphate groups, small amounts of a functional group capable of interacting more or less strongly with various cations.[1] They studied the ion selectivity by plotting the logarithm of the distribution coefficients, K_d, as a function of the pH at a constant value of the load.

Albertsson extended the study to the sorption of Na^+, Cs^+, Sr^{2+}, UO_2^{2+} and Ce^{3+} ions on a crystalline zirconium phosphate.[2] The log K_d *vs.* pH curves for Na^+ and Cs^+ have the theoretical slopes, but the slopes for UO_2^{2+} and Ce^{3+} curves have somewhat lower values than those expected. Strontium ion behaves peculiarly, and the sorption by no means proceeds *via* a perfect ion exchange.

The aim of the present experiment is the further investigation of the ion-exchange equilibria of divalent ions such as Zn^{2+} on a crystalline zirconium phosphate, $Zr(HPO_4)_2 \cdot H_2O$ (abbreviated as α-ZP). The equilibrium of the Cs^+ ion was also reexamined. Both Cs^+ and Zn^{2+} ions have appreciably high K_d values in acidic-solution media and are suitable for the study.

Theoretical

If α-ZP behaves as a monofunctional exchanger, the mass action law can be applied to the following equilibrium:

$$n\overline{AH} + M^{n+} \rightleftharpoons \overline{AnM} + nH^+$$

$$K_d = \frac{[\overline{AnM}]}{[M^{n+}]} = K \cdot \frac{[\overline{AH}]^n}{[H^+]^n} \quad (1)$$

where the bar denotes the exchanger phase; A, an anionic functional group; M^{n+}, metal ions, and K, an equilibrium constant. When the load is sufficiently small, $[\overline{AH}]$ is nearly equal to the H^+ ion concentration before loading, $[\overline{AH}]_0$. Thus, the plots of log K_d *vs.* pH should result in a straight line with a slope of n.

If the exchanger contains some kinds of functional groups, A_1, whose affinities for cations are different from each other, K_d is expressed as follows:

$$K_d = \frac{\sum[\overline{A_{1n}M}]}{[M^{n+}]} = \frac{\sum(K_1 \cdot [\overline{A_1H}]^n)}{[H^+]^n}$$

$$\log K_d = \log (\sum K_1 \cdot [\overline{A_1H}]^n) + n\,\mathrm{pH} \quad (2)$$

When one functional group is of an amount comparable to the load, but has an appreciable affinity for the cations involved, the first term of Eq. (2) is no longer constant and the log K_d *vs.* pH plot does not give a straight line with a slope of n. This is actually the case for zirconium phosphate gels.

As a simple case, let us consider an exchanger containing two kinds of functional groups, A and B, where A is a major component with an equilibrium constant of K_A, and where B is a minor component with K_B and $K_B \gg K_A$. We obtain:

$$K_d = \frac{1}{[H^+]^n}\{K_B[\overline{BH}]^n + K_A[\overline{AH}]^n\}$$

Now that the load is kept sufficiently low in comparison with the exchange capacity, *i.e.*, $[\overline{AH}] \gg [\overline{A_nM}]$, the above equation can be re-written as follows:

$$K_d = \frac{1}{[H^+]^n}[K_B\{[\overline{BH}]_0 - [\overline{B_nM}]\}^n + K_A[\overline{AH}]_0{}^n] \quad (3)$$

where the subscript 0 denotes the concentration before loading. Further, the following cases can be considered under these conditions:

i) If the initial amount of $\overline{BH}$ is larger than the load, C_M, the latter is considered to be equal to $[\overline{B_nM}]$. Then

$$K_d = \frac{1}{[H^+]^n}[K_B\{[\overline{BH}]_0 - C_M\}^n + K_A[\overline{AH}]_0{}^n] \quad (4)$$

ii) If $C_M > [\overline{BH}]_0$, then $[\overline{B_nM}] = [\overline{BH}]_0$ and

$$K_d = \frac{1}{[H^+]^n} \cdot K_A[\overline{AH}]_0{}^n \quad (5)$$

This value is constant when pH is kept constant.

From the above considerations, it is at least possible to deduce whether or not the exchanger in question is monofunctional from the general shape of the K_d *vs.* C_M curve determined experimentally.

Experimental

Exchanger. α-ZP was prepared and treated as has been reported previously.[3] The particle sizes range from 100 to 200 mesh. Identification was made by means of X-ray powder diffraction.

Distribution Coefficients. All the measurements were carried out at 25°C using 250 mg of α-ZP and 25 ml of a contact solution in the same manner as before.[3] The hydrogen-ion concentrations were adjusted with hydrochloric acid for the cesium chloride solution and with nitric acid for the zinc nitrate solution. Radioactive tracers such as ^{65}Zn and ^{137}Cs with known specific activities were used to determine the concentrations of the cations. The radioactivities were measured with a well-type NaI(Tl) scintillation counter.

Usually, three runs were carried out under the same conditions and the mean values of the K_d values thus obtained were taken.

Results and Discussion

In general, it is difficult to keep the experimental media at a constant ionic strength in this kind of ion-

2) J. Albertsson, *ibid.*, **20**, 1689 (1966).

3) Y. Hasegawa and I. Tomita, This Bulletin **43**, 3011 (1970).

exchange study because small amounts of functional groups might have an unusual affinity for cations other than those in question. In this experiment, the variation in the involved activity coefficients is disregarded over the pH range studied, but this does not seem to have influenced the discussion given below.

Dependence of K_d upon C_M at a Constant pH. Figure 1 shows typical examples of the plots of K_d *vs.* C_M

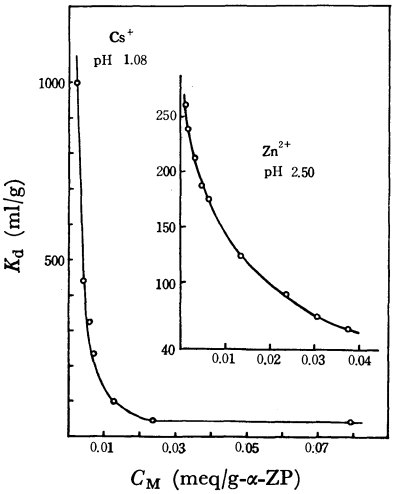

Fig. 1. The plot of K_d *vs.* C_M at constant pH values.

at constant pH values for the Cs^+ and Zn^{2+} ions respectively. Similar curves have been obtained at pH values of 0.70, 1.08. 1.58, and 2.03 for Cs^+, and at 1.59, 2.08, 2.50, and 2.99 for Zn^{2+} ions. In the region of very low loading, the K_d values decrease rapidly with an increase in C_M for both metal ions. This is what is to be expected from Equation (4). However, as the value of C_M increases further, the K_d values still decrease slowly and do not attain constant values over the C_M range studied. It is not easy to judge from the results whether or not the left part of the cesium curve is rectilinear or whether or not that of the zinc curve is parabolic. There might be an oversimplification of the assumptions in deriving Eq. (3)~(5), and the possible existence of more than one kind of functional group with a high affinity can not be excluded. However, it is possible roughly to estimate the upper limit of concentration of the B group by intercepting the extrapolated parts of the left- and right-hand sides of each curve. Values of about 0.01 meq/g α-ZP for cesium and of about 0.05 meq/g α-ZP for zinc were thus obtained. The total exchange capacity of α-ZP is theoretically 6.64 meq/g, and the quantity of the high-affinity group is less than 1%. This makes the chemical identification and characterization of the group extremely difficult.

The purity of the exchanger used is good, and so is the crystallinity. Thus, the existence of any functional group other than the phosphate group is not likely. However, the incorporation of amorphous zirconium

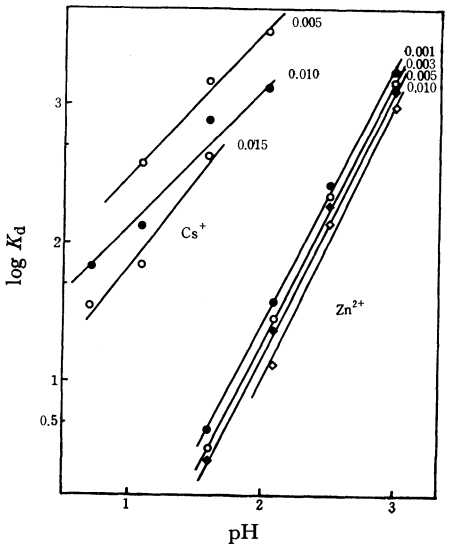

Fig. 2. The plot of log K_d *vs.* pH at constant C_M values. Numerical value beside each line denotes C_M in meq/g α-ZP.

phosphate into the crystals is probable, because the crystals have been prepared from the gels by refluxing them in phosphoric acid. Further, from steric considerations,[4] the phosphate groups on the crystal surface should have a higher affinity for Cs^+ and Zn^{2+} ions than those inside the crystal. Even inside the crystal, there might be small amounts of sorption sites which occupy particular positions leading to a different acidity of the phosphate protons from that of a majority of the monohydrogen phosphate groups. If each of the above-mentioned phosphate groups is responsible for the sorption of cations, but to a different extent, K_d values which are independent of the C_M can not be attained within the range of the present experiment, in which the extent of the exchanged sites is only about 1% of that of the total exchangeable ones.

The log K_d vs. pH Plots at Constant Loads. From the curves of K_d *vs.* C_M at different constant pH values, it is possible to find the K_d values for a constant C_M. The logarithm of the values were then plotted against the pH, as is shown in Fig. 2. The slopes of the resulting straight lines were calculated by a least-squares method. For cesium, these values are 1.01, 1.02, and 1.24 for the C_M values (meq/g α-ZP) of 0.005, 0.010, and 0.015 respectively. With regard to zinc, the slopes are 1.86, 1.91, 1.97, and 2.05 for the C_M values of 0.001, 0.003, 0.005, and 0.010 respectively. The approximate values of +1 for cesium and +2 for zinc are what can reasonably be expected from their normal valency states. Figure 2 also shows the parallel displacement of straight lines with the change in the C_M values. This is again to be expected from Eq. (4).

The authors wish to express their thanks to Professor Kozo Nagashima for his interest and encouragement. They are also indebted to Mr. Yoshitsugu Hasegawa for his valuable discussions. Finally, they are grateful to Mr. Yasuhiko Saito for his help with the experiments.

4) The ion-sieving property of α-ZP is known for relatively large ions, such as cesium and rubidium. A strongly hydrated polyvalent ion is considered also to be hindered to a considerable extent.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1007—1008 (1973)

The Photoreaction of 2,6-Diphenyl-4*H*-thiopyran-4-one 1,1-Dioxide

Hiromu AOYAMA, Yoshiaki SATO, Takehiko NISHIO, and Noboru SUGIYAMA

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Tokyo

(Received July 19, 1972)

Previously, we have reported that the irradiation of 2,6-diphenyl-4*H*-thiopyran-4-one (Ia) in non-polar solvents gave a head-to-tail anti-dimer[1] and in polar solvents gave photooxidized products,[2] while that of 2,6-diphenyl-4*H*-pyran-4-one (Ib) gave the corresponding cage dimer.[2] This paper will be concerned with the photoreaction of 2,6-diphenyl-4*H*-thiopyran-4-one 1,1-dioxide (II).

The irradiation of II in a methanol solution (0.02 mol/l) with a high-pressure mercury lamp under a nitrogen atmosphere gave a methanol-adduct (III) (mp 208—210°C) in a 14% yield and a trace of benzoic acid. The structure of III was determined as follows. The NMR spectrum of III showed a singlet at δ 3.51 (3H) assignable to methoxy protons and a singlet at δ 4.86 (2H) assignable to methylene protons. The IR spectrum of II showed a carbonyl band at 1640 cm^{-1}, but that of III showed it at 1690 cm^{-1}. The mass spectrum of III showed a peak at *m/e* 328 (M^+, $C_{18}H_{16}O_4S$) and base peaks at *m/e* 134 ($M-C_9H_6O_3S$) and 264 ($M-SO_2$). The hydrogenation of III in a mixture of acetic acid and ethanol by means of palladium-charcoal gave IV. Its NMR spectrum exhibited a pair of doublets at δ 4.42 (1H) and 4.73 (1H) due to methylene protons at C-3. The irradiation of II in benzene gave an intractable mixture.

When a mixture of II and cyclohexene in benzene was irradiated under the same conditions for 4 hr, a 1 : 1-adduct (V) was obtained in a 93% yield. The NMR spectrum of V showed two doublets at δ 6.59 (0.75 H) and 6.52 (0.25 H) assignable to an olefinic proton. The product V was therefore considered to be a mixture of stereoisomers at the cyclobutane ring. Furthermore, the results of the elemental analysis confirmed that V was a 1 : 1-adduct, and the UV and IR spectra indicated the presence of an enone system.[3] Also, the hydrogenation of V afforded VII quantitatively. The NMR spectrum of VII exhibited a multiplet at δ 4.94 (1H) attributable to the methine proton at C-2. The IR spectrum also indicated a saturated carbonyl band at 1710 cm^{-1}.

When a mixture of II and cyclooctene in benzene was irradiated under the same conditions for 5 hr, a 1 : 1-adduct (VI) was also obtained in a 50% yield. The structure of VI was determined on the basis of its elemental analysis and spectral data. The product VI also seems to be a mixture of stereoisomers at the cyclobutane ring like V, for the NMR spectrum of VI exhibited two doublets at δ 6.57 (0.55 H) and 6.47 (0.45 H) assignable to an olefinic proton.

Experimental

Material. 2,6-Diphenyl-4*H*-thiopyran-4-one 1,1-dioxide (II)[4] was synthesized by Arndt's method,[5] mp 143—144.5°C (lit,[5] 144—145°C).

Irradiation of II. A solution of 600 mg of II in 100 ml of methanol was irradiated with a high-pressure mercury lamp through a Pyrex filter under nitrogen for 6 hr. After the removal of the solvent, the residue was chromatographed on a silica-gel column. Elution with benzene–ethyl acetate (19 : 1) yielded 86 mg of II and 91 mg of III. Recrystallizations of III from benzene afforded colorless prisms. Found: C, 65.69; H, 4.94%. Calcd for $C_{18}H_{16}O_4S$: C, 65.85; H, 4.91%. UV: λ_{max}^{EtOH} nm (ε), 217 (21,700) and 292 (9,900). IR: ν_{max}^{KBr} cm^{-1}, 1690 (C=O). NMR: (δ in $CDCl_3$) 7.85—7.33 (m, 10H, phenyl), 6.54 (s, 1H, olefinic), 4.86 (s, 2H, methylene), 3.51 (s, 3H, methoxy).

Hydrogenation of III. When 40 mg of III was hydrogenated in 10 ml of acetic acid and 5 ml of ethanol with 30 mg of palladium-charcoal, IV was quantitatively obtained. Recrystallizations of IV from benzene afforded colorless prisms; mp 231—232°C. Found: C, 65.43; H, 5.61%. Calcd for $C_{18}H_{18}O_4S$: C, 65.44; H, 5.49%. IR: ν_{max}^{KBr} cm^{-1}, 1728 (C=O), 1312, 1113 (SO_2). NMR: (δ in $CDCl_3$) 7.40 (s, 10H, phenyl), 4.73 (d, 1H, J=15, methylene at C-3) and 4.42 (d, 1H, J=15, methylene at C-3), 4.43 (d, 1H, J=3.5, methine), 3.80 (d, 1H, J=15, methylene at C-5) and 3.02 (dd, 1H, J=15, J=3.5, methylene at C-5), 3.37 (s, 3H, methoxy).[6] When the signal of the methine proton at δ 4.43 was irradiated, the signal of the methylene protons at δ 3.80 and 3.02 changed into a pair of doublets (AB q.) at δ 3.12 and 2.89.

Irradiation of the Mixture of II and Cyclohexene. A solution of 500 mg of II and 2 ml of cyclohexene in 30 ml of benzene was irradiated under the same conditions as have been described above for 4 hr. After the solvent had been removed, the residue was chromatographed on a silica-gel column with benzene–*n*-hexane (9 : 1). The evaporation of the solvent from the eluted fraction gave a crude product as a pale yellow crystals, which were then collected, and washed with *n*-hexane to afford colorless prisms; 594 mg of V; mp 175.5—177°C. Found: C, 72.79; H, 5.97%. Calcd for $C_{23}H_{22}O_3S$: C, 73.00; H, 5.86%. UV: λ_{max}^{EtOH} nm (ε), 220 (16,200) and 294.5 (10,600). IR: ν_{max}^{KBr} cm^{-1}, 1685 (C=O), 1308, 1135 (SO_2). NMR: (δ in $CDCl_3$) 7.50—7.25 (m, 10H, phenyl), 6.59 (d, 0.75H, olefinic

6) This assignment was determined by comparing the NMR spectrum of IV with that of 2,6-diphenyl-2,3,5,6-tetrahydro-4*H*-thiopyran-4-one 1,1-dioxide. δ ($CDCl_3$) 7.39(s, 10H, phenyl), 4.52 (dd, 2H, J=15, J=3.5, methine), 3.67 (dd, 2H, J=15, J=15, methylene), 2.90 (br d, 2H, J=15, methylene).

and 6.52 (d, 0.25H, olefinic), 3.82—2.92 (m, 3H, methine), 2.80—0.88 (m, 8H, methylene).

Hydrogenation of V. When a 300-mg portion of V was hydrogenated in 25 ml of acetic acid and 40 ml of ethanol with 50 mg of palladium-charcoal, VII was quantitatively obtained. Recrystallizations of VII from benzene afforded colorless prisms; mp 178—179°C. Found: C, 72.88; H, 6.36%. Calcd for $C_{23}H_{24}O_3S$: C, 72.61; H, 6.36%. IR: ν_{max}^{KBr} cm^{-1}, 1710 (C=O), 1305, 1125 (SO_2). NMR: (δ in $CDCl_3$) 7.5—6.9 (m, 10H, phenyl), 4.94 (m, 1H, methine at C-2), 3.92—3.2 (m, 5H, methylene at C-3 and methine), 2.95—1.0 (m, 8H, methylene). When the signal of the methine proton at δ 4.94 was irradiated, the signal of the methylene protons at C-3 appeared as a broad singlet at δ 3.38.

Irradiation of the Mixture of II and Cyclooctene. A solution of 500 mg of II and 5.5 ml of cyclooctene in 30 ml of benzene was irradiated under the same conditions as have been described above for 5 hr. After the solvent had been removed, the residue was chromatographed on a silica-gel column. Elution with benzene–ethyl acetate (9 : 1) yielded 203 mg of VI. Recrystallizations of VI from *n*-hexane afforded colorless prisms; mp 209—211°C. Found: C, 73.53; H, 6.48%. Calcd for $C_{25}H_{26}O_3S$: C, 73.86; H, 6.45%. UV: λ_{max}^{EtOH} nm (ε), 220.5 (19,500) and 293.5 (11,000). IR: ν_{max}^{KBr} cm^{-1}, 1692 (C=O), 1300, 1125 (SO_2). NMR: (δ in $CDCl_3$) 7.48—7.05 (m, 10H, phenyl), 6.57 (d, 0.55H, olefinic) and 6.47 (d, 0.45H, olefinic) 3.8—3.0 (m, 3H, methine), 2.1—0.85 (m, 12H, methylene).

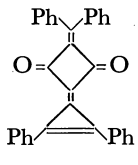
The Synthesis of 2-(Diphenylcyclopropenylidene)cyclobutane-1,3-dione (1,2-Diphenylbutatriafulvalene-3,5-dione)[1]

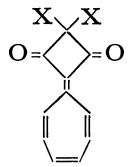
Toyonobu Asao,* Morio Yagihara, and Yoshio Kitahara
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received August 4, 1972)

Recently, 4-diphenylmethylene-1,2-diphenylbutatriafulvalene-3,5-dione (**1**)[2] and heptabutafulvalenedione derivatives (*e.g.*, **2**)[3] have been synthesized, and their spectral data have been discussed.



(**1**)



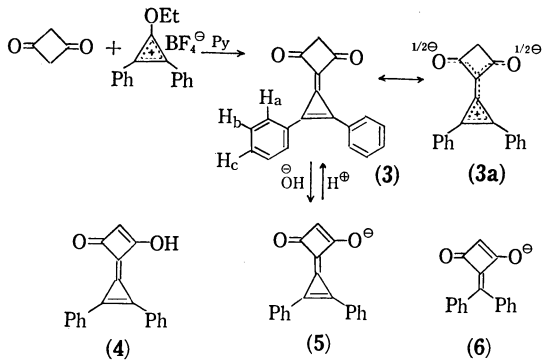
(**2**) X=Cl, Me

In the course of synthetic studies of fulvalenes, we have prepared 2-(diphenylcyclopropenylidene)cyclobutane-1,3-dione (1,2-diphenylbutatriafulvalene-3,5-dione); the results will be reported herein.

The reaction of cyclobutane-1,3-dione and 1,2-diphenyl-3-ethoxycyclopropenylium tetrafluoroborate in methylene chloride in the presence of a minute amount of pyridine afforded pale yellow needles (**3**) (mp 225—230°C (decomp.)) in a 14% yield; the structure of 2-(diphenylcyclopropenylidene)cyclobutane-1,3-dione was inferred from the following spectroscopic data as well as from the results of elemental analyses.

Compound **3** exhibits the mass-spectral parent ion at *m/e* 272 (relative intensity 69), and fragment ions at 257 (14), 230 (100), 216 (18), 215 (19), 202 (88), 178 (23), and 165 (27); IR (KBr) 1840 (m) (methylenecyclopropene), 1660 (s) (C=O), 1600 (w), and 1510 (s) cm^{-1}; UV λ_{max}^{EtOH} 225^{sh} (log ε 4.23), 266 (4.28), and 325 nm (4.65); NMR ($CDCl_3$) δ 3.5 (2H, s, methylene protons), 7.6—7.8 (6H, m, Hb and Hc), and 8.35—8.55 (4H, m, Ha).

The strong deshielding of Ha by the diamagnetic anisotropy of the carbonyl group is similarly observed in compound **1**[2] and diphenylpentatriafulvalenedione derivatives.[4]



From the facts that the C=O stretching frequency appears at 1660 cm^{-1}, and that methylene protons in NMR appear at δ 3.5 as a singlet, compound **3** must be stabilized by a contribution of a dipolar structure **3a**; it seems that an enol structure **4** does not contribute to the structure.

Compound **3** is not soluble in aqueous sodium hydrogen carbonate, but it is soluble in NaOH–EtOH. The ultraviolet absorption curve in a dilute acidic medium does not change from that in ethanol. However, in an alkaline solution, the curve shows absorption maxima at 265 (log ε 4.12), 328 (4.39), and 342 nm (4.37); this curve is reversibly backed to the original curve by the addition of an acid. From these data, an enolate

anion **5** may be assigned for compound **3** in an alkaline solution. A similar anion **6** has been assigned for 2-diphenylmethylenecyclobutane-1,3-dione.[2)]

Experimental

*2-(Diphenylcyclopropenylidene)cyclobutane-1,3-dione (**3**).* To a stirred solution of cyclobutane-1,3-dione (42 mg) and diphenylethoxycyclopropenylium tetrafluoroborate (320 mg) in anhydrous methylene chloride (6 ml), 3 drops of pyridine were added at room temperature. After 30 min, the color of the solution turned red. Water was added, and the solution was extracted with methylene chloride and dried over anhydrous magnesium sulfate, the subsequent removal of the solvent left an oil, which was chromatographed on silica gel to give pale yellow crystals (225 mg). An ether-insoluble part of the crystals was recrystallized from a mixture of methanol and methylene chloride to give 18 mg (14%) of pale yellow needles (**3**) (mp 225—230°C (decomp.)). From the ether-soluble part diphenylcyclopropenone was obtained.

Found: C, 83.42; H, 4.28%. Calcd for $C_{19}H_{12}O_2$: C, 83.80; H, 4.44%.

Photochemical Type II Elimination of Diisobutyl Trichloromethylphosphonate*

Yoshio OGATA, Yasuji IZAWA, and Toshiyuki UKIGAI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received August 12, 1972)

The type II photo-elimination of carbonyl compounds containing γ-hydrogen to form olefins and degradated carbonyl compounds *via* a cyclic transition state is well known.[1] However, little information is available on the analogous photochemistry of phosphoryl group. In view of the strongly polar character of P^+–O^- bond in ordinary phosphorus compounds, no absorption of the P=O group appears in the near UV region.[2]

We reported previously that no reduction of the phosphoryl portion occurred in photoreduction of carbonyl group of dialkyl β-ketophosphonates (I) to β-hydroxyphosphonates (II) (Eq. (1)). The quantum yield for disappearance of ketones were 0.6—0.7.[3]

$$\underset{\text{I}}{RCOCH_2P(O)(OR')_2} \rightarrow \underset{\text{II}}{RCH(OH)CH_2P(O)(OR')_2} \quad (1)$$

a, $R=CH_3$, $R'=C_2H_5$
b, $R=C_2H_5$, $R'=C_2H_5$
c, $R=C_2H_5$, $R'=(CH_3)_2CH$

The extent of $p\pi-d\pi$ character of the P=O bond may be determined by the overlap integral and the electron affinity of the bonded atoms at phosphorus. Thus, the electronegativity of substituent on the phosphorus atom may exert a considerable effect on the $p\pi-d\pi$ overlap integral and hence on its bond energy.[4] Electron-withdrawing groups on phosphorus compete with a double-bonded oxygen atom to attract electron, resulting in a stiffer P=O bond and a higher frequency.[5]

The values of bond orders of some phosphoryl compounds have been reported, *e. g.*, $P(O)Br_3$: 1.92, $P(O)Cl_2$: 1.95, $P(O)(CF_3)_3$: 2.00, $P(O)FCl_2$: 2.05, $P(O)F_2Cl$: 2.11, and $P(O)F_3$: 2.22.[4]

Consequently, the absorption spectrum of the phosphoryl group is expected to appear in a near UV region, if a strongly electron-withdrawing group is present on phosphorus. In fact, diisobutyl trichloromethylphosphonate (III)[6] shows a new absorption (shoulder) at $\lambda_{max}^{n\text{-hexane}}$ 253.7 nm ($\varepsilon\sim2$). The present paper reports on photochemical type II decomposition of III to give the corresponding half ester and isobutylene.

A solution of III (1.5 g, 0.25 M) in *n*-hexane was irradiated with a low-pressure Hg lamp in a quartz tube for 60 hr and the photoproducts were separated by column chromatography, giving colorless crystals (IV), mp 104—105°C, in an 11% yield and viscous liquid (V)[7] (0.18 g). The IR spectrum of IV showed strong bands of P–OH at 1640 and 1110 cm^{-1}. The mass spectrum showed the fragment ions *m/e* 83 [34%, $HP^+(OH)_3$], 137 (22%), 199 (12%), and 56 (100%, $C_4H_8^+$), although the expected parent peaks did not appear. Accurate mass numbers of

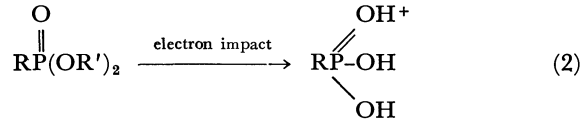
6) III: bp 109—110°C (1 mm); IR (film) 1280 (P=O), 1020 (P–O–C), 765 (P–C), 545 (C–Cl), 1370, and 1395 cm^{-1} ($CH(CH_3)_2$); NMR ($CDCl_3$) isobutyl methyl H (δ 1.10, d, J=7.5 Hz), isobutyl methine H (δ 2.11, m), and isobutyl methylene H (δ 4.20, t, J=6.6 Hz); mass *m/e*, P: 31.0 (20%), fragment ions: 199 [55%, $Cl_3CP^+(OH)_3$], 137 (60%, $P^+(OH)(O)(OC_4H_9)$], 117 (15%, CCl_3^+), 83 [10%, $HP^+(OH)_3$], and 56 (100%, $C_4H_8^+$).

7) Although V showed similar IR and NMR spectra to that of III, its structure is not clear. V is not identical with III because of its mass spectrum, M^+ 500.

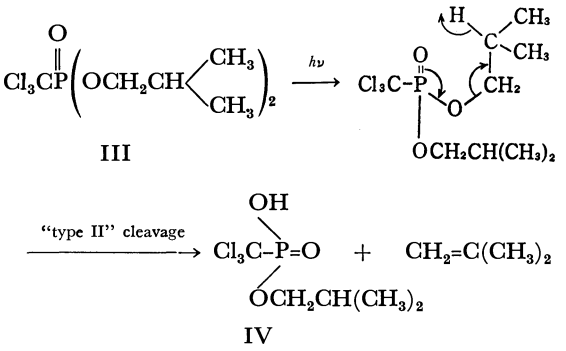
ions at *m/e* 137 and 199 were 137.037 and 198.889, respectively. Hence, the former is due to $P^+(O)(OH)(OC_4H_9)$ (calcd 137.036), the latter to $C^{35}Cl_3P^+(OH)_3$ (calcd 198.899). In the mass spectrum of III, no peak corresponding to $Cl_3CP^+(OH_2)(OC_4H_9)$ ion was observed. In support of this, a β-scission to P=O group under electron impact is knwon.[8]



(2)

Thus it is certain that $Cl_3CP^+(OH)_3$ ion for IV is produced *via* electron impact fragmentation of $Cl_3CP(O)(OH)(OC_4H_9)$. On the basis of this fact as well as in spectroscopic property, the photoproduct (IV) was identified to be $Cl_3CP(O)(OH)(OC_4H_9)$. If IV is produced *via* a type II cleavage of III, isobutylene should be simultaneously formed as a photoproduct. In fact, it was isolated by means of glpc using di-*n*-butyl maleate-β,β'-oxydipropionitrile on C–22.

Thus, it is probably valid to write the process for the photochemical cleavage of III in analogy with the type II cleavage for ketones.



III

(3)

IV

Indeed, no decomposition was observed in 54 hr irradiation of dimethyl ester, $Cl_3CP(O)(OCH_3)_2$,[9] in which a six-membered transition state for hydrogen abstraction is impossible. No isobutane was detected in the photodecomposition of III.

Sesquiterpene Hydrocarbons of the Liverwort, *Scapania parvitexta*

Akihiko MATSUO, Mitsuru NAKAYAMA, and Shûichi HAYASHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda, Hiroshima 730

(Received September 7, 1972)

The liverworts (*Hepaticae*), which are phylogenetically placed between the vascular plants and the algae, and which contain several oil bodies in each cell, form a unique division in the plant kingdom. About 8500 species of the plants are distributed throughout the world. The essential oils of liverworts have hardly been investigated at all to date because of the difficulty of collecting a sufficient amount of the plants to examine their constituents. In the course of our studies of the constituents of *Hepaticae*,[1] the present investigation was undertaken on the essential oil of a leafy liverwort, *Scapania parvitexta* Steph. (Japanese name, Koamimehishakugoke), belonging to the *Scapaniaceae* family; we were able to identify nine sesquiterpene hydrocarbons.

The hexane extract of the liverwort was subjected to fractional distillation under reduced pressure, followed by elution chromatography; we thus obtained a hydrocarbon fraction, which showed thirteen peaks in gas chromatography with a Golay column, as is shown in Fig. 1. Since the fraction was very small in amount, its analysis depended upon a method combining a gas chromatograph and a mass spectrometer (GC-MS); by a comparison of the mass spectra thus obtained (*cf.* Table 1) with the previously-reported data, nine sesquiterpene hydrocarbons of β-bourbonene,[2] β-ylan-

Table 1. Abundant ions in mass spectra of identified sesquiterpene hydrocarbons[a)]

Compound	M (%)	H_1	H_2 (%)	H_3 (%)
β-Bourbonene	204 (9)	81	80 (74)	123 (63)
β-Ylangene	204 (35)	161	41 (82)	204 (35)
β-Cubebene	204 (45)	161	119 (60)	105 (55)
γ-Cuprenene	204 (25)	119	93 (53)	105 (40)
Calamenene	202 (12)	159	157 (35)	142 (18)
β-Chamigrene	204 (55)	189	41 (90)	93 (75)
β-Selinene	204 (100)	204	41 (85)	105 (80)
Bazzanene	204 (5)	109	108 (52)	67 (31)
Cuparene	202 (15)	132	131 (42)	145 (30)

a) Percentages in parentheses represent the relative abundance.

gene,[3] β-cubebene,[4] γ-cuprenene,[4] calamenene,[5] β-chamigrene,[6] β-selinene,[7] bazzanene,[8] and cuparene,[9] were identified.

The biogenetic pathways of the hydrocarbons may be shown as in Chart 1: β-chamigrene (VI), γ-cuprenene (VII), bazzanene (VIII), and cuparene (IX) are synthesized from *cis*-farnesol (I) *via* the (III) cation, and β-ylangene (X), β-cubebene (XI), and calamenene (XII), from the same precursor *via* the (IV) cation, whereas the other compounds, β-selinene (XIII) and β-bourbonene (XIV), are synthesized from *trans*-farnesol (II) *via* the (V) cation. Although most of these biogenetic courses have already been known in higher plants,[10,11] it is very interesting that so many kinds of sesquiterpene hydrocarbons were also detected in the liverwort.

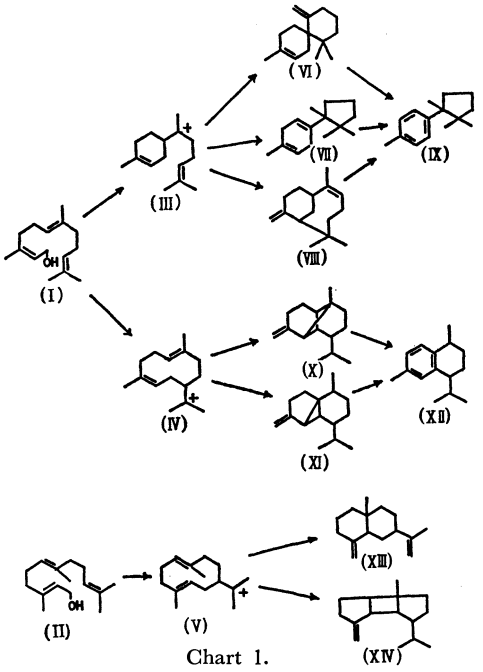

Chart 1.

Experimental

Separation of a Sesquiterpene Hydrocarbon Fraction. Liverwort collected at Yaku Island in Kagoshima Prefecture (October, 1969) was dried in the shade for a week; the plants (3.85 kg) were then digested with hexane (15 l) to obtain a dark brown, viscous matter (5.3 g) in a 0.14% yield. This matter was subjected to distillation under reduced pressure by using a small-type distillation column packed with single-turn spirals of stainless steel. The distillate (bp 70—90°C/2 mm Hg; 0.45 g) thus obtained was then chromatographed over a silica gel column (1.5×25 cm) to collect a hydrocarbon fraction (0.37 g), which was then quickly eluted with hexane.

Gas Chromatography. The gas chromatograms were taken on a Hitachi K-53 gas chromatograph equipped with a flame-ionization detector in connection with a Golay column (coating, PEG-20 M; 0.5 mm×45 m): the column temperature was programmed from 120 to 170°C at a rate of 2°C/min, and the carrier (nitrogen gas) had a pressure of 1.0 kg/cm^2.

An Apparatus Combining a Gas Chromatograph and a Mass Spectrometer. The hydrocarbon fraction described above was analyzed with an instrument combining a gas chromatograph and a mass spectrometer, Hitachi RMU-6E Model, using a Golay column (PEG-20 M, 0.5 mm×45 m); the gas-chromatograph part was operated under the same conditions as above, except that helium was used instead of nitrogen gas as the carrier gas. The column effluent was admitted to an ion source *via* a heated line and a Watson-Biemann-type helium separator. The mass spectrometer part was operated under the following conditions: 70 eV, ionization voltage; 100 μA, total emission; 1800 eV, ion-accelerating voltage, and 220°C, ion source temperature.

Mass Spectrum of Each Constituent. From the mass spectra thus taken, four abundant ions of molecular (M), base (H_1), second-highest (H_2), and third-highest (H_3) ions and their abundance were read, as is shown in Table 1. These spectral patterns were then a compared with the respective reported spectra, and the listed sesquiterpene were identified.

The authors are indebted to Drs. Yoshio Hirose and Kumiko Morikawa, The Institute of Food Chemistry, for sending the mass spectra.

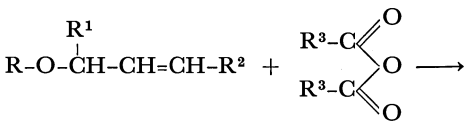
Palladium-catalyzed Exchange of Allylic Groups of Ethers and Esters with Carboxylic Anhydrides

Kuniyuki TAKAHASHI*, Go HATA, and Akihisa MIYAKE

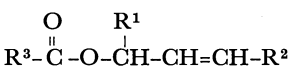
Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura

(Received October 12, 1972)

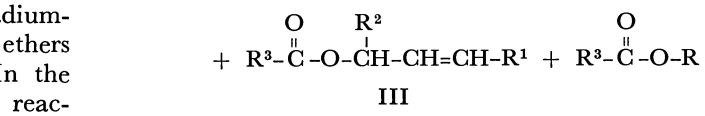
Previously we have reported[1,2] the palladium-catalyzed exchange reaction of allylic groups of ethers and esters with active-hydrogen compounds. In the course of the studies, it has been found that the reaction of the allylic compounds (I) with carboxylic anhydrides in the presense of palladium catalysts also gives the exchanged products (II and III) of allylic groups.



I



II



III

$R = C_6H_5$, CH_3CO, CH_3CH_2CO
$R^1 = H$, $CH_2CH_2CH_2CH{=}CH_2$
$R^2 = H$, $CH_2CH_2CH_2CH{=}CH_2$
$R^3 = CH_3$, C_6H_5

An active and easily available catalyst is prepared by mixing palladium acetate and triphenylphosphine. Tetrakis(triphenylphosphine)palladium(0) is also an effective catalyst. However, the catalytic activity of the combination of dichlorobis(triphenylphosphine)-palladium (II) and sodium phenoxide is much smaller than that of the above two catalysts. Some platinum catalysts also showed the catalytic activity, but it was smaller than that of palladium catalysts.

The results on the reaction of allylic ethers and

esters with carboxylic anhydrides are shown in Table 1.

Experimental

Reagents. $Pd(OAc)_2$[3], $PdCl_2(Ph_3P)_2$,[4] $Pd(Ph_3P)_4$,[4] $PtCl_2(Ph_3P)_2$[5] $Pt(Ph_3P)_4$,[5] 1-phenoxy-2,7-octadiene,[6] 1-phenoxy-2-propene,[7] octadienyl carboxylate[8] were prepared by previously reported methods. Carboxylic anhydrides and allyl acetate were purified by distillation. Dimethylformamide was dried on calcium hydride and purified by distillation.

Reaction Procedure. All the reactions were carried out under an argon atmosphere. In a 50 ml two necked flask, catalysts, reagents, and dimethylformamide were charged and the reaction mixture was stirred at 85°C. The reaction products were characterized by elemental analysis, molecular weight measurement, and IR and NMR spectral measurement or by comparison with authentic samples. The gas chromatography was used for the quantitative analysis of products.

Synthesis of Sugar Derivatives of *N*-Methyl-*N*-nitrosourea

Tomoya MACHINAMI and Tetsuo SUAMI

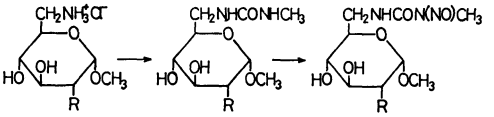
Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama

(Received October 27, 1972)

Streptozotocin is a broad spectrum antibiotic and possesses antitumor,[1,2] mutagenic,[3] and diabetogenic[2,4–9] activities. Its isolation from a fermentation broth of *Streptomyces achromogenes var. streptozoticus* was reported in 1960[10–13], and the structure has been established to be *N*-carbamyl-*N'*-methyl-*N'*-nitroso-D-glucosamine along with the synthesis.[14,15]

In previous papers, a synthesis of methyl glycosides of this antibiotic[16] and that of the analogs in which D-glucosamine was substituted for aminocyclitols[17] were described. In the present note, we wish to report the analogs of methyl 6-amino-6-deoxy-α-D-glucopyranoside and methyl 2,6-diamino-2,6-dideoxy-α-D-glucopyranoside.

Methyl 6-amino-6-deoxy-α-D-glucopyranoside hydrochloride (**1**)[18] and methyl 2,6-diamino-2,6-dideoxy-α-D-glucopyranoside dihydrochloride (**4**) were used as starting materials. **1** and **4** were treated with methyl isocyanate in the presence of silver carbonate giving respective *N*-carbamyl-*N'*-methyl derivatives (**2**) and (**5**) in 75 and 65% yield. Nitrosation of **2** and **5** were carried out with sodium nitrite in aqueous acetic acid to give *N*-nitroso derivatives (**3**) and (**6**) in 49 and 67% yield respectively. **3** and **6** were active against Ehrlich ascites tumor in mice.



Experimental

General. Melting points were determined in capillary tubes and are uncorrected. Solutions were evaporated below 50°C under reduced pressure.

*Methyl 6-Amino-6-deoxy-α-D-glucopyranoside hydrochloride (**1**).* This compound was prepared by the method of Cramer.[18]

Methyl N-*Carbamyl*-N'-*methyl-6-amino-6-deoxy-α-D-glucopyranoside (**2**).* A 502 mg portion of **1** was dissolved in 65% aqueous acetonitrile (72 ml). To the solution, silver carbonate (363 mg) and methyl isocyanate (0.16 ml) were added and the mixture was heated for 1 hr under reflux. After cooling, the mixture was filtered and the filtrate was evaporated. The residue was crystallized in acetonitrile to give a crude product (426 mg, 78%). Recrystallization from *n*-propanol yielded crystals of mp 176—177°C. $[\alpha]_D^{22}$ +99° (*c* 1.0, methanol).

Found: C, 42.91; H, 6.93; N, 11.13%. Calcd for $C_9H_{18}N_2O_6$: C, 43.19; H, 7.25; N, 11.20%.

Methyl N-*Carbamyl*-N'-*methyl*-N'-*nitroso*-6-*amino*-6-*deoxy*-α-D-*glucopyranoside* (**3**). **2** (120 mg) was dissolved in 5.6% aqueous acetic acid (18 ml) under ice cooling. 0.1 M Sodium nitrite solution (6.5 ml) was added to the solution and the mixture was settled overnight at room temperature. After sodium ions were removed by treating with Amberlite IR-120 (H^+ type), the solution was lyophilized. The residue was crystallized in ethanol under ice cooling to give the product (65 mg, 49%), mp 106—107°C. $[\alpha]_D^{22}$ +82.0° (*c* 0.5, methanol).

Found: C, 39.08; H, 6.20; N, 14.80%. Calcd for $C_9H_{17}N_3O_7$: C, 38.71; H, 6.14; N, 15.05%.

Methyl N-*benzyloxycarbonyl*-6-O-*tosyl*-α-D-*glucosaminide*. The product was prepared by the method of Foster *et al.*[19].

Methyl 2,6-*Diamino*-2,6-*dideoxy*-α-D-*glucopyranoside dihydrochloride* (**4**). A mixture of methyl *N*-benzyloxycarbonyl-6-*O*-tosyl-α-D-glucosaminide[19] (7.3 g) and sodium azide (5.4 g) in 70% aqueous 2-methoxyethanol (140 ml) was heated for 21 hr under reflux. The solution was evaporated and the residue was extracted with warm acetone. The acetone extracts were evaporated and the residue was hydrogenated in ethanol (55 ml) with 5% palladium on carbon and conc hydrochloric acid (1.7 ml) at 3.4 kg/cm² hydrogen pressure for 21 hr. After the catalyst was removed by filtration, the solution was evaporated to give a crude product (1.97 g, 49%), mp 198—201°C (decomp.). Recrystallization from ethanol–methanol gave hygroscopic crystals with the same decomposition point. $[\alpha]_D^{21}$ +125° (*c* 1.28, water). The product showed a ninhydrin-positive single spot on paper chromstography (R_f 0.26) in *n*-butanol–pyridine–water (6 : 4 : 3) system in an ascending development (R_f D-glucosamine hydrochloride 0.36).

Found: C, 31.59; H, 6.73; N, 10.56; Cl, 24.82%. Calcd for $C_7H_{18}N_2O_4Cl_2$: C, 31.71; H, 6.84; N, 10.57; Cl, 26.75%.

Methyl Di-N,N'-(N-*methyl*-*carbamyl*)-2,6-*diamino*-2,6-*dideoxy*-α-D-*glucopyranoside* (**5**). To a solution of **4** (911 mg) in 70% aqueous acetonitril (45 ml), methyl isocyanate (0.5 ml) and silver carbonate (1.4 g) were added and the mixture was heated for 1 hr under reflux. After cooling, the mixture was filtered and the filtrate was evaporated to give a crude product (684 mg, 65%). Recrystallization from ethanol afforded an analytically pure sample, mp 247—249°C. $[\alpha]_D^{22}$ +108° (*c* 0.88, water).

Found: C, 43.02; H, 7.30; N, 18.30%. Calcd for $C_{11}H_{22}N_4O_6$: C, 43.14; H, 7.24; N, 18.29%.

Methyl Di-N,N'-(N-*methyl*-N-*nitroso*-*carbamyl*)-2,6-*diamino*-2,6-*dideoxy*-α-D-*glucopyranoside* (**6**). **5** (684 mg) was treated with 0.5 M sodium nitrite solution (7.6 ml) in 5.7% aqueous acetic acid (26.5 ml) as described in **3**. After the solution was settled overnight, the crystals were collected by filtration to give a first crop of the product (338 mg), mp 154—156°C. The mother liquor was treated with Amberlite IR-120 (H^+ type) and then lyophilized. The residue was crystallized in ethanol to give a second crop of the product (204 mg), mp 154—156°C. Total yield was 67%. Recrystallization from methanol afforded a sepcimen for analysis, mp 154.5°C (decomp.). $[\alpha]_D^{22}$ +106° (*c* 0.75, methanol).

Found: C, 36.25; H, 5.66; N, 22.94%. Calcd for $C_{11}H_{20}N_6O_8$: C, 36.26; H, 5.53; N, 23.07%.

The authors wish to thank Professor Sumio Umezawa for his helpful advice and Mr. Saburo Nakada for his elementary analysis.

Synthesis of Planteose

Tetsuo SUAMI, Toshiki OTAKE,* Tatsuo NISHIMURA, and Toshihide IKEDA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama

** Nippon Electric Varian Co., Ltd., Azabu Iigura-cho, Minato-ku, Tokyo*

(Received November 22, 1972)

Planteose[1] was first isolated by Wattiez and Hans[2] in 1943 from the seeds of *Plantago major* and *Plantago ovata*. The structure has been established by French and his coworkers[3] in 1953 as *O*-α-D-galactopyranosyl-(1→6)-*O*-β-D-fructofuranosyl-(2→1)-α-D-glucopyranoside. The presence of this nonreducing trisaccharide in other plant sources was descirbed by Wada and Yamazaki[4] and by French and Wild.[5]

In connection with previous papers on sucrose chemistry[6–9], we have attempted to synthesize planteose (**4**) by a chemical method. The attractive starting material in this attempt was 2,3,4,6,1′,3′,4′-hepta-*O*-acetylsucrose (**2**) which was described by Otake[10] and more recently by Buchanan *et al.*[11]. **2** was condensed with tetra-*O*-benzyl-α-D-galactopyranosyl chloride[12] (**1**) giving *O*-(2,3,4,6-tetra-*O*-benzyl-α-D-ga-

lactopyranosyl)-(1→6)-*O*-(1,3,4-tri-*O*-acetyl-β-D-fructofuranosyl)-(2→1)-2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside (**3**) as an amorphous solid in 59% yield. Deacetylation of **3** in 0.1 M methanolic sodium methoxide and subsequent catalytic hydrogenolysis afforded a crude product of **4** in 44% yield.

The PMR spectrum of **4** revealed two doublets at δ 5.02 (J=2.7 Hz) and 5.46 (J=3.5 Hz) which were attributed to an anomeric proton of the α-D-galactopyranosyl group and that of the α-D-glucopyranosyl group respectively. The assignment of the signals was reasonably acceptable, because the corresponding proton of the α-D-galactopyranosyl group in melibiose showed its signal at δ 4.96 (J=2.9 Hz)[13] and that of the α-D-glucopyranosyl group in sucrose at δ 5.45 (J=3.2 Hz).[8,13]

4 was acetylated in the usual manner to give the crystalline undecaacetate (**5**) in 32% yield. The mp and the optical rotation were in good agreement with those described in the literature.[3] The PMR spectrum of **5** revealed eight sharp signals for the eleven acetoxy groups and a doublet at δ 5.75 (J=3.6 Hz) for an anomeric proton of the α-D-glucopyranosyl group, since the corresponding proton of sucrose octaacetate[14] and raffinose undecaacetate[9] resonated at δ 5.68 (J=3.5—3.7 Hz). Also a signal of the methylene bridge was observed at δ 3.69 and 3.98 supporting an existence of a bond between 0-6′ of sucrose and D-galactosyl residue, because the methylene bridge in 1-kestose undecaacetate was observed at δ 3.67 ($J_{geminal}$=9.5 Hz).[14]

On the other hand, when **2** was condensed with tetra-*O*-acetyl-α-D-galactopyranosyl bromide[15] (**6**) in nitromethane, an isomeric trisaccharide undecaacetate (**7**) was obtained in 22% yield.

The PMR spectrum of **7** revealed seven sharp signals in the δ 1.98—2.15 region for the eleven acetoxy groups and two doublets at δ 4.62 (J=7.5 Hz) and 5.60 (J=3.5 Hz) for an anomeric proton of the β-D-galactopyranosyl group and that of the α-D-glucopyranosyl group respectively. Because the corresponding proton of the β-D-galactopyranosyl group in β-allolactose octaacetate[9] showed its signal at δ 4.55 (J=7.4 Hz) as a doublet.

The undecaacetate **7** was deacetylated in 0.1 M methanolic sodium methoxide to give a trisaccharide (**8**).

The PMR spectrum of **8** revealed two doublets at δ 4.48 (J=7.2 Hz) and 5.44(J=3.4 Hz) which were attributed to an anomeric proton of the β-D-galactopyranosyl group and that of the α-D-glucopyranosyl group respectively, since the corresponding proton of the β-D-galactopyranosyl group in *O*-β-D-galactopyranosyl-(1→6)-*O*-α-D-glucopyranosyl-(1→2)-β-D-fructofuranoside[9] and allolactose[9,16] revealed their signals at δ 4.44 (J=7.5—7.9 Hz) as a doublet.

Experimental

General. Melting points were determined in capillary tubes and are corrected. Optical rotations were measured with a Japan Spectroscopic DIP-SL polarimeter. The PMR spectra were recorded at 100 MHz with a Varian HA-100D and at 60 MHz with a Varian A-60D spectrometer in deuteriochloroform or deuterium oxide with tetramethylsilane or sodium trimethylsilylpropanesulfonate as an internal standard. The peak positions are given in δ-values. Tlc was performed on silica gel plates (Wakogel B-10). Solutions were evaporated below 40°C under diminished pressure.

*Tetra-O-benzyl-α-D-galactopyranosyl Chloride (**1**).* The product was prepared by the method of Austin *et al.*[12]

*2,3,4,6,1′,3′,4′-Hepta-O-acetylsucrose (**2**).* The crude product was prepared by the method of Otake.[10] Recrystallization from toluene afforded the crystalline product of mp 159—160°C. $[\alpha]_D^{20}$ +50.1° (*c* 1.46, chloroform). Lit,[11] mp 160°C, $[\alpha]_D^{20}$ +49.5° (*c* 0.4, chloroform).

*O-(2,3,4,6-Tetra-O-benzyl-α-D-galactopyranosyl)-(1→6)-O-(1,3,4-tri-O-acetyl-β-D-fructofuranosyl)-(2→1)-2,3,4,6-tetra-O-acetyl-α-D-glucopyranoside (**3**).* To a solution of **1** (994 mg, 1.8 mmol) and **2** (498 mg, 0.8 mmol) in dry benzene (30 ml), mercuric cyanide (1.4 g, 5.5 mmol) and "Drierite" (1.4 g) were added and the mixture was heated for 40 hr under reflux with an exclusion of moisture. The reaction mixture was filtered and the filtrate was evaporated. The residue was dissolved in benzene, washed with water and again evaporated to give a residue (1.10 g). The residue was chromatographed on a silica gel column (Wakogel C-200, 4 g, 1.5×45 cm) in butanone-toluene (1 : 10, v/v). Fractions which showed a single spot on tlc at R_f 0.21 in the same solvent were combined and evaporated to give a solid product (538 mg, 59%). $[\alpha]_D^{20}$ +53,5° (c 0.93, chloroform). PMR (60 MHz, $CDCl_3$): δ 2.01 (s, 3H, OAc), 2.015 (s, 6H, OAc×2), 2.02 (s, 3H, OAc), 2.06 (s, 3H, OAc), 2.11 (s, 3H, OAc), 2.16 (s, 3H, OAc), 5.03 (d, 1H, J 3.6 Hz, H^{α}_{gal}—1), 5.80 (d, 1H, J 3.5 Hz, H^{α}_{glu}—1) and 7.25—7.34 (m, 20H, phenyl).

*O-α-D-Galactopyranosyl-(1→6)-O-β-D-fructofuranosyl-(2→1)-α-D-glucopyranoside (**4**).* **3** (538 mg) was dissolved in 0.1 M methanolic sodium methoxide (20 ml) and the solution was settled for 16 hr at room temperature. The solution was deionized with Amberlite IR-120 (H^+ type) until pH 7 and the solution was subsequently hydrogenated

with palladium black under hydrogen pressure (3.4 kg/cm²) for 22 hr. The mixture was filtered to remove the catalyst and the filtrate was evaporated to give a solid product (211 mg), which showed a single spot on tlc at R_f 0.20 in chloroform–methanol (5 : 4, v/v). The product was dissolved in water, decolorized with active charcoal and again evaporated. The residue was dissolved in a small amount of water and ethanol was added to the solution. The solution was settled in a refrigerator to give precipitates (104 mg, 44%) which were collected by filtration. Mp 120—123°C, $[\alpha]_D^{20}$ +122.5° (*c* 1.42, water). PMR (60 MHz, D_2O): δ 5.02 (d, 1H, *J* 2.7 Hz, $H^{\alpha}_{gal}-1$) and 5.46 (d, 1H, *J* 3.5 Hz, $H^{\alpha}_{glu}-1$). The sample for an analysis was obtained by drying over phosphorus pentoxide at 75°C *in vacuo* overnight. The product did not reduce a Fehling's solution.

Found: C, 42.53; H, 6.35%. Calcd for $C_{18}H_{32}O_{16}$: C, 42.86; H, 6.39%.

Lit,[3] mp 124°C, $[\alpha]_D$ +129.0° (c 4, water).

*Planteose Undecaacetate (**5**).* **4** (112 mg) was acetylated with acetic anhydride and pyridine in the usual manner to give a glassy solid (179 mg). Recrystallization from *n*-butanol yielded **5** (69 mg, 32%), mp 134—135°C, $[\alpha]_D^{25}$ +97.2° (*c* 1.03 chloroform). PMR (100 MHz, $CDCl_3$): δ 1.99 (s, 3H, OAc), 2.01 (s, 3H, OAc), 2.04 (s, 6H, OAc×2), 2.08 (s, 9H, OAc×3), 2.10 (s, 3H, OAc), 2.135 (s 3H, OAc), 2.14 (s, 3H, OAc), 2.15 (s, 3H, OAc), 5.75 (d, 1H, *J* 3.6 Hz, $H^{\alpha}_{glu}-1$) and 3.69, 3.98 (o, 2H, $J_{geminal}$ 9.1, *J* 4.2, 5.6 Hz, CH_2 bridge).

Found: C, 49.47; H, 5.63%. Calcd. for $C_{40}H_{54}O_{27}$: C, 49.68; H, 5.63%.

Lit,[3] mp 135°C, $[\alpha]_D^{26}$ +97° (c 1, chloroform).

*Tetra-O-acetyl-α-D-galactopyranosyl Bromide (**6**).* The product was prepared by the method of Ohle *et al.*[15]

*O-(2,3,4,6-Tetra-O-acetyl-β-D-galactopyranosyl)-(1→6)-O-(1,3,4-tri-O-acetyl-β-D-fructofuranosyl)-(2→1)-2,3,4,6-tetra-O-acetyl-α-D-glucopyranoside (**7**).* A mixture of **6** (526 mg, 1.3 mmol), **2** (468 mg, 0.7 mmol), "Drierite" (1.1 g), mercuric cyanide (1.1 g, 4.4 mmol) and nitromethane (17 ml) was agitated for 24 hr at room temperature in the dark with an exclusion of moisture. Insoluble matters were removed from the mixture and the solution was evaporated. The residue was dissolved in chloroform (40 ml) and the solution was washed with water, dried over anhydrous sodium sulfate and evaporated. The residue was acetylated as usual and the acetylated product was chromatographed on a silica gel column (Wakogel C–200, 40 g, 1.5×45 cm) in butanone–toluene (1 : 5, v/v). Each fraction was monitored by tlc with the same solvent. Fractions having a single spot at R_f 0.34 were combined and evaporated to give a glassy solid (387 mg, 54%). The product was dissolved in a warm mixture of *n*-butanol and 50% aqueous ethanol (3 : 1, v/v) and the solution was settled in a refrigerator to give an amorphous product (157 mg, 22%), mp 87—89°C, $[\alpha]_D^{25}$ +44.9° (c 2.51, chloroform). PMR (100 MHz, $CDCl_3$): δ 1.98 (s, 3H, OAc), 2.02 (s, 3H, OAc), 2.04 (s, 6H, OAc×2), 2.06 (s, 3H, OAc), 2.09 (s, 3H, OAc), 2.11 (s, 9H, OAc×3), 2.15 (s, 6H, OAc×2), 4.62 (d, 1H, 7.5 Hz, $H^{\beta}_{gal}-1$) and 5.60 (d, 1H, *J* 3.5 Hz, $H^{\alpha}_{glu}-1$).

Found: C, 49.82; H, 5.95%. Calcd. for $C_{40}H_{54}O_{27}$: C, 49.68; H, 5.63%.

*O-β-D-Galactopyranoyl-(1→6)-O-β-D-fructofuranosyl-(2→1)-α-D-glucopyranoside (**8**).* **7** (235 mg) was deacetylated in 0.1 M methanolic sodium methoxide analogously as described in **4** to give a crude product (101 mg, 82%), $[\alpha]_D^{18}$ +51.3° (*c* 1.6, water). The product did not reduce Fechling's solution. PMR (60 MHz, D_2O): δ 4.48 (d, 1H, *J* 7.2 Hz, $H^{\beta}_{gal}-1$) and 5.44 (d, 1H, *J* 3.4 Hz, $H^{\alpha}_{glu}-1$). A sample for analysis was obtained by drying over phosphorus pentoxide at 50°C for 3 days *in vacuo*.

Found: C, 42.65; H, 6.45%. Calcd. for $C_{18}H_{32}O_{16}$: C, 42.86; H, 6.39%.

This work has been supported financially in part by the grant of the Japanese Ministry of Education. We thank Professor Sumio Umezawa for his helpful advice and Mr. Saburo Nakada for performing elementary analysis.

Cationic Arylation. VI. Phenylation of Arenes with Benzenediazonium Trifluoroacetate

Nobumasa KAMIGATA, Ryuki HISADA,* Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo

** Faculty of Education, University of Shizuoka, Shizuoka*

(Received December 20, 1972)

Nesmeyanov *et al.* first reported that the decomposition of aryldiazonium tetrafluoroborate in aromatic solvents yields aryl cation as a reactive intermediate which attacks the aromatic nucleus, forming biaryls.[1] However, concerning the substitution of arenes with aryl cation only few papers have been published, mainly by Abramovitch *et al.*[2]

The investigations carried out in our laboratories on cationic arylation have established that phenyl cation can readily be generated by one of the following three routes; a) thermal decomposition of benzenediazonium tetrafluoroborate in aprotic polar solvents,[3] b) thermal decomposition of phenylazo *p*-tolyl sulfone in the presence of trifluoroacetic acid,[4] and c) thermal decomposition of phenylazotriphenylmethane in tri-

fluoroacetic acid.[5]

a) PhN_2BF_4

b) $PhN{=}N{-}S(=O)(=O){-}C_6H_4{-}CH_3$ $\xrightarrow{CF_3CO_2H}$ $C_6H_5{+}$

c) $PhN{=}NCPh_3$ $\xrightarrow{CF_3CO_2H}$

Benzenediazonium trifluoroacetate (I) was first prepared and isolated by Pettit *et al.*[6] They concluded that phenyl radical was an intermediate simply because biphenyl was found in 24% yield when I was decomposed in benzene. This conclusion contradicts with our hypothesis that in the decomposition of phenylazo *p*-tolyl sulfone[4] or phenylazotriphenylmethane[5] in trifluoroacetic acid I is formed in the first step and subsequently degrades, not to phenyl radical, but to phenyl cation. Since I may exist either in the covalent diazoacetate structure ($Ph{-}N{=}N{-}O_2CCF_3$) which will give aryl free radical or in the ionic diazonium ion pair form ($PhN_2^+CF_3CO_2^-$) which should yield aryl cation, its decomposition mechanism can be formulated in terms of these two reactive species.

In order to clarify the mechanism of the decomposition of I, phenylation of arenes by I has been investigated, and the isomer distributions and partial rate factors in the phenylation have been determined. The results are described in this paper.

Results and Discussion

Phenylation of Arenes. I is insoluble in aromatic solvents and soluble in water and such aprotic polar solvents as acetonitrile and nitromethane. Therefore, I was decomposed in arene–acetonitrile mixture in order to carry out the phenylation in homogeneous solution. The isomer distributions and partial rate factors determined are compared in Tables 1 and 2 with the data reported in the literature. The isomer distributions of phenylarenes are quite similar to those obtained in the phenylation with benzenediazonium tetrafluoroborate,[3] phenylazo *p*-tolyl sulfone in the presence of trifluoroacetic acid,[4] and phenylazotriphenylmethane in trifluoroacetic acid,[5] but significantly differ from the values observed in the phenylation with *N*-nitrosoacetanilide.[7] Namely, in the former cases the methoxy, ethyl and chloro groups behaved as *o,p*-directors and nitro group behaved as a *m*-director, whereas in the latter case the nitro group behaved as an *o,p*-director.

The partial rate factors observed with I are also similar to the values in the phenylation with benzenediazonium tetrafluoroborate,[3] phenylazo *p*-tolyl sulfone[4] or phenylazotriphenylmethane[5] in trifluoroacetic acid but different from the figures reported for phenylation with *N*-nitrosoacetanilide.[7] These results clearly show that the decomposition of I does not yield phenyl radical, but yields phenyl cation. Thus, I is a new reagent for production of phenyl cation, and one can choose from PhN_2BF_4, $PhN_2O_2SAr{+}CF_3CO_2H$, $PhN_2CPh_3{+}CF_3CO_2H$, and $PhN_2O_2CCF_3$ (I).

$$PhN_2^+CF_3CO_2^- \longrightarrow Ph^+ + N_2 + CF_3CO_2^-$$

$$\xrightarrow{PhX} Ph{-}C_6H_4{-}X + CF_3CO_2H$$

Reaction with Oxygen[18]*-enriched Water.* When I was dissolved in water and decomposed at 25°C, phenol was obtained in 60—65% yield. This finding further supports the ionic decomposition mechanism and the formation of phenyl cation as a reactive intermediate. The reaction seems to be a convenient method for preparation of phenols, especially for preparation of ^{18}O-labeled phenols. When I was decomposed in water containing 1.3 atom % excess ^{18}O, phenol with 0.89 atom % excess ^{18}O was obtained in

61% yield.

Oxygen-18 labeled phenols could be produced by such methods as 1) $ArMgX+{}^*O_2$, 2) $ArSO_3Na+Na^*OH$, 3) $ArX+Na^*OH$ and 4) $ArN_2BF_4+CH_3C^*O_2H\rightarrow Ar^*OAc\rightarrow Ar^*OH$. The method 1) requires ^{18}O-enriched oxygen gas which is not commercially available. The method 2) and 3) require Na^*OH and rather high temperatures. The method 4) requires large excess of $CH_3C^*O_2H$ which is also not commercially available. Hydrolysis of $PhN_2^+BF_4^-$ or $PhN_2^+Cl^-$ in $H_2{}^*O$ needs high temperature and tends to give phenol with a lot of tarry mixture. On the contrary, the reaction between I and $H_2{}^{18}O$ proceeds smoothly at room temperature, the procedure is very simple, and therefore, one can say that this method is most convenient for preparation of ^{18}O-labeled phenol.

Experimental

Materials. I was prepared by diazotization of aniline with a concentrated aqueous solution (*ca.* 40%) of sodium nitrite in trifluoroacetic acid at 0—5°C. The crystals formed were filtered off, washed with small quantities of ice-water, and then dried for several hours *in vacuo* at 0°C over phosphorus pentoxide.[6] Purification of benzene and several arenes and preparation of authentic samples of substituted biphenyls were described previously.[3]

General Procedure for Determination of the Relative Reactivities of PhX toward Benzenediazonium Trifluoroacetate in Acetonitrile. A solution of I (2.0 g) in acetonitrile (2.0 g) was diluted with an equimolar mixture of PhH and PhX (the molar ratio (PhH+PhX)/I was 75). The homogeneous solution was placed in a bath at 20±0.1°C, and the decomposition was followed by evolution of nitrogen. After the evolution of nitrogen ceased, the reaction mixture was washed with water, a 5% sodium hydroxide solution, water, and then dried over anhydrous magnesium sulfate. The amounts of substituted biphenyl isomers were determined by a Hitachi Gas Chromatograph K–53 (Apiezon L 10% on Chromosorb W).

Not benzene but chlorobenzene was used as the standard for the competitive phenylation of PhOMe, PhEt, and $PhNO_2$, since unsubstituted biphenyl easily sublimes during the evaporation of arenes.[3-5]

Preparation of ^{18}O-labeled Phenol. Dry I (53 g) was dissolved in 70 ml of water (1.3 excess atom % ^{18}O) and spontaneously decomposed at 25°C. After the evolution of nitrogen ceased, the reaction mixture was diluted with ether, washed with water and dried over anhydrous magnesium sulfate. Oxygen-18 excess phenol was isolated by distillation under reduced pressure, bp 70°C/30 mmHg, yield 6.2 g (61%).

Determination of Oxygen-18 Contents. Phenol was brominated to 1,3,5-tribromophenol, which was purified by sublimation three times, and then converted into carbon dioxide according to the method of Rittenberg and Ponticorvo[8] for determination of the oxygen-18 contents. The ^{18}O-contents of the carbon dioxide was determined by use of a Hitachi RM–50 Type Mass Spectrometer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1019—1020 (1973)

Synthetic Studies of Amino Acids by the Use of the Copper(II) Complex. IV.[1d] A Facile Procedure for Isolating Amino Acids from Their Copper(II) Complexes by Means of Amberlite IR-120B

Shohji OHDAN, Tetsuya ICHIKAWA, Younosuke ARAKI, and Yoshiharu ISHIDO

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo

(Received September 27, 1972)

It has been shown in a series of investigation[1)] that the base-catalyzed condensation reaction of *N*-pyruvylideneglycinatoaquocopper(II) with a variety of aldehydes is useful for the preparation of β-hydroxy amino acids and 2-amino-2-deoxyaldonic acids. The isolation of the resultant amino acids from the corresponding copper(II) complexes has been performed by the treatment of their aqueous solutions with hydrogen sulfide gas or sodium sulfide, followed by the filtration of the precipitated cupric sulfide, adsorption on a column of Amberlite IR-120B(H form), and elution with a dilute aqueous ammoniacal solution. However, treatment with sodium sulfide makes the resultant solution strongly alkaline, and an alkaline condition is unsuitable for such amino acids as 2-amino-2-deoxyaldonic acids susceptible to isomerization. Moreover, hydrogen sulfide gas is, if anything, unsuitable for the isolating procedure in view of its toxicity. In these connections, an investigation was undertaken in order to establish a more favorable procedure for the isolation of amino acids by the use of some reagents;[2)] the application of Amberlite IR-120B(H form) was proved to afford amino acids in high yields quite simply.

A solution of *N*-pyruvylideneglycinatoaquocopper-(II)[1c)] (10 mmol) in distilled water (100 ml) was treated on a column (3×9 cm) of the resin, washed with distilled water, and then eluted with a dilute

TABLE 1. AN EXAMINATION ON THE WASHING PROCEDURE WITH DISTILLED WATER PRIOR TO THE ELUTION WITH AQUEOUS AMMONIACAL SOLUTION[a)]

Run	The volume of water for washing, l	Yield of isolated glycine	
		g	%
1	5	0.732	97.6
2	3	0.727	96.9
3	1	0.702	93.6

a) All the examinations were carried out by the use of 10 mmol of *N*-pyruvylideneglycinatoaquocopper(II) dissolved in distilled water (100 ml). In each case, the elution was carried out with 2000 ml of 0.5 M aqueous ammoniacal solution.

TABLE 2. AN EXAMINATION ON THE ELUTING PROCEDURE WITH 0.5 M AQUEOUS AMMONIACAL SOLUTION AFTER THE WASHING WITH DISTILLED WATER[a)]

Fractions[b)]	Yield of isolated glycine	
	g	%
1	0.722	96.3
2	0.005	0.7
3	0.003	0.3
4	0.002	0.3

a) All the examinations were carried out by the use of 10 mmol of *N*-pyruvylideneglycinatoaquocopper(II) dissolved in distilled water (100 ml). Prior to the elution, the column was washed with distilled water (5000 ml). b) The eluate was divided into the fractions of 500 ml, and the fractions were numbered in turn in the order of eluting-out.

TABLE 3. ISOLATION OF AMINO ACIDS FROM THE CORRESPONDING COPPER(II) COMPLEXES BY THE USE OF AMBERLITE IR-120 B[a)]

Copper(II) complexes	Mol. weight	Yield of isolated glycine or alanine	
		g	%
N-Pyruvylidene-glycinatoaquocopper(II)[b)]	260	0.732	97.6
Bisglycinatocopper(II)[c)]	230	1.485	99.0
N-Salicylidene-glycinatoaquocopper(II)[d)]	278	0.564	75.2
N-Pyruvylidene-glycinatopyridinecopper(II)[e)]	339	0.705	94.0
Bisalaninatocopper(II)	258	1.768	98.6

a) All the isolations were carried out by the use of 10 mmol of the corresponding copper(II) complexes and the column (3×9 cm) of the resin(H form). b) On removing the copper(II) ion by treating with hydrogen sulfide gas prior to the treatment on the column, glycine was obtained in 82.1% yield. c) Glycine was obtained in 97.5% yield by decomposing the complex with concentrated aqueous ammoniacal solution prior to the treatment on the column. d) The yield is considered to be arisen from the low solubility of the complex. e) On treating the complex as described in b), glycine was obtained in 82.0% yield.

1) a) T. Ichikawa, S. Maeda, Y. Araki, and Y. Ishido, *J. Amer. Chem. Soc.*, **92**, 5514 (1970); b) T. Ichikawa, T. Okamoto, S. Maeda, S. Ohdan, Y. Araki, and Y. Ishido, *Tetrahedron Lett.*, **1971**, 79; c) T. Ichikawa, S. Maeda, T. Okamoto, Y. Araki, and Y. Ishido, This Bulletin, **44**, 2779 (1971); d) S. Ohdan, T. Okamoto, S. Maeda, T. Ichikawa, Y. Araki, and Y. Ishido, *ibid.*, **46**, 981 (1973).

2) a) The copper(II) complex was not decomposed by a concentrated aqueous ammoniacal solution, although it has been well known that bisglycinatocopper(II) can be decomposed by the solution; b) The separation of the excess amines from glycine could not be achieved distinctly by the same ion-exchange resin-column technique, although the complex was decomposed by the use of 1.5—2.0 equivalents of ethylenediamine, diethylenetriamine, and triethylenetetramine respectively; c) Amberlite IR-120B (H form) was used since *N*-salicylideneglycinatoaquocopper-(II) has been shown to be decomposed by 6 M aqueous hydrochloric acid [K. Harada and J. Oh-hashi, *J. Org. Chem.*, **32**, 1103 (1967)].

Table 4. Isolation of glycine from *N*-pyruvylideneglycinatoaquocopper(II) in alkaline solution by the treatment with amberlite IR-120 B[a]

Run	Solvent system	Conditions		Yield of isolated glycine	
		pH[b]	Treating time, hr	g	%
1	H_2O (100 ml)	9.5	0	0.677	90.3
2	H_2O–DMF(80+80 ml)	9.0	0	0.715	95.3
3	H_2O–DMF(80+80 ml)	9.0	2	0.511	68.1

a) All the isolations were carried out by the use of *N*-pyruvylideneglycinatoaquocopper(II) and a column (3×9 cm) of the resin(H form). The washing of the column and the elution were carried out with distilled water (5000 ml) and 0.5 M aqueous ammoniacal solution (2000 ml), respectively. b) These conditions were adjusted by the use of a pH meter and by the addition of 1 M aqueous sodium hydroxide solution.

aqueous ammoniacal solution; the eluate was then concentrated *in vacuo* to give white crystals of glycine in a 97.6% yield. Incidentally, the amounts of solvents necessary for the washing and the elution were found to be 1000 ml and 500 ml respectively by such examinations as are shown in Tables 1 and 2. By the application of best condition, the isolation of glycine and alanine were attempted with respect to bisglycinatocopper(II),[3] *N*-salicylideneglycinatoaquocopper(II),[4] *N*-pyruvylideneglycinatopyridinecopper (II),[1c] and bisalaninatocopper(II);[5] they were proved to give the corresponding amino acids in 99.0, 75.2, 94.0, and 98.6% respectively, under the conditions summarized in Table 3. Except in the case of *N*-pyruvylideneglycinatopyridinecopper(II), these results are greatly improved in comparison with those obtained by conventional procedures. On the basis of these results, the isolation of glycine with respect to *N*-pyruvylideneglycinatoaquocopper(II) treated under the conditions(pH 9.5) previously used in the base-catalyzed condensation reaction;[1] glycine was thus obtained in a 90.3% yield, as is shown in Table 4. Furthermore, the base-catalyzed condensation reaction of the complex with some aldehydes can not be carried out even in aqueous methanol because of their low solubility; it is thus necessary to examine the application of other solvents to the reaction. The isolation of glycine from the complex in aqueous *N,N*-dimethylformamide was attempted as is shown in the table as a model experiment postulating the case that the condensation reaction was carried out in the solvent system. The yield is also fairly good in this case (95.3%).[6] On the other hand, the treatment of the complex under the same condition for 2 hr was proved to afford glycine in a 68.1% yield, and it was concluded that the condensation reaction can be carried out in aqueous *N,N*-dimethylformamide since the extent of the degradation of glycine in the complex is comparable with that observed in an aqueous solution.[1c]

It can thus be concluded that the isolating procedure involving a simple treatment on a column of Amberlite IR-120B(H form) is facile and useful for the isolation of amino acids from the corresponding copper(II) complexes.

Experimental

Isolation of Glycine from the Aqueous Solution of N-*Pyruvylideneglycinatoaquocopper(II).* A solution of *N*-pyruvylideneglycinatoaquocopper(II)[1c] (2.600 g, 10 mmol) in distilled water (100 ml) was treated on a column(3×9 cm) of Amberlite IR-120B(H form). This column was then washed with distilled water(5000 ml) and eluted with a 0.5 M aqueous ammoniacal solution(2000 ml). The eluate was concentrated *in vacuo* almost to dryness and subsequently triturated with ethanol(10 ml) to give glycine(0.732 g, 97.6%); mp 232°C (decomp.). The IR spectrum of this product was identical with that of the authentic specimen.

Incidentally, the alkaline solution was prepared by the addition of a 1 M aqueous sodium hydroxide solution, and its pH was adjusted by the use of a pH meter.

Isolation of Amino Acids from Bisglycinatocopper(II),[3] N-*Salicylideneglycinatoaquocopper(II),*[4] N-*Pyruwylideneglycinatopyridinecopper(II),*[1c] *and Bisalaninatocopper(II).*[5] The isolations were accomplished under the conditions described in each table in the same way as has been described for the preceeding experiment.

4) A. Nakahara, *ibid.*, **32**, 1195 (1959).

5) Z. E. Gol' braikh, *Zh. Neorg. Khim.*, **1**, 1739 (1956); *Chem. Abstr.*, **51**, 2446c (1957).

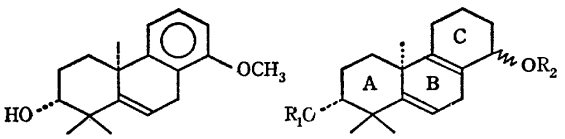
6) When the solution was treated with hydrogen sulfide gas according to the conventional procedure, the resultant fine precipitates of cupric sulfide could not be filtered off; they passed through the filter cell on filtration. The cupric sulfide remained in the isolated glycine in spite of the filtration and treatment on a column of the resin.

The Crystal Structure of *d,l*-1,1,4aα-Trimethyl-2α-hydroxy-8α-acetoxy-1,2,3,4,4a,5,6,7,8,9-decahydrophenanthrene

Akio FURUSAKI, Nobuyuki HAMANAKA, and Takeshi MATSUMOTO
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo
(Received August 24, 1972)

The conformation of *d,l*-1,1,4aα-trimethyl-2α-hydroxy-8α-acetoxy-1,2,3,4,4a,5,6,7,8,9-decahydrophenanthrene has been studied by means of X-ray methods. The crystals are triclinic, with two molecules in a unit cell with the dimensions of $a=11.463$, $b=11.509$, $c=7.430$ Å, $\alpha=84°42'$, $\beta=102°47'$, and $\gamma=115°40'$. The space group is $P\bar{1}$. The intensity data were collected on an automatic four-circle diffractometer with Cu$K\alpha$ radiation. The structure was solved by the symbolic-addition method, and was refined by the block-diagonal-matrix least-squares method with anisotropic temperature factors for all the non-hydrogen atoms. From a difference Fourier map, all the 28 hydrogen atoms were also found. Further least-squares refinement including these hydrogen atoms reduced the R factor to 5.4%. In the present molecule, the cyclohexene ring has the normal half-chair conformation, and does not show the unusual behavior found in the *p*-bromobenzoate of 1,1,4aα-trimethyl-2α-hydroxy-8β-methoxy-1,2,3,4,4a,5,6,7,8,9-decahydrophenanthrene. The 8α-acetoxyl group, like the 8β-methoxyl group in the *p*-bromobenzoate, takes the axial orientation notwithstanding the inversion of the configuration. Such a conformation seems to be the preferred one for a cyclohexene ring which has a methoxyl or an acetoxyl group at the allylic position.

It has recently been found that the Birch reduction of 1,1,4aα-trimethyl-2α-hydroxy-8-acetoxy-1,2,3,4,4a,9-hexahydrophenanthrene, I, affords an unusual product, II, and that, in the acetolysis of II, the methoxyl group is much more easily replaced with an acetoxyl group than those in usual allyl methyl ethers.[1] On the other hand, for the purpose of inquiring into the cause of the high reactivity, the stereostructure of II has been studied by means of the X-ray crystallographic analysis of its *p*-bromobenzoate derivative, III.[2] The study has revealed not only that the methoxyl group is axially bonded to the cyclohexene ring with a considerably flattened half-chair form, but also that the two carbon atoms in the ring vibrate vigorously in a direction almost perpendicular to the mean plane of the ring. In order to examine whether or not these remarkable features are also observed in the acetolysis product, IV, and to establish the configuration of the acetoxyl group, an X-ray analysis of IV has now been carried out.



I

II $R_1=H$, $R_2=CH_3$
III $R_1=BrC_6H_4CO$, $R_2=CH_3$
IV $R_1=H$, $R_2=CH_3CO$

Experimental

Colorless, single crystals of IV (racemate), $C_{19}H_{28}O_3$, mp 146—7°C, were grown in an ether solution. A sample with dimensions of about $0.1\times0.2\times0.4$ mm was cut out of one of the single crystals and used for the X-ray measurement. The crystal data are summarized in Table 1. The cell dimensions were measured by using a single-crystal diffractometer with Cu$K\alpha$ radiation ($\lambda=1.54178$ Å). The space group was assumed to be $P\bar{1}$ at the beginning of the study; this choice was confirmed later by successful refinement. The intensities of reflections with 2θ values up to 140° were collected on an automatic four-circle diffractometer at this University, using Cu$K\alpha$ radiation monochromatized with a LiF crystal. The intensity measurement was made by the use of the ω-2θ scanning technique. The scan rate was about 0.5°(ω)/min, and the background was measured for each reflection for 30—60 s at the beginning and end of each scanning range. The intensity data were corrected for the usual Lorentz and polarization factors, but not for the absorption effect. Out of the structure factors thus obtained, 2769 above $2\sigma(F)$ were selected for the structural study.

TABLE 1. THE CRYSTAL DATA

Crystal system Space group	Triclinic $P\bar{1}$
a	11.463±0.003 Å
b	11.509±0.003
c	7.430±0.003
α	84°42'±3'
β	102°47'±3'
γ	115°40'±3'
Z	2
D_x	1.173 g/cm³

Structure Determination

The structure was elucidated by means of the symbolic addition method[3] on the basis of 585 $|E|$ values above 1.30. After 286 phases had been expressed by three symbols, A, B, and C, the values of the R factor ($R=\Sigma||E_o|-|E_c||/\Sigma|E_o|$) were calculated for all eight possible combinations of the numerical values of the symbols. Since it was certain that the set ($A=B=C=0$) with the lowest R value, 0.171, did not lead to the true structure, an E-Fourier synthesis was carried

out using 558 phases based on the set ($A=B=0$, $C=\pi$) with the second lowest R, 0.199. As was expected, the resulting E-map yielded the locations of all the non-hydrogen atoms. The structure thus obtained was refined by the block-diagonal-matrix least-squares method, first with individual isotropic temperature factors and then with anisotropic thermal parameters for all the atoms. In this way, the value of the discrepancy factor, $R(R=\Sigma||F_o|-|F_c||/\Sigma|F_o|)$, dropped to 11.2%. After the 28 hydrogen atoms were located in a difference Fourier map, the least-squares refinement was further repeated including these hydrogen atoms with isotropic temperature factors. In this refinement, the following weighting scheme was used:

$$W = 1/\{\sigma(F_o)^2 \exp(AX^2+BY^2+CXY+DX+EY)\},$$

where $X=|F_o|$, $Y=\sin\theta/\lambda$. The $\sigma(F_o)$ values were calculated from the counting statistics. The intensity data were grouped with constant intervals along two coordinates, $|F_o|$ and $\sin\theta/\lambda$. The coefficients, A, B, C, D, and E, were determined by the least-squares fit so as to give as equal values of $<W\Delta|F|^2>$ for all the groups as possible. The final R factor was 5.4%. The atomic parameters thus obtained are listed in Table 2.

The calculations in the present study were carried out on a FACOM 230—60 computer at the Computer Center of Hokkaido University using our own programs. The atomic scattering factors were taken from the International Tables for X-ray Crystallography (1962), Vol. III.

Tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan. (Document No. 7309).

Results and Discussion

The molecular framework of IV thus obtained is shown in Fig. 1. First of all, it is found that the acetoxyl group has the *cis* relation with the angular methyl,

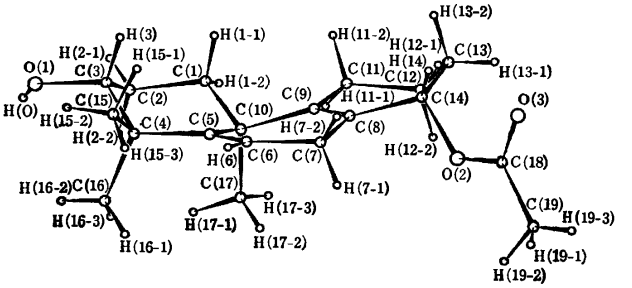

Fig. 1. The molecular framework of IV and the numbering system of the atoms.

$C(17)H_3$; this shows that the acetolysis of II proceeds with an inversion of the configuration at the C(14) atom. Thus, Compound IV can be fully expressed by the name: *d,l*-1,1,4aα-trimethyl-2α-hydroxy-8α-acetoxy-1,2,3,4,4a,5,6,7,8,9-decahydrophenanthrene.

The torsion angles for the tricyclic system are given in Fig. 2. The A and B rings take, respectively, distorted chair and boat forms very similar to those found in III.[2] On the other hand, the C ring has the ordinary half-chair form, which is nearly as puckered

as those in many other cyclohexene derivatives. The acetoxyl group, like the methoxyl group in III, is axially oriented by the flipping of the C ring, although the configuration at the C(14) atom is inverted. The bond lengths and angles calculated with the final coordinates are listed in Tables 3 and 4 respectively. These values are all reasonable, considering their estimated standard deviations. Table 5 gives the intramolecular H···H distances smaller than 2.40 Å.

It may be said that the A ring in the present molecule is still less puckered than that in III, because the average torsion angle for the former, 50.0°, is about 2.2° smaller than that for the latter. Out of the corresponding torsion angles in these two rings, those around the C(3)-C(4), C(4)-C(5), and C(5)-C(10) bonds especially differ by about 4° to 6°. These differences may be attributable partly to the replacement of the benzoyl group with the hydrogen atom, but seem to arise mainly from the flipping of the C ring. Considering the fact that, in IV, the hydrogen atoms attached to the C(1) and C(11) atoms keep distances of at least 2.23 Å without any great distortion of the C ring, the flipping of the C ring would remarkably lessen the steric repulsion between the A and C rings. Consequently, the two axial methyl groups, C(16)H_3 and C(17)H_3, would be allowed to become somewhat more distant from each other by the conformational change in the A and B rings. In fact, as may be seen in Fig. 3, the deviations of the C(16)H_3 and C(17)H_3 groups from the staggered conformation, 6° and 8°, are somewhat smaller than the corresponding values for III, 13° and 10° respectively, although the H(16—3) and H(17—1) atoms keep a distance of about 2.09 Å, which is nearly equal to that in III, 2.05 Å. On the contrary, the C(15)H_3 group is forced to rotate by about 8° from the staggered arrangement, so that the H(15-3) atom may be separated at a distance of about 2.14 Å from the H(6) atom. This rotation angle is about 5° larger than the corresponding angle for III. The O(1)-H(O) bond takes approximately the eclipsed conformation with the C(2)-C(3) bond, the deviation being about 14°. This conformation seems to be caused by the hydrogen-bond formation of the hydroxyl group with the acetyl oxygen atom of another molecule, O(3′). Because of the unstable eclipsed conformation of the hydroxyl group, the angle between the O(1)-H(O) and O(1)···O(3′) directions is reduced to about 12°. It is interesting to notice that the alternate valence angles in the A ring are significantly larger than the usual tetrahedral angle. This may show a way in which a cyclohexene ring is distorted by forming an exocyclic double bond.

The conformation of the B ring is almost symmetrical with respect to the plane which approximately bisects the C(6)-C(7)-C(8) and C(5)-C(10)-C(9) angles. The two nonconjugated double bonds in the ring, C(5)=C(6) and C(8)=C(9), are both twisted to some extent. The deviations of the atoms from the least-squares best planes through the C(4), C(5), C(6), C(7), and C(10) atoms and through the C(7), C(8), C(9), C(10), C(11), and C(14) atoms are given in Table 6. The two planes make a dihedral angle of about 20°; this is about 5° larger than the corresponding angle for III.

In the present molecule, the C ring does not show the unusual behavior found in III.[2] The thermal motions of the C(12) and C(13) atoms as well as the bond distances and angles related to these atoms are normal,as

(4) I···VIII (VIII···I)			
C(17)···C(17)	3.715(3)		

I: $x/a, y/b, z/c$ (given in Table 2). II: $1+x/a, y/b, z/c$. III: $-1+x/a, y/b, z/c$. IV: $x/a, y/b, 1+z/c$. V: $x/a, y/b, -1+z/c$. VI: $1+x/a, y/b, 1+z/c$. VII: $-1+x/a, y/b, -1+z/c$. VIII: $1-x/a, -y/b, -z/c$. IX: $1-x/a, -y/b, 1-z/c$. X: $2-x/a, 1-y/b, -z/c$. XI: $2-x/a, -y/b, 1-z/c$. XII: $2-x/a, 1-y/b, 1-z/c$.

compared with those in III. The C ring has a somewhat unsymmetrical half-chair form, the displacements of the C(12) and C(13) atoms from the mean plane through the C(8), C(9), C(11), and C(14) atoms being 0.51 and 0.22 Å respectively. The sum of these deviations, 0.73 Å, is in good agreement with that in cyclohexene, 0.7346 Å.[4] The distance between the H(1-2) and H(11-1) atoms is about 2.23 Å; this is nearly equal to the H(1-2)···H(11-2) distance in III, 2.17 Å. As has already been mentioned, the acetoxyl group in the present molecule, like the methoxyl group in III, takes the axial orientation. The fact that, independently of the configuration at the C(14) atom, the C ring has a half-chair conformation with these axially-oriented groups implies that such a conformation may be the preferred one of a cyclohexene ring which has a methoxyl or an acetoxyl group at the allylic position. It is also of interest that the internal valence angles of the sp^3 type at the C(11) and C(14) atoms, 113.1° and 114.8°, lie between those of the sp^2 type at the C(9) and C(8) atoms, 120.8° and 123.0°, and those of the sp^3 type at the C(12) and C(13) atoms, 109.5° and 111.0°, respectively. This may show a typical distribution of strains in a cyclohexene ring. The acetyl group is located at such a position that the torsion angles, O(3)-C(18)-O(2)-C(14) and C(18)-O(2)-C(14)-H(14), are about −3.4° and −15° respectively. Consequently, the O(3) atom is very close to the H(14) atom; the distance between them is only about 2.30 Å. This close contact suggests that the negatively-charged carbonyl oxygen atom and the more or less positively-charged hydrogen atom may exert quite strong attractive forces on each other.

The molecular arrangement viewed along the *c* axis is shown in Fig. 4. The short intermolecular distances are also given in Table 7. The molecules are connected by an intermolecular hydrogen bond, O(1)···O(3′), at a distance of 2.881 Å, forming a linear chain parallel to [101]. These molecular chains are further held together mainly by the usual van der Waals interactions.

Studies of Ionic Association. I. Alkali Halide and Sodium Nitrate in the Butyl Alcohol-Water System

Norio Yui, Yōichi Kurokawa, and Masami Nakayama

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai

(Received October 28, 1971)

It has previously been reported that the dissociation of alkali halide and sodium nitrate between butanol and water phases could be explained reasonably if they were dissociated into free ions in each phase. The present investigation was undertaken to see to what extent dissociation occurs in the butanol phase. Conductometric measurements were carried out on solutions of LiBr, NaBr, NaCl, KCl, RbCl, and $NaNO_3$ in the *n*-butanol–water system and on the solution of NaCl in the *t*-butyl alcohol–water system at 20°C or 25°C. These data were analyzed by using the Fuoss-Onsager equation for associated electrolytes, and the association constants were calculated to be as follows: NaBr 250, NaCl 600, KCl 610, RbCl 1850, $NaNO_3$ 180, and NaI 220 in the *n*-butanol–water (11 wt%) system at 25°C (except NaBr), and NaCl; 590, 160, and 75 for water wt% 30, 45, and 60 in the *t*-butyl alcohol–water system at 25°C, respectively. The association constants of NaCl in the *t*-butyl alcohol–water system were explained in terms of the simple electrostatic theory. The results were discussed briefly in comparison with conductance data reported in the literature.

The solvent extraction of various species has been widely investigated and reviewed by Marcus and by Diamond and Tuck.[1,2] However, the investigations have been restricted to systems involving a distribution of the species between aqueous and organic solvents immiscible with water. These distributions have, in general, been interpreted in terms of the association of ions in organic solvents. We reported previously that the distribution of alkali halide and sodium nitrate between *n*-butanol and water phases could be explained most reasonably if they were treated as dissociating into free ions.[3] The present investigation was undertaken to see to what extent dissociation occurs in the butanol–water system. Many authors have studied the conductometric behavior of strong electrolytes in binary mixtures of solvents in order to establish the effect of ion-solvent interaction.[4] However, there is insufficient information on the behavior of electrolytes in the butanol–water system. Butanol, which is an associated solvent with a low vapor pressure and with a moderate value of the dielectric constant at 25°C, offers an interesting solvent for the study of ion-ion and ion-solvent interactions.

Experimental

Materials. The conductivity water used in the present study was prepared by the passage of distilled water through mixed-bed ion exchange resin. The specific conductance of this water was below 5×10^{-7} ohm^{-1} cm^{-1}. We treated *n*-butanol with a sodium bisulfite solution, then we boiled it for 4 hours with a 10% solution of NaOH, washed the separated butanol with water, and neutralized it to remove any NaOH. The butanol was boiled with fresh lime for 3 hr. The butanol was decanted from the lime and refluxed with magnesium turning. Then, we collected the middle of a distillation under an atmospheric pressure.[5] The salts and t-butanol were of a reagent grade and were used without further purification. The salts were dried at 110°C before use.

Procedure. The electric equipment, conductance cell (flask type), and general techniques were essentially the same as had been previously described[6] except for the conductance bridge, which was of a YOKOGAWA BV-Z-103B type. A quartz flask cell with lightly platinized electrodes was used. The cell constant was determined by means of an aqueous KCl solution to be 0.1893 cm^{-1}. The solvents and solutions were prepared by weight. All the measurements were carried out in a thermostat of 25±0.01°C or 20±0.01°C. The conductance of the solution was determined by subtracting the conductance of the solvent. Since the specific conductance of solvent was below 10^{-6} ohm^{-1}·cm^{-1} at 25°C, no solvent correction was necessary even for the most dilute solution. Relative viscosity measurements were made by using an Ostwald viscometer immersed in a thermostat of 25±0.01°C or 20±0.01°C.

Results and Discussion

Alkali Halide in n-*Butanol–Water System.* The properties of *n*-butanol–water solvents are listed in Table 1. The conductances were determined in the range of salt concentration of 0.5—10×10^{-3} mol/l. The salts used in this investigation were LiBr, NaCl, KCl, $NaNO_3$, and NaI. The distributions of these salts have all previously been studied except for $NaNO_3$. The solvent compositions are in the range of the upper phase (rich in *n*-butanol) compositions that correspond to the composition of the separation of the two phases. Because of solubility limitations, many data were not available in the precision required.[7] The addition of salt above the

extent of solubility brought about the separation of the solution into two phases. The values of conductance Λ (ohm^{-1} cm^2), are presented in Table 2. The measurements temperatures were 20 °C for LiBr and NaBr, and 25 °C for the others. Λ *vs.*$\sqrt{c}$ plots for each salt are shown in Fig. 1. The curves are similar in form and show the same behavior as weak electrolytes. It is considered from these results that the salts are considerably associated.

NaCl in t-Butyl Alchohol–Water System. The other butanols have dielectric constants above 18, while *t*-butyl alcohol has a dielectric constant of 11.8 and yet is the only butanol completely miscible with water at 25°C.[8] Appropriate conductance measurements provides a useful indication of ion-solvent interaction, but conductance studies over the range of solvent composition have not been previously published for the *t*-butyl alcohol–water system at 25 °C. The properties of the solvents are summarized in Table 3.

Table 3. Properties of *t*-butyl alcohol–water mixture at 25°C

Water content (wt%)	η (poise)	ε	Density (g/cm^3)
15	0.04569	14.3	0.8154
30	0.04845	21.4	0.8519
45	0.05105	31.5	0.8869
60	0.03757	43.9	0.9023
75	0.02568	57.1	0.9567
100	0.008937	78.5	0.9971

The viscosity reaches its maximum in the vicinity of a water content of 40%, as in the cases of water–methanol, –ethanol, and –propanol. The values of Λ are represented in Table 4 and show a sharp increase in the conductance with an increase in water content. As shown in Fig. 2, the values of Λ change smoothly with the increase in water content, despite the maximum in viscosity. Obviously, ion mobility is not predominantly controlled by the bulk viscosity.

Calculation. In order to ascertain whether any variation in the conductance could be due to ion-pair formation, the limiting equivalent conductance and the ion-pair formation constants, K_A were calculated by the Fuoss and Fuoss-Onsager methods. The data were initially treated by the method of Fuoss.[9]

$$F(z)/\Lambda = 1/\Lambda^0 + (K_A \cdot c\Lambda f_\pm^2)/(F(z)/\Lambda^{02}) \quad (1)$$

where $F(z)$ is the Fuoss function and where $f_\pm^2$ is calculated from the Debye-Hückel theory. The initial value of Λ° was obtained by the extrapolation of Λ *vs.* $\sqrt{c}$ plot to an infinite dilution. After we had obtained the apparent Λ^0 and value of K_A, the data were analyzed by the Fuoss-Onsager extended equation for associated electrolytes in this form.[10]

$$\Lambda = \Lambda^0 - S(c\gamma)^{1/2} - Ec\gamma \log c\gamma + Jc\gamma - K_A c\gamma \Lambda f_\pm^2 \quad (2)$$

Here, γ is the degree of dissociation, S is the Onsager limiting slope, and both E and J are the parameters as defined in the Fuoss-Onsager equation. In computing the Λ' defined by the equation:

$$\Lambda' = \Lambda + S(c\gamma)^{1/2} - Ec\gamma \log c\gamma \quad (3)$$

the following variables are defined thus;

$$\Delta\Lambda = \Lambda' - \Lambda^0 \quad (4)$$

$$y = \Delta\Lambda/c\gamma \quad (5)$$

$$x = f_\pm^2 \Lambda \quad (6)$$

Then, Eq. 2 is transformed into Eq. 7;

$$y = J - K_A x \quad (7)$$

If Λ° was known, y could be calculated, then a plot of y against x should be linear and K_A could be evaluated.[10] The association constans, K_A, obtained by the above two methods are given in Table 5. The values of K_A calculated by the Fuoss method are approximately twice as large as those calculated by the Fuoss-Onsager method.[11] As can be seen in Table 5, K_A increases in the order of NaCl<KCl<RbCl with an increase in the size of the cation, and increases in the order of NaI<NaBr<NaCl with a decrease in the size of the anion. That is, RbCl, in spite of its greater size, is more associated than the others. This means that the cations are hydrated, while halide ions are not. This is in agreement with the order found by Kay and Fuoss for the alkali halide in various hydrogen-bonded solutions.[12,13] That is, the association increases in this order; Li<Na<K<Rb<Cs. Fuoss and his co-workers have found the same order for alkali halides in a dioxane–water system, and Smith has reported that KNO_3 is more associated than $LiNO_3$ in pure ethanol.[14] However, Evans has reported that tetraethyl ammonium salts in alcohol do not exhibit the simple dependence upon the order of association predicted by the electrostatic theory, that is, K_A increases with an increase in the anion size.[4]

TABLE 5. ASSOCIATION CONSTANT OF ALKALI HALIDE IN *n*-BUTANOL–WATER SYSTEM

	K_A		Λ^0	Temp. (°C)
	Fuoss	Fuoss-Onsager		
$NaNO_3$	350	180	20.7	25
NaI	490	220	25.5	25
NaCl	1170	600	23.0	25
KCl	1140	610	24.0	25
RbCl	4060	1850	29.0	25
NaBr(1)		250	25.57	20
NaBr(2)		280	20.83	25

(1) and (2) in NaBr indicate 15 and 9 water content (wt%), respectively.

The coulombic theory predicts that a plot of log K_A against $1/\varepsilon$ for any given salt will be a straight line with a slope proportional to $1/a_K$.[10] Such a plot

$$K_A = K_A^0 \exp(e^2/a_K \cdot \varepsilon \cdot kT) \quad (8)$$

for NaCl in the *t*-butanol–water system is shown in Fig. 3. An approximately straight line is obtained, and the value of a_K, 5.6 Å is calculated from the slope of the line. The point for NaCl in the *n*-butanol–water(11 wt%) system seems to fall on the line. Therefore, it seems that the solvent structure

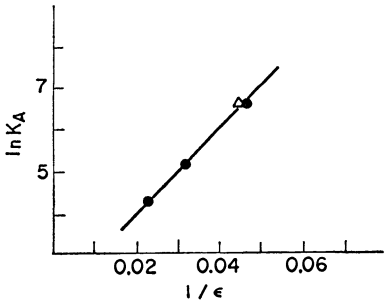

Fig. 3. Logarithm of association constant *vs.* reciprocal of dielectric constant for NaCl in *t*-butyl alcohol–water system at 25°C. △: NaCl in *n*-butanol–water (11 wt%)

plays a negligible role in the association process. Water molecules in the primary solvation shell are not easily replaced by butanol molecules. This hydrated ion is further solvated either by more water molecules or by the butanol molecules through hydrogen-bonding, thus forming the secondary solvation shell.

In conclusion, we can say that the alkali halide is partly associated in the *n*-butanol phase which is equilibrated with the aqueous phase at 20°C or 25°C, and that the Fuoss and Fuoss-Onsager equation describe the behavior of alkali halide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1030—1035 (1973)

Excitation Transfer in the Radiolysis of Solid Alkane Mixtures at 77 K

Tetsuo MIYAZAKI, Terunobu WAKAYAMA, Mitsuharu FUKAYA, Yoshiyuki SAITAKE, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received March 10, 1972)

The radiolysis of isobutane–propane (less than 5 mol %) or neopentane–alkane (5 mol%) mixtures has been studied at 77 K by means of ESR spectroscopy. When these alkane mixtures are γ-irradiated, the solute radicals are mainly formed by energy transfer from γ-irradiated isobutane or neopentane to the solutes. It is discussed whether the energy transfer is due to a proton transfer, a positive-charge transfer, or an excitation transfer, and it is concluded, for the following reasons, that the energy tranfser is probably due to the excitation transfer and that the excitation transfer may occur *via* highly-excited states of isobutane or neopentane; (i) The ionization potentials and the energies of the first singlet-excited states of the some additives are higher than those of isobutane or neopentane. (ii) The decrease in the solvent radical yields and the increase in the solute radical yields upon the addition of the solutes to the isobutane or neopentane amount approximately to 2—2.5 G-units. (iii) The yields of hydrogen increase sharply upon the addition of cyclopentane in the radiolysis of solid neopentane. (iv) It was concluded in previous studies that the formation of the solvent radical in the radiolysis of solid isobutane is due to the fragmentation of excited isobutane produced directly by γ-irradiation.

It was reported in previous studies that, while the fragmentation of excited ions plays an important role in the radiolysis of isobutane in the gas[1] and liquid[2] phases, the fragmentation of excited molecules is an important process in the solid phase at 77 K.[3] It was found that the physical conditions of the matrix appreciably affects the radiolysis in the solid phase; this is the case for isobutane,[4] phenylacetate,[5] and succinic

acid.[6]

Then, we have indicated that two important problems must be solved in order to elucidate the cause of the peculiar phenomena in the radiolysis of solid hydrocarbons. One is the problem of the extent to which the formation of an exciton plays an important role; the other is how the state of the solid matrix, such as the phase and the defects, affects the fate of the exciton.

It was previously concluded that, in the radiolysis of solid isobutane at 77 K,[3] C–H bond rupture occurs by way of the fragmentation of an excited isobutane molecule produced directly by γ-irradiation. This conclusion is based on the following observation:

i) The yields of the C_4H_9 radical in the radiolysis of polycrystalline isobutane are not changed by the presence of conventional electron scavengers, such as phenyl iodide, ethyl iodide, nitrous oxide, and sulfur hexafluoride.

ii) The yields of the C_4H_9 radical do not increase upon the photobleaching of toluene anions in the γ-irradiated isobutane–toluene (5 mol/100 mol of i-C_4H_{10}) mixture in the polycrystalline state.

iii) The yields of the C_4H_9 radical do not increase upon the photo-bleaching of electron trapped in the γ-irradiated isobutane–methylcyclohexane (4 mol/100 mol of i-C_4H_{10}) mixture in the glassy state or upon the photobleaching of benzene anions in the γ-irradiated isobutane–methylcyclohexane (4 mol/100 mol of i-C_4H_{10})–benzene (5 mol/100 mol of i-C_4H_{10}) mixture in the glassy state.

iv) The yields of H_2 in the radiolysis of glassy isobutane are not changed at all by the presence of conventional electron scavengers, such as nitrous oxide and sulfur hexafluoride.

Since the yields of the C_4H_9 radical and H_2 decrease upon the addition of CCl_4 or toluene, it was suggested that the migration of an exciton to the solutes may be an important process in the radiolysis of solid isobutane. The role of the exciton was also studied by the measurement of the luminescence from eleven kinds of alkanes containing toluene (2 mol %) during γ-irradiation at 77 K.[7]

In this paper we will report clearer results suggesting the excitation transfer in the radiolysis of isobutane and neopentane in the solid phase.

Experimental

The ethane, propane, and isobutane were supplied by the Takachiho Shoji Co. and were of a high purity; the isobutane was more than 99.7% pure. The cyclopentane, methylcyclopentane, *n*-hexane, and cyclohexane supplied by the Tokyo Kagaku Seiki Co. were more than 99.0% pure. They were passed through a 30-cm column packed with activated alumina and were used after distillation on a vacuum line. The neopentane was more than 99.9% pure.

Samples were sealed into a quartz cell and irradiated at 77 K with γ-rays from Co-60 at a dose rate of 7.6×10^5 rad/hr. The total doses were 3.8×10^5 rad for the ESR measurements and 1.0×10^7 rad for the product analysis. The ESR spectra of irradiated samples were measured at 77 K on a JES-3BX ESR spectrometer. H_2 and CH_4 were analyzed by a gas burette connected to a Toepler pump and a copper oxide furnace kept at 240°C.

Results

Figure 1a shows the ESR spectrum of γ-irradiated pure isobutane, which is assigned to an isobutyl radical. Figure 1b shows the ESR spectrum of γ-irradiated isobutane containing 4.8 mol% propane. It may be seen from Figures 1a and 1b that there is a drastic difference in the spectra. The spectra in Fig. 1b represent those assigned to two species; the main spectrum is ascribed to the i-C_3H_7 radical.

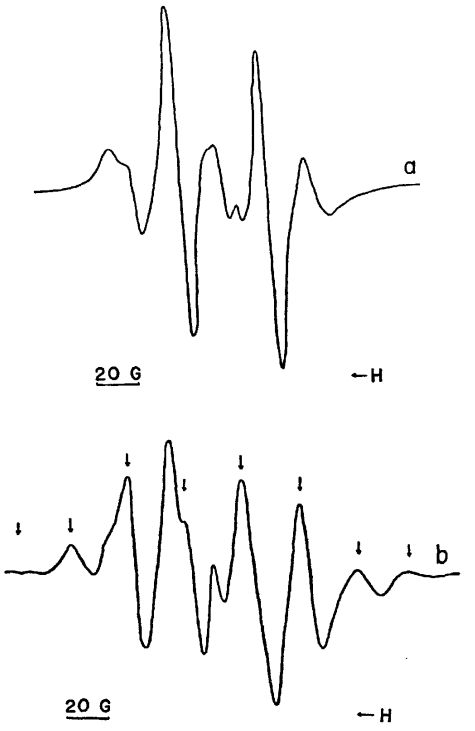

Fig. 1. a) ESR spectrum of γ-irradiated isobutane at 77 K. b) ESR spectrum of γ-irradiated isobutane-propane(4.8 mol%) at 77 K. The arrows indicate signals of C_3H_7 radical.

When pure neopentane is γ-irradiated at 77 K, t-C_4H_9 and *neo*-C_5H_{11} radicals are formed; their ESR spectra are shown in Fig. 2a.[8] The spectrum of eight narrow lines is ascribed to the t-C_4H_9 radical. The spectrum of three broad lines is ascribed to the *neo*-C_5H_{11} radical. When neopentane containing a small amount of alkane is γ-irradiated at 77 K, a solute radical and a neopentyl radical are formed, while the t-C_4H_9 radical disappears completely. The ESR spectra of γ-irradiated neopentane–ethane, propane,

methylcyclopentane, cyclohexane, and cyclopentane systems are shown in Figs. 2b, c, d, e, and f respectively. When neopentane containing a small amount of isobutane, 2,3-dimethylbutane, or *n*-hexane is γ-irradiated, solute radicals are mainly formed also. The structures and splittings of the solute radicals formed in the radiolysis of neopentane-alkane mixtures are shown in Table 1. The splittings of the radicals formed by other methods are also shown there.

The effect of propane on the formation of radicals in the radiolysis of solid isobutane is shown in Fig. 3. The i-C_4H_9 radical decreases sharply upon the addition

○: H_2 ●: CH_4

of propane, while the C_3H_7 radical increases complementally. The sum of $G(C_3H_7)$ and $G(i\text{-}C_4H_9)$ decreases slightly upon the addition of 1 mol% propane. It is uncertain whether this result is due to experimental errors or to some characteristic phenomena upon the addition of C_3H_8.

The yields of H_2 and CH_4 in the radiolysis of *neo*-C_5H_{12}–*cyclo*-C_5H_{10} mixtures in the solid are shown in Fig. 4.

Discussion

The C_4H_9 radical decreases sharply upon the addition of propane in the radiolysis of isobutane, while the C_3H_7 radical increases complementally (Fig. 1b and Fig. 3). Since the electron fraction of propane is smaller than 0.04 in the experimental concentration, the results represent some type of energy transfer from γ-irradiated isobutane to propane. Since the electron fraction of the solutes is about 0.05 in the radiolysis of neopentane–solute mixtures, the formation of solute radicals also represents the energy transfer from γ-irradiated neopentane to the solute (Fig. 2). We will discuss here whether the energy transfer is due to a proton transfer, a positive-charge transfer, or an excitation transfer.

Proton-transfer Reaction in γ-irradiated Alkane Mixtures in the Solid Phase. Willard *et al.* proposed that the solvent radical may be formed by the proton-transfer reaction in the radiolysis of 3-methylpentane in the solid phase.[9] According to this mechanism, the formation of the solute radical in the radiolysis of neopentane (or isobutane) may be represented as follows:

$$\textit{neo}\text{-}C_5H_{12} \rightsquigarrow C_5H_{12}^+ + e^- \quad (1)$$

$$C_5H_{12}^+ + C_5H_{12} \longrightarrow C_5H_{11}\cdot + C_5H_{13}^+ \quad (2)$$

$$C_5H_{12}^+ + RH \longrightarrow R\cdot + C_5H_{13}^+ \quad (3)$$

where RH represents an alkane as a solute. These mechanisms, however, seem unlikely because for the following three reasons: i) Though the proton-transfer reaction of polar molecules has been found in the mass spectrometer, the reaction cannot be detected in any alkane systems except for methane and ethane. The reaction seems to become more difficult as the molecular weight of alkane increases.[10] Recently it has been reported, from a study of the high-pressure mass spectrometry of propane, that the protonated alkane ion ($C_3H_9^+$) was not detected at all, but only a clustered parent ion ($(C_3H_8)_2^+$).[11] The formation of a clustered parent ion was also reported in the high-pressure mass spectrometry of butane.[12]

ii) Only the fragmentation of the parent ion ($C_4H_{10}^+$ or $C_5H_{12}^+$) has been observed in the radiolysis of isobutane and neopentane in the liquid phase.[2,13,14] The existence of the parent ion (*cyclo*-$C_5H_{10}^+$ or *cyclo*-$C_6H_{12}^+$) has been also shown in the radiolysis of cyclopentane or cyclohexane in the liquid phase.[15]

Since the proton-transfer reaction between *neo*-$C_5H_{12}^+$ and *neo*-C_5H_{12} (Reaction (2)) does not occur in the liquid phase, Reaction (2) may be endothermic; in it the heat of reaction is taken as ΔH_2 kcal/mol. Therefore, the heat of hydrogen-transfer reaction between $C_5H_{12}^+$ and C_2H_6 (Reaction (4)) may be expected to be $\Delta H_2+3.7$ kcal/mol:

$$\textit{neo}\text{-}C_5H_{12}^+ + C_2H_6 \longrightarrow C_5H_{13}^+ + C_2H_5\cdot \quad (4)$$

Therefore, Reaction (4) is also endothermic and its occurrence may be more difficult than that of Reaction (2).

