An Additional Formation of $CH_2{}^{80}BrBr$ *via* a Kinetic-energy-independent Process in the Highly Moderated ^{80m}Br-CH_4 Systems

Kenshi NUMAKURA,* Masakatsu SAEKI, and Enzo TACHIKAWA

Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-Mura, Ibaraki

(Received July 21, 1971)

The moderator effect of Kr on the reaction of (I.T.)-activated ^{80}Br with CH_4 has been examined, keeping the ratio of Br_2/CH_4 at 0.02 or 0.05. The yield of $CH_2{}^{80}BrBr$ shows a slight decrease at the beginning of moderation and then tends to increase with further moderation. These facts suggest an additional formation of $CH_2{}^{80}BrBr$ *via* a thermal ionic process in highly-moderated systems. When the concentration of Br_2 is varied in the system containing 10 cmHg of CH_4 and from 40 to 36 cmHg of Kr, the yield of $CH_2{}^{80}BrBr$ first increases and then decreases, showing a broad maximum. This dependence not only partly explains the inconsistence of the present results with those previously reported, but also suggests the competition of two types of reaction in its formation. One must be the reaction of a radioactive radical with Br_2, leading to the formation of $CH_2{}^{80}BrBr$:

$$\cdot CH_2{}^{80}Br + Br_2 \longrightarrow CH_2{}^{80}BrBr.$$

The other type of reaction is a scavenging reaction of Br_2 for the reacting ^{80}Br atom.

The determination of the relative importance of the kinetic energy and the positive charge in reactions of the recoil Br atom is a current subject in the recoil Br chemistry. So far, many extensive investigations of the subject have been carried out, particularly on the reactions of ^{80}Br with CH_4.[1-4]

While the (n,γ)-activated ^{80}Br reacts with CH_4 to yield $CH_3{}^{80}Br$, mainly as a result of the recoil kinetic energy acquired by the ^{80}Br atom,[5] the (I.T.)-activated ^{80}Br reacts by two processes, one involving excess kinetic energy, and the other, a thermal process.

Following the determination of the total organic yield by Spicer and Gordus,[6] Tachikawa and Kahara[3] examined the molecular distribution of the products under a high concentration of bromine and reached the conclusion that $CH_2{}^{80}BrBr$ is formed principally *via* the kinetic energy-independent process, while $CH_3{}^{80}Br$ is formed *via* both kinetic-energy and kinetic energy-independent (thermal ionic) processes. Since the Br_2 additive is an efficient moderator of the ^{80}Br atom, it is rather desirable to use the smallest pressure of Br_2. Recently Yagi *et al.*[4] reexamined the above reactions in a Kr-moderated system, keeping $Br_2/CH_4=0.029$; they reached the different conclusions that $CH_3{}^{80}Br$ is principally formed *via* the kinetic-energy process and that $CH_2{}^{80}BrBr$ is formed *via* both processes.

These experiments were all carried out in the total pressure range from 50 cmHg to 76 cmHg. It has been reported that the yields of individual organic products increase with an increase in the total pressure, but tend to level off around 50 cmHg.[3] Thus, one of the possible factors which are responsible for the inconsistency among the results previously reported was the variation in the Br_2 added as a scavenger in the systems.

In the current set of experiments, we carefully studied the reactions, particularly in highly-moderated systems. The results obtained showed a characteristic in $CH_2{}^{80}BrBr$ with the Br_2 concentration. A qualitative explanation of the above contradiction has been attempted.

Experimental

The experimental procedure was the routine one for the study of ^{80}Br activated by the isomeric transition of ^{80m}Br; it involved the irradiation of Br_2 in a quartz ampoule, mixture with reactants and analysis of the products by means of radio-gas chromatography. The details can be found elsewhere.[3]

Materials. Bromine came from the Kanto Chemical Co., and was used after simple purification by vacuum distillation. Methane and krypton, the nominal purities of which were both 99.995%, were supplied by the Takachiho Chemical Co., and were used directly from the vessel.

Measurement of Br_2-pressure. In our previous experiments,[2,3] we used an oil manometer to measure the pressure of irradiated Br_2 added to reaction ampoules. However, it was rather difficult to measure a pressure of less than 1.0 cmHg by means of this apparatus. In the present set of experiments, therefore we used a digital precision pressure gauge, model 145 (Texas Instruments), which involves a quartz buldon gauge. This apparatus allows us to measure pressures down to 0.1 mmHg with precision of better than $\pm 5\%$.

Sample Processing. All relative products distributions were determined by radio-gas chromatography, employing a side window-type gas-flow counter. The inorganic bromides were isolated from the organic bromides by the insertion of a short glass column packed with potassium ferrocyanide into the gas stream ahead of the organic separation column. The separation column consisted of a celite base (60—80 mesh) coated with dioctyl sebacate (15% by weight) packed in a glass tube 4 mm in inside diameter and 5 m long. The major products observed were, in all cases, $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$, although several minor products, such as $C_2H_5{}^{80}Br$ and $CH_2{}^{80}BrBr_2$, were also observed.

In the determination of the total organic yields, the products were frozen by dipping an ampoule into a liquid-nitrogen bath. The tip of the ampoule was cut in order to pour a mixture of 5 ml of 0.5M Na_2SO_3 and 3 ml of CCl_4. After sealing-off the tip, the ampoule was vigorously shaken. The organic phase was then separated from the inorganic one. Each phase contained in a vessel specially designed for count-

ing was measured by an end window-type gas-flow counter. The activity of ^{80}Br in each phase was corrected for ^{80m}Br and ^{82}Br using the decay curves of the activities. No correction for freezing, shaking, or separation was applied in the calculations of the total organic yield, since the decay correction based on the time spent for these processes was less than a few percent and could be disregarded. The percentage yields reported in this paper were the percentage of individual activities relative to the total organic activities observed, multiplied by the total organic yield.

Results

The effects of the moderator gas, Kr, on the individual product yields are graphically depicted in Fig. 1. The plots include all the results obtained from systems where the concentrations of Br_2 as a scavenger, relative to CH_4, were 0.02 and 0.05. In all cases, the total pressure was kept constant at 50±1 cmHg. At zero m.f. of Kr, the yields were 4.3±0.4% $CH_3{}^{80}Br$, 2.1±0.2% $CH_2{}^{80}BrBr$, and 6.4±0.6% total organic.

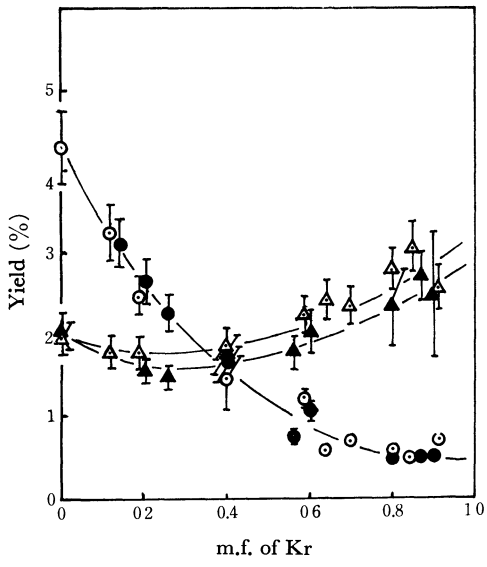

Fig. 1. The Kr-moderator effects on the individual products.
The ratio, Br_2/CH_4 was 0.02 and 0.05
Br_2/CH_4: 0.02 ●: $CH_3{}^{80}Br$ ▲: $CH_2{}^{80}BrBr$
Br_2/CH_4: 0.05 ⊙: $CH_3{}^{80}Br$ △: $CH_2{}^{80}BrBr$

As the dilution of the reaction system with Kr proceeded, the yield of $CH_3{}^{80}Br$ decreased and could be extrapolated to 0.6±0.1% at 1.0 m.f. of Kr in either case. However, the yield of $CH_2{}^{80}BrBr$ showed a slight decrease at the beginning of dilution, but it tended to increase when the m.f. of Kr exceeded 0.5. At 1.0 m.f. of Kr, the limiting yield of $CH_2{}^{80}BrBr$ was 2.9±0.3% or 3.2±0.3%; depending upon the value of Br_2/CH_4.

In order to examine the yield variation with the concentration of Br_2 in highly-moderated systems, the Br_2/CH_4 ratio was varied from 0.01 to 0.4, while keeping the pressure of CH_4 constant at 10 cmHg. Consequently, the pressure of Kr (40 to 36 cmHg) was adjusted to attain a total pressure of 50±1 cmHg. In view of the relative efficiency of Br_2 and Kr as kinetic-energy moderators for an energetic ^{80}Br, the change in moderator efficiency accompanied by the small variation in composition, cannot be important. The results obtained are plotted in Fig. 2. The variation in $CH_3{}^{80}Br$ did not exceed the experimental fluctuation from the value of 0.6±0.1% over the range studied. On the other hand, the yield of $CH_2{}^{80}BrBr$ increased with the increase in the ratio of Br_2/CH_4 at the beginning, and then decreased when the ratio exceeded around 0.15, showing a broad maximum in the range from 0.05 to 0.10 of Br_2/CH_4.

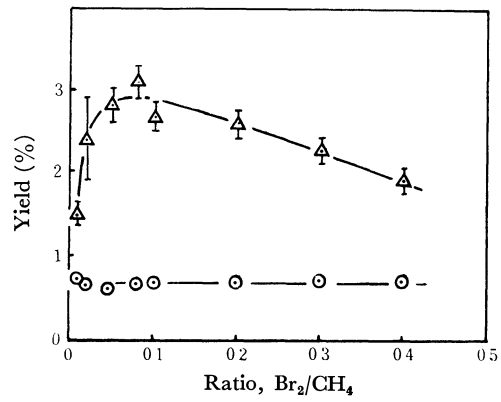

Fig. 2. The effects of the variation of the ratio, Br_2/CH_4 on the yields of $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ in the highly moderated systems (CH_4: 10 cmHg, Br_2: 0.1—4.0 cmHg, and the total pressure was kept constant at 50±1 cmHg by adjusting Kr-pressure).

Discussion

Comparisons with Reported Results. The total organic yield (6.4±0.6%) with no additive agreed reasonably well with those reported by Spicer and Gordus (6.8±0.8%)[6] and by Yagi *et al.* (7.0±0.3%).[4] However, when the limiting yields of the individual products at 1.0 m.f. of Kr are compared, a significant difference can be noticed between the present results and the Yagi *et al.* results. They reported the limiting yield of zero percent for $CH_3{}^{80}Br$ and 1.4% for $CH_2{}^{80}BrBr$. In their series of moderator experiments, the smallest m.f. of CH_4 reached was 0.25, and their extrapolation of the yields of products to 1.0 m.f. of Kr relied on results covering the range from zero to 0.75 m.f. of Kr. According to the present results, however, their extrapolated curves do not necessarily represent the real moderator curves under highly moderated conditions. For example, when the variations in $CH_3{}^{80}Br$ from zero to 0.7 m.f. of a moderator in the present results are taken into account, the extrapolation of $CH_3{}^{80}Br$ to zero percent at 1.0 m.f. of moderator is rather probable. Thus, their results can be understood to show the moderator effects of the products up to around 0.75 m.f. of moderator, but can not be extented to much further moderation.

The most significant difference between the present results and the reported ones, however, can be seen in the yield of $CH_2{}^{80}BrBr$ at a higher moderation, and consequently in its limiting yield at 1.0 m.f. of Kr. When the Br_2/CH_4 ratio was varied while keeping the pressure of CH_4 constant, at 5.0 cmHg (the pressure of Kr was also varied from 45 to 41 cmHg to attain

the total pressure of 51 cmHg), a dependence of the yield of $CH_2{}^{80}BrBr$ as the Br_2/CH_4 ratio similar to that shown in Fig. 2 was observed. This suggests that this kind of variation in the yield curve of $CH_2{}^{80}BrBr$ with the ratio can always be expected at high moderations and that a small variation in the ratio sometimes leads to a large difference in the yield of $CH_2{}^{80}BrBr$. Consequently, the limiting yields of $CH_2{}^{80}BrBr$ and of the total organic at 1.0 m.f. of Kr may vary considerably depending upon the amount of Br_2 added in highly moderated systems. Thus, if the Br_2/CH_4 ratio is varied little from 0.02 in such a high moderation, the difference in the yield of $CH_2{}^{80}BrBr$ between the two experiments, the present and the previous ones, can be easily accounted for.

In most of the moderator experiments previously reported,[7] the amount of Br_2 relative to that of the reactant was determined from scavenger curves in the unmoderated systems. Once it was determined, the Br_2/reactant ratio was kept constant or nearly constant throughout the m.f. of the moderator. With regard to this conventional selection of the Br_2/reactant ratio the present results are thus very suggestive. In conclusions, in order to identify the yields of the organic products as the kinetic-energy or kinetic-energy-independent yields, the present types of behavior of the products under highly moderated conditions, as well as the physical natures of the moderator[8] must be taken into account.

Kinetic-energy-independent Yields of Products. From the results shown in Fig. 1, it may be concluded that the kinetic-energy-independent yield of $CH_3{}^{80}Br$ was $0.6\pm0.1\%$, which corresponded to *ca.* 14% of the total $CH_3{}^{80}Br$ formed. This conclusion, however, includes the assumption that the moderator curve obtained reflects the true reaction processes involved in the formation of $CH_3{}^{80}Br$. Recent moderator experiments on ^{80m}Br–C_2H_6,[8] however, have indicated that when the reaction system is diluted with inert gases, the distribution of the charged ^{80}Br is modified so that an additional formation of $CH_3{}^{80}Br$ *via* the kinetic-energy-independent process occurs. Furthermore, in the present work the increase in the yield of $CH_2{}^{80}BrBr$ at a high moderation is an indication of the additional formation of the compound *via* the kinetic-energy-independent process. Thus, the present value of 0.6% for the kinetic-energy-independent yield of $CH_3{}^{80}Br$ should be understood to be a maximum value.

On the other hand, it is not possible to identify the observed yield of $CH_2{}^{80}BrBr$ with no additive as kinetic-energy and kinetic-energy-independent yields on the basis of the present results alone. Nevertheless, we preferred to conclude that it was mainly formed *via* the kinetic-energy-independent process and that the formation due to the kinetic-energy process was less important. This is qualitatively consistent with the conclusion reached in the early experiments using a rather high concentration of Br_2.[9] One support for the above prediction is given by the recent experiments in our laboratory.[10] When the $^{82}BrBr$ molecule is irradiated with the light of the wavelength of 2537 Å, an energetic ^{82}Br atom with 1.2 or 1.7 eV, but with no charge is formed. This atom reacts with CH_4 to give $CH_3{}^{80}Br$. The $CH_2{}^{80}BrBr$ was not detected within the limits of experimental uncertainty, and its yield, if it is also formed, must be less than a small percentage of that of $CH_3{}^{82}Br$. The results obtained with the reaction of ^{80}Br activated by the (n,γ) process with CH_4 were also consistent with the above prediction. The ^{80}Br thus activated has a higher energy and less charge than that from the (I.T.) activation, and it reacts with CH_4 to yield a total organic yield of 13.8%, principally *via* the kinetic energy process.[5,11] Spicer and Gordus reported that 89% of the total organic yield was $CH_3{}^{80}Br$, while 11% was $CH_2{}^{80}BrBr$. A further analysis of the results using the Estrup-Wolfgang kinetic theory showed that the yields due to the kinetic-energy processes were 12.3% for $CH_3{}^{80}Br$ and 1.0% for $CH_2{}^{80}BrBr$.[12] These values gave the ratio of 0.08 for $CH_2{}^{80}BrBr/CH_3{}^{80}Br$.

As a crude approximation, we attempt to evaluate the maximum yield of $CH_2{}^{80}BrBr$ due to the kinetic-energy process in the present reaction with the assumption that the value of 0.08 for the $CH_2{}^{80}BrBr/CH_3{}^{80}Br$ ratio also holds in the present reaction system. The maximum yield of the kinetic-energy process to form $CH_2{}^{80}BrBr$ was estimated to be $0.08\times3.9=0.3\%$, this, however, explains only 14% of the total yield of $CH_2{}^{80}BrBr$.

Effects of the Br_2 Concentration on $CH_2{}^{80}BrBr$ in Highly Moderated Systems. The appearance of the maximum in the yield of $CH_2{}^{80}BrBr$ in Fig. 2 can only be explained in terms of the competition between two types of reaction.[13] If at least a part of the yield is directly dependent on the presence of inactive bromine, the latter contributes to their formation. An example would be the reaction of a radioactive radical with Br_2, leading to the formation of $CH_2{}^{80}BrBr$:

$$\cdot CH_2{}^{80}Br + Br_2 \longrightarrow CH_2{}^{80}BrBr.$$

The other type of reaction involved is a scavenging reaction of Br_2 for the reacting ^{80}Br atom, since Br_2 is the reacting scavenger. At higher concentrations of inactive bromine, the collision of the reacting ^{80}Br with Br_2 becomes important and the yield is progressively

9) E. Tachikawa and J. Okamoto, *Radiochim. Acta*, **13**, 159 (1970). In the series of previous experiments, the yield of $CH_2{}^{80}BrBr$ was constantly smaller than those expected from the present works. This is partly due to the experimental method used. In the previous works, the reaction mixture was once transferred into the injection loop for the radio-gas chromatographic analysis. Thus a constant fraction of $CH_2{}^{80}BrBr$ was lost due to the adsorption, mainly on the stopcock involved. Furthermore an addition of Xe or Ar as a moderator may lead to a different behavior of $CH_2{}^{80}BrBr$. However, this does not alter the conclusion previously reached that $CH_2{}^{80}BrBr$ was mainly formed *via* the kinetic-energy-independent process.

reduced and the usual scavenger curve prevails.

The fact that a small concentration of Br_2 (6×10^{-2} m.f.) brings about such a sharp increase in the yield also means that the radical responsible for it must be reasonably stable and long-lived to be able to react with Br_2. Assuming the Maxwellian distribution of both $CH_2{}^{80}Br$ and Br_2, the life-time of the radical was calculated as $\geq10^{-7}$ sec.[14]

14) The calculation based on the equation,

$$Z = N_2\sigma_{12}^2\left(\frac{8kT}{\pi\mu}\right)^{1/2}$$

for the collision density (see S. W. Benson "The Foundations of Chemical Kinetics," MacGraw-Hill, New York, (1960) p. 153). The molecular diameter used are 4.27 Å for Br_2 and 4.0 Å for CH_2Br in analogy with CH_3Br (ref. J. O. Hirschfelder, C. F. Curtiss, and R. B. Bird, "The Molecular Theory of Gases and Liquid," John Wiley and Sons, Inc., New Yrok, (1960) p. 1110).

The formation of the $CH_2{}^{80}Br$ radical must involve the breaking of two C–H bonds. In an energetic reaction, the importance of the double-replacement reaction is already known.[15] However, the foramtion of the $CH_2{}^{80}Br$ radical in the present reaction system is probably initiated mostly *via* the kinetic-energy-independent process of ^{80}Br. The direct application of the double-replacement reaction to the present case, therefore cannot be made. As was suggested in a previous paper,[9] the formation of $(CH_4{}^{80}Br)^+$ is the most realistic primary step involved. However, the details of the reaction pass leading to $CH_2{}^{80}BrBr$ from $(CH_4{}^{80}Br)^+$ must await the carrying-out of further experiment.

The Isomerization of Propylene Oxide on Metal Oxides and Silica-Magnesia Catalysts

Yasuaki OKAMOTO, Toshinobu IMANAKA, and Shiichiro TERANISHI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka

(Received December 6, 1971)

The isomerization of propylene oxide was carried out over silica-magnesia catalysts and metal oxides at 260—270°C using a pulse reactor. The main products of the reaction were propionaldehyde, acetone, allyl alcohol, 1-propanol, and acrolein. Propionaldehyde and acetone are produced on acidic and basic sites respectively. Allyl alcohol is formed over acid-base bifunctional catalysts. 1-Propanol and acrolein are mainly produced through hydrogen-transfer reactions between allyl alcohol and propionaldehyde and propylene oxide. As regards these reactions, acid-base bifunctional catalysts are favorable and the reaction rate depends on the electron-donating power of the hydrogen acceptor and the basic strength of the catalyst. The acid sites on silica-magnesia catalysts are attributed to the forsterite produced by the reaction of magnesium oxide and silica gel, and the basic sites, to the magnesium oxide remaining. The metal oxides, such as magnesium and calcium oxides, are considered to have very weak acid sites.

The activities and selectivities of a reaction on solid acids and bases are determined by studying their acidic and basic properties. It is important to clarify the relations between them. In our preceding papers,[1,2] it was found that the activities and selectivities of propylene oxide isomerization on zeolite catalysts and metal phosphates could be elucidated by the acidic and basic properties of catalysts.

According to Niiyama and his co-workers,[3] silica-magnesia catalysts prepared from magnesium hydroxide and silica gel by calcination at 600°C have acid and basic sites. In the present investigation, propylene oxide isomerization was carried out on silica-magnesia and metal oxide catalysts in order to confirm the proposed mechanisms of the reaction and the relationships between the selectivities and acidic and basic characters of the solid acids and bases. In the cases of zeolites[1] and metal phosphates,[2] the main products were acetone, propionaldehyde, and allyl alcohol. However, it was found that silica-magnesia and metal oxides produce considerable 1-propanol, the hydrogenated compounds of allyl alcohol, propionaldehyde, and propylene oxide. The reaction steps of 1-propanol formation are discussed. Moreover, the production mechanism of the acidic and basic properties of silica–magnesia catalysts was deduced from the results of X-ray diffraction.

Experimental

Materials. Silica-magnesia catalysts with different compositions were prepared as follows. Silica gel (Nakarai Chemicals, Ltd.; Silica gel No. III 200 mesh) and magnesium hydroxide (Wako Pure Chemical Industries, Ltd.) were mixed in water at 90°C for 12 hr, filtered, and calcined at 600°C for 6 hr in air. The compositions of the silica-magnesia catalysts used in our experiments were 0, 34, 51, 67, 76, and

100 mol% of the magnesium oxide content. The surface areas of these catalysts were 405, 142, 307, 158, 145, and 68 m^2/g respectively. The metal oxides used were MgO, CaO, MnO, BaO, SrO, and ZnO. They were all commercial-grade except for MnO. MnO was prepared by the decomposition of $MnCO_3$ at 500°C under a vacuum for 48 hr. The reactants were commercial-grade.

Procedures. The isomerization of propylene oxide was carried out using a conventional pulse reactor in a helium carrier. The catalysts (20 mg) were treated at the reaction temperature in streaming helium for about 2 hr before reactions. The amount of reactant injected into the catalyst was 2 μl.

The acidic and basic properties of the catalysts, which were heated at 300°C for 2 hr in air, were measured by the conventional titrating method in benzene with a benzene solution of *n*-butylamine, and benzoic acid, using Hammett indicators.[4]

The structures of the calcined silica–magnesia catalysts were determined by X-ray analysis.

Results and Discussion

The surface areas, acidities, and basicities of the metal oxides are shown in Table 1. Figure 1 shows the dependencies of the acidity (measured at $H_0=+6.8$) and the basicity ($H_0=+7.2$) of the silica-magnesia catalyst on the magnesium-oxide content. Niiyama *et al.*[3] have reported almost the same behavior

Table 1. Properties of metal oxide catalysts

○: acidity, ●: basicity

of the acidic and basic properties of these catalysts. According to Fig. 1, the acidities of silica–magnesia catalysts increase and then decrease with an increase in the magnesium oxide content. An equimolar mixture of silica gel and magnesium oxide has the maximum acidity. The maximum acid strength of the silica–magnesia catalyst (measured for the 51% MgO-catalyst) is stronger than that of silica gel only; their H_0 values are +1.5 and +2.0 respectively. These facts indicate that new compound produced by a reaction of silica gel and magnesium oxide possesses stronger acid sites than does silica gel. According to Brewer and Steinberg,[5] silica–magnesia catalysts tempered at 400—700°C, and which have been prepared from an equimolar mixture of silica tetraethoxide and magnesium ethoxide, have a forsterite structure (Mg_2SiO_4) and strong Lewis acid sites. In the case of magnesia–boria catalysts, Tanaka and his co-workers[6] have reported that the unknown product formed is an active center for the aldol condensation of acetone. The X-ray analysis of our silica–magnesia catalysts indicates that silica gel has a structure of α-cristobalite, magnesium hydroxide disappears, magnesium oxide is formed, and forsterite is produced. According to Jander and Wuhrer,[7] the main product of the solid-state reaction of silica gel and magnesium oxide is forsterite and the amount of enstatite ($MgSiO_3$) is very small. Our results coincide with theirs. Figure 2 shows the dependence of the amounts of magnesium oxide, silica gel, and forsterite, as measured by X-ray analysis, on the magnesium oxide content. A comparison of Figs. 1 and 2 shows that the acidity correlates to the amount of forsterite and that the basicity correlates to that of the magnesium oxide remaining. Consequently, the strong acid sites on the silica–magnesia catalysts are

deduced to be caused by the forsterite produced by the reaction of magnesium oxide and silica gel, and the basic sites, by the magnesium oxide. It is considered that the production of strong acid sites can be ascribed to the difference in electronegativity between silicon and magnesium, and that magnesium forms strong Lewis acid sites.

The isomerization of propylene oxide was carried out on silica–magnesia and metal oxide catalysts at 260°C. Tables 2 and 3 show the product distributions of this reaction on these catalysts. Barium oxide and zinc oxide have only a very low activity. The "other products" in these Tables contain condensed products. The gaseous products and acetaldehyde are decomposed products. Here, we will discuss the formation of propionaldehyde, acetone, allyl alcohol, *n*-propanol, and acrolein. In them, propionaldehyde, acetone, and allyl alcohol are the products of the propylene oxide isomerization. Figure 3 shows the dependence of the formations of propionaldehyde and acetone on the magnesium-oxide content of the silica–magnesia catalysts. When we compare Figs. 1 and 3, it is clear that propionaldehyde is formed on acid sites, and acetone on basic sites, as has been reported earlier.[2] Figure 4 shows the dependence of allyl alcohol and 1-propanol on the magnesium-oxide content. In the cases of zeolite catalysts and metal phosphates (except for calcium phosphate), the production of 1-propanol is very small, but silica–magnesia and metal oxide catalysts form very large amounts of 1-propanol. Taking into account the effects of pyridine and dichloroacetic acid on reactions over metal phosphates, 1-propanol has been assumed to be produced from hydrogen-transfer reactions of allyl alcohol.[2] In this paper, 1-propanol formation will be studied in detail.

1-Propanol is considered to be a hydrogenated compound of allyl alcohol, propionaldehyde, and propylene oxide and to be formed by the following reaction processes (1)—(4):

$$CH_2=CH-CH_2OH + CH_2=CH-CH_2OH \longrightarrow CH_2=CHCHO + CH_3CH_2CH_2OH \quad (1)$$

$$CH_2=CH-CH_2OH + CH_3-CH-CH_2 \longrightarrow CH_2=CHCHO + CH_3CH_2CH_2OH \quad (2)$$

$$CH_2=CH-CH_2OH + CH_3CH_2CHO \longrightarrow CH_2=CHCHO + CH_3CH_2CH_2OH \quad (3)$$

$$CH_3CH_2CHO + CH_3-CH-CH_2 \longrightarrow CH_2=CHCHO + CH_3CH_2CH_2OH \quad (4)$$

AA: Allyl alcohol
PO: Propylene oxide
PA: Propionaldehyde

In Table 4, the reactivities for each reaction are given; here, in the case of propylene oxide, the formation of 1-propanol from Process (3) caused by the isomerization of propylene oxide is corrected. As is shown in Tables 2 and 3, considerable acrolein is produced over a series of catalysts. Though the amount of acrolein is smaller than that of 1-propanol, this fact is due to the high reactivity of the polymerization of acrolein; there is an approximate correlation between the amount of acrolein and that of 1-propanol. Therefore, Reactions (2) and (3) are found to be the main processes of 1-propanol formation. As alcohol is more easily dehydrogenated on basic sites than other reactants, it is deduced that allyl alcohol is the hydrogen donor and propionaldehyde and propylene oxide are acceptors. When one mole of 1-propanol is formed, one mole of allyl alcohol is consumed. Therefore, the sum of the formations of allyl alcohol and 1-propanol is considered to be the original amount of allyl alcohol formed. In Fig. 4, their sum is plotted against the magnesium-oxide content. The original formation of allyl alcohol has a maximum; this fact indicates that allyl alcohol is formed by an acid-base bifunctional catalyst, as was reported earlier.[2]

As regards the metal oxides, magnesium and calcium oxides have a high activity of allyl-alcohol formation. Malinowski *et al.*[8] deduced from ammonia adsorption studies that magnesium oxide has a very weak acid site. Taking into account the products of propylene-oxide isomerization, the other metal oxides can also be considered to have very weak acid sites, though the presence of acid sites cannot be detected by the indicator method. For allyl-alcohol production, even very weak acid sites are deduced to be favorable.

The acidic and basic properties of manganese monoxide cannot be measured because of its dark color. It is considered, on the basis of the product distribution of the propylene-oxide isomerization, that it has both acidic and basic properties.

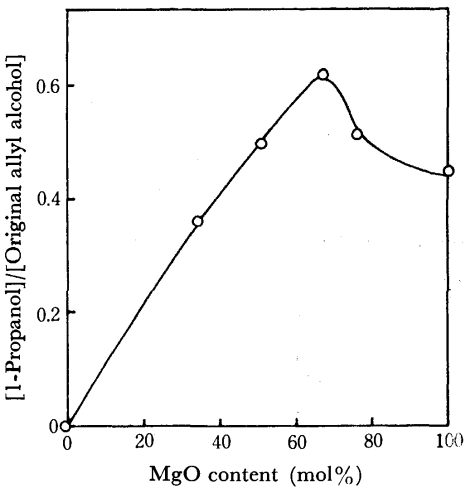

Fig. 5. Dependence of the ratio of 1-propanol to original allyl alcohol on magnesium oxide content.

Niiyama *et al.*[9] have reported that hydrogen-transfer reactions between alcohol and ketone are catalyzed by acid-base bifunctional catalysts. Figure 5 shows the relation between the ratio of the formation of 1-propanol and the original formation of allyl alcohol and magnesium oxide contents. The ratio has a maximum; this fact suggests the same conclusion. According to Table 4, magnesium and calcium oxides produce a very large amount of 1-propanol among all the metal oxides used. Magnesium oxide prepared from magnesium hydroxide gives a product distribution different from that of magnesium oxide supplied in the production of 1-propanol; that is, the selectivities for 1-propanol are 24.9 and 31.9% for prepared and supplied MgO respectively. According to the basic-strength measurements, the supplied MgO($H_0=+17.2$) has stronger basic sites than the prepared MgO($H_0=+15.0$). Therefore, as regards the basic properties favorable to the reaction, strong basic sites are effective.

The order of the activity of the hydrogen-transfer reaction between allyl alcohol and hydrogen acceptor is: propionaldehyde>propylene oxide>allyl alcohol; this order is that of the electron-donating power, $\Delta\nu_D$, of the hydrogen acceptor, which is given in Table 4. According to Kagiya,[10] the electron-donating power of a compound is defined as the relative difference (counted as wave numbers) of the OD adsorption band of methanol-*d* observed in the compound from

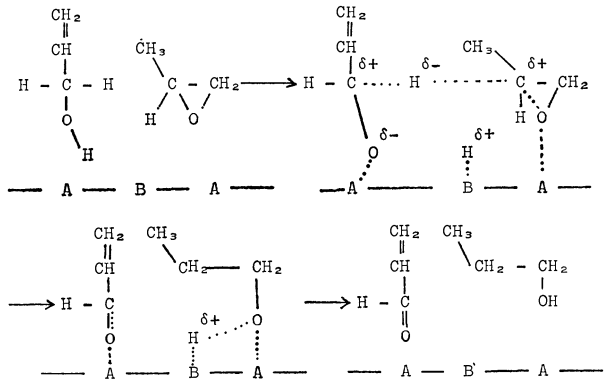
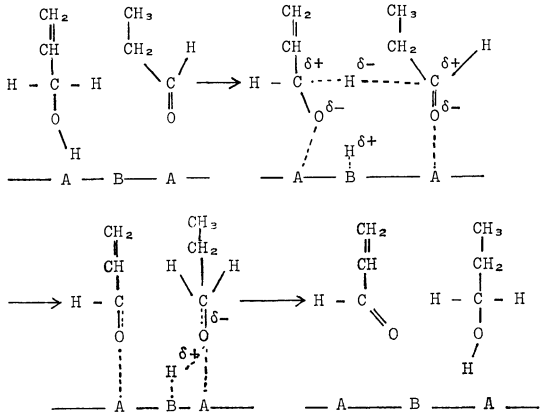
that observed in benzene. The $\Delta\nu_D$ of allyl alcohol is estimated by taking into account the values of the electron-donating power of the C–C double bond in benzene ($\Delta\nu_D$; 0 cm^{-1}), styrene ($\Delta\nu_D$; 4 cm^{-1}), and so forth.

As regards the mechanism of the hydrogen-transfer reaction Niiyama *et al.*[9] have proposed a mechanism similar to that of Meerwein-Ponndorf reduction. Our results support their mechanism in the case of silica-magnesia catalysts. The following mechanism is plausible.

For process (2)



For process (3)



A: acid site B: basic site

That is, propionaldehyde or propylene oxide adsorbs on the acid site at the oxygen atom in them, and the electron density of the carbon atom adjacent to the oxygen atom becomes more positive. The larger the electron-donating power of the hydrogen acceptor, the more positive the carbon atom becomes. Allyl alcohol adsorbs on the basic site, dissociating the hydroxyl group, the electron density of the hydrogen atom at α-carbon becomes negative, and the hydride ion transfers to the positively-charged carbon atom of aldehyde or oxide. Therefore, a strong base is favorable. In the case of propylene oxide adsorbed on a weak acid site, 1-propanol is formed preferentially, as the electron density of α-carbon is smaller than that of β-carbon.[11]

However, in the cases of metal oxides which have only very weak acid sites, it may be considered that the interaction between the acid site and the oxygen atom of the hydrogen acceptor is negligible.

Conclusion

Propylene-oxide isomerization was carried out over silica-magnesia catalysts and metal oxides at 260—270°C using a pulse reactor. It has been concluded that propionaldehyde and acetone are produced on acidic and basic sites respectively. Considerable amounts of 1-propanol are formed on these catalysts, whereas it is not produced on metal phosphates and zeolites. Allyl alcohol is formed by acid-base bifunctional catalysts. It has been found that 1-propanol is mainly produced through the hydrogen-transfer reactions between allyl alcohol and propionaldehyde and propylene oxide. It has also been made clear that acid-base bifunctional catalysts are favorable for the hydrogen-transfer reactions and that the reaction rate depends on the electron-donating power of the hydrogen acceptor and also on the basic strength of the catalyst.

The production mechanisms of the acidic and basic properties of silica–magnesia catalysts were studied by X-ray analysis. The acid site is due to forsterite, while the basic site is due to the magnesium oxide remaining. In view of their reaction products, the metal oxides, such as magnesium and calcium oxides, are considered to have very weak acid sites.

An Electron Spin Resonance Study of the Steroid Conformation — 6-Oxohelvolic Acid (Triketone) —

Takiko FUJISAWA, Shigenobu OKUDA,* and Yuzaburo FUJITA

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo
**Institute of Microbiology, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo*

(Received March 30, 1972)

The triketone (6-oxohelvolic acid (IIa) or its tetrahydro-derivative (IIb)) was readily oxidized in air into the anhydride (IIIa or b) in an alkaline solution; it spontaneously turned red or deep green and then gradually lost its color. In this reaction process, the presence of a relatively stable intermediate radical was confirmed by the ESR measurement. As a result of an analysis of the well-resolved proton hyperfine structure of this radical, it was explained that the structure of helvolic acid is of the protostane type: that is, it is a distinctive structure of the *trans*-fusion of the A/B ring juncture and a boat form of the B-ring. A reasonable oxidation mechanism including this intermediate radical was presented.

In general, the physical methods of ORD or CD, NMR, and X-ray diffraction are widely used in conformational analyses of steroids; much valuable information has been thus obtained, as is illustrated in the textbook.[1]

However, although the most exact structural information can be derived from an X-ray analysis, provided that the steroid is obtained in a single crystal form, such an analysis can not tell us about delicate conformational changes in steroids in various solvents. Such information is, though, important for the study of stereochemical reaction processes.

On the other hand, ORD or CD is especially useful for the elucidation of the stereoconformations of steroids or terpenes in solutions. However, even in these cases, the determination has to be done in comparison with compounds of a close structure or of a known absolute configuration.

Apart from these methods, the proton NMR spectroscopy is a powerful method for use in the stereochemistry of steroids, and recent advances in this field, for example, the double-resonance method and high-field resonance method (100 MHz or higher frequency), provide valuable information on the absolute configurations of steroids.

The application of the ESR method to the study of the conformations of macromolecules is rather limited in the field of the stereochemistry of steroids because of necessity for an unpaired electron spin in the molecules. The "spin-labeling" method developed by McConnell *et al.*,[2] which involves attaching a stable simple radical (generally an *N*-oxide radical) on a macromolecule and detecting the subsequent delicate environmental conformational change around the labeled spin, has been proved to be a powerful tool for the study of biomolecules,[2] such as haemoglobin, DNA, and cell membranes. From a slightly different point of view, Russell *et al.*[3] have studied the conformations of various steroids, changing them into "semidione" radicals and treating them with *t*-BuOK in air; they have thus been able to classify the reactivities of $-CH_2$ groups neighboring a carbonyl or hydroxyl group. This method also informs us about the dynamic characters of ring inversion under various environmental conditions.

We are interested in the application of ESR to the stereoconformational studies of steroids, by making use of the extra-high sensitivity (10^{11} spins/gauss) of the ESR method and sensitive changes in hf splittings depending on the slight conformational change in the spin environment.

Helvolic acid (I), one of antibiotics first isolated from *Asperigillus fumigatus* by Waksman *et al.*,[4] has a growth-retarding effect on Gram-positive bacteria. Later, Okuda *et al.*[5] found that *Cephalosporium caerulenes* produced it in a much better yield than did *A. fumigatus*, and that this compound had a unique skeleton (protostane type)[6] of tetracyclic triterpenoid, in which the B-ring had a boat form. That is, this compound has a *trans*-syn-*trans* juncture in the A/B/C rings, unlike the *trans*-anti-*trans* juncture in usual steroids and triterpenoids. A revised absolute configuration has recently been presented based on extensive stereochemical and NMR studies of helvolic acid and its relatives.[7] In the course of this investigation, Inoue, Machida, and Okuda[8] have found that 6-oxohelvolic acid (IIa) or 1,2,24,25-tetrahydro-6-oxohelvolic acid (IIb) is very sensitive to oxygen in an alkaline solution, turning red or deep green respectively, gradually losing its color, and ultimately oxidizing into the anhydride (IIIa or b). These results, indicating a radical mechanism of the oxidation process, have prompted us to search for the presence of a relatively stable intermediate radical by making ESR measurements.

In this report, we will present some ESR results on the conformations of the triketone radicals—in other words, on that of helvolic acid.

Experimental

Materials. The triketones, IIa and IIb, were synthesized from helvolic acid in the laboratory of professor Okuda. The other reagents used were all of a G. R. grade.

Methods. ESR measurements were carried out at room temperature using a JEOL P-10 apparatus (Japan Electron Optics Laboratory Co., Ltd.) at the X-band and 100 KHz field modulation. The field calibration was made with reference to a standard sample of Mn^{2+}/MgO and a solution of Fremy's salt.

For the detection of an intermediate radical by the ESR method, an ESR sample tube with two compartments and a capillary tube was used in order to degas, introduce oxygen, mix the two solutions, and measure the ESR spectrum of the solution at room temperature.

Since an alkaline solution of the triketone is unstable toward oxygen, two separate solutions, one a neutral methanol solution of triketone and the other methanol containing KOH, were degassed thoroughly in each compartment attached to the sample tube by repeating the freeze-degas-thaw cycle; then the two solutions were mixed in one of the compartments at room temperature, followed by the introduction of an appropriate amount of oxygen. For the ESR measurements, a small amount of the colored solution was transferred into the capillary part of the sample tube, which was then inserted into the effective part of the microwave cavity.

The oxygen absorption kinetics were studied with a Warburg manometer.

Results and Discussion

It was confirmed that the two triketones, IIa and IIb, were very unstable toward oxygen in alkaline solutions, and were oxidized into the corresponding anhydrides, IIIa and IIIb. The molecular structures of the anhydrides were explained by the results of the UV, IR, and NMR measurements.[8] After a methanol solution of the triketone had been flushed with nitrogen and then made alkaline with 1 N NaOH, the color of the solution instantaneously changed from yellow to deep green or red in the case of IIb or IIa respectively. On the neutralization of this solution with HCl, the color of the solution returned again to yellow; enolized IIa (IVa) or its tetrahydro-derivative (IVb) was thus obtained in the yield of 100%.

It was found by Warburg's manometry that the amount of oxygen necessary to oxidize the triketone to its anhydride was one mole for one mole of triketone.

ESR experiments were carried out at room temperature, changing the concentration of the triketone in the range of 10^{-1}—10^{-3}M, and the concentration of alkali in the range of 1—1/100N.

According to the concentration of hydroxide relative to that of the triketone, various types of ESR spectra, A, B, C, D, and E (E'), with well-resolved hf structures and the *g*-factor of 2.004_3 were observed as is shown in Fig. 1. These spectra were fairly stable provided the amount of oxygen was not in excess, and they persisted even after one day.

With an increase in the hydroxide concentration relative to that of triketone, the ESR spectra were observed in the order of A, B, C, D, and E spectra for tetrahydro-triketone. For example, the mixed solution of 0.3 ml of 10^{-1}M tetrahydro-triketone in acetone, 0.05 ml of 2N NaOH, and 0.2 ml H_2O exhibited the D spectrum. After the observation of this spectrum, an appropriate amount of water was added, little by little, into the sample solution, and then the spectral type changed successively from D to C, to B, and finally to A. On the other hand, in the case of Δ^1-triketone, only the E' spectrum was observed in a low hydroxide concentration. A distinct difference between the E and E' spectra is that the latter has a well-resolved quartet hf structure in addition to that of the E spectrum.

Table 1. Hf splitting constants of triketone radicals (in gauss)

a) Numbers of equivalent protons.
b) Observed only for Δ^1-triketone.

All the spectra were analyzed; the respective stick diagrams are shown below the spectra in Fig.1. The hyperfine constants of each spectrum are tabulated in Table 1. Some of the computer-simulated spectra are also shown in Fig. 2.

It is obvious that these hf structures are attributable to certain protons in these radical structures, since the proton is the only nuclear species to show the hf structure. As can easily be seen from the splitting constants in Table 1, the finding that the observed spectral patterns changed in a delicate manner with an increase

All the spectra were recorded at room temperature under the following operation condition; microwave power 3 mW, modulation width 0.05—0.3 G.

Fig. 1. ESR spectra of the triketone radical.

in the hydroxide concentration is due to a gradual decrease in the largest hf constant, a_1, down to the value of the second hf constant, a_2, while the third hf constant, a_3, remains nearly constant throughout, from the A spectrum to the E spectrum. On the other hand, in the E′ spectrum of the Δ^1-triketone radical, the hf splitting constants, a_1 and a_2, are already equal in a rather low concentration of hydroxide ions compared with the case of tetrahydro-triketone, and it has the smallest quartet hf splitting, a_4=0.4 G.

These spectral patterns were observed not only with the oxidation by molecular oxygen, but also with that by H_2O_2 or $Fe(CN)_6^{3-}$, and no change in the spectral patterns was observed even in the H_2O (D_2O), MeOH (MeOD), acetone, and DMSO solvents. From these results, it can be considered that the radical may be an ion-type radical produced by the one-electron oxidation of the triketones.

It is reasonable to consider that the radical has a structure spin-localized in the B-ring rather than in the A-ring, because essentially similar spectral patterns, E and E′, were observed with both triketones. Accordingly, the protons at the 1- and 2-positions are not responsible for the observed hf structure.

The proton at the 5-position is so labile that it is easily detached by enolization in an alkaline solution, as is confirmed by the finding that IVa or IVb is obtained in a full yield by alkalization and subsequent neutralization in the absence of oxygen. With regard to this nature of the 5α-H and the finding that no apparent change in the spectral pattern was observed in a CH_3OD or D_2O containing solvent, it can rea-

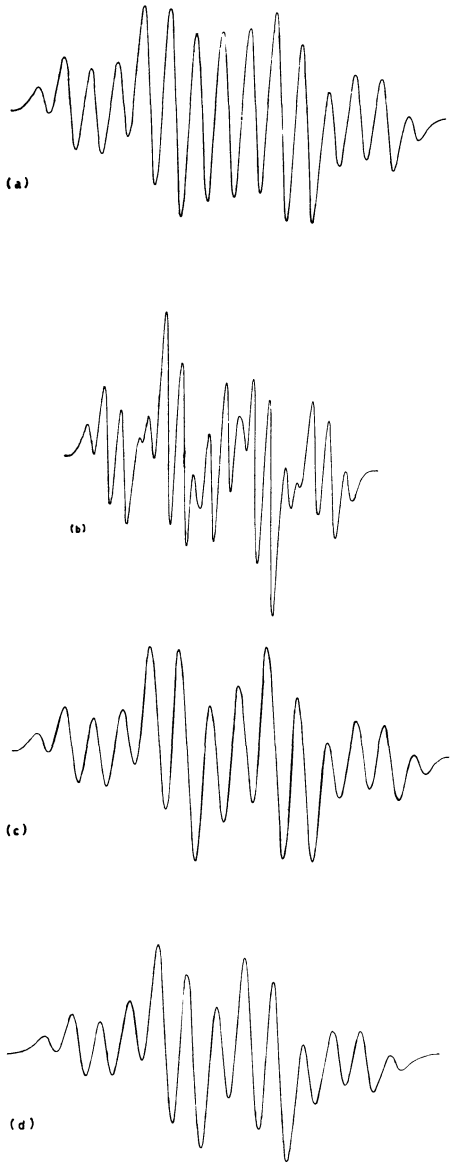

Fig. 2. Computer-simulated spectra of the triketone radical.
(a): A spectrum, (b): C spectrum, (c): D spectrum,
(d): E spectrum

sonably be concluded that this proton does not contribute to the hf structure either.

At first sight, it can easily be seen in Table 1 that each hf splitting constant makes two or three pairs of three equivalent protons, at least in the E and E′ spectra. This probably indicates that each hf splitting is due to a certain methyl group in the A- or B-ring.

Let us consider which methyl group causes the corresponding hf splitting.

The enolization processes for Δ^1- or tetrahydrotriketone with an increase in the hydroxide concentration may be ascribed to the group shown in Fig. 3, in view of the degrees of stabilization by π-conjugation, the relative enolizabilities of protons at various positions, and the structures of the final oxidation products.

Canonical structures of reliable radical species produced by one-electron oxidation at each step are shown in the brackets. The spin density in these radicals is thought to be mainly localized at the carbon atom of the 5-position. The fact that the observed g-factor,

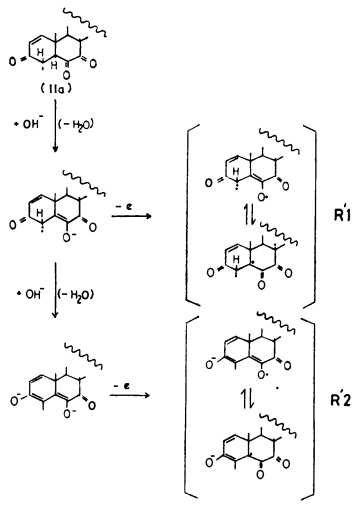

Fig. 3. Enolization processes for Δ^1-triketone and canonical structures of reliable radical species produced by one-electron oxidation.

$g=2.004_3$, is slightly larger than that of the free spin, $g_e=2.0023$, but much smaller than the empirical values of organic peroxy radicals,[9] $g_{av}=2.015$, is reasonably consistent with the envisaged radical structures.

It can easily be visualized, by means of the molecular models of the triketone radicals constructed on the basis of the confirmed *trans*-syn-*trans* juncture in

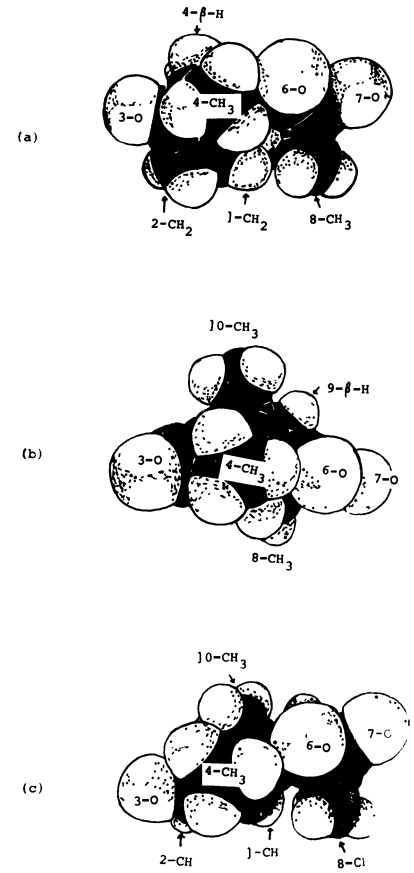

Fig. 4. Molecular models of the triketone radicals.
(a): R 1 radical, (b): R 2 radical, (c): R′ 2 radical

9) M. Bersohn and J. R. Thomas, *J. Amer. Chem. Soc.*, **86**, 959 (1964); K. U. Ingold and J. R. Morton, *ibid.*, **86**, 3400 (1964).

the A/B/C rings of helvolic acid (or triketone), that the rotational motion of a certain methyl group in the triketone radicals is significantly affected with the progress of the step-by-step enolization of the 5α-H and 4β-H. Let us denote the radicals as R1 and R2 for the tetrahydro-triketone radicals, and as R'1 and R'2 for the Δ^1-triketone radicals which are produced by the one-electron oxidation at each enolization step. Molecular models of the R1, R2, and R'2 are shown in Figs. 4a, b, and c respectively.

First, the structure of the tetrahydro-triketone radical is discussed. In the structure of the R1 radical, the free rotation of the 4-CH_3 group is partly hindered by the steric hindrance due to the bulky oxygen atom at the 6-position; that of the 8-CH_3 is also hindered by the 1-CH_2 as is shown in Fig. 4a. On the other hand, it can be seen that the 10-CH_3 group, floating above the molecular plane, rotates freely notwithstanding a degree of enolization (this is also the case with the Δ^1-triketone radical). In the R2 radical, the 4-CH_3 is able to rotate freely, since the proton at the 4-position is removed, extending the π-conjugation and increasing the planarity of the A-ring with the progress of enolization. This situation is clearly shown in Fig. 4b. However, the steric hindrance upon the 8-CH_3 due to the 1-CH_2 can not be removed in spite of further enolization. This is comprehensible from the fact that the 8-position, being apart from the π-conjugation around the 3, 4, and 5-positions, is buried in the rigid structure of the molecules. It goes without saying that the 10-CH_3 is free to rotate.

Next, let us proceed to the structure of the Δ^1-triketone radical. In this radical, the planarity of the A-ring is large compared with that of the tetrahydro-triketone radical because of the presence of a double bond between the 1-C and 2-C atoms. Moreover, in accordance with the methine group, =CH–, at the 1-position in place of the $-CH_2-$ group of the tetrahydro-triketone, there is no steric hindrance between the 8-CH_3 and the 1-CH before the enolization.

At the second step of the enolization, the free rotation of the 4-CH_3 group, which is partly hindered in the first step, becomes possible, as in the case of the tetrahydro-triketone radical.

It should be stressed here that a large spectral red-shift in an alkaline solution was observed for Δ^1-triketone compared with tetrahydro-triketone, and that only one ESR spectrum was observed in the former. This result may indicate that the former is further subjected to the second step of the enolization under similar conditions, as can easily be understood from the structure of its ready π-conjugation.

It may thus be considered that the observed E' spectrum corresponds to the R'2 radical, and that the smallest hf splitting constant of this radical can reasonably be assigned to the equivalent three protons of the 8-CH_3, since this hf splitting is observable only in the Δ^1-triketone radical. This is in accordance with the free rotation of this group; otherwise, such a small hf splitting might be obscured by the line-broadening due to hindered rotation, as is the case of the tetrahydro-triketone radical.

As to the third hf splitting constant, a_3=1.2 G, observed commonly throughout the spectra, A, B, C, D, E, and E', it is safe to assign this to the 10-CH_3 group.

The above two assignments are reasonable in view of configuration of the spin-localization in the radicals.

The remaining assignments for the hf splitting constants of a_1 and a_2 are not so simple, because the hf splitting constant, a_1, gradually decreases from the 6.1 G of the A spectrum to the 4.1 G of the E spectrum, while, on the other hand, the a_2 value increases slightly from the 3.7 G of the A spectrum to the 4.0 G of the E spectrum. Since the 4β-H and 4α-CH_3 are close to the 5-position, where an unpaired electron is localized, and are common for both triketones, these protons can be expected to exhibit rather large hf splittings.