The same conclusion can be obtained also from the results in the radiolysis of an ethane–neopentane mixture in the liquid phase.[6] It has been shown that the proton-transfer reaction between $C_2H_6^+$ and *neo*-C_5H_{12} (Reaction (5)) does not occur:

$$C_2H_6^+ + \textit{neo}\text{-}C_5H_{12} \longrightarrow C_2H_5 + C_5H_{13}^+ \quad (5)$$

Reaction (5) is expected to be an endothermic reaction and the heat of its reaction is taken to be ΔH_5 kcal/mol. The heat of Reaction (4) may, then, be expected to be ΔH_5+30 kcal/mol. Therefore, the occurrence of Reaction (4) may be more difficult than that of Reaction (5).[17,18]

iii) When neopentane containing cyclopentane

11) L. W. Sieck, S. Searles, and P. Ausloos, *J. Chem. Phys.*, **54**, 91 (1971).
12) T. A. Milne, J. E. Beachey, and F. T. Greene, Annual Conference on Mass Spectrometry and Applied Topics, 17th ASTM Committee, E-14, Dallas Tex., U. S. A., May, 1969.
13) K. Tanno, T. Miyazaki, K. Shinsaka, and S. Shida, *J. Phys. Chem.*, **71**, 4290 (1967).
14) G. J. Collin and P. Ausloos, *J. Amer. Chem. Soc.*, **93**, 1336 (1971).
15) P. Ausloos, A. A. Scala, and S. G. Lias, *ibid.*, **89**, 3677 (1967).
16) J. A. Stone and G. Matsushita, *Can. J. Chem.*, **49**, 3287 (1971).
17) Neopentane has a solid phase transition at 140 K (J. G. Aston and G. H. Messerly, *J. Amer. Chem. Soc.*, **58**, 2354 (1936); E. O. Stejskal, D. E. Woessner, T. C. Farrar, and H. S. Gutowsky, *J. Chem. Phys.*, **31**, 55 (1959)), but it has no phase transition near 77 K. The reaction (4) is not facilitated at 77 K by the phase transition.

(5 mol%) is γ-irradiated at 77 K, the cyclopentyl radical is mainly formed (Fig. 2f). If the formation of the cyclopentyl radical is due to Reaction (3), the amounts of the $C_5H_{13}^+$ ion do not change upon the addition of cyclopentane. $C_5H_{13}^+$ ion may produce a H atom or a H_2 molecule upon neutralization with an electron:

$$C_5H_{13}^+ + e^- \longrightarrow C_5H_{12} + H\cdot \quad (6)$$

$$\searrow\ C_5H_{11}\cdot + H_2 \quad (7)$$

$$H\cdot + H\cdot \longrightarrow H_2 \quad (8)$$

Therefore, it may be expected from Reactions (1)—(3) and (6)—(8) that the yields of hydrogen do not change upon the addition of cyclopentane if the proton-transfer reaction is responsible for the formation of the cyclopentyl radical. The experimental results, however, show that the yields of hydrogen increase sharply upon the addition of cyclopentane in the radiolysis of solid neopentane (Fig. 4). This result suggests that the C–H bond rupture of cyclopentane is accelerated by the energy transfer from γ-irradiated neopentane to cyclopentane.

Positive-charge Transfer in the γ-irradiated Alkane Mixtures in the Solid Phase. Isobutane Containing Propane: Though a positive-charge transfer is generally proposed in the γ-irradiated alkane mixtures in the liquid phase,[16,19] such a mechanism (Reactions (7)—(10)) cannot be adopted here for the following two reasons:

$$C_4H_{10} \rightsquigarrow C_4H_{10}^+ + e^- \quad (7)$$

$$C_4H_{10}^+ + e^- \longrightarrow C_4H_9\cdot + H\cdot \quad (8)$$

$$C_4H_{10}^+ + C_3H_8 \longrightarrow C_4H_{10} + C_3H_8^+ \quad (9)$$

$$C_3H_8^+ + e^- \longrightarrow C_3H_7\cdot + H\cdot \quad (10)$$

i) As has been described in the Introduction, the C_4H_9 radical is not formed by the neutralization reaction between the butane cation and the electron.

ii) Though the gas-phase ionization potentials may be different from the condensed-phase ionization potentials, the charge-transfer reaction in the liquid alkane mixtures can be discussed by using the gas-phase ionization potentials.[16,19] The ionization potential of an alkane ion is always higher than that of a charge acceptor. Therefore, the relative magnitude of the gas-phase ionization potentials of alkanes may hold even in the condensed phase. Since the ionization potential of isobutane is lower than that of propane (Table 2), it is impossible for a charge transfer from the isobutane cation in a ground state to propane to occur.

Table 2. Energies of first electronic excited state and ionization potentials of alkanes

	Energies of first electronic excited state,[a] eV	Ionization potentials,[b] eV
C_2H_6	9.3	11.65
C_3H_8	9.0	11.07

b) K. Watanabe, T. Nakayama, and J. Mottl, *J. Quant. Spectrosc. Radiat. Transfer*, **2**, 369 (1962).

If the energy transfer in the γ-irradiated i-C_4H_{10}–C_3H_8 mixture is due to a charge-transfer reaction, we will have to introduce a mechanism of a charge-transfer *via* the excited state of the solvent cation, as has been suggested by Hamill *et al.*[20] Since our information about the excited cation produced by γ-irradiation is very scanty at present, the energy transfer *via* the excited cation and its chemical reaction cannot be discussed in detail. There are, however, some drawbacks to this mechanism. First, the yields of the excited alkane ion may amount only to 20% of the total alkane ions.[21,22] The G-value of the excited ion is likely to be 0.8 if we take the G-value for ion-pair production as the gas-phase value of about 4. This value is much smaller than the decrement ($G\sim2.0$) in the i-C_4H_9 radical or the increment ($G\sim1.9$) in the C_3H_7 radical upon the addition of propane in the radiolysis isobutane (Table 3). Second, a migration of the excited isobutane ion is considered to be rather difficult, for the toluene cation was not observed at 77 K in the γ-irradiated isobutane containing toluene.[3b] Third, supposing the excited isobutane ion is formed, it may decompose in the period of one vibration because of the fact that the C–C bond of the isobutane ion is very weak.[2,21] It is highly unlikely, judging from the mass spectrum of isobutane, that the i-C_4H_9 radical is formed by the fragmentation of an excited isobutane ion:

$$i\text{-}C_4H_{10}{}^{+*} \longrightarrow i\text{-}C_4H_9\cdot + H^+ \quad (11)$$

Neopentane Containing Alkanes: When neopentane containing ethane, propane, cyclopentane, or methylcyclopentane is γ-irradiated at 77 K, ethyl, propyl, cyclopentyl, or methylcyclopentyl radicals are mainly formed respectively (Fig. 2). Since these additives have higher ionization potentials than that of neopentane (Table 2), it is not possible that a charge transfer from the neopentane cation in a ground state to the additive occurs. The yields of the solute radicals amount to approximately 2.5 G-units (Table 3),

18) The possibility of Reaction (4) was diminished by the recent experiments (M. Ito, T. Miyazaki, Y. Saitake, and Z. Kuri, Japanese Conferrence on Radiation Chemistry, Osaka, Japan, Oct. 1972). The addition of CCl_4, which is an efficient electron scavenger and an excitation quencher, to the *neo*-C_5H_{12}–C_2H_6 mixture suppresses the formation of C_2H_5 radical in the solid radiolysis. If the formation of C_2H_5 radical is due to the Reaction (4), the yield of C_2H_5 radical should not decrease upon the addition of CCl_4.

Table 3. Yields of radicals in the γ-irradiated alkane at 77 K[a)]

γ-Irradiated system	G(solvent radical)	G(solute radical)
i-C_4H_{10}	2.5	0
i-C_4H_{10}-C_3H_8 (4.8%)	0.5	1.9
neo-C_5H_{12}	2.3	0
neo-C_5H_{12}-C_2H_6 (4.8%)	0.9	0.9
neo-C_5H_{12}-C_3H_8 (4.9%)	0.4	1.3
neo-C_5H_{12}-*cyclo*-C_5H_{10} (4.7%)	0.9	2.0
neo-C_5H_{12}-C_6H_{12}[b)] (4.9%)	0.3	2.3
neo-C_5H_{12}-*cyclo*-C_6H_{12} (6.5%)	0.2	2.6
neo-C_5H_{12}-*n*-C_6H_{14} (4.8%)	0.5	2.4

a) G value of the radicals were determined by assuming G(radical) = 1.6 for the radicals produced in the γ-irradiated 3-methylpentane at 77 K. (M. Shirom and J. E. Willard, *J. Phys. Chem.*, **72**, 1702 (1963)) The errors of radical yields are about 20%. When neopentane–alkane mixtures are irradiated, neopentyl and solute radicals are formed. A standard ESR spectrum of neopentyl radical was obtained by the γ-irradiation of neopentane containing N_2O. (*cf.* J. Lin and F. Williams, *J. Phys. Chem.*, **72**, 3707 (1968)). The yields of neopentyl radical were obtained from the height of central peak in the ESR spectrum and the standard spectrum of neopentyl radical. The yields of solute radical was obtained by subtracting the yields of neopentyl radical from the total radical yields.

b) C_6H_{12} represents methylcyclopentane.

which may be much higher than the yields of the mobile excited cations. Even if the excited neopentane cation is formed, it may decompose in the period of one vibration[13,14)] before transferring its charge to the additive.

Excitation-transfer Reaction in γ-irradiated Alkane Mixtures in the Solid Phase. It seems from the above discussions that the energy transfer from γ-irradiated isobutane or neopentane to the solutes cannot be ascribed to the ionic processes, although the possibility of a transfer *via* the excited cation cannot be excluded completely. The excitation transfer reaction may be responsible for the energy transfer in the radiolysis of an alkane mixture, as in the radiolysis of the *i*-C_4H_{10}–CCl_4 (or $C_6H_5CH_3$) system:[3)]

$$\textit{neo}\text{-}C_5H_{12} \sim\!\!\sim\!\!\sim C_5H_{12}^* \quad (12)$$

$$C_5H_{12}^* \longrightarrow C_4H_9\cdot + CH_3\cdot \quad (13)$$

$$\searrow\ C_5H_{11}\cdot + H\cdot \quad (14)$$

$$C_5H_{12}^* + RH \longrightarrow C_5H_{12} + RH^* \quad (15)$$

$$RH^* \longrightarrow R\cdot + H\cdot \quad (16)$$

where $C_5H_{12}^*$ represents an excited molecule. CH_3 radicals are not observed by ESR spectroscopy, although their formation is expected from Eq. (13). This is because the CH_3 radical may migrate in the neopentane matrix even at 77 K and may recombine with other CH_3 radicals or H atoms.

When the *i*-C_4H_{10}–C_3H_8 or *neo*-C_5H_{12}–C_2H_6, C_3H_8, or *i*-C_4H_{10} systems are γ-irradiated at 77 K, solute radicals are mainly formed. As is shown in Table 2, it is impossible for an excitation transfer from isobutane or neopentane in the first excited state to the solute alkanes to occur. Therefore, the excitation transfer may occur by way of the highly-excited states of isobutane or neopentane.

Yields of Hydrogen in the Radiolysis of Neopentane Containing Cyclopentane at 77 K in the Solid Phase. The effect of cyclopentane on the yields of H_2 and CH_4 in the radiolysis of neopentane at 77 K in the solid phase is shown in Fig. 4. The yields of H_2 increase sharply upon the addition of a small amount of cyclopentane, while the yields of CH_4 are not affected. The broken line indicates the yields which may be expected when the energy transfer between neopentane and cyclopentane does not occur.

Since the cyclopentyl radical is the main radical formed in the radiolysis of the solid neopentane–cyclopentane (5 mol %) system (Fig. 2f), the large yields of H_2 upon the addition of cyclopentane may be due to an excitation transfer from highly-excited neopentane to cyclopentane (*cf.* Reactions (12)—(16)). Since the increase in H_2 becomes approximately constant above 2 mol % of cyclopentane, the excitation transfer occurs entirely below this concentration. The increase in the cyclopentyl radical shows the same concentration dependency in the radiolysis of the solid neopentane–cyclopentane mixture.[23)] Though it is expected from the ESR study that the yields of the CH_3 radical decrease upon the addition of cyclopentane (*cf.* Reactions (13) and (15)), the yields of CH_4 do not decrease. Therefore, methane may be formed mainly *via* a non-radical process, such as molecular detachment from neopentane.

Effect of Matrix on the Formation of Solvent Radicals in the Radiolysis of Alkanes in the Solid State at 77 K

Mitsuharu FUKAYA, Terunobu WAKAYAMA, Tetsuo MIYAZAKI*,
Yoshiyuki SAITAKE, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received March 10, 1972)

The effect of the matrix on the radiolysis of 2,3-dimethylbutane, neopentane, 2,2-dimethylbutane, and isobutane in the solid state has been studied at 77 K by means of ESR spectroscopy. Though only the $\cdot CH_2CH(CH_3)CH(CH_3)_2$ radical is formed by the γ-irradiation of 2,3-dimethylbutane in the I crystal, the $CH_3\dot{C}(CH_3)CH(CH_3)_2$ radical is formed by the γ-irradiation of 2,3-dimethylbutane in the II crystal. Though the t-C_4H_9 and neo-C_5H_{11} radicals are formed by the γ-irradiation of pure neopentane, the formation of radicals is affected appreciably by the addition of a small amount of alkanes. When neopentane containing ethane, *etc.* is γ-irradiated, the solute radical is mainly formed by energy transfer form the γ-irradiated neopentane to the solute. Most of the solutes have a spherical molecular structure like that of neopentane or are smaller than neopentane. When neopentane containing 3-methylpentane, *etc.* is γ-irradiated, only the neopentyl radical is formed. The molecular structures of the solutes are very different from that of neopentane. The formation of the solvent radical in the radiolysis of 2,2-dimethylbutane is affected by the addition of 3-methylpentane or methylcyclohexane. The formation of the butyl radical in the radiolysis of isobutane is also changed drastically by addition of alkanes. It is concluded that the formation of solvent radicals in the radiolysis of solid alkane is appreciably affected by the conditions of the matrix.

It has previously been found that the isobutyl radical is formed by the radiolysis of isobutane in the polycrystalline state, while the t-C_4H_9 radical is formed in the transparent solid state.[1] The study of the radiolysis of isobutane-2-d_1 showed that the phase change affects the primary process of the C–H bond rupture in the radiolysis of solid isobutane.[2] The phase effect was also reported in the radiolyses of phenyl acetate[3] and disodium succinate[4] in the solid state. Recently it was found in the radiolysis of solid succinic acid that the $G(CO+H_2)$ from the powder is much higher than that from the single crystal. It was suggested that the exciton produced by the γ-irradiation of solid succinic acid migrates to a surface or a defect of the powder and thus produces CO and H_2.[5] It was also been reported that, in the radiolysis of alkanes at 77 K, solvent radicals are formed by the fragmentation of excited molecules produced directly by γ-irradiation.[6]

Therefore, we have proposed that two important problems must be solved in order to elucidate the mechanism of the solid-phase radiolysis. One is the problem of the extent to which the formation of an exciton plays an important role: the other is how the condition of the matrix affects the reaction in the solid phase. Here we will report about the latter problem in the radiolyses of 2,3-dimethylbutane, neopentane, 2,2-dimethylbutane, and isobutane in the solid phase.

Experimental

The isobutane was more than 99.7% pure. The neopentane was more than 99.9% pure. The 2,3-dimethylbutane and 2,2-dimethylbutane were more than 99.0% pure and were passed through a 30-cm column packed with activated alumina. They were used after distillation on a vacuum line. The additives, such as ethane, propane, n-hexane, cyclohexane, and methylcyclohexane, were the same as those which had been used before.[6d] The additives, such as n-pentane, n-octane, isooctane, and *trans*-decaline, were Tokyo Kagaku Seiki's guaranteed reagents. The n-heptane, n-decane, n-hexadecane, isopentane, cyclooctane, adamantane, and carbon tetrachloride were Nakarai Chemicals' guaranteed reagents. The n-butane and nitrous oxide were supplied by Takachiho Shoji Co. and were of a high purity. The 3-methylpentane (Aldrich Chemical Co.) was washed with concentrated sulfuric acid. After this treatment the specimen was separated from the sulfuric acid solution by distillation.

Samples were sealed into a silica cell and irradiated at 77 K with γ-rays from Co-60 at a dose rate of 7.6×10^5 rad/hr. The total dose was 3.8×10^5 rad. The ESR spectra of the irradiated samples were measured at 77 K on a JES-3BX ESR spectrometer.

Results and Discussion

Effect of Phase on the Formation of Radicals in the Radiolysis of 2,3-Dimethylbutane at 77 K. Recently Adachi, Suga, and Seki have reported a calorimetric

Dotted lines represent the spectra of trapped electrons which are easily bleached by illumination with visible light.

study of 2,3-dimethylbutane in the solid state.[7] The heat-capacity curves measured by them are shown in Fig. 1. 2,3-Dimethylbutane has three crystalline phases: a high-temperature form (the I crystal) which is stable at temperatures between 136 K to 145 K, a low-temperature form (the II crystal) which is stable below 126 K, and a metastable intermediate phase (the III crystal).[8] When 2,3-dimethylbutane is cooled repidly at 77 K, it forms a supercooled crystal (I′ in Fig. 1), which is a transparent solid.[9] When the supercooled I crystal is warmed to some temperature lower than 136 K and then cooled to 77 K, and when annealing is repeated several times, it forms a II crystal.

The ESR spectrum of γ-irradiated 2,3-dimethylbutane in the supercooled I crystal at 77 K is shown in Fig. 2a. The spectrum consists of five lines, with a splitting of 22 G, which is approximately consistent with the reported value of 21 G for the $\cdot CH_2CH(CH_3)CH_3$ radical.[10] The spectrum may be assigned to the $\cdot CH_2CH(CH_3)CH(CH_3)_2$ radical which is formed by the rupture of a primary C–H bond.

A quite different ESR spectrum is, however, obtained by the γ-irradiation of 2,3-dimethylbutane in the II crystal form at 77 K (Fig. 2b). The spectrum consists of eight lines, with a splitting of 24 G. The spectrum may be assigned to the $CH_3\dot{C}(CH_3)CH(CH_3)_2$ radical which is formed by the rupture of a tertiary C–H bond, or to the C_3H_7 radical which is formed by the rupture of a C–C bond. The yield of H_2 in the radiolysis of 2,3-dimethylbutane in the II crystal at 77 K is the same as that in the radiolysis of 2,3-dimethylbutane in the I crystal. The spectrum of eight lines coincides well with that of the $CH_3\dot{C}(CH_3)CH(CH_3)_2$ radical which is produced by H-atom abstraction from 2,3-dimethylbutane during the UV illumination of a 2,3-dimethylbutane-hydrogen iodide mixture at 77 K in the II crystal.[11] Therefore, it is probable that the solvent radical of γ-irradiated 2,3-dimethylbutane in the II crystal may be the $CH_3\dot{C}(CH_3)CH(CH_3)_2$ radical.

The following two conclusions are obtained from the results of the radiolysis of 2,3-dimethylbutane at 77 K. First, in the previous studies of the effect of the phase on the radiolysis of solid isobutane[1,2] the phase change was caused by the addition of alkane and the phase change was not ascertained by the calorimetric measurements. The present results for the radiolysis of solid 2,3-dimethylbutane, however, clearly show that quite different radicals are formed in the two different phases, as determined by calorimetric measurement.

Second, it was proposed that, in the radiolysis of isobutane,[1b] the phase effect on the formation of the solvent radical may be explained by the cage effect. The present results, however, show that the phase effect on the radiolysis of solid 2,3-dimethylbutane cannot be explained by the cage effect. In effect, since the C–C bond of the $CH_3\dot{C}(CH_3)CH(CH_3)_2$ radical is formed by sp^2-hybrid orbitals, two CH_3 groups and $CH(CH_3)_2$ group constitute a planar structure. Therefore, a structural rearrangement of C–C bonds would be necessary for the formation of the $CH_3\dot{C}(CH_3)CH(CH_3)_2$ radical from the 2,3-dimethylbutane molecule, while such a change would not be necessary for the formation of the $\cdot CH_2CH(CH_3)CH(CH_3)_2$ radical. Therefore, it would be expected from the hypothesis of the cage effect that the for-

7) K. Adachi, H. Suga, and S. Seki, This Bulletin, **44**, 78 (1971).
8) Unfortunately, the crystal structures of crystal–I, II and III are unknown at present. X-Ray analysis of these crystals is desirable in future.
9) The terms "glass" or "glassy state" were often used in the previous studies by the present authors.[1,2,5,6] These terms, however, mean only that the solid is in the transparent state.
10) P. B. Ayscough and H. E. Evans, *J. Phys. Chem.*, **68**, 3066 (1964).

mation of the C–C bonds may be suppressed in the II crystal, which is more rigid than the I crystal (i.e., the plastic crystal). The experimental results, however, show that the $CH_3\dot{C}(CH_3)CH(CH_3)_2$ radical is formed only in the II crystal.

The phenomenon that different solvent radicals are formed selectively by the change in the phase is quite mysterious for us. When a solvent radical is formed by H-atom abstraction from 2,3-dimethylbutane during the UV illumination of a 2,3-dimethylbutane-hydrogen iodide mixture at 77 K, the $\cdot CH_2CH(CH_3)CH(CH_3)_2$ radical is formed in the I crystal, while the $CH_3\dot{C}(CH_3)CH(CH_3)_2$ radical is formed in the II crystal.[11] Therefore, the effect of the phase on the H-atom abstraction reaction is similar to the effect on the radiolysis. The results suggest that the matrix of 2,3-dimethylbutane itself possesses a selectivity for the formation of the solvent radical.

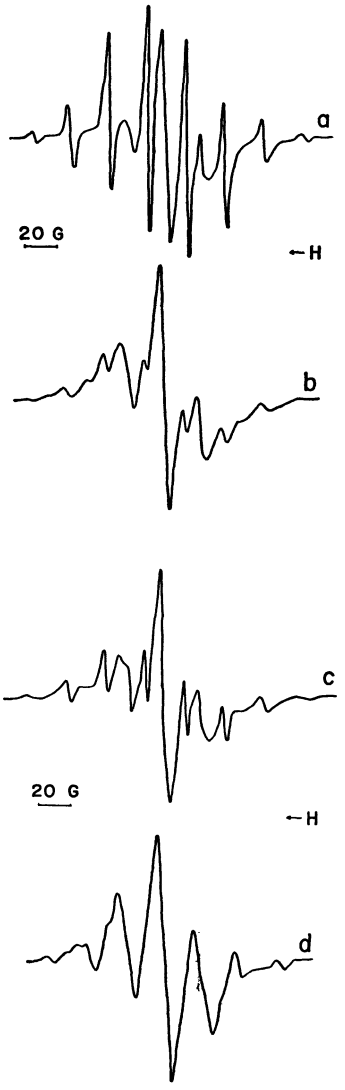

Fig. 3. ESR spectra of γ-irradiated neopentane and neopentane-alkane mixture at 77 K.

Effect of the Addition of Alkanes on the Formation of Radicals in the Radiolysis of Neopentane at 77 K.
When pure neopentane is γ-irradiated at 77 K in the solid phase, the ESR spectrum of the radicals is as is shown in Fig. 3a.[12] The spectrum of eight narrow lines is ascribed to the t-C_4H_9 radical. The spectrum of three broad lines is ascribed to the *neo*-C_5H_{11} radical. When neopentane containing a small amount of alkane is γ-irradiated at 77 K, a quite different ESR spectrum is obtained. The effects of the addition of alkanes may be classified into two types. Type A is as follows: when neopentane containing ethane *etc.* is γ-irradiated, the solute radical is mainly formed by excitation transfer from the γ-irradiated neopentane to the solute. The details of Type A were reported in a previous study.[6] Type B is as follows: when neopentane containing 3-methylpentane, *etc.* is γ-irradiated, only a neopentyl is formed, while the formation of the t-C_4H_9 radical and the solute radical is suppressed. A small quantity of solute radicals, however, seems to be formed in a few cases. The ESR spectra of γ-irradiated neopentane containing 3-methylpentane, isooctane, and *n*-butane are shown in Figs.

3b, c, and d respectively. A small amount of the *t*-C_4H_9 radical is formed in the radiolysis of neopentane containing isooctane (Fig. 3c).

The effects of various alkanes on the radiolysis of neopentane are classified in Table 1. Most of the alkanes of Type A have approximately spherical molecular structures, like that of neopentane, or are smaller than neopentane. The molecular structures of the additives of Type B, however, are very different from that of neopentane. Although adamantane is spherical like neopentane, it is larger than that of neopentane.

Since the information on the radiolysis of solid alkane is very scanty at present, it is difficult to explain why the effects of alkane mixtures fall into two types. The phenomena may be related to the behavior of an exciton formed by γ-irradiation, the local crystalline structure near the additive, or some such thing.

It is noted that when neopentane containing 4 mol% nitrous oxide is γ-irradiated at 77 K, only the *neo*-C_5H_{11} radical is formed. Lin and Williams ascribed this phenomenon to the electron-scavenging effect of nitrous oxide.[13] Since the solvent radical may be formed by the fragmentation of an excited neopentane molecule,[6] and since a decrease in the *t*-C_4H_9 radical is also observed upon the addition of alkanes, it is possible that nitrous oxide acts similarly to the addition-effect of alkanes in the radiolysis of solid neopentane.

Effects of the Addition of Alkane on the Formation of Radicals in the Radiolysis of 2,2-*Dimethylbutane at* 77 *K.* The ESR spectrum of γ-irradiated pure 2,2-dimethylbutane in the solid state is shown in Fig. 4a. The spectrum consists mainly of three lines, with a splitting of 23 G, which is consistent with that of 23 G for the $\cdot CH_2C(CH_3)_2CH_3$ radical. The spectrum may be assigned to the $\cdot CH_2C(CH_3)_2CH_2CH_3$ radical.

When 2,2-dimethylbutane containing 5 mol% of 3-methylpentane is γ-irradiated at 77 K, the spectrum of the triplet decreases, while the very small peaks on both sides of the triplet are not affected by the addition of 3-methylpentane. Therefore, the spectrum of γ-irradiated 2,2-dimethylbutane containing 3-methylpentane consists of five lines, as is shown in Fig. 4b. The assignment of the quintet ESR spectrum is not possible at present. A similar effect is also observed upon the addition of methyl-cyclohexane.

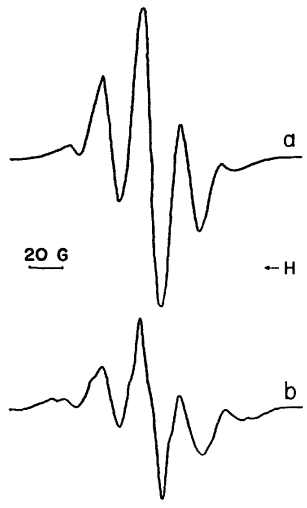

Fig. 4. a) ESR spectrum of γ-irradiated pure 2,2-dimethylbutane at 77 K.
b) ESR spectrum of γ-irradiated 2,2-dimethylbutane-3-methylpentane (4.9 mol%) at 77 K.

Effect of the Addition of Alkane on the Formation of Radicals in the Radiolysis of Isobutane at 77 *K.* When pure isobutane is γ-irradiated at 77 K in the solid state, the isobutyl radical is formed,[6a,b] while a quite different ESR spectrum is obtained in the radiolysis of isobutane containing a small amount of alkane at 77 K.[1] The effects of the addition of alkanes on the radiolysis of solid isobutane may be classified into two types. When isobutane containing propane is γ-irradiated at 77 K, the propyl radical is mainly formed, while the formation of the isobutyl radical is suppressed. As was discussed in a previous study,[6d] the exciton by the γ-irradiation of isobutane migrates to propane to produce the propyl radical. We could not, however, find any other alkanes which behave like propane in the radiolysis of solid isobutane.

When isobutane containing other alkanes is γ-irradiated at 77 K, the formation of the isobutyl radical is suppressed without the solute radical appearing, while the *t*-C_4H_9 radical is formed as has been shown in the previous reports.[1]

○: Its size is smaller than that of isobutane.

13) J. Lin and F. Williams, *J. Phys. Chem.*, **72**, 3707 (1968).

The effects of various alkanes on the radiolysis of isobutane are shown in Table 2. It may be noted that propane is smaller than isobutane, while the other alkanes of Type B are larger than isobutane.

It may be concluded that the radiolysis of alkane in the solid phase is appreciably affected by the condition of the matrix. The effect is characteristic of the solid phase; further studies are desired for the elucidation of the solid kinetics.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1040—1045 (1973)

The Proton Chemical Shift of *n*-Pentane

Isao ANDO and Atsuo NISHIOKA

Department of Polymer Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received April 8, 1972)

The temperature dependence of the proton chemical shift of *n*-pentane was calculated by the CNDO/2 method, taking into account the possible preferred conformations and the contributions from the diamagnetic, paramagnetic, and bond anisotropy terms. It was found that the bond anisotropy term contributes predominantly, while the diamagnetic term is not negligible, and that the paramagnetic term is negligible in comparison with these terms. The observed temperature dependence of the chemical shift can be reasonably explained by calculations using 570 cal/mol as the energy difference between the *trans* and *gauche* conformations, and also using 9.1×10^{-30} cm^3 as the magnetic anisotropy of the C–C bond.

So far quantum-chemical calculations of the shielding constants in the chemical shifts of hydrocarbons have been done for some typical simple molecules, such as methane, acetylene, and ethylene,[1,2] by the LCAO MO method, but for more complex molecules which have some rotational isomers, *e. g.*, the *n*-pentane under consideration, these rigorous calculations becomes virtually impossible. Thus, for estimating the chemical shift of such molecules we must make some approximations by dividing the shielding constant into contributions from electrons localized on atoms and in the chemical bond.

According to Pople,[3] the shielding constant, σ_A, of a nucleus A is written as:

$$\sigma_A = \sigma_A^{dia} + \sigma_A^{para} + \sum_{B(\neq A)} \sigma_{AB} \qquad (1)$$

where the σ_A^{dia} term arises from induced diamagnetic currents on the A atom, depending upon the electron density around the nucleus, A; where σ_A^{para} is the contribution of induced paramagnetic currents on A, and where σ_{AB} is the contribution arising from locally-induced currents on the atoms, B's, other than A in the molecule, referred to as the neighbour anisotropy effect. In estimating these terms, we will use the electron density calculated by the CNDO/2 (Complete Neglect of Differential Overlap) method[4] for σ_A^{dia}, and will apply Marshall and Pople's theory[5] to the evaluation of σ_A^{para}, which is here assumed to be contributed by the excess or deficient charges on the carbon atom bonded to the specified proton; we will also calculate the bond anisotropy term[6] for σ_{AB}, because it is difficult to obtain exactly information about the excitation energy which is used in the point dipole equation.[3]

Many attempts using the LCAO MO method have been made to estimate the proton and the ^{13}C chemical shift of hydrocarbon molecules by calculating the electron density. Yonezawa *et al.*[7] calculated the electron densities on hydrogen atoms of hydrocarbons by the simple LACO MO method for the σ electron system, and estimated the chemical shifts. The calculated results are consistent with the observed ones, but the simple LCAO MO method is too simple for a discussion of the proton chemical shift of *n*-pentane, which can take various conformations. Sichel and Whitehead[8] calculated the electron density on atoms of hydrocarbons using the extended Hückel theory, which can take into account the molecular conformations; they found that the calculated electron densities on the carbon atoms correspond well to the observed ^{13}C chemical shifts, but that those on the hydrogen atom do not correspond to the proton chemical shift. Baird and Whitehead[9] discussed the correlation between the proton chemical shift of hydrocarbons and the electron density calculated by the electronegativity equation method, and found that the ^{13}C chemical shift reasonably corresponds to the charge on the carbon atom, while the proton chemical shift does not correspond to that on the hydrogen atom.

As has been described above, a good correlation between the calculated electron densities on the hy-

drogen atoms and the chemical shifts of proton in hydrocarbons has not been obtained. One cause may be the neglect of the second and third terms in Eq. (1). In the proton chemical shift of non-polar hydrocarbon molecules, it is usually conjectured that the contribution of the second term to the chemical shift is negligible in comparison with those of the other terms. Generally discussing the chemical shift of such molecules, we will report that the third term is important.

It is the purpose of this paper to calculate the proton chemical shift of *n*-pentane, considering the various conformations, and to estimate plausible values of the *trans-gauche* potential barrier and the magnetic bond anistropy of the C–C bond, $\Delta\chi_{C-C}$, by comparing the observed temperature dependences of the proton chemical shifts with the calculated ones.

Experimental

The NMR spectra of *n*-pentane (99.9%) were measured in neat liquid at temperatures from −70 °C to +60 °C, using a JEOL 4H-100 type spectrometer (100 MHz). Tetramethylsilane (TMS) was used as the internal standard. The chemical shift is expressed in ppm downfield.

Calculation

In estimating the chemical shift of *n*-pentane, we calculate separately the first, second, and third terms in Eq. (1).

The first term[10] is expressed as;

$$\sigma_A^{dia} = \frac{e^2}{3mc^2} = \langle 0 \left| \sum_k \frac{1}{r_k} \right| 0 \rangle \tag{2}$$

where e is the electron charge; m, the mass of the electron; c, the velocity of light, and r_k the distance of the k-th electron from the nucleus, and where $|0\rangle$ refers to the electronic ground state of the molecule. σ_A^{dia} is fairly easy to calculate, since it depends only on the electron distribution in the electronic ground state. Thus, in practice, we used the following equation[3] to estimate the proton chemical shift;

$$\sigma_A^{dia} = k \cdot \rho \tag{3}$$

where we used 17.8 ppm[3] as k and where ρ is the electron density of the atom under consideration, being calculated by the CNDO/2 method.

The second term, the paramagnetic one, which represents the effect of the mixing of the ground and excited states by the magnetic field, is usually more difficult to evaluate. Thus, we will evalute this term by the following expression, proposed by Marshall and Pople,[5] which was obtained from a calculation of the nuclear magnetic shielding in a hydrogen nucleus placed in an electric field, due to the excess or deficient charge on the carbon atom bonded to the hydrogen atom, neglecting any effect of the spin of the electron:

$$\sigma_A^{para} = k \cdot \sigma_\perp^{para} \sin^2\theta \tag{4a}$$

$$\sigma_\perp^{para} = -\frac{233}{144}\frac{a^3E^2}{mc^2} \tag{4b}$$

where $\sigma_\perp^{para}$ is the paramagnetic shielding constant in the case of H (magnetic field) perpendicular to E (electric field); σ_A^{para}, the value of σ for an intermediate direction making an angle of θ with E, and a, the Bohr radius. Therefore, when we evaluate σ_A^{para}, one must average all the θ angles. Thus, σ_A^{para} becomes:

$$\sigma_A^{para} = \frac{1}{2}\sigma_\perp^{para} = -\frac{1}{2}\cdot\frac{233}{144}\frac{a^3E^2}{mc^2} \tag{5}$$

When we estimate E in any specified hydrogen nucleus, we assume that the hydrogen nucleus experiences the electric field of the carbon atom bonded to it, which arises from its excess electron charge.

As to the third term, although the point dipole equation proposed by Pople[3] should be used, it is difficult to estimate the equation because the excited states are not known. Thus, we used approximately the McConnell equation[6], neglecting only the small contribution from the C–H bond.

$$\sigma_{AB} = \frac{\Delta\chi_{C-C}}{3r^3}(1 - 3\cos^2\theta_M) \tag{6}$$

in which $\Delta\chi_{C-C}(=\chi_\parallel - \chi_\perp)$ is the magnetic anisotropy of the C–C bond, where r is the distance between any specified proton and the midpoint of the C–C bond, and where θ_M is the angle between the directions of r and the C–C bond. So far, although various values for the magnetic anisotropy of the C–C bond have been reported,[11] the most reliable value is not known at present. However, to promote the discussion, we adopted tentatively the value of 5.5×10^{-30}cm^3 reported by Bothner-By and Narr-Colin.[11] We will discuss the value of $\Delta\chi_{C-C}$ in a later chapter.

Here, the rotational isomeric states of *trans*(T) and *gauche* (G and G′) are defined to occur at the rotational angles about 0°, 120°, and 240° respectively by the clockwise rotation around the C–C bond as expressed in the Newman projection.

We numbered the carbon atoms in pentane as follows:

$$CH_3(1)\text{-}CH_2(2)\text{-}CH_2(3)\text{-}CH_2(4)\text{-}CH_3(5)$$

The C–C and C–H bond lengths are set as 1.54 Å and 1.10 Å respectively, and both of the C–C–C and C–C–H bond angles are set at 109°28′.[12]

Results and Discussion

n-Pentane can take seven isomeric states (TT, TG, TG′, GT, G′T, GG and G′G′), where GG′ and G′G were ignored due to the large steric hindrance. Because the observed chemical shift is usually considered to be the average of the chemical shifts of rapidly interconverting rotamers, the chemical shift, $\sigma(j)$, of the j-th proton in *n*-pentane should be expressed as follows:

$$\sigma(j) = \sum_{i=1}^{7} X_i \sigma_i(j) \tag{7}$$

where X_i and σ_i are the fraction and the chemical shift of the i-th isomer respectively. X_i is expressed as:

$$X_i = e^{-\Delta E_i/RT} / \left(\sum_{i=1}^{7} e^{-\Delta E_i/RT}\right) \tag{8}$$

where R is the gas constant; T, the absolute temperature, and ΔE_i the energy difference between TT and the i-th conformation.

Now, let us discuss the electron-density distributions of *n*-pentane in Fig. 1, we show the electron densities of the protons in the TT, TG and GG conformations as obtained by the CNDO/2 method; one of the three protons of the methyl group is assumed to take the *trans* position in relation to the central carbon atom. The electron density of the methyl protons is averaged by the three protons in the methyl group, since it may be considered that the methyl group rotates freely, and the parameters used in the CNDO/2 calculation are the same as those proposed by Pople.[4] The electron densities of the protons in the other conformations can be at once obtained from those of the TT, TG and GG conformations. The calculated total energies of these conformations were −1221.4326, −1221.4136, and −1221.3698 eV respectively. Thus, the energy difference between the *trans* and *gauche* conformations, ΔE_g, is *ca.* 440 cal/mol in an isolated pentane. This agrees fairly well with the value (450±60 cal/mol) obtained by the spectroscopic method,[13] the value (*ca.* 500 cal/mol) obtained by an inherent bond potential, and the energy of interaction between nonbonded substituents.[14] This is one of several successful cases[15] of the application of the CNDO/2 method to problem of the energy difference between the rotational isomers. Recently Fujiyama *et al.*[16] reported obtaining a value of 600 cal/mol by laser-Raman spectroscopy, and Ishikawa and Nagai.[17] obtained *ca.* 800 cal/mol by means of the

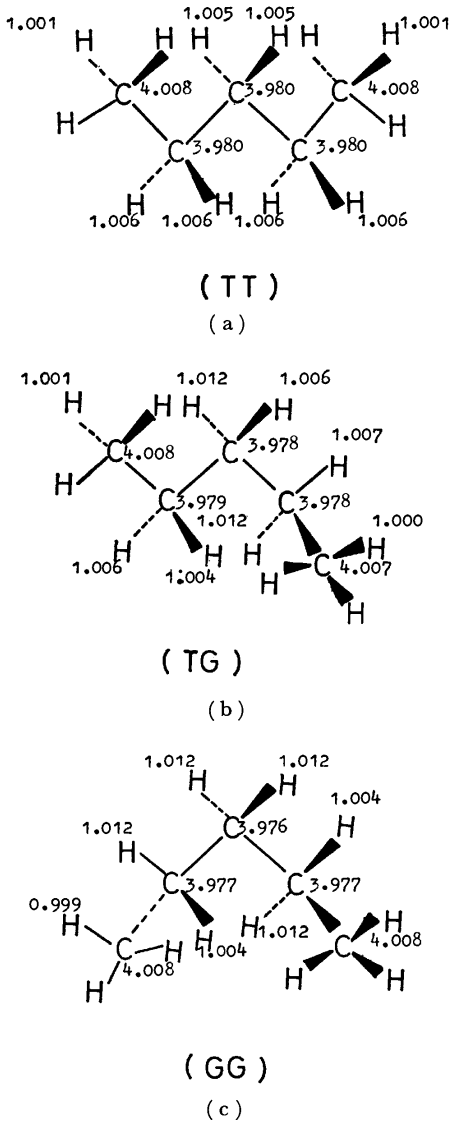

Fig. 1. The electron densities on the atoms of *n*-pentane in (a) TT, (b) TG, (c) GG conformations.

electro-optical effect. Our value is more or less lower than the experimental ones shown above. We will discuss this point below.

The temperature dependences of the proton diamagnetic shielding constants calculated by using Eqs. (3), (7), and (8) are shown in Fig. 2, in which the 440 and 600 cal/mol obtained by the CNDO/2 method and the laser-Raman spectroscopy respectively as described above are used as ΔE_g, and in which the $CH_2(2)$ and the $CH_2(4)$ are equivalent to each other. For reference, the values at 22°C are listed in Table 1. The temperature dependences of the chemical shifts calculated with 440 and 600 cal/mol as ΔE_g differ considerably from each other; the finding that the methyl protons are less shielded than the methylene groups is opposite to the observed one, as is shown in Fig. 3. This is true over a wide temperature range, as is shown in Fig. 4. Thus, the proton chemical shift of *n*-pentane cannot be explained by the first term only, but it is noticeable that there is a small and detectable chemical shift between the $CH_2(2)$

and $CH_2(3)$ protons in this calculation.

The second term, the paramagnetic contribution, was calculated according to Eq. (4), estimating E at any specified proton by the excess or deficient charge from the neutral one at the carbon atom bonded to the proton; the results are shown in Table 2. As expected, the contribution of the paramagnetic term to the proton chemical shift of *n*-pentane is almost negligible in comparison with the diamagnetic one shown in Table 1. It may be considered that the formation of the *S*-state electron localized around the hydrogen nucleus resulting from the adjacent carbon atom, is very small in *n*-pentane. Thus, we may neglect this term.

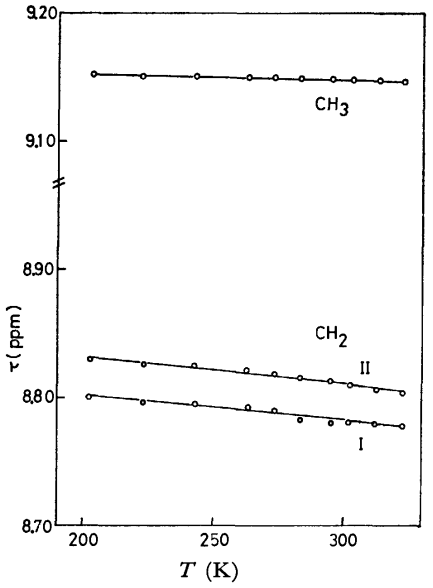

Fig. 4. The temperature dependence of the observed chemical shift of *n*-pentane.

TABLE 2. THE PARAMAGNETIC TERM σ^{para} OF THE TT, TG AND GG CONFORMATIONS OF *n*-PENTANE.

Preferred conformation	TT (ppm)	TG (ppm)	GG (ppm)
$CH_3(1)$	−0.00029	−0.00029	−0.00029
$CH_2(2)$	−0.00180	−0.00179	−0.00243
$CH_2(3)$	−0.00180	−0.00226	−0.00265

$CH_3(5)$	−0.00029	−0.00023	−0.00029

Next, we shall discuss the third term, which was calculated by assuming the C–C bond anisotropy effect. The results obtained are shown in Fig. 5, in which 440 and 600 cal/mol are used as ΔE_g. It has been found that the order of the arrangement of the calculated chemical shifts of each proton agrees fairly well with those observed over a wide temperature range, the temperature dependences of the chemical shifts of the CH_3 and $CH_2(2)$ groups differing from each other, and the contribution of this term to the chemical shift of *n*-pentane is larger than that of the diamagnetic term. Then, summing up σ^{dia} and $\Delta\chi_{C-C}$ contributions, we obtained the results shown in Figure 6. For reference, the sum of both contributions at 22 °C is listed in Table 1, which reveals that the chemical shifts of the $CH_2(2)$ and $CH_2(3)$

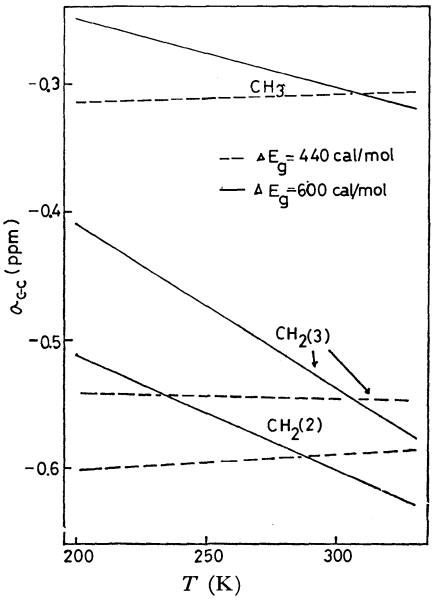

Fig. 5. The temperature dependence of the bond anisotropy term used 440 and 600 cal/mol as ΔE_g.

differ from each other slightly. The spectrum shown in Figure 3 suggests that the signal of the CH_2 group shows a weak shoulder, II,[18] on the higher-field side of the main peak, I, with a chemical-shift difference of 0.058 ppm, and that the ratio of the intensities of the peaks, I to II, is about 2 : 1. Moreover, it is found that the calculated temperature dependences of the chemical shifts for CH_3, $CH_2(2)$, and $CH_2(3)$, shown in Fig. 6, correspond qualitatively to those of these peaks, I and II, which shift to a lower field with an increase in the temperature. Comparing these observed and calculated results, it may tentatively be assumed that the peaks, I and II, are assignable to the $CH_2(2)$ and $CH_2(3)$ groups respectively. However, taking into account the effect of the spin-spin coupling, this assignment is more or less tentative; a detailed and more reliable assignment of these protons could be obtained by using some deuterated compounds and spectrum simulation.

As may be seen from Table 1, the chemical shifts between the CH_3 and $CH_2(2)$ groups in the cases of ΔE_g=440 cal/mol and 600 cal/mol are 0.180 and 0.210 ppm respectively, and those between the CH_3 and $CH_2(3)$ groups in the cases of ΔE_g=440 and 600 cal/mol are 0.140 and 0.170 ppm respectively. The quantitative agreement between the observed and the calculated values is not good. As to the temperature dependence of the chemical shift, it is found that the sign of the slope of the chemical shift of the $CH_2(3)$ group calculated using 440 cal/mol as ΔE_g coincides with that observed, while those of the CH_3 and $CH_2(2)$ groups do not, and that those of the CH_3, $CH_2(2)$ and $CH_2(3)$ groups derived by taking 600 cal/mol as ΔE_g coincide with those observed. Thus, the results calculated for 600 cal/mol agree with the observed values better than those calculated for 440 cal/mol in neat liquid. This is natural because 440 cal/mol for ΔE_g is the value calculated in an isolated n-pentane molecule. From these calculations, it may be seen that the slopes of the chemical shifts against the temperature depend on the magnitude of ΔE_g. For discussing the slope and ΔE_g, we plotted the observed and calculated chemical-shift differences between the CH_3 and $CH_2(2)$ groups ($\Delta\sigma_{CH_3-CH_2(2)}$) and the CH_3 and $CH_2(3)$ ($\Delta\sigma_{CH_3-CH_2(3)}$) against the temperature in Fig. 7. This figure also shows that 600 cal/mol is better than 440 cal/mol for ΔE_g. The

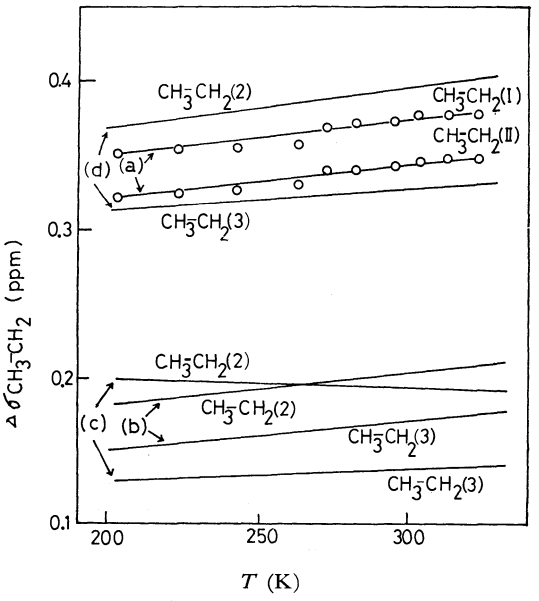

Fig. 7. The temperature dependence of the chemical shift difference between the CH_3 and CH_2 (2) groups.
(a) observed. (b) calculated with 440 cal/mol and (c) 600 cal/mol for ΔE_g, and 5.5×10^{-30} cm^3 for $\Delta\chi_{C\text{-}C}$. (d) calaclated with 570 cal/mol for ΔE_g and 9.1×10^{-30} cm^3 for $\Delta\chi_{C\text{-}C}$.

18) This peak splits more clearly in benzene, pyridine and α-chloronaphthalene than in this case (neat liquid).

best-fitting calculated slope to the observed one can be obtained by taking 570 cal/mol for ΔE_g, as is shown in Fig. 7(c), but the quantitative agreement between the chemical shifts observed and calculated is not satisfactory. The discrepancy may be caused by our choice of the value of $\Delta\chi_{C-C}$. As may be seen from Figure 8, the observed chemical shift differences $\Delta\sigma_{CH_3-CH_2}$ $(=\sigma_{CH_3}-\sigma_{CH_2})$ can be fitted by choosing 8.5—9.7×10^{-30} cm^3 as $\Delta\chi_{C-C}$. Thus, using 9.1×10^{-30} cm^3 at its averaged value of $\Delta\chi_{C-C}$ and 570 cal/mol as ΔE_g, the calculated temperature dependence

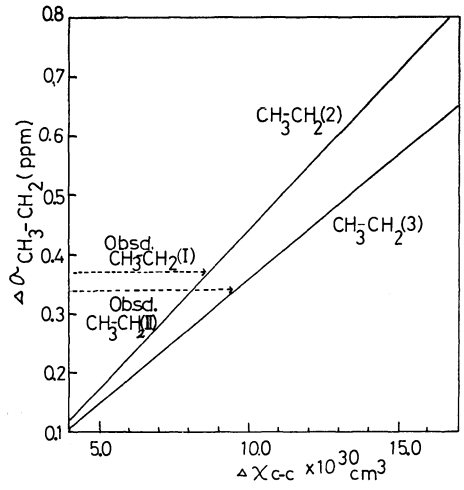

Fig. 8. The chemical shift dependences (CH_3–CH_2 (2) and CH_3–CH_2 (3)) on $\Delta\chi_{C-C}$. ----→: observed results.

of the chemical shift difference, $\Delta\sigma_{CH_3-CH_2}$, is shown in Fig. 7(d). It is found that the calculated results agree fairly well with the observed ones. However, the chemical-shift difference between the CH_2(2) and CH_2(3) groups disagrees slightly. We consider that this is partly due to the ambiguity of the assignment of the CH_2 (II) group. It is necessary to use some deuterated compounds and to simulate the NMR spectrum, taking the spin-spin coupling into account, in order to obtain a more reliable assignment. The above value of $\Delta\chi_{C-C}$, 9.1×10^{-30} cm^3, is near to the value, 10.0×10^{-30} cm^3, proposed by Moritz and Shappard.[11f] However, Homer and Callaghan[11] reported 7.26×10^{-30} cm^3 as the $\Delta\chi_{C-C}$ value of the magnetic anisotropy, but neglected the effect of electron density. If we neglect the contribution of the diamagnetic effect in order to fit the observed results with the calculated ones, we obtain 7.0×10^{-30} cm^3 as $\Delta\chi_{C-C}$. This value is nearly equal to that proposed by Homer and Callaghan. However, we consider that it is better to adopt 9.1×10^{-30} cm^3 as $\Delta\chi_{C-C}$ in *n*-pentane because the diamagnetic contribution to the chemical shift depends upon the conformation.

The authors gratefully acknowledge the helpful comments made by Dr. N. Nakagawa of the University of Electro-Communication and by Dr. T. Yonemoto of the Electrotechnical Laboratory, and the use of the program of the CNDO/2 method made by Dr. T. Hirano of the University of Tokyo.

The Crystal and Molecular Structure of *meso*-2,4-Pentanediol Borate

Shunsuke KURIBAYASHI

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda

(Received April 12, 1972)

The crystals of *meso*-2,4-pentanediol borate are monoclinic with a space group of C2/c. There are eight molecules in the unit cell with dimensions of: $a=15.36$, $b=13.53$, $c=7.68$ Å, and $\beta=113.3°$. The crystal structure was determined by the X-ray method. The final discrepancy index is 0.121 for 1030 non-zero reflections. The molecule has a six-membered ring composed of one boron, three carbon, and two oxygen atoms. The borate group and the two carbon atoms of the pentane group are nearly co-planar. The five carbon atoms are also co-planar, and they are in *trans* positions. The molecule was proved to be of the *meso* type.

In the course of our investigation of model compounds of polymers, the molecular and crystal structure of 2,4-pentanediol seemed of great interest for us as a model compound for polyvinyl alcohol.

As has been reported earlier,[1,2] chemically-synthesized 2,4-pentanediols are composed of three components, of the *meso*, *d*, and *l* types. They are separated into two components by column chromatography; one of them is assumed to be of the *meso* form, and the other, of the racemic form.

When eluted by chromatography, the compounds are separated in a form of borate. The present paper will report the crystal and molecular structure of *meso*-2,4-pentanediol borate.

Experimental

The sample was prepared by a method reported earlier.[1] The crystals are monoclinic and colorless. They crystallize in the form of needles elongated along the *c*-axis or in a lozenge shape. The cell dimensions were determined by the method of least-squares for a *c*-axis oscillation photograph, using Si powder as the standard. The systematic

absences showed that the space group was C2/c or Cc. The former was chosen on the basis of the Wilson statistics. The measured density was about 1.17—1.19, which is in good agreement with the density calculated assuming that the unit cell contains eight molecules. It was difficult to determine the accurate density of the crystal by the ordinary flotation method, as this compound is very hygroscopic and is easily dissolved in nearly all kinds of solvents. The crystal data are shown in Table 1.

Multiple-film equi-inclination Weissenberg photographs were taken about the c-axis, with Ni-filtered Cu$K\alpha$ radiation from zero to the sixth layer. Oscillation and precession photographs were also taken about the b-axis using Zr-filtered Mo$K\alpha$ radiation; they were used mainly for the scaling of the structure amplitudes obtained from the Weissenberg photographs. The intensities were estimated visually by comparison with a standard scale prepared by the same crystal. They were corrected for the Lorentz, polarization, and spot-shape factors. No absorption correction was made. 1030 non-zero structure factors were obtained by these procedures.

Structure Determination

A Patterson projection along the c-axis and a consideration of the packing offered us effective clues for analyzing the structure. Reflections with $l=2n$ are generally stronger than those with $l=2n+1$. Especially, the $\bar{3}12$ and $\bar{2}02$, reflections are extremely strong. From these facts, a trial structure was deduced; it was then refined by the Fourier method in the (001) projection. By these procedures, the discrepancy index, R, became 0.217 for $F(h\ k\ 0)$. At this stage, the z parameters were introduced for every atom, on the assumption that the planar molecule lies nearly on the $(\bar{3}12)$ plane. The block-diagonal least-squares method with isotropic temperature factors was applied, using a program written by N. Yasuoka for the OKITAC 5090 C. After 6 cycles of iterations, the discrepancy index, R, for all the observed reflections decreased from 0.253 to 0.179. Then, a block-diagonal least-squares procedure with anisotropic temperature factors was applied on a TOSBAC 3400-41 using a program, HBLS IV, written by T. Ashida.[3] The function to be minimized was $\Sigma w\Delta^2$, where the weighting scheme used was:

$w=(25.0/|F_o|)^2$ for $|F_o|\geq 25.0$

$w=1$ for $25.0>|F_o|\geq 5.0$, and

$w=0.2$ for $|F_o|<5.0$

After five cycles of interactions, the R factor decreased to 0.134.

With these positional parameters and temperature factors, a difference Fourier map was synthesized, but hydrogen atoms were not found clearly in this map. Therefore, the co-ordinates of hydrogen atoms were assumed to have C–H bond lengths of 1.09 Å and bond angles of 109.5°. They were included in the structure-factor calculation, and the R value was reduced to 0.121. The final atomic co-ordinates and temperature factors, with their estimated standard deviations, are shown in Tables 2 and 3. A list of

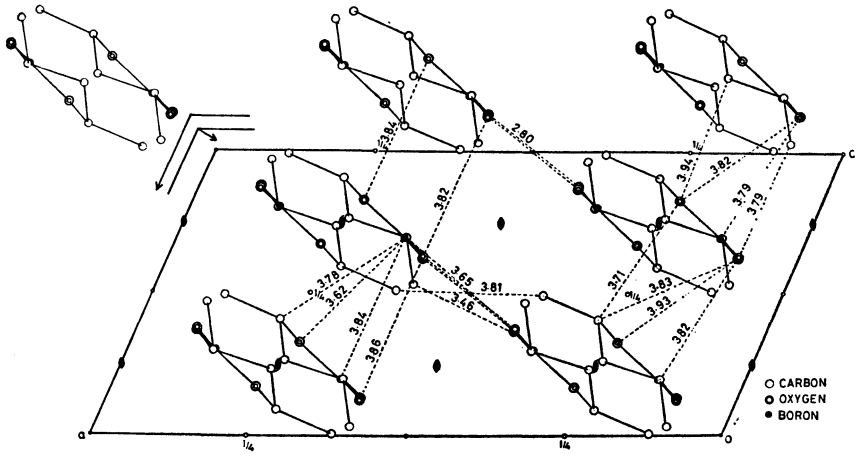

Fig. 1. The crystal structure projected onto the ac plane, with some distances shorter than 4.0 Å.

the observed and calculated structure factors is given in Table 6.[4]

Results and Discussion

The crystal structure projected along the b- and c-axes is shown in Figs. 1 and 2. The molecular structure is shown in Figs. 3 and 4. In Table 4, the bond lengths and angles are listed. As was assumed in the earlier report,[5] the five carbon atoms are in a *trans* position and the molecule is of the *meso* type.[1,2]

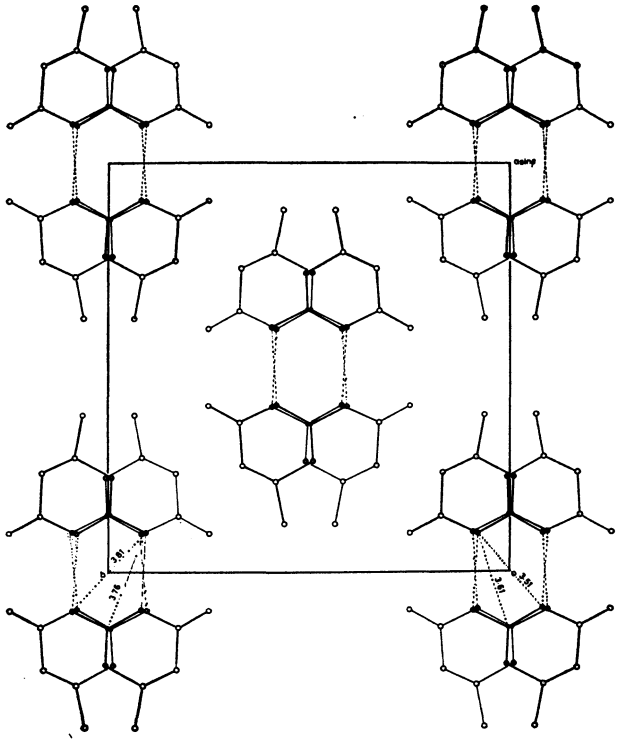

Fig. 2. The crystal structure projected onto ab plane, with some distances shorter than 4.0 Å. The broken lines which connect two oxygen atoms indicate the hydrogen bonds.

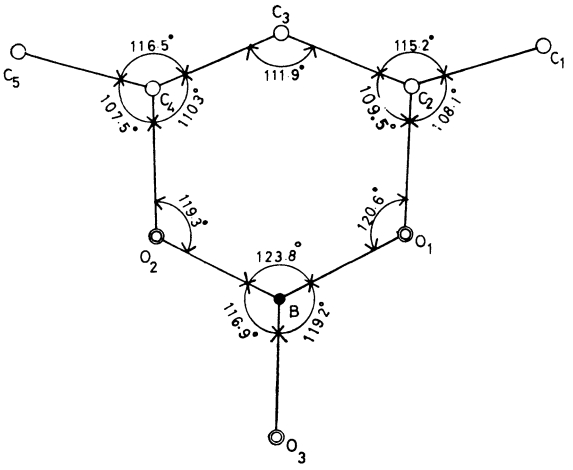

Fig. 3. The molecular shape looking along the direction normal to the molecular plane. The bond angles are also shown.

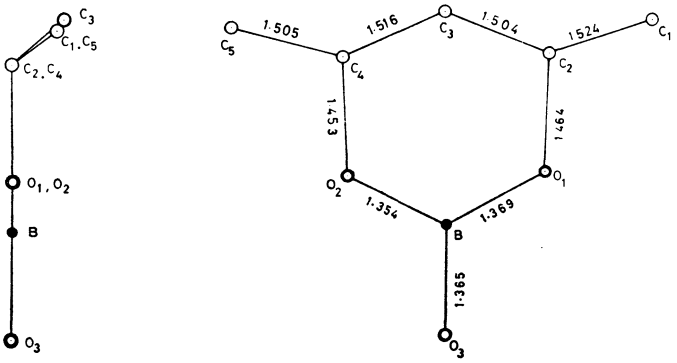

Fig. 4. The molecular shape looking along the direction normal to the molecular plane and the side view, with bond lengths.

All the C–C bond lengths (mean value, 1.51 Å) are a little shorter than the ordinary single bond, and the corresponding length in *dl*-2,4-pentanediol diacetate is 1.52 Å.[6] The C–O bond distances are very close to the values found in various compounds. The B–O bond lengths are the same as those observed

		O (2) - B - O (3)	116.9 (0.5)

for H_3BO_3 and HBO_2.[7,8] The C(1)–C(2)–C(3) and C(3)–C(4)–C(5) bond angles are remarkably larger than those found for ordinary aliphatic compounds. Similar results have been also reported for *dl*-2,4-pentanediol diacetate.[6] The five carbon atoms are nearly co-planar, but C(3) is a little apart from this plane in the direction opposite of that for C(1) and C(5). This plane is expressed by the equation:

$$-0.1549x + 0.6848y + 0.7151z = 2.3405,$$

where x, y, and z are in Å units with repect to the crystallographic axes. The C(2), C(4), O(1), O(2), O(3), and B atoms are also co-planar. The equation of this plane is:

$$-0.6959x - 0.0085y + 0.9349z = -0.1248.$$

As can easily be realized from the co-efficients of the equation, this plane is nearly parallel to the b-axis. The deviations of atoms from these planes are listed in Table 5. The boron atom is surrounded by three oxygen atoms, which form an almost equilateral triangle about the boron.

TABLE 5. DEVIATION OF EACH ATOM FROM PLANES
Plane (I) (five carbon atoms)
Plane (II) (C(2), C(4), O(1), O(2), O(3) and B)

C (3)	0.0741	O (1)	−0.0056
C (4)	−0.0121	O (2)	−0.0312
C (5)	−0.0329	O (3)	0.0151
		B	0.0006

Surrounding the center of symmetry, two molecules are linked together by hydrogen bonds. The hydrogen-bond distances are 2.80 Å. The van der Waals distances shorter than 4.0 Å are shown in Figs. 1 and 2. The nearest intermolecular B–B and B–O distances are 3.84 and 3.61 Å respectively. These values are a little longer than the shortest distances found for H_3BO_3 and HBO_2.[7,8] The bond lengths, bond angles, van der Waals distances, and coefficients of the best planes were computed by means of a program written by T. Sakurai for the UNICS.[3]

The author wishes to express his thanks to Dr. T. Ashida, Dr. T. Sakurai, and Dr. N. Yasuoka for providing him with computing facilities. The author is also indebted to Dr. M. Shiraki for supplying the sample.

Mercury-Photosensitized Decomposition of Ethylbenzene

Hitoshi MIKUNI, Azuma TAKASE*, Motohiro MURANO** and Makoto TAKAHASI

Department of Pure and Applied Sciences, College of General Education, University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received April 28, 1972)

The decomposition of ethylbenzene sensitized by $Hg(^3P_1)$ was studied in gas phase. Hydrogen, methane and ethane were obtained as the main gaseous products. Their rates of formation were determined as a function of the pressure of ethylbenzene or xenon. To decide whether methyl or ethyl radical is the primary product in the photolysis, ethylbenzene-β-d_1 was photolyzed. It was concluded that methyl radical is the primary product, since methane-d_1 and ethane-d_2 were obtained as products. A probable reaction mechanism is proposed to interpret the effect of pressure and light intensity on the rate of formation of ethane and methane. It is suggested that a biphotonic process is involved, which can explain the fact that the rate of formation of ethane is proportional to the square of light intensity.

Studies on the decomposition of organic compounds by excited mercury atoms have been reported by many authors.[1] The mechanism of the reaction is generally classified into two types; (a) the abstraction of hydrogen atom by excited mercury atom as found in the decomposition of alkanes, and (b) the excitation transfer from excited atoms to organic compounds as in the decomposition of unsaturated compounds such as ethylene and butenes. In (b), the acceptor compound should have its triplet state below the level of $Hg(^3P_1)$.

1) R. J. Cvetanović, "Progress in Reaction Kinetics," Vol. 2, Pergamon Press, London (1964), p. 39.

Unsaturated compounds generally have larger cross sections than saturated ones. Until recently, the formation of triplet state of unsaturated compounds by mercury-sensitization was only presumed from the spin conservation rule and relatively long lifetime of the intermediate. Recently Burton and Hunzicker[2] gave direct evidence of the formation of triplet benzene and toluene by excitation transfer from $Hg(^3P_0)$, by means of modulation type kinetic spectroscopy. However, not many studies have been made on the mercury-sensitized decomposition of aromatic compounds, probably due to their low vapor pressure, and details of the mechanism have not been clarified yet. Scott and Steacie[3] reported the mercury-photosensitized reaction of benzene, and Sehon and Darwent[4] proposed a mechanism involving two types of excited toluene in the reaction of toluene with $Hg(^3P_1)$. Hentz and Burton[5] studied the photochemistry of toluene, mesitylene and ethylbenzene in comparison with radiation chemistry. The present authors[6] reported preliminary results of mercury photosensitized decomposition of ethylbenzene. Yamamoto *et al.* also photolyzed ethylbenzene with mercury and investigated the reaction products.[7] We report herewith on the study of mercury-photosensitized decomposition of ethylbenzene, taking into consideration the effects of pressure of ethylbenzene and xenon and light intensity on the rate of formation of gaseous products. Since the compound has both alkyl and phenyl groups in one molecule, it may be interesting to decide whether abstraction of hydrogen or excitation transfers reaction plays the more important role in a single molecule in mercury-photosensitized decomposition.

Experimental

Materials. Commercial ethylbenzene was purified by gas chromatographic separation through a DOP column, dried with sodium and distilled in a reaction cell. Ethylbenzene-β-d_1 was prepared from 2-phenylethyl bromide by the Grignard reaction with deuterium oxide of 99.9% isotopic purity, and fractionated by gas chromatography. No impurity was found either in ethylbenzene or ethylbenzene-β-d_1 by FID through the DOP column. Isotopic purity of ethylbenzene-β-d_1 was determined to be about 90% by reduced ionization voltage technique of mass spectrometer. Xenon (Takachiho Co.) was used without further purification.

Apparatus. We constructed a low pressure spiral type mercury lamp, its light intensity being determined occasionally by mercury-photosensitized decomposition of propane, and found to be $9.7—12\times10^{15}$ photon/sec. Variation in lamp intensity in a series of experiments was small. A slight gradual decrease of absorbed light was due to the decrease of transparency of the quartz window of the reaction cell caused by the deposition of reaction products. The reaction cell, a cylindrical one of 1 cm length and 5 cm diameter and connected to a glass bulb of 500 ml was placed in an electric furnace with temperature regulated to ±1°C. A filter (Toshiba UVD 25) placed in front of the reaction cell removed 184.9 nm light. The pressure of ethylbenzene was measured with a glass Bourdon gauge outside the furnace. Ethylbenzene with mercury vapor was circulated with a glass fan and a mercury booster pump. The pressure of mercury was not determined, but was presumed to be fairly high from the temperature of the furnace. Two metal valves are fitted to the inlet and outlet parts of the reaction system. In order to control incident light intensity, single or double blackened gauzes were inserted in front of the reaction cell. Transmission of the gauze was calibrated both by spectrophotometry and actinometry with mercury-photosensitized decomposition of propane. Both methods gave almost the same ratios of transmission.

Analysis of Reaction Products. After irradiation, the reaction mixture was passed through two helical traps kept at -196 °C. Hydrogen and methane were collected in Toepler gauge, and the combined amount of hydrogen and methane was measured first. Hydrogen was oxidized to water in copper oxide combination tube at 300 °C, and unoxidized gas was assumed to be methane. Ethane was pumped out by warming the traps up to -140 °C with a refrigerant mixture. In the quenching experiment with Xe, the quantitative determination of ethane was carried out by gas chromatography with FID, but the amounts of methane and hydrogen were not determined.

Results and Discussion

Long Irradiation Experiment and Direct Photolysis of Ethylbenzene. The rate of decomposition of ethylbenzene with mercury at 253.7 nm at room temperature is too small to be measured. Reactions at 150—300 °C gave hydrogen, methane and ethane as main products of low boiling point with a small amount of propane, but no ethylene was detected. The formation of toluene and styrene was confirmed by gas-chromatography, but not conclusive. Yamamoto *et al.*[7] reported on the formation of benzene, toluene, isopropylbenzene, bibenzyl, and 1,2-diphenylpropane, but not styrene. A detailed comparison of the present results with theirs may be not appropriate, since the experimental conditions differ. However, as far as gaseous products are concerned, qualitative results of both experiments seem to be in good agreement. In Fig. 1, the rates of formation of hydrogen, methane and ethane (R_{H_2}, R_{CH_4}, $R_{C_2H_6}$[8]) are plotted against irradiation time under 1.9 Torr of ethylbenzene at 150 °C. $R_{C_2H_6}$ is constant for 3 hr, and R_{CH_4} is also almost constant irrespective of time. It seems that R_{H_2} decreases gradually with time. This may be explained as being caused by internal scavenging by some unsaturated product as known in mercury-

8) $R_{C_2H_6}$ is proportional to the square of light intensity. Thus, we use rate instead of quantum yield. The apparent quantum yield of ethane at 2 Torr of ethylbenzene, 1.2×10^{16} photon and 150 °C is 0.04.

photosensitized decomposition of alkanes.[9] However, since our result on styrene formation was not conclusive, it is left for future investigation.

It was confirmed that no pure thermal reaction of ethylbenzene took place up to 300°C. Since ethylbenzene has an absorption band below 270 nm, the direct photolysis of ethylbenzene may be involved to some extent in the mercury-photosensitizing reaction system. Although quantitative determination of the relative amounts of light by mercury and ethylbenzene is not possible, the amount of light absorbed directly by ethylbenzene is presumed to be much less than that by mercury. For the sake of comparison, ethylbenzene of 10 Torr was photolyzed at 25°C in the reaction system where the contamination of mercury vapor was carefully avoided. It was found that $R_{C_2H_6}$ was 0.93×10^{-10} mol/sec, fairly less than the value 5.7×10^{-10} mol/sec obtained in the mercury photosensitizing reaction system (Fig. 1). Hentz and Burton[5] reported the rough quantum yields of gaseous products in the direct photolysis of ethylbenzene to be the order of 10^{-4}. We may presume that the mercury photosensitizing reaction predominates in the present reaction system, but we can not eliminate completely the possibility of involvement of direct photolysis.

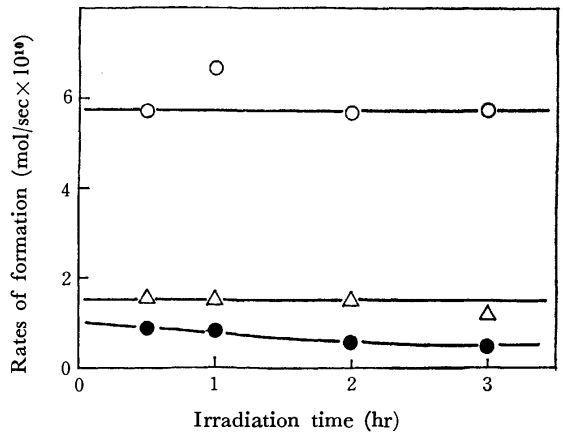

Fig. 1. The variations of $R_{C_2H_6}$, R_{CH_4} and R_{H_2} with irradiation time.
○ ethane, △ methane, ● hydrogen.

Except for long irradiation experiments, we carried out our experiments keeping the conversion below 10% to avoid complication of internal scavenging.

Mercury-Photosensitized Decomposition of Ethylbenzene-β-d_1. In order to decide whether methyl or ethyl radical is the primary reaction entity to give ethane, ethylbenzene-β-d_1 was irradiated for 3 hr at 150°C under pressure of 2 Torr of ethylbenzene-β-d_1. The mole ratios of deuterium substituted methanes and ethanes were determined by mass spectrometry. The results are given in Table 1.

TABLE 1. MOLE RATIOS OF DEUTERIUM SUBSTITUTED METHANES AND ETHANES PRODUCED BY MERCURY-SENSITIZED PHOTOLYSIS OF ETHYLBENZENE-β-d_1

CH_4	CH_3D	C_2H_6	C_2H_5D	$C_2H_4D_2$
15	85	0	20	80

It is seen that the main primary product in the reaction is methyl radical considering the following reaction scheme.

$$C_6H_5CH_2CH_2D(\text{excited}) \rightarrow C_6H_5CH_2\cdot + CH_2D\cdot$$
$$CH_2D\cdot + C_6H_5CH_2CH_2D \rightarrow CH_3D + C_6H_5\dot{C}HCH_2D$$
$$2\ CH_2D\cdot \rightarrow CH_2DCH_2D$$

The presence of about 20% C_2H_5D in the products can be explained by the reaction of undeuterated ethylbenzene contained in the reactant.

Effect of Pressure of Ethylbenzene and Xenon on $R_{C_2H_6}$, R_{CH_4} and R_{H_2}. The effect of pressure of ethylbenzene on $R_{C_2H_6}$, R_{CH_4} and R_{H_2} was investigated at 150°C. The variable range of pressure of ethylbenzene was limited in a narrow range due to its low vapor pressure, but we see that a maximum exists in $R_{C_2H_6}$ at 1 Torr, but no maximum for R_{CH_4} and R_{H_2} (Fig. 2). Sehon and Darwent[4] observed a similar maximum in the quantum yield of hydrogen at 2 Torr, but no maximum for methane and ethane in the mercury-photosensitized decomposition of toluene. An interpretation of the decrease of the rates of formation below 1 Torr may not be so simple, as Cvetanović pointed out.[1] The incomplete quenching of excited mercury atom by ethylbenzene and/or the inefficient absorption of radiation due to the decrease of pressure broadening[10] might cause the fall-off. The decrease of $R_{C_2H_6}$ above 1 Torr is understood in terms of the collisional deactivation of excited ethylbenzene of relatively long lifetime by normal ethylbenzene as proposed in the case of ethylene[11] and toluene.[4] A good linearity was obtained by plotting $1/R_{C_2H_6}{}^{1/2}$ against pressure of ethylbenzene, although the pressure is

limited to a narrow range. We investigated the effect of pressure of Xe on $R_{C_2H_6}$ up to 66 Torr, keeping the pressure of ethylbenzene at 2.0 Torr at 150 °C. A good linearity was also obtained between $1/R_{C_2H_6}$ and the pressure of Xe, as shown in Fig. 3. The fact that $R_{C_2H_6}$ decreased with the increase of the pressure of ethylbenzene or of Xe indicates that the concentration of methyl radical decreased with the increase of pressure of these quenching substances. R_{CH_4} is almost constant above 1 Torr of ethylbenzene. This might be qualitatively interpreted by considering the compensation of the decrease of methyl radical concentration by the increase of ethylbenzene (see equation (3)). The behavior of R_{H_2} against the pressure of ethylbenzene is apparently similar to that of R_{CH_4}, but the mechanism of hydrogen formation may be more complicated.

Dependence of $R_{C_2H_6}$, R_{CH_4} and R_{H_2} on Light Intensity. $R_{C_2H_6}$, R_{CH_4} and R_{H_2} were measured at 150 °C at 2 Torr of ethylbenzene, varying the light intensity with blackened copper gauzes. When log R^0/R is plotted against log I^0/I, where R^0 and I^0 are the reaction rate and light intensity, respectively, without gauze, a good linearity for $R_{C_2H_6}$, R_{CH_4} and R_{H_2} each is obtained. Each slope gives 2 for ethane, 1 for methane and 0.5 for hydrogen. The findings that $R_{C_2H_6}$ is proportional to square of light intensity and that R_{CH_4} is proportional to light intensity suggest that some biphotonic process may be involved.

Many studies have been reported[12] on photophysical and photochemical processes by flash technique involving biphotonic processes. However, even in steady irradiation experiments with usual lamps several studies[13a-d] indicate the participation of some biphotonic process. Strausz and Gunning[13d] reported that in the mercury-photosensitized decomposition of carbon dioxide at 253.7 nm the rate of decomposition of carbon dioxide is proportional to the square of light intensity. Considering that the mechanism of formation of ethane is most simple in the present system, we will discuss mainly the mechanism of formation of methyl radical. In order to interpret result where $R_{C_2H_6}$ is proportional to the square of light intensity, the following three mechanisms are considered for a possible biphotonic process to produce methyl radicals.

$Hg + h\nu \rightarrow Hg^*$	I_a	common to all three processes below
$Hg^* \rightarrow Hg + h\nu$	k_2	
$Hg^* + E \rightarrow Hg + E^*$	k_3	
$E^* + E \rightarrow 2E$	k_4	
$E^* + Xe \rightarrow E + Xe$	k_5	
(a) $E^* + h\nu' \rightarrow E^{**}$ (triplet)		possible three processes
or		
(b) $E^* + Hg^* \rightarrow E^{**}$ (singlet or triplet) + Hg		
or		
(c) $E^* + E^* \rightarrow E^{**}$ (singlet or triplet) + E	k_6	
$E^{**} \rightarrow C_6H_5CH_2\cdot + CH_3\cdot$	k_7	common to all three processes
E^{**}(singlet) $\rightarrow E + h\nu''$	k_8	
$CH_3\cdot + CH_3\cdot \rightarrow C_2H_6$	k_9	
$CH_3\cdot + E \rightarrow CH_4 + C_6H_5\dot{C}HCH_3$	k_{10}	

(E is ethylbenzene)

At present, we have no conclusive evidence to select one mechanism from these three, but process (c) seems to be most suitable to interpret our experimental results. In process (2), T-T absorption of 253.7 nm

A. Gibbons, F. T. Lang, G. Porter, and M. I. Savadatti, *Trans. Faraday Soc.*, **62**, 1793 (1966), d) O. P. Strausz and H. E. Gunning, *Can. J. Chem.*, **39**, 2244 (1961).

by triplet ethylbenzene is assumed. Burton and Hunzicker[2] reported the absorption spectra of triplet benzene and toluene formed by $Hg(^3P_0)$. T–T absorption spectrum of toluene covers the region 210—370 nm. A similar absorption spectrum can be expected for ethylbenzene. However, the amount of light absorbed by triplet ethylbenzene under our experimental conditions should be very small, considering the fact that our light source consists of atomic lines of a low pressure mercury lamp and that the molar extinction coefficient of triplet ethylbenzene may be much less than that of mercury. Assuming process (a) or (b), the rate equations in terms of pressure of ethylbenzene or Xe and light intensity were derived, but they were not in line with our experimental results. If process (c) is assumed, the following expression is derived.

$$R_{C_2H_6} = \frac{k_3^2 k_6 [E]^2 I_a^2}{(k_2 + k_3[E])^2 (k_4[E] + k_5[Xe])^2} \quad (2)$$

In this derivation we assumed that $k_4[E]+k_5[Xe] \gg k_6[E^{**}]$ and $[CH_3]^2 k_9 \gg [CH_3][E]k_{10}$. The first assumption may be justified if we consider that the quantum yields of ethane and methane are fairly small (less than 0.10). The second assumption is generally used in the competitive reactions of abstraction and recombination of methyl radical. We also neglected the radiative process of E**, but this is not essential in the interpretation of pressure and light dependence in the rate expression. The above expression is consistent with the results where $R_{C_2H_6}$ is proportional to the square of light intensity, and the linear relationship between $1/R_{C_2H_6}^{1/2}$ and pressure of ethylbenzene or Xe is satisfied. From the slope of the plot in Fig. 4, we can calculate k_4/k_5 to be about 39, indicating that ethylbenzene is much more efficient as a quencher than Xe. In a similar way, we can derive the following expression for R_{CH_4}.

$$R_{CH_4} = \frac{k_{10}}{k_4}\left(\frac{k_3 k_6}{k_9}\right)^{1/2} \frac{I_a[E]}{(k_2 + k_3[E])} \quad (3)$$

This is consistent with the experimental result where R_{CH_4} is proportional to light intensity and approaches a constant value at high pressure of ethylbenzene.

Comparison of the Rate of Formation of Methyl Radical with That of Hydrogen Atom. A comparison of excitation transfer process with hydrogen atom abstraction process might be of interest, if both processes actually take place in ethylbenzene. There can be no doubt that methyl radical formation proceeds through excited ethylbenzene, but the mechanism of hydrogen formation in the present system is not conclusive. For the formation of atomic hydrogen, the following two processes are possible, (a) abstraction of hydrogen atom from ethylbenzene by excited mercury atom, and (b) decomposition of excited ethylbenzene to produce hydrogen atom. At present, we have no evidence to differentiate the two processes from a consideration of our experimental results, and we therefore can not eliminate the possibility of simultaneous occurrence of excitation transfer process and abstraction process. We tentatively calculated the values $(R_{CH_4}+2R_{C_2H_6})/R_{H_2}$ under various pressures of ethylbenzene, considering the values may correspond to the ratio of rate of production of methyl radical to that of hydrogen atom. Since R_{CH_4} and R_{H_2} do not vary remarkably with pressure of ethylbenzene above 1 Torr (Fig. 2), the value $(R_{CH_4}+2R_{C_2H_6})/R_{H_2}$ mainly depends on the change of $R_{C_2H_6}$, which gradually increases with the decrease of pressure. We obtained the value of about 17 for the ratio in the pressure range 0.6—2 Torr.

The Effect of the Reaction Temperature on $R_{C_2H_6}$, R_{CH_4} and R_{H_2}. We investigated the change of $R_{C_2H_6}$, R_{CH_4} and R_{H_2} with respect to reaction temperatures 100—350 °C at constant light intensity. The pressure of ethylbenzene was kept at 2 Torr at each temperaute. $R_{C_2H_6}$ increases first up to 250 °C and begins to decrease above 250 °C, while R_{CH_4} increases gradually in the whole temperature range. The behavior of $R_{C_2H_6}$ is not completely understood, but its increase up to 250 °C indicates that the rate constant of decomposition of excited ethylbenzene (k_7) is dependent on the reaction temperature, considering that the rate constant of recombination of methyl radicals is almost independent of temperature. Although the amounts of energy contained in E* and E** are not known, it is rather surprising that the decomposition of E** is dependent on temperature, since the bond energy of $C_6H_5CH_2$–CH_3 is reported to be only 63 kcal/mol.[14] The amount of energy of E* must be in the range from the lowest triplet level of ethylbenzene (probably ~85 kcal/mol) up to 112 kcal/mol, which is the maximum amount of energy transferable from $Hg(^3P_1)$. The decrease of $R_{C_2H_6}$ above 250 °C may be partly interpreted by considering the increase of R_{CH_4} with temperature, but the fact that the sum of $2R_{C_2H_6}+R_{CH_4}$ still decreases above 250 °C is not understood yet.

In order to calculate the activation energy of hydrogen abstraction process by methyl radical from ethylbenzene, we derived the following equation by combining equations (2) and (3), assuming $E_9 \cong 0$

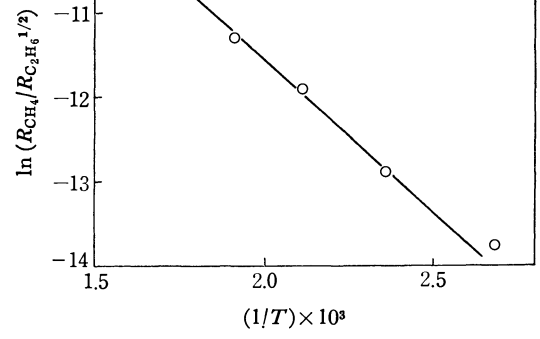

Fig. 5. Arrhenius plot of $R_{CH_4}/R_{C_2H_6}^{1/2}$ at a constant concentration of ethylbenzene in the temperature range from 100 to 350°C.

14) M. Szwarc, *J. Chem. Phys.*, **17**, 431 (1949).

$$R_{CH_4}/R_{C_2H_6}{}^{1/2}[E] = k_{10}/k_9,$$

or

$$\log k_{10}/k_9 = R_{CH_4}R_{C_2H_6}{}^{1/2}[E] = E_{10}/RT + \log A_{10} - \tfrac{1}{2}\log A_9$$

$\log k_{10}/k_9 = \log R_{CH_4}/R_{C_2H_6}{}^{1/2}[E] = E_{10}/RT + \log A_{10} - 1/2 \log A_9$. Thus, $R_{CH_4}/R_{C_2H_6}{}^{1/2}$ obtained keeping the pressure of ethylbenzene at 2 Torr at each temperature should be recalculated by dividing it by [E] at each temperature. The Arrhenius plot, recalculated log $R_{CH_4}/R_{C_2H_6}{}^{1/2}$ against $1/T$, gives a good linearity (Fig. 5). From the slope we obtained 7.1 kcal/mol for the activation energy of abstraction of methyl radical, comparable with the reported values of the abstraction of methyl radical from toluene, which are rather scattered as 7[15 a)], 7.3[b)], 9.5[c)] and 11.0[d)] kcal/mol according to the source of radicals and to the authors. It is found that R_{H_2} also depends on temperature, but since we cannot obtain a unique rate expression for R_{H_2}, we tentatively calculated an apparent activation energy from the Arrhenius plot of R_{H_2} which gives the value of 4.1 kcal/mol.

We would like to thank Mr. H. Horiguchi for valuable comments and also Mr. S. Hirano and Mr. M. Takakubo for their assistance in the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1053—1055 (1973)

The Temperature Dependence of the Nuclear Quadrupole Resonance of ^{35}Cl in $KClO_3$, $AgClO_3$, $Ba(ClO_3)_2 \cdot H_2O$, and $Cu(ClO_3)_2 \cdot 6H_2O$

Masahiko SUHARA

Department of Chemistry, Faculty of Science, Kanazawa University, Maru-no-uchi, Kanazawa

(Received May 8, 1972)

The nuclear quadrupole resonance (NQR) frequencies of ^{35}Cl in $KClO_3$, $AgClO_3$, $Ba(ClO_3)_2 \cdot H_2O$, and $Cu(ClO_3)_2 \cdot 6H_2O$ have been measured as a function of the temperature in the range from 77 to 350 K at a constant (atmospheric) pressure. These data have then been analyzed by the method of Brown. The torsional frequencies of the ClO_3^- ion in the crystals have been determined by fitting the experimental data with the Bayer theory, modified by taking into account the anharmonicity in torsional oscillation. The low barrier height obtained in Cu salt indicates that a freer rotational motion of the chlorate ion is to be expected in this crystal.

Many attempts have been carried out to investigate the torsional oscillation in crystals through the NQR experiments. One approach is to determine the torsional frequency by measuring the temperature and the pressure dependences of the NQR frequencies by means of the theoreis developed by Bayer,[1] Kushida,[2] and Kushida, Benedek and Bloembergen.[3] Another approach is to study the characteristics of the torsional or reorientational motion by measuring the NQR linewidth or the relaxation times as a function of the temperature.

The present investigation is of the former type. At lower temperatures, the Bayer theory (if there is a small torsional amplitude, so that the harmonic oscillation approximation is valid) gives a reliable torsional frequency in many cases, though not at very low temperatures. At higher temperatures, a large discrepancy appears between the theory and the experimental results. The purpose of the present work is to estimate the magnitude of the anharmonicity, using the quasi-harmonic approximation and assuning that the discrepancy originates from the anharmonic character of the torsional oscillation.

Experimental

The NQR signal was detected by means of a Kushida-type regenerative oscillator detector,[4] with a Zeeman modulation of an antisymmetric sinusoidal magnetic field of 30 Hz. The detected signals were suitably amplified by means of an audio-amplifier and automatically recorded on a chart (Hitachi Model QPD-33) through a lock-in-amplifier (NF Circuit Design Block Co., Model LI-572A). The resonance frequency was measured by means of pip marks at 1-kHz intervals on a chart which was generated by a frequency counter (Matsushita Communication Ind. Co., Model VP-0428). The details of the spectrometer system have been reported elsewhere.[5]

The accuracy in the frequency measurement is ± 0.1 kHz at the temperature of liquid nitrogen or at the freezing temperature of coolants, and is $\pm(0.2 \sim 0.1)$ kHz when the temperature is regulated by letting in cold nitrogen gas evaporated from the liquid-nitrogen container by heating it with a small heater. Combining with a chart-recorder voltmeter (Shimadzu Seisakusho, Ltd., Model A-521) for recording the junction voltage, a copper-constantan thermocouple was used to measure the temperature; it was affixed to the sample tube, which had been calibrated by the boiling temperatures of liquid nitrogen, benzene, and water,

the sublimation temperature of dry ice, and the triple point of water. The error in the temperature measurement was ±0.5 K, which causes an ambiguity in the resonance frequency of ±1 kHz.

The calculation of the best-fitting parameters in the theoretical equation was carried out by using a digital computer, FACOM 230-35, at Kanazawa University. The errors in the calculated parameters were estimated by assuming the condence coefficient to be 0.99.

The $AgClO_3$ was prepared by mixing hot aqueous solutions of 0.5 M of $AgNO_3$ and 0.5 M of $NaClO_3$, cooling the mixture in a refrigerator, filtering the crystals, and repeating the recrystallization. The sample must be kept in the dark. The $KClO_3$ and $Ba(ClO_3)_2 \cdot H_2O$ were commericial grade materials purified by repeating the recrystallization from hot water. The $Cu(ClO_3)_2 \cdot 6H_2O$ was obtained by mixing a hot aqueous solution of 1 M of $CuSO_4 \cdot 5H_2O$ and $Ba(ClO_3)_2 \cdot H_2O$, filtering off the $BaSO_4$ by means of No. 50 filterpaper, evaporating the blue filtrate at room temperature by a vacuum pump, filtering the crystals, and then repeating the recrystallization from cold water.

Results and Discussion

The NQR of ^{35}Cl in K, Ag, Ba, and Cu chlorates has been detected from 77 K to 350 K. The observed spectrum of each chlorates consists of a single line. This fact indicates that all the chlorate ions in a unit cell are located in crystallographically-equivalent positions; this could be expected from the crystal structure except for the Cu salt, whose structure has not been known. The resonances of the K and Ag salts were rather more intense than others throughout the temperature region examined.

The temperature dependence of the resonance frequency is shown in Fig. 1, together with the results of the previous works. The resonance frequencies of these four chlorates at the temperature of liquid nitrogen were in good agreement with the reported data, but at room temperature there was a large discrepancy between Moshier's results[6] and the present ones except in the case of K salt. When the temperature variation was repeated (by increasing or decreasing it), the temperature dependence showed a good reproducibility, so the phase transitions have not been detected in all the chlorates. The intensity of each line decreased with an increase in the temperature.

The experimental data were analyzed by the method of Brown,[7] in which the temperature dependence of the resonance frequency is represented by a polynomial of the form:

$$\nu(T) = a_0 + a_1 T + a_2 T^2 \qquad (1)$$

where:

$$a_0 = \nu_0$$
$$a_1 = -3ka_0/(4\pi^2 \nu_{t0}^2 \Theta)$$
$$a_2 = 2a_1 g$$

$\nu(T)$ and ν_0 are the NQR frequencies at T and 0 K respectively, Θ is a constant moment of inertia, and ν_{t0}, a torsional oscillation frequency. In this analysis,

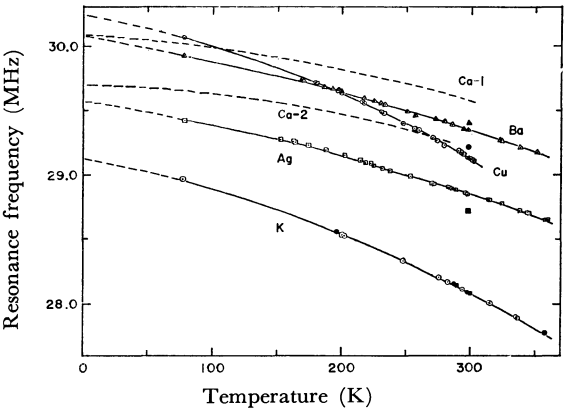

Fig. 1. Temperature dependence of the NQR frequencies of ^{35}Cl in several chlorates.
The quoted data are indicated by the corresponding solid symbols except Ca salt, for which the broken lines are used.

a quasi-harmonic approximation for the anharmonic oscillation is used; the temperature variation in the torsional frequency is assumed to be:[8]

$$\nu_t = \nu_{t0}(1 - gT) \qquad (2)$$

with g a small positive constant. From the experimentally-determined values of a_0, a_1, and a_2, the values of ν_{t0} and g have been evaluated, using 83×10^{-40} g·cm² as the value of Θ. The results are summarized in Table 1. together with the values for Ca salt obtained by Kumar and Nageswara Rao.[9] The uncertainties in the g and ν_t values were $\pm 0.2 \times 10^{-4}$ K^{-1} and ± 2 cm^{-1} respectively. The a_1 values for the four chlorates are of the same order of magnitude, but the a_2 values for Ag and Ba salts are rather smaller than those of the others. On the other hand, the a_1 value in Ca salt is significantly smaller than those of the four chlorates, although the a_2 values lie in the middle between them. Since the values of a_0 in all the chlorates considered are 29~30 MHz, the difference in the coefficient, a_1, indicates the difference in the torsional frequency at 0 K, when all the chlorate ions have the same value of the moment of inertia. The torsional frequencies at 0 K and 300 K are also shown in Table 1.

Using different assumptions and methods, the temperature dependence of the resonance frequency of ^{35}Cl in $KClO_3$ has been analyzed in various temperature regions by three authors.[3,10,12] The torsional frequency thus obtained has been compared with the room-temperature values[11] of the Raman lines; 54, 82, 98, 127, and 145 cm^{-1}.

From the present analysis, which differs from the above three the torsional frequency at room temperature, was found to be $\nu_t(300)=81$ cm^{-1}, which was in agreement with the observed Raman line[11] at 82 cm^{-1} at 297 K. The g value was found to be 1.47×10^{-3} K^{-1}, which was larger than the 2×10^{-4} K^{-1} for the 98 cm^{-1} line; the temperature coefficient for the 82 cm^{-1} line has not been measured, however.

Recently, the temperature dependence of the resonance frequency in $Ba(ClO_3)_2 \cdot H_2O$ has been independently measured by Ramanohan and Sobhanadri.[13] The same procedure as that in the present study has been employed to analyze the experimental data. The parameters obtained by them give the values of 30039.7 kHz, −1.45 kHz/K, and -3.28×10^{-3} kHz/K^2 for a_0, a_1, and a_2 respectively; these values are in agreement with the present results. The torsional frequency of 125 cm^{-1} at 300 K is also in good agreement with the present finding.

If a simple sinusoidal potential for the torsional oscillation in crystal is assumed, the frequency, ν_t, is given by:[14]

$$\nu_t = (n/2\pi)\sqrt{V_0/(2\Theta)} \qquad (3)$$

where V_0 is the height of the potential barrier with an n-th-fold symmetry. In Table 1, the calculated V_0 values are shown. The potential barrier substantially decreases with an increase in the temperature. This indicates that the chlorate ion may rotate at the crystal site at room temperature; then the torsional oscillation has a large amplitude, so anharmonic motion takes place. In Ag and Ba salts it can be seen that the torsional motion of the chlorate ion as a whole hardly occurs, even at room temperature. On the other hand, a freer rotational motion can be expected in Ca and Cu salts from the low barrier height, which is of nearly the same order as, or several times larger in magnitude than that in organic molecular crystals—*i.e.*, it is of the order of 10 kcal/mole.[15] In Ca salt, it is clear from the results reported by Kumar *et al.*[9] that ν_2 has an anomalous temperature dependence. A very large g value gives a negative $(1-gT)$ factor at room temperature. Although Kumar *et al.* did not discuss this fact, it can be suggested that the present method for the analysis of the experimental results can not be used to illustrate the motion of the chlorate ion in the crystal site corresponding to ν_2.

The author wishes to thank Professor S. Aono for his encouragement and Mr. H. Ichikawa for the preparation of the sample.

Line Shapes of the ^{35}Cl Nuclear Quadrupole Resonance in $KClO_3$, $AgClO_3$, $Ba(ClO_3)_2 \cdot H_2O$, and $Cu(ClO_3)_2 \cdot 6H_2O$

(Received May 8, 1972)

The nuclear quadrupole resonance (NQR) of ^{35}Cl in $KClO_3$, $AgClO_3$, $Ba(ClO_3)_2 \cdot H_2O$, and $Cu(ClO_3)_2 \cdot 6H_2O$ at room temperature has been measured by using a spectrometer system capable of reproducing with fidelity the line shape. The line-shape parameters were determined from the observed spectrum. All the line shapes of the four chlorates are of an intermediate character between Gaussian and Lorentzian. The line-width in K and Ag salts seems to originate from the inhomogeneity of the electric-field gradient, itself a result of the imperfection of the crystal. In Ba salt, it was found that the line-width is determined by the magnetic dipole-dipole interaction between chlorine and protons in the water of crystallization. The Lorentzian is the superior component of the line shape in Cu salt. This is explained in terms of the anharmonicity of the torsional oscillation of the ClO_3^- group.

Most of the works on the NQR line shape have dealt with the line-width rather than with the actual line shape. This is also the case in the investigations of NQR in chlorates. Wang[1] studied the temperature change of the full half-width in $NaClO_3$ and found that the width increases with a decrease in the temperature. Zeldes and Livingston[2] observed the full width between the flex of the second derivative of the spectrum in $NaClO_3$, $KClO_3$, and $Ba(ClO_3)_2 \cdot H_2O$, and found the sharpest line in $KClO_3$. Grechishkin[3] measured the full half-width in $Ba(ClO_3)_2$, $KClO_3$, and $NaClO_3$ by using a super-regenerative spectrometer, which does not generally give the actual line shape. More precise observations have been reported by Koi and his co-workers[4,5,6] on the Br NQR line in $NaBrO_3$ and $KBrO_3$ using a regenerative spectrometer. However, no precise line-shape study has been done in metal chlorate. We have now determined the line-shape parameters in several chrorates by using a spectrometer capable of reproducing the line shape with fidelity.

Experimental

The NQR line was detected by utilizing a Kushida-type regenerative oscillator[7] with a magnetic field modulation of a 200 Hz on-off field. The spectrum was recorded on a chart by means of a lock-in detection technique, together with pip marks at 1 kHz intervals. In order to obtain an undistorted line shape, the rf level was kept as weak as possible, the sweep rate was 2 kHz/min, and the time constant, 0.3 sec. Details of the spectrometer system have been given in a previous paper.[8] During the observation, the temperature of the sample was maintained within 0.01 K, which corresponds to the shift of the resonance frequency of ~0.05 kHz. The accuracy of the temperature measurement was ±0.5 K. The chlorates were prepared in the usual way.[9]

Line-shape Analysis

A block diagram of the process of the line-shape analysis from the observed spectrum is shown in Fig. 1, together with the line-shape parameters to be determined. The analysis was performed by means of a NEAC 2230 computer at Kanazawa University.

The In-put Data consisted of the reading of the out-put voltage on the recorded chart with a constant frequency interval (order of 10^{-2} kHz), the number

of sample points (200~300), and the frequency at initial point.

Smoothing and Differentiation. When the observed spectrum has a poor S/N ratio, a least-squares smoothing technique (convolution method)[10] is employed to determine the smoothed spectrum. The m-th derivative of the original spectrum can also be obtained by a similar technique. Details of the technique were given by Savitzky and Golay.[11] The smoothing interval chosen is smaller than half of the full line-width at half-maximum intensity, seventeen sample points being included in this interval. Under these conditions, the line distortion error is expected to be smaller than 1%.[10] When a small base-line drift occurs, the true absorption spectrum can be obtained by subtracting the drift from the observed spectral intensity on a chart. The drift was assumed to be linear; by means of the least-squares method, the linear equation was determined using the ten data points, which consisted of two blocks of five successive sample points from both terminals of the frequency in the observed spectrum.

Separation of Gaussian and Lorentzian. Assuming the observed absorption curve to be a convolution of Gaussian and Lorentzian shape (Voigt profile), the full half-widths of each component ($\Delta\nu_G$ and $\Delta\nu_L$) can be determined by the Fourier transformation of the spectrum.[12] Using the least-squares method to fit the logarithm of cosine-transform of the observed spectrum to a quadratic function of the time, the linear and quadratic coefficients give the values of $\Delta\nu_L$ and $\Delta\nu_G$ respectively.

The reliability of the process and the results of the analysis were confirmed by checking the consistency between the observed value, $\Delta\nu_{1/2}$, and the calculated one, $\Delta\nu_{1/2}{}^c$. According to the steps:

(i) $a = \Delta\nu_L/[(\ln 2)^{-1/2}\Delta\nu_G]$, (ii) $a \xrightarrow[\text{Table}]{\text{Posener's}} \omega$,

(iii) $\Delta\nu_{1/2}{}^c = \Delta\nu_G\omega/(\ln 2)^{1/2}$,

the $\Delta\nu_{1/2}{}^c$ value was calculated from the $\Delta\nu_G$ and $\Delta\nu_L$ values by using the relationship between the a and ω parameters in the table[13] of the Voigt profile.

A Gaussian function was examined in order to check the error in the processes shown in Fig. 1. An excellent reproducibility of the line-shape parameters was obtained, as is shown in Table 1.

Results and Discussions

For all the chlorates, the S/N ratio of the observed spectrum was 10~20 even when using a slow sweep and a short time constant. An example is given in Fig. 2, in which the original spectrum and the true absorption line after smoothing and the base-line-drift correction are compared. The absorption line shapes of the four chlorates were almost symmetrical. The values of the first moment were smaller than ±0.1 kHz. The relative intensities of the chlorates of K and Ag were larger than those of Ba and Cu. The results of the measurement are summarized in Table 2. The full width between the half-maximum intensities ($\Delta\nu_{1/2}$), the full width between maximum slopes ($\Delta\nu_{msl}$), and second and fourth moments increase in the order (K, Ag), Ba, and Cu salts. The $\Delta\nu_L$ and $\Delta\nu_G$ values for each chlorate are also given in Table

2, together with the values of $\Delta\nu_{1/2}{}^C$. The excellent agreement between $\Delta\nu_{1/2}$ and $\Delta\nu_{1/2}{}^C$ indicates that the values of $\Delta\nu_L$ and $\Delta\nu_G$ for the four chlorates we obtained are reliable. Thus, it was found that each of the resonance lines of the four chlorates has an intermediate character between Gaussian and Lorentzian. In K salt, the line shape is close to Gaussian. On the other hand, a large amount of Lorentzian contributes to the line shape in Cu salt. Several spectral parameters are compared in Table 3, in which a relation similar to that seen in Table 2 is found.

The possible mechanisms of the line broadening are as follows: (1) quadrupole spin-lattice relaxation, (2) magnetic dipole-dipole interaction, and (3) field fluctuation due to the crystal strain. From (1) a Lorentzian shape would result, and from (2), a Gaussian, if there are many interacting neighbours. The line shape due to (3) depends on the nature of the strain. However, the second and the third mechanisms are assumed to give a single Gaussian shape. Koi[5] found that the main cause of the line-width of the $NaBrO_3$ crystal is the magnetic dipole interaction and that the contribution from the relaxation to the line-width is very small, since the ratio of the line-width for the ^{79}Br and ^{81}Br isotopes is equal to 0.94, agreeing closely with 0.928, the ratio of their magnetic dipole moments. Koi *et al.*[6] also reported that, in $KBrO_3$, the crystal strain is primarily responsible for the observed Br NQR line-width. Hashi[14] found that the free-induction-decay curve on Br NQR in $NaBrO_3$ has a Gaussian shape and that its decay time, $T_2{}^*$, is mostly determined by the distribution of the electric-field gradients in the crystal due to strain, imperfections, or temperature gradient. For $KClO_3$ and $AgClO_3$, the line shape we observed was almost Gaussian. The mechanism which contributes to the line-width is probably due to mechanism (2) and/or (3). Weber[15] observed that the free induction signals of the Zeeman components, the α and α' resonances, exhibit an increased decay lifetime relative to the lifetime in the zero-field resonance. It was found that the observed increase agrees with the predicted value obtained from the second moment, $\langle\Delta\nu^2\rangle = 0.0127$ (kHz)^2, due to the magnetic dipole interaction, calculated by the equations of Abragam and Kambe.[16] The observed second moment in $KClO_3$ was greater than the calculated one by one order of magnitude. A similar calculation of the second moment in $AgClO_3$ gave the value of $\langle\Delta\nu^2\rangle = 0.0058$ (kHz)^2. calculated by using the crystal parameters of $AgClO_3$[17] by means of NEAC 2230. In $AgClO_3$ as well as in $KClO_3$, the calculated second moment is considerably smaller than the observed one. Even the second moment expected from the value of $\Delta\nu_G$ does not agree with the calculated one. It can, therefore, be concluded that the mechanism which contributes to the $\Delta\nu_G$ values in $KClO_3$ and $AgClO_3$ might be mainly due to the random distribution of the electric-field gradient originating from the strain in the crystal. Using the crystal parameters of $Ba(ClO_3)_2 \cdot H_2O$,[18,19] we found that the line-width, $\Delta\nu_G$, corresponding to the calculated second moment, is 2.5 kHz and that it is mainly determined by the protons in the water of crystallization. In contrast to K and Ag salts, the rough agreement between the calculated line-width and the observed one indicates that the dominant effect on the Gaussian width in Ba salt is the magnetic

dipole interaction between the chlorine nucleus and the proton. Although the crystal parameters are not known in $Cu(ClO_3)_2 \cdot 6H_2O$, it is considered that the observed line-width also originates from the dipolar interaction, as in the case of Ba salt, since many protons in the water of crystallization can give a broad line-width.

It is reasonable to consider that the Lorentzian width is attributable to the lifetime in the energy states of the nuclear spin system. A general theory of line shape was developed by Freed and Fraenkel[20] in terms of a relaxation matrix theory. They have shown that a composite line arising from a set of degenerate nuclear-spin states should, in general, consist of a sum of superimposed lines of the Lorentzian shape with different widths rather than a single line with an overall Lorentzian shape. However, as a limiting case, a single Lorentzian line is still obtained when the torsional oscillation in the crystal is represented a simple model in which, in am olecular frame, the by field gradient has a cylindrical symmetry around the oz axis (since the asymmetry parameter in chlorates has the value of almost zero, all the chlorates satisfy this condition); the motion of this frame is the rotation of oz by a small angle, θ, around a position of stable equilibrium, oZ, in a plane perpendicular to the axis, oX, of the laboratory frame. The time-dependent perturbation responsible for the broadening of the NQR line is thus given by:[21]

$$H_1(t) = A\left\{-\frac{1}{2}(\theta^2-\overline{\theta^2})[3I_z^2-I(I-1)] - \frac{3}{4}(\theta^2-\overline{\theta^2})(I_+^2+I_-^2) - 3\theta(I_zI_y+I_yI_z)\right\} \quad (1)$$

where $A=e^2qQ/4I(2I-1)$ However, it is easy to prove that, for half-integral spins, the two transitions, $m\rightarrow(m-1)$ and $-m\rightarrow-(m-1)$, are actually uncoupled, all the off-diagonal elements of the relaxation matrix being zero for the Hamiltonian $H_1(t)$. Each $m\rightarrow(m-1)$ transition is thus a simple line that has the shape of a single Lorentzian. For $I=3/2$, the line width, $1/T_2$, is expressed in terms of the spectral density functions of the random functions, $\theta^2(t)-\overline{\theta^2}$ and $\theta(t)$. The non-adiabatic terms in Eq. (1) also cause a spin-lattice relaxation, the decay time (or relaxation time, T_1) of which is expressed in terms of the same spectral density functions as in the case of T_2. In view of the fact that the quadrupole resonance frequency is small relative to the reciprocal of the correlation time for the random functions, the spectral density is assumed to be independent of the frequency. By using a damped oscillator model for the effect of the thermal bath, when the frequency distribution of the torsional oscillation is relatively sharp, the relation between the Lorentzian width, $1/T_2$, and the reciprocal of the spin-lattice relaxation time, $1/T_1$, is given by:[22]

$$1/T_2 = (7/2)(1/T_1) \quad (2)$$

In ionic crystals the additional relaxation due to crystal lattice vibrations should be considered. Chang[23] developed a general theory of quadrupole spin-lattice relaxation in solids based on the interaction of the quadrupole moment of the nucleus with the fluctuating crystalline electric-field gradient produced by thermal lattice vibrations of neighboring electronic charges. Although the theory was confirmed by the measurement[24] of the temperature dependence of T_1, Weber[15] found that the measurement of T_1 does not provide a critical test of the correctness of the model and that the Chang theory is inadequate for the ^{35}Cl relaxation in ClO_3^- groups, whereas the Bayer theory is consistent with the measurement of the individual transition probabilities corresponding to $\Delta m=\pm1$ and $\Delta m=\pm2$ by using a selective excitation experimental technique.

If the observed line-width for a Lorentzian component were determined by the torsional oscillation of the ClO_3^- ion in $KClO_3$, we might obtain the spin-lattice relaxation time, T_1, as about 4 msec, which is shorter by a factor of 1/5 than the reported value,[15] $T_1=21$ msec, at 300 K. It seems that the present c. w. experiment gives a much broader Lorentzian width than the one to be expected from the transient measurements. This discrepancy is probably due to the following factors: (1) A single mechanism of broadening, *i.e.*, the torsional motion, was considered. (2) Simple assumptions were used to derive Eq. (2), which was then used to obtain the line-width. (3) In the transient experiment, a large departure from the thermal equilibrium was achieved. On the other hand, the c. w. measurement was carried out without saturation. (4) The distribution of the electric-field gradient due to the strain and the imperfection in the crystal, which determine the major part of the line-width, was assumed to be Gsussian. In Ba salt, a similar discrepancy was obtained. We can not discuss Ag and Cu salts in detail because of the lack of the T_1 values. However, it should be noted that in Cu salt the superior component of the line shape is not Gaussian, but Lorentzian. If the Lorentzian width originates from spin-lattice relaxation due to the torsional oscillation of the ClO_3^- group, T_1 is found to be 0.5 msec, which is much shorter than that of $KClO_3$. This may be explained as follows. The relaxation mechanism due to torsional oscillation is mainly the transition process of $\Delta m=\pm2$, as is shown by the Bayer theory. When the temperature increases and the torsional frequency ν_t decreases, the $h\nu_t/kT$ factor becomes much smaller than unity and the transition probability corresponding to $\Delta m=\pm2$ becomes large. This situation is achieved when the anharmonicity of torsional oscillation can not be neglected;[9] from it the large temperature dependence of the torsional frequency of the ClO_3^- group has been found

in Cu salt. Since the temperature at which the linewidth measurement was carried out is relatively close to the melting point, 65°C, a vigorous lattice motion can be expected. Thus, the transition probability or the spectral function corresponding to $\Delta m=\pm 2$ must have a large value, and a large lifetime broadening can thus be expected. More detailed discussions will be possible when the temperature dependence of the line shape is investigated experimentally.

The authors wish to thank Professor S. Aono for his encouragement, Dr. A. Sado for his discussions, and Mr. H. Ichikawa for the preparation of the sample.

The Photoreduction of 2-Nitronaphthalene in 2-Propanol

Kinichi OBI, Jan W. BOTTENHEIM, and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received July 25, 1972)

The photoreduction of 2-nitronaphthalene in 2-propanol has been studied at 313 nm. The photoreduction is suppressed in the presence of dissolved oxygen or a triplet quencher such as 1,3-cyclohexadiene. The results are consistent with the triplet state of 2-nitronaphthalene being the reactive species. 2-Naphthylhydroxylamine is formed as the reaction product. The quantum yield for the disappearance of 2-nitronaphthalene is estimated to be 0.037. The low quantum yield results from the slow reaction rate of hydrogen abstraction by the $\pi\pi^*$ triplet state of 2-nitronaphthalene.

The photoreduction of simple aromatic nitrocompounds has been the subject of several recent publications.[1] Whereas the photoreduction occurs with good efficiency in the presence of protons[2,3] or such reducing agents as tri-*n*-butylstannane,[4] the reduction in alcoholic solvents is much less efficient. The photoreduction of nitrobenzene in 2-propanol[5] has been reported to occur with a low quantum yield ($\Phi \sim 0.01$). While several groups have studied the photoreduction of 1-nitronaphthalene,[3,6] no concordant conclusion has yet been obtained.

It has generally been agreed that the photoreduction of the aromatic nitrocompounds should take place through their triplet state in accordance with the aromatic carbonyl compounds, of which very extensive researches have been established rather conclusively that the $n\pi^*$ triplet state as the reacting state.[7] However, much less agreement exists as to the nature ($n\pi^*$ or $\pi\pi^*$) of the reacting triplet state of aromatic nitrocompounds.

The phosphorescence study[8] has suggested that the lowest triplet states of nitrobenzene are $n\pi^*$ and that those of 1- and 2-nitronaphthalenes are $\pi\pi^*$ states. The hydrogen abstraction reaction of the $n\pi^*$ triplet state has been widely understood, whereas generally that of the $\pi\pi^*$ triplet has not been observed or occurs at significantly lower reaction rates.

In this paper, we wish to report on the photoreduction of 2-nitronaphthalene in 2-propanol and to discuss the hydrogen abstraction reaction by the $\pi\pi^*$ triplet state of 2-nitronaphthalene.

Experimental

Chemicals. 2-Nitronaphthalene was obtained from K & K, Ltd., and was purified by recrystallization from hexane. Spectral-grade 2-propanol was obtained from Merck and was used as received.

Procedures. Unless otherwise specified, all the samples were thoroughly degassed on a high-vacuum line by freeze-pump-thaw cycles. A medium-pressure mercury lamp (Toshiba H-400P) was used as the 313 nm radiation source; it was equipped with a combination filter of a nickel sulfate solution and a Toshiba UV-31 filter, while a high-pressure mercury lamp (Toshiba SHL-1200) with a Pyrex filter was used for the ESR studies. The light intensity was measured with a potassium ferroxalate actinometer.

The disappearance of 2-nitronaphthalene was determined spectrophotometrically. The ultraviolet absorption spectra were taken with Hitachi 124 and EPS-2 spectrophotometers. The ESR spectra were measured by means of a JEOL JES-3BS-X.

Results and Discussion

The spectrum of the 2-propanol solution of 2-nitronaphthalene changed upon irradiation with 313 nm light, as shown in Fig. 1. The absorption bands of 2-nitronaphthalene at 254, 261, and 305 nm decreased, and new bands with maxima at 244 and *ca.* 280 nm appeared, as the irradiation time increased, with isosbestic points at 250, 270, and 288 nm and probably also at 330 and 340 nm. If the irradiated solution was allowed to stand for several days in contact with air,

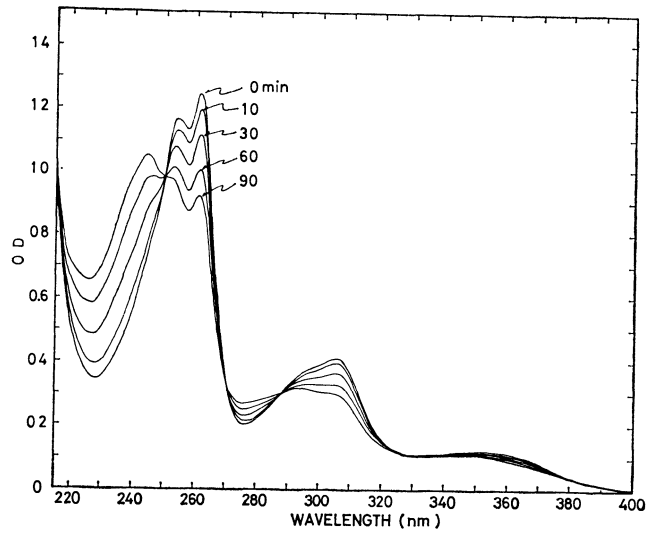

Fig. 1. Spectral change of 2-propanol solution of 2-nitronaphthalene on 313 nm irradiation.

the band of the products at 244 nm disappeared and a broad new band appeared around 520 nm assignable to the azoxy compound. By adding a small amount of hydrochloric acid to the irradiated solution, the absorption peak of the products disappeared and a new peak appeared at 233 nm, which corresponded to 2-naphthylamine hydrochloride. It has been established that N-aromatic-hydroxylamines are autoxidized to the corresponding azoxy compounds in contact with air,[9] and also undergo a reaction to give the corresponding amines when a small amount of hydrochloric acid is added.[10] Thus, a possible candidate for the products is thought to be 2-naphthylhydroxylamine. In the photolysis of 2-propanol solutions of nitrobenzene[5,10] and 1-nitronaphthalene,[6] the nitrocompounds are photoreduced to phenylhydroxylamine and 1-naphthylhydroxylamine respectively. The similar reaction is also observed in the photolysis of 4-nitropyridine-1-oxide.[11] Therefore, it is reasonable to consider the reaction product of 2-nitronaphthalene to be 2-naphthylhydroxylamine.

The quantum yields of the disappearance of 2-nitronaphthalene were measured. The yields decreased slightly with the irradiation time; the results are shown in Fig. 2. The small decline must come from the internal filter effects of the produdts. The initial quantum yield (Φ_0) of the disappearance of 2-nitronaphthalene was obtained by extrapolating it to the zero irradiation time. The 2-nitronaphthalene concentration did not affect the quantum yield, which was 0.037, as is shown in Fig. 3. In order to study the effects of the dissolved oxygen, the aerated solution was photolyzed. The results, however, showed no spectra change after a 120-min irradiation.

Quenching experiments with 1,3-cyclohexadiene were also carried out; the results are shown in Fig. 4.

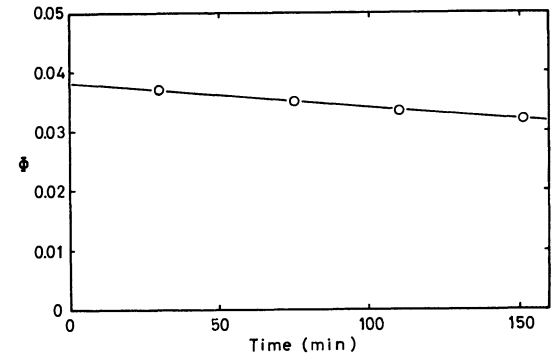

Fig. 2. Dependence of apparent disappearance quantum yields on irradiation time with 7.0×10^{-5} M 2-nitronaphthalene.

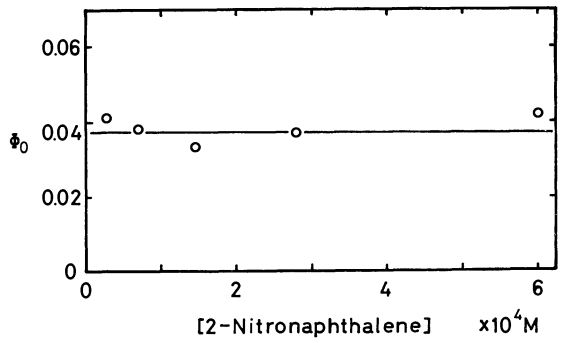

Fig. 3. Dependence of disappearance quantum yields on 2-nitronaphthalene concentration.

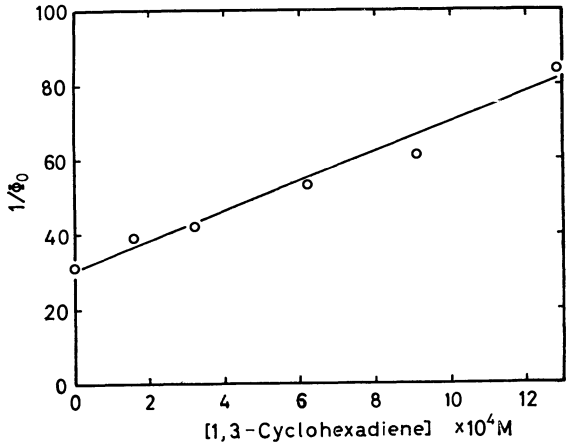

Fig. 4. Reciprocal of disappearence quantum yields *vs.* 1,3-cyclohexadiene concentration with 1.6×10^{-4} M 2-nitronaphthalene.

Since the triplet energy of 1,3-cyclohexadiene[12] (E_T= 54 kcal) is lower than that of 2-nitronaphthalene[8] (E_T=56.8 kcal), this compound is effective as a triplet quencher. The linear Stern-Volmer plots shown in Fig. 4 indicate that the triplet state of 2-nitronaphthalene plays an important role in the photoreduction. The absence of any product formation by the photochemical reaction in the aerated solution also supports the triplet mechanism.

12) N. J. Turro, "Energy Transfer and Organic Photochemistry" Wiley, New York (1969), p. 133.

According to the above discussion, the following reaction scheme is obtained:

$$S_0 + h\nu \longrightarrow S_1 \quad (1)$$

$$S_1 \longrightarrow S_0 \quad (2)$$

$$S_1 \longrightarrow T_1 \quad (3)$$

$$T_1 \longrightarrow S_0 \quad (4)$$

$$T_1 + \text{IPA} \longrightarrow \text{products} \quad (5)$$

$$T_1 + Q \longrightarrow S_0 + {}^3Q \quad (6)$$

where S_0, S_1, and T_1 are the ground state, the excited singlet state,[13] and the lowest triplet state of 2-nitronaphthalene respectively, IPA is 2-propanol, and Q is 1,3-cyclohexadiene. This scheme leads to the following equation:

$$\frac{1}{\Phi_0} = \frac{1}{\Phi_T}\left\{1 + \frac{k_4 + k_6[Q]}{k_5[IPA]}\right\}$$

where Φ_T is the quantum yield of the 2-nitronaphthalene triplet. Using the value of $\Phi_T = 0.83$ given by Rusakowicz and Testa,[8] the following values are obtained:

$$k_4/k_5[IPA] = 24.3 \text{ and } k_6/k_5[IPA] = 3.19 \times 10^4\ M^{-1}$$

Since the flash photolysis of 2-nitronaphthalene in 2-propanol at room temperature showed no triplet-triplet absorption, the lifetime of the triplet state is probably less than 20 μ sec; that is, $\tau_T^{-1} = k_4 + k_5 \times [IPA] > 5 \times 10^4\ s^{-1}$. On the other hand, the 1,3-cyclohexadiene quenching of the triplet is thought to be diffusion-controlled at the most; $k_6 \leq 3 \times 10^9\ M^{-1}\ s^{-1}$. Using these relations, the following limits are obtained:

$$5 \times 10^4 < k_4 < 2 \times 10^6\ s^{-1}$$

$$2 \times 10^3 < k_5[IPA] < 8 \times 10^4\ s^{-1}$$

$$6 \times 10^7 < k_6 < 3 \times 10^9\ M^{-1}\ s^{-1}$$

The radiationless decay rate of the triplet 2-nitronaphthalene is roughly of the same order as that of benzophenone[14] ($5.3 \times 10^5\ s^{-1}$), while it is significantly slower than that of nitrobenzene[15] ($\sim 10^9\ s^{-1}$). On the other hand, the rate of Reaction (5), which is the hydrogen abstraction reaction, is much slower than those of benzophenone[16] ($k_5[IPA] = 1.3 \times 10^7\ s^{-1}$) and of nitrobenzene ($k_5[IPA] \simeq 1.7 \times 10^7\ s^{-1}$), which is estimated from the triplet yield[15] (0.67), the radiationless decay rate[15] ($\sim 10^9\ s^{-1}$), and the disappearance quantum yield[5] in 2-propanol (0.011) of nitrobenzene. Therefore, the slower abstraction rate of 2-nitronaphthalene results in the disappearance quantum yield of 2-nitronaphthalene being lower than that of benzophenone ($\Phi = 1$).

In order to study the reaction mechanism in more detail, the ESR spectrum of the reaction intermediates

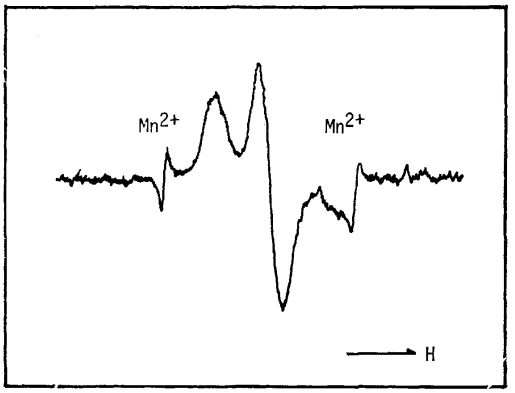

Fig. 5. ESR spectra obtained during the photolysis of 2-nitronaphthalene at −110 °C with 3.5×10^{-4} M 2-nitronaphthalene.

were measured at −110 °C. The spectrum observed at short irradiation time consists of three broad absorption lines and is shown in Fig. 5. The formation of this intermediate was saturated within about a 20-s irradiation, while no 2-propanol radicals were observed in this period. Since no radical was formed in the carbon tetrachloride solution of 2-nitronaphthalene at −110 °C, this radical is probably formed by the interaction between excited 2-nitronaphthalene and 2-propanol and would be the precursor of 2-naphthylhydroxylamine. Since the observed ESR spectrum did not give a hyperfine structure at −110 °C, it was difficult to identify the intermediate.

In the photolysis of nitrobenzene in alcohols at room temperature, $C_6H_5N(R)CH(O\cdot)OH$ and $C_6H_5NH(O\cdot)$ radicals have been observed in the primary and secondary alcohols respectively, while no alcohol radicals have been observed by means of the ESR technique.[17,18] The following reaction scheme is proposed.[18]

$$C_6H_5NO_2 + h\nu \longrightarrow C_6H_5NO_2^* \quad (7)$$

$$C_6H_5NO_2^* + RCH_2OH \rightarrow C_6H_5\dot{N}O_2H + R\dot{C}HOH \quad (8)$$

$$C_6H_5\dot{N}O_2H + R\dot{C}HOH \rightarrow \cdot OH + C_6H_5N(R)CH(O\cdot)OH \quad (9)$$

and if the alcohol is secondary, C_6H_5NOH radicals are formed. As no alcohol radicals appeared in the photolysis of nitrobenzene and 2-nitronaphthalene in 2-propanol, it seems reasonable to expect that similar reaction mechanisms are operative in the two systems. Therefore, the absence of 2-propanol radicals, which should be formed by the abstraction reaction, indicates their consumption by some secondary reactions similar to Reaction (9). However, the detailed reaction mechanism has not yet been determined.

Whereas the lowest triplet state of 2-nitronaphtha-

13) As the 313 nm absorption belongs to the second absorption band of 2-nitronaphthalene, S_1 does not mean the lowest excited singlet state.

lene has been identified as $\pi\pi^*$ by the phosphorescence study,[8] the hydrogen abstraction reaction from 2-propanol occurs with a higher quantum yield (0.037) than that (0.01) for nitrobenzene, the lowest triplet state of which[15] is $n\pi^*$. The reaction rate of the hydrogen abstraction by 2-nitronaphthalene seems likely to be slower than those by such $n\pi^*$ triplet states as benzophenone and nitrobenzene. However, the longer triplet lifetime would compensate for the slower reaction rate and may result in the relatively high quantum yield.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1063—1067 (1973)

Emission Spectra of Aromatic Halides by Controlled Electron Impact

Teiichiro OGAWA, Masaharu TSUJI, Minoru TOYODA, and Nobuhiko ISHIBASHI

Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received July 29, 1972)

Fluorobenzene, chlorobenzene, and bromobenzene were excited at a very low pressure in the vapor phase by a controlled electron beam of 60—300 V. Their emission spectra were then measured and compared with those excited by the photon. Fluorobenzene showed a characteristic photoemission of the parent molecule in the 260—320 nm region. The band was assigned to the transition from the lowest excited state to the ground state, and its shape did not vary appreciably with the energy of the electron beam. Though the spectrum had some features of "resonance fluorescence," the vibrational structure of the band was not identical with that of any of the spectra obtained by photon impact between 4.7—4.9 eV. This seems to indicate that the molecule gave different spectra according to the excitation energy. However, the excitation by 60 V electrons and that by 300 V electrons did not produce any remarkable difference in the spectra under the resolution of the spectrometer used. Other aromatic halides failed to show any characteristic band of the parent molecules; instead, they showed weak lines due to Cl^+ or Br^+ and pronounced bands due to HCl^+ or HBr^+. This result was ascribed to the spin-orbit coupling effect and the predissociation of the excited parent molecules.

Photochemical investigations of the excited states of aromatic molecules have been carried out by various authors. The effects of pressures and exciting wavelengths on the fluorescence spectra and their lifetimes have given information on the relaxation processes. However, few studies have been carried out at very low vapor pressures, and ultraviolet radiation has been used for the excitation in most of the previous studies.

Electric-discharge methods of various sorts have been effective sources of molecular excitation. The complicated character of the discharge, however, disturbs the detailed studies of the mechanism of fragmentation and excitation. The crossed electron and molecular beam method was proposed to overcome the difficulties and the emission spectra of the OH radical upon electron impact were studied.[1] Since then various di- and tri-atomic molecules have been studied by this method. This method has recently been developed for the investigation of large molecules,[2] and the emission spectra of some aromatic molecules have been reported.[3] In this controlled electron impact method, the photoemission of excited species is obtained at a very low pressure where the effect of molecular collisions is greatly reduced. The energy of electrons can be controlled from the outside. Thus, the method has proved to be of great use in studying the excited states and the emission spectra of various molecules.

The ionization and the fragmentation of molecules by electron impact have also been studied by mass spectroscopy. The information thus obtained, however, has been restricted to the ionized species, and little is known on the excited species in the ionization chamber. Thus, spectroscopic studies of the excited species by electron impact in a high vacuum would be of use.

The fluorescence of fluorobenzene in the vapor phase has been measured by Bass and Sponer[4] and by Nakamura.[5] Both the fluorescence spectra and the quantum yield have been measured at various wavelengths of excited radiation, and the mechanism of energy relaxation has been discussed.[5] If the molecules are raised to a certain vibrational level of an upper electronic state on the absorption of monochromatic light, and if the gas pressures are sufficiently low so that practically no collisions occur during the lifetime of the excited molecules, the light emission of these molecules will show a resonance fluorescence and the shape of fluorobenzene band will vary according to wavelengths of the radiation used for excitation. However, the energy values in his study were confined between 253—266 nm.[5] In the electron excitation method, the impact energy can be varied easily over a wider range, though the experimental

difficulties prevented us from using an excitation energy of less than 60 V. Chloro- and bromobenzenes are known not to show any fluorescence; this is attributable to a heavy halogen atom inducing spin-orbit relaxation.[4]

In the present study, the emission spectra of fluoro-, chloro-, and bromobenzenes under electron impact excitation will be reported. The relations of the spectra under electron impact excitation with those under photon irradiation excitation will also be discussed.

Experimental

The sample vapor from a nozzle was crossed so as to collide with an electron beam in a chamber, as is shown schematically in Fig. 1. The details of the apparatus were described elsewhere.[6] The cell was made of glass; it was 4.5 cm in diameter and 40 cm in length. The electron beam (b) from a tungsten filament (a) was accelerated by grids (not shown in the figure) and was introduced into the chamber through a slit. The sample (c) was jetted through a nozzle 0.1—1.0 mm in diameter and was excited by electrons. The chamber was evacuated (e) continuously to a high vacuum; a penning gauge attached to the chamber indicated a pressure of the order 10^{-4}~10^{-5} mmHg during electron impact. The actual pressure in the impact region was expected to be higher than the above value and smaller than 10^{-2} mmHg. The photoemission (d) was observed through a quartz window.

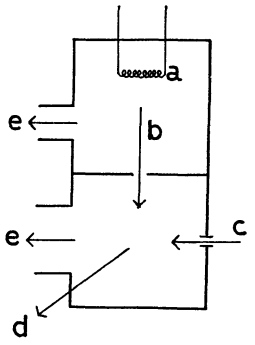

Fig. 1. Schematic diagram of the collision chamber. a; tungsten filament, b; electron beam, c; sample vapor, d; photoemission, e; to vacuum pump.

The spectra were obtained with a Jarrell-Ash JE 25 monochromator, which was equipped with two 1200 grooves/mm gratings blazed for 300 and 600 nm; it had a 100 μm slit and a reciprocal dispersion of about 33 Å/mm. The photometric measurements were carried out with an EMI 9558QB photomultiplier and a Burr-Brown 3421J OP amplifier. The mass spectrum was taken with a Hitachi RML-6E mass spectrometer. Fluorobenzene (Kishida, guaranteed grade), chlorobenzene (Kishida, guaranteed grade) and bromobenzene (Tokyo Kasei, guaranteed grade) were frozen and degassed in a high vacuum just before use.

Results and Discussion

A typical emission spectrum of fluorobenzene under electron-impact excitation is shown in Fig. 2. The

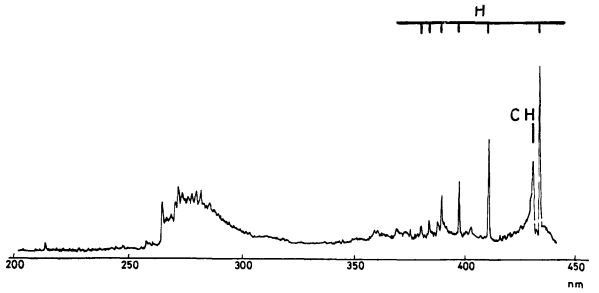

Fig. 2. Emission spectrum of fluorobenzene by electron impact. Impact voltage 200 V, electron beam current 1 mA.

band in the 260—320 nm region is similar to that of toluene,[3] which is identical to fluorobenzene in symmetry and which may, therefore, be expected to have similar vibronic interaction. The fluorine atom causes little change in the position of the absorption band around 260 nm, which is a typical band of aromatic molecules. The vibrational structure of the emission spectrum of fluorobenzene upon electron impact is similar to the fluorescence spectra in the vapor phase,[5] but not identical to any of them. Aromatic hydrocarbons such as benzene, toluene, xylenes and cumene show the band in a similar region in the electron-impact emission spectra[7] and in the fluorescence spectra,[8] as does fluorobenzene. Consequently, the observed band was assigned to the transition from the lowest excited singlet state to the ground state as in the cases of other hydrocarbons.[3,7] The other features in the spectrum in Fig. 2 were assigned to the hydrogen Balmer series and to the CH radical.

The intensities of the photoemission of fluorobenzene were determined for various amounts of incident electrons and for various gas pressures. The intensities of the emissions from H and CH were found to

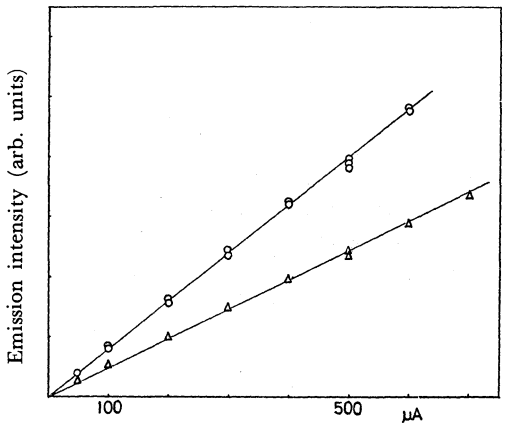

Fig. 4. Relationship between the emission intensity and the electron beam current. Intensities at 265 nm (△) and at 272 and 278 nm (○). For the sake of clarity, 12 data for each species were omitted from the figure below 100 μA, all of which lay on the same straight line. Impact voltage 200 V.

be proportional to the electron-beam current, as is shown in Fig. 3. This result is in agreement with that in the case of methane;[2] it shows that the fragmentation and the excitation of these species consist of a one-electron process. The relationship between the electron-beam current and the emission intensities of three peaks of the excited parent molecules in the 260—320 nm region is shown in Fig. 4. The excitation of a π electron of fluorobenzene was also concluded to be a one-electron process like the excitations of H and CH. The intensities of photoemissions of all species mentioned above were found to be proportional to the pressure in the gas reservoir, as is shown in Fig. 5. The pressure in the gas reservoir was estimated to be proportional to the pressure in the region of collisions by the use of a penning gauge attached to the impact chamber. Thus, inter-molecular quenching processes by collision seem to be unimportant. These results seem to indicate that the excitation

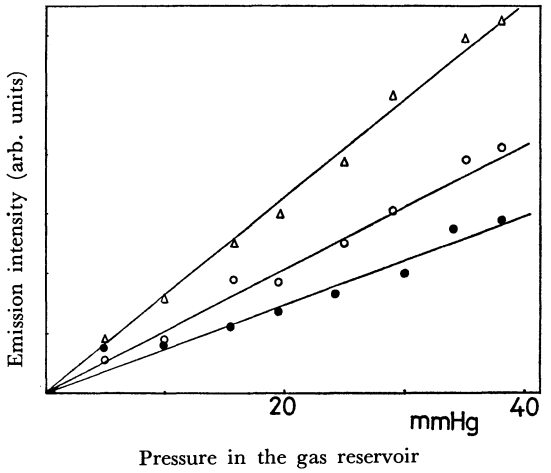

Fig. 5. Relationship between the emission intensity and the gas pressure in the gas reservior. Hydrogen Balmer series (△), CH radical (○) and the parent band at 264 nm (●). Impact voltage 200 V, electron beam current 50 μA.

and the fragmentation take place through one-electron processes, such as;

$$X \xrightarrow{e} X^* \tag{1}$$

$$X \xrightarrow{e} X^{**} \begin{cases} \xrightarrow{\text{fast}} X^* \\ \xrightarrow{\text{fast}} H,\ CH^* \cdots \end{cases} \tag{2}$$

where X stands for fluorobenzene, where ** indicates highly-excited states, and where * indicates the lower electronically-excited state from which the photoemission was observed. The relative importance of the two processes (1) and (2) could not be determined in the present study. X** would be a kind of superexcited state[9] which has excitation energy in excess of the first ionization energy. These superexcited states are considered to play an important role in the radiation chemistry[9] and in the fragmentation in mass spectrometry.[10]

The behavior of the first excited singlet state of fluorobenzene in the vapor phase was studied by Nakamura[5] by exciting the molecule with monochromatic light between 253 and 266 nm. The emission spectra varied in shape according to the wavelengths of incident radiation. The fluorescence spectra excited at longer wavelengths (*e.g.* 263 and 266 nm) were confined at wavelengths longer than the (0, 0) band (264 nm) and had the pronounced vibrational structure. The fluorescence spectra excited at shorter wavelengths (*e.g.* 253 and 258 nm), however, were broad and showed some emission at wavelengths shorter than the (0, 0) band. It was concluded that some resonance emission occurred at the shorter wavelengths of incident radiation.[5]

The present spectrum observed by the electron-impact excitation has some features at wavelengths shorter than the (0, 0) band; they probably arise from transitions which start at vibrational levels higher than those in statistical equilibrium with the surroundings. A comparison of the present emission spectra with those obtained by Nakamura reveals that the present spectra are close to those excited at the shorter wavelengths. However, the present spectrum, shown in Fig. 2, has a pronounced peak at 265 nm, whereas his spectrum, excited at 253 nm, has only a small peak at 265 nm; thus, the details of the vibrational structure of the present spectrum does not coincide with those of any of the fluorescence spectra. In the present study, the variation in the impact voltage between 60—200 V did not induce any appreciable change in the appearance of the spectrum under the present experimental resolution. It may be concluded that the molecule received enough excess energy and showed the resonance emission even when it was excited with electrons of 60 V, and that a similar resonance emission was observed for the excitation by electrons of higher energies.

A typical emission spectrum of chlorobenzene by electron impact and that of bromobenzene are shown

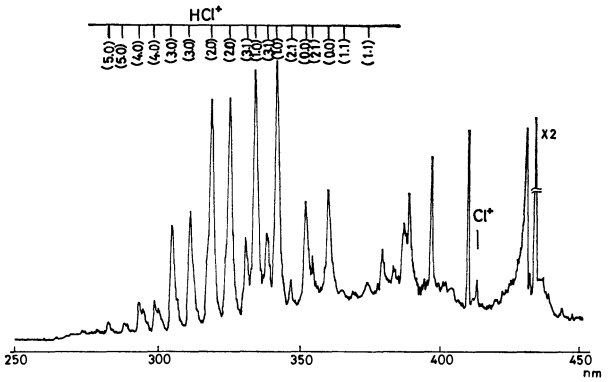

Fig. 6. Emission spectrum of chlorobenzene by electron impact. Impact voltage 300 V, electron beam current 300 μA.

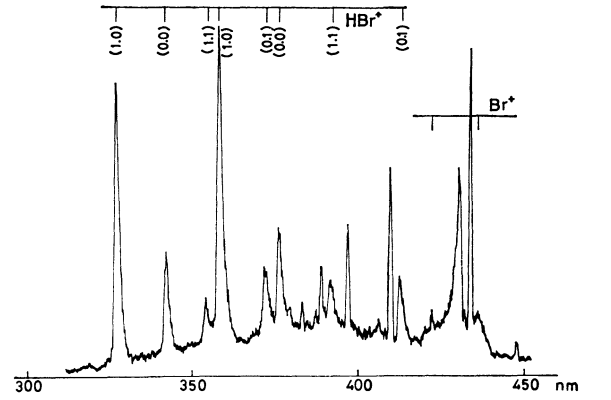

Fig. 7. Emission spectrum of bromobenzene by electron impact. Impact voltage 200 V, electron beam current 500 μA.

in Figs. 6 and 7 respectively. No appreciable bands of parent molecules could be detected in the spectra. Instead, they show strong bands of HCl^+ or HBr^+ and weak lines of Cl^+ or Br^+. Heavy atoms generally tend to reduce the fluorescence quantum yield through an spin-orbit coupling effect.[8] That is, the rate for intersystem crossing becomes large and competes effectively with the rate for fluorescence. Thus, the radiationless transition from the lowest excited singlet state to the triplet state should have a much higher probability when heavy substituents are involved. Bass and Sponer[4] tried to measure the fluorescence of fluoro- and chlorobenzenes in the vapor phase and observed no emission from the latter. The present finding that both chloro- and bromobenzenes did not show any remarkable photoemission under electron-impact excitation is consistent with the previous findings.

In addition to the spin-orbit coupling effect mentioned above, the predissociation of the carbon-halogen bond may have some effect on the disappearance of the photoemission of the parent species. The mass spectra of fluoro- and chlorobenzenes were taken in order to determine the relative probability of the cleavage of the carbon-halogen bond of the two molecules. The electron-accelerating voltage used was 80 V. In both cases, the peak of the parent cation was the strongest peak. The sum of the intensity of the phenyl cation peak and that of the halogen cation peak, which are peaks of the fragments produced by the cleavage of the carbon-halogen bond, was measured in relation to that of the parent peak. The relative intensities were 0.02 for fluorobenzene and 0.68 for chlorobenzene. Thus, it can be concluded that the carbon-chlorine bond is much weaker and more scissile by electron impact and that the predissociation of the excited chlorobenzene probably plays an important role. This is consistent with the bond energy of the carbon-halogen bond. Furthermore, this conclusion is supported by the presence of the emissions of HCl^+ and Cl^+ and by the absence of the emissions of F^+ and HF^+, as will be discussed below.

In the spectra of chloro- and bromobenzenes, pronounced doublet bands were observed in the 280—400 nm region, as is shown in Figs. 6 and 7 respectively. These bands were assigned to the HCl^+ $^2\Sigma$—$^2\Pi$ transition and the HBr^+ $^2\Sigma$—$^2\Pi$ transition respectively.[2,11-13] The bands are split by the coupling of rotation and electronic motions in the ground Π state. The vibrational assignment of the HCl^+ band was carried out by means of the following formula;[12]

$$v = \begin{Bmatrix} 28446 \\ 27788 \end{Bmatrix} + 1561p - 30.3p^2 - 2573n \qquad (cm^{-1})$$

where p is the vibrational quantum number of the upper electronic state and n that of the ground state. The order of intensities of transitions among various vibrational levels is $(1, 0) > (2, 0) > (3, 0) \fallingdotseq (0, 0)$ for HCl^+ and $(1, 0) > (0, 0)$ for HBr^+. No emission from HBr^+ above $p=1$ was observed clearly, probably because of predissociation.[14] On the other hand, the (0, 0) band was the strongest one in the study of the electric discharge.[11] Haugh measured the emission of HCl^+ in the collision of He^+ with HCl and found that the (0, 0) and (0, 1) transitions were by far stronger than any other transition.[15] The vibrational populations of the excited state of HCl^+ were also studied in the collision of $He^*(2^3S_1)$ with HCl, and the vibrational ground state of the upper electronic state of HCl^+ was found to be markedly populated.[16] Although the large difference in the internuclear lengths of the ground state (1.32 Å) and of the excited state (1.52 Å)[17] favors the present result as the calculated Franck-Condon factors[16] show, it is noteworthy that the relative intensity of the vibrational component of $HCl^+(^2\Sigma)$ varies with the method of excitation. Lines of Cl^+ and Br^+ were

also observed in the 400—600 nm region, as is shown in part in Figs. 6 and 7. Neither HF^+ nor F^+ was observed in the spectrum of fluorobenzene. This is probably because the carbon-fluorine bond is stable against electron impact.

The authors wish to thank to Professor Tetsuro Seiyama and Dr. Makoto Egashira of Kyushu University for the measurement of the mass spectra and to Professor Emeritus Kozo Hirota of Osaka University for his encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1067—1071 (1973)

A CNDO Study of Biphenyl

Akio TAJIRI, Shohji TAKAGI and Masahiro HATANO

The Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received August 2, 1972)

The ground-state electronic structure of biphenyl were studied by the use of the CNDO/2 method. It was found that the lengthening of the central C–C bond in biphenyl gave a reasonable minimum point for the potential energy curve. A modified version of the CNDO/2 method was used in order to calculate the electronic spectra of biphenyl for three possible (planar, angular, and vertical) conformations. The method gave a reasonable interpretation of the spectral features of biphenyl.

The most important aspect of the CNDO/2 method[1–3] has been considered to lie in its usefulness for the predictions of the equilibrium nuclear arrangements and the stable conformations of various kind of molecules in their ground states. In fact, the CNDO/2 method has been shown to lead to reasonably successful predictions of the equilibrium bond angles and lengths of small molecules.[2,3] It has been theoretically illustrated for the H_2 molecule[4] that the approximate location of its potential energy minimum is established on a balance between the total Coulombic repulsion between the two atoms and the resonance integral. As for the predictions of the equilibrium bond lengths of relatively large conjugated hydrocarbons, composed of 10—15 carbon atoms,[5] the CNDO/2 method leads to satisfactory results comparable to those obtained from the more sophisticated LCAO-MO-SCF theory on the basis of the π-electron approximation, in which the σ-bond compression energies are taken into account.[6]

Unfortunately, however, several authors have failed in using the CNDO/2 method to calculate the rotational barriers and to predict the stable conformers in some conjugated systems. This is the case with biphenyl. The angle of twist around the central C–C bond in biphenyl is about 42°[7,8] in the gaseous phase, while the molecule is planar in the crystal.[9] Recently, Tinland[10] has calculated the total energy of biphenyl as a function of the twisting angle, θ (Fig. 1), by means of the CNDO/2 method, assuming the fixed bond length of 1.50 Å[11] observed for the twisted bond. The potential energy decreases as the twisting angle, θ, increases and is minimized at 90°, in disagreement with the experimental results.

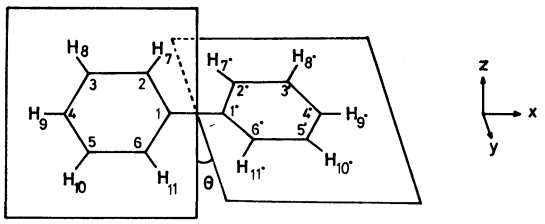

Fig. 1. Numbering of atoms and choice of axis in biphenyl.

More recently, Gropen and Seip[12] have given conclusive results for the CNDO/2 calculations aimed at making it possible to predict the stable conformation of the molecules. Their calculation for biphenyl has given the same result as Tinland's. Even for rather simple molecules such as glyoxal, the calculated total energy minimum was found for a torsional angle, θ, slightly above 90°, in disagreement with the experimental results.

In spite of the deficiencies of the CNDO/2 method pointed out, we venture to present this article out of our desire to elucidate the electronic spectra of biphenyl, which have long been of interest both to theoretical and experimental chemists, especially from a stereochemical point of view.

Method of Calculation

Although the calculation of the electronic transition energies of biphenyl is of much interest, it has been well established that the original CNDO/2 method predicts markedly high excitation energies, almost twice as high, of molecules.[13] Several authors[13-19] have proposed some modifications of the CNDO/2 method aimed at making it more useful for predicting and interpreting spectroscopic data. One of the present authors[5,20] has succeeded in interpreting the electronic spectra of some non-alternant conjugated hydrocarbons and heterocyclics by use of a modified version of the CNDO/2 method, using a new parametrization for the Del Bene-Jaffé's parameter, κ, for the π-bonds and the bonding parameter, β_x^0, which correlates with the two-center core matrix element, $\beta_{\mu\nu}$, by menas of the following equation:

$$\beta^{\sigma}_{\mu\nu} = \frac{1}{2}(\beta^0_A+\beta^0_B)S_{\mu\nu} \quad (1)$$

$$\beta^{\pi}_{\mu\nu} = \frac{\kappa}{2}(\beta^0_A+\beta^0_B)S_{\mu\nu} \quad (2)$$

where μ and ν denote the AO's on the A and B atoms respectively. The values of κ, β_C^0, and β_H^0 are chosen to be 0.75, -15.0 eV, and -8.0 eV so as to give the most consistent spectroscopic agreements for methane, ethylene and benzene. In this work, the above equation (2) is used to determine the value of the resonance integral for all π-type interactions, wherever they occur. It is also used to evaluate the π-component of the interaction of the two "2p" atomic orbitals which are part of the sigma framework, and to evaluate the interaction of the two "2p" orbitals which are perpendicular to the molecular plane. Only under these conditions could the symmetry of the nonplanar molecule hold; accordingly, this method could be used to study nonplanar molecules. One-center and two-center electron repulsion integrals are evaluated with the Sichel-Whitehead formula[21,22] and the Mataga-Nishimoto formula[23] respectively, and the local core matrix elements, with the Sichel-Whitehead procedures.

Results and Discussion

Ground-state Properties. As was dsecribed above, the CNDO/2 method has predicted a conformation with $\theta=90°$ instead of 42°.[7,8] It is apparent that this is mainly due to the overestimation of the core repulsions evaluated from the point-charge approximation between non-bonded atoms, especially between ortho-hydrogen atoms at the 7, 7′, 11, and 11′ positions; that is, if we assume the central bond length to be 1.50 Å, the change in the core-repulsion energy overcomes the change in the electronic energy in the neighbourhood of the expected equilibrium conformation of biphenyl. The minimum point of the potential energy curve no longer exists at $\theta=42°$, but at $\theta=90°$, where the core repulsions between non-bonded atoms have the smallest values. Of course, these repulsions will be reduced if the distance of the central bond is increased in the case of biphenyl, as was suggested by Tinland. A minimization of the total energy with respect to an angle variation is possible when we adopt a value of 1.54 Å for the central bond, in accordance with the results of Karle and Blockway.[24] This is shown in Fig. 2. It is interesting to note that the curve has a very shallow trough and that the energy difference between $\theta=0°$ and $\theta=42°$ is calculated to be 0.08 eV (about 1.8 kcal/mol). This is in good agreement with the experimentally-determined rotational potential barrier in biphenyl, 2 kcal/mol.[25]

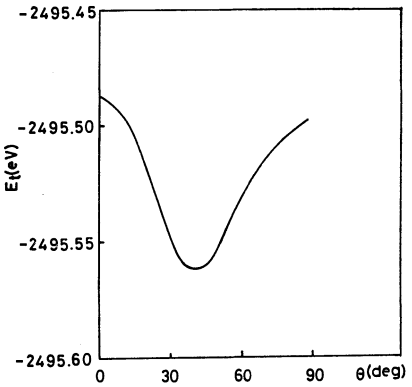

Fig. 2. Calculated potential energy curve for biphenyl with central C–C bond length 1.54 Å.

The calculated AO and atom populations calculated at this energy minimum point are summarized in Table 1. It should be stressed that the electron densities on the carbon atoms at the positions of 2, 6, 2′, and 6′ are larger than those on the other carbon atoms.

Excited-state Properties. The behavior of a so-called "conjugation band" has long been of interest to theoretical and experimental chemists. As early as 1936 Pickett[26] found a strong absorption band at

$$g_{AA} = \frac{1}{16}\sum_i\sum_j g_{ij}$$

where g_{ij}'s are evaluated from atomic valence state energies.

about 250 nm characteristic of a series of biphenyl derivatives, and suggested a correlation between the location of this strong band and the conformation of biphenyl. It has also been shown[27] that the intensity of this band weakens as the conjugation of the two benzene rings decreases.

From the theoretical point of view, several authors[28–33] have tried to elucidate the spectral shift of the conjugation band with the conformational change of the biphenyl skeleton on the basis of the π-electron LCAO-MO method. Murrell and Longuet-Higgins[28] have calculated the lower singlet excitation energies by the use of the "molecules in molecules" method, while Gondo[31] and Grinter[32] have compared the transition energies calculated using a modified version of the PPP method[34,35] over a wide range of twisting angles, θ.

According to the above discussions, it seems to be appropriate to compare the results calculated over the wide range of θ values from $\theta=0°$ to $\theta=90°$ in order to clarify the spectral change in biphenyl. We have calculated the transition energies of biphenyl at each point corresponding to the planar ($\theta=0°$; D_{2h}), angular ($\theta=42°$; D_2), and vertical ($\theta=90°$; D_{2d}) conformations. In the CI calculations, 55 singly-excited configurations are taken into account for each conformation. Throughout the calculations, the central C–C bond length has been assumed to be 1.50 Å[11] and the C–C bond lengths of the two benzene rings to be equal and 1.40 Å.

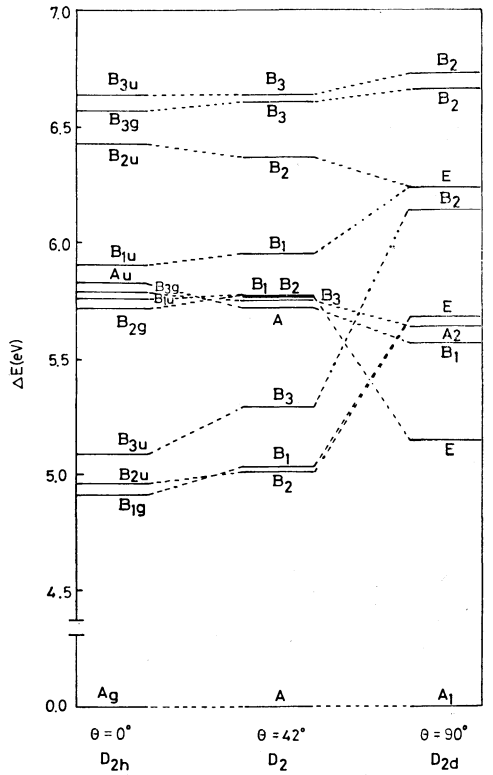

Fig. 3. The energies and symmetries of the lower excited states of three possible conformations of biphenyl.

Figure 3 shows a schematic diagram of the lower singlet states of biphenyl predicted for the three possible conformations. It is apparent from Fig. 3 that the conjugation band is to be assigned to the $A_g \rightarrow B_{3u}$ electronic transition in the D_{2h} conformation, to the $A \rightarrow B_3$ transition in the D_2 conformation, and to the $A_1 \rightarrow B_2$ transition in the D_{2d} conformation, respectively. Table 2 summarizes the calculated energies and symmetries of the lower singlet states of biphenyl, together with the oscillator strengths due to the transitions from the totally-symmetric ground state to the excited states.

In the D_{2h} conformation, the lowest $\pi \rightarrow \pi^*$ electronic transition energy is predicted to be 4.91 eV, corresponding to a symmetry-foribidden $A_g \rightarrow B_{1g}$ transition. The excitation energy corresponding to the next $\pi \rightarrow \pi^*$ electronic transition, $A_g \rightarrow B_{2u}$, is calculated to be 4.96 eV, with its moment directed along the short axis. As for the order of these two states, the results are in disagreement with those obtained by Grinter[32], who concluded that the B_{2u} state was lower than the B_{1g} state, while it is in agreement with the results of Suzuki.[30] An $A_g \rightarrow B_{3u}$ transition which gives rise to the conjugation band is predicted at 5.04 eV, and its oscillator strength is calculated to be 0.80. Although several transitions associated with σ-MO's are predicted to exist in the range of 5.5—5.6 eV, they are predicted to be forbidden by symmetry or very weak in intensity. It should be noted that the higher $\pi \rightarrow \pi^*$ transition energies, corresponding to the $A_g \rightarrow B_{2u}$ and $A_g \rightarrow B_{3u}$ electronic transitions, are

$A_g \rightarrow B_{3u}$	5.04 (0.80)	$A \rightarrow B_3$	5.29 (0.68)	$A_1 \rightarrow A_2$	5.64 (forb.)
$A_g \rightarrow B_{2g}$	5.71 (forb.)	$A \rightarrow A$	5.72 (forb.)	$A_1 \rightarrow E$	5.67 (0.00)
$A_g \rightarrow B_{1u}$	5.75 (0.00)	$A \rightarrow B_3$	5.75 (0.01)	$A_1 \rightarrow B_2$	6.14 (0.41)
$A_g \rightarrow B_{3g}$	5.78 (forb.)	$A \rightarrow B_1$	5.76 (0.00)	$A_1 \rightarrow E$	6.22 (0.02)
$A_g \rightarrow A_u$	5.82 (forb.)	$A \rightarrow B_2$	5.76 (0.00)	$A_1 \rightarrow B_2$	6.65 (0.00)
$A_g \rightarrow B_{1u}$	5.90 (0.00)	$A \rightarrow B_1$	5.95 (0.00)	$A_1 \rightarrow B_2$	6.72 (1.52)
$A_g \rightarrow B_{2u}$	6.42 (0.67)	$A \rightarrow B_2$	6.36 (0.24)		
$A_g \rightarrow B_{3g}$	6.56 (forb.)	$A \rightarrow B_3$	6.60 (0.02)		
$A_g \rightarrow B_{3u}$	6.63 (0.90)	$A \rightarrow B_3$	6.63 (0.83)		

predicted to be 6.42 eV and 6.36 eV, with their moments directed along the short and long axes of biphenyl respectively.

The correlation between two point groups, D_{2h} and D_2, is easily found. The B_{1g} and B_{2u} states turn out to be B_1 and B_2 states respectively in an angular conformation. It should be noted that the B_2 state is lower than the B_1 state. It can clearly be seen from Fig. 3 that the conformational change in biphenyl is well reflected in the change both in the energy and in the intensity of the electronic transition, which has the same character as the $A_g \rightarrow B_{3u}$ transition in planar biphenyl. The excitation energy corresponding to this electronic transition is calculated to be 5.29 eV, with its moment directed along the long axis. Its oscillator strength is predicted to be 0.68, which is smaller than that of the corresponding transition in D_{2h} biphenyl because of the decrease in the conjugation of π-electrons in the two benzene rings. It is interesting to note that the higher $A \rightarrow B_3$ transition energy is unaffected by the conformational change in biphenyl.

In a vertical conformation, the lowest excitation energy corresponding to an electronic transition from the ground state, A_1, to a degenerate excited state, E, is predicted to be 5.15 eV, with a small value of oscillator strength, 0.04. This lowest degenerate excited state can be correlated to the nearly degenerate B_1 and B_2 states located near 5.8 eV in D_2 conformation, while in the study of Grinter the lowest E state come from the lowest B_1 and B_2 states. A long-axis polarized transition, $A_1 \rightarrow B_2$, in the D_{2d} conformation has come from the $A \rightarrow B_3$ electronic transition in the D_2 conformation. The effect of the twist is most evidently reflected in the blue-shift of this transition and in the oscillator strength. The higher B_2 state is little affected, as in the case of reduction from D_{2h} to D_2.

From the experimental point of view, many authors[26,27,36-42] have been interested in the electronic spectra of biphenyl and its derivatives. Unfortunately, however, we have no spectral data on biphenyl itself with a vertical conformation.

We are forced to compare the calculations for $\theta=0°$ and $\theta=42°$ with solid[43-47] and solution or vapor-phase[48,49] spectra of the unsubstituted biphenyl respectively.

With regard to the energy of the transition which gives rise to the conjugation band, it is unfortunate that the measurement of this band has not been made for crystalline biphenyl. Dale,[48] however, has measured the spectrum of solid biphenyl by the pressed KCl-disk technique and found an intense, structureless band with a maximum at 2530 Å (=4.94 eV). Suzuki[30] has suggested, after a correction for the normal red-shift observed when samples are measured in KCl-disks, that planar biphenyl which is free from intermolecular interactions should show the characteristic conjugation band at 2495 Å (=4.97 eV). This is in excellent agreement with the results of this calculation for $\theta=0°$, *i. e.*, 5.04 eV. Coffman and McClure[43,44] have reported bands at 33340 cm^{-1} (=4.13 eV, B_{1g}) and 33714 cm^{-1} (=4.18 eV, B_{2u}). The order of these states is in agreement with this calculation, while the predictions of their energy are too high.

The spectrum of biphenyl has also been measured in the vapor phase[50]; absorption maxima were found at 5.2 eV and 5.18 eV for the temperatures of 170° and 520°C respectively. In non-polar solvents, the

Table 3. Singlet transition energies ΔE(eV) and oscillator strengths f(C.G.S.) calcuted at the point corresponding to the energy minimum in Fig. 2

Type	$\Delta E(f)$	Type	$\Delta E(f)$
$A\rightarrow B_2$	5.00(0.03)	$A\rightarrow B_2$	5.92(0.00)
$A\rightarrow B_1$	5.01(0.01)	$A\rightarrow B_1$	6.05(0.00)
$A\rightarrow B_3$	5.41(0.67)	$A\rightarrow B_3$	6.30(0.01)
$A\rightarrow A$	5.77(forb.)	$A\rightarrow B_2$	6.44(0.35)
$A\rightarrow B_3$	5.79(0.00)	$A\rightarrow B_3$	6.62(0.75)
$A\rightarrow B_1$	5.92(0.00)		

conjugation band is found at 2480 Å (=5.00 eV)[36], with an oscillator strength of 0.411.[50] These values are to be compared with the value of 5.29 eV determined here for $\theta=42°$. The agreement between theory and experiment seems to be fairly good.

Finally, we have listed the transition energies calculated with $\theta=42°$ and the central C–C bond length of 1.54 Å in Table 3. It is apparent from the table that the bond lengthening has little, if any, effect on the electronic spectra.

The authors wish to thank Professor Nakajima of Tohoku University for his encouragement and helpful discussions.

Orbital Symmetry Control in the Interaction of Three Systems

Hiroshi FUJIMOTO, Shigeki KATO, Shinichi YAMABE, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received August 8, 1972)

Some perturbation equations for calculating the interaction energy of three independent systems have been derived in the frame of the simple Hückel MO approximation. The results of the numerical calculation of some typical interactions of three conjugated systems are presented in order to show the effect of the orbital symmerty upon the interaction energy. The role of the d orbitals of transition-metal catalysis olefin metathesis is examined.

Some important information on the nature of chemical interactions in unimolecular reactions has been derived by considering the conjugation between two parts of a molecule, using a partitioning technique.[1] To discuss the stability of a molecular system by means of the conjugation stabilization of the interaction of three or four parts of a molecule properly partitioned seems to be promising for the purpose of illuminating the essential features of complicated chemical reactions.[2] Recently, Goldstein and Hoffmann extended the concept of aromaticity to some multi-centric interactions of more than three systems.[3] They discussed the interaction of three systems by regarding it as two successive cyclic interactions of two systems, based upon the concept of orbital interaction between the highest occupied (HO) molecular orbital (MO) of one system and the lowest unoccupied (LU) MO of the other system. The applicability of the theory of the HOMO–LUMO interaction to predicting the favorable reaction paths has been verified in numerous cases.[1,4] Therefore, the generalization of aromaticity by Goldstein and Hoffmann may be accepted. Since such multi-centric interactions of three systems are highly related to the catalytic action of transition-metal complexes, we would like to present some simple formulae for the simultaneous cyclic interactions of three independent systems. These formulae will be useful for a semi-quantitative comparison of various types of interactions of three systems.

Interaction Energy

Longicyclic Interactions. First, let us consider the longicyclic interaction[3] of three systems, A, B,

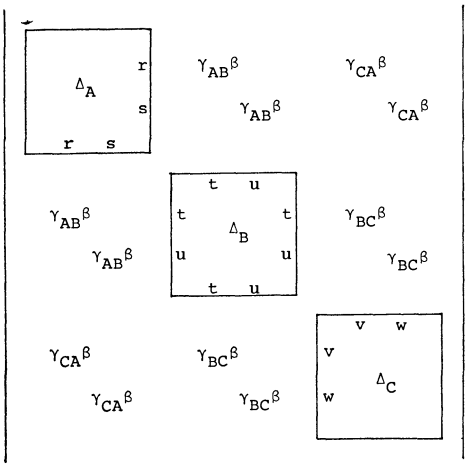
and C, which are joined together at the AO's, r and s of A, t and u of B, and v and w of C. The interaction of these three systems is represented by the $\gamma_{AB}\beta$, $\gamma_{BC}\beta$, and $\gamma_{CA}\beta$, resonance integrals respectively, as is shown in Fig. 1. The simple Hückel secular equation for the system is given by:



(1)

where $\Delta_A(\varepsilon)=0$, $\Delta_B(\varepsilon)=0$, and $\Delta_C(\varepsilon)=0$ are the secular equations for the A, B, and C systems respectively in their isolated states. By expanding Eq. (1) in the power series of the interaction integrals, $\gamma\beta$, we obtain:

$$\begin{aligned}&\Delta_A\Delta_B\Delta_C\\&-(\gamma_{AB}\beta)^2\{\Delta_{Arr}\Delta_{Btt}+\Delta_{Ass}\Delta_{Buu}+2(-1)^{r+s+t+u}\Delta_{Ars}\Delta_{Btu}\}\\&-(\gamma_{BC}\beta)^2\{\Delta_{Btt}\Delta_{Cvv}+\Delta_{Buu}\Delta_{Cww}+2(-1)^{t+u+v+w}\Delta_{Btu}\Delta_{Cvw}\}\\&-(\gamma_{CA}\beta)^2\{\Delta_{Cvv}\Delta_{Arr}+\Delta_{Cww}\Delta_{Ass}+2(-1)^{v+w+r+s}\Delta_{Cvw}\Delta_{Ars}\}\\&+\cdots\cdots\\&=0\end{aligned} \tag{2}$$

where Δ_{Ars}, for instance, is the minor of Δ_A with respect to the (r, s) element of the determinant. Assuming that $|\gamma_{AB}|$, $|\gamma_{BC}|$, $|\gamma_{CA}|$ are small in comparison with unity, we may expand the eigenvalues of the perturbed secular equation in the power series of the interaction integrals.[5] When the ith root, ε_{Ai}, of the secular equation, $\Delta_A(\varepsilon)=0$, is not simultaneously the root of $\Delta_B(\varepsilon)=0$ and $\Delta_C(\varepsilon)=0$, the perturbed eigenavlue of Eq. (1) is given by:

$$\begin{aligned}\varepsilon_{Ai}' = \varepsilon_{Ai} &- \sum_j^{all}\frac{(c_r^{(i)}c_t^{(j)}+c_s^{(i)}c_u^{(j)})^2}{\varepsilon_{Bj}-\varepsilon_{Ai}}(\gamma_{AB}\beta)\\&-\sum_k^{all}\frac{(c_r^{(i)}c_v^{(k)}+c_s^{(i)}c_w^{(k)})^2}{\varepsilon_{Ck}-\varepsilon_{Ai}}(\gamma_{CA}\beta)^2+\cdots\cdots\end{aligned} \tag{3}$$

where $C_r^{(i)}$, for instance, is the coefficient of the (AO) r atomic orbital in the MO i of A, and where j and k denote the MO's of B and C respectively. Similar equations can be derived for ε_{Bj}', and ε_{Ck}', corresponding to the jth root of $\Delta_B(\varepsilon)=0$ and the kth root of $\Delta_C(\varepsilon)=0$ respectively. When all of the three systems have closed-shell electronic structures, the conjugation stabilization energy due to the interaction is given by:

$$\begin{aligned}\Delta E\cong 2&\Big(\sum_i^{occ}\sum_j^{uno}-\sum_i^{uno}\sum_j^{occ}\Big)\frac{(c_r^{(i)}c_t^{(j)}+c_s^{(i)}c_u^{(j)})^2}{\varepsilon_{Ai}-\varepsilon_{Bj}}(\gamma_{AB}\beta)^2\\&+2\Big(\sum_j^{occ}\sum_k^{uno}-\sum_j^{uno}\sum_k^{occ}\Big)\frac{(c_t^{(j)}c_v^{(k)}+c_u^{(j)}c_w^{(k)})^2}{\varepsilon_{Bj}-\varepsilon_{Ck}}(\gamma_{BC}\beta)^2\\&+2\Big(\sum_k^{occ}\sum_i^{uno}-\sum_k^{uno}\sum_i^{occ}\Big)\frac{(c_v^{(k)}c_r^{(i)}+c_w^{(k)}c_s^{(i)})^2}{\varepsilon_{Ck}-\varepsilon_{Ai}}(\gamma_{CA}\beta)^2\end{aligned} \tag{4}$$

where the $\sum^{occ}$ and $\sum^{uno}$ symbols imply the summation over all the doubly-occupied and unoccupied MO's respectively. Equation (4) indicates that, as to the second-order perturbation energy, the conjugation stabilization due to the interaction of three systems is simply given by the sum of those of the interaction between two systems. By the use of the results of calculations for cyclic interaction between two systems presented in our previous paper,[6] we obtain the results shown in Table 1. The conjugation stabilization of the cyclic syn-interaction[6] of two systems is large when the number of electrons forming a cycle is 4n+2, while the stabilization is not large when the number of electrons is 4n.[1,6] When A is a 4n-electron system, both B and C should be (4n+2)-electron systems in order to make the conjugation stabilization due to the interaction between A and B and that between A and C large. When the A system is a (4n+2)-electron system, the case in which both B and C are 4n-electron systems leads to a large stabilization.

Table 1. The conjugation stabilization energy in longicyclic interaction of three conjugated systems

A[a]	B[a]	C[a]	$\Delta E/\gamma^2\beta$[b]
2	2	2	0.0
4	4	4	2.147
6	6	6	2.987
2	4	4	4.293
2	2	6	1.244
2	6	6	2.239
6	4	4	4.200
4	2	2	3.578
4	2	6	4.153
4	6	6	4.480

a) 2; ethylenic, 4; butadienic, 6; hexatrienic: by the term ethylenic, for instance, is meant the employment of the π MO's of ethylene.

b) $|\gamma_{AB}|=|\gamma_{BC}|=|\gamma_{CA}|=\gamma$: hereafter β is taken always negative.

In both the cases, however, the interaction between B and C does not produce a large stabilization. In this sense, the interaction can be classified into doubly-stabilized and unstabilized cases, following the notations introduced by Goldstein and Hoffmann.[3] Equation (4) supplies us with a simpler and even more quantitative means than the step-by-step method of Goldstein and Hoffmann to discuss the cyclic interactions of three independent systems.

5) a) K. Fukui, C. Nagata, T. Yonezawa, H. Kato, and K. Morokuma, *J. Chem. Phys.*, **31**, 287 (1959). b) K. Fukui, K. Morokuma, T. Yonezawa, and C. Nagata, This Bulletin, **33**, 963 (1960).

6) K. Fukui and H. Fujimoto, *ibid.*, **39**, 2166 (1966).

When one of the three systems, say A, has a singly-occupied MO, 0, the following additional term appears:

$$+\left(\sum_{j}^{\text{uno}}-\sum_{j}^{\text{occ}}\right)\frac{(c_r^{(0)}c_t^{(j)}+c_s^{(0)}c_u^{(j)})^2}{\varepsilon_{A0}-\varepsilon_{Bj}}(\gamma_{AB}\beta)^2$$
$$+\left(\sum_{k}^{\text{uno}}-\sum_{k}^{\text{occ}}\right)\frac{(c_r^{(0)}c_v^{(k)}+c_s^{(0)}c_w^{(k)})^2}{\varepsilon_{A0}-\varepsilon_{Ck}}(\gamma_{CA}\beta)^2$$

Laticyclic Interactions. The equation representing the conjugation stabilization energy of the laticyclic interaction[3] of A, B, and C is immediately derived from Eq. (4) by putting one of the three integrals, say $\gamma_{CA}\beta$, equal to zero. When B is interposed between A and C, as is shown in Fig. 2, we obtain:

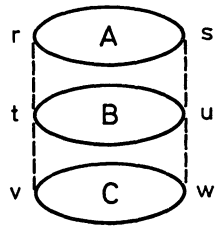


Fig. 2. Laticyclic interaction of three systems A, B and C.

$$\Delta E\cong 2\left(\sum_{i}^{\text{occ}}\sum_{j}^{\text{uno}}-\sum_{i}^{\text{uno}}\sum_{j}^{\text{occ}}\right)\frac{(c_r^{(i)}c_t^{(j)}+c_s^{(i)}c_u^{(j)})^2}{\varepsilon_{Ai}-\varepsilon_{Bj}}(\gamma_{AB}\beta)^2$$
$$+2\left(\sum_{j}^{\text{occ}}\sum_{k}^{\text{uno}}-\sum_{j}^{\text{uno}}\sum_{k}^{\text{occ}}\right)\frac{(c_t^{(j)}c_v^{(k)}+c_u^{(j)}c_w^{(k)})^2}{\varepsilon_{Bj}-\varepsilon_{Ck}}(\gamma_{AB}\beta)^2 \quad (5)$$

The results of the calculation for several laticyclic interactions of three conjugated systems are given in Table 2. We can see that the conjugation stabilization is large in the following two cases: (i) when A and C are (4n+2)-electron systems and B is a 4n-electron system, and (ii) when A and C are 4n-electron systems and B is a (4n+2)-electron system.

b) $|\gamma_{AB}|=|\gamma_{BC}|=\gamma$

Pericyclic Interactions. Next, let us consider the pericyclic interaction[3] of the three systems, A, B, and C, as is shown in Fig. 3. The perturbed secular equation is:

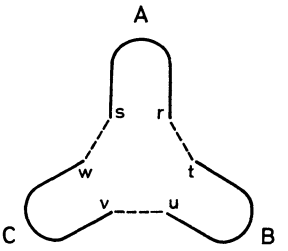

Fig. 3. Pericyclic interaction of three systems A, B and C.

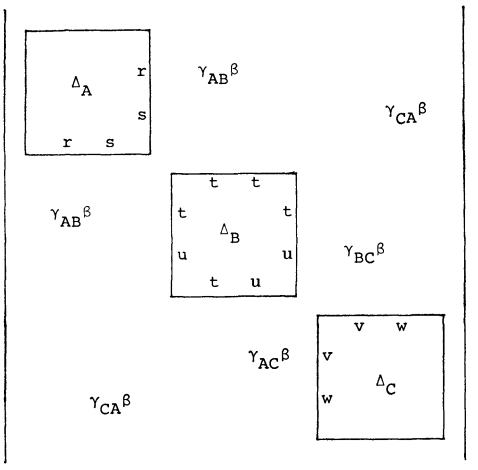

(6)

Expanding the perturbed MO energies in the power series of $\gamma\beta$, the second-order perturbation energy is given by:

$$\Delta E=2\left(\sum_{i}^{\text{occ}}\sum_{j}^{\text{uno}}-\sum_{i}^{\text{uno}}\sum_{j}^{\text{occ}}\right)\frac{(c_r^{(i)}c_t^{(j)})^2}{\varepsilon_{Ai}-\varepsilon_{Bj}}(\gamma_{AB}\beta)^2$$
$$+2\left(\sum_{j}^{\text{occ}}\sum_{k}^{\text{uno}}-\sum_{j}^{\text{uno}}\sum_{k}^{\text{occ}}\right)\frac{(c_u^{(j)}c_v^{(k)})^2}{\varepsilon_{Bj}-\varepsilon_{Ai}}(\gamma_{BC}\beta)^2$$
$$+2\left(\sum_{k}^{\text{occ}}\sum_{i}^{\text{uno}}-\sum_{k}^{\text{uno}}\sum_{i}^{\text{occ}}\right)\frac{(c_w^{(k)}c_s^{(i)})^2}{\varepsilon_{Ck}-\varepsilon_{Ai}}(\gamma_{CA}\beta)^2 \quad (7)$$

The results of the calculations are given in Table 3. Unfortunately, as to the second-order perturbation terms, we can not distinguish the 4n and (4n+2)-electron cycles. For example, the pericyclic interaction of the ethylenic, butadienic, and allyl cationic systems gives the same conjugation stabilization energy as the interaction of the ethylenic, butadienic, and allyl anionic system, 2+4+(3−1). The interaction energy of the third-order with respect to γ is given by:

$$\Delta E=8\left\{\sum_{i}^{\text{occ}}\sum_{j}^{\text{all}}\sum_{k}^{\text{all}}\frac{c_r^{(i)}c_s^{(i)}c_t^{(j)}c_u^{(j)}c_v^{(k)}c_w^{(k)}}{(\varepsilon_{Bj}-\varepsilon_{Ai})(\varepsilon_{Ck}-\varepsilon_{Ai})}\right.$$
$$+\sum_{j}^{\text{occ}}\sum_{k}^{\text{all}}\sum_{i}^{\text{all}}\frac{c_t^{(j)}c_u^{(j)}c_v^{(k)}c_w^{(k)}c_r^{(i)}c_s^{(i)}}{(\varepsilon_{Ck}-\varepsilon_{Bj})(\varepsilon_{Ai}-\varepsilon_{Bj})}$$
$$\left.+\sum_{k}^{\text{occ}}\sum_{i}^{\text{all}}\sum_{j}^{\text{all}}\frac{c_v^{(k)}c_w^{(k)}c_r^{(i)}c_s^{(i)}c_t^{(j)}c_u^{(j)}}{(\varepsilon_{Ai}-\varepsilon_{Ck})(\varepsilon_{Bj}-\varepsilon_{Ck})}\right\}\gamma_{AB}\gamma_{BC}\gamma_{CA}\beta^3 \quad (8)$$

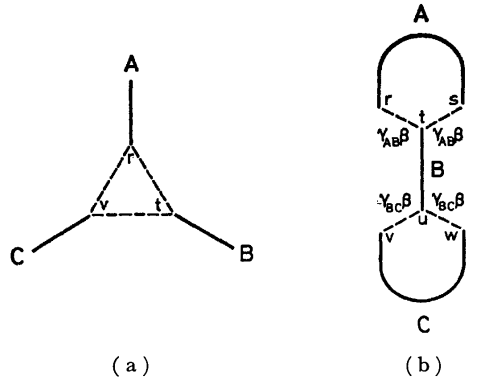
2	2	3+1	0.000
2	4	3−1	−2.000
2	4	3+1	2.000

a) Degeneracy was removed by the method reported in Ref. 5 b).

The results of the calculations for several examples are given in Table 4. For instance, the third-order perturbation energy of the cycle composed of the ethylenic, butadienic, and allyl cationic systems is calculated to be $-2.000\,\gamma_{AB}\gamma_{BC}\gamma_{CA}\beta$, while that of the cycle composed of the ethylenic, butadienic and allyl anionic systems is $2.000\,\gamma_{AB}\gamma_{BC}\gamma_{CA}\beta$. Therefore, in order to make the stabilization large, $\gamma_{AB}\gamma_{BC}\gamma_{CA}$ should be negative in the former case, while it should be positive in the latter case. The cyclic conjugation of the three systems in which $\gamma_{AB}\gamma_{BC}\gamma_{CA}$ is positive obviously corresponds to the usual Hückel-type conjugation, while that in which $\gamma_{AB}\gamma_{BC}\gamma_{CA}$ is negative corresponds to the anti-Hückel or Möbius-strip-type conjugation.[7] The conclusions thus derived from the third-order perturbation energy, that the 2+4+(3−1) system favors the anti-Hückel interaction and that the 2+4+(3+1) system favors the Hückel interaction, are in agreement with the results obtained by Goldstein and Hoffmann.[3] However, it should



(a) (b)

Fig. 4. Other types of interactions of three systems A, B and C.

be noted here that whether or not a pericyclic interaction of three independent systems takes place preferentially in the Hückel-type or in the anti-Hückel-type interaction depends not on the symmetry properties of the MO's of the three independent systems, but on the number of electrons forming a cycle. This conclusion is completely consistent with that given in our previous paper,[8] and also with the theory of aromaticity.[9]

Other Kinds of Interactions. Let us now discuss some other kinds of interactions of three independent systems. The first case is the interaction of three systems at the r, t, and v termini, as is shown in Fig. 4(a). The interaction energy is given by:

$$\Delta E \cong 2\Big(\sum_{i}^{occ}\sum_{j}^{uno}-\sum_{i}^{uno}\sum_{j}^{occ}\Big)\frac{(c_r^{(i)}c_t^{(j)})^2}{\varepsilon_{Ai}-\varepsilon_{Bj}}(\gamma_{AB}\beta)^2 + 2\Big(\sum_{j}^{occ}\sum_{k}^{uno}-\sum_{j}^{uno}\sum_{k}^{occ}\Big)\frac{(c_t^{(j)}c_v^{(k)})^2}{\varepsilon_{Bj}-\varepsilon_{Ck}}(\gamma_{BC}\beta)^2 + 2\Big(\sum_{k}^{occ}\sum_{i}^{uno}-\sum_{k}^{uno}\sum_{i}^{occ}\Big)\frac{(c_v^{(k)}c_r^{(i)})^2}{\varepsilon_{Ck}-\varepsilon_{Ai}}(\gamma_{CA}\beta)^2 \quad (9)$$

The next case is the interaction of three systems, A, B, and C, in which the AO's r and s of A conjugate with the AO t of B and the AO's v and w of C conjugate with the AO u of B, as is shown in Fig. 4 (b). The conjugation stabilization energy is then given by:

$$\Delta E \cong 2\Big(\sum_{i}^{occ}\sum_{j}^{unc}-\sum_{i}^{uno}\sum_{j}^{occ}\Big)\frac{(c_r^{(i)}c_t^{(j)}+c_s^{(i)}c_t^{(k)})^2}{\varepsilon_{Ai}-\varepsilon_{Bj}}(\gamma_{AB}\beta)^2 + 2\Big(\sum_{k}^{occ}\sum_{j}^{uno}-\sum_{k}^{uno}\sum_{j}^{occ}\Big)\frac{(c_t^{(j)}c_v^{(k)}+c_t^{(j)}c_w^{(k)})^2}{\varepsilon_{Ck}-\varepsilon_{Bj}}(\gamma_{BC}\beta)^2 \quad (10)$$

The results of the calculations are given in Table 5. We can see that the number of electrons of the bridge, B, has little influence upon the interaction energy in the interaction of type (b). In addition, when B is neutral, as in the cases of ethylenic, butadienic, *etc.*, the conjugation stabilization does not depend on the number of electrons, *i. e.*, 4n or 4n+2, of A and of C. When B is cationic, the stabilization is large when both A and C have 4n+2 electrons. On the other hand, when B is anionic, when both A and C are

4n-electron systems there will be a large conjugation stabilization. The results in Table 5 correspond to the case in which A, B and C interact through the π-like overlapping of terminal p AO's.

Interaction with d Orbitals

Numerous chemical reactions take place simultaneously with catalysis. In bimolecular reactions of two reactants, A and B, under the influence of a catalysis, C, we must consider the interaction of three independent systems, A, B, and C. Therefore, a theoretical means of handling three systems simultaneously is necessary in order to investigate the role of catalysis in chemical reactions. Recently, the important role of the d orbitals of transition-metal complexes in olefin metathesis was clearly recognized.[4d,10] Some theoretical papers have been published concerning this reaction.[10] However, these consider the process as an interaction between the orbitals of the transition metal and two weakly-coupled olefin molecules or tetramethylene. By the use of Eq. (4), we can examine the role of the d orbitals at the begining of the reaction. The modes of the orbital-overlap interactions are schematically illustrated in Fig. 5. We can see that the HOMO of olefin can interact with $d_{x^2-y^2}$ and that the LUMO can overlap with d_{xy}. Accordingly, the interaction between the d orbitals and π MO's of olefins will result in a net stabilization, although the interaction between two olefins is symmetry-unfavorable and does not lead to stabilization.[6,11] The donation of electrons from the occupied MO's of olefins to the unoccupied d orbital, and that from the occupied d orbital to the unoccupied MO's of olefins, will bring about a loosening of the π bonds of olefins. Consequently, the mixing of the chemically-induced excited state of olefins through the charge-transfer interaction with d orbitals will activate olefins and lessen the symmetry constraint. As the reaction proceeds, it is reasonable to regard the process as an interaction between the d orbitals and two weakly-coupled olefin molecules or a tetramethylene system.[10]

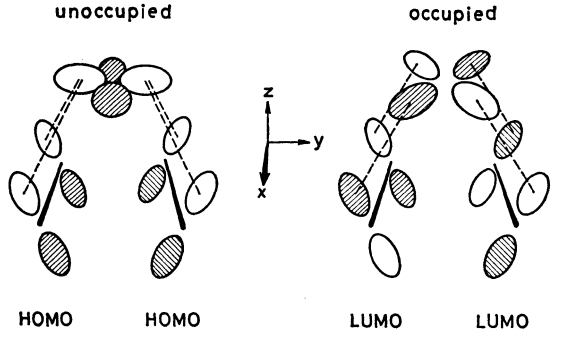

Fig. 5. A schematic representation of orbital overlap interactions in olefin metathesis.

Equation (4) suggests that the two reactants should have the same MO symmetry properties in order for both of them to be activated by the same pair of occupied and unoccupied d orbitals. Olefins metathesis is such a case. Polyenes with an even number of electrons can be classified into two classes; one possessing 4n electrons, and the other, 4n+2 electrons. The HOMO of a 4n-electron system is antisymmetric (A) and the LUMO is symmetric (S). The HOMO of a (4n+2)-electron system is S and the LUMO is A. Therefore, when one reactant is a 4n-electron system and the other is a (4n+2)-electron system, only one of them can be activated by one occupied d orbital and one unocupied d orbital of the central metal of catalysis. In order to activate both, more than two occupied and two unoccupied d orbitals should participate in the reaction. Thus, the important role of the d orbitals of transition-metal complex catalysis can be most clearly observed in the interactions of two conjugated systems belonging to the same class, such as the cases of (2+2), (4+4), (2+6), (6+6), ·····, which are thermally unfavored without catalysis.[1,6,11,12]

Some concenient equations have been derived for the purpose of calculating the stabilization energy of the simultaneous interaction of three independent systems. The stabilization energy for some types of interactions of three systems has been given in the second-order perturbation forms, using the energies and AO coefficients of the MO's of the isolated reactants. These equations can be used for the semi-

quantitative estimation of the conjugation stabilization at the initial stage of three bodies interactions, regardless of whether or not some particular symmetry exists. The method presented here will be helpful for understanding the important role of the d orbitals of transition metals in complex formations and in the activation of organic molecules in chemical reactions. When the HOMO of one system happens to be degenerate with the LUMO of another, the HOMO-LUMO interaction can be expressed by a first-order perturbation term and comes to play a discriminatively important role.[12]

Appendix

In the case of longicyclie interaction, the third-order interaction energy with respect to $\gamma_{AB}\gamma_{BC}\gamma_{CA}$ is given by

$$\Delta E = 8\left\{\sum_{i}^{occ}\sum_{j}^{all}\sum_{k}^{all}\frac{(c_r^{(i)}c_t^{(j)}+c_s^{(i)}c_u^{(j)})(c_t^{(j)}c_v^{(k)}+c_u^{(j)}c_w^{(k)})(c_v^{(k)}c_r^{(i)}+c_w^{(k)}c_s^{(i)})}{(\varepsilon_{Bj}-\varepsilon_{Ai})(\varepsilon_{Ck}-\varepsilon_{Ai})}\right.$$
$$+\sum_{j}^{occ}\sum_{k}^{all}\sum_{i}^{all}\frac{(c_t^{(j)}c_v^{(k)}+c_u^{(j)}c_w^{(k)})(c_v^{(k)}c_r^{(i)}+c_w^{(k)}c_s^{(i)})(c_r^{(i)}c_t^{(j)}+c_s^{(i)}c_u^{(j)})}{(\varepsilon_{Ck}-\varepsilon_{Bj})(\varepsilon_{Ai}-\varepsilon_{Bj})}$$
$$\left.+\sum_{k}^{occ}\sum_{i}^{all}\sum_{j}^{all}\frac{(c_v^{(k)}c_r^{(i)}+c_w^{(k)}c_s^{(i)})(c_r^{(i)}c_t^{(j)}+c_s^{(i)}c_u^{(j)})(c_t^{(j)}c_v^{(k)}+c_u^{(j)}c_w^{(k)})}{(\varepsilon_{Ai}-\varepsilon_{Ck})(\varepsilon_{Bj}-\varepsilon_{Ck})}\right\}\gamma_{AB}\gamma_{BC}\gamma_{CA}\beta^3$$

In the case of laticyclic interaction, the third-order interaction energy does not appear.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1076—1080 (1973)

The Polarized Phosphorescence Spectra of Phenazine in a Phenanthrene Crystal

Kasumi IKEGAMI, Naohiko MIKAMI, and Mitsuo ITO

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai

(Received September 1, 1972)

The polarized phosphorescence spectra of phenazine in phenanthrene was observed at 4.2 K. From the assignments of vibrations that were made on the basis of the results of polarized Raman spectra measurements for the single crystal, it was concluded that the possible mechanisms for the appearance of the vibronically-induced part of the spectrum are the following:

$$^3B_{1u}(\pi, \pi^*) \xrightarrow{\text{s. o.}} {}^1B_{3u}(n, \pi^*) \xrightarrow{\text{vib.}} {}^1B_{2u}(\pi, \pi^*)$$

$$^3B_{1u}(\pi, \pi^*) \begin{cases} \xrightarrow[\text{vib}]{} {}^3B_{3u}(n, \pi^*) \xrightarrow[\text{s.o.}]{} {}^1B_{1u}(\pi, \pi^*) \\ \xrightarrow[\text{s.o.}]{} {}^1B_{3u}(n, \pi^*) \xrightarrow[\text{vib}]{} {}^1B_{1u}(\pi, \pi^*) \end{cases}$$

Furthermore, it has been found that the vibrational modes which give rise to the more intense in-plane polarized bands are out-of-plane ring modes. These results seem to support the regularity found by Lim *et al.*

It is well known that the different vibronic bands associated with the phosphorescence spectra of organic molecules gain the intensity through different routes of spin-orbit and vibronic couplings. In order to determine the coupling routes, it is necessary to know the polarizations of the individual vibronic bands. Interesting contributions along this line have been made by several investigators. However, they have used mainly the method of photoselection, and this method has problems arising from the necessary use of a rigid glass solution—that is, the broadening of the vibronic bands, the restriction of the lowest temperature employed, and so on. These difficulties may be eliminated by polarization measurements for mixed crystals at very low temperatures.

In the present paper, we will report the polarized phosphorescence spectra of phenazine embedded in a single crystal of phenanthrene at 4.2 K. The results obtained were used to determine the possible coupling routes of the individual vibronic bands. The phosphorescence spectra of phenazine have been studied by Pavlopoulos by the method of photoselection.[1] He has associated some vibronic bands with the infrared active u-vibrations. In view of the results obtained here, his assignments should be revised. We also provide additional evidence supporting the regularity found by Lim *et al.* in the perturbing vibrations which appear in the phosphorescence spectra of polycyclic azine.[2]

Experimental

The phenazine was obtained from the Tokyo Kasei Co. and was purified by recrystallization from various solvents and by alumina-column chromatographic extraction. The phenanthrene which was used as a host crystal was treated with maleic anhydride to remove the contaminated anthracene, then it was subjected to extensive zone melting. The

phenanthrene crystal (3% phenazine concentration) was grown by the Bridgman method. The crystal was cleaved along the ab-plane, and then cut down perpendicular to it.

To measure the phosphorescence spectrum of phenazine in phenanthrene, the crystal was submerged in liquid helium and front-surface excitation of the crystal was provided by a mercury line of 365 nm from a 500 W high-pressure mercury lamp. A Toshiba UV39 glass filter and a 0.25 m Bausch & Lomb monochromator were used to filter to other mercury lines. The phosphorescence was collected in the same direction as that of excitation with a lens on the slit of a 0.75 m Nalumi double-grating monochromator (dispersion, 11A/mm) after having passed through a polarized sheet and a Babine plate. The spectrum was recorded with an EMI 9558BQ multiplier phototube and a photon-counting system.

The polarized Raman spectra of a phenazine single crystal were also measured with the exciting light of 4880Å of an Ar-ion laser and a Nalumi double-grating monochromator.

Results and Discussion

The phosphorescence spectrum of phenazine in a phenanthrene crystal at 4.2 K is shown in Fig. 1. The intense and sharp band at 15787 cm^{-1} is onsidered to be an 0-0 band. The vibrational analysis of the observed bands is shown in Table 1, in which the wave number differences from the 0-0 band are compared with the vibrational frequencies obtained from the Raman spectrum. Pavlopoulos[1] observed the phosphorescence spectrum of phenazine in *n*-heptane at 77 K and assigned the 0—486, 0—581, 0—761, 0—823 cm^{-1} bands in the phosphorescence spectrum to the 474, 596, 751, and 820 cm^{-1} infrared active

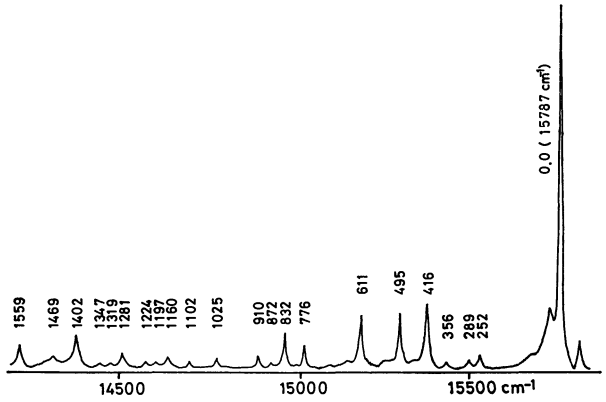

Fig. 1. Phosphorescence spectrum of phenazine in phenanthrene at 4.2 K.

u-vibrations respectively. The 0—486, 0—761, and 0—823 cm^{-1} bands in his spectrum correspond to the 0—495, 0—776, and 0—832 cm^{-1} bands in our spectrum; no band corresponding to his 0—581 cm^{-1} band was observed here. As is shown in Table 1, the 0—495 cm^{-1} band is assigned to the Raman line of 494 cm^{-1}, and it is more reasonable to assign the 0—776 and 0—832 cm^{-1} bands to 416+356 cm^{-1} and 416 $cm^{-1}\times 2$ respectively. Thus, Pavlopoulos' assignment of some vibronic bands to the infrared active u-vibrations should be revised. It is the Raman active vibrations which are associated with all the vibronic bands in the phosphorescence spectrum of phenazine.

Table 1 also gives the symmetry species of the Raman lines, which were determined from polarization mea-

surements for the phenazine single crystal, as well as from depolarization factors for liquid phenazine obtained by melting. As for the nontotally symmetric lines, the Raman line at 494 cm^{-1} can definitely be assigned to the b_{1g} species on the basis of the polarization characteristics of the crystal spectra, while the Raman lines at 245 and 286 cm^{-1} remain ambiguous due to their weak Raman intensities. The latter probably correspond to the 243 and 290 cm^{-1} of anthracene, which belong to b_{1g} and b_{2g} respectively.[3] The 358 cm^{-1} line remains unassigned because of its weak intensity.

In order to determine the polarization directions of individual vibronic bands of the phosphorescence spectrum, the polarized phosphorescence spectra of phenazine were observed for the single crystal of phenanthrene containing 3% phenazine at 4.2 K. The phenanthrene crystal belongs to a monoclinic system with the space group $P2_1$. The bimolecular unit cell has dimensions of $a=12.967$ Å, $b=4.981$ Å, $c=7.056$ Å, and $\beta=109.0°$.[4] Table 2 gives the squared direction cosines of the L, M, and N-axes of the molecule (L, M, and N respersent the long molecular axis, the short molecular axis, and the normal to the molecular plane respectively) with respect to the a, b, and c* axes of the crystal respectively. If we assume that, in the mixed crystal, the phenazine molecules substitutionally occupy the molecular sites of the phenanthrene crystal in such a way that the, L, M, and N axes of the phenazine molecule are parallel to the corresponding axes of the phenanthrene molecule, Table 2 will predict that the vibronic bands of the phosphorescence spectrum of phenazine having transition moments parallel to the L, M, and N-axes should favorably appear along the c*, b, and a-axis spectra respectively. The polarized phosphorescence spectra from the ab and bc* planes are shown in Figs. 2 and 3 respectively. Although the polarization ratios deviate appreciably from the values expected from Table 2 because of the depolarization caused by the cryostat windows, the crystal surface, and so on, the directions of the polarization of the individual vibronic bands may be determined uniquely from Figs. 2 and 3. The 0—0, 0—416, and 0—611 cm^{-1} bands are polarized along the a-axis, so these bands are of the N-axis polarization. The 0—495 and 0—252 cm^{-1} bands are of the L-axis polarization, for these bands appear strongly in the c* axis spectrum. The 289 cm^{-1} band appears strongly along the b axis, and so it is of the M-axis polarization. Similarly, the polarization directions of all the vibronic bands observed were determined; these results are listed in the fifth column of Table 1.

To discuss the origin of vibronic bands appearing in the phosphorescence spectrum of phenazine, we need information about the electronic states of phenazine; the information can be obtained from the absorption studies by Mikami[5] and by Hochstrasser[6] for a phenazine single crystal. The crystal spectrum of phenazine has an n–π^* absorption at 20800 cm^{-1} and three strong π–π^* absorption at about 47600, 40000, and 27800 cm^{-1}. The n–π^* absorption at 20800 cm^{-1} is assigned to the symmetry-allowed $^1B_{3u}\leftrightarrow {}^1A_g$ transition. The π–π^* absorption at 47600 and 40000 cm^{-1} are attributed, respectively to a $^1B_{1u}\leftrightarrow {}^1A_g$

transition with the transition moment parallel to the short axis of the molecule and to a $^1B_{2u}\leftrightarrow{}^1A_g$ transition with the transition moment parallel to the long axis of the molecule. However, there are two alternatives for the assignment of the 27800 cm^{-1} π–π^* absorption; one is the assignment of the $^1B_{1u}\leftrightarrow{}^1A_g$ π–π^* transition with the transition moment parallel to the short axis of molecule, and the other is the superposition of two kinds of π–π^* transitions, $^1B_{1u}\leftrightarrow{}^1A_g$ and $^1B_{2u}\leftrightarrow{}^1A_g$. As for the triplet states, the lowest triplet states is known to be $^3B_{1u}(\pi, \pi^*)$. The second triplet state, studied recently by Mikami and Ito,[7] was assigned to $^3B_{3u}$ on the basis of the polarized absorption spectra of the single crystal. The low-lying electronic states of phenazine described above are shown in Fig. 4.

Now, we shall discuss the origin of each vibronic band, based on the vibronic spin-orbit interaction scheme. The Hamiltonian involving spin-orbit interaction[8] is written to the first order in nuclear displacement by:

$$\mathbf{H} = \mathbf{H}_o^\circ + \mathbf{H}_{so}^\circ + \sum_a \left\{\left(\frac{\partial \mathbf{H}_o}{\partial \mathbf{Q}_a}\right)^0 + \left(\frac{\partial \mathbf{H}_{so}}{\partial \mathbf{Q}_a}\right)^0\right\}\mathbf{Q}_a$$

where $\mathbf{H}_o^\circ$ is an unperturbed term, where $\mathbf{H}_{so}^\circ$ is a spin-orbit coupling operator, and where $\mathbf{Q}_a$ indicates a normal coordinate, the superscript zero referring to the equilibrium nuclear configurations. The vibronic wave function of the triplet state with which we are now concerned is thus written, according to the second-order perturbation theory, by:

$$\begin{aligned}{}^T\theta = {}^T\theta_o &+ \sum_S \frac{\langle S|\mathbf{H}_{so}^\circ|T\rangle}{E_{ST}}\,{}^S\theta_o + \sum_S \frac{\langle S|\mathbf{H}_{so}'|T\rangle}{E_{ST}}\,{}^S\theta_o \\ &+ \sum_S \sum_{S'} \frac{\langle S|\mathbf{H}_o'|S'\rangle}{E_{SS'}} \frac{\langle S'|\mathbf{H}_{so}^\circ|T\rangle}{E_{S'T}}\,{}^S\theta_o \\ &+ \sum_S \sum_{T'} \frac{\langle S|\mathbf{H}_{so}^\circ|T'\rangle}{E_{ST'}} \frac{\langle T'|\mathbf{H}_o'|T\rangle}{E_{TT'}}\,{}^S\theta_o\end{aligned}$$

where $\mathbf{H}_o'$ and $\mathbf{H}_{so}'$ represent $(\partial\mathbf{H}_o/\partial\mathbf{Q}_a)^\circ\mathbf{Q}_a$ and $(\partial\mathbf{H}_{so}/\partial\mathbf{Q}_a)^\circ\mathbf{Q}_a$ respectively. S′ and T′ indicate intermediate singlet and triplet states. The second term represents a usual spin-orbit coupling for a pure electronic state. The third term represents a "direct spin vibronic coupling". The fourth and last term are called "vibronic coupling in the singlet manifold with spin-orbit coupling" and "spin-orbit coupling with vibronic coupling in the triplet manifold" respectively.

It may be seen from Table 1 that the 0—0 band and the bands involving the totally symmetric vibrations are out-of-plane polarized. Since the lowest triplet state is $^3B_{1u}$, these bands borrow their intensities from the $^1B_{3u}\leftrightarrow{}^1A_g$ transition through usual spin-orbit coupling. The lowest n–π^* $^1B_{3u}$ state is considered to be most responsible for the coupling. This confirms the previous conclusions about the origin of the 0—0 band reached by many workers. As for the origin of the vibronic bands of the in-plane polarizations, that is, the 0—252, 0—289, and 0—495 cm^{-1} bands, we have to consider the spin-orbit coupling in the singlet manifold or triplet manifold (the third or fourth term of the above equation). Since the 0—252 and 0—495 cm^{-1} bands are long-axis polarized, they must borrow their intensity from the $^1B_{2u}\leftrightarrow{}^1A_g(\pi, \pi^*)$ transition. There are two low-lying $^1B_{2u}$ states in the 27800 and 40000 cm^{-1} regions, but energy considerations suggest that the intensity borrowing from the $^1B_{2u}\leftrightarrow{}^1A_g(\pi, \pi^*)$ transition in the 27800 cm^{-1} region contributes mainly to the long-axis polarized vibronic bands. Since the $^1B_{2u}(\pi, \pi^*)$ state can not couple effectively with $^3B_{1u}(\pi, \pi^*)$ state by means of spin-orbit coupling, and since all the long-axis polarized bands involve the b_{1g} vibrations, the following scheme is considered to be the most likely one:

$$^3B_{1u}(\pi, \pi^*) \xrightarrow[R_y]{\text{s.o.}} {}^1B_{3u}(n, \pi^*) \xrightarrow[b_{1g}]{\text{vib}} {}^1B_{2u}(\pi, \pi^*)$$

As for the short-axis polarized vibronic band of 0—289 cm^{-1}, it borrwos its intensity from the $^1B_{1u}\leftrightarrow{}^1A_g(\pi, \pi^*)$ transition. Either the $^1B_{1u}$ state of 47600 cm^{-1} or the $^1B_{1u}$ state of 27800 cm^{-1} must be responsible for it. Since the 0—289 cm^{-1} band involves the b_{2g} vibration, the most likely coupling routes are:

$$^3B_{1u}(\pi, \pi^*) \xrightarrow[b_{2g}]{\text{vib}} {}^3B_{3u}(n, \pi^*) \xrightarrow[R_y]{\text{s.o.}} {}^1B_{1u}(\pi, \pi^*)$$

$$^3B_{1u}(\pi, \pi^*) \xrightarrow[R_y]{\text{s.o.}} {}^1B_{3u}(n, \pi^*) \xrightarrow[b_{2g}]{\text{vib}} {}^1B_{1u}(\pi, \pi^*)$$

It is interesting to note here that all three schemes given above contain vibronic coupling between n–π^* and π–π^* states. Vibronic coupling between n–π^* and π–π^* states is realized only through and out-of-plane vibration. In the study of the perturbing vibrations of the phosphorescence spectra of polycyclic azines, Lim *et al.*[2] showed that the out-of-plane hydrogen wagging vibration of the CH group adjacent to the heteroatoms is responsible for the appearance of relatively strong in-plane polarized vibronic bands in the π–π^* phosphorescence of dibenzo (*f*, *h*) quinoxaline, while, in dibenzo (*a*, *c*) phenazine, where there is no CH group adjacent to the nitrogen atoms, the

7) N. Mikami, and M. Ito, This Bulletin **45**, 992 (1972)
8) A. C. Albrecht, *J. Chem. Phys.* **38**, 354 (1963).

vibrational modes which give rise to the more intense in-plane polarized vibronic bands are of the out-of-plane ring mode. In the case of phenazine, where there is no CH group adjacent to the nitrogen atoms, the out-of-plane ring mode should be active if the regularity found by Lim *et al.* applies in our case also. The active fundamental vibrations in the phosphorescence spectrum of phenazine are of frequencies less than 500 cm^{-1}. Therefore, they are not due to the CH vibration (their frequencies are too low), but are probably due to the out-of-plane ring mode. In our recent study of the polarized phosphorescence spectra of quinoxaline, phthalazine, and quinoline, whose molecules have the CH group adjacent to the nitrogen atoms, we found that the out-of-plane CH bending vibrations (872 cm^{-1} of quinoxaline and 921 cm^{-1} of phthalazine)[9] are active vibrations in the phosphorescence spectra. These facts seem to support the regularity found by Lim *et al.* for the perturbing vibrations in the phosphorescence spectra of polycyclic azines.

The authors wish to thank Mr. Isamu Suzuka for his assistance and encouragement during the course of this work.

Kinetics of Oxygen Exchange between Selenate Ions and Water

Akiko OKUMURA and Nobukazu OKAZAKI

Department of Chemistry, Nara Women's University, Nara 630

(Received October 3, 1972)

The rate of oxygen exchange between selenate ions and solvent water has been measured by using oxygen-18 as a tracer. At 30°C in the concentration range of $[H_2SeO_4]=0.57$—1.5 M, and at 80°C in the region of pH= 1.0—2.3, the rate may be expressed as $R=k_1[H^+][HSeO_4^-]$. The values of the energy and entropy of activation are 23.1 kcal/mol and −5.0 e.u.(80°C) at pH=1.12, and 21.8 kcal/mol and −9.9 e.u.(30°C) at $[H_2SeO_4]=1.64$ M. An A-2 mechanism has been suggested for this path. Above *ca* 1.5 M H_2SeO_4, an additional rate term proportional to $[H_2SeO_4]^2$ comes into play.

Oxygen exchange between oxyanions and water has been the subject of many investigations, but the nature of the reaction is not fully understood. The kinetics of the oxygen exchange of oxyanions of typical elements of the fourth period has, except for that of bromine,[1] received hitherto relatively little attention. For a better understanding of the nature of the reaction, it seems desirable to obtain information on the exchange behaviour of oxyanions of these elements. To this end, we have studied the oxygen exchange reactions between oxyanions of selenium and water.

Experimental

Materials. Water enriched in oxygen-18(1.8 atom%) was obtained from a fractionating column of this laboratory. It was refluxed with alkaline permanganate, distilled three times, and used without normalizing its deuterium content (<1 atom %). The selenic acid (Especially pure) was used without further purification. It contained 98% (by weight) of selenic acid (as analysed by the hydrazine method[2]) and 1.7% of selenious acid (as analysed by the permanganate method[3]). The absence of a catalytic effect of selenious acid on the oxygen exchange of selenic acid has been checked by preliminary experiments. The results will be given in a later section. Guanidine hydrochloride (Special grade, JIS) was recrystallized from absolute methanol, dried at 110°C, and stored in a descicator. All the other chemicals were of an analytical-reagent grade and were used without further purification.

Procedure. The solutions used for kinetic runs in the pH region were prepared as follows. Weighed amounts of selenic acid and oxygen-18 water were sealed in a glass ampoule, and the ampoule was heated for *ca.* 2 hr at 100°C to equilibrate the oxygen-18 content of selenic acid with that of the water. This solution was used as a stock solution. In a measuring flask (25 ml), a weighed amount of the isotopically-equilibrated solution was diluted with water of a normal isotopic content to 25 ml, proper amounts of sodium perchlorate and of sodium hydroxide or perchloric acid being added to adjust the ionic strength and the pH of the solution. A portion of the solution was analysed to check its composition. The pH values of the solutions were measured with Hitachi-Horiba M-5- or F-5-type pH meter. For the runs in the more acidic region ($[H_2SeO_4]>0.5$ M), the following procedure was chosen to minimize the induced exchange upon mixing. Selenic acid was added to oxygen-18 water which had been frozen in a dry ice-ethanol bath, and the mixture was caused to melt in an ice-water bath. Even with this procedure, the zero time exchange amounted to *ca.* 20% of the total exchange. The concentrations of selenic acid and hydrogen ion in the solution were determined by titration. The amount of water in the solution was determined by density measurement.

Portions of the solution were sealed in glass ampoules and

placed in a constant-temperature bath. At appropriate intervals an ampoule was removed and cooled rapidly, and the selenate ions were precipitated by adding a barium chloride solution. The precipitate was separated by centrifuge washed three times with absolute ethanol, and dried at 110°C. It was then converted into carbon dioxide by heating it at 400°C for 1 hr with guanidine hydrochloride in a borosilicate glass tube. This method[4] was originally proposed for the oxygen-18 analysis of water and of acid phosphates, and the reaction involved in the method is a hydrolytic one. In the present case, however, the reaction is of an oxidation-reduction type. The conversion of selenate oxygen into carbon dioxide was>60%. The carbon dioxide, being freed from ammonia and water vapour, was analysed on a Hitachi RMS-I-type mass spectrometer.

The rate of oxygen exchange in g atom per liter in unit of time was calculated by means of the formula:

$$R = -\frac{4[\mathrm{Se(VI)}][\mathrm{H_2O}]}{4[\mathrm{Se(VI)}]+[\mathrm{H_2O}]}\cdot\frac{1}{t}\cdot\ln(1-F),$$

$$F = (O_0 - O_t)/(O_0 - O_\infty),$$

where O_0, O_t, and O_∞ are the ^{18}O atom% of the selenate oxygen at time zero, t, and infinity respectively, and where [Se(VI)] and [H_2O] are the molar concentrations of the selenate ion and water respectively. For each run, 4 or 5 samples were taken at intervals over about two half-lives, and the infinity value was taken after ten half-lives. The McKay plots were satisfactorily linear over two half-lives.

Results and Discussion

Oxygen Exchange in the pH Region. This has been studied at 80°C in the pH region of 1.0—2.3 (Fig. 1). The total selenate concentrations were kept in the 0.064—0.068 M range, and the pH values were adjusted by the addition of a small amount of perchloric acid or of a sodium hydroxide solution. The ionic strengths of the solutions were not adjusted and were in the 0.08—0.16 M range. The pH values were measured at 80°C with solutions of the same compositions (but without oxygen-18 label) as those of the kinetic runs. Figure 1 shows that the pH dependence changes from first-order(pH<1.4) to second-order(pH>2.00) with the increase in the values of pH. The straight line through the four points on the left of the figure has a slope of $-(0.95\pm0.04)$, and the line through the three points on the right, one of $-(2.01\pm0.11)$. This change in kinetic order occurs in the region of the pK_2 value of selenic acid, which has been determined by potentiometric titrations with a glass electrode to be 1.93±0.01(at 80°C).

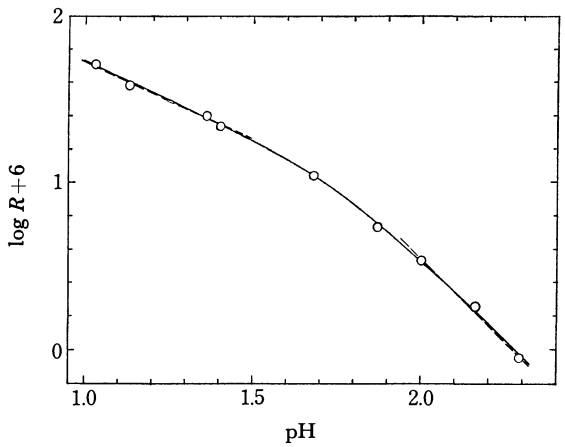

Fig. 1. Dependence of exchange rate on pH at 80 °C ([Se(VI)]=0.064—0.068 M).

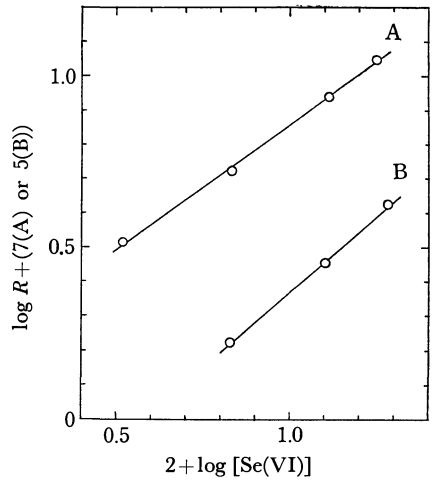

Fig. 2. Dependence of exchange rate on total concentration of selenate [Se(VI)] at 80 °C. The ordinate is 7+log R for A(pH=2.03) and 5+log R for B(pH=1.23).

The dependence of the exchange rate on the total selenate concentration has been studied at two fixed pH values at 80°C. The observed rates were corrected for small differences in pH values (<0.05) by the observed pH dependence. Plots of log R against log [Se(VI)] yield straight lines with slopes of 0.88±0.02 at pH=1.23(I=0.61 M) and of 0.73±0.01 at pH=2.03(I=1.15 M) (Fig. 2). It may be inferred that the exchange reaction is first-order with respect to the total selenate concentration over the entire pH range studied.

These results may be best interpreted in terms of the rate law:

$$R = k[\mathrm{H^+}][\mathrm{HSeO_4^-}] = k[\mathrm{H^+}][\mathrm{Se(VI)}]/(1+(K_2/[\mathrm{H^+}]))$$

$$\simeq k[\mathrm{H^+}][\mathrm{Se(VI)}], \qquad [\mathrm{H^+}]>K_2, \qquad (1)$$

$$\simeq (k/K_2)[\mathrm{H^+}]^2[\mathrm{Se(VI)}], \qquad [\mathrm{H^+}]<K_2. \qquad (1')$$

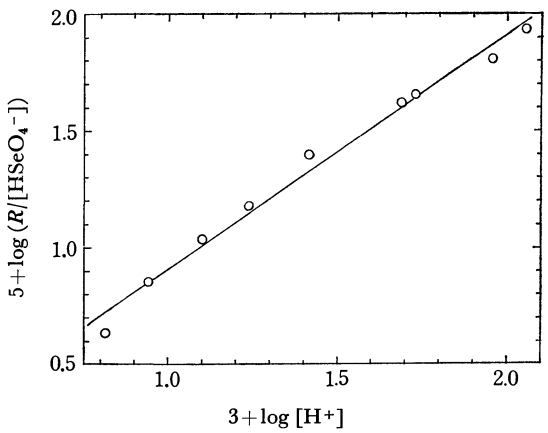

Fig. 3. $R/[\mathrm{HSeO_4^-}]$ as a function of log[H^+] at 80°C.

4) P. D. Boyer, D. J. Graves, C. H. Suelter, and M. E. Dempsey, *Anal. Chem.*, **33**, 1906 (1961).

Fig. 3 shows a plot of log $(R/[HSeO_4^-])$ against log $[H^+]$. The straight line through the points has a slope of 1.00±0.03. The exchange reaction is first-order in both hydrogen-ion and biselenate-ion concentrations, which is in agreement with the rate law. The least-squares treatment of the plots yields the rate constant of $k=(8.2\pm0.8)\times10^{-3}$ l mol^{-1} s^{-1}. In the above treatment, the concentrations of the selenate ion species at each pH value were calculated from [Se(VI)] and $K_2=a_{H^+}\cdot[SeO_4^{2-}]/[HSeO_4^-]$, and the values of K_2 by the formula:

$$pK_2^\circ = pK_2 + \log(f_{SeO_4^{2-}}/f_{HSeO_4^-}),$$

where pK_2° is the thermodynamic dissociation constant and where f's are the activity coefficients. The value of pK_2° at 80°C was obtained from Ghosh and Nair's results[5] by extrapolation, and the values of the activity coefficients were estimated by means of the Debye-Hückel equation by using the ion-size parameters tabulated by Kielland.[6] Succesive approximations yielded the pK_2 values of 2.03—1.93 for I=0.08—0.16 M, which are consistent with the experimentally-determined value; they were used to calculate $[HSeO_4^-]$.

The temperature dependence of the exchange rate has been studied at two fixed pH values, 1.12(at 60, 80, and 95 °C) and 1.81(80, 100, and 120 °C) (Fig. 4). These pH values were measured at room temperature and correspond to pH values of 1.36 and 2.30 at 80 °C. A batch of a solution with a fixed pH was divided into three portions, and each portion was brought to the appropriate reaction temperature. Thus, the observed temperature variation in the exchange rate includes a contribution from the variation in the pH with the temperature. The activation parameters were calculated in the usual way to be E_a=23.10± 0.19 kcal/mol and $\Delta S^\ddagger$=−5.0±0.6 e.u.(80 °C) at pH= 1.12 and E_a=17.18±0.17 kcal/mol and $\Delta S^\ddagger$=−23.4± 0.5 e.u.(80 °C) at pH=1.81. At pH=1.12, where the solution consists of aqueous selenic acid plus a small amount of perchloric acid, the dissociation of the biselenate ion changes little with the pH and contributes only a small fraction to the total hydrogen-ion concentration. Under these circumstances, the temperature variation in log R measures the variartion of log k with the temperature (Eq. (1)). On the other hand, at pH=1.81(buffer region), the temperature variation in log R may be expressed from Eq. (1′) as;

$$\frac{d\log R}{dT} = \frac{d\log k}{dT} - \frac{d\log K_2}{dT} + 2\frac{d\log a_{H^+}}{dT} - 2\frac{d\log f_{H^+}}{dT}$$

and the variation of a_{H^+} at a constant buffer ratio as;

$$\frac{d\log a_{H^+}}{dT} = \frac{d\log K_2^\circ}{dT} - \frac{d\log f_{SeO_4^{2-}}}{dT} + \frac{d\log f_{HSeO_4^-}}{dT}$$

The $d\log f/dT$'s terms may be ignored as compared with $d\log K_2/dT$.[7] Therefore,

$$E_a = E_a^\circ - \Delta H + 2\Delta H^\circ \simeq E_a^\circ + \Delta H^\circ,$$

where E_a° is the true activation energy of the exchange reaction and where ΔH° is the enthalpy of dissociation of the biselenate ion. The value of ΔH° is −5.70±0.2 kcal/mol.[5] Thus, the discrepancy between the activation energies at the two pH values seems quite reasonable.

The effect of the ionic strength has been studied at 80°C, pH=1.33, and [Se(VI)]=0.064 M, with solutions of I=0.82, 0.61, and 0.087 M. The observed rates were 1.47, 1.67, and 2.36×10^{-5} mol/l s respectively. The exchange reaction shows a negative salt effect which is probably due to an equilibrium salt effect on the dissociation of the biselenate ion.

The effect of selenious acid on the exchange rate is shown in the following table.

Table 1. The effects of selenious acid on the oxygen exchange rate of selenic acid at 80°C

Composition of the solution, M×10² [Se(VI)]	[Se(IV)]	pH	R(mol/l s)×10⁵
6.77	0.662	1.39	2.18±0.02
6.38	0	1.40	2.20±0.01
3.09	0.295	1.61	0.0391±0.0003
3.29	0	1.61	0.0370±0.0001

Oxygen Exchange in the Region, $[H_2SeO_4]$=0.56—5.46 M. Figure 5 shows a plot of log R against the logarithm of the total selenic acid concentration, log [Se(VI)], in the region of [Se(VI)]=0.56—5.46 M at 30°C. It may be seen that the [Se(VI)] dependence is nearly second-order up to 1.6 M, and approximately fourth-order above 3.8 M. As selenic acid is almost completely ionized into hydrogen and biselenate ions in this region, the concentrations of each of these ions may be taken to be proportional to [Se(VI)]. Thus, the rate law of the exchange reaction may be written;

$$R = k_1[H^+][HSeO_4^-] + k_2[H^+]^2[HSeO_4^-]^2. \quad (2)$$

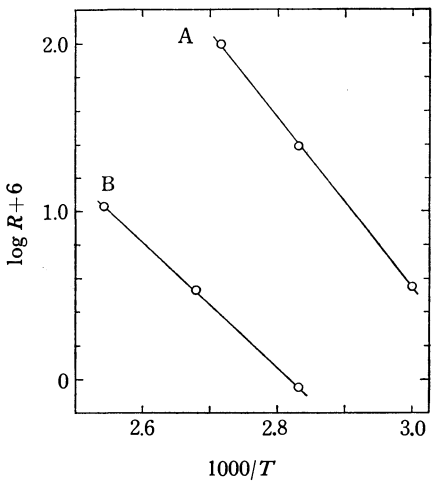

Fig. 4. Temperature dependence of exchange rate in the pH region. A: pH=1.36, [Se(VI)]=0.068 M, B: pH= 2.30, [Se(VI)]=0.067 M.

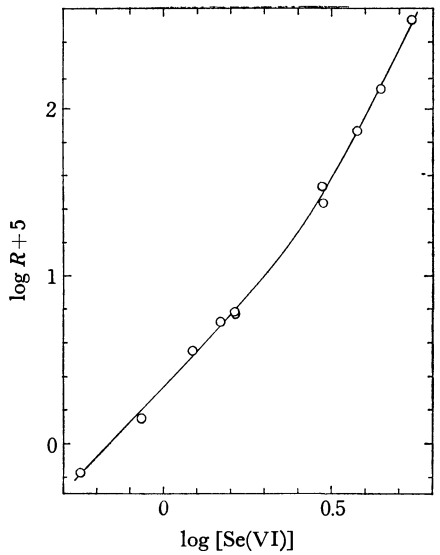

Fig. 5. Rate of oxygen exchange of selenic acid as a function of total concentration of selenic acid at 30°C.

The k_2 term may be interpreted as a bimolecular path involving two selenic acid molecules.