At the first enolization step, the rotation of the 4α-CH_3 group is so restricted that the protons in this group are not magnetically equivalent because of the steric hindrance and also partly because of a weak interaction, probably a hydrogen-bond-like one between the oxygen atom at the 6-position and two of the three protons of the 4α-CH_3 group; such a configuration is also supported by the similar interaction between the oxygen atom at the 3-position and the remaining proton of the methyl group. In such a configuration, one of the three protons of the methyl group is nearly equatorial, while the others are axial, to the plane of the A-ring. Therefore, the latter two protons may contribute equivalently to a hf splitting, while the former does not.

One can expect a larger hf splitting due to the 4β-H than that due to the 4α-CH_3, since the 4β-H is axial to the plane and is located closer to the 5-position of spin-localization. The variation in the hf splitting constant, a_1, during the first enolization process may be explained by a delicate change in the angle between the $2p_z$ axis of the 5-carbon atom and the C–H axis of the 4β-H.

At the final step of the enolization process, the 4β-H is removed, leaving the 4-CH_3 at the 4-position; correspondingly, in their ESR spectral patterns, the observed hf splitting becomes the one due to three equivalent protons—that is, a_1 (one proton)=4.1 G≒ a_2 (two protons)=4.0 G. Thus, the three protons of the 4-CH_3 group can be attributed to the equivalent observed hf structure of the E or E' spectrum.

The above discussions are entirely based on the *trans*-syn-*trans* juncture in the A/B/C rings of helvolic acid; thereby, the hf splittings of the intermediate radicals are all reasonably explained. In other words, this result supports the conformation of helvolic acid, which has also been confirmed by other methods. The possibility of the epimerization of the A/B ring juncture during the oxidation reaction can reasonably be rejected on the basis of an analysis of the ESR spectra of the radicals; that is, such a conformational change obviously is not consistent with the observed hf splittings.

As has been described above, in the oxidation process of tetrahydro-triketone, the presence of an intermediate radical, R1 or R2, depending on the hydroxide

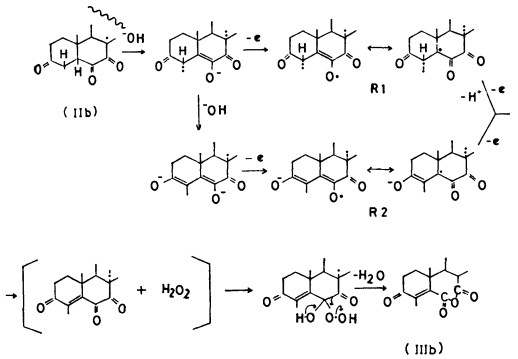

Fig. 5. The oxidation mechanism of the triketone to the anhydride.

concentration, has been confirmed by the ESR measurements, while, in the case of Δ^1-triketone, only the R'2 radical has been detected even in a rather low bydroxide concentration range. Therefore, the oxidation mechanism of the triketone to the corresponding anhydride *via* an intermediate radical may be shown as Fig. 5. In the case of tetrahydro-triketone, the reaction proceeds: IIb→R1→IIIb or IIb→R2→IIIb, depending on the hydroxide concentration. On the other hand, for Δ^1-triketone, only the way of IIa→R'2→IIIa is available independent of the hydroxide concentration, as can easily be understood from the above discussion.

Since the intermediate product, Int., has not been isolated in the present work, the rate-determining step is considered to be the one of its formation. The oxidation of the intermediate, thereafter, proceeds rapidly by the reaction with H_2O_2, which is formed in the preceding oxidation processes:

$$\left.\begin{array}{l}\text{the first one-electron oxidation step: } O_2+e=O_2^- \\ \text{the second one-electron oxidation step: } O_2+e=O_2^-\end{array}\right\} \xrightarrow{+2H^+} 2HO_2 \longrightarrow H_2O_2 + O_2$$

The oxidation of ketones with H_2O_2, leading to the insertion of an oxygen atom into a steroid nucleus, is well known in steroid chemistry.[10]

The above oxidation mechanism accords well with the experimental findings that one mole of oxygen was consumed in the oxidation of the triketone to the anhydride, and that a trace of hydrogen peroxide was detected in the final oxidation products.

Ion-Solvent Interaction of Tetraalkylammonium Ions in Solvents of High Dielectric Constant. III. Conductance and Walden Product of Some Partially Substituted Alkylammonium Ions in *N*-Methylacetamide and *N*-Methylpropionamide at Different Temperatures

Raj Deo SINGH

Department of Chemistry, Lucknow University, Lucknow, India

(Received March 8, 1972)

Ion-solvent interaction of some partially substituted alkylammonium ions in *N*-methylacetamide (NMA) and *N*-methylpropionamide (NMP) has been investigated from the point of view of electrical conductance and the derived Walden product. From the results, it seems that like tetraalkylammonium (R_4N^+) ions, Me_3NH^+ and $CeMe_3N^+$ ions are structure breakers in these solvents while Me_3PhN^+ ion is neither structure breaker nor structure maker.

In previous communications,[1,2] ion-solvent interaction of some symmetrically substituted tetraalkylammonium (R_4N^+) ions in NMF, NMA, and NMP has been investigated from the conductance data. It would be interesting to investigate how the partial and unsymmetrical substitution in the NH_4^+ ion will affect the nature of the ion-solvent interaction in these solvents. With this aim in view, the conductances of some available such salts namely, Me_3NHI, Me_3PhNI, and $CeMe_3NBr$ in NMA and NMP at different temperatures have been reported in the present communication and the data have been used to throw light on the mode of ion-solvent interaction.

Experimental

Trimethylammonium iodide (Me_3NHI), trimethylphenylammonium iodide (Me_3PhNI) and cetyltrimethylammonium bromide ($CeMe_3NBr$), obtained from B.D.H., were purified as follows:

Me_3NHI and Me_3PhNI were recrystallized twice from a mixture of methanol and ether (3:1). The salts were dried in a vacuum desiccator.

$CeMe_3NBr$ was dissolved in methanol and precipitated

2) R. D. Singh and R. Gopal, This Bulletin, **45**, 2088 (1972).

with ether. The precipitated salt was dried in a vacuum desiccator.

NMA and NMP were purified in the manner given elsewhere.[1,2] The purified samples were stored in dark amber-coloured bottles in a dry nitrogen box and were used, as far as possible, the day after distillation. Although the solvents appeared to be quite stable, solvent correction was applied in determining the conductances of solutions. The rest of the experimental procedure and the degree of reliability of the apparatus were the same as those given in the previous communications on NMF, NMA, and NMP.

Results and discussion

Within the concentration (0.0005M to 0.02M) and temperature (30° to 55°) ranges studied here, the plots of equivalent conductance Λ and $\sqrt{c}$ were found to be almost straight lines for all the salts in NMA and NMP. It appears, therefore, that these salts are completely dissociated in NMA and NMP as has been reported by earlier workers.[3-7] Extrapolation of Λ *vs.* $\sqrt{c}$ curves to zero concentration leads to Λ_0-values given in Table 1. From these Λ_0-values, the ionic conductances λ_0^+ of the cations at different temperatures were obtained, using the appropriate transport number data already reported in literature;[8] these λ_0^+-values are given in Table 1.

Table 1. Limiting equivalent conductance in NMA and NMP at different temperatures

$CeMe_3N^+$	5.69	6.38	7.21	8.04	8.79	...

The applicability of limiting Debye-Hückel-Onsager conductance equation to solutions under study was examined. The conductance equation for 1:1 electrolyte can be written in the form

$$\Lambda = \Lambda_0 - \left[\frac{82.42}{(\epsilon T)^{1/2}\eta_0} + \frac{8.203\times 10^5}{(\epsilon T)^{3/2}}\Lambda_0\right]\sqrt{c}$$

which simplifies to

$$\Lambda = \Lambda_0 - (A + B\Lambda_0)\sqrt{c} = \Lambda_0 - S_T\sqrt{c}$$

for a constant temperature. The values of A and B are

$$A = \frac{82.42}{(\epsilon T)^{1/2}\eta_0},\quad B = \frac{8.203\times 10^5}{(\epsilon T)^{3/2}}$$

and the theoretical slope $S_T = (A + B\Lambda_0)$.

From Λ_0-values and other appopriate data on dielectric constant[7,9] and on viscosity η_0 (determined in this laboratory,[1,2]) the theoretical slopes S_T of the Λ *vs.* $\sqrt{c}$ curves have been obtained and are given in Table 2 at one temperature (40°C) only.

Table 2. Onsager slopes in NMA and NMP at 40°C

Salt	Theoretical slope (S_T)	Experimental slope (S_E)	% Deviation $\left(\frac{S_E - S_T}{S_T}\times 100\right)$
		NMA	
Me_3NHI	−13.9	−15.6	12
Me_3PhNI	−13.7	−15.8	15
$CeMe_3NBr$	−13.5	−15.4	14
		NMP	
Me_3NHI	−12.1	−13.2	9
Me_3PhNI	−12.1	−13.4	11
$CeMe_3NBr$	−11.0	−13.3	12

It may be noted from Table 2 that the experimental slopes S_E of the Onsager plots for these salts in the two solvents, are numerically greater than the theoretical slopes S_T. In view of the high dielectric constant of these solvents, incomplete dissociation of the salts in the usual sense is unthinkable, although Dawson and coworkers[3,5,6] have tried to explain the conductance results in NMA and NMP on this ground. As discussed in previous communication,[2] these deviations may be ascribed to the penetration[10-13] of cations by anions causing a sort of association[14] or to the greater resistance offered to the movement of the cations by solvent molecules, than that caused by viscosity of the solvent medium, so that the movement of the cations is more sluggish than expected from the theory.

The Walden products of the partially substituted alkylammonium ions at different temperatures have been calculated from the appropriate λ_0^+-values (given in Table 1) and viscosity data. From the cationic Walden product data, thus obtained, $\lambda_0^+\eta_0$ *vs.* temperature curves have been drawn and are given in Figs. 1 and 2.

It is obvious from the curves that like those of symmetrical tetraalkylammonium (R_4N^+) ions, the Walden product of Me_3NH^+ and $CeMe_3N^+$ ions in these amides decreases with the rise of temperature while for Me_3PhN^+ ion, it is approximately constant. The decrease in

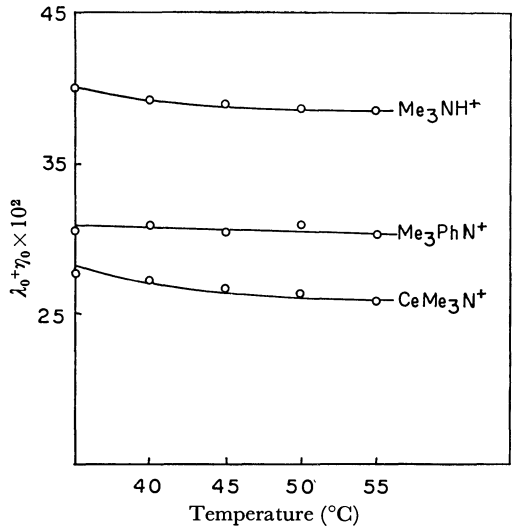

Fig. 1. Plot of $\lambda_0^+\eta_0$ *vs.* T in NMA

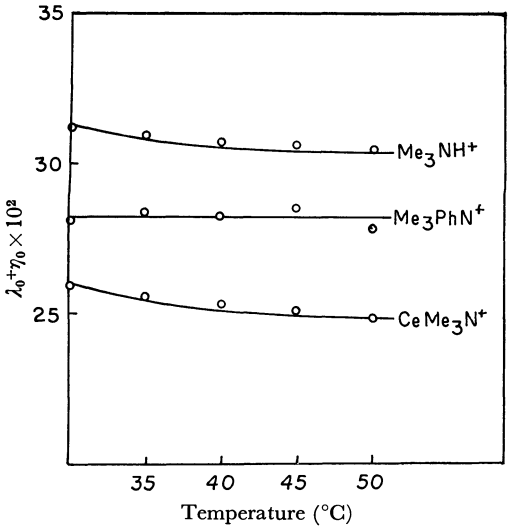

Fig. 2. Plot of $\lambda_0^+\eta_0$ *vs.* T in NMP

$\lambda_0^+\eta_0$ values of Me_3NH^+ and $CeMe_3N^+$ ions with the rise of temperature can be explained on the similar grounds as for R_4N^+ ions *i.e.*, electrostatic solvation and resultant breaking-up of the structure of the solvent medium occurs around the ions. The partially substituted alkylammonium ions, being similar to NMA and NMP in having the alkyl groups, do not promote the structure of the solvent[15] *i.e.*, "structure promotion" or "lyophobic solvation" is missing in these solvents in the presence of these ions. Further, although these ions are large which would reduce ion-solvent interaction, the large dipole moment[16] of the solvent molecule makes up for the large size of the ions so that an appreciable ion-solvent interaction would occur. Thus, there appears a net structure breaking[17] in the presence of the partially and mixed alkyl substituted ammonium ions because the electrostatic ion-solvent interaction would be stronger than the interaction between the solvent molecules themselves.

The approximate constancy of the Walden product of the Me_3PhN^+ ion indicates that this ion has, apparently no net effect on the structure of the solvents although it is rather unexpected since the $CeMe_3N^+$ ion which is quite large, appears to be a structure breaker. It may be that, due to the bulky phenyl group which may shield the positive charge on the nitrogen atom from the influence of the solvent dipole, the ion-solvent intraction is weak as is the case with the larger R_4N^+ ions in these solvents.[1,2]

Although it is rather unsafe to make any generalisation in view of the restricted number of salts studied, it appears that unsymmetrical and partially substituted ammonium ions, in general, behave similarly in NMA and NMP; also their behaviour is similar to that of R_4N^+ ions. The author feels the necessity of an extensive study, involving more ions of this type before a definite conclusion can be arrived at.

The author is grateful to Prof. Ram Gopal, Head, Department of Chemistry, Lucknow University, Lucknow, India for providing laboratory facilities and giving valuable suggestions during the course of this investigation. The financial assistance given by the Society of Sigma Xi and RESA of U.S.A., is gratefully acknowledged. The assistance given by C.S.I.R., India has also been valuable.

Dielectric Relaxation and Molecular Structure. III. Dielectric Relaxation Study of Some Anilines in Benzene Solutions at Different Temperatures

J. K. Vij,* Iqbal Krishan, and K. K. Srivastava
Physics Department, Panjab University, Chandigarh, India
(Received February 28, 1972)

Measurements of relative permittivity at 1 MHz and at 9.46 GHz, the refractive index for the Sodium D-line, have been made for (a) *N,N*-dimethylaniline, (b) *N,N*-diethylaniline, (c) *o*-chloroaniline, (d) *m*-chloroaniline and (e) *p*-chloroaniline at temperatures of 15, 25, 35, and 45°C in dilute solutions of benzene. Dielectric relaxation times $\tau(1)$ and $\tau(2)$ have been calculated by the method recently suggested by Higasi, Koga, and Nakamura in terms of the slopes a_0, a', a'', and a_D. It is remarked that $\tau(2)$ at the experimental frequency of 9.46 GHz leads to τ_1, the relaxation time for overall rotation, whereas $\tau(1)$ becomes an explicit function of τ_1 and τ_2. These determinations suggest the presence of both molecular and intramolecular rotations in the molecules. The results for $\tau(2)$ show a systematic decrease with increase in temperature whereas for $\tau(1)$ there seems to be no observable trend. The enthalpy and entropy of activation for molecular dielectric relaxation process has been determined. The enthalpy of activation for (a) and (b) is of the same order of magnitude (*i.e.*, 3 kcal/mol), and the same is true for the case of (d) and (e) (1.8 kcal/mol) but 6.8 kcal/mol for (c). It appears that in *o*-chloroaniline, there is a finite probability of H-Cl bond formation between one of the amino hydrogens and the neighbouring chlorine atom.

This work deals with the dielectric relaxation mechanism of systems with two Debye dispersions. A study on these molecules in different non-polar solvents at various temperatures has been reported.[1] On an examination of the values of $(a_\infty - a_D)$, the authors suggested the possibility of two Debye dispersions in these substances. Chitoku and Higasi[2] studied dimethylaniline in benzene and dioxane solutions at 20°C at three different frequencies in the main dispersion region. Besides giving useful information on the behaviour in two solvents, their results also suggested the presence of two Debye dispersions. Pure dimethylaniline has been studied by Grubb and Smyth,[3] Garg and Smyth[4] and, Srivastava.[5] Though the results differ to some extent, all agree that two dispersions exist in dimethylaniline. Pure diethylaniline was studied by Srivastava.[5] He reported the (Cole–Cole) distribution parameter value to be as high as 0.52/30°C. Recently Tucker and Walker[6] studied *m*- and *p*-chloroanilines at 25°C in dilute solutions of cyclohexane. They gave two dielectric relaxation time values, one for overall dielectric relaxation process and another for intramolecular process. Another remarkable result of their studies is the variation of the weight factor for intramolecular relaxation process with the concentration of the solute.

The present study has two objects. Firstly to get more insight into the nature of dielectric relaxation process, and secondly, since not many molecules of this type have been studied in a non-polar solvent at different temperatures, to get some clue as to their behaviour from the heats of activation for the dielectric relaxation process. For this, the validity of Eyring's equation[7–10] has been taken for granted although its validity is still a matter of debate.

The possibility of getting information on the presence of an intramolecular relaxation mechanism from the data at a single frequency in the dispersion region has been another controversial problem. But recent analysis by Higasi *et al.*,[12] shows that there definitely exists a possibility of estimating either of the two relaxation times. An attempt has therefore been made to use this method for an estimation of the dielectric relaxation time for the overall rotational process. It is pointed out that this method may become an alternative to Bergmann's[13] method for estimating both the dielectric relaxation times, under certain conditions.

Experimental

The liquids are of purity standards. The measurements for determining the relative permittivity at the temperatures of 15, 25, 35, and 45°C have been made by the same techniques. The values of the slopes are calculated from the experimental plots of the data *vs.* weight fraction.[1]

Calculations and Results

The Debye equation[14,15] in terms of a_0, a', a'', and a_∞ yields two independent equations

$$\tau(1)=\frac{a''}{\omega(a'-a_\infty)} \quad (1)$$

$$\tau(2)=\frac{a_0-a'}{\omega a''} \quad (2)$$

where a_0, a', a'', and a_∞ are defined in the linear range by the equations:

$$\epsilon=\epsilon_1+a_0\omega_2$$
$$\epsilon'=\epsilon'_1+a'\omega_2$$
$$\epsilon''=a''\omega_2$$
$$\epsilon_\infty=\epsilon_{1\infty}+a_\infty\omega_2$$

Subscript 1 refers to pure solvent, 2 to solute and ∞ to the values at infinite frequency. ω_2 may be taken as weight fraction of the solute. Having defined; $\tau(1)$ and $\tau(2)$ by Eqs. (1) and (2), Higasi, Koga, and Nakamura[12] have set up the following relations (3) and (4), between $\tau(1)$, $\tau(2)$; τ_1 and τ_2. τ_1 and τ_2 are the dielectric relaxation times for molecular and intramolecular rotations, respectively.

$$\tau(1)=A\tau_2$$

where $$A=\frac{[m-(m-1)C_2]+mx^2[1+(m-1)C_2]}{1+[1+(m^2-1)C_2]x^2} \quad (3)$$

$$m=\frac{\tau_1}{\tau_2},\quad x=\omega\tau_2$$

$$\tau(2)=B\tau_2$$

where $$B=\frac{m^2-(m^2-1)C_2+m^2x^2}{m-(m-1)C_2+mx^2[1+(m-1)C_2]} \quad (4)$$

At the experimental frequency of 9.46 GHz, the value of x (with the preknowledge of the approximate value of τ_2) is of the order of 10^{-1}. One can therefore safely neglect 1 in comparison to m without introducing much error.

Equation (4) is therefore reduced to

$$\tau(2)=\frac{\tau_1}{\tau_2}\cdot\tau_2=\tau_1 \quad (5)$$

Under similar circumstances, Eq. (3) yields

$$\tau(1)=\tau_1(1-C_2)+C_2\tau_2 \quad (6)$$

This shows that the results given by Eq. (2) in our case would correspond to the dielectric relaxation time for overall rotation and those given by Eq. (1) are the implicit functions of τ_1, τ_2, and C_2, the weight factor for intramolecular relaxation mechanism. It should be remarked that since the value given by $\tau(1)$ is a sort of average dielectric relaxation time, a_∞ should be the one corresponding to a_D after a due account for the infrared dispersion (Δa_D) has been made. In the present calculations, Δa_D has been neglected owing to its expected value between 5—10% of a_D which is within the range

Table 1. Values of a_0 (slope of ϵ *vs.* concn. curve), a' (slope of ϵ' *vs.* concn. curve), a'' (slope of ϵ'' *vs.* concn. curve) and a_D (slope of n_D^2 *vs.* concn. curve)

of the accuracies for a_0, a', a'', and a_D.

The determined values of a_0, a', a'', and a_D at temperatures of 15, 25, 35, and 45°C for the various molecules in benzene solutions are given in Table 1.

Free energy of activation (ΔF_ε), enthalpy of activation (ΔH_ε) and entropy of activation for the dielectric relaxation and viscous flow are calculated by using Eyring's equations.[10]

$$\tau = \frac{h}{kT} \exp \frac{\Delta F_\varepsilon}{kT}$$

$$\eta = \frac{hN}{V} \exp \frac{\Delta F_\eta}{kT} \tag{7}$$

where

$$\Delta F_\varepsilon = \Delta H_\varepsilon - T\Delta S_\varepsilon$$

and

$$\Delta F_\eta = \Delta H_\eta - T\Delta S_\eta \tag{8}$$

According to Eqs. (7) and (8), plots of $\log(\tau T)$ *vs.* $1/T$ and $\log(\eta T)$ *vs.* $1/T$ should be straight lines. Their slopes are equal to $\Delta H_\varepsilon/R$ and $\Delta H_\eta/R$, respectively. The plots of $\log(\tau_1 T)$ *vs.* $1/T$ for various substances are given in Figs. 1—5.

Discussion

A perusal of dielectric relaxation time values for the molecules in Table 1 shows that $\tau(1)$ and $\tau(2)$ differ and the difference is beyond the theoretical and experimental errors involved in computing these with the help of Eqs. (1) and (2). An examination of $\tau(2)$ values for

all the molecules also shows a systematic decrease with an increase in temperature whereas $\tau(1)$ dose not seem to follow any trend. It might suggest the following:

i) The intra-molecular relaxation mechanism is such that the dielectric relaxation time associated with it does not change much with temperature. It might mean that the amino or substituted amino group relaxes by an inversion mechanism as postulated by Smyth.[16]

ii) The weight factor (C_2) for intramolecular relaxation mechanism increases with the increase in temperature such that at a higher temperature the total contribution to $\tau(1)$ according to Eq. (6) increases due to intramolecular rotation term and contribution to $\tau(1)$ decreases due to the remaining term for overall rotation both because of less $(1-C_2)$ value as well as lesser τ_1 value.

These suggestions perhaps can be verified if these types of measurements can be conducted at a few more frequencies particularly in the range of mm wavelength. However, the interpretation of the results might be difficult particularly for the substances like *o*, *m*, and *p*-chloroanilines, in view of the possibility for such molecules to have an intramolecular relaxation time associated with the rotation of the chloro group.[17-20]

N,N-*Dimethylaniline and* N,N-*Diethylaniline.* The values of dielectric relaxation time τ_1 or τ_2 for dimethylaniline and diethylaniline are 12.8 ps and 30.5 ps, respectively, at 25°C. These values show good agreement with those reported[1] from this laboratory *i.e.*, 13.4 ps and 32.9 ps at 25°C. These also show good agreement with even τ_0 values given by Chitoku and Higasi,[2] *i.e.*, 14.5 ps and 33.2 ps respectively at 20°C.

Enthalpy of activation for the two molecules is nearly the same which indicates that both have to overcome almost the same barrier height for overall rotation although the molecular size of diethylaniline might be more comparable to that of dimethylaniline. The entropy of activation for the two molecules is a small positive quantity indicating that the activated system is in a state of slight disorder in comparison to the initial system.

o-*Chloroaniline.* The dielectric relaxation time of overall rotation for *o*-chloroaniline at 25°C is 11.5 ps. This might seem to be small in comparison to the molecular size, but greater than that of the molecule formed by attaching any of the two groups. The reported[17] τ values for chlorobenzene are 7.4 ps to 9.6 ps. Recently $\tau(1)$ value of 3.9 ps has been reported[17] for this molecule at 20°C from observations at 100 GHz which might lead to some very interesting conclusion for the rigid molecules. For aniline in non-polar solvents, literature[6,17] τ values vary from 1.2—8.1 ps. The most remarkable observation appears to be the large enthalpy of activation in comparison to that of other molecules of this type. This suggests that at a particular temperature there exsits a finite probability of H–Cl bond formation between one of the amino hydrogens and the neighbouring chlorine atom and this possibility decreases with the increase in temperature. This conclusion supports that already given by Cumper and Singleton[21] from the dipole moment studies.

m- *and* p-*Chloroanilines.* The value of dielectric, relaxation time at 25°C incidentally is 15.2 ps for both the molecules. The value compares favourably well with 13.2 ps and 15.3 ps determined by Tucker and Walker in dilute solutions of cyclohexane for *m*- and *p*-chloroanilines respectively. The enthalpy of activation for both molecules is the same and the order of magnitude is quite less as compared to *o*-chloroaniline. This indicates that both molecules have the same potential barrier and H–Cl type of bond formation as stipulated for *o*-chloroaniline seems improbable. This appears quite acceptable due to the large distance between the amino hydrogens and chloro groups in these molecules.

The literature values of dielectric relaxation time of overall rotation are available only for *m*- and *p*-chloroanilines in dilute solutions of cyclohexane. An agreement with these values suggests that in future $\tau(1)$ and $\tau(2)$ method given by Higasi *et al.* might become a good alternative method for finding the dielectric relaxation times. Perhaps both τ_1 and τ_2 can be estimated with reasonable accuracy provided the measurements are made at two suitably selected frequencies depending upon the type and nature of the molecule.

One of us (JKV) is grateful to Prof. B. K. P. Scaife of Trinity College, Ireland, for his useful suggestions.

A Study on the Kinetics and Mechanism of the Oxidation of Carbon Monoxide over Zinc Oxide

Jae Shi CHOI and Bo Won KIM

Department of Chemistry, Yonsei University, Seoul, Korea

(Received December 13, 1971)

A kinetic study on the oxidation reaction of carbon monoxide has been carried out between 260 and 350°C by means of the static method using *n*-type ZnO semiconductor as a catalyst under various oxygen and carbon monoxide pressure. The order of reaction between 260 and 320°C was found to be 1.5, with $dP_{CO_2}/dt=kP_{CO}\cdot P_{O_2}^{1/2}$. The Roginsky-Zeldovitsch equation,[1] $dP_{CO_2}/dt=ke^{-aP}$, fits well at 350°C. The mechanism of the reaction can be explained by the *n*-type character of ZnO.[2-4]

Hauffe,[5] Wagner,[6] and Schwab[7] studied the oxidation reaction of CO using metal oxide semiconductors. Several papers have affected on the activity and electronic configuration. Wagner and Schwab, who measured the conductivity on various metallic oxides, continued their researches on ZnO containing impurities such as Al_2O_3 and Li_2O. However, their theories did not agree with each other, or with those of many other investigators after them. Ambigues and Teichner[8] showed that a kinetic study combined with measurements of catalyst conductivity in the presence of reagents or products gives valuable information on the mechanism of the reaction. Chizhikova[9] studied the oxidation of CO over pure ZnO, ZnO (0.5 at % In), ZnO (0.5 at % Li) and ZnO (1.0 at % Li) *in vacuo* (10^{-2}–1 mmHg) from room temperature to 450°C. Their results and also those of the others did not agree with each other.

Ambigues and Teichner[8] showed that correlations between the electronic conductivity and catalytic activity could be investigated in two ways. First, a correlation exists between the conductivity and the rate constant of the reaction or the apparent activation energy of the reaction. The conductivity is usually modified by doping the catalyst with altervalent cations. Second, the electrical properties of the catalyst without doping can be studied during the course of reaction. From the change of the conductivity the state of the solid can be clarified.

Krause[10] conducted research on the oxidation of CO to CO_2 on oxide catalysts such as ZnO, NiO, and V_2O_5, and offered explanation in term of chemisorption of oxygen or carbon monoxide on the catalyst and desorption of the oxidized product. Otsuka[11] *et al.* studied the oxidation of CO over ZnO by measuring the adsorption of CO, O_2, and CO_2 on the catalyst in the temperature range 200—250°C under 50—300 mmHg. They concluded that the reaction rate was independent of the adsorption of CO and O_2. Matsuura *et al.*[12] also studied the oxidation of CO in the presence of ZnO as a catalyst at 200—500°C under 0.1—760 mmHg by both the flow and static methods. They concluded that the chemisorption of oxygen is the rate determining step.

We carried out research on the CO oxidation on pure ZnO prepared under various conditions by the static method. The kinetics and mechanism are discussed in this paper.

Experimental

Materials. Four samples A, B, C, and D of ZnO were prepared under different initial conditions (temperature and pressure).

ZnO: *Sample A*: Prepared by the thermal decomposition of c.p. $ZnCO_3$ in an electric furnace at 350°C in air for 1 hr.

After being cooled to room temperature, it was etched with $(NH_4)_2S_2O_8$ and dilute HNO_3, washed in distilled water and then dried in a vacuum desiccator.

Sample B: Prepared by the same method as for Sample A except for the decomposition temperature being 500°C, kept in a vacuum desiccator until used in experiment.

Sample C: Prepared by the same method as for Sample A except for the decomposition temperature being 650°C.

Sample D: Prepared by the same method as for Sample C except for the pressure of 10^{-3} mmHg.

Sample of ZnO prepared by the above methods were verified by X-ray diffraction. The yellow color was found to deepen in the order A<B<C<D.

The degree of nonstoichiometry (Zn excess) in Samples A, B, C, and D increased in the order A<B<C<D.[13]

Carbon Monoxide: The apparatus used for preparation of the CO gas is shown in Fig. 1.

Carbon monoxide was prepared by the reaction of formic acid with concentrated sulfuric acid. The reaction was carried out by passing formic acid through concentrated sulfuric acid in an evacuated Pyrex flask connected to a vacuum system. CO was purified with glass wool, KOH, $CaCl_2$, and P_2O_5, and stored in a container, which had been

evacuated to 10^{-5} mmHg.

Oxygen: The apparatus used for preparation of O_2 gas is shown in Fig. 1.

Oxygen obtained by heating potassium chlorate at about 600°C[14] was purified by passing over glass wool, P_2O_5 and $CaCl_2$. This was found to give a oxygen sufficiently free of catalytic poisons when used in catalytic reactions. The purity of the CO and O_2 gases was confirmed by gas chromatography.

Experimental Procedure. A half gram of ZnO (200 mesh) was distributed uniformly in the reaction chamber. After the pressure was reduced to 10^{-3}mmHg at room temperature, oxygen and carbon monoxide were added in a ratio of 70:140 (mmHg). The chamber was then placed in the electric furnace maintained at a constant temperature.

The change in pressure due to the progress of the reaction was monitored by a manometer connected to the reaction chamber at regular time intervals. To check separately the influence on this reaction of P_{O_2} and P_{CO} which are almost interdependent, the ratio of P_{O_2} and P_{CO} was varied, 70:70, 70:210, and 140:140 (mmHg), and the reaction rate measured in the same manner.

The resulting gas was confirmed to be carbon dioxide by gas chromatography after the reaction.

Results

The results from the reactions with Samples A, B, C, and D as catalysts at 260°C, 290°C, 320°C, and 350°C, respectively are given in Figs. 2—7.

The order of reaction is 1.5 for Samples A, B, C, and D at 260—320°C giving $dP_{CO_2}/dt=kP_{CO}P_{O_2}^{1/2}$. At 350°C, the Roginsky-Zeldovitsch equation,[1] $dP_{CO_2}/dt=ke^{-ap}$ (a; parameter, p; the amount of conversion, k; rate constant) holds; $\log(t+t_0)=ap-\log ka$ (Fig. 6). The rate constants from Figs. 2—6 are given in Tables 1 and 2. The activation energies calculated from Figs. 2—5 and Tables 1 and 2 are 16.04, 15.97, 14.86, and 13.69 kcal/mol, respectively. To check the influence of P_{O_2} and P_{CO} on these reactions separately, the ratio of P_{O_2} and P_{CO} was varied; 70:210, 70:140, 70:70, 140:70, and 140: 140 (mmHg) at 260°C on Sample C. The results can be seen in Fig. 6 and the rate constants in Table 2.

Discussion

The rate equations on Samples A, B, C, and D can be classified into two types; one between 260 and 320°C and the other at 350°C. The 260 to 320°C readings do not agree with those of Ambigues and Teichner,[8] who showed that the rate is proportional to the square root of the oxygen pressure and independent of CO pressure, nor with those of Chizhikova,[9] who proposed that the kinetics of the oxidation of CO over pure ZnO is given by the equation $-dP_{CO}/dt=kP_{CO}^{0.5}$ and that over Li- and In-doped ZnO by the equation $-dP_{CO}/dt=kP_{CO}^{0.7}$. However, there is an agreement with the results

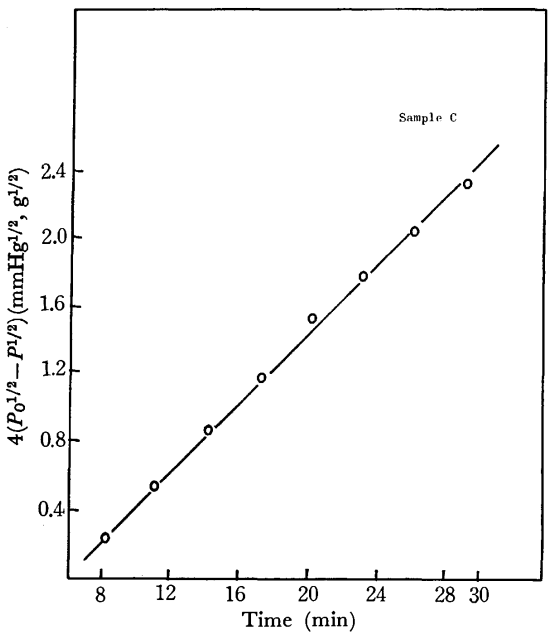

Fig. 7. The determination of the order of oxygen pressure in this kinetic equation at 260°C; P_{O_2}:P_{CO}=20:255; $dP_{CO_2}/dt=KP_{O_2}^{1/2}$

TABLE 2. k VALUES AS A FUNCTION OF P_{CO} AND P_{O_2} AT 260°C ON SAMPLE C

P_{O_2}	P_{CO}	k(mmHg$^{-1/2}$ g$^{1/2}$min^{-1})
70	210	2.24×10^{-4}
70	140	1.62×10^{-4}
70	70	0.52×10^{-4}
140	70	0.30×10^{-4}
140	140	0.96×10^{-4}

The 350°C reading does not correspond to any of the above research. We see from Fig. 3 that the catalytic activity of the ZnO Samples is in the order A<B<C <D. Thus the effect can be explained by the increase of *n*-type characteristic. Oxygen deficiency in ZnO can be due to the excess Zn dissolved in the interstitial sites of ZnO[15-19] when $ZnCO_3$ is decomposed thermally. The catalytic activity of ZnO dependent on the amount of excess Zn (or the amount of oxygen deficiency). The mechanism of the CO oxidation reaction is explained as follows; at first oxygen accepts electrons from the activated ZnO surface to be adsorbed on the active sites, O^-(ads) being thus formed.

$$\frac{1}{2}O_2(g) + e = O^-(ads)$$

Carbon monoxide reacts then with the O^-(ads) forming CO_2(ads). Carbon dioxide is then desorbed from the ZnO surface. This corresponds to Ambigues and Teichner's conclusions[8] that oxygen gas is adsorbed weakly while carbon monoxide gas is strongly adsorbed on the ZnO surface and carbon monoxide gas reacts on the O^-(ads) to form CO_2(g), *viz.*

$$\frac{1}{2}O_2(g) + e^- = O^-(ads)$$

$$O^-(ads) + CO(g) = CO_2(ads) + e^-$$

$$CO_2(ads) = CO_2(g)$$

where (g) is an abbreviation for the gas state and (ads) the adsorbed state. The mechanism is explained by means of the Rideal mechanism. For the same catalyst the reaction rate at high temperature is greater than that at a low temperature. At the same temperature the reaction rate for the catalyst prepared at high temperature is greater than that for the catalyst prepared at a lower temperature. The reaction rate for the case in which the catalyst prepared in a vacuum (the same temperature condition) is used is greater than that for the catalyst prepared in air (Table 1). At 260°C for Sample C the reaction rate is small when P_{O_2} is greater than P_{CO} and great when P_{O_2} is smaller than P_{CO} (Table 2). The results correspond to the deductions from the conductivity data obtained by Ambigues and Teichner[8] and also the degree of nonstoichiometry of ZnO (Zn excess). They correspond also to the result by Teichner. The conductivity at $P_{O_2}=3$ mmHg was greater than that at $P_{O_2}=160$ mmHg. After evacuation to 10^{-5} mmHg again, the conductivity at the initial oxygen pressure of $P_{O_2}=3$ mmHg became greater than that at $P_{O_2}=160$ mmHg.

	P_{O_2}	
log σ	3(mmHg)	160(mmHg)
log σ	$\bar{6}.80$	$\bar{7}.1$
log σ_0	$\bar{3}.50$	$\bar{4}.50$

Cited from *Discuss. Faraday Soc.*, **41**, 362 (1966).

These results show that if the oxygen pressure is increased, the amount of irreversibly adsorbed oxygen is increased, and if the oxygen pressure is decreased, the amount of irreversibly adsorbed oxygen is decreased. The mechanism for the CO oxidation reaction proposed here with is in line with the findings of Otsuka *et al.*[11] in that the adsorbed carbon monoxide did not influence this reaction either. The catalytic effect of ZnO depends on the sintering temperature and pressure, and the amount of excess Zn (or the amount of deficient oxygen) has an important effect on these reaction rates.

Studies of the Molybdenum Catalysts. Part I. Changes in the State of the Hydrated Molybdenum Oxide Catalyst during a Reaction between Thiophene and Hydrogen

Noriyuki SOTANI and Masatomo HASEGAWA

College of Liberal Arts, Kobe University, Tsurukabuto, Nada, Kobe, 657

(Received March 31, 1972)

The reaction between thiophene and hydrogen on hydrated molybdenum oxide was studied. Structural and compositional changes in the catalyst were found during the hydrodesulfurization of thiophene. The main products of the reaction were *n*-butane, butenes, and hydrogen sulfide. The conversion of thiophene increased with the progress of the reaction and reached a steady value after passing through a maximum. This reaction process was distinguished into two stages. One is the "aging stage," and the other is the "stationary stage." At the aging stage, three reactions, that is: i) dehydration, ii) reduction, and iii) sulfurization occur. The catalyst reacts with the reactants and changes in structure and composition. Hydrated molybdenum oxide was converted to MoO_3 by liberating the structural water, and MoO_3 was reduced to MoO_2. A part of the MoO_3 was also sulfurized directly with thiophene to MoS_2 during the aging stage, but MoO_2 could not easily be sulfurized. At the stationary stage, no further change in the catalyst was found, and only the catalytic hydrodesulfurization of thiophene occurred. The conversion at the stationary stage, when the aging temperature was low, was larger than the conversion at a high temperature. The difference between the conversions at different reaction temperatures was assumed to result from the structural and compositional changes in the catalyst caused by the different temperatures of the aging processes. In this reaction, the dehydration at the aging stage controls the activity of the catalyst.

The mechanism of the hydrodesulfurization of thiophene has been studied by a number of workers, and the findings up to 1957 have been reviewed by McKinley.[1] Recently, because of the industrial importance of the desulfurization of petroleum, very many workers have studied the hydrodesulfurization of thiophene on cobalt molybdate supported on alumina[2-4] as a model reaction for the desulfurization of petroleum, and several mechanisms have been proposed for the reaction.

In most of these works, catalysts have been activated and stabilized by pretreatment with hydrogen,[5] hydrogen sulfide,[3] or thiophene[2] before the kinetic measurements. However, only a little attention has been given to the structural changes in the catalyst during the reaction and to the relation between such structural changes and the activities.[4]

The purpose of this work is to obtain basic information about such structural and compositional chagnes in the hydrated molybdenum oxide catalyst during the hydrodesulfurization of thiophene and the relation between such changes and the activity of the catalyst.

As a catalyst, we used hydrated molybdenum oxide powder, without any promoter and supporter, in order to avoid the complexity introduced by the addition of these substances.

In this investigation, the structural and compositional changes in hydrated molybdenum oxide during the hydrodesulfurization of thiophene were investigated by means of chemical, X-ray diffraction, and thermal analyses. We also tried to learn how the structural and compositional changes influence the activity of the catalyst.

Experimental

A usual flow method was used for the reaction. The reactants and products were analyzed by means of gas chromatograph directly connected to the flow line. Hydrogen purified by passing through the platinum catalyst and molecular sieves flowed at a rate accurately controlled to 0.1 mol/hr by means of a needle valve and an auxiliary regulator. The flow rate was measured by means of a rotor meter and a soap film meter. Thiophene was fed as a liquid to the evaporator by means of a calibrated hypodermic pump. The feed rate of the thiophene, 1.4×10^{-2} mol/hr, was so small compared with that of hydrogen that the partial pressure had no effect on the reaction. A small amount of benzene, 1×10^{-3} mol/hr, was used as a marker, because benzene did not decompose under the reaction conditions.

Catalyst. (A) Hydrated molybdenum trioxide, $MoO_3\cdot nH_2O$, was precipitated from a solution of ammonium molybdate by the addition of HNO_3. The precipitate was dried at 110°C for a day and was then calcined in air at 200°C for 6 hr. By differential thermal analysis (DTA) and thermogravimetric analysis (TGA), this oxide was found to be a hydrate of molybdenum trioxide. The water included in this oxide was kept at 400°C. This water was assumed to be a structural water. When this hydrated molybdenum oxide was left standing in a desicator, it absorbed about 0.26 mol of water, which was easily removed by heating at 200°C. This was physically-absorbed water.

(B) Anhydrous molybdenum trioxide, MoO_3, was prepared from hydrated molybdenum oxide by calcination in air at 600°C for 6 hr.

(C) Anhydrous molybdenum dioxide, MoO_2 was formed by reducing hydrated molybdenum oxide with hydrogen at 450°C for 5 hr.

(D) Molybdenum disulfide, MoS_2, was purchased from Wako Chemical Industries.

The analysis of the sulfur content of the catalyst after the reaction was done gravimetrically by the $BaSO_4$ methods.[6]

Results

Conversion of Thiophene. Hydrated molybdenum oxide (1 gram) was used as the catalyst. To begin with, the catalyst was heated at a reaction temperature, of 350, 375, or 400°C. Then the reactants were introduced over the catalyst.

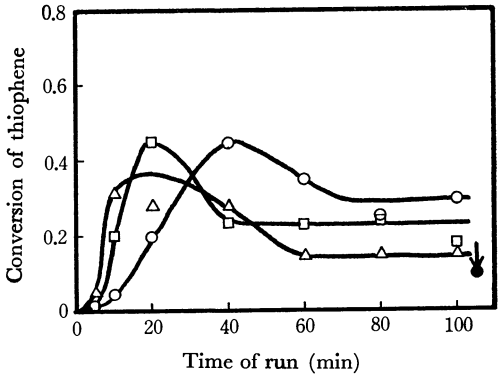

Fig. 1. The conversion of thiophene.
○: 350°C, □: 375°C, △: 400°C, ●: 350°C after 400°C

The conversion of thiophene, expressed in the ratio of the concentration decrease to the initial concentration, is shown in Fig. 1. The conversions at all the reaction temperatures have very similar curves with the reaction time. The conversion increased gradually and reached a steady value after reaching a maximum. We term the period when the conversion reached a steady value after the maximum, the "aging stage," and the period after the conversion reached the steady value, the "stationary stage."

The main products were *n*-butane, 1-butene, *cis*-2-butene, *trans*-2-butene, and hydrogen sulfide. Mercaptane, *tetra*-hydrothiophene and butadiene were not found, though they had been reported in previous works.[2,3] The products are also shown in Fig. 2a. The concentration of *n*-butane in the products was relatively large and reached a maximum when the conversion showed its maximum, at the aging stage. The ratio of C_4 products, calculated from the concentration of *cis*-2-butene as a standard, is shown in Fig. 2b. Only the ratio of *n*-butane shows its maximum at the aging stage, that of the butene shows a steady value. Hydrogen sulfide was not detected during the "aging stage." This suggests that most of the sulfur removed from thiophene by the reaction was consumed in the sulfurization of the catalyst. This shows that the reaction at the aging stage between thiophene and the catalyst is important in producing *n*-butane and molybdenum sulfide.

Reaction during the "Aging Stage." (1) Sulfurization of the Catalyst: sulfur content of the catalyst, determined by chemical analysis, is shown in Fig. 3 against the reaction time. This clearly shows that the catalyst was sulfurized by thiophene or by the hydrogen

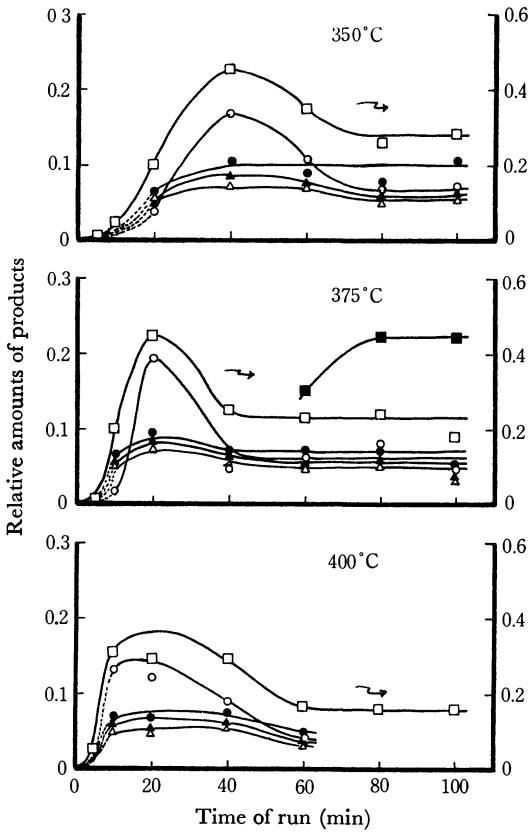

Fig. 2a. Reaction products.

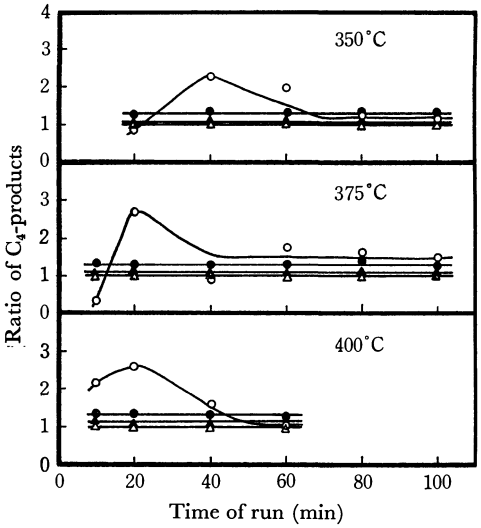

Fig. 2b. The ratio of reaction products.

sulfide produced by the hydrodesulfurization of thiophene. The sulfurization proceeded during the aging process and stopped when the aging process was over. Only the hydrodesulfurization of thiophene occurred at the stationary stage. The sulfur content of the catalyst at the stationary stage was large when the aging temperature was low. It is interesting that the catalyst is sulfurized more in the bulk when the temperature is low.

(2) Reduction of the Catalyst: besides the sulfuriza-

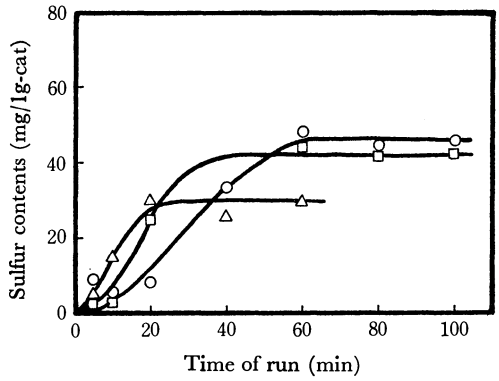

Fig. 3. Sulfur content of the catalyst.
○: 350°C, □: 375°C, △: 400°C

tion, the catalyst was reduced to MoO_2 during the aging stage. During the aging stage, the catalyst was transformed from $MoO_3 \cdot nH_2O$ to MoO_3 and then to MoO_2, as determined by the X-ray diffraction studies. The catalyst was found to be a mixture of these compounds in the course of the aging process. At the stationary stage, therefore, the catalyst was composed of MoO_2 and molybdenum sulfide.

Conversion during the "Stationary Stage." The lower the aging temperature, the larger the stationary value of the conversion at the stationary stage. The value of the conversion after the aging stage at 350°C was 0.3, about twice the value at 400°C.

The conversion was observed after the aging process at 400°C. The reaction temperature was subsequently lowered to 350°C, and then the conversion was determined. The conversion had decreased from 0.15 to 0.10, as is shown in Fig. 1 (the arrowed black point). We also observed the conversion at different reaction temperatures in order to obtain the temperature coefficient after the aging process at 350°C. The apparent activation energies calculated from these values were 3.2—4.4 kcal/mol. Therefore, the high stationary value of the conversion at a low temperature may be considered to be caused by chemical changes in the catalyst at the aging stage. Aging at low temperatures is more useful in obtaining a high activity for the hydrated molybdenum oxide catalyst.

Reactions on Other Samples. As has been described above, the catalyst in the course of the reaction consisted of a mixture of $MoO_3 \cdot nH_2O$, MoO_3, MoO_2, and MoS_2 at any reaction time and at any reaction temperature. Therefore, we also studied the conversion of thiophene, using each of these components as a catalyst. The results are shown in Fig. 4. In the case of MoO_3, the conversion changed in a manner similar to that in the case of $MoO_3 \cdot nH_2O$, but the stationary value of the conversion was somewhat smaller. In the case of MoO_2, the conversion was nearly constant throughout the reaction. On MoS_2, the conversion was not reproducible, so it was difficult to compare it with the conversion on other compounds. However, on MoS_2, the conversion was always high at first, rapidly decreased with the reaction time, and then reached a stationary value. We also studied partially-reduced MoO_3 at 350°C for 3 hr prior to the reaction. The conversion was very high at first, decreased, and then reached a stationary value.

Discussion

As has been described above, the hydrated molybdenum oxide catalyst reacts with reactants at an early stage of the hydrodesulfurization of thiophene. The changes in the structure and composition caused by the reaction influence the final activity of the catalyst. That is, the aging temperatures dominate the activities of the hydrated molybdenum oxide catalyst.

Change in the Surface Area. The differences in the activities may be explained by the changes in the surface area of the catalyst. The BET surface area of hydrated molybdenum oxide before use was 3.4 m^2/g. The area increased to 8.6 m^2/g when the catalyst was used for 100 min at 350°C and to 8.0 m^2/g at 400°C. Thus, the difference in the surface area between the two reaction temperatures is not so large that we can not explain the difference in the conversion. That is, the activity does not depend on the surface area. Therefore, it is reasonable to conclude that the difference in the activity is attributable to the structural and compositional changes in the catalyst caused during the aging process.

Process of Structural Changes in the Catalyst. During the aging stage, three reactions occurred on the catalyst: i) dehydration, ii) reduction, and iii) sulfurization.

i) Dehydration: The catalyst removed the structural water during the aging process. The presence of the structural water seems to affect the reduction and the sulfurization. The process of the dehydration will be reported on in detail later.

ii) Reduction: The hydrated oxide was reduced to MoO_2 through an intermediate mixture of MoO_3 and MoO_2. At the stationary stage, a large portion of the catalyst consisted of MoO_2 at either reaction temperature.

iii) Sulfurization: At the same time, a small portion of the dehydrated MoO_3 was sulfurized. On the other hand, MoO_2 was not sulfurized easily.

To summarize the processes discussed above, we may conclude that the catalyst changes during the aging process as follows;

$$MoO_3 \cdot nH_2O \longrightarrow MoO_3 \begin{cases} \nearrow MoO_2 \\ \searrow MoS_2 \end{cases}$$

The catalyst is mainly composed of MoO_2 and MoS_2 at the stationary stage. The aging temperature has effects on the relative rate of the reduction and the sulfurization of MoO_3. In other words, the dehydration plays an important role in determining the rates of the reduction and the sulfurization.

Mechanism of the Sulfurization. The catalyst is considered to be sulfurized by two possible processes. One is direct sulfurization by thiophene (I). The other is sulfurized by hydrogen sulfide produced by the hydrodesulfurization of thiophene (II). That is:

(I) $MoO_3(MoO_2) + C_4H_4S + H_2 \longrightarrow MoS_2 + C_4\text{-Products} + H_2O$

(II) a) $C_4H_4S + H_2 \xrightarrow{\text{Catalyst}} H_2S + C_4\text{-Products}$

b) $H_2S + MoO_3(MoO_2) \longrightarrow MoS_2 + H_2O$

Biltz and Kochen proposed that MoS_3 is labilized at a high temperature.[7] Nanba and Aonuma[8] reported that the final state of molybdenum sulfide is MoS_2 in the hydrodesulfurization of thiophene. By a hydrogenation reaction, MoS_3 is easily reduced at a high temperature; $MoS_3+H_2 \rightleftharpoons MoS_2+H_2O$.[9] It is reasonable to suppose that MoS_2 is formed under these reaction conditions, even though the formation of MoS_2 has not been confirmed by X-ray diffraction analysis. It can be assumed that MoS_2 does not have a perfect hexagonal crystal structure, but an amorphous mosaic-like structure.

As is shown in Figs. 1 and 3, the sulfurization of the catalyst stops and only the (IIa) reaction proceeds at the stationary stage. During the aging stage, the sulfurization by two processes (I) and (IIb), is possible. However, for the following reasons, the (I) process may be concluded to be the main reaction process.

(1) When hydrated molybdenum oxide was sulfurized for 60 min at 350°C by a mixture of H_2+H_2S, there was only a trace of sulfur content of the catalyst. The catalyst was partially reduced to MoO_2, but a large portion of the hydrated molybdenum oxide was maintained unchanged. This shows that the sulfurization by thiophene (I) is easier than that by hydrogen sulfide (IIb). This is inconsistent with the results of Tarama *et al.*[10] on vanadium molybdate. They reported that molybdenum in vanadium molybdate supported on alumina was more easily sulfurized by hydrogen sulfide than by thiophene.

(2) Figure 2b shows the ratio of C_4 products. Only the ratio of *n*-butane shows a maximum, that of butenes shows a constant value from the beginning. This suggests that, at the aging stage, the (I) process occurs much more than the (IIa) process. The sulfurization by the I process occurs more than that by the (IIb) process.

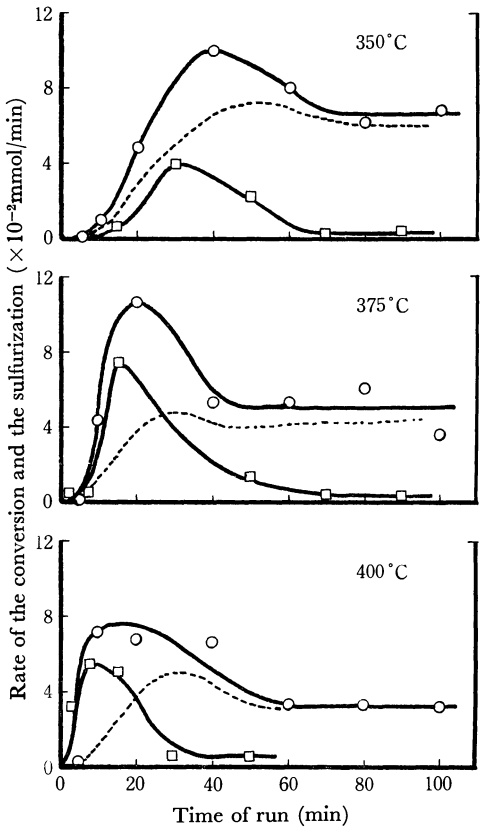

Fig. 5. The rate of the conversion of thiophene and the sulfurization of the catalyst.
○: conversion, □: sulfurization

(3) Figure 5 shows the rate of the sulfurization calculated from the sulfur analysis in Fig. 3 and the rate of the conversion of thiophene. A comparison of the two curves gives interesting information about the aging process. The rate of the conversion represents the rate of the total consumption of thiophene (I+IIa), which corresponds to the sum of the rate of the sulfurization of the catalyst (I+IIb) and the hydrodesulfurization (IIa). From these two reasons (I) and (2), the (IIb) process can be neglected more safely than the (I) process. Therefore, the difference between the rate of the conversion and the rate of the sulfurization represents the rate of hydrodesulfurization (IIa). The peaks of both curves agree at the aging stage. The dotted line in Fig. 5, which is the difference between the rate of the conversion and that of the sulfurization, shows the rate of net hydrodesulfurization (IIa). As it is relatively difficult for the (IIb) process to occur ,this suggests that the maximum of the conversion results from the overlapping of the sulfurization (I) with the hydrodesulfurization reaction (IIa).

When anhydrous MoO_2 was used as a catalyst, the sulfur content was 1.3 wt% after a reaction for 100 min at 350°C. This shows that MoO_2 is not easily sulfurized. On the other hand, the sulfur content of anhydrous MoO_3 after a reaction for 100 min at 350°C was 9.0 wt%. The conversion of neither anhydrous MoO_3 nor MoO_2 was very high compared with that

of hydrated molybdenum oxide at the stationary stage. Richardson[11] has reported that MoO_2 itself has a mild activity in the hydrodesulfurization of thiophene.

From the results presented above, it may be concluded that the dehydration at the aging stage controls the rates of the reduction and the sulfurization and, consequently, influences the activity of the catalyst.

The Primary Process of the Photochemical Dimerization of Carbostyril (2-Quinolone) in an Aqueous Solution

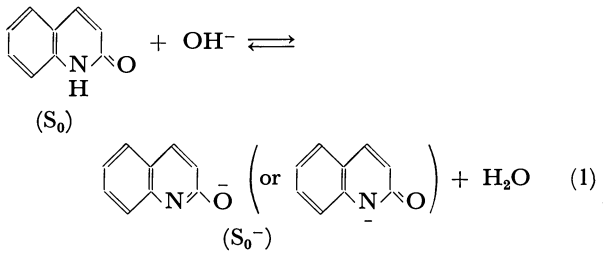
Tetsu YAMAMURO, Norisuke HATA,* and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo
**Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo*

(Received March 16, 1972)

Carbostyril dimerizes photochemically in an aqueous solution, in order to investigate the effect of a hydroxide ion on the primary process of the photochemical dimerization in an aqueous solution, both measurements of the quantum yields and flash spectroscopic experiments were carried out under various conditions. The experiments revealed that the photodimerization reaction proceeded through a bimolecular interaction between the triplet and the unexcited carbostyril molecules, although the triplet carbostyrilate ion was in equilibrium with the triplet carbostyril. The triplet carbostyrilate ion was proved not to be involved in the dimerization process.

As has been described in a previous paper,[1] the photochemical dimerization of carbostyril in deaerated ethanol proceeds through a bimolecular interaction of the triplet carbostyril with the unexcited one. Such a photodimerization has also been reported to take place in an aqueous solution.[2] Meanwhile, the acid-base equilibrium between the carbostyril (S_0) and the carbostyrilate ion (S_0^-) in their ground states has been shown spectrophotometrically in alkaline aqueous solutions as follows:[3]



(S_0) (S_0^-) (1)

Therefore, in order to elucidate the primary process of the photochemical dimerization of carbostyril in such an alkaline solution, the present authors carried out investigations by means of measurements of the quantum yields and by means of flash spectroscopy.

Experimental

The carbostyril used in the experiment was prepared by treating quinoline *N*-oxide with tosyl chloride.[4] The product was purified by recrystallization from methanol several times. Standard specified solutions of sodium hydroxide (Yoneyama Yakuhin Co., Ltd.) were used as the solvents.

The light source employed in the steady-light experiments was a Toshiba high-pressure mercury lamp (H-400 P), while for the 313 nm irradiation a filter combination of a nickel sulfate solution with a UV-31 Toshiba filter was used. The measurements of the quantum yields were carried out by a procedure described previously.[1]

The flash photolysis apparatus was the same as was employed in the previous investigations.[1] The xenon flash lamp used for excitation was operated by discharging a bank of condensers of 1 μF charged to 14.75 kV, 109 joules of energy being dissipated; the duration time of the flash was 5 μsec.

Since the quantum yield of the disappearance of carbostyril was reduced to almost zero in the presence of oxygen in a solution, just as in the case of the ethanol solution,[1] all the experiments—both steady-light and flash spectroscopic—were performed on solutions deaerated by flushing nitrogen at room temperature.

Results

Figure 1 shows the absorption spectra of carbostyril in aqueous solutions containing different amounts of

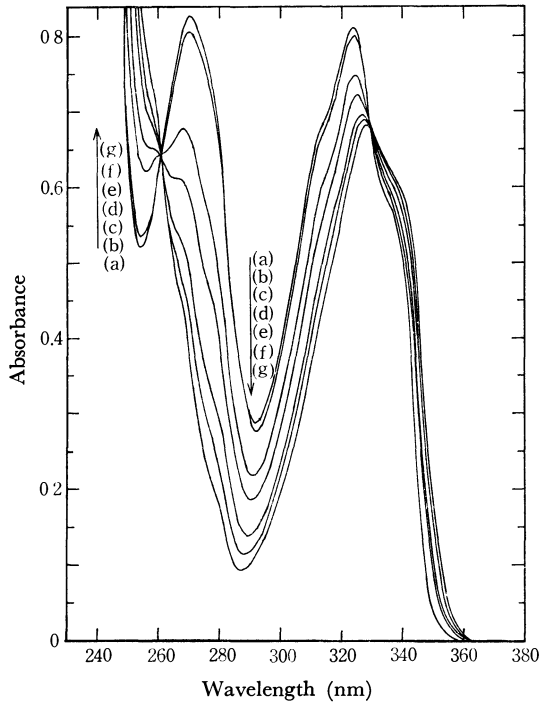

Fig. 1. Absorption spectra of carbostyril in aqueous solution containing different amounts of sodium hydroxide at room temperature (C: 1.23×10^{-4}M).
[OH$^-$]: (a) 0M, (b) 0.001M, (c) 0.01M, (d) 0.02M, (e) 0.05M, (f) 0.10M, (g) 1.0M

sodium hydroxide, where the isosbestic points were observed at 260.5 and 329.5 nm; that is, an acid-base equilibrium was indicated to exist between the carbostyril (S_0) and the carbostyrilate ion (S_0^-), as is represented by Eq. (1). In the present experiments, therefore, the concentrations of S_0 and S_0^- at equilibrium were evaluated by the following equations, respectively:

$$[S_0] = C/(1+K_G[OH^-])$$
$$[S_0^-] = CK_G[OH^-]/(1+K_G[OH^-]) \quad (2)$$

where K_G represents the equilibrium constant, and C, the sum of $[S_0]$ and $[S_0^-]$. The equilibrium constant (K_G) was calculated by means of Eq. (3), where ε_λ or ε'_λ is the molar extinction coefficient of S_0 or S_0^- at the λ wavelength and where D_λ is the absorbance of a solution containing S_0 and S_0^-. Thus, the slope of the straight-line obtained by:

$$\frac{(\varepsilon_\lambda-\varepsilon_\lambda')C}{D_\lambda-\varepsilon_\lambda'C} = 1 + K_G[OH^-] \quad (3)$$

plotting $(\varepsilon_\lambda-\varepsilon'_\lambda)C/(D_\lambda-\varepsilon'_\lambda C)$ against $[OH^-]$, gave the value of K_G as 62.3M^{-1}.

Steady-light Experiments. The quantum yields (Φ) of the carbostyril disappearance were determined as a function of the concentration of a hydroxide ion in an aqueous solution ($C=1.23\times10^{-4}$M) at room temperature. Figure 2 shows the results thus obtained where the plot of Φ against $[OH^-]$ was replaced by that of Φ *vs.* $[S_0]$. As may be seen from Fig. 2, the quantum yield increased very rapidly with an increase in the concentration of S_0 expect at very low concentrations of S_0, but at higher concentrations the quantum yield

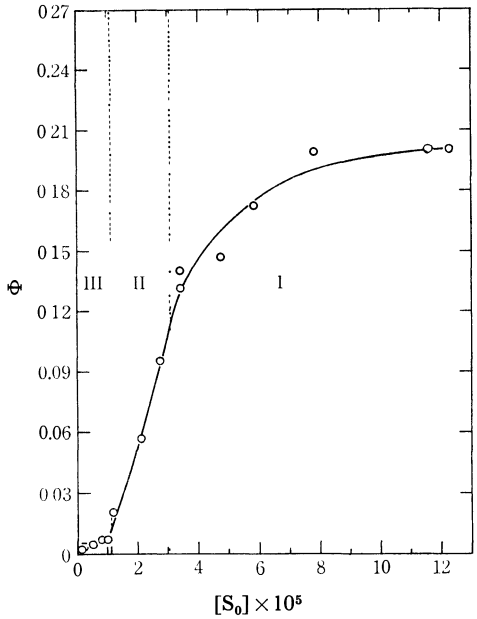

Fig. 2. Quantum yield of carbostyril disappearance *vs.* $[S_0]$ in alkaline aqueous solution at room temperature ($C=1.23\times10^{-4}$M).

gradually approached about 0.2. Because of such a characteristic dependence of Φ on $[S_0]$, it is convenient for the subsequent discussion to divide the concentration range of S_0 into three regions, I, II, and III, as is indicated in Fig. 2. On the other hand, the quantum yield in water was 0.21, regardless of the concentration of S_0 ($\approx C$).

Flash Spectroscopic Experiments. Figure 3 shows the T–T absorption of carbostyril in aqueous solutions con-

△: in 0.5M NaOH aqueous solution (C: 1.13×10^{-4}M)
□: in 1.0M NaOH aqueous solution (C: 1.13×10^{-4}M)
●: in 70% ethanol aqueous solution (C: 0.30×10^{-4}M)

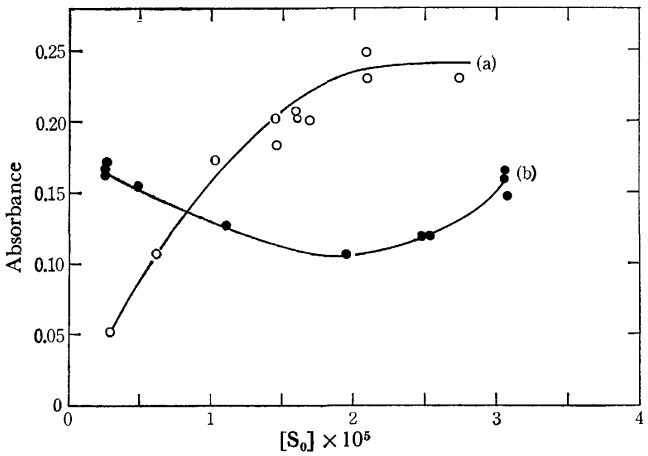

Fig. 4. Absorbance of transient absorption at 450 nm *vs.* $[S_0]$ at room temperature.
(a), ○: in water
(b), ●: in NaOH solution (C: 1.0×10^{-4}M)

taining different amounts of sodium hydroxide, and also in a 70% ethanol aqueous solution at room temperature. As can be seen from Fig. 3, the transient absorption was altered significantly when the solvent was changed from water to alkaline solutions. Figure 4 shows the plot of the absorbance of the transient absorption at 450 nm against $[S_0]$ in water (a) or a NaOH solution (b). It is clear from these figures that the transients observed in alkaline solutions consist of two kinds of species, the carbostyril (T_1) around 420—470 nm and the carbostyrilate ion (T_1^-) at about 440—490 nm, in their lowest triplet states. In addition, the transient absorption was confirmed to decay by means of first-order kinetics.

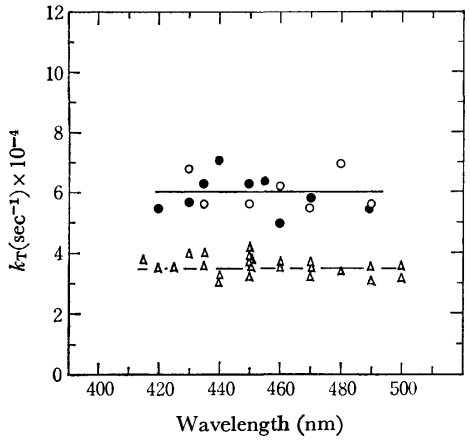

Fig. 5. Decay rate constant (k_T) of transient at various wavelengths at room temperature.
●: in water (C: 0.16×10^{-4}M)
○: in 0.1M NaOH aqueous solution (C: 1.08×10^{-4}M)
△: in 1.0M NaOH aqueous solution (C: 1.13×10^{-4}M)

Figure 5 shows first-order decay rate constants (k_T) determined at different wavelengths; the data indicate that the decay constant of the triplet carbostyril is nearly equal to that of the triplet carbostyrilate ion.

Next, the effect of the concentration of a hydroxide ion on the decay constant of the transients at 450 nm was examined at room temperature (Fig. 6). The (a)

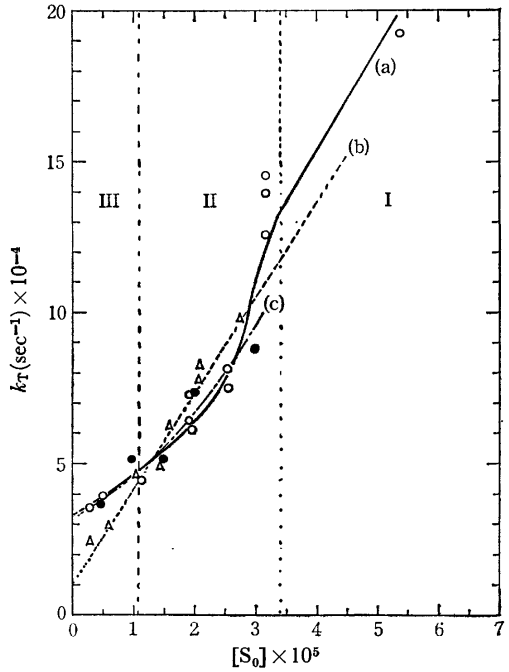

Fig. 6. Decay rate constant (k_T) of transients at 450 nm *vs.* $[S_0]$ at room temperature.
curve (a), ○: in alkaline aqueous solution (C: 1.13×10^{-4}M)
curve (b), △: in water
curve (c), ●: in alkaline aqueous solution ($[S_0^-]$: 1.0×10^{-4}M)

curve in Fig. 6 shows the plot of k_T against $[S_0]$ in the place of $[OH^-]$. The (b) curve illustrates the plot of k_T *vs.* $[S_0]$ in water, while the (c) curve is the plot of k_T *vs.* $[S_0]$ when $[S_0^-]$ was kept to 1.0×10^{-4}M. The slope (3.18×10^9 $sec^{-1}M^{-1}$) of the (a) curve in Region I was in good agreement with that (3.12×10^9 $sec^{-1}M^{-1}$) of the (b) curve, whereas the (a) curve in Region III coincided in slope with the (c) curve. It is obvious from these results that the dependence of $[S_0]$ of k_T is quite similar to that of the quantum yield shown in Fig. 2.

The decay constants of the transients at 450 nm were also measured as a function of the concentration of S_0^-, while the concentration of S_0 was kept constant at 0.15×10^{-4}M (Fig. 7). As a result, it was found to remain constant at 5.5×10^4 sec^{-1}, regardless of the concentration of S_0^-. Therefore, it seems reasonable to

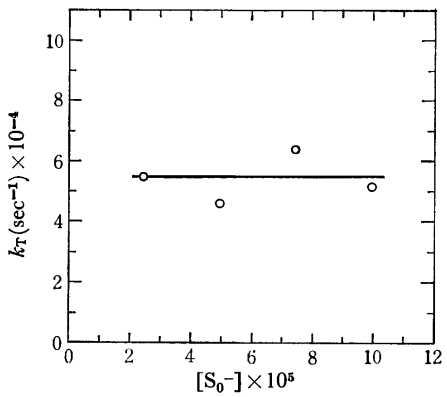

Fig. 7. Decay rate constant (k_T) of transients at 450 nm *vs.* $[S_0^-]$ in alkaline aqueous solution at room temperature ($[S_0]$: 0.15×10^{-4}M)

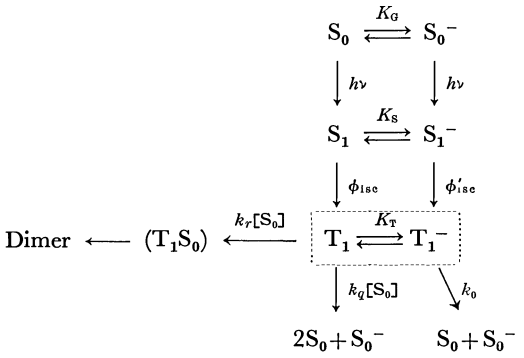
conclude that the decay rate constant is dependent on the concentration of only S_0, not S_0^-.

Discussion

The experimental results described in the preceding section suggest that the photochemical dimerization of carbostyril in an alkaline solution proceeds through a bimolecular interaction between the triplet and the ground-state carbostyrils, although the triplet carbostyrilate ion is considered to be in equilibrium with the triplet carbostyril. When we also assume an acid-base equilibrium between the carbostyril (S_1) and the carbostyrilate ion (S_1^-) in their excited singlet states, the following scheme, Scheme 1, can be generally postulated for the primary process of the photodimerization in an alkaline aqueous solution:



Scheme 1.

where K_G, K_S, and K_T represent the equilibrium constant in the ground, the excited singlet, and the lowest triplet states, and where ϕ_{isc} and ϕ'_{isc} are the efficiencies of the $S_1 \rightarrow T_1$ and, $S_1^- \rightarrow T_1^-$ intersystem crossing.[5]

Assuming photostationary state conditions, the quantum yield (Φ) of the carbostyril disappearance can be given by the following equation:

$$\Phi = \frac{k_r[S_0]}{k_T} \frac{\phi_{isc}+K_S[OH^-]\phi'_{isc}}{1+K_S[OH^-]} \quad (4)$$

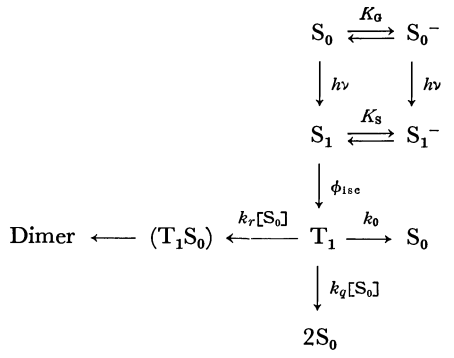
where: $$k_T = (k_r+k_q)[S_0] + k_0 \quad (4')$$

and where k_r represents the apparent rate constant for the formation of the transient complex (T_1S_0), and k_q and k_0, the apparent quenching rate constants by S_0 or the apparent first-order decay rate constant of the transient species ($T_1+T_1^-$). We can then obtain Eq. (5) by substituting $[OH^-]=[S_0^-]/K_G[S_0]$ into Eq. (4):

$$\Phi = \frac{k_r[S_0]}{k_T} \frac{K_G[S_0]\phi_{isc}+K_S[S_0^-]\phi'_{isc}}{K_G[S_0]+K_S[S_0^-]} \quad (5)$$

On the basis of Eq. (5), a subsequent discussion of the primary process of the photochemical dimerization of carbostyril in an alkaline solution will be made in the concentration ranges of S_0 and OH^-, each divided into three regions, I, II, and III, as has been described before.

Region I ($[S_0] \gtrsim 3.40\times10^{-5}$M or $[OH^-] \lesssim 0.052$M).
In view of the results shown in Fig. 6 that the slope of the (a) curve in Region I is substantially equal to that of the (b) curve, the transient absorption observed may be regarded as being due mostly to the triplet carbostyril; hence, the triplet carbostyrilate ion is assumed not to exist appreciably in this region (Scheme 2).



Scheme 2.

According to Scheme 2, Eq. (5) could be approximately expressed by Eq. (6).

$$\Phi = \frac{k_r[S_0]}{k_T} \frac{K_G[S_0]\phi_{isc}}{K_G[S_0]+K_S[S_0^-]} \quad (6)$$

On the other hand, k_r+k_q and k_0 were evaluated from the (b) curve in Fig. 6 to be 3.12×10^9 sec^{-1}M^{-1} and 1.12×10^4 sec^{-1} respectively, indicating that $(k_r+k_q)[S_0]/k_0$ is greater than 9.5. Consequently, Eq. (6) can be simplified to Eq. (7), if we assume that k_0 can be neglected compared with $(k_r+k_q)[S_0]$:

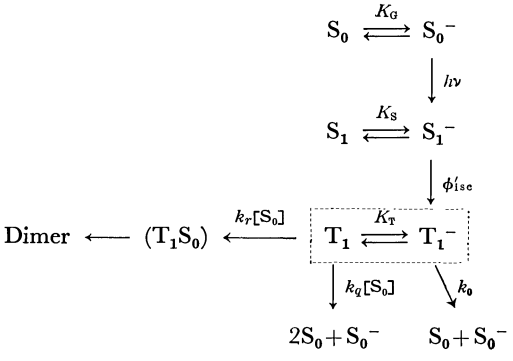
$$\Phi = \frac{k_r}{k_r+k_q} \frac{K_G[S_0]\phi_{isc}}{K_G[S_0]+K_S[S_0^-]} \quad (7)$$

By substituting for $[S_0^-]$ its equivalent, $C-[S_0]$, we obtain Eq. (8):

$$\frac{1}{\Phi} = \frac{1}{\phi_{isc}}\left(1+\frac{k_q}{k_r}\right)\left(\frac{K_SC}{K_G}\frac{1}{[S_0]}+\frac{K_G-K_S}{K_G}\right) \quad (8)$$

That is, $1/\Phi$ in Region I is expected to increase in proportion to $1/[S_0]$. It is shown in Fig. 8 that the plot of $1/\Phi$ against $1/[S_0]$ gives a straight-line relation; this is consistent with Eq. (8). From the slope (1.24×10^{-4}M) and the intercept (3.83) of the straight line, ϕ_{isc} and K_S were evaluated to be $0.21(1+k_q/k_r)$ and 13.0M^{-1} respectively.

Region III ($[S_0] \lesssim 1.11\times10^{-5}$ or $[OH^-] \gtrsim 0.23$M).
In Region III the concentration of carbostyril is extremely low compared with that of the carbostyrilate ion; thus, the latter is considered to be mainly concerned with a light absorption (Scheme 3).



Scheme 3.

5) Although there exists quenching from the excited singlet states (S_1, S_1^-) to the ground states (S_0, S_0^-), there are not written in Scheme 1.

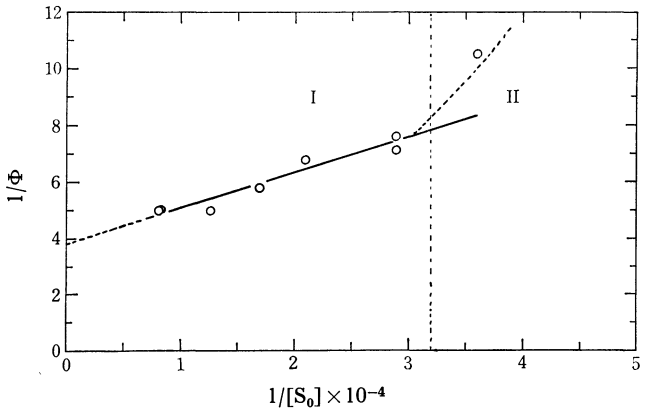


Fig. 8. $1/\Phi$ *vs.* $1/[S_0]$ in Regions I.

According to Scheme 3, Eq. (5) can be simplified as follows:

$$\frac{1}{\Phi} = \frac{1}{\phi'_{isc}}\left(1+\frac{k_q}{k_r}\right)\left\{\left(1+\frac{k_0}{k_r+k_q}\frac{1}{[S_0^-]}\frac{K_G}{K_S}+\frac{k_0}{k_r+k_q}\frac{1}{[S_0]}\right)+\frac{K_G[S_0]}{K_S[S_0^-]}\right\} \quad (9)$$

On the other hand, the values of k_r+k_q and k_0 were evaluated from the (a) curve in Fig. 6 to be 1.15×10^9 $sec^{-1}M^{-1}$ and 3.40×10^4 sec^{-1} respectively. In addition, the concentration of S_0^- in this region is around 11.8×10^{-5}M; hence:

$$1+\frac{k_0}{k_r+k_q}\frac{1}{[S_0^-]}\frac{K_G}{K_S}+\frac{k_0}{k_r+k_q}\frac{1}{[S_0]} \gtrsim 4.0$$

and $K_G[S_0]/K_S[S_0^-] \lesssim 0.48$; that is, $K_G[S_0]/K_S[S_0^-]$ is considered to be negligible compared with the other terms in Eq. (9). For this reason, we can further simplify Eqs. (9) to (10):

$$\frac{1}{\Phi} = \frac{1}{\phi'_{isc}}\left(1+\frac{k_q}{k_r}\right)\left(1+\frac{k_0}{k_r+k_q}\frac{1}{[S_0^-]}\frac{K_G}{K_S}+\frac{k_0}{k_r+k_q}\frac{1}{[S_0]}\right) \quad (10)$$

Accordingly, $1/\Phi$ in Region III is expected to vary linearly with $1/[S_0]$. In fact, it is shown in Fig. 9 that the plot of $1/\Phi$ against $1/[S_0]$ gives a linear relationship in accordance with Eq. (10); ϕ'_{isc} was estimated from the slope (9.91×10^{-4}M) of the straight line to be $3.0\times10^{-2}(1+k_q/k_r)$.

Region II ($1.11\times10^{-5}M \lesssim [S_0] \lesssim 3.40\times10^{-5}M$ or $0.23M \gtrsim [OH^-] \gtrsim 0.052M$). As can be seen from Fig. 6, both k_r+k_q and k_0 in Region II depend on the concentration of S_0. In Eq. (5) the ratio of $K_G[S_0]\phi_{isc}/(K_G[S_0]+K_S[S_0^-])$ to $K_S[S_0^-]\phi'_{isc}/(K_G[S_0]+K_S[S_0^-])$ corresponds to $[T_1]/[T_1^-]$, where T_1 and T_1^- are the triplet species produced by the intersystem crossing from S_1 and S_1^- respectively. Assuming that the triplet carbostyrilate ion is not quenched by S_0, k_q/k_r should be independent of $[S_0]$ and $[OH^-]$; thus, there could be $3.32 \lesssim [T_1]/[T_1^-] \lesssim 12.8$. Under these circumstances, the triplet carbostyrilate ion can be inferred to be mainly produced by the $S_1\rightarrow T_1\rightarrow T_1^-$ process, but not from S_1^- (Scheme 4).

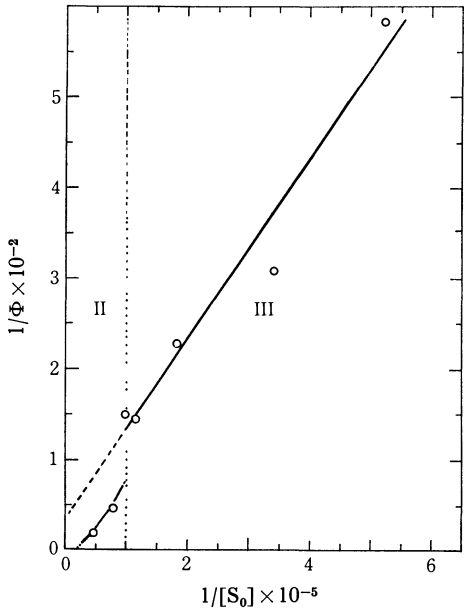

Fig. 9. $1/\Phi$ *vs.* $1/[S_0]$ in Region III.

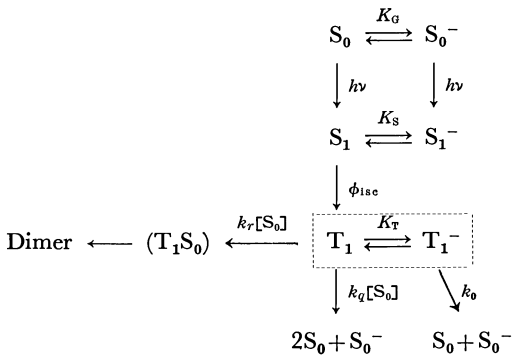

Scheme 4.

According to Scheme 4, Eq. (5) can be approximated as follows:

$$\frac{1}{\Phi} = \frac{1}{\phi_{isc}}\left(1+\frac{k_q}{k_r}\right)\left(\frac{k_0}{k_r+k_q}\frac{1}{[S_0]}+1\right)\times\left(\frac{K_S C}{K_G}\frac{1}{[S_0]}+\frac{K_G-K_S}{K_G}\right) \quad (11)$$

Figure 10 shows the plot of $1/\Phi$ against $1/[S_0]$, where a clear-cut straight-line relation was not observed in Region II as has been expected from Eq. (11). The decay rate (R) of the transient species ($T_1+T_1^-$) at equilibrium is given by the following equation:

$$R = \{(k_r+k_q)[S_0]+k_0\}[T_1+T_1^-]$$

Based on the fact that the photochemical dimerization proceeds through an interaction between T_1 (not T_1^-) and S_0, the decay rate (R) could also be given by the following relation:

$$R = (k_{ro}+k_{qo})[S_0][T_1] + k_0[T_1+T_1^-]$$

where k_{ro} and k_{qo} correspond to k_r and k_q respectively in water. Accordingly, Eq. (12) is obtained by a combination of the equations described above:

$$\frac{k_{ro}+k_{qo}}{k_r+k_q} = 1+\frac{[T_1^-]}{[T_1]} \quad (12)$$

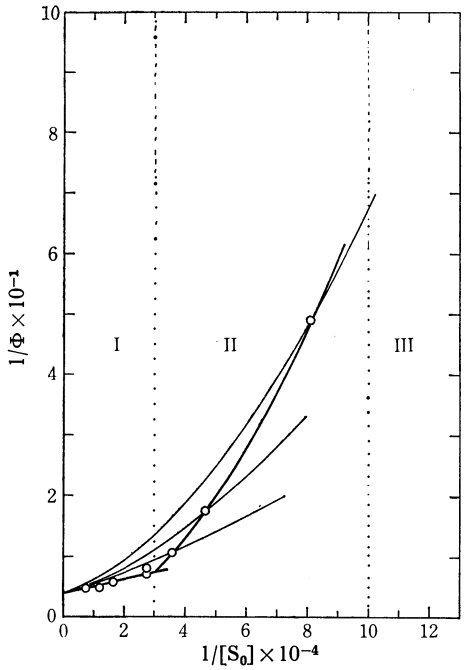

Fig. 10. $1/\Phi$ *vs.* $1/[S_0]$ in Regions I and II.

Since $[T_1^-]/[T_1]=K_T[OH^-]$, Eq. (12) can then be converted into Eq. (13).

$$\frac{k_{ro}+k_{qo}}{k_r+k_q} = 1 + K_T[OH^-] \qquad (13)$$

That is, if the assumptions that an acid-base equilibrium exists between the triplet carbostyril and the triplet carbostyrilate ion, and that the dimerization process involves only the triplet carbostyril, not the carbostyrilate ion, are reasonable, a linear relationship could be obtained between $(k_{ro}+k_{qo})/(k_r+k_q)$ and $[OH^-]$.

On the other hand, the values of $k_0/(k_r+k_q)$ at several concentrations of S_0, such as 2.77×10^{-5}M, 2.13×10^{-5}M, and 1.23×10^{-5}M, were calculated, by substituting the observed values of Φ (0.095, 0.057, and 0.021) respectively at these concentrations of S_0 into Eq. (11), to be 0.78×10^{-5}M, 1.79×10^{-5}M, and 3.21×10^{-5}M, respectively (Fig. 10). The value of $k_0/(k_r+k_q)$ in Region I or III was also estimated from the results in Fig. 6 to be 0.359×10^{-5}M or 2.96×10^{-5}M. From such estimations, $k_0/(k_r+k_q)$ in Region II was shown to exist between those in Regions I and III obtained from the flash experimental data; this is parallel to an increase in the concentration of the triplet carbostyrilate ion with a decrease in the S_0 value or an increase in the OH^- value.

The decay constant (k_T) of the transient species $(T_1+T_1^-)$ is derived from Eqs. (2) and (4') as follows:

$$k_T = (k_r+k_q)\left(\frac{C}{1+K_G[OH^-]}+\frac{k_0}{k_r+k_q}\right) \qquad (14)$$

Therefore, k_r+k_q and k_0 at various concentrations of OH^-, or S_0, were estimated by substituting the observed values of k_T into Eq. (14); the results are listed in Table 1. Both k_r+k_q and k_0 in Region II were observed to exist between the corresponding values in Regions I and III.

Table 1. Values of (k_r+k_q) and k_0 in Regions I, II, and III

Region	$[OH^-]$	$(k_r+k_q)\times10^{-9}$ ($sec^{-1}M^{-1}$)	$k_0\times10^{-4}$ ($sec^{-1}M^{-1}$)
I	0.0	3.12	1.12
	0.01	3.12	1.12
	0.02	3.12	1.12
	0.05	3.12	1.12
II	0.07	2.34	1.82
	0.1	1.68	3.01
	0.2	1.33	3.53
III	0.25	1.15	3.40
	0.3	1.15	3.40
	0.5	1.15	3.40
	1.0	1.15	3.40
	1.5	1.15	3.40

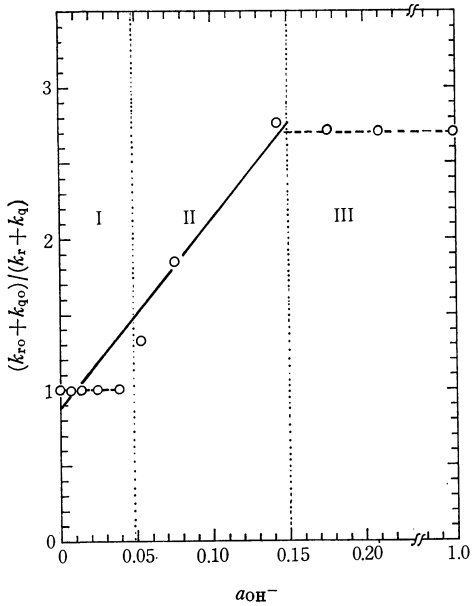

Fig. 11. $(k_{ro}+k_{qo})/(k_r+k_q)$ *vs.* a_{OH^-} in Regions I, II, and III.[6]

As can readily be seen from Fig. 11 using the values in Table 1, the plot between them gave a linear relationship, consistent with Eq. (13); the equilibrium constant (K_T) was then estimated from the slope to be $12.5M^{-1}$.

These facts also support the present idea about the primary process of photochemical dimerization in an alkaline aqueous solution.

The authors with to express their hearty thanks to Professor Yuji Mori of the Tokyo Institute of Technology for his kind discussion and to Professor Shiro Matsumoto of Aoyama Gakuin University for his permission to use the flash-photolysis apparatus.

6) The activities (a_{OH^-}) were estimated from the values of mean activity coefficients described in the following literatures; H. S. Harned and J. C. Heckel, *J. Amer. Chem. Soc.*, **55**, 4838 (1933) and G. Akerlof and G. Kegels, *ibid.*, **62**, 620 (1940).

Counterion Effect in the Electron-Transfer Reactions between a Tetracyanoethylene Radical Anion and Its Neutral Molecule

Masaaki OGASAWARA, Hidetoshi TAKAOKA, and Koichiro HAYASHI
Faculty of Engineering, Hokkaido University, Sapporo
(Received April 28, 1972)

The rates of homogeneous electron-transfer reactions between radical anions and neutral molecules were studied in a variety of tetracyanoethylenide systems in order to obtain information concerning the counterion effect on the electron-transfer reactions. The estimated values of the rate constants had the same order of magnitude at room temperature for all the systems, while the activation energies and the preexponential factors were markedly dependent on the natures of the counterions and the solvents. The obtained results are discussed in terms of the forms and structures of the radical anions.

The mechanism of an electron-transfer reaction between an organic radical anion and its neutral molecule is one of the most interesting problems concerning the relationship between the reactivities and the structures of radical ions in solution. Since Ward and Weissman[1] established the method for measuring the rapid rate of electron-transfer reaction by electron spin resonance (ESR), a number of electron-transfer reaction rates have been measured and it has been found that they are essentially dependent on the forms and structures of radical ions in solutions.[2-10]

In the systems where radical anions and their counterions exist in the form of an ion pair, any electron-transfer reaction is thought to be accompanied by a counterion-transfer through the formation of a sandwich structure at the transition state, as has been suggested by Adam *et al.*[2,11] Therefore, it can reasonably be expected that the natures of the counterions and solvent molecules coordinated to the ions profoundly affect the reaction behavior.

As for the radical ions of aromatic hydrocarbons, many authors[7,9,10] have reported in detail on the transfer rates in a number of different ion pairs with various alkali metal ions in various solvents. However, few studies have been made on the systems of *N*-containing radical anions.[5,8,12,16] In this article we will report the results obtained by the ESR technique on the electron-transfer reactions between the tetracyanoethylene radical anion ($TCNE^-$) and neutral tetracyanoethylene (TCNE) in 1,2-dimethoxyethane (DME) and tetrahydrofuran (THF). The effect of different counterions on the reaction rate was studied; the results will be discussed in terms of the ionic forms and structures of the radical ions in solution.

Experimental

Materials. TCNE of a guaranteed Reagent grade was purified by repeated sublimations *in vacuo*. The DME and THF were fractionally distilled over sodium metal, and the middle portions were stored over calcium hydride. They were rigorously dried with sodium mirror or sodium-potassium alloy *in vacuo* and degassed until 10^{-5} Torr before use. The alkali metal tetracyanoethylenides were prepared by reactions between alkali metals and TCNE dissolved in DME or THF. All the operations were carried out on the vacuum line.

The tetra-*n*-butylammonium salt was generated electrochemically in the solvent, using 0.1M tetra-*n*-butylammonium perchlorate as the supporting electrolyte. Alternatively, the crystalline tetra-*n*-butylammonium tetracyanoethylenide was prepared from tetra-*n*-butylammonium iodide and TCNE[13] and was dissolved in the solvent before use.

Measurements of Reaction Rates. Each radical anion solution for a rate experiment was sealed *in vacuo* into a ESR sample tube made of Pyrex, and then a known amount of TCNE was added through a break seal. The second-order rate constants were evaluated from the linewidth broadening in the ESR spectra produced by the addition of neutral TCNE. All the experiments were carried out at a slow exchange limit.[1] The ESR measurements were made with a JES-NE-2X spectrometer equipped with 100 kc field modulation. The temperature was kept constant within $\pm 1°$ with a JES-UCD-2X variable-temperature adaptor on the ESR cavity. The temperatures were determined by means of a copper-constantan thermocouple placed just under the sample tube in the cavity.

Results

The obtained ESR spectrum of a dilute solution of $TCNE^-$ was the same as that reported by Phillips *et al.*[12] No alkali metal splitting was observed in the various tetracyanoethylenide systems studied here. The increase in linewidth produced by the addition of neutral TCNE was linearly dependent on the concentration of added TCNE in the range from 1 to 6×10^{-2}M.

Table 1. Rate constants and activation energies for the electron-transfer reactions between tetracyanoethylene radical anions and their neutral molecules

Solvents	Counterions	Temp, °C	$k\times10^{-8}$ M^{-1} sec^{-1}	E_a[a] kcal mol^{-1}	Log A[a]
DME					
	Li^+	20	1.8	3.8±0.4	11
	Na^+	20	1.7	6.0±0.6	13
	K^+	20	1.5	7.6±0.6	14
	Bu_4N^+	10	1.3	6.5±0.6	14
THF					
	Li^+	20	1.5	2.2±0.4	10
	Na^+	20	1.3	3.6±0.5	11
	K^+	20	1.6	3.2±0.7	11
	Bu_4N^+[b]	20	1.9	4.7±0.6	12

a) Determined from the equation $k=A\exp(-E_a/RT)$.
b) Electrochemically prepared radical anion was used.

The estimated values of the rate constants were of the same order of magnitude at room temperature in all the systems, as is shown in Table 1.

The temperature dependence of the rates was investigated in the temperature range from −30° to 20°C. The plots of $\log k$ *vs.* $1/T$ gave almost straight lines, as is shown in Fig. 1. The apparent activation energies, calculated from the Arrhenius plots, are summarized in Table 1, together with the rate constants and the preexponential factors. The activation energies were markedly dependent on the natures of the counterions and the solvents. In DME it was found that the activation energies for alkali metal salts were in the order of $Li^+<Na^+<K^+$, and that of tetra-*n*-butylammonium salt gave a value intermediate between those of sodium and potassium salts. In THF, the evaluated activation energies were rather small in comparison with DME.

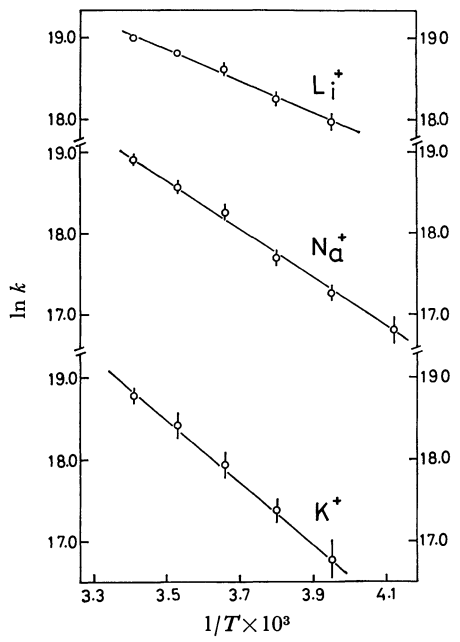

Fig. 1. Temperature dependence of the electron-transfer rates of various alkali metal tetracyanoethylenide systems in DME at the temperature range from −30° to 20°C; upper line: lithium salt; middle line: sodium salt; lower line: potassium salt.

The values for the alkali metal salts were found to be close to each other. Especially, almost the same value was obtained for the sodium and potassium salts, within the limits of experimental error. The system of tetra-*n*-butylammonium salt showed the largest activation energy in the solvent.

We also studied the cesium tetracyanoethylenide system, but the anomalously large ESR linewidth at higher concentrations of $TCNE^-$ prevented us from obtaining reliable data for this counterion.

Discussion

In order to understand the ionic forms and structures of the radical anions, it is profitable to compare the rate constants and activation energies obtained in this study with those of naphthalenide-naphthalene systems. Hirota *et al.*[9] clearly demonstrated the relationship between the structures of ion pairs and the kinetics of electron-transfer reactions in this system. The rate constants for solvent-separated ion pairs at 25°C were found to be of the order $10^9 M^{-1}sec^{-1}$, while those for contact ion pairs range from 5×10^6 to $10^8 M^{-1}sec^{-1}$. The activation energies were 2.9—3.6 kcal/mol for solvent-separated ion pairs and 4—6 kcal for contact ion pairs.

Although it is expected, on the basis of the information described above, that DME-alkali metal tetracyanoethylenide systems involve contact ion-pair structures, no metal splittings and spectral distortions characteristic to contact ion pairs were observed in the ESR spectra of these systems. Consequently, it may be supposed that these systems involve essentially solvent-separated ion pairs. This consideration is in accordance with the fact that small alkali metal ions are well solvated by DME and THF molecules.[14,15] Since normal straight lines are obtained in Arrhenius plots for these systems, we can conclude that essentially only one ionic form is present, at least in this temperature range.[9] This conclusion can be applied to all

14) D. N. Bhattacharyya, C. L. Lee, J. Smid, and M. Szwarc, *J. Phys. Chem.* **69**, 608 (1965).
15) C. Carvajal, K. J. Tölle, J. Smid, and M. Szwarc, *J. Amer. Chem. Soc.*, **87**, 5548 (1965).

the systems investigated, since similar straight lines are obtained in the remaining systems, also. Accepting the solvent-separated ion-pair model, the order of the activation energies in DME-alkali metal tetracyanoethylenide systems can easily be understood in the following manner. The thickness of the solvation shells around the metal ions is presumed to be in the order of $Li^+ > Na^+ > K^+$, therefore, the reverse order can be expected in the electrostatic interactions between metal ions and $TCNE^-$.[14] Accordingly, it seems reasonable that the activation energies estimated in this experiment are in the order of $Li^+ < Na^+ < K^+$, since a higher electrostatic interaction of the ion pair is thought to give a higher activation energy in the electron-transfer reactions.

In THF-alkali metal tetracyanoethylenide systems, the observed values of the rate constants suggest the contact-ion-pair model, whereas the values of the activation energy suggest the solvent-separated ion-pair model. However, the latter structure is more realistic in these systems, because no metal splittings and spectral distortions were observed in the ESR spectra, as in the case of DME. The activation energies for the alkali metal salts are rather small in comparison with those in the DME systems and are close to each other. These results suggest that alkali metal ions paired with $TCNE^-$ are well solvated in THF. In fact, it is reported that sodium ions have a larger solvated radius in THF as compared with DME.[15] A small but not negligible difference in the activation energies between lithium and the other metals can be attributed to the fact that the former ion is more highly solvated than the latter.[14]

In both solvents, tetra-*n*-butylammonium salt gives relatively large activation energies, indicating a strong electrostatic interaction between the alkylammonium ion and the radical anion in spite of its bulkiness. This is because bulky ammonium ions are not coordinated with either DME or THF molecules, as has been suggested by Szwarc *et al.*[15]

The magnitudes of the preexponential factors estimated increase with an increase in the activation energies. This is connected with the fact that nearly the same rate constant is obtained for all the systems. The preexponential factors for the THF systems range from 10^{10} to $10^{12} M^{-1} sec^{-1}$. These values are within the limits of those observed in usual liquid-phase reactions. However, rather unexpectedly large preexponential factors are evaluated in all the DME systems except for the lithium salt. It is likely that such large preexponential factors are characteristic of *N*-containing radical anions, because a similar phenomemon has been reported in the potassium 2,2′-bipyridinide system.[16] However, we cannot exclude another possibility that the activation energies are partly contributed by charge-transfer interaction between DME and neutral TCNE. In order to make a conclusive discussion of this problem, more detailed studies should be done in the future.

Group Interactions in Polyelectrolytes. VI.[1] Amination Kinetics of Chloromethylated Polystyrene in *N,N*-Dimethylformamide and Dimethyl Sulfoxide

Hiroshi KAWABE and MASAYA YANAGITA

The Institute of Physical and Chemical Research, Wako-shi, Saitama

(Received May 2, 1972)

Although the apparent second-order rate constant of the amination of chloromethylated polystyrene with *n*-butylamine or with 2-aminobutanol decreased or increased, respectively, during the course of the amination in dioxane, as has been reported previously, both aminations as well as the aminations of benzyl chloride have been found to conform to the ordinary second-order kinetics in DMF and DMSO. The viscometric measurements have indicated that the viscosity of the reaction mixture decreased during the amination with *n*-butylamine and increased slightly during the amination with 2-aminobutanol, but no relation between the kinetic behavior and the viscometric changes in the reaction mixtures could be found. The magnitude of the rate constants was comparable to that of the amination of benzyl chloride, and it increased with an increase in the dielectric constant of the solvents in this order: dioxane$\ll$DMF$<$DMSO. The effects of the solvents on both the kinetic behavior in the aminations of the polymer and the magnitude of the rate constants have been discussed in terms of the interactions between the solvent and the solute molecules.

The quaternization of chloromethylated polystyrene (CMPS) with tertiary amines in various solvents was studied by Noda and Kagawa.[2] They reported that the initial rate of the quaternization with triethylamine increased with an increase in the dielectric constant of the solvents, like in ordinary Menschutkin reactions; they also reported that the rate in *N,N*-dimethylformamide (DMF) conformed completely to the ordinary second-order equation. Kawabe and Yanagita[3,4] investigated the aminations of CMPS with some primary and secondary amines in dioxane and found that the aminations apparently did not obey the second-order rate law. In the amination with *n*-butylamine or di-*n*-butylamine, the apparent second-order rate constant decreased as the amination proceeded, whereas it increased in the amination with 2-aminobutanol. In these cases, the amination kinetics could be expressed by rate equations which were derived by assuming that the reaction is subjected to the steric hindrance or "hydrophilic effect" of the already-aminated neighboring groups.

In the present study, the authors will deal with the amination of CMPS with *n*-butylamine in DMF and with that with 2-aminobutanol in DMF and dimethyl sulfoxide (DMSO); they will show that the rates conform to the second-order equation and that the rate constants in these solvents are markedly higher than those in dioxane. The effects of the solvents on the kinetic behavior in the aminations of CMPS, and also the dependence of the rate constants on the polarity of the solvents, will be discussed.

Experimental

Materials. The polystyrene and chloromethylated polystyrene (CMPS) were prepared and purified by the procedures described in previous papers.[3,4] The chlorine contents and the molecular weights of CMPS used in the present study are tabulated in Table 1. The 2-aminobutanol was prepared by the procedure described in a previous paper.[4] The other amines, benzyl chloride and the solvents, all of a reagent grade, were distilled before use; they were proved to be pure by their refractive indices. All the other chemicals were of a reagent grade, and de-ionized, de-carbonized water was used throughout the experiments.

Table 1. Chloromethylated polystyrene

Code	Content of Cl %	Degree of Chloromethylation	Molecular weight
SC-4	22.04	0.93	7.3×10^4
SC-5	21.15	0.87	10.3×10^4
SC-6	18.76	0.74	—

Kinetic Measurements. As has been described in the previous papers,[3,4] 150 m*l* of a solution containing one gram of CMPS or benzyl chloride and a large excess of amine (about twenty times as many moles as the chloromethyl group) was stirred at a constant temperature (within$\pm$0.1°). At appropriate intervals, aliquots were taken out, poured into dilute nitric acid, and titrated with 0.1N silver nitrate. The experimental conditions in the aminations of CMPS are listed in Table 2, where *a* denotes the initial concentration of an amine, and *b*, the initial concentration of the chloromethyl group of CMPS. In the amination of benzyl chloride, *a* was 1.06 mol/*l* and *b* was 0.053 mol/*l*. All the reaction except the amination of CMPS with di-*n*-butylamine, which was accompanied by the emulsification of the reaction mixture, were homogeneous and reached completion.