The dependence of the exchange rate on [Se(VI)] at a fixed hydrogen ion concentration has been studied at $[H^+]=3.92$ and 8.7 M. At $[H^+]=3.92$ M, [Se(VI)] was varied between 0.32 and 1.96 M by replacing a part of the selenic acid with an equivalent quantity of perchloric acid. The plot of $\log R$ against log[Se(VI)] is linear, with a slope of 1.09±0.03 at 60°C (Fig. 6-A). At $[H^+]=8.7$ M, selenic acid was replaced by an equivalent quantity of sulfuric acid, which has almost the same acid strength. In this case, the exchange was followed by measuring the decrease in the oxygen-18 content of water. After appropriate reaction times, about 70% of the water in the solution was recovered by the freeze-dry method and was analysed by the guanidine hydrochloride method. It had been confirmed preliminarily that no exchange of oxygen atoms of sulfuric acid occurs in these systems. Figure 6-B gives a plot of $\log R$ against log [Se(VI)] at 30°C. The observed rates were normalized to a hydrogen-ion concentration of 8.7 M.

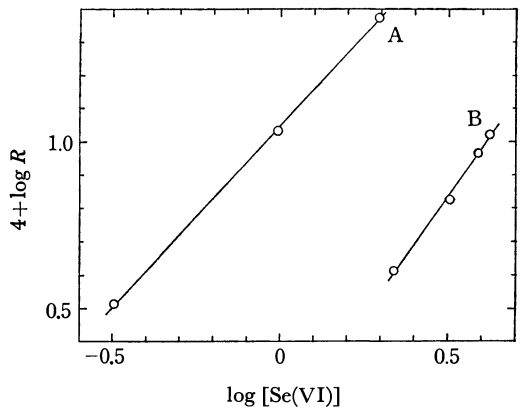

Fig. 6. Dependence of exchange rate on total concentration of selenic acid at constant hydrogen ion concentration.
A: $[H^+]=3.92$ M, 60°C; B: $[H^+]=8.7$ M, 30°C.

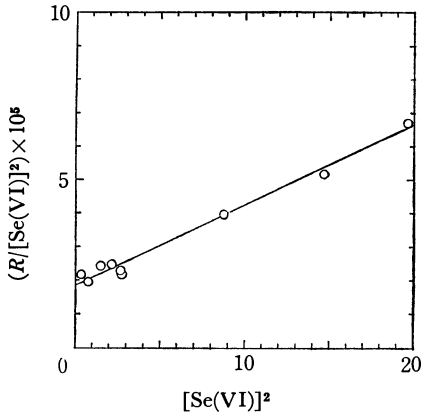

Fig. 7. $R/[Se(VI)]^2$ as a function of $[Se(VI)]^2$ at 30°C.

The least-squares treatment of the plots gives a straight line with a slope of 1.5±0.1. These results support the rate law given in Eq. (2).

Walrafen[8] has studied quantitatively the ionic species present in aqueous selenic acid by the Raman spectroscopic method. According to his results, the concentration of the H_2SeO_4 molecule is practically zero below *ca* 11 M, and from Fig. 3 of his paper, it may be estimated that, up to *ca* 4 M, the concentration of the selenate ion $[SeO_4^{2-}]$ is about three tenths of the total selenic acid concentration. Thus,

$$[HSeO_4^-] = [Se(VI)] - [SeO_4^{2-}] \simeq 0.7\,[Se(VI)],$$

$$[H^+] = [HSeO_4^-] + 2[SeO_4^{2-}] \simeq 1.3[Se(VI)],$$

and the rate law (2) becomes;

$$R/[Se(VI)]^2 = 0.91\,k_1 + 0.828\,k_2[Se(VI)]^2.$$

In Fig. 7, the data shown in Fig. 5 are replotted according to this equation, the points at [Se(VI)]= 5.64 and 2.99 M being ignored. The least-squares treatment yields the rate constants;

$$k_1 = (2.0_1 \pm 0.0_1) \times 10^{-5}\ \text{l/mol s} \quad (30°C),$$

$$k_2 = 0.3 \times 10^{-5}\ \text{l}^3/\text{mol}^3\ \text{s} \quad (30°C).$$

From the values of $k_1(=8.2\times10^{-3}$ l/mol s) and the activation energy(=23.10 kcal/mol) obtained in the pH region at 80°C, the rate constant at 30°C is calculated to be 3.6×10^{-5} l/mol s, which is in satisfactory agreement with the above value. This fact suggests that the exchange reaction has the same mechanism in both the pH and molar regions.

The temperature dependence of the exchange rate in the molar region has been studied at [Se(VI)]= 1.64 M and at 30, 40, and 50°C (Fig. 8). The energy and entropy of activation are calculated to be $E_a=$ 21.82±0.11 kcal/mol and $\Delta S^{\neq}=-9.9\pm0.4$ e.u.(30°C).

Mechanisms of the Exchange Reaction. The second-order rate term, $k_1[H^+][HSeO_4^-]$, suggests the following mechanism;

$$H^+ + HSeO_4^- \rightleftarrows H_2SeO_4, \quad (3)$$

$$H_2SeO_4^* + H_2O \rightleftarrows H_2SeO_4 + H_2O^*, \quad (4)$$

$$\text{or} \quad H_2SeO_4 \rightleftarrows H_2O + SeO_3. \quad (5)$$

8) G. E. Walrafen, *J. Chem. Phys.*, **39**, 1479 (1963).

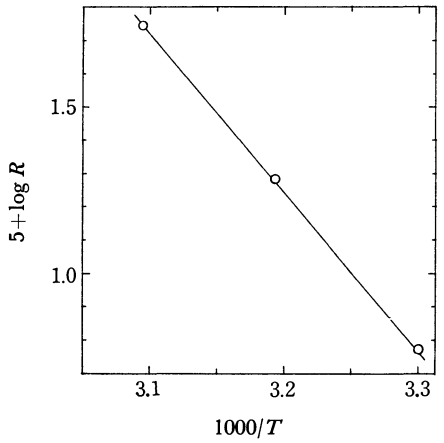

Fig. 8. Temperature dependence of exchange rate at [Se(VI)]=1.64 M.

The negative values of $\Delta S^{\neq}$ obtained for the reaction favour the bimolecular path (4).

Bunton and Hendy[9] have studied the acid hydrolysis of the methyl selenate ion. In contrast to the analogous reaction of the alkyl sulfate ion, the reaction is characterized by a negative value of the entropy of activation (−27 e.u.) and a relatively small deuterium solvent effect ($k_{D_2O}/k_{H_2O}=1.36$), and by a linear dependence of the hydrolysis rate on the hydrogen ion concentration. On the basis of these facts, these authors suggests an A-2 mechanism for the hydrolysis of the methyl selenate ion. Our results are not conclusive at present, but in view of the well-known analogy between the mechanisms of the oxygen exchange of oxyanions and the hydrolysis of its simple alkyl esters, it is probable that the oxygen exchange of the biselenate ion also proceeds through an A-2 mechanism (Path (4)). It is interesting to note that the plot of $\log(R/[\mathrm{Se(VI)}])$ against Hammett's acidity function $-H_0$ of selenic acid[10] gives a straight line with a slope of 0.66±0.01 over the entire range of acidity studied (up to 5.46 M, at 30 °C).

The fourth-order rate term, $k_2[H^+]^2[HSeO_4^-]^2$, which gains importance with an increase in the concentration of selenic acid, may be interpreted as a bimolecular path between two selenic acid molecules;

$$H_2SeO_4 + H_2SeO_4 \rightleftarrows H_2Se_2O_7 + H_2O.$$

The occurrence of $H_2Se_2O_7$ in water-free selenic acid has been suggested by Raman-spectroscopic and conductivity measurements.[11]

The authors wish to thank Professor Shinichi Kawaguchi of Osaka City University for helpful discussions, and Mrs. Masayo Yamamoto and Mrs. Junko Kajihara for their assistance.

Kinetics of Oxygen Exchange between Selenite Ions and Water

Akiko Okumura and Nobukazu Okazaki

Department of Chemistry, Nara Women's University, Nara 630

(Received October 3, 1972)

The rate of oxygen exchange between selenite ions and solvent water has been measured at 0°C over the pH range of 8.7—12.5. The rate of exchange, R, may be expressed by the rate law;

$$R = k_1[SeO_3^{2-}] + k_2[HSeO_3^-] + k_3[HSeO_3^-]^2 + k_4[HSeO_3^-][SeO_3^{2-}].$$

The observed rates were analysed in order to obtain the values of the rate constants. The over-all exchange reaction shows a negative salt effect; this has been shown to be an equilibrium salt effect on the dissociation of the hydrogen selenite ion.

No kinetic study of oxygen exchange between selenite ions and water has ever been reported. Earlier qualitative studies[1] have revealed that selenite ions exchange their oxygen atoms with water very rapidly even in a strongly alkaline solution. As a part of the study of oxygen exchange between water and oxyanions of selenium, we have studied the exchange of selenite ions.

Experimental

Materials. Sodium selenite(Special grade, JIS) was used without further purification. Water enriched in oxygen-18 and guanidine hydrochloride were treated as has been described in a previous paper.[2] The other materials were of an analytical reagent grade and were used without further purification.

Procedure. The procedures were almost the same as those used in the previous work.[2] Exchange was started by diluting an isotopically-equilibrated solution of sodium selenite in oxygen-18 water with a relatively large amount of isotopically-normal water. The pH was adjusted by the addition of hydrochloric acid or a sodium hydroxide solution, and the ionic strength, by the addition of sodium

chloride. The reaction was carried out in an ice-water bath or in a low-temperature bath. At appropriate intervals, the reactant was precipitated by adding a barium chloride solution. For the runs at pH>11, care was taken to avoid contamination with atmospheric carbon dioxide. The water used for the preparation of the solution was boiled to exclude the dissolved carbon dioxide, and the operations were carried out in a nitrogen atmosphere freed from carbon dioxide. The precipitate, after being washed three times with absolute ethanol, was dried in an oven at 110°C, and then converted into carbon dioxide by the guanidine hydrochloride method.[3] The precipitate of barium selenite is not oxidized by air during the drying at 110°C. The isotopic analysis of the carbon dioxide was made on a Hitachi RMS-I-type mass spectrometer.

The rate of oxygen exchange in g atom per liter per unit of time was calculated by the relation;

$$R = -\frac{3[\mathrm{Se(IV)}][\mathrm{H_2O}]}{3[\mathrm{Se(IV)}]+[\mathrm{H_2O}]}\cdot\frac{1}{t}\cdot\ln\frac{O_t-O_\infty}{O_0-O_\infty}$$

where O_0, O_t, and O_∞ are the oxygen-18 atom per cent of the selenite ion at time 0, t, and infinity respectively, and where [Se(IV)] and [H_2O] are molar concentrations of selenite and water respectively. The McKay plots were linear over two half-periods.

For the analysis of the results, it is desirable to obtain the pK_2 values of selenious acid under the conditions of the kinetic runs. These were obtained by potentiometric titrations with a glass electrode.[4] The 0.053 M sodium selenite solution was titrated with 0.55 N hydrochloric acid with and without added sodium chloride, the values of the ionic strength at the half-neutralisation points being I=0.56 and 0.14 M respectively. The values of pK_2(at 0°C) obtained are $8.10_1\pm0.00_3$ at I=0.56 M, and $8.38_2\pm0.01_5$ at I=0.14 M.

Results and Discussion

pH Dependence of the Exchange Rate. Figure 1 shows the variation in the exchange rate with the pH

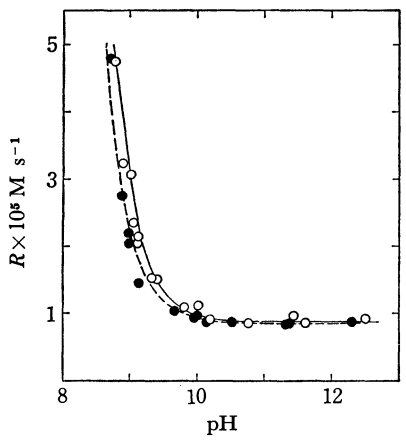

Fig. 1. Rate of oxygen exchange of selenite ions as a function of pH at 0°C. [Se(IV)]=0.055—0.059 M. Open circle: I=0.16 M, Solid circle: I=0.54 M. The curves show the calculated rates. Solid line: I=0.16 M, Broken line: I=0.54 M.

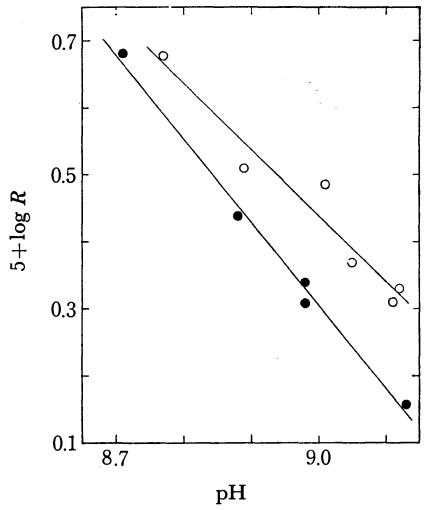

Fig. 2. Dependence of exchange rate on pH in the region of pH<9.1. Open circle: I=0.16 M, Solid circle: I=0.54 M.

at 0 °C and at a fixed total selenite concentration ([Se(IV)]=0.055—0.059 M). The exchange was studied at two different values of ionic strength, I=0.16(±0.02) M and I=0.54(±0.01) M. In the region of pH<9, plots of log R against pH for the runs at I=0.54 and 0.16 M are linear with slopes of 1.24±0.05 and 0.99±0.08 respectively (Fig. 2). On the other hand, above pH=11, the rate is practically independent of the pH.

To check the possibility of hydroxide-ion catalysis, the exchange reaction was studied in a strongly alkaline medium in the following way. A solution of sodium selenite was mixed with a solution of sodium hydroxide in oxygen-18 water in an ice-water bath. The mixed solution was 1.94 M in hydroxide ion and 2.21 M in sodium selenite. At appropriate intervals, a portion of the solution was removed and subjected to vacuum distillation to separate the water. The water thus obtained was analysed for its oxygen-18 content by the guanidine hydrochloride method. As a control, a solution containing an equivalent amount of sodium chloride instead of sodium hydroxide was also studied ([Se(IV)]=2.09 M). The rate observed were;

$$R(\mathrm{NaOH}) = (1.9\pm0.1)\times10^{-4}\ \mathrm{mol/l\,s},$$

and $$R(\mathrm{NaCl}) = (10.1\pm0.4)\times10^{-4}\ \mathrm{mol/l\,s}.$$

The value of R(NaOH) may be recalculated to the rate for [Se(IV)]=0.057 M by the observed first-order dependence on [Se(IV)]. The value thus obtained is 0.5×10^{-5} mol/l s, which compares well with the values obtained at pH=10—12 (see Fig. 1). These facts suggest the absence of hydroxide-ion catalysis.

Salt Effect. In the region of pH<9.5, the addition of sodium chloride exhibits a retarding effect on the exchange rate (see Fig. 1). The effect decreases with the increase in pH and above pH≃11 merges into the experimental errors. In Fig. 1, a plot at pH=8.98 and I=0.54 M was obtained with a solution the ionic strength of which was adjusted by the addition of sodium perchlorate instead of sodium chloride. The plot falls on a line with other plots. This fact

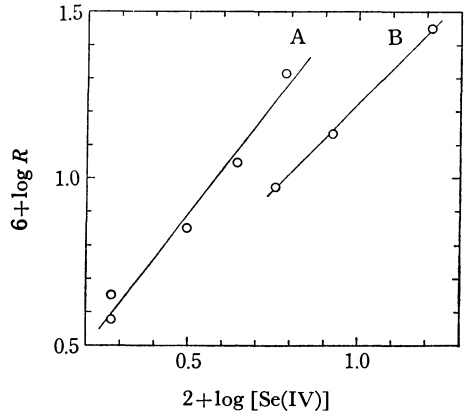

Fig. 3. Dependence of exchange rate on [Se(IV)]. I= 0.54 M. A: pH=9.19, B: pH=10.1.

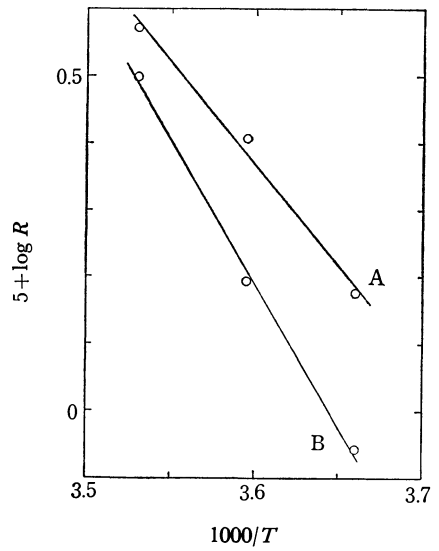

Fig. 4. Temperature dependence of the exchange rate. [Se(IV)]=0.052 M, I=0.54 M. A: pH=9.1, B: pH= 10.1.

shows the absence of any specific effects of these anions.

Dependence on [Se(IV)]. The dependence of the exchange rate on the total concentration of selenite [Se(IV)] was studied at 0°C and at a constant ionic strength (I=0.54 M) for two fixed values of pH (9.19 and 10.1) (Fig. 3). These pH values are representative of the two pH regions of different rate-pH relationships. The observed rates were corrected for the difference in pH values (<0.05 pH). The slopes of the plots of log R against log [Se(IV)] are 1.32±0.08 for pH=9.19 and 1.04±0.03 for pH= 10.1.

Activation Energies. Because of the rapidity of the exchange reaction, the temperature dependence of the exchange rate could be studied only over a limited temperature range (0—10°C) (Fig. 4). In Fig. 4 the rates observed at pH=9.1 are corrected for the difference in pH values (<0.1 pH). The values of the activation energy were calculated to be;

E_a=14.0±0.9 kcal/mol, at pH=9.1 and I=0.54 M,

and

E_a=19.6±0.8 kcal/mol, at pH=10.1 and I=0.54 M.

Analysis of the Exchange Rate. In the region of pH > *ca.* 10, where SeO_3^{2-} is the dominating ionic species and where the concentration of $HSeO_3^-$ is less than 1 per cent of the total selenite-ion concentration, the rate is independent of the pH and depends on the first power of the total selenite concentration. This fact, together with the finding that hydroxide ion catalysis is absent, suggests that the exchange occurs through the mechanism;

$$SeO^*_3{}^{2-} + H_2O \rightleftarrows SeO_3^{2-} + H_2O^*. \quad (1)$$

In the region of pH<*ca.* 9, the observed kinetic order with respect to the [Se(IV)] of 1.32 at pH=9.2 suggests bimolecular mechanisms between selenite ions as important paths;

$$HSeO_3^- + HSeO_3^- \rightleftarrows Se_2O_5^{2-} + H_2O, \quad (3)$$

$$HSeO_3^- + SeO_3^{2-} \rightleftarrows Se_2O_5^{2-} + OH^-. \quad (4)$$

The occurrence of the pyroselenite ion in aqueous solutions of alkali hydrogen selenite (0.5—4 M) has been demonstrated by Raman spectroscopic investigation.[5] Moreover, SeO_3^{2-} being still the major species, exchange occurs through Path (1), and Path (2);

$$HSeO^*_3{}^- + H_2O \rightleftarrows HSeO_3^- + H_2O^*, \quad (2)$$

should gain increasing importance with an increase in the biselenite-ion concentration. Thus, the rate law of the oxygen exchange of the selenite ion over the entire range studied may be written as;

$$R = k_1[SeO_3^{2-}] + k_2[HSeO_3^-] + k_3[HSeO_3^-]^2 + k_4[HSeO_3^-][SeO_3^{2-}]. \quad (I)$$

In the region of pH>10, we may, to a good approximation, ignore the occurrence of the k_2 and k_3 paths. The observed [Se(IV)] dependence of 1.04 at pH= 10.1 suggests some contribution to the exchange of the bimolecular path, k_4. The rate equation may be simplified as;

$$R = k_1[SeO_3^{2-}] + k_4[SeO_3^{2-}][HSeO_3^-],$$

or $$R/[SeO_3^{2-}] = k_1 + k_4[HSeO_3^-].$$

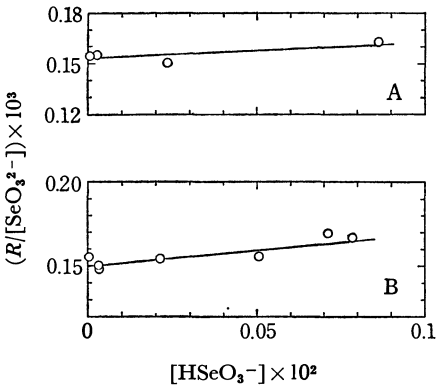

Fig. 5. Evaluation of the rate constants k_1 and k_4. A: I=0.16 M, B: I=0.54 M.

5) A. Simon and R. Paetzold, *Z. Anorg. Allgem. Chem.*, **303**, 46 (1960).

Fig. 5 shows the plots of $(R/[SeO_3^{2-}])$ against $[HSeO_3^-]$ for I=0.16 and 0.54 M. The values of $[SeO_3^{2-}]$ and $[HSeO_3^-]$ were calculated by using the appropriate values of pK_2 (see experimental part). From the intercepts and the slopes of the plots, the values of k_1 and k_4 have been obtained as;

$$k_1(0.16\text{ M}) = (0.15_3 \pm 0.00_2) \times 10^{-3}\ s^{-1},$$
$$k_1(0.54\text{ M}) = (0.15_0 \pm 0.00_2) \times 10^{-3}\ s^{-1},$$
$$k_4(0.16\text{ M}) = (0.10 \pm 0.04) \times 10^{-1}\ M^{-1}\ s^{-1},$$
$$k_4(0.54\text{ M}) = (0.21 \pm 0.03) \times 10^{-1}\ M^{-1}\ s^{-1}.$$

As may be expected, the k_1 path is free from the salt effect and the k_4 path shows a positive salt effect.

By using the $[Se(IV)] = [HSeO_3^-] + [SeO_3^{2-}]$ relation, Eq. (I) may be rewritten in the form;

$$(R - k_1[SeO_3^{2-}])/[HSeO_3^-] = (k_2 + k_4[Se(IV)]) + (k_3 - k_4)[HSeO_3^-]. \quad \text{(II)}$$

Fig. 6 shows the plots of $(R - k_1[SeO_3^{2-}])/[HSeO_3^-]$ against $[HSeO_3^-]$ at a constant [Se(IV)] for two values of the ionic strength. The least-squares treatment yields;

$$(k_2 + k_4[Se(IV)]) = (0.68 \pm 0.16) \times 10^{-3}\ s^{-1},$$
and $$(k_3 - k_4) = (1.16 \pm 0.16) \times 10^{-1}\ M^{-1}\ s^{-1},$$
for I=0.16 M, and
$$(k_2 + k_4[Se(IV)]) = (1.05 \pm 0.14) \times 10^{-3}\ s^{-1},$$
and $$(k_3 - k_4) = (1.54 \pm 0.25) \times 10^{-1}\ M^{-1}\ s^{-1},$$
for I=0.54 M. By using the values of k_4 obtained above, k_3 may be evaluated from the values of $k_3 - k_4$ as;

$$k_3(0.16\text{ M}) = (1.3 \pm 0.2) \times 10^{-1}\ M^{-1}\ s^{-1},$$
and $$k_3(0.54\text{ M}) = (1.8 \pm 0.3) \times 10^{-1}\ M^{-1}\ s^{-1},$$

As it is expected that the value of k_2 is only a small fraction of the value of $k_2 + k_4[Se(IV)]$, it is unadvisable to evaluate k_2 from $k_2 + k_4[Se(IV)]$. By using the relation, $[HSeO_3^-] = [Se(IV)]/(1 + (K_2/a_{H^+}))$, Eq. (II) may be rewritten in the form;

$$(R - k_1[SeO_3^{2-}])/[HSeO_3^-] = k_2 + S[Se(IV)], \quad \text{(III)}$$
$$S = (k_3 a_{H^+}/(K_2 + a_{H^+})) + (k_4 K_2/(K_2 + a_{H^+})).$$

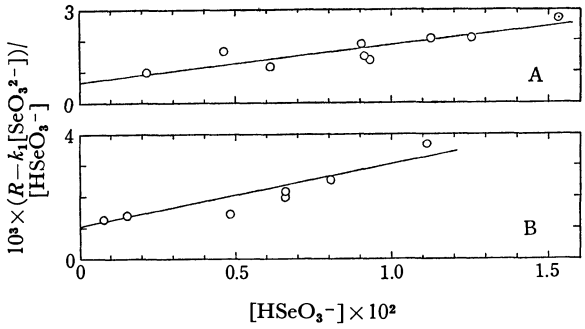

Fig. 6. $(R - k_1[SeO_3^{2-}])/[HSeO_3^-]$ as a function of $[HSeO_3^-]$. A: I=0.16 M, B: I=0.54 M.

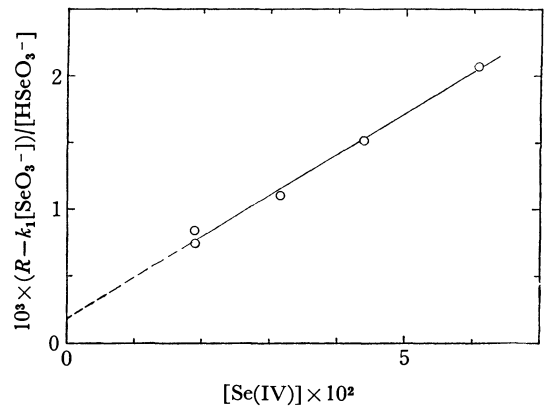

Fig. 7. Evaluation of the rate constant k_2 at I=0.54 M.

Figure 7 shows a plot of $(R - k_1[SeO_3^{2-}])/[HSeO_3^-]$ against [Se(IV)] at a constant pH(9.19) and ionic strength (0.54 M); here the data in Fig. 3 are replotted according to the equation above. The least-squares treatment of the plot yields the values;

$$k_2(0.54\text{ M}) = (0.19 \pm 0.04) \times 10^{-3}\ s^{-1},$$
$$S(0.54\text{M}) = (0.31 \pm 0.01) \times 10^{-1}\ M^{-1}\ s^{-1}.$$

As Path (2) may be expected to be free from any kinetic salt effect, the rate constant, k_2, at I=0.16 M should have almost the same value as k_2(0.54 M).

The values of k_4 calculated from the values of k_2 and $k_2 + k_4[Se(IV)]$ are $k_4(0.16\text{ M}) = 0.09 \times 10^{-1}$ and $k_4(0.54\text{ M}) = 0.15 \times 10^{-1}\ M^{-1}\ s^{-1}$. The value of $k_3(0.54\text{ M})$ may also be calculated from the values of k_4 and of the slope, S, of Eq. (III). The result is $k_3(0.54\text{ M}) = 1.5 \times 10^{-1}\ M^{-1}\ s^{-1}$. These values are in satisfactory agreement with the values of k_3 and k_4 obtained above. This fact gives evidence of the self-consistency of this analysis.

The values of the rate constants obtained are summarized in the following table. By using the rate law (I) and the values of the rate constants, the rates of oxygen exchange are recalculated and shown as curves in Fig. 1. The agreement of the calculated rates with the observed rates is satisfactory except at the acidic end of the curve for I=0.54 M.

The reactivities of the hydrogen-selenite and selenite ions towards water are almost equal, the former being somewhat larger. The hydrogen-selenite ion is about ten times as reactive as the selenite ion towards the

Table 1. The values of rate constants at 0°C

Exchange path	Rate const. (unit)	Ionic strength 0.16 M	Ionic strength 0.54 M
$SeO_3^{2-} + H_2O \rightleftarrows$	$k_1(s^{-1})$	0.15×10^{-3}	0.15×10^{-3}
$HSeO_3^- + H_2O \rightleftarrows$	$k_2(s^{-1})$	0.2×10^{-3}	(0.2×10^{-3})
$HSeO_3^- + HSeO_3^- \rightleftarrows Se_2O_5^{2-} + H_2O$	$k_3(M^{-1}\ s^{-1})$	1.3×10^{-1}	1.8×10^{-1}
$HSeO_3^- + SeO_3^{2-} \rightleftarrows Se_2O_5^{2-} + OH^-$	$k_4(M^{-1}\ s^{-1})$	0.1×10^{-1}	0.2×10^{-1}

hydrogen-selenite ion. This is in part due to the electrostatic repulsion between the reactants.

It may be seen from the table that none of the paths, (1)—(4), show a negative salt effect. Thus, the negative salt effect observed for the over-all oxygen exchange rate cannot be attributed to a kinetic origin. It must be due to an equilibrium salt effect on the dissociation of the biselenite ion. An increase in the ionic strength increases the dissociation of the biselenite ion and reduces the concentration of the reactive species, $HSeO_3^-$. The negative salt effect observed for the exchange of selenite[2] probably has the same origin.

The authors wish to thank Professor Shinichi Kawaguchi of Osaka City University for his helpful discussions and Mrs. Chiyoko Morimoto for her assistance.

The Electronic Structure of the Electron Donor-Acceptor Complex in Its Lowest Excited Singlet State. II

Hiroshi MASUHARA, Nobuyuki TSUJINO, and Noboru MATAGA

Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received October 4, 1972)

The electronic spectra of some 1,2,4,5-tetracyanobenzene complexes in the lowest excited singlet state at 77 K were obtained by laser photolysis method. The observed spectra can be well reproduced with the superposition of the bands similar to those of acceptor anion as well as donor cation, independent of donors. Comparing the spectra with those of ionic radical salts, it is concluded that the electronic structure of these complexes is quite polar and the fluorescent state is a contact ion-pair. The electronic structures of excited electron donor-acceptor systems have been discussed, on the basis of the interaction between donor cation and acceptor anion. The charge-transfer degree in the excited complexes was found to increase in the following order; 1,2,4,5-tetracyanobenzene-hexamethylbenzene complex in the phosphorescent state < hydrocarbon-amine heteroexcimers < the present complexes in the fluorescent state.

The electronic spectra of excited electron donor-acceptor (EDA) systems such as EDA complexes in the fluorescent as well as phosphorescent states and heteroexcimer have been investigated by laser photolysis method. The excited singlet-singlet ($S_n \leftarrow S_1$) absorption spectra of EDA complexes, which are stable in the ground state, were observed for the first time in the case of 1,2,4,5-tetracyanobenzene (TCNB) and pyromellitic dianhydride (PMDA) complexes with methylsubstituted benzenes.[1-3] The spectra were similar to those of acceptor anion, which indicated the quite polar structure of the lowest excited charge-transfer singlet (^{1}CT) state of EDA complexes. On the other hand, the absorption spectra of intermolecular as well as intramolecular heteroexcimers show numerous bands in the visible region, some of which were found to coincide with those of acceptor anion and donor cation.[4,5] The absorption spectra of the charge-transfer triplet (^{3}CT) state of EDA complex were found to be different from those of acceptor anion and donor cation. The triplet-triplet ($T_n \leftarrow T_1$) absorption spectra of naphthalene, pyrene as well as phenanthrene complexes are similar to those of the donor.[6-8] In the case of the $T_n \leftarrow T_1$ spectra of TCNB complexes with methylsubstituted benzenes, some bands which cannot be ascribed to those of the component triplet state have been reported.[7,9]

In view of the above results, the problems on the electronic structures of the excited EDA systems may be summarized as follows; (1) elucidation of the relation between the electronic spectra and CT degree in these systems, (2) investigation of the difference among the electronic structures of ^{1}CT as well as ^{3}CT states of EDA complexes and heteroexcimer, (3) theoretical study on energies as well as intensities of back CT transitions from acceptor anion to donor cation,[2] (4) investigation of the structural change, which occurs in the course of the relaxation from the excited Franck-Condon (FC) to fluorescent states.[2,10]

We have been studying the electronic spectra of some excited EDA complexes for elucidating the above problems. Although the $S_n \leftarrow S_1$ spectra of TCNB complexes with benzene, toluene and mesitylene were obtained at room temperature, the observation of the $S_n \leftarrow S_1$ spectra of TCNB complexes with α-methylstyrene, durene and hexamethylbenzene (HMB)

donors was difficult because of their short lifetimes of the lowest excited singlet state. However, in rigid solutions the fluorescence lifetimes of the latter complexes become long enough for measurement of the $S_n \leftarrow S_1$ spectra. In the present paper, the $S_n \leftarrow S_1$ spectra of several TCNB complexes in polymethylmethacrylate (PMMA) at room temperature as well as in rigid glass at 77 K will be reported.

Experimental

The fluorescence intensities of the present TCNB complexes are stronger than the monitoring light intensity. Accordingly, the observation of the $S_n \leftarrow S_1$ spectra is difficult. However, we can obtain those spectra by the re-absorption method developed by us.[11] Namely, the $S_n \leftarrow S_1$ spectra have been obtained by comparing fluorescence spectra observed by laser excitation of low intensity (one three hundredth of high intensity) with those observed by laser excitation of high intensity which are partially re-absorbed by the complex in the fluorescent state. Some points should be noted on this method. The first one is the selection of the wave number, at which both fluorescence spectra are normalized. Secondly, it is difficult to obtain the $S_n \leftarrow S_1$ spectra in the wave number regions where the fluorescence intensity is about one tenth of its peak intensity, because in this case the noise of the out-put of photomultiplier is in the same order of magnitude as the signal and a slight fluctuation of fluorescence intensity out-put leads to a large uncertainty of the $S_n \leftarrow S_1$ spectra. Thirdly, it is necessary to remove the contribution of the absorption of ^{3}CT state from the observed spectra since ^{3}CT state of some TCNB complexes is confirmed to be formed from the excited FC state, competing with the formation of ^{1}CT state.[12] The wave number where we have normalized two fluorescence spectra obtained by high and low laser excitations, and the absorbances of the $T_n \leftarrow T_1$ transitions at those wave numbers respectively, are indicated in Table 1. At the longer wavelength regions, we have measured $S_n \leftarrow S_1$ spectra by usual nsec flash photolysis method.[13] The apparatus and the chemicals were the same as used before.[12,13]

Table 1. Normalization conditions of fluorescence spectra of some TCNB complexes, obtained by high and low intensity laser excitations

Donors	Wave number of normalization	Optical density of $T_n \leftarrow T_1$ spectra at the wave number of normalization
Toluene	20 kK	0.1
Mesitylene	24.8	~0 (neglected)
	18.9~19.2	~0 (neglected)
Durene	22.5	~0 (neglected)
HMB	17~18	~0 (neglcctcd)
Naphthalene	18.2	0.1

occurs from the excited FC state, the contribution of the $T_n \leftarrow T_1$ spectra to the observed transient spectra should be taken into consideration. The transient absorption band with maximum at about 21 kK cannot be ascribed to the TCNB anion produced by laser excitation, but is due to the fluorescent state of TCNB complexes which has a very polar structure, since the fluorescence at this wave number shows a particular nonexponential decay as shown in Fig. 6.

In the case of TCNB-toluene complex, the peak at 21.2 kK is similar to the band of TCNB anion.[14] A slight red shift and broadening of this band, compared to the case of the solution spectra of TCNB anion, can be noted. In the lower wave number region, no information is available by means of the present reabsorption method. In the present $S_n \leftarrow S_1$ spectra, one cannot observe any band which can be ascribed to the toluene cation.

In the transient spectra of TCNB-mesitylene system, the peak at 21.6 kK may be attributed to the TCNB anion-like component in the fluorescent state of the complex. In this case no red shift in comparison with the solution spectra of TCNB anion was observed. The broad band in the region of 22.4~24 kK may be attributed to the $T_n \leftarrow T_1$ transition, while the band at 20 kK may be ascribed to mesitylene cation-like

14) A. Ishitani and S. Nagakura, *Theoret. Chim. Acta (Berl.)*, **4**, 236 (1966).

component in the excited complex, since Badger and Brocklehurst have reported the cation band at 19.2 kK.[15]

Quite similar interpretation of the spectra may be possible also in the case of TCNB-durene-PMMA system. One can recognize a little broadening of 21.5 kK band. The band at about 18 kK may be related to the durene cation-like state in the fluorescent complex as well as the ^{3}CT state.[9]

In the case of TCNB-HMB complex, the bands in high wave number region cannot be obtained by the present re-absorption method. The band, 21.2 kK is similar to that of TCNB anion. The red shift and a little broadening of the latter band are observed. The absorption band in the low wave number region is almost identical with that of HMB cation.[15] The contribution of $T_n \leftarrow T_1$ absorption to the spectra is rather small.

The spectra of TCNB-naphthalene-PMMA system can be well reproduced by a superposition of the $T_n \leftarrow T_1$ spectra and the band similar to those of TCNB anion and naphthalene cation.[16] The peak at 21.4 kK and the shoulder at 20.8 kK are similar to those of TCNB anion and naphthalene cation, respectively. The strong broad band near 23 kK can be attributed to the superposition of the $T_n \leftarrow T_1$ spectra with large intensity and the $S_n \leftarrow S_1$ band similar to those of naphthalene cation. The similarity of the $S_n \leftarrow S_1$ band to the band of naphthalene cation can be observed clearly also in the low wavenumber region, where the spectra were measured by nsec flash photolysis method.[13]

These spectra are the first observations of the $S_n \leftarrow S_1$ spectra of EDA complexes at 77 K. Although the $S_n \leftarrow S_1$ spectra of TCNB complexes with benzene, toluene and mesitylene donors at room temperature have been reported,[1-3] the absorption spectra of TCNB complexes in the fluorescent state with rather strong donors such as durene, HMB and naphthalene are given for the first time in the present work.

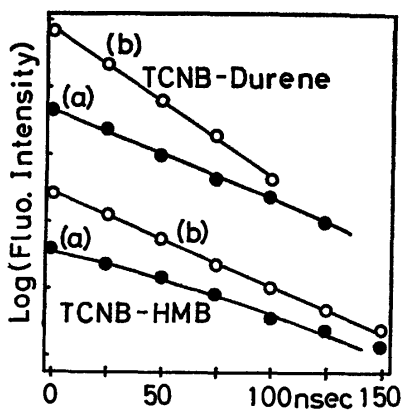

Fig. 6. Fluorescence decay curves of TCNB-durene and TCNB-HMB complexes. (a) 475 nm. (b) 515 nm. In the case of TCNB-mesitylene and TCNB-naphthalene complexes, similar results were obtained but the deviation from the exponential decay is small. The decay curve of TCNB-toluene complex in *n*P–*i*P has been reported in Ref. 12.

Discussion

The $S_n \leftarrow S_1$ spectra of the present TCNB complexes at 77 K can be well reproduced by the superposition of the bands similar to those of TCNB anion as well as donor cation. Although the wave numbers and bandwidths of the ion-like bands in the $S_n \leftarrow S_1$ spectra are a little different from those of the free ions in solution, the electronic structures of the fluorescent states may be concluded to be quite polar in general even at 77 K, irrespectively of the donors. This result is the same as that obtained from some TCNB complexes at room temperature. Since it can be expected theoretically[17] that the CT degree of the excited FC state is not so large as that of the fluorescent state and depends on the strength of the donor, there may exist a relaxation process involving structural changes as well as solvent re-orientation from the excited FC state to the fluorescent state, leading to the quite polar structure.[2]

The $S_n \leftarrow S_1$ spectra of the present complexes may be compared with the spectra of ionic radical salts, since the latter are deemed to be composed of donor cation and acceptor anion. The characteristics of the spectra of some ionic radical salts are summarized as follows.[18-20] (1) The blue shift of the bands associated with component ions is observed to be about 2~4 kK. (2) The absorption bands of the original ions are broadened. (3) The CT transition from acceptor anion to donor cation is observed in the near-infrared region, which is not obtained in solution spectra of both ions. The shift as well as the broadening of the bands of component ions in the present case of the TCNB complexes are rather different from those of the ionic radical salts. On the other hand, Kimura et al. have reported electronic spectra of ion-pair produced by irradiating EDA complexes and those of photoionized molecules in rigid solution and have pointed out a slight red shift of the ion bands in the ion-pair.[21] These comparisons suggest that the component ions in the fluorescent state of TCNB complexes does not interact with each other through the overlap integrals as in the case of ionic radical salts, but are influenced only by electrostatic interaction between both ions. Since fluorescence, which is accompanied with an electron transfer from anion to cation, is observed, it is concluded that the fluorescent state of these complexes at 77 K is not a solvent-shared but a contact ion-pair. However, the latter ion-pair

may be strongly solvated, which leads to weak interaction. Although the CT band is reported in the case of ionic radical salts, we have observed no back CT transition from TCNB anion to donor cation in the $S_n \leftarrow S_1$ spectra. This result is consistent with the above conclusion.

Now it is interesting to discuss generally the electronic structure of the excited EDA systems such as ^{1}CT as well as ^{3}CT states of EDA complexes and heteroexcimer. In the case of heteroexcimer formed through the quenching of aromatic hydrocarbon by aromatic amines and nitriles, the polar character of the electronic structure has been confirmed by a number of investigations.[22] The direct observation of the electronic spectra of heteroexcimer has been made possible by nsec flash photolysis. Potashnik *et al.* reported the spectra of diethylaniline-aromatic hydrocarbon systems, which seem to be interpretable as originating from the local transitions in aromatic hydrocarbon anion as well as dietylaniline cation and the back CT transition from anion to cation.[4] Similar results have been obtained in the pyrene–dimethylaniline systems in various solvents and also in the case of the intramolecular EDA systems containing the aromatic hydrocarbon and dimethylaniline moieties in the same molecule.[5] In the case of ^{3}CT state of TCNB complexes with methylsubstituted benzene donors, the CT degree was concluded to increase with the decrease of ionization potential of donor.[23] The CT degree of TCNB-HMB complex in the phosphorescent state was calculated to be about 95%. Thus, its electronic structure is quite polar. Therefore, it seems to be appropriate to study on the electronic structure of ^{1}CT state of the present TCNB complexes, ^{3}CT state of TCNB-HMB complex and the above mentioned heteroexcimer, based on the interaction between donor cation and acceptor anion.

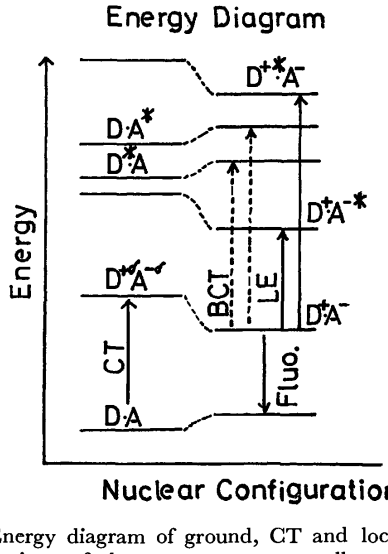

Fig. 7. Energy diagram of ground, CT and locally excited configurations of donor, acceptor as well as component ions. LE; local excitations of donor cation or acceptor anion. BCT; back CT transition from acceptor anion to donor cation.

We made a theoretical study on the fluorescent state by considering the configuration interactions (CI) among the ground, CT, back CT configurations and locally excited configurations of the acceptor anion-donor cation system.[2] This method may be useful also in analyzing ^{3}CT state of TCNB-HMB complex and the fluorescent state of heteroexcimer. The wave functions of several configurations may be given in the same form as in the previous paper.[2] The energies of the locally excited configurations of anion and cation may be taken from the observed values of the ions. It is rather difficult to estimate the energy of back CT transition from acceptor anion to donor cation. We have proposed a semiempirical method for obtaining the latter transition energy in terms of the rearrangement energy.[2] As indicated in Fig. 7, the transition energy can be given as

$$E(\text{back CT}) = E(\text{D*A}) \text{ or } E(\text{DA*}) - h\nu_{\text{f, 0-0}} + E_{\text{rea}}$$

where E(D*A) and E(DA*) represent the energies of locally excited configurations of donor and of acceptor, respectively, and $h\nu_{\text{f,0-0}}$ is the 0–0 band of fluorescence. E_{rea} is the rearrangement energy in question. Two methods for the evaluation of E_{rea} were proposed. In one method, it is assumed that E_{rea} involves the effects of the change of the geometrical structure and the CT degree in the higher excited state of the complex. In the other method, it is assumed that the contribution of the solvation energy to E_{rea} is overwhelming. The latter method is applied in the present work, since the problem of the structural change in the higher excited state is not yet elucidated. Putting E_{rea} as E_{des}, destablization energy in the FC ground state due to the solvent orientation, one can obtain the following equation.

$$\begin{aligned} E(\text{back CT}) &= E(\text{D*A}) \text{ or } E(\text{DA*}) - h\nu_{\text{f, 0-0}} + E_{\text{des}} \\ &= E(\text{D*A}) \text{ or } E(\text{DA*}) - h\nu_{\text{f, max}} \end{aligned}$$

where $h\nu_{\text{f,max}}$ represents the fluorescence maximum energy. The nondiagonal terms of CI secular equation should be evaluated theoretically using open shell MO.

Using the above theoretical treatment, we will now discuss the electronic structures of some excited EDA systems. In the first place, the $S_n \leftarrow S_1$ spectra of the present TCNB complexes and the absorption spectra of heteroeximers will be examined. The spectra of heteroexcimers were assigned to the transition associated with component ions and to the back CT transitions, where the intensities of both transitions are in the same order.[4] This assignment is consistent with theoretical model proposed by us. On the other hand, no large band due to back CT transition was observed

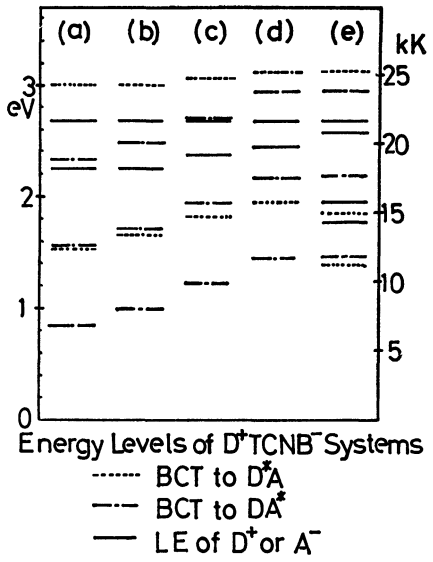

Fig. 8. Estimated energy levels for higher excited states of donor cation-TCNB anion system. The energy of fluorescent state of some TCNB complexes at 77 K was set as the standard. Donors are (a) benzene (b) toluene (c) mesitylene (d) HMB and (e) naphthalene. The energy levels of TCNB-durene complex are omitted since the precise value of higher excited state of durene is not known. However, almost the same values as in the case of TCNB-HMB complex are expected. Each value is estimated, using the data of Refs. 10, 24 and 25.

in the present work, which is the important difference between the ^{1}CT state of EDA complex and heteroexcimer. We have estimated the back CT transition energy using the above theoretical model and obtained the results as shown in Fig. 8. Here only *ungerade* states of locally excited configurations of donor as well as acceptor are included, although notations of *gerade* and *ungerade* are meaningless in the symmetry of the EDA complex. There may be more locally excited configurations, which corresponds to the *gerade* state of component molecules, and more back CT transitions may be expected. However, we have observed no absorption bands other than those due to the transitions associated with component ions. Since back CT transitions are forbidden without CI interaction the mixing of the back CT and locally excited configuration is required for the observation of these transitions. The fact that it is possible to observe the back CT transitions in the case of heteroexcimer means the more extensive mixing of both configurations than in the case of ^{1}CT state of the TCNB complexes. Hence, it may be concluded that ^{1}CT state of TCNB complexes at 77 K is more polar than heteroexcimer.

In the second, the $S_n \leftarrow S_1$ spectra of the present complexes and $T_n \leftarrow T_1$ spectra of TCNB-HMB complex will be discussed. Because the diagonal terms are the same in both cases, there may be nondiagonal matrix element that leads to the different electronic spectra. In the first approximation, the matrix elements between CT and other configurations may be important for elucidating the electronic structure of both of lowest singlet and triplet states. Under the condition of neglecting intermolecular differential overlap integrals, the matrix elements of the triplet state are identical with those of the singlet state and consist of one core attraction term.[7] Assuming the same geometrical structure in the fluorescent and phosphorescent states, it is expected that the $T_n \leftarrow T_1$ spectra are similar to $S_n \leftarrow S_1$ spectra. However, the observed results are different from this expectation and in the $T_n \leftarrow T_1$ spectra[7] we have found no band which coincides with that of TCNB anion. This result may be attributed to the difference of CT degree of the triplet state from that of the singlet state which may have different geometries, contrary to the above treatment.

We have made clear that the observed $S_n \leftarrow S_1$ spectra similar to those of TCNB anion can be explained statisfactorily when donor cation and acceptor anion are completely overlapped each other in C_{2v} symmetry or when both ions are loosely interacting with each other at a longer distance.[2] Moreover the CT degree was determined to be $\sim$100% in the case of these geometrical configurations. Thus, it is concluded that the CT degree in the phosphorescent state of TCNB-HMB complex is lower than that in the fluorescent state and the geometrical configurations of the former state are different from those of the latter. Moreover, the CT degree in the ^{3}CT state of the TCNB-HMB complex may be lower than that of heteroexcimer since any band similar to that of the acceptor anion was not observed in the case of the former system.

Now it is concluded that the CT degree increases in the following order; ^{3}CT state of TCNB-HMB complex < heteroexcimer < ^{1}CT state of some TCNB complexes.

The Crystal and Molecular Structure of 5-Chloro-7-iodo-8-quinolinol, Chinoform

Setsuo KASHINO and Masao HAISA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received October 28, 1972)

Isomorphous crystals of 5-chloro-7-iodo- and 5,7-dibromo-8-quinolinols have been examined by X-ray analysis. Both compounds crystallize in the monoclinic space group $P2/a$ with four formula units in the unit cell. The cell dimensions are: $a=16.98$; $b=4.16$; $c=14.84$ Å, and $\beta=112.0°$ for 5-chloro-7-iodo-8-quinolinol, and $a=16.34$, $b=4.02$, $c=15.52$ Å, and $\beta=115.6°$ for 5,7-dibromo-8-quinolinol. The structure of the former, chinoform, has been determined by the Patterson methods from data collected with Mo$K\alpha$ radiation on Weissenberg photographs, and refined by the block-diagonal least-squares method, with anisotropic temperature factors. The final R value is 0.081 for 836 observed reflections. The quinolinol molecule is nearly planar. In the crystals, the molecules related by two-fold axis are held together by hydrogen bonds to form bent dimers, which are stacked closely by van der Waals forces along the b axis.

The derivatives of 8-quinolinol are widely used as chelating agents in analytical chemistry and a number of their complexes are investigated, especially by Prout and his coworkers,[1] by means of X-ray diffraction structure analysis in connection with the Mulliken's "overlap and orientation" principle.[2] 5-Chloro-7-iodo-8-quinolinol is medically important as so-called "chinoform". In this study the cell dimensions and the space group of 5-chloro-7-iodo- and 5,7-dibromo-8-quinolinols were determined, and the structure of the former compound was studied by X-ray diffraction analysis.

Experimental

5-Chloro-7-iodo-8-quinolinol (prepared by Tanabe Seiyaku Co., Ltd.) was recrystallized from ethanol. Crystals obtained by slow evaporation from ethanol solution were monoclinic needles elongated along the b-axis. Cell constants were determined from Weissenberg and oscillation photographs taken with Cu$K\alpha$ radiation ($\lambda=1.5418$ Å). Crystal data are given in Table 1 along with those of 5,7-dibromo-8-quinolinol, which have been determined by the same way as those of chinoform. Since crystals of 5,7-dibromo-8-quinolinol gave no suitable photographic spots for intensity measurements, the structure analysis was not tried. A possible space group of these two compounds is determined to be Pa or $P2/a$ from the absent spectra: $h0l$ when h is odd. Structure analysis of chinoform was made on the basis of the latter space group symmetry and gave a reasonable structure. The space group of 5,7-dibromo-8-quinolinol may also be $P2/a$ because its molecular symmetry is the same as that of chinoform.

Intensity data of chinoform were initially collected with Cu$K\alpha$ radiation by means of the equi-inclination Weissenberg photographs, for the layers of $h0l$ to $h3l$. However, in view of the large absorption effect the data were recollected, after the structure was determined, with Mo$K\alpha$ radiation, for the layers of $h0l$ to $h4l$ using a crystal of $0.11\times0.12\times0.60$ mm³. A total of 836 independent non-zero reflections were measured visually. The inter-layer scaling was made according to the exposure time. Corrections were made for the Lorentz and polarization factors, and for the spot shape.

Table 1. Crystal data

Structure Determination

Approximate positional parameters of all non-hydrogen atoms were easily determined from a three-dimensional Patterson map. The structure was then refined isotropically by the block-diagonal least-squares method.[3] An R value dropped from 0.24 for the trial structure to 0.18. The structure was refined anisotropically for the non-hydrogen atoms to the R value of 0.123 for the copper data. Using the positional parameters thus obtained and $B=5.35$ Å² from Wilson's method as initial parameters, an isotropic refinement was made with the molybdenum data. Thereafter the data of each layer were re-scaled on the basis of the ratio of $\Sigma|F_o|$ and $\Sigma|F_c|$. The refinement with anisotropic thermal parameters reduced the R value to 0.084. Three hydrogen atoms attached to a quinoline ring were located from a difference map, but the other two hydrogen atoms were not revealed. Assuming suitable geometries of the C–H bond (C–H=1.08 Å), the positional parameters of the four ring hydrogen atoms were computed. These parameters and an isotropic temperature factor, $B=4.5$ Å², were introduced as

Table 2. Final atomic parameters

All values should be multiplied by 10^{-4}. The e.s.d.'s of atomic coordinates are shown in parentheses. The anisotropic thermal parameters are expressed as $\exp(-B_{11}h^2-B_{22}k^2-B_{33}l^2-B_{12}hk-B_{13}hl-B_{23}kl)$.

Atom	x/a	y/b	z/c	B_{11}	B_{22}	B_{33}	B_{12}	B_{13}	B_{23}

C(10)	5444(13)	617(49)	2677(14)	41	578	48	−11	11	−80

fixed parameters, and the parameters for all non-hydrogen atoms were refined anisotropically, using the following weighting scheme:

$\sqrt{w} = 1.0$, if $10.0 \leqq F_o \leqq 27.0$,

$\sqrt{w} = 27.0/F_o$, if $F_o > 27.0$,

and $\sqrt{w} = 0.0$ for unobserved reflections.

The final R value was 0.081 for the 836 non-zero reflections. The final atomic parameters are given in Table 2. A composite drawing of the final electron density map is shown in Fig. 1. The observed and calculated structure factors are listed in Table 3.

The atomic scattering factors used were those of Hanson, Herman, Lea, and Skillman.[4] The numerical calculations were performed with the aid of a HITAC 5020 E computer of the Computer Center of the University of Tokyo.

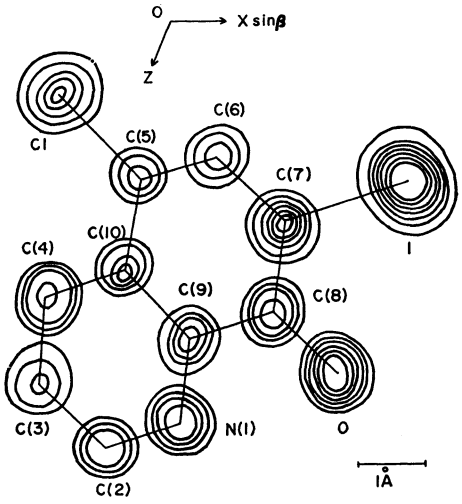

Fig. 1. Composite three-dimensional final electron-density map projected along the b axis. Contours are at intervals of 1 e Å^{-3} for C, N and O atoms, 5 e Å^{-3} for Cl atom and 10 e Å^{-3} for I atom, each starting at 3 e Å^{-3}.

Results and Discussion

Bond lengths and angles are shown in Fig. 2. The average C–C bond length within the quinoline ring is 1.42 Å. Although the average standard deviation of the bond lengths amounts to 0.03 Å, the shortening of the C(3)–C(4) and C(5)–C(6) bonds and the lengthening of the C(4)–C(10) and C(8)–C(9) bonds may be significant. The results of semi-empirical SCF-MO calculation[5] and X-ray crystallographic studies[1,6,7] of quinoline and its derivatives have shown the similar shortening and lengthening of the corresponding bonds as compared in Table 4. The C–O bond length (1.36 Å) is almost the same as those

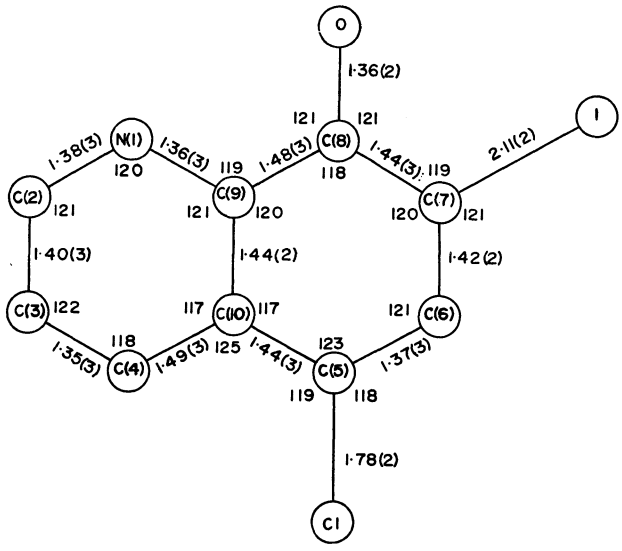

Fig. 2. Bond lengths(Å) and angles(°). The e.s.d.'s are shown in parentheses for bond lengths, and are 2° for all the bond angles.

ring as a whole is substantially planar within the limit of experimental errors. Among three substituents, only iodine atom deviates significantly from the quinoline ring plane, P(1).

The arrangements of the molecules viewed along the *b* and *c* axes are shown in Fig. 3. In the crystals, the molecules related by the two-fold axis are held together by the hydrogen bonds between oxygen and nitrogen atoms to form bent dimers, which are stacked closely by van der Waals forces along the *b* axis. The hydrogen bond length is 2.85 Å, which is comparable to the intermolecular O–H···N hydrogen bond lengths in 8-hydroxyquinoline dimers in 8-hydroxyquinoline–chloranil[8] and 8-hydroxyquinoline–1,3,5-trinitrobenzene[1] complexes (2.80 and 2.914 Å,

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1098—1101 (1973)

The Kinetics of Association-Dissociation Reaction in an Aqueous Solution of *n*-Butylamine by Means of Ultrasonic Absorption

Sadakatsu NISHIKAWA and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received October 30, 1972)

The ultrasonic absorptions of *n*-butylamine in aqueous solutions were measured at 25°C in the range of frequency from 15 to 220 MHz and of concentration from 0.698 to 3.00 M. The peak sound absorption was found. The mechanism of the observed peak sound absorption was attributed to the $4A \rightleftarrows A_4$ reaction where A and A_4 are the monomer and tetramer of the solute respectively. The rate constants of the forward and backward reaction were determined to be 2.2×10^6 M^{-3} sec^{-1} and 9.0×10^7 sec^{-1} respectively, and the standard volume change between the initial and final state in the reaction was calculated to be 14 ml mol^{-1}.

The method of ultrasonic absorption has been successfully applied to the investigation of reaction kinetics which occurs rapidly, since the relaxation time and excess absorption determined from the absorption data are related to the kinetic parameters.

It is well known that a number of binary liquid mixtures exhibit a maximum in their excess absorption at an intermediate concentration. Andreae and his coworkers[1] have summarized the data for these systems and developed a theory which is associated with the solute-solvent interactions. However, this analysis employs a rather unusually defined equilibrium constant and some of the stoichiometries reported appear to be implausible. Moreover, the data reported are insufficient for a reasonable analysis of the excess absorption mechanism.

It has reported that some amines also show the peak sound absorption phenomena at intermediate concentrations of their aqueous solutions.[1] The purpose of the present investigation is to report the ultrasonic absorption data on aqueous solutions of *n*-butylamine and to clarify the mechanism of the peak sound absorption using the relaxation theory.

Experimental

The *n*-butylamine was of a guaranteed reagent grade and was purified by distillation once. The purity was verified to be higher than 99.9% by the gas-chromatographic method. Deionized and distilled water was used as the solvent. The measurements of the ultrasonic absorption were made at the odd harmonic frequencies of 5 and 20 MHz X-cut quartz transducers by means of the pulse technique.[2] The frequency range of the measurement was from 15 to 220 MHz. The sing-around method was employed at 1.92 MHz to measure the sound velocity. The densities were measured by the standard pycnometer. The pH values of the solutions were measured by a Hitachi-Horiba type F-5 pH meter. All the measurements were made at 25°C.

Results

In Fig. 1 the plots of α/f^2 *vs.* the concentration are shown, where α is the sound absorption coefficient and f is the frequency. As may be seen in this figure, the absorption and the peak sound absorption concentration(P. S. A. C) depend on the frequency. This absorption behavior leads us to predict the existence of the relaxation phenomena.

In general, the sound absorption caused by the several relaxation processes can be described by the following equation:

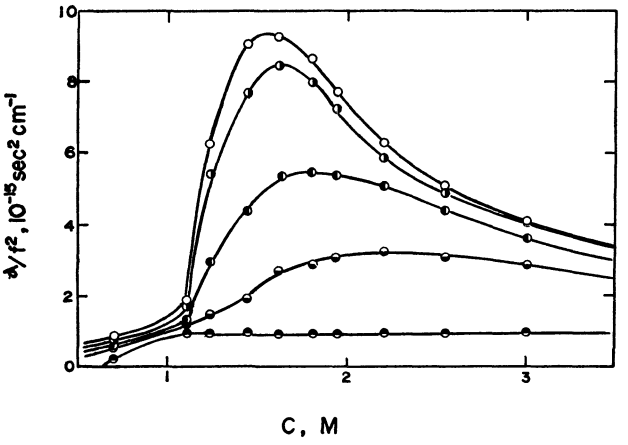

Fig. 1. The plots of α/f^2 *vs.* concentration in aqueous solutions of *n*-butylamine at 25 °C. ○: $f \rightarrow 0$, ◑: $f=15$ MHz, ◐: $f=45$ MHz, ◒: $f=100$ MHz, ◓: $f \rightarrow \infty$.

2) N. Tatsumoto, *J. Chem. Phys.*, **47**, 4561 (1967).

$$\alpha/f^2 = \sum_i \frac{A_i}{1+(f/f_{ri})^2} + B \quad (1)$$

where f_{ri} is the relaxation frequency for the i-th process and A_i and B are constants. In particular, for single and double relaxation processes Eq. (1) can be rewritten as:

$$\alpha/f^2 = \frac{A}{1+(f/f_r)^2} + B \quad (2)$$

and:

$$\alpha/f^2 = \frac{A_1}{1+(f/f_{r1})^2} + \frac{A_2}{1+(f/f_{r2})^2} + B \quad (3)$$

Figure 2 shows the representative ultrasonic absorption spectra of aqueous solutions of *n*-butylamine. All these spectra except the one at 1.10 M show the characteristic behavior due to the single relaxation process which is represented by Eq. (2). The spectrum at 1.10 M is represented by Eq. (3). The relaxation parameters were determined so as to obtain the best fit of the data of Eq. (2) or (3). As may be seen in this figure, the excess absorptions observed in more than 1.10 M are different from those in less than 1.10 M. The latter was attributed to hydrolysis, which was reported in a previous paper by the present authors.[3] In the concentrated solution, the experimental values of α/f^2 at high frequencies tend to be lower than the theoretical ones, as is shown in Fig. 2. This is because the excess absorptions associated with hydrolysis exist in a higher frequency range than that investigated here and the effect due to this relaxation process appears in the experimental values at high frequencies. However, the excess absorption in the concentrated solutions could be treated approximately as a single relaxation process. The concentration dependences of the sound velocity, c, and of the excess absorption, A, are shown in Fig. 3. The concentration at which the sound velocity shows its maximum is lower than that of the excess absorption. This kind of phenomenon has also been observed in binary mixtures.[1,4] The relaxation parameters and the sound velocity obtained are listed in Table 1, together with the density, the pH and the activity coefficient of ions, the last of which was calculated by Davis equation,

$$-\log \gamma = 0.5[\{\sqrt{I}/(1+\sqrt{I})\} - 0.3I].$$

Interpretation of Results

Theoretical. The molecules which consist of hydrophilic and hydrophobic groups have a tendency to associate in an aqueous solution as in the case of surfactants.[5] Therefore, let us consider the reaction expressed by the next formula:

$$nA \underset{k_b}{\overset{k_f}{\rightleftharpoons}} A_n \tag{4}$$

where A is the monomer, A_n is the aggregate, n is the aggregation number, and k_f and k_b are the forward and backward rate constants respectively. If one denotes the molar concentrations of the components, A and A_n, by C_1 and C_2, the rate of return of the system to equilibrium is governed by the rate law:

$$\frac{dC_2}{dt} = k_f(C_1)^n - k_bC_2 \tag{5}$$

Provided that very small periodic perturbations are applied to the system, it may be assumed that the perturbed rate constants and the concentrations differ only slightly from their equilibrium values. One can write for the perturbed variables a series of relations such as:

$$\left.\begin{aligned} C_1 &= \bar{C}_1 + \delta C_1\cdot\exp(i\omega t), \quad C_2 = \bar{C}_2 + \delta C_2\cdot\exp(i\omega t), \\ k_f &= \bar{k}_f + \delta k_f\cdot\exp(i\omega t), \quad k_b = \bar{k}_b + \delta k_b\cdot\exp(i\omega t), \end{aligned}\right\} \tag{6}$$

where the equilibrium values of the rate constants and the concentrations are indicated by a bar over each symbol and the quantities δC_i and δk_i represent the amplitudes of the small variations associated with the sound wave. As the relation between δC_1 and δC_2 is $\delta C_1 = -n\delta C_2$, one obtains the next equation:

$$\delta C_2 = \frac{(\bar{C}_1)^n\delta k_f - \bar{C}_2\delta k_b}{i\omega + \bar{k}_f n^2(\bar{C}_1)^{n-1} + \bar{k}_b} \tag{7}$$

The relaxation time, τ, can be defined as:

$$\tau^{-1} = 2\pi f_r = \bar{k}_f n^2(\bar{C}_1)^{n-1} + \bar{k}_b \tag{8}$$

Since the equilibrium constant is $K = k_b/k_f = (C_1)^n/C_2$,

$$\delta K = \frac{\bar{k}_f\delta k_b - \bar{k}_b\delta k_f}{(\bar{k}_f)^2} \tag{9}$$

The thermodynamic dependence of the equilibrium constant on the pressure is given by the equation:

$$\left(\frac{\partial K}{\partial P}\right)_T \frac{1}{K} = -\frac{\Delta V^\circ}{RT} \tag{10}$$

where ΔV° is the standard volume change, R is the gas constant and T is the absolute temperature. The standard volume change, ΔV°, is defined by $\Delta V^\circ = \bar{V}_2 - n\bar{V}_1$ where $\bar{V}_1$ and $\bar{V}_2$ are the partial molar volumes of A and A_n respectively. The complex compressibility, defined as $\beta' = (-1/V)(\delta V/\delta P)_T$, is related to the relaxational compressibility, β_r:

$$\beta' = \frac{\beta_r}{1 + i\omega\tau} = -\frac{1}{V}\left(\frac{\partial V}{\partial C_2}\right)_T\left(\frac{\partial C_2}{\partial P}\right)_T \tag{11}$$

The relaxational compressibility in a reacting system close to the equilibrium is given by:

$$\beta_r = \frac{2\mu_{max}}{\pi\rho c^2} \tag{12}$$

where ρ is the density and μ_{max} is the maximum excess absorption per wavelength. Therefore, one obtains the next equation:

$$\mu_{max} = \frac{\pi\rho c^2}{2}\cdot\frac{(\Delta V^\circ)^2}{RT}\bar{k}_f(\bar{C}_1)^n\tau \tag{13}$$

Comparison with Experiment. In aqueous solutions of *n*-butylamine, there exists the following equilibrium in addition to that of Eq. (4):

$$R\text{-}NH_3^+ + OH^- \rightleftharpoons R\text{-}NH_2 + H_2O \tag{14}$$

The equilibrium constant, $\bar{K}_b$, is defined by:

$$K_b = \frac{\gamma^2[OH^-]^2}{[R\text{-}NH_2]} \tag{15}$$

where γ is the activity coefficient. Therefore, Eq. (8) may be rewritten as:

$$\tau^{-1} = 2\pi f_r = \bar{k}_f n^2\left(\frac{\gamma^2[OH^-]^2}{\bar{K}_b}\right)^{n-1} + \bar{k}_b \tag{16}$$

The value of n was determined so as to obtain the straight line of the plots of $2\pi f_r$ *vs.* $(\gamma^2[OH^-]^2)^{n-1}$; the result was $n=4$. Figure 4 shows the plots of $2\pi f_r$ *vs.* $(\gamma^2[OH^-]^2)^3$. The forward and backward rate

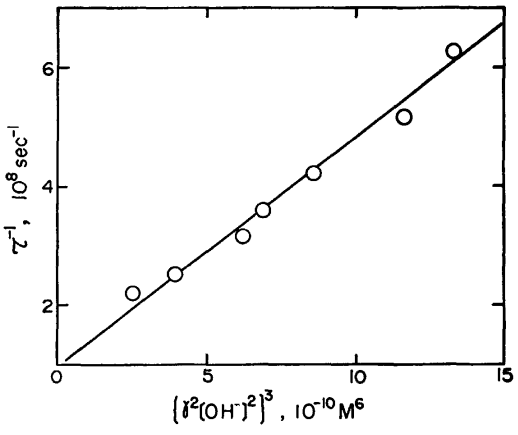

Fig. 4. The plots of τ^{-1} vs. $\{\gamma^2[OH^-]^2\}^3$.

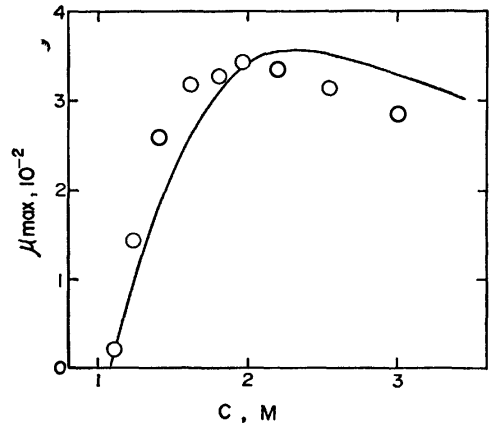

Fig. 5. Comparison of experimental values of μ_{max} with the theoretical ones.

5) K. Shinoda and T. Nakagawa, "Colloidal Surfactants," Academic Press, New York (1963).

constants were determined from the slope and the intercept of this line, using the equilibrium constant, $\bar{K}_b = 4.44 \times 10^{-4}$ M, in the literature.[6]

On the other hand, the maximum excess absorption per wavelength, μ_{max}, was calculated from Eq. (13). The result of the theoretical calculation of μ_{max} at $n=4$ is shown in Fig. 5, together with the experimental values. A considerably good agreement between the experimental and theoretical values was obtained, as is seen in this figure. The value of ΔV° was calculated from Eq. (13) by using the experimental value for μ_{max} at the concentration of 1.94 M. The rate constantes and the standard volume change obtained in the present investigation are $\bar{k}_f = 2.2 \times 10^6$ M^{-3} sec^{-1}, $\bar{k}_b = 9.0 \times 10^7$ sec^{-1} and $\Delta V^\circ = 14$ ml mol^{-1}.

Discussion

The phenomena that the excess absorption and velocity of ultrasonic wave exhibit the maximum in the intermediate concentration have previously been reported in many binary mixtures. The excess absorption mechanism has been explained in terms of the solute-solvent interaction.[1,4] The models are:

$$AA + BB \rightleftharpoons 2AB, \tag{17}$$

$$A + B_m \underset{k_b'}{\overset{k_f'}{\rightleftharpoons}} AB_m \tag{18}$$

where A is the solute molecule, B is the water molecule, B_m is the aggregate of water molecules and the AB or AB_m complex is formed by hydrogen bonding. First, if the mechanism of the excess absorption in the aqueous solution of *n*-butylamine is due to the perturbation of the equilibrium expressed by Eq. (17), P. S. A. C should be 0.5 mole fraction of the solute. However, the observed value of P. S. A. C is 0.04 mole fraction of amine for the aqueous solution of *n*-butylamine. Secondary, if the mechanism is associated with the model of Eq. (18), the relation between the relaxation time and the concentration is derived to be $\tau^{-1} = 2\pi f_r = \bar{k}_f' \sqrt{\{\bar{K}' + \bar{C}_a - (\bar{C}_b/m)\}^2 + (4\bar{C}_b/m)\bar{K}'}$ where $\bar{K}' = \bar{k}_b/\bar{k}_f'$ and $\bar{C}_a$ and $\bar{C}_b$ are the total concentrations of the solute and the solvent respectively. However, the concentration dependence of the relaxation time cannot be interpreted by this equation, since the reasonable parameters, $\bar{k}_f'$ and $\bar{K}'$ have not been determined unitarily. Therefore, these two mechanisms must be ruled out as the cause of the excess absorption in the aqueous solution of *n*-butylamine.

6) M. C. Cox, D. H. Everett, D. A. Landsman, and R. J. Munn, *J. Chem. Soc., B*, **1968** 1373.

The *n*-butylamine, which consists of hydrophilic and hydrophobic groups, is one of the surface active agent.[7,8] Therefore, the molecule has a tendency to aggregate in an aqueous solution. The aggregate is formed by hydrophobic bonding. Expressing Eq. (8) in terms of $C_0 = [R\text{-}NH_2] + n[(R\text{-}NH_2)_n]$ yields:

$$\tau^{-1} = 2\pi f_r = n\bar{k}_b\bar{K}_b \frac{C_0}{\gamma^2[OH^-]^2} + (1-n)\bar{k}_b \tag{19}$$

One can estimate the equilibrium constant, $\bar{K}_b$, from this equation. The value is $\bar{K}_b = (8 \pm 3) \times 10^{-4}$ M which is very close to the value in the literature.[6] This information also confirms that the cause of the excess absorption in the aqueous solution of *n*-butylamine is attributable to the perturbation of the equilibrium expressed by Eq. (4).

As there exist two types of equilibria in the solution, it may be necessary to consider precisely the two-step mechanism, that is, the reaction which is coupled by Eqs. (4) and (14). Therefore, the following formula may be considered:

$$A^+ + B^- \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} A \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \frac{1}{n}A_n \tag{20}$$

The relaxation times are derived from the next determinant:[9]

$$\begin{vmatrix} a_{11} - \tau^{-1} & a_{12} \\ a_{21} & a_{22} - \tau^{-1} \end{vmatrix} = 0 \tag{21}$$

where $a_{11} = \bar{k}_{12}(\bar{C}_{A^+} + \bar{C}_{B^-}) + \bar{k}_{21}$, $a_{12} = n\bar{k}_{21}$, $a_{21} = \bar{k}_{23} \times (\bar{C}_A)^{n-1}$, and $a_{22} = \bar{k}_{32} + \bar{k}_{23}(\bar{C}_A)^{n-1}n^2$. If one denotes the relaxation time for the faster process by τ_1, and that for the slower process by τ_2, one obtains the next equation under the condition $\tau_1 \ll \tau_2$:

$$\tau_2^{-1} = \bar{k}_{23}(\bar{C}_A)^{n-1}\left\{\frac{n^2(\bar{C}_{A^+} + \bar{C}_{B^-})}{\bar{C}_{A^+} + \bar{C}_{B^-} + \bar{K}_b}\right\} + \bar{k}_{32} \tag{22}$$

Therefore, the contribution from the faster process to the slower one is expressed in terms of $(\bar{C}_{A^+} + \bar{C}_{B^-})/(\bar{C}_{A^+} + \bar{C}_{B^-} + \bar{K}_b)$ comparing with Eq. (8). The neglect of this term alters the calculated values of $\bar{k}_f$ and $\bar{k}_b$ in Eq. (4) by less than 2%.

Similar investigations for aqueous solutions of other amines will give an insight into the more detailed clarification of the cause of the phenomena associated with the peak sound absorption.

Vibration-Rotation Interaction Constants, *l*-Type Doubling Constants and Cubic Force Constants of CH_3I and CD_3I

Hiroatsu MATSUURA and John OVEREND*

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

**Molecular Spectroscopy Laboratory, School of Chemistry, University of Minnesota, Minneapolis, Minnesota 55455, U.S.A.*

(Received November 22, 1972)

The harmonic parts of the vibration-rotation interaction constants and the *l*-type doubling constants were calculated for CH_3I and CD_3I from the harmonic force field. The harmonic parts were subtracted from the experimental values to obtain the anharmonic parts which give relations among the cubic normal-coordinate force constants. Some of the individual values for the cubic force constants associated with the bending modes were obtained by using the derived relations and the previously estimated values for the stretch-stretch-stretch cubic force constants of the methyl group.

Spectroscopic data for CH_3I and CD_3I have been accumulated by the systematic studies of high-resolution infrared spectra and microwave spectra. The observed values of rotational constants in the ground vibrational state and a knowledge of the dependence of these rotational constants on each of the normal modes of vibration made it possible to determine accurately the equilibrium geometry of the methyl iodide molecule.[1] From the experimental values of the vibration-rotation interaction constants (α) and the *l*-type doubling constants (q), supplemented by the calculation of the harmonic contributions to these constants, relations among the cubic normal-coordinate force constants may be derived.[2,3] Although the determination of the individual force constants is not possible for this molecule,[4] these relations are still important in the estimation and discussion of vibrational anharmonicity in the methyl iodide molecule. In the present study, we have derived such relations for CH_3I and CD_3I from the α and q constants, and have used the relations together with the previously estimated cubic force constants of the CH stretching modes[5] to obtain some of the individual cubic force constants associated with the bending modes.

Vibration-Rotation Interaction Constants

The vibration-rotation interaction constants α_s^B and α_s^A are defined according to the relations[6]

$$B_{[v]} = B_e - \sum_s \alpha_s^B(v_s + d_s/2), \tag{1}$$

and

$$A_{[v]} = A_e - \sum_s \alpha_s^A(v_s + d_s/2). \tag{2}$$

The α_s^B and α_s^A constants consist of harmonic and anharmonic parts, namely

$$\alpha_s^B = \alpha_s^B(\text{harm}) + \alpha_s^B(\text{anharm}), \tag{3}$$

and

$$\alpha_s^A = \alpha_s^A(\text{harm}) + \alpha_s^A(\text{anharm}). \tag{4}$$

$\alpha_s^B(\text{harm})$ and $\alpha_s^B(\text{anharm})$ are given by the following general expressions[7]

$$\alpha_s^B(\text{harm}) = -\frac{2B_e^2}{d_s\omega_s} \times \sum_\sigma \left[\sum_{\substack{s'\sigma' \\ (s' \neq s)}} \frac{3\omega_s^2 + \omega_{s'}^2}{\omega_s^2 - \omega_{s'}^2} (\zeta_{s\tau,s'\sigma'}^{(y)})^2 + \frac{4}{3} \sum_\xi \frac{(a_{s\tau}^{(y\xi)})^2}{I_{\xi\xi}^{(e)}} \right], \tag{5}$$

and

$$\alpha_s^B(\text{anharm}) = -4\pi \frac{B_e^2}{d_s} \left(\frac{c}{h}\right)^{1/2} \times \sum_\sigma \left[\frac{3k_{sss}a_{s\sigma}^{(yy)}}{\omega_s^{3/2}} + \sum_{\substack{s'\sigma' \\ (s' \neq s)}} \frac{k_{sss'}a_{s'\sigma'}^{(yy)}}{\omega_{s'}^{3/2}} \right]. \tag{6}$$

$\alpha_s^A(\text{harm})$ and $\alpha_s^A(\text{anharm})$ are given by the corresponding expressions with A_e and z, in place of B_e and y, respectively. The harmonic parts of α_s^B and α_s^A may be rewritten into forms more convenient for the present case, as will be given below. k_{sss} and $k_{sss'}$ appearing in the anharmonic parts are the cubic force constants when the potential function of a molecule is expanded in terms of dimensionless normal coordinates q_s:

$$V(q)/hc = \frac{1}{2}\sum_s \omega_s q_s^2 + \sum_{s\leq s'}\sum_{s''} k_{ss's''}q_s q_{s'} q_{s''} + \sum_{s\leq s'}\sum_{s''\leq s'''}\sum_{s'''} k_{ss's''s'''}q_s q_{s'} q_{s''} q_{s'''} + \cdots\cdots \tag{7}$$

For the non-degenerate modes, $\alpha_s^B(\text{harm})$ and $\alpha_s^B(\text{anharm})$ are given by

$$\alpha_s^B(\text{harm}) = -\frac{2B_e^2}{\omega_s} \times \left[\sum_{t\in E} \frac{4\omega_t^2}{\omega_s^2 - \omega_t^2} (\zeta_{s,ta}^{(y)})^2 + 3\{1 - \sum_i (l_{t,s}^{(y)})^2\} \right], \tag{8}$$

and

$$\alpha_s^B(\text{anharm}) = -4\pi B_e^2 \left(\frac{c}{h}\right)^{1/2} \times \left[\frac{3k_{sss}a_s^{(yy)}}{\omega_s^{3/2}} + \sum_{\substack{s'\in A_1 \\ (s' \neq s)}} \frac{k_{sss'}a_{s'}^{(yy)}}{\omega_{s'}^{3/2}} \right], \tag{9}$$

and for the doubly-degenerate modes

$$\alpha_t^B(\text{harm}) = -\frac{2B_e^2}{\omega_t}\left[\sum_{s\subset A_1}\frac{2\omega_s^2}{\omega_t^2-\omega_s^2}(\zeta_{s,ta}{}^{(y)})^2 + \sum_{\substack{t'\subset E\\(t'\neq t)}}\frac{4\omega_{t'}{}^2}{\omega_t^2-\omega_{t'}{}^2}(\zeta_{ta,t'a}{}^{(y)})^2 + 3\left\{1-\frac{1}{2}\sum_i[(l_{i,ta}{}^{(y)})^2+(l_{i,tb}{}^{(y)})^2]\right\}\right], \quad (10)$$

and

$$\alpha_t^B(\text{anharm}) = -4\pi B_e^2\left(\frac{c}{h}\right)^{1/2}\sum_{s\subset A_1}\frac{k_{tatas}a_s{}^{(yy)}}{\omega_s{}^{3/2}}. \quad (11)$$

Similarly for α_s^A(harm) and α_s^A(anharm); for the non-degenerate modes

$$\alpha_s^A(\text{harm}) = -\frac{2A_e^2}{\omega_s}\cdot 3[1-\sum_i(l_{i,s}{}^{(z)})^2], \quad (12)$$

and

$$\alpha_s^A(\text{anharm}) = -4\pi A_e^2\left(\frac{c}{h}\right)^{1/2} \times\left[\frac{3k_{sss}a_s{}^{(zz)}}{\omega_s{}^{3/2}}+\sum_{\substack{s'\subset A_1\\(s'\neq s)}}\frac{k_{sss'}a_{s'}{}^{(zz)}}{\omega_s{}^{3/2}}\right], \quad (13)$$

and for the doubly-degenerate modes

$$\alpha_t^A(\text{harm}) = -\frac{2A_e^2}{\omega_t}\left[\sum_{\substack{t'\subset E\\(t'\neq t)}}\frac{4\omega_{t'}{}^2}{\omega_t^2-\omega_{t'}{}^2}(\zeta_{ta,t'b}{}^{(z)})^2 - 3(\zeta_{ta,tb}{}^{(z)})^2 + 3\{1-\sum_i(l_{i,ta}{}^{(z)})^2\}\right], \quad (14)$$

and

$$\alpha_t^A(\text{anharm}) = -4\pi A_e^2\left(\frac{c}{h}\right)^{1/2}\sum_{s\subset A_1}\frac{k_{tatas}a_s{}^{(zz)}}{\omega_s{}^{3/2}}. \quad (15)$$

Since the harmonic parts, α_s^B(harm) and α_s^A(harm), are determined by only the quadratic force constants, we may calculate their values from the harmonic force field. That of methyl iodide is reasonably well known,[8-10] and we have used in the present calculations the hybrid-orbital force field determined by Russell, Needham and Overend.[9] The anharmonic parts, α_s^B(anharm) and α_s^A(anharm), are then obtained by subtracting the calculated values of α_s^B(harm) and α_s^A(harm) from the experimental values of α_s^B and α_s^A. The experimental values of α_s^B and α_s^A, the calculated values of α_s^B(harm) and α_s^A(harm), and α_s^B(anharm) and α_s^A(anharm) are listed in Tables 1 and 2.

a) For sources, see Table I of Ref. 1. Recently microwave spectra of CD_3I in the excited vibrational states have been measured and values for α_2^B, α_3^B, α_5^B, and α_6^B have been obtained (Y. Kawashima and K. Kozima, Symposium on Molecular Structure, Sendai, 1972).

The observed values of α_2^B and α_5^B for CH_3I have been corrected for the Coriolis interaction between ν_2 and ν_5[11]; we use the symbols $\alpha_2^{B'}$ and $\alpha_5^{B'}$ for these corrected quantities. Thus $\alpha_2^{B'}$ and $\alpha_5^{B'}$ are given by

$$\alpha_s^{B'} = \alpha_s^{B'}(\text{harm}) + \alpha_s^B(\text{anharm}) \quad (s=2 \text{ or } 5) \quad (16)$$

and $\alpha_s^{B'}$(harm) corresponds to the quantity obtained by dropping the term containing $\zeta_{2,5a}{}^{(y)}$ from the expression in Eq. (5).

l-Type Doubling Constants

The l-type doubling constant q_t consists of harmonic and anharmonic parts[3] like α_s^B and α_s^A;

$$q_t = q_t(\text{harm}) + q_t(\text{anharm}). \quad (17)$$

For CH_3X type molecules, q_t(harm) and q_t(anharm) are given by

$$q_t(\text{harm}) = \frac{2B_e^2}{\omega_t}\left[\sum_{s\subset A_1}\frac{3\omega_t^2+\omega_s^2}{\omega_t^2-\omega_s^2}(\zeta_{s,ta}{}^{(y)})^2 - \frac{3}{4}\frac{(a_{tb}{}^{(yz)})^2}{I_{zz}{}^{(e)}}\right], \quad (18)$$

which may be rewritten into

8) J. Aldous and I. M. Mills, *Spectrochim. Acta*, **19**, 1567 (1963).
9) J. W. Russell, C. D. Needham, and J. Overend, *J. Chem. Phys.*, **45**, 3383 (1966).
10) J. L. Duncan, A. Allan, and D. C. McKean, *Mol. Phys.*, **18**, 289 (1970).

$$q_t(\text{harm}) = \frac{2B_e^2}{\omega_t}\left[\sum_{s\subset A_1}\frac{4\omega_s^2}{\omega_t^2-\omega_s^2}(\zeta_{s,ta}{}^{(y)})^2 + 3\sum_i\{(l_{i,tb}{}^{(y)})^2-(l_{i,ta}{}^{(y)})^2\}\right], \quad (19)$$

and

$$q_t(\text{anharm}) = 8\pi B_e^2\left(\frac{c}{h}\right)^{1/2} \times\left[\frac{3k_{tatata}a_{ta}{}^{(yy)}}{\omega_t{}^{3/2}} + \sum_{\substack{t'\subset E\\(t'\neq t)}}\frac{k_{tatat'a}a_{t'a}{}^{(yy)}}{\omega_{t'}{}^{3/2}}\right]. \quad (20)$$

The observed value of q_5 for CH_3I does not include the effect of the Coriolis interaction between ν_2 and ν_5,[11] and its harmonic part, q_5'(harm), is obtained by dropping the term containing $\zeta_{2,5a}{}^{(y)}$ from the expression in Eq. (18), which is then rewritten as

$$q_5'(\text{harm}) = \frac{2B_e^2}{\omega_5}\left[\frac{4\omega_1^2}{\omega_5^2-\omega_1^2}(\zeta_{1,5a}{}^{(y)})^2 + \frac{4\omega_3^2}{\omega_5^2-\omega_3^2}(\zeta_{3,5a}{}^{(y)})^2 - 3(\zeta_{2,5a}{}^{(y)})^2 + 3\sum_i\{(l_{i,5b}{}^{(y)})^2-(l_{i,5a}{}^{(y)})^2\}\right]. \quad (21)$$

The harmonic parts of the l-type doubling constants were calculated from the harmonic force field of Russell *et al.*[9] and were subtracted from the observed values[12] to obtain the anharmonic parts of the l-type doubling constants, q_t (anharm) (Table 3).

TABLE 3. q_t FOR CH_3I AND CD_3I, IN cm^{-1}

	6	−0.000126[d]	−0.000204	0.000078

a) Ref. 11. b) Not affected by the Coriolis interaction between ν_2 and ν_5. c) H. Matsuura and J. Overend, *Spectrochim. Acta*, **27A**, 2165 (1971); see also footnote 18 of Ref. 11. d) D. R. Anderson and J. Overend, *Spectrochim. Acta*, **28A**, 1231 (1972). The signs of q_5 and q_6 of CD_3I listed in this table are opposite to and the values are twice those reported by Anderson and Overend, because of different definitions of the q_t constant used. The values in this table are in accord with Mills' sign convention[13] and Eqs. (18)—(20).

Cubic Force Constants

From the anharmonic parts of the $\alpha_s{}^B$, $\alpha_s{}^A$ and q_t constants, we obtain relations among the cubic normal-coordinate force constants through Eqs. (9), (11), (13), (15) and (20). $\alpha_s{}^B$(anharm) and $\alpha_s{}^A$(anharm) relate the cubic constants k_{ss1}, k_{ss2} and k_{ss3}, and q_t(anharm) relates k_{tt4}, k_{tt5} and k_{tt6}. Thus $\alpha_s{}^B$ and $\alpha_s{}^A$, and q_t are complementary in the anharmonic information they provide. Making use of the harmonic potential function[9] incalculating the $a_s{}^{(\xi\,\eta)}$ coefficients appearing in the equations, we obtain the following explicit relations[14] for CH_3I from the $\alpha_s{}^B$ constants:

$$\begin{aligned}
-0.08\,k_{111} + 0.08\,k_{112} - 2.83\,k_{113} &= 24\ cm^{-1},\\
-0.03\,k_{221} + 0.23\,k_{222} - 2.83\,k_{223} &= 78\ cm^{-1},\\
-0.03\,k_{331} + 0.08\,k_{332} - 8.50\,k_{333} &= 247\ cm^{-1},\\
-0.03\,k_{441} + 0.08\,k_{442} - 2.83\,k_{443} &= -4\ cm^{-1},\\
-0.03\,k_{551} + 0.08\,k_{552} - 2.83\,k_{553} &= 15\ cm^{-1},
\end{aligned}$$

and

$$-0.03\,k_{661} + 0.08\,k_{662} - 2.83\,k_{663} = 68\ cm^{-1}, \quad (22)$$

from the $\alpha_s{}^A$ constants:

$$\begin{aligned}
-0.54\,k_{111} - 0.24\,k_{112} - 0.08\,k_{113} &= 96\ cm^{-1},\\
-0.18\,k_{221} - 0.71\,k_{222} - 0.08\,k_{223} &= -9\ cm^{-1},\\
-0.18\,k_{331} - 0.24\,k_{332} - 0.24\,k_{333} &= -4\ cm^{-1},\\
-0.18\,k_{441} - 0.24\,k_{442} - 0.08\,k_{443} &= 90\ cm^{-1},\\
-0.18\,k_{551} - 0.24\,k_{552} - 0.08\,k_{553} &= -4\ cm^{-1},
\end{aligned}$$

and

$$-0.18\,k_{661} - 0.24\,k_{662} - 0.08\,k_{663} = -48\ cm^{-1}, \quad (23)$$

and from the q_t constants:

$$0.28\,k_{554} - 3.04\,k_{555} + 0.15\,k_{556} = -10\ cm^{-1},$$

and

$$0.28\,k_{664} - 1.01\,k_{665} + 0.44\,k_{666} = 66\ cm^{-1}. \quad (24)$$

Similar relations are obtained for CD_3I:

$$\begin{aligned}
-0.11\,k_{111} + 0.03\,k_{112} - 2.23\,k_{113} &= 20\ cm^{-1},\\
-0.04\,k_{221} + 0.09\,k_{222} - 2.23\,k_{223} &= 43\ cm^{-1},\\
-0.04\,k_{331} + 0.03\,k_{332} - 6.69\,k_{333} &= 168\ cm^{-1},\\
-0.04\,k_{441} + 0.03\,k_{442} - 2.23\,k_{443} &= 16\ cm^{-1},\\
-0.04\,k_{551} + 0.03\,k_{552} - 2.23\,k_{553} &= -4\ cm^{-1},
\end{aligned}$$

and

$$-0.04\,k_{661} + 0.03\,k_{662} - 2.23\,k_{663} = 41\ cm^{-1}, \quad (25)$$

$$\begin{aligned}
-0.31\,k_{111} - 0.14\,k_{112} - 0.02\,k_{113} &= 38\ cm^{-1},\\
-0.10\,k_{221} - 0.43\,k_{222} - 0.02\,k_{223} &= -2\ cm^{-1},\\
-0.10\,k_{441} - 0.14\,k_{442} - 0.02\,k_{443} &= 33\ cm^{-1},\\
-0.10\,k_{551} - 0.14\,k_{552} - 0.02\,k_{553} &= -3\ cm^{-1},
\end{aligned}$$

and

$$-0.10\,k_{661} - 0.14\,k_{662} - 0.02\,k_{663} = -16\ cm^{-1}, \quad (26)$$

$$0.38\,k_{554} - 4.79\,k_{555} + 0.10\,k_{556} = -64\ cm^{-1},$$

and

$$0.38\,k_{664} - 1.60\,k_{665} + 0.31\,k_{666} = 78\ cm^{-1}. \quad (27)$$

The signs of the k constants are in accord with those of the $\boldsymbol{L}$ matrix elements given in Table 4.[15]

CD_3I	0.188	1.113	−0.051	−0.103	0.111	0.679

The determination of individual values for the k constants is not possible from the above relations; the combination of Eqs. (22) and (23), or Eqs. (25) and (26) gives only relations between two k constants. For planar or pyramidal XY_3 molecules, the k constants appearing in the relations similar to Eqs. (22), (23), (25) and (26) can be determined uniquely, and some of the k constants have, in fact, been obtained from observed α_s^B and α_s^C for NH_3 and ND_3.[2]

Overend and Machida[5] have made a simple calculation of the anharmonic force constants of the CH stretching modes for the methyl group, assuming a Morse function for a CH bond. Their estimation of the cubic force constants may be used to obtain other force constants, making use of the relations derived in this study. While the stretch-stretch-stretch cubic force constants may be estimated relatively easily,[5] the estimation of the constants involving bending modes is not so simple, and the relations among the k constants are useful in estimating the latter. In Table 5 are listed the force constants estimated by Overend and Machida[5] and the new force constants of CH_3I and CD_3I determined in the present work. They are compared with the corresponding constants for NH_3 and ND_3. The values of k_{111}, k_{444}, and k_{441} (the CD stretch-stretch-stretch force constants) for CD_3I were derived from the corresponding values for CH_3I by multiplying by the factor $[(\mu_D+\mu_C)/(\mu_H+\mu_C)]^{3/4}\simeq 0.63$, where μ_H, μ_D, and μ_C are the reciprocals of the masses of H, D, and C atoms.

Duncan *et al.*[10] have estimated the interaction terms of the Fermi resonance between ν_1 and $2\nu_5$ of CH_3I from the intensities of these parallel bands. From the interaction term, the value of $|k_{551}|$ is found to be 61 cm^{-1}. By comparing with the corresponding value (+87 cm^{-1}) for NH_3,[2] it seems reasonable to take a positive sign for k_{551}. The values for k_{552} and k_{553} derived through the relations in Eqs. (22) and (23) are listed in Table 5. A value for k_{356} of CH_3I is also listed. This was obtained by the detailed analyses of the Fermi doublet, ν_5 and $\nu_3+\nu_6$.[11,16,17]

Discussion

There are 38 independent cubic normal-coordinate force constants for CH_3I or CD_3I. Of these, we have estimated or observed 11 constants for the former and 7 for the latter, as shown in Table 5. The stretch-stretch-stretch constants (k_{111}, k_{444} and k_{441}) previously estimated for the CH_3 and CD_3 groups[5] are of the reasonable magnitudes, compared with those of NH_3 and ND_3, and the systematic variations of the values from those of the ammonia molecule are related closely to the values of the quadratic internal-coordinate force constants (*i.e.*, 5.5 mdyn/Å for the methyl group and 7 mdyn/Å for ammonia).

In the present study, we have been able to estimate two stretch-stretch-bend interaction constants (k_{112} and k_{442}) of the CH_3 or CD_3 group. The values obtained for k_{442} for CH_3I and CD_3I are found to be about ten times smaller than the corresponding values for NH_3 and ND_3. This difference may be real and may reflect structural differences between the CH_3 group and ammonia. Alternatively it may stem from approximation made in our analysis and, with this possibility in mind, we refrain from further comments. It is interesting to note, on the other hand, that the bend-bend-stretch constant (k_{551}) and the bend-bend-bend constant (k_{552}) of CH_3I have magnitudes similar to those for NH_3.

The cubic constant k_{356} for CH_3I has been determined experimentally from the analyses of the perpendicular bands, ν_5 and $\nu_3+\nu_6$.[11,16,17] The value obtained is only an absolute one, but is very accurate, *i.e.*, $|k_{356}|=29.6144\pm0.0007$ cm^{-1}.[11] The same force constant has also been determined from the Fermi doublets, $\nu_5+\nu_6$ and $\nu_3+2\nu_6$, and $\nu_2+\nu_5$ and $\nu_2+\nu_3+\nu_6$, to be 29.572 ± 0.002 cm^{-1} and 29.1 ± 0.2 cm^{-1}, respectively.[18]

At the present time, we do not have individual values for the cubic force constants other than those listed in Table 5. However, the relations among the cubic force constants derived in the present study are useful in estimating other force constants and in discussing the vibrational anharmonicity in the methyl

The Adiabatic Compressibility of Nonelectrolyte Aqueous Solutions in Relation to the Structures of Water and Solutions

Harumi ENDO

Department of Applied Physics, Defense Academy, Yokosuka 239

(Received May 23, 1972)

The sound velocity (V) and density of aqueous solutions of urea, dimethylurea, thiourea, acetamide, acetone, and dimethylformamide have been measured, and the adiabatic compressibility (β) has been calculated at various concentrations (μ: mole fraction). The β-μ curves and V-μ curves at various temperatures have a common intersection at the fixed concentrations of μ_c^β and μ_c^V respectively. At these concentrations, the compressibility (β_c) and the sound velocity (V_c) of a solution are independent of the temperature over a certain range. When β_c is plotted against the mole ratio, r_c^β=(water)/(solute) at μ_c^β, the plots for acetyl-derivatives fall on one straight line, and those for urea-derivatives, on another line. In the cases of acetone and ethanol, the r_c^β values of these solutes coincide with the number of water molecules constituting the framework of the solid clathrate hydrate. Also, for the other aqueous solutions, it may be reasonable to conclude that the r_c^β value corresponds to the number of water molecules constituting some other type of liquid-clathrate hydrate characteristic of each solute.

A number of papers have been published on the properties of nonelectrolyte aqueous solutions from the view point of the dependence of the sound velocity (V) on the concentration (μ: mole fraction). The V-μ curves for the aqueous solutions of methanol (Me), ethanol (Et), propanol (Pr), acetone (A), *etc.*, have been known to show some unusual behaviors.

The V-μ curves of these solutions at a constant temperature exhibit maxima (maximum sound velocity: V_p) at certain concentrations[1-3] (velocity peak concentration: C_p). As both V_p and C_p decrease with an increase in the temperature, the V-μ curves for two different temperatures meet at a certain concentration (μ_c^V) ($<C_p$). Usually, a number of the V-μ curves within a certain temperature range (ΔT_c^V) have a common intersection[4,5] at a fixed concentration (μ_c^V), although Kuhnkies and Schaaffs[6] have pointed out the gradual displacement of the point of intersection with the temperature range in the case of alcohol solutions, among others. This behavior of the V-μ curves is found not only for the aqueous solutions of liquids of simple molecules, but also for those of complicated molecules such as morpholine[7] (Mo) $O(CH_2CH_2)NH$, for which the V_c at μ_c^V=0.0369 is constant in the temperature range of 20—60 °C.

In the present study, the adiabatic compressibilities, (β) of aqueous solutions of urea (U), dimethylurea (DMU), acetamide (AA), acetone (A), and dimethylformamide (DMF) are determined over the temperature range of 20—50 °C, and that of thiourea (TU), in the 50—60 °C range, by measuring the density and the sound velocity.

From these results, it is found that the β-μ curves of various temperatures also show a common intersection at a characteristic concentration (μ_c^β). At this concentration, the adiabatic compressibility (β_c) is independent of the temperature over a certain temperature range (ΔT_c^β). The parameters such as V_c, β_c, ΔT_c^V, ΔT_c^β, μ_c^V and μ_c^β are determined for these solutes in order to examine their relation with the solution structure.

When β_c is plotted against the mole ratio, r_c^β=(water)/(solute), the plots for acetyl-derivatives fall on one straight line, and those for urea-derivatives, on another line. From these β_c—r_c^β curves, the properties and the dissolved state of solute in water are discussed. The reason why the peak concentration shifts to the lower-concentration side with an increase in the molecular weight in each homologue series is explained.

Experimental

Materials. The U, DMU, TU, and AA are purified by the recrystallization of reagent-grade products from absolute alcohol. To purify A and DMF, reagent-grade products are distilled twice before use.

Apparatus. A crystal-controlled ultrasonic interferometer operating at a frequency of 5 MHz is used to measure the sound velocity. To determine the wavelength, one hundred standing waves are used. The measuring cell containing the solutions is immersed in an oil bath, the temperature of which is kept constant within ±0.1 °C.

Results

In Figs. 1—6, the sound velocity is plotted against the mole fraction for aqueous solutions of U, DMU, AA, A, and DMF respectively, over the temperature range of ΔT=20—50 °C, while that for TU is plotted

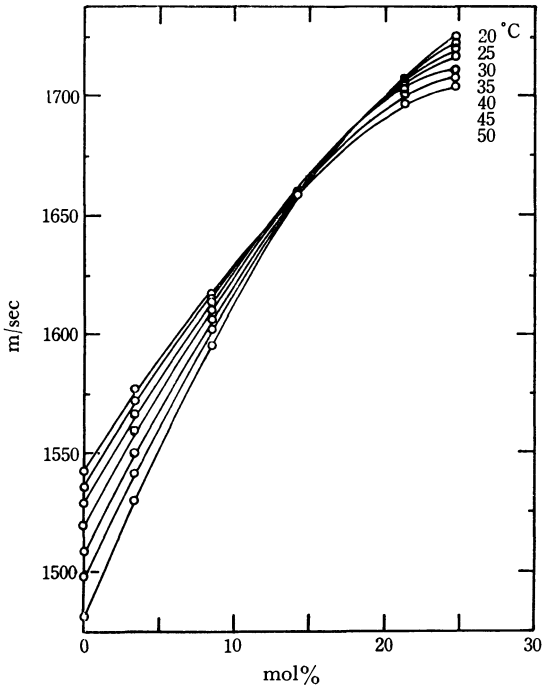

Fig. 1. Sound velocity *vs.* concentration of urea aqueous solutions.

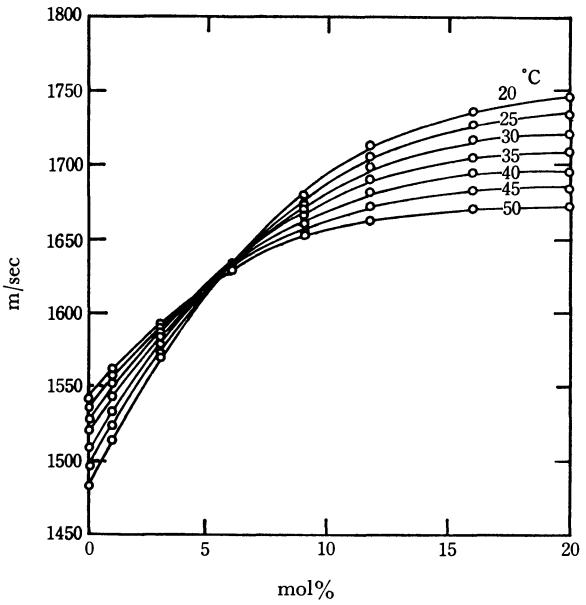

Fig. 2. Sound velocity *vs.* concentration of DMU aqueous solutions.

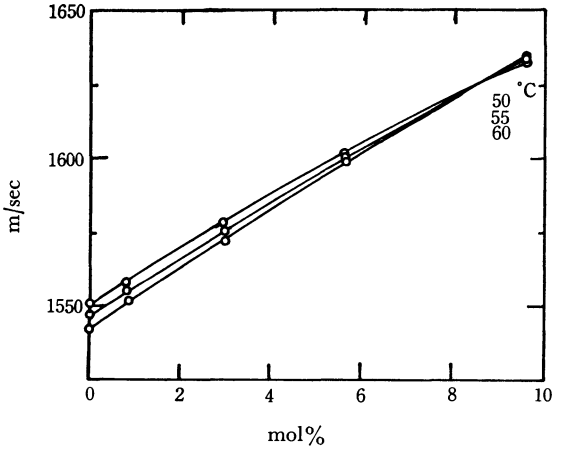

Fig. 3. Sound velocity *vs.* concentration of thiourea aqueous solutions.

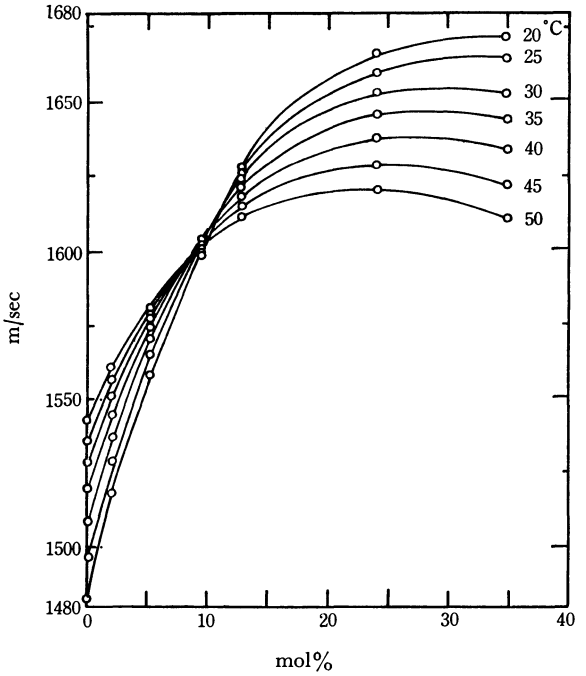

Fig. 4. Sound velocity *vs.* concentration of acetamide aqueous solutions.

over the range of ΔT=50—60 °C. The sound velocity always increases with an increase in the concentration, reaches a maximum, and then decreases. In the cases of U and TU, no maximum was observed within the concentration range measured because of the solubility limit. It is found that V_p gradually decreases and shifts towards the lower-concentration side with an increase in the temperature (*cf.* Fig. 5 and Ref. 1). At the higher temperatures, the V-μ curves show no maximum and decrease nearly linearly.

For the aqueous solutions of TU and DMF, the intersection points of V-μ curves of various temperatures converge at one point over the observed temperature range (20—50 °C) (Figs. 3 and 6). For the aqueous systems of U, DMU, AA, and A (Figs. 1, 2, 4, and 5), on the other hand, the converging temperature range is rather narrower. The V_c, ΔT_c^V, and μ_c^V values at the converging point in the V-μ curves are summarized in the left-hand half of Table 1.

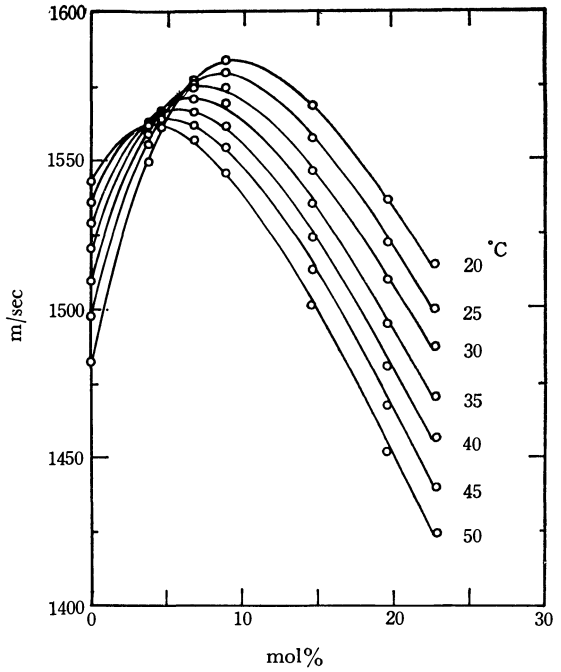

Fig. 5. Sound velocity *vs.* concentration of acetone aqueous solutions.

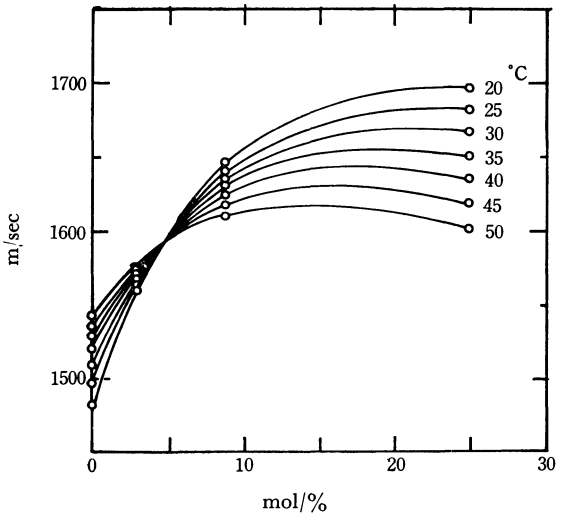

Fig. 6. Sound velocity *vs.* concentration of DMF aqueous solutions.

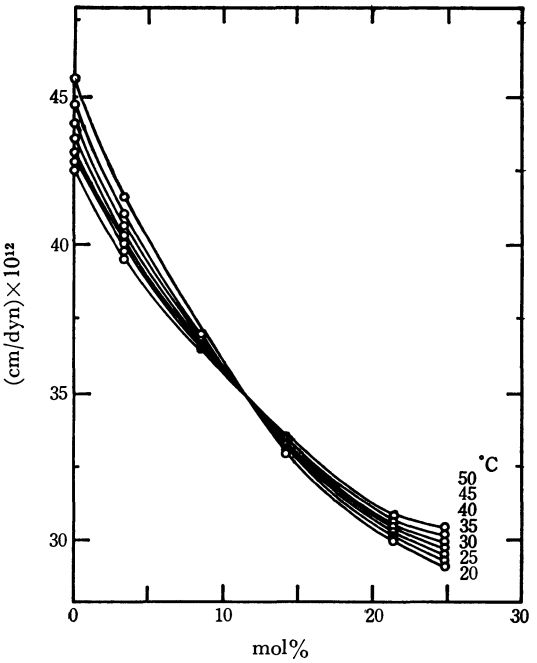

Fig. 7. Compressibility *vs.* concentration of urea aqueous solutions.

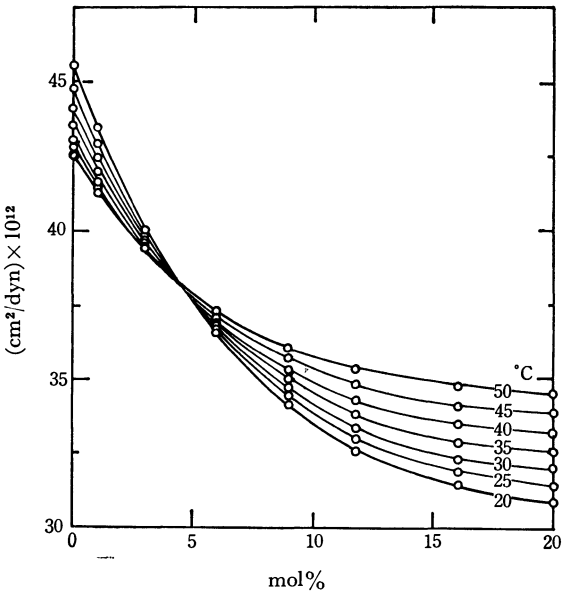

Fig. 8. Compressibility *vs.* concentration of DMU aqueous solutions.