Viscometric Measurements. In the amination of CMPS, the viscosity change in the reaction mixture was also checked. After the reaction mixture had been prepared, a 10 m*l* portion of the solution was taken out and put into an Ostwald-type viscometer, while the temperature was kept constant (within $\pm$0.1°). At appropriate intervals, the flow times were measured, and the relative viscosity (η_{rel}) and the reduced viscosity (η_{sp}/c_p) were determined:

$$\eta_{rel} = \rho_p t/\rho_0 t_0, \quad \eta_{sp} = \eta_{rel} - 1$$

where c_p is the concentration of CMPS expressed by g/100 m*l* where ρ_0 and ρ_p are the densities of a pure solvent and a CMPS solution of the same concentration as the reaction mixture

c) b: Initial concentration of the polymer expressed in moles of chloromethyl group per litre

respectively, and where t_0 and t are the flow times of a pure solvent and the reaction mixture respectively. The values of c_p were 0.67—0.69, and those of ρ_p/ρ_0 were lower than 1.01 in the present experiments. The observed viscosity change in the reaction mixture was expressed in terms of the viscosity ratio (H), defined by the following equation:

$$H \equiv (\eta_{sp}/c_p)/(\eta_{sp}/c_p)_{\beta\to 0}$$

where β is the fractional conversion of the chloromethyl group. The numerical values of $(\eta_{sp}/c_p)_{\beta\to 0}$, which are the extraporated values of η_{sp}/c_p to $\beta=0$, are as follows:

n-butylamine: 0.5 (dioxane, 50°C), 0.46 (DMF, 50°C)
2-aminobutanol: 0.67 (dioxane, 40°C), 0.8 (DMF, 40°C), 0.51 (DMSO, 30°C)

Results

Amination with n-*Butylamine.* As has been reported previously,[3] the amination of benzyl chloride with *n*-butylamine in dioxane obeyed the second-order rate law, and the rate constant, k, was given by:

$$kt = \frac{1}{(a-b)} \ln \frac{b(a-x)}{a(b-x)} \equiv \overline{kt} \qquad (1)$$

where a and b are the initail concentrations of an amine and the chloromethyl group respectively, while x is the concentration of chloride ions after time t. The dependence of k on the temperature was expressed by:

$$k = A \exp(-E_a/RT) \qquad (2)$$

where A is the frequency factor and E_a, the activation energy.

In the amination of CMPS with *n*-butylamine in dioxane, the rate constant computed by Eq. (1) was not constant, but decreased as the amination proceeded, and the plot of $\overline{kt}$ against t could be expressed approximately by two lines which intersected near the half-amination.[3] This behavior can be explained by the assumption that the amination of the chloromethyl group situated between two already-aminated neighboring groups is sterically obstructed, and the over-all kinetics in the presence of a large excess of the amine ($a \gg b$) can be expressed by Eq. (3):

$$\beta = x/b = 1 - \frac{k_1-k_2}{2k_1-k_2} e^{-2k_1at} - \frac{k_1}{2k_1-k_2} e^{-k_1at} \qquad (3)$$

$$k_1 = \frac{1}{[(2-k_2/k_1)a-b]t} \ln \frac{1-\beta}{1-(2-k_2/k_1)\beta} \qquad (4)$$

$$k_2 = \frac{1}{(a-b)(t-\tau)} \left(\ln \frac{1-\alpha}{1-\beta} - \ln \frac{1-\chi/a}{1-\chi/b} \right) \qquad (5)$$

where k_1 and k_2 are the rate constants of the elementary reactions which are independent of the neighboring groups and under this influence respectively. In Eqs. (4) and (5), $\alpha=x/a$, τ and χ are the values of t and x respectively when $x_1 \simeq b/2$, and x_1 is the concentration of the group which is aminated independently of its neighbors.

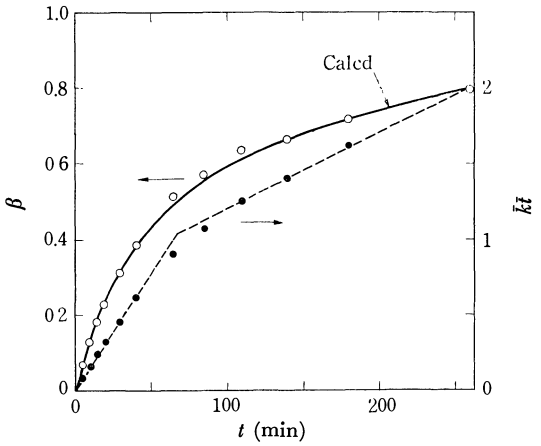

Fig. 2. Amination of chloromethylated polystyrene with di-*n*-butylamine in DMF.

The rate of the amination of CMPS with *n*-butylamine in dioxane has been re-mesaured in the present study in order to obtain a more accurate value for E_a; the results are shown in Fig. 1 and Table 3. The solid lines in Fig. 1, calculated on the basis of Eq. (3) by using the numerical values for k_1 and k_2 listed in Table 4, are in good agreement with the observed values of β, represented by the white circles. The values of E_a and A, computed by the least-squares method on the basis of Eq. (2), are also listed in Table 3.

20	—	1.61	(k_P) 11.4±0.1	4.89
30	2.78	3.21		
40	5.24	6.10	(k_B) 11.6±0.2	7.42
50	8.89	10.2		

a) k_P: Rate constant of chloromethylated polystyrene
b) k_B: Rate constant of benzyl chloride

In DMF, on the other hand, the aminations of both CMPS and benzyl chloride have turned out to obey the second-order law; their rate constants can be determined on the basis of Eq. (1). The rate constants are tabulated in Table 4. The figures of E_a and A are also listed in Table 4. The rate constants in DMF are much higher than those in dioxane.

In contrast to the amination of CMPS with *n*-butylamine, the amination of CMPS with di-*n*-butylamine in DMF showed a kinetic behavior similar to that in dioxane.[3] The results of the amination in DMF at 30°C are shown in Fig. 2. The $\overline{kt}$-t plot can be expressed approximately by two lines which intersect near $\beta=0.5$, and k_1 and k_2 are given by Eqs. (4) and (5) as follows:

$$k_1 = 1.83\times10^{-2},\ k_2 = 4.98\times10^{-3}\ l/\text{mol}\cdot\text{min}$$

In Fig. 2, the solid line was calculated on the basis of Eq. (3), and the observed values, represented by the white circles, fall substantially on the line.

The amination rates of CMPS with these amines could not be determined in DMSO, because the polymer was precipitated in the initial stage of the amination with *n*-butylamine and di-*n*-butylamine was not dissolved in DMSO.

Amination with 2-Aminobutanol. Although self-acceleration was observed during the amination of CMPS with 2-aminobutanol in dioxane,[4] in DMF or DMSO the amination of CMPS as well as that of benzyl chloride has been found to conform to the second-order rate equation. The rate constants computed by Eq. (1) are tabulated in Tables 5 and 6. The rate constants in DMF are much higher than those in dioxane,[4] and the rate constants in DMSO are even higher than those in DMF. The numerical values for E_a and A are also listed in Tables 5 and 6.

As has been mentioned above, the aminations of CMPS with *n*-butylamine and 2-aminobutanol, which show abnormal kinetic behavior in dioxane, are normal

in DMF and DMSO; that is, their rates, like those of benzyl chloride, are fully represented by the ordinary second-order equation. In these cases, therefore, even the amination of CMPS is considered to be controlled by the bimolecular reaction of chloromethyl groups and amine molecules, and the rate constants are considered to be independent of the initial concentrations of these amines. This has been confirmed in the amination of CMPS with 2-aminobutanol in DMSO. The rate constants computed by Eq. (1), which are shown in Table 7, are much the same over a wide range of amine concentrations.

□: *n*-butylamine in dioxane, ▨: *n*-butylamine in DMF
○: 2-aminobutanol in dioxane, ⊖: 2-aminobutanol in DMF, ●: 2-aminobutanol in DMSO

Viscosity Change in the Reaction Mixture During the Amination of Chloromethylated Polystyrene. The viscosity change in the reaction mixture in the amination of CMPS ($a/b=20$) is shown in Fig. 3, where the viscosity ratio, $H\equiv(\eta_{sp}/c_p)/(\eta_{sp}/c_p)_{\beta\to0}$, is plotted against β.

In the amination with *n*-butylamine, H decreases with an increase in β ($H<1$), whereas H increases slightly with an increase in β ($H>1$) in the amination with 2-aminobutanol. On the other hand, the influence of the solvent is less marked. These results show that there is no relation between the kinetic behavior in the amination of CMPS and the viscometric changes in the reaction mixtures.

Discussion

The apparent second-order rate constant of the amination of CMPS with *n*-butylamine in dioxane decreases as the amination proceeds, but the rate in DMF conforms to the ordinary second-order equation. This difference is considered to be related to the expansion and contraction of butylamine molecules in the two solvents, which are present as reagent molecules and also as substituents of the polymer. The Hildebrand solubility parameter, δ, is an index of cohesive interaction among molecules in a solution, and the calculated values of δ at 25°C are as follows: 9.15 (*n*-butylamine), 9.98 (dioxane), and 12.11 (DMF).[5] Since DMF is a poorer solvent for *n*-butylamine than dioxane, it may be possible that the relatively long molecule of *n*-butylamine contracts in DMF because of the attraction among segments of the molecule. On the other hand, in the amination of CMPS with di-*n*-butylamine ($\delta=8.42$[5]), a decrease in the rate constant with an increase in β has been observed even in DMF. In this case, however, di-*n*-butylamine is a secondary amine of a larger molecular weight than *n*-butylamine, and so the former is more bulky than the latter. The contraction of *n*-butylamine molecules in DMF may not be pronounced, but it seems to be sufficient to cancel a small steric obstruction of the neighboring groups, because no such steric effect has been observed in the amination of CMPS with *i*- or *s*-butylamine in dioxane.[7]

Although the rate of the amination of CMPS with 2-aminobutanol is self-accelerated in dioxane as a result of the "hydrophilic effect" of the neighboring hydroxyl group,[4] it conforms to the ordinary second-order kinetics in DMF and DMSO. The effect of the solvents on the kinetic behavior may be explained in terms of interactions between 2-aminobutanol molecules and solvent molecules. The additional solubility parameters of the related substances are: 16.17 (2-aminoethanol) and 13.31 (DMSO).[5] Dioxane must be a poorer solvent for 2-aminobutanol than DMF and DMSO. Not only are DMF and DMSO better solvents for aminoalcohol, but also these dipolar aprotic solvents are hydrogen-bond acceptors; therefore, they may interact with the hydroxyl groups to obstruct the accelerating effect of the neighboring hydroxyl group on the polymer.

The enthalpy of activation, ΔH^*, the entropy of activation, ΔS^*, and the free energy of activation, ΔG^*, are computed by these equations:

$$\begin{cases} \Delta H^* = E_a - RT \\ A/60 = e(kT/h)\exp(\Delta S^*/R) \\ \Delta G^* = \Delta H^* - T\Delta S^* \end{cases}$$

The numerical values for these thermodynamic quantities at 25°C, obtained on the basis of the E_a and A values, are summarized in Table 8.

The value of the rate constant of CMPS is about the same as that of benzyl chloride in any solvent; this is indicated by the ΔG^* values in Table 8. Provided that benzyl chloride is a proper model for DMPS, this fact suggests that the intrinsic reactivity of the functional group of CMPS may be essentially independent of its molecular weight.

The rate constant of the amination with 2-aminobutanol is lower than that of the amination with *n*-butyl-

5) The δ values are calculated at 25°C on the basis of the data given in Ref. 6.

		Benzyl	11.9	−34.4	22.2

a) Calculated on the basis of the data given in Ref. 3.
b) Calculated on the basis of the data given in Ref. 4.

amine; *e.g.*, in DMF the former is about 20% of the latter, corresponding to a difference in $\Delta G^{\ddagger}$ of 0.9 kcal, and the $\Delta H^{\ddagger}$ of the former reaction is about 1.7 kcal higher than the latter. Accordingly, the lower rate in the amination with 2-aminobutanol seems to be related to the inductive effect of the hydroxyl group; however, it is necessary for a strict interpretation to compare 2-aminobutanol with 2-aminobutane.

On the other hand, the magnitude of the rate constants is greatly influenced by the solvents. The approximate values for the relative rate, expressed on the basis of the rate constant of benzyl chloride or CMPS in dioxane, are as follows:

n-butylamine (benzyl chloride): dioxane(1)<DMF(40)

2-aminobutanol (benzyl chloride and CMPS): dioxane(1) <DMF(20)<DMSO(80)

In the amination of both CMPS and benzyl chloride with 2-aminobutanol in dioxane, the rate constant is somewhat influenced by the initial concentration of the amine;[7] the relative rates, expressed on the basis of the rate constant extrapolated to a zero concentration of the amine, are:

2-aminobutanol (benzyl chloride and CMPS): dioxane(1) <DMF(40)<DMSO(160)

The order of the rate constants is in agreement with that of the dielectric constants of the solvents, D: dioxane (2.21)<DMF (36.71)<DMSO (46.68). It should be noted, however, that the plot of log k against $1/D$ is not linear.

In the amination with *n*-butylamine, the change of solvent from dioxane to DMF lowers the $\Delta H^{\ddagger}$ and increases the $\Delta S^{\ddagger}$. The lower $\Delta H^{\ddagger}$ in DMF may be explained principally in terms of the solvation of the transition state in this dipolar aprotic solvent. This solvation, however, is considered to be accompanied by a lowering of $\Delta S^{\ddagger}$. The observed enhancement of $\Delta S^{\ddagger}$ must be caused by some other factors, one of which may be the change in the configurational entropy of the solvent in the reaction mixture. The solubility parameter of benzyl chloride (δ=9.79[8]) is almost the same as that of dioxane, but the transition state is rather ionic and may have a considerably higher value for δ. The formation of the transition state may thus be accompanied by a decrease in the entropy of the solvent, dioxane. Since the δ value of DMF is much higher than that of dioxane, its entropy change may be relatively small.

In the amination with 2-aminobutanol, the lowering of the $\Delta G^{\ddagger}$ from dioxane to DMF is principally ascribable to the increase in the $\Delta S^{\ddagger}$, and the lowering of the $\Delta H^{\ddagger}$ is not so marked as in the case of *n*-butylamine. This discrepancy cannot be explained at the present time; further investigation is needed, especially in order to establish the dependence of the rate constant on the initial concentration of 2-aminobutanol in dioxane. On the other hand, the lowering of the $\Delta G^{\ddagger}$ from DMF to DMSO is substantially caused by the lowering of the $\Delta H^{\ddagger}$. This small entropy change can be understood if we assume that both DMF and DMSO are dipolar aprotic solvents and that their δ values are approximately the same. The lowering of the $\Delta H^{\ddagger}$ is brought about by the lowering of the potential energy of the activation complex, which may be more strongly solvated in DMSO than it is in DMF, for the former is more polar than the latter.

The authors wish to express their thanks to Mr. Masayuki Takahashi, Mr. Akihiro Kishi, and Mr. Sachio Fukushima for their helpful assistance in preparing the polymer and in carrying out the measurements.

8) The δ value is calculated on the basis of the data given in the book: Kirk-Othmer "Encyclopedia of Chemical Technology," second edition, Vol. 5, Interscience Publishers (1964), p. 282.

Kinetic Studies of the Dissociation and the Recombination Reaction in Aqueous Solutions of Monocarboxylic Acids by Means of Ultrasonic Absorption Measurements

Takayuki SANO, Tomohiro MIYAZAKI, Nobuhide TATSUMOTO, and Tatsuya YASUNAGA
Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima
(Received April 25, 1972)

The ultrasonic absorptions were measured in aqueous solutions of acetic, propionic, butyric, valeric, and chloroacetic acids as a function of the pH over the frequency range from 1.5 to 220 MHz at 25°C. From the dependences of μ'_{max} and f_r on pH, it was deduced that the perturbation of the ionization equilibrium of acids was the cause of the excess absorptions in dilute aqueous solutions. The kinetic parameters thus calculated were compared with those obtained by other methods.

It is well known that the ionization equilibrium exists in aqueous solutions of carboxylic acids. Their equilibrium constants have thus far been determined by means of static methods. However, the reaction is so rapid that the kinetic studies of this process could not be done until the appearance of the relaxation methods.

In 1964, Nürnberg and his co-workers[1] determined the dissociation and the recombination rate constants for a number of carboxylic acids by a kind of the relaxation method, the high-level faradaic rectification method. Eigen and his co-workers[2] have also determined the rate constants for some acids by the electric-field method.

On the other hand, the ultrasonic absorption measurements in liquid carboxylic acids have been carried out by many investigators.[3] As a result, it has been concluded that the absorption in pure carboxylic acid is due to the perturbation of the equilibrium between the cyclic dimer and the open dimer. However another type of absorption different from that in the liquid of pure acids has been observed in comparatively dilute aqueous solutions. The perturbation of the ionization equilibrium[4] has been expected to be a cause of this type of absorption, but no thorough consideration has been done of this absorption. Therefore, it seems that it would be very interesting to clarify the mechanism of the absorption and to compare the kinetic parameters obtained by the ultrasonic method with those obtained by other methods.

Experimental

In aqueous solutions of monocarboxylic acids, the ultrasonic absorption was measured by means of the pulse technique[5] over the frequency range from 1.5 to 220 MHz at various concentrations and pH's. The sing-around[6] method operated at 1.92 MHz was used to measure the sound velocity. The concentrations of the hydrogen ion were determined with a Hitachi-Horiba F-5 type pH meter. The densities were measured using a pycnometer. All the measurements were made at 25°C.

The monocarboxylic acids used were acetic, propionic, butyric, and valeric acids, in which the alkyl group consists of hydrocarbon only, and monochloro-, dichloro-, and trifluoro-acetic acids, which contain halogen atoms in the alkyl group. Guaranteed reagents were used throughout this study without further purification.

Results

The spectra of the ultrasonic absorption in the aqueous solutions of acetic acid are shown in Fig. 1. Double relaxations are observed in 3—6M solutions and are expressed by the following equation:

$$(\alpha\lambda)' = vf\left(\frac{\alpha}{f^2} - B\right) = vf\left[\frac{A_1}{1+(f/f_{r1})^2} + \frac{A_2}{1+(f/f_{r2})^2}\right], \quad (1)$$

where α is the ultrasonic absorption coefficient, λ is the wavelength of the acoustic wave, $(\alpha\lambda)'$ is the excess absorption per wavelength, v is the velocity of sound, f is the frequency of sound, A and B are the relaxational and classical absorptions respectively, and f_r is the relaxation frequency, and where the subscripts 1 and 2 refer to the absorption at the lower and higher fre-

quencies respectively.

In 1, 1.5, and 8M solutions single relaxations are observed; they may be represented as follows:

$$(\alpha\lambda)' = vf\left(\frac{\alpha}{f^2} - B\right) = vf\frac{A}{1+(f/f_r)^2} \qquad (2)$$

The solid lines in Fig. 1 are theoretical curves which are expressed by either Eq. (1) or (2). The values of the parameters, the relaxation frequency (f_r), and the maximum absorption per wavelength (μ'_{max}) are listed in Table 1, together with the velocity of sound (v), and the density (ρ).

Table 1. The acoustical characteristics of acetic acid at various concentrations at 25°C

M	f (MHz)	μ'_{max} (10^{-4})	pH	v (10^5 cm·sec^{-1})	ρ (g·cm^{-3})
8.02	3.8	95.0	1.43	1.4984	1.0494
6.02	4.0	51.9	1.67	1.5255	1.0392
	240	35.8			
4.01	4.3	21.3	1.85	1.5369	1.0270
	180	17.8			
3.00	3.5	13.9	1.93	1.5341	1.0147
	130	10.8			
1.45	60	5.2	2.23	1.5216	1.0066
1.00	35	3.1	2.26	1.5160	1.0047

As can be seen in Fig. 1, the excess absorption at the lower frequency decreases with a decrease in the concentration, and it entirely disappears in 1 and 1.5M solutions over the frequency range measured. This behavior of the spectra shows that the excess absorptions in 1 and 1.5M solutions correspond to those at the higher frequency in 3—6M solutions. On the other hand, the excess absorption in 8M, and that at the lower frequency in 3—6M solutions, seem to be identical with that in pure acetic acid. The mechanism of these absorptions has been discussed in detail by Atkinson and his co-workers.[7] Since our purpose in this paper is to investigate the mechanism of the absorption at higher frequencies, the measurements of the ultrasonic absorption were carried out in detail for a 1M solution, in which the absorption at lower frequencies disappears.

Now, assuming that the excess absorption is associated with the dissociation and the recombination reaction of the acetic acid, the best way to justify the above assumption is to measure the ultrasonic absorption at various pH's in the 1M solution, in which the excess absorption disappears at lower frequencies. Under these conditions, the results obtained are shown in Fig. 2, while the values of the ultrasonic parameters are listed in Table 2. It can be seen from Fig. 2 that both f_r and μ'_{max} are dependent on the pH. This fact may imply the validity of the above assumption.

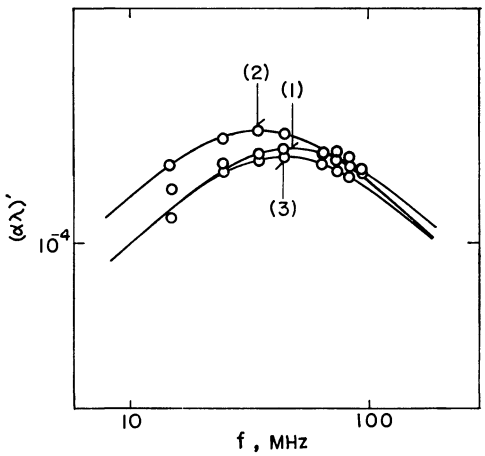

Fig. 2. Ultrasonic absorption spectra in 1.00M solution of acetic acid at 25°C. (1): pH 1.76, (2): pH 2.26, (3): pH 3.20.

In the dissociation and the recombination reaction of acid, which is generally represented by the following equation:

$$AH \underset{k_r}{\overset{k_d}{\rightleftarrows}} A^- + H^+$$

the relaxation time, τ, and μ'_{max} are given by the following equations:

$$\frac{1}{\tau} = 2\pi f_r = k_d + k_r(A^- + H^+) = k_r(K + A^- + H^+) \qquad (3)$$

Table 2. The acoustical characteristics of carboxylic acids at various pH's at 25°C

7) R. D. Corsaso and G. Atkinson, *J. Chem. Phys.*, **55**, 1971 (1971).

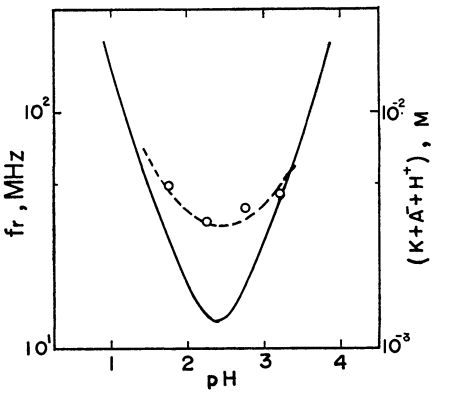

Fig. 3. Plot of the relaxation frequency *versus* pH; the experimental values of f_r are indicated by circles, and solid line shows the dependence of the calculated concentration term on pH.

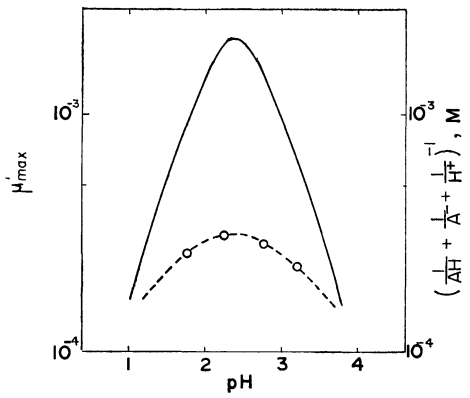

Fig. 4. Plot of maximum of the absorption per wavelength *versus* pH; the experimental values of μ'_{max} are indicated by circles, and the solid line shows the calculated concentration terms.

$$\mu'_{max} = \frac{(\Delta V)^2}{2\beta_0 RT}\left[\frac{1}{AH} + \frac{1}{A^-} + \frac{1}{H^+}\right]^{-1} \quad (4)$$

where k_d and k_r are the rate constants of the dissociation and the recombination respectively, K is the equilibrium constant, β_0 is the adiabatic compressibility, $\boldsymbol{R}$ is the gas constant, T is the absolute temperature, and ΔV is the volume change per mole for the reaction.

In Eqs. (3) and (4), k_r, k_d, and $\pi(\Delta V)^2/2\beta_0 \boldsymbol{R} T$ may be taken as constant, so both f_r, and μ'_{max} are directly proportional to the concentration. The concentration terms at various pH's can be calculated by using the equilibrium constant listed in the literature.[8] From the calculation of the terms in Eqs. (3) and (4), it is found that these terms have a maximum and a minimum at the corresponding pH. The results are presented in Figs. 3 and 4, together with the experimental values of f_r and μ'_{max} respectively. In view of the similarity of the behavior of the experimental values to that of the calculated terms against the pH, the assumption that the excess absorption in aqueous acetic acid is to be attributed to the perturbation of the ionization equilibrium of acid is strongly supported.

absorptions at the lower frequency correspond to those in pure propionic acid, and that the absorptions in 0.5 and 1M solutions, represented by the single relaxation curves are identical with those at higher frequencies in solutions more concentrated than 2M. The relaxation parameters are listed in Table 4.

Next, Fig. 6 shows the ultrasonic absorption spectra in a 1M solution of the propionic acid at various pH's. Similarly, as is shown in Fig. 7, the ultrasonic absorptions were observed in 0.5M solutions of butyric acid at various pH's. In the butyric acid, however, the low solubility prevented the measurement of the dependence of the absorption on the concentration of the acid. Valeric acid is less soluble than butyric acid, so it is very difficult to investigate the dependence of the absorption not only on the acid concentration, but also on the pH. As the result of our great effort, however, the absorptions were measured in a 0.1M solution of the valeric acid at the values of pH, 2.69 and 2.75. The spectra are shown in Fig. 8. The relaxation parameters for propionic, butyric, and valeric acids are presented in Table 2.

As can be seen in Figs. 6—8, both f_r and μ'_{max} are dependent on the pH. The mechanism of these

acid. The kinetic parameters based on the reaction for each acid are calculated in a manner similar to the case of the acetic acid; they are listed in Table 3. The kinetic parameters for the acetic and propionic acids at various concentrations are presented in Table 5.

Table 5. The kinetic parameters for the dissociation and recombination reaction of acetic and propionic acids at various concentrations at 25°C

absorptions, therefore, may be due to the dissociation and recombination reaction of acid, as in the acetic

Thirdly, it is very interesting to study the variation in the kinetic parameters of monocarboxylic acids with the change in molecular structure. For this purpose, the ultrasonic absorptions were measured in aqueous solutions of halogeno carboxylic caids, which have quite different electronegativities from the above acids. The single relaxation curves obtained from the measurements of the absorption in 0.5 and 1M solutions of monochloro acetic acid are graphed in Fig. 9. The relaxation parameters are listed in Table 6. As the values of f_r, 180, and 220 MHz are near the end of the frequency range measured, it is thought that the experimental error may be larger than that of other acids. In this case, the kinetic parameters were also calculated on the basis of the expectation that the absorptions are associated with the perturbation of the ionization equilibrium of acid. The results are listed in Table 3. The ultrasonic absorptions were measured in 1M solutions of dichloro- and trifluoroacetic acids, but in both acids no excess absorption was observed in the fre-

quency range from 15 to 95 MHz. The values of α/f^2 are 31×10^{-17} and 36×10^{-17} cm^{-1}sec^2 in solutions of dichloro- and trifluoroacetic acids respectively, so the f_r values associated with the ionization equilibrium of acid can be expected to be higher than the frequency measured in this work.

Discussion

As can be seen in Table 3, the values of ΔV are in close agreement with those determined from the density measurements by Kauzman and his co-workers.[9] The values of the recombination rate constant, $\sim10^{10}$M^{-1}sec^{-1}, may be of an adequate order of magnitude as the rate of the diffusion-controlled reaction. As for the acetic acid, the values of the parameters may be comparable to those obtained from the ultrasonic absorption measurement by Yeager,[4] $k_r=5.5\times10^{10}$ M^{-1}sec^{-1}, $k_d=1.0\times10^6$ sec^{-1}, and $\Delta V=12.2$ cc·mol^{-1}.

Next, the Taft rule[10] can be applied to the relationship between the rate constants and the polar substituent constants. Taft's equation is given by:

$$\log k = \rho^*\sigma^*$$

where k is the rate constant, ρ^* is the constant characterized by only the type of the reaction, and σ^* is the polar substituent constant. In Fig. 10, the plots of $\log k_d$ and $\log k_r$ against σ^* are presented, together with the values for formic and benzoic acids obtained by Eigen and his co-workers.[2] $\log k_d$ is linearly correlated with σ^*, whereas $\log k_r$ is nearly constant within the experimental error. From the linear relationship between $\log k_d$ and σ^*, ρ^* was determined to be 1.7.

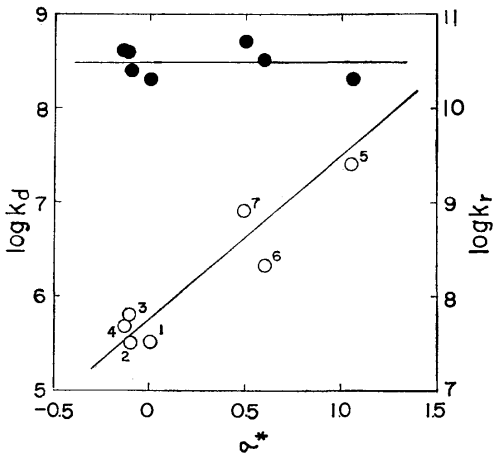

Fig. 10. Plot of $\log k_d$ (open circles) and $\log k_r$ (solid circles) *versus* polar substituent parameter σ^* for the various carboxylic acids. 1: acetic, 2: propionic, 3: butyric, 4: valeric, 5:monochloroacetic, 6: benzoic, 7: formic acids.

The value[11] of ρ^* found in the literature, estimated from the relationship between the ionization equilibrium constants of the carboxylic acids and σ^*, is 1.721 ± 0.025; this is in good agreement with that obtained for the recombination rate constants in the present work. This result suggests that the difference in the values of the equilibrium constants among the various carboxylic acids results not from the recombination rate constant, but from the dissociation rate constant. From these discussions, it can reasonably be concluded that the excess absorptions in dilute aqueous solutions of the carboxylic acids measured in the present work are associated with the perturbation of the ionization equilibrium of acids.

Finally, the kinetic parameters obtained from the ultrasonic absorption measurements of the acetic and propionic acids at various concentrations are listed in Table 5. As is shown in this Table, the rate constants for both the acids may be considered to be independent of the concentration, but the values of ΔV increase with an increase in the concentration of the solutions for each acid. For this result, the following three causes may be considered as the origin of the change in ΔV: 1) the experimental error, 2) the neglect of the activity coefficient, and 3) the change in the state of carboxylic acids in the solutions. The change in ΔV with the concentration, however, is far greater than the effects of 1) and 2). On the other hand, in the case of the ionization reaction of carboxylic acids it seems that the difference in the amount of hydration between the two species gives rise to the volume change, ΔV. The carboxylic acids form dimeric and polymeric molecules by intermolecular hydrogen bonding in concentrated solutions, and become electrically more neutral than the monomeric molecule. Therefore, the amount of hydrating water may decrease in the following order: ionic>monomeric>dimeric molecules, and the volume change between ionic and nonionic molecules may increase with an increase in the concentration. Consequently, the above feature in ΔV seems to result from the 3) effect, although this conclusion cannot be confirmed quantitatively at present.

Heat Capacity of Tetramethylsilane in the Region from 2 to 26 K and Premelting Range[1)]

Takako SHINODA, Hisae ENOKIDO, Yoji MAEDA,* Hiroshi TOMITA, and Yo-ichiro MASHIKO
National Chemical Laboratory for Industry, Shibuya-ku, Tokyo
(Received April 26, 1972)

The heat capacity of tetramethylsilane was measured at temperatures from 2 to 26 K and in the premelting temperature range for two crystalline forms. There are two crystalline forms in solid tetramethylsilane. The heat of fusion and triple point temperature of a stable form were found to be 1611.2±0.9 cal/mol and 174.049 K, while those of a metastable form to be 1396.0±0.8 cal/mol and 170.981 K. Tetramethylsilane was highly purified by preparative gas chromatography. The amount of impurity in the specimen of $Si(CH_3)_4$ was estimated to be 0.004_6 mol% from measurement of the melting point range for two crystalline forms. The Debye characteristic temperature at 0 K, $\theta_D(0)$, was derived from low temperature heat capacity data, and the $\theta_D(T)/\theta_D(0)$ curve was compared with those for $C(CH_3)_4$ and CF_4. Despite high purity, C_p values for two crystalline forms in the region below melting points increases abnormally with the rise of temperature. The phenomena were interpreted as due to effects of formation of vacancies in the crystals and of melting accompanied by molecular orientation transition; analysis of heat capacity curves for the two crystalline forms was made in the region befow the melting point.

In previous papers[2,3)] we reported on the thermodynamic properties of tetrahedral molecules, $C(CH_3)_4$ and CF_4, which undergo orientationally disordering transition below their melting point. In the present paper we treat tetramethylsilane $Si(CH_3)_4$ which does not undergo phase transition below its melting point.

Heat capacity data for $Si(CH_3)_4$ were given by Aston *et al.*[4)] In their work the sample used was of 99.88 mol% purity, and the heat capacity data were reported for temperatures 12 to 290 K. We have attempted to prepare $Si(CH_3)_4$ of higher purity, and provide more complete and accurate data on the heat capacity at lower temperatures and in the premelting range, supplementing the data for $T<12$ K.

The Debye characteristic temperature at 0 K, $\theta_D(0)$, is derived from the low temperature heat capacity data, and a comparison of the temperature dependence of $\theta_D(T)/\theta_D(0)$ is made with that for other tetrahedral molecules reported by the present authors taking into account the octupole interaction of molecules in the crystals.

A possible interpretation of premelting anomalies in two crystalline forms of $Si(CH_3)_4$ is offered by theories of lattice vacancies and simultaneous positional and orientational transitions, and the activation energies are estimated from the analysis of the heat capacity curves in the region below melting point.

Experimental

Materials. Tetramethylsilane was obtained from Matheson Coleman & Bell Co. In analytical experiments, a Shimadzu 4AT gas chromatograph was used with a thermal conductivity detector under the following conditions:

Column	3 mm×3 m, Silicone SE 30 (20%) on Shimalite W (80—100 mesh)
Temperature	30°C
Carrier gas	Helium at 40 ml/min.

A chromatogram of crude $Si(CH_3)_4$ is shown in Fig. 1. Retention times and percentage composition of crude $Si(CH_3)_4$ are shown in Table 1. The percentage composition was calculated by means of area under peaks.

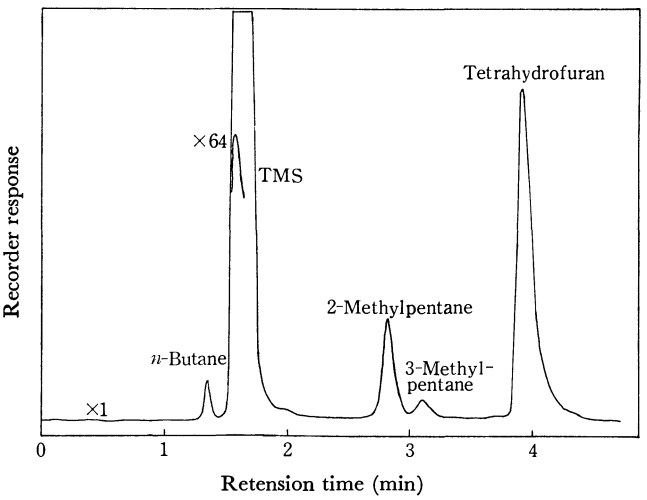

Fig. 1. Analytical gas chromatogram of crude $Si(CH_3)_4$.

TABLE 1. RETENTION TIMES AND PERCENTAGE COMPOSITION OF CRUDE $Si(CH_3)_4$

Components		Retention time	Calculated composition
Peak No.	Compound	(min)	(%)
1	*n*-Butane	1.3	0.02
2	Tetramethylsilane	1.6	98.12
3	2-Methylpentane	2.8	0.29
4	3-Methylpentane	3.1	0.03
5	Tetrahydrofuran	3.8	1.52

Attempts to remove impurities by a fractional distillation or zone refining were unsuccessful, but they were completely removed by preparative scale gas chromatography. A Varian Aerograph Autoprep 712 preparative instrument with a hydrogen flame ionization detector was used to prepare a

total of 100 ml of pure $Si(CH_3)_4$ under the following conditions:

Column	3/8 in (O.D.) × 50 ft Silicone SE 30 (10%) on Chromosorb A (60—80 mesh)
Temperature	80°C
Carrier gas	Nitrogen at 150 ml/min.
Sample size	2.0 ml injected manually

No impurities of the collected $Si(CH_3)_4$ were detected by analytical gas chromatography. However, the amount of solid-insoluble liquid-soluble impurity was determined by the measurement of melting point, the purity being found to be 99.995_4 mol%.

Apparatus. A new calorimeter was constructed to measure the heat capacity of substances which are solid or liquid at room temperature in the range from 2 K to 150°C. In basic design the cryostat is similar to the adiabatic calorimeter for condensed gases described previously.[5] The general assembly is illustrated in Fig. 2. About three liters of liquid helium can be held by a coolant container F (brass cylinder) which allows measurement to continue for a period longer than 12 hours at low temperature. A thermal station E (copper cylinder) has an internal volume of about 500 cc, and can contain liquid helium in the measurements at low temperature. A heater (#34 manganin) is wound around E, and a difference thermocouple is placed between the thermal station and the top of an adiabatic shield B. Thermocouple junctions (chromel p—constantan) are provided at the bottom of F and at E for their absolute temperature measurements. All electrical lead wires come from the top of the cryostat through a stainless steel pipe at the center. They wound round the cylinder at the bottom of F and also round E and B, entering inside the shield through 30 holes drilled at the bottom edge of the side of the adiabatic shield. In assembly, an inside jacket G is soldered to the bottom of F and an outside jacket H to the top plate both with Wood's alloy or solder.

A sectional view of the calorimeter vessel, made of silver-plated copper (0.2 mm thick) and with an internal volume of about 60 cc, is shown in Fig. 3. It is hung by means of nylon cords within the adiabatic shield. Eight vanes are soldered inside the vessel. The cap of the vessel is made of Kovar and attached to a Pyrex glass tube through which the vessel can be evacuated and sealed in a vacuum. A platinum thermometer with a heater (#34 manganin, 65 Ω) wound on it is cast into a re-entrant well with Wood's alloy. A germanium thermometer is attached to the bottom of the vessel by means of a sheath (copper). The platinum resistance thermometer used above 13.5 K had been calibrated at the National Bureau of Standards (J. L. Riddle, 1959). The temperature scale was re-calculated on the International Practical Temperature Scale of 1968 by using the tables of differences between the NBS-55 scale, the IPTS-48 and the IPTS-68 derived by Douglas[6] and Bedford *et al.*[7] The germanium resistance thermometer (Cryocal, Inc.) which had been calibrated on the thermodynamic scale at the NBS (Jacquelyn A. Wise, 1969) was used in the temperature range below 13.5 K. All measuring operations of the heat input and the resistances of the thermometers were manually carried out. The monitoring and control of adiabatic conditions were automatically made.[2]

Results and Discussion

Heat Capacity of $Si(CH_3)_4$. The amount of sample in the calorimeter was determined to be 23.0475 g (=0.261233 mol, 35 cc) as liquid by measuring the filling weight. The measured values of heat capactiy in the region 2—26 K and in the premelting range are listed in Table 2. Corrections were made for curvature where necessary. At low temperature, temperature increments were about 0.3—1°. These increased to about 2° at higher temperature. The measurements of heat capacity below melting point were also made several times with various small temperature rise (0.1—0.8°) to determine detailed shapes of heat capacity curves for two crystalline forms in the premelting region. Equilibrium time after heating varied from less than one minute at low temperature to about 7—8 min at higher temperature. In the

vicinity of melting point and for the melting duration, it became about 14—30 min. We observed heat capacity anomaly to have a very large value (*i.e.* 49.69 cal/mol deg at 173.193 K for a stable form, and 135.4 and 308.7 cal/mol deg at 170.623 and 170.776 K for a metastable form). No hysteresis was observed.

Triple Points of Two Crystalline Forms of $Si(CH_3)_4$. When a sample of $Si(CH_3)_4$ is cooled from room temperature, it crystallizes in a metastable form and is then transforms into a stable form. The transition temperature is dependent upon the cooling rate.

The triple point of each form was obtained from a plot of equilibrium temperatures against reciprocals of the fraction melted. The result is summarized in Table 3. The triple point temperature for the sample of the stable form of $Si(CH_3)_4$ was found to be 174.049 K, and that of the metastable form 170.981 K. The values are also compared with those given by Aston *et al.* in Table 3.

Heats of Fusion of Two Crystalline Forms of $Si(CH_3)_4$. Data of the heat of fusion for the-two crystalline forms are summarized in Table 4 together with those obtained by Aston *et al.* The agreement is not very good, being beyond assigned uncertainties. This is probably due to the fact that it is difficult to estimate exactly a $\int C_p dT$ correction at temperatures slightly below melting point, because C_p value in the premelting range increases unusually with temperature, despite high purity of the

and unreasonable for the enthalpy of formation of vacancies as compared with the value of 3240±220 cal/mol obtained for neopentane. We attempted to interpret these values by assuming that $Si(CH_3)_4$ undergoes simultaneous positional and orientational transitions at melting point. According to a statistical treatment[8] of Ising lattice of three dimensions in terms of a series expansion method, the tail of heat capacity at sufficiently low temperature is given by the first term of low-temperature expansion:

$$C(\text{trans.}) \simeq (1/k)(E/T)^2 \exp(-E/(kT)), \quad (4)$$

where E corresponds to total (positional and orientational) energies of molecular interaction. It was also found by Aston *et al.*[3] that the height of potential barrier hindering internal rotation of methyl groups was considerably lower than that of neopentane. Thus, the values obtained may be regarded as the summation of the enthalpy of vacancy formation and the total energies of positional and orientational disordering of the molecules and internal rotation of methyl groups. However, it is very difficult to estimate each value from the summation without some information on crystal structure and molecular motions in the two forms of $Si(CH_3)_4$.

The calculation of the difference in entropy of metastable and stable forms at 170.981 K is summarized in Table 5. If the metastable form is cooled, it is transformed into the stable form with heat evolution. The entropy of transition is equal to the difference in the entropies of metastable and stable forms at transition temperature.

Table 5. Entropy difference between metastable and stable forms of Si $(CH_3)_4$

Low Temperature Heat Capacity of $Si(CH_3)_4$. Figure 6 gives a graph of heat capacity measurement for solid $Si(CH_3)_4$ expressed in the form C_p/T^3 *versus* T^2. In the region $T^2<10$ (*i.e.*, $T<3.1$ K), the experimental value of C_p/T^3 increases sharply as T decreases. The situation resembles that of CD_4 crystal in the region $T<20$ K reported by Colwell *et al.*[9] The anomalous shape of the graph of C_p/T^3 *versus* T^2 may be accounted for by a certain amount of crystalline disorder, removal of the spatial degeneracy by crystalline field, isotope effects of partially deuterated methyl groups and some experimental errors. However, it does not seem worthwhile to do any analysis of heat capacity at this stage without further evidence.

If we are to describe the extra contribution to heat capacity as a Schottky-type anomaly, the heat capacity may be separated into a T^{-2} term and normal lattice terms. In a graph of $C_p \times T^2$ versus T^5, the intercept is the coefficient of extra contribution in T^{-2} to the heat capacity. The value 0.0051052 was used for the coefficient derived from the heat capacity data. The calculated $(C_p - 0.0051052)/T^3$ values are shown as a dashed curve in Fig. 6. This curve continues to decrease and approaches a constant value asymptotically, as shown in usual crystals. The constant value obtained corresponds to the Debye characteristic temperature of 136.8±2.0° at 0 K, $\theta_D(0)$. In order to compare the temperature dependence of $\theta_D(T)$ assuming $6N$ degrees of freedom for $Si(CH_3)_4$ with those for $C(CH_3)_4$ and CF_4, the values of $\theta_D(T)$ were plotted against temperature on a reduced scale using the $\theta_D(0)$, as shown in Fig. 7. Here the mean intramolecular rotational frequency of the methyl group in $Si(CH_3)_4$, 170.5 cm^{-1}, obtained by Durig *et al.*[10] from their far-infrared spectrum, was used and $C_p - C_v$ correction was neglected. In Fig. 7 the shape of the $\theta_D(T)/\theta_D(0)$ curve for $Si(CH_3)_4$ is rather similar to that for $C(CH_3)_4$ and CF_4, although there are differences in detail. This seems to demonstrate that the $Si(CH_3)_4$ crystal does not differ from a tetrahedral plastic crystal. Only its transition point of orientational disordering is very close to melting point as observed in the premelting phenomena in the heat capacity curve.

The Crystal Structures of Methyl Bromide and Methyl Iodide

Takemi KAWAGUCHI,* Masaya HIJIKIGAWA, Yoshinori HAYAFUJI, Masashi IKEDA, Reizo FUKUSHIMA, and Yujiro TOMIIE†

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received May 6, 1972)

The crystal structures of methyl bromide and methyl iodide have been determined by the X-ray diffraction method at about −120°C and about −80°C respectively. Both the crystals are isomorphous, with orthorhombic space group D_{2h}^{16}—*Pnma*. Unit cells containing four molecules have the dimensions: $a=4.47_4(1)$, $b=6.42_0(2)$, and $c=9.15_0(1)$ Å for methyl bromide, and: $a=4.59_7(2)$, $b=6.98_7(1)$, and $c=10.11_7(1)$ Å for methyl iodide. These structures are quite different from that of methyl chloride, which has a symmetry of C_{2v}^{12}—$Cmc2_1$. In the three crystals, all the molecules are found on the mirror planes; the difference lies in the mutual orientations of the molecules.

As part of a series of investigations of various halogenated methanes, the crystal structures of methyl bromide and methyl iodide have been determined by the X-ray diffraction method. Since Burbank reported the crystal structure of methyl chloride,[1] several spectroscopists have discussed whether or not the crystal structures of methyl bromide and methyl iodide are isomorphous with that of methyl chloride.[2] The present authors will here report the crystal structures of these two compounds.

Experimental

Methyl bromide and methyl iodide, both from commercial sources (Tokyo Kasei Industries, Ltd. and Wako Pure Chemical Industries, Ltd., respectively), were purified repeatedly by recrystallization by cooling and by vacuum distillation, followed by sealing in thin-wall glass capillaries in vacuum (0.3 mm in internal diameter and 0.01 mm in wall thickness). The specimen was placed on an X-ray goniometer head and was crystallized by letting flow thereby a cold gas stream from liquid nitrogen. By means of careful temperature control, it was possible to grow a seed of a crystal very near to the size of the capillary at temperatures directly below the melting point (−93.7°C for methyl bromide and −66.5°C for methyl iodide); the crystal was then cooled gradually. It was found later that a single crystal of methyl bromide was grown with the [110] axis, and that a single crystal of methyl iodide was grown with the [100] axis, of the respective orthorhombic lattices nearly along the capillaries.

The cell dimensions of the two crystals were determined from oscillation and Weissenberg photographs around the axes mentioned above. These measurements were made at about −120°C for methyl bromide and at about −80°C for methyl iodide. From systematic extinctions ($0kl$ with $k+l$ odd and $hk0$ with h odd) and intensity distributions, both the crystals were found to belong to space group *Pnma* or $Pn2_1a$, with four molecules per cell. The crystal data for these two compounds are summarized in Table 1. The intensity data were collected by means of multiple-film oscillation photographs, using Ni-filtered Cu $K\alpha$ radiation; 212 independent reflections around the [110] axis for methyl bromide, and 177 such reflections around the [100] axis for methyl iodide, were used for the following analyses. The intensities measured visually were corrected for Lorentz-polarization and absorption effects by the cylindrical approximation, after which they were brought into respective common scales by considering different time exposures.

Structure Determination and Results

Approximate co-ordinates of the halogen (bromine or iodine) and carbon atoms, deduced from the three-dimensional Patterson diagrams, indicated that these atoms lie on the mirror planes given by the space group *Pnma*. Least-squares refinement, omitting the hydrogen atoms, was applied by using isotropic temperature factors. No positive evidence was found that the space group should not be *Pnma*. The discrepancy indices, $R=\sum||F_o|-|F_c||/\sum|F_o|$, dropped to 0.11 for methyl bromide and to 0.12 for methyl iodide.

The observed and calculated structure factors are listed in Table 2, while the final sets of the positional and thermal parameters of the halogen and carbon atoms are listed in Table 3. The two crystal structures are isomorphous, having the symmetry D_{2h}^{16}-*Pnma*. There are four molecules in each unit cell. The halogen and carbon atoms lie on the mirror planes. Figure 1 shows a schematic drawing of the molecular

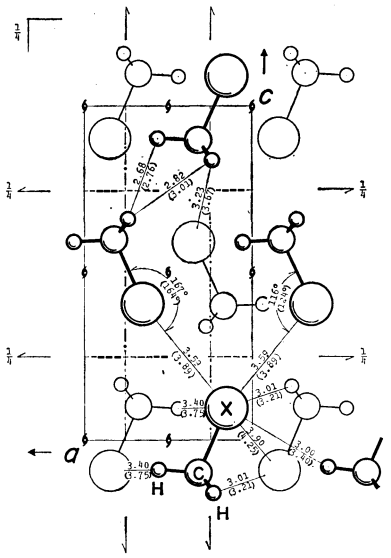

Fig. 1. Schematic drawing of the crystal structure of methyl bromide and methyl iodide, projected along the b axis. Interatomic distances and angles between neighboring molecules for methyl bromide and those for methyl iodide (in parentheses) are given.

arrangement of the two crystals, projected along the b axis. In this figure, an assumed orientation of the methyl group, as will be described later, is given, and the interatomic distances and angles between neighboring molecules for methyl bromide and those for methyl iodide (in parentheses) are given.

The bond distances between the halogen and carbon atoms are found to be $1.86_3\pm0.04$ for Br–C and $2.13_4\pm0.06$ Å for I–C. The corresponding values obtained by a microwave study[4] in the gaseous state are 1.9391 and 2.1392 Å. Because of the large e.s.d.'s of the carbon positions, it can not be said that these bond distances are different in their gaseous and crystalline states.

Each halogen atom is in contact with two halogen atoms of the neighboring molecules lying on the same mirror plane, with distances of 3.587 ± 0.008 for Br···Br and 3.895 ± 0.010 Å for I···I. These distances are much shorter than twice the conventional van der Waals radii, 3.90 for the bromine atom and 4.30 Å for the iodine atom. The juxtaposition of the molecules is such that:

	∠ C–X···X
Methyl bromide	116° and 167° ± 1°
Methyl iodide	124° and 164° ± 2°,

where X denotes the halogen atom. It should be noted that the smaller values, 116° and 124°, can be compared to the sp^3 tetrahedral angle, while the larger ones are not far from 180°.

Discussion

Egan and Kemp[5] have reported that there is a first-order phase transition in the crystal of methyl bromide, occurring at −99.4°C with a latent heat of 0.113 kcal/mol. Although the present structure determination was carried out for the crystal at about −120°C, much lower than the transition point, it might have been of a supercooled form of the high-temperature one (α). In order to clarify this question, the following experiment was carried out.

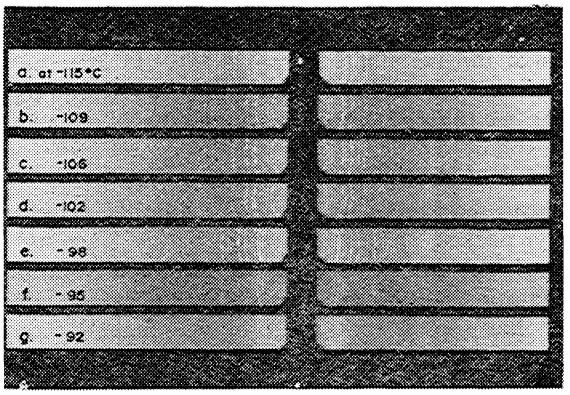

Fig. 2. Powder patterns for methyl bromide at various temperatures. a–d correspond to the low-temperature phase, e and f to the high-temperature phase, and g to the liquid phase.

A polycrystalline specimen of methyl bromide was heated to almost its melting point (−93.7°C), then cooled slowly, and subsequently repeatedly warmed-up and cooled-down. Powder patterns, given in Fig. 2, were taken at several temperatures, from −120° to −90°C. These patterns clearly show the existence of the phase transition between the temperatures of −102° and −98°C. The low-temperature phase (β) was identified as the crystal structure described in the previous section. The crystal structure of the high-temperature phase (α) must be of a form related to that of the low-temperature form, since the heat of transition is very small.

It is found that the crystal structure of methyl bromide (β) and methyl iodide are isomorphous and that they are quite different from that of methyl chloride. The crystal of methyl chloride is orthorhombic, with a tetramolecular cell with dimensions of a=6.495, b=5.139, and c=7.523 Å, and it belongs to space group C_{2v}^{12}—$Cmc2_1$.[1] However, if one replaces the methyl group by its counterpart halogen atom, the three

5) C. J. Egan and J. D. Kemp, *J. Amer. Chem. Soc.*, **60**, 2097 (1938).

crystal structures will become almost the same as the structures of solid halogen crystals, Cl_2, Br_2, and I_2, which are known to be isomorphous.[6] The difference between the crystal structure of methyl chloride and those of methyl bromide and methyl iodide can be seen in the mutual orientation of the molecules. In the crystal of methyl chloride, the molecules lying on the mirror plane are aligned head to tail and are parallel with the molecules lying on the adjacent mirror planes. On the other hand, in the crystals of methyl bromide (β) and methyl iodide, the molecules lying on the mirror plane are aligned head to head and are antiparallel with the molecules lying on the adjacent mirror planes.

It was previously inferred by one of the present authors[7] that, in the crystals of Br_2 and, particularly, I_2, partial covelency, based upon the charge transfer from the $p\pi^*$- to the $p\sigma^*$-orbitals between the neighboring molecules lying on the mirror plane, plays a part in the intermolecular bonding. In the crystals of methyl bromide (β) and methyl iodide also, the mutual orientation of the molecules lying on the mirror planes seems to favor a covalent bonding between the halogen atoms of the neighboring molecules. It may be suggested that this intermolecular bonding is responsible for the exceedingly short distances for X···X; it can also explain why those crystal structures differ from that of methyl chloride.

As can be seen in Fig. 1, the methyl groups are loosely packed in the structures; this suggests that these groups are in a state of hindered rotation or reorientation. Indeed, an NMR study[8] of methyl iodide has shown that the observed second moment, ΔH_2^2, at -183°C is 8.4 gauss^2 and that the rotation sets in at about -150°C, where the line width, δH, decreases from 5 to 3 gauss. When an NMR study of powdered specimen of methyl bromide was carried out, it showed that an appreciable rotation of the methyl group occurred from its melting point down to the boiling point of liquid nitrogen. The line width, $\delta H \approx 4.7$ gauss, and the second moment, $\Delta H_2^2 \approx 7.5$ gauss^2, remain constant in this temperature range. Here, the theoretical values for the second moment are 27.6 and 5.0 gauss^2 for the stational and rotational states respectively. Figure 1 gives the most stable orientation of the methyl group, as suggested by the lattice-energy calculations.[9]

The actual alignment of molecules should correspond to the potential energy minimum. By keeping the unit-cell dimensions and the crystal symmetry, variations in the potential energies with the positional and orientational parameters of the respective molecules, which are X, Z, and θ for methyl bromide and methyl iodide and Y and θ for methyl chloride, were calculated by means of the lattice-energy calculations, as cited in the previous paper.[9] It was found that the potential minima based upon the rotational models of the methyl groups are in better agreement with the respcetive molecular arrangements than those based upon the stational models. Burbank assigned the crystal structure of methyl chloride the stational orientation of the methyl group by comparing the observed structure factors. However, it can be expected from the lattice-energy calculations that the rotation of the methyl group also occurs in the crystal of methyl chloride.

The authors wish to thank Professor Tokunosuké Watanabé for his helpful discussions during the preparation of this manuscript. They are also indebted to Dr. Akio Furusaki and Mr. Hiroyuki Utsumi for their assistance in these analyses, and to Dr. Asako Kawamori for her assistance in the NMR measurements.

The Crystal Structures of Methylene Dibromide and Methylene Diiodide

Takemi KAWAGUCHI,* Akira WAKABAYASHI, Mitsuhiro MATSUMOTO,
Toru TAKEUCHI, and Tokunosuké WATANABÉ
Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received May 6, 1972)

The crystal structures of methylene dibromide and methylene diiodide (Form II) have been determined by the X-ray diffraction method at about −90°C and about −20°C respectively. Both the crystals are isomorphous, with monoclinic space group C_{2h}^6-C2/c. Unit cells containing eight molecules have these dimensions: $a=12.239$ (12), $b=4.459(15)$, $c=15.212(16)$ Å, and $\beta=113.54(7)°$ for methylene dibromide, and $a=13.346(3)$, $b=4.720(90)$, $c=16.479(5)$ Å, and $\beta=114.48(8)°$ for methylene diiodide. The orientations of the methylene groups have been obtained by lattice-energy calculations.

As part of a series of investigations of molecular interactions on various halogenated methanes, the crystal structures of bromoform,[1] iodoform,[2] methyl bromide and methyl iodide[3] have already been reported. It has been found that bromoform and iodoform are isomorphous, and that methyl bromide and methyl iodide are also isomorphous, but their chlorine congeners have quite different structures. In this and succeeding papers, the crystal structure sof methylene diiodide, methylene dibromide, and methylene dichloride will be reported.

Marzocchi *et al.*[4] ascertained, by their spectroscopic studies, that methylene diiodide exists in two solid phases; one is a metastable form, I, melting at 5.54°C, while the other is a stable form, II, melting at 6.01°C; Form I is easily and irreversibly transformed to Form II at temperatures above 0°C. They also reported that methylene dibromide and methylene diiodide (II) are isomorphous and have a structure based on $P2_1/c$, while methylene dichloride has a structure based on *Pbcn*.

Experimental

Methylene dibromide and methylene diiodide from Nakarai Chemicals, Ltd., were purified by vacuum distillation and were sealed in thin-wall glass capillaries (0.3 mm in internal diamter and 0.01 mm in wall thickness). A single crystal was carefully produced in a way which has previously been described.[1,3] In all the experiments on these two crystals thus far carried out, it has been found that only one kind of zone axes grows nearly along the capillaries. This is the [010] axis of a monoclinic lattice. The single crystal obtained was gradually cooled to about −90°C for methylene dibromide and to about −20°C for methylene diiodide for the taking of oscillation and Weissenberg photographs.

The cell dimensions of both the crystals were determined from oscillation and Weissenberg photographs taken around the [010] axis, using Cu $K\alpha$ radiation. Intensity distributions and systematic extinctions ($h+k$ odd for hkl and l odd for $h0l$) showed that the crystals belong to space group Cc or $C2/c$, with eight molecules per cell. The crystal data are summarized in Table 1. The densities calculated are much larger than that for liquid, much as in the cases of bromoform, methyl bromide, and methyl iodide. These intensity distributions and the cell dimensions strongly suggest that the two crystals are isomorphous.

$\mu=274.0$ cm^{-1} (Cu $K\alpha$)	$\mu=1121.2$ cm^{-1} (Cu $K\alpha$)
	139.2 (Mo $K\alpha$)

Integrated intensities were collected by means of the multiple-film method and the equi-inclination Weissenberg technique, using Ni-filtered Cu$K\alpha$ radiation for methylene dibromide and Zr-filtered Mo$K\alpha$ radiation for methylene diiodide. Here, the intensity data for methylene diiodide were recorded jointly by means of different time exposures. Reflections were observed up to the third layers around the [010] axes, though for methylene dibromide, 205, and for methylene diiodide, 244 independent reflections from the zero-th and first layers were used in order to determine the respective structures. The intensities were measured visually and corrected for Lorentz-polarization and absorption effects with the cylindrical approximation; then the intensities were brought into respective common scales by considering them at different time exposures.

Structure Determination

Approximate co-ordinates of the iodine atoms of methylene diiodide were found from the Patterson diagrams. With isotropic temperature factors, these

co-ordinates were refined by the least-squares method, based upon the centrosymmetric space group, $C2/c$. The reliability factor, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$, dropped from 0.25 to 0.16. The difference Fourier synthesis gave merely a hint of the position of the carbon atom. Further refinement was applied in order to determine the positions of the iodine atoms with anisotropic temperature factors, where the anomalous dispersion effect was considered. The R values were finally indicated to be 0.12.

Another refinement based upon the non-centrosymmetric space group, Cc, was made in parallel. However, this gave no significant improvement. It was, therefore, concluded that the crystal structure of methylene diiodide belongs to the space group C_{2h}^6—$C2/c$.

The crystal structure determination of methylene dibromide was started using the least-squares method by substituting the final co-ordinates of the iodine atoms of methylene diiodide for those of the bromine atoms. The R value was about 0.3 at the begining and decreased to 0.25 with isotropic temperature factors of bromine atoms, where the anomalous dispersion effect was also considered. The difference synthesis gave merely a diffuse indication of the position of the carbon atom, much as for methylene diiodide. The least-squares refinement with anisotropic temperature factors for the bromine atoms reduced the R value to 0.21.

Results and Discussion

X-Ray Analysis. The observed and calculated structure factors are listed in Table 2, and the final sets of the positional and thermal parameters of the halogen atoms are summarized in Table 3. The two crystal structures are isomorphous, with the symmetry of $C2/c$. As has been mentioned in the previous section, Marzocchi *et al.* reported that the crystal of methylene diiodide has two forms, I and II, and that Form II is isomorphous with the crystal of methylene dibromide.[4] In view of our experimental procedure in obtaining the single crystal, the measurement for methylene diiodide must have been carried out on the stable form, II.

The interatomic distances for X···X in the molecules, where X denotes the halogen atom, are calculated to be 3.17 ± 0.02 Å for methylene dibromide and 3.56 ± 0.01 Å for methylene diiodide. These values are in excellent agreement with those given by electron dif-

fraction studies for the gaseous state—3.16_4[5] and 3.57_0 Å[6] (see Table 4). It may, therefore, be permissible to assume a rigid molecule in these crystals. Schematic drawings of the crystal structures of methylene dibromide and methylene diiodide are given in Figs. 1 and 2. Figure 1 is the projection of the structure on the (010) plane, and Fig. 2, the bounded projection on the (001) plane of the molecules lying in $Z\approx\pm0.13$. In these figures, the orientations of the methylene groups shown are those derived by the following lattice-energy calculations.

Lattice-energy Calculations. Though the carbon atoms of the two crystals were not located accurately on the basis of the X-ray intensity data, the most probable positions of these atoms could be derived by the following two methods. The first was to find the most plausible orientation of the methylene groups among their neighboring molecules. When the positions of the halogen atoms in the unit cell are accurately known, intermolecular atomic contacts can be obtained for various orientations by subjecting a rotation, θ, around the axis connecting the two halogen atoms,

a) Assumed.
b) Calculated by the present authors.

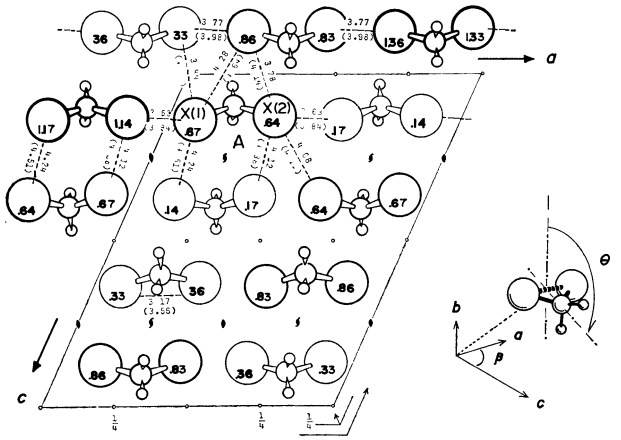

Fig. 1. Schematic drawing of the crystal structure of methylene dibromide and methylene diiodide, projected along the b axis. Numbers within circles indicate fractional co-ordinates, Y, of the iodine atoms. Interatomic distances for methylene bromide and those for methylene iodide (in parentheses) are also given.

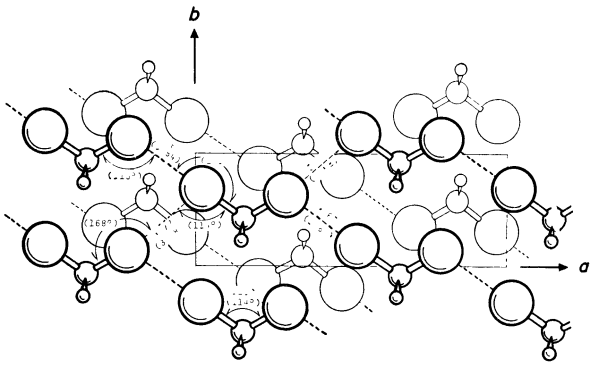

Fig. 2. Bounded projection of the crystal structure on the (001) plane. Molecules lying in $Z\simeq 0.13$ are drawn with thick lines and those lying in $Z\simeq -0.13$ with thin lines. Interatomic distances and angles for methylene dibromide and those for methylene diiodide (in parentheses) are also given.

X(1)···X(2), of a reference molecule, **A** (see Fig. 1), accompanied by the rotations of other molecules around their similar axes in accordance with the symmetry of the space group $C2/c$. The starting point of θ is taken as the orientation where the X–C–X plane of the **A** molecule is parallel to the b axis. Figure 3 shows the variations with θ of a number of contacts. (a) indicates methylene dibromide, and (b), methylene diiodide. Both of them indicates that the most plausible orientation located in the vicinity of $\theta\approx 190°$.

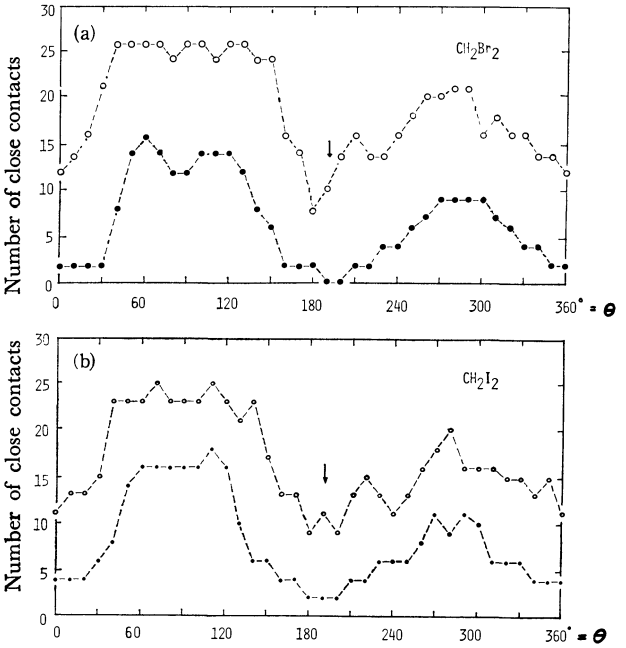

Fig. 3. Variation of number of contacts between neighboring molecules less than the van der Waals contacts, plotted by curve —○—. Curve—●— shows comparison with the van der Waals contacts multiplied by 0.9.
(a) for methylene dibromide and (b) for methylene diiodide.

The most reasonable orientation of the methylene group can also be found quantitatively by obtaining the potential energy minimum of the crystal, which can be calculated from the molecular interactions. Here, it is assumed that the potential energy can be described by the dispersion, the exchange repulsive, the dipole-dipole coupling, and the induced dipole interactions. Calculations were carried out by using Eq. (2) and the constants of A_{ij}, B_{ij}, and C_{ij}, which have been given in a previous paper,[1] together with the following constants:

Molecule	Dipole moment (debye)	Molecular polarizability (10^{-24} cm^3)
CH_2Br_2	1.39	8.30
CH_2I_2	1.10	11.84

The rotating scheme about the methylene group is the same as that described above.

In Fig. 4, (a) and (b) show the variations in the interaction energies for methylene dibromide and for methylene diiodide respectively. One can find results similar to those indicated in Fig. 3; the most probable orientation of the methylene group was found in the vicinity of $\theta\approx 190°$ for both the crystals. In Table 4 the positional parameters of the carbon and hydrogen atoms corresponding to the $\theta=190°$ orientation are given. As has been mentioned ealier, the X-ray intensity data were not sufficient to be used in the refinement

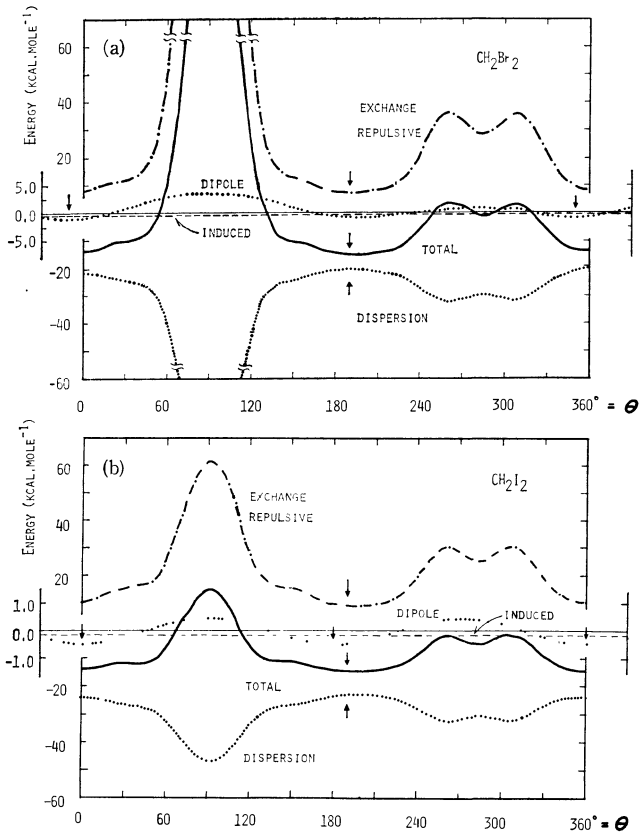

Fig. 4. Variations of the interaction energies with rotation θ. (a) for methylene dibromide, and (b) for methylene diiodide.

of the structures. In these orientations, the lattice energies arising from the four kinds of interaction amount to 14.4 for methylene dibromide and to 14.3 kcal/mol for methylene diiodide. The lattice energy of methylene diiodide can be compared with the sum of the experimental heats of vaporization, 10.2, and of fusion, 3.00 kcal/mol, for the stable form, II.[7] Most of the energies calculated came from the dispersion and the exchange repulsive interactions (see Table 5). As is shown in Fig. 4, the orientation of the methylene group is dominated by the repulsive term.

7) "Amercican Institute of Physics Handbook," McGraw-Hill Book Comp. Inc. (1957).

Table 5. Calculated lattice energies for the most probable orientation, $\theta=190°$, of the methylene group (in kcal/mol)

Compound	Dispersion	Exchange repulsive	Dipole dipole	Induced dipole	Total
CH_2Br_2	−20.57	7.24	−0.82	−0.26	−14.41
CH_2I_2	−23.06	9.35	−0.40	−0.15	−14.26

The crystal structure can be described as a sort of a layer structure parallel to the (001) plane. The X–C–X planes of all the molecules lie nearly on the layer planes. As can be seen in Fig. 1, the orientations of the molecular axes or the dipoles in the two immediate layers are almost parallel and almost antiparallel respectively.

Within the layer, the molecules are held together by noticeable short contacts. The interatomic distances between halogen atoms are 3.63 and 3.77 Å for Br···Br, and 3.84 and 3.98 Å for I···I; these are far less than twice the van der Waals radii, 3.90 for bromine and 4.30 Å for iodine. The two kinds of angles, C–X···X, between the neighboring molecules are not far from 90° (or the tetrahedral angle, 109.5°) and 180°. The quite close contacts and the characteristic geometries presented above with regard to the halogen atoms can be seen in other crystals, for example, solid bromine and iodine,[8] methyl bromide and methyl iodide,[3] and bromoform[1] and iodoform.[2] The partial intermolecular bonding effect between the bromine and, particularly, iodine atoms, which was suggested by Tomiie,[9] may contribute appreciably to the molecular arrangements of simple molecules with bromine or iodine atoms.

The authors wish to express their thankfulness to Dr. Akio Furusaki and Dr. Akio Takenaka for their help in these analyses.

The Crystal Structure of Methylene Dichloride, CH_2Cl_2

Takemi KAWAGUCHI,* Kazuo TANAKA, Toru TAKEUCHI, and Tokunosuké WATANABÉ
Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received May 6, 1972)

The crystal structure of methylene dichloride has been determined by the X-ray diffraction method at about −120°C. The structure has a symmetry D_{2h}^{14}—*Pbcn*, and its orthorhombic tetramolecular cell has these dimensions: $a=4.249\pm0.001$, $b=8.138\pm0.020$, and $c=9.492\pm0.002$ Å. The positional parameters of the chlorine and carbon atoms are obtained by a three-dimensional Patterson function, followed by a least-squares refinement including the hydrogen atom. The structure thus obtained is in excellent agreement with the results of lattice-energy calculations. The crystal structure is quite different from that of methylene dibromide (and of methylene diiodide).

The crystal structures of various halogenated methanes have been reported on in previous papers in order to elucidate the molecular interactions in these molecular crystals. It has been shown that, in the crystals of mono- and tri-halogenated methanes, CH_3X and CHX_3, those of bromine- and iodine-substituted methanes are isomorphous, while those of chlorine-substituted methanes are quite different.[1-3]

Marzocchi *et al.* reported, based upon their spectroscopic measurements, that the crystals of methylene dibromide and the stable form of methylene diiodide, Form II, are isomorphous, but not with that of methylene dichloride.[4,5] In the preceding paper, it has been shown that the crystals of methylene dibromide and methylene diiodide (II) are isomorphous, with a symmetry C_{2h}^{6}—$C2/c$.[6]

In this paper the crystal structure of methylene dichloride, as determined by the X-ray diffraction method, will be reported. It will also be shown that the structure is in good agreement with that derived by means of lattice-energy calculations.

Experimental

Methylene dichloride from Wako Pure Chemical Industries, Ltd., was sealed in thin-wall glass capillaries (0.3 mm in internal diameter and 0.01 mm in wall thickness). A single crystal was carefully produced in the way described in previous papers.[1,3] The crystal used grew with the [010] zone axis of an orthorhombic lattice nearly along the capillary, and was then gradually cooled to about −120°C.

The unit-cell dimensions were determined from oscillation and Weissenberg photographs around the [010] axis taken by using Cu$K\alpha$ radiation. The intensity distributions and systematic extinctions (none for *hkl*, *0kl* with *k* odd, *hk0* with $h+k$ odd and *h0l* with *l* odd) indicated that the crystal belongs to the orthorhombic system, with a symmetry of space group D_{2h}^{14}—*Pbcn*. There are four molecules per cell and the X-ray density amounts to 1.718 g/cm³, where the observed densities, 1.327 at 20° and 1.761 g/cm³ at −194°C,[7] are referred to. The crystal data are summarized in Table 1.

Table 1. Crystal data

Compound	methylene dichloride, CH_2Cl_2
MW	84.83
Bp	39.95°C
Mp	−96.8°C
Exp. temp.	−120°C
Orthorhombic; D_{2h}^{14}—*Pbcn*	
Z	= 4
a	$=4.249\pm0.001$ Å
b	$=8.138\pm0.020$
c	$=9.492\pm0.002$
V	=328.21 Å³
D_x	=1.718 g/cm³
D_m	=1.327 (at 20°C)
	1.761 (at −194°C)
μ	=153.2 cm⁻¹ (for Cu$K\alpha$ radiation)

Integrated intensities of reflections, taken from six layers between the zeroth and the fifth layers around the [010] axis, were collected by means of the multiple-film method and the equi-inclination Weissenberg technique. The X-rays used were Ni-filtered Cu$K\alpha$ radiations. The intensities were measured visually and were corrected for Lorentz-polarization and absorption effects by cylindrical approximation, followed by bringing them into a common scale by considering with different time exposures. Inorder to determine the structure, 226 independent reflections were used.

Structure Determination

Since the crystal has the symmetry *Pbcn*, each molecule should be located on the C_2 site in the tetramolecular cell. Approximate co-ordinates of the chlorine and carbon atoms were immediately found with the aid of the three-dimensional Patterson function. A least-squares refinement was made for these co-ordinates with isotropic temperature factors. The reliability factors, $R=\sum||F_o|-|F_c||/\sum|F_o|$, decreased from 0.25 to 0.17.

Further refinement was made for the relative scales of the intensities from the six different layers, followed

by the least-squares refinement, where the anomalous dispersion effect was taken into consideration for the chlorine atom. The difference Fourier synthesis indicated the probable coordinates of the hydrogen atoms. Successive refinement with anisotropic temperature factors for the chlorine and carbon atoms and with an isotropic temperature factor for hydrogen atom finally decreased the R value to 0.109.

Results

The observed and calculated structure factors are

a) **A** and **B** denote the structures obtained by the lattice energy calculations.

given, one can describe the crystal structure, by using two structural parameters, Y and ϕ, where Y is the co-ordinate of the carbon atom, and ϕ, the angle of tilt of the reference molecule located on the two-fold axis, as is shown in Fig. 1. Lattice-energy calculations were made by using four kinds of molecular interactions; the dispersion, the exchange repulsion, the dipole-dipole coupling, and the induction effects, using the constants cited in the previous paper,[1)] together with a dipole moment of 1.62 Debye and a molecular polarizability of 6.48×10^{-24} cm^3. Calculations of the dipole-dipole interaction were carried out for every pair of molecules within a range of 40 Å, while those of the other three interactions were carried out for every pair of atoms within a range of 20 Å. The dipole-dipole interactions between eight nearest neighboring molecules were substituted for interactions between the divided bond moments (referred to 2.3 for $C^{(+)}-Cl^{(-)}$ bond and 0.4 debye for $C^{(+)}-H^{(-)}$ bond[9)]).

A potential map, $U(Y,\phi)$, was obtained; it is given in Fig. 3. Contours with solid lines are located at 1 kcal/mol intervals, while contours with dashed lines show the positive energy region, being at 25 kcal/mol intervals. Two stable structures were found as deep ravines, **A** and **B**, in the map, (Ravine **A'** is crystallographically equivalent to **A**): $U_A(Y=0.0,\ \phi=35°)=-13.08$ and $U_B(Y=0.25,\ \phi=35°)=-13.03$ kcal/mol. The present X-ray analysis gives a structure which is very close to Structure **A**, corresponding to $Y=0.030_7\pm0.003$ and $\phi=32.3\pm0.1°$, as is indicated by **X** in the map.

The lattice energy for the structure obtained by the X-ray analysis, together with those for Structures **A** and **B**, are given in Table 5. In this table, the lattice energies calculated for the crystals of methylene dibromide and methylene diiodide are also summarized for the sake of comparison.

Discussion

On the basis of an infrared spectroscopic study,[5)] Marzocchi and Manzelli reported that all the observed data on methylene dichloride are consistent with an orthorhombic *Pbcn* unit cell, in which four molecules are located on C_2 sites and tilt their symmetrical planes at $29\pm2°$ from one of the crystal axes. These spectroscopic conclusions, except for the mutual molecular arrangement, are in excellent agreement with those of the present work.

The potential map, $U(Y,\phi)$ in Fig. 3, suggests another probable crystal structure corresponding to the ravine, **B**. This structure can be derived from Structure **A** by a translation (0.25) of Y, while keeping ϕ constant. This structure can also be looked upon as being derived by orienting every molecule inversely along the *b* axis. It might be possible to obtain crystals with this structure by means of different procedures of crystallization.

The crystal structures of methylene dibromide and methylene diiodide, which are isomorphous with the symmetry *C2/c*, are quite different from that of methylene dichloride. The lattice energies calculated for the two crystals are added in Table 5. It is noticeable that the contribution of the dipole-dipole interactions in the crystal of methylene dichloride is much larger than those in the crystals of methylene dibromide and methylene diiodide. This suggests that the dipole-dipole interactions play an important role upon solidification, leading to a different crystal structure from those of methylene dibromide and methylene diiodide.

The authors are indebted to the Kwansei Gakuin University Computing Center for calculations.

The Vacuum Ultraviolet Photolysis of Liquid *n*-Hexane in the Presence of SF_6

Vadim I. PITCHOOZHKIN,* Hideo YAMAZAKI, and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received May 10, 1972)

The photolysis of liquid *n*-hexane has been studied at room temperature and at −78°C by using the resonance lines of Xe and Kr. The main process is hydrogen detachment, giving the same amount of hydrogen and of hexenes; relatively small amounts of the decomposition and dimer products were also formed. Upon the addition of SF_6, the yield of the hydrogen detachment decreased strongly with an increase in the concentration of SF_6, and then approached a constant value of 0.65 relative to that in pure *n*-hexane. The total amount of fluorine-containing products detected in the presence of SF_6 was relatively small compared with the amount of the decrease in the hydrogen detachment. As another electron scavenger, $C_6H_{13}F$ was also tested; here, the decrease in the hydrogen detachment was quite small.

The ionic process in the radiolysis of hydrocarbons is one of the most important problems in radiation chemistry; as chemical approaches to this problem, various charge scavengers are used to elucidate the reaction mechanism.[1,2] By using this technique, a number of interesting results, such as the existence of ion-molecule reactions in liquid hydrocarbons,[3] have been obtained. However, the charge scavengers added may possibly react as radical scavengers or as deactivators of the excited states.[4] For quantitative experiments, the suitability of the charge scavenger should, therefore, be tested by using various methods. Along those lines, Holroyd[5,6] examined the energy-transfer process by using vacuum ultraviolet light in the system of liquid cyclohexane with N_2O; he observed a marked decrease in the photoproducts upon the deactivation of the solute. Lipsky and Hirayama[7-10] found that the donor fluorescence state in a hydrocarbon solution of the scintillator was deactivated by the addition of various electron scavengers, such as O_2, SF_6, N_2O, and CO_2. These experiments seem to indicate that the excited states of hydrocarbons can be quenched by electron scavengers. However, the details of this process are still unknown, so the present experiment was undertaken in order to clarify this process and to find ideal electron scavengers.

Experimental

The Xe and Kr lamps were constructed by the usual method.[11] The LiF window of the lamps was jointed with Araldite, and a Ba getter was used to obtain an intense resonance line by the removing impurity lines. The Xe and Kr lamps were operated with a microwave generator of 2450 MHz and 200 W made by the Ito Chotanpa Co. The intensities of the lamps were about $10^{15}-5\times10^{14}$ photon/sec, depending on the diameter of the lamps.

A sample of *n*-hexane (99.99% purity) was obtained from the Phillips Co.; it was purified by passing it through $Mg(ClO_4)_2$ and NaOH column to remove any CO_2 and H_2O and then led into the reaction vessel through a greaseless stopcock. SF_6 of a spectroscopic purity obtained from the Takachiho Co. and $C_6H_{13}F$ (purum) obtained from the Fluka A. G. Co. were used as electron scavengers without any further purification. The concentrations of SF_6 in the liquid *n*-hexane in the samples were determined by means of the partition ratios of SF_6 between the gas and liquid phases at room temperature and at −78°C, as measured by the use of a large amount of *n*-hexane.

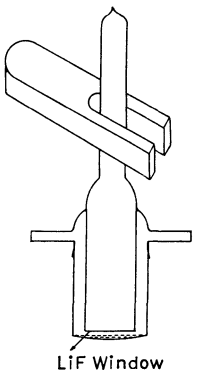

Fig. 1. Apparatus of photolysis in liquid phase.

The apparatus for the photolysis of liquid *n*-hexane is shown in Fig. 1. In the present experiment, the distance between the outer surface of the LiF window and the liquid surface was maintained at about 1 mm. Some experiments were also carried out by placing the LiF window in contact with the liquid surface. In the former case, the temperature of the reaction system was kept at −78°C to prevent direct photolysis in the gas phase. The intensity of light absorbed in the case of −78°C was fairly constant compared with that in the latter case.

After each run, the reactant and the products were condensed in a liquid-nitrogen trap. The noncondensable gases were gathered and measured by means of a Teopler-McLeod

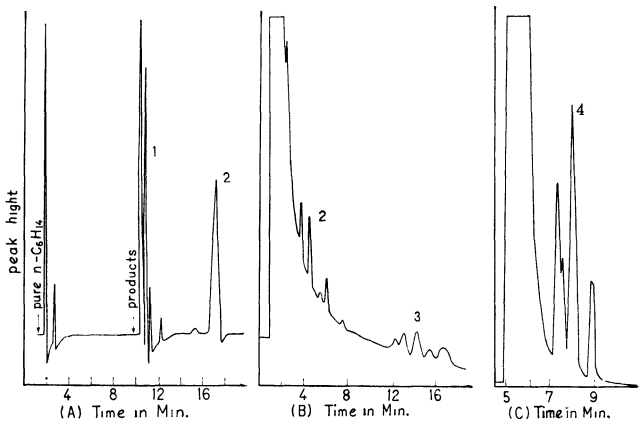

Fig. 2. Gas chromatogram of condensable products.

system. The noncondensable gases were mainly hydrogen. The condensable products, such as olefins and dimers, were analyzed by means of a Shimadzu gas chromatograph (Silicone D.C. 550, 5 m at 140°C and dimethyl sulpholane (10 m) at room temperature), equipped with a flame ionization detector. A Shimadzu electron-capture gas chromatograph was also used to detect the fluorine-containing products. The gas chromatograms of the condensable products are shown in Fig. 2, where (A) stands for the electron-capture detector, and where (B) and (C) indicate the flame-ionozation detector. The two peaks, Peak 1 and Peak 2, of the fluorine-containing products are magnified by the use of the electron-capture detector.

Results and Discussion

In the photolysis of liquid *n*-hexane, the main products were hydrogen and hexenes in almost identical amounts; small amounts of dimers and the decomposition products were also found. This means that the molecular detachment of hydrogen is the main process, unlike the radiolysis, where the hydrogen-atom splitting is the more important process. No difference was observed in the products between the Xe and Kr resonance lines. Holroyd[6] obtained almost the same results in his photolysis of liquid cyclohexane.

In the presence of SF_6, the relative yields of the major products, *i.e.* hydrogen and hexenes, decrease greatly, as is shown in Fig. 3. For sufficiently high

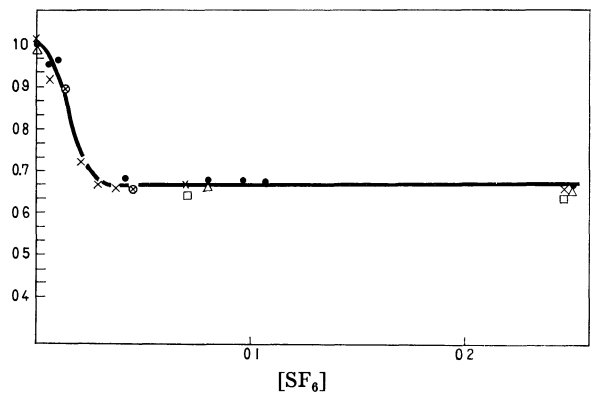

Fig. 3. The relative yields of hydrogen (●1470 Å, ×1236 Å) and hexenes (△1470 Å, □1236 Å) as a function of concentration of SF_6.

concentrations of SF_6, the yields of hydrogen and the total hexenes approach a constant value (*ca.* 0.65 relative to that of pure hexane), irrespective of the Kr and Xe resonance lines; a preliminary experiment with the Br resonance line showed the same tendency. The photolysis of *n*-hexane in the gas phase was also carried out, but no decrease in the relative yield was observed upon the addition of SF_6. As one possible mechanism, the energy transfer between *n*-hexane molecules may occur faster in the liquid phase than in the gas phase, and then the energy may be trapped by SF_6. The energies of the Kr (1236 Å), Xe (1470 Å), and Br (1634 Å) resonance lines are 0.4, 2.0, and 2.8 eV below the ionization potential of *n*-hexane. The Xe and Kr resonance lines may be able to excite the *n*-hexane molecule in the semi-ionized states or in locally-ionized states.[12]

The experimental results are quite similar for both the Xe and Kr resonance lines, indicating that the main process is the molecular detachment of hydrogen, which was often observed in the lower excitation of paraffins in the gas phase. As a general rule in the photolysis of paraffins, it was observed that the ratio of the atomic and molecular detachments of hydrogen increased with an increase in the photon energy.[14] Slightly below the ionization potential, the radius of the wave function of the excited electron is quite large; for example, the maximum of the radial-distribution function of the hydrogenic 2*s* orbital is five times larger than that of the 1*s* orbital. In liquid paraffin, the Onsager radius is several hundreds Ångstrom, so that within this radius the probability of geminate recombination is larger than that of free-ion formation. The states in which electrons reside between the Onsager radius and a radius several times larger than the radius of the ground state of a molecule may be called semi-ionized or locally ionized states, and a number of molecule may be present inside the orbital. When an electron approaches the positive ion, thus decreasing the radius of the orbital and the kinetic energy, the electron may enter into the lower excited state of the neutral molecule, where the molecular detachment of hydrogen, then takes place, as in the case of the photolysis of the gas phase.[14] Since the photolysis products in the liquid phase were quite similar to those in the gas phase, the same precursor of the reaction can be expected in both phases, as in the case of cyclohexane.[6] The preliminary experiment on the Br resonance line also shows the same dependence of the hydrogen-molecule splitting on the concentration of SF_6. The absorption coefficient of hexane is quite large at 1470 and 1236 Å, while that of SF_6 is relatively small.[15,16] Therefore,

12) The Br resonance line excites the *n*-hexane molecule to the first singlet excited state (8.2 eV (calcd), 8.3 eV (obsd)).[13]

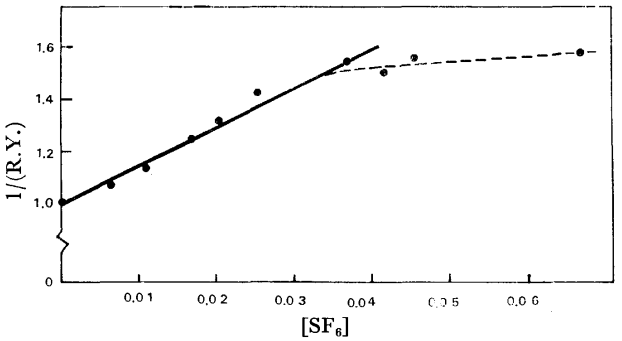

Fig. 4. The reciprocal plot of relative yields of hydrogen against concentration of SF_6.

the direct absorption of light by SF_6 is negligibly small.

In Fig. 4 the reciprocal relative yields (1/R.Y.) of the hydrogen detachment are plotted against the concentration of SF_6. A nearly straight line (solid line) is obtained for lower concentrations of SF_6. If the following reactions are postulated:

$$RH + h\nu \xrightarrow{k_1} RH^* \quad (1)$$

$$RH^* \xrightarrow{k_2} H_2 + R(-H) \quad (2)$$

$$RH^* + SF_6 \xrightarrow{k_3} \text{no hydrogen product} \quad (3)$$

$$RH^* + RH \longrightarrow RH + RH^* \quad (4)$$

where Eq. (4) shows the energy-transfer process to transport the excited state, RH*, to the vicinity of SF_6. Then, the steady-state treatment of the reaction yields the following relation:

$$1/\text{R.Y.} = 1 + k_3[SF_6]/k_2 \quad (5)$$

The k_3/k_2 ratio is obtained from the slope of the straight line extrapolated at the low concentration of SF_6. The value observed in this experiment is 15.0, while that of Holroyd was 4.5 in the photolysis of *n*-hexane in the presence of N_2O.[5] SF_6 is, thus, an acceptor stronger than N_2O in the energy-transfer process. This tendency is consistent with the measurement[7] of the fluorescence from the scintillator in a cyclohexane solution in the presence of various electron scavengers. The leveling-off at the higher concentrations of SF_6 (Fig. 3) was explained by the introduction of more than two excited states. Therefore, it may be considered that, in these excited states, only one excited state is responsible for discriminating the molecular detachment of hydrogen upon the addition of SF_6, as is shown in Eqs. (2) and (3), while the other excited states are not affected by the introduction of SF_6. The low-lying excited states of *n*-hexane were observed by the use of the electron reflection spectrum[17] and the emission spectrum.[18,19]

A prominent result is that the critical concentration of the scavenger is lower than that in the case of radiolysis. The reaction cross section calculated from the critical concentration of the scavenger is several hundred square Ångstrom. Such a large cross section was also observed in the energy-transfer process i n a propane isobutane mixture at a low temperature using EPR measurements[20] for isopropyl and isobutyl radicals; in this method, the effect of electron transfer is ruled out by the experimental condition that the ionization potential of the acceptor molecule is higher than that of the donor molecule. The large cross section may be explained by the fast movement of a pair of an electron and a positive ion. It is assumed that the excited state of hydrocarbon can react with SF_6 and form the state of charge separation[20,21]

$$RH^* + SF_6 \longrightarrow RH^+ + SF_6^- \quad (6)$$

The neutralization between RH^+ and SF_6^- is expected to form fluorine-containing products. The sharp decrease in the yield of hydrogen molecular detachment upon the addition of SF_6 can be explained by assuming a fast energy transfer or charge transfer to produce RH^+ and SF_6^-.

In a recent study of the radiolysis of benzene in presence of N_2O and COS, Sato *et al.*,[23] concluded that the energy transfer can take place neither through the superexcited state (20 eV) nor through the first excited state ($^1B_{2u}$), but must take place through some intermediate excited states between these states, although the details of energy transfer are not known.

Another possible explanation of the large reactive cross section is that a charge-transfer complex between *n*-hexane and SF_6 in either the ground or excited state may be formed and the detachment process may be perturbed by this complex formation. The weak interaction between the halogen molecule or halogen-containing compounds including SF_6 and paraffin was observed by the use of the spectroscopic method.[24,25] The gas chromatographic measurement with an iodine column showed the existence of a weak interaction between iodine and paraffins.[26] Therefore, the complex-formation mechanism appears to be a plausible explanation.

The quenching process by SF_6 may produce various fluorine-containing products. Several large peaks were detected in the electron-capture gas chromatogram (Fig. 1). One of the products was determined to be 1-fluorohexane (peak 1 in Fig. 2). These products increased with the increase in the concentration of SF_6. The total amount of these fluorine-containing products is smaller than that of the decrease in the hydrogen molecule.

To find an ideal electron scavenger without any deactivation by the energy-transfer process, 1-fluorohexane was tested. In the photolysis of liquid *n*-hexane,

Luminescence from 2,3-Dimethylbutane Containing Toluene in the Solid Phase at 77°K during γ-Irradiation

Tetsuo MIYAZAKI, Yoshiyuki SAITAKE, Zen-ichiro KURI, and Shigenori SAKAI
Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya
(Received May 12, 1972)

The luminescence from 2,3-dimethylbutane(2,3DMB) containing toluene in the solid phase has been measured at 77°K during γ-irradiation. The emission consists of fluorescence and phosphorescence from toluene. Since the emission becomes zero upon the removal of a γ-ray source, it cannot be due to a post-irradiation effect. It is concluded from the dependency of the intensity on the concentration of toluene that the luminescence is due to an intermolecular energy transfer from 2,3DMB to toluene during γ-irradiation. ESR studies of γ-irradiated 2,3DMB containing toluene have also been undertaken at 77°K in order to obtain some information on the intermolecular energy transfer. The toluene anion is formed in the γ-irradiated 2,3DMB containing toluene. The dimer cation of toluene is formed in the γ-irradiated 2,3DMB containing toluene and an electron scavenger. The luminescence from toluene in the 2,3DMB matrix decreases upon the pre-irradiation of the sample at 77°K. When the pre-irradiated sample is illuminated by the light from a tungsten lamp to photobleach the toluene anion, the luminescence during γ-irradiation is recovered. Since the intensity of the luminescence does not correspond at all to the amount of toluene anions, the luminescence from toluene in the 2,3DMB matrix during γ-irradiation must not be due to a neutralization reaction between a toluene anion and a migrating hole. It is suggested that the migration of energy from the irradiated 2,3DMB to toluene may occur *via* an excitation transfer reaction.

We have previously studied the radiolysis of hydrocarbons in the solid phase in order to elucidate the primary process and in order to obtain information about the reaction kinetics in the solid phase. In the previous studies, some phenomena peculiar to the solid-phase radiolysis have been reported.[1-3] On the basis of these results, we have proposed that two important problems must be solved in order to elucidate the mechanism of the solid-phase radiolysis. One is the species of the mobile entities produced in the solid-phase radiolysis. The other is how the condition of the solid-matrix, such as phase and defect, affects the chemical reactions.

It was found in the radiolysis of solid isobutane[1] that H_2 and C_4H_9 radicals are formed by the fragmentation of the excited isobutane molecule and that their yields decrease upon the addition of CCl_4 or toluene. These findings were interpreted as the assumption that the excitation transfer from the excited isobutane molecule to CCl_4 or toluene occurs in the solid state at 77°K.

If toluene is an efficient acceptor of excitation in the radiolysis of solid alkane, the luminescence from the excited toluene may be observed; the expected results were observed in the solid 2,3-dimethylbutane(2,3DMB) with the toluene additive during γ-irradiation at 77°K.

Those additives which are generally used as electron scavengers or charge scavengers in the liquid-phase radiolysis may react also with an excited molecule in solid-phase radiolysis.[4] Therefore, it is quite difficult to study the nature of the mobile entity in the radiolysis of solid alkane using the scavenger method. Since the ESR spectroscopy and the measurement of the luminescence reveal different aspects of the mobile entity, the radiolysis of an alkane-toluene mixture in the solid phase at 77°K was studied using both methods.

Experimental

2,3-Dimethylbutane(2,3DMB), supplied by the Tokyo Kagaku Seiki Co. with a purity of more than 99%, was passed through a 30 cm column packed with activated alumina and then distillated on a vacuum line before use. Gas-chromatographic analysis of 2,3DMB showed that the concentration of the other hydrocarbons with molecular weights smaller than 2,3DMB is less than 0.01%. The spectrograde toluene

and phenylbromide were of a high purity and were used after distillation on a vacuum line. The nitrous oxide was also of a high purity and was used without further purification.

The samples were irradiated with γ-rays from a ^{60}Co source at 77°K, and in most cases at a dose rate of 3.84×10^{19} eV/g·hr, for the ESR studies and at one of 4.83×10^{17} eV/g·hr for the measurements of the luminescence.

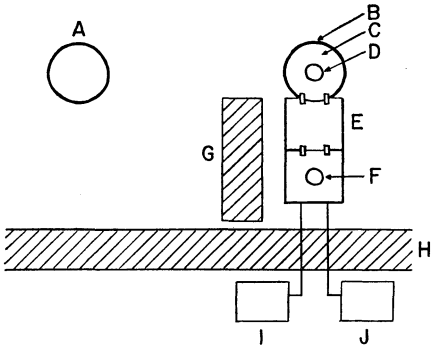

Fig. 1. Schematic diagram of the measurement of luminescence during γ-irradiation at 77°K.

The ESR spectra of irradiated samples were measured at 77°K on a JES-3BX ESR spectrometer. The luminescence was measured during γ-irradiation at 77°K. The apparatus for measuring the luminescence consisted of a high voltage supplier, a Shimadzu-Bausch-Lomb monochrometer, a photomultiplier tube (R-136) of the Hamamatsu TV Co. and a DC microvolt-ammeter. A schematic diagram of the apparatus is given in Fig. 1. When 2,3DMB containing toluene (2 mol%) was γ-irradiated at 77°K in the solid state, the photocurrent caused by the emission from toluene was about 1.2×10^{-6} ampere during γ-irradiation at a dose rate of 4.83×10^{17} eV/g·hr.

Results and Discussion

Luminescence from Toluene in the Solid 2,3DMB at 77°K during γ-Irradiation. Luminescence studies previously undertaken in radiation chemistry have mostly been concerned with the thermoluminescence or photo-induced luminescence of γ-irradiated samples, or with the luminescence in the liquid phase during γ-irradiation. There have been no studies of the limunescence from solid saturated hydrocarbons during γ-irradiation. The emission from a pure 2,3DMB is very weak during γ-irradiation at 77°K, but a small amount of toluene in 2,3DMB enhances the emission remarkably. The intensity of the luminescence is shown in Fig. 2 as a function of the concentration of toluene. The intensity increases sharply with an increase in the concentration of toluene and then gradually decreases beyond 2 mol% toluene. Since the intensity does not increase linearly with an increase in the concentration of toluene, the liminescence is not due to the direct absorption of the radiation energy by the solute toluene. The intensity of the emission from pure solid toluene during γ-irradiation is about three times stronger than that from 2,3DMB–toluene (1.3 mol%). With an electron fraction of toluene of 0.013 in the 2,3DMB–toluene,

□—□: Yields of toluene anion at the dose of 9.6×10^{18} eV/g.

the emission due to the direct absorption of the radiation energy by the toluene itself can be expected to amount at most to 4% of the total emission from 2,3DMB–toluene (1.3 mol%).

Since the emission from toluene in 2,3DMB becomes zero upon the removal of a γ-ray source, the emission cannot be due to a post-irradiation effect. The emission from toluene in the 2,3DMB matrix may be attributable to intermolecular energy transfer from 2,3DMB to toluene.

The emission spectrum from toluene in 2,3DMB is shown in Fig. 3. The spectrum consists of two peaks, with emission maxima near 280 and 390 nm. Since the fluorescence spectrum of toluene has a band with a maximum near 280 nm,[5] the emission band near 280 nm may be due to the fluorescence from the singlet-excited toluene. Since the phosphorescence spectrum

of toluene has a band with a maximum near 390 mn,[6] the emission band observed near 390 nm may be due to the phosphorescence from the triplet-excited toluene. The vibrational structure of the emission bands could not be measured with this instrument because of the noises caused by the γ-irradiation of photomultiplier, the bubbling of liquid nitrogen in the Dewar flask, and so on.

ESR Studies of γ-Irradiated 2,3DMB Containing Toluene in the Solid Phase at 77°K. The ESR spectrum of γ-irradiated 2,3DMB at 77°K is shown in Fig. 4A. It consists of five lines, with a splitting constant of 22 G. The spectrum may be assigned to the $\cdot CH_2CH(CH_3)$-$CH(CH_3)_2$ radical.[7]

The ESR spectrum of γ-irradiated 2,3DMB–toluene (2 mol%) is shown in Fig. 4B. The new spectrum, which is obtained by subtracting the spectrum of the solvent radicals, is shown with dotted lines. The spectrum consists of five lines, with a splitting constant of 3.8 G, and it is easily photo-bleached upon illumination with light from a tungsten lamp. It coincides well with that of the toluene anion produced by the γ-irradiation of i-C_4H_{10} containing toluene.[1a] The ESR spectrum of the toluene anion produced chemically consists mainly of five lines, with a splitting constant of 4.0 G.[7] The formation of the new spectrum is suppressed completely upon the addition of an electron scavenger, such as N_2O, C_6H_5Br, SF_6, or HBr, to the system. Therefore, the new spectrum may be assigned to the toluene anion.

The ESR spectra of γ-irradiated 2,3DMB–toluene (2 mol%) containing N_2O or C_6H_5Br are shown in Figs. 4C and D respectively. The new spectrum, which is obtained by subtracting the spectrum of the solvent radicals, is shown with dotted lines. Since the spectra have the splitting constants of 6.6 G and 7.0 G in Figs. 4C and D respectively, they cannot be assigned to the toluene anion. As the splitting constants of the monomer cation and the dimer cation of toluene are 14 G and 7.0 G respectively,[9] they may be assigned to the

dimer cation of toluene. These results suggest that the toluene is not always completely dissolved, but stands sometimes in the form of a cluster, depending upon the concentration.

The yields of the toluene anion and the solvent radical are shown in Fig. 2 as a function of the concentration of toluene.

The dose dependences of the yields of toluene anion and solvent radical are shown in Fig. 5. The rate of the production of the toluene anion decreases gradually with an increases in the dose, while the yields of solvent radical increase linearly.

Pre-irradiation Effect on the Luminescence from Toluene. A quite interesting effect is found on the luminescence from toluene in the 2,3DMB matrix. When the sample is pre-irradiated at 77°K with a certain dose, the intensity of the in-source luminescence becomes much lower than that from the sample without pre-irradiation. The emission spectra from the pre-irradiated sample are shown in Fig. 3 in comparison with the emission from the sample without pre-irradiation. The intensity of the luminescence at $\lambda=390$ nm is shown in Fig. 6 as a function of the dose of pre-irradiation. The liminescence is efficiently suppressed by the pre-irradiation of 3.84×10^{19} eV/g.

Since the toluene ions produced absorb the light of 390 nm, a part of the emission may be absorbed by the toluene ions. If the optical density of the toluene anion in γ-irradiated 2,3DMB–3-methylpentane(10 mol%)–toluene(2 mol%)[10] is measured at 77°K by means of UV–VL absorption spectroscopy, the intensity of the luminescence can be corrected by considering the optical density of the toluene ions at 390 nm. The pre-irradiation effect on the luminescence from 2,3DMB–3-methylpentane-toluene is approximately the same as that of 2,3DMB–toluene, which forms a cracked transparent plastic crystal (Fig. 6). Therefore, the optical density of the toluene anion in the γ-irradiated 2,3DMB–3-methylpentane–toluene may be used for the correction of the intensity of the luminescence from 2,3DMB–toluene. Thus, the corrected intensity is shown in Fig. 6 with a dotted line.