Figures 7—12 show the β-μ curves for aqueous solutions of U, DMU, AA, A, and DMF respectively, over the observed temperature range of 20—50 °C, and that for TU, over the range of ΔT=50—60 °C. Similarly, the β-μ curves of various temperatures intersect at one common point. The numerical values of the μ_c^β values of the β-μ curves are slightly different from those of the μ_c^V values of the V-μ curves, and the converging temperature range, ΔT_c^β, is nearly the same as ΔT_c^V. The values of β_c, μ_c^β, r_c^β, and ΔT_c^β are reproduced in the right-hand half of Table 1. Table 1 also contains the data for alcohol homologues, obtained from the data of Larionov.[8]

In Fig. 13, β_c is plotted against r_c^β for various solutes. According to this plot, the solutes studied can be classified into two groups. One group consists of the urea-derivatives, for which

$$\beta_c = (0.22 r_c^\beta + 33.3) \times 10^{-12} \text{ (cm}^2\text{/dyn)} \quad (1)$$

while the other group consists of the acetyl-derivatives, for which

$$\beta_c = (0.49 r_c^\beta + 33.3) \times 10^{-12} \text{ (cm}^2\text{/dyn)} \quad (2)$$

They have a common intercept with the ordinate of $\beta_c^\circ = 33.3 \times 10^{-12}$ (cm²/dyn).

Figure 14 shows a similar plot of V_c *vs.* r_c^V (mole ratio,=(water)/(solute) at μ_c^β). Here, however, no

clear relationship between them is found.

Discussion

As is well known, the X-ray diffraction studies of liquid water[9,10] suggest that it has a long-range ordered structure. The number of nearest neighbors in liquid water is slightly larger than in ice, and it increases slightly with an increase in the temperature. The framework of the structure of liquid water consists of a hexagonal ice-1 structure with numerous cavities, which can accommodate another species of water (non-hydrogen-bonded water); this structure is very stable against thermal agitation up to higher temperatures.

According to Hall,[11] the compressibility (β) of liquid water is given by:

$$\beta = \beta_\infty + \beta_{st} \tag{3}$$

where β_∞ is the instantaneous compressibility due to the compression of the molecules and the intermolecular distance, and where β_{st} is the structural compressibility due to the breakdown of intermolecular bonds accompanying the destruction of the open structure.

The mechanism of ultrasonic absorption in water has been studied by Hall[11] and by others.[12–14] By using the two-state-model theory of water, they have explained the bulk viscosity and the relaxational compressibility of water. In Hall's paper, it is assumed that β_∞ is independent of the temperature (T), *i.e.*, that $d\beta_\infty/dT=0$. On the basis of the X-ray diffraction data of liquid water obtained by Narten *et al.*[10], we[15] have previously studied the mechanism of ultrasonic absorption in water in relation to the liquid-water structure.

It is assumed that Eq. (3) is also applicable for nonelectrolyte aqueous solutions. The temperature derivatives of β in aqueous solutions are given by:

$$\frac{d\beta}{dT} = \frac{d\beta_\infty}{dT} + \frac{d\beta_{st}}{dT} \tag{4}$$

In the aqueous solutions at μ_c^β in ΔT_c^β, Eq. (4) leads to $d\beta/dT=0$. Accordingly, from the assumption that $d\beta_\infty/dT$ is zero, $d\beta_{st}/dT$ becomes zero also. For $\mu < \mu_c^\beta$, $d\beta/dT$ becomes negative from Figs. 7—12; therefore, $d\beta_{st}/dT$ also becomes negative. On the other hand, for $\mu > \mu_c^\beta$, $d\beta_{st}/dT$ is also equal to zero, because $d\beta_{st}/dT$ cannot become positive because of physical considerations. Therefore, it is found from Figs. 7—12 that $d\beta_\infty/dT>0$. A schematical illustration of the relationship between $d\beta/dT$ and μ is shown in Figs. 15 (a) and 15 (b).

It is assumed that the cavities contained in the framework of the water-cluster are gradually filled up by the solutes, or that the framework water in the lattice of clusters involves an exchange of solute molecules with an increase in the concentration up to μ_c^β with a maintenance of the structure of ice-1. This accompanies a decrease in the β_{st} and also in the $d\beta_{st}/dT$ of the solution. When a nonelectrolyte is dissolved in water, a new structure is formed of the water and solute molecules. This structure change accompanies a decrease in the compressibility of liquid water (*cf.* Fig. 15 (c)).

Also, it is assumed that the number of clusters of water molecules does not change appreciably up to μ_c^β. The instantaneous compressibility, β_∞, consists of two parts, one due to the compression of the clusters

and the other due to the compression of the intermolecular distance. The former does not change appreciably when we adopt the solute molecules in cavities because the elasticity of a cluster is mainly caused by the framework. Also, the latter does not change up to μ_c^β, because the number of the cluster does not change up to μ_c^β. Therefore, we may conclude that β_∞ is appreciably constant and that $d\beta_\infty/dT=0$ up to μ_c^β.

For higher concentrations, it is assumed that the increase in the number of solute molecules accompanies an increase in the number of clusters, thus decreasing β_{st} and increasing β_∞ (*cf.* Fig. 15 (c)). These two opposite effects serve to form a minimum of compressibility, or a maximum of sound velocity, at C_p.

A model of the structure of a solution has been proposed by Glew[16] on the basis of density measurements of an Et aqueous solution; there the name "solution hydrate" has been suggested. It seems better, however, that this structure of solution be named "liquid-clathrate hydrate," because the composition of this structure in Et is the same as that of the solid clathrate hydrate.[17] In this model, the solute is surrounded by a three-dimensionally hydrogen-bonded framework of water molecules. The solute molecules in the liquid-clathrate hydrate may be oriented in the cavity of a water-cluster hydrogen-bonded with framework-water molecules. In talking about the "solution hydrate"[16] or the "liquid-clathrate hydrate" in solution, it must be emphasized that the meaning of the definite composition in a hydrate does not indicate the hydration number of the solute, but is, rather, a structural unit.

It may be suggested here that the number of water molecules composing the framework of the liquid-clathrate hydrate corresponds to r_c^β for each solute. Also, the empirical relation between β_c and r_c^β may be indicative of the change in the water structure. From Eqs. (1) and (2), we obtained the following equations for the decrease in the strucutural compressibility in water caused by the solute. Here, the value of β_0, the compressibility of liquid water, is 45.6×10^{-12} cm²/dyn at 20 °C: for the urea-derivatives,

$$\Delta\beta=\beta_o-\beta_c=(12.3-0.22r_c^\beta)\times10^{-12}\ (\mathrm{cm^2/dyn}) \quad (5)$$

and for the acetyl-derivatives:

$$\Delta\beta=\beta_o-\beta_c=(12.3-0.49r_c^\beta)\times10^{-12}\ (\mathrm{cm^2/dyn}) \quad (6)$$

Since we have assumed that the number of clusters in water remains appreciably constant up to the concentration of r_c^β (μ_c^β mole fraction), the β_∞ values are nearly the same for both water and the solution at this concentration; therefore, $\Delta\beta$ indicates the difference in the structural compressibility of a solution, *i.e.*, $\Delta\beta_{st}$. For the solutes with larger r_c^β values, the water strucuture is less modified, or the cavities are less occupied, so the decrease in $\Delta\beta_{st}(=\Delta\beta)$ is smaller. This explains the negative signs of the coefficients of r_c^β in Eqs. (5) and (6). By comparing the urea-derivatives and the acetyl-derivatives, it is obvious from Eqs. (5) and (6) that the coefficient of r_c^β in the latter is nearly twice that for the former. This presumably indicates that the latter fills up the cavity only, while the former also collaborates to make the framework[18] as a constitutive part.

For Et[17] and A[19,20] aqueous solutions, it may be seen in Table 1 that r_c^β is equal to the composition in the Structure-II solid clathrate hydrate with the formula of $M\cdot17H_2O$.[21] Here, M is the guest molecule. Glew has proposed, in an Et aqueous solution over the temperature range of 0—30 °C, the existence of the liquid-clathrate-hydrate (Structure-II type of composition, $Et\cdot17H_2O$) to account for an anomaly molar volume at $\mu=ca.$ 0.06. For other aqueous solutions, it may be reasonable to assume that r_c^β corresponds to the number of water molecules constituting some other type of liquid-clathrate hydrate characteristic for each solute. Accordingly, the discussion and interpretation of results may be based on the following non-stoichiometric reaction scheme:

$$M+r_c^\beta H_2O \rightleftarrows M\cdot r_c^\beta H_2O \quad (7)$$

Since the number of water molecules constituting the liquid-clathrate hydrate in a homologues series increases with an increase in the molecular weight, r_c^β decreases with the molecular weight. Accordingly, μ_c^β (as well as C_p of aqueous solution) also shifts to a lower-solute concentration with an increase in the molecular weight of the homologue series.

It may be seen in Table 1 that the upper limiting temperature (T_c^u) of ΔT_c^β decreases with the addition of a non-polar group to the derivatives of urea and acetyl, so it may be reasonable to assume that the strength of the water-water hydrogen bond adjacent to the non-polar group is weaker than that of the polar group. Accordingly, it may be concluded that the framework of the liquid-clathrate hydrate adjacent to a non-polar group is selectively decomposed by the thermal agitation of molecules with a rise in the temperature. T_c^u is higher for the urea-derivatives than for the acetyl-derivatives for this same reason.

Chekalin *et al.*[5] report that V_c is independent of the sort of solute and that it is equal to 1580 m/sec within ±1.5% (*ca.* 1556—1604 m/sec). This rule is, however, not of universal validity, as may be seen in Fig. 14.

The author wishes to thank Prof. Tsunetaka Sasaki of the Tokyo Metropolitan University for his helpful discussions and generous support of this research and also Prof. Otohiko Nomoto of the Defense Academy for his valuable suggestions and discussions.

Dielectric Relaxation and Molecular Structure. IV. Dielectric Relaxation and Hydrogen Bonding in Chloroanilines

J. K. VIJ* and K. K. SRIVASTAVA**

Physics Department, Panjabi University, Patiala, India

***Physics Department, Panjab University, Chandigarh, India*

(Received May 12, 1972)

Measurements of relative permittivity were carried out at 30.0 °C in *p*-dioxane at 1 MHz and at 9.48 GHz for *ortho* (A), *meta* (B), and *para* (C) chloroanilines. The results are interpreted in terms of hydrogen bonding between amino hydrogens and the oxygen atoms of the dioxane molecule, the dipole moments and dielectric relaxation time values being given. The relative behaviour of chloroanilines has been discussed. It seems that a finite probability of H-Cl bond formation exists between one of the amino hydrogens and the neighbouring chlorine atom in *o*-chloroaniline.

Curran and Estok[1] assume that hydrogen bonding between amino hydrogens and dioxane oxygens is a normal phenomenon. Few and Smith[2] incline to the view that hydrogen bonding occurs when the actual structure is that of resonance between several possible structures and that it also receives considerable contribution from highly polar structures. Chitoku and Higasi[3] showed, from dipole moment and dielectric relaxation study, that an increase in the dielectric relaxation time of certain anilines in dioxane is a measure of the strength of hydrogen bonds and have verified the viewpoint of Few and Smith[2] by concluding that the strength of hydrogen bonds depends upon the increment in mesomeric moment of amino group. Smith and Walshaw[4] had demonstrated that the mesomeric interaction and presumably the *p*-character of the lone pair orbital of nitrogen atom increases upon *n*-methylation of the amino group and with the introduction of the electro-negative substituent in the phenyl ring. Cumper and Singleton[5] have carried out measurements on dipole moments of a large number of systems including chloroanilines. Their results support the observations of Smith and Walshaw.[4] They interpret the '$\Delta\mu$' increment (*i.e.*, $\mu_D - \mu_B$) as the increase in mesomeric moment since their results for '$\Delta\mu$' and mesomeric interaction correspond with each other in most of the systems they studied. The behaviour of different isomers can be estimated by this method. We have made measurements[6] on *o*-, *m*-, and *p*-, chloroanilines for calculating both the dipole moments and dielectric relaxation times in benzene and dioxane with the hope that additional relaxation data for these molecules might give more information on their relative behaviour.

Experimental and Results

Benzene and *p*-dioxane were purified by standard methods. Purification of solutes, instruments, methods of measurement and of analysis were given previously.[7]

Aniline (D)	—	0.25[f]	—	2.9[f]

d) Ref. 5. e) Ref. 10, Chap. X, p. 329. f) Ref. 3.

Both parts, real and imaginary, of relative permittivity were found, from observation, to be linear functions of solute concentration in the range studied.

The results have been discussed in terms of $\tau(1)$ and $\tau(2)$, which are the dielectric relaxation time values defined by the following two independent equations derived from the Debye equation for dilute solutions:

$$\tau(1) = \frac{1}{\omega}\frac{a''}{a'-a_D} \quad (1)$$

$$\tau(2) = \frac{1}{\omega}\frac{a_0-a'}{a''} \quad (2)$$

This method of analyzing the single frequency data has recently been proposed by Higasi *et al.*[8] and has been discussed in more detail.[9] The values of the "so-called slopes" for *o*-, *m*-, and *p*-, chloroanilines in *p*-dioxane are given in Table 1 along with those in benzene.[7] Possible errors in the value of the slopes are also indicated. Values for dipole moments and dielectric relaxation times are given in Table 2, and dipole moment increments (*i.e.*, $\Delta\mu=\mu_D-\mu_B$) and ratios of both $\tau(1)_D/\tau(1)_B$ and $\tau(2)_D/\tau(2)_B$ in Table 3.

Discussion

The values of moments show a close agreement with those in literature indicating the reliability of technique and purity of the chemicals.

A small increment in $\Delta\mu$ and consequently a small increase in mesomeric moment of amino group has been interpreted[5] as either of two possibilities:

(i) H–Cl bond between one of two amino hydrogens and the neighbouring chlorine atom, leaving the second hydrogen atom free for hydrogen bonding.

(ii) An electrostatic repulsion between the electronegative chlorine atom and the oxygen atoms of a dioxane molecule.

$\tau(1)$ at the experimental frequency is a combination of τ_1, and τ_2 whereas $\tau(2)$ corresponds very nearly to τ_1.[9] The relaxation data show that the ratio $\tau(1)_D/\tau(1)_B$ remains almost constant. This suggests that intramolecular relaxation time does not depend much on the solvent, whereas molecular relaxation time is affected possibly because of complex formation[3] of the molecule in *p*-dioxane. Intramolecular relaxation time seems to be independent as the result of its inversion mechanism postulated by Smyth.[10]

The ratio $\tau(2)_D/\tau(2)_B$ follows a decreasing trend in contrast to that observed from dipole moment studies and the ratio for *o*-chloroaniline, in particular, is large. This may imply that the system formed for this molecule in *p*-dioxane is relatively one with more complexities. It appears to favour (i), since (ii) would not lead to the large increase in the molecular relaxation time for *o*-chloroaniline in *p*-dioxane. Our observations support the postulates already made from the examination of the dissociation constants[11] and N–H stretching frequencies[12] in *o*-chloroanilines.

Structure of Ethylene Oxide Oligomer Complexes. I. A 1:1 Complex of Tetraethylene Glycol Dimethyl Ether with Mercuric Chloride

Reikichi IWAMOTO

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received March 11, 1972)

Molecular and crystal structure of a 1 : 1 molecular complex of tetraethylene glycol dimethyl ether $CH_3O(CH_2CH_2O)_4CH_3$ (TGM) with mercuric chloride has been determined by means of X-ray diffraction. The complex has a monoclinic unit cell with $a=14.29$, $b=15.10$, $c=7.84$ Å, and $\beta=97.0°$. The space group is $P2_1/n$. Four molecules of both TGM and mercuric chloride are contained in the unit cell. The structure was determined by the ordinary heavy atom method. The molecular conformation of TGM in the complex is approximately

$$\underset{T}{CH_3}\text{-}\underset{G}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{\bar{G}}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{G}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{\bar{G}}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{G}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{CH_2}\text{-}O\text{-}CH_3,$$

where T, G, and $\bar{G}$ indicate *trans*, *gauche*, and minus *gauche* forms, respectively. All the CH_2–O bonds are *trans*, while the CH_2–CH_2 bonds are *gauche* and minus *gauche* in the adjacent chemical units. The conformational unit of

$$\underset{T}{O}\text{-}\underset{G}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{\bar{G}}{CH_2}\text{-}\underset{T}{CH_2}\text{-}$$

was found to be very important and favorable for coordination between the O and Hg atoms. The molecule is circular but not closed, and the five oxygen atoms, which are nearly coplanar and located at the inner side of the circular molecule, enclose one $HgCl_2$ molecule with close interatomic distances (2.78—2.96 Å) between the O and Hg atoms.

The molecular complexes of polyethylene oxide (PEO) with $HgCl_2$ were previously investigated,[1,2] and it was found that they have two crystalline forms, one having the composition of CH_2CH_2O: $HgCl_2$= 4 :1 (type I) and the other that of CH_2CH_2O: $HgCl_2$= 1: 1 (type II). The conformation of PEO in the complexes is

$$\text{-}\underset{T}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{G}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{\bar{G}}{CH_2}\text{-}$$

in type I and

$$\text{-}\underset{T}{O}\text{-}\underset{G}{CH_2}\text{-}\underset{G}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{\bar{G}}{CH_2}\text{-}$$

in type II, where T, G, and $\bar{G}$ denote *trans*, *gauche*, and minus *gauche*, respectively. These differ significantly from the conformation of PEO in the ordinary PEO,[3] which is helical consisting of a uniform succession of $\underset{T}{O}\text{-}\underset{T}{CH_2}\text{-}\underset{G}{CH_2}$. In the type I complex two of the four oxygen atoms in the identity period are coordinated with one Hg atom, while in the type II complex each oxygen atom is coordinated with two Hg atoms. In these complexes the interatomic interactions between the Hg and O atoms cause the complex formation and have important influence on the conformation of PEO.

On the other hand, according to Pedersen,[4,5] macrocyclic polyethers especially those containing CH_2CH_2O units form stable crystalline molecular complexes with many metal salts including $HgCl_2$. Investigations have recently been carried out on the crystal structures of some complexes in which an alkali ion is enclosed in a cavity surrounded by oxygen atoms of the molecule.[6,7] This spatial arrangement indicates the existence of strong interactions between oxygen and alkali ions. It was reported that there occurs specific solvation between dimethoxy ethane and $HgCl_2$ in solution.[8] Ethylene oxide oligomers, $CH_3O(CH_2CH_2O)_m$-CH_3, have specific solvation with alkali-carbanion ion pairs in solution and the solvation has significant influence on reactivity of the ion pairs, which are the initiators of living polymerization of styrene.[9-11] Dimethoxy ethane has specific interaction with alkali metals, also.[12,13]

These studies indicate that ethers composed of the CH_2CH_2O groups have a specific property to interact with metal salts or ions. In the structural studies of the PEO–$HgCl_2$ complexes,[1,2] it was not possible to determine the precise structure of PEO and to discuss the structure of the complexes in details on account of the small number of reflections and predominant contribution of $HgCl_2$ to the diffraction intensities. Recently it has been found that ethylene oxide oligomers, $RO(CH_2CH_2O)_mR$, form molecular complexes with $HgCl_2$ and some of the complexes give single crystals available for structural investigation by means of X-ray diffraction. It was hoped that the X-ray structure determination of the complexes would give important and more detailed information on the interaction between ethylene oxide groups and mercuric chloride and on the conformational change of the molecules. From this point of view structural studies of a series

of the complexes of ethylene oxide oligomers, RO-$(CH_2CH_2O)_mR$, with $HgCl_2$ have been undertaken. The present paper deals with the $CH_3O(CH_2CH_2O)_4$-CH_3–$HgCl_2$ complex.

Experimental

Samples. Commercially available sample of tetraethylene glycol dimethyl ether (TGM) was used (Tokyo Kasei Kogyo Co., Ltd.). Crystals of the TGM–$HgCl_2$ complex were prepared by dissolving crystalline powder of $HgCl_2$ into an ethanol-TGM (about 10:1 volume ratio) mixture to saturation at about 35 °C and cooling the saturated solution to room temperature, single crystals of the complex being precipitated in solution. The crystals are transparent needles grown along the *c* axis. The melting point of the complex is 66 °C as determined microscopically. The density of the crystal was measured by the flotation method by use of a liquid mixture of CCl_4 and $CHBr_3$ as the flotation medium. The observed density was 1.96 g/cc. The composition of the complex was found to be TGM: $HgCl_2$=1:1 by elemental analysis (Found: Hg, 40.8%. Calcd for the 1:1 complex: Hg, 40.6%).

Table 1. Crystallographic and physical data of the TGM–$HgCl_2$ complex

Formula	$CH_3O(CH_2CH_2O)_4CH_3 \cdot HgCl_2$

b	15.10 Å
c	7.84 Å
β	97.0°
Z	4
Vol.	1697.0 Å^3
D_c	1.95 g/cc
D_m	1.96 g/cc
μ (Cu$K\alpha$)	206.4 cm^{-1}
F(000)	944

Unit Cell and Space Group. The unit cell parameters were determined with a Weissenberg camera and calibrated by silicon powder. Systematic absences were observed with respect to reflections having indices $h0l$ with $h+l$ odd and $0k0$ with k odd. The space group, thus, is $P2_1/n$. The crystallographic data are given in Table 1 together with some physical constants.

Intensity Measurement. X-Ray diffraction photographs of the complex crystal were taken by using Cu$K\alpha$ radiation. The crystals used were about 0.2 mm × 0.2 mm × 0.2 mm in size. Intensity data were recorded on photographs by using equi-inclination Weissenberg multiple film method about the *c* axis from l=0 to 6 layers and about the *b* axis for a k=0 layer. The number of recorded reflections having non-zero intensities was 2455. The intensities were measured by visual comparison with standard intensity scales. Intensity data were corrected for the Lorentz and polarization factors. Although the absorption coefficient is very large (μ=206 cm^{-1} for Cu$K\alpha$ radiation), the intensity data were not corrected for absorption. The smallest possible crystal was used for collecting the intensities. When the crystal was exposed to radiation for longer than 100 hr under operation conditions of 35 kV and 20 mA, it became opaque and light brown, and the diffraction photographs were contaminated with Debye ring reflections due to the decomposed material. The crystal was renewed for each layer line.

Structure Determination

Since atomic scattering power of a Hg atom is much stronger than that of other atoms contained in the complex, the general feature of reflections can be explained approximately by considering the Hg atom only. The crystal structure has been determined according to the ordinary heavy atom method. Atomic scattering factors were taken from *International Tables of X-Ray Crystallography* (1962). The atomic parameters refined by the block diagonal least squares method[14] were set as the final result. For this, the

Results and Discussion

The crystal structure of the complex as a whole is shown in Fig. 1. Each TGM molecule encloses one $HgCl_2$ molecule in the crystal of the complex. Bond lengths and angles for the TGM molecules are listed in Table 3, together with those for the $HgCl_2$ molecule. These values are reasonable considering the fact that the Hg atoms contribute predominantly to the diffration intensities in the complex. Table 4 gives internal rotation angles around each bond of the TGM molecule in the complex. Internal rotation angles around the CH_2–O bonds are approximately *trans* (170—179°), while those around the CH_2–CH_2 bonds are nearly *gauche* with alternation of *gauche* and minus *gauche* in the succeeding chemical units (71—77°):

$$\underset{T}{-CH_2}\text{–}\underset{G}{CH_2}\text{–}O\text{–}\underset{T}{CH_2}\text{–}\underset{T}{CH_2}\text{–}O\text{–}\underset{\bar{G}}{CH_2}\text{–}\underset{T}{CH_2}\text{–}O\text{–}.$$

The conformation of the whole molecule is, therefore, denoted by

$$\underset{T}{CH_3}\text{–}O\text{–}\underset{G}{CH_2}\text{–}\underset{T}{CH_2}\text{–}O\text{–}\underset{T}{CH_2}\text{–}\underset{\bar{G}}{CH_2}\text{–}O\text{–}\underset{T}{CH_2}\text{–}\underset{T}{CH_2}\text{–}O\text{–}\underset{G}{CH_2}\text{–}\underset{T}{CH_2}\text{–}O\text{–}$$

$$\underset{\bar{G}}{CH_2}\text{–}\underset{T}{CH_2}\text{–}O\text{–}CH_3.$$

Figure 2 shows the molecular structure of TGM in the complex, where the molecule is projected on the plane formed by the five oxygen atoms. The molecule has an open circular structure and the five oxygen atoms are on the inner side, enclosing one Hg atom in the way shown in Fig. 3. Table 5 gives interatomic distances involving Hg atoms and angles for $O_i\cdots Hg\cdots O_{i+1}$, Cl_j–$Hg\cdots O_i$, and C_j–$O_i\cdots Hg$. Interatomic dis-

tances between the Hg and O atoms range from 2.78 to 2.96 Å. All the angles of $Cl_j-Hg\cdots O_i$ are 86—98° and the five oxygen atoms of the TGM molecule enclose one Hg atom in the plane nearly perpendicular to the Cl-Hg-Cl direction and passing through the Hg atom. The angles of $O_i\cdots Hg\cdots O_{i+1}$ are 59—62°. The five oxygen atoms are located at the five corners of a hexagon with the remaining one corner empty, the Hg atom being located at the center of the hexagon. Since the $C_j-O_i\cdots Hg$ angles are 108—116° and nearly of a tetrahedral angle, the Hg atom is located at one of the tetrahedral directions of an oxygen atom with respect to the bonded carbon atoms. The above geometry of the coordination indicates that the circular structure of TGM is very favorable for coordination of the O atoms with the Hg atom. Figure 4 shows the structure of the complexed pair projected along the *a* axis.

The chain conformation of TGM in the complex is very similar to that of PEO[3] with respect to the single chemical unit of $O-CH_2-CH_2-$. However, since the CH_2-CH_2 bonds are alternately *gauche* and minus

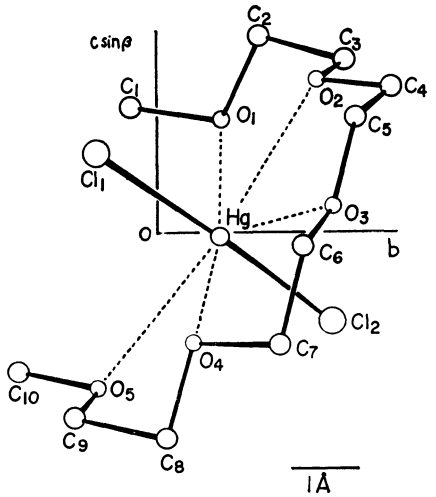

Fig. 4. Structure of one pair of the TGM-$HgCl_2$ complex projected along the *a* axis.

gauche in the adjacent CH_2CH_2O groups, the shape of the molecule as a whole becomes open circular in contrast to the helical conformation of PEO which consists of a uniform succession of $-\underset{T}{CH_2}-\underset{G}{CH_2}-\underset{T}{O}$. It has been shown that when PEO forms molecular complexes with $HgCl_2$, the conformation of the asymmetric unit changes either to $-\underset{T}{O}-\underset{T}{CH_2}-\underset{T}{CH_2}-\underset{T}{O}-\underset{T}{CH_2}-\underset{G}{CH_2}-$ (type I)[1] or to $-\underset{T}{O}-\underset{G}{CH_2}-\underset{G}{CH_2}-$ (type II).[2] It might be of interest to compare these conformations with that found in the complex $-\underset{T}{CH_2}-\underset{G}{CH_2}-\underset{T}{O}-\underset{T}{CH_2}-\underset{\bar{G}}{CH_2}-\underset{T}{O}-$. The stability of these conformations will be considered next. With respect to the CH_2-CH_2 bonds, the *gauche* form may be more stable by about 400 cal/mol than the *trans* form,[15] while for the CH_2-O bonds the *trans* form is more stable by 1.2 kcal/mol than the *gauche* one.[16] Consequently, the conformation of TGM in the present complex must be stable as an isolated molecule. The conformational stability of PEO in the type I complex,[1] which contains equal number of *gauche* and *trans* forms of the CH_2-CH_2 bond, must be next to the most stable form of $-\underset{T}{CH_2}-\underset{G}{CH_2}-\underset{T}{O}-\underset{T}{CH_2}-\underset{\bar{G}}{CH_2}-\underset{T}{O}-$. In contrast to this, the conformation of PEO in the type II complex is less stable as a single chain, since one half of the CH_2-O bonds is gauche. This may be clearly understood from Fig. 5, where the five possible conformations of $O-CH_2-CH_2-O-CH_2-CH_2-$ are given in the order of decreasing stability from the top to the bottom. The conformations of TGM and ordinary PEO correspond to A, the most stable one. PEO of type I complex corresponds to B, and PEO of type II complex to E.

	O—C—C—O—C—C—
A	T G T T G($\bar{G}$) T
B	T G T T T T
C	T T T T T T

E	T G G T G($\bar{G}$) G($\bar{G}$)

Fig. 5. Possible five conformations for the $O-CH_2-CH_2-O-CH_2-CH_2-$ unit. $\bar{G}$ in parentheses indicates alternative possibility for G. A is the most stable and *E* is the least stable conformation.

It is interesting to compare the spatial configuration of the TGM-$HgCl_2$ complex with that of the complex of a cyclic ether with Rb and Na isothiocyanate.[6] In the latter complex, two kinds of molecules are contained in the crystal. One is complexed with the metal ion and the other is free. For the complexed molecule, a Rb or Na ion is enclosed by six oxygen atoms of the cyclic ether molecule, the six oxygen atoms being coplanar. The interatomic distances are 2.73—2.88 Å for Na···O and 2.86—2.93 for Rb···O. Thus, the

16) H. Wieser, W. G. Lailaw, P. T. Krueger, and H. Fuhrer, *Spectrochim. Acta*, **24** *A*, 1055 (1968).

way of coordination between the cyclic ether molecule and the metal ion is very similar to that found in the TGM–$HgCl_2$ complex.

The fact that the ethers composed of CH_2CH_2O, linear or cyclic, form complexes not only with $HgCl_2$ but also with many other metal salts[4] and that a metal ion is coordinated to coplanar five or six oxygen atoms might suggest that the complex is formed by electrostatic forces acting between positively charged metal atom or ion and the negatively charged O atoms, although the tetrahedral arrangement of Hg and O may indicate that some other factors contribute to the coordination.

The angle Cl–Hg–Cl is distorted to 174° from the complete linear form as in the case of the PEO–$HgCl_2$ complexes.[1,2]

The author would like to thank Professor H. Tadokoro, Dr. Y. Chatani, and Dr. M. Kobayashi, Osaka University, for their helpful discussions and encouragement. He is also indebted to Dr. S. Kuribayashi of this Institute for his helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1118—1123 (1973)

Structure of Ethylene Oxide Oligomer Complexes. II. A 1:1 Complex of Tetraethylene Glycol Diethyl Ether with Mercuric Chloride

Reikichi IWAMOTO

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received March 18, 1972)

Structure of a 1:1 complex of tetraethylene glycol diethyl ether $CH_3CH_2O(CH_2CH_2O)_4CH_2CH_3$ (TGE) with mercuric chloride has been investigated by means of X-ray diffraction. The complex has a cubic unit cell with $a=12.54$ Å and four molecules of both TGE and $HgCl_2$ are contained in the unit cell. The space group is Pa3-T_h^6. Four Hg atoms are located at the positions corresponding to the face centered arrangement. The TGE molecule is statistically arranged around the Hg atom located at the position having site symmetry $\bar{3}$. The following molecular conformation of TGE was suggested:

$$CH_3\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{G}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{\bar{G}}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{G}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{\bar{G}}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{G}{O}\text{-}CH_2\text{-}CH_3,$$

where T, G, and $\bar{G}$ indicate *trans*, *gauche*, and minus *gauche* forms, respectively. The TGE molecule encloses the $HgCl_2$ molecule around the Hg atom with close interatomic distances between the Hg and O atoms.

Structure of the molecular complex of tetraethylene glycol dimethyl ether $CH_3O(CH_2CH_2O)_4CH_3$ (TGM) with $HgCl_2$ has been reported in a previous paper.[1] Tetraethylene glycol diethyl ether $CH_3CH_2O(CH_2CH_2O)_4CH_2CH_3$ (TGE) also forms a 1:1 molecular complex with $HgCl_2$. Replacement of CH_3 by CH_2CH_3 for the terminal groups causes a remarkable change in the symmetry of the unit cell: that is, the TGM–$HgCl_2$ complex has a monoclinic unit cell, while the TGE–$HgCl_2$ complex has a cubic unit cell. The occurrence of the cubic unit cell for the complex may be noticeable because, generally speaking, only simple or highly symmetric molecules form a cubic unit cell. In the present paper the structure of the TGE–$HgCl_2$ complex is described.

Experimental

Samples. TGE was synthesized according to the method of Fordyce, Lovell, and Hibbert.[2] The synthesized TGE was purified by distillation, the purity being checked by means of gas chromatography.

Crystals of TGE–$HgCl_2$ were prepared in the same way as for TGM–$HgCl_2$.[1] The crystal is transparent; the melting point is 88°C as determined microscopically. The density of the crystal was measured by the flotation method with the use of a liquid mixture of CCl_4 and $CHBr_3$ as the flotation medium. The observed density was 1.76 g/cc. The composition was found to be TGE: $HgCl_2$=1:1 by elemental analysis (Found: Hg, 38.3%. Calcd for the 1:1 complex: Hg, 38.2%).

Unit Cell and Space Group. At first the unit cell was mistaken as monoclinic but more detailed investigation revealed that the crystal has a three-fold symmetry axis along the direction perpendicular to the axis around which X-ray photographs were taken at an early stage. Finally, it was found that the unit cell is cubic. The unit cell para-

1) R. Iwamoto, This Bulletin, **46**, 1114 (1973).

2) R. Fordyce, E. L. Lövell, and H. Hibbert, *J. Amer. Chem. Soc.*, **61**, 1095 (1939).

meter was measured by a powder camera with diameter of 11.46 cm and calibrated with silicon powder. The crystallographic data are given in Table 1, together with some physical constants. The assumption that the unit cell contains four molecules of both TGE and $HgCl_2$ gives the calculated density of 1.76 g/cc, which is reasonable as regards the observed density of 1.76 g/cc. The systematic absences observed are $h0l$ with l odd, $hk0$ with h odd, and $0kl$ with k odd. The space group is, therefore, $Pa3\text{-}T_h^6$.

Intensity Measurement. X-Ray diffraction photographs of the complex crystal were taken by using Cu$K\alpha$ radiation. The crystal used were about 0.2 mm × 0.2 mm × 0.2 mm. Intensity data of the complex were recorded on photographs, using equi-inclination Weissenberg multiple film method, around the [110] direction from the equator to the fifth layer line. The number of recorded reflections having non-zero intensities was 200. The intensities were measured by visual comparison with standard scales. Although the absorption coefficient ($\mu = 178\ cm^{-1}$ for Cu$K\alpha$ radiation) is large, the intensity data were not corrected for absorption. They were corrected only for Lorentz and polarization factors. The smallest possible crystals were used for collecting diffraction intensities. The crystal used for collection of intensity data was renewed for each layer line.

Infrared Measurement. Infrared spectra of the TGE–$HgCl_2$ and related complexes were measured by the Nujol mull method with a Japan Spectroscopic Co., Ltd. model IR-G and 402G infrared spectrometers.[3]

Structure Determination

Reflections having indices hkl with $h+k$ even, $k+l$ even, and $h+l$ even are selectively very strong and reflections of other indices are, in general, quite weak. These strong reflections decrease in intensity apparently only with increasing $\sin\theta/\lambda$. Since the general feature of the diffraction pattern was supposed to be regulated by the atomic position of Hg, the characteristic feature led to the conclusion that the four Hg atoms are located at such special positions as 0,0,0; 0,1/2,1/2; 1/2,0,1/2; 1/2,1/2,0. Thus, the contribution of the Hg atoms to a reflection having an index, hkl, is as follows.

$$F(hkl)_{Hg} = 4f_{Hg}(hkl)$$

for hkl with h even, k even, and l even, and

$$F(hkl)_{Hg} = -4f_{Hg}(hkl)$$

for hkl with h odd, k odd, and l odd. Thus, the Hg atoms do not interfere with each other among themselves for these reflections but contribute to them to their full scattering power, making the contribution of the Hg atoms to intensities of these reflections overwhelming as compared with that of the C and O atoms of TGE. The atomic position of Cl was easily determined by the Fourier method. However, due to the dominant contribution of the Hg atom, it was not possible to determine the atomic positions of the C and O atoms by the heavy atom method. Therefore, the conformation of the TGE molecule and the arrangement of the molecules in the crystal lattice was assumed by referring to the TGM–$HgCl_2$ complex[1] as described below.

In the first place, it seems reasonable to assume the following conformation of TGE which is similar to that of TGM[1];

$$CH_3\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_3$$
$$T\ T\quad G\quad T\ T\quad \bar{G}\quad T\ T\quad G\quad T\ T\qquad \bar{G}\quad T\ T$$

However, this model gives the very short interatomic distance of 2.2 Å between the two C atoms of the terminal CH_3 groups. To overcome the difficulty, one of the internal rotation angles about the terminal CH_2–O bonds was changed to a gauche form (−80°) by referring to the angles of the *gauche* CH_2–O bond in the $CH_3CH_2O(CH_2CH_2O)_6CH_2CH_3$ (HGE)[4] and PEO of type II[5] in the complexes with $HgCl_2$ so that the molecular model gave reasonable distances between the terminal groups. The assumed model is shown in Fig. 1 for which the conformation of the bonds along the chain can be given approximately by

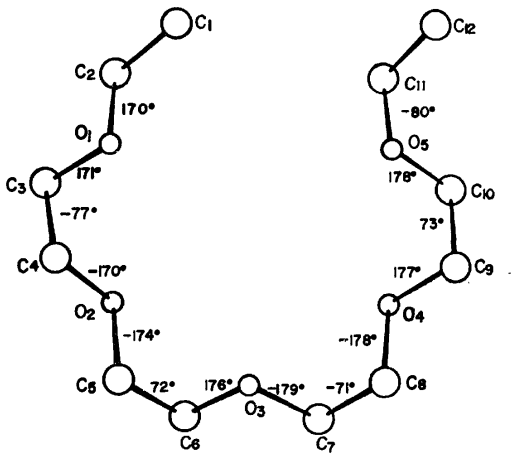

Fig. 1. The adopted molecular model for TGE in the complex.

$$CH_3\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_2\text{-}O\text{-}CH_2\text{-}CH_3$$
$$T\ T\quad G\quad T\ T\quad \bar{G}\quad T\ T\quad G\quad T\ T\qquad \bar{G}\quad T\ G$$

For this model, the nearest distance between C_1 and

C_{11} is 3.84 Å (for the numbering of atoms, see Fig. 1). This value may be allowable in comparison with the van der Waals distance, 4.0 Å. The assumed molecular dimensions are listed in Table 2 and were taken from those of TGM–$HgCl_2$[1] except for the terminal C–C bonds.

Next, we have to consider the arrangement of the TGE molecules in the crystal lattice. By analogy with the case of TGM–$HgCl_2$,[1] it was assumed that the TGE molecule encloses one $HgCl_2$ molecule with nearly equal interatomic distances between Hg and five O atoms. The atomic parameters of the atoms were determined in the following way.

First, a Cartesian right-handed coordinate system fixed to the molecule was assumed and is denoted by X^m. In this coordinate system the x axis is along the first bond and the y axis is in the plane of the first and second bonds and perpendicular to the x axis. The z axis was chosen so as to be perpendicular to the x and y axes and to make the right-handed system. Here, a dummy oxygen atom was assumed to be bonded to the first C atom with the bond length of 1.43 Å, bond angle of 109°28′ and internal rotation angle of 70°. This was chosen to facilitate the setting of the origin of the following X_0^m coordinate system at the position equidistant from the five oxygen atoms. The dummy atom is denoted by O_0.

Secondly, the coordinate system X^m was transformed into the other Cartesian coordinate system X_0^m fixed to the molecule. In this system, the z axis was set along the direction of the following vector.

$$\overrightarrow{O_0O_1} \times \overrightarrow{O_1O_2} + \overrightarrow{O_1O_2} \times \overrightarrow{O_2O_3} + \overrightarrow{O_2O_3} \times \overrightarrow{O_3O_4} + \overrightarrow{O_3O_4} \times \overrightarrow{O_4O_5} + \overrightarrow{O_4O_5} \times \overrightarrow{O_5O_0} + \overrightarrow{O_5O_0} \times \overrightarrow{O_0O_1},$$

where O_i is the ith oxygen atom and each vector product $O_{i-1}O_i \times O_iO_{i+1}$ was normalized to a unit vector. The origin of the coordinate system was set at the center of gravity of the five oxygen atoms and the dummy atom. The x axis is perpendicular to the plane including the z axis and O_0; that is, it is parallel to the $\overrightarrow{O_gO_0} \times \vec{z}$ direction, where O_g is the center of gravity. The y axis is taken along the $\vec{z} \times \vec{x}$ direction as shown in Fig. 2.

Finally the X_0^m was transformed into the coordinate system fixed to the crystal lattice so that the molecular axis (z axis) is along [111] as shown in Fig. 3, where the TGE molecule was simply drawn around the $HgCl_2$ molecule located at the origin. This transformation was made according to the transformation matrix expressed by the Eulerian angles. The rotation angle around [111] is denoted by χ.

Figure 4 shows some of the symmetry elements existing in the space group Pa3-T_h^6. The Hg atoms are located at the positions having site symmetry $\bar{3}$. Since the TGE molecule enclosing the Hg atom has no symmetry, it should be assumed that the TGE molecules are rotated statistically around the Cl–Hg–Cl direction in order to satisfy the site symmetry. Figure

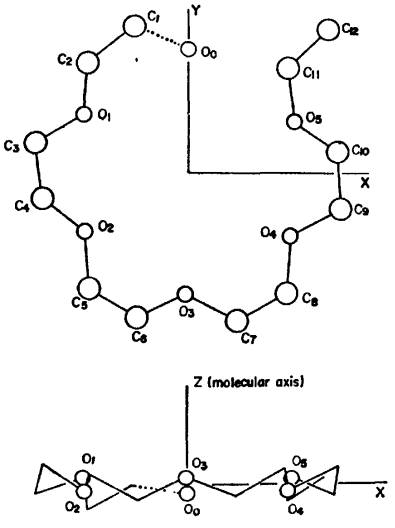

Fig. 2. Molecular coordinate system for the TGE molecule. The dummy atom O_0 was assumed to be bonded to C_1 in order to set the origin at the equi-distant position from the five oxygen atoms.

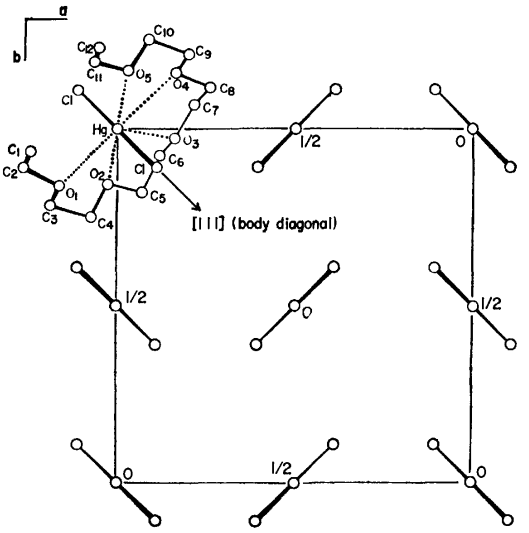

Fig. 3. Molecular arrangement of the TGE molecule in the complex crystal. Only one molecule around $HgCl_2$ at the origin is shown for simplicity.

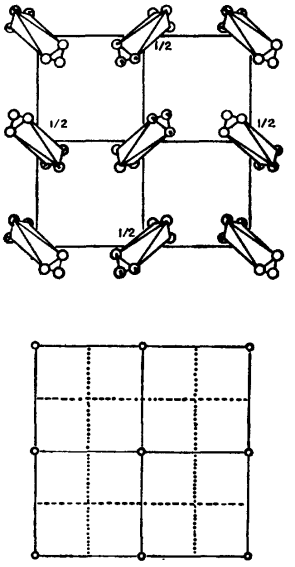

Fig. 4. Some of the symmetry elements in the space group Pa3–T_h^6.

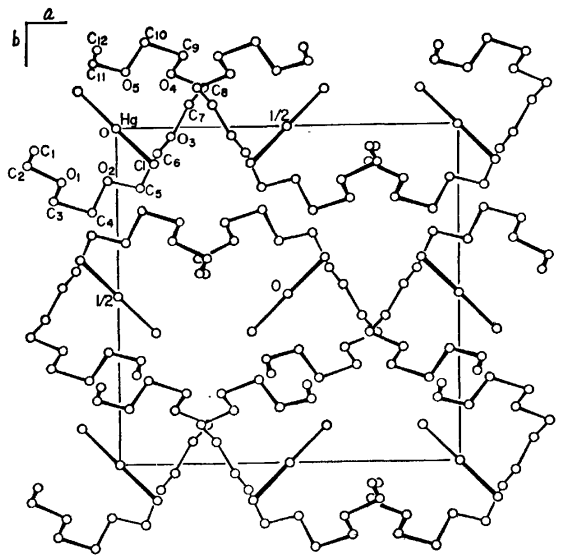

Fig. 5. Crystal structure of the TGE-$HgCl_2$ complex. The statistical arrangement of TGE molecules in the crystal lattice is not drawn for simplicity.

5 shows the crystal structure of the complex. However, the statistical arrangement of the TGE molecule is not shown in order to avoid complication of the figure. Structure factors of the TGE–$HgCl_2$ complex were calculated on the basis of the atomic coordinates deduced above assuming the statistical structure. It was found that the R factor ($\sum||F_o|-|F_c||/\sum|F_o|$) varies with χ. From this dependence the χ angle of 115° was found most reasonable.

Least squares refinement of isotropic approximation was applied to all the atoms except hydrogen and the resulting R factor was 11.0%. However, the resulting molecular dimensions for the TGE molecule were so distorted that they were not allowable in comparison with the ordinary bond lengths and angles. The atomic coordinates for TGE were, then, fixed and the least squared method was applied to the Hg and Cl atoms only, the resulting R factor being 12.3%. The $HgCl_2$ molecule was assumed to be linear. The atomic coordinates are given in Table 3.

Table 3. Atomic coordinates and temperature factors in the TGE–$HgCl_2$ complex

Discussion

Since it is not possible to determine the atomic positions of the C and O atoms directly by the heavy atom method, it is necessary to consider whether the adopted molecular model is reasonable.

Since the composition (TGE: $HgCl_2$) of the complex is 1 : 1 and all the four $HgCl_2$ molecules contained in the unit cell are symmetrically equivalent, one TGE molecule should enclose one $HgCl_2$ molecule. In the HGE–$HgCl_2$,[4] each half part of the HGE molecule enclosing one $HgCl_2$ has the conformation

$$\underset{T}{CH_3}-\underset{T}{CH_2}-O-\underset{G}{CH_2}-\underset{T}{CH_2}-O-\underset{G}{CH_2}-\underset{T}{CH_2}-O-\underset{G}{CH_2}-\underset{G}{CH_2}-O-.$$

It should be noted that this conformation and the spatial configuration are very similar to those of TGM in the complex,[1] indicating that the conformation is very stable and favorable to form coordination between the O and Hg atoms. Therefore, it seems reasonable to assume essentially the same conformation of TGE for TGM except for the terminal groups to which a *gauche* CH_2–O bond is assigned in order to avoid too close approach between the terminal groups.

Improvement of the R factor by 4% (from 16.4 to 12.3) by taking into account the TGE molecule having the adopted molecular conformation might indicate that the molecular model and the arrangement are reasonable. Although the 4% improvement for the TGE–$HgCl_2$ is smaller in comparison with 6% for the TGM–$HgCl_2$,[1] this may be accounted for by the fact that in the former complex the Hg atoms are located at special positions and contribute much more greatly to structure factors, while in the latter complex they are located at general positions.

In the present structure, the TGE molecule must be located around the position whose site symmetry is $\bar{3}$. However, the molecule does not have any symmetry and the statistical structure must be assumed, in which the six molecules having the structure shown in Fig. 1

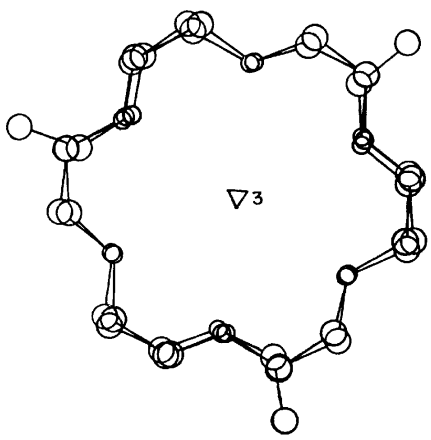

Fig. 6. Statistical sructure having the symmetry 3 produced by the three molecules of TGE.

are arranged around the Hg atom with the weight of 1/6 for each molecule, satisfying symmetry 3. Figure 6 shows the statistical arrangement in which the three TGE molecules are arranged so as to produce symmetry 3. In order to give the statistical arrangement having the $\bar{3}$ symmetry, another of these molecules related by $\bar{1}$ at the position of Hg should be superposed in the figure. It should be noticed that the molecules generated by the symmetry operation 3 coincide approximately with the original molecule if the molecular ends are neglected.

In the adopted molecular model of Fig. 1, a *gauche* form was fixed to the O_5–C_{11} bond in order to avoid the intramolecular steric hindrance, but there is no necessity of assigning the gauche CH_2–O bond to the O_5–C_{11} bond. Any CH_2–O bond of the TGE molecule can be *gauche* and furthermore there is a possibility that the *gauche* CH_2–O bond can move from time to time through the whole molecule; that is, the *gauche* CH_2–O bond may be delocalized over the whole molecule. The delocalization of the *gauche* CH_2–O bond may give rise to vigorous molecular motion of the TGE molecule around the Hg atom. Evidence of some kind of molecular motion is shown by the temperature dependence of the infrared spectra as discussed below. Combination of the molecular model in which the *gauche* CH_2–O bond moves through the whole molecule with time and the molecular motion around the Hg atom may produce the apparent site symmetry, $\bar{3}$, observed for the TGE–$HgCl_2$ complex.

Figure 7 shows infrared spectra of the TGE–$HgCl_2$ at room temperature and at a low temperature (liquid nitrogen). Absorption bands, even if they are weak or have shoulders at room temperature, become strikingly sharp and well-defined at low temperature in the whole region. On the other hand, for TGM–$HgCl_2$, temperature dependence of the infrared spectrum (Fig. 8) is not so marked as in the former. It should be noted that, although the nature of the spectral change in TGE–$HgCl_2$ is not clear, each absorption corresponds well between the two temperatures, even if some bands are very weak or have shoulders at room temperature.

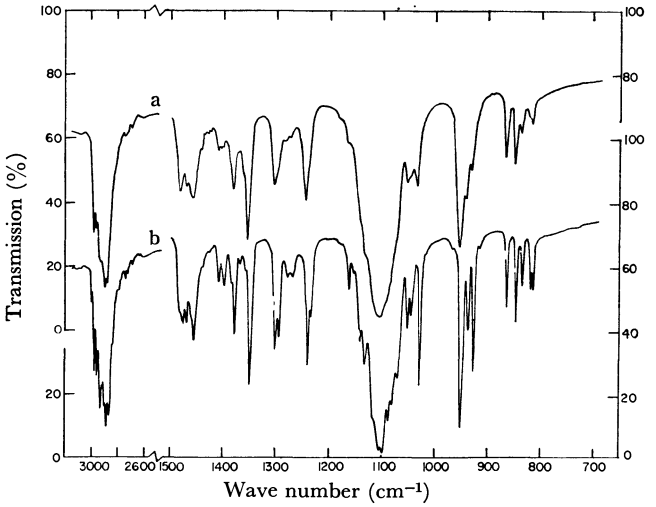

Fig. 7. Infrared spectra of the TGE–$HgCl_2$ complex at (a) room temperature and (b) a low temperature (liquid nitrogen).

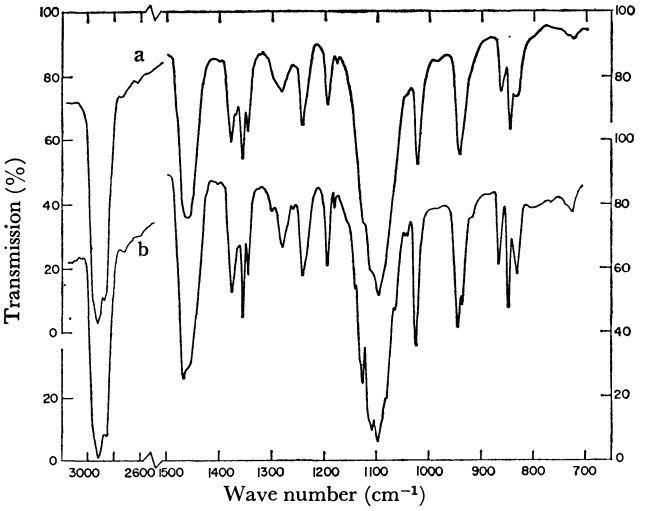

Fig. 8. Infrared spectra of the TGM–$HgCl_2$ complex at (a) room temperature and (b) a low temperature (liquid nitrogen).

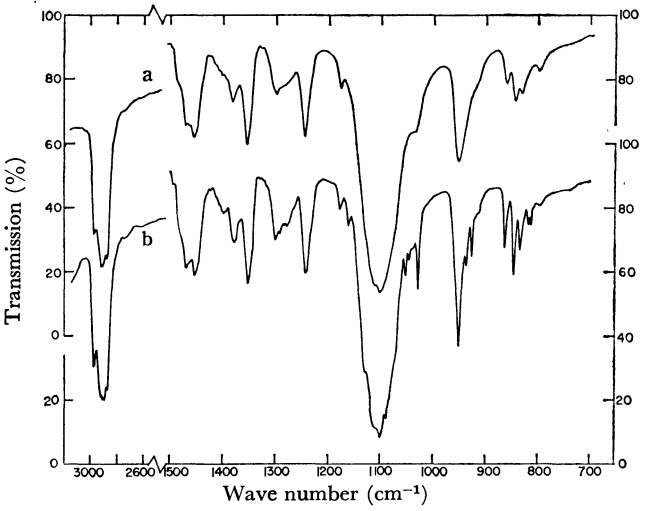

Fig. 9. Infrared spectra of the TGE–$HgBr_2$ complex at (a) room temperature and (b) a low temperature (liquid nitrogen).

Consequently, the observed spectral change is due to a molecular motion but not to a conformational change of the TGE molecule.

A similar spectral change is observed for the $HgBr_2$ complex of TGE as shown in Fig. 9, which has a monoclinic unit cell. The infrared spectrum of the TGE–$HgBr_2$ becomes sharp and well-defined at low temperature as observed in the $HgCl_2$ complex. Since it is considered that a TGE molecule encloses one Hg atom in TGE–$HgBr_2$, the same kind of intramolecular steric hindrance must occur between the terminal groups as was found in TGE–$HgCl_2$. These observations lead to the conclusion that too close approach between the terminal groups causes some kind of molecular motion of the chain in the complex crystal.

Since the $HgCl_2$ molecule is bent by 4—5° from the linear form both in the cases of TGM–$HgCl_2$ and HGE–$HgCl_2$,[1,4] it may be reasonable to consider that the $HgCl_2$ molecule is also deviated from the linear form in TGE–$HgCl_2$. This study gave no conclusive information as to whether the molecule is bent or not,

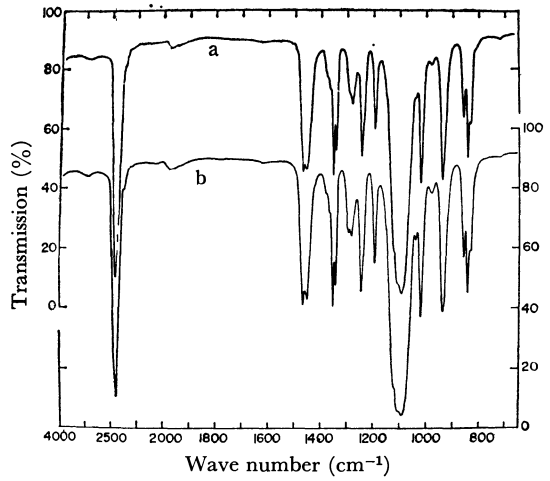

Fig. 10. Infrared spectra of (a) $HgCl_2$ and (b) $HgBr_2$ complexes of TGM at room temperature.

although the R factor was slightly improved for the structure having the bent $HgCl_2$.

It is interesting to note that the complex consisting of such fairly complicated molecules as TGE and $HgCl_2$ forms a cubic unit cell, while the $HgBr_2$ complex which should have the same situation as the $HgCl_2$ complex with respect to the intramolecular steric hindrance of the TGE molecule, has a monoclinic unit cell. The infrared spectrum of the TGE–$HgBr_2$ (Fig. 9) is similar to that of the $HgCl_2$ complex as a whole but they differ to some extent in detail in the whole region. On the other hand, the infrared spectra of the $HgCl_2$ and $HgBr_2$ complexes of TGM are quite the same in detail as shown in Fig. 10 but their unit cells differ. Therefore, the observed spectral difference between the $HgCl_2$ and $HgBr_2$ complexes of TGE must be closely correlated with the occurrence of the cubic unit cell for the $HgCl_2$ complex.

The author would like to thank Professor H. Tadokoro, Dr. Y. Chatani, and Dr. M. Kobayashi, Osaka University, for their helpful discussions and encouragement. He is much indebted to Mr. A. Ueda of Nippon Zeon Co., Ltd. for his valuable assistance in the synthesis of TGE, and also grateful to Dr. S. Kuribayashi of this Institute for his helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1123—1127 (1973)

Structure of Ethylene Oxide Oligomer Complexes. III. A 1:2 Complex of Hexaethylene Glycol Diethyl Ether with Mercuric Chloride

Reikichi IWAMOTO

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received March 24, 1972)

Molecular and crystal structure of a 1 : 2 complex of hexaethylene glycol diethyl ether $CH_3CH_2O(CH_2CH_2O)_6CH_2CH_3$ (HGE) with $HgCl_2$ has been determined by means of X-ray diffraction. The unit cell is monoclinic with $a=23.34$, $b=7.84$, $c=16.69$ Å, and $\beta=115.0°$. The space group is C2/c. The unit cell contains four HGE and eight $HgCl_2$ molecules. The HGE molecule in the complex has the conformation

$$CH_3\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{G}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{\bar{G}}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{G}{CH_2}\text{-}\underset{G}{CH_2}\text{-}\underset{G}{O}\text{-}\underset{G}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{\bar{G}}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{G}{CH_2}\text{-}\underset{T}{CH_2}\text{-}\underset{T}{O}\text{-}CH_2\text{-}CH_3,$$

where T, G, and $\bar{G}$ denote *trans*, *gauche*, and minus *gauche*, respectively, two $HgCl_2$ molecules being coordinated with one HGE molecule. The asymmetric unit consists of a half of HGE and one $HgCl_2$ molecule. The four oxygen atoms of either half of HGE, which are coplanar, are coordinated with one Hg atom with close interatomic distances (2.66—2.91 Å) between the O and Hg atoms, the central oxygen atom of HGE being coordinated with two Hg atoms. The $HgCl_2$ molecule is distorted from the linear form by 4°.

Structures of the molecular complexes of tetraethylene glycol dimethyl ether $CH_3O(CH_2CH_2O)_4CH_3$ (TGM) and tetraethylene glycol diethyl ether $CH_3CH_2O(CH_2CH_2O)_4CH_2CH_3$ (TGE) with $HgCl_2$ were reported in previous papers.[1,2] It has been found that TGE is the limiting case in which one TGE molecule encloses one $HgCl_2$ without drastic change of the molecular conformation consisting of a succession of $\underset{T}{CH_2}\text{-}\underset{G}{CH_2}\text{-}\underset{T}{O}\text{-}\underset{\bar{G}}{CH_2}\text{-}\underset{T}{CH_2}\text{-}O$-. The present paper deals with the complex of hexaethylene glycol diethyl ether $CH_3CH_2O(CH_2CH_2O)_6CH_2CH_3$ (HGE) with $HgCl_2$.

Experimental

Samples. HGE was synthesized according to the method of Fordyce *et al.*[3] The synthesized HGE was purified by distillation and the purity was checked by gas chromatography.

The crystalline complex with $HgCl_2$ was prepared in quite the same way as the TGM–$HgCl_2$ complex.[1] The crystal is transparent and long along the *b* axis. The melting point was found to be 103°C by microscopy. The density of the crystal was measured by the flotation method with the use of a liquid mixture of $CHBr_3$ and CCl_4 as flotation medium.

3) R. Fordyce, E. L. Lovell, and H. Hibbert, *J. Amer. Chem. Soc.*, **61**, 1905 (1939).

The observed value was 2.13 g/cc. From elemental analysis with respect to Hg, the composition was found to be HGE: $HgCl_2$=1:2 (Found: Hg, 46.4%. Calcd for the 1:2 complex: Hg, 45.6%).

Unit Cell and Space Group. The unit cell parameters were determined with a Weissenberg camera and calibrated by silicon powder. Systematic absences were observed for *hkl* with $h+k$ odd and *h0l* with *l* odd. From the observed absences the possible space groups were C2/c and Cc, C2/c being finally chosen. The crystallographic data are given in Table 1, together with some physical constants.

Table 1. Crystallographic and physical data of the HGE–$HgCl_2$ complex

Formula	$CH_3CH_2O(CH_2CH_2O)_6CH_2CH_3 \cdot 2HgCl_2$
MW	881.3
Mp	103 °C
Crystal system	monoclinic
Space group	C2/c-C_{2h}^6
a	23.34 Å
b	7.84 Å
c	16.69 Å
β	115.0°
Z	4
Vol.	2767.9 Å
D_c	2.18 g/cc
D_m	2.13 g/cc
μ (Cu$K\alpha$)	256.9 cm^{-1}
F (000)	1656

Intensity Measurement. The X-ray diffraction photographs were taken by use of Cu$K\alpha$ radiation. The crystals used were about 0.2 mm×0.3 mm×0.2 mm in size. Intensity data were collected around the *b* axis from k=0 to 4 layer lines by equi-inclination Weissenberg multiple film method, the number of the observed reflections being 1491. The intensities were measured by visual comparison with standard scales. Intensity data were corrected only for Lorentz and polarization factors, although the absorption coefficient is very large (μ=257 cm^{-1} for Cu$K\alpha$ radiation). The smallest possible crystal was used for collecting the intensity data and was renewed for each layer line because of its decomposition under irradiation of X-rays.

Structure Determination

The atomic positions of the Hg and Cl atoms were easily determined by the Patterson method. The Patterson map showed strong peaks due to Hg at v=0.0. This suggested that the crystal lattice should have a two-fold symmetry axis along the *b* axis and the space group should be C2/c. Based upon the atomic positions of the Hg and Cl atoms, the atomic positions for all the C and O atoms of HGE, the asymmetric unit of which is a half, were determined by the difference Fourier method. Calculation of structure factors and the Fourier synthesis were made according to the space group C2/c. The results were quite reasonable. The space group was, thus, taken as C2/c. Atomic scattering factors were taken from the *International Table for X-Ray Crystallogrphy* (1962).

The atomic coordinates and temperature factors for all the atoms except hydrogen were refined by the least squares method of isotropic and diagonal approximation. The least squares method improved the *R* factor ($\Sigma||F_o|-|F_c||/\Sigma|F_o|$) to 14.0%. The resulting atomic coordinates and temperature factors are given in Table 2, and the molecular dimensions in Table 3.

Results and Discussion

Figure 1 shows the crystal structure of the HGE–$HgCl_2$ complex. Table 4 gives the internal rotation angles for each bond of the asymmetric unit of the molecule. The CH_2–CH_2 bonds are approximately *gauche* (67—77°) and the CH_2–O bonds are nearly *trans* (169—176°) with the exception of the *gauche* CH_2–O bonds located at the center of the molecule, the angle of which is 88° and considerably deviated from the ordinary *gauche* angle. The conformation of the whole molecule is then denoted by

$$CH_3\text{-}\underset{T}{CH_2}\text{-}O\text{-}\underset{T}{CH_2}\text{-}\underset{G}{CH_2}\text{-}O\text{-}\underset{\bar{G}}{CH_2}\text{-}\underset{T}{CH_2}\text{-}O\text{-}\underset{T}{CH_2}\text{-}\underset{G}{CH_2}\text{-}O\text{-}$$

$$\underset{G}{CH_2}\text{-}\underset{T}{CH_2}\text{-}O\text{-}\underset{T}{CH_2}\text{-}\underset{\bar{G}}{CH_2}\text{-}O\text{-}\underset{T}{CH_2}\text{-}\underset{G}{CH_2}\text{-}O\text{-}\underset{T}{CH_2}\text{-}CH_3.$$

The HGE molecule encloses two $HgCl_2$ molecules in the way shown in Figs. 2 and 3, having the two-fold symmetry axis passing through the central O_1 atom. It should be noted that each half of HGE enclosing

Table 5 gives the interatomic distances and angles for non-bonded atoms in HGE-$HgCl_2$. The four oxygen atoms contained in the half of HGE enclosing one Hg atom are nearly coplanar and the interatomic distances between the O and Hg atoms range from 2.66 to 2.91 Å. The angles O_i···Hg···O_{i+1} are nearly 60° (61.7—63.0°) and the angles C_j–O_i···Hg are nearly a tetrahedral angle. The spatial arrangement of the Hg and O atoms in the part enclosing one $HgCl_2$ is very similar to the case of TGM-$HgCl_2$.[1] In the HGE-$HgCl_2$, genearlly, one oxygen atom is coordinated to one Hg but the O_1 atom only is coordinated with two Hg atoms. It may be considered that the interatomic interactions between the Hg and O atoms

Table 6. Molecular constants of $HgCl_2$, interatomic distances Hg··O, the angles for O··Hg··O and Hg··O··Hg, the number of coordinating oxygen atoms per Hg(N), and the average number of coordination per oxygen atom (M) in the TGM–$HgCl_2$, TGE–$HgCl_2$, HGE–$HgCl_2$, and PEO–$HgCl_2$ complexes

must have greater influence on the O_1 atom causing the two CH_2–O bonds involving the O_1 atom to take a *gauche* form.

Table 6 summarizes the molecular constants of $HgCl_2$,Hg···O interatomic distances, the angles for O···Hg···O and Hg···O···Hg, the number of coordination per Hg (N) and the average number of coordination per O (M) in the TGM–$HgCl_2$,[1] TGE–$HgCl_2$,[2] HGE–$HgCl_2$, and polyethylene oxide (PEO)–$HgCl_2$.[4,5] The molecular constants of $HgCl_2$ reveal some differences among these complexes. The longest bond length of Hg–Cl is 2.35 Å in the TGE–$HgCl_2$ and the shortest is 2.23 Å in the PEO–$HgCl_2$ of type II. The two Hg–Cl bonds of $HgCl_2$ are non-equivalent in the TGM–$HgCl_2$, HGE–$HgCl_2$, and PEO–$HgCl_2$ (type II), and they are significantly different in the bond length. The $HgCl_2$ molecule is, in general, deviated from the linear form in the complexes. The angle of the deviation ranges from 3.4 (PEO–$HgCl_2$ of type I) to 8.3° (PEO–$HgCl_2$ of type II). The interatomic distances between the O and Hg atoms are in the 2.66—2.96 Å range and the O···Hg···O angle is in the 59.9—64.0° range for all these complexes. The Hg···O···Hg angle is 86.3 and 85.5° in HGE–$HgCl_2$ and PEO–$HgCl_2$ (type II), respectively. The number of the coordinating oxygen atoms around a Hg atom (N) ranges from 2 to 5 among these complexes.

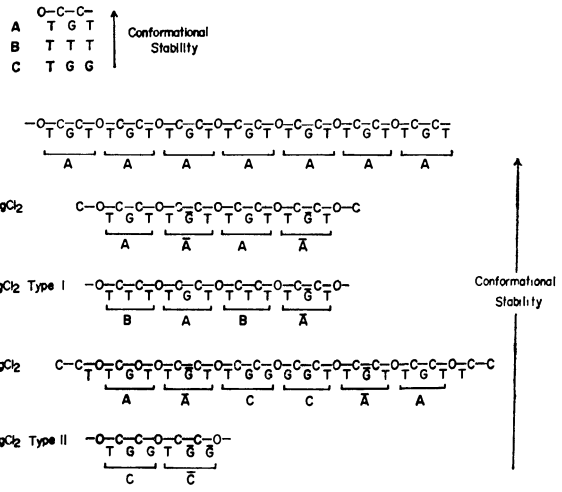

Fig. 4. Molecular conformations of TGM and HGE in the crystalline complex with $HgCl_2$, and of PEO in the ordinary polymer and the complexes with $HgCl_2$.

General Discussion

In the molecular conformations of $RO(CH_2CH_2O)_mR$ and PEO in the complexes with $HgCl_2$,[1,2,4,5] the *gauche* form of the CH_2–CH_2 bond is essentially favorable for coordination between the O and Hg atoms, while the CH_2–O bond takes either a *trans* or a *gauche* form depending on the situation, although the *gauche* form

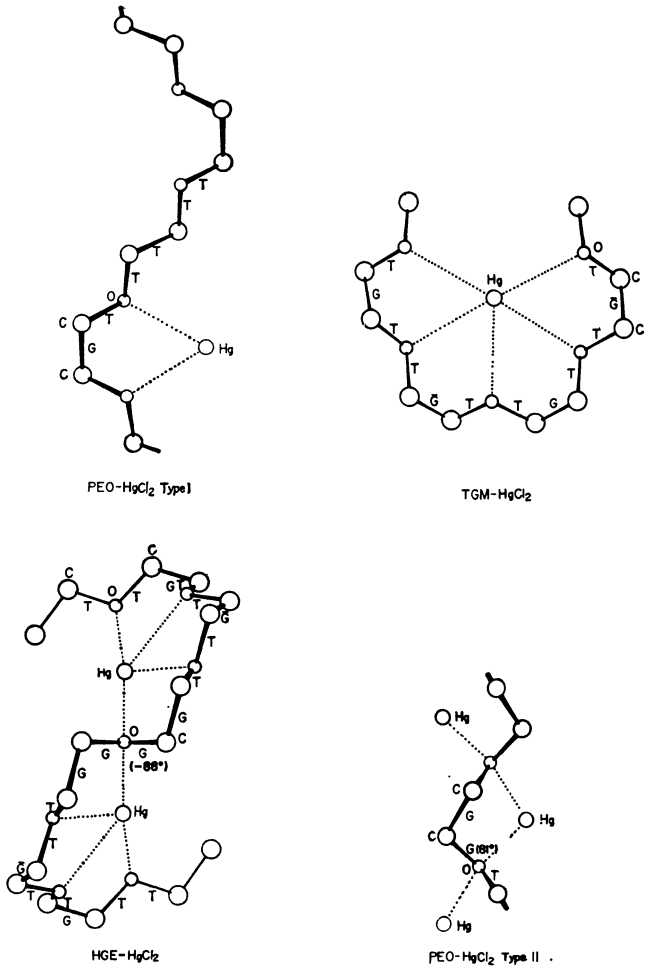

Fig. 5. Way of the interactions between the O and Hg atoms in the TGM–$HgCl_2$, HGE–$HgCl_2$, and PEO–$HgCl_2$ complexes.

is considerably deviated from the ordinary *gauche* angle. These molecular conformations in the complexes may be considered to be governed by two factors: (i) conformational stability of a single chain and (ii) stabilization by the interactions between the O and Hg atoms.

Figure 4 gives the molecular conformations of TGM,[1] HGE in the $HgCl_2$ complexes and of PEO in the pure polymer[7] and the $HgCl_2$ complexes.[4,5] The three possible forms for the $O-CH_2-CH_2-$ group are TGT, TTT, and TGG in the order of conformational stability,[1] and are denoted as types A, B, and C, respectively, as shown in Fig. 4.

PEO in the pure polymer consists of type A only[7] and the TGM molecule is composed of alternations A and $\bar{A}$ ($\bar{A}$: minus A).[1] PEO in the type I complex is composed of A (or $\bar{A}$) and B,[4] and the HGE molecule has the $A\bar{A}CC\bar{A}A$ form. PEO in the type II complex is composed of type C only.[5] Therefore, from the viewpoint of conformational stability, these molecules can be arranged from top to bottom in the order of conformational stability as shown in Fig. 4. PEO in the pure polymer and TGM are the most stable as a single chain, while the PEO molecule in the type II complex is the least stable among these molecules.

The correlation of the conformational stability with the mode of coordination between the O and Hg atoms in the complexes is considered next. Figure 5 gives the way of coordination between the O and Hg atoms in the complexes. The numbers given under *M* in Table 6 indicate the average number of coordination per oxygen atom and are, therefore, a measure of the strength of the interactions between $HgCl_2$ and the oligomer or polymer molecules. In the PEO–$HgCl_2$ of type I,[4] only two of the four oxygen atoms in the fiber identity period are coordinated with one Hg atom and *M* is 1/2. In the case of the TGM–$HgCl_2$[1] all the five oxygen atoms are coordinated with one Hg and *M* is 1. In the HGE–$HgCl_2$, three oxgyen atoms of either half of HGE are coordinated with one Hg atom as in the TGM–$HgCl_2$[1] and the central oxygen atom between the two gauche CH_2-O bonds is coordinated to two Hg atoms, giving 8/7 for *M*. In the PEO–$HgCl_2$ of type II,[5] each oxygen atom is coordinated to two Hg atoms just as the central oxygen atom of HGE and *M* is 2. Thus, the strength of the interactions between ethylene oxide oligomers or polymer and $HgCl_2$ is least effective for the PEO–$HgCl_2$ of type I and most effective for the PEO–$HgCl_2$ of type II, increasing from upper left to down right in Fig. 5.

It is thus found that the less stable conformation has stronger interactions between the O and Hg atoms in the complexes. These interactions might cause the molecule to take a more favorable conformation for coordination between ethylene oxide oligomers or polymer and $HgCl_2$ in the complexes, which is usually less stable as a single chain. Thus, the two factors, conformational stability and stabilization by the interactions between the O and Hg atoms, are very important when we consider the resulting conformation of these molecules.

The author would like to thank Professor H. Tadokoro, Dr. Y. Chatani and Dr. M. Kobayashi, Osaka University, for their helpful discussions and encouragement. He is also much indebted to Mr. A. Ueda of Nippon Zeon Co., Ltd. for his valuable assistance in the synthesis of HGE, and to Dr. S. Kuribayashi of this Institute for his helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1127—1129 (1973)

Structure of Ethylene Oxide Oligomer Complexes. IV. Infrared Study of $CH_3O(CH_2CH_2O)_mCH_3$-$HgCl_2$ Complexes

Reikichi IWAMOTO

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda, Osaka 563

(Received April 15, 1972)

Infrared spectra of $CH_3O(CH_2CH_2O)_mCH_3$ (m=1—4) in their crystalline complexes with $HgCl_2$ have been measured. There is no significant regular variation of band frequencies depending upon m. Molecular conformations of the compounds in the complexes have been concluded to be CH_3-O(T)-CH_2(G)-CH_2(T)-O(T)-CH_2($\bar{G}$)-CH_2(T)-O-CH_3 for m=2 and CH_3-O(T)-CH_2(G)-CH_2(T)-O(T)-CH_2($\bar{G}$)-CH_2(T)-O(T)-CH_2(G)-CH_2(T)-O-CH_3 for m=3 from molecular structures for m=1 and 4.

Molecular and crystal structures of the molecular complexes of $CH_3O(CH_2CH_2O)_4CH_3$,[1] CH_3CH_2O-$(CH_2CH_2O)_4CH_2CH_3$,[2] and $CH_3CH_2O(CH_2CH_2O)_6$-CH_2CH_3[3] with $HgCl_2$ have been studied by means of X-ray diffraction. It has been found that the conformational unit of O(T)-CH_2(G)-CH_2(T)-O(T)-CH_2($\bar{G}$)-CH_2(T)-O is favorable for the coordination between the molecules

1) R. Iwamoto, This Bulletin, **46**, 1114 (1973).
2) R. Iwamoto, *ibid.*, **46**, 1118 (1973).
3) R. Iwamoto, *ibid.*, **46**, 1123 (1973).

and $HgCl_2$. The ethylene oxide oligomer molecules enclose the $HgCl_2$ molecules with close interatomic distances between the Hg and O atoms (2.66—2.97 Å).[1-3]

According to Snyder and Zerbi[4] the molecular conformation of $CH_3OCH_2CH_2OCH_3$ in the crystalline state is of TGT form. In a previous paper,[5] the $CH_3OCH_2CH_2OCH_3$ molecule in the crystalline complex with $HgCl_2$ was concluded to have the TGT form from analogy with the molecular conformation of the $CH_3O(CH_2CH_2O)_4CH_3$–$HgCl_2$ complex[1] and from a comparison of the infrared spectrum of the $CH_3OCH_2CH_2OCH_3$–$HgCl_2$ complex with that of the pure crystalline compound of $CH_3OCH_2CH_2OCH_3$.[4] Therefore, the molecular structures of $CH_3O(CH_2CH_2O)_mCH_3$ for $m=2$ and 3 in the complexes with $HgCl_2$ may be inferred by infrared spectroscopy, since it has been found that the O_T–CH_{2G}–CH_{2T}–O_T–$CH_{2\bar{G}}$–CH_{2T}–O conformation is favorable for coordination between Hg and O in the complexes. From this view-point the infrared spectra of the $CH_3O(CH_2CH_2O)_mCH_3$–$HgCl_2$ complexes have been studied.

Experimental

Commercial $CH_3O(CH_2CH_2O)_mCH_3$ was used (Tokyo Kasei Kogyo Co., Ltd.). Crystalline complexes of these compounds with $HgCl_2$ were prepared by dissolving powdered crystals of $HgCl_2$ in an ethanol solution containing the compounds in volume ratio about 4:1 at 35 °C and by cooling the saturated solution to room temperature. In the case of $CH_3OCH_2CH_2OCH_3$, crystalline powder of $HgCl_2$ was dissolved directly in the pure liquid, the crystalline complex being precipitated in the solution. Infrared spectra were measured by a Japan Spectroscopic Co., Ltd. Model IR-G grating infrared spectrometer by means of Nujol mull method. Frequencies were calibrated by the standard bands of polystyrene.

Results and Discussion

Infrared spectra of the $CH_3O(CH_2CH_2O)_mCH_3$–$HgCl_2$ ($m=1$—4) complexes in the region 1500—700 cm^{-1} are shown in Fig. 1. The absorption bands are listed in Table 1. The absorption spectra of these complexes are, on the whole, very similar to each other.

The band around 940 cm^{-1} which is not observed for $m=1$ appears as a well-defined and fairly strong band when m is equal to or greater than 2. The band becomes stronger with increasing m, no significant frequency change being observed. The band is observed for crystalline diethyl ether.[4] The band should be characteristic when the chain molecule is composed of a sequence of two or more CH_2CH_2O units. The spectral feature around 850 cm^{-1} changes depending on m until $m=3$. The absorption bands are similar for $m=3$ and 4 in this region. In the other regions, the absorption bands of these complexes correspond to

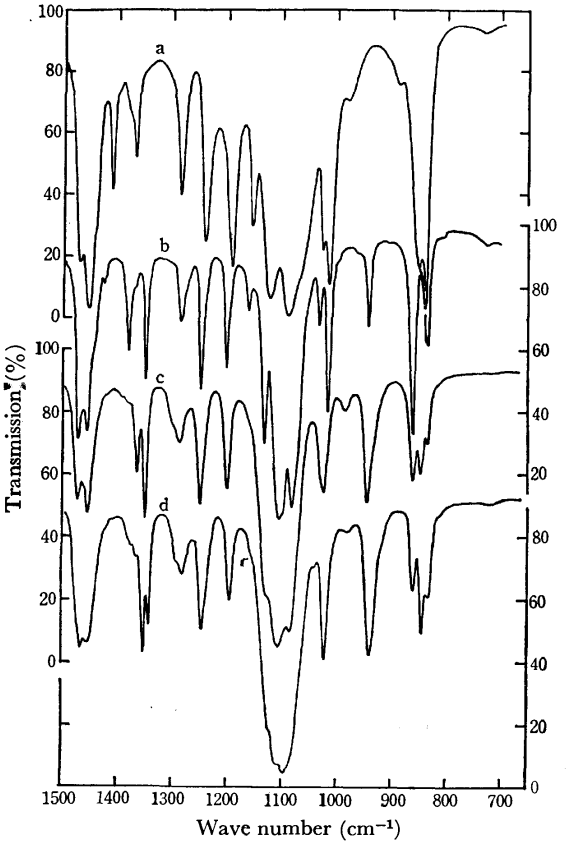

Fig. 1. Infrared spectra of $CH_3O(CH_2CH_2O)_mCH_3$-$HgCl_2$ complexes for (a) $m=1$, (b) $m=2$, (c) $m=3$, and (d) $m=4$ in the crystalline state.

4) R. G. Snyder and G. Zerbi, *Spectrochim. Acta*, **23A**, 391 (1967).
5) R. Iwamoto, *ibid.*, **27A**, 2385 (1971).

each other, especially when m is equal to or greater than 2. The two bands at 1150 and 1200 cm^{-1} are associated with the terminal CH_3 groups[4] and display different behavior with increasing m. The 1200 cm^{-1} band decreases in intensity very gradually with increasing m. It appears as a fairly strong and well-defined band even for $m=4$, while the 1150 cm^{-1}, band which is weak but well-defined for $m=1$ and 2, is hardly observable for $m=3$ and 4.

Thus, the infrared spectra of these complexes for $m=2$ and 3 are very similar to those of the $CH_3O(CH_2CH_2O)_4CH_3$–$HgCl_2$ complex in the whole region. In the $CH_3O(CH_2CH_2O)_4CH_3$–$HgCl_2$ complex, the conformation was found to be essentially a sequence of O_T–CH_{2G}–CH_{2T}–O_T–$CH_{2\bar{G}}$–CH_{2T}–O.[1] From the similarity of the infrared spectra of the members of $m=2$ and 3 to those of the $CH_3O(CH_2CH_2O)_4CH_3$–$HgCl_2$ complex, the following conformations can be assumed in the complexes:

$$CH_3\text{-}O_T\text{-}CH_{2G}\text{-}CH_{2T}\text{-}O_T\text{-}CH_{2\bar{G}}\text{-}CH_{2T}\text{-}O\text{-}CH_3$$

for $m=2$, and

$$CH_3\text{-}O_T\text{-}CH_{2G}\text{-}CH_{2T}\text{-}O_T\text{-}CH_{2\bar{G}}\text{-}CH_{2T}\text{-}O_T\text{-}CH_{2G}\text{-}CH_{2T}\text{-}O\text{-}CH_3$$

for $m=3$.

It has been found reasonable to consider that the molecular conformation of $CH_3O(CH_2CH_2O)_mCH_3$ ($m=4$) in the complexes with $HgCl_2$ consists of a sequence of O_T–CH_{2G}–CH_{2T}–O with alternation of G and $\bar{G}$ in the adjacent chemical units. It is noticed that "band progression" or regular variation of band frequencies depending on m is not observed for these complexes, but their infrared spectra can be reasonably interpreted in terms of group characteristic vibrations.

The author would like to thank Prof. H. Tadokoro and Dr. M. Kobayashi, Osaka University, for their helpful discussions and encouragement. He is also grateful to Dr. S. Kuribayashi of this Institute for his valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1129—1134 (1973)

Magnetic Properties of Some Iminoxyl Polyradicals. V. EPR Studies of the TEMPAD Biradical

Akira NAKAJIMA

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received September 20, 1972)

The EPR of pure and diluted crystals of bis(2,2,6,6-tetramethylpiperidine-4)azine-1,1′-dioxyl (the TEMPAD biradical) was studied. From the spectra of the diluted cyrstal, the intra- and inter-molecular dipole-dipole interactions were identified. The crystal-field parameters of the intra-molecular coupling determined for the EPR spectra were: $|D|/hc \simeq 0.00477$ cm^{-1} and $|E|/hc \simeq 0.00032$ cm^{-1} and two kinds of principal axes were found. As the z-axis of the intra-molecular dipole-dipole coupling is in the direction connecting two N–O bonds in a molecule, the TEMPAD molecules in a unit cell may be said to occupy two different sites. The crystal-field parameters of the inter-molecular dipole-dipole coupling were determined to be: $|D'|/hc \sim 0.012$ cm^{-1} and $|E'|/hc \sim 0.003$ cm^{-1} and the z-axis of the tensor was in the direction of the a-axis. The assumed molecular-stack model could account for the aforementioned results. The EPR spectra of the pure TEMPAD biradical are one symmetrical Lorentzian line in all the directions; the angular dependence of the peak-to-peak linewidths was explained by means of the term of the inter-molecular dipole-dipole interaction obtained from the spectra of the diluted crystal using the three-dimensional Anderson-Weiss formula. The exchange parameter for the best-fit curve was of the order of magnitude of the weak exchange interaction estimated roughly from the small Weiss constant appearing in the paramagnetic susceptibility of the diluted crystals.

There have been many investigations regarding the magnetic properties of organic, stable free-radical solids; they have been adequately discussed elsewhere.[1] In these works, some short-range ordering effects caused by the exchange interaction between unpaired electrons have been of special interest. On the other hand, the dipole-dipole interactions of organic free-radical solids have been little studied in spite of their importance for the spin correlation.

Recently, Takizawa *et al.* reported the EPR spectra of the radical pair of di-p-anisyl-nitric-oxide in the diamagnetic host, and assumed the structure of the radical pair in the host.[2] In the case of diluted biradicals, we can expect the existence of the intra- and inter-molecular radical pairs which will have an influence on the magnetic behavior of the dense system.

Previous magnetic studies of bis(2,2,6,6-tetramethylpiperidine-4)azine-1,1′-dioxyl (the TEMPAD biradical) have revealed two kinds of exchange interaction; one is the strong inter-molecular exchange interaction which produces the broad maximum in the paramagnetic susceptibility (χ_M) of the 100% case at the temperature of 16.5 K[3] and the large Weiss

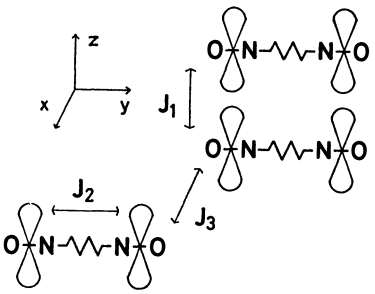

Fig. 1. Simplified molecular-stack model assumed from the $\chi_M - T$ results.

constant in the $\chi_M - T$ curves of the diluted crystals,[4] and the other is the weak intra-molecular exchange interaction which affects the hyperfine structure in the EPR spectrum in solution[5] and the small Weiss constant in the $\chi_M - T$ curves of the diluted crystals.[4] As the unpaired electron is localized around the N–O bond, the aforementioned results can be explained by the simplified molecular-stack model (shown in Fig. 1) on the basis of the localized spin treatment.[4] The EPR spectrum of the powdered TEMPAD biradical at room temperature was a symmetrical line, and new lines appeared on both sides of the central line at low temperatures. They have been explained in terms of the dipole-dipole interaction of the intra-molecular spin pair on the basis of the triplet exciton theory.[6]

In this paper, the author will report on his EPR studies of pure and diluted crystals of the TEMPAD biradical, determine the orientations of the intra- and inter-molecular radical pairs, and discuss the magnetic behavior of the dense system according to the assumed molecular-stack model.

Experimental

The TEMPAD biradical and bis(2,2,6,6-tetramethyl-piperidine-4)azine (the diamine), which are shown in Figs. 2(a) and 2(b) respectively, were prepared from 2,2,6,6-tetramethyl-4-piperidone supplied by the Aldrich Chemicals Co. following the method described by Rassat *et al.*[5,7] The single crystals of both the pure and diluted TEMPAD in the diamine host (less than 2 mol % in concentration) were crystallized from their ether solutions. The monoradical impurity, shown in Fig. 2(c), was formed in the diamine crystal by the air-oxidation, and its EPR spectra were used for the analysis of the hyperfine structure of the biradical spectra.[8]

The EPR measurements were carried out at room temperature using an X-band spectrometer, JEOLCO JES-ME-3X, equipped with a 100 kHz-field modulation for the first derivatives and an 80 Hz-field modulation for the second derivatives. As a standard sample, peroxylamine disulfonate, $[\cdot ON(SO_3)_2]^=$ (A_N=13.0 gauss and g=2.00537), was used. The mount for holding the crystals in the microwave cavity was made of Teflon, and it had a quartz rod; the crystals were fixed to the mount with silicon grease. The error in the measurements of the angle was about 2 degrees.

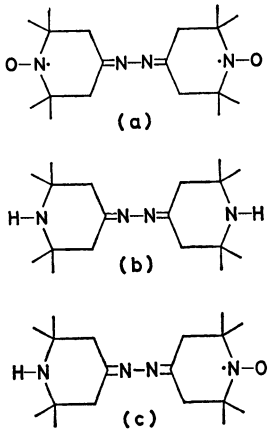

Fig. 2. Molecular structure of the TEMPAD biradical (a), the corresponding diamine (b), and the monoradical (c).

Results and Discussion

Diluted Crystal. The Hamiltonian of the biradical with a strong exchange interaction, introduced by Kurita,[9] is given by:

$$\mathcal{H} = \mathcal{H}_z + \mathcal{H}_{hf} + \mathcal{H}_{dip} + \mathcal{H}_{ex} + \mathcal{H}' \quad (1)$$

$$\mathcal{H}_z = \mu_B \sum_{ij} \bar{g}_{ij} H_i (S_{1j} + S_{2j}) \quad (2)$$

$$\mathcal{H}_{hf} = (1/2) g_0 \mu_B \sum_{ij} (A^{I}_{ij} I^{I}_j + A^{II}_{ij} I^{II}_j)(S_{1i} + S_{2i}) \quad (3)$$

$$\mathcal{H}_{dip} = (4\mu_B^2/R^3)[(\boldsymbol{S}_1 \cdot \boldsymbol{S}_2) - 3(\boldsymbol{S}_1 \cdot \boldsymbol{R})(\boldsymbol{S}_2 \cdot \boldsymbol{R})R^{-2}] \quad (4)$$

$$\mathcal{H}_{ex} = J(\boldsymbol{S}_1 \cdot \boldsymbol{S}_2) \quad (5)$$

$\mathcal{H}'$: inter-molecular term

where μ_B is the Bohr magneton and where the other notations are all the same as in Kurita's equation except for the last inter-molecular term in Eq. (1). In the case of the orthorohmbic symmetry, the term of the intra-molecular dipole-dipole interaction (Eq. (4)) can be rewritten as follows:

$$\mathcal{H}_{dip} = D_{xx} S_x^2 + D_{yy} S_y^2 + D_{zz} S_z^2$$
$$= D[S_z^2 - (1/3)S(S+1)] + E(S_x^2 - S_y^2) \quad (6)$$

where $S_j = S_{1j} + S_{2j}$ ($j = x, y$, and z),

S is the eigen value of the total spin: $\boldsymbol{S} = \boldsymbol{S}_1 + \boldsymbol{S}_2$,

$$D_{jj} = (1/2) g_0^2 \mu_B^2 \langle (R^2 - 3X_j^2)/R^5 \rangle \quad (X_j = X, Y, \text{and } Z) \quad (7)$$

$$D_{xx} = -D/3 + E, \; D_{yy} = -D/3 - E, \; D_{zz} = 2D/3 \quad (8)$$

where D and E are the crystal-field parameters of the biradical.

In a monoclinic crystal, some couples of sites exist in a unit cell and can be superposed upon each other by a symmetry transform of the crystal. When $\beta \simeq 90°$ in the case of the diamine host (see Table 1), we can adopt the *a*-, *b*-, and *c*-axes as the rectangular coordinate system (Fig. 3). Some typical EPR spectra with the static magnetic field at several orientations of the *ab*- and *ca*-planes are shown in Fig. 4. The observed positions of the EPR spectra in the *ca*-plane shown in Fig. 5 have two parts of the angular depend-

ence, namely, the intra- and the inter-molecular parts.

Intra-molecular Part: The g-value of the biradical is the mean-value, $\bar{g}_{ij}$, of the two radicals in a molecule.[9] As the angular dependence of the g-value is almost isotropic for the TEMPAD biradical, $\bar{g}_{ij}$ can be replaced by the $g_0=2.0060$ obtained from the EPR spectrum in solution. Although the principal axes of the tensor of the intra-molecular dipole-dipole interaction are nearly equal to those of the hyperfine tensor, it is difficult to analyze the spectra because of the complexity caused by the unequivalent molecules in a unit cell.

To solve this problem, the author chose the half-value of the hyperfine tensor of the monoradical formed

in the diamine, as that of the biradical. The angular dependence of the hyperfine structure of the monoradical with regard to the *abc*-system is shown in Fig. 6.[8] Then, the principal values and the direction cosines of the tensor of the intra-molecular dipole-dipole interaction with regard to the *abc*-system, which are summarized in Table 2, could be determined. The calculated angular dependence on the *ca*-plane is shown in Fig. 7 in comparison with the experimental

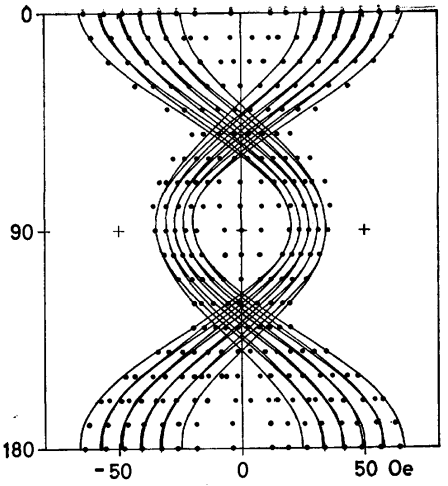

Fig. 7. Calculated angular dependence of the EPR spectra for the intra-molecular dipole-dipole interaction compared with the experimental results.

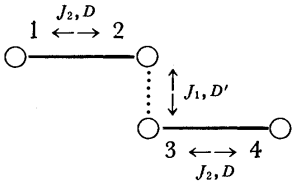
results. From Table 2 we can find that the tensor of the intra-molecular dipole-dipole interaction has two principal axes (p and q). As the z-axis of the tensor of the intra-molecular dipole-dipole coupling is in the direction connecting two N–O bonds in a molecule, the TEMPAD molecule in a unit cell occupies two different sites. A suitable molecular-stack model is shown in Fig. 8; each segment indicates the TEMPAD molecules, and the angles from the b-axis are about 22.0° and −12.5° for the p- and q-sites respectively. The distance between the two radicals in a molecule could be estimated from the equation: $|D| \sim 3\mu_B/R^3$, and then $R \sim 8.2$ Å.

Inter-molecular Part: Outside of the intra-molecular spectra broad lines appeared, apparently under the large field-modulation width (2—10 gauss). The angular dependence of the broad lines shown in Fig. 5 can be explained as a result of the inter-molecular dipole-dipole interaction between biradical molecules. According to the aforementioned molecular-stack model, the system of the coupled two biradicals can be shown as:



where J_1 and J_2 are the inter- and intra-molecular exchange interactions, and where D' and D are the inter- and intra-molecular dipole-dipole interactions. In the case of the TEMPAD biradical, $|J_1| \gg g_0\beta H_0 > |J_2| \simeq |D'| > |D|$; then, the spin Hamiltonian can be briefly given by:

$$\mathcal{H} \simeq g_0\beta \boldsymbol{H}_0 \cdot (\boldsymbol{S}_0 + \boldsymbol{S}_1 + \boldsymbol{S}_4) + \boldsymbol{S}_0 \cdot \boldsymbol{D}' \cdot \boldsymbol{S}_0 + \boldsymbol{S}_0 \cdot \boldsymbol{D} \cdot (\boldsymbol{S}_1 + \boldsymbol{S}_4) \quad (9)$$

where $\boldsymbol{S}_0 = \boldsymbol{S}_2 + \boldsymbol{S}_3$ and where $\boldsymbol{D}$ and $\boldsymbol{D}'$ are the tensors of the intra- and inter-molecular dipole-dipole interactions respectively. When $|D'| \gg |D|$, the system can be treated as one with one spin-pair (S_2 and S_3) and two monomers (S_1 and S_4). On this assumption, the principal values which are listed in Table 3 were roughly calculated: the z-axis of the tensor, $\boldsymbol{D}'$ was found to be in the direction of the a-axis. The calculated angular dependence, which is shown in Fig. 5, agreed with the experimental results except for the case of the ab-plane. The slight lack of agreement in the case of the ab-plane can be reduced by disregarding the $\boldsymbol{D}$-tensor. The distance between the radicals along the a-axis can be estimated from the value of D' at 6.0 Å, which agrees with the separation between the nearest neighbors in the direction of the a-axis, $a/4 = 7.2$ Å (Table 1).

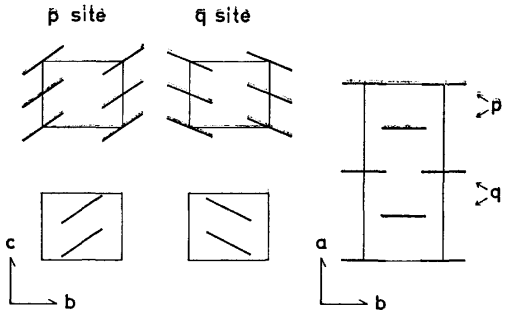


Fig. 8. Assumed stack model for the TEMPAD molecules in a unit cell. Each segment indicates the TEMPAD molecule and the angles from the b-axis are about 22.0° and −12.0° for the p- and q- sites, respectively.

TABLE 3. THE PRINCIPAL VALUES OF THE TENSOR OF THE INTER-MOLECULAR DIPOLE-DIPOLE INTERACTION WITH REGARD TO THE *abc*-SYSTEM AND THE CRYSTAL FIELD PARAMETERS

Principal values		Crystal field parameters	
D'_{xx}	±13 gauss	$\|D'\|/g_0\mu_B$	130 gauss
D'_{yy}	±73	$\|E'\|/g_0\mu_B$	30
D'_{zz}	∓86		

The EPR spectra with the static magnetic field around the a-axis showed three other kinds of weak broad lines, which can be explained as dipole-dipole interactions among the next nearest and further neighbors. The distances of these couplings were roughly estimated to be 6.6, 7.5, and 8.5 Å respectively.

The obtained crystal-field parameters of the intra- and inter-molecular dipole-dipole interactions are summarized in Table 4 in comparison with those of other triplet states. The order of magnitude of our results was in the class of the thermally-excited triplets or of the radical pair.

Pure Crystal. As the crystal structure of the TEMPAD biradical is nearly equal to that of the diamine (see Table 1),[4] we can adopt the same a-, b-, and c-axes as the rectangular coordinate system as in the case of the diamine (Fig. 9). The EPR spectra of the TEMPAD biradical have one absorption line in all the directions, and the angular dependence of the g-value is almost the same isotropically as in the diluted crystal. The absorption lines are all symmetrical Lorentzian, and the peak-to-peak linewidths, shown in Fig. 10, varied with the static magnetic field in the bc-,

ca-, and *ab*-planes.

The strong inter-molecular exchange interaction (J_1 in Fig. 1), which determines the energy levels of the magnetic system, will never affect the linewidth. On the other hand the weak intra-molecular exchange interaction (J_2) will cause a narrowing of the linewidth. In the case of a narrowing, we can apply the usual three-dimensional Anderson-Weiss formula for a Lorentzian line:[18]

$$\Delta H_{pp} = \Delta H_d^2/\sqrt{3}H_{ex} + C, \quad (10)$$

where ΔH_{pp} is the peak-to-peak linewidth; ΔH_d^2, the second moment of the sum of the dipole-dipole interactions; H_{ex}, an effective exchange field, and C, a residual linewidth. As the angular dependence of the linewidth is smallest in the *bc*-plane, the inter-molecular dipole-dipole interaction along the *a*-axis is dominant in the second moment. Therefore the secular part of the second moment was calculated using the term of the inter-molecular dipole-dipole interaction obtained from the spectra of the diluted crystal. In Eq. (10), two adjustable parameters, H_{ex} and C, were estimated to be 4300 and 9.5 gauss respectively. The calculated curves are also shown in Fig. 10. The value of H_{ex} (~0.6 K) was of about the same order of magnitude as the weak intra-molecular interaction, 1 K, estimated from the $\chi_M - T$ curve of the diluted TEMPAD biradical.[4] The residual linewidth, C, represents all the broadening mechanisms besides the secular part of the inter-molecular dipole-dipole interaction: (1) the non-secular part of the inter-molecular dipole-dipole coupling, (2) the residual nuclear hyperfine broadening, and (3) the intra-molecular or long-range dipole-dipole couplings.

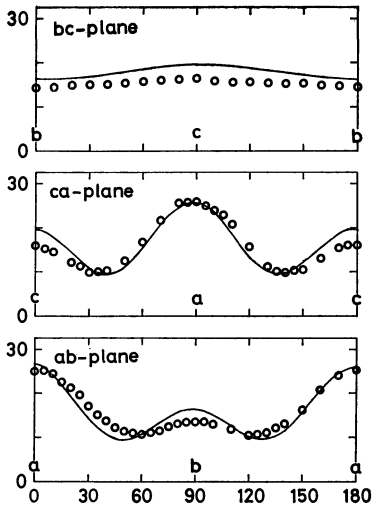

Fig. 10. The angular dependence of the EPR linewidths of the TEMPAD biradical. The solid curves are the calculated results using the three-dimensional Anderson-Weiss formula.

Summary

The EPR of the diluted and pure crystals of the TEMPAD biradical was studied at room temperature. From the spectra of the diluted crystal, the intra- and inter-molecular dipole-dipole interactions were identified. The crystal-field parameters of the dipole-dipole couplings were obtained as:

a) Intra-molecular couplings:

$|D|/hc \simeq 0.00477$ cm^{-1} and $|E|/hc \simeq 0.00032$ cm^{-1},

b) Inter-molecular coupling:

$|D'|/hc \sim 0.012$ cm^{-1} and $|E'|/hc \sim 0.003$ cm^{-1}.

In the assumed molecular-stack model, the TEMPAD molecules in a unit cell occupy two different sites (*p*- and *q*-sites), and the inter-molecular coupling is in the direction of the *a*-axis. The linewidth variation in the EPR spectra of the pure TEMPAD biradical could be explained in terms of the inter-molecular dipole-dipole interaction, using the three-dimensional Anderson-Weiss formula. The obtained exchange parameter was of the order of magnitude of the weak intramolecular interaction estimated from the $\chi_M - T$ of the diluted TEMPAD biradical.

The author wishes to thank Professor Yasuo Deguchi, Dr. Hiroaki Ohya-Nishiguchi, Dr. Jun Yamauchi and their collaborators for their helpful advice and discussions. He is also indebted to Professors Hideo Takaki and Mamoru Mekata for their continual guidance and encouragement during this work.

Study of the Poisoning Effect on Nickel and Nickel Boride Catalysts by Means of a Flow Microcalorimeter

Toshinobu IMANAKA, Yuriko NITTA, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Osaka 560

(Received July 5, 1972)

The relation between the poisoning effect on nickel and nickel boride catalysts in the liquid-phase hydrogenation of styrene and the bond strength of inhibitors on the catalysts has been studied by means of liquid-phase chromatography using a thermal detector. The results show that the sequence of poisoning effect is in agreement with that of the adsorption heat of inhibitors, and that the adsorption heat of each inhibitor on nickel boride is smaller than that on nickel. Besides, this sequence is also in agreement with that of the bond strength of the central metal ion and the coordinated ligand of some manganese complexes in a homogeneous system. These facts indicate that the adsorption energy of inhibitors on a catalyst in a heterogeneous system corresponds to the bond strength of the ligand coordinated to metal complexes in a homogeneous system.

The poisoning effect on nickel and nickel boride catalysts in the liquid-phase hydrogenation of styrene has mainly been studied by the kinetic method, and it has previously been reported that the resistibility of the nickel boride catalyst was greater than that of the nickel catalyst.[1)]

Since the poisoning effect is assumed to be connected with the bond strength between a catalyst and an inhibitor, the adsorption heat of the inhibitor was measured by means of liquid-phase chromatography using a thermal detector.

The results showed that the sequence of the poisoning effect was in agreement with that of the adsorption heats of inhibitors on the catalysts. Besides, the resistibility to inhibition on nickel and nickel boride catalysts was also studied in relation to the adsorption heats of inhibitors on the catalysts. Each adsorption heat of inhibitor on nickel boride was smaller than that on nickel; accordingly, nickel boride can be said to exhibit a higher resistibility than that of nickel. Furthermore, the sequence of the poisoning coefficient estimated by taking the steric effect into account was in agreement with that of the bond strength of adsorption obtained with the thermal measurements; this sequence was also in agreement with that of the bond strength between the central metal ion and the ligand coordinated to some manganese complexes[2)] in a homogeneous system.

Experimental

Materials. The Ni_2B catalyst was prepared by adding $NaBH_4$ to a solution of $(CH_3COO)_2Ni$ (Ni=0.6 g), as has been desdribed in the previous publication;[1)] the precipitate was washed and centrifuged with ethanol. The BET surface area of the Ni_2B catalyst was 21.8 m^2/g. The Ni catalyst used was degassed by heating $(HCOO)_2Ni$ at about 250°C for 3—4 hr under a vacuum and cooled after charging in hydrogen gas; then ethanol was poured into the reaction vessel. The BET surface area of this Ni catalyst was 13.8 m^2/g.

The dichlorophenyl phosphine, trialkyl phosphites, and 2,3-dimercaptopropanol were used without further purification. The styrene was purified by distillation before use.

Procedures. The apparatus used for the thermal measurements is shown schematically in Fig. 1. The catalyst prepared was charged in the columns of both the detector and reference parts. In order to remove the oxygen soluted in the carrier liquid (99.5% ethanol), the hydrogen was saturated by bubbling it through the gas-adsorption vessel. Stable thermal measurements were made possible by this procedure. The inhibitors were injected into the carrier liquid from the inlet part as an ethanol solution of a certain

concentration of the inhibitor.

The exothermic value calculated from the peak area per unit of the catalyst was determined by means of liquid chromatography using a thermal detector (NIHON Electric Company, JLC-A). First, the heats of adsorption of inhibitors per unit of catalyst were determined against the amounts of inhibitors injected, without the adsorption column (C). Second, the amounts of injected inhibitors adsorbed by the catalyst in the detector column (B) were estimated by determining the heat effects produced by the same inhibitors after they had left an identical column (C), filled with the same catalyst and connected in series between the sample injection part (F) and the detector column (B). Since the residual inhibitor passing through the first column (C) subsequently entered the detector column (B) and produced a heat effect similar to those produced by the inhibitors injected directly, the amount of that inhibitor was obtained from the relations, determined previously, between different amounts of the inhibitors injected directly and the heat effects they produce.

Thus, the quantity of inhibitor adsorbed in the first column was determined by subtracting the amount obtained above from that of the inhibitor injected.[3] However, the adsorption heat of the inhibitor was corrected by subtracting the heat of dilution of the sample solution with ethanol.

The measurements of the rate of hydrogenation reaction were performed directly in the usual manner[4] at 30°C, using 1 ml of styrene as a reactant and 40 ml of ethanol as a solvent. In order to eliminate the change in catalytic activity arising from the preparation of the catalyst, the rate of hydrogenation on the catalyst without any inhibitor was at first measured using 1 ml of styrene. When the reaction was complete, the inhibitor was added to the reaction mixture; it was stirred for 10 min, and then the rate of hydrogenation was again measured by adding 1 ml of styrene. As the hydrogenation reaction proceed in zero-order in the styrene concentration, the rate of hydrogen uptake was used as the hydrogenation rate when 50% of the added styrene had been hydrogenated to ethylbenzene.

The catalytic activity was determined by means of the ratio of the hydrogenation rate on the catalyst with and without an inhibitor. In this case, it was confirmed that the catalyst was not poisoned with styrene or ethylbenzene, a hydrogenated substance, and that the activity of the catalyst without an inhibitor did not change with a repetition in the reaction.

Results and Discussion

The relation between the exothermic value of trimethylphosphite, $P(OMe)_3$, as an inhibitor and the amount of inhibitor added to nickel and nickel boride catalysts is shown in Fig. 2. In these catalysts, the exothermic values are proportional to the amounts of several inhibitors. Figure 3 shows the amount of inhibitor added against the amount of triphenylphosphite, $P(Oph)_3$, adsorbed per unit of catalyst when the adsorption column is connected in series to the sample column. It was found that the amount of adsorption increases with an increase in the amount of inhibitor added. The fact that the amount of adsorption on nickel boride is more than that on nickel may be due to the difference in the surface areas of the catalysts. Table 1 shows the adsorption heats of several inhibitors on nickel and nickel boride catalysts against the modified poisoning coefficients, α'[1,5], calculated from the poisoning coefficients, α,

5) $\alpha' = \alpha/s$, s; the occupied area of adsorbed inhibitor molecule (Å²).

TABLE 1. HEAT OF ADSORPTION AND POISONING COEFFICIENT OF SEVERAL INHIBITORS

Inhibitor	Catalysts			
	Ni_2B		Ni	
	Heat of adsorp. (cal/mol)	Poisoning coeff. (gNi/mmol, Å²)	Heat of adsorp. (cal/mol)	Poisoning coeff. (gNi/mmol, Å²)
$CH_2(SH)CH(SH)CH_2OH$	84.2	0.169	104	1.41
$PPhCl_2$	124	0.341	142	1.73
$P(OCH_3)_3$	0.610		5.72	0.695
$P(OPh)_3$	0.332		4.31	0.203
$P(On\text{-}Bu)_3$	0.317		3.34	0.163

of the Maxted equation[6] $K_c=K_0(1-\alpha C)$, obtained from the hydrogenation rate of styrene [K_c, K_0; activity with or without an inhibitor, C; amount of added inhibitor(mmol/gNi)]. As has been shown in the preceding paper,[1] it was also found by means of thermal measurements that the resistibility to the inhibitor of nickel boride is more than that of nickel. The high resistibility to the poisoning of the nickel boride catalyst is probably due to the effect that the bonding electrons of the boron atom occupy the vacant d-orbitals of the nickel atom and make it difficult for the lone pairs of the inhibitors to coordinate with and so poison the nickel catalyst. Furthermore, the sequence of the poisoning coefficients for nickel and nickel boride catalysts was as follows;

$$PPhCl_2>CH_2(SH)CH(SH)CH_2OH>P(OCH_3)_3>P(OPh)_3>P(On\text{-}Bu)_3$$

In addition, the sequence of the adsorption heats of inhibitors for nickel and nickel boride catalysts obtained from the thermal measurements agrees completely with the preceding sequence; therefore, it was found that the poisoning coefficient for a catalyst is subject to the bond strength of the adsorption of the inhibitor.

6) E. B. Maxted, *Advan. Catal.*, **3**, 129 (1951).

It has previously been reported that the infrared spectra of some $Mn(CO)_4LX$ (X=Cl, Br, I)[2] complexes in the CO stretching region show an increase in the wave number of adsorption with the changes in L in this sequence:

$$P(C_6H_5)Cl_2\geq P(OCH_2)_3CCH_3>P(OC_6H_5)_3\geq P(OC_4H_9)_3>Sb(C_4H_9)_3\sim As(C_6H_5)_3\sim P(C_6H_5)_3>P(C_4H_9)_3$$

When styrene is used as the ligand of the manganese complex, it can be considered that the electron-attracting ability of styrene is weaker than that of the $P(C_4H_9)_3$ ligand.

The increase in the wave number of the C–O absorption suggests that the strong electron-attracting ligand results in less electron density on manganese, which means less back-donation of the d-orbital electron and, therefore, less Mn–C bond strength. The sequence of increase along the $P(C_6H_5)Cl_2\gg P(OC_6H_5)_3>P(OC_4H_9)_3$ series agrees completely with the sequence of the poisoning coefficients for nickel and nickel boride catalysts, as is shown in Table 1. This fact indicates that the magnitude of the adsorption energy of inhibitors on a catalyst in a heterogeneous system corresponds to the bond strength of the ligand coordinated to metal complexes in a homogeneous system.

The Crystal Data of Ternary Rare Earth Borides, RCo_2B_2

Koichi NIIHARA, Toetu SHISHIDO, and Seishi YAJIMA

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai 980

(Received July 19, 1972)

Compounds with the composition of RCo_2B_2 (R=La, Nd, Sm, Gd, Tb, Dy, and Y) were prepared by arc-melting methods. Their crystal structure was investigated by means of X-ray diffraction. These ternary rare earth borides crystallize in the tetragonal lattice. The lattice parameters are $a=3.616\pm0.003$ Å and $c=10.215\pm0.005$ Å for $LaCo_2B_2$ and $a=3.561\pm0.002$ Å and $c=9.358\pm0.005$ Å for YCo_2B_2. The good agreement between the X-ray diffraction intensities observed and those calculated shows that the ternary borides, $LaCo_2B_2$ and YCo_2B_2, crystallize in the $ThCr_2Si_2$-type structure. The crystallographic data obtained for $LaCo_2B_2$ and YCo_2B_2 are as follows: space group $14/mmm(D_{4h}^{17})$; 2R in 2(a), 4Co in 4(d), and 4B in 4(e) with $z\sim3/8$. The boron atoms in this structure are situated at the center of a trigonal prism formed by four rare earth atoms and two cobalt atoms. We also found the RCo_2B_2 compounds to be isostructural with $LaCo_2B_2$ and YCo_2B_2, where R=Nd, Sm, Gd, Tb, and Dy. However, efforts to prepare $CeCo_2B_2$ and $ErCo_2B_2$ by arc-melting were unsuccessful.

In the binary systems of rare earth–cobalt and cobalt–boron, there exist a series of intermetallic compounds, (R_3Co, R_3Co_2, RCo, R_2Co_3, RCo_2, RCo_3, RCo_5, R_2Co_7, R_2Co_{17}, Co_3B, Co_2B, and CoB), many of which possess interesting magnetic properties.[1-3] On the other hand, there are five compounds in the rare earth–boron system,[4] (RB_2, RB_4, RB_6, RB_{12}, and RB_{66}), which are interesting for their possible electric and high-temperature uses. Taking into consideration the properties of these binary compounds, the ternary system of the rare earth–cobalt–boron combination seems quite interesting. Unfortunately, there have been few investigations concerning this ternary system.

While investigating the phase equilibria in the Y–Co–B system, we found a new ternary compound with a composition close to YCo_2B_2.[5] The purpose of the present investigation is to prepare the ternary rare earth borides, RCo_2B_2 (R=rare earth elements), and to determine their crystal structures.

Experimental

Materials. All the rare earth metals[6] except samarium were prepared in our laboratory by the calcium-metal reduction of rare earth trifluorides. The samarium metal was prepared from samarium oxide by lanthanum-metal reduction. The purity of the metals obtained by these methods was 99.5%. Cobalt and crystalline boron were obtained from Wako Pure Chemical Industries, Ltd., Tokyo. The purities were 99.99% and 99.9% respectively.

Preparation of Samples. The ternary samples were synthesized by arc-melting mixtures of rare earth metal, cobalt, and boron in the atomic ratio of 1 : 2 : 2. Argon was used as a protective atmosphere in the arc-melting furnace, and the small amount of residual oxygen was eliminated prior to melting by fusing a button of titanium. The samples, weighing approximately 10 g, were melted three times to insure homogeneity. The fused samples were then wrapped with tantalum foil, sealed in quartz capsules under a vacuum, and annealed for 150 hr at 800°C. The samples were then pulverized in an agate motar under an inert gas atmosphere to prevent oxidation and examined by chemical and X-ray analyses. The chemical analyses for the content of rare earth metals and boron were preformed by a method previously reported.[7] The cobalt content was determined by X-ray fluorescence analysis. The losses of the rare earth metals, cobalt, and boron during the melting process were negligible for the ternary systems of (La, Nd, Gd, Tb, Dy, and Y)-Co-B. In the case of the Sm–Co–B system, though 10—15 wt% of the Sm metal vaporized during the melting process. Therefore, mixtures containing an excess of the Sm metal were melted by means of an arc-furnace.

The density of the samples was determined at 20.5°C by a floatation technique, using CCl_4.

X-Ray Diffraction Measurements. The X-ray diffraction patterns of the samples were taken with a Debye-Scherrer camera 114.6 mm in diameter. The correction of the diameter of the Debye-Scherrer camera was performed using standard silicon powder. Mn-filtered Fe ($K\alpha_1=1.9360$ Å, $K\alpha_2=1.9399$ Å, and $K\bar{\alpha}=1.9373$ Å) radiation was employed. The lattice parameters were determined by extrapolating the lattice parameters for $\cos^2\theta$ up to $\theta=90°$. The relative intensities were obtained by measuring the counts under the peaks which were produced using a diffractometer conbined with a scintillation counter and a pulse-height analyser. The scanning speed of the diffractometer was one-fourth degree (2θ) per minute.

Results and Discussion

A new compound was prepared by the arc-melting method in the ternary system of Y–Co–B. This compound was in equilibrium with YCo_2, YB_2, YCo_3B_2,[7] and YCo_4B_4[8] at 800°C. It was found by chemical analyses that the samples in the single-phase region had compositions of 17.3—20.7 at% Y, 40.3—41.5at%

8) This compound has a composition close to YCo_4B_4 and crystallizes in a tetragonal lattice. The lattice parameters are $a=5.07$ Å and $c=7.13$ Å, respectively.

Co, and 39.6—42.3 at% B. The stoichiometric composition of YCo_2B_2 was proposed on the basis of the results of X-ray and chemical analyses and the density measurements. The ternary compounds with the same composition were also prepared for La, Nd, Sm, Gd, Tb, and Dy.

Y was used as a crystal chemical stand-in for heavy rare earths since its atomic radius is located between those of Tb and Dy.[9] It may be assumed that the ternary compounds (RCo_2B_2) of the lanthanides will be structurally similar if $LaCo_2B_2$ and YCo_2B_2 are found to be isostructural. Therefore, particular emphasis in this experiment was placed on the investigation of the La–Co–B and Y–Co–B systems.

The Crystal Structures of $LaCo_2B_2$ and YCo_2B_2. The X-ray diffraction patterns of both ternary borides, $LaCo_2B_2$ and YCo_2B_2, could be indexed on the basis of the tetragonal lattices. The lattice parameters were $a=3.616\pm0.003$ Å and $c=10.215\pm0.005$ Å for $LaCo_2B_2$, and $a=3.561\pm0.002$ Å and $c=9.358\pm0.005$ Å for YCo_2B_2. The agreement between the observed and calculated d-values is excellent, as is shown in Tables 1 and 2. The unit-cell content is $2RCo_2B_2$, and the densities observed are in good agreement with those calculated, as is shown in Table 3.

$B=0.74$, $R=0.142$

Table 3.

It may be seen from Tables 1 and 2 that there is systematic absence of reflections when $h+k+l=2n+1$. Therefore, the possible space groups are 14, $1\bar{4}$, 14/m, 1422, 14 mm, 14 m2, and 14/mmm. The structures of $LaCo_2B_2$ and YCo_2B_2 were considered to be similar to that of $ThCr_2Si_2$ because the lattice parameters and X-ray diffraction intensities of these three compound appeared to be similar to one another. The structure of $ThCr_2Si_2$[10–13] belongs to the $BaAl_4$ type, whereby the two nonequivalent sites of aluminium are occupied by crominum and silicon. The X-ray diffraction intensities were calculated on the assumption, by analogy with the $ThCr_2Si_2$ structure, that the atomic

configurations of $LaCo_2B_2$ and YCo_2B_2 are as follows: space group 14/mmm (D_{4h}^{17}), 2R in 2(a), 4Co in 4(d), and 4B in 4(e). In this structure, the positions of the rare-earth and cobalt atoms are fixed by symmetry and the only variable parameter is z, which defines the positions of the boron atoms. The value of the z-parameter was assumed to be 3/8 from the geometrical argument for $LaCo_2B_2$ and YCo_2B_2.

The calculated intensities were derived from:

$$\mathbf{I}(\text{cal}) \propto p \frac{1+\cos^2 2\theta}{\sin^2\theta \cdot \cos} |\mathbf{F}|^2$$

where p is the multiplicity, θ is the Bragg diffraction angle, and $\mathbf{F}$ is a structure factor. The structure factors were calculated from the atomic coordinates (x_n, y_n, z_n) and the total atomic scattering factors, f_n:

$$\mathbf{F} = \sum_n f_n \exp 2\pi i(hx_n + ky_n + lz_n)$$

$$f_n = f_0 + \Delta f_n' + i\Delta f_n''$$

where f_0 is the atomic scattering factor for radiation with a frequency much higher than any absorption edge, and where $\Delta f_n'$ and $\Delta f_n''$ are the real and imaginary dispersion corrections respectively. The respective values of $\Delta f_n'$ for Y, La, Co, and B were -0.56, -7.09, -1.74, and 0, while those of $\Delta f_n''$ were 3.08, 12.45, 0.84, and 0.[14] The correction of the absorption by the sample was not employed because the absorption does not depend on the diffraction angle in the case of the diffractometer. The temperature factor was found by a least-squares solution of the plot of $\log |\mathbf{I}_{cal}/\mathbf{I}_{ob}|$ *vs* $(\sin\theta/\lambda)^2$.

In the calculation of the X-ray diffraction intensities for YCo_2B_2[5] previously reported, we did not employ any corrections for the abnormal dispersion in the structure factor or for the temperature dependence. Therefore, the calculation in present paper is more accurate.

The observed and calculated intensities of $LaCo_2B_2$ and YCo_2B_2 are summarized in Tables 1 and 2. The temperature factors for $LaCo_2B_2$ and YCo_2B_2 were 0.85 and 0.74 respectively. The reliability factor, $R = \sum_{hkl} |I_{obs} - I_{cal}| / \sum_{hkl} I_{obs}$, is 0.148 and 0.142 for $LaCo_2B_2$ and YCo_2B_2 respectively.

From these results, it can be considered that the rare earth and cobalt atoms occupy the 2(a) and 4(d) sites respectively. The variable parameter, z, however, could not be evaluated with sufficient accuracy because of the small atomic scattering factor of the boron atoms. In general, the boron atoms of the binary borides,[15] such as Re_3B, Pd_3B, Cr_5B_3, and Pd_5B_3, are situated at the center of the trigonal prism formed by six metal atoms. In the ternary borides,[16] such as Mo_2CoB_2, Mo_2NiB_2, W_2FeB_2, W_2CoB_2, and W_2NiB_2, with U_3Si_2-type structure, the boron atoms are also situated at the center of the trigonal prism formed by two kinds of metals. On the other hand, it is impossible to consider that the boron atoms occupy the 4(c) site in the 14/mmm space group with respect to the atomic sizes of rare earth, cobalt, and boron, and the coordination of the boron atoms.

Thus, from these geometrical arguments it is reasonable to think that the boron atoms in $LaCo_2B_2$ and YCo_2B_2 occupy the 4(e) site and that the z-parameter is about 3/8. The crystallographic data for $LaCo_2B_2$ and YCo_2B_2 are summarized in Table 3.

Tb	3.557±0.004	9.419±0.007	8.25	8.31
Dy	3.546±0.004	9.354±0.006	8.50	8.53
Y	3.561±0.003	9.358±0.005	6.30	6.39

Figure 1 shows the projection of the RCo_2B_2 structure on the (010) plane. As is shown in Fig. 1, each boron atom is situated at the center of a trigonal prism formed by the four rare earth atoms and the two cobalt atoms. The interatomic distances of 4R–B and 2Co–B in the trigonal prism are 2.86 and 2.21 for $LaCo_2B_2$, and 2.78 and 2.13 for YCo_2B_2. These values are close to the sum of the corresponding Pauling metallic radii for the 12-coordination of La(1.87 Å), Y(1.78 Å), Co(1.25 Å), and B(0.98 Å).

The X-Ray Diffraction Data for RCo_2B_2 (R=Nd, Sm, Gd, Tb, and Dy). The RCo_2B_2 compounds were found to be crystallized isostructurally with $LaCo_2B_2$ and YCo_2B_2, since the X-ray diffraction data of these samples were similar to those of $LaCo_2B_2$ and YCo_2B_2. The X-ray diffraction data are shown in Table 4 for $NdCo_2B_2$, $SmCo_2B_2$, $GdCo_2B_2$, $TbCo_2B_2$, and $DyCo_2B_2$. As is shown in this table, there is a good agreement between the observed and calculated *d*-spacings. Efforts to prepare $CeCo_2B_2$ and $ErCo_2B_2$ by arc-melting were unsuccessful. The failure to obtain these compounds may be caused by a decomposition process occurring during the arc-melting.

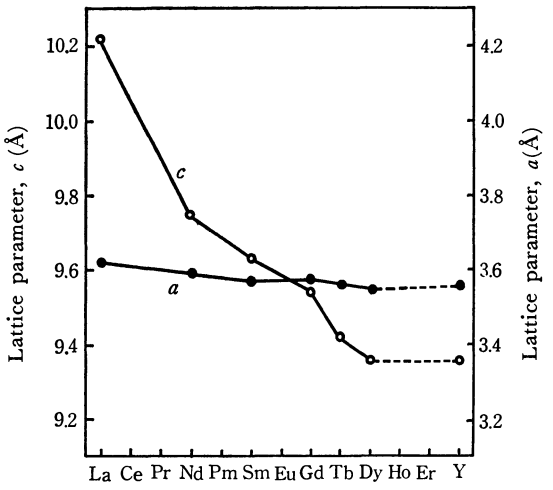

Fig. 2. The variation of the lattice parameters for RCo_2B_2 with the atomic number.
The open circles: the *c* parameter, The closed circles: the *a* parameter.

The lattice parameters of the RCo_2B_2 compounds obtained in this study are summarized in Table 5, while their variation with the atomic number is plotted in Fig. 2. The contraction in the *c* parameter against the atomic number of the rare earth elements is approximately 10 percent, about the same as that of the rare-earth metals. On the other hand, the *a* parameter is fairly constant, decreasing only slightly with the atomic number of the rare earth elements.

The Mechanism of the Lumiflavin-sensitized Photooxygenation of Tryptophan Accelerated by Adenine

Akio YOSHIMURA and Shunji KATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received August 10, 1972)

It was found that the lumiflavin-sensitized photooxygenation of tryptophan in a dilute aqueous solution is greatly accelerated by the addition of adenine. This effect of adenine on the photosensitized oxygenation is specific for flavin dyes, and the quantum yield increases with the oxygen concentration at very low oxygen concentrations, but decreases at higher oxygen concentrations. Therefore, singlet oxygen can be excluded from the intermediates of this oxidative reaction. The oxygen adduct of the dye is considered to be a possible intermediate for the photooxygenation of tryptophan accelerated by adenine.

The photosensitized inactivation of various enzymes has been studied by many investigators[1] and is known to be a sort of photodynamic action. Uehara *et al.* have shown that the riboflavin-sensitized photoinactivation of yeast alcohol dehydrogenase [EC 1.1.1.1] is greatly accelerated by the addition of adenine.[2] The present authors expected that such a photoinactivation promoted by adenine might result from the photosensitized decomposition of some components which constitute the enzyme. After examining several substances, it was found that adenine similarly promotes the lumiflavin-photosensitized oxygenation of indoles, including tryptophan, indole-3-acetic acid, and serotonin, which are biologically important substances in dilute aqueous solutions. Therefore, in this paper we will examine this interesting phenomenon from the viewpoint of photochemical kinetics and will discuss the mechanism of the flavin-sensitized photooxygenation of indoles. Lumiflavin was chosen as the sensitizer in this research because it is much more stable against irradiation than such a flavin dye as riboflavin, which has a reducible ribityl side chain. The function of lumiflavin in the sensitized photooxygenation of indoles seems equal to that of other flavin dyes, such as riboflavin, flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD), because adenine promotes the photosensitizing action of these flavin dyes.

Experimental

Materials. Lumiflavin was prepared from riboflavin (Wako Pure Chemical Co., Ltd.) in the way described by Kuhn *et al.*,[3] and the purity was confirmed by paper chromatography with Toyo Roshi No. 51A paper (*n*-butanol: acetic acid: water, 4 : 1 : 5 by volume, ascending). (Found: C, 60.75; H, 4.70; N, 20.92%. Calcd for $C_{13}H_{12}N_4O_2$: C, 60.93; H, 4.72; N, 21.82%.) The other chemicals used were of G. R. grade. Redistilled water was used throughout.

Apparatus and Procedure. The photolysis was carried out in a quartz reaction cell (1×1×4 cm) with a glass tube inlet, set in a reaction apparatus as in Ref. (4), thermostated (30±0.1°C) with circulated water. Light from a Toshiba SHL-100UV-2 Hg lamp was passed through Toshiba filters VV-40 and VY-43, and an almost monochromatic radiation of 435.8 nm was obtained. The intensity of the illumination was determined by means of the potassium ferrioxalate actinometry described by Hatchard and Parker.[5]

All the experiments were carried out in a 0.05 M phosphate buffer at pH 7.2. The pH values of sample solutions were measured with a Hitachi-Horiba M-5 pH meter. The solution was bubbled before irradiation with a mixture of oxygen and nitrogen of a known composition, and the concentration of the dissolved oxygen was calculated by the use of Ostwald's absorption coefficient of oxygen in water, disregarding the effect of dissolved substances. The deaerated solution was prepared by five cycles of freezing-pumping-thawing by the use of a mercury diffusion pump.

The tryptophan concentration was followed by the fluorometric method, using a Hitachi MPF-2A fluorescence spectrophotometer. For the fluorometry, the exciting light was reduced enough so as not to cause photolysis during the measurement. Since the fluorescence of tryptophan is very sensitive to changes in the temperature,[6] care was taken to keep control solution in the thermostat and then to transfer it into the fluorometer compartment together with the samples. The excitation of dilute tryptophan for the fluorometry was done at its absorption maximum, 285 nm. In order to determine concentration of tryptophan higher than 50 μM, the sample solutions were diluted for every measurement of a fluorescence or a different wavelength with less absorbance was used as the exciting light, so that a linear relationship was kept between the fluorescence intensity and the concentration of tryptophan. It was confirmed that the reaction products do not quench the fluorescence of tryptophan. Accordingly, the fluorometry of the reaction system measures the true concentration of tryptophan in these experiments. The reaction quantum yields were always calculated from the initial reaction rate in order to avoid the effects of products, because such products retarded the photosensitized oxygenation of tryptophan.

Results and Discussion

Figure 1 shows the quantum yield of the lumiflavin-sensitized photooxygenation of tryptophan in solutions which contain 0—0.2 mM adenine, plotted against

the concentration of tryptophan. Figure 2 shows that a linear relationship holds between the reciprocal of the quantum yield of photooxygenation and the reciprocal of the tryptophan concentration in the absence of adenine. The acceleration of this reaction by the addition of adenine is shown as a decrease in the slope in Fig. 2. As is evident from these figures, the addition of adenine enhances the quantum yield greatly at a very low concentration of tryptophan, but it little affects the yield at a higher concentration. Adenine seems to act as a unit, keeping the memory of irradiation in the face of quenching actions until the oxygenation of tryptophan occurs.

Such an effect of adenine was observed for the photooxygenation of indoles when lumiflavin, riboflavin, FMN, or FAD (all these are flavin dyes), is used as the sensitizer, while it was not observed for the systems with rose bengal, methylene blue, thiopyronine, or fluorescein as the sensitizer, as is shown in Table 1. Table 1 also shows that this accelerating effect of adenine is

observed for the flavin-sensitized photooxygenation of such indoles as indole, tryptophan, serotonin, indole-3-acetic acid, and bovin serum albumin (BSA).

Although it is known that adenine forms a molecular complex with flavin in a concentrated solution, the association constant has been estimated to be about 100 l/mol and the addition of 0.2 mM adenine decreases the fluorescence of lumiflavin by only 2%. Therefore, such a large increment of the reaction quantum yield by the addition of adenine can be explained neither by the formation of a ground-state lumiflavin-adenine complex nor by the attack of adenine on the excited singlet state of lumiflavin.

This accelerating effect of adenine is not accounted for by the energy transfer mechanism to adenine, either, because the energy level of the adenine triplet state[7] is higher than that of lumiflavin.[8]

The mechanism of many dye-sensitized photooxygenation reactions have recently been considered to involve singlet oxygen.[9] Among the dyes examined in the present work, rose bengal and some others might sensitize the oxidation through singlet oxygen. However, flavin dyes cannot be the case, because adenine is effective only when flavin dyes is used as sensitizers.

When a solution of 5 μM tryptophan and 10 μM lumiflavin in a 0.05 M phosphate buffer (pH 7.2) was irradiated under deoxygenated conditions, the fluorescence of tryptophan increased by 15% and the photofading of lumiflavin occurred slowly. For a similar solution of 5 μM indole instead of tryptophan, a slow photofading of the lumiflavin and a very slight change in the fluorescence of indole took place. Photofading also occurred slowly when lumiflavin alone was irradiated under deoxygenated conditions. Therefore, it may be said that the cleavage of the indole ring does not occur in the deoxygenated conditions, and that

the product of the oxidative deamination of tryptophan accompanied by the photoreduction of lumiflavin[10] fluoresces more than tryptophan.[11] This reaction under the deoxygenated condition was not affected by the addition of adenine; therefore, the reaction mechanism is considered to have no correlation with that for photosensitized oxygenation.

Oxygen is one of the substrates of the photosensitized cleavage reaction of the indole ring; the effect of the concentration of dissolved oxygen on the quantum yield of the photooxygenation is shown in Fig. 3. This figure shows that the quantum yield increases with the oxygen concentration at very low oxygen concentrations, but decreases at higher concentrations; that is, oxygen also acts as a quencher. An optimum oxygen concentration for the photosensitized oxygenation of 5 μM tryptophan was about 10 μM, which is much lower than that of an air-saturated solution (0.23 mM). Under such conditions, the fluorescence of lumiflavin was not actually quenched by oxygen. The possibility of a reaction mechanism including singlet oxygen generated by the lumiflavin triplet state was obviated by this retarding effect of oxygen as well as by the selective accelerating effect of adenine.

A similar dependence of a reaction's quantum yield on the oxygen concentration was found by Bellin and Yankus[12] in the photooxygenation of histidine by rose bengal, and by Knowles and Mautner[13] for the lumiflavin-sensitized photooxygenation of nucleotides. The former authors suggested the quenching of a reaction intermediate, "photoperoxide." The latter ones proposed that the primary reaction is between the dye triplet state and the nucleotide, and that oxygen is involved in a later stage.

The dependence of the reaction quantum yield on the oxygen concentration in the presence of adenine is also shown in Fig. 3. Adenine apparently prevents the reaction intermediate from being quenched by oxygen, but at higher oxygen concentrations the protecting effect is not complete. The retarding action of oxygen on the photooxygenation reaction was apparently observed when the tryptophan concentration was low, but it was not evident when the concentration was high or when adenine was added. This behavior of oxygen implies that the retarding action of oxygen competes with the oxidation process of tryptophan or with a process involving adenine, followed by the oxidation of tryptophan.

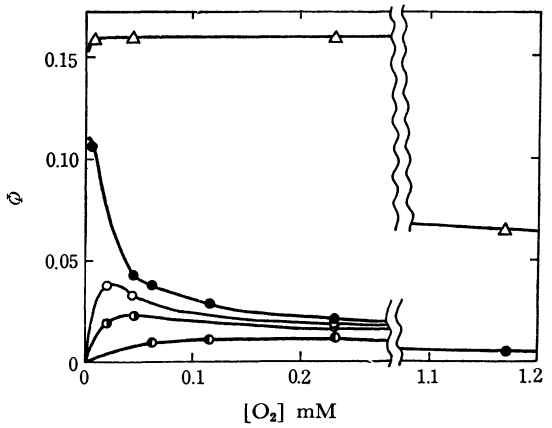

Fig. 3. Effect of dissolved oxygen concentration on the quantum yield of photosensitized oxygenation of 5 μM tryptophan with 2.5 μM lumiflavin in 0.05 M phosphate buffer at pH 7.2, ● alone, and containing △ 0.2 mM adenine, ○ 5 μM KI, ◑ 10 μM KI, ◐ 50 μM KI.

The fluorescence of lumiflavin is little affected by oxygen, tryptophan, or adenine, as has been mentioned above. Therefore, it can be expected that these reactions start from the triplet state of lumiflavin. This was confirmed by an experiment using the iodide ion as a triplet quencher. When potassium iodide is added to the reaction system, the quantum yield of the photooxygenation decreases, as is shown in Fig. 3. The fact that the quenching efficiency decreases with the oxygen concentration shows that oxygen attacks the triplet state of the dye, competing with the iodide ion. The variation in the ratio of the quantum yield (Φ_0/Φ) with the change in the concentration of KI is shown in Fig. 4; a Stern-Volmer-type relation is obtained. This figure also presents the following results.

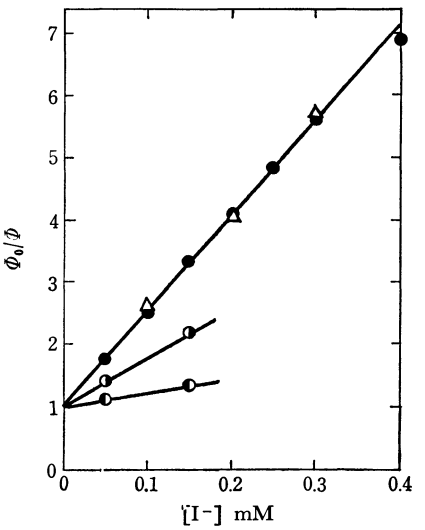

Fig. 4. Effect of KI upon the ratio of quantum yield (Φ_0/Φ) for photosensitized oxygenation of 0.005 mM (●, △), 0.05 mM (◑), and 0.5 mM (◐) tryptophan, alone (●, ◑, ◐), and with 0.2 mM adenine (△).

As the tryptophan concentration increases, the slopes of the plots decrease; that is, tryptophan as well as oxygen competes with the iodide ion. Moreover, the finding that adenine does not affect the quenching action of the iodide ion shows that adenine does not directly attack the triplet state of the dye. Under these conditions, the oxidation of the iodide ion to I_3^- was not detected by the iodine-starch reaction.

We now propose the following reaction scheme, which satisfies all the results mentioned above. In this scheme, D_0, $^1D^*$, and $^3D^*$ denote the ground state,

the first excited singlet state, and the triplet state of lumiflavin respectively. The triplet state of lumiflavn reacts with oxygen, tryptophan, and the iodide ion, but not with adenine, and a linear relationship between $1/\Phi$ and the inverse of the tryptophan concentration can be expected. From the kinetical data, it was estimated that $k_2 \approx k_3 \approx k_4(k_1+k_1')$ and $k_5 \approx 4k_6$. We have no other explicit evidence about $(D\cdots O_2)^*$, but it must be taken into consideration in explaining the accelerating effect of adenine. The intermediate, $(D\cdots O_2)^*$, reacts with adenine to form "X," which reacts finally with tryptophan with very great efficiency. From this reaction mechanism in the presence of adenine, the process in which $(D\cdots O_2)^*$ reacts directly with tryptophan may be possible, but was poorly proved.

In this investigation, the reaction could easily be followed in a very low concentration of the substrate because fluorometry is a sensitive method for analyzing indoles. This is the reason why the promoting effect of adenine on the photosensitized oxygenation was apparently observed and could be analyzed kinetically. In the case where the components of biochemical macromolecules, such as proteins and nucleic acids, are photochemically sensitive, the substrate concentration must usually be very low. This is the case in which Uehara found an anomalous promoting effect of adenine on the flavin-sensitized photoinactivation of enzymes. The authors are inclined to think that analogous phenomena will be found if kinetical experiments are done under very dilute conditions of the substrates.

The authors would like to express their gratitude to Professor Kihachiro Uehara for his helpful discussions.

ESR Study of γ-Irradiated Ammonia–Silica Gel System

Siro NAGAI

Osaka Laboratory for Radiation Chemistry, Japan Atomic Energy Research Institute, Mii, Neyagawa-shi, Osaka 572

(Received September 22, 1972)

Ammonia–silica gel system was γ-irradiated at -196 °C. ESR spectrum observed from samples with low ammonia content showed a marked linewidth anomaly in the hf lines at -196 °C and changed with temperature reversibly. The free radical responsible for the spectrum was assigned to NH_2 radical which undergoes a preferential rotation about an axis perpendicular to the radical plane at low temperatures and a substantially free rotation above -90 °C.

In the previous papers[1-4] of our ESR studies on the γ-irradiated adsorbed systems, we reported the structures of free radicals produced at -196 °C and also the effects of temperature on the ESR spectra. The investigation of the temperature effects on the spectra gave us some informations concerning not only to the structural change but also to the thermal motion of adsorbed radicals. The change of the structure was observed in adsorbed methylbenzenes where monomer cations formed by γ-irradiation at -196 °C change to the corresponding dimer cations by raising the temperature.[2] Restricted motion of adsorbed radicals was suggested from the asymmetry and/or linewidth variations appeared in the spectra.[2-4] More detailed analysis as for the motion on silica gel, however, can be made when we can observe ESR spectra of adsorbed radicals containing some nucleus with a larger anisotropy in the hf interaction. In this viewpoint, NH_2 radical is suitable for such study because of the large anisotropy in the nitrogen splitting.[5]

Experimental

NH_3 was obtained commercially from Takachiho Trading Co. Ltd. Deuterated ammonia ND_3 was synthesized from Mg_3N_2 and D_2O in an evacuated system. $^{15}NH_3$ was synthesized from $(^{15}NH_4)_2SO_4$ (^{15}N atom 90%) and NaOH. Silica gel was the same as that reported.[2] For deuteration of silica gel, the heat-treated gel was immersed in D_2O at 100 °C for 2—3 hr and then degassed at 500 °C *in vacuo*. The other procedures employed in the present study were the same as those described in the previous paper.[2]

Results and Discussion

ESR Spectra at Low Temperature. ESR spectra of adsorbed ammonia after γ-irradiation at −196°C were dependent on the ammonia content. In the samples with the content larger than the monolayer value 2×10^{-3} mol/g, the observed spectrum consists of poorly resolved nine lines and is similar to that of NH_2 radical in solid ammonia matrix.[6-8] When the ammonia content was below the monolayer coverage, the complex spectrum shown in Fig. 1a was observed predominantly. It consists of a dominant quintet with a central triplet splitted by 25 gauss and outermost broad signals, and several weak lines. The spectrum arises from single species in view of the thermal behavior to be discussed later. When the ammonia content became still lower, the spectrum showed additional weak signals other than the predominant one described above(see Fig. 1b). No change was observed in the overall feature of the spectrum when the adsorption amount was further reduced.

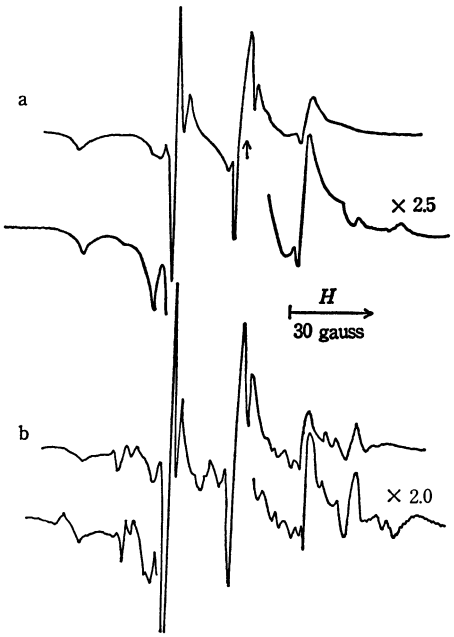

Fig. 1. ESR spectra of γ-irradiated ammonia-silica gel at $^{14}NH_3$ content, a; 1.1×10^{-3} mol/g, and b; 1.2×10^{-4} mol/g. The arrow in a denotes the position of DPPH signal.

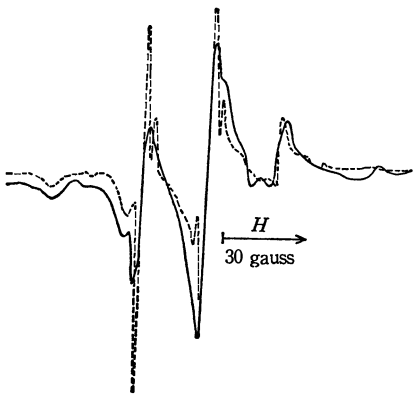

Fig. 2. A comparison of the predominant spectrum on silica gel (broken line) with that of γ-irradiated aqueous ammonia (solid line).

It should be noted that the central triplet in the dominant quintet shows a marked linewidth anomaly, linewidths being 1.9 gauss, 4.8 gauss, and 3.0 gauss from the low field side. A similar triplet spectrum has been previously observed from photolyzed hydrazoic acid in inert gas matrices.[9]

For comparison, frozen aqueous solutions of ammonia were γ-irradiated and examined at −196 °C. When the concentration of ammonia was 30%, the spectrum showed a quintet structure quite similar to that in Fig. 1a (see Fig. 2). ESR spectra of γ-irradiated aqueous ammonia have been previously observed and assigned to NH_2 radical by other workers.[10,11] Al-Naimy *et al.*[10] observed a triplet spectrum similar to the central triplet in our spectrum and assigned it to NH_2 radical with the assumption that the nitrogen splitting is quenched due to the hindered rotation of the radical. Tupikov *et al.*, [11] on the other hand, observed a poorly resolved five-line spectrum and obtained hf splitting values of 24.5 gauss for proton

and 31 gauss for nitrogen. Their value for nitrogen, however, seems to be too large compared with that of the same radical in ammonia matrix.[7] The assignment of the splitting value should be made by taking into account an anisotropic motion of NH_2 radical as shown in the present investigation.

The deuterated samples showed ESR spectra as given in Fig. 3a, b, and c. Fig. 3a is the spectrum of ND_3 adsorbed on deuterated silica gel. The central part of the spectrum consists of five intense lines with a hf splitting value of 4 gauss which is about one-sixth of the value of the central triplet in Fig. 1. The triplet splitting in Fig. 1, therefore, is ascribed to two equivalent protons. Both the spectrum Fig. 3b for NH_3 on deuterated silica gel and the spectrum Fig. 3c for ND_3 on silica gel are well explained by appropriate superpositions of the non-deuterated spectra Fig. 1 and the deuterated spectrum Fig. 3a. The hydrogen-deuterium exchange reaction occurs to some extent.

Temperature Dependence of Spectra. On raising the temperature, the nine-line spectrum of high content samples diminished in intensity without any change of the feature. The spectrum observed from samples with low content, on the other hand, showed a remarkable temperature dependence as represented in Fig. 4. The linewidth anomaly in the central triplet as well as some weak lines observed at low temperature gradually disappeared at higher temperatures. The separation of the outermost broad signals became smaller with temperature while the splitting of the central triplet remained constant in the whole temperature range. Above −90 °C was observed only the narrowing of the widths of the hf lines. On recooling the sample, the lower temperature spectra were reproduced satisfactorily.

The sample with the lower content of adsorbed ammonia showed essentially the same reversible change of the spectrum (see Fig. 5). In addition, the four weak lines indicated by arrows in Fig. 5b increased in intensity at an early stage of the rise of temperature and then diminished above −150 °C. The four-line spectrum might be attributed to NH_3^+ [13] possibly formed by charge transfer reaction from silica gel to adsorbed ammonia. A similar reaction was found to play an important role in the formation of cation radicals of benzene on silica gel.[14]

Assignment of Spectra. The spectra observed above −90 °C consist of nine lines and may be assigned to NH_2 radical with hf splitting values of 25 gauss for proton and 19 gauss for nitrogen. The assignment is supported by studying the spectrum of adsorbed $^{15}NH_3$ after γ-irradiation. An apparent four-line spectrum shown in Fig. 6c is the same as that of $^{15}NH_2$ radical in solid $^{15}NH_3$ matrix.[7] Because the nine-line spectrum for $^{14}NH_2$ and the four-line one for $^{15}NH_2$ are explained by the isotropic values of hf splittings, the adsorbed NH_2 radicals are consi-

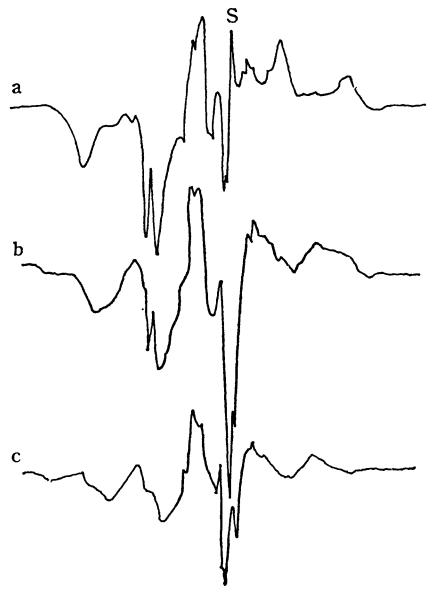

Fig. 6. Change of ESR spectrum of γ-irradiated $^{15}NH_3$–silica gel a; −196 °C, b; −150 °C, and c; −90 °C. A line designated by S in a is due to the silica gel defect.

dered to carry out a substantially free rotation at the relatively high temperatures. The reversible temperature dependence, therefore, arises from motional change of adsorbed NH_2 radicals from fixed or some restricted state at low temperatures to free rotation above −90 °C.

The low temperature spectrum in Fig. 1a can now be explained on the basis of the anisotropic data of NH_2 radical. The ESR data in the coordinate axis system in Fig. 7 are summarized in Table 1. Anisotropies in the proton hf splitting and in the g value are fairly small compared with the anisotropy in the nitrogen splitting. Since the central triplet is due to two protons and the splitting value is constant in the whole temperature range, the other part of the spectrum may be ascribed to the hf splitting of nitrogen. If the separation of the outermost broad signals~114 gauss is assumed to be a sum of hf splittings of proton and nitrogen, a_H and a_N, we obtain

Table 1. ESR data of NH_2 radical

	Isotropic	x	y	z	Ref.

a_H[b]	−27.3	−4.1	+1.8	+2.3	5
g	2.0037	2.0029	2.0058	2.0023	12

a) Calculated values from $^{15}NH_2$ data in Ref. 5.
b) Splitting values are given in gauss.

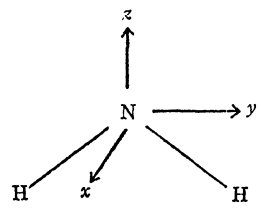

Fig. 7. A coordinate axis system of NH_2 radical.

32 gauss for a_N by taking 25 gauss for a_H from the splitting value of the central triplet. As can be seen from Table 1, such a large value of a_N is expected when the adsorbed NH_2 radical remains immobile or carries out a preferential rotation about z-axis. The rotation hypothesis seems to be more probable in view of the linewidth anomaly in the central triplet as well as the narrow linewidths.

Linewidth Anomaly. The linewidth anomaly similar to that in the central triplet has been often observed in the spectra of adsorbed radicals[2-4] and may arise from the modulation of the anisotropic hf and g tensor interactions coupled with molecular rotation. To shed some light on the nature of the tumbling of NH_2 radical, a qualitative analysis of the triplet was made according to the theory of ESR linewidth in solution.[15,16] The linewitdh of each line of the triplet can be written;

$$T_2^{-1}(M_H) = A + BM_H + CM_H^2 \quad (1)$$

where M_H is the total field-direction component of spin angular momentum for two protons, and A, B and C are parameters. The term B arises from the anisotropic g tensor in conjunction with the anisotropic hf interaction between the unpaired electron and the protons. The theoretical expression for B is given by

$$B = \frac{16}{3} j_H^{(DG_2)}(0) B_0, \quad (2)$$

where B_0 is the external magnetic field and $j_H^{(DG_2)}(0)$ is the spectral density due to the cross term between anisotropic hf and g tensor interactions. Equation (2) is valid for the case that a condition $\omega^2\tau_R^2 \gg 1$ holds, where ω is the angular resonance frequency of the electron, and τ_R the correlation time for molecular tumbling. This condition seems to be satisfied for the central triplet because of the narrow widths, 2—5 gauss.

Relative linewidth of $M_H=-1$ and $M_H=+1$ depends on the sign of B, that is, $T_2^{-1}(-1) < T_2^{-1}(+1)$ for $B>0$, and $T_2^{-1}(-1) > T_2^{-1}(+1)$ for $B<0$.

For the isotropic rotation, the spectral density $j_H^{(DG_2)}(0)$ is given by

$$j_H^{(DG_2)}(0)/\tau_R = \frac{1}{5}\sum_m F_{D,H}^{(m)} F_G^{(-m)}, \quad (3)$$

where $F_{D,H}^{(m)}$ and $F_G^{(-m)}$ are the irreducible tensor components corresponding to the anisotropic hf interaction and g tensor interaction, respectively.

Evaluation of the $F_{D,H}^{(m)}$ and $F_G^{(m)}$ using the values in Table 1 gives

$$\left.\begin{aligned} F_{D,H}^{(0)} &= 24.8 \times 10^6\ \text{sec}^{-1}, \\ F_{D,H}^{(\pm 2)} &= -26.0 \times 10^6\ \text{sec}^{-1}, \\ F_G^{(0)} &= 0.0074 \times 10^6\ \text{sec}^{-1}\ \text{gauss}^{-1}, \\ F_G^{(\pm 2)} &= 0.0065 \times 10^6\ \text{sec}^{-1}\ \text{gauss}^{-1}. \end{aligned}\right\} \quad (4)$$

The spectral density in Eq. (3) becomes using the results in Eq. (4) and $B_0=3260$ gauss as

$$j_H^{(DG_2)} B_0/\tau_R = -1.00 \times 10^{14}\ \text{sec}^{-2}. \quad (5)$$

15) J. H. Freed and G. K. Fraenkel, *J. Chem. Phys.*, **39**, 326 (1963).
16) J. H. Freed, *ibid.*, **41**, 2077 (1964).
17) B. L. Barton and G. K. Fraenkel, *ibid.*, **41**, 695 (1964).

Since $a_H<0$ and $j_H^{(DG_2)}(0)$ and B should have the same sign,[17] B should be negative for the isotropic rotation, which is inconsistent with our spectrum.

When anisotropic rotation is taken into account, the appropriate spectral density can be written in place of Eq. (3),[16]

$$j_H^{(DG_2)}(0) = \frac{1}{5}\sum_{m,m'} F_{D,H}^{(m)} F_G^{(m')} \lambda_{mm'}. \quad (6)$$

where $\lambda_{mm'}$ are functions of the principal values of the molecular diffusion tensor, R_1, R_2, and R_3. In our calculation, the principal axes of the diffusion tensor are chosen as molecule-fixed axes in Fig. 7, that is, R_1, R_2, and R_3 denote the principal values along x, y, and z axis, respectively.

We obtain using Eq. (4);

$$j_H^{(DG_2)}(0)B_0 = [1.20\lambda_{00} - 0.41\lambda_{02} - 2.20\lambda_{22} - 2.20\lambda_{2-2}] \times 10^{14}\,\mathrm{sec}^{-2}. \quad (7)$$

Results of our calculation of Eq. (7) using values $\lambda_{mm'}$ for various ratios of $R_1 : R_2 : R_3$ show that the sign of $j_H^{(DG_2)}(0)$ can be positive only when $R_3 > R_1$, R_2. For the special case of the axial rotation, *e.g.* $R_1 = R_2$, the third principal value R_3 should be larger than twice of R_1. A preferential rotation about z axis, therefore, may explain the observed linewidth anomaly, $T_2^{-1}(-1) < T_2^{-1}(+1)$.

Summary

The dominant species produced in γ-irradiated ammonia–silica gel system is assigned to NH_2 radical. The observed dependence of the ESR spectrum on both the ammonia content in the sample and temperature is due to the motional change of the radical on silica gel surfaces. The NH_2 radical in the high content samples is considered to carry out a substantially free rotation even at −196 °C. The radical produced in the low content samples, on the other hand, carries out a preferential rotation about the axis perpendicular to the radical plane at low temperatures and becomes free above −90 °C.

Finally, the observed dependence of the NH_2 radical spectrum on three matrices, silica gel, frozen aqueous ammonia and solid ammonia, is ascribed to the result of the different environments of the radical.

The author wishes to express his hearty thanks to Professor Isamu Nitta and Professor Shun-ichi Ohnishi for their helpful discussions.

Infrared Absorption Spectra of Aminobenzoic Acid Coordination Compounds

Tadaaki INOMATA and Takao MORIWAKI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received October 3, 1972)

Several divalent metal–aminobenzoic acid coordination compounds were prepared in aqueous solutions and their thermal analyses, magnetic moments, and infrared spectra were investigated. These coordination compounds have the structure of ML_2 or $ML_2 \cdot nH_2O$ and are coordinated with amino and carboxyl groups of the ligand. Metal–*o*-aminobenzoic acid chelates give approximately the same infrared spectra but metal–*m*- and *p*-aminobenzoic acid coordination compounds are classified into two groups by their infrared spectra. Detailed assignments for the infrared absorption bands of the metal-coordination compounds have been made by a comparison of the spectra with those of the ligand and its related compounds.

The infrared spectra of aliphatic α-amino acid chelates have been investigated in great numbers but not those of metal aromatic amino acid coordination compounds. Hill and Curran[1] prepared several divalent metal–*o*-aminobenzoic acid coordination compounds in aqueous solutions, and showed them to have a *trans* square-planar configuration from their ultraviolet spectra and infrared spectra at about 3200 cm^{-1}.

Several stability constants of metal–*o*-aminobenzoic acid coordination compounds have been reported.[2,3] Decker and Frye[4,5] measured the infrared spectra of metal *N*- and ring- substituted *o*-aminobenzoic acid coordination compounds and studied the substituent effect on stability constants. They also prepared[6] metal coordination compounds of aminoterephthalic acid and 3-aminophthalic acid and indicated that the compounds have a dimer structure and nitrogen and oxygen are coordinated to the metal cations. In the former two carboxyl groups and one amino group are coordinated to each metal, but in the latter two amino groups and one carboxyl group are coordinated to one metal and three carboxyl groups to the other metal. Alyariya *et al.*[7] studied the infrared spectra of *o*-, *m*-, and *p*-aminobenzoic acid cadmium(II) coordination compounds and indicated that nitrogen and oxygen are coordinated to cadmium(II) in *o*-isomer but only

nitrogen is coordinated in *m*- and *p*-isomer. Aggarwal and Singh[8] prepared the tin(IV) coordination compounds of three isomers in many organic solvents and showed that coordination occurs through nitrogen only. Khakimow and Azizov[9] indicated that cobalt (II) coordination compounds of three isomers had the following molecular formulas. $[(o\text{-}C_7H_6NO_2)_2Co]$, $[(m\text{-}C_7H_6NO_2)_2Co]H_2O$, $[(p\text{-}C_7H_6NO_2)_2Co]\cdot 4H_2O$.

In this investigation, the infrared spectra of several divalent metal coordination compounds of the three isomers of aminobenzoic acid have been studied in the region 4000—200 cm^{-1} and detailed assignments for the observed bands have been made.

Experimental

Preparation of compounds. Bis(*o*-, *m*-, *p*-aminobenzonato) copper(II), zinc(II), nickel(II), cobalt(II), and cadmium(II) were prepared as follows. To a solution of 0.2 mol of aminobenzoic acid and 0.2 mol of sodium hydroxide dissolved in 200 ml of water was added 0.1 mol of metal chloride with stirring. The solution was heated to 80 °C and stirred for two days in the case of bis(*p*-aminobenzonato)-nickel, cobalt, zinc, and cadmium and for half an hour for all the other compounds.

Bis(*o*-aminobenzonato)-palladium (II) and bis(*m*-aminobenzonato)-palladium (II) were prepared by the same method as above but at room temperature. The resulting precipitate was filtered and washed several times with hot water and then with dioxane and was dried at 100 °C *in vacuo* for several hours.

o-Aminobenzoic acid chelates, Found: C, 49.96; H, 3.47; N, 8.42%. Calcd for $C_{14}H_{12}N_2O_4Cu$: C, 50.07; H, 3.60; N, 8.34%. Found: C, 49.60; H, 3.84; N, 8.28%. Calcd for $C_{14}H_{12}N_2O_4Zn$: C, 49.80; H, 3.58; N, 8.30%. Found: C, 43.50; H, 3.22; N, 7.25%. Calcd for $C_{14}H_{12}N_2O_4Cd$: C, 43.71; H, 3.14; N, 7.28%. Found: C, 50.90; H, 3.68; N, 8.21%. Calcd for $C_{14}H_{12}N_2O_4Ni$: C, 50.81; H, 3.65; N, 8.46%. Found: C, 50.82; H, 3.61; N, 8.55%. Calcd for $C_{14}H_{12}N_2O_4Co$: C, 50.77; H, 3.65; 8.46%. C, 44.45; H, 3.42; N, 7.46%. Calcd for $C_{14}H_{12}N_2O_4Co$: C, 50.77; H, 3.65; N, 8.46%. Found: C, 40.53; H, 3.95; N, 7.06%. Calcd for $C_{14}H_{12}N_2O_4Pd$ $2H_2O$: C, 40.55; H, 3.88; N, 6.75%.

p-Aminobenzoic acid coordination compounds, Found: C, 50.04; H, 3.28; N, 8.13%. Calcd for $C_{14}H_{12}N_2O_4Cu$: C, 50.07; H, 3.60; N, 8.34%. Found: C, 38.17; H, 3.90; N, 6.45%. Calcd for $C_{14}H_{12}N_2O_4Cd$ $3H_2O$: C, 38.30; H, 4.14; N, 6.38%. Found: C, 46.01; H, 4.47; N, 7.78%. Calcd for $C_{14}H_{12}N_2O_4Ni$ $2H_2O$: C, 45.82; H, 4.38; N, 7.63%. Found: C, 43.75; H, 3.76; N, 7.57%. Calcd for $C_{14}H_{12}N_2O_4Pd$ $1/2H_2O$: C, 43.37; H, 3.38; N, 7.22%.

Deuteration of Compounds. The *N*-deuterated metal coordination compounds were prepared according to the same procedures as mentioned above in 99.7% deuterium oxide solution.

Absorption Measurements. The infrared spectra from 4000 to 200 cm^{-1} were recorded on Leitz 221, Hitachi EPI-G_2 and Hitachi EPI-L infrared spectrophotometers and were calibrated with polystyrene, 1,2,4-trichlorobenzene, carbon dioxide and water vapour. Samples were prepared as potassium bromide discs in the region 4000—700 cm^{-1} and nujol mulls in the region 700—200 cm^{-1}. All spectra were checked using nujol mulls.

Thermal Analysis. Thermal analysis was carried out with Rigaku Denki D. T. A. 8001 from room temperature to 400 °C in air, the decrease in weight being measured when an endothermic reaction occurred. The results coincided with those of elemental analyses.

Magnetic Moment. Magnetic susceptibility measurements were carried out on finely divided powdered samples using the conventional Gouy method. All determinations were made at room temperature(20 °C). The cell constants were obtained using $Hg(CoSCN)_4$ as a standard. The magnetic moments were calculated by the formula $\mu_{eff}=\sqrt{2.83\chi_g}$.

Rusults and Discussion

o-*Aminobenzoic Acid Chelates.* The infrared spectra of the copper(II) and cobalt(II) chelates and ligand are shown in Fig. 1. The infrared spectra of all other chelates are similar to those of copper(II) or cobalt(II) in the region 4000—500 cm^{-1}. In the case of copper(II) chelates, two peaks at 3234 and 3135 cm^{-1} shifted to 2432 and 2294 cm^{-1} on *N*-deuteration are about 300 cm^{-1} lower than those of ligand and ligand sodium salt and are assigned to NH_2 stretching vibrations of the coordinated NH_2 groups. The carboxylate stretching vibrations are assigned to the two bands at 1551 and 1384 cm^{-1}, since the observed bands in the region 1350—1660 cm^{-1} not disappearing on N-deuteration are COO^- and C=C stretching vibrations, and two peaks at 1551 and 1384 cm^{-1} are shifted with the variation of metals as shown in Table 1.

The remaining bands can thus be assigned to C=C stretching vibrations.

The infrared spectra of copper(II) and palladium(II) chelates of *o*-aminobenzoic acid differ slightly from those of other metal chelates. However, the difference is not so great as in the case of *m*- and *p*-aminobenzoic acid coordination compounds. Curran and Hill reported that copper(II) chelate of *o*-aminobenzoic acid has a *trans* square planar configuration. The magnetic moment of nickel(II) chelate is 3.22 B.M. which shows that it has no *trans* square planar configuration. Nyholm[10] reported that the magnetic moments of nickel(II) chelates of various ligands having an octahedral configuration are 3.1—3.6 B.M.. Thus, from the similarity of their infrared spectra, we may assume that copper(II) and palladium(II) chelates have a *trans* square planar configuration and the other metal chelates an octahedral configuration. Since the sodium chloride region spectra of all chelates are approximately similar, absorption bands except for vibrations related with metal-ligand bonds should be observed at approximately the same position also in the far infrared region. Since the frequency shifts of carboxylate stretching vibrations by the difference of metals are smaller than those of amino stretching vibrations and in aliphatic α-amino acid metal

10) R. S. Nyholm, *Record Chem. Progr.*, **19**, 45 (1958).

chelates,[11,12] the metal-nitrogen and metal-oxygen stretching vibrations are observed in the region 450—300 cm^{-1} and 300—180 cm^{-1}, respectively. Thus the most metal sensitive band at about 380 cm^{-1} which is not observed in the ligand and ligand sodium salt[13] is reasonably assigned to metal-nitrogen stretching vibration and the bands at 222 cm^{-1} for palladium(II) and 210 cm^{-1} for copper(II) are assigned to metal-oxygen stretching vibration.

Detailed assignments were made by a comparison of the spectra of ligand, ligand sodium salt[13], *o*-chlorobenzoic acid,[14] *o*-chloroaniline,[15] and *o*-dichlorobenzene.[16] The results are shown in Table 1.

m-*Aminobenzoic Acid Coordination Compounds.* The infrared spectra of the copper(II) and cobalt(II) coordination compounds and ligand are shown in Fig. 2.

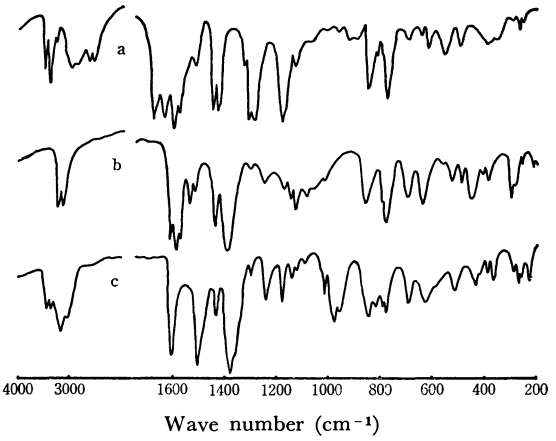

Fig. 2. Infrared absorption spectra of *m*-aminobenzoic acid and its coordination compounds in KBr discs.
(a): *m*-aminobenzoic acid, (b): Cu(II), (c): Co(II)

In the region 3400—2800 cm^{-1}, the important frequencies are those due to NH_2 stretching vibrations in the metal coordination compounds. Two peaks at 3255 and 3147 cm^{-1} in the copper(II) coordination compound are shifted on *N*-deuteration to 2428 and 2298 cm^{-1}, respectively, and the ratios (ν_{NH_2}/ν_{ND_2}) between NH_2 and ND_2 stretching vibrational frequencies of these two bands are 1.34 and 1.37, respectively, being similar to those of aliphatic α-amino acid chelates.[11,12] The two peaks are observed at frequencies lower than those of *m*-aminobenzoic acid sodium salt[13] by about 180—200 cm^{-1}, and are assigned to NH_2 stretching vibrations of the coordinated NH_2 groups. In the region 600—270 cm^{-1}, the spectra contain a new band at 382 cm^{-1} in addition to the vibrations in the spectra of ligand. The frequencies of NH_2 and COO^- stretching vibrations in the metal *m*-aminobenzoic acid coordination compounds are observed in approximately the same region as in *o*-isomer chelates, the frequency shifts due to the different metals being also approximately the same as in *o*-isomer chelates. Thus, it is reasonable to assign this band to the metal-nitrogen stretching vibration. The ligand can be assumed to be coordinated to copper through the nitrogen atom. The frequency shifts of the COO^- stretching vibrations on coordination in the copper(II) coordination compound are smaller than those of NH_2 stretching vibration. However, it can hardly be said that the carboxyl group is not coordinated to the metal and remains as a carboxylic acid as Alyariya *et al.*[7] reported with the cadmium coordination compound,[7] since OH and C=O stretching vibrations, the combination bands of OH in plane deformation and C–O stretching vibration are not observed in copper(II) *m*-aminobenzoic acid coordination compound (Fig. 2 and Table 2.). This is also inconsistent with the result of elemental analysis which excludes the existence of the carboxyl group as a sodium salt. A new band is observed at 223 cm^{-1} which is not present in the ligand. This band is assigned to the metal-oxygen stretching vibration by considering the results of metal *o*-aminobenzoic acid chelates and aliphatic α-amino acid chelates.[11,12] It is therefore concluded that the oxygen of the carboxyl group is also coordinated to copper atom. Similar conclusions can be drawn for the palladium(II) and Zinc(II) coordination compounds from the similarity of their infrared spectra to that of the copper(II) coordination compound as shown in Table 2.

The infrared spectrum of cobalt(II) coordination compound is shown in Fig. 2. This differs somewhat from that of the copper(II) coordination compound. In the region 1300—1650 cm^{-1} only four peaks are observed in cobalt(II) but seven in copper(II). In cobalt(II) the strong bands at 1006 and 989 cm^{-1} are observed instead of the strong bands around 1110 cm^{-1} in copper(II). In the region 600—800 cm^{-1} the number of bands are the same but their shapes differ. Nevertheless, these spectra indicate that the coordination to metal has occurred through both nitrogen and oxygen in the cobalt(II) coordination compound for the same reasons mentioned above.

The spectrum of cadmium(II) coordination compound is similar to that of cobalt(II). Though the nickel(II) coordination compound has two molecules of water as thermal and elemental analyses show, the spectrum of the nickel(II) dihydrate is also similar to that of cobalt(II). It is therefore concluded that the six metal coordination compounds of *m*-aminobenzoic acid have a coordination of both nitrogen and oxygen with metal. The result is inconsistent with that of Alyariya *et al.*[7] in which only nitrogen is coordinated to cadmium(II).

In the case of aliphatic α-amino acids chelates, the antisymmetric carboxylate stretching frequency increases and symmetric frequency decreases in comparison with those of ligand and ligand sodium salt,

Rosenberg[17] showed that the nickel–oxygen bond is essentially ionic, and the frequencies of carboxylate stretching vibration are the same as those of an amino acid sodium salt. In the case of *m*-aminobenzoic acid, palladium(II), copper(II), and zinc(II) coordination compounds have a similar tendency but for nickel(II), cobalt(II), and cadmium(II) the frequencies of antisymmetric and symmetric carboxylate stretching vibrations shift to lower frequencies in comparison with those of the sodium salt[13] and the positions are

17) A. Rosenberg, *Acta. Chem. Scand.*, **10**, 840 (1956).

nearly the same for these compounds. This leads to conclusion that when the carboxyl group is coordinated to palladium(II), copper(II), and zinc(II) they have the structure $-C\begin{matrix}O-M\\O\end{matrix}$, and nickel(II), cobalt(II), and cadmium(II) derivatives can be represented as the structure $-C\begin{matrix}O\\O-M\end{matrix}$.

These coordination compounds can be divided into two groups which shows that each group has the same configuration. The magnetic moments of copper(II) (2.02 B.M.), cobalt(II) (5.08 B.M.), and nickel(II) (3.12 B.M.) indicate that both cobalt(II) and nickel (II) have an octahedral configuration (cobalt(II) has 4.8—5.2 B.M. and nickel(II) 3.1—3.6 B.M.[10]), but it is not easy to deduce the configuration from the magnetic moment alone.

Detailed assignments for observed bands were made by comparing them with ligand, ligand sodium salt,

ligand hydrochloride,[13] deuterated compound of metal coordination compounds, *m*-chlorobenzoic acid,[14] *m*-cnloroaniline,[15] and *m*-dichlorobenzene.[16] The results are shown in Table 2.

p-*Aminobenzoic Acid Coordination Compounds.* The infrared spectra of copper(II) and nickel(II) *p*-aminobenzoic acid coordination compounds and ligand are shown in Fig. 3 and their detailed assignments in Table 3. The assignments have been made by the same method as for the metal *m*-aminobenzoic acid coordination compounds. These spectra indicate that the compounds are also classified into two groups, one group including palladium(II) and copper(II) and the other cadmium(II) and nickel(II).

By the same discussions as for metal *m*-aminobenzoic acid coordination compounds, such as the shifts of NH_2 and COO^- stretching vibrations, existence of new peaks due to metal–nitrogen and metal–oxygen stretching vibrations, disappearance of absorption bands due to COOH and the elemental analysis of these compounds, it is clear that the coordination with metal has occurred through both nitrogen and oxygen in metal *p*-aminobenzoic acid coordination compounds as in metal *m*-aminobenzoic acid. This also differs from the results of Alyariya *et al.*[7] in which the nitrogen was only coordinated to cadmium(II).

The magnetic moment of nickel(II) (3.37 B.M.) indicates that nickel(II) has an octahedral configuration[10] but the configuration could not be determined from magnetic moment alone.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1154—1158 (1973)

Radiation Synthesis of Hydrogen Cyanide from Nitrogen-Ethylene System. Effect of Temperature, Gas Density, and Reactor Wall

Yasumasa IKEZOE, Shoichi SATO, and Akibumi DANNO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken 319-11

(Received November 1, 1972)

The rate of formation of hydrogen cyanide from the nitrogen–ethylene system by ^{60}Co gamma rays was found to depend on irradiation temperature, gas density, gas composition, and the nature of the wall surface of the reaction vessel. Above 100 °C, the G(HCN) value increased with the rise of temperature. Below 100 °C, the G(HCN) value remained constant down to −196 °C. In the temperature range from 400 °C to −196 °C, it increased with reduction of nitrogen gas density. The largest G(HCN) value obtained was 2.0. In certain cases, the wall surface influenced the suppression of hydrogen cyanide formation. As an active species responsible for hydrogen cyanide formation, excited nitrogen molecules are proposed in addition to nitrogen atoms. Excited nitrogen molecules are decomposed to nitrogen atoms with small activation energy or deactivated by collision with other molecules. They play an important role in cyanide formation at low pressures and at high irradiation temperatures.

Radiation reactions of activated nitrogen have been investigated in many systems. In the radiolytic isotopic exchange reaction of nitrogen, the G-value of the exchange reaction is in the range 9—19.[1-3] The large exchange G-value seems to indicate that nitrogen molecules are activated by radiation. Ammonia synthesis from the nitrogen–hydrogen system,[4] nitrogen fixation from the nitrogen–oxygen system[5] and ammonium synthesis from the air–water system[6] are also reported. The G-values of nitrogen fixation reactions in these systems are generally about one, and reach three at most.

As a radiation reaction involving activated nitrogen, formation of hydrogen cyanide from nitrogen–ethylene system has been studies by Oka *et al.*, and the G-values of about 0.5 and 0.2 were reported for the reactions in gas phase and in liquid nitrogen.[7-9] In order to elucidate the reactivity of the radiation activated nitrogen and attain higher yields of cyanide, we investigated in detail the effects of irradiation temperature, density, gas composition, and the nature of the wall surfaces of reaction vessels.

Experimental

Nitrogen gas (purity; 99.9995%, oxygen content; 0.5 ppm, Nihon Sanso Co.) was used after removal of condensable gases with a liquid nitrogen trap. Ethylene gas (purity; 99.9%, acetylene content; 1 ppm, oxygen content; 0 ppm, Nihon Sekiyukagaku Co.) was purified by trap to trap distillation in a vacuum line. The two gases mixed in a vacuum line were analysed with a mass spectrometer and the absence of oxygen, water or carbon dioxide was confirmed.

steel, were used. The glass ampoules were washed in two ways, by washing them thoroughly with only distilled water or by immersing them in concentrated nitric acid solution for several days and washing with distilled water four or five times. The stainless steel ampoules were immersed in a rust removing reagent (Dipsol ST-305 solution) for 5—10 minutes, washed with water, treated with 20% NaCN solution and washed with water again. The ampoules were evacuated to a vacuum of 1×10^{-4} Torr while they were being heated. Known amounts of gases were then charged into the ampoules, pressure being measured with a quartz Bourdon gage.

Irradiation of the gases was carried out with ^{60}Co-γ rays. The dose rate of γ-rays was measured with a Fricke dosimeter. The absorbed dose in nitrogen gas was estimated from the Fricke dosimetry corrected for the ratio of stopping power of nitrogen to that of glass against secondary electrons.[10-11] The absorbed dose in ethylene was neglected in the calculation of G(HCN). High temperature irradiation was carried out in an electric furnace, in which the temperature was controlled to an accuracy of ±2 °C. Low temperature irradiations were carried out in liquid nitrogen (−196 °C) and in dry ice (−78 °C).

Hydrogen cyanide was measured as follows. The product was trapped at the bottom of the irradiated ampoule with a liquid nitrogen trap. The top of the ampoule was then broken and 10 ml of 1/100 N NaOH solution quickly poured into the ampoule to dissolve hydrogen cyanide. In the case of high ethylene partial pressure, a device was connected to the top of the ampoule in order not to release hydrogen cyanide. After purging the dissolved ethylene and other hydrocarbons by bubbling with nitrogen gas about 5 minutes, hydrogen cyanide remaining in the 1/100 N NaOH solution was titrated with 10^{-4} M mercuric nitrate solution, using 1 ml of 38 ppm carbon tetrachloride solution of copper diethyldithiocarbamate[12] as an indicator. Hydrogen cyanide in the solution was also analysed with an electrode potentiometer (Cyanometer CN-IA, Toa Electronics Ltd.) for confirmation of the titration method. The two methods gave the same result.

Results

When nitrogen–ethylene mixtures are irradiated, acetylene, *n*-butane, ethane, and propane are formed besides hydrogen cyanide. Hydrogen cyanide formation was studied in connection with reaction of nitrogen activated by radiation. It was found to depend on the irradiation temperature, the density, and composition of the mixed gas and the nature of the wall.

The formation of hydrogen cyanide at various temperatures, shown in Fig. 1, is linear to the absorbed radiation energy in nitrogen gas. Estimated errors in titration are also given. The G(HCN) values calculated from the slopes were 1.9 at 400 °C, 1.5 at 300 °C, 0.8_0 at 100 °C and 0.7_3 at −196 °C. The G(HCN) value 0.7_3 at −196° C was very close to the one, 0.8_0 at 100 °C. This is of interest when we consider the small partial pressure of ethylene at −196 °C.[13]

○; irradiated at 300 °C in 170 ml Pyrex ampoule.
△; irradiated at 25 °C in 170 ml Pyrex ampoule.
▲; irradiated at 25 °C in 64 ml Pyrex ampoule.

The G(HCN) values at 300 °C and 25 °C are shown in Fig. 2 as a function of nitrogen gas density, for a constant C_2H_4/N_2 ratio of 0.075. At both temperatures the G-values depended on the density of gas and became larger as the density was reduced. At 25 °C and at high nitrogen gas density, the G-values converged to 0.5, in agreement with a reported value.[7] The density dependence might be attributed to heterogeneous reactions on the wall surface of the reaction vessels. Two kinds of Pyrex ampoules with different surface to volume ratios were used to examine the effect of heterogeneous reaction. However, no difference in density dependence of G(HCN) was seen between the two ampoules within the experimental error (Fig. 2).

At 300 °C, the G(HCN) value converged to 0.8 at high nitrogen gas density, becoming as large as 2.0

12) Y. Tanaka and S. Yamamoto, *Bunseki Kagaku*, **9**, 6 (1960).
13) At −196 °C the vapor pressure of ethylene becomes 6.5×10^{-4} Torr. Ethylene in the irradiation ampoules is condensed on the wall surface for the most part, and the C_2H_4/N_2 ratio in gas phase is equal to 3.3×10^{-5}, which is much smaller than the one, 7.5×10^{-2} at other temperatures.

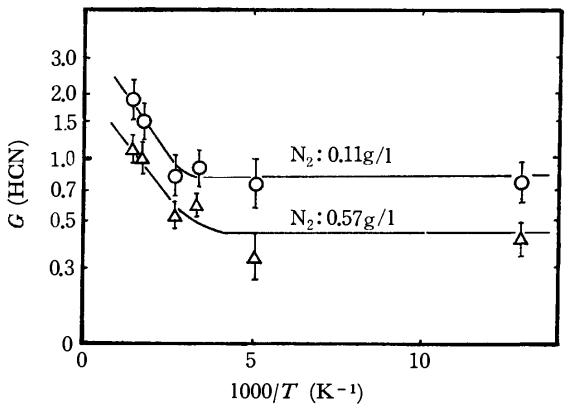

Fig. 3. Arrhenius' plot of G(HCN).
γ-rays; 6.8×10^6 R/hr, 0—6 hr irradiated, $C_2H_4/N_2=0.075$.
○; N_2 gas density=0.11 g/l.
△; N_2 gas density=0.57 g/l.

(±0.3) as the density was reduced to 0.054 g/l. The latter value is one of the greatest obtained experimentally. At both temperatures, a constant value was reached with high gas density, and became larger as the density was reduced. However, the extent of increase in G(HCN) at 300 °C was greater than that at 25 °C.

Arrhenius' plots of G(HCN) are shown in Fig. 3 for two nitrogen gas densities, 0.11 and 0.57 g/l, with a constant C_2H_4/N_2 ratio, 0.075. All the plotted G(HCN) values were obtained from the slopes of the cyanide formation as in Fig. 1. At low gas density, the G(HCN) values were larger than those at high density in the whole temperature range, —196—400 °C, but the temperature dependences corresponding to the two gas densities were similar. Above 100 °C, the G(HCN) values increased with an apparent activation energy of 1.2 kcal/mol, and below 100 °C, they were constant down to —196 °C. This indicates that the mechanism of hydrogen cyanide formation at high temperature differs from that at low temperature.

The G(HCN) value is known to be independent of ethylene partial pressure in the C_2H_4/N_2 ratio range 0.1—0.001.[7,14] The variation of G(HCN) with higher ethylene partial pressures is shown in Table 1. Since the ionization potential of nitrogen, 15.6 eV, is fairly larger than that of ethylene, 10.6 eV, it is not probable that nitrogen molecules are activated by the excited ethylene molecules to form hydrogen cyanide.[15] In the calculation of the G(HCN) value, only the energy absorbed by nitrogen was counted and that by ethylene neglected.

The G(HCN) values at 25 °C (Table 1) decreased from 0.6_4 to 0.3_0 as the C_2H_4/N_2 ratio was increased from 0.036 to 1.92. Decreasing G(HCN) values were obtained with both high nitrogen gas density and high ethylene partial pressure, the tendency being the same at 25 °C and at 300 °C.

Table 1. G(HCN)[a] dependence on C_2H_4/N_2 ratio at 300 and 25 °C

C_2H_4/N_2	G(HCN), 300 °C	G(HCN), 25 °C
0.036	—	0.6_4
0.075	0.9_4	0.6_1
0.36	—	0.5_2
0.72	—	0.4_6
1.09	—	0.3_9
1.92	0.6_7	0.3_0

γ-rays; 6.8×10^5 R/hr, 0—2 hr irradiated, N_2; 0.57 g/l in 170 ml ampoules.
a) Calculation of G(HCN) is based on the energy absorbed by the nitrogen.

Table 2. Wall effect

Reactor	G(HCN)
Pyrex A[a]	0.5±0.05
Pyrex B[b]	0.5±0.05
Quartz A[c]	0.5±0.1
Quartz B[d]	0.3±0.1
Steel[e]	0.3±0.1

$C_2H_4/N_4=0.07\pm0.02$, N_2; 1.1 g/l, γ-rays; 0—3×10^6 Rad, 25 °C.
a) 170 ml Pyrex ampoule washed with distilled water.
b) 64 ml Pyrex ampoule washed with distilled water.
c) 64 ml quartz ampoule washed with distilled water.
d) 64 ml quartz ampoule washed with concentrated nitric acid solution and distilled water.
e) 55 ml stainless steel ampoule, treated with rust removing reagent (Dipsol ST-305 solution) and with NaCN 20% solution, and then washed with water.

Ampoules of different size and material were used as the irradiation vessel to investigate the surface effect on hydrogen cyanide formation under the same experimental conditions. The results are shown in Table 2. In the Pyrex and quartz ampolues washed only with distilled water, the G(HCN) values were 0.5±0.1. In the quartz and stainless steel ampoules treated with nitric acid and washed with water, they were 0.3±0.1, reproducibility being poor.

Discussion

The results show that the formation of hydrogen cyanide depends on the irradiation temperature, the density, composition of the mixed gas and the wall. The mechanism of the formation of hydrogen cyanide will be discussed.

Nitrogen molecules are activated by radiation to form a variety of active species.[19-20]

14) Y. Ikezoe, O. Tokunaga, N. Moriyama, R. Shimozawa, T. Tamura, and A. Danno, JAERI-memo 3506 (1969).
15) Excitation spectrum of ethylene[16-17] shows that ethylene can be excited to higher energy levels than dissociation energy 9.76 eV, and ionization potential of nitrogen 15.6 eV. Such highly excited ethylene can dissociate or ionize a nitrogen molecule. However, the direct ionization, autoionization, and dissociation process of ethylene are much faster[18] than the nitrogen activation process by the excited ethylene in our experimental conditions. Thus, the ethylene molecules directly activated by radiation seem to make no contribution to cyanide formation.

$$N_2 \text{ -WWW-} \rightarrow N_2^+, N^+, N, N_2^*, N_2^{+*}, e^- \quad (1)$$

Nitrogen molecule ions N_2^+ are thought to take no part in the formation of hydrogen cyanide, on account of their fast charge transfer reaction with ethylene.[7]

$$N_2^+ + C_2H_4 \longrightarrow N_2 + C_2H_4^+ \quad (2)$$

Thus an active species considered able to take part in the formation of hydrogen cyanide should be sought from nitrogen atoms, atom ions, excited nitrogen molecules, and excited molecule ions.

In the study of active nitrogen produced by electric discharge, hydrogen cyanide has been said to be formed by the following reactions.[21-23]

$$N + C_2H_4 \longrightarrow HCN + CH_3 \quad (3)$$

$$N + CH_3 \longrightarrow HCN + 2H \quad (4)$$

Reaction (4) is faster in electric discharge but can be neglected in the case of radiolysis, because of low concentration of active species.[24] As the reaction of hydrogen cyanide formation by radiation, the following reaction has been proposed by Oka *et al.*[7]

$$N(\text{or } N^+) + C_2H_4 \rightarrow HCN + CH_3\cdot(\text{or } CH_3^+) \quad (3')$$

They found the G(HCN) value to be independent of nitrogen pressure in the range 250—750 Torr and explained the phenomena by this reaction.

Our results, however, show that the G(HCN) value depends both on gas density and irradiation temperature. It therefore seems apparent that a mechanism other than reaction (3′) is important for our experimental conditions.

Absorbed Dose of Gas in an Ampoule at Low Gas Density. Before discussing the mechanism of hydrogen cyanide formation, absorbed dose at low gas density should be considered. Absorbed dose of high density gas in an ampoule is proportional to the electron density, and that of low density to the stopping power ratio to the secondary electrons.[10] In general, absorbed dose varies as the gas density varies. In the case of nitrogen gas in a glass ampoule, both the stopping power ratios of nitrogen and of glass are nearly equal, and the absorbed dose of nitrogen can be obtained from the electron density of nitrogen irrespective of nitrogen gas density.[11] The difference in the G(HCN) value at high and low nitrogen gas density in Fig. 3 can not be explained by the deviation of absorbed doses at low gas density.

Excited Nitrogen Molecule. Heterogeneous reactions on the wall of the Pyrex glass ampoules were not detected (Fig. 2). We might thus assume the following reactions to explain the gas density dependence of G(HCN) value.

$$N_2^* (\text{or } N_2^{+*}) \longrightarrow N + N (\text{or } N^+) \quad (5)$$

$$N_2^* (\text{or } N_2^{+*}) + M \longrightarrow N_2 + M (\text{or } M^+) \quad (6)$$

Reaction (5) is predominant at low gas density, and reaction (6) at high gas density.

Nitrogen atom formed by reaction (5) then reacts with ethylene to form hydrogen cyanide. This means excited nitrogen molecules and/or excited nitrogen molecule ions in addition to the atoms and/or the atom ions can be precursors of hydrogen cyanide. The difference in G(HCN) values at low and high nitrogen gas density, $\Delta G_{25\,^\circ C}=0.4$ and $\Delta G_{300\,^\circ C}=1.2$, can be explained if they correspond to the initial G-value of excitation of nitrogen molecules, $g(N_2^*$ or $N_2^{+*})$.[26]

It is of interest to see whether the excited nitrogen molecules form cyanide by reactions (5) and (3′) or directly by the following reaction.

$$N_2^* (\text{or } N_2^{+*}) + C_2H_4 \longrightarrow HCN + \text{others} \quad (7)$$

The result given in Table 1 indicates that reaction (7) does not take place at 25 °C and 300 °C, and the excited nitrogen molecules are deactivated by ethylene by the following reaction.

$$N_2^* (\text{or } N_2^{+*}) + C_2H_4 \rightarrow N_2 + C_2H_4^* (\text{or } C_2H_4^{+*}) \quad (6')$$

Excited nitrogen molecules can not directly form hydrogen cyanide but after reaction (5), they react to form hydrogen cyanide.

Irradiation Temperature Dependence. At temperatures above 100 °C, the G-values were dependent on temperature, but at lower temperatures they were independent of temperature (Fig. 3). This indicates that an elementary reaction which requires some activation energy is the rate-determining step in the cyanide formation reaction at high temperatures. The nitrogen gas density dependence of G(HCN)

23) B. Brocklehurst and K. R. Jennings, "Progress in Reaction Kinetics," Vol. 4 ed. by G. Porter, Pergamon Press, Oxford, p. 1.

24) Nitrogen atom concentration in our experimental conditions is estimated. When partial pressure of nitrogen is 1 atm, ethylene 0.1 atom, dose rate of γ-rays 10^6 Rad/hr, the initial G (N) value 0.5 and the rate constant of disappearance reaction of nitrogen atoms, reaction (3), ($k=1\times10^7$ litre mol^{-1} s^{-1})[23], the rate of nitrogen atom formation per one mole nitrogen κ, is

$\kappa=(10^6 \text{ Rad/hr})\times(1/3600 \text{ h/s})\times(6.24\times10^{13} \text{ eV/g Rad})$
$\times(28 \text{ g/N}_2 \text{ mole})\times(G(\text{N})/100 \text{ atom/eV})=4.85\times10^{15}\,G(\text{N})$
atom/N_2 mol sec$=2.43\times10^{15}$ atom/N_2 mol sec

The mean life time of nitrogen atom τ, is

$\tau=1/k[C_2H_4]=2.2\times10^{-5}$ s.

The mean concentration of nitrogen atom (N), is

$(\text{N})=\kappa\tau=5.4\times10^{10}$ atom/N_2 mol.

The ratio, $(\text{N})/(N_2)=5.4\times10^{10}/6\times10^{23}=0.9\times10^{-13}$. This value is much smaller than 1×10^{-1} in the electric discharge experiment.[25]

25) D. R. Safrany and W. Jaster, *J. Phys. Chem.*, **72**, 518 (1968).

26) It is possible to calculate a $g(N_2^*)$ value with an excitation energy range 11.4—13.6 eV, which lies between the dissociation energy and the ionization potential of nitrogen molecules. As the oscillator strength in the range is known to be 0.87,[27] the $g(N_2^*$, 11.4—13.6) value can be calculated by the equation.[28]

$$g(N_2^*,\ 11.4\text{—}13.6) = \frac{(M_{11.4-13.6})^2}{(M_i')^2}\times\frac{100}{W}$$

where $(M_{11.4-13.6})^2$ is the dipole matrix element squared for the excitation energy range and is equal to $fR/E(=0.95)$, R Rydberg constant, E excitation energy (taken as an average in the energy range), $(M_i')^2$ the dipole matrix element squared for ionization ($=3.85$), and W the average energy for an ion pair production ($=34.4$ eV). Thus $g(N_2^*$; 11.4—13.6) is calculated to be 0.72.

27) S. M. Silverman and E. N. Lassettre, *J. Chem. Phys.*, **42**, 3420 (1965).

was more remarkable at high temperatures than at low. Thus, excited nitrogen molecules seem to play a more important role at high temperatures making reaction (5) require some activation energy.

G(HCN) values reached constant values at a high gas density, but differed with differing temperature (Fig. 2). The G(HCN) value became constant at low temperature, but also took a different value at a different gas density (Fig. 3). This seems to indicate that two kinds of nitrogen atoms, one directly formed by radiation according to reaction (1) and the other indirectly formed by radiation according to reactions (1) and (5), can not be distinguished clearly from each other.

Wall Effect. In glass ampoules washed with only distilled water, the G(HCN) value was constant irrespective of ampoule volume, but in glass ampoules and stainless steel ampoules treated with nitric acid solution, cyanide formation was suppressed. In the former case, the surface/volume ratio did not differ so much that it is difficult to say whether the wall surface affects cyanide formation at all. In the latter case, the suppression may be due either to the active species being trapped on the wall surface or to hydrogen cyanide formed being decomposed on the surface.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1158—1161 (1973)

Formation of Uranium Nitride by the Reaction of Uranium Hydride with Nitrogen and Ammonia

Hiroaki TAGAWA

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken 319-11

(Received June 23, 1972)

The hydrogenation of uranium metal and the nitrogenation of uranium and its hydride with either nitrogen or ammonia have been studied using thermogravimetry. The reactions were examined at different pressures of hydrogen, nitrogen, and ammonia. The reaction of uranium with hydrogen takes place at 200°C and proceeds quickly above 210°C. The conversion curve depends greatly on the hydrogen pressure. In the reaction of the hydride with nitrogen, the weight gain occurs at about 160°C and becomes fast above 240°C. The reaction is shown to proceed in two steps: the formation of the mononitride and that of the sesquinitride. The reaction between uranium hydride and ammonia begins at 150°C and becomes rapid above 300°C. The reaction proceeds monotonously, and no step is observed. The nitrogenation behavior of uranium hydride with ammonia is found to be quite different from that in reaction with nitrogen.

The phases in the uranium–nitrogen system were first characterized by Rundle *et al.*[1]: NaCl-type face-centered cubic UN, Mn_2O_3-type body-centered cubic U_2N_3, and CaF_2-type face-centered cubic UN_2. Another nitride was found by Mallett and Gerds[2] and by Vaughan,[3] and was indexed as La_2O_3-type hexagonal close-packed U_2N_3. The bcc and hcp U_2N_3 are designated as the α- and β-U_2N_3, respectively. The α-U_2N_3 phase exhibits a wide range of composition, and ordinarily contains more nitrogen than is represented by its chemical formula; *i. e.*, $UN_{1.54}$-$UN_{1.75}$. α-U_2N_3 is transformed into β-U_2N_3 above 800 °C near the decomposition pressure of the α phase. Uranium nitride, prepared at temperatures below 1300 °C in a nitrogen atmosphere, is usually the α phase. The composition depends on the fabrication conditions–the temperature and the nitrogen pressure. Uranium mononitride is obtained by decomposing α-U_2N_3 at 1500—1600 °C *in vacuo*.

Uranium nitride is prepared by the following methods:

1) $U+N_2$[2,4–7]
2) UH_3+N_2[4,8]
3) $U+NH_3$[4,9]
4) UO_2+C+N_2[8,10,11]
5) UCl_4+NH_3[12]
6) UX_4+Me+N_2(X=F, Cl; Me=Si Al)[13,14]

Methods (1) and (2) are commonly used for preparing the pure material, but the reaction process is not known well in detail. Method (4) is useful for producing the

nitride on an industrial scale. All the reactions except (4) produce the sesquinitride. The composition of α-U_2N_3 produced varies with the fabrication methods and the annealing conditions. This report describes a study of the behavior of the hydrogenation of uranium metal and of the nitrogenation of uranium and its hydride in thermogravimetry. Although TG does not give precise data on the kinetics, the use of TG will yield some valuable information on the kinetics of these reactions and on the preparations of hydride and nitride of uranium

Experimental

Apparatus and Procedures. The experimental apparatus for heating uranium metal or its hydride in either hydrogen, nitrogen, or ammonia was very similar to that described in an earlier paper reporting on the measurement of the equilibrium nitrogen pressure over a UN and U_2N_3 mixture.[15] It consisted of a Cahn RH-type automatic electrobalance, used as a thermobalance, a Kanthal resistance furnace, a pressure measurement system, a gas supply system, and vacuum pumps. The volume of the reaction system, including the balance chamber and mercury manometer, was 5550 ml. The reaction behavior was examined in a closed system in an atmosphere of hydrogen, nitrogen, or ammonia.

The balance was adjusted so as to have a maximum weight change of 500 mg and a sensitivity of 0.01 mg. A quartz crucible, 25 mm in height and 18 mm in outer diameter, was hung from the balance, and then a quartz tube of 30 mm in outer diameter was connected to the vessel containing the balance. After the connection, the system was evacuated to 5×10^{-6} mmHg or below.

The temperature of the specimen was measured by means of a Pt/Pt+13%Rh thermocouple placed close to the crucible inside the reaction tube. Most of the experiments were made by the thermogravimetric method, with a heating rate of 2 °C/min.

Materials. Pure uranium metal, in the form of chips 0.5 mm thick, 5 mm wide, the 7 mm long, was washed successively with 1 : 1 HNO_3, distilled water, and acetone. About 1 g of the bright metal thus prepared was quickly weighed; it was then placed in the quartz crucible and converted into the hydride and the nitride *in situ.*

High-purity nitrogen was further purified by passing it over a copper gauze heated at 520 °C, and then through a liquid nitrogen trap. The hydrogen was purified by passage through palladium asbestos heated at 300 °C and through a liquid nitrogen trap. The ammonia was solidified in a liquid nitrogen trap, and was then gasified after evacuating the trap.

Results and Discussion

Formation of Uranium Hydride. The bright uranium metal was placed in the quartz crucible, which was hung from one end of the balance arm. The reaction chamber was evacuated, and then hydrogen was admitted into the system. The hydrogen pressures applied were 75, 100, 150, and 300 mmHg. The temperature was raised at a rate of 2 °C/min. Some typical results are shown in Fig. 1. As seen in the figure, the temperature at which the hydrogenation begins depends on the hydrogen pressure. The temperatures are 200, 210, 220, and 260 °C at the hydrogen pressures of 300, 150, 100, and 75 mmHg, respectively. As the initial hydrogen pressure is lowered, the rate of the reaction becomes smaller. After the reaction terminated, the pressure of the hydrogen consumed was found to decrease by 20 mmHg from the initial level. At the hydrogen pressure of 100 mmHg or less, the hydrogenation did not terminate: the conversion into UH_3 was 87% at 100 mmHg and 20% at 75 mmHg. In these cases, the hydride once formed conversely decomposed into uranium and hydrogen above 350 °C before the hydrogenation was complete. The composition of the hydride was $UH_{3.00}$ at room temperature and $UH_{2.97}$ at temperatures between 200 and 400 °C. The values were in agreement with those obtained by equilibration.[12,16] The product was a fine black powder.

The reaction between uranium and hydrogen was found to occur at temperatures exceeding 200 °C, but the initiation temperature and the rate of the reaction were affected by the surface conditions, the shape of the metal-powder, the film or block, and the heating rate, as well as by the hydrogen pressure. When the oxide layer on metal surface was not completely removed, or when the surface was slightly oxidized, the temperature at which the hydrogenation began became obviously higher than that on the clean surface.

In the reactions at the hydrogen pressures of 100 and 75 mmHg, a plateau on the conversion curve appeared, as seen in Fig. 1. The formation of the hydride did not proceed any further beyond a certain temperature, resulting in a pseudo-equilibrium state. Its temperature was 325 °C at the hydrogen pressures of both 100 and 75 mmHg. Spedding *et al.*[17] and Albrecht and Mallett[18] have reported that the reaction

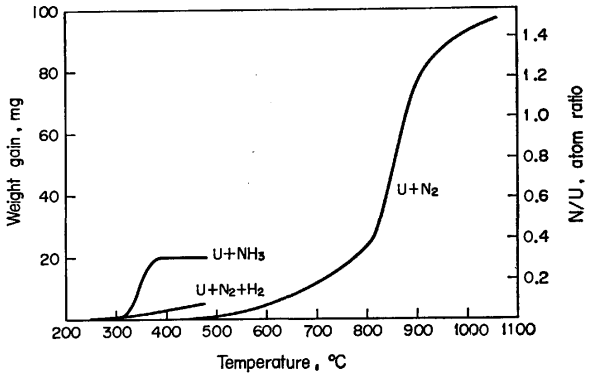

Fig. 2. Thermograms for the reactions of uranium metal with nitrogen and ammonia: the weight of uranium metal, 1.110 g; p_{N_2}, p_{NH_3}=300 mmHg; p_{H_2}=150 mmHg; a heating rate, 2 °C/min.

rate is a function of the $p-p_0$ value, i. e., $C(p-p_0)^{5/2}$ and $k(p-p_0)/p_0$, respectively, where p is the system pressure, p_0, the dissociation pressure of uranium hydride, and C and k, constants. In the present experiment, the $p-p_0$ values at 325 °C were 29 and 19 mmHg at the initial hydrogen pressures of 100 and 75 mmHg, respectively. The hydrogenation did not actually proceed before the value became zero.

Reaction between Uranium Metal and Nitrogen. As in the hydrogenation, 1 g of chips was heated in a nitrogen atmosphere at 300 mmHg up to 1000 °C. The results for the heating rate of 2 °C/min are shown in Fig. 2. The curve shows that the reaction begins at about 400 °C and that the weight changes rapidly in the temperature range between 800 and 900 °C. The temperature range with the maximum velocity did not vary, even if the heating rate was changed. Mallett and Gerds[2] found, in the reaction of uranium rods with nitrogen, that the Arrhenius plot of the reaction rate was made from two slopes below and above the temperature band of 750—775 °C and that the activation energy changed from 25.5 kcal/mol below 750 °C to 15.1 kcal/mol above 775 °C, where the reaction rate obeyed the parabolic law. If their results are plotted as the relation between the reaction rate and the temperature, the curve is similar to that in Fig. 2. The nitride formed on the metal surface was in the form of a film below 800 °C and coarse powder above 800 °C. The rapid increase in the reaction vleocity in the upper temperature region must be based on the formation of highly porous reaction layers, accompanied by spalled powders.

From the fact that the hydrogenation of uranium metal proceeds at a lower temperature than the nitrogenation of uranium with nitrogen, the nitride formation in the presence of hydrogen may be expected to occur more readily than in the absence of hydrogen. The reaction was examined in a mixture of hydrogen of 150 mmHg and nitrogen of 300 mmHg. The results are also shown in Fig. 2. The nitride formation proceeded slightly more rapidly, but it was not like the case for the hydrogenation in Fig. 1. The surface of the metal was covered with a grayish nitride film, and no powder such as that observed in the hydrogenation appeared. The hydrogenation of the metal, followed by the nitrogenation of the hydride, was scarcely found to occur; thus, the growing of the nitride film on the surface was inferred to be rather predominant over the hydrogenation.

When ammonia of 300 mmHg was used, the reaction began at about 250 °C, but the reaction was terminated at 380 °C, before it was complete. These results are also shown in Fig. 2. As in the case of the mixture of nitrogen and hydrogen, the metal surface was coated with a nitride film, and there existed a small amount of a fine black powder spalled at the bottom of the crucible.

Reaction between Uranium Hydride and Nitrogen. Uranium hydride was prepared in a crucible at about 280°C in a hydrogen atmosphere of 200 mmHg. The nitrogenation behavior was examined by varying the pressures of nitrogen and hydrogen. Figure 3 shows the reaction of uranium hydride with nitrogen of 75, 150, and 300 mmHg in the absence of hydrogen. The reaction began at about 160°C and became rapid above 240°C. In the case of each pressure, the slope of the curve appeared to vary sharply at about 290°C at a composition a little below $UN_{1.0}$. The temperature at the bend was lowered somewhat as the nitrogen pressure increased, but the shapes of the curves

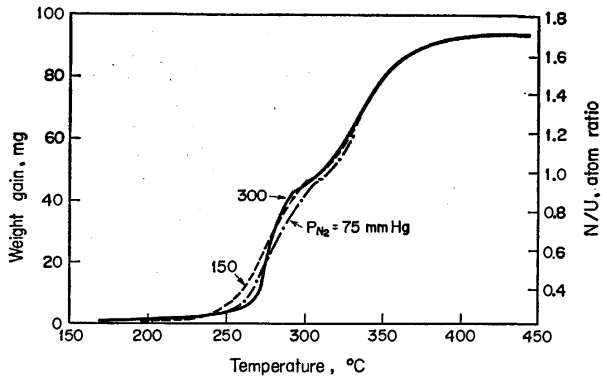

Fig. 3. Thermograms for the nitrogenation of uranium hydride in nitrogen of various pressures in mmHg: The weight of uranium metal, 1.070 g; a heating rate, 2 °C/min.

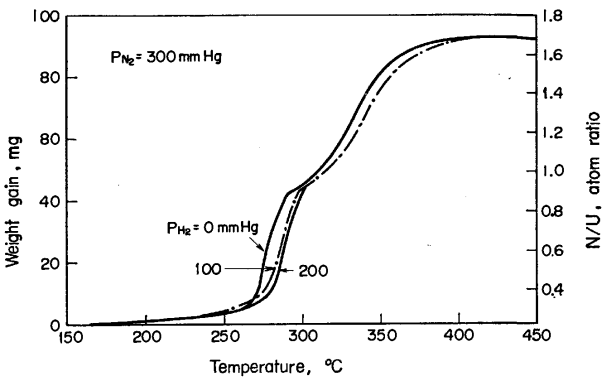

Fig. 4. Thermograms for the reaction of uranium hydride with nitrogen in the presence of hydrogen in mmHg: the weight of uranium metal, 1.070 g; p_{N_2}=300 mmHg; a heating rate, 2 °C/min.

were hardly altered at all by varying the nitrogen pressure. The change in the slope shows two steps of the reaction-the formation of the mononitride, followed by that of the sesquinitride. The nitrogen content increased as the temperature was raised to 420 °C. However, the nitride formed, having more nitrogen than that expressed by the chemical formula of U_2N_3, seemed not to be in an equilibrium state. When the nitride was kept at a temperature below 500 °C, the nitride observed to dissolve more nitrogen with the passage of time.

Figure 4 shows the effect of the pressure of hydrogen on the nitrogenation of the hydride at the nitrogen pressure of 300 mmHg. The hydrogen pressures used were 100 and 200 mmHg. The shape of the curve was not dependent on the variation in the hydrogen pressure. The temperature at which there was a sharp weight gain was 260 °C in the absence of hydrogen, but it shifted higher by about 10 °C when hydrogen was present in the system. The equilibrium hydrogen pressures over UH_3 have been reported to be 4.8, 6.6, and 10.0 mmHg at 250, 260, and 270 °C, respectively.[12,16] When hydrogen was not present, the reaction would occur between nitrogen and the uranium metal produced by the spontaneous thermal decomposition of the hydride. At 100 and 200 mmHg of hydrogen, however, the hydride reacted directly with nitrogen, because the decomposition pressure of the hydride was lower than the system pressure.

The reaction behavior of the hydride with nitrogen at a fixed temperature between 260 and 340 °C was examined by the procedure in which nitrogen of 300 mmHg was added a system which contained the hydride in a hydrogen atmosphere of 150 mmHg. The results are shown in Fig. 5. The velocity of the weight gain at $N/U<1$ is shown to be greater than that at $N/U>1$. The former corresponds to the formation of UN by the reaction of the hydride with nitrogen, and the latter to the formation of the sesquinitride by the reaction between the mononitride and nitrogen.

As mentioned above, the reaction sequence of the nitride formation is expressed as follows:

$$UH_3 + 1/2N_2 = UN + 3/2H_2, \quad \Delta H^\circ_{298} = -40.24 \text{ kcal}$$

$$UN + 1/4N_2 = 1/2U_2N_3, \quad \Delta H^\circ_{298} = -16.7 \text{ kcal}$$

$$U_2N_3 + x/2N_2 = U_2N_{3+x}$$

where the heats of formation, $-\Delta H^\circ_{f298}$, for UH_3,[16] UN,[19] and $1/2U_2N_{3.08}$[15] are 30.59, 70.59, and 86.3 kcal/mol, respectively. Thermochemically, the formation of the mononitride is indicated to take precedence over the sesquinitride in the early stage of the reaction. As seen in Fig. 5, the rate of the weight increase at $N/U<1$ is greater than that at $N/U>1$. Therefore, it may be deduced that the hydride converts to the mononitride, which then reacts with nitrogen to form the sesquinitride after the composition approaches $UN_{1.0}$.

Reaction between Uranium Hydride and Ammonia. The reaction was examined in an ammonia atmosphere

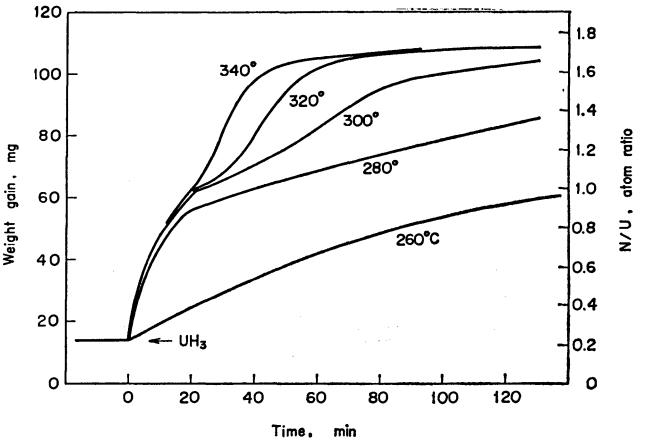

Fig. 5. Nitrogenation of uranium hydride in the mixture of nitrogen of 300 mmHg and hydrogen of 150 mmHg at constant temperatures between 260 and 340 °C: the weight of uranium metal, 1.070 g.

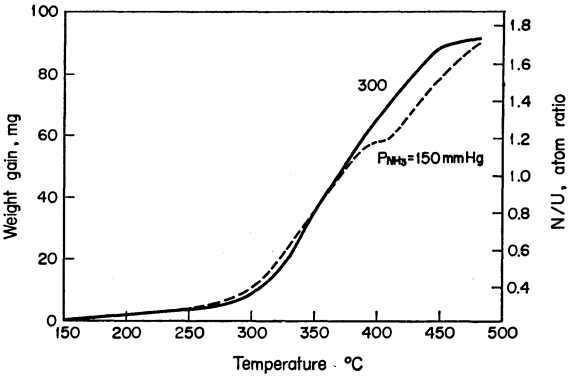

Fig. 6. Thermograms for the nitrogenation uranium hydride in ammonia of various pressures in mmHg: the weight of uranium metal, 1.030 g; a heating rate, 2 °C/min.

of 150 and 300 mmHg. The results are shown in Fig. 6. The reaction began at about 150 °C, and became fast above 250 °C. With ammonia of 300 mmHg, the shape of the curve was obviously different from that of the reaction between the hydride and nitrogen. The reaction is shown to form the sesquinitride directly. In ammonia of 150 mmHg, a plateau on the curve appeared around 400 °C. The plateau seems to indicate that the amount of ammonia becomes too small to continue the reaction with the hydride, but the further reaction of the more reactive uranium powder, produced by the decomposition of the hydride, with the residual ammonia takes place above 400 °C. This is because the partial pressure of hydrogen in the system is about 300 mmHg, and the hydride, of which the equilibrium pressure is 300 mmHg, does not yet proceed to decompose at 390 °C. When the equilibrium pressure is more than the system pressure as the temperature is raised, the thermal decomposition of the residual hydride occurs. As far as the pressure change was followed with time, the decomposition of ammonia was not seen to be catalysed by the nitride or the hydride.

The Determination of Beryllium in Several Alloys by Means of Atomic Absorption Spectrophotometry

Taketoshi NAKAHARA, Makoto MUNEMORI, and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai 591

(Received June 24, 1972)

The atomic absorption spectrophotometric determination of beryllium in aqueous solutions and the effect of some water-miscible organic solvents were studied in a nitrous oxide-acetylene flame, using a Perkin-Elmer Model 303 atomic absorption spectrophotometer. The beryllium atomic absorptions were measured at the 234.9-nm resonance line of beryllium. The sensitivity for beryllium was 0.03 ppm for a 1% absorption. With the exception of palladium and silicon, none of the elements interfered with the determination of beryllium. Phosphoric acid caused an enhancement, while hydrochloric and nitric acids had a slight depressing effect. Furthermore, there seems to be a tendency for organic solvents with a higher ratio of the number of carbon atoms to that of oxygen atoms to cause greater enhancements in beryllium absorption, though there are a good number of exceptions. The atomic absorption method was applied to the determination of beryllium in several aluminum-, copper-, and magnesium-base alloys, with satisfactory results.

Since beryllium is one of the elements capable of forming highly refractory compounds, it cannot be atomized efficiently to give a measurable atomic absorption in low-temperature flames such as in air-acetylene flame, in which a sensitivity of 300 ppm for a 1% absorption has been reported.[1] Slavin and Manning[2] used a fuel-rich oxygen-acetylene flame in conjunction with an ethanolic solution of beryllium to obtain a sensitivity of 0.2 ppm for a 1% absorption. The introduction of a high-temperature and highly-reducing nitrous oxide-acetylene flame enabled Amos and Willis[3] to determine trace levels of beryllium (a sensitivity of 0.02 ppm for a 1% absorption) by means of atomic absorption spectrophotometry. Later Ramakrishna *et al.*[4] described that the nitrous oxide-acetylene flame was useful as well as an oxygen-acetylene flame at a 1 ppm level of beryllium and that the sensitivity was improved when an aqueous solution of 10% in diethylene glycol diethyl ether was used.

In this paper, the enhancement of depressant effects on the atomic absorption of beryllium in a nitrous oxide-acetylene flame will be described. Furthermore, the method was applied to the determination of beryllium in several aluminum-, copper-, and magnesium-base alloys with satisfactory results.

Experimental

Apparatus. All the atomic absorption signals were obtained by using a Perkin-Elmer Model 303 atomic absorption spectrophotometer, fitted with a 5-cm slot burner head for a premixed nitrous oxide-acetylene flame. A beryllium hollow-cathode lamp (Atomic Spectral Lamps Pty., Australia) was used as the source of radiation. A Yanagimoto GCG-252 chart recorder was used after modification so as to adapt it to the Perkin-Elmer instrument.

Reagents. The stock solution of beryllium, 1000 ppm, was prepared by dissolving 9.83 g of analytical-reagent grade beryllium sulfate tetrahydrate in distilled water and by then diluting it to 500 ml. Various concentrations were made by the appropriate dilution of the stock solution.

Results and Discussion

Operating Conditions. The optimum operating conditions listed in Table 1 were established with a 2.0-ppm solution of beryllium. The atomic absorptions for beryllium were measured at different flame heights under various flame conditions in an attempt to find the optimum flame conditions for beryllium. The results are shown in Fig. 1. Under these flame conditions, about 3-cm-long "red feather" zone was produced above the burner head, and the sample aspiration rate was about 13 ml/min.

Table 1. Operating conditions for the measurement of beryllium atomic absorption

Wavelength	234.9 nm
Slit width	0.3 mm
Spectral bandpass	0.2 nm
Lamp current	20 mA
Scale expansion	×1
Acetylene flow rate	8.1 l/min
Acetylene pressure	0.6 kg/cm²
Nitrous oxide flow rate	18.0 l/min
Nitrous oxide pressure	1.5 kg/cm²
Flame height	3—4 mm above the top of the burner head
Burner slot	0.48 mm × 50 mm

Calibration Graph and Sensitivity for Beryllium. Under the optimum operating conditions described above, a straight calibration graph passing through the point of origin was obtained over the concentration range of 0—5 ppm for beryllium aqueous solutions. A good linearity held to the relatively high absorbance of about 0.6. The sensitivity for beryllium was 0.03 ppm for a 1% absorption. In this range, beryllium absorbances were measured with a precision of a relative standard deviation of 2.1%.

Effects of Other Elements. It has already been presented that a number of foreign elements have no

1: Acetic acid, 2: phosphoric acid, 3: sulfuric acid, 4: hydrofluoric acid, 5: perchloric acid, 6: nitric acid, 7: hydrochloric acid.

effect on the beryllium atomic absorption.[3-5] In the present investigation, the effects of various elements were also examined. The concentration of beryllium was 2 ppm, and that of the element, 200 ppm. The elements examined were Al, As, Au, Ba, Bi, Ca, Cd, Co, Cr(III), Cs, Cu, Fe(III), Hg(II), In, La, Mg, Mn(II), Mo, Na, Ni, Pb, Pd, Sb, Se, Si, Sn(II), Sr, Te, Th, Ti, V, Zn, and Zr. These elements were added as chloride, nitrate, or sulfate in most instances. An element was considered to interfere with the beryllium atomic absorption when it produced a variation in the absorbance of more than twice the relative standard deviation for beryllium alone.

With the exception of palladium and silicon, none of the elements interfered with the determination of beryllium at this concentration level. Palladium and silicon depressed the beryllium absorbance by about 29 and 8% respectively. A large amount of aluminum, however, depressed the beryllium atomic absorption, as will be described later.

Effects of Acids. Amos and Willis[3] have reported no interference from 2.5 N sulfuric acid with, and a slight enhancement by phosphoric acid of the beryllium absorption. On the other hand, Fleet *et al.*[5] have described that no interference occurred from hydrochloric, hydrofluoric, nitric, and phosphoric acids at the 10000 ppm level with respect to Cl, F, N, and P respectively.

In this study, the effect of hydrochloric, hydrofluoric, nitric, perchloric, phosphoric, sulfuric, and acetic acids in the concentration range of 0—2.0 N or 0—6.0 N on the beryllium atomic absorption was studied for 2-ppm solutions of beryllium. The results are shown in Fig. 2. Phosphoric acid caused an enhancement, as has been reported by Amos and Willis.[3] Sulfuric acid caused, but in a somewhat different way and in a higher concentration, an enhancement such as has been described by Fleet *et al.*[5] Hydrochloric and nitric acids in the 0—6.0 N range had, contrary to expectations, a slight depressing interference. Acetic acid caused an enhancement. A similar effect has been observed on the atomic absorption of vanadium in a nitrous oxide-acetylene flame.[6] The enhancement by acetic acid may be considered to be a kind of organic-solvent effect, such as has been described by Ramakrishna *et al.*[4] and by Fleet *et al.*[5]

As has been mentioned above, somewhat different results for the interference effects have been observed in the several investigations in this field, including this study. This may be ascribable to the difference in the efficiency of the nebulizers employed in those investigations.

Effect of Water-miscible Organic Solvents. Ramakrishna *et al.*[4] have described that the addition of glycols considerably enhanced the beryllium atomic absorption and that the sensitivity for beryllium was increased by 25% in the presence of 5% of diethylene glycol diethyl ether, which was the most effective on the glycols. Fleet *et al.*[5] have reported that the presence of methanol, ethanol, and isopropyl alcohol in the concentration of 20 vol% enhanced by 11—20% the beryllium atomic absorption, while glycol had a depressing effect of 17%.

In this study, the effect of water-miscible organic solvents, *e.g.*, alcohols, ketones, and glycols, on the beryllium absorption was studied. Solutions of 1 ppm in beryllium and 5- or 10-% in commonly-available alcohols, ketones, or glycols were prepared. These solutions were nebulized into the flame, and the beryllium absorptions were measured. At the same time, sample aspiration rates were measured. The results are shown in Table 2. It can be seen from Table 2 that the enhancement in the presence of organic

solvents has no relation to their molecular weights and boiling points. As for alcohols alone, however, the beryllium absorbance was increased in the order of the molecular weights and the boiling points. With an increase in the concentration of alcohols, the absorbance was increased as is shown in Fig. 3. Butyl alcohol was the most effective for the enhancement of the beryllium absorption, though its concentration was limited below 10% because of its solubility. Table 2 shows also that the absorbance was increased in the reverse order of the increase in the sample aspiration rate. If it can be assumed that the increase in the sample aspiration rate signifies an increase in the amount of the solution reaching the flame, the enhancement must be explained in terms of an increase in the efficiency of atomization. Perhaps a hotter or more reducing condition was created in the flame, with the result that the vaporization and dissociation of the metal compounds were increased.

The ratio of the number of carbon atoms to that of oxygen atoms (C/O ratio) in the flame is taken into account in determining the reducing properties of the flame.[7] L'vov[8] calculated the variation in the flame composition with a variation in the fuel-to-oxidant flow ratio for a total-consumption nebulizer-burner using an oxygen-acetylene flame and nebulizing aqueous or ethanolic solutions. According to L'vov's conclusions, optimum reducing properties of the flame are achieved when the composition of the flame, including the solvent, have a C/O ratio equal to unity. Solvents with a higher ratio of C/O increase the reducing properties of the flames more efficiently than ethanol. It should be remembered also that, when using organic solvents, the cooling effect due to an aspirated solution is decreased and a temperature rise takes place.[9] The C/O ratios of the organic solvents used are shown in Table 2. There seems to be a tendency for solvents with higher C/O ratios to cause greater enhancements, though there are a good number of exceptions. It may be concluded that the organic solvent provides a more reducing property for the flame, resulting in an increased production of beryllium atoms in the flame.

Application to the Determination of Beryllium in Several Aluminum-, Copper-, and Magnesium-base Alloys. The use of small amounts (0.01 to 0.5%) of beryllium as an additive to aluminum-, copper-, and magnesium-base alloys to improve their yield strength has created the need for a rapid and simple method for the determination of beryllium. For such a determination, atomic absorption spectrophotometry is the most

useful. In this investigation the determination of beryllium in several aluminum-, copper-, and magnesium-base alloys was studied.

The effect of a great amount of aluminum, copper, and magnesium, which are matrix elements in the sample alloys, on the beryllium atomic absorption was studied first. The effects observed in the actual concentration levels (200—20000 ppm) of these elements for 2 ppm of beryllium are shown in Fig. 4. Copper and magnesium showed no interference, but a great amount of aluminum (above 600 ppm of aluminum) had a depressing interference. At the 2000- and 20000-ppm aluminum levels, depressions of 6 and 28% respectively were observed. This depression must be taken into consideration in the case of the determination of trace beryllium in aluminum-base alloys; otherwise, serious errors will obviously result.

It has been already reported by Fleet *et al.*[5] that the depressing effect by aluminum can be overcome by the addition of oxine (8-hydroxyquinoline) to a solution containing beryllium and aluminum. The "masking" of aluminum by oxine, however, falls off steadily if the concentration of aluminum is increased to above 4000 ppm, and a corresponding increase in the oxine concentration to, say, 5% can not offset this.

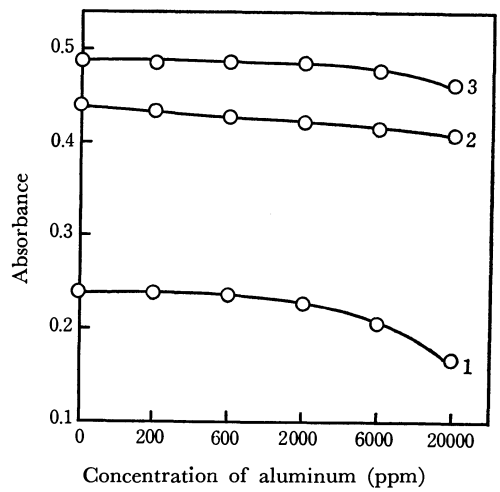

Fig. 5. Effect of aluminum in the presence of diethylene glycol monobutyl ether or butyl alcohol on beryllium atomic absorption. Concentration of beryllium: 2 ppm.
1: With no addition, 2: with the addition of diethylene glycol monobutyl ether(20 vol%), 3: with the addition of butyl alcohol(10 vol%).