○: Intensity of luminescence from 2,3DMB–toluene (2 mol%) which is pre-irradiated at the dose of 3.84×10^{19} eV/g and then photobleached with light from a tungsten lamp for 10 min.
□: Intensity of luminescence from 2,3DMB–3-methylpentane (10 mol%)–toluene (2 mol%) which is pre-irradiated at the dose of 3.84×10^{19} eV/g and then photobleached with light from a tungsten lamp for 1 min.
The intensity of luminescence is measured at the wavelength of 390 nm. Initial rate of formation of toluene anion is nomalized to 10 for the comparison with the intensity of luminescence.

The results of Figs. 5 and 6 show that the intensity of the luminescence does not correspond at all to the yields of the toluene anions, but to their rates of formation. The luminescence diminished upon the pre-irradiation can be almost restored to the former value by the photobleaching of the toluene anion with the light from a tungsten lamp (Fig. 6). If the luminescence from toluene in the 2,3DMB matrix is due to a neutralization reaction between a toluene anion and a migrating hole, the intensity of the liminescence should be roughly proportional to the amount of the toluene anion (Reactions (1)—(4)). The experimental results, however, show that these mechanisms are not responsible for the luminescence of toluene:

$$2,3DMB \rightsquigarrow 2,3DMB^{+}_{m} + e^{-} \quad (1)$$

$$e^{-} + C_6H_5CH_3 \longrightarrow C_6H_5CH_3^{-} \quad (2)$$

$$2,3DMB^{+}_{m} + C_6H_5CH_3^{-} \longrightarrow 2,3DMB + C_6H_5CH_3^{*} \quad (3)$$

$$C_6H_5CH_3^{*} \longrightarrow C_6H_5CH_3 + h\nu \quad (4)$$

where $2,3DMB^{+}_{m}$ represents a migrating hole.

Therefore, the energy may be transferred from the matrix to the solute by non-ionic processes until the ionization occurs partly. One plausible mechanism may be represented as follows:

$$2,3DMB \rightsquigarrow 2,3DMB^{*} \quad (5)$$

$$2,3DMB^{*} + C_6H_5CH_3 \longrightarrow C_6H_5CH_3^{+} + e^{-} \quad (6)$$

$$\searrow\ C_6H_5CH_3^{*} \quad (7)$$

$$C_6H_5CH_3^{+} + e^{-} \longrightarrow C_6H_5CH_3^{*} \quad (8)$$

$$C_6H_5CH_3 + e^{-} \longrightarrow C_6H_5CH_3^{-} \quad (2)$$

$$C_6H_5CH_3^{*} \longrightarrow C_6H_5CH_3 + h\nu \quad (4)$$

where 2,3DMB* means an exciton. The absence of the migrating hole in the γ-irradiated 2,3DMB has also been suggested in the γ-irradiation of 2,3DMB containing carbon dioxide.[4b]

When the excited 2,3DMB is formed by the γ-irradiation at 77°K in the solid phase, the excitation of 2,3-DMB may migrate in the solid, probably as an exciton. The exciton may be trapped at the toluene molecule to form a toluene cation, an electron, or an excited

10) When 3-methylpentane is added in the 2,3 DMB matrix, the matrix becomes transparent without a cracking at 77°K and is suitable for the measurement of absorption spectra.

toluene molecule (Reactions (5), (6), and (7)). A part of the toluene cations and electrons may neutralize with each other (Reaction (8)) to form an excited toluene molecule. Then, the excited toluene molecule formed in Reactions (7) and/or (8) may emit light. The formation of a solute cation by excitation transfer was also pointed out in previous studies of the radiolysis of 2,3DMB in the solid phase[4b] and in polyethylene.[11]

The decreases in the intensity of the luminescence and in the rate of the formation of the toluene anion with dose may be due to the decrease in the amount of residual toluene with the dose. When the toluene ions formed by the pre-irradiation of 3.84×10^{19} eV/g are photobleached (Reaction (9)), the intensity of the luminescence recovered by the photobleaching is about 5 arb. unit, as is shown in Fig. 6.

$$C_6H_5CH_3^- \xrightarrow{h\nu} C_6H_5CH_3 + e^- \qquad (9)$$

The concentration of toluene anions before the photobleaching is about 3.3×10^{-3} mol%, if G(toluene anions)=0.6. The amount of toluene for the intensity of luminescence of 10 arb. unit in Fig. 6 is about $3.3\times10^{-3}\times2=6.6\times10^{-3}$ mol%.

We can, then, roughly estimate the distance of the exciton migration. The real concentration of toluene in the 2,3DMB crystalline lattice is about 6.6×10^{-3} mol%, *i.e.*, 6.6×10^{-5} mol fraction. Assume that the exciton migrates to the nearest neighboring molecules of toluene to give its energy to the toluene. Supposing that the number of molecules of the nearest neighbors of toluene is twelve; the number of 2,3DMB molecules, through which the exciton migrates before encountering a toluene, can then be estimated roughly as follows;

$$\frac{1}{6.6\times10^{-5}}\times\frac{1}{12} = 1.3\times10^{3} \text{ molecules}$$

This number of molecules is approximately equal to the calculated migration distance (10^3—10^4 molecules) of the exciton corresponding to the lowest singlet-excited state of alkane.[12]

However, the concentration of toluene anions 6.6×10^{-3} mol% is far below that of the solute, 2 mol%. This result can not yet be explained clearly, but the following assumption can be made temporarily: effective parts to receive the migrating energy are limited by the solubility or cluster formation of the additive, defect formation with the solute.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 74—79 (1973)

Thermodynamic Properties of Some Isomeric Butyl Alcohol Mixtures[1]

Sachio MURAKAMI[2] and G. C. BENSON
Division of Chemistry, National Research Council of Canada, Ottawa, Canada, K1A OR6

(Received May 16, 1972)

Molar excess enthalpies and molar excess volumes are reported for binary mixtures of *n*-butyl alcohol with isobutyl alcohol, *sec*-butyl alcohol, and *t*-butyl alcohol. All of the measurements were carried out at 25°C except for the excess enthalpies of *n*-butyl alcohol–*t*-butyl alcohol which were determined at 26°C. Interpretation of the results in terms of a lattice model was investigated.

Measurements of the thermodynamic properties of binary mixtures of methanol with the four isomeric butyl alcohols were reported in previous publications.[3–5] Differences in the behaviour of these mixtures were attributed primarily to differences in hydrogen bonding. As an extension of our studies, we have measured the enthalpy and volume changes for the mixing of *n*-butyl alcohol with isobutyl alcohol (2-methyl-1-propanol), with *sec*-butyl alcohol (2-butanol) and with *t*-butyl alcohol (2-methyl-2-propanol).

Experimental

Details of the chromatographic purification of the isomeric butyl alcohols have been described.[5] Enthalpies and volumes of mixing were measured by successive dilution techniques, using a calorimeter[6] and dilatometer.[4] The uncertainties in the results for equimolar mixtures are estimated to be ± 0.5 J mol^{-1} for the molar excess enthalpies, and ± 0.0005 cm^3 mol^{-1} for the molar excess volumes.

Results

All of the measurements were carried out at 25.00 ± 0.01°C except for the determinations of the excess enthalpies of *n*-butyl alcohol–*t*-butyl alcohol mixtures. The latter were measured at 26.00 ± 0.01°C, since at 25°C

operation of the calorimeter was upset by the tendency of the *t*-butyl alcohol to solidify in the hypodermic needle. Results for the molar excess enthalpy H^E and the molar excess volume V^E are listed in Tables 1 and 2, respectively. In all cases, x_1 indicates the mole fraction of *n*-butyl alcohol. Graphs of the results are shown in Figs. 1 and 2, where it should be noted that scales differing by a factor of 10 have been used in plotting the excess functions for some of the systems.

The method of least squares was used to fit the results with equations of the type

$$X^E = x_1(1-x_1)\sum_{j=1}^{n} c_j(1-2x_1)^{j-1} \qquad (1)$$

where X^E is either H^E or V^E. The minimum number of coefficients required to represent the results adequately was determined by examining the statistical significance of the improvement in the fit with the increase in the number of coefficients. The values obtained for the coefficients c_j are summerized in Table 3, along with the standard error of estimate σ associated with each representation. The curves in Figs. 1 and 2 were calculated from Eq. (1) using these values for the coefficients.

Discussion

There is a fairly close similarity between Figs. 1 and 2, and graphs presented previously[5] for the excess enthalpies and volumes of methanol-isomeric butyl alcohol systems. In general the signs of the excess functions are the same for systems of the two sets with a common second component. However, the greater similarity in size of the component molecules in the present systems leads to smaller magnitudes for the excess functions than those observed for the methanol systems. Thus it appears that the qualitative discussion[5] of the role of hydrogen bonding in determining the excess properties of methanol–isomeric butyl alcohol mixtures is also valid for the present systems.

The generalized quasi-lattice theory of Barker[7,8] should be well suited for analysing the excess properties of mixtures in which association by hydrogen bonding occurs, since it deals explicitly with the specific interactions between different parts of the component molecules. It is customary to adjust the parameters characterizing these interactions to fit the theoretical values of the excess energy and/or free energy to the experimental results. In developing a Barker type of model for binary mixtures of butanol isomers, we found it useful also to consider the results reported earlier for methanol–isomeric butyl alcohol mixtures.[5]

The mixing process treated by Barker is one in which the volume for each molecule remains constant. However, it is useful to compare the theoretical values with experimental results measured essentially at constant pressure and corrected to constant total volume. In the case of the free energy, this correction is negligible and values of A_V^E, the molar excess Helmholtz free energy at constant volume are identified with values

7) J. A. Barker, *J. Chem. Phys.*, **20**, 1526 (1952).
8) J. A. Barker and F. Smith, *ibid.*, **22**, 375 (1954).

of G^E, the molar excess Gibbs free energy at constant pressure. The difference between U_V^E, the molar excess energy at constant volume, and H^E, the molar excess enthalpy at constant pressure, is more significant and can be estimated from the relation

$$H^E - U_V^E \approx TV^E(\alpha_1\phi_1+\alpha_2\phi_2)/(\kappa_1\phi_1+\kappa_2\phi_2) \quad (2)$$

where ϕ_i is the volume fraction of component i in the mixture, and α_i and κ_i are respectively the coefficients of expansion and isothermal compressibility for pure i. The curves for A_V^E and U_V^E at 25°C (Figs. 3—5) were obtained from the smoothed representations of the experimental results for G^E, H^E, and V^E. In calculating U_V^E, the values of α and κ listed in Table 4 were used. These values were derived previously[9] from density, velocity of sound, and heat capacity data. The one degree temperature deviation (from 25°C) of the *n*-butyl alcohol–*t*-butyl alcohol results for H^E was neglected.

Table 4. Values of the coefficient of thermal expansion α, and the isothermal compressibility κ for the component liquids at 25°C

Component	$10^3\alpha$ K^{-1}	$10^6\kappa$ atm^{-1}
Methanol	1.185	126.4
n-Butyl alcohol	0.937	94.5
Isobutyl alcohol	0.948	102.6
sec-Butyl alcohol	0.988	98.2
t-Butyl alcohol	1.344	126.1

Our model for binary alcohol mixtures assumes that an alcohol molecule of species i, containing m carbon atoms, occupies $r_i=m+1$ sites of a lattice with coordination number equal to four. Three different types of contact areas are recognized on the surface of the moledule: hydrocarbon denoted by I, hydroxyl oxygen by O, and hydroxyl hydrogen by H. A subscript (1) or (2) is added to these symbols when it is necessary to indicate that the contact is on a molecule of the first or second component in the mixture. The number of contact points of type a on a molecule of species i is denoted by Q_i^a. The values of Q_i^a were chosen to satisfy the condition

$$\sum_a Q_i^a = zr_i + z$$

Q^I was assigned values of 3 and 9 for methanol and the isomeric butyl alcohols respectively; values of $Q^O=2$ and $Q^H=1$ were adopted for all of the alcohols.

Table 5. Simplified scheme for interchange parameters U_{ij}^{ab} and A_{ij}^{ab}

Bond	U_{ij}^{ab}	A_{ij}^{ab}
$I_{(1)}$—$O_{(1)}$, $I_{(1)}$—$H_{(1)}$, $I_{(2)}$—$O_{(2)}$, $I_{(2)}$—$H_{(2)}$	0	0
$O_{(1)}$—$H_{(1)}$	U_1	A_1
$O_{(2)}$—$H_{(2)}$	U_2	A_1
$I_{(1)}$—$I_{(2)}$, $I_{(1)}$—$O_{(2)}$, $I_{(1)}$—$H_{(2)}$, $O_{(1)}$—$I_{(2)}$, $O_{(1)}$—$O_{(2)}$, $H_{(1)}$—$I_{(2)}$, $H_{(1)}$—$H_{(2)}$	U_3	A_3
$O_{(1)}$—$H_{(2)}$	U_1+U_3	A_1+A_3
$H_{(1)}$—$O_{(2)}$	U_2+U_3	A_2+A_3

Normally, 15 interchange energies U_{ij}^{ab} and 15 interchange free energies A_{ij}^{ab} would be needed to describe the interaction between all possible pairs of contacts of type a on species i and type b on species j. However, differences in the behaviour of the systems under consideration seem to be attributable primarily to differences in the proton accepting facility of the oxygen atoms attached to primary, secondary, and tertiary carbon atoms. We have therefore attempted to describe the interactions by three energy parameters and three free energy parameters according to the scheme shown in Table 5. This scheme singles out the four hydrogen bonds for special consideration, and divides them into two classes according to the host molecule of the oxygen atom involved. In addition it assumes that a nonspecific van der Waals interaction occurs between contacts on unlike molecules.

Detailed equations for the calculation of A_V^E and U_V^E can be found in Barker's original publications,[7,8] examples of their application to particular cases being also available.[8,10] The presentation here is limited to outlining the course of the calculations leading to the final selection of the interchange energies and free energies summarized in Table 6. The use of these parameters in the formulas of Barker leads to the results represented by the points in Figs. 3—5.

The methanol-isomeric butyl alcohol mixtures were considered first since experimental results for both A_V^E and U_V^E were available. In methanol–*n*-butyl alcohol and methanol–isobutyl alcohol mixtures, all of the oxygen atoms are attached to primary carbons. For these mixtures, A_1 and A_2 were set equal to -11420 J mol^{-1} and U_1 and U_2 to -28200 J mol^{-1}, where the numerical values are the same as those used by Barker and Smith[8]

Table 6. Values of interchange parameters for methanol–isomeric butyl alcohol mixtures and *n*-butyl alcohol–isomeric butyl alcohol mixtures

Component 1	Component 2	Interchange parameters J mol^{-1}					
		U_1	A_1	U_2	A_2	U_3	A_3

for the hydrogen bonds in acetone–ethanol mixtures. The nonspecific interaction was assumed to be the same between methanol and any of the butyl alcohol molecules. It was further assumed that $U_3=A_3$; this also is in line with the findings for acetone–ethanol. Quite clearly these assumtions foregothe possibility of distinguishing theoretically between methanol–*n*-butyl alcohol and methanol–isobutyl alcohol mixtures. The experimental values of U_V^E for both sets of mixtures are very similar and a value of 50 J mol^{-1} for U_3 provides a fairly good representation of either. It can be seen from Fig. 3 that the points calculated for A_V^E reach a maximum falling between the peaks of the two experimental curves. Better individual fits of A_V^E were obtained by adjusting A_3 separately for each system, but even in that case it was not possible to reproduce the negative values of A_V^E observed experimentally. In both methanol–*sec*-butyl alcohol and methanol–*t*-butyl alcohol mixtures, A_2 and U_2 can be expected to differ from A_1 and U_1 since the configurations around the oxygen atoms are different. Values of A_2 and U_2 were obtained by successively adjusting them to make the theoretical results for A_V^E and U_V^E approximate the experimental observations.

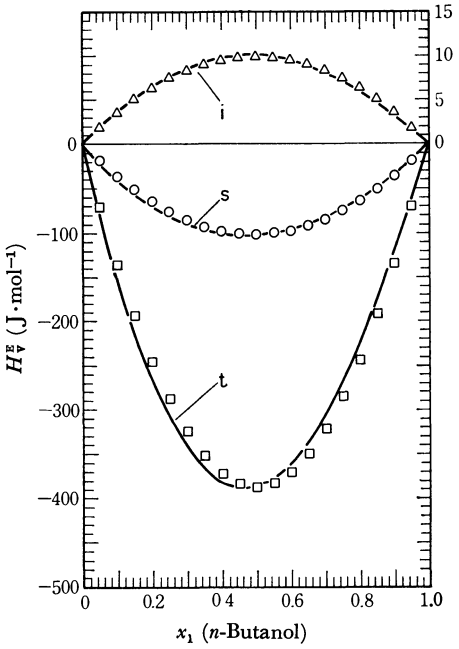

Fig. 5. Comparison of theoretical and experimental excess energies at constant volume for *n*-butyl alcohol–isomeric butyl alcohol mixtures at 25°C. Points calculated from Barker theory; △: *n*-butyl alcohol–isobutyl alcohol; ○: *n*-butyl alcohol–*s*-butyl alcohol; □: *n*-butyl alcohol–*t*-butyl alcohol. Curves represent the smoothed experimental results. Labels *i*, *s*, and *t* indicate the three isomeric butyl alcohols used as second components. Ordinate scale at right is for mixtures containing isobutyl alcohol, and ordinate scale at left is for those containing *sec*-butyl alcohol or *t*-butyl alcohol.

Calculations for *n*-butyl alcohol–isomeric butyl alcohol mixtures followed as closely as possible the treatment described for the methanol systems. However, since experimental results for A_V^E were not available it was further assumed that the bond interchange entropy terms

$$TS_{ij}^{ab} = U_{ij}^{ab} - A_{ij}^{ab} \qquad (4)$$

were the same as in the corresponding methanol systems. Fitting the U_V^E results for *n*-butyl alcohol–isobutyl alcohol led to a value of 3.3 J mol^{-1} for the nonspecific interchange energy between *n*-butyl alcohol and its isomers. Values of U_2 for the hydrogen bonds at secondary

and tertiary OH groups were then obtained by adjusting the calculations to fit U_V^E for mixtures of *n*-butyl alcohol with *sec*-butyl alcohol and *t*-butyl alcohol.

It should be noted that the calculations for methanol mixtures give values for the parameters characterizing the hydrogen bonds at secondary and tertiary OH groups which differ by five to ten percent from those resulting from the calculations for *n*-butyl alcohol mixtures. If the values of A_2 and U_2 obtained from the methanol mixtures are used to estimate U_V^E for mixtures of *n*-butyl alcohol with *sec*-butyl alcohol and *t*-butyl alcohol, the results have the correct sign but are three to five times larger in magnitude than observed experimentally. Thus it appears that estimates of U_V^E are fairly sensitive to the values of the interchange parameters used to describe the hydrogen bonds.

In summary, the Barker model described above reproduces the thermodynamic behavior of *n*-butyl alcohol–isomeric butyl alcohol mixtures fairly satisfactorily. Although it is doubtful that the absolute values of the bond interchange parameters are meaningful, the general features of these values are reasonable. In particular, the nonspecific interactions are very small compared to the hydrogen bonding, and furthermore the nonspecific interaction between the isomeric butyl alcohol is smaller than that between methanol and the butanols. Finally, the relative order of the values for the hydrogen bonds agrees with experimental evidence indicating that the proton accepting facility of the oxygen atoms in the present alcohols increases in the order primary<secondary<tertiary.[11]

The authors wish to express their thanks to Mr. P. J. D'Arcy and Mr. C. J. Halpin for their technical assistance throughout the course of this work.

Mössbauer Study of the Thermal Decomposition Products of K_2FeO_4

Toshio ICHIDA*

Institute for Chemical Research, Kyoto University, Uji, Kyoto

(Received May 17, 1972)

The thermal decomposition process of a hexavalent iron compound, K_2FeO_4, was studied by means of the Mössbauer effect. The compound began to decompose in air at about 170°C, and an amorphous product was obtained by the decomposition below 200°C. The product showed a paramagnetic Mössbauer spectrum at 293°K, with an isomer shift and quadrupole splitting of $+0.40 \pm 0.02$ mm/sec and 0.64 ± 0.02 mm/sec respectively; it also showed a magnetically-split six-line spectrum at 4.2°K, with an internal magnetic field of 480 ± 5 kOe. These Mössbauer parameters are characteristic of the Fe^{3+} state. The intermediate valence states, Fe^{5+} or Fe^{4+}, were not observed during the decomposition process, and so it was concluded that the Fe^{6+} ions in K_2FeO_4 were reduced directly to Fe^{3+} ions. $KFeO_2$ was formed in air above 250°C, and the temperature dependence of the internal magnetic field showed the Néel temperature of $KFeO_2$ to be very high, 983 ± 10°K.

Previously, Scholder *et al.*[1,2] reported on the thermal decomposition process of a hexavalent iron compound, K_2FeO_4. According to their reports, the decomposition process below 700°C is represented as the following formula:

$$2K_2Fe^{6+}O_4 \longrightarrow K_3Fe^{5+}O_4 + KFe^{3+}O_2 + O_2,$$

and that above 700°C by:

$$K_3Fe^{5+}O_4 \longrightarrow KFe^{3+}O_2 + K_2O + (1/2)O_2.$$

Although Scholder[2] reported the existence of K_3FeO_4 and Na_3FeO_4 as examples of pentavalent iron compounds, there was no crystallographic justification of them. Indeed, the existence of no pentavalent iron compound has yet been established by physical means.

In recent years, it has been well known that the Mössbauer effect is very useful in the determination of iron valency in the solid state.[3-5] In the present study of the thermal decomposition products of a hexavalent iron compound, K_2FeO_4, the valence state of iron and the magnetic properties of the products were investigated by means of the Mössbauer effect.

Sample Preparation and Measurements

The sample-preparation method of K_2FeO_4 was similar to the procedure of Thompson *et al.*[6]

Into a sodium hypochlorite solution, granular sodium hydroxide was slowly stirred, while we permitted the

temperature to rise as high as 30°C; finally, the mixture was cooled to about 0°C. The precipitated sodium chloride was removed by filtration through a glass filter. To the alkaline hypochlorite solution at about 10°C, fine powder of ferric nitrate was slowly added. The solution was saturated with sodium hydroxide, and the temperature was maintained at about 30°C. The mixture was then filtered with suction through a coarse glass filter. By adding a saturated potassium hydroxide solution with stirring, precipitates of K_2FeO_4 were produced. The following cycle of purification was repeated more than three times: the precipitates of K_2FeO_4 were leached on a glass filter of a fine porosity with a 3M-KOH chilled solution. The liquid was drawn through the filter into a saturated potassium hydroxide solution, whose temperature was also kept at about 0°C. Because the solubility of K_2FeO_4 into a concentrated potassium hydroxide solution is much less than into a dilute solution, recrystallized K_2FeO_4 was thus obtained. The sample was purified by repeating this recrystallization.

The filtered precipitates of K_2FeO_4 were washed with benzene, 95% alcohol, and ether successively. The sample thus obtained was rapidly dried up and stored in a dry atmosphere. Particles of K_2FeO_4 showed a dark purple color and a needle shape (the longest axis was a few mm long).

By the X-ray diffraction technique, the sample was confirmed to be a single phase of K_2FeO_4. The measurements of the magnetization and the Mössbauer effect were carried out on the obtained samples at 80°K in order to confirm the absence of a ferromagnetic impurity and all iron ions except the hexavalent ones.[5]

Using the pure sample thus obtained, the thermal decomposition process of K_2FeO_4 was investigated. In the case of heating under high oxygen pressures, the K_2FeO_4 was held in a test tube of silica or gold. This test tube was placed in a cone-seal hydrothermal reaction vessel made of Stellite.

The decomposition products obtained were identified by using an X-ray diffractometer. Mössbauer effect measurements were carried out using an apparatus consisting of Elron's driving unit, AME-20, and Northern Scientific Co.'s 1024-channel pulse-height analyzer, NS-600. The temperature of the absorber was varied between 4.2 and 1023°K. The gamma ray source, ^{57}Co embedded in Cu metal, was always kept at room temperature. The calibration of the velocity scale was done by using pure Fe and α-Fe_2O_3 as the standard absorbers. The isomer shift is expressed relative to pure Fe.

Results and Discussion

Potassium ferrate, K_2FeO_4, gradually began to decompose in air at about 170°C. The X-ray diffraction pattern of the sample obtained by keeping K_2FeO_4 at 170°C in air for 10 days (Sample A) showed a slight trace of K_2FeO_4, but the sample kept for 90 days (Sample B) showed no diffraction peak. The Mössbauer spectra of the two samples measured at room temperature are shown in Fig. 1. As for Sample B, the Mössbauer spectrum measured at the temperature of liquid helium is shown in Fig. 2.

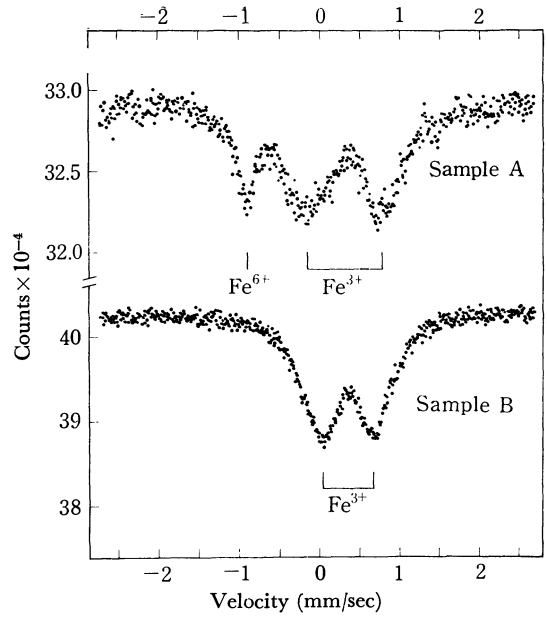

Fig. 1. Mössbauer absorption spectra at room temperature of ^{57}Fe in thermal decomposed products of K_2FeO_4 obtained at 170°C for 10 days (Sample A) and for 90 days (Sample B).

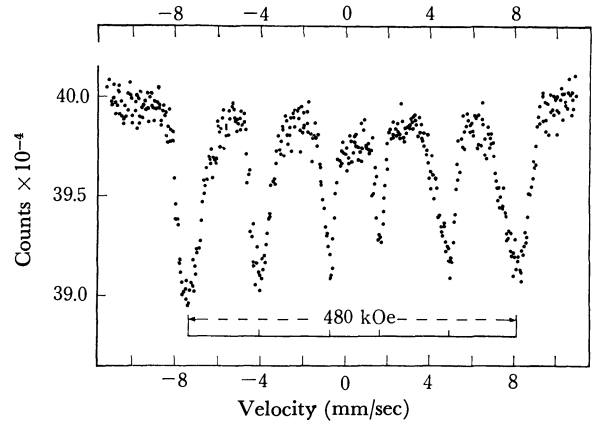

Fig. 2. Mössbauer absorption spectrum of ^{57}Fe in Sample B measured at 4.2°K.

As has previously been reported,[3-5] the Mössbauer absorption of K_2FeO_4 at room temperature is a sharp single line whose isomer shift is -0.89 ± 0.03 mm/sec; this is characteristic of the Fe^{6+} state. Below 5°K, magnetic hyperfine splitting appears. The internal magnetic field extrapolated to 0°K was 140 ± 7 kOe. The narrow single-line absorption at −0.90 mm/sec in Fig. 1 (Sample A) was due to the remaining Fe^{6+} ions. A broad quadrupole doublet was observed in the spectrum of Sample A; a similar broad symmetric absorption spectrum was also found in Sample B. As is shown in Fig. 2, the Mössbauer spectrum of Sample B measured at 4.2°K consisted of six broad absorption lines. The values of the internal magnetic field, 480 ± 5 kOe and the isomer shift, $+0.44\pm0.05$ mm/sec, show that the state of the iron was not Fe^{4+} or Fe^{5+} ions, but Fe^{3+} ions. The broad symmetric doublet in Fig. 1 was ascribed to the paramagnetic absorption of Fe^{3+}

in Fig. 4. Every iron atom occupies a crystallographically-equivalent site, tetrahedrally-surrounded by four oxygen atoms. The adjacent tetrahedrons of the oxygen atoms hold an apex in common, and the angle of Fe–O–Fe is 180°. The closest atomic approaches are O–O=2.72 Å, Fe–O=1.73 Å, and K–O=3.32 Å.

The Mössbauer spectrum of $KFeO_2$ at 293°K is shown in Fig. 5. The spectrum shows that iron is in trivalent state in $KFeO_2$ and that there is a magnetic ordering, even at room temperature, with an internal magnetic field of 505±5 kOe. The Mössbauer spectra obtained above 873°K are shown in Fig. 6. The internal magnetic field disappeared at 983±10°K. Therefore, the Néel temperature of $KFeO_2$ was estimated to be 983±10°K from the temperature variation in the internal magnetic field. Figure 7 shows the temperature dependence of the internal field. The Brillouin function for $S=5/2$ is also represented there for the sake of comparison. Previously, Kerler *et al.*[9,10]

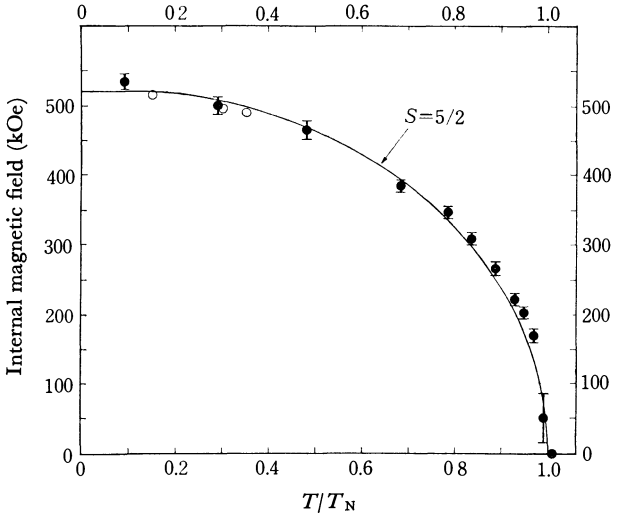

Fig. 7. The temperature dependence of the internal magnetic field in $KFeO_2$. Open circles are after Ref. 10. T_N is 983°K. Solid line represents the Brillouin function for $S=5/2$.

also measured the Mössbauer effect of $KFeO_2$ below 348°K. As is shown in Fig. 7, their data show a good agreement with the present data.

According to the results of the magnetic susceptibility measurements, $KFeO_2$ is a compensated antiferromagnet, but no anomaly was observed around the T_N value in the susceptibility-temperature curve. The present value, 983±10°K, is the highest among all the Néel temperatures of iron compounds thus far reported. Since the angle of Fe–O–Fe is 180° and the distance is very short (3.46 Å), the superexchange interaction must be very strong. Assuming that the spin directions of all the neighboring Fe^{3+} ions are antiparallel with each other, a completely compensated antiferromagnetic spin arrangement can be composed. This structure seems reasonable, although no experimental confirmation has yet been presented.

The decomposition temperature of K_2FeO_4 changed slightly with the oxygen pressure. Under the oxygen pressure of 500 atm, K_2FeO_4 began to decompose at about 250°C, while it began to decompose at 170°C in air. Independently of the oxygen pressure, it was confirmed by the Mössbauer-effect measurements that the Fe^{6+} ions in K_2FeO_4 were reduced directly to Fe^{3+} ions. There was no difference in the crystal structure and magnetic properties of the $KFeO_2$ samples obtained under various conditions. It was concluded that, in the low-temperature range, ultra-fine particles of a trivalent iron compound were formed and that, in the high-temperature range, K_2FeO_4 decomposed as follows:

$$K_2FeO_4 \longrightarrow KFeO_2 + KO_x + (2-x/2)O_2$$

The author would like to express his hearty thanks to Professor Toshio Takada, Professor Yoshichika Bando, Dr. Teruya Shinjo, Dr. Masao Kiyama, and Dr. Koji Kosuge for their prominent guidance and helpful discussions. Thanks are due to Dr. Mitsuo Imai and Dr. Koji Sanbongi of the Research Laboratories, Kawasaki Steel Corporation, for their warm encouragement. He also wishes to thank the Kawasaki Steel Corporation for giving him an opportunity to study at Kyoto University.

The Photolysis of Cyclopentanone

Shigeru TSUNASHIMA, Osamu OHSAWA, Chiharu TAKAHASHI, and Shin SATO
Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo
(Received May 19, 1972)

The 326.1 nm direct photolysis and the cadmium-photosensitized reactions of cyclopentanone have been compared in order to clarify the role of the triplet state of cyclopentanone in the photolysis. The products observed in the both photolyses were carbon monoxide, ethylene, cyclobutane, and 4-pentenal. The results obtained in the direct photolysis were very similar to those obtained in the cadmium photosensitization. The ethylene/cyclobutane ratio was not affected by the pressure and temperature changes. The 4-pentenal/CO ratio increased with a decrease in the temperature. These similarities suggest that the decomposition of cyclopentanone takes place through the lowest triplet state in both the photolyses. The efficiency of cyclopentanone in quenching triplet cadmium was found to be about 0.8 times that of *cis*-2-butene.

The photochemistry of cyclopentanone has been the subject of active investigations for forty years.[1,2] It has been found that gaseous cyclopentanone decomposes to carbon monoxide and ethylene or cyclobutane, or rearranges to 4-pentenal, upon irradiation with 313.0 nm light, which corresponds to a weak n-π^* transition.[1,2] In the cases of aliphatic ketones, such as acetone, it is believed that the decomposition takes place through the triplet state. In spite of many investigations, however, there still remains considerable doubt about the role of the triplet state in the cyclopentanone photolysis.

Since Srinivasan could not observe the effects of oxygen, he proposed that the excited singlet states with various vibrational levels are responsible for the product formations.[3] Recently, Chup Yew Mok reinvestigated the system in detail and observed small effects of the addition of oxygen and 1,3-pentadiene. As he pointed out, the results could not be used either to prove or to disprove the role of the triplet state during the photolysis of cyclopentanone.[4] He explained his results in terms of the first excited singlet state.[4] On the other hand, Lee found that triplet benzene sensitized the 4-pentenal formation and suggested that the cyclopentanone triplet was important as a reaction intermadiate.[5] From their detailed studies of the fluorescence emission, they also suggested that the rate of intersystem crossing from the first excited singlet to the triplet is very fast.[6] Frey *et al.* examined the photolysis of *trans*-2,3-dimethylcyclopentanone and found that the products, such as cyclopentanone-, 4-pentenal-, and cyclobutane-derivatives, contained the *cis-trans* isomers.[7] They proposed that the reaction intermediate is a biradical form which can rotate freely. The biradical intermediate assumption had already been made by Benson and Kistiakowsky and by Blacet and Miller.[8,9]

Since a triplet cyclopentanone will be formed even in the triplet cadmium photosensitization, it is expected that a comparison with direct photolysis will give further information about the cyclopentanone photolysis. In the case of acetone photolysis, the method of cadmium photosensitization has been successfully applied to the investigation of the triplet state.[10]

Experimental

The cyclopentanone (Tokyo Kasei Ind.) was distilled bulb-to-bulb, with the middle third retained, after treating it with diphosphorus pentoxide. Gas-chromatographic analysis showed a trace amount of water as an impurity. Pure-grade *cis*-2-butene (Takachiho Shoji Co.,) was used as supplied. The cyclohexane (Tokyo Kagaku Seiki Co., pure-grade) was passed through a 2-m-silica gel column before use.

The quartz reaction cell used was 5.0 cm long and 4.8 cm in diameter, with a total volume, including access tubing, of about 90 m*l*; it was inserted in an electric furnace kept at the desired temperature within ± 1°C by means of an electric controller. A home-made cadmium discharge lamp, with argon (2 torr) as the buffer gas, was heated in a furnace kept at 270 ± 2°C by means of an electric controller. The 228.8 nm resonance line and visible lines were filtered out by means of a combination of a Toshiba UV-D25 filter and a Pyrex plate, so that the emerging light was mainly the 326.1 nm resonance line.

The reaction products obtained were analyzed by means of a gas chromatograph using a column of 5 m propylene glycol at 65°C, after removing the non-condensable gases at -196°C with a Toepler pump.

In the cadmium photosensitization, the light intensity absorbed by cadmium was measured by using the *cis-trans* isomerization of *cis*-2-butene as the actinometer. The quantum yield was assumed to be 0.5.[11]

Results and Discussion

Cadmium Photosensitization. In the case of the cadmium photosensitization, it is necessary to elevate the reaction temperature in order to increase the vapor

pressure of cadmium metal. The thermal reactions of cyclopentanone at 273°C were found to be negligibly small. The products in the cadmium photosentitization were identified as carbon monoxide, ethylene, cyclobutane, and 4-pentenal, which were the same as those obtained in the 313.0 nm direct photolysis. The quantum yields of the product formations are listed in Table 1 as functions of the pressure and the temperature. The rate of carbon monoxide formation was almost constant at pressures higher than 10 Torr. A comparison with the case of the acetone photolysis[10] suggests that the effect of the light other than the 326.1 nm resonance line on the cyclopentanone photolysis is negligibly small in the present experiment. The quantum yield of carbon monoxide formation was 0.18 at 273°C. The relative yields of carbon monoxide, ethylene, cyclobutane, and 4-pentenal were almost constant at pressures above a few Torr; they were, respectively, 1.0, 1.2, 0.3, and 0.3 at 273°C.

a) $P_{c\text{-}C_5H_8O}$=22.6 Torr

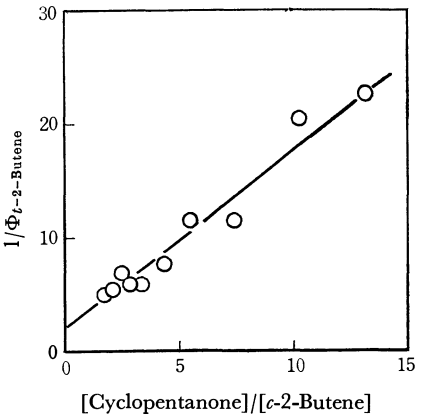

Fig. 1. Plots of the reciplocal of the quantum yield of *trans*-2-butene against the cyclopentanone/*cis*-2-butene pressure ratio.

When *cis*-2-butene was added to 22.6 Torr of cyclopentanone at 270°C, the quantum yields of the decomposition products (CO, ethylene, and cyclobutane) decreased with the increase in the quantum yield of *trans*-2-butene formation (Table 2). The reciprocal of the quantum yield of *trans*-2-butene is plotted against the cyclopentanone/*cis*-2-butene pressure ratio in Fig. 1. Obviously, a straight line was obtained. This result may be explained by the competitive quenching for triplet cadmium, as was discussed previously.[12] From the slope of the straight line in Fig. 1, the relative quenching efficiency of cyclopentanone against that of *cis*-2-butene was calculated to be 0.8 ± 0.2. The value is very large compared with that of paraffins and is close to that of olefins.[12] This suggests that the cyclopentanone molecule interacts with triplet cadmium strongly and is excited to the triplet state:

$$Cd + h\nu(326.1\text{ nm}) \longrightarrow Cd^* \quad (1)$$

$$Cd^* \longrightarrow Cd + h\nu \quad (2)$$

$$Cd^* + S_0 \longrightarrow Cd + T \quad (3)$$

where Cd*, S_0, and T represent, respectively, triplet cadmium, and the ground state and the triplet state of cyclopentanone.

In the presence of *cis*-2-butene, the observed decrease in the quantum yield of the decomposition product agreed with that calculated assuming the competitive quenching for triplet cadmium within the limits of experimental error. That is, the reaction of the excited cyclopentanone is not affected by the presence of *cis*-2-butene.

As is shown in Table 1, the quantum yields of the products formation at lower pressures were slightly smaller than those at higher pressures. This difference may be explained in terms of Reaction (2).

The total quantum yields of CO and 4-pentenal were less than unity, even at the highest pressure examined. This suggests that a part of the triplet cyclopentanone formed loses its excitation energy without forming any product.

12) S. Tsunashima and S. Sato, This Bulletin, **40**, 2987 (1967); S. Tsunashima, S. Satoh, and S. Sato, *ibid.*, **42**, 329 (1969).

In spite of the increase in the quantum yields of ethylene and cyclobutane formations with the increase in the temperature, the ethylene/cyclobutane ratio was independent of the temperature change. This suggests that the activation energy of the ethylene formation is slmost the same as that of the cyclobutane formation. It has been proposed that the tetramethylene diradical is an intermediate for the ethylene and cyclobutane formations:[7]

$$T \longrightarrow CO + \dot{C}H_2CH_2CH_2\dot{C}H_2 \quad (4)$$

$$\dot{C}H_2CH_2CH_2\dot{C}H_2 \longrightarrow 2C_2H_4 \quad (5a)$$

$$\longrightarrow c\text{-}C_4H_8 \quad (5b)$$

If the Process (4) occurs with a negligibly small activation energy, the Processes (5a) and (5b) should occur with an equal energy of activation.

The decomposition of cyclopentanone to carbon monoxide and ethylene is endothermic by 44.1 kcal/mol.[13] The excess energy for the decomposition is 43.6 kcal/mol in the cadmium photosensitization. If the total spin is conserved during the reaction, one of the ethylenes formed should be in the triplet and should be almost in the perpendicular form, since the excitation energy of the lowest triplet ethylene decreases with an increase in the twisting angle around the C–C bond from about 106 to 43 kcal/mol.[14]

In the presence of a large amount of cyclohexane, the quantum yield of the decomposition decreased, and that of 4-pentenal formation increased slightly; that is, the 4-pentenal/CO ratio increased. Since the products ratio of 4-pentenal/CO is independent of the competitive quenching of cyclohexane for triplet cadmium, the increase in the ratio suggests the presence of a collisional deactivation process for the 4-pentenal formation.

The results can, therefore, be explained in terms of the following simplified scheme:

$$T \longrightarrow CO + 2C_2H_4(\text{or } c\text{-}C_4H_8) \quad k_d \quad (6)$$

$$\longrightarrow C_4H_7CHO \quad k_i \quad (7)$$

$$\longrightarrow S_0 \quad k_s \quad (8)$$

$$T + M \longrightarrow C_4H_7CHO \quad k_{mi} \quad (9)$$

$$\longrightarrow S_0 + M \quad k_{ms} \quad (10)$$

The steady-state treatment of the above mechanism gives the following equation:

$$R(4\text{-pentenal})/R(CO) = k_i/k_d + (k_{mi}/k_d)[M] \quad (11)$$

Using the data in Table 1, k_i/k_d is estimated to be 0.3 at 273°C. The value of k_{mi}/k_d may be very small, so that the second term on the right-hand-side of Eq. (11) is negligibly small, even at the pressure of 80 torr.

With the increase in the reaction temperature, the quantum yield of the decomposition increased and that of the 4-pentenal formation decreased; however, the decrease in the 4-pentenal formation was less than the increase in the quantum yield of the decomposition. The apparent activation energy for the 4-pentenal/CO ratio was estimated to be 9 ± 3 kcal/mol. This may be explained by the difference in the activation energy between the Reactions (6) and (7) being 9 kcal/mol, on the assumption that the second term on the eight-hand-side of Eq. (11) is negligibly small. The second term is negligibly small at 273°C and at the pressures of cyclopentanone below 40 torr, as has been shown, and it is expected to decrease with an increase in the temperature, since the activation energy of Reaction (9) is probably smaller than that of Reaction (6).

326.1 nm Direct Photolysis. In the absence of cadmium vapor, carbon monoxide, ethylene, cyclobutane, and 4-pentenal were formed from cyclopentanone upon irradiation with the cadmium lamp. These products were the same as those obtained in the cadmium photosensitization, and also the same as those obtained in the 313.0 nm direct photolysis.[1,2] The experimental conditions were the same except for the absence of cadmium. The rates of the product formation were less than those obtained in the cadmium photosensitization. The relative yields of the products are listed in Table 3.

Table 3. Relative Yields of the Products in the 326.1 nm Direct Photolysis

Temp. °C	$P_{c\text{-}C_5H_8O}$ Torr	Relative Yields		
		$\frac{C_2H_4}{CO}$	$\frac{c\text{-}C_4H_8}{CO}$	$\frac{C_4H_7CHO}{CO}$
273	9.9	1.1	0.21	
273	37.9	1.5	0.21	
273	39.4	1.3	0.27	0.17
273	61.2	1.2	0.23	0.13
273	85.8	1.3	0.23	0.20
225	60.8	1.4	0.27	0.42
177	56.8	1.2	0.26	0.73

Assuming that the light intensity is the same as that in the cadmium photosensitization and that the value of ε is 4.7 l/mol cm,[15] the quantum yield of the carbon monoxide formation was estimated to be about 0.6 at 273°C. This value may be an upper limit, since the light intensity absorbed has been underestimated in the above treatment.[10]

The results obtained in the 326.1 nm direct photoolysis of cyclopentanone were very similar to those obtained in the cadmium photosensitization; *i.e.*, (1) the distributions of the products were almost the same at 273°C, (2) each product formation at 273°C was scarcely affected at all by the pressure change in either case, (3) the ethylene/cyclobutane ratios were constant whatever the pressure and temperature changes and were the same in both cases, and (4) the 4-pentenal/CO ratio decreased with the increase in the temperature, the apparent activation energy for the ratio in the direct photolysis being roughly 6 kcal/mol, slightly smaller than that obtained in the cadmium photosensitization. These similarities suggest that the precursor of the reaction products in the 326.1 nm direct photolysis is the same as that in the cadmium photosensitization.

14) T. Terao, S. Hirokami, S. Sato, and R. J. Cvetanović, *Can. J. Chem.*, **44**, 2173 (1966).

15) C. Takahashi, S. Tsunashima, and S. Sato, unpublished data.

By the absorption of 326.1 nm light, the lowest excited singlet cyclopentanone may be formed in the direct photolysis. The excited singlet cyclopentanone will cross over to the triplet state or converge to the ground state with or without fluorescence emission. The triplet cyclopentanone thus formed will disappear through Reactions (6)—(10), as was assumed in the case of the cadmium photosensitization.

The small pressure effect on the 4-pentenal/CO ratio may be explained by the small value of k_{mi}/k_d. The apparent activation energy in the ratio can also be explained as in the case of the cadmium photosensitization.

The 4-pentenal/CO ratio at 273°C and the apparent activation energy in the ratio obtained in the direct photolysis were slightly smaller than those obtained in the cadmium photosensitization. These differences may arise from the difference in the excess energy of the triplet cyclopentanone formed.[16] This difference in the excess energy may be small, however, because only small differences were observed between the two photolyses.

Comparison with 313.0 nm Direct Photolysis. In the case of the 313.0 nm direct photolysis of cyclopentanone, almost the same results were obtained as in the 326.1 nm photolyses, except for the pressure effect upon the 4-pentenal/CO ratio.

In the 313.0 nm photolysis, the 4-pentenal/CO ratio increased with the increase in the pressure at 123.8°C.[3] Chup Yew Mok has explained the pressure dependence of the ratio by a relation which is essentially the same as Eq. (11), although the assumed the singlet cyclopentanone to be the precursor of the reaction products; he found that the rate-constant ratio, which corresponds to k_{mi}/k_d in Eq. (11), decreased with an increase in the temperature.[4] A similar temperature dependence of the k_{mi}/k_d ratio was considered in the 326.1 nm photolyses. The differences in the reaction temperature and in the excitation energy may be enough to explain the difference in the 4-pentenal/CO ratio. It is not necessary to assume a different reaction mechanism for the 313.0 nm photolysis.

Srinivasan assumed that the reaction products were formed from the first excited singlet state, with various vibrational levels in the 313.0 nm photolysis.[3] His discussions were based on the fact that the effect of oxygen on the reaction was comparable to those of inert gasses.[3] Similar effects were obtained by Chup Ye Mok, using oxygen and 1,3-pentadiene.[4] These results cannot, however, conclusively exclude the presence of a triplet precursor for the reaction products, as was pointed out by Chup Yew Mok.[4] If oxygen and 1,3-pentadiene are inefficient in quenching the triplet cyclopentanone and/or if the lifetime of the triplet cyclopentanone is very short, the effect of oxygen or 1,3-pentadiene on the reaction can be expected to be small. If the excited singlet cyclopentanone is the precursor for the decomposition, the rate of the decomposition should be faster than that of the intersystem crossing. Lee *et al.* suggested that the rate of the intersystem crossing in cyclopentanone is very fast, as it is in acetone.[6] As was discussed in the previous sections, the assumption of the triplet precursor explains well the results of cyclopentanone photolyses.

Consequently, it may be said that the triplet state is responsible for the reaction products in the cyclopentanone photolysis, as is in the case of acetone.

Temperature Effect on Raman Intensity of Liquid Sample and Local Field Correction

Tsunetake FUJIYAMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 30, 1972)

The relative intensities of the 996 cm^{-1} line of liquid benzene and the 367 cm^{-1} line of liquid chloroform were observed at various temperatures with a high accuracy. The apparent intensity change due to the temperature was explained completely in terms of the local field effect, the density change, and the statistical distribution. The validity of Eckardt's correction factor was strongly supported. In the case of liquid chloroform, an intensity change due to intermolecular interaction was observed after the elimination of the above three factors. The reliability of the relative intensity measurements of Raman lines was discussed.

The reliability of relative intensity measurements of Raman spectra has been greatly increased in the past few years by improvements in laser Raman spectrophotometers. Raman intensity measurements observe light energy scattered from a sample; therefore, they have a great advantage, in principle, over intensity measurements of absorption spectra. They are free from the effects of a slit-function,[1] the effects related to anomalous dispersion,[2-6] the effects of multi-reflections inside sample layers,[7-10] the so-called baseline effects,[1,11] and so on, all of which are notorious difficulties in the intensity measurements of liquid samples by infrared absorption methods. Moreover, the handling of a sample is much easier in Raman than in infrared spectroscopy, especially when temperature-control is involved in the measurements. On the other hand, the reproducibility of successively-observed Raman intensities is often spoiled by casual changes in the experimental conditions; the setting of a sample cell, a slight deviation in optical alignment, the purity of the sample, the cleanness of the cell-window, and so on.

Paying careful attention to these factors, the intensities of the fundamental lines of liquid benzene and chloroform were measured. Liquid benzene was chosen because the intensity of the 996 cm^{-1} line is very strong and was expected to be observed with a high accuracy. Another reason for choosing that molecule was that the intensity change due to intermolecular interactions was expected to be very small in its system. In the case of liquid chloroform, strong intermolecular interaction was expected; therefore, the intensity change due to the temperature may exhibit different features from that of liquid benzene.

Experimental

The spectrometer used for the present work was designed and constructed by the authors.[12] The instrument is composed of a He-Ne gas laser source (NEC, GLG 108, 50 mW), a Spex 1401 double monochromator, a HTV R-376 photomultiplier (S-20 response), a handmade lock-in amplifier (375 cps), and a recorder.

The linearity of the whole system was carefully checked. First, the out-put current of the photomultiplier was plotted against the light energy. The linearity was perfect for the out-put from zero through 20 microampere, which was equivalent to an out-put voltage of 20 volts with $R_p = 1$ megaohm. Then, the linearity of the amplifier was tested using attenuator (0.1 − 120 db for each 0.1 db). Finally, the linearity of the whole system was checked by plotting the final recorder out-put voltage against the light-energy which passes through the entrance slit of the monochromator. The light-energy was attenuated by using neutral filters (Kenko, ND). From the standard errors estimated from the linear-fitting, the linearity of the whole system was ascertained to be less than 1 per cent of the full scale as long as the out-put voltage was less than 10 volts.

Special attention was paid to the temperature of the room so as to keep the out-put power of the laser source constant. The stability of the laser out-put during the individual spectral measurements was observed by monitoring the light energy

which penetrated through the 100 per cent reflectance mirror of the laser cavity. When the power of the laser source drifted more than 1 per cent during the measurements, the data observed were completely discarded.

The high-temperature cell used for the measurements is illustrated in Fig. 1. It is mainly made of *pyrophyllite*, which is easy to shape and which is a good thermal insulator. Brass was used for the sample cylinder of Fig. 1 so as to obtain a homogeneous temperature atmosphere inside the cylinder, in which a sample cell (a $10\times10\times15$ mm cube) was placed. The temperature was controlled by changing the electric current supplied to the nichrome heater. The temperature was observed by means of a thermocouple directly inserted into the samples. The accuracy of the temperature measurements was believed to be within ±1°C.

The benzene and chloroform used for the measurements were commercial products and were used for the measurements just after fractional distillation. The purity of the samples was checked by the use of gas chromatography.

Results and Discussions

996 cm^{-1} Line of Benzene. The Raman intensity of the 996 cm^{-1} line of liquid benzene was observed in the temperature range from 24 through 70°C. The intensity was determined from the band area by the weight-method. The averaged value of the five intensity data was taken as the observed Raman intensity; it had a standard deviation of from 0.3 to 0.6 per cent. The observed relative intensity ratios are summarized in Table 1, where the relative intensity at 24°C is chosen as the standard. The relative error of the individual ratio is estimated to be ±1 per cent. Obviously, the relative intensity decreases more than 10 per cent as the temperature changes from 24 to 70°C. The results are also illustrated in Fig. 2.