In this study, another method for eliminating the interference from aluminum was examined; that is, beryllium absorptions were measured upon the addition of 20% of diethylene glycol monobutyl ether or 10% of butyl alcohol; such additions caused a relatively great enhancement, as is shown in Table 2, to 2-ppm beryllium solutions containing aluminum in the 200—20000 ppm range. The results are shown in Fig. 5. It can be seen that the addition of diethylene glycol monobutyl ether or butyl alcohol was effective not only in enhancing the beryllium absorption, but also in eliminating the depressing interference of aluminum. This fact also suggests that the organic solvents play an important role in the process of beryllium atom-production. However, the interference-suppressing effect of diethylene glycol monobutyl ether and butyl alcohol falls off slightly in the presence of a a greater amount (6000 ppm) of aluminum (as is is shown in Fig. 5); therefore, a standard addition technique in the presence of diethylene glycol monobutyl ether was employed in the determination of beryllium in aluminum-, copper-, and magnesium-base alloys.

The methods of preparing the sample solutions were as follows. Aluminum-base alloy: A 1-g sample was weighed precisely and dissolved in 25 ml of 6 N hydrochloric acid by gentle heating on a hot plate. After cooling, the resultant solution was transferred to a 100-ml volumetric flask and diluted to volume with distilled water. Copper-base alloy: A 1-g sample containing less than 0.1% of beryllium was weighed and dissolved in 10 ml of 6 N nitric acid, or a 0.1-g sample containing more than 0.1% of beryllium was weighed and dissolved in 4 ml of 2 N nitric acid by gentle heating on a hot plate. After cooling, the resulstant solutions were transferred to 100-ml volumetric flasks and diluted to volume with distilled water. Magnesium-base alloy: A 1-g sample was weighed

and dissolved in 25 ml of 6 N hydrochloric acid by gentle heating on a hot plate. After cooling, the resultant solution was transferred to a 100-ml volumetric flask and diluted to volume with distilled water.

Five 10-ml portions of the sample solutions and 5 ml of diethylene glycol monobutyl ether were taken into 25-ml volumetric flasks, 0-, 1-, 2-, 3-, and 4-ml portions of the 12.5 ppm standard solution of beryllium were added, and the mixtures were diluted to volume with distilled water. The solutions were sprayed into the nitrous oxide-acetylene flame, and the beryllium atomic absorption signals were measured under the optimum operating conditions. The determinations were performed three times on each aliquot of aluminum-, copper-, and magnesium-base alloys.

The beryllium contents in the samples were determined by using a standard addition method. The results are shown in Table 3. Table 3 shows the results of the colorimetric determination of beryllium with Arsenazo I[10] on the alloy samples. Atomic absorption spectrophotometry and colorimetry with Arsenazo I gave consistent results on the aluminum-, and copper-base alloys, but inconsistent results on the magnesium-base alloy. The latter results were possibly caused by the irrelevance of the application of the colorimetric method to such a sample, but, at any rate, they may be tolerable in view of the smallness of the beryllium content in the sample.

The Atomic Absorption Spectrophotometric Determination of Bismuth in Premixed Inert Gas(Entrained Air)-Hydrogen Flames

Taketoshi NAKAHARA, Makoto MUNEMORI, and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai 591

(Received June 26, 1972)

The atomic absorption spectrophotometric determination of bismuth in aqueous solutions was established in premixed inert gas(entrained air)-hydrogen flames with a "multi-flame" burner in conjunction with a Nippon Jarrell-Ash Model AA-1 atomic absorption/flame emission spectrophotometer. Under the optimum operating conditions, a straight calibration graph was obtained at 223.1 nm in the concentration range of 0–10 ppm and the bismuth sensitivity for a 1% absorption was 0.1 ppm. The effects of acids and other elements on the bismuth atomic absorption were examined. Phosphoric acid caused a considerable depressing effect on the bismuth absorption. Hydrochloric acid remarkably depressed the bismuth absorption at acid concentrations lower than 0.5 N, but it gave no interference in acid concentrations higher than 0.5 N, in which water-insoluble bismuth oxychloride was quickly dissolved in hydrochloric acid. Hydrofluoric, nitric, perchloric, and sulfuric acids had no effect on the bismuth absorption. Most of the elements examined, with the exception of aluminum, boron, cerium, silicon, and zirconium, gave no interference to the bismuth absorption. The depressing interferences due to some elements were removed in appearance by adding a large amount (2000 ppm) of magnesium (as chloride). Furthermore, it was found that most of the depressing interferences could be eliminated by adding a large amount (0.1 M) of ammonium salts (as chloride or perchlorate) to the sample solutions. Bismuth in the presence of magnesium chloride, ammonium chloride, or ammonium perchlorate could be determined without interference from various other elements. The atomic absorption spectrophotometric method was applied to the determination of bismuth in sulfide ores, aluminum-, tin-, and lead-base alloys with satisfactory results.

Bismuth is determined readily in an air-acetylene flame. The bismuth line at 306.8 nm is of limited usefulness, however, because it falls on the band head of the major hydroxyl band in the flame; moreover, the flame luminosity makes the atomic absorption measurement uncertain. The resonance line at 223.1 nm is usually the most useful. The best sensitivity for a 1% absorption in the determination of bismuth in an aqueous solution by atomic absorption spectrophotometry with an air-acetylene fiame is 0.7 ppm at the 223.1 nm line.[1] Kinser[2] has reported the determination of bismuth in biological samples with an air-acetylene flame without any interference from the materials found in the samples. Bismuth could be readily extracted from aqueous solutions into organic solvents with such chelating agents as ammonium pyrrolidine dithiocarbamate (APDC), dithizone, etc. An APDC-organic solvent extraction system has been used in the analysis of urine samples[3] and the lead-base and tin-base metals.[4] The dithizone-carbon tetrachloride system has been used in the determination of bismuth in ferrous alloys.[5] Furthermore, Headridge and Richardson[6] have reported on the use of a bismuth iodide-methyl isobutyl ketone system for the determination of bismuth in ferrous alloys. On the other

hand, McGee and Winefordner[7] have described the determination of bismuth using a modified long-path absorption cell and a xenon lamp as a continuum radiation source, with an argon-hydrogen flame. Burke[8] has studied the scavenger property of manganese (IV) oxide for the separation of less than 100 ppm of bismuth by atomic absorption spectrophotometry with an air-acetylene fiame.

Several authors have examined the so-called "cool" flames with respect to their use in flame methods of analysis. These flames are usually entrained air-hydrogen flames in which the combustible gas is diluted with an inert gas, such as nitrogen or argon. Winefordner *et al.*[9,10] have used an argon (entrained air)-hydrogen flame in the flame-emission spectrophotometric determination of 14 elements and have obtained limits of detection which are better than, or as good as, those obtained with an oxygen-hydrogen flame. Their success has been attributed to the low background noise associated with the argon-hydrogen fiame and also to possible chemiluminescence with certain elements. Dagnall *et al.*[11] have used a hydrogen flame diluted with nitrogen to observe the molecular band emission of S_2 in the determination of sulfur. The argon (entrained air)-hydrogen flame has also been used in atomic absorption spectrophotometry because of its low flame background absorption in the ultraviolet region; this has resulted in improving the atomic absorption sensitivities for several elements.[12]

This paper will decribe an investigation of the flame characteristics for bismuth in the premixed argon (entrained air)- and nitrogen(entrained air)-hydrogen flames produced using a specially-constructed "multi-flame" burner,[13] and an investigation of the interference with bismuth atomic absorptions. A depressing interference was observed over a wide range of concentration of several elements. It may, however, be noted that a large amount of magnesium can eliminate the depressing effect due to some of the elements examined. This was successfully applied to the determination of bismuth in several metallurgical samples.

Experimental

Apparatus. All the atomic absorption measurements were performed using a Nippon Jarrell-Ash Model AA-1 atomic absorption/flame emission spectrophotometer on a single-pass system. A "multi-flame" burner[13] was used in conjunction with a Techtron standard nebulizer-chamber. The height in the flame was taken as zero when the light beam from the hollow-cathode lamp just touched the top of the burner head. The analytical wavelength was 223.1 nm, and the light source was a bismuth high-spectral-output hollow-cathode lamp (Westinghouse, Type No. 45467), operated at 8 mA. The gas flow rates were carefully regulated and were monitored on calibrated flow meters.

Reagents. A stock solution of bismuth (1000 ppm) was prepared by dissolving 1.000 g of high-purity bismuth metal in 10 ml of concentrated nitric acid by gentle heating, and by then diluting it to 1000 ml with distilled water. It was necessary to keep the acid concentration high enough (pH 1) to prevent its hydrolysis. Lower concentrations of standard bismuth solutions were freshly prepared daily by diluting the stock solution.

All the other reagents used were either of a reagent grade or of the highest quality available. Blanks were run on each solution in the case of the interference study with the bismuth atomic absorption.

Results and Discussion

Bismuth Sensitivity in Various Flames. Slavin[1] and Kinser[2] have reported a sensitivity of 0.7 ppm for a 1% absorption in aqueous solutions with an air-acetylene flame at the wavelength of the 223.1 nm bismuth resonance line. The bismuth sensitivities for a 1% absorption in aqueous solutions were obtained in several flames produced with a "multi-flame" burner[13] under optimum flame and measuring conditions. They were 0.14, 0.80, 0.18, 1.00, 0.10, and 0.11 ppm in the premixed air-acetylene, nitrous oxide-acetylene, air-hydrogen, nitrous oxide-hydrogen, argon (entrained air)-hydrogen, and nitrogen(entrained air)-hydrogen flames respectively. The sensitivities in the inert gas(entrained air)-hydrogen flames were considerably better than those obtained in the other hydrogen or acetylene flames. Furthermore, it was found that the inert gas(entrained air)-hydrogen flames gave extremely low background absorptions at the 223.1 nm line compared with the other flames examined. These higher sensitivities indicated that such relatively volatile elements as arsenic, bismuth, cadmium, lead, selenium, tin, and zinc were sufficiently atomized, even in the low-temperature flames.

Effect of Flame Composition and Flame Height. At a fixed flow rate of argon or nitrogen as a nebulizing gas, the hydrogen flow rates were varied from 3.6 to 12.6 l/min and the absorptions were measured for 10 ppm of bismuth in various flame heights in order to find the optimum flame composition and flame height. The results obtained in the argon(entrained air)-hydrogen flame are shown in Fig. 1. It may be seen from Fig. 1 that the bismuth atomic absorption may be depends remarkably on both the flame composition and the flame height. Similar results were obtained in the nitrogen(entrained air)-hydrogen flame. The optimum conditions for bismuth atomic absorption are summarized as follows. Argon(entrained air)-hydrogen flame: hydrogen flow rate, 5.4 l/min; argon flow rate, 4.5 l/min; argon pressure, 1.5 kg/cm^2; height in the flame, 4 mm above the top of burner head. Nitrogen(entrained air)-hydrogen flame: hydrogen flow rate, 5.4 l/min; nitrogen flow rate 5.0 l/min; nitrogen pressure, 1.5 kg/cm^2; height in the flame,

Hydrogen flow rate: (○) 3.6 l/min; (●) 5.4 l/min; (△) 7.2 l/min; (▲) 9.0 l/min; (□) 10.8 l/min; (■) 12.6 l/min.

5 mm above the top of the burner head. Under these conditions, both the flames were completely invisible and quiet.

Effect of Acids. No detailed study has been previously reported on the effect of acids on the determination of bismuth by atomic absorption spectrophotometry in either an air-acetylene flame or an air-hydrogen flame. The bismuth absorptions were, therefore, measured in inert gas(entrained air)-hydrogen, flames for 10 ppm of bismuth in the presence of acids, the concentrations of which were varied from 0.1 to 2.0 N. The acids examined included hydrochloric, hydrofluoric, nitric, phosphoric, perchloric, and sulfuric acids. The results obtained in the argon(entrained air)-hydrogen flame are shown in Fig. 2. Similar results were obtained in the nitrogen(entrained air)-hydrogen flame. Phosphoric acid had a considerable depressing effect on the bismuth atomic absorption. The effect of phosphoric acid may be due to the difficulty of the thermal decomposition of the phosphate in the low-temperature flame. On the other hand, hydrofluoric, perchloric, and sulfuric acids caused a slight enhancement of the bismuth atomic absorption.

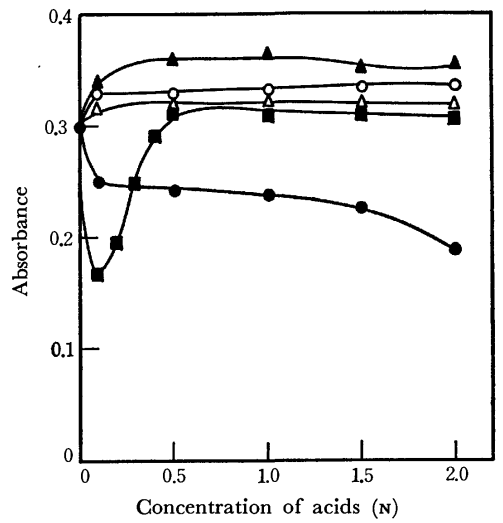

Fig. 2. Effect of acids on bismuth atomic absorption.
Concentration of bismuth: 10 ppm. Flame: an argon(entrained air)-hydrogen flame. (▲) Perchloric acid; (○) hydrofluoric and sulfuric acids; (△) nitric acid; (■) hydrochloric acid; (●) phosphoric acid.

Hydrochloric acid was found, as is shown in Fig. 2, to depress remarkably the bismuth atomic absorption in acid concentrations lower than 0.5 N, but this depressing interference disappeared in acid concentrations higher than 0.5 N because water-insoluble bismuth oxychloride is quickly dissolved in hydrochloric acid of a higher concentration. The bismuth solution containing hydrochloric acid at the 1.0 N level was used in all the later work, because the effect of hydrochloric acid caused the smallest interference in the determination of bismuth of all the acids examined.

Effect of Various Other Elements. Winefordner *et al.*[9,10] have described that an argon(entrained air)-hydrogen flame was useful for atomic fluorescence and flame emission spectrophotometry. Kirkbright and Ranson[14] have reported that the determination of some elements, such as arsenic and selenium, in the argon(entrained air)-hydrogen flame suffered from interference from foregin elements because of the inability of the cool flame to vaporize or atomize the other elements present in the sample solution.

The effects of various other elements on the atomic absorption spectrophotometric determination of bismuth were studied in detail at constant concentration levels: aqueous solutions containing 10 ppm of bismuth and 200 ppm of other elements. The results obtained in both the flames are shown in Table 1. Most elements, with the exception of aluminum, beryllium, silicon, etc., gave no interference, the deviation of the absorbance of bismuth being less than 5%. As is shown in Table 1, however, aluminum, beryllium, boron, cerium, silicon, and zirconium, which easily produce refractory metallic oxides in the flame, depressed the bismuth atomic absorption. These depressing effects on the bismuth absorption can not be satisfactorily explained.

Because the flame composition has been shown to be an important parameter in interference studies,[1,15,16] the hydrogen-flow rate and the flame height in inert gas(entrained air)-hydrogen flames were varied to see what effect, if any, would be thus produced on the depressing interference. For example, an aluminum depression showed a dependency on these parameters. As is shown in Fig. 3, this interference could be negative

or occasionally positive, depending on the hydrogen flow rate and the flame height. This phenomenon can not be explained adequately, but it is possibly due to a perturbation of basic flame chemistry or it is possibly related to the specific chemistry of the elements and bismuth in the flame.

On the other hand, no element was found to enhance the bismuth atomic absorption.

Effect of Magnesium on the Depressing Interference. The depressing interference described above depends considerably on the concentration of the depressing elements, the flame composition, and the flame height. In an attempt to eliminate the depressing interference due to aluminum, beryllium, *etc.*, the effect of the further addition of such an element as gave no interference with the bismuth absorption, *i. e.*, mercury, potassium, lanthanum, magnesium, and yttrium, was examined on a bismuth solution containing interferents. The results on the aluminum interference are shown in Fig. 4. As is shown in Fig. 4, magnesium was the most effective in eliminating the depressing interference among the elements examined. Then, the bismuth (10 ppm) absorptions were measured in the presence

Table 2. Effect of magnesium on the depressing interference

Element	Relative absorbance			
	Argon(entrained air)-hydrogen flame		Nitrogen(entrained air)-hydrogen flame	
	In the absence of magnesium	In the presence of magnerium	In the absence of magnesium	In the presence of magnesium
None	1.00	1.00	1.00	1.00
Al	0.43	1.03	0.37	1.03

Zr	0.18	1.05	0.07	1.04

The concentrations of bismuth, the elements added, and magnesium were 10, 200, and 1000 ppm, respectively.

of the depressing elements (200 ppm) with and without the addition of magnesium (as chloride) (1000 ppm). The results obtained in both the flames are shown in Table 2. The interference from all the depressing elements, with the exception of that of cerium, disappeared completely. This phenomenon could be applied to the atomic absorption spectrophotometric determination of bismuth without any interference from matrix elements.

The mechanism of the interference-elimination due to magnesium cannot be satisfactorily explained. If the interference from aluminum in the determination of bismuth is considered to be due to the formation of bismuth aluminate in the flame, the elimination of the interference by adding a large amount of magnesium may be explained in terms of the predominant formation of magnesium aluminate in the flame, resulting in a release of the bismuth atoms from the influence of aluminum.

Effect of the Ammonium Ion on the Interference. As is shown in Table 2, chromium depressed the bismuth absorption in the nitrogen(entrained air)-hydrogen flame, but it did not do so in the argon(entrained air)-hydrogen flame. This fact seemed to be very interesting; therefore, the interference from chromium in the nitrogen(entrained air)-hydrogen flame was studied with various kinds of chromium compounds. The results are shown in Fig. 5. The ammonium salts gave no interference with the bismuth atomic absorption, while the others remarkably depressed the bismuth atomic absorption. This fact indicated that the ammonium ion possibly plays an important role in the elimination of the depressing interference. Further investigation showed that the depressing interference from chromium could be eliminated with the addition of a large amount of ammonium chloride or ammonium perchlorate, as is shown in Fig. 6.

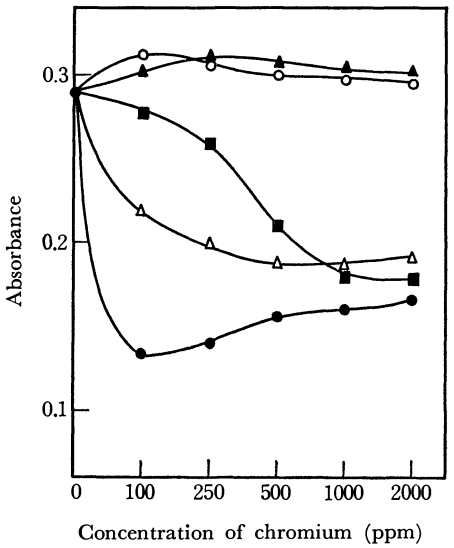

Fig. 5. Effect of chromium compounds on bismuth atomic absorption in the nitrogen(entrained air)-hydrogen flame. Concentration of bismuth: 10 ppm. (▲) Ammonium chromate; (○) ammonium dichromate; (■) potassium chromate; (△) potassium dichromate; (●) chromium(III) chloride.

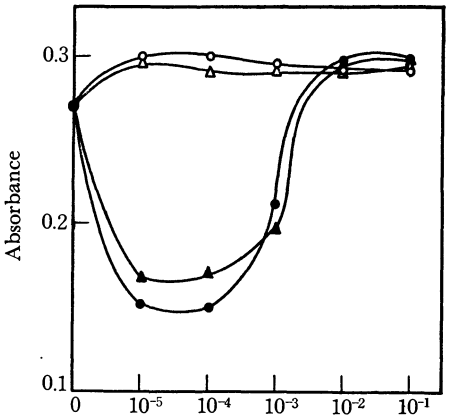

Fig. 6. Effect of ammonium salts on the depressing interference from chromium(III) chloride in the nitrogen (entrained air)-hydrogen flame. Concentration of bismuth: 10 ppm. (○) Ammonium perchlorate alone; (△) ammonium chloride alone; (●) ammonium perchlorate in the presence of chromium(III) chloride (Concentration of chromium: 1000 ppm); (▲) ammonium chloride in the presence of chromium(III) chloride (Concentration of chromium: 1000 ppm).

Then, the atomic absorptions were measured for a solution containing bismuth (10 ppm) and the depressing elements (200 ppm) in the presence of a large amount (0.1 M) of ammonium chloride or ammonium perchlorate in the inert gas (entrained air)-hydrogen flames. The results are shown in Table 3. The interferences from all the depressing elements appeared to disappear completely.

TABLE 3. EFFECT OF AMMONIUM CHLORIDE AND AMMONIUM PERCHLORATE ON THE DEPRESSING INTERFERENCE

Element	Relative absorbance			
	Argon(entrained air)-hydrogen flame		Nitrogen(entrained air)-hydrogen flame	
	In the presence of ammonium chloride	In the presence of ammonium perchlorate	In the presence of ammonium chloride	In the presence of ammonium perchlorate
None	1.00	1.00	1.00	1.00

Co	1.00	1.00	1.02	1.01
Cr	0.99	1.02	1.02	0.98
Cs	0.95	1.02	0.96	0.98
Ni	0.98	1.02	0.99	0.98
Pd	0.95	0.93	0.97	0.92
Si	1.02	1.00	1.05	0.95
Sr	1.02	0.99	0.98	0.98
Zr	1.02	0.97	1.05	0.98

The concentrations of bismuth, ammonium chloride, and ammonium perchlorate were 10 ppm, 0.1 M, and 0.1 M, respectively.

Effects of Organic Solvents. The effects of organic solvents on the bismuth atomic absorption were also examined. A series of primary alcohols were selected, and the concentrations of the alcohols added were from 10 to 50% by volume. The effect of the alcohols was found to be a depressing interference; that is, the bismuth atomic absorption was decreased with an increase in the alcohol concentrations in the sample solutions. A more detailed investigation was not made on the effects of organic solvents.

Calibration Graphs and Sensitivity. Typical calibration graphs for bismuth are shown in Fig. 7. With magnesium or ammonium chloride added, the same graph was obtained in the presence and in the absence of aluminum. The bismuth sensitivities for a 1% absorption were 0.10 and 0.11 ppm in the argon(entrained air)-hydrogen flame and the nitrogen(entrained air)-hydrogen flame respectively.

Application to the Determination of Bismuth in Sulfide Ores, Aluminum-, Tin-, and Lead-base Alloys. On the basis of the above-mentioned observations, the following procedures were followed for determination of bismuth in some practical samples, *e. g.*, sulfide ores, aluminum-, tin-, and lead-base alloys.

Sulfide Ores: A 2.5-g ore sample was weighed and dissolved in about 70 ml of dilute aqua regia by gentle heating on a hot plate. After the solution had then been cooled to room temperature, the insoluble matter was filtered out. The filtrate was transferred to a 100-ml volumetric flask and diluted to volume with distilled water. The final solution was adjusted to provide a concentration of about 1.0 N hydrochloric acid. The major constituents in the ore samples were found spectrographically to be copper, iron, silicon, and lead by means of a d. c. arc technique on a Shimadzu Type GE-340 Ebert mounting emission spectrograph. Furthermore, these elements were determined in a nitrous oxide-acetylene flame by using a Hitachi Model 207 atomic absorption spectrophotometer. As a result, the contents of the sulfide ore sample of A mine were found to be 18.3, 17.9, 14.0, and 3.9% for copper, iron, zinc, and lead respectively. The contents of the sulfide ore sample of B mine were found to be 83.0, 0.3, 0.2, and 0.1% for iron, copper, zinc, and lead respectively. The silicon and sulfur in the samples were separated as silicate and elementary sulfur from the sample solutions by filtration after the dissolution of the samples.

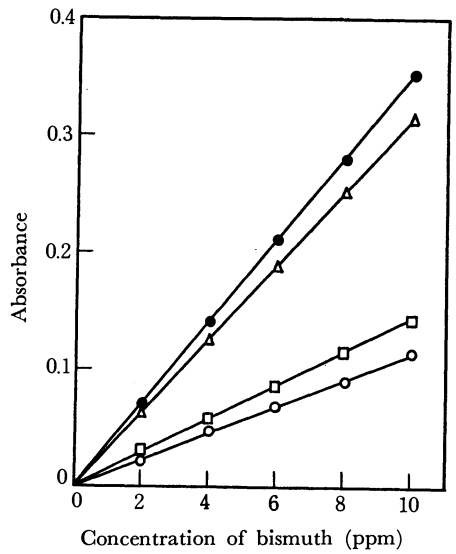

Fig. 7. Calibration graphs for bismuth. Flame: an argon (entrained air)-hydrogen flame. (○) In the presence of aluminum (2000 ppm); (□) in the presence of aluminum (1000 ppm); (●) in the presence of magnesium (2000 ppm) alone, magnesium (2000 ppm) and aluminum (1000 ppm), or magnesium (2000 ppm) and aluminum (2000 ppm); (△) bismuth alone.

Table 4. Results of the determination of bismuth in sulfide ores

Sample	Bismuth content (%)		
	Atomic absorption method		Colorimetric method

A mine ore (Cu conc.)	0.0041[c] 0.0038[d]	0.0044[c] 0.0042[d]	0.0039
B mine ore (S conc.)	0.0068[c] 0.0065[d]	0.0072[c] 0.0064[d]	0.0066

a) Argon(entrained air)-hydrogen flame.
b) Nitrogen(entrained air)-hydrogen flame.
c) Determined by using the calibration graph method.
d) Determined by using the standard addition method.

The bismuth in the ore samples was determined by the standard addition method and by the calibration graph method. Copper, iron, lead, and zinc did not interfere with the determination of bismuth, as has been described above. However, since small amounts of silicon and other interferents were presumably present in the samples, both sample and standard solutions were prepared so as to contain magnesium of 2000 ppm and hydrochloric acid of 1.0 N in the final solutions. The bismuth atomic absorptions were measured at 223.1 nm in the inert gas(entrained air)-hydrogen flames under optimum conditions. The results of the determinations are shown in Table 4. The results were compared with those obtained by the colorimetric method, in which the bismuth contents in sulfide ores were determined by a two-stage extraction with sodium diethyldithiocarbamate into carbon tetrachloride.[17]

Aluminum-base Alloys: As is shown in Fig. 3, the presence of aluminum caused a depressing interference with the bismuth atomic absorption. Therefore, a sufficient amount of magnesium (5000 ppm) was added to the sample solutions in order to eliminate the interference from the matrix element, *i. e.*, aluminum, in the determination of bismuth. A 0.5-g sample was dissolved in 20 ml of aqua regia by gentle heating on a hot plate. After cooling, the sample solution was transferred to a 100-ml volumetric flask and diluted to volume with distilled water. A 10-ml aliquot was taken out, 2.5 ml of a 50000 ppm magnesium solution and 5 ml of 5 N hydrochloric acid were added, and then the mixture was diluted to 25 ml with distilled

water. The resultant solution was sprayed into the flame, and the determination of bismuth was carried out by both the standard addition method and the calibration graph method. The results are shown in Table 5. The results agreed closely with the certificate values.

Tin- and Lead-base Alloys: A 0.9-g sample was dissolved in 30 ml of 6 N acid by slowly heating it on hot plate. The acid employed was hydrochloric acid for tin-base alloys and nitric acid for lead-base alloy. After cooling the sample solution was transferred to a 100-ml volumetric flask and diluted to volume with distilled water. A 10-ml aliquot was taken out and diluted to 25 ml with distilled water. The resultant solution was sprayed into the flame, and the bismuth absorption was measured. Magnesium was not added to the solutions, because the matrix elements do not interfere with the bismuth absorption, as is shown in Table 1. The results are shown in Table 5. When hydrochloric acid was added to the solution of the lead-base alloy, lead chloride precipitated on cooling; then, the supernatant solution was used for the atomic absorption measurement. The determination of bismuth after the removal of lead as chloride was successful, since little or no bismuth was lost, as has been reported by Lau *et al.*,[4] who confirmed radiometrically the recovery of over 99% of the bismuth.

In the standard addition method, the concentrations of bismuth added to the sample solutions were 0, 2, 4, 6, and 8 ppm in the final solutions. The calibration graphs for bismuth were prepared in the concentration range of 0—8 ppm.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1172—1177 (1973)

Determination of Titanium in Some Metallurgical Materials by Atomic Absorption Spectrophotometry

Taketoshi NAKAHARA, Makoto MUNEMORI, and Sôichirô MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-umemachi, Sakai 591

(Received June 29, 1972)

The atomic absorption spectrophotometric determination of titanium was subject to interference by other elements in a nitrous oxide-acetylene flame with a Perkin-Elmer Model 303 atomic absorption spectrophotometer, fitted with a 5-cm long-path slot burner. The effects of various other elements, acids, and water-miscible organic solvents on the titanium atomic absorption were examined. Aluminum produced the greatest enhancement of the titanium absorption of all the elements examined. Both butyric acid (2.0 M) and diethylene glycol monobutyl ether (20%) enhanced the titanium absorption by about 100% in aqueous solutions. In the presence of 5000 ppm aluminum or 20% diethylene glycol monobutyl ether, the interferences from other elements appeared to be completely removed. Furthermore, the extraction of titanium with cupferron into methyl isobutyl ketone was successful in effecting an increase in the sensitivity of titanium and in eliminating, or at least diminishing the interferences from other elements. The atomic absorption method was then applied to the determination of titanium in ferric oxides, nickel-chromium steel, nickel alloy, and steels with satisfactory results.

Titanium is one of the elements which are difficult to determine by means of atomic absorption spectrophotometry because it forms a stable refractory oxide in the flame. However, after Amos and Willis[1] introduced a nitrous oxide-acetylene flame into atomic absorption spectrophotometry, many refractory elements including titanium have become determinable by means of atomic absorption spectrophotometry. Headridge and Hubbard[2] reported the atomic absorption spectrophotometric determination of titanium in steels, permanent magnet alloys, and cast iron with hydrofluoric acid solutions. Bowman and Willis[3] obtained satisfactory results in the determi-

nation of titanium in bauxite and steel. Amos and Willis[1] found that iron at the 2000 ppm level in the presence of 20% hydrofluoric acid considerably enhanced the titanium atomic absorption. Recently Kirkbright *et al.*[4] reported the sensitive, indirect determination of titanium by means of atomic absorption spectrophotometry, with the extraction of molybdotitanophosphoric acid into butyl alcohol.

The effect of organic solvents has been well studied on the atomic absorption of many elements, but scarcely not at all on the atomic absorption of titanium. In this investigation, the effects of various extraneous elements and water-miscible and immiscible organic solvents on titanium absorption in a nitrous oxide-acetylene flame were investigated. Many elements interfered with the titanium absorption, but effective means, including solvent extraction, were found to eliminate the interferences. This paper will also describe the results of the atomic absorption spectrophotometric determination of titanium in ferric oxides, steels, and a nickel-base alloy.

Experimental

Table 1. Operating conditions for titanium absorption

Wavelength	364.3 nm
Slit-width	0.3 mm
Spectral bandpass	0.2 nm
Lamp current	40 mA
Scale expansion	×1
Nitrous oxide flow rate under the pressure of 30 p.s.i.	14.0 l/min
Acetylene flow rate under the pressure of 8 p.s.i.	7.6 l/min for aqueous solution
	6.4 l/min for methyl isobutyl ketone
Flame height	3 mm above burner head
Burner slot	0.48 mm × 50 mm

Apparatus. A Perkin-Elmer Model 303 atomic absorption spectrophotometer, equipped with a nitrous oxide burner head, was used in this work. The experimental conditions are shown in Table 1. The titanium 364.3 nm line was slightly less intensive, but it was more strongly absorbed by titanium atoms, than the 365.4 nm line; therefore, the 364.3 nm line was chosen as the analytical absorption line. A Perkin-Elmer titanium hollow-cathode lamp was used as the radiation source. Under the optimum flame conditions, shown in Table 1, about a 3 cm long "red feather" was produced above the burner head, and the sample aspiration rate was about 8.6 ml/min.

Reagents. A stock solution of titanium(5000 ppm) was prepared by dissolving 5.000 g of high-purity titanium sponge (99.99%) with 50 ml of 6 N hydrochloric acid by heating on a hot plate and by then diluting to 1000 ml with distilled water. Various standard titanium solutions were prepared by suitably diluting the stock solution.

A cupferron solution (5%) was prepared by dissolving 5.0 g of cupferron with distilled water. The solution was prepared daily.

All the other chemicals used were of an analytical-reagent grade.

Results and Discussion

Effects of Inorganic Acids. The effects of the inorganic acids generally used for sample decomposition were studied in the concentration range of 0—2.0 N on a 100 ppm titanium solution. The acids studied were hydrochloric, hydrofluoric, nitric, perchloric, phosphoric, and sulfuric acids. Hydrochloric and nitric acids had no effect on the titanium absorption, even at higher concentrations up to 6.0 N. The other acids enhanced the titanium atomic absorption, as is shown in Fig. 1.

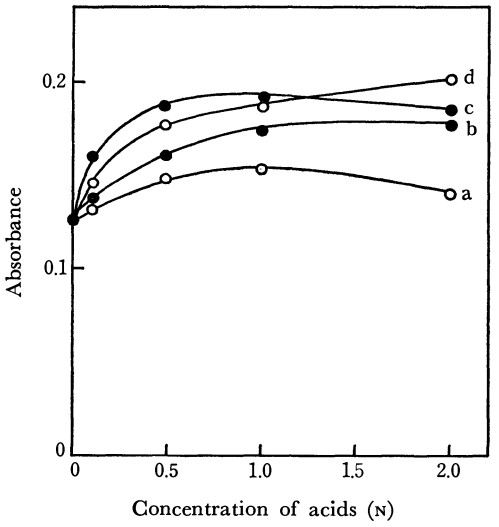

Fig. 1. Effect of inorganic acids on titanium atomic absorption.
Concentration of titanium: 100 ppm.
(a) Sulfuric acid; (b) phosphoric acid; (c) perchloric acid; (d) hydrofluoric acid.

As has been described by Amos and Willis,[1] the enhancement by hydrofluoric acid is possibly due to the inhibition of the formation of titanium monoxide in the flame by forming a more stable fluoro-complex, which decomposes easily at the temperature of the nitrous oxide-acetylene flame. Since sulfate and phosphate ions are known to form complexes with titanium, the enhancement by sulfuric and phosphoric acids may be explained, as in the case of hydrofluoric acid, in terms of the inhibition of monoxide formation, but the enhancement by perchloric acid, the extent of which is nearly equal to that by hydrofluoric acid, is difficult to explain because of its inability to form stable complexes with titanium. At any rate, when hydrofluoric acid and/or perchloric acid are used in the sample decomposition, the acid concentrations of the sample solution and the standard solution should match.

Effects of Organic Acids. The effects of monocarboxylic acids, *i.e.*, formic, acetic, trichloroacetic, propionic, and butyric acids, on the titanium absorption were also studied. The absorption measure-

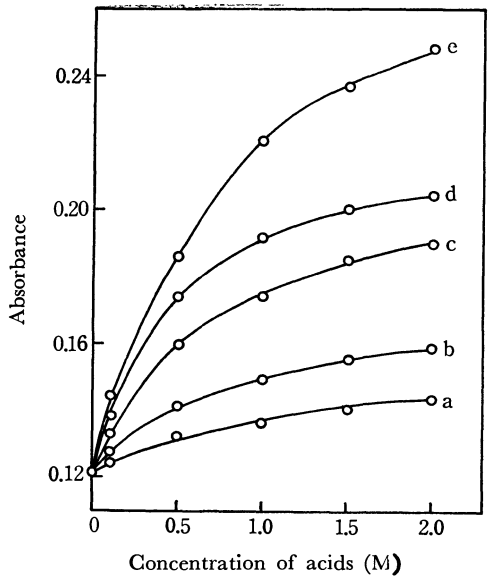

Fig. 2. Effect of organic acids on titanium atomic absorption.
Concentration of titanium: 100 ppm.
(a) Formic acid; (b) acetic acid; (c) propionic acid; (d) trichloroacetic acid; (e) butyric acid.

ments were made on a 100 ppm titanium solution in the presence of the acids, the concentrations of which were changed from 0.1 to 2.0 M. These acids produced an enhancement, and the titanium absorptions were increased, with an increase in the acid concentrations, as is shown in Fig. 2. Butyric acid was the most effective, enhancing the titanium absorption 2-fold at 2.0 M. The enhancing effect of these acids is probably due to the formation of stable complexes of titanium, which decompose easily in the flame. On the other hand, these acids may play the same role as organic solvents, as will be discussed later, since the enhancement in the presence of the acids increased with an increase in the carbon numbers, the molecular weight, and the boiling point except in the case of trichloroacetic acid.

Effects of Various Other Elements. Amos and Willis[1] have reported the enhancing effects of hydrofluoric acid and of iron in the determination of titanium. Headridge and Hubbard[2] have described that there is no interference from various foreign elements, such as chromium, cobalt, manganese, molybdenum, nickel, niobium, sulfur, tantalum, tungsten, and vanadium, in the presence of iron in the aqueous ethanolic hydrofluoric acid solution, and that aluminum interferes with the determination of titanium.

The effects of various other elements on the atomic absorption of titanium were studied at constant concentration levels in aqueous solutions. The elements examined and their effects on the atomic absorption of titanium are shown in Table 2. The concentration of titanium was 100 ppm, and that of the interferent, 1000 ppm. Table 2 indicates that most elements except for antimony and selenium enhanced the titanium absorption. It is also evident from Table 2 that such elements as aluminum, beryllium, cerium, lanthanum, and silicon, which are apt to form stable

oxides in the flame, produced a greater enhancement. Aluminum produced the greatest enhancement. Such an enhancement is possibly caused by competition between titanium and the other refractory elements to form stable oxides in the flame, as has been described in the case of aluminum[5] and vanadium[6] by Robinson *et al.*, but the enhancement cannot be explained completely satisfactorily. The decreasing effect of antimony and selenium is ascribable to the formation of insoluble precipitates in aqueous solutions. Although bismuth and thallium produced insoluble precipitates, they slightly enhanced the titanium absorption.

Thus, titanium absorption suffers serious interference from many elements, so a suitable means for eliminating or suppressing them must be found. Otherwise, atomic absorption will be of little analytical use. David[7] has already demonstrated that aluminum suppresses interferences from other elements in the determination of molybdenum in an air-acetylene flame. In this study, the suppressing effect of aluminum on the interferences with titanium absorption was studied. At first, the effect of an increase in the

concentration of aluminum was studied on 100 ppm of titanium; it was found that the titanium absorption was increased with an increase in the aluminum concentration until a constant enhancement was attained at more than 2000 ppm of aluminum. Then, in the presence of aluminum at 5000 ppm the effects of various other elements were studied at the 1000-ppm concentration level. None of the elements listed in Table 2 showed any more effect on the titanium absorption; thus, the interferences from other elements on titanium absorption appeared to disappear completely. Furthermore, the titanium absorption was measured in the presence of aluminum (5000 ppm) by varying the concentrations of the interferents. Figure 3 shows the results, with iron as an example. Similar results were obtained with other interferents.

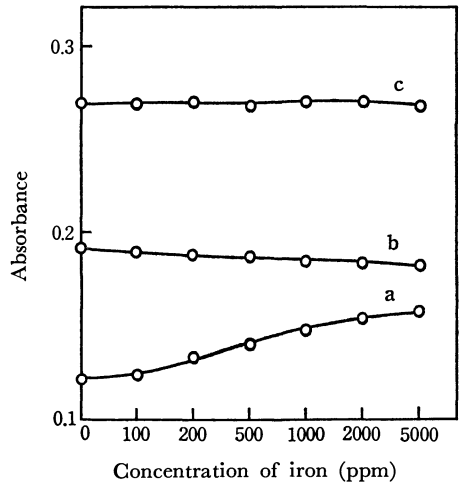

Fig. 3. Suppressing effect of aluminum and diethylene glycol monobutyl ether on the interference from iron with titanium atomic absorption.
Concentration of titanium: 100 ppm.
(a) With no addition; (b) with the addition of aluminum (5000 ppm); (c) with the addition of diethylene glycol monobutyl ether (20 vol%)

Effects of Water-miscible Organic Solvents. Atomic absorptions were measured on 100 ppm titanium solutions containing water-miscible organic solvents, such as alcohols, ketones, and glycols, at 10 vol%. The results are shown in Table 3. Among the alcohols, butyl alcohol produced the greatest enhancement, and very stable chart readings were obtained in its presence. Glycols produced greater enhancements. The greatest enhancement was produced by diethylene glycol monobutyl ether, which had previously reported to be very effective in the enhancement of vanadium absorption in a nitrous oxide-acetylene flame.[6] The effect of an increase in the concentration of diethylene glycol monobutyl ether on the titanium absorption was studied; it was found that about 20 vol% of diethylene glycol monobutyl ether increased the absorption by about 100% and that concentrations higher than 20 vol% did not produce further enhancement.

It can be seen from Table 3 that the organic solvents with higher boiling points and longer carbon chains increased the titanium absorption more, and that the absorption was contrary to the increase in the sample aspiration rate when the enhancement effect was compared in its extent among solvents of the same kinds.

Interferences from other elements with titanium

Table 3. Effect of water-miscible organic solvents on titanium absorption

Solvent	Molecular weight	Boiling point (°C)	Sample aspiration rate (ml/min)	Absorbance	Enhancement

absorption were studied in the presence of 20 vol% of diethylene glycol monobutyl ether. As in the case of a large amount of aluminum, the interferences seemed to disappear completely. Some representative results are shown in Fig. 3. This fact suggests that diethylene glycol monobutyl ether competes with other elements, as aluminum does, in suppressing the formation of titanium monoxide by providing the flame with reducing properties through the burnt gases. The difference in titanium absorbance observed between Curves b and c in Fig. 3 is probably due to the difference in the efficiencies of the nebulizing sample solutions. It seems, therefore, that diethylene glycol monobutyl ether, a representative water-miscible organic solvent, plays a dual role, *i.e.*, as an atomizing aid and a nebulizing aid, in enhancing the titanium atomic absorption.

Extraction of Titanium Complexes into Organic Solvents. Extractions were carried out with the following reagents for titanium: cupferron,[8] 8-hydroxyquinoline,[9] *N*-benzoyl-*N*-phenyl hydroxylamine,[10] morin,[11] and quinalizarin.[12] Of these, the first three proved to be applicable to the atomic absorption spectrophotometric determination of titanium. The chelates of titanium with morin and quinalizarin were not extracted into methyl isobutyl ketone, which is well known to be suitable for atomic absorption measurements. Cupferron was finally selected as the best chelating reagent. The extraction procedure for titanium cupferrate was as follows: standard solutions containing 10, 20, 30, 40, and 50 μg/ml of titanium were prepared by diluting a stock solution of titanium. A 10-ml aliquot of each standard solution was then placed in a 100-ml separatory funnel, and 40 ml of 1.2 N hydrochloric acid was added. Then 2 ml of a 5% cupferron solution was added, and the titanium cupferrate formed in the solution was extracted into 10 ml of methyl isobutyl ketone with shaking for two minutes. The organic phase which was thus separated, after dehydration with anhydrous sodium sulfate, was sprayed into the flame. The titanium absorption was measured in the nitrous oxide-acetylene flame under the optimum operating conditions described in Table 1. As is shown in Fig. 4, the most sensitive results were obtained with cupferron.

Furthermore, the extractions of titanium cupferrate were carried out with mixed organic solvents of methyl isobutyl ketone containing 25% of oleic acid, as had been done by Sachdev *et al.*[13] in the case of vanadium using an oxygen-acetylene flame created by a total-consumption nebulizer-burner. However, the effects of mixed organic solvents were not as compared with that of methyl isobutyl ketone alone by aspirating the organic extract into the nitrous oxide-acetylene flame.

Effects of Other Elements: Some elements were extracted along with titanium under the conditions described above. Their effects on titanium absorption were studied by the following procedure: a 5-ml portion of a standard solution containing 100 μg/ml of titanium and 5 ml of other metal solutions (1000 μg/ml) was diluted to 50 ml with 1.2 N hydrochloric acid. The solution was then transferred into a 100-ml separatory funnel and extracted into 10 ml of methyl isobutyl ketone after adding 2 ml of a 5% cupferron solution. The absorption measured on the organic extract was compared with that measured on an organic phase containing the titanium chelate alone. The results are shown in Table 2. With the exception of the elements which can be extracted with cupferron, essentially no interference was observed from the other

elements present at a concentration 10 times that of titanium. Iron, molybdenum, vanadium, and zirconium, which can be extracted with cupferron, showed depressing effects on the titanium absorption, but the depressing interference could be completely eliminated by successive extractions with two 10-ml portions of methyl isobutyl ketone even if the interfering element was present at a concentration 100 times that of titanium in an aqueous solution, as is shown in Fig. 5. When the concentration of interfering elements was more than 100 times that of titanium, the extraction had to be repeated three times or more. However, a large amount of these interfering elements should preferably be separated before the titanium-cupferrate extraction. Iron, for example, can be extracted as the chloro-complex from 6 N hydrochloric acid solution with methyl isobutyl ketone.

Calibration Graphs for Titanium. Calibration graphs for aqueous titanium, aqueous titanium in the presence of aluminum, butyric acid, and diethylene glycol monobutyl ether, and titanium complexes extracted into methyl isobutyl ketone are shown in Figs. 4 and 6, respectively. Sensitivities for aqueous titanium alone, for aqueous titanium in the presence of aluminum, for aqueous titanium in the presence of butyric acid, for aqueous titanium in the presence of diethylene glycol monobutyl ether, and for titanium complexes with cupferron, *N*-benzoyl-*N*-phenyl hydroxylamine, and 8-hydroxyquinoline extracted into methyl isobutyl ketone were 3.2, 2.0, 1.5, 1.4, 0.8, 1.4, and 1.8 ppm for a 1% absorption respectively.

Application to the Determination of Titanium in Ferric Oxides, Steels, and a Nickel-base Alloy. The present method was then applied to the determination of titanium in ferric oxides, steels, and a nickel-base alloy. The sample was decomposed with the smallest necessary amount of hydrochloric acid and/or nitric acid. After the addition of the amount of aluminum, butyric acid, or diethylene glycol monobutyl ether necessary to bring the final concentration to 5000 ppm, 2.0 M, or 20% respectively, the solution was diluted with distilled water. The resultant solution was sprayed into the nitrous oxide-acetylene flame, and the absorption was measured. The results are shown in Table 4. The results with the methyl-isobutyl-ketone extraction of titanium cupferrate are also shown in Table 4. In this case, iron was separated from the 6 N hydrochloric acid solution with methyl isobutyl ketone before the titanium extraction. The determination was made by referring to the corresponding calibration graphs, shown in Figures 4 and 6. As a result, it was found that the atomic absorption spectrophotometric method could be applied to the determination of titanium in ferric oxides, steels, and a nickel-base alloy with satisfactory results.

Table 4. Results of the determination of titanium in a few kinds of materials

Sample	Titanium content (%)

Formation of Zinc(II) Complexes with Several Carboxylic Acids and Their Extraction with Carbon Tetrachloride

Hiromitsu MORIYA and Tatsuya SEKINE

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received July 7, 1972)

The distribution of zinc(II) was determined between 0.1 M constant-ionic-strength media containing sodium perchlorate and/or carboxylate ions, A^-, and carbon tetrachloride containing a neutral ligand, quinonline, Q, or the dimer of the same carboxylic acid, $(HA)_2$. The distribution ratio was measured as a function of the concentration of carboxylate ions in the aqueous phase or of that of one of the above neutral ligands, in the organic phase. The extraction constant of the ZnA_2 species in the caproic acid system was found to be $K_{exA}=[ZnA_2]_{org}/[Zn^{2+}][A^-]^2=10^{-0.15}$, while that in the valeric or butyric acid system was too small to be determined. The distribution ratio of zinc(II) increased with an increase in the concentration of the ligand in the organic phase. These increases were explained by the formation of adducts in the organic phase; in the caproate system, the species found were ZnA_2Q and ZnA_2Q_2, ($\beta_{1(org)}=[ZnA_2Q]_{org}/[ZnA_2]_{org}[Q]_{org}=10^{1.92}$, $\beta_{2(org)}=[ZnA_2Q_2]_{org}/[ZnA_2]_{org}[Q]_{org}^2=10^{2.84}$) or $ZnA_2(HA)_4$ ($\beta_{2(org)}=[ZnA_2(HA)_4]_{org}/[ZnA_2]_{org}[(HA)_2]_{org}^2=10^{2.92}$). No polynuclear species was found in these organic phases when the initial zinc(II) concentration in the aqueous phase was less than 10^{-3} M.

Carboxylic acids, especially acetic acid, are widely employed as buffering agents in weakly acidic solutions because they buffer aqueous solutions at around pH 5 and they usually form only weak complexes with various metal ions.

For solvent extraction work, they are also useful buffering reagents. However, the equilibria of carboxylic acid in liquid-liquid distribution systems are rather complicated; in such systems, not only the dissociation of protons in the aqueous phase, but also the two-phase distribution of the acid and its dimerization in the organic phase, should be taken into account. The distribution and dimerization of several carboxylic acids have been studied in systems of carbon tetrachloride by the present authors[1] and in systems of benzene and various other solvents by Kojima, Yoshida, and Tanaka.[2]

The solvent extraction equilibria of metal ions with carboxylic acids are more complicated; the extracted metal species very often contain an undissociated form of the acid as well as the carboxylate anions, and in many cases, various types of polymerized metal species are also found in the organic phase, as has been reported by many authors.

The present study has been carried out in order to determine the distribution equilibria of zinc(II) in the carbon tetrachloride-aqueous system containing carboxylic acids; zinc(II) was extracted with these acids into carbon tetrachloride containing various amounts of quinoline. The results were statistically analyzed, and the equilibrium constants were evaluated. The results were considered on the basis of the present authors' previous work on the distribution equilibria of several carboxylic acids between carbon tetrachloride and the aqueous phase.[1] The extractability of this metal ion in these systems under vairous conditions was also considered.

Experimental

Reagents. The zinc-65 tracer was used throughout this study; it was obtained from the New England Nuclear Co. as a hydrochloric acid solution. In some experiments, a zinc(II) carrier which has been prepared by dissolving a reagent-grade zinc powder in perchloric acid was added. The stock solution of the tracer or of the carrier always contained 0.01 M perchloric acid. Analytical-grade butyric, valeric, and caproic acids were obtained from the Tokyo Kasei Co., the Kanto Chemical Co., or the Merck Co. (Germany). They were of a reagent grade and were distilled before use. The quinoline was obtained from the Merck Co. Carbon tetrachloride was washed three times with same volume of water before use. The other reagents were the same as those reported in previous paper.[1,3,4]

Procedures. All of the experiments were carried out in a thermostated room at 25°±0.3 °C. Five ml of carbon tetrachloride containing a carboxylic acid and, in some cases, quinoline, and 5 ml of an aqueous solution containing sodium hydroxide and sodium perchlorate (the total salt concentration was 1.0×10^{-1} M) and 10^{-3}—10^{-6} M zinc(II) (except when stated otherwise) were placed in stoppered glass tubes (volume, 20 ml); the two phases were agitated by hand or by means of a shaker until the distribution equilibrium was reached, after which the two phases were centrifuged. The distribution ratio of zinc(II) was determined from the γ-radioactivity of each phase. The details of the procedures were the same as those described in previous papers.[3,4] The distribution ratio is always defined as;

$$D=\frac{[Zn(II)]_{org.total}}{[Zn(II)]_{total}}=\frac{\gamma\text{-count-rate in 1 ml of the org. phase}}{\gamma\text{-count-rate in 1 ml of the aq. phase}}$$

Statistical

The complex formation equilibrium of zinc(II) in the aqueous phase with the anion of a carboxylic acid, HA, can be written as follows;

$$Zn^{2+}+nA^- \rightleftarrows ZnA_n^{2-n} \quad (1)$$

$$\beta_n=\frac{[ZnA_n^{2-n}]}{[Zn^{2+}][A^-]^n} \quad (2)$$

1) T. Sekine, M. Isayama, S. Yamaguchi, and H. Moriya, This Bulletin, **40**, 27 (1967).
2) I. Kojima, M. Yoshida, and M. Tanaka, *J. Inorg. Nucl. Chem.*, **32**, 987 (1970).
3) H. Moriya and T. Sekine, This Bulletin, **44**, 3347 (1971).
4) H. Moriya and T. Sekine, *ibid.*, **45**, 1626 (1972).

and the total concentration of zinc(II) in such an aqueous phase can be represented by;

$$[Zn^{2+}]_{total} = [Zn^{2+}](1 + \beta_1[A^-] + \beta_2[A^-]^2 + \cdots) \quad (3)$$

The extraction of zinc(II) as the uncharged complex with this anion into a nonpolar solvent can be represented as follows;

$$Zn^{2+} + 2A^- \rightleftarrows ZnA_2(org) \quad (4)$$

$$K_{exA} = \frac{[ZnA_2]_{org}}{[Zn^{2+}][A^-]^2} \quad (5)$$

When the extracted species, ZnA_2, can add n molecules of a neutral ligand, L, such as quinoline or dimerized acid molecule, in the organic phase, the equilibrium can be written as follows;

$$ZnA_2(org) + nL(org) \rightleftarrows ZnA_2L_n(org) \quad (6)$$

$$\beta_{n(org)} = \frac{[ZnA_2L_n]_{org}}{[ZnA_2]_{org}[L]_{org}^n} \quad (7)$$

The distribution ratio of zinc(II) in the presence of quinoline can be written as follows when the adduct formation with the dimer of the carboxylic acid is assumed to be negligible, and, furthermore, when only the first and the second quinoline adducts are formed in the organic phase, while only the first complex with the acid is formed in the aqueous phase;

$$D = \frac{[ZnA_2]_{org} + [ZnA_2Q]_{org} + [ZnA_2Q_2]_{org}}{[Zn^{2+}] + [ZnA^+]} \quad (8)$$

By introducing Eqs. (5) and (7) and the stability constant in Eq. (2), Eq. (8) can be rewritten as follows:

$$D = \frac{K_{exA}[A^-]^2(1 + \beta_{1(org)}[Q]_{org} + \beta_{2(org)}[Q]_{org}^2)}{1 + \beta_1[A^-]} \quad (9)$$

The distribution ratio of zinc(II) in the absence of quinoline can be rewritten as follows if the formation of only the first and second adducts in the organic phase, and that of only the first complex in the aqueous phase, are assumed:

$$D = \frac{[ZnA_2]_{org} + [ZnA_2(HA)_2]_{org} + [ZnA_2(HA)_4]_{org}}{[Zn^{2+}] + [ZnA^+]} \quad (10)$$

By introducing Eqs. (5) and (7), and the stability constant for the complexes in the aqueous phase, Eq. (10) can be rewritten as follows:

$$D = \frac{K_{exA}[A^-]^2(1 + \beta_{1(org)}[(HA)_2]_{org} + \beta_{2(org)}[(HA)_2]_{org}^2)}{1 + \beta_1[A^-]} \quad (11)$$

Since only the initial concentrations of the carboxylic acid and the hydroxide ion, and the equilibrium concentration of the hydrogen ion are usually obtained, the following treatments are necessary in order to calculate the other concentrations at equilibrium.

When the volumes of the two phases are the same, the following relation can be given for the total concentration of the carboxylic acid in the initial organic phase:

$$C_{HA(org)} = [A^-] + [HA] + [HA]_{org} + 2[(HA)_2]_{org} \quad (12)$$

The total concentration of the carboxylic acid in the aqueous phase can be written as follows:

$$[HA]_{total} = [A^-] + [HA] \quad (13)$$

By introducing the dissociation constant, $K_a = [H^+][A^-]/[HA]$, Eq. (13) can be written as:

$$[HA]_{total} = [A^-](1 + [H^+]/K_a) \quad (14)$$

When the sodium hydroxide concentration in the initial aqueous phase is denoted by C_{OH}, the $C_{OH} + [H^+] = [A^-] + [OH^-]$ relation is obtained; when the pH is not too high and not too low (for example, 10^{-10} M $< [H^+] < 10^{-4}$ M), this can be written as $C_{OH} = [A^-]$. The $[HA]_{total}$ value can be estimated from Eq. (14) by using this relation, the value of $[H^+]$ experimentally obtained, and the value of the dissociation constant.

The following relation is obtained from Eqs. (12) and (13):

$$[HA]_{org.total} = C_{HA(org)} - [HA]_{total} = 2[(HA)_2]_{org} + [HA]_{org} \quad (15)$$

By introducing the dimerization constant, $K_{dim(org)} = [(HA)_2]_{org}/[HA]_{org}^2$, Eq. (15) can be rewritten as:

$$[HA]_{org.total} = 2[(HA)_2]_{org} + \sqrt{[(HA)_2]_{org}/K_{dim(org)}} \quad (16)$$

However, when $[HA]_{org} \ll [(HA)_2]_{org}$ as under the conditions employed in this study (this will be discussed later), the following relation is obtained from Eq. (15):

$$[(HA)_2]_{org} = \frac{1}{2}[HA]_{org.total} \quad (17)$$

The experimental data of D at a given value of $[A^-]$, determined as a function of $[Q]_{org}$ or as a function of $[(HA)_2]_{org}$, can be transformed to the following equation:

$$\log y = \log c_0(1 + c_1x + c_2x^2) \quad (18)$$

The c_0, c_1, and c_2 constants can be obtained from the plot of the experimental data by a curve-fitting method, as has already been demonstrated.[3,4] The equilibrium constants in Eqs. (5) and (7) can be obtained from these values of c_0, c_1, and c_2.

Results

The experimental results were reproducible, and the recovery of zinc(II) from the two phases was quantitative within the limit of experimental accuracy.

It was found in another work of the present authors[5] that only the first zinc(II) complex is formed with the carboxylic acid in a 0.1 M sodium perchlorate constant ionic medium at 25 °C; the values for $\beta_1 = [ZnA^+]/[Zn^{2+}][A^-]$ are $10^{1.10}$(butyrate), $10^{1.10}$(valerate) and $10^{1.10}$(caproate). These values were used for the analysis of the experimental data of the present work.

The following equation can be written on the basis of the electrical neutrality:

$$[Na^+] + [H^+] + 2[Zn^{2+}] + [ZnA^+] = [OH^-] + [ClO_4^-]$$

Since the concentration of zinc(II) was very low (less than 10^{-5} M), the hydrogen-ion concentrations was in the range of 10^{-5} M $> [H^+] > 10^{-9}$ M (and thus $[H^+] \ll 0.1$ M and $[OH^-] \ll 0.1$ M), and the initial aqueous phase was a mixture of 0.1 M sodium

5) H. Moriya and T. Sekine, to be published.

perchlorate and 0.1 M sodium hydroxide at various mixing ratios, the following relation can be introduced:

$$0.1 \simeq C_{OH} + [ClO_4^-] = [A^-] + [CO_4^-]$$

The term of the concentration of the undissociated acid in the aqueous phase, [HA], can be regarded as negligible in the statistical analysis of the results of experiments with quinoline because the K_a values for these acids are about 10^{-5}(in 0.1 M sodium perchlorate at 25 °C, they are 1.51×10^{-5}(butyric acid), 1.41×10^{-5} (valeric acid) and 1.45×10^{-5}(caproic acid)),[2] it can be assumed that $[A^-]\gg[HA]$ when $-\log[H^+]$ is higher than 7 (in Figs. 1 and 2). For the experiments in the absence of quinoline, the $[H^+]$ values ranges from $10^{-5.5}$ to $10^{-6.5}$; thus, the [HA] term can not be neglected. This value was calculated from $[H^+]$, which was determined by potentiometry, $[A^-]$ (which is equal to C_{OH}), and K_a.

Extraction in the Presence of Quinoline. The distribution ratio of zinc(II) in an aqueous phase at a given $[A^-]$ is enhanced by the addition of quinoline to the organic phase. Since the distribution constant of quinoline is not small (77 between carbon tetrachloride and 3 M sodium perchlorate[6]), the $[Q]_{org\cdot initial}=[Q]_{org}$ relation can be assumed. Figure 1 shows the change in the distribution ratio with the change in the quinoline concentration when $[A^-]$ is 1.0×10^{-1} M and when the total concentration of carboxylic acid in the organic phase at equilibrium is less than 10^{-2} M. Figure 2 shows the dependence of

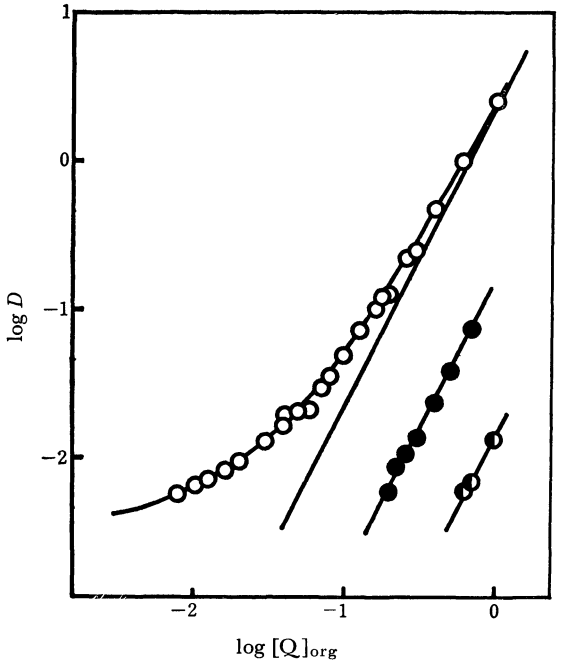

Fig. 1. Extraction as a function of quinoline concentration when the aqueous phase initially contains 1.0×10^{-1} M of caproate (○), valerate (●) and butyrate (◑) anion. The solid curve for caproate represents; $\log D=\log K_{exA}[A^-]^2(1+\beta_1[A^-])^{-1}(1+\beta_{1(org)}[Q]_{org}+\beta_{2(org)}[Q]_{org}^2)$ and the straight lines for these three acids represent; $\log D=\log K_{exA}[A^-]^2(1+\beta_1[A^-])^{-1}\beta_{2(org)}[Q]_{org}^2$. These constants are listed in Table 1.

6) P. Antikainen and D. Dyrssen, *Acta Chem. Scand.*, **14**, 86 (1960).

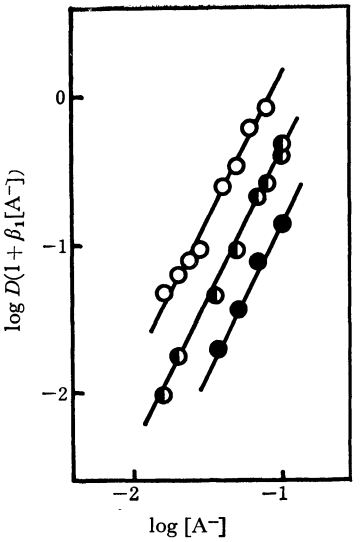

Fig. 2. Extraction as a function of the concentration of the caproate ion in the aqueous phase when the quinoline concentration in the organic phase is 0.5 M (○), 0.25 M (◐) and 0.1 M (●), the straight lines represent; $\log D(1+\beta_1[A^-])=\log K_{exA}[A^-]^2(1+\beta_{1(org)}[Q]_{org}+\beta_{2(org)}[Q]_{org}^2)$. These constants are listed in Table 1.

the distribution ratio on the concentration of the caproate anion in the aqueous phase when the organic phase contains less than 10^{-2} M of the carboxylic acid and a certain amount of quinoline (0.1 M, 0.25 M or 0.5 M). In this figure, the effect of the carboxylate complex in the aqueous phase has been corrected by plotting $\log D(1+\beta_1[A^-])$ instead of $\log D$ (*cf.* Eq. 9). As may be seen from Fig. 2, the extraction is proportional to the square of $[A^-]$; thus, it can be concluded that the metal species in these organic phases contains at least two carboxylate anions. Furthermore, as will be seen later, no adduct of zinc(II) caproate with the dimer of the acid is formed under these conditions, the distribution ratio can well be represented by Eqs. (8) and (9). Since the extraction with butyric and valeric acid is very poor in the absence of quinoline, the K_{exA} value in Eq. (5) for these extractions could not be determined and the distribution ratio could be given for these systems by the equation:

$$D=\frac{K_{exA}\beta_{2(org)}[A^-]^2[Q]_{org}^2}{1+\beta_1[A^-]} \qquad (19)$$

On the other hand, the distribution ratio in the caproate system in the absence of quinoline was $10^{-2.50}$ when $[A^-]$ is 0.1 M; it was enhanced by the increase in the quinoline concentration. Hence, the data can be concluded to be well represented by Eq. (9).

The constants for the butyrate and valerate systems were determined directly from the data in Fig. 1, but those for the caproate were determined by the curve-fitting. The constants are listed in Table 1.

Extraction in the Absence of Quinoline. The extraction of zinc(II) in the absence of quinoline was further studied by changing $[A^-]$, $[HA]_{org.total}$, or the total zinc(II) concentration.

Since the distribution and dimerization constants are knwon for butyric acid,[1] but are not known for valeric and caproic acids in carbon tetrachloride sys-

Table 1. Equilibrium constants for zinc(II) extraction with carboxylic acids (HA) in the presence and absence of quinoline at 25 °C

Org. phase: CCl_4

Aq. phase: 0.1 M $Na(A^-, ClO_4)$

[a] $K_{exA}=[ZnA_2]_{org}/[Zn^{2+}][A^-]^2=10^{-0.15}$ (for caproate ion)

caproic	2.77	2.92
valeric	1.20	—

a) The distribution ratio of zinc(II) between CCl_4 containing a very small amount of caproic acid and an aqueous phase containing 0.1 M caproate ion is $10^{-2.50}$.

b) The formation of the first adduct $ZnA_2(HA)_2$ is negligible.

tems, the concentrations of the monomer and of the dimer of these acids in the organic phase were treated as follows.

The dimerization constants for acetic, propionic, and butyric acids in carbon tetrachloride are 5.92×10^2, 9.40×10^2, and 2.91×10^3,[1] respectively. From these facts, it can reasonably be assumed that the dimerization constants for valeric and caproic acid are large; it should not be unreasonable to asume that the dimerization constants for these acids are higher than 3×10^3. From this assumption and Eq. (16), we find that even when $[HA]_{org.total}$ is only 5×10^{-2} M, less than 5% of the acid in the organic phase exists in the form of the monomer, and since the total concentration of the acid in the organic phase in the following experiments is always higher than 5×10^{-2} M, all the acid in the organic phase can be regarded as existing in the form of a dimer, —in other words, Eq. (17) can be used for these experimental results.

Figure 3 shows the change in the distribution ratio when the concentration of the anions, $[A^-]$, is kept at 9.6×10^{-2} M, but when the concentration of the dimer of the acid changes and when quinoline is absent. Figure 4 gives the dependence of the extraction on the concentration of the carboxylate anions in the aqueous phase. Since the total concentration, $[HA]_{org.total}$, is high (2M), it can be assumed as will be described later, that only the second adduct exists in the organic phase. In order to make a correction for the small change in the $[(HA)_2]_{org}$ and for the change in the complex formation in the aqueous phase, $\log D(1+\beta_1[A^-])[(HA)_2]_{org}^{-2}$ is plotted in this figure instead of $\log D$. As may be seen from Fig. 4, the extraction is proportional to the square of $[A^-]$; thus, it was concluded that the metal species in these organic phases also contains two carboxylate anions.

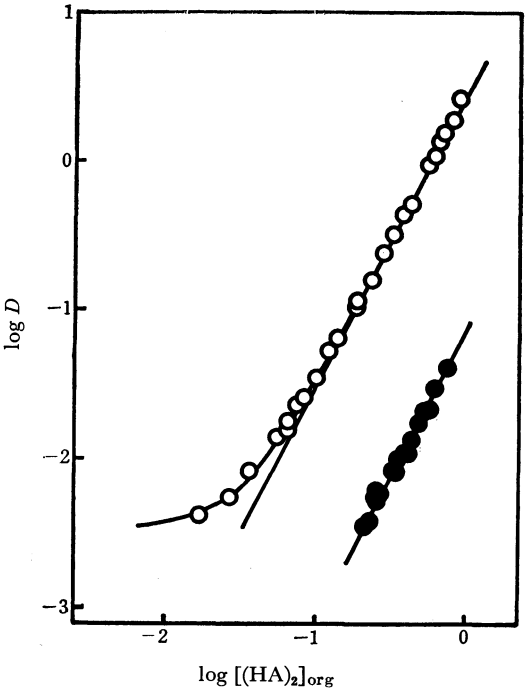

Fig. 3. Extraction in the absence of the quinoline as a function of the concentration of dimer of caproic acid (○) and valeric acid (●) in the organic phase when the concentration of $[A^-]$ is kept at 9.6×10^{-2} M. The solid curve for caproic acid represents; $\log D=\log K_{exA}[A^-]^2(1+\beta_1[A^-])^{-1}(1+\beta_{2(org)}[(HA)_2]_{org}^2)$ and the straight lines for the two acids; $\log D=\log K_{exA}[A^-]^2(1+\beta_1[A^-])^{-1}\beta_{2(org)}[(HA)_2]_{org}^2$.
These constants are listed in Table 1.

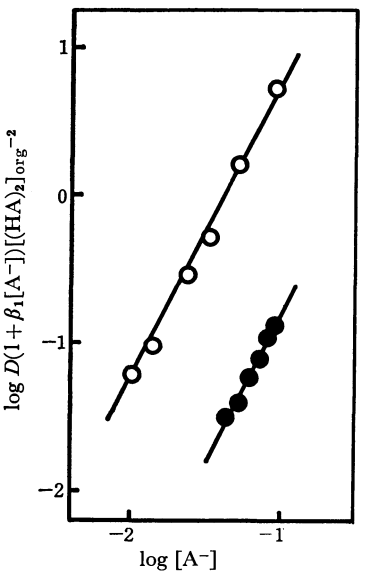

Fig. 4. Extraction in the absence of quinoline as a function of the concentration of caproate ion (○) and valerate ion (●) in the aqueous phase, the straight lines for the two acids; $\log D(1+\beta_1[A^-])[(HA)_2]_{org}^{-2}=\log K_{exA}[A^-]^2\beta_{2(org)}$.
These constants are listed in Table 1.

As may be seen from Fig. 3, the distribution ratio in the higher-acid-concentration region is proportional to the square of $[(HA)_2]_{org}$. This fact indicates that the zinc(II) species in the organic phase of this region

is $ZnA_2(HA)_4$. Furthermore, since the increase in the distribution ratio is very abrupt, we assumed that the first adduct was not formed. This was confirmed by the fact that the extraction curve can be well fitted with the standard-curve $Y=\log(1+v^2)$; $X=\log v$. The equilibrium constants obtained by the curve-fitting are also given in Table 1.

Since extractions of polynuclear species have very often been observed in systems containing carboxylic acid, the effect of the total metal concentration of zinc(II) on the distribution ratio was determined. It was found that when the acid is caproic, when $[HA]_{org,total}$ is 0.9 M, and when $[A^-]$ is 0.1 M, the distribution ratio of zinc(II) is constant in the range of $[Zn^{2+}]_{initial}$, 10^{-3}—10^{-6} M. Thus there was no extraction of polynuclear species within this range of metal concentrations.

Discussion

The chemical equilibria of metal extraction with carboxylic acids are generally very complicated because the distribution equilibria of the carboxylic acid are complicated as a result of dimerization in the organic phase and the extraction of polynuclear species combining various numbers of the dimer of the acid molecules. However, as has been described above, the chemical equilibria in the systems studied in this paper could be treated much more easily than those systems previously reported.

This is because of the following reasons: (i) The extraction of the ZnA_2 species could be determined separately. This was possible because the extraction could be carried out when $[A^-]$ was relatively high and $[HA]_{org,total}$ was small; in order to achieve this condition, the pH of the solution must be high (for example, when $[A^-]$ is 0.1 M and when $[HA]_{org,total}$ is less than 10^{-2} M, $[H^+]$ should be $10^{-6.5}$ M). Many other metal ions undergo hydrolysis at such high pH values, and thus the equilibria become very complicated. However, the hydrolysis of zinc(II) at this pH is fortunately negligible provided the metal concentration is very low.[7] (ii) It was possible to assume that all the acid in the organic phase can be regarded as existing as the dimers, judging from the results of Ref. 1. The dimerization constant in carbon tetrachloride is much larger than that, for example, in benzene; thus, the above assumptions are possible in the former solvent under the conditions employed. (iii) The fact that $C_{OH}\simeq[A^-]$ could be reasonably assumed under the conditions employed also simplified the analysis.

There have been several reports on the extraction of zinc(II) with carboxylic acids.[8–11] Among these, Schweizer and Clifford have made a systematic analysis of their extraction date and have concluded that the distribution ratio of zinc(II) increased (i) upon an increase in the molecular weight of the acid, (ii) upon an increase in the concentration of the acid, (iii) upon an increase in the concentration of 1-aminobutane added to the system, and (iv) upon a decrease in the hydrogen-ion concentration, but that the distribution ratio is independent of the metal concentration. These observations agree qualitatively with the present results. However, their interpretation of the results is different from that by the present authors, although the solvent of the present study is different from that employed in the previous work.[11] It seems difficult to explain why the conclusion in that work[11] is different from that of the present work. However, some oversimplified assumptions, such as that there is no formation of the zinc(II) carboxylate complex in the aqueous phase, might be one of the reasons.

Among the systems studied in the comprehensive series of papers on metal extraction with carboxylic acid carried out by Tanaka and his co-workers,[12–18] only lead(II)[18] was found to be extractable as a monomeric species over a wide range of metal concentrations. The extraction of zinc(II) is similar to that of lead(II) although only the $MA_2(HA)_4$ species was found to be extracted in addition to the MA_2 species. The extraction of the MA_2 species has not been found for the metal ions studied by the above workers.

As long as we are concerned only with the data obtained by distribution experiments, no information about the structure of the extracted metal species can be obtained. Thus, we do not know the nature of the bonds between the ZnA_2 species and the quinoline or the carboxylic acid in the organic phase. It is very remarkable that the stability constants for the second adduct, $\beta_{2(org)}$, with quinoline and carboxylic acid dimer are similar to each other.

The authors are grateful to Mr. Naohiko Ihara and and Mr. Yoshihiro Takahashi of the present laboratory for their experimental aid. Part of this work has been carried out in the Laboratory of Analytical and Nuclear Chemistry, Institute of Physical and Chemical Research. The authors are grateful to Professor Nobufusa Saito, the head of that laboratory.

A Study of Silver(I) Complexes with Some π-Donors and n-Donors in Chloroform by the Solvent Extraction Method

Tatsuya SEKINE and Yoshihiro TAKAHASHI

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received July 17, 1972)

The solvent extraction of silver(I) in a 0.1 M constant-ionic-strength solution into chloroform with 2-thenoyltrifluoroacetone(TTA) and with caproic acid was studied by means of radiometry. It was found that these extractions are enhanced by the addition of aliphatic and cyclic alkenes, of aromatic hydrocarbons, and of some n-donors. The enhancement of the extraction was explained in terms of the formation of molecular complexes of the silver(I)-TTA chelate or of silver(I) caproate in chloroform. By an analysis of the experimental data, the stability constant of the silver(I)-TTA chelate in the aqueous phase, and the stability constants of the molecular complexes in the chloroform phase with these donors, were determined. Some consideration was made of these results and of the possibility of the application of these extraction systems to analytical chemistry.

Many workers have reported the complex formation of silver(I) with various n-donor ligands, and the stability constants have been determined by various experimental techniques.[1] At the same time, some workers have also reported that silver(I) can form complexes with π-donor ligands, such as unsaturated aliphatic or aromatic hydrocarbons.[2,3]

The complex formation equilibria of silver(I) with n-donor ligands have been determined, in most cases, in aqueous solutions because the complexes with n-donors which are usually anionic have often been of interest to analytical and inorganic chemists from the standpoint of the chemical behavior of silver(I) in aqueous solutions. The π-donors are, on the other hand, usually uncharged, and they are often relatively insoluble in water. However, the complex formation of silver(I) with these ligands has also been determined in aqueous solutions or mixed solutions of water and polar organic solvents, because silver(I) salts with ordinary inorganic anions are insoluble in nonpolar organic solvents.

The formation of various other molecular complexes, however, has been studied very often in nonpolar organic solvents such as carbon tetrachloride,[2,3] in many cases, the formation constants of molecular complexes seem to be affected by the nature of the solvent—they are usually larger in organic solvents than in water.[2] This could be due to a great interaction of water molecules with various ionic or molecular substances; the comparison of the formation constants of a given complex in water and in other kinds of solvents should give some information about that complex.

The present study has been undertaken from this standpoint. The present authors have determined the complex formation of silver(I) extracted from aqueous solutions into chloroform as a chelate complex with thenoyltrifluoroacetone(TTA) or as a complex with caproic acid. Thenoyltrifluoroacetone and caproic acid were used in order to make silver(I) extractable into the organic solvent, and the complex formation was determined from the enhancement of the extraction due to the formation of molecular complexes in the organic phase. The stability constants thus obtained were compared with those determined in aqueous solutions, the results obtained in these different solvents were discussed. The effect of the formation of these molecular complexes on the solvent extraction of silver(I) with the chelating reagent or with the fatty acid was considered, and the possibility of the application of such extractions to analytical chemistry was discussed.

Experimental

Reagents. The silver-110 m tracer was obtained from the New England Nuclear Corp. U. S. A., as silver nitrate in a dilute nitric acid solution. It was diluted with 0.1 M nitric acid and used as the stock tracer solution. The quinoline and caproic acid were obtained from the Merck Co. Germany. The tributyl phosphate (TBP) and unsaturated hydrocarbons were obtained from Tokyo Kasei Co., and the TTA and trioctylphosphine oxide (TOPO), from Dojindo Co. All of the reagents were of a reagent-grade. TBP was washed with 0.1 M perchloric acid, water, and 0.1 M sodium hydroxide, and then several times with water. Chloroform was washed three times with water just before use. The other reagents were used without further purification. The concentration of the sodium hydroxide solution was determined by means of acid titration, and the concentrations of the other solutions were determined by means of gravimetry.

Procedures. All of the procedures were carried out in a thermostatted room at 25 °C. Stoppered glass tubes (volume, 20 ml) were used to equilibrate the two phases. For the experiments on the silver(I)-TTA chelate, sodium perchlorate solutions containing sodium hydroxide and a chloroform solution of TTA were placed in the tubes. After the two phases has been equilibrated by shaking them for one minute by hand, a certain amount of a silver(I) solution labelled by silver-110 m was added; the two phases were then again agitated by hand for three minutes and centrifuged. For the experiments on the silver(I) caproate complex, aqueous solutions containing sodium perchlorate and/or sodium caproate, and chloroform were placed in the tubes and the labelled silver(I) was added. The two phases were agitated for three minutes by hand and then centrifuged. The initial volumes of the two phases were always 5.0 ml, and

3) G. Briegleb, "Elektronen-Donator-Acceptor-Komplexe", Springer, Berlin (1961).

the inoic strength of the aqueous phase was 0.1 M. The initial concentration of the silver(I) ion in the aqueous phase was 2×10^{-5} to 3×10^{-6} M. The concentration of TTA in the organic phase was 0.1 M. The concentration of caproate ions in the aqueous phase was 0.1 M unless otherwise stated. The pH of the aqueous phase at equilibrium was in a range from 7 to 8 in both cases.

A 2 ml portion was pipetted out from each equilibrated phase and transferred into a test tube. The γ-radioactivity was measured with a well-type(NaI) scintillation counter, and the distribution of silver(I) was calculated as follows;

$$D=\frac{[\mathrm{Ag(I)}]_{\mathrm{org,total}}}{[\mathrm{Ag(I)}]_{\mathrm{total}}}=\frac{\gamma\text{-count-rate per ml of the organic phase}}{\gamma\text{-count-rate per ml of the aqueous phase}}$$

Statistical

The extraction of silver(I) in an aqueous solution with an organophilic and acidic extracting reagent, HA, can be written as follows:

$$\mathrm{Ag^+ + HA(org) \rightleftarrows AgA(org) + H^+} \quad (1)$$

$$K_{\mathrm{ex}}=\frac{[\mathrm{AgA}]_{\mathrm{org}}[\mathrm{H^+}]}{[\mathrm{Ag^+}][\mathrm{HA}]_{\mathrm{org}}} \quad (2)$$

When the organic phase initially contains C_{HA}M of the extractant and when the volumes of the two phases are the same, the following equation can be used:

$$C_{\mathrm{HA}}=[\mathrm{HA}]_{\mathrm{org}}+[\mathrm{HA}]+[\mathrm{A^-}] \quad (3)$$

However, if the aqueous phase initially contains C_{OH}M of sodium hydroxide (which is smaller than C_{HA}M) and if the pH is not very high (that is, $[\mathrm{OH^-}]\ll 1$), the following equation can be used:

$$C_{\mathrm{OH}}\simeq[\mathrm{A^-}] \quad (4)$$

Thus, under such conditions, the concentration of the dissociated extractant anion, $[\mathrm{A^-}]$, in Eq. (4) can be calculated from the amount of sodium hydroxide added to the initial aqueous phase, regardless of the total concentration of the extractant in the system.

The distribution ratio of silver(I) into an inert solvent such as chloroform can be described as:

$$D=\frac{[\mathrm{Ag(I)}]_{\mathrm{org,total}}}{[\mathrm{Ag(I)}]_{\mathrm{total}}} \quad (5)$$

$$=\frac{[\mathrm{AgA}]_{\mathrm{org}}}{[\mathrm{Ag^+}]+[\mathrm{AgA}]+\cdots}=\frac{K_{\mathrm{dm}}\beta_1[\mathrm{A^-}]}{1+\beta_1[\mathrm{A^-}]+\cdots} \quad (6)$$

where β_1 is the stability constant of the silver(I) complex with the extractant in the aqueous phase and where K_{dm} is the distribution constant of the uncharged chelate between the two phases:

$$K_{\mathrm{dm}}=\frac{[\mathrm{AgA}]_{\mathrm{org}}}{[\mathrm{AgA}]} \quad (7)$$

From the acid dissociation constant and the distribution constant of HA, that is, $K_{\mathrm{a}}=[\mathrm{A^-}][\mathrm{H^+}]/[\mathrm{HA}]$ and $K_{\mathrm{d}}=[\mathrm{HA}]_{\mathrm{org}}/[\mathrm{HA}]$, we obtain:

$$[\mathrm{A^-}]=\frac{K_{\mathrm{a}}[\mathrm{HA}]_{\mathrm{org}}}{K_{\mathrm{d}}[\mathrm{H^+}]} \quad (8)$$

When no aqueous complex with $\mathrm{A^-}$ is formed, the following equation is obtained from Eqs. (6) and (8):

$$D=K_{\mathrm{dm}}\beta_1[\mathrm{A^-}]=K_{\mathrm{dm}}\beta_1K_{\mathrm{a}}K_{\mathrm{d}}^{-1}[\mathrm{HA}]_{\mathrm{org}}[\mathrm{H^+}]^{-1} \quad (9)$$

From Eqs. (2) and (9), we obtain:

$$K_{\mathrm{ex}}=K_{\mathrm{dm}}\beta_1K_{\mathrm{a}}K_{\mathrm{d}}^{-1} \quad (10)$$

When the metal complex forms molecular complexes with a neutral ligand, L, in the organic phase, the equilibrium can be written as:

$$\mathrm{AgA(org)} + n\mathrm{L(org)} \rightleftarrows \mathrm{AgAL}_n\mathrm{(org)} \quad (11)$$

$$\beta_n\mathrm{(org)}=\frac{[\mathrm{AgAL}_n]_{\mathrm{org}}}{[\mathrm{AgA}]_{\mathrm{org}}[\mathrm{L}]_{\mathrm{org}}^{\,n}} \quad (12)$$

where $\beta_{n(\mathrm{org})}$ is the over-all stability constant of the "n-th" molecular complex in the organic phase.

The distribution ratio in such a system can be written as:

$$D=\frac{[\mathrm{AgA}]_{\mathrm{org}}+[\mathrm{AgAL}]_{\mathrm{org}}+[\mathrm{AgAL_2}]_{\mathrm{org}}+\cdots}{[\mathrm{Ag^+}]+[\mathrm{AgA}]+\cdots} \quad (13)$$

From Eqs. (6), (12), and (13), the following equation is obtained:

$$D=\frac{K_{\mathrm{dm}}\beta_1[\mathrm{A^-}]}{1+\beta_1[\mathrm{A^-}]+\cdots}\times(1+\beta_{1(\mathrm{org})}[\mathrm{L}]_{\mathrm{org}}+\beta_{2(\mathrm{org})}[\mathrm{L}]_{\mathrm{org}}^{\,2}+\cdots) \quad (14)$$

If the concentration, $[\mathrm{L}]_{\mathrm{org}}$, is kept at a constant value, $\mathrm{L_1}$, Eq. (14) can be written as:

$$D=C_{\mathrm{L}}\times\frac{K_{\mathrm{dm}}\beta_1[\mathrm{A^-}]}{1+\beta_1[\mathrm{A^-}]+\cdots} \quad (15)$$

where C_{L} is a constant which is equal to $(1+\beta_{1(\mathrm{org})}\mathrm{L_1}+\beta_{2(\mathrm{org})}\mathrm{L_1}^2+\cdots)$

If the concentration, $[\mathrm{A^-}]$, is kept at a constant value, $\mathrm{A_1}$, the following equation can be obtained from Eqs. (6) and (14):

$$D/D_{\mathrm{A}}=(1+\beta_{1(\mathrm{org})}[\mathrm{L}]_{\mathrm{org}}+\beta_{2(\mathrm{org})}[\mathrm{L}]_{\mathrm{org}}^{\,2}+\cdots) \quad (16)$$

where D_{A} is a constant which is equal to $K_{\mathrm{dm}}\beta_1\mathrm{A_1}(1+\beta_1\mathrm{A_1}+\cdots)^{-1}$ in such a case.

The stability constants, β_n and $\beta_{n(\mathrm{org})}$, and the distributation constant, K_{dm}, can be determined from the experimental results by a curve-fitting method.[4]

If only the first complex is formed in the aqueous phase, the log D *vs.* log $[\mathrm{A^-}]$ plot of the data represented by Eq. (15) can be fitted with the standard curve represented by Eq. (17), while if only the first complex is formed in the organic phase, the log D/D_{A} *vs.* log $[\mathrm{L}]_{\mathrm{org}}$ plot of the data represented by Eq. (16) can be fitted with the standard curve represented by Eq. (18):

$$Y=-\log(1+v^{-1});\ X=\log v \quad (17)$$

$$Y=\log(1+v);\ X=\log v \quad (18)$$

If both the first and second complexes are formed in the organic phase, the plot can be fitted with the following family of standard curves:

$$Y=\log(1+pv+v^2);\ X=\log v \quad (19)$$

The equilibrium constants can be obtained from the parameters of the fitted curve.

Results

TTA Extraction. The extraction of silver(I) with TTA in chloroform is poor. The open circles in Fig. 1 gives the distribution ratio of silver(I) between chloroform and the aqueous phase as a function of the concentration of the TTA anion. The extraction is less than 10 percent even when the aqueous phase contains nearly 0.1 M TTA anions.

This extraction is enhanced very much if a molecular complex-forming ligand is added to the chloroform phase. Figure 1 also gives the extraction curves when the chloroform phase contains 5×10^{-1} M toluene, 1×10^{-2} M cyclohexene, or 1×10^{-3} M quinoline. It also gives the extraction curve of silver(I) with TTA in benzene. As may be seen from Fig. 1, each plot has two asymptotes, with slopes of +1 and 0. This fact indicates that the data can be represented by Eq. (15). The equilibrium constants obtained by the curve-fitting method are listed in Table 1.

Figures 2 to 6 show the enhancement of the extraction of the silver(I)-TTA chelate by an addition

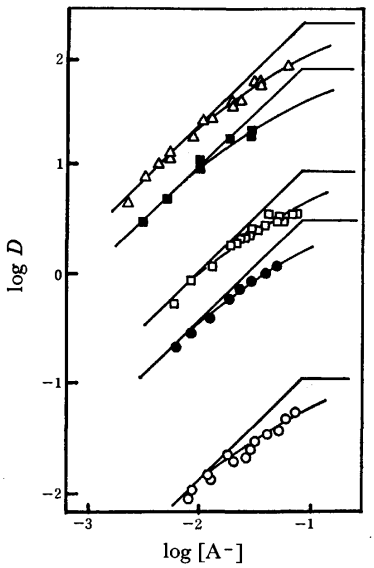

Fig. 1. Distribution ratio of Ag(I) as a function of the concentration of TTA anion. Org. phase: ○: $CHCl_3$, ●: $CHCl_3$ containing 5×10^{-1} M toluene, □: $CHCl_3$ containing 1×10^{-2} M cyclohexene, ■: benzene, △: $CHCl_3$ containing 1×10^{-3} M quinoline.

TABLE 1. EQUILIBRIUM CONSTANTS OBTAINED FROM Fig. 1

Organic solvent	$\log\beta_1$[a]	$\log K_{dm}'$[b]	$\log K_{ex}'$[c]
$CHCl_3$	1.10	−0.96	−7.94
$CHCl_3$ containing 5×10^{-1} M toluene	1.10	0.50	−6.48
$CHCl_3$ containing 1×10^{-2} M cyclohexene	1.10	0.94	−6.04
$CHCl_3$ containing 1×10^{-3} M quinoline	1.10	2.30	−4.68
C_6H_6	1.10	1.95	−4.78

a) $\beta_1=[AgA]/[Ag^+][A^-]$ in the aqueous phase where A^- is the dissociated TTA anion.
b) $K_{dm}'=K_{dm}C_L$ (K_{dm}, *cf.* Eq. (7) and C_L, *cf.* Eq. (15)).
c) $K_{ex}'=K_{ex}C_L$ (K_{ex}, *cf.* Eqs. (2) and (10) and C_L, *cf.* Eq. (15)).
These values are calculated from the values of K_{dm}' by using the following constants for TTA: $pK_a=6.23$, $\mu=0.1$[6] and $K_d=71$[5] ($CHCl_3$–0.1 M $NaClO_4$), $K_d=40$ (C_6H_6–0.1 M $NaClO_4$).[17]

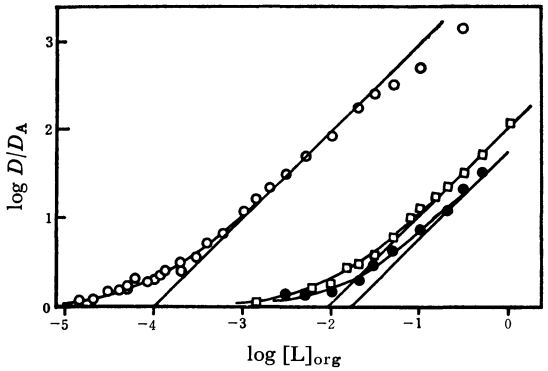

Fig. 5. Enhancement of Ag(I)-TTA extraction by an addition of one of the two ligands into $CHCl_3$. ○: 1-pentene, ●: *p*-xylene. Enhancement of Ag(I) caproate extraction by an addition of cyclohexene (□) into $CHCl_3$ is also shown.

of the molecular complex-forming ligand to the chloroform phase. By the curve-fitting, it was concluded that both the first and second complexes are formed with *o*-xylene, mesitylene, and TOPO, while only the first complex is formed with the other ligands. The stability constants of these complexes were determined from the parameters of the fitted standard curve; they are given in Table 2. Table 2 also lists the literature stability constants of silver(I) complexes with these ligands in an aqueous solution.

Caproate Extraction. The extraction of silver(I) with the caproate ion into chloroform is also poor. The distribution ratio was found to be only $10^{-2.29}$ even when the concentration of the caproate ion is

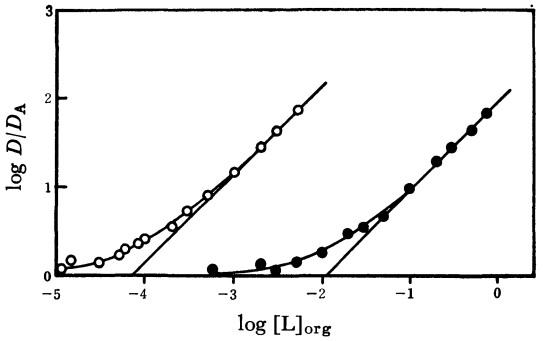

Fig. 6. Enhancement of Ag(I)-TTA extraction by an addition of one of the two ligands into $CHCl_3$. ○: 1-heptene, ●: *m*-xylene.

0.1 M.[12] This extraction is also enhanced by the addition of 1-hexene, cyclohexene, or TOPO. Figures 2, 3, and 5 also show the enhancement of the silver(I) caproate extraction caused by these ligands. The data were analyzed by the curve-fitting method. The constants thus obtained are also listed in Table 2.

Discussion

The results in Fig. 1 and Table 1 show that the stability of the silver(I) complex with the TTA anion in the aqueous phase is rather small and that the distribution constant of the silver(I)-TTA chelate between chloroform and the aqueous phase is very small. It is known that β-diketones are not effective extractants for silver(I) (see, for example, Ref. 13). This seems

to be because of this small distribution constants of of the silver(I) chelate. Since this distribution constant of the silver(I)-TTA chelate is much lower than that of the acid-form TTA (the distribution constant of TTA between chloroform and a 0.1 M sodium perchlorate solution has been reported to be 71[5]), it is assumed that the silver(I) ion in the TTA chelate interacts with water molecules in the aqueous phase rather strongly.

The results in Table 2 can be summarized as follows: (i) In all cases, the molecular complexes of silver(I) combined with the thenoyltrifluoroacetonate ion in chloroform are more stable than those with the caproate ion in chloroform and those of the silver(I) ion in aqueous solutions. (ii) The stabilities of the molecular complexes of the silver(I) TTA chelate with the three unsaturated aliphatic hydrocarbons and with cyclohexene are similar to one another. (iii) The stabilities of the molecular complexes with the aromatic hydrocarbons increase as the number of the methyl group increases. Among the three xylenes, the stability becomes larger in this order: ortho-, meta-, and para-xylene. On the other hand, the stability constants of the molecular complexes of Ag^+ in an aqueous solution with these ligands are not very different. (iv) The three n-donors also form stable molecular complexes. TOPO forms more stable complexes than does TBP, and quinoline forms the most stable first complex. (v) The stabilities of the molecular complexes of silver(I)-caproate with cyclohexene are similar to that of the silver(I) cyclohexene complex in an aqueous solution, but the molecular complex with 1-hexene in chloroform is somewhat less stable than the corresponding complex in the aqueous phase.

Although no information has been obtained about the structure of the complexes from only these distribution data, there is no doubt that TOPO, TBP, and quinoline form complexes through the lone-pair electrons on the oxygen or nitrogen atom, whereas the unsaturated hydrocarbons form complexes with the π-electrons.

It is remarkable that these donors form more stable complexes with the silver(I)-TTA chelate in chloroform than with the silver(I) ion in aqueous solutions. In the chloroform phase, the silver(I) in the TTA chelate is probably combined with the TTA anion through the lone-pair electrons on the two oxygens in the anion. At the same time, it is possible that both the complex and the ligand in the chloroform phase are combined with some molecules of water. In an aqueous solution, the silver(I) ion is probably hydrated with several water molecules; the ligands may also interact with some water molecules. The complex formation and the interaction of the silver atom and of the ligand with other molecules probably interfere with the formation of the molecular complexes to some extent. The stability constants are affected by many factors; thus, it seems to be very difficult to estimate the contributions of the interactions of TTA or of water molecules on the silver(I) or on the ligands. However, since the stability constants of the molecular complexes in the chloroform phase are much higher, even though the silver(I) is coordinated with TTA, the effect of the interactions with water molecules is probably very large.

In the present study, chloroform was employed as the organic solvent. However, as has been pointed out on the basis of various pieces of evidence, this solvent interacts with these molecular complex-forming ligands and probably also with the silver(I)-TTA chelate more strongly than do many other inert solvents, such as saturated hydrocarbons or carbon tetrachloride, and the stabilities of various molecular complexes in this solvent are usually lower than in the above other inert solvents. For example, in the adduct formation of various metal chelates with organophilic neutral ligands in solvent extraction systems, the stabilities of the molecular complexes are larger in carbon tetrachloride than in chloroform.[14] Thus, the stabilities of the molecular complexes studied in the present paper may also be larger in other non-polar solvents. It has also been reported that the stability of the molecular complexes of Ag^+ with alkenes is much lower in ethylene glycol than in water.[2] This can not be compared with the present results, however, because this alcohol may also interact with the silver(I) and with the donors.

It may be reasonable to assume that the length of the hydrocarbon chain does not have any significant effect on the stabilities of the molecular complexes with the 1-alkenes, as can be seen in the cases of many ther chemical properties. At the same time, it may also be reasonable to assume that the stabilities of the molecular complexes increase in the order of the increase in the density of the π-electrons in the aromatic ring; a similar order of the stabilities was pointed out among the complexes between Ag^+ and substituted benzenes in an equivalent molar mixture of water and methyl alcohol.[15] There seems to be no reasonable explanation of why this tendency of the stability of the molecular complexes does not appear in the complexes of Ag^+ with the same ligands in water (*cf.* Table 2).

The molecular complexes of various metal chelates, especially of TTA chelates, with these three n-donors have been determined from the enhancement of the metal-chelate extraction in solvent extraction systems, which is called "synergism".[14] It is known that TOPO forms more stable adducts than does TBP. However, it was found that quinoline forms a less stable adduct with europium(III)-TTA chelates in chloroform than does TOPO or TBP;[16] this seems to indicate that the stability order of adducts with ligands coordinating through an oxygen atom and through a nitrogen atom can be different when the central metal ion is different.

Carboxylic acids are said to form no chelate type complexes with various metal ions. Thus, the interaction

of silver(I) with the caproate anion should be weaker than in a complex with the TTA anion. This difference in the nature of the bond between silver(I) and the adjacent anion may cause a difference in the stability of the molecular complex of silver(I) with the donors studied in this work. However, since only the formation of molecular complexes with quinoline,[12] and that of cyclohexene, 1-hexene, and TOPO complexes with silver(I) caproate, have been studied, no final conclusion can be drawn with regard to this interesting problem; further information is necessary in order to make a detailed discussion.

The synergism due to the molecular complex formation has been studied in many metal chelate extraction systems by using various n-donors. It is very remarkable that the silver(I)-TTA chelate shows a synergism with both n-donors and π-donors. Such molecular complexes of silver(I) with π-donors can be used for some analytical purpose. For example, although the extraction of silver(I) with β-diketones in an inert solvent is usually poor,[13] the addition of 1×10^{-3} M quinoline makes the extraction quantitative, as may be seen from Fig. 1. When aromatic solvents such as benzene are used as the diluents of TTA, silver(I) can also be extracted nearly quantitatively (more than 90%).

The chelate extraction of silver(I) has often been carried out with dithizone or oxine. The dithizone extraction is excellent and is favorable for the colorimetry of silver, but it is interferred by many ions. The oxine extraction, on the other hand, is comparable with the present TTA extraction into, for example, benzene.[13] However, the oxine extraction is not very specific. The metal extraction with TTA is also not very specific. However, since only a few metal ions form π-complexes with aromatic hydrocarbons, the synergism of TTA extraction with aromatic hydrocarbons may occur in only a few cases. Thus, when a sample solution containing various metal ions is pretreated by extraction with TTA in chloroform ($[A^-]<10^{-2}$ M), only silver(I) and a small number of metal ions may remain in the aqueous phase; thus, when the solution is shaken twice with benzene or toluene containing 0.1 M TTA (and $[A^-]\simeq10^{-2}$ M), only silver(I) will be extracted from the residue in the aqueous phase, while the other metal ions, such as alkaline earths, will remain in the aqueous phase. Such an extraction method seems to be quite favorable for the separation of silver(I) from among many other metal ions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1188—1195 (1973)

The Oxidation of Iron(II) by Molecular Oxygen Catalyzed by Chloride Ion, Thiocyanate Ion, and Ethylenediamine in Dimethyl Sulfoxide

Yuriko UNNO and Goro WADA*

Department of Chemistry, Nara Women's University, Nara 630

(Received August 3, 1972)

The rates of the oxidation reactions of iron(II) to iron(III) by molecular oxygen in DMSO were measured under the catalyses of Cl^-, SCN^-, and en. The rate was proportional to the partial pressure of oxygen and was of the second order to [Fe(II)] in catalyses of Cl^- and SCN^-, while it was of the first order to [Fe(II)] in catalysis of en. The reaction rate was also linear to $[X]^2$ and $[H^+]$, where X represents Cl^- or SCN^-, indicating that the reaction proceeds via both the electron-transfer and hydrogen-atom-transfer mechanisms, side by side. The reaction order of [Fe(II)] depends upon which step is rate-determining among those of the oxygenation of Fe(II), its spontaneous decomposition, and its bimolecular reaction with another Fe(II) and, therefore, may be variable according to the concentrations of the reacting species. The autoxidation rate can be affected by the kinds of the catalyzing ligands. The autoxidation may be slow when an Fe(II) complex with low spin is oxidized to an Fe(III) complex with high spin and may be fast when from high spin type to low spin one. In the present cases of Cl^-, SCN^-, and en in DMSO, it seems to go from high spin type to high spin one with moderately large rates.

The autoxidation of iron(II) proceeds considerably slow in acidic aqueous solutions being catalyzed by a variety of existing anions and molecules as coordinating ligands. The rate equations for the oxidation of iron(II) in aqueous media are expressed in the first order with respect to the concentration of iron(II) when $H_2PO_4^-$,[1,2] $H_2P_2O_7^{2-}$,[2,3] F^-,[4] Cl^-,[5] ethylenediaminetetraacetic acid (EDTA),[6] or one of other specific chelating ligands[7,8] is present in the reaction system, while they are of the second order with respect to that of iron(II) when either of NO_3^-,[9] SO_4^{2-},[10,11]

or ClO_4^- [12] is present in the reaction system, although ClO_4^- ion does not necessarily act as a coordinating ligand.

George pointed out[13] that the one-electron-transfer mechanism proposed first by Haber and Weiss[14,15] was not satisfactory to explain the cases in which the reaction took place at a rate of the second order with respect to the iron(II) concentrations. Weiss, then, revised his mechanism and extended it to the so-called two-electron-transfer mechanism. George, on the other hand, showed an idea on another novel mechanism of hydrogen-atom-transfer in which the oxidation occurred via transfer of a hydrogen atom from a water molecule coordinated with an iron(II) ion to FeO_2^{2+}, instead of considering a radical mechanism.[12] Fallab discussed the autoxidation of various transition metal ions by molecular oxygen on the basis of the redox potentials of oxygen.[16]

The autoxidation of iron(II) in alcohols is known to occur much faster than that in aqueous solutions,[17] although those in other non-aqueous solutions than alcohols are not known yet. In the present research, therefore, the reactions in dimethyl sulfoxide (DMSO) as catalyzed by Cl^-, SCN^- ions and ethylenediamine (en) were investigated. As the results, the reaction proceeded at a rate proportional to $[Fe(II)]^2$ when it was catalyzed by Cl^- or SCN^- ion, and at one proportional to [Fe(II)] when catalyzed by en. The reaction schemes in each case in DMSO will be developed below.

Experimental

Materials. Commercial DMSO was distilled in a reduced atmosphere of nitrogen at about 3 mmHg, dried over activated alumina overnight to remove water, distilled again in the same way as before, and stocked for use. Sodium chloride, ammonium thiocyanate, ammonium perchlorate, and sodium perchlorate of the guaranteed reagent grade were recrystallized twice from water. Ethylenediamine of the guaranteed reagent grade was used without further purification. Perchloric acid in DMSO was prepared by passing a DMSO solution of ammonium perchlorate through a column charged with cation-exchange resin Dowex 50 of H-type. Iron(II) perchlorate was prepared by dissolving pure iron wire in perchloric acid and recrystallizing it under an atmosphere of nitrogen to protect it from oxidation.

Procedure. The reaction was initiated by mixing a solution of iron(II) perchlorate in DMSO with that containing one of the catalyzing substances, Cl^-, SCN^- ion or en, and perchloric acid in DMSO. Two methods were adopted for the kinetic measurements. In a flow-method, air or a mixed gas of oxygen and nitrogen at various ratios was let to flow into the reaction solution at a constant flow rate and aliquots were taken out of the solution into quenching solutions for analyses at appropriate time intervals. When Cl^- ion or en was adopted as a catalyst, α,α′-bipyridyl was contained in the quenching solutions, forming $Fe(bipy)_3^{2+}$ at once which not only interupted further progress of the reaction but also was used for the spectrophotometric determination of iron(II) concentration at 522 nm at the individual reaction times. When SCN^- ion was adopted as a catalyst, on the other hand, aliquots of the reaction solution were diluted into a definite amount of water to slow down the reaction velocity and were soon used for the spectrophotometric determination of iron(III) concentration in the form of thiocyanato complex at 470 nm.

As a second method, a Warburg apparatus was used for the volumetric pursuit of oxygen gas consumed by oxidation. The procedure for the initiation of the reaction was the same with that of the flow method.

The ionic strength and the temperature of the reaction systems were always kept constant at 0.2 M and 25 °C respectively.

Photometry. A Hitachi-Perkin-Elmer UV-VIS spectrophotometer Model 139 and a Hitachi Recording spectrophotometer Model EPS-3T were used for the optical determinations of the concentrations of iron species and for the measurements of the absorption spectra of reaction solutions, respectively.

Results and Discussion

Catalyses by Cl^- and SCN^- Ions. Under a constant partial pressure of oxygen, p, the relationship of $(1/[Fe(II)]-1/[Fe(II)]_0)$ *vs.* time, t, was linear for reactions catalyzed by Cl^- or SCN^- ion, as is shown in Fig. 1, as an example at $[Fe(II)]_0=2\times10^{-2}$ M, $p=$ 0.2 atm, $\mu=0.2$ M, and 25°C, and at various $[Cl^-]$ and $[H^+]_0$. Here, $[Fe(II)]_0$ and $[H^+]_0$ represent the initial concentrations of Fe(II) and H^+. These linearities indicate that the reaction proceeds in the second order of the concentration of iron(II). When the partial pressure of oxygen, p, was varied under a fixed reaction condition except p, another proportionality between the reaction rate and p was recognized,

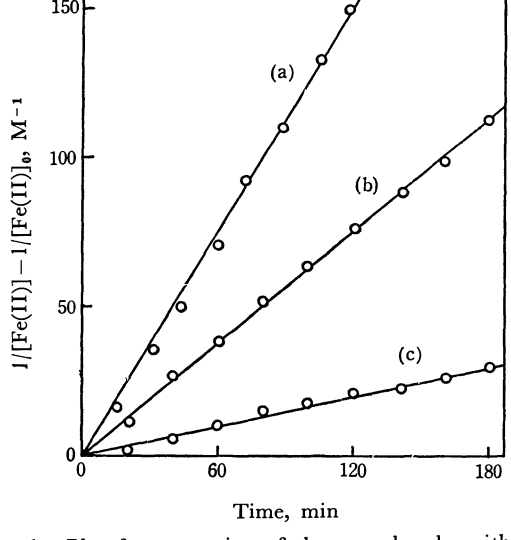

Fig. 1. Plot for a reaction of the second order with respect to [Fe(II)] at $[Fe(II)]_0=2.00\times10^{-2}$ M, $p=0.2$ atm., $\mu=0.2$ M, and 25°C.

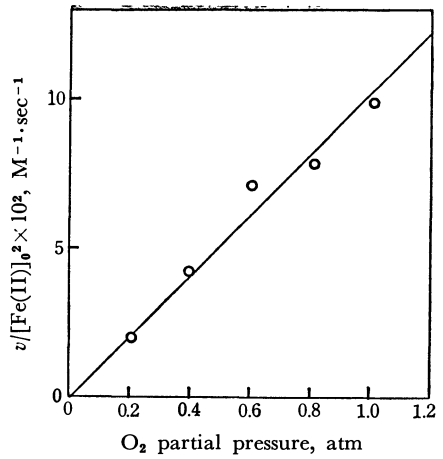

Fig. 2. The proportionality of the reaction rate with the partial pressure of oxygen at $[Fe(II)]_0 = 2.00 \times 10^{-2}$ M, $[Cl^-] = 3.50 \times 10^{-2}$ M, $[H^+]_0 = 3.00 \times 10^{-2}$ M, $\mu = 0.2$ M, and 25°C.

indicating that the reaction is of the first order with respect to p. This is shown in Fig. 2. Similar relationships were also observed in the case of SCN^- catalysis. Thus, the reaction rate equation for the both catalytic reactions is expressed in the form:

$$v = -\frac{d[Fe(II)]}{dt} = kp[Fe(II)]^2 \qquad (1)$$

The mole ratio of the reacting iron(II) to the consumed oxygen was found to be 4 : 1, indicating that one molecule of oxygen oxidizes four ions of iron(II) to iron(III). The spectral changes during the reaction supported this stoichiometric relation. A spectrum of an acidic solution containing iron(II) after the completion of the reaction coincided well with that containing iron(III) at the same concentration, as shown in Fig. 3. Therefore, the overall chemical equation of the reaction is written as follows:

$$4Fe(II) + O_2 + 4H^+ \rightarrow 4Fe(III) + 2H_2O \qquad (2)$$

The rate constant, k, defined in Eq. (1) was also observed to be dependent upon the concentrations of both acid and catalyzing ions. Approximate linear relationships of k with $[Cl^-]^2$ at various $[H^+]_0$ and with $[H^+]_0$ at various $[Cl^-]$ are shown in Figs. 4 and 5, respectively, although their linearities look like worse than those revised by theoretical treatment below.

The stoichiometry of the reaction in the case of SCN^- ion and the dependence of k upon $[SCN^-]^2$ and $[H^+]_0$ were quite similar to the case of Cl^- ion, although their plots corresponding to Figs. 1—5 are not shown here.

Reaction Schemes for Cl^- and SCN^- Catalyses. Since the reaction proceeds at rates linearly depending upon $[X]^2$ and $[H^+]_0$, k can be expressed empirically as below, where X stands for Cl^- or SCN^- and A, B, C,

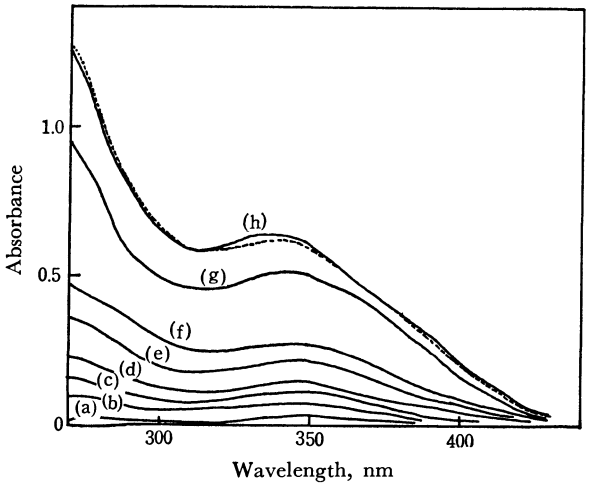

Fig. 3. Spectral changes during the reaction to complete oxidation at $[H^+]_0 = 1.00 \times 10^{-2}$ M, $[Cl^-] = 2.00 \times 10^{-2}$ M, and $\mu = 0.2$ M.

(c) $[Cl^-] = 2.00 \times 10^{-2}$ M (d) $[Cl^-] = 1.50 \times 10^{-2}$ M
(e) $[Cl^-] = 1.00 \times 10^{-2}$ M (f) $[Cl^-] = 5.00 \times 10^{-3}$ M

and D are constants:

$$k = A + B[X]^2 + C[H^+] + D[H^+][X]^2 \quad (3)$$

The following four paths from (a) through (d) are reasonably deduced corresponding to the respective four terms on the right-hand side of Eq. (3).

(a) $Fe^{2+} + O_2 \overset{K_0}{\rightleftharpoons} FeO_2^{2+}$ (a1)

$FeO_2^{2+} + Fe^{2+} \overset{k_a}{\longrightarrow} [Fe.O_2.Fe]^{4+}$

$\longrightarrow Fe^{3+} + O_2^{2-} + Fe^{3+}$ (a2)

(b) $Fe^{2+} + X^- \overset{K_1}{\rightleftharpoons} FeX^+$ (b1)

$FeX^+ + O_2 \overset{K_0'}{\rightleftharpoons} XFeO_2^+$ (b2)

$XFeO_2^+ + FeX^+ \overset{k_b}{\longrightarrow} [X.Fe.O_2.Fe.X]^{2+}$

$\longrightarrow FeX^{2+} + O_2^{2-} + FeX^{2+}$ (b3)

(c) $Fe^{2+} + O_2 \overset{K_0}{\rightleftharpoons} FeO_2^{2+}$ (c1), (a1)

$Fe^{2+} + H^+ \overset{K_H}{\rightleftharpoons} FeSH^{3+}$ (c2)

$FeO_2^{2+} + FeSH^{3+} \overset{k_c}{\longrightarrow} [Fe.O_2.HS.Fe]^{5+}$

$\longrightarrow Fe^{3+} + HO_2^- + Fe^{3+}$ (c3)

(d) $Fe^{2+} + X^- \overset{K_1}{\rightleftharpoons} FeX^+$ (d1), (b1)

$FeX^+ + O_2 \overset{K_0'}{\rightleftharpoons} XFeO_2^+$ (d2), (b2)

$FeX^+ + H^+ \overset{K_H'}{\rightleftharpoons} HSFeX^{2+}$ (d3)

$XFeO_2^+ + HSFeX^{2+} \overset{k_d}{\longrightarrow} [X.Fe.O_2.HS.Fe.X]^{3+}$

$\longrightarrow FeX^{2+} + HO_2^- + FeX^{2+}$ (d4)

Equilibrium constants and rate constants appearing in the individual steps are represented by respective symbols in the equations, and S stands for DMSO as solvated with iron ions which functions as a proton acceptor. The bracketed species shown in every path means activated complexes.

In the whole reaction, these four paths may be prevailing in parallel with one another; (a) and (b) involve two electron-transfer processes from two Fe(II) ions to an O_2, and (c) and (d) involve, on the other hand, a hydrogen-atom-transfer process from an Fe(II) to an O_2 as well as an electron-transfer process from another Fe(II) to the same O_2, producing O_2^{2-} and HO_2^- respectively.

The common products of the above reactions, O_2^{2-} and HO_2^-, will be followed by further reactions of their own, being finally reduced to H_2O in order to hold the stoichiometry as shown in the reaction (2).

(t) $O_2^{2-} + H^+ \longrightarrow HO_2^-$ (t1)

$HO_2^- + H^+ \longrightarrow H_2O_2$ (t2)

$H_2O_2 + Fe(II) \longrightarrow OH + OH^- + Fe(III)$ (t3)

$OH + Fe(II) \longrightarrow OH^- + Fe(III)$ (t4)

$H^+ + OH^- \longrightarrow H_2O$ (t5)

Thus, the overall rate constant of the reaction is expressed in a following form:

$$k = \frac{k_aK_0 + k_bK_0'K_1^2[X]^2 + k_cK_0K_H[H^+] + k_dK_0'K_H'K_1^2[H^+][X]^2}{\{1 + K_1[X] + K_H[H^+] + K_H'K_1[H^+][X] + K_0[O_2] + K_0'K_1[X][O_2]\}^2} \quad (4)$$

where the last two terms appearing in the denominator of the right-hand side of Eq. (4) are negligibly small as compared to the rest ones in it, because the solubilities of oxygen in the reaction media, $[O_2]$, are very small.[18]

When the denominator of the right-hand side of Eq. (4) is denoted by d^2 for brevity, kd^2, instead of k itself, should be linearly dependent upon $[X]^2$ at constant $[H^+]_0$ and upon $[H^+]_0$ at constant $[X]$.

$$kd^2 = 4k_aK_0 + 4k_bK_0'K_1^2[X]^2 + 4k_cK_0K_H[H^+] + 4k_dK_0'K_H'K_1^2[H^+][X]^2 \quad (5)$$

If d does not vary much within the concentration ranges of $[X]$ and $[H^+]_0$ employed under the present consideration, k will also show approximately linear relationships with $[X]^2$ and $[H^+]$, which are the cases of Eq. (3) and Figs. 4 and 5. In the case of Cl^- ion catalyst, the values of $K_1 = 20\ M^{-1}$ and $K_H = K_H' = 5\ M^{-1}$ give best fits for the linearities of kd^2 with $[Cl^-]^2$ and $[H^+]_0$, which are drawn in Figs. 6 and 7. As are clearly recognized in the figures, the linearities in Figs. 4 and 5 are fairly revised to give those in Figs. 6 and 7, respectively. In Fig. 7, the curves fail from the linearities at very low concentrations of hydrogen ion below 1.00×10^{-2} M, where the steps as controlled by $[H^+]$ might be rate-determining.

The straight lines at various hydrogen ion concentrations in Fig. 6 will give intercepts and slopes, indicating as follows:

$$\text{Intercept} = 4k_aK_0 + 4k_cK_0K_H[H^+] \quad (6)$$

$$\text{Slope} = 4k_bK_0'K_1^2 + 4k_dK_0'K_H'K_1^2[H^+] \quad (7)$$

Plotting of those slopes against $[H^+]$ will also give a

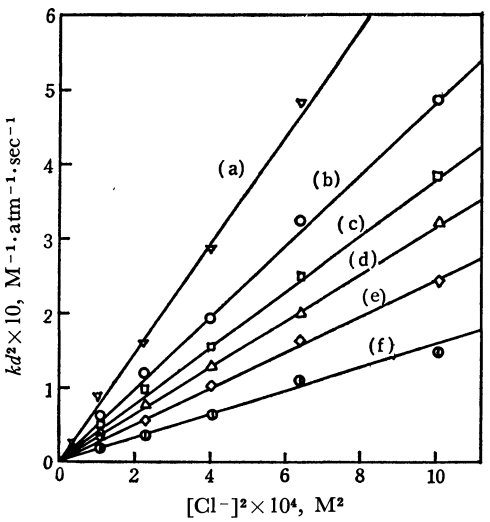

Fig. 6. Relations between kd^2 and $[Cl^-]^2$ at the same conditions with Fig. 4.

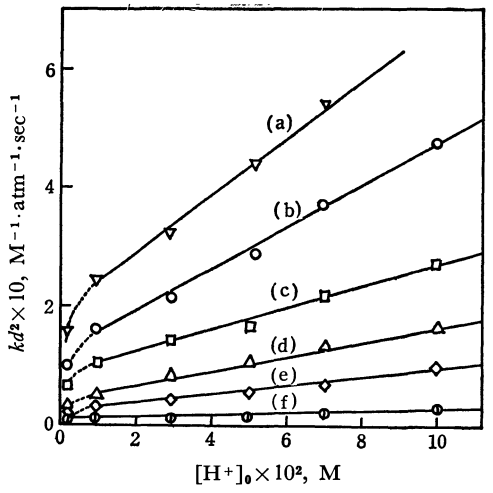

Fig. 7. Relations between kd^2 and $[H^+]_0$ at the same conditions with Fig. 5.

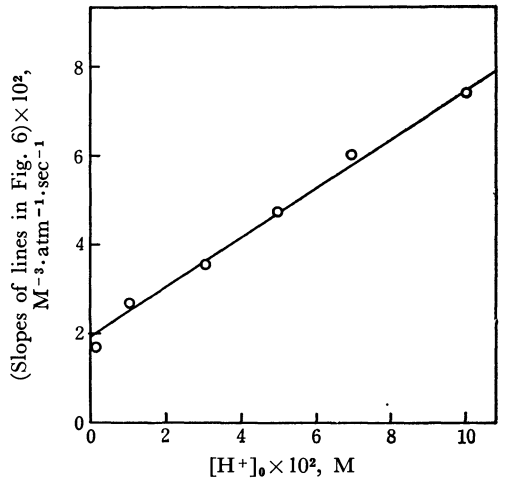

Fig. 8. Linear relationship of the slopes in Fig. 6 *vs.* $[H^+]_0$.

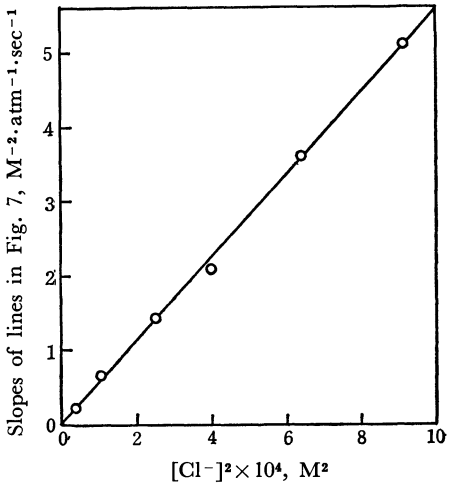

Fig. 9. Linear relationship of the slopes in Fig. 7 *vs.* $[Cl^-]^2$.

straight line having an intercept $4k_bK_0'K_1^2$ and a slope $4k_dK_0'K_H'K_1^2$, as shown in Fig. 8.

In quite a similar way, the straight lines in Fig. 7 give slopes at different Cl^- ion concentrations, and those slopes have also a linear relationship with $[Cl^-]^2$, as shown in Fig. 9. The intercept and the slope in Fig. 9 correspond to $4k_cK_0K_H$ and $4k_dK_0'K_H'K_1^2$, respectively.

Table 1. Various rate and equilibrium constants in the cases of Cl^- and SCN^- ions used as catalysts

Constants $M^{-1}\cdot atm^{-1}\cdot sec^{-1}$	Catalysts	
	Cl^-	SCN^-
k_aK_0	~0	~0
k_bK_0'	1.3×10^{-1}	7.5×10^{-3}
k_cK_0	1.0×10^{-3}	1.0×10^{-3}
k_dK_0'	6.8×10^{-1}	4.2×10^{-2}

Various linearities are similarly noticed in the case of SCN^- ion as a catalyst, as well as in that of Cl^- ion. Thus, constants obtained directly by means of the least-squares method from Eq. (5) are summarized in Table 1 in both catalysts. In the case of SCN^- ion, the values of $K_1=10\ M^{-1}$ and $K_H=K_H'=5\ M^{-1}$ were adopted for the best linearities.

Since neither K_0 nor K_0' can be estimated at the present stage, we have to compare rate constants multiplied by K_0 or K_0'. Fortunately, nevertheless, the ratios k_d/k_b are found to be almost equal, being 5.2 in Cl^- and 5.6 in SCN^-. It is worth noticing that, although the rate constant at each path seems smaller in SCN^- than in Cl^-, the acceleration ratio, k_d/k_b, of the oxidation due to the participation of the hydrogen-atom-transfer mechanism is approximately the same in both catalysts. Of course, k_a and k_c are indifferent to the kind of catalyzing ions because no catalyst is involved in the reaction scheme (a) and (c), and this is definitely proved by the results in the table, k_aK_0 and k_cK_0 being nearly zero and $1.0\times10^{-3}\ M^{-1}\cdot atm^{-1}\cdot sec^{-1}$ in both systems.

Catalysis by Ethylenediamine and its Reaction Scheme. When en is added in the reaction system, the oxidation reaction goes much faster than the cases catalyzed by Cl^- and SCN^- ions. Figure 10 indicates that the reaction is of the first order with respect to [Fe(II)] under

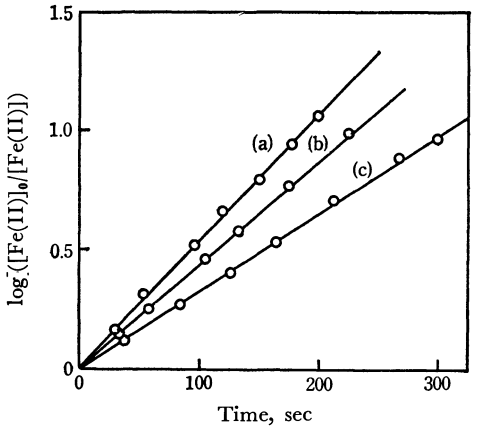

Fig. 10. Plot for a reaction of the first order with respect to [Fe(II)] at $[Fe(II)]_0=2.00\times10^{-2}$ M, $p=0.2$ atm, $\mu=0.2$ M, and 25 °C.
(a) $[en]_0=9.00\times10^{-2}$ M, $[H^+]_0=1.00\times10^{-2}$ M
(b) $[en]_0=1.20\times10^{-1}$ M, $[H^+]_0=3.00\times10^{-2}$ M
(c) $[en]_0=1.05\times10^{-1}$ M, $[H^+]_0=5.00\times10^{-2}$ M

a constant partial pressure of oxygen, because log-[Fe(II)] decreases linearly with the lapse of reaction time, being in contrast with the cases of Cl^- and SCN^- ions. The dependence of the reaction rate upon the partial pressure of oxygen, p, was found to be in a proportional correlation, as equally to the cases of Cl^- and SCN^- ions. Therefore, the rate equation is established as:

$$v = kp[\mathrm{Fe(II)}] \tag{8}$$

The absorption spectra of a reaction solution containing iron(II) and en were observed to vary with time and finally to agree with those of iron(III) at the same concentration with the initial one of iron(II). This observation shows that the reaction only goes by simple oxidation of iron(II) to iron(III) without any further chemical changes of the substances involved. The rate of consumption of oxygen also showed the stoichiometry of the overall reaction to be quite the same with the cases of Cl^- and SCN^- ions, as represented by Eq. (2).

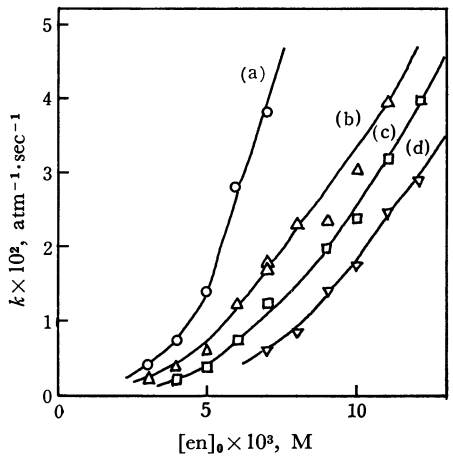

Fig. 11. The dependence of k upon $[en]_0$ and $[H^+]_0$ at $p=0.2$ atm, $\mu=0.2$ M, and 25 °C.
(a) $[H^+]_0=2.00\times10^{-3}$ M (b) $[H^+]_0=3.00\times10^{-3}$ M
(c) $[H^+]_0=4.00\times10^{-3}$ M (d) $[H^+]_0=6.00\times10^{-3}$ M

The apparent rate constant k in Eq. (8) is affected by the concentrations of both en and acid; the higher the concentration of en and the lower that of acid, the larger the rate constant, as is shown in Fig. 11. Judging from these experimental facts, the following reaction scheme (e) can be deduced in addition to those of (a) and (c), although the contribution due to (a) and (c) may be negligibly small.

(e) $\mathrm{Fe^{2+} + en \overset{K_1}{\rightleftharpoons} Fe.en^{2+}}$ (e1), (b1)

$\mathrm{Fe.en^{2+} + O_2 \overset{K_0'}{\rightleftharpoons} en.FeO_2^{2+}}$ (e2), (b2)

$\mathrm{en.FeO_2^{2+} \overset{k_e}{\longrightarrow}}$ (e3)

$\mathrm{en.FeO_2^{2+} + Fe.en^{2+} \longrightarrow}$ (e4)

$\mathrm{en + H^+ \overset{K_e}{\rightleftharpoons} enH^+}$ (e5)

Since the reaction is of the first order with respect to [Fe(II)], either the forward reaction of (e2) or (e3) may be rate-determining, with the rate constant k_0' or k_e, respectively. If (e2) is rate-determining, it may be followed by (e3) and/or (e4), and if (e3) is so, (e4) must not occur and (e2) establishes an equilibrium. Whichever the rate-determining step may be, they will produce O_2^{2-} and will be succeeded similarly by the reactions as shown in (t). Thus, k is expressed as follows:

$$k = \frac{EK_1[\mathrm{en}]}{1+K_1[\mathrm{en}]} \tag{9}$$

in which E represents $4k_0'$ or $4k_1K_0'$ according to whether the rate-determining step is (e2) or (e3). When the total concentration of en is expressed by $[en]_0$, the concentration of free en is defined approximately by

$$[\mathrm{en}]_0 = (1+K_e[H^+]+K_1[Fe^{2+}])[\mathrm{en}] \tag{10}$$

The values of log K_e in aqueous media is as large as about 10.[19] Although DMSO is more basic than water in nature,[20] log K_e in DMSO can be regarded to be still so large as compared with $(1+K_1[Fe^{2+}])$ and $K_1[en]_0$. Then, k is rewritten as:

$$k = \frac{EK_1[\mathrm{en}]_0}{K_e[H^+]} \tag{11}$$

At constant total acid concentrations, $[H^+]_0$, the hydrogen ion concentration $[H^+]$ decreases with increasing $[en]_0$. This is the reason why k exhibits no rigorous linear relationship with $[en]_0$ but a trend of abrupt increase with increasing $[en]_0$ as shown in Fig. 11. From the slope of the curve at very low $[en]_0$, EK_1/K_e is roughly estimated to be 3.5×10^{-4} $atm^{-1}\cdot sec^{-1}$.

General Consideration on the Order of the Reaction with Respect to [(Fe(II)]. In a reaction system, FeL^{2+}, $FeSH^{3+}$, and $HSFeL^{3+}$ can be considered to exist in individual equilibria with their composing species, where L stands for one of the catalyzing ligands, Cl^-, SCN^-, or en. If any one of these iron(II) complexes is simply denoted by Fe(II), the reaction schemes as have been described above are generalized as follows:

$$\mathrm{Fe(II) + O_2 \xrightarrow{(A)} Fe(II).O_2 \overset{(B)}{\underset{(C)}{\nearrow\!\searrow}} +Fe(II)}$$

Depending upon the rates of the reaction of passing the steps, (A), (B), and (C), there may possibly come out the following three cases:

(i) (A)<(B), (C)

(ii) (A)>(B), (C), and (B)≫(C)

(iii) (A)>(B), (C), and (B)≪(C)

The rate-determining step will be (A), (B), or (C) according to the case (i), (ii), or (iii), respectively. In the cases (i) and (ii), the reaction is of the first order with respect to [Fe(II)], while in the case of (iii), it is of the second order with respect to [Fe(II)]. When Cl^- and SCN^- ions are employed as ligands, the case (iii) must actually happen because of the fact that the reaction is of the second order. When en is used, on

19) "Stability Constants of Metal-Ion Complexes," ed. by L. G. Sillén and A. E. Martell, The Chemical Society Special Publication No. 17 (1964), p. 370.

20) G. Wada, This Bulletin, **42**, 890 (1969).

the other hand, the case must be (i) or (ii) although it is not decided yet which it is, at the present stage.

By taking into account all of the possible elementary reactions of the schemes from (a) through (e), and by using the steady-state method for the species appearing as intermediates, a set of probable elementary reactions and a rate equation can be drawn out as follows:

$$Fe^{2+} + L \rightleftharpoons FeL^{2+} \quad (K_1) \quad (b1, d1, e1)$$

$$Fe^{2+} + H^+ \rightleftharpoons FeSH^{3+} \quad (K_H) \quad (c2)$$

$$FeL^{2+} + H^+ \rightleftharpoons HSFeL^{3+} \quad (K_H') \quad (d3)$$

$$Fe^{2+} + O_2 \overset{k_0}{\rightleftharpoons} FeO_2^{2+} \quad (K_0) \quad (a1, c1)$$

$$FeL^{2+} + O_2 \overset{k_0'}{\rightleftharpoons} LFeO_2^{2+} \quad (K_0') \quad (b2, d2, e2)$$

$$FeO_2^{2+} \xrightarrow{k_1}$$

$$LFeO_2^{2+} \xrightarrow{k_e} \quad (e3)$$

$$FeO_2^{2+} + Fe^{2+} \xrightarrow{k_a} \quad (a2)$$

$$LFeO_2^{2+} + FeL^{2+} \xrightarrow{k_b} \quad (b3, e4)$$

$$FeO_2^{2+} + FeSH^{3+} \xrightarrow{k_c} \quad (c3)$$

$$LFeO_2^{2+} + HSFeL^{3+} \xrightarrow{k_d} \quad (d4)$$

$$v = \frac{4p\{\alpha + (\beta/\delta)[Fe(II)]\}\gamma[Fe(II)]}{\{\alpha + (\beta/\delta)[Fe(II)] + \gamma\}\delta} \quad (12)$$

$$\alpha = k_1K_0 + k_eK_0'K_1[L] \quad (13)$$

$$\beta = k_aK_0 + k_bK_0'K_1^2[L]^2 + k_cK_HK_0[H^+] + k_dK_H'K_0'K_1^2[H^+][L]^2 \quad (14)$$

$$\gamma = k_0 + k_0'K_1[L] \quad (15)$$

$$\delta = 1 + K_H[H^+] + K_1[L] + K_H'K_1[H^+][L] \quad (16)$$

Under limiting conditions, the following extreme three cases can be derived, corresponding to the three ones, (i), (ii), and (iii) respectively, as mentioned above and Eq. (12) results in typically simple forms.

(i) If $\alpha + (\beta/\delta)[Fe(II)] \gg \gamma$,

$$v = \frac{4\gamma}{\delta}p[Fe(II)] \quad (17), (8)$$

(ii) If $\alpha + (\beta/\delta)[Fe(II)] \ll \gamma$ and $\alpha \gg (\beta/\delta)[Fe(II)]$

$$v = \frac{4\alpha}{\delta}p[Fe(II)] \quad (18), (8)$$

(iii) If $\alpha + (\beta/\delta)[Fe(II)] \ll \gamma$ and $\alpha \ll (\beta/\delta)[Fe(II)]$

$$v = \frac{4\beta}{\delta^2}p[Fe(II)]^2 \quad (19), (1)$$

Equation (19) coincides with the empirical rate equation (1), which was seen in the cases of Cl^- and SCN^- catalysts, while Eqs. (17) and (18) coincide with the empirical one (8) under the catalysis of en.

In the cases (i) and (ii), it is possible to distinguish whether Eq. (17) or (18) is actually available, in the following manner. When [Fe(II)] is made larger, Eq. (17) remains unchanged as a function of the first order of [Fe(II)], while Eq. (18) becomes no longer useful and the reaction order with respect to [Fe(II)] gradually grows higher up to the second order, with increasing [Fe(II)]. Even in the case (iii), on the other hand, the reaction order may fall down from the second order to the first at the extremely low value of [Fe(II)] as is easily understood from Eq. (19). Unfortunately, we could not realize these extreme cases at very high and very low [Fe(II)] due to the experimental difficulties. Anyway, it is worth noticing that the reaction order is not definitely specific nor characteristic to the catalyzing ligands but depends upon their reaction conditions; a similar kind of thing to this is also known in the Lindemann mechanism in which a reaction of the first order at a certain concentration may become to be of the second order at a lower concentration than that with respect to a reacting species. Therefore, the order of the reaction itself is not essentially important, unless the reaction conditions are rigorously taken into account.

Ligand and Solvent Effects upon the Reaction Rates of Oxidation. Aquocobalt(II) ion in aqueous solution is thermodynamically stable and is, therefore, impossible to be oxidized to cobalt(III). However, when Co(II) is coordinated with ammonia,[21] en,[22] or histidine,[23] it forms a high spin complex which acts as an oxygen carrier and is rapidly oxidized to a Co(III) complex of low spin. In the cases of iron complexes, it is known that $Fe(bipy)_3^{2+}$ and $Fe(phen)_3^{2+}$ which are of low spin complexes in aqueous solution are very stable and inert against oxidation, whereas another low spin complex of iron(II), $Fe(CN)_6^{4-}$, is easily oxidized to produce $Fe(CN)_6^{3-}$ which is also of a low spin complex. The overall formation constants, $\log\beta$, of $Fe(bipy)_3^{2+}$, $Fe(phen)_3^{2+}$, and $Fe(CN)_6^{4-}$ are 17.6,[24] 21,[25] and 24[26] respectively, and those for their oxidized states are unknown for $Fe(bipy)_3^{3+}$ and 14.1 and 31 for $Fe(phen)_3^{3+}$ [25] and $Fe(CN)_6^{3-}$ [26], respectively. The oxidation of iron(II), therefore, results in the decrease in stabilities in the cases of bipy and phen complexes, while it results in the increase in stability in the case of cyano complex. This is likely to be the reason why only the cyano complex undergoes a rapid oxidation. Kurimura and others[6] found out that there exists a linear relationship between $\log k$ and $\log[\beta(III)/\beta(II)]$ among many iron complexes coordinated with organic ligands of various polyaminoacetic and other acids, where k, $\beta(III)$, and $\beta(II)$ stand for rate constant of oxidation reaction, overall formation constants of iron(III) and iron(II) complexes, respectively. This relationship is, in other words, a linear relation between the activation free energies and the thermodynamical standard free energies of the reaction, similar cases to which are also observed in the electron transfer reactions between iron(II) and iron(III) complexes coordinated with

Table 2. Types of changes in electronic structures associated with the oxidation Fe(II)→Fe(III)

Types	Electronic configurations Fe(II) → Fe(III)	Examples of ligands
L→H	$t_{2g}^6e_g^0 \rightarrow t_{2g}^3e_g^2$	
L→L	$t_{2g}^6e_g^0 \rightarrow t_{2g}^5e_g^0$	CN^-, phen, bipy
H→H	$t_{2g}^4e_g^2 \rightarrow t_{2g}^3e_g^2$	en, Cl^-, SCN^-, H_2O
H→L	$t_{2g}^4e_g^2 \rightarrow t_{2g}^5e_g^0$	

various ligands.[27]

Summarizing the above-described considerations, as long as the linear free energy relation is available, four types of the autoxidation reaction in connection with the electronic structures of the reactants and products can be deduced, as shown in Table 2. On the basis of stability variations involved in the course of oxidation, a change in the electronic configuration from low spin to high spin (L→H) might be most difficult to take place, while a change of the reverse direction (H→L) might occur most easily, although such cases have not been found yet. Examples of L→L type are seen in the cases of bipy, phen, and CN^- ion, among which the former two are slow and the latter is fast.

The formation constants, log K_1, of $FeCl^{2+}$ and $FeSCN^{2+}$ in DMSO have been measured as 3.6 [28] and 2.9,[29] although those of iron(II) species with the same ligands were not determined due to their low stabilities. Moreover, those of Fe–en complexes for both oxidation states in DMSO are not known either. In spite of such lacks of data, it may be safely said that the autoxidation catalyzed by these three ligands, en, Cl^-, and SCN^- ions, in DMSO proceeds via H→H type, with moderately large reaction rates in the sequence of en>Cl^->SCN^-, being faster than L→H type and slower than H→L one.

The solvent effect that the reaction proceeds much faster in DMSO than in water can be attributed to the larger differences in the formation constants of the iron complexes between the two oxidation states in DMSO than those in water. The electrostatic repulsion between ions of like signs is clearly larger in DMSO of a lower dielectric constant than in water of a higher one. This effect should contribute toward the reaction disadvantageously and make the reaction proceed slower in DMSO than in water, this being not the case though. Consequently, the latter effect in repulsion must be conquered by the former in stability after all.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1195—1198 (1973)

The Preparation and Spectroscopic Properties of Fumaronitrile Complexes of Palladium(0) and Platinum(0)

Keinosuke SUZUKI and Hideshi OKUDA

Inorganic Chemistry Laboratory, Faculty of Science, Nagoya University, Chikusa, Nagoya 464

(Received Septembet 11, 1972)

Fumaronitrile complexes, $M(FMN)(AsPh_3)_2$ (M=Pd, Pt and FMN=fumaronitrile), have been prepared. Various chelating agents replaced $AsPh_3$ in the complexes, giving M(FMN)L (L is a chelating agent containing N, P, or As as donor atoms). The chemical shift of the methine protons of these complexes increased in the order:

$$Pd\text{–}As < Pd\text{–}P < Pt\text{–}As < Pt\text{–}P.$$

This is probably the increasing order of the π-back donation in these complexes. The UV spectra of the complexes are also described.

In recent years, olefin complexes of transition metals in the low oxidation state have been the subjects of many studies.[1] These investigations have established that stable complexes are formed with olefins containing electronegative substituents (activated olefin). Fumaronitrile is a typical activated olefin and is expected to give stable complexes of Pd(0) and Pt(0). However, only two complexes, $Pd(FMN)(PPh_3)_2$[2] and $Pt(FMN)(PPh_3)_2$,[3] have been reported so far. In this paper we will describe the preparation, spectroscopic properties, and some ligand-exchange reactions of fumaronitrile complexes of zero-valent Pd and Pt. The effect of a donor atom, N, P, or As, on the metal-olefin bonding will also be discussed.

Results and Disucssion

Preparation and Ligand-exchange Reactions. The complex $Pt(FMN)(AsPh_3)_2$ was prepared by the reac-

tion of $Pt(AsPh_3)_4$ with FMN in benzene. A corresponding palladium complex, $Pd(FMN)(AsPh_3)_2$, was synthesized by the reduction of $PdCl_2(AsPh_3)_2$ with hydrazine monohydrate in the presence of FMN. The similar reduction of $PdCl_2(PPh_3)_2$ also gave the complex $Pd(FMN)(PPh_3)_2$ reported by MaClure *et al.*[2]

The reactivities of these two arsine complexes towards bidentate ligands are very similar except for the reaction with the ligands (N–N) containing two nitrogen donor atoms. As is shown in the Scheme, all of the ligands (N–N) studied here replaced $AsPh_3$ in $Pd(FMN)(AsPh_3)_2$, thus forming Pd(FMN)(N–N), but only ethylenediamine (en) and cyclohexanediamine (cyhn) could react with $Pt(FMN)(AsPh_3)_2$. The other three ligands failed to replace $AsPh_3$ in the complex. Two factors are conceivable to explain the difference in their reactivities: the pK values and the steric factors of the bidentate ligands(N–N). Steric factors do not seem to be serious in the present case, because cyhn reacts with both palladium and platinum complexes; also two ligands, bipy and o-phen, replace $AsPh_3$ in $Pt(CF_2{=}CF_2)(AsPh_3)_2$, thus giving $Pt(CF_2{=}CF_2)L$ (L is bipy, o-phen), as has been reported by Kemmitt and Moore.[4] As is clear from Table 1, the pK values of en and cyhn are larger than those of the other three ligands. Thus, it may be reasonable to assume that the pK values of the ligands (N–N) are important in the ligand-exchange reactions studied here. The replacement of $AsPh_3$ in the perfluoroolefin complex may be due to the strong *trans*-effect of perfluoroolefin, which weakens the Pt–As bond and makes the substitution of $AsPh_3$ by the ligand with a small pK value possible.

Table 1. The pK values of bidentate ligands (N–N)[a]

	en	cyhn	o-phen	2,9-phen	bipy
pK_1	9.87	9.99(*trans*) 9.89(*cis*)	4.92	6.15	4.49

a) L. G. Sillen and A. E. Martell ed., "Stability Constants," Special Publication No. 17, The Chemical Society, London (1964).

$Pd(FMN)(EPh_3)_2$ (E=P, As) reacts with $SbPh_3$ to give white precipitates. The porduct of E=P was identified as $Pd(SbPh_3)_2(PPh_3)_2$ as reported by Takahashi *et al.*[5] on the basis of its analytical data and decomposition point. The analytical data of the compound of E=As corresponds to $Pd(SbPh_3)_3(AsPh_3)$, and the presence of $SbPh_3$ and $AsPh_3$ in the complex was confirmed by its far-infrared spectrum, which gave absorptions at 455(s), 270(s), and 260(s) cm^{-1} assignable to $SbPh_3$ and 472(m), 325(m), and 315(m) cm^{-1} assignable to $AsPh_3$.

PMR Spectra. The PMR spectra of fumaronitrile complexes were measured in $CDCl_3$, with TMS as the internal standard; the data are summarized in Table 2. Unfortunately, the spectra of the complexes formed with a bidentate ligand (N–N) were not obtained because of their low solubility in common organic solvents. As is clear from Table 2, the olefinic protons show the large high-field shift which is characteristic of the olefin coordinated to a transition metal in the low-oxidation state. The chemical shifts increased in the order:

$$Pd\text{-}As < Pd\text{-}P < Pt\text{-}As < Pt\text{-}P$$

for both monodenate ligands (PPh_3 and $AsPh_3$) and bidentate ligands (P–P and As–As), although the shifts of the complexes with monodentate ligands are always larger than those of the corresponding chelates. Cenini *et al.*[6] related this shift to the amount of π-back donation from the metal to the ligand. Therefore, the order seems to indicate the increasing ability of π-back donation of the ME_2 system (M=Pd, Pt and E=P, As).

Scheme.

one phosphorus atom is coupled with the methine protons, as is shown in Fig. 1, although the coupling of two phosphorus atoms to ^{19}F or ^{1}H has been reported in the complexes $Pt(CF_2{=}CF_2)(PPh_3)_2$[7], $Pt(CH_2{=}CH_2)(PPh_3)_2$[8], and $Pt(RC{\equiv}CH)(PPh_3)_2$.[1] Similar results are also obtained for $Pt(FMN)(PPh_3)_2$[3] and some other olefin complexes.[6] The phosphorus atom which couples with a methine proton is probably *trans* to the carbon atom of the methine group, as has been suggested by Cenini *et al.*[6] It is likely that the appearance of a doublet in our complexes is due to the small coupling constant of a *cis*-phosphorus atom with the olefinic proton, since Greaves *et al.*[9] observed that the 60 MHz spectrum of the methyl protons of $Pt(MeC{\equiv}CPh)(PPh_3)_2$ gave only a doublet, while the 100 MHz spectrum split the methyl doublet into symmetrical doublets.

The satellites of the complex $Pt(FMN)(AsPh_3)_2$ are very broad, but its central peak is sharp, as is shown in Fig. 1. A similar phenomenon is also observed in the PMR spectrum of $Pt(CH_2{=}CClCN)(AsPh_3)_2$.[10] Recently Mann *et al.*[11] reported the complex behaviour of the satellites of $Pt_2Cl_2(2\text{-methylallyl})_2$ with the temperature; they suggested the possibility of a partial contribution of a relaxation phenomenon of the platinum-195 nucleus. A similar consideration might explain the phenomenon observed here.

In the platinum complexes, J(Pt–H) was *ca.* 60 Hz for the phosphine complexes and ca. 70 Hz for the arsine complexes (Table 2). A decrease in J(Pt–H) with the change from As to P has also been reported for *trans*-$[Pt(Me)L(PMe_2Ph)_2]$ (L=PPh_3, $AsPh_3$).[12] This order is expected on the basis of the fact that

(c) Pd(FMN)(cyhn), (d) Pt(FMN)(cyhn).

J(Pt–C–H) seems to have a close relation with the s-character of Pt,[13] and the Pt(6s) character in the Pt–olefin bond will be decreased by the coordination of a better σ-donor atom, as has been discussed by Church and Mays,[14] although Nelson and Jonassen[1] suggested that the contributions from terms other than the Fermi contact term are important.

UV Spectra. The UV spectra of M(FMN)(cyhn) (M=Pd, Pt) are shown in Fig. 2. Similar spectra are also obtained for the complexes M(FMN)(en). The bands in the 25000—38000 cm^{-1} region arise from the complex formation, because FMN do not show strong

absorptions below 42000 cm^{-1}. Since the formal charge of Pd and Pt in the complexes is zero, these bands are probably due to charge transfer from the metal d-orbitals to the FMN π^*-orbital. In their spectroscopic study of *trans*-[(ol)$PtCl_2L$] (ol=olefin), Denning *et al.*[15] also reported that the transitions from metal d-orbitals to olefin π^* are observed in the 31000—45000 cm^{-1} range. The molar extinction coefficients of M(FMN)(cyhn) also support the above assignment, because they are $\sim 10^3$ and comparable to those reported for *trans*-[(ol)$PtCl_2L$].[15,16] For the other complexes studied here we could not find any bands assignable to charge transfer from metal d-orbitals to FMN π^* or vacant d-orbitals of a phosphorus atom[17] because of the strong absorption of the ligand other than FMN (Fig. 2).

Experimental

The PMR spectra were recorded with a JEOL-C-60H spectrometer. The UV spectra were recorded with a HITACHI 323 spectrophotometer, using acetonitrile as the solvent. All the reagents were commercially available and were used without further purification. The $Pd(PPh_3)_4$,[18] $Pt(PPh_3)_4$,[19] and $Pt(AsPh_3)_4$[20] were prepared by the methods reported in the literature.

Fumaronitrilebis(triphenylarsine)palladium(O). To an ethanol solution of $AsPh_3$ (3.2 g) we added an aqueous solution of K_2PdCl_4 (1.6 g) at 50—60°C. Fumaronitrile (0.5 g) and then 10 ml of an ethanol solution of $NH_2NH_2 \cdot H_2O$ (10%) were added slowly to the mixture at 50—60°C. About 20 min later, the pale yellow products were filtered off and washed with water, ethanol, and diethyl ether.

Fumaronitrilebis(triphenylarsine)platinum(O). $Pt(AsPh_3)_4$ (2.1 g) was stirred into a benzene solution (100 ml) of FMN (0.2 g). After the complete dissolution of the $Pt(AsPh_3)_4$, the solution was filtered and concentrated to about 10 ml *in vacuo*. The white precipitates formed by adding methanol were filtered off and washed with diethyl ether.

Fumaronitrile-1,2-bis(diphenylarsino)ethanepalladium(O). A solution of 1,2-bis(diphenylarsino)ethane (0.6 g) in benzene (20 ml) was added to a solution of $Pd(FMN)(AsPh_3)_2$ (0.8 g) in benzene (50 ml) at room temperature. The solution turned pale yellow; by adding ethanol to the concentrated solution, pale yellow materials were precipitated. Recrystallization from chloroform–diethyl ether gave pale yellow crystallines.

In a similar manner, Pd(FMN)(P-P), Pt(FMN)(As-As), and Pt(FMN)(P-P) were prepared.

Fumaronitrile(α,α'-bipyridyl)palladium(O). To a solution of $Pd(FMN)(AsPh_3)_2$ (0.8 g) in benzene (60 ml), we added a solution of α,α'-bipyridyl (0.3 g) in benzene (40 ml) at room temperature. The solution turned yellow-green and then gave pale yellow precipitates. It was filtered and washed with benzene. By analogous methods, Pd(FMN)L was prepared (L is o-phen and 2,9-phen).

Fumaronitrile(ethylendiamine)palladium(O). To a solution of $Pd(FMN)(AsPh_3)_2$ (0.8 g) in benzene (60 ml), we added a solution of ethylenediamine (0.1 ml) in benzene (40 ml). White materials started to precipitate in a few minutes. After the mixture had been stirred for 1 hr, the precipitates were filtered off and washed with benzene. Pt(FMN)(en), Pd(FMN)(cyhn) and Pt(FMN)(cyhn) were prepared in a similar way.

Triphenylarsinetris(triphenylantimony)palladium(O). A solution of triphenylantimony (1.4 g) in benzene (40 ml) was added to a solution of $Pd(FMN)(AsPh_3)_2$ (0.8 g) in benzene (60 ml) at room temperature. The solution turned yellow and then gave white precipitates. After 1 hrs' stirring, the precipitates were filtered off and washed with benzene and ether. Found: C, 58.0; H, 3.8.% Calcd for $C_{72}H_{60}AsPdSb_3$: C, 58.8, H, 4.1%.

The analytical data for the fumaronitrile complexes are summarized in Table 3.

A Separation Scheme for the Analysis of Metal Ions Using Column Extraction Chromatography. Grouping of Nineteen Metal Ions into Six Fractions[1]

Ikuko AKAZA,* Takatoshi TAJIMA,** and Toshiyasu KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa

(Received October 3, 1972)

A new scheme for the quantitative group separation of 19 common cations by reversed-phase extraction column chromatography has been devised. The following six columns, in which the organic solvent was adsorbed on Daiflone(polytrifluorochloroethylene), were prepared: a TBP–2N HCl column for Fe(III), Hg(II), and Sn(IV); a TOA(CCl_4)–2N HCl column for Ag(I), Bi(III), Zn(II), and Cd(II); a TBP–6N HCl column for Sb(III); an AcAc($CHCl_3$)–pH 5.0 column for Cr(III) and Al(III); a TTA(MIBK)–pH 5.0 column for Cu(II), Co(II), Ni-(II), Pb(II), Mn(II), and Mg(II), and a TTA(MIBK)-pH 7.0 column for Ca(II), Sr(II), and Ba(II). After a test solution had been passed through the six columns successively in the above order, the metal ions are grouped and entirely retained on the specified columns.

Most of the investigations of the mutual separation of metal ions have been mainly concerned with the specific problems involved in separating some desired elements from their mixture, or in separating an important element from many other unimportant ones; therefore, a more general separation method for each ion from a mixture of various metals, of any composition, is much to be desired.

We aimed to establish a systematic scheme for the separation of many metals in macro to trace amounts; as the first report on our continuing study, this paper will present a quantitative grouping scheme for 19 common metals by reversed-phase extraction chromatography using six different columns.

A sequential separation scheme for the quantitative analysis of many different metal ions had been the object of much searching; recently, among the many kinds of separation techniques, the solvent extraction technique has been preferred for this purpose; there having been several reports on it, including those by Chalmers *et al.*[2–4] and more recently by Morsches and Tölg.[5]

Unless the distribution coefficients of metal ions differ remarkably from each other, multiple extraction steps such as counter-current extraction are required for any quantitative separation, and this is tedious. If reversed-phase extraction-column chromatography, which is closely related to liquid-liquid extraction in the batch system, could be adopted for the purpose, the multiple extraction would take place successively in the column; the extraction column technique can be used for trace to macro levels with a very simple apparatus, and this apparatus can, if necessary, be automatized. There have been a few reports in which the extraction chromatography has been used for the separation of a mixture involving many metals. Among these, one described the use of a α-benzoinoxime–$CHCl_3$–polytetrafluoroethylene bed,[6] and others, the use of a di(2-ethylhexyl)orthophosphoric acid–Kieselguhr column,[7,8] both being combined with an ion-exchange column; the metals were thus separated into several groups suitable for their gamma spectrometry. Recently, a comprehensive separation scheme has been devised by Fritz and Latwesen[9] for the separation of 27 metal ions with trioctyl phosphine oxide, isopropyl ether, and isobutylmethyl ketone columns in combination with an ion-exchange column; it seems an excellent work in our field of investigation. The procedure of Deing *et al.*,[10] involving extraction with a tri-*n*-butylphosphate and di(2-ethylhexyl)orthophosphoric acid column, has also been proposed for the separation of fission products of irradiated uranium. The present paper will describe the systematic and quantitative group separation of 19 common metal ions using six columns based on reversed-phase extraction chromatography; tri-*n*-butylphosphate(TBP)–6 N HCl, TBP–2 N HCl, tri-*n*-octylamine(TOA)–CCl_4–2 N HCl, acetylacetone(AcAc)–$CHCl_3$–pH 5.0, 2-thenoyltrifluoroacetone(TTA)–methyl isobutyl ketone–(MIBK)–pH 5.0, and TTA–MIBK–pH 7.0 columns. These columns were named the TBP-(1) column, the TBP-(2) column, the TOA column, the AcAc column, the TTA-(1) column, and the TTA-(2) column respectively. The grouping metal ions from a complex mixture of various metals in varying concentrations is the first step to a quantitative separation of each metal alone from the respective column.

The Selection of The Extraction System and The Construction of a Separation Scheme. It is necessary to select a good extractant, a suitable solvent, and the optimum conditions for the purpose from the wide variety of extraction systems which have been reported. The authors chose the extraction systems described above for those reasons. Extraction systems should

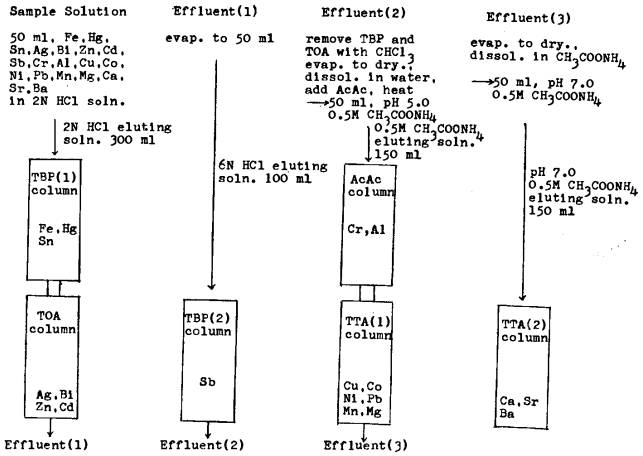

Fig. 1. Scheme of group separation.

be selective; that is, the extractability of the metal ions to be separated must be high enough for them to be retained on the upper part of the extraction column. The distribution of each metal ion should be markedly dependent on the acidity or pH of the aqueous medium; if so, the metal ions retained on the column can be eluted easily by varying the acidity or pH of the eluting solution. A simple medium in which no masking agent or nonvolatile salt exists is also preferred as an eluant, for its use will facilitate the subsequent determination of metals and the simple isolation of the compound.

The scheme shown in Fig. 1 was prepared for the group separation of 19 common cations by reversed-phase extraction column chromatography, with reference to sufficient information about the behavior of each element in the extraction system, taking the following points into consideration: (1) the extractions of the metal ions, readily hydrolyzable in a weakly acidic solution, were done in the earier stage of the separation process; (2) two columns in which eluting solutions of an identical acidity or pH could be used were joined together, and (3), the separation conditions were set up so as none of the retained metals could be released from the column even when a sample solution of a large volume flowed through.

Experimental

Reagents and Materials. *Daiflon*: Daiflon (a trade name of polytrifluorochloroethylene) M-300 moulding powder was purchased from the Daikin Kogyo Co.; 42-to 80-mesh powder was used.

Metals: Chlorides and nitrates of metals of an analytical reagent grade were dissolved in hydrochloric, nitric acid, or redistilled water.

Organic Reagents and Solvents: TTA, MIBK, chloroform, TOA, carbon tetrachloride, AcAc, and TBP were all of a chemically pure grade.

Radiochemicals: Several radionuclides were employed in order to ascertain the behavior of individual ions in the chromatography: Fe-59, Hg-203, Sn-113, Bi-207, Ag-110m, Zn-65, Cd-115m, Sb-124, Co-60, Ni-63, Sr-90, and Ca-45 were employed. The radiochemical purity of these nuclides was examined by measuring their half-lives, γ-ray spectra, and β-ray adsorption curves with aluminum foils.

Organic Solvent Solutions Available for the Stationary Phase of the Column. In each case the organic solvent solution used for the stationary phase should be in equilibrium with the eluting solution which comes in contact with the column.

100% TBP Solution for the TBP(1) and TBP(2) Columns: The TBP was equilibrated with 2 N (or 6 N) HCl.

20% TOA–CCl_4 Solution for the TOA Column: This solution was equilibrated with an equal volume of 2N HCl.

50% AcAc–$CHCl_3$ Solution for the AcAc Column: This solution was equilibrated with an equal volume of an 0.5 M ammonium acetate solution of pH 5.0 which had been saturated with an AcAc–$CHCl_3$ solution.

1.5 M TTA–MIBK Solution for the TTA(1) and TTA(2) Columns: This solution was equilibrated with an equal volume of an 0.5 M ammonium acetate solution of pH 5.0 (or 7.0) which had been saturated with MIBK.

Eluting Solutions. Each eluting solution was equilibrated with a proper organic solvent solution placed in the column.

Eluting Solution for the TBP(1) and TBP(2) Columns: 2 N (for Column 1) or 6 N (for Column 2) HCl which had been saturated with a small amount of TBP was used.

Eluting Solution for the TOA Column: 2 N HCl saturated with a TOA–CCl_4 solution was used.

Eluting Solution for the AcAc Column: Fifty milliliters of AcAc were placed in a 1-l separating funnel, and then 300 ml of water saturated with $CHCl_3$ and 125 ml of a 2 M ammonium acetate solution which had been saturated with $CHCl_3$ were added. The funnel was shaken, and a very small amount of the undissolved AcAc was rejected; then the aqueous phase was transferred into a measuring flask, and its volume was made up to 500 ml with water saturated with $CHCl_3$. The pH of this solution was then adjusted to 5.0 by adding 0.5 M acetic acid saturated with $CHCl_3$.

Eluting Solution for the TTA(1) Column: A TTA reagent (3.1 g) was dissolved, with shaking for 30 minutes, in 900 ml of a 0.5 M ammonium acetate solution which had been saturated with MIBK, then the pH of the solution was adjusted to 5.0 by adding 0.5 M acetic acid saturated with MIBK. The total volume was made up to 1 l with a solution of 0.5 M ammonium acetate solution saturated with MIBK.

Eluting Solution for the TTA(2) Column: With a TTA reagent (3.2 g), the eluting solution was prepared in the manner described just above, but the pH was adjusted to 7.0.

The amount of a TTA reagent to be dissolved in the eluting solution was determined in accordance with Reference 11.

Test Solutions. Stock solutions, each containing 0.5 mg of the metal ion in question per ml, were prepared. A test solution was prepared by diluting the stock solution so as it contained 1.0 mg of each element per 100 ml; in some cases, a radioactive tracer was added to the test solution. Fifty milliliters of the test solution were used for the column experiment. It is often desirable, but not in all cases, that the test solution have a composition similar to that of the eluting solution except for the metal ion. According to the variety of the metal ion in the sample solution to be tested, some part of the scheme shown in Fig. 1 may be omitted. Therefore, in such a case a test solution should have a composition similar to that of the eluting solution for the column from which the systematic separation starts.

The "test solution used for the AcAc column" was prepared as follows: Two milliliters of a stock solution (if necessary, with a radioactive tracer) were placed in a beaker and

11) I. Akaza, M. Kozaka, and T. Imamura, *Bunseki Kagaku*, **14**, 825 (1965).

diluted to about 20 ml with water saturated with AcAc–$CHCl_3$. The pH was adjusted to 5.0 by adding 0.5 M acetic acid or aqueous ammonia, both saturated with $CHCl_3$; 5 ml of AcAc were then added to this solution. The beaker was heated gently for an hour, and then cooled. Twenty-five milliliters of a 2 M ammonium acetate solution saturated with AcAc–$CHCl_3$ were added to this solution, and the pH was adjusted to 5.0 by adding 0.5 M acetic acid or aqueous ammonia, both saturated with $CHCl_3$. Finally, the solution was transferred into a measuring flask and its volume was made up to 100 ml with water of pH 5.0 which had been saturated with the AcAc–$CHCl_3$ solution.

Experimental Procedure. Column Preparation. A glass chromatographic column, 0.94 cm in diameter and 30 cm long, and with a coarse frit at the bottom, was used. The Daiflon powder (5.5 g) was placed in an Erlenmyer flask fitted with a stopper, and then a definite volume of a proper "organic solvent solution for the stationary phase" (described above) was poured in. The preferable volumes of the organic solvent are 6.0 ml of TBP, 7.0 ml of 20% TOA–CCl_4, 5.0 ml of 50% AcAc–$CHCl_3$ and 6.5 ml of 1.5 M TTA–MIBK for each 5.5-g portion of Daiflon; these volumes were derived from the results of other preliminary experiments, in which the adsorbable amount of each organic solution on Daiflon had been determined. The stoppered flask was shaken gently by hand and was then left to stand over three hours. A small volume of an adequate eluting solution was added, and the slurry was poured into the chromatographic column. Every time a small portion of slurry was added, the column bed was gently pressed with a glass rod; the bed length eventually reached about 20 cm. About 50-ml portion of an adequate eluting solution was passed through the column in order to remove any contaminant.

In such a way, the six columns were prepared.

Basic Chromatographic Procedure. Fifty milliliters of a test solution prepared as above were percolated through the column at the rate of about 0.3 ml per minute, and then an eluting solution of a definite composition was passed through at a flow rate of about 0.5 ml per minute. The effluent was taken in a fraction collector or in beakers.

In the chromatographic process, some metal ions in the test solution were retained on the column, while others passed through the column and went into the subsequent column.

Systematic Procedure for the Group Separation. One systematic procedure for the group separation of 19 common cations from their mixtures is based on the scheme shown in Fig. 1, in compliance with the basic chromatographic procedure described above. The following descriptions of the individual columns show that the method may be applicable for the grouping of 19 cations when the entire course of the scheme is followed. Nevertheless, if some part of the scheme is omitted when the ions which would be retained in the omitted column are known to be absent in a sample solution, the test solution should be prepared as described in the appropriate paragraph discussing the test solutions.

The test solution(a) for the TBP(1) column was fed into the TBP(1) column, which was joined with the TOA column. A 300-ml portion of the "eluting solution for the TBP(1) column" was run through both columns. The effluent(1) from the lower column was collected in a beaker and evaporated to a small volume, and then the volume was make up to 50 ml with water saturated with TBP (test soln. (b)). The test solution (b) was fed into the TBP(2) column, and then 100 ml of "the eluting solution for the TBP(2) column" was run through this column. The effluent (2) was collected, 1 ml of concentrated nitric acid was added, and then the solution was shaken, together with a small volume of chloroform, for a minute in order to remove the small amount of dissolved TBP and TOA from the aqueous solution. After that, the aqueous phase was collected and evaporated to dryness under an infrared lamp in order to expel the free nitric acid and hydrochloric acid. The residue was dissolved in about 20 ml of water saturated with AcAc–$CHCl_3$ solution. After the pH of this solution had been adjusted to 5.0, 2.5 ml of AcAc was added to this solution; then the mixture was heated gently for an hour until the completion of the formation of the AcAc-chelates with metal ions. After cooling, 12.5 ml of a 2 M ammonium acetate solution saturated with $CHCl_3$ was added to the solution, and the pH of the solution was adjusted again to 5.0. Finally, the volume was made up to 50 ml with water saturated with the AcAc–$CHCl_3$ solution (test soln. (c)). The test solution (c) was poured into the upper column of the combined set of AcAc and TTA(1) columns, and 150 ml of "the eluting solution for the AcAc column" was run through these combined columns. The effluent (3) from the lower column was collected in a beaker and evaporated to dryness. The residue was dissolved again in "the eluting solution for the TTA(2) column," and the volume was made up to 50 ml with the solution (test soln. (d)). The test solution (d) was placed in the TTA(2) column, and then 150 ml of "the eluting solution for the TTA(2) column" was run through the column in order to wash it (effluent (4)). Finally, the columns were separated from one another, and the metal ions retained on each column were eluted with a suitable solution or were removed from the column, together with the stationary phase, by washing the column with ethanol. The metal ions thus released were determined as will be described below.

Determination of Metal Ions. In general, the metal ions in the effluent from each column were determined colorimetrically, radiometrically, or flamephotometrically. The

Table 1. The analytical methods used for the determination of the metal ions

Metal	Method
Fe	Radiometric (Fe-59)
Hg	Radiometric (Hg-203)
Sn	Radiometric (Sn-113)
Bi	Radiometric (Bi-207)
Ag	Radiometric (Ag-110 m)
Zn	Radiometric (Zn-65)
Cd	Radiometric (Cd-115 m)
Sb	Radiometric (Sb-124)
Cr	Spectrophotometric as dichromate (440 mμ)
Al	Spectrophotometric as oxinate (390 mμ)
Cu	Spectrophotometric as diethyldithiocarbamate (435 mμ)
Co	Radiometric (Co-60)
Ni	Radiometric (Ni-63)
Pb	Spectrophotometric as dithizonate (510 mμ)
Mn	Spectrophotometric as permanganate (520 mμ)
Mg	Spectrophotometric as oxinate (380 mμ)
	Atomic adsorptiometric
Ca	Radiometric (Ca-45)
	Flamephotometric (554 mμ)
Sr	Radiometric (Sr-90)
	Flamephotometric (460.7 mμ)
Ba	Flamephotometric (515 mμ)

analytical method used for the determination of each metal ion is described in Table 1. In the case of colorimetric methods, MIBK, chloroform, and carbon tetrachloride were apt to be present in the effluent; they had to be removed by evaporation. A small amount of TBP and TOA in the effluent did not interfere with the colorimetric method, but TTA and AcAc did. When TTA or AcAc was present in the effluent, concentrated nitric acid was added to the solution and then the solution was evaporated to dryness to decompose the organic matter.

When the effluent was fractionated in the tubes of a fraction collector, each fraction was submitted to the determination of the metal ions. On the other hand, the whole effluent from one column was collected and evaporated to a small volume under an infrared lamp; then the final solution was made up to 50 ml with a suitable acidic solution. An aliquot of this solution was also pipetted out for the determination of the metal ions.

When a radioactive tracer was employed, each metal ion in the effluent or on the column was checked not only by means of its radioactivity, but also by means of its specific reagent.

Visuable colored bands appearing on a column during the elution (for example, on the AcAc and TTA(1) columns) generally provided a good measure for the column separation: TBP(1) column–Fe(yellow), Sn(yellow); TBP(2) colun–Sb(yellow); AcAc column–Cr(light violet-brown); TTA(1) column–Cu(green), Co(red-brown), Ni(light yellow-green), Pb(light yellow), Mn(orange-yellow).

Results and Discussion

Chromatographic Behavior of Metal Ions. If separation proceeds chromatographically on the basis of only the partition phenomenon, the chromatographic behavior of each metal ion on the column can be predicted by means of this equation: $E=D\cdot B+F$, where D is the batch distribution ratio, which has been otherwise obtained under conditions corresponding to those in the column extraction; E, the volume of the effluent before the emergence of the solute in a maximal concentration in the column; B, the volume of the stationary phase, and F, the volume of the mobile phase in the column.

Actually, the behavior of each metal ion was in good agreement with that predicted from the distribution ratio in the batch extraction. For example, in the TBP–HCl system, the extraction behavior of many metal ions against the concentration of HCl has been investigated in batch extraction by Ishimori *et al.*[12] and with reversed-phase thin layer chromatography by Bark *et al.*[13]; their extraction mechanisms have been also discussed by the latter. Their data, shown by the values of D or R_f, and the results we have obtained here are given in Fig. 2. The behavior of the metal ions in this reversed-phase chromatography agreed with those predicted from the data of the batch extraction and the thin-layer chromatography in relation to the concentration of HCl of the aqueous phase.

Retention of Individual Ions on the Column. To examine quantitatively the retention of each metal ion on a column, a 50-ml portion of a test solution containing a metal ion was first fed into the column, and then a 100-ml portion of an adequate eluting solution was passed through the column. The amounts of both the metal ion retained on the column and that in the effluent were determined, and the percentages of retention were calculated. No loss of metal ions was found in any column experiment; more than 99% of them could be recovered. The results obtained are illustrated in Table 2. Iron, mercury and tin were perfectly retained on the TBP(1) column from 2 N HCl, and Bi, Ag, Zn, and Cd were also retained on the TOA column from 2 N HCl; Sb was completely retained on the TBP(2) column from 6 N HCl. Chromium and aluminum were retained on the AcAc

column, and Cu, Co, Ni, Pb, Mn, and Mg on the TTA column from a 0.5 M ammonium acetate buffer solution of pH 5.0. Calcium, strontium, and barium were perfectly retained on the TTA column from a 0.5 M ammonium acetate solution of pH 7.0. The bismuth, silver, zinc, and cadmium on the TBP(1) column ($D=10$), Sb on the TOA column ($D=5$), Zn and Cd on the TBP(2) column ($D=15$) and Cu on the AcAc column ($D=8$) were not completely washed down from the column because of their relatively higher distribution ratios; they still remained on the lower part of the column. These metal ions could, however, be eluted from the column by the subsequent passing of an adequate eluting solution through the column.

The Bahavior of the Metal Ions in a Mixed Solution on Each Column. In achieving the group separation of cations, it is also necessary to examine the chromatographic behavior of the metal ion in question as well as that of all the other ions by passing mixed solutions through the respective columns in the scheme of group separation. Fig. 3 summarizes the features of the chromatographic behavior of each metal ion in the presence of all the others. This has been constructed of the data collected by many experiments carried out with 50-ml portions of test solutions containing all the metal ions except the metal ion in question. In such a case, the behavior of all the metal ions can not be defined simultaneously; therefore, only the behavior of the desired metal ion was followed by the use of its radioactive tracer, or by other methods, in the presence of all the others.

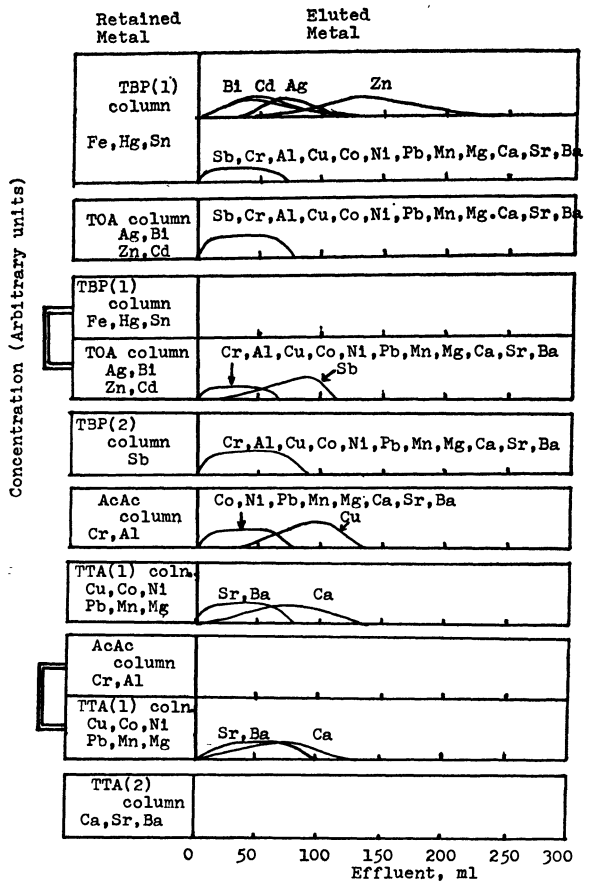

Fig. 3. The behavior of the 19 metal ions on each column. Sample solution: 50 ml, containing each 0.5 mg of cations.

As is shown at the left-hand side in Fig. 3, Fe, Hg, and Sn on the TBP(1) column, Ag, Bi, Zn, and Cd on the TOA column, Sb on the TBP(2) column, Cr and Al on the AcAc column, Cu Co, Ni, Pb, Mn, and Mg on the TTA(1) column, and Ca, Sr, and Ba on the TTA(2) column were retained completely on the upper part of the column, even after 300 ml of the eluting solution had been passed through. On the other hand, most of the other cations passed through each column easily; these data were represented by the elution curves. These results are in good agreement with those shown in Table 2; the results on the TTA(2) column are also in good agreement with those obtained in the previous paper.[14]

A Combined Column Consisting of the TBP(1) and the TOA Columns in Fig. 3: As has been mentioned above, the eluting solutions for both the TBP(1) and TOA columns were of the same acidity. Therefore, if the TBP(1) column could be joined to the top of the TOA column, the separation procedure would become simpler. Fifty milliliters of a test solution containing 19 cations were fed into the combined columns. After a 300-ml portion of the "eluting solution for the TBP(1) column" had been run through the two columns, the metal ions were determined in each fraction of the effluent. Finally, the two columns were disjoined and the metals retained on each column were determined respectively. The result was in good agreement with that obtained with a single column. Therefore, when both the TBP(1) and TOA columns must be employed, a combined column should always be used in the separation process.

The Combined Columns Consisting of the AcAc and TTA (1) Columns in Fig. 3: The acetylacetone column was joined to the top of the TTA(1) column for the same reason as in the case of the TBP(1) and TOA columns. Fifty milliliters of the test solution for the AcAc column were fed into the combined column, and then 200 ml of "the eluting solution for the AcAc column" was run through the column; each fraction of the effluent from the lower column was submitted to a determination of the metal ions. The columns were then disjoined from each other, and the retained metal ions were determined. The results agreed with those obtained in the experiment using the two columns were separately. Thus, it is possible to effect the group separation by using a combination of the AcAc column and the TTA column.

The Group Separation of 19 Common Cations. On the basis of the scheme shown in Fig. 1, the group separation of 19 common cations from their mixtures was carried out without a fraction collector in order to prove the practical usefulness of the method. After the entire course of the scheme had been finished, each column was separated from the other and the metal ions retained on each column were determined.

14) I. Akaza, This Bulletin, **39**, 980 (1966).

The actual separation into the six groups was successfully achieved; the results agreed well with the expectations mentioned in the previous paragraph. Consequently, it was clarified that the scheme devised by the present authors was useful and effective for the group separation of 19 common cations, and might also be useful for the practical analysis of a sample solution containing these cations.

The Catalytic Effect of the Bismuth Nitrate on the Autoxidation of Olefins

Fujio TSUCHIYA and Tsuneo IKAWA

Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo

(Received March 9, 1972)

The catalytic effect of the bismuth nitrate on the autoxidation of olefins has been investigated. Nitrogen dioxide, oxygen atoms, and bismuth oxynitrate, which are the thermal decomposition products of the bismuth nitrate, are not involved in the initiation of the reaction. The bismuth nitrate is only effective on olefinic compounds, not on saturated hydrocarbons, and it does not decompose hydroperoxide. The catalysis of the bismuth nitrate is supposed to result from direct interaction with olefin.

Metal-ion catalysts have generally been used in autoxidation in the form of metal salts of organic acids, and the catalyses of metal ions on the autoxidation of hydrocarbons are classified into the following three effects on the initial step of the oxidation: the formation of alkoxy and alkylperoxy radicals by the metal-ion-catalyzed decomposition of hydroperoxide, the formation of alkyl radicals from hydrocarbons by a higher valent metal ion, and the formation of radicals by the metal-oxygen complex.[1]

In the previous paper,[2] it has been reported that the bismuth nitrate is the most effective catalyst among many bismuth compounds as an initiator for the oxidation of isobutene. In this paper, the mechanism of catalysis by the bismuth nitrate has been mainly investigated from the point of view of the character of the nitrate. The effect of nitrogen dioxide, oxygen atoms, and bismuth oxynitrate, which may be formed from bismuth nitrate by its thermal decomposition during the reaction, have been examined, but their formation and contribution have been negligibly small. Iodometric observation has been undertaken in order to ascertain whether or not the bismuth nitrate decomposes hydroperoxide to active free radicals; it has been found not to decompose hydroperoxide. The autoxidation of nonolefinic hydrocarbons, such as cumene and tetralin, has not been catalyzed by the bismuth nitrate. The catalysis of the bismuth nitrate can not be attributed to the three mechanisms mentioned above, but can be assumed to result from the direct interaction between the bismuth nitrate and the double bond of olefin.

Experimental

A stainless autoclave with a reservoir and a magnetic stirrer[2] was used for the autoxidation of olefins. The volume of the reaction mixture was kept at 50 ml; the total pressure, 20 kg/cm^2; the partial pressure of oxygen, 5 kg/cm^2, and the reaction temperature, 100°C. Acetonitrile was used as the solvent. The oxidation of cyclohexene and some saturated hydrocarbons has been carried out in an oxygen-absorption apparatus[3] under atmospheric pressure. Iodometry was carried out by means of the chloroform method.[4]

The gaseous olefins were 99.0% pure grade. Cyclohexene and other hydrocarbons were purified by distillation in a nitrogen atmosphere. The glycerol was of a chemical pure grade. The metal nitrates, stored in a dark ice box, were of a chemical pure grade and were used without further purification. The nitrogen dioxide was obtained by the thermal decomposition of the lead nitrate at 500°C and was stored in a dry ice box.

Gas chromatography was used to analyse the reacted and unreacted substances; the volatile substances using a 3-m column of polyethylene glycol(PEG) 1000 at 80°C; the nonvolatile substances using temperature-programed gas chromatography with a 3-m column of PEG 20M, and unreacted butenes using a 5-m column of benzyl cyanide-$AgNO_3$ at room temperature.

Results and Discussion

Decomposition of Hydroperoxide. The bismuth nitrate oxidized potassium iodide to iodine, and the

amount of iodine produced was measured by iodometry in a chloroform solution. The results are tabulated in Table 1. The iodine isolated increased with the increase in the amount of the bismuth nitrate, but the molar ratio of the iodine isolated to the initially-added bismuth nitrate was nearly constant. Then, the bismuth nitrate was added into an acetonitrile solution of cumyl hydroperoxide and iodemetry was carried out on this mixture. The amount of iodine thus isolated was equal to the sum of the quantities of iodine which were obtained in each iodometry of the bismuth nitrate and cumyl hydroperoxide (Table 1). These were increased in the amounts of the bismuth nitrate and cumyl hydroperoxide initially added, but the total amount of iodine was nearly equal to the sum of the individual quantities of iodine (Table 1). From these results, we consider that the bismuth nitrate does not decompose hydroperoxide in the atmosphere.

The Autoxidation of Nonolefinic Hydrocarbons in the Presence of the Bismuth Nitrate. The autoxidation of nonolefinic hydrocarbons, such as tetralin, cumene, and *p*-xylene, was carried out in the presence of the bismuth nitrate; the results are listed in Table 2. The induction periods were very long, even in the presence of the bismuth nitrate, on the autoxidation of saturated hydrocarbons. Although cumene has an active tertiary hydrogen atom, on which can easily be abstracted, no oxygen absorption was observed. This indicates that the bismuth nitrate promotes only the autoxidation of olefins and that the catalytic effect is not based on the direct hydrogen abstraction from an organic compound by a metal ion, such as a higher valence metal ion or a metal-oxygen complex.

The Effect of Metal Nitrates. Metal nitrates such as cobaltous, manganous, ferric, and lead nitrates, were added to a solution of isobutene in order to investigate the effect of nitrates. The results are shown in Table 3. The nitrate effect was observed in the cases of ferric nitrate and the bismuth nitrate; some oxygen was absorbed, and some products, such as acetone and isobutene oxide, were obtained. The cobaltous and manganous nitrates scarcely promoted the oxidation, while these metal salts of organic acids are known to be effective catalysts for the autoxidation of hydrocarbons. This is interesting phenomenon and must be due to the ligand effect of a metal complex. The lead nitrate did not have promoting effect at all.

These nitrates oxidized potassium iodide to iodine; the results are tabulated in Table 4. The amounts of iodine isolated per mole of each metal nitrate were nearly equal to one another except for the ferric nitrate. For the ferric nitrate, the higher value of iodine may be due to the higher valence of the ferric ion. However, this oxidizing ability does not correspond to the promoting effect of the autoxidation.

The decomposition temperatures of the metal nitrates, which were taken from the literature, are also tabulated in Table 4. The promoting effect of the nitrate corresponded to the decomposition temperature of the nitrate except for the cobaltous nitrate; the bismuth nitrate and the ferric nitrate, which decompose at comparatively low temperatures, were effective promoters, and the lead nitrate, which decomposes at a very high temperature, did not have any promoting effect at all. From these results, it can be supposed that nitrogen dioxide, the oxygen atom, and bismuth oxynitrate, which may be formed by the thermal decomposition of the bismuth nitrate during the oxidation of hydrocarbons in the presence of the bismuth nitrate, will contribute to the initial step of the oxidation. Therefore, it became necessary to examine whether or not, nitrogen dioxide, the oxygen atom, and bismuth oxynitrate participate in the initiation of the reaction.

First of all, the effect of nitrogen dioxide was exa-

mined; a blue solution of nitrogen dioxide–acetonitrile was introduced into the reaction mixture, after with oxygen was introduced at 100°C under a reaction pressure of 15 kg/cm². After few minutes of oxygen introduction, the absorption of oxygen began and some oxygenated products were obtained (Table 5). The distribution of these products was the same as Brill's[5] and Imamura's[6] reports. It is obvious that nitrogen dioxide initiates the reaction; this result corresponds to Titov's indication[7]: nitrogen dioxide adds to the double bond of olefin and form a radical. If the bismuth nitrate thermally decomposes to give nitrogen dioxide, the autoxidation will be initiated by nitrogen dioxide. On the other hand, when glycerol (2.7 mol/l) was added to the solution on the oxidation of isobutene in the presence of the bismuth nitrate, the absorption of oxygen was suppressed and oxygen absorption was not observed until about 70 min after the introduction of the oxygen. The inhibiting effect of glycerol was examined at 70°C(Fig. 1). The rate of oxygen absorption decreased with the increase in the amount of glycerol added. However, the apparent absorption of oxygen was observed a few minutes after oxygen introduction on the oxidation of butene in the presence of nitrogen dioxide, and oxygenated products were obtained (Table 5). These results indicate that glycerol only disturbs the oxidation of isobutene in the presence of the bismuth nitrate and does not inhibit the oxidation initiated by nitrogen dioxide. Moreover, nitrogen dioxide was not observed experimentally on the oxidation of olefin in the presence of the bismuth nitrate(Table 3). If the nitrogen dioxide is formed from the bismuth nitrate, it should be effective for the oxidation of cumene, for it has been reported by Nanba *et al.*[8] that nitrogen dioxide is able to abstract a hydrogen atom from cumene at 70°C. Judging from these results, it is difficult to take nitrogen dioxide as the active origin of the bismuth nitrate on the autoxidation of olefins. An oxygen atom in the triplet state is able to abstract hydrogen atom from hydrocarbons[9] and to initiate the autoxidation. A singlet oxygen atom can not abstract a hydrogen atom from hydrocarbons, but it can give rise to insertion reaction.[10] If the bismuth nitrate generates an oxygen atom by its thermal decomposition, the autoxidation of hydrocarbons will occur by hydrogen abstraction in case of the triplet oxygen atom generated. However, it is difficult to take the oxygen atom possibly generated from the nitrate as the active origin of the bismuth nitrate on the oxidation of olefins, because no catalytic effect of the bismuth nitrate was observed in the case of the oxidation of saturated hydrocarbons, such as cumene and tetralin (Table 2).

The effect of bismuth oxynitrate was examined by means of infrared absorption spectra. The IR spectra of the bismuth nitrate, $Bi(NO_3)_3 5H_2O$, is shown in Fig. 2; the characteristic absorption bands at 830, 1380, and 1620 cm^{-1} have been attributed to the modes of bending, stretching, and harmonics of the bending of the(N–O) bond respectively by Vratny.[11] The

absorption at 1620 cm^{-1} can also be attributed to the bending of H–O–H in the lattice. The IR spectra of the white substance recovered from the solution after a 50-min reaction using bismuth nitrate as the catalyst at 100°C are shown in Fig. 3. The absorptions at 830 and 1620 cm^{-1} decreased a little in their intensities, and the band at 1380 cm^{-1} became broad. However, the characteristic absorption were the same as those in Fig. 2. Cismaru *et al.*[12] indicate that the oxynitrate has split absorptions at 1320 and 1380 cm^{-1} as a result of an increase in the covalent bond-character of the (N–O) bond. Therefore, we can regard the recovered substance as a bismuth nitrate containing no bismuth oxynitrate. The spectra of the bismuth nitrate treated in benzene at 80°C for 1 hr were the same as those of the untreated one(Fig. 4). From these results, we can suppose that the bismuth nitrate is rather stable in circumstances, even if it is heated, and that the active origin of the bismuth nitrate is of itself.

cis-trans *Isomerization.* It has been reported in the previous paper[2] that the recovered *cis*-2-butene contained the *trans*-isomer after the oxidation of *cis*-2-butene at 100°C under a pressure of 20 kg/cm^2 in the presence of the bismuth nitrate. The isomerization of *cis*-2-butene was examined further in this paper. It was observed to take place in the presence of the bismuth nitrate with and without oxygen. It was also observed when nitrogen dioxide and bismuth trichloride were added; our findings are summarized in Table 6.

Glycerol did not prevent the isomerization so much, but it did prevent the oxidation. In the presence of glycerol, nitrogen dioxide promoted both the isomerization and the oxidation. The isomerization with the catalysts used here must be due to both protonic acid and to the coordinating of olefin to the bismuth

nitrate. In the case of the oxidation, the coordination of olefin is probably prevented by the glycerol coordinated on the bismuth nitrate and the rate of oxidation is reduced. It can be assumed from above results that the initiation of the oxidation by the bismuth nitrate occurs by the direct interaction of the bismuth nitrate with olefin. The direct interaction was examined by studying the infrared spectra of the solution of bismuth nitrate–cyclohexene (Fig. 5). New bands, which were not observed on either the bismuth nitrate or cyclohexene, were observed at 430, 780, 1000, and 1880 cm^{-1}. Though the assignment of these bands is not clear, the newly-observed absorption, especially at 430 cm^{-1}, is significant because the absorption is near the characteristic absorption of Pt–C_2H_4(405 cm^{-1} in the Zeise salt. The coordination of cyclohexene is not clear in detail, but it is certain that the initiation of cyclohexene depends on this coordinated olefin. However, there is a possibility that a bismuth-oxygen complex may be formed during the reaction and that it contributes to the initiation by adding to the double bond of olefins. This possibility will be further investigated kinetically, and the direct interaction of the bismuth nitrate with olefin will be confirmed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 1208—1211 (1973)

A Study of the Catalytic Partial Oxidation of Hydrocarbons. XVI. The Effect of the Bi_2O_3 Content in the MoO_3-Bi_2O_3-P_2O_5 Catalysts on the Oxidation of Various Olefins, Acids, and Aldehydes

Mamoru Ai and Sadao Suzuki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 24, 1972)

The vapor-phase oxidation of various kinds of olefins, acids, aldehydes, etc. was carried out in a flow system over a series of MoO_3–Bi_2O_3–P_2O_5 catalysts with different Bi/Mo ratios (P/Mo=0.2 atomic ratio) under fixed reaction conditions, in order to elucidate how the oxidation of these compounds is affected by the Bi_2O_3 content in the catalysts. The oxidation activity for these compounds varies in different individual manners as the Bi_2O_3 content increases. The results were interpreted successfully on the basis of the acid-base nature of the reactant and the catalyst. Then, the relationship between the character of the partial oxidations and the nature of the catalysts was discussed.

The present authors have reported in recent papers[1,2] that the MoO_3–Bi_2O_3–P_2O_5 catalyst containing a high Bi_2O_3 content, which is well-known as an excellent catalyst for such an allylic oxidation as those of *n*-butene to butadiene and of propylene to acrolein, is inadequate for the oxidation of butene, butadiene, and furan to maleic anhydride, while a low-Bi_2O_3-content catalyst (Bi/Mo=0.1 atomic ratio) is quite good for the formation of maleic anhydride. Furthermore, it has also been proved that, with in increase in the Bi_2O_3 content in the catalyst, the oxidation activities for butene, butadiene, furan, and maleic anhydride vary, that the kinetics of both butene and butadiene is of about a 0.5 order in oxygen and a 0.8 order in olefin over the low Bi_2O_3 (Bi/Mo<0.15) catalysts, and that it becomes almost zero-order in oxygen and first-order in olefin over a high Bi_2O_3 (Bi/Mo> 0.5) catalyst.[2,3]

The authors have tried to interpret these results in terms of the acid-base nature of the catalyst and the reactant. With an increase in the Bi_2O_3 content, the basicity of the catalyst increases and its interaction with such electron donor-type compounds (base) as olefin decreases, while that with acids and oxygen increases. Thus it was interesting to confirm whether or not the oxidation aspects of other organic compounds could also be interpreted by the above-mentioned acid-base conception. In the present work, the oxidation of various kinds of organic compounds, including olefins, acids, and aldehydes, over a series of MoO_3–Bi_2O_3–P_2O_5 ternary catalyst system, while varying their Bi/Mo proportions in the presence of a large excess of oxygen, was performed in order to elucidate how the oxidation of these compounds is affected by the Bi_2O_3 content in the catalyst, and to obtain more detailed information about the oxidation over catalyst systems.

Experimental

The vapor-phase oxidation of various kinds of olefins, acids, aldehydes, etc., was carried out over a series of molybdenum-bismuth-phosphorus oxide catalysts with different Bi/Mo ratios (P/Mo=0.2 atomic ratio) in an ordinary continuous-flow-type reaction system, as has been described in an earlier paper.[4]

The concentration of the reactant was in the range of 0.6—1.5 mol% in air, the flow rate was kept at 1.5 l/min (at about 20°C), and the amount of the catalyst used was 40 ml; the contact time, which was shown by the volume of the catalyst (ml) per total flow rate (ml/s), was 1.6 s. The reaction temperature was increased at intervals of 10~20 from 250°C to 650°C, and the efflux from the reactor was analysed at each temperature until the conversion be-

came more than 50%. Before the analysis, the feed flow was passed over the catalyst at the desired temperature for more than about 20 min in order to obtain the data under steady-state conditions. The experimental and the analytical procedures were also identical with those employed in the earlier works.[1-4]

The catalysts used in these experiments were the same as those used in some preceding works.[2,3] They were calcined under flowing air at 550°C for 5 hr. The surface area of these catalysts was of the order of 3 m^2/g, as determined by the BET method, and the variation in the Bi_2O_3 content had little effect on the surface area.

Results

Oxidation of Olefins. The oxidation of such olefins as *cis*-2-heptene, 2-hexene, 2-pentene, *cis*-2-butene, butadiene, propylene, and ethylene was examined over a series of MoO_3–Bi_2O_3–P_2O_5 catalysts with different Bi/Mo ratios (P/Mo=0.2 atomic ratio) under fixed reaction conditions. The relationship between the catalyst composition and the oxidation activity for such olefins as 2-heptene, 2-hexene, 2-pentene, and *cis*-2-butene is plotted in Fig. 1. The range of activity variation is so wide that it is hard to express it by a reaction rate at a constant temperature. Therefore, the value of $1000/T_{50}$ is adopted as a measure reflecting the oxidation activity, where T_{50} means the reaction temperature (K) corresponding to the reactant conversion of 50%.

The results indicate that the catalytic activity for these olefins, excluding propylene, varies similarly when the Bi_2O_3 content in the catalyst increases; the activity increases and goes through a maximum at a Bi/Mo atomic ratio of about 0.1, and then it decreases to the value of the Bi_2O_3 alone catalyst, which is extremely inactive for olefins. The higher the olefin, the higher becomes the reactivity over the whole range of Bi/Mo ratios. It is also clear that the difference in the reactivity among these olefins is relatively small in the range of low Bi_2O_3 content (Bi/Mo<0.15), but in the range of Bi/Mo=1—2, the difference becomes very significant—*i.e.*, the reactivity increases as the number of carbon atoms increases.

The activity for lower olefins, including *cis*-2-butene, propylene, and ethylene, is shown as a function of the Bi_2O_3 content in Fig. 2. In the case of olefins lower than butene, the reactivity decreases markedly with a decrease in the carbon number; besides, the maximum activity is not observed at Bi/Mo=0.1. The activity for propylene passes through a maximum at about Bi/Mo=1—2. The reactivity of ethylene is too low to obtain detailed information about it, but it appears

that the Bi_2O_3-rich catalyst is more active than the Bi_2O_3-poor catalyst.

The activities for unsaturated C_4 compounds, that is, *cis*-2-butene, butadiene, and furan, are compared in Fig. 3. As has been mentioned in an earlier paper,[2] the reactivity-order of these compounds varies with an increase in the Bi_2O_3 content.

Oxidation of Acids. The oxidation of both saturated and unsaturated carboxylic acids—acetic acid, propionic acid, butyric acid, acrylic acid, crotonic acid, and maleic anhydride—is performed under fixed reaction conditions. The activities obtained are plotted as a function of the Bi_2O_3 content and compared in Fig. 4.

The results reveal:

a) the low Bi_2O_3 catalyst is very inactive for the oxidation of carboxylic acid, especially for unsaturated acid, but the high Bi_2O_3 catalyst is fairly active for the oxidation.

b) the activity for the oxidation of carboxylic acid always increases steadily with an increase in the Bi_2O_3 content.

c) acetic acid is much more stable than the higher saturated acids.

d) the reactivities of propionic acid and butyric acid are almost the same.

e) unsaturated acids are fairly stable in comparison with the corresponding saturated acids.

Oxidation of Aldehydes. Figure 5 shows the activity for the oxidation of various aldehydes, including propionaldehyde, butyraldehyde, acrolein, and crotonaldehyde, as a function of the Bi/Mo ratio. The results indicate:

a) the saturated aldehydes are much more reactive over the catalyst system than the other compounds.

b) the reactivities of propionaldehyde and butyraldehyde are almost the same.

c) unsaturated aldehydes are much less reactive than the corresponding saturated aldehydes.

d) the activity-curves for propionaldehyde, butyraldehyde, and crotonaldehyde vary with the same trend as for olefins higher than propylene.

e) the activity for acrolein changes in a unique manner; at a relatively low content of Bi_2O_3(Bi/Mo<1), acrolein is very stable, but at a higher Bi_2O_3 content (Bi/Mo> 2), it increases sharply.

Discussion

First, we attempted to discuss the oxidation aspects of these organic compounds, by supposing that the rate of contact oxidation is mainly affected by these three factors: (1) the amount of species adsorbed on the catalyst surface, which is closely related to the interaction strength between the catalyst and the reactant; (2) the reactivity or stability of the adsorbed species of the reactants, and (3) the availability of surface oxygen.

When the Bi_2O_3 content in the catalyst increases, the oxidation activities for the olefins of C_4—C_7 vary in a fashion similar to the activity for the dehydration of alcohol to olefin, which was adopted as a measure of the acidity of the catalyst, assuming that the dehydration occurs at acid sites of the catalyst.[5] This indicates that the oxidation activities for higher olefins, as well as those for butene and butadiene,[2,3] are intimately related to the acidity of the catalyst. According to the closeness of their ionization potential, if the amount of the adsorption is of about the same

5) M. Ai and S. Suzuki, This Bulletin, **46**, 321 (1973).

order of magnitude in C_4—C_7 olefins, the difference in the activities for these olefins observed in the Bi_2O_3-rich composition (Bi/Mo=1—2) may be attributed to the difference in reactivity of their adsorbed species, presumably in the C–H bond-strength at the allylic position, as has been suggested by Adams *et al.*[6] In the cases of the low Bi_2O_3 content catalyst (Bi/Mo< 0.15), the difference in the oxidation rate of these olefins is not so great. Probably the rate is limited, to some extent, by the activation of oxygen because the adsorption of olefin is strong and almost reaches its saturation point, while that of oxygen is very weak.[3]

On the other hand, the activity for propylene and ethylene varies in a way different from the activity for higher olefins; this way cannot be explained directly by the adsorptive nature of the olefins. However, the fact that the interaction of the catalyst with oxygen increases with an increase in the Bi_2O_3 content[3] seems to suggest that the availability of surface oxygen increases with the Bi_2O_3 content. On this assumption, it may be considered that the lower olefins resist oxidation more strongly than the higher olefins, and that their oxidation requires more activated oxygen, that is, a higher Bi_2O_3 content catalyst.

The difference in the reactivity between butene and butadiene at various Bi/Mo ratios can be explained by the difference in their adsorption nature, that is, their basicity. As the ionization potential of butadiene (8.75—9.18 eV) is lower than that of butene (9.3—9.8 eV), the basicity of butadiene is presumably higher than that of butene. Thus, butadiene is adsorbed more strongly on the Bi_2O_3-poor catalysts and less strongly on the Bi_2O_5-rich catalysts, than is butene.

Regarding the oxidation of saturated carboxylic acids and aldehydes, it may be reasonable to consider that the carboxylic and carbonyl group play main roles in their adsorption. In the case of acid, since both acid and oxygen act as electron acceptors and since these adsorptions are promoted with an increase in the Bi_2O_3 content, the oxidation activity increases steadily with the Bi_2O_3 content. The high reactivity of the saturated aldehyde compounds may be attributed to the nature of their carbonyl group polarizing as $-C^+-O^-$, which can be attacked either by an electron-donor-type (basic) or by an electron-acceptor-type (acidic) reagent. The shapes of the curves in Fig. 5 follow the same trend as those for higher olefins. This suggests that the saturated aldehydes are, rather, basic compounds, and that they are inclined to be attacked by an electrophilic reagent.

The presence of a double bond in an aldehyde or an acid molecule increases their stability markedly. This may be, in part, due to a resonance-stabilization by their conjugated double bond, but it may be also attributed to the difference in the character of adsorption. As has been mentioned by Gorshkov *et al.*[7] some of these compounds, *e.g.*, acrolein, may be linked with the catalyst by a double bond and may thus form stable π-complexes. The stability of the adsorbed species is so great that the oxidation of acrolein may require highly activated oxygen—that is, a higher-Bi_2O_3-content catalyst.

Finally, according to the data obtained in this and past studies,[1,2,6,8,9] the relationship between the character of the partial oxidation of organic compounds and the nature of the catalyst can be generalized as follows:

a) Formation of acids from olefins and furan: an acidic catalyst (low Bi_2O_3 catalyst) is favarable, and a relatively good yield can be expected because the products is much more stable than the reactant.

b) Formation of diene from mono-olefin: the high Bi_2O_3 content catalyst has an advantage in selectivity, but the Bi_2O_3 content is limited from the point of view of the activity. Bi/Mo=1—2, therefore, is considered to be optimum.

c) Formation of acrolein from propylene: the Bi_2O_3 content of Bi/Mo=1—2 is favorable both in the activity and in the selectivity.

d) Formation of crotonaldehyde from olefin: it is difficult to get a good result, for crotonaldehyde is more reactive than olefin over every catalyst.

The Condensation Reactions of 5-Azidotropolone Derivatives with Active Methylene Compounds[1)]

Hiroshi HORINO* and Takashi TODA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai

(Received April 20, 1972)

The reactions of 5-azidotropolone (I), its methyl ether (II), and tosylate (XIII) with active methylene compounds were investigated. Several tropolones and azulenes which possess the 1,2,3-triazole ring as a substituent were obtained. The order of reactivities in these reactions were found to be: tropolone tosyl groups>azido groups>tropolone methyl ether groups. The direction of the addition of the azido groups to active methylene compounds was also clarified.

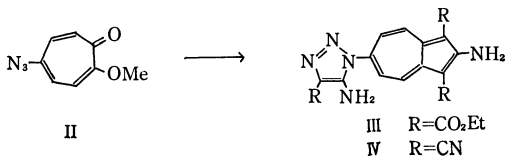
In 1902, Dimroth reported that the reaction of phenyl azide with ethyl acetoacetate gave a 1,2,3-triazole derivative,[2)] and this type of reactions has been reviewed by Benson and Savell.[3)]

Recently, much attention has been focused on organic azido compounds, because of their interesting 1,3-dipolar characteristics, and on nitrene-formation reactions.[4)] We ourselves have also been interested in azido derivatives of troponoid compounds and have investigated several reactions of 5-azidotropolones.[1,5)]

Active troponoid compounds have been known to give azulene derivatives or their related compounds by reactions with active methylene compounds.[7)] As a part of our studies of azidotropolones, we have investigated the reactions of 5-azidotropolones with active methylene compounds in order to obtain the 1,2,3-triazole derivatives of troponoid and azulenoid compounds and to investigate their properties.

5-Azidotropolones possess two active centers in their molecules toward active methylene compounds. Therefore, their order of reactivity is interesting. Moreover, if the addition reactions take place, the direction of addition to the azido group must be determined, because the direction will indicate the degree of interaction between the azido group and tropolone moiety.

The treatment of 5-azidotropolone methyl ether (II) with an excess of ethyl cyanoacetate afforded a crystalline substance (III). The elemental analysis of III ($C_{21}H_{23}O_6N_5$) showed that III was a condensation product of II with three moles of ethyl cyanoacetate. The UV and visible spectra of III are agreeable to classifying it as an azulene derivative,[7)] and the NMR spectrum of III shows two peaks (2H, d, J=11 Hz respectively) at 9.10 and 7.46 ppm which correspond to adjacent hydrogens on the seven-membered ring moiety.[8)] The IR spectrum of III shows the existence of two different kinds of amino groups (3545, 3488, and 3380 cm^{-1}) and of ester groups (1680 and 1656 cm^{-1}). Therefore, the structure of III is 2-amino-1,3-diethoxycarbonyl-6*N*-(5′-amino-4′-ethoxycarbonyl-1,2,3-triazol-1-yl)azulene, and the attack of ethyl cyanoacetate takes place at the azido group and the tropolone moiety at the same time. Also, the reaction of II with malononitrile gave 2-amino-1,3-dicyano-6*N*-(5′-amino-4′-cyano-1,2,3-triazol-1-yl)azulene (IV).



II

III R=CO_2Et
IV R=CN

When II was treated with a rather weak active methylene compound—diethyl malonate, a sodium salt (V) was obtained. The acid treatment of V afforded a yellow crystalline substance (VI), whose molecular formula was agreeable with $C_{13}H_{13}O_5N_3$; VI also showed a strong absorption at 2140 cm^{-1} in its IR spectrum. These data suggest that VI possesses an azido or diazo group.[9)] If the azido group of II was kept unchanged, VI might be 6-azido-3-ethoxycarbonyl-1-oxaazulan-2-one. However, the UV and visible spectra of VI are not of the oxaazulanone type,[6,7)] but are very similar with those of tropolone methyl ethers. Thus, the structure of VI is 5α-diazo-α-ethoxycarbonyl-acetylamino-2-methoxytropone, and V is the sodium salt of the ring-closed enol tautomer of VI. VI is interchangeable with V upon treatment with sodium hydroxide. This relaxation is also proved by the following fact: when the silver salt of VI was treated with methyl iodide, the enol ether of VI—5-(4′-ethoxycarbonyl-5′-methoxy-1,2,3-triazol-1-yl)-2-methoxytropone (VII)—was obtained. The existence of this type of ring-chain tautomer was suggested by Dimroth[10)] and proved by Leffler.[11)]

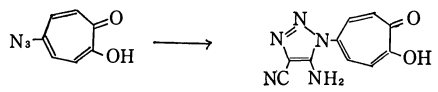
VI

In order to obtain stable triazole derivatives, the reactions of II with suitable active methylene compounds which should not enolized at the C-5 position of the triazole ring were carried out. These compounds were ethyl acetoacetate, acetylacetone, ethyl benzoylacetate and dibenzoylmethane. The products obtained are listed in Table 1. Although the active methylene compounds were used in excess amounts, no azulene or oxaazulane formation was observed in any case. The methoxy groups in the tropone moieties of X and XI were replaced by the ethoxy group of the solvent used during the reactions.

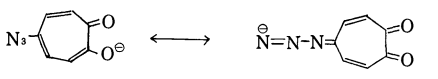
Table 1.

	R_1	R_2	R_3
VII	Me	OMe	CO_2Et
VIII	Me	Me	CO_2Et
IX	Me	Me	COMe
X	Et	Ph	CO_2Et
XI	Et	Ph	COPh

Under the same conditions as above, the reaction of I itself with malononitrile, cyano acetoacetate, and other active methylene compounds was examined. The reaction with malononitrile gave the corresponding triazolyltropolone (XII). However, with other active methylene compounds it did not give any condensation products, but resulted in the recovery of the starting substances. The reason why the reactivity of the azido group of I is lower than that of II is that the tropolone anion is formed under the reaction conditions and the electron density on the azido group become higher than that of II. This phenomenon is shown below as the resonance contribution of the anion:



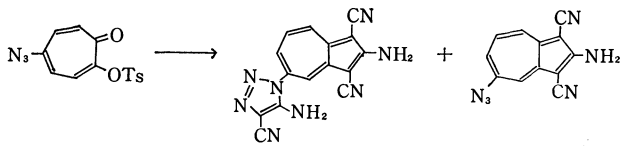
I XII



Thus, the condensation reaction did not take place except with a strong, active methylene compound such as malononitrile.

The reaction of the tosylate (XIII) of I with malononitrile afforded an azulene derivative (XIV) which differs from III. The IR spectrum of XII shows absorptions at 877 and 800 cm^{-1}. Those correspond to an isolated hydrogen and the three adjacent hydrogens on the seven-membered ring moiety[12] of XIV. It had previously been established that 2-halotropones and tropolone tosylates gave abnormal substitution products or addition products in those reactions.[7,13] The structure of XIV is 2-amino-1,3-dicyano-5*N*-(5′-amino-4′-cyano-1,2,3-triazol-1-yl)azulene.

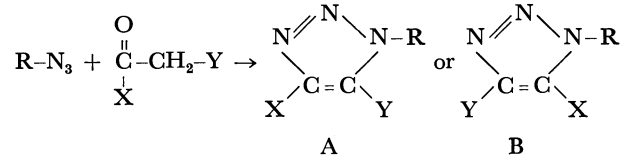
When this reaction was carried out under controlled conditions, a minor product (XV) was also obtained in addition to XIV. The elemental analysis ($C_{12}H_6N_6$), the IR spectrum (2110 cm^{-1}, N_3: 872 and 787 cm^{-1}, an isolated hydrogen and three adjacent hydrogens respectively), and the UV and visible spectra (typical azulene type) all suggested that the structure of XV was 2-amino-5-azido-1,3-dicyanoazulene.



XIII XIV XV

The results obtained above indicate that the order of the reactivity of the each functional group with active methylene compounds is : the tosyl group> the azido group>the methyl ether group.

As far as the 1,3-dipolar character of the azido group is concerned,[4,14] there are two possible 1,2,3-triazole ring formation by the reaction of azidotropolones with acetive methylene compounds. In the cases of phenyl azides, it has been proved that the 1,2,3-triazole derivatives formed are of the A type.[4,15]



A B

No special interactions between the 5-azido groups and tropolone moieties were observed in several reactions of 5-azido tropolones.[5] Therefore, the direction of the addition of the above condensation might be similar to the case of phenyl azides. In order to clarify this question, the following experiments were carried out. The rearrangement of VIII with sodium ethoxide[16] and subsequent hydrolysis afforded *N*-phenyl-1,2,3-triazole dicarboxylic acid. On the other hand, the condensation reaction of methyl *p*-azido-

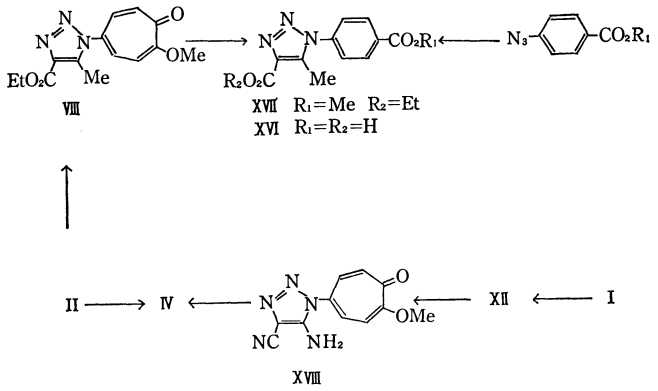
benzoate[17] with ethyl acetoacetate gave the *N*-phenyl-1,2,3-triazole dicarboxylic acid mentioned above. Therefore, the structure of VIII and the direction of the addition of active methylene compounds to II are proved.

When the methyl ether of XII was treated with malononitrile, IV was obtained in a good yield. Therefore, in this case the direction of the addition of the active methylene compounds is proved to be the same as in the case of phenyl azides. Therefore, the influence of the tropolone moiety on the azido group is not strong enough to change the direction of the addition of active methylene compounds to the azido group.



Experimental[18]

The Reaction of II with Ethyl Cyanoacetate. Into a solution of 2.1 g of ethyl cyanoacetate and 130 mg of sodium in 10 ml of absolute ethanol, 1.0 g of 5-azido-2-methoxytropone (II) was stirred; the mixture was then allowed to stand overnight. The precipitate formed was collected and extracted with hot benzene to give 1.14 g of yellowish-orange crystals of 2-amino-1,3-diethoxycarbonyl-6*N*-(5′-amino-4′-ethoxycarbonyl-1,2,3-triazol-1-yl)azulene (III), which were recrystallized from benzene; mp 237 °C (dec).

Found: C, 57.34; H, 5.61; N, 15.70%. Calcd for $C_{21}H_{23}O_6N_5$: C, 57.13; H, 5.25; N, 15.87%. λ_{max}, mμ(log ε); 246 (4.3), 332 (4.7), 418 (3.9). ν_{max}(KBr); 3546, 3485, 3380, 1680, 866, 844 cm^{-1}.

The Reaction of II with Malononitrile. Into a mixture of 270 mg of triethylamine and 270 mg of malononitrile in 3 ml of absolute ethanol, 200 mg of II was stirred while the mixture was being cooled in an ice bath. After the mixture had been allowed to stand for 4 hr, the precipitates formed were collected to yield 390 mg of a yellow powder of 2-amino-1,3-dicyano-6*N*-(5′-amino-4′-cyano-1,2,3-triazol-1-yl)azulene (IV), which was subsequently recrystallized from dimethylformamide; mp 280 °C (dec).

Found: C, 60.41; H, 2.75; N, 37.39%. Calcd for $C_{15}H_8N_8$: C, 59.99; H, 2.69; N, 37.32%. λ_{max}, mμ (log ε); 231 (4.49), 328 (5.29), 404 (3.75). ν_{max}; 3500, 3390, 3280, 2230, 858, 833 cm^{-1}.

The Reaction of II with Diethyl Malonate. Two hundred mg of II were dissolved in a solution of 650 mg of diethyl malonate and 35 mg of sodium in 3 ml of absolute ethanol. After the mixture had stood overnight, the precipitates were separated and washed with 2 M hydrochloric acid to leave 166 mg of yellow crystals of 5α-diazo-α-ethoxycarbonylacetylamino-2-methoxytropone (VI), which were subsequently recrystallized from ethanol; mp 144 °C.

Found: C, 53.46; H, 4.67; N, 14.43%. Calcd for $C_{13}H_{13}O_5N_3$: C, 53.61; H, 4.50; N, 14.43%. λ_{max}, mμ (log ε); 225 (4.41), 244 (4.33 sh), 340 (4.16). ν_{max}; 2140, 1685, 1630, 881, 857 cm^{-1}.

5-(4′-Ethoxycarbonyl-5′-methoxy-1,2,3-triazol-1-yl)-2-methoxytropone (VII). The precipitate made from a mixture of 1.30 g of II, 2.15 g of diethyl malonate, and 175 mg of sodium in 8 ml of absolute ethanol according to the above method was dissolved in 15 ml of water, and to this we added an excess aqueous solution of silver nitrate. The greenish gray deposits were collected, dried, and weighed (245 mg). A suspension of this precipitate and 460 mg of methyl iodide in 6 ml of acetone was then refluxed on a water bath for 5 hr. After it had been filtered, the solution was concentrated and the residue was recrystallized from ethanol to afford 87 mg of yellow crystals (VII); mp 211 °C.

Found: C, 54.69; H, 5.19; N, 13.60%. Calcd for $C_{14}H_{15}O_5N_3$: C, 55.08; H, 4.95; N, 13.77%. λ_{max}, mμ (log ε); 224 (4.41), 246 (4.41), 334 (4.17). ν_{max}; 1721, 1695, 1670, 851, 844 cm^{-1}.

The Reaction of II with Ethyl Acetoacetate. To a solution of 2.24 g of ethyl acetoacetate and 194 mg of sodium in 10 ml of absolute ethanol, 1.4 g of II was added at once with cooling in an ice bath; the mixture was then allowed to stand overnight. The collection of the precipitate and washing with 2 M hydrochloric acid gave 2.20 g of yellow needles of 2-methoxy-5*N*-(4′-ethoxycarbonyl-5′-methyl-1,2,3-triazol-1-yl) tropone (VIII); mp 178 °C from alcohol.

Found: C, 58.30; H, 5.26; N, 14.41%. Calcd for $C_{14}H_{15}O_4N_3$: C, 58.12; H, 5.23; N, 14.53%. ν_{max}; 1721, 1637, 851, 833 cm^{-1}.

The Reaction of II with Acetylacetone. Into a mixture of 250 mg of acetylacetone and 26 mg of sodium in 2.5 ml of absolute ethanol, 200 mg of II were stirred. After the solution had been allowed to stand overnight, the precipitate produced was collected to yield 242 mg of yellow plates, 2-ethoxy-5*N*-(5′-methyl-4′-acetyl-1,2,3-triazol-1-yl)tropone (IX); mp 170 °C.

Found: C, 60.45; H, 5.28; N, 16.20%. Calcd for $C_{13}H_{13}O_3N_3$: C, 60.22; H, 5.50; N, 16.21%. λ_{max}, mμ (log ε); 243 (4.49), 326 (4.15). ν_{max}; 1692, 862, 855 cm^{-1}.

The Reaction of II with Ethyl Benzoylacetate. Two hundred mg of II were added to a solution prepared from 434 mg of ethyl benzoylacetate and 26 mg of sodium in 2 ml of ethanol. After it had stood overnight in a refrigerator, the deposits were separated and crystallized from ethanol to afford 402 mg of colorless crystals of 2-ethoxy-5*N*-(4′-ethoxycarbonyl-5′-phenyl-1,2,3-triazol-1-yl)tropone (X); mp 217 °C.

Found: C, 66.54; H, 5.44; N, 11.84%. Calcd for $C_{20}H_{19}O_4N_3$: C, 65.74; H, 5.24; N, 11.50%. λ_{max}, mμ (log ε); 228 (4.52), 246 (448 sh), 328 (4.12). λ_{max}; 1730, 843, 811, 780, 709 cm^{-1}.

The Reaction of II with Dibenzoylmethane. Two hundred mg of II were added to a solution of 560 mg of dibenzoylmethane dissolved in a sodium ethoxide solution (sodium (35 mg) and absolute ethanol (6 ml)). The orange solution was then concentrated, acidified with 2 M hydrochloric acid, and extracted with benzene to give 400 mg of orange prisms of 2-ethoxy-5*N*-(4′-benzoyl-5′-phenyl-1,2,3-triazol-1-yl)tropone (XI), which were subsequently recrystallized from ethanol; mp 164°C.

17) M. O. Foster and H. M. Judd, *J. Chem. Soc.*, **97**, 259 (1910).
18) All the melting points are uncorrected.

Found: C, 72.65; H, 4.92; N, 10.55%. Calcd for $C_{24}H_{19}O_3N_3$: C, 72.53; H, 4.82; N, 10.57%. λ_{max}, mμ (log ε); 228 (4.46), 252 (4.49), 328 (4.14). ν_{max}; 1618, 1580, 820, 752, 739, 709 cm^{-1}.

The Reaction of 5-Azidotropolone (I) with Malononitrile. An alcoholic solution of 200 mg of I, 180 mg of malononitrile, and 410 mg of triethylamine was stirred for 12 hr. The solvent was then evaporated, and the residue was acidified with 2 M hydrochloric acid to afford 95 mg of a brown powder of 5*N*-(5'-amino-4'-cyano-1,2,3-triazol-1-yl)tropolone (XII), which was recrystallized from DMF; mp 256 °C (dec).

Found: C, 52.24; H, 3.50; N, 30.30%. Calcd for $C_{10}H_7O_2N_5$: C, 52.40; H, 3.08; N, 30.56%. λ_{max}, mμ (log ε); 227 (4.41); 246 (4.20), 346 (3.88).

The Reaction of I with Ethyl Cyanoacetate. Two hundred mg of I, 170 ml of ethyl cyanoacetate, and 270 mg of triethylamine were treated as above. The precipitates given by acidification, when extracted with ethyl acetate from its mother liquid, afforded about 160 mg of I.

The Reaction of 2-(p-Toluenesulfonyloxy)tropone (XIII) with Malononitrile. A suspension of 300 mg of XIII and 204 mg of malononitrile in 2 ml of absolute ethanol was treated with a solution of 100 mg of triethylamine in 2 ml of absolute alcohol. The solution was stirred for 1 hr and then allowed to stand for 7 hr. The precipitates were collected and extracted with hot ethanol. This afforded 69 mg of a brown powder of 5-azido-2-amino-1,3-dicyanoazulene (XV); mp 290°C.

Found: C, 60.97; H, 2.73; N, 36.12%. Calcd for $C_{12}H_6N_6$: C, 61.53; H, 2.58; N, 35.88%. λ_{max}, mμ (log ε); 238 (4.23), 326 (4.45 sh), 336 (4.56), 403 (4.37). ν_{max}; 3350, 3215, 2220, 2110, 872, 787 cm^{-1}.

The non-extractable residue was recrystallized from DMF to afford a yellowish-organge powder of 2-amino-1,3-dicyano-5*N*-(5'-amino-4'-cyano-1,2,3-triazol-1-yl)azulene (XIV); mp 300 °C (dec).

Found: C, 60.36; H, 2.95; N, 36.92%. Calcd for $C_{15}H_8N_8$: C, 59.99; H, 2.69; N, 37.32%. λ_{max}, mμ (log ε); 230 (4.23), 315 (4.27), 238 (4.50), 410 (3.61), 426 (4.80). ν_{max}; 3400, 3280, 2230, 877, 800 cm^{-1}.

The Determination of the Structures of the Condensed Products. *a) The Condensation Reaction of p-Methoxycarbonylphenyl Azide*: To a solution of 150 mg of sodium and 950 mg of ethyl acetoacetate in 2 ml of absolute ethanol, 1.0 g of *p*-methoxycarbonylphenyl azide was added, after which the mixture was cooled in an ice bath. It was allowed to stand for 7 hr, and washed with 2 M hydrochloric acid to afford 1.1 g of colorless plates of 1*N*-*p*-methoxycarbonylphenyl-4-ethoxycarbonyl-5-methyl-1,2,3-triazol (XVII), which was recrystallized from ethanol; mp 174—175 °C.

Found: C, 58.14; H, 5.25; N, 14.64%. Calcd for $C_{14}H_{15}O_4N_3$: C, 58.12; H, 5.23; N, 14.53%. ν_{max}; 2130, 1718, 1285, 852, 841, 765 cm^{-1}.

A solution of 500 mg of XVI, 3 ml of 2 M sodium hydroxide, and 2 ml of ethanol was refluxed for 1 hr, and then acidified with 6 M hydrochloric acid to give 390 mg of colorless, amorphous 4*N*-(4'-carboxyl-5'-methyl-1,2,3-triazol-1-yl)benzoic acid (XVI), which was subsequently recrystallized from ethanol; mp 235°C (dec).

Found: C, 53.88; H, 3.82; N, 16.75%. Calcd for $C_{11}H_9O_4N_3$: C, 53.44; H, 3.67; N, 17.00%. ν_{max}; 2940～2860, 2680～2654, 1685, 859 cm^{-1}.

b) The Rearrangement of VIII: A solution of 0.5 g of VIII in a sodium ethoxide mixture (sodium (87 mg) and absolute ethanol (10 ml)) was refluxed for 16 hr on an oil bath. After the evaporation of the solvent and the addition of water, the solution was heated for 1 hr on a water bath. Then it was acidified with 2 M hydrochloric acid and extracted with ethyl acetate, which had itself been extracted with a sodium bicarbonate solution. It was acidified to afford 200 mg of a colorless powder which can be identified with the XVI given in *a)* by a comparison with their IR spectra and by a mixed-melting-point-test.

The Reaction of XII with Ethyl Cyanoacetate. *a)* To a solution of 200 mg of XII in 200 ml of ethyl acetate in 5 ml DMF, an ethereal diazomethane solution was added until no color change was shown by a ferric chloride test. After it had then been allowed to stand overnight, the solution was concentrated to give 141 mg of a gray powder of 5*N*-(5'-amino-4'-cyano-1,2,3-triazol-1-yl)-2-methoxytropone (XVIII); mp 233 °C (dec).

Found: C, 54.78; H, 3.99; N, 28.31%. Calcd for $C_{11}H_9O_2N_5$: C, 54.32; H, 3.73; N, 28.80%.

b) Into a solution of 100 mg of triethylamine and 65 mg of malononitrile in 2 ml of absolute ethanol, 100 mg XVIII was stirred; the mixture was then allowed to stand for 3 days. The precipitates were collected to afford 143 mg of a gray powder which was found to be identical with IV by a comparison with their IR spectra.

The authors are very much indebted to Professor Tetsuo Nozoe for his kind encouragement and guidance during the course of their work.

The Calculation of Dipole Polarizability and Anisotropy by the CNDO Method

Tomoo MIYAZAKI and Hiroyuki SHINODA

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo 160

(Received May 23, 1972)

The dipole polarizabilities and the anisotropies of small linear molecules have been calculated according to a formula in which the frequency of the incident light is taken into account, as derived by the time-dependent perturbation theory. The wave functions and the energies were calculated by the CNDO method, involving the configuration interaction treatment. The effect of the parametrization in the CNDO method on the calculated polarizability and anisotropy has also been discussed. The method has been used to calculate the variations in the anisotropy, the polarizability, α, and its derivatives, $(\partial\alpha/\partial S_i)_0$ and $(\partial^2\alpha/\partial S_i^2)_0$, with the frequency of the incident light, where S_i is the appropriate symmetry coordinate of the molecular vibration.