TABLE 1. INTENSITY CHANGE OF THE 996 cm^{-1} LINE OF BENZENE

t(°C)	L/L_{24}	s/s_{24}	d/d_{24}	Lsd/Lsd_{24}	I/I_{24}
24	1.000	1.000	1.000	1.000	1.000
36	0.979	1.002	0.986	0.967	0.960
47	0.959	1.002	0.972	0.934	0.930
58	0.939	1.005	0.958	0.905	0.912

○: I/I_{24}, ○: d/d_{24}, +: Ld/Ld_{24}, ●: Lsd/Lsd_{24}

The apparent intensity change due to the temperature has been discussed by Person[13] for the infrared absorption case, where the importance of the local-field correction has been emphasized. For the case of Raman intensity, various authors have proposed correction factors to the local field that allow Placzek's intensity formula to be applied to liquids and/or solutions.[14-19] In addition to the local-field effect, the density change and the statistical distribution of molecules in relation to a vibrational state may contribute to the change in the apparent Raman intensity due to the temperature. These factors are all temperature-dependent and should be taken into account in interpreting the present results.

The density, d, as a function of the temperature may be found in the International Critical Tables.[20] The relative values of the density at various temperatures are summarized in Table 1, where the density at 24°C is chosen as a standard.

The statistical factor, s, may be expressed as:

$$s = \frac{1}{1-\exp(-hcv/kT)}$$

where v is the frequency displacement of a Raman line from that of the incident wave, T is the temperature, h is the Planck's constant, k is the Boltzmann constant, and c is the velocity of light. The calculated relative values of s are summarized in Table 1, where the s-value at 24°C is taken as a standard. The contribution of s to the change in the intensity is much smaller than the experimental error.

Eckardt[18] emphasized that the most appropriate factor for the local-field correction in Raman scattering, L, is:

$$L = (n_s/n_0)(n_s^2+2)^2(n_0^2+2)^2/81$$

where n_s is the refractive index at the Stokes frequency and where n_0 is the index at the frequency of the incident light. If the variation in the refractive index over the frequency range of the Raman shift is ignored, the equation reduces to:

$$L = \frac{(n^2+2)^4}{81}.$$

The calculated relative values of the local-field correction factor, L/L_{24}, are summarized in Table 1. Again, L at 24°C is taken as the standard. In the calculation, the refractive indices for different temperatures were

estimated from the empirical Eykman equation:

$$\frac{n^2-1}{n+0.4} = \frac{d}{M} \times C,$$

where C is a constant characteristic for a molecule; M, the molecular weight, and d, the density.[21]

Finally, the products of L, s, and d were calculated; they are summarized in Table 1 (designated as (Lsd)). The relative values, $(Lsd)/(Lsd)_{24}$, are expected to agree with those of the relative intensity, I/I_{24}, if the factors considered here mainly contribute to the apparent intensity change due to the change in temperature. Actually, the agreement between these two sets of values is excellent. In Fig. 2, the observed relative intensities are compared with those corrected for these three factors, L, s, and d.

Table 2. Intensity change of the 367 cm^{-1} line of chloroform

t(°C)	L/L_{24}	s/s_{24}	d/d_{24}	Lsd/Lsd_{24}	I/I_{24}
24	1.000	1.000	1.000	1.000	1.000
35	0.981	1.002	0.986	0.970	0.866
40	0.957	1.003	0.980	0.941	0.815

367 cm^{-1} Line of Chloroform. Exactly the same procedures were applied to the 367 cm^{-1} line of liquid chloroform. The results are summarized in Table 2. It can be seen in the table that the relative intensity of the 367 cm^{-1} line decreases more than 20 per cent as the temperature changes from 24 to 40°C, while the calculated correction factor, $(Lsd)/(Lsd)_{24}$, decreases only 6 per cents. The discrepancy between the observed and the calculated intensity ratios corresponds to the real change in the intensity of the line on passing from 24 to 40°C; this can be explained with respect to the intermolecular interactions, such as the break-down of hydrogen bonding between chloroform molecules in the liquid phase on the elevating of the temperature. The details will be discussed elsewhere, together with the intensity change in the absorption spectra.

Local-field Correction and Conclusion. A few important conclusions can be drawn from the present results. The intensity change in the 992 cm^{-1} Raman line of liquid benzene can be completely explained by L, s, and d; that is, the Raman scattering cross section per molecule does not change when the temperature varies. Among the three factors, the local-field correction is the main factor changing the apparent intensity. Eckardt's formula is based upon these ideas: (1) the Lorentz-field consideration is applicable to the system, and (2) the scattering may be thought of as the absorption of a light quantum, followed by the emission of another quantum; therefore, the local-field correction for the scattering is the product of the local-field corrections for absorption and for spontaneous emission.[22,23] Therefore, the effect of the local field on the apparent intensity is much greater for the Raman than for the infrared absorption intensity. In the latter case, L is expressed as:

$$L = \frac{(n^2+2)^2}{9}$$

assuming the Lorentzfield.[3] It can easily be ascertained that the intensity change due to temperature variation cannot be explained by this formula, which means that the present results strongly support the assumption (2) of Eckardt and contradicts the propositions of the references.[14,15] It may also be concluded from the present results that the choice of the Lorentzfield for the liquid benzene is reasonable.

The other important conclusion drawn from the present result is that the L and d factors do not depend upon the frequency, ν; this means that the apparent intensity change due to the change in temperature is the same magnitude for all the Raman-shift region. Therefore, the factors do not contribute to the observed relative intensities of Raman lines with different frequencies. In the preceding discussions, the refractive index of a sample was assumed to take a constant value for all the frequency range under consideration. In a case where a sample is absorbing, *e.g.*, the case of a resonance Raman, the refractive index value changes considerably over the Raman-shift range. Therefore, the consideration of the local-field effect is extremely important.

Incidentally, it may be concluded that the measurements of the relative intensities of Raman lines are much easier and more reliable than those of the infrared absorption in the sense that the observed data are nearly free from any systematic errors which spoil the reliability of the relative intensities.

The author wishes to express his sincere thanks to Professor Takehiko Shimanouchi and all the members of his laboratory for giving the opportunity of completing this work.

Catalytic Diacetoxylation of Dihaloethylenes in the Presence of Palladium Salts

Masahiro YAMAJI, Yuzo FUJIWARA, Ryuzo ASANO, and Shiichiro TERANISHI
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka
(Received June 5, 1972)

The reaction of dihaloethylenes with acetate anions in the presence of palladium(II) salts gave *trans*-diacetoxyethylenes catalytically. It was found that the system, $PdCl_2$–NaOAc–CH_3CN is the best for the diacetoxylation of dihaloethylenes, and that palladium(II) salts catalyze the isomerization of *trans*-diacetoxyethylene to its 1,1-diacetoxy derivative. The mechanism was also discussed.

Palladium salts have been known to cause a wide variety of reaction.[1] It was generally thought that halide ion displacement of vinyl halides with nucleophiles was difficult because of their double bond character between carbon and halogen atoms.

Since Stern *et al.* explored the possibility of the nucleophilic substitution of vinyl chloride by an acetate anion in the presence of palladium(II) chloride to give vinyl acetate,[2] a few reports appeared concerning with the substitution.[3] However, examples are limited to only monohalides such as vinyl chloride or 2-chloropropylene. Interest in whether dihalides also undergo substitution reaction or not, prompted us to investigate the reaction of dihaloethylenes in detail. Interestingly enough we have found that in the presence of catalytic amounts of palladium(II) salts, various dihaloethylenes such as dichloro-, dibromo-, diiodo-, and bromochloroethylenes react readily with an acetate anion to produce diacetoxyethylenes,[4] and that they also react with various substituted acetate anions (XCH_2COO^-: X= C_2H_5, CH_3, Cl). In addition, in the course of this study, an isomerization of *trans*-diacetoxyethylene to 1,1-diacetate by palladium(II) salts was also found.

In this paper, we will describe the substitution reaction of dihaloethylenes with acetate anions, and the observation that *trans*-diacetoxyethylene isomerizes to its 1,1-diacetate derivatives in the presence of palladium(II) salts.

Results and Discussion

Reaction of cis-*Dichloroethylene with Acetate Anion.* In the substitution reaction of vinyl halide, the system, $PdCl_2$–Na_2HPO_4–isooctane-acetic acid was used,[2] but a dihaloethylene, *cis*-dichloroethylene, afforded no acetates under the similar reaction conditions. So, first, we investigated the reaction conditions under which the olefinic dihalides suffer the nucleophilic substitution reaction with an acetate anion.

Table 1 summarizes the results and shows that the system, $PdCl_2$–NaOAc can cause the diacetoxylation of *cis*-dichloroethylene catalytically, and that acetonitrile is the best solvent for the reaction. It seems that the solvent which has an appropriate ability of coordination to palladium(II) and can be easily displaced by the substrate dihalo-olefin, is suitable for the reaction. In typical, the reaction of *cis*-dichloroethylene with sodium acetate in the presence of a catalytic amount of $PdCl_2$ gave *trans*-diacetoxyethylene (123%[5]) and 1,1-diacetoxyethylene (39%) with a small amount of

Table 1. Diacetoxylation of *cis*-dichloroethylene by palladium(II) salts[a]

Palladium salt	Acetoxylating agent	Solvent	Yield, %[b] of *trans*-diacetoxyethylene
$Pd(OAc)_2$	AcOH	Isooctane	trace
$Pd(OAc)_2$	AcOH	—	trace
$Pd(OAc)_2$	—	Acetonitrile	7[c]
$PdCl_2$	NaOAc	Acetic acid	14[c]
$PdCl_2$	NaOAc	Acetonitrile	123[c]
$PdCl_2$	NaOAc	Dimethylformamide	42[c]
$PdCl_2$	NaOAc	Benzonitrile	8[c]
$PdCl_2$	NaOAc	Ethanol	trace
$PdCl_2$	NaOAc	Pyridine	—
$PdCl_2$[d]	AcOH	Isooctane	—

a) Reactions were carried out at 80°C for 8 hr unless otherwise stated.
b) Based on the Pd(II) catalyst.
c) 1,1-Diacetoxyethylene and *cis*-isomer were also formed in small amount.
d) Disodium hydrogen phosphate (Na_2HPO_4) was employed and the reaction was performed for 48 hr at room temperature.

Table 2. Reactivity of palladium(II) salts[a]

Palladium salt	Product and yield, %[b]	
	trans-diacetoxy-	1,1-diacetoxyethylene
$PdCl_2$	123	39[c]
$PdBr_2$	36	9
PdI_2	0.5	trace

a) Reactions were carried out at 80°C for 8 hr charging 0.09 mol of *cis*-dichloroethylene, 0.18 mol of NaOAc, 0.03 mol of palladium salt, and 200 ml of CH_3CN as a solvent.
b) Yields are based on palladium salt used.
c) *cis*-Isomer was also formed in a very small amount.

1) For example, P. M. Maitlis, "The Organic Chemistry of Palladium," Vol. I and II, Academic Press, New York, 1971.
2) E. W. Stern, M. L. Spector, and H. P. Lefti, *J. Catal.*, **6**, 152 (1966).
3) a) C. F. Kohll and R. van Helden, *Rec. Trav. Chim. Pays-Bas*, **87**, 481 (1968); b) H. C. Volger, *ibid.*, **87**, 501 (1968); c) M. Tamura and A. Yasui, *Kogyo Kagaku Zasshi*, **72**, 572 (1969); d) P. M. Henry, *J. Amer. Chem. Soc.*, **93**, 3853 (1971); **94**, 1527 (1972).
4) M. Yamaji, Y. Fujiwara, T. Imanaka, and S. Teranishi, This Bulletin, **43**, 2659 (1970).
5) Yields given in this paper are based on the amount of palladium salt used.

cis-diacetoxyethylene. And interestingly in this case, no monoacetate was produced.

In order to study the ligand effect on the reaction, the reactivities of $PdCl_2$, $PdBr_2$, and PdI_2 were compared (Table 2). The reactivity decreases in the order: Cl>Br>I. This may be explained in the following way: π-acceptor character increases with the order, Cl<Br<I,[6] so back donation from palladium to the substrate dihalo-olefin would be more restricted in the case of PdI_2. Thus the ease with which palladium(II) and the olefin form a stable π-complex, increases in the order, I<Br<Cl, then resulting in increase of the reactivity in this order. In addition, the bulkiness of the iodine atom would prevent the coordination of the substrate olefin to palladium(II). Consequently, $PdCl_2$–NaOAc–CH_3CN is the most effective system for the diacetoxylation of dihaloethylene.

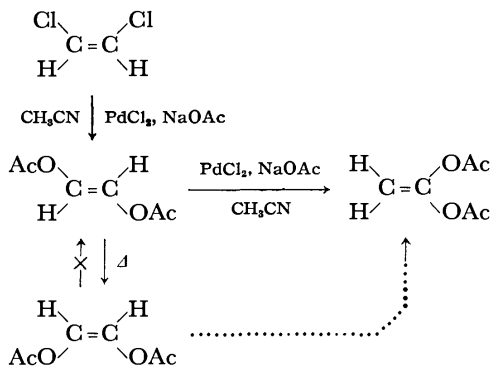
The acetoxylation of *cis*-dichloroethylene gave 1,1- and *cis*-diacetoxyethylene as by-products. In order to study the reaction path of these products, isomerization of *trans*-diacetoxyethylene, a main product, was examined (Table 3).

Table 3. Isomerization of *trans*-diacetoxyethylene[a]

$PdCl_2$ mmol	NaOAc mmol	Reaction time, hr	Yield, %[b] diacetoxyethylenes	
			1,1-isomer	*cis*-isomer
0.06	None	6	31	trace
0.06	0.12	8	64	trace
None	0.12	8	—	30
0.06[c]	0.12	8	trace	98

a) Reactions were carried out at 80°C for 8 hr using CH_3CN as a solvent.
b) Based on *trans*-diacetoxyethylene.
c) The starting material was *cis*-diacetoxyethylene.

As is apparent from Table 3, *trans*-diacetoxyethylene isomerized to 1,1-diacetate (64% yield) in the presence of $PdCl_2$ and NaOAc. In addition, the table indicates that thermal isomerization of *trans*-diacetoxyethylene to its *cis* isomer takes place in the absence of $PdCl_2$. Therefore, it seems that both 1,1-diacetoxyethylene and its *cis* isomer[7] are derived from *trans*-diacetoxyethylene which is formed by diacetoxylation of the starting *cis*-dichloroethylene.



6) J. Chatt and B. L. Shaw, *J. Chem. Soc.*, **1962**, 5075.
7) *cis*-Diacetate produced in a small amount is not an initial product since it does not isomerize to *trans*-diacetate under the reaction conditions.

Table 4. Reaction of *cis*-dichloroethylene with substituted acetate anions[a]

Sodium salt	Yield, % of diacetate[b]	
	trans-isomer	1,1-isomer
C_2H_5–CH_2COONa	77	14[c]
CH_3–CH_2COONa	55	11[d]
Cl–CH_2COONa	trace[e]	—

a) Reactions were all carried out at 80°C for 8 hr, charging 0.02 mol of $PdCl_2$, 0.12 mol of sodium salt, 0.06 mol of *cis*-dichloroethylene, and 160 ml of CH_3CN.
b) Based on $PdCl_2$ used.
c) A trace amount of butyric anhydride was also formed.
d) A trace amount of propionic anhydride was also formed.
e) 1-Chloro-2-chloroacetoxyethylene was formed in a 0.4% yield.

Reaction of cis*-Dichloroethylene with Substituted Acetate Anions.* As it became apparent that $PdCl_2$–NaOAc causes diacetoxylation of *cis*-dichloroethylene, we further tried to extend this reaction. Examination was performed using the substituted acetate anions (XCH_2COO^-: X=C_2H_5, CH_3, Cl) as nucleophiles. The data listed in Table 4 show that the diacetoxylation could also occur in the cases of sodium butyrate, propionate, and chloroacetate other than sodium acetate, and that an electron donating group (CH_3, C_2H_5) increases the reactivity, indicating the nucleophilic nature of the reaction.

Reaction of trans*-Dichloroethylene, -Diiodoethylene, -Bromoiodoethylene, and-Dibromoethylene with Acetate Anion.* Since *cis*-dichloroethylene has been found to undergo diacetoxylation, other dihaloethylenes were investigated toward the reactivity in the presence of $PdCl_2$ and NaOAc (Table 5).

Table 5. Diacetoxylation of various dihaloethylenes[a]

Dihaloethylene	Yield, % of diacetoxyethylene[b]			
	trans-	1,1-	*cis*-	Total
trans-ClHC=CHCl	138	70	trace	208
cis-ClHC=CHCl	123	39	trace	162
BrHC=CHBr[c]	160	30	trace	190
trans-BrHC=CHI	33	23	5	61
trans-ICH=CHI	3	2	—	5

a) Reactions were carried out at 80°C for 8 hr using CH_3CN as a solvent.
b) Based on $PdCl_2$.
c) *cis* and *trans* Mixture (5:7).

It can be seen from Table 5, various dichloroethylenes can undergo diacetoxylation in the presence of $PdCl_2$ and NaOAc as *cis*-dichloroethylene does. The reactivity decreases in the order: Cl>Br>I.

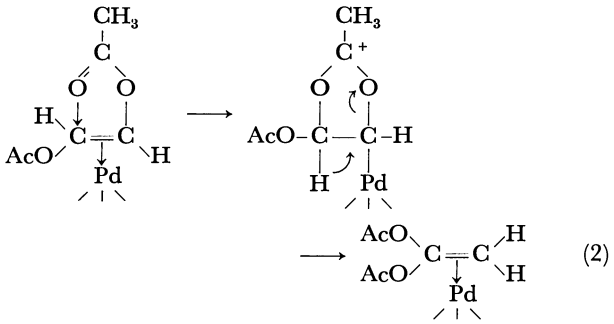
1,2-Transfer of Acetoxy Group on Ethylenic Carbon Atoms. As mentioned above, it has been found that $PdCl_2$ catalyzes the isomerization of *trans*-diacetoxyethylene to 1,1-diacetoxyethylene. Palladium chloride without NaOAc can also affect the isomerization, but the yield decreases from 64% to 31%. This indicates that an acetate anion of NaOAc other than the starting *trans*-

diacetoxyethylene, is partly involved in the reaction.[8]

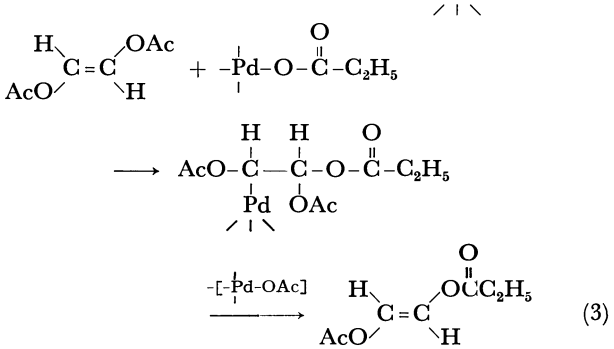
Palladium(II) catalyzed allylic isomerization of an acetate anion is well known,[9] but vinylic isomerization is the first example to our knowledge. Henry reported a palladium(II) catalyzed allylic isomerization of an acetate anion, and that two reactions actually take place involving an acetoxypalladation-deacetoxypalladation mechanism and 1,3-acetoxonium ion mechanism.[9]

$$MeCH{=}CHCH_2\overset{*}{O}Ac + -PdOAc \underset{AcOH}{\rightleftharpoons} MeCH(OAc)-CH{=}CH_2 + -Pd\overset{*}{O}Ac \quad (1)$$

In the present case, the isomerization reaction might proceed through a 1,2-acetoxonium intermediate (Eq. 2), and an acetoxypalladation-deacetoxypalladation might be operative in the exchange reaction of acetate anions (Eq. 3).



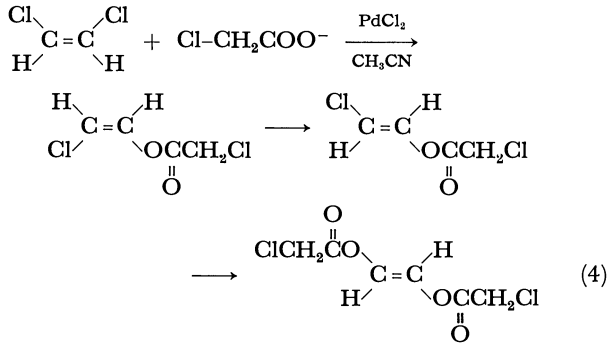
(2)



(3)

$PdBr_2$, PdI_2, $Pd(OAc)_2$, and $PdCl_2(CH_3CN)_2$ gave the isomerization but other metal salts, such as $RhCl_3$, $IrCl_3$, $NiCl_2$, $PtCl_2$, $FeCl_3$, or $CoCl_2$ gave no reaction.[10] Thus it can be said that this isomerization is characteristic for Pd(II) salts. This provides a very convenient synthetic method for preparing 1,1-diacetoxyethylene of which preparation was rather troublesome by other methods.

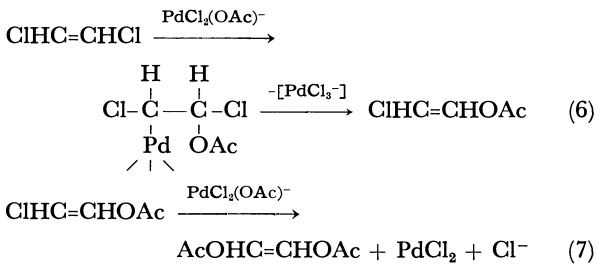
Mechanism of Acetoxylation. The Pd(II) catalyzed acetoxylation of dihaloethylenes gives a *trans*-diacetate as a main product. It seems that the acetoxylation takes place step by step[11] since the monoacetate was obtained from the reaction of *cis*-dichloroethylene and sodium chloroacetate.



(4)

Finally, the diacetoxylation would proceed through the similar mechanism proposed to the acetoxylation of vinyl halides.[1,3a]

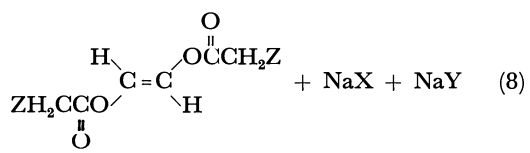
$$PdCl_2 + AcO^- \rightleftharpoons PdCl_2(OAc)^- \quad (5)$$



(6)

(7)

In conclusion, olefinic dihalides such as dihaloethylenes can also undergo acetoxylation by palladium(II) salt catalysts, to give *trans*-diacetates rather exclusively (Eq. 8). In addition, palladium(II) salts affect the isomerization of *trans*-diacetates to their 1,1-diacetate derivatives. These reactions provide a very convenient route to a wide variety of diacetate derivatives.



(8)

Experimental

All temperatures were uncorrected. The IR spectra were recorded on a JASCO IR-E spectrometer and the NMR spectra were measured on a Japan Electron Optics JNM-4H-100 spectrometer. Chemical shifts are given in τ units together with splitting patterns and relative integrated area.

Materials. *cis*- and *trans*-Dichloroethylene, and dibromoethylene (5: 7 *cis* and *trans* mixture) were commercial grade and distilled before use. *trans*-Diiodoethylene (mp 73—73.5°C)[12] and *trans*-bromoiodoethylene (bp 70—71°C/40-mmHg)[13] were prepared according to the methods reported.

8) This external acetate anion participation was confirmed by the fact that dipropionyloxyethylenes were obtained when *trans*-diacetoxyethylene was treated with sodium propionate and palladium chloride.[3d]

9) P. M. Henry, *Chem. Commun.*, **1971**, 328.

10) In the case of allylic isomerization, $PdCl_2$, $PtCl_2$, $RuCl_3$, $OsCl_3$, and $RhCl_3$ are reported to be effective catalysts.[9]

11) The reaction of the monoacetate to the diacetate may be very fast since no monoacetate was obtained in the reaction of dihaloethylenes with an acetate anion, and the *cis-trans* isomerization might take place in the stage of the monoacetate presumably due to its thermal stability.

12) A. Sabanejeff, *Ann. Chem.*, **178**, 109 (1875).

13) H. G. Viehe and E. Franchimont, *Ber.*, **96**, 3153 (1963).

Palladium(II) salts were commercial grade.

General Procedure for Diacetoxylation of Dihaloethylenes with Acetate Anion. Mixtures of the palladium salt, the dihaloethylene in three equiv amount, sodium acetate in six equiv amount, and the solvent were stirred for 8 hr at 80°C. The resulting mixture was filtered to remove $PdCl_2$ and small amounts of Pd metal formed. The filtate was poured into water and the organic material was treated with aqueous sodium carbonate solution, washed with water, and then dried over anhydrous $MgSO_4$. After evaporation of about half of the solvent, the residue was kept standing for several hours, and then *trans*-diacetoxyethylene crystallized, and mother liquid was subjected to preparative gas chromatography (Yanagimoto G-8, Apiezon L) to give 1,1-diacetate and/or *cis* diacetate. Specific examples of the reaction are given in detail below.

Reaction of cis-Dichloroethylene with Sodium Acetate. In a 250 ml, three necked, round-bottomed flask provided with a condenser with a calcium chloride tube at the top, and a stirrer, was placed a mixture of 0.09 mol of *cis*-dichloroethylene, 0.18 mol of sodium acetate, 0.03 mol of $PdCl_2$ and 200 ml of acetonitrile. The mixture was stirred for 8 hr at 80°C. After work-up as decsribed above, the residue crystallized partly. Recrystallization from ether-petroleum ether gave colorless crystals, mp 42—43.7°C. Purification was done by sublimation (4 mmHg) (5.31 g, 123% based on $PdCl_2$), mp 44—45°C which was assigned as *trans*-diacetoxyethylene by comparison of the IR spectra and mixture melting point with an authentic sample,[14] IR (neat) cm^{-1}: 976 (*trans* C-H), 1200 (C–O–C), 1380 (CH_3COO) and 1770 (C=O); NMR (CCl_4): 3.17 (s, 2H) and 7.83 (s, 6H). Found: C, 49.93; H, 5.60%. Calcd for $C_6H_8O_4$: C, 50.00; H, 5.60%.

From the mother liquor, two products were detected and these were separated by glpc. One (1.68 g, 39%) was assigned as 1,1-diacetoxyethylene and the other (trace amount) as *cis*-diacetoxyethylene by comparison with authentic samples,[14] 1,1-diacetoxyethylene; IR (neat) cm^{-1}: 877 (CH_2=), 1200 (C–O–C), 1380 (CH_3COO) and 1760 (C=O); NMR (CCl_4): 2.50 (s, 2H) and 7.80 (s, 6H). *cis*-Diacetoxyethylene; IR (neat) cm^{-1}: 1200 (C–O–C), 1380 (CH_3COO), 1620 (C=C) and 1760 (C=O); NMR (CCl_4): 5.40 (s, 2H) and 7.84 (s, 6H).

From the solvent evaporated, the starting *cis*-dichloroethylene was recovered without isomerization. Authentic *trans*- and *cis*-diacetoxyethylenes and 1,1-diacetate isomer were prepared by the modification of the method described by Shostakovskii *et al.*[14]

Reaction of cis-*Dichloroethylene with Sodium Propionate, Butyrate, and Chloroacetate.* The reaction of *cis*-dichloroethylene with sodium propionate was performed as described above. The products were *trans*-dipropionyloxyethylene (55%), 1,1-dipropionyloxyethylene (11%) and propionic anhydride (trace), *trans*-dipropionyloxyethylene; IR (neat) cm^{-1}: 935, 1150, 1343, 1460, and 1760; NMR (CCl_4): 3.27 (s, 2H), 7.56 (q, 4H, J=7 Hz), and 8.80 (t, 6H, J=7 Hz). 1,1-Dipropionyloxyethylene; IR (neat) cm^{-1}: 900, 1150, and 1750; NMR (CCl_4): 2.26 (s, 2H), 7.64 (q, 4H, J=7 Hz), and 8.84 (t, 6H, J=7 Hz).

Similarly the reaction with sodium butyrate gave *trans*-dibutyryloxyethylene (77%), IR (neat) cm^{-1}: 970, 1245, 1345, and 1760; NMR (CCl_4): 3.27 (s, 2H), 7.62 (t, 4H, J=7 Hz), 8.30 (m, 4H), and 9.00 (t, 6H, J=7 Hz), and 1,1-dibutyryloxyethylene (14%), IR (neat) cm^{-1}: 900, 1150, and 1750; NMR (CCl_4): 2.60 (s, 2H), 7.68 (t, 4H, J=6 Hz), 8.33 (m, 4H), and 9.02 (t, 6H, J=6 Hz), and butyric anhydride (trace).

The reaction with sodium monochloroacetate gave small amounts of 1,2-dichloroacetoxyethylene (probably *trans*), NMR (CCl_4): 3.60 (s, 2H) and 5.98 (s, 4H), and 1-chloro-2-chloroacetoxyethylene (0.4%), NMR (CCl_4): 2.58 (d, 1H, J=4.5 Hz), 4.40 (d, 1H, J=4.5 Hz), and 5.87 (s, 2H).

Isomerization of trans-*Diacetoxyethylene.* The reaction were carried out at 80°C for 8 hr with stirring, charging 0.18 mmol *trans*-diacetoxyethylene, 0.06 mmol of palladium chloride, 0.12 mmol of sodium acetate and 2 ml of acetonitrile. The reaction mixture was analyzed by glcg using tetralin as an internal standard. The results are shown in Table 3.

Isomerization of trans-*Diacetoxyethylene in the Presence of Sodium Propionate.* The reaction was performed at 80°C for 6 hr, charging 0.12 mmol of *trans*-diacetoxyethylene, 0.06 mmol of sodium propionate, 0.056 mmol of palladium chloride and 2.5 m*l* of acetonitrile. After work-up as usual, the reaction mixture was analyzed by glcg. There were obtained *trans*-1-acetoxy-2-propionyloxyethylene (28%), 1,1-diacetoxyethylene (14%) with small amounts of unidentified acetates. The starting *trans*-diacetoxyethylene was recovered in 42% yield. *trans*-1-Acetoxy-2-propionyloxyethylene, IR (neat) cm^{-1}: 945, 1105, 1150, and 1762; NMR (CCl_4): 3.22 (s, 2H), 7.55 (q, 2H, J=7 Hz), 7.80 (s, 3H) and 8.78 (t, 3H, J=7 Hz).

Phase Transition in the Ionic Modification of Phosphorus Pentachloride, $[PCl_4][PCl_6]$. Chlorine Nuclear Quadrupole Resonance Study

Hideaki CHIHARA and Nobuo NAKAMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka 560

(Received June 14, 1972)

Chlorine-35 nuclear quadrupole resonance frequencies in the ionic crystal $PCl_4^+ \cdot PCl_6^-$ were redetermined. Ten resonance lines were found and their temperature dependences were measured below the second order phase transition point at 102 K. The splitting $\Delta\nu_i$ in the resonance lines in the low temperature phase showed a similar temperature dependence as the order parameter. This was accounted for by a librational soft mode theory based on an anharmonic coupling between molecular or ionic librational modes in the crystal.

In 1967 we reported on the ^{35}Cl nuclear quadrupole resonance (NQR) and calorimetric studies of both ionic and molecular modifications of phosphorus pentachloride.[1] It was found that the ionic crystal $[PCl_4][PCl_6]$ undergoes a second order phase transition at 102 K, but the mechanism of the phase transition was not fully clarified because of insufficient accuracy in the heat capacity measurement as well as other experimental data concerning the phase transition.

Meanwhile, DiLorenzo and Schneider[2] measured the NQR frequencies in the same substance and observed some resonance lines at different frequencies from those reported by the present authors. Smith and Tong[3] pointed out later that there are altogether nine lines due to ^{35}Cl and that we missed a pair of doublets at 30.05 MHz and one of four lines at about 32.3 MHz. However, they did not report a broad line at 28.6 MHz which we had described previously.[1]

Now it has become evident from the three previous papers that there are ten NQR lines in Phase II (the low temperature phase) of $[PCl_4][PCl_6]$. This fact clearly indicates that all chlorine atoms in the chemical formula unit (P_2Cl_{10}) are at crystallographically non-equivalent sites in Phase II. Since our failure to observe three more resonance lines seems to be due to insufficient sensitivity of the spectrometer used, we attempted to re-examine all the ten resonance lines using a carefully constructed cryostat. In the present paper, we will discuss the NQR spectra in Phase II in relation to the crystal symmetry of both Phase I and II. It will be shown that the temperature dependence of the NQR frequencies can be explained by a librational soft-mode theory[4,5] which is based on an anharmonic coupling between the molecular or ionic librational modes.

Experimental

The NQR frequencies were measured on the same specimen as was used in the previous NQR study.[1] This had been stored in a sealed glass tube at room temperature for about three and half years after the original measurements of the temperature dependence of the NQR frequencies were carried out.

Some modifications were made of the experimental arrangement. The coaxial cable wire connecting the spectrometer and the sample coil was replaced by a thin-walled cupronickel tube running down the axis of a stainless-steel tube. Both tubes were silver-plated in order to improve spectral sensitivity.[6] The NQR frequencies were determined with a Takeda Riken Model TR-5578 digital frequency counter instead of the one used previously.

Results and Discussion

Spectra in Relation to Structure. The stable phase of phosphorus pentachloride contains two types of complex ion, PCl_4^+ and PCl_6^-, in a tetragonal unit cell of the space group P4/n at room temperature (Phase I).[7] The phosphorus atom and two of the six chlorine atoms in PCl_6^- lie on the four-fold axis and the phosphorus atom in PCl_4^+ is on the $\bar{4}$ axis. Other chlorine atoms are at general positions. All the four chlorine atoms in a PCl_4^+ cation are crystallographically equivalent and the four chlorine atoms in the PCl_6^- that lie in the *ac* plane are also equivalent.

Therefore, the number of resonance lines in Phase I observed in the previous work agrees with the number expected from the crystal structure. In Phase II, on the other hand, ten ^{35}Cl NQR lines were observed

instead of the seven detected previously. The resonance frequencies at 20.9 K and their assignment are given in Table 1.

The present results are compared with the previous results[1,2] at 78 K (Phase II) and 109 K (Phase I) in Table 2. Our results in the two independent measurements differ slightly, which may be due to some error in the frequency and/or temperature measurements. DiLorenzo and Schneider[2] pointed out that the solid maintained at liquid nitrogen temperature for a period of four weeks gave a spectrum differing from that of a rapidly cooled sample both in the resonance frequency (see Table 2) and intensity. They attributed this aging phenomenon to the remedy of lattice strain by annealing. In an attempt to confirm such an effect of annealing we compared the spectrum of Phase II cooled rapidly down to liquid nitrogen temperature with that of the sample which had been stored at liquid nitrogen temperature for five weeks. No appreciable change in the spectrum due to aging was observed except for slight enhancement in the intensity of ν_5, ν_6, and ν_9.[8]

Temperature Dependence. The temperature dependence of all the resonance frequencies was measured again between 20 and 110 K. The result is shown in Fig. 1. Of the four resonance lines in Phase I, the two higher-frequency lines split into four when the crystal was cooled through the transition point ($T_{tr}=103\pm0.6$ K), whereas the other two lines (ν_1 and ν_2 in PCl_6^-) remained unsplit.

As was mentioned above two chlorine atoms in PCl_6^- are in special positions in Phase I (on the 4-fold axis). Therefore we can unambiguously assign ν_1 and ν_2 to these chlorines also in Phase II.

The four chlorine atoms in PCl_6^- (in the basal plane) as well as four in PCl_4^+ become non-equivalent in Phase II. This fact shows that both 4 and $\bar{4}$ symmetry axes are not conserved in Phase II. Thus, it is obvious that the transition is of the second order according to Landau's classification.[10] It is interesting to note that each set of four chlorine atoms in PCl_4^+ and PCl_6^- appears to split into quartets symmetrically separated on either side of the average frequency in Phase II. Moreover, ν_1 shows a discontinuous change in slope at T_{tr} whereas ν_2 shows barely discernible anomaly around T_{tr}. In Fig. 2 the splitting $\Delta\nu_i$ (i=3—6) is plotted against the reduced temperature T/T_{tr} for PCl_6^-. The magnitude of the splitting was measured from the averaged frequency of the four lines and reduced by $\Delta\nu_i(0)$, the splitting being extrapolated to 0 K. It can be seen from Fig. 2 that all $\Delta\nu_i$ depend

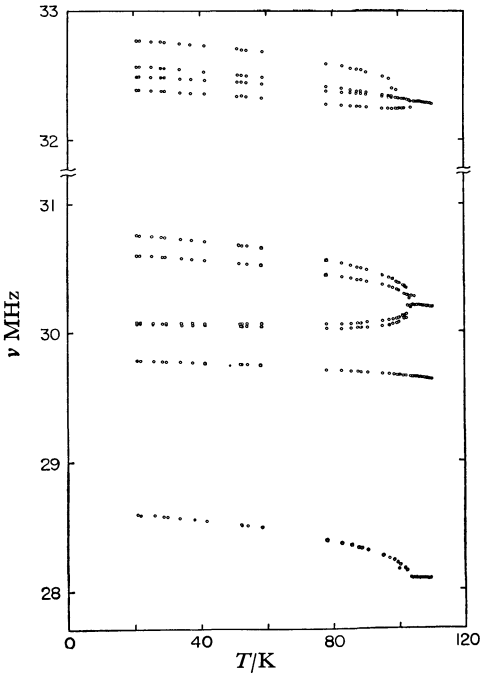

Fig. 1. Nuclear quadrupole resonance frequencies of $[PCl_4]$-$[PCl_6]$ between 20 and 110 K.

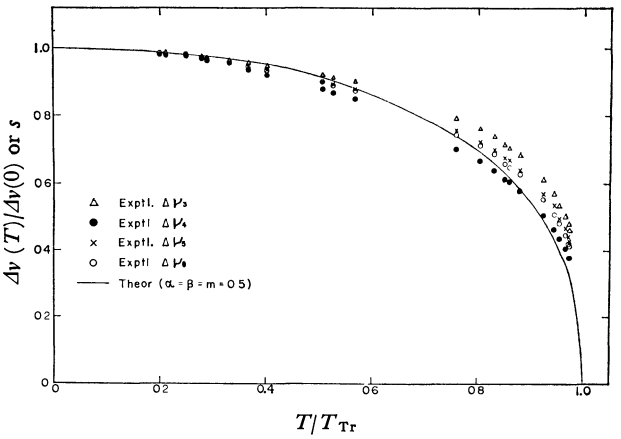

Fig. 2. Separation of lines ν_3 to ν_6 from their average, reduced by the separation at 0 K, as function of temperature (taken as the order parameter s).

8) The effect of the sample treatment on the heat capacity has been observed in the phase transition region.[9]

9) H. Chihara, M. Nakamura, and K. Masukane, This Bulletin, **46**, 97 (1973).

10) L. D. Landau and E. M. Lifshitz, "Statistical Physics," Pergamon Press, London, (1958).

similarly on temperature, suggesting that the splittings have a common cause.

Mechanism of the Transition. It is reasonable to consider that the phase transition is brought about by some reorientation of a PCl_6^- group about an axis perpendicular to its figure axis. Such a reorientation may be expressed by one parameter, *i.e.*, the angle of rotation θ from a fixed direction in the lattice. The magnitude of separation of the resonance line can be expanded in terms of θ as

$$\Delta\nu_i = A_i\theta + B_i\theta^2 + \cdots, \tag{1}$$

where θ can be measured from the original direction of the figure axis in Phase I. Here the tilt angle θ can be regarded as an order-parameter of the phase transition, and $\Delta\nu_i$ given in Fig. 2 can be taken as the same quantity if we neglect higher order terms of θ in Eq. (1).

In order to explain a similar type of phase transition in a chloranil crystal we have developed a librational soft mode theory which is based on an anharmonic coupling between molecular librational modes.[5,9,11] As the PCl_4^+ and PCl_6^- groups can be considered as rigid bodies, we can apply this theory to the phase transition of P_2Cl_{10}.

The Hamiltonian of the whole libration system is given by

$$H = \frac{P_\theta^2}{2I} + V(\theta) + \sum_i\left(\frac{P_i^2}{2I} + \frac{1}{2}I\omega^2\varphi_i^2\right) + \sum_i f(\theta)\varphi_i^2, \tag{2}$$

where $V(\theta)$ is the potential energy for a uniform mode, P_θ is its conjugate angular momentum, and the last term expresses the anharmonic coupling between the uniform mode and other librational modes φ_i treated as harmonic oscillators with frequency ω. We assume that $V(\theta)$ is of the form

$$V(\theta) = a(\theta^2 - p\theta^4 - q\theta^6), \tag{3}$$

which has a minimum at $\theta=\theta_0$ and satisfies the symmetry conditions in Phase I. The PCl_6^- ion is in the orientation of minimum potential energy θ_0 at 0 K. If the anharmonic coupling is taken into account in such a way as to make the librational frequencies $\Omega(\theta)$ of the Einstein mode to decrease with a decrease in θ, the Helmholtz energy is given by

$$A = V(\theta) + \boldsymbol{N}\boldsymbol{k}T\ln[1-\exp(-\hbar\Omega(\theta)/\boldsymbol{k}T)], \tag{4}$$

and the orientation giving the minimal A changes toward smaller θ as the temperature increases. The equilibrium orientation $\bar{\theta}$ can be determined from the condition $\partial A/\partial\theta=0$ at any temperature. The result is

$$\ln\left[\frac{\alpha}{\beta(1-s^2)\{1+(1-2m)s^2\}}+1\right] = (1+\alpha s^2)/t, \tag{5}$$

where $\alpha=If''(0)\theta_0^2/8\omega^2$, $\beta=a\theta_0^2/\hbar\omega$, $t=\boldsymbol{k}\boldsymbol{T}/\hbar\omega$, and $m=p\theta_0^2$ must be treated as adjustable parameters. The order parameter $s=\bar{\theta}/\theta_0$ was then calculated by using a NEAC-2200 electronic computer. The result is shown in Fig. 2 by a solid line, where α, β, and m were chosen so as to give the best fit to the experimental points. The adequacy of the set of parameters has been favorably examined by analyzing the excess heat capacity associated with the phase transition.[9]

On the other hand, the splitting of the resonance line due to PCl_4^+ ion shows no such regularity as is observed for PCl_6^- (Fig. 2) and the extent of the splitting is significantly small compared with the case of PCl_6^-. These facts suggest that the anharmonic coupling between the librational and the uniform modes of PCl_6^- plays a principal role in the cooperative ordering process and the splitting in the resonance line of PCl_4^+ is produced as a result of the second-order effect of ordering.

The authors wish to express their sincere gratitude to Professor M. Tachiki for his illuminating suggestions by which they have greatly benefitted.

Heat Capacity of Solid Phosphorus Pentachloride between 4 and 150 K. Nature of the Transition at 102 K.

Hideaki CHIHARA, Minoru NAKAMURA,* and Kazuyuki MASUKANE**
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, 560
(Received June 14, 1972)

Molar heat capacity of solid P_2Cl_{10} was measured between 4 and 150 K with an adiabatic calorimeter, with particular attention to the phase transition at 102.0 ± 0.2 K. The heat and entropy of the transition were 148 ± 3 $Jmol^{-1}$ and 1.67 ± 0.03 $JK^{-1}mol^{-1}$. Shape and magnitude of the anomalous heat capacity depend on the method of preparation. Anomaly in the heat capacity begins at about 75 K, rises gradually to a maximum of 9.12 ± 0.08 $JK^{-1}mol^{-1}$ at 102.0 K and tails off at about 110 K. The shape of the excess heat capacity curve can be explained satisfactorily by the librational soft-mode theory which assumes that PCl_6 anions tend to change equilibrium orientation with temperature.

Stable ionic form (P_2Cl_{10}) of phosphorus pentachloride has a higher-order phase transition at about 102 K. A detailed study of nuclear quadrupole resonance in ionic and molecular forms of P_2Cl_{10} was reported together with a preliminary heat capacity measurement.[1] Reinvestigation of the nuclear quadrupole resonance and precision measurements of the solid heat capacities have now been carried out with particular attention to the phase transition. The present paper describes the heat capacity and its relation to the soft-mode theory of phase transition. The quadrupole resonance part has been revised and presented in the preceding paper.[2]

Experimental

Material. Solid phosphorus pentachloride (reagent grade, Yashima Chemicals Co.) was pulverized and subjected to fractional vacuum sublimation to remove phosphorus oxychloride $POCl_3$ which had contaminated the specimen through hydrolysis by humid air. Sublimation in a vacuum of 10^{-2}—10^{-3} Torr at 60°C onto a glass wall at room temperature gave about 100 g of Sample I out of 250 g of the original material. After the heat capacity measurements were concluded with Sample I in 1966, it was found that the results were not entirely consistent with the preliminary results. In view of the recent observations in the case of chloranil[3] that a broad phase transition is extremely sensitive to crystal imperfections, it was decided to prepare another specimen, Sample II, of well-developed crystallinity. Sample II differed from Sample I in that it was obtained by slow vacuum sublimation onto a glass wall maintained at liquid nitrogen temperature. This procedure gives rise to molecular modification, which upon warming to room temperature is transformed into the stable ionic modification.[1] In fact Sample II gave a sharp, intense quadrupole resonance spectrum both at room temperature and at liquid nitrogen temperature.[2] Unfortunately, Sample I was not examined by quadrupole spectroscopy when its heat capacity was determined, but it showed a perfectly normal quadrupole spectrum four years after its preparation.

The heat capacities of Sample I and II differed only in the transition region. Charging of the calorimeter with the specimen was done in a dry-box in nitrogen atmosphere and the calorimeter was sealed by use of Woods' alloy after about 2—3 Torr of He gas replaced the air in the calorimeter.

Heat Capacity Measurements. The calorimeter vessel is made of gold and has an inner volume of about 50 cm^3. A Leeds & Northrup platinum thermometer was inserted into the reentrant well at the center of the calorimeter using Wood's alloy to fill in the void space. Six radiant vanes inside the calorimeter improved thermal diffusivity in the specimen. Heater wires (#36 manganin) were wound both round the entire length of the platinum thermometer and round the lower quarter of the outside wall of the calorimeter. A carbon resistor (Allen-Bradley, 1/8W, 10 Ω at room temperature) was used for the temperature below 11K. Gold-plated, thin copper sheath which covered the lower part of the calorimeter and the head of the platinum thermometer was used to reduce the heat exchange due to radiation.

The temperature scale above 11K is based on the 1948 International Temperature Scales and the U.S. National Bureau of Standards Scale. The working scale below 11K has been described in a previous paper.[4] The measuring circuitry including control of the adiabatic mantles is the same as reported earlier.[5]

Results and Discussion

Measured Heat Capacities. The measured heat capacity values are given in Tables 1 and 2 for Samples I and II, respectively.[6] The measurements for Sample I extend between 4.6 and 134.2 K, whereas those for Sample II cover only the region between 55 and 150 K because the two separate measurements agreed quite satisfactorily (to within ±0.3%) below 85 K and above 107 K. The results for either sample were internally consistent with scatter of points within ±0.1% except for those of Sample I below 11 K where maximum scatter amounted to about 5%. Figure 1 gives a plot of the two measurements; In the transition region, Sample I gives smaller heat capacities than Sample II, the maximum difference being as large as about 5.23 $JK^{-1}mol^{-1}$ at 102 K. The most pronounced qualitative difference lies in the fact that the Sample I heat

capacity has nowhere a negative temperature coefficient, while the Sample II heat capacity shows a broad but distinct maximum at about 102 K. The behavior of the former is quite unlike the preliminary results obtained by use of a smaller calorimeter.[1] This is why we redetermined the heat capacities with the use of Sample II after about three years. In the following, we will use only the results of Sample II in discussing the effect of phase transition.

Table 3. Fundamental intra-ionic vibrations in P_2Cl_{10} (after Carlson).

Separation of Anomalous Part of Heat Capacity. In order to amplify the extra heat capacity associated with the phase transition, contributions from the intra-ionic oscillations were calculated by the Einstein approximation and subtracted from the measured heat capacity values because all these contributions combined were expected to give a monotonous temperature dependence. Table 3 lists the relevant information on

the vibrational spectra of PCl_4^+ cation having T_d symmetry and of PCl_6^- anion having O_h symmetry according to Carlson.[7] The wave numbers given in Table 3 are those at room temperature. We assumed that they do not change with temperature. Such contributions[8] having been subtracted, the residual heat capacity values were plotted on a large graph paper and a smooth 'normal' heat capacity curve was drawn to obtain the anomalous part, which is shown in Fig. 2. Estimates of the 'normal' heat capacity (including intra-ionic contributions) are given in Table 4. We see from Fig. 2 that the maximum extra heat capacity is 9.12 ± 0.08 J K^{-1} mol^{-1} at 102.0 ± 0.2 K,[9] the transition point being slightly lower than that determined from Fig. 1. The anomaly starts at about 75 K, gradually rises to maximum over a range of 27 K, and tails off at about 110 K. A shoulder centering at 90 K in Fig. 2 is not considered to be real but is probably due to some inadequacy in the tempreature scale. Since the temperature increments used in the measurements are about 0.6 K in the vicinity of the maximum, the transition is apparently of higher order than the second order transition in the Ehrenfest definition.[10] The heat of transition is 148 ± 3 Jmol^{-1} and the entropy of transition is 1.67 ± 0.03 J K^{-1} mol^{-1}.

Comparison with the Soft-mode Theory. As discussed

7) G. L. Carlson, *Spectrochim. Acta*, **19**, 1291 (1963).

8) The heat capacities corresponding to ν=62 cm^{-1} (f_{1u}) and to an unknown frequency (f_{2u}) were not taken into account for the reason discussed earlier.[1]

9) Extrapolation of the order parameter to zero gives 103~0.6 K as determined by quadrupole resonance but the difference is considered trivial.

10) From nuclear quadrupole resonance study,[2] symmetry elements appear abruptly at the transition and thus this is a second-order transition according to Landau's classification.[11]

11) L. Tisza, "On the General Theory of Phase Transitions" in "Phase Transformations in Solids" edited by R. Smoluchowski, *et al.*, John Wiley & Sons, Inc., New York, (1951).

in the preceding paper,[2] the transition in P_2Cl_{10} is related to a cooperative change in the orientation θ of the figure axis of PCl_6^- anions. The broad nature of the transition as well as the very small entropy of transition suggest that it is due to a kind of soft librational mode for which a simple theory has been developed.[12] By use of Eq. (4) of the preceding paper, we have

$$\Delta C = -Nk\frac{\alpha s x}{2\sinh^2(x/2)}\cdot\frac{ds}{dt},$$

where

$$x = (1+\alpha s^2)/t$$

and

$$\frac{ds}{dt} = \frac{\alpha x/2s}{\alpha^2 - 8\beta t\{m+(1-2m)s^2\}\sinh^2(x/2)}.$$

The significance of the parameters is the same as in Ref. 2. Numerical calculation of the excess heat capacity ΔC was made by using the parameter values

$$\alpha = \beta = m = 0.5$$

which give the best fit to the temperature dependence of the order parameter s as shown in Fig. 2 of Ref. 2. The result is shown in Fig. 2 by a solid curve. The theoretical curve, which was scaled down by a factor of 0.668, reproduces the important portion of the experimental ΔC. In view of the difficulty in estimating the 'normal' heat capacity values particularly below 90 K, the agreement between theory and experiment is considered excellent below the transition point. The scaling factor may be interpreted as indicating that only such librational modes that have small k, the wave vector, can couple with the uniform mode. Lack of agreement above the transition point is obviously due to inadequacy of the theory and may suggest the existence of some other lattice vibrational modes that play an important role in the transition phenomenon.

The authors would like to thank Mr. Tooru Atake for technical assistance during the course of this investigation.

The Second CMC of an Aqueous Solution of Sodium Dodecyl Sulfate. IV. Fluorescence Depolarization

Yukio KUBOTA, Michiko KODAMA,* and Masaji MIURA*

Department of Chemistry, Yamaguchi University, Yamaguchi

**Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima*

(Received June 20, 1972)

The depolarization of the fluorescence emitted from a dye solubilized in the micelle was measured over a wide concentration range of sodium dodecyl sulfate (SDS). The polarization of the fluorescence showed an abrupt increase at the 1st CMC and at about 70 mM of SDS; the latter agrees very closely with the 2nd CMC revealed by conductivity and viscosity measurements. This phenomenon implies that there is a certain change in the micelle structure at the 2nd CMC. The micellar size was calculated from the fluorescence depolarization data using Perrin's equation. The results showed that: (1) the micellar volume below the 2nd CMC is in good agreement with that determined by light-scattering, (2) the micellar volume gradually increases with an increase in the concentration of SDS, and (3) the micellar volume increases abruptly at the 2nd CMC.

In our previous papers, the micelle structure of aqueous solutions of sodium dodecyl sulfate (SDS) was investigated by systematic studies including measurements of the conductivity,[1] the density,[2] the viscosity,[2] and the light-scattering.[3] It was revealed by these measurements that, in addition to the 1st critical micelle concentration (CMC), there exists a 2nd CMC, where a change in the micelle structure takes place. Further, the viscosity and light-scattering measurements suggested that the size of the micelle increases at the 2nd CMC.

The micellar sizes of the surfactants in the neighborhood of the 1st CMC have been determined by such methods as light-scattering and osmotic pressures. However, little is known about the micellar size in the high-concentration region because some complications arise upon the application of the above methods to a concentrated solution.[4] Since the theoretical basis of the fluorescence depolarization method has been established by Perrin,[5,6] it has been used successfully in the study of the Brownian motion of a macromolecule in solution.[7-9] This method will provide a powerful tool for the determination of the size of a micelle if we obtain a suitable fluorescent molecule which can tightly

combine with the micelle.[10-12] Very recently, we succeeded in preparing a derivative of acridine orange (AO) which possesses a dodecyl group; this dye can be expected to bind firmly to the SDS micelle, because the dye molecule has a long hydrocarbon chain and its charge is opposite to that of the micelle. The present paper will report some information about the size of the SDS micelle, particularly in the high-concentration region above the 2nd CMC.

Experimental

Materials. The SDS used in this study was the same as that described in a previous paper.[1] AO-10-dodecyl bromide (Fig. 1) was prepared by modifying the method of Miethke and Zanker;[13] a mixture of AO and 1-bromododecane (ten times the molar quantity of AO) was heated in an oil bath at 110—120°C for 12 hr. The dye thus produced was recrystallized from ethanol–ether and then subjected twice to chromatography on alumina, using ethanol as the eluent.

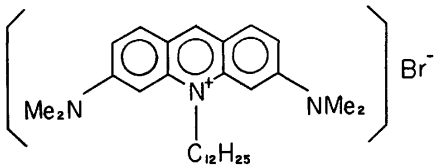

Fig. 1. AO-10-dodecyl bromide.

Methods. The absorption spectra were recorded with a Hitachi ESP-3T spectrophotometer.

The fluorescence spectra were measured with a Hitachi MPF-2A fluorescence spectrophotometer, using an R-106 photomultiplier. They were corrected for the spectral sensitivity of an optical system consisting of lenses, a monochromator, and a photomultiplier.

The degree of polarization of the fluorescence light (P) was measured with a Shimadzu light-scattering photometer equipped with a pair of polaroid dichroic filters to serve as the polarizer as well as the analyzer, and with suitable filters for the incident and fluorescence lights. A 436 nm mercury line was used as the exciting light; it was plane-polarized. The value of P was calculated by means of the following equation:

$$P = (I_{//} - I_{\perp})/(I_{//} + I_{\perp}) \quad (1)$$

where $I_{//}$ and $I_{\perp}$ are, respectively, the components of the fluorescence light parallel to and perpendicular to the direction of the polarization of the exciting light.

The fluorescence lifetimes were measured by means of a JASCO FL-10 phase fluorometer.[14]

All the measurements were carried out at temperatures from 17 to 40°C for SDS solutions containing constant amounts of the dye, (1—2.0)$\times 10^{-6}$M. In order to control the temperature of the solution, water from a thermostat was circulated through a water jacket surrounding the cell; the temperature was measured with a calibrated thermistor. One-centimeter quartz cells were used in all the measurements.

Results and Discussion

Figure 2 shows some typical findings on the absorption and fluorescence spectra of the SDS-dye systems. As may be noted from Fig. 2a, there occurred a many-fold enhancement in the fluorescence intensity of the dye above the 1st CMC. In addition, the dye fluorescence in the SDS solutions above the 1st CMC was markedly polarized (Fig. 2b), though that in water showed no polarization. The absorption spectra of the dye in SDS solutions had a peak at 500 nm corresponding to a monomeric species of the dye; this peak was shifted by a few nm towards longer wavelengths compared with that in water (Fig. 2a). The absorbance at 500 nm is plotted against the concentration of SDS in Fig. 3; the absorbance increases abruptly at about the 1st CMC, and then remains constant above that point. These spectral phenomena are rather common results in studies of the association of the dye with the micelle[10,11] and may imply that most of the dye molecules are tightly solubilized in the SDS micelles as a monomeric form. Hence, it is expected that the

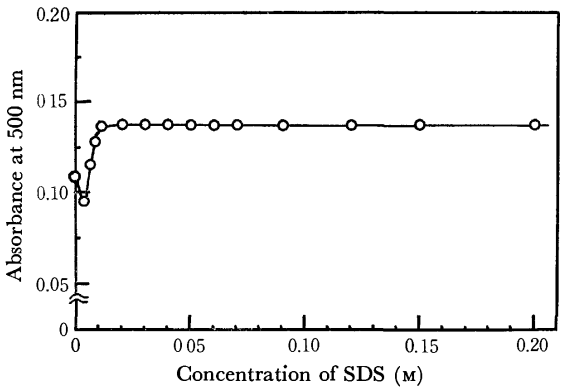

Fig. 3. Absorbance of the SDS-dye systems at 500 nm as a function of the concentration of SDS at 25°C.

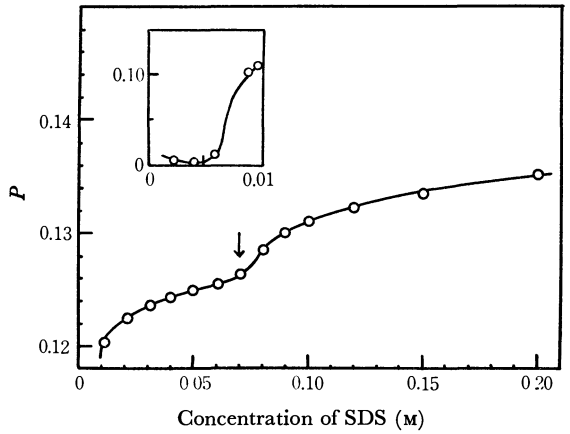

Fig. 4. A plot of the P value against the concentration of SDS at 25°C. The result in the neighborhood of the 1st CMC is shown under enlargement.

value of P reflects exactly the Brownian rotation of the SDS micelle in the solution.[10,11]

Figure 4 shows the relation between the P value and the concentration of SDS at 25°C. It may be seen in Fig. 4 that the P value increases abruptly at the 1st CMC and, in addition, at about 70 mM of SDS; the latter agrees very closely with the 2nd CMC revealed by other measurements.[1-3] This phenomenon may be attributed to a certain change in the micelle structure at the 2nd CMC.

According to Perrin,[5,6] the P value is related to the molar volume of the fluorescent molecule (V) by the following equation, on the assumption that the molecule undergoing rotation is spherical:

$$1/P - 1/3 = (1/P_0 - 1/3)(1+\tau RT/\eta V) \qquad (2)$$

where P_0 is the limiting value of P when $T/\eta=0$; R, the gas constant; T, the absolute temperature; τ, the lifetime of the fluorescence, and η, the viscosity of the solvent. The rotational relaxation time of this molecule (ρ) equals $3V\eta/RT$. In the micelle-dye systems, V in Eq. (2) is taken as the effective volume of the micelle in which the dye is solubilized.

The V value is dependent not only on the measured values of P, η, and T, but also on the values of τ and P_0. Singleterry *et al.*[10-12] developed an elegant technique for the determination of the effective micellar volume from the fluorescence-depolarization data. Their method, however, was incomplete because the fluorescence lifetimes had never been measured directly. In the present study, the values of τ in the SDS-dye systems were determined directly by means of a phase fluorometer.[14] The results at 25°C were as follows: (1) τ in water was 0.37 nsec and (2) τ in SDS solutions was constant (2.0 nsec) over a wide concentration range above the 1st CMC. According to Eq. (2), a straight line which cuts the $1/P$ axis at $1/P_0$ should be obtained when $1/P$ is plotted against T/η. Thus, the values of P_0 in the SDS-dye systems were determined experimentally by measuring the P value in the temperature range from 17 to 40°C and by then extrapolating the straight line to $T/\eta=0$. Some results are shown in Fig. 5, where the plots of $1/P$ *vs.* T/η at each concentration of SDS give the concordant value of $P_0=0.167$.

The effective micellar volumes of SDS at 25°C were calculated by introducing the quantities obtained above into Eq. (2), on the assumption that the micelle is spherical. In view of the findings on small-angle X-ray

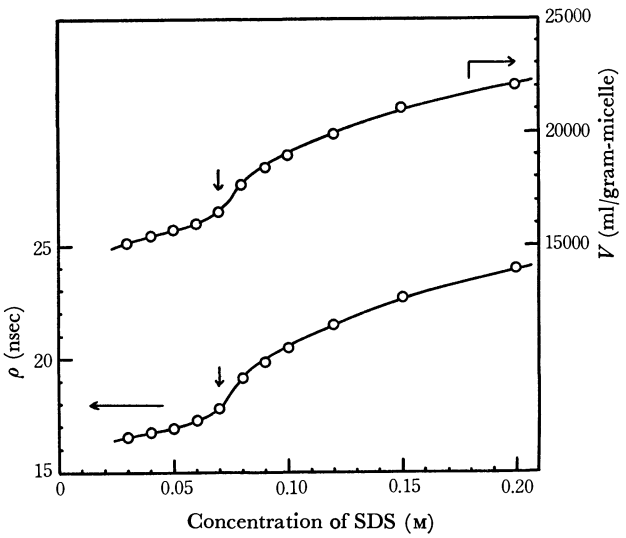

Fig. 6. Plots of ρ and V against the concentration of SDS at 25°C.

scattering,[15,16] this assumption seems reasonable in the concentration range investigated. The results are summarized in Table 1, where ρ and V represent, respectively, the rotational relaxation time of the micelle and the effective micellar volume. Figure 6 shows plots of ρ and V against the concentration of SDS. The depolarization results presented in Table 1 and Fig. 6 can be summarized as follows:

(1) The micellar volumes below the 2nd CMC range from 15500 to 16000 ml/gram-micelle.

(2) The micellar volume increases gradually with an increase in the concentration of SDS below the 2nd CMC.

(3) The micellar volume increases abruptly at the 2nd CMC, and then it increases again gradually with the comcentration.

The micellar density was estimated to be 1.09 g/ml by using the density data[2] obtained according to the method of Mukerjee.[17] Therefore, the micellar weight below the 2nd CMC becomes $(169—174)\times10^2$, which is in good agreement with the value (170×10^2) obtained by light-scattering measurements.[3] This agreement seems to confirm the assumption that the dye has no freedom of rotation with respect to the micelle in which the dye is solubilized. This may be caused by the firm binding of the dye to the SDS micelle, since the dye molecule has not only a charge opposite to the micelle, but also a long hydrocarbon chain. It can be concluded, therefore, that the depolarization of fluorescence observed reflects correctly the Brownian rotation of the SDS micelle and that the fluorescence depolarization method provides a direct means for the determination of the micellar size over a wide concentration range of SDS.

Evidence (2) is consistent with the studies of other investigators;[15,16,18-22] they showed that the micellar size increases with the concentration of the surfactant.

Evidence (3) is a fact which has newly observed in the case of SDS. This fact accounts well for the results of light-scattering, *i.e.*, the marked rise in the reduced intensities at the 2nd CMC. The reason why the micellar volume increases abruptly at the 2nd CMC is still not clear, however; this subject will be dealt with in the future.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 103—106 (1973)

Low-frequency Lattice Vibrations and Intermolecular Forces of the 9,10-Anthraquinone Crystal

Yoshio MIYAZAKI and Mitsuo ITO

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai

(Received July 4, 1972)

The low-frequency Raman active lattice vibrations of the 9,10-anthraquinone single crystal were measured at various temperatures from 26°C to −190°C, and the symmetry species of the observed Raman bands were determined by polarization measurements. From a comparison between the observed and calculated frequencies, it seems that Dashevsky's potential expresses well the intermolecular potential of the 9,10-anthraquinone crystal. It was also found that the temperature dependence of lattice vibrations can be explained reasonably with this potential.

The lattice vibrations of molecular crystals have attracted great attention because of their importance in the elucidation of the intermolecular potentials in crystals. One of the most important characteristics of the low-frequency lattice vibrations of molecular crystals is the great dependence of the frequencies upon the temperature. The frequency shifts due to changes in the temperature are generally different for different lattice vibrations; they often amount to 20—30% of the frequencies in the region from room temperature to the temperature of liquid nitrogen. These characteristics may be utilized in the study of the intermolecular potentials. Unfortunately, however, in molecular crystals it is very seldom that crystal structures at various temperatures over a wide range are well known in detail. For this reason, the highly useful experimental data of the effects of the temperature have been neglected.

One of the crystals whose structures have been determined at various temperatures over a wide range is the 9,10-anthraquinone crystal; Lonsdale *et al.* have reported the crystal structures at 20.5, −12.5, −72, −112, and −170°C.[1] It is, therefore, a good example

for use in testing the intermolecular potentials at various temperatures.

In the present experiment, the polarized Raman spectra of the low-frequency lattice vibrations of the single crystal of 9,10-anthraquinone were measured at various temperatures, and assignments of the observed Raman bands were given. The results obtained were then used to examine the intermolecular potentials proposed by various authors.

Experimental

9,10-Anthraquinone was purified by repeated zone refinements, and the single crystal was grown by Bridgman's method. The single crystal used in the Raman measurements was about $4\times5\times8$ mm, one of the edges of the crystal being parallel to the crystallographic b axis, which was determined by taking oscillation X-ray photographs.

The optical arrangement for the measurement of the polarized Raman spectra is almost the same as that reported previously.[2] A He-Ne gas laser of 6328 Å (Japan Electron Optics Laboratory Co., 50 mW) and a Nalumi model 750 Z-1200 double monochromator combined with a cooled head-on-type photomultiplier tube, followed by a photon-counting detector, were used for taking the Raman spectra.

The temperature of the single crystal was controlled in the region between room temperature and −190°C by regulating the flow speed of cooled nitrogen gas introduced into a cryostat. Even at the lowest temperature, no cracking of the crystal occurred, so the polarization experiments were carried out successively.

Results and Assignments

The crystal structure of 9,10-anthraquinone belongs to a monoclinic system, space group C_{2h}^5—$P2_1/a$, and it contains two molecules in a unit cell.[1] The optically-active lattice vibrations can therefore be divided into two parts; six librational modes ($3A_g+3B_g$) and three translational modes ($2A_u+B_u$). The vibrations of the g species are active only in the Raman spectrum, while those of the u species are active only in the infrared spectrum. The three A_g and three B_g Raman active lattice vibrations should be differentiated by means of a polarization experiment; that is, when the single crystal is excited by incident light polarized parallel to the b axis of the crystal, the Raman lines of the A_g and B_g vibrations should appear in the spectra of the $b_{//}$ and $b_{\perp}$ components of the scattered light respectively. Figure 1 shows typical spectra obtained in this way at 26 and −122°C. It may be seen that all the Raman lines except one of the B_g species are clearly identified.

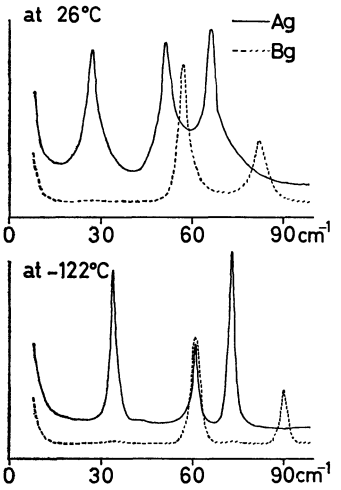

Fig. 1. Polarized Raman spectra of 9,10-anthraquinone single crystal.

The frequencies observed at various temperatures are summarized in Table 1, together with their assignments.

A Raman line of 115 cm^{-1} has been reported in the Raman measurement at room temperature by Singh *et al.*,[3] who assigned it to the lattice vibration. In our measurements, however, we were unable to find any Raman lines in the neighbourhood of 115 cm^{-1}. Instead, we found a weak Raman line at 148 cm^{-1}, which appears preferentially in the B_g spectrum. It is probably due to the combination band of 66 cm^{-1} (A_g) and 82 cm^{-1} (B_g).

Calculation of Lattice Vibrations

The calculation of lattice vibrations was performed in a rigid-body approximation according to the **GF** matrix method developed by Shimanouchi *et al.*[4,5] The intermolecular potential used was approximated by the sum of the atom-atom pair-by-pair potentials of the form:

$$V(r) = -Ar^{-6} + B\exp(-Cr),$$

where r is the interatomic distance and where A, B, and C are constants characteristic of the kind of atom pair. The potential of this type has often been used with great success in the calculation of many properties of molecular crystals, such as lattice vibrations, specific heat, and elastic constants.

We employed several sets of values of A, B, and C as proposed by different authors for the H···H and

C···C atom pairs; they are the values proposed by Williams[6] (Set I), Kitaigorodsky[7] (Set II), Bartell-Crowell[8] (Set III), and Dashevsky *et al.*[9] (Set IV). For O···O, the values given by Dashevsky *et al.*[9] were always used. The values of *A*, *B*, and *C* used in the calculations are summarized in Table 2. The values for the heteroatom pairs were taken as follows;

$$A_{ab} = \sqrt{A_{aa} \times A_{bb}},$$
$$B_{ab} = \sqrt{B_{aa} \times B_{bb}},$$
$$C_{ab} = (C_{aa} + C_{bb})/2$$

for a···b.

The crystal structures of 9,10-anthraquinone at 20.5, −12.5, −72, −112, and −170°C have been reported by Lonsdale *et al.*[1] Therefore, the calculations were made for the structures at these temperatures by taking account of all the interactions of interatomic distances shorter than 3.2, 3.5, 3.5, 3.6, 4.0, and 4.1 Å for H···H, H···O, H···C, O···C, O···O, and C···C respectively. These limits were selected for the following reasons: (1) For the distances over these limits, the force constants are generally very small, (2) the numbers of the atom pairs to be included are almost the same over the range from 20.5°C to −170°C, and (3) when the limits of interactions are extended to 4.5 Å, the number of the atom pairs to be included increases about twice, but the calculated frequencies and eigen vectors change only a little.

Table 3. Observed and calculated frequencies at 20.5°C (cm^{-1})

	Set I	Set II	Set III	Set IV	Obsd[a]

	83	71	68	50	—

a) Interpolated values to 20.5°C from Table 1.

The frequencies of lattice vibrations calculated under the above restrictions are given in Table 3. It may be seen that the calculated frequencies with the potentials of Set IV agree reasonably with the observed Raman frequencies, while the potentials of the other sets give higher frequencies. In Table 4, the frequencies obtained with the potentials of Set IV and the atomic coordinates at various temperatures are listed, together with the approximate vibration modes for 20.5°C.

Discussion

In the preceding section, we noted a great difference in the calculated frequencies between the potentials of Set I—III and Set IV. An inspection of the crystal structures shows that there exist interatomic pairs involving hydrogen atoms of short distances. Especially, we have a very short H···H distance of 2.2 Å, and found that the great difference in the calculated frequencies is mainly to be ascribed to the difference in the potentials of the H···H pair (and thereby of the H···C and H···O pairs) in the region of the short distances.

Beside the calculated lattice vibrational frequencies, their dependences upon the temperature provide a good check to see which potentials are more realistic. The observed and calculated frequency shifts of the indi-

vidual lattice vibrations between 20.5 and −170°C are given in Table 5. It may be seen that the calculated shifts with Set IV are of the same order of magnitude as the observed ones, while the calculated shifts with the other sets give larger shifts. This difference was found again to be ascribable mainly to the difference in H···H potentials in the region of short distances.

The fact that both the lattice vibrational frequencies and their shifts induced by the temperature change are well reproduced with the potentials of Set IV seems to indicate the preferability of the H···H potential of Set IV over those of the other sets, especially in the region of short interatomic distances.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 106—109 (1973)

Conductometric Determination of Ion-association Constants for Magnesium and Nickel Sulfates in Aqueous Solutions at Various Temperatures between 0°C and 45°C

Shunzo KATAYAMA

The Institute of Physical and Chemical Research, Hirosawa, Wako-shi, Saitama

(Received July 5, 1972)

Thermodynamic equilibrium constants for the ion-association in aqueous solutions of magnesium and nickel sulfates were determined by electrical conductivity measurements at various temperatures between 0°C and 45°C. The standard Gibbs energy and the enthalpy and entropy for the reaction $M^{2+}+SO_4^{2-} \rightleftharpoons M^{2+}\cdot SO_4^{2-}$ (M: Mg or Ni) were then calculated from the temperature-dependence of the ion-association constants. The values obtained are as follows: $\Delta G^\circ_{298} = -2.91$ kcal mol^{-1}, $\Delta H^\circ = 2.04$ kcal mol^{-1}, and $\Delta S^\circ_{298} = 16.6$ cal deg^{-1} mol^{-1} for $Mg^{2+}\cdot SO_4^{2-}$; and $\Delta G^\circ_{298} = -3.10$ kcal mol^{-1}, $\Delta H^\circ = 1.27$ kcal mol^{-1}, and $\Delta S^\circ_{298} = 14.7$ cal deg^{-1} mol^{-1} for $Ni^{2+}\cdot SO_4^{2-}$.

Different values are sometimes obtained for the formation constant of a given ion-pair when different experimental methods are used in its determination. For example, the formation constant of the ion-pair $[Co(NH_3)_6]^{3+}\cdot X^-$ (X: Cl, Br, I, NO_3) as determined by the spectroscopic method is significantly smaller than that determined by the conductometric method.[1,2] It is, thus, important to study whether such a discrepancy in the thermodynamic constant is attributable to the different working principles of various methods or simply to experimental errors.

This paper will deal with the conductometric determination of ion-association constants for magnesium and nickel sulfates in aqueous solutions at temperatures from 0 to 45°C. Except for a few investigations, the determination of ion-association constants has mostly been done at one particular temperature (say, 25°C). The temperature dependence of ion-association constants, however, is important because the standard enthalpies and entropies of ion-association will provide more useful information concerning the interaction between the ions than the formation constants at some fixed temperature.[3] The thermodynamic quantities determined by the present study are compared with the values obtained by Nair and Nancollas[4,5] by emf measurements, and also with the theoretical values based upon the electrostatic model of ion-pairs.

Experimental

Magnesium and nickel sulfates of an analytical reagent grade were recrystallized twice from conductivity water at a temperature between 10 and 20°C and then dried at room temperature. The purity of the samples was examined by a conventional chemical analysis of the components; the analysis gave results which were in good agreement with the theoretical values (Found: Mg^{2+}, 9.82; SO_4^{2-}, 38.93; H_2O, 51.20% for $MgSO_4\cdot 7H_2O$ and Ni^{2+}, 20.95; SO_4^{2-}, 34.39; H_2O, 44.73% for $NiSO_4\cdot 7H_2O$).

Solutions of different concentrations were carefully prepared by using conductivity water of a specific conductivity lower than 2.4×10^{-7} ohm^{-1} cm^{-1} at 25°C in an atmosphere of purified nitrogen gas.

The electrical conductivities at different temperatures were measured by the apparatus shown in Fig. 1. The apparatus consisted of the following two parts: (a) a deviation-linear-bridge operated at 1000 Hz which detected the difference in conductance between a conductivity cell and a given standard,

(2) The starting approximation for γ is given by the classical Onsager equation:

$$\gamma_1 = \Lambda/[\Lambda_0 - S(c\cdot\Lambda/\Lambda_0)^{1/2}] \quad (8)$$

and higher approximations for the degree of dissociation, γ_i (i=2, 3, ···), are calculated by:

$$\gamma_i = \Lambda/[\Lambda_0 - S(c\gamma_{i-1})^{1/2} + Ec\gamma_{i-1}\log(c\gamma_{i-1}) + Jc\gamma_{i-1}] \quad (9)$$

(3) The mean activity coefficient, f, is estimated by means of the Debye-Hückel equation:

$$\log f = \frac{-Az^2\sqrt{I}}{1+Ba\sqrt{I}} \quad (10)$$

where z ($z=|z_+|=|z_-|$ for a symmetrical electrolyte) is the charge number; I, the ionic strength, and A and B, the theoretical coefficients.

All the calculations were performed on a FACOM 270-20/30 computer using a FORTRAN program.

Table 2 summarizes the values of Λ_0, K_A, and a thus determined for $MgSO_4$ and $NiSO_4$ at different temperatures. The K_A-values for $NiSO_4$ were larger than those for $MgSO_4$ at each temperature, while the temperature-coefficient of K_A for $NiSO_4$ was smaller than that for $MgSO_4$. The ion-size parameters for $NiSO_4$ and $MgSO_4$ were about 6 Å at temperatures ranging from 0 to 45°C. In Table 2, the present results are compared with the K_A values (shown in parentheses) obtained by Nair and Nancollas[4,5] using the emf method.

The standard enthalpy of association, $\Delta H°$, was determined from the linear plots of $\log K_A$ against T^{-1}, as is shown in Fig. 4, according to the relation:

$$d\ln K_A/d(1/T) = -\Delta H°/R \quad (11)$$

The standard Gibbs energy and the standard entropy of association, $\Delta G°$ and $\Delta S°$, were calculated by means of the well-known thermodynamic equations:

TABLE 2. LIMITING EQUIVALENT CONDUCTIVITIES, Λ_0, ION ASSOCIATION CONSTANTS, K_A, AND ION-SIZE PARAMETER, a, OF $MgSO_4$ AND $NiSO_4$ IN AQUEOUS SOLUTIONS AT VARIOUS TEMPERATURES

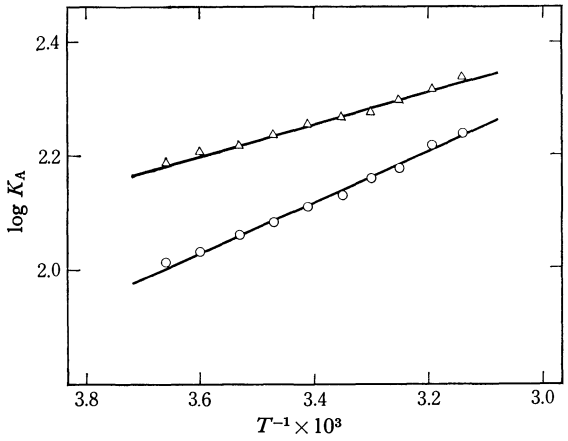

Fig. 4. Plots of log K_A against T^{-1} for magnesium sulfate (○) and nickel sulfate (△).

Table 3. Standard Gibbs energy, enthalpy, and entropy of ion-pair formation of $Mg^{2+} \cdot SO_4^{2-}$ and $Ni^{2+} \cdot SO_4^{2-}$

Ion-pair	ΔG°_{298} [kcal mol^{-1}]	ΔH° [kcal mol^{-1}]	ΔS°_{298} [cal deg^{-1} mol^{-1}]
$Mg^{2+} \cdot SO_4^{2-}$	−2.91	2.04	16.6
	(−3.07)	(4.84)	(26.2)
$Ni^{2+} \cdot SO_4^{2-}$	−3.10	1.27	14.7
	(−3.16)	(3.31)	(21.7)

(The values obtained by Nair and Nancollas from the emf measurement are shown in parentheses)

$$\Delta G^\circ = -RT \ln K_A \tag{12}$$

and:

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \tag{13}$$

The values of ΔG°, ΔH°, and ΔS° for the association reaction (1) are given in Table 3, in which the values of Nair and Nancollas are also presented (in parentheses). Qualitatively, the present results show a tendency similar to those of Nair and Nancollas[4,5] obtained by the emf measurements. Quantitatively, however, the values of ΔH° and ΔS° obtained from the conductivity data are significantly smaller than those determined from the emf data.

It seems worthwhile to compare the experimental values of ΔH° and ΔS° with those theoretically predicted from the electrostatic model of ion-pairs. According to Fuoss' theory of electrostatic interaction, the ion-pair association constant, K_A, is given by this equation:[3,9]

$$K_A = \bar{v}e^b \tag{14}$$

with

$$\bar{v} = \frac{4\pi La^3}{3000}, \quad b = \frac{|z_+z_-|e^2}{\varepsilon akT}$$

where z_+ and z_- are the charge numbers of the cation and anion respectively, where ε is the dielectric constant, and where the other symbols have their usual meaning. Provided $\bar{v}$ is independent of the temperature, we obtain the following expressions for ΔH° and ΔS° from Eq. (14):[3]

$$\Delta H^\circ = -RTb\left(1 + \frac{d\ln\varepsilon}{d\ln T}\right) \tag{15}$$

and:

$$\Delta S^\circ = R\ln\bar{v} - Rb\left(\frac{d\ln\varepsilon}{d\ln T}\right) \tag{16}$$

With the values of $d\ln\varepsilon/d\ln T = -1.37$ for water at 25°C and $a = 6$ Å as determined from the conductivity data (see Table 2), Eqs. (15) and (16) give the theoretical values of $\Delta H^\circ = 1.05$ kcal mol^{-1} and $\Delta S^\circ = 14.4$ cal deg^{-1} mol^{-1} for the ion-pair formation of $M^{2+} \cdot SO_4^{2-}$ (M: Mg and Ni) at 25°C. These theoretical values are reasonably close to the experimental values we give in Table 3; this suggests that the electrostatic interaction exerts a dominant influence on the ion-pair formation of $Mg^{2+} \cdot SO_4^{2-}$ and $Ni^{2+} \cdot SO_4^{2-}$.

The author wishes to thank Dr. Reita Tamamushi for his many helpful discussions and suggestions during this work, and Dr. Katsuo Takahashi for the construction of the apparatus. He also wishes to thank Mrs. Kinuyo Takahashi and Miss Yoko Taguchi for the computer calculation.

^{14}N Nuclear Quadrupole Resonances of 2-Aminopyrimidine

Hisao NEGITA, Kaoru SHIBATA, and Tsuneo KUBO
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima
(Received July 28, 1972)

Four nuclear quadrupole resonance (NQR) lines due to ^{14}N nuclei of the ring nitrogens in 2-aminopyrimidine were paired for the powder sample by use of a frequency-modulated spectrometer and a Helmholtz coil for the Zeeman field (H). NQR parameters $e^2Qq=3707.2$ kHz and $\eta=0.0646$ were obtained for one nitrogen, and $e^2Qq=3759.6$ kHz and $\eta=0.0329$ for the other. Moreover, the frequency of the lower line of a pair of lines for the amino nitrogen was predicted from the shift of the higher line subjected to the Zeeman field in a single crystal. The region around the expected position was carefully swept and a very weak line was found at 2357.8 kHz. Thus $e^2Qq=3428.0$ kHz and $\eta=0.2488$ were deduced for the amino nitrogen. The quadrupole coupling constant for the amino nitrogen in 2-aminopyrimidine was smaller than that for the amino nitrogen in 2-aminopyridine. The asymmetry parameter for the amino nitrogen in 2-aminopyrimidine was smaller than that for the amino nitrogen in 2-aminopyridine and roughly equal to that for the amino nitrogen in aniline.

In the case of ^{14}N NQR, only one resonance line is found for the axially symmetric field gradient, and a pair of resonance lines are usually found for the asymmetric field gradient. However, when one of the pair, mostly the lower line, is too weak to detect, it may be difficult to determine whether the resonance is caused by a symmetric field gradient or not, as long as a frequency-modulated spectrometer is used. To overcome this difficulty, it is advantageous to inspect the line shift as well as the line broadening by applying the Zeeman field from a given direction. In the case of the axially symmetric field gradient, the line is flattened to both sides, whereas in the case of the non-axially symmetric one, the higher line shifts to the higher and *vice versa*, and the smaller the asymmetry parameter, the greater the line broadens.[1] In this way, two pairs of lines for the ring nitrogens in 2-aminopyrimidine were determined, the results being in good agreement with the assignment by Schempp.[2] As for the resonance due to the amino nitrogen in 2-aminopyrimidine, only the higher line of the pair was reported for the first time by Schempp. Thus the frequency of the lower line was calculated from its shift by the Zeeman field on a single crystal sample. A very weak line was found in the neighborhood of the calculated frequency. The resonance frequency differs from that reported recently by Schempp and Bray.[3] The derived quadrupole coupling constant and asymmetry parameter for the amino nitrogen in 2-aminopyrimidine were compared with those for the amino nitrogens in aniline and 2-aminopyridine.

Experimental

The ^{14}N NQR spectra of 2-aminopyrimidine were obtained by the frequency-modulated spectrometer described previously.[4] The resonance frequencies were measured by a heterodyne-type frequency meter BC-221 whose frequency was checked by a frequency counter TR-5578 of Takeda Riken Co. The Zeeman field was supplied by a Helmholtz coil, 40 cm in diameter and 20 cm in gap-width. The exact field strength of the coil was calibrated by measuring the Zeeman shifts of a given resonance line. The crystal was mounted in a rf coil so as to rotate independently about the horizontal and vertical axes. Thus, the Zeeman field could be applied to the crystal from any direction. All the measurements were carried out at liquid nitrogen temperature.

Commercial 2-aminopyrimidine was purified by recrystallization from a solution in organic solvent. About 10 g of the sample was used. The single crystal, 15 mm in diameter and 35 mm in length, was prepared by the Bridgman-Stockbarger method.

Results and Discussion

Since ^{14}N has a nuclear spin of unity, we can usually obtain a pair of resonance frequencies, ν_I and ν_{II}, as follows:

$$\nu_I = K(3-\eta), \quad (1)$$

$$\nu_{II} = K(3+\eta), \quad (2)$$

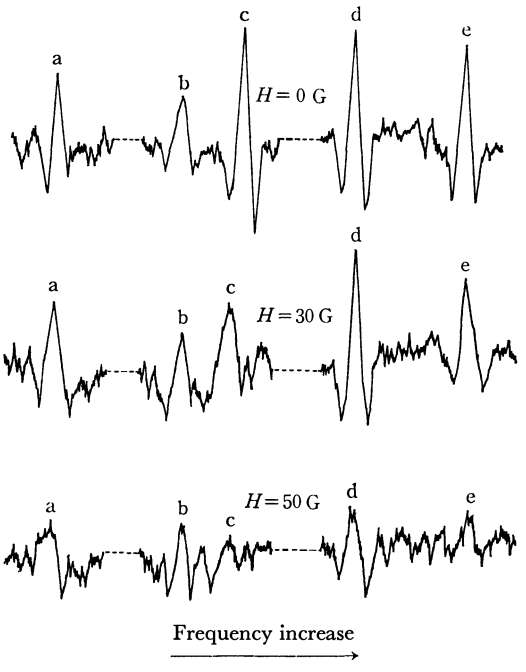

Fig. 1. Line shapes of ^{14}N NQR in the powder sample of 2-aminopyrimidine under the Zeeman field.

where $K=e^2Qq/4$, and e^2Qq and η are the quadrupole coupling constant and asymmetry parameter, respectively.

Determination of two Pairs of Resonance Lines for the Ring Nitrogens. Figure 1 shows how the shapes of five resonance lines of the powder sample, denoted by *a*, *b*, *c*, *d*, and *e* in the order of increasing frequency, change with the increase in strength of the Zeeman field. We see that resonance lines *c* and *e* become broader than *a* and *d*, with the increase in field strength. Therefore, *c* and *e* are paired together and they have a considerably smaller η value than *a* and *d*. From Eqs. (1) and (2), e^2Qq=3759.6 kHz and η=0.0329 were obtained for *c* and *e*, whereas the corresponding values for *a* and *d* are 3707.2 kHz and 0.0646, respectively. The results are consistent with those of Schempp[2] within experimental error.

On the other hand, as line *b* scarcely broadens even when H=50 G, it must have a large η value.

Detection of the Lower Line for the Amino Nitrogen.

The frequency of the higher resonance line for the amino nitrogen in 2-aminopyrimidine was reported by Schempp to be 2784.2 kHz.[2]

When $H \neq 0$ and η is small, the first-order perturbation method can be used, and the resonance frequencies are as follows:[5]

$$\nu_I' = 3K - (\eta^2K^2 + D^2\cdot\cos^2\theta)^{1/2}, \quad (3)$$

$$\nu_{II}' = 3K + (\eta^2K^2 + D^2\cdot\cos^2\theta)^{1/2}, \quad (4)$$

where $D=g\mu_0H$, and θ is the polar angle of the direction of the Zeeman field in the coordinates of the principal field gradients. The subscripts refer to the resonance lines corresponding to those in Eqs. (1) and (2) when D=0. When $H \neq 0$ and η is large, the second-order perturbation method has to be used. The resonance frequencies are as follows:[5]

$$\nu_I'' = K(3-\eta) + D^2(A+2B-C)/K, \quad (5)$$

$$\nu_{II}'' = K(3+\eta) + D^2(2A+B+C)/K, \quad (6)$$

where

$$A = \sin^2\theta\cdot\cos^2\varphi/(3+\eta), \quad (7)$$

$$B = \sin^2\theta\cdot\sin^2\varphi/(3-\eta), \quad (8)$$

$$C = \cos^2\theta/(2\eta), \quad (9)$$

and φ is the azimuthal angle of the direction of the Zeeman field in the coordinates of the principal field gradients.

The polar angle θ is related to the Eulerian angles ψ_1, ψ_2, and ψ_3 as shown in Fig. 2 by the equation:

$$\cos\theta = \sin\psi_2\cdot\sin\psi_3\cdot\sin\alpha\cdot\cos\beta + \cos\psi_2\cdot\sin\psi_3\cdot\sin\alpha\cdot\sin\beta + \cos\psi_3\cdot\cos\alpha, \quad (10)$$

where α and β are the polar and azimuthal angles of the direction of the Zeeman field in the coordinates fixed to the sample, respectively. The exact value of D is determined from the Zeeman shifts of line *c*, which has e^2Qq=3759.6 kHz and η=0.0329, in the single crystal. That is, Eqs. (3) and (10) can be used in order to obtain the value of D, since line *c* has a small η. From the Zeeman study of line *c* in the single crystal, it is found that ν_I' takes 2785.5, 2786.0, and 2783.1 kHz for the cases (α=0°, β=180°), (α=90°, β=180°), and (α=90°, β=200°), respectively. From these values, the value of D^2 was determined to be 807.8 kHz.[2]

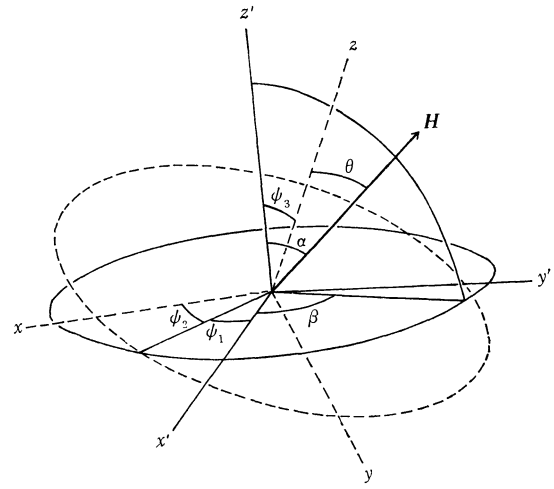

Fig. 2. Eulerian angles ψ_1, ψ_2, and ψ_3.
x, y, and z: the coordinates of the principal field gradients.
x', y', and z': the coordinates fixed to the sample.

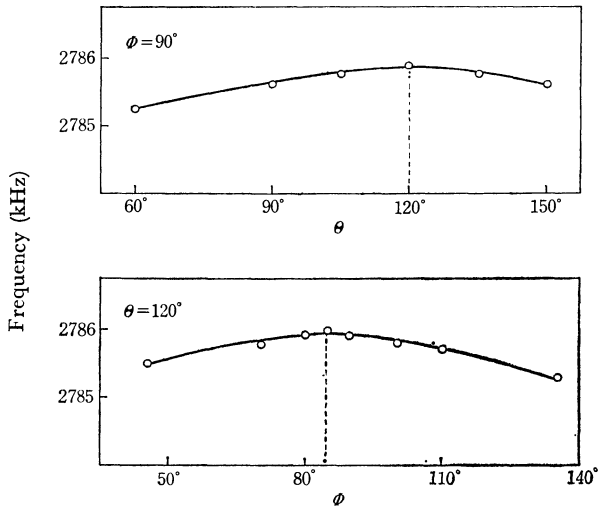

Fig. 3. The angular dependence of the Zeeman shifts of line *b*.

Figure 3 shows the anglar dependence of the Zeeman shifts of line *b* when the sample is rotated about a given axis. The Zeeman field was applied along the *Y*-axis of the laboratory frame as shown in Fig. 4, and the frequencies of line *b* were measured at various rotating angles (Θ) about the *X*-axis for a constant rotating angle (Φ=90°) about the *Z*-axis. The maximum frequency or shift was found for Θ=120°. Next, the frequencies were measured at various rotating angles (Φ) about the *Z*-axis for Θ=120°. The shift was maximum at Φ=85° and ν_{II}'' was estimated to be 2786.0 kHz. It is thus concluded that the principal *z*-axis of the field gradient lies in the *XY* plane when Θ=120° and Φ=90°, and coincides with the direction of the Zeeman field when

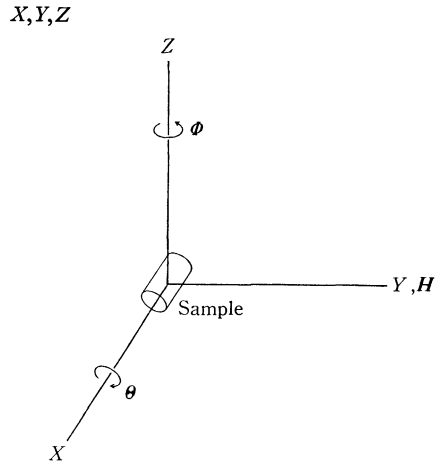

Fig. 4. The rotating angles Θ and Φ in the laboratory frame.

$\Theta=120°$ and $\Phi=85°$. Under the latter conditions, the relations $A=B=0$ and $C=1/(2\eta)$ are obtained from Eqs. (7), (8), and (9). Hence the following equation for ν_{II}'' is derived from Eq. (6): $2786.0=K(3+\eta)+807.8/(2\eta K)$. On the other hand, the higher line for the non-Zeeman field is expressed by $2784.2=K(3+\eta)$. Thus the NQR parameters for the amino nitrogen are calculated as $e^2Qq=3414.0\pm17.6$ kHz and $\eta=0.2630\pm0.0179$. Substituing these values into Eq. (1), the frequency of the lower line for the amino nitrogen is obtained to be 2335.4 ± 26.4 kHz for the non-Zeeman field. The neighborhood of this frequency was carefully swept again, and a very weak line was observed at 2357.8 kHz. These results are summarized in Table 1.

TABLE 1. ^{14}N NQR PARAMETERS IN 2-AMINOPYRIMIDINE

		ν_I (kHz)	ν_{II} (kHz)	$\lvert e^2Qq\rvert/h$ (kHz)	η (%)
Ring	N_1	2720.5	2840.3	3707.2	6.46
	N_2	2788.8	2850.7	3759.6	3.29
NH_2		2357.8	2784.2	3428.0	24.88

In general, we can not always attain the condition $\theta=0°$ by the consecutive procedures stated above. Accordingly, it is recommended to repeat the procedures until the self-consistent maximum shift is obtained, especially when the angle Φ for the maximum shift in the second procedure differs much from that fixed in the first procedure.

TABLE 2. ^{14}N NQR PARAMETERS FOR THE AMINO NITROGENS

Compound	$\lvert e^2Qq\rvert/h$ (kHz)	η (%)
Aniline[6]	3933	26.9
2-Aminopyridine[7]	3550.3	34.65
2-Aminopyrimidine	3428.0	24.88

Table 2 shows the quadrupole coupling constants and asymmetry parameters for the amino nitrogens in several similar compounds. The quadrupole coupling constant for the amino nitrogen in aniline is the largest,

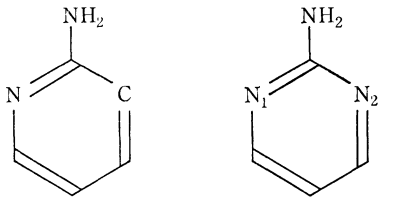

Fig. 5. The molecular frames of 2-aminopyridine and 2-aminopyrimidine.

while that for the amino nitrogen in 2-aminopyrimidine is the smallest. This suggests that the lone pair electrons of the amino nitrogen in aniline conjugate with π-electrons of the ring most weakly, while those of the amino nitrogen in 2-aminopyrimidine most strongly.

The asymmetry parameter of the amino nitrogen in 2-aminopyrimidine is nearly equal to that in aniline, but considerably smaller than that in 2-aminopyridine as shown in Table 2. This may be attributed to the molecular structure in which the nitrogen and carbon atoms in the ring are situated symmetrically or asymmetrically with respect to the C–N bond at the amino group.

Recently, π- and σ-electron densities for the ring nitrogen were derived from the following equations by Lucken:[8]

$$y - x = 2\eta e^2Qq/(3e^2Qq_p), \tag{11}$$

$$2 - y = (1-\eta/3)\cdot e^2Qq/[(1-\cot^2\gamma)\cdot e^2Qq_p], \tag{12}$$

where x and y are π- and σ-electron densities respectively, 2γ is the $\angle$CNC bond angle, and e^2Qq_p the quadrupole coupling constant due to one $2p$-electron of nitrogen atom. If it is assumed that $2\gamma=115.2°$ [9] and $e^2Qq_p=9$ MHz in Eqs. (11) and (12), both π- and σ-electron densities can be evaluated. Table 3 lists these values obtained for the ring nitrogens in pyrimidine[10] and 2-aminopyrimidine. We see that the amino group behaves like an electron-donor to the ring nitrogens. Simple LCAO MO calculations were carried out in order to make comparison with the results of NQR. The calculated values of π-electron densities for the ring nitrogens are qualitatively in good agreement with those predicted by NQR.

TABLE 3. π- AND σ-ELECTRON DENSITIES IN PYRIMIDINE AND 2-AMINOPYRIMIDINE

Compound		π		σ
		NQR	MO[a]	
Pyrimidine[9]		1.138	1.144	1.281
2-Aminopyrimidine	N_1	1.308	1.203	1.325
	N_2	1.299		1.308

a) The values of LCAO MO were calculated by the parameters such as $\alpha_N=\alpha+0.5\beta$, $\alpha_{C-N}=\alpha+0.1\beta$, $\alpha_{NH_2}=\alpha+0.4\beta$, $\alpha_{C-NH_2}=\alpha$, $\beta_{C-N}=\beta$, and $\beta_{C-NH_2}=0.6\beta$.

The total electron excess on the ring nitrogen can be computed from the values for the orbital occupation

numbers as follows:

$$z = x + 2y - 3 \quad (13)$$

From Table 3 and Eq. (13), the values of z are obtained to be 0.700 e^- for the ring nitrogens in pyrimidine and 0.958 e^- and 0.915 e^- for those in 2-aminopyrimidine. Thus, it is to be noted that the magnitudes of the electron transfer from the amino group to the ring nitrogens in 2-aminopyrimidine are larger by 0.258 e^- and 0.215 e^- respectively than that from the hydrogen atom in pyrimidine.

The Salting-out Adsorption of Isomeric Butyl Alcohols by Macroreticular Resin

Kie HISHINUMA, Hideo ŌKI, Yōichi KUROKAWA, and Norio YUI

Department of Applied Science, Faculty of Engineering, Tōhoku University, Aoba, Aramaki, Sendai

(Received October 14, 1971)

The salting-out adsorption of isomeric butyl alcohols on Amberlite (200) type designated as the macroreticular ion-exchange resin (MR type) was studied. On the basis of the difference in the salting-out effect of isomers, the separation of the isomer mixture in a dilute aqueous solution was attempted by using an aqueous ammonium sulfate solution as an eluent and the MR resin as a stationary phase. It seems that MR resin as the stationary phase is inadequate for the salting-out chromatography of isomeric butyl alcohols.

The salting-out effect in the two-phase system has been investigated on butyl alcohol in the aqueous and the butanol phases.[1] The present paper will report the salting-out adsorption of isomeric butyl alcohols on ion-exchange resin by determining the relative solubilities in an ammonium sulfate solution. The Amberlite (200) type of cation exchange resin was used. This resin, designated as macroreticular (MR) ion-exchange resin, is entirely different from the conventional homogeneous gels and has a rigid macroporous structure similar to those of the conventional absorbents.[2,3] Whereas the specific surface area for a conventional resin is very small (0.1 m^2/g), this resin has a surface area of 54.8 m^2/g.[2] On the basis of the difference in the salting-out effect on isomers, the separation of an isomer mixture in a dilute aqueous solution was attempted by using an aqueous ammonium sulfate solution as an eluent and the MR resin as the stationary phase. The designation "Salting-out Chromatography" has been proposed for such a method of separation.[4,5] The only convenient method known to the authors for the determination of each isomer in the above mixture is that of gas chromatography. However, in this case, such a method is not applicable because of the undesirable phenomena of water tailing.

Experimental

Procedure. All the chemicals were reagent-grade and were used without further purification. The Amberlite (200) type of cation exchange resin was converted to the ammonium form by the passage of 1 M ammonium sulfate solution and was then dried at 50°C overnight. This resin has the capacity of 4.3 meq/(g of dry resin), a water content of 44.8% and a pore size of 60—300 Å. The batch adsorption was made by adding 3—4 g of MR resin to 50 ml of a 0.5% butanol solution with a 0.5—3M ammonium sulfate solution. After this mixture had been allowed to stand at 25°C, overnight, the butyl alcohol in the aqueous solution was determined. In the case of column adsorption, the resin was packed into a column (ϕ 1.25 cm × 22.5 cm) water-jacketed and connected to a bath maintained at 25°C. Before elution, the resin was equilibrated with the eluent to be used. This was accomplished by allowing 300 ml of the eluent to pass through the column. A 0.5 mmol portion of the butyl alcohol was pipetted onto the bed. Then, the column was drained with a flow rate of 0.3 cm/min. The separation of isomers was attempted with the above-mentioned column and with a larger column of ϕ 1.7 × 70 cm. Both columns had an interstitial volume of 36%.

Analysis. The butyl alcohols were determined by oxidizing them in 50% sulfuric acid with dichromate and by measuring the reduced Cr(III) spectrophotometrically.[6] A 100 g portion of sodium dichromate was dissolved in water, and the mixture was diluted with water to 100 ml. A 5 ml portion of this solution was added to an 1000 ml solution of the concentrated sulfuric acid. At this time, the precipitate appeared, but it was redissolved on shaking. A 25 ml portion of a sample contanining 0.0025—0.01 mmol of butyl alcohol was pipetted into a 100 ml flask containing 25 ml of above oxidizing agent. Similarly, a flask was prepared by adding 25 ml of water to 25 ml of the oxidizing agent. The flask was heated in a boiling water bath for 15 min. After cooling to room temperature, the absorbance was measured at 610 mμ against the blank. Oxidizing anions such as nitrate and reducing ions such as halides interfered with this determination. Ammonium sulfate was the best eluent because of its large solubility in water and its great salting-out power.[4] Since the absorbance was slightly affected by ammonium sulfate,

Results and Discussion

The distribution ratio of butyl alcohol was defined as D=(the quantity of adsorption mmol/g-dry resin)/(concentration of aqueous solution mmol/l). Correction was made for the swelling and shrinking of the resin. The logarithms of these ratios are plotted against the concentration of ammonium sulfate in Fig. 1. These plots followed fairly closely this equation:

$$\log D = \log D^\circ + kM \qquad (1)$$

where D° is the distribution ratio in pure water, k is a salting-out coefficient, and M is the molarity of ammonium sulfate. Eq. (1) is very similar to Setshenow's equation.[1] The obtained values are represented in Table 1. D showed a rough tendency to decrease as the hydrophilic nature of the butyl alcohol increased. That is, the order of k was the same as that of the solubilities of butyl alcohols in water, (*tert*-butanol is completely miscible with water). The MR resin is observed to be much less sensitive to the nature of the solvent than conventional resin, but the results are not so much

Table 1. Distribution ratio and salting-out coefficinet

less sensitive in the literature.[3] The increase in the salt concentration of the eluent produced a greater affinity of the resin for butyl alcohol. The ionic groups on the resin would be solvated preferentially by water, and when salt was added, the resin would shrink because a part of the water was withdrawn to solvate the salt. Then, the solvated position around the ionic group on the resin could now be occupied by butyl alcohol.[7] Two kinds of solvent uptake by the resin might be considered. One might be a chemisorption as solvation around the ionic group on the resin, and the other, physisorption as fixing into the rigid macropores.[8] The adsorption of butyl alcohol on the MR resin was rather small, whereas the MR resin had a capacity as large as that of the conventional resin and had a much larger surface area. This suggests that water molecules are tightly bound to resin and may not be easily substituted by butyl alcohol molecules. Each isomeric butyl alcohol was eluted with a 3M ammonium sulfate solution. The elution graphs are shown in Fig. 2. They are very like each other. The ordinate is the absorbance of the Cr(III) formed by the reduction of dichromate by the butyl alcohol and is, therefore, proportional to the concentration of butyl alcohol in the eluent. Generally, a smaller mesh size of a resin produced a sharper elution curve, but no significant shift of the peak was observed. When the

quantity of butyl alcohol taken for elution was too large, the curve was wide and subject to tailing.

The distribution ratios in the column were obtained from the elution curves by using the following plate theory of chromatography:[9]

$$U = DV + V \quad (2)$$

U is the volume of the effluent collected by adding the sample to the peak. D is the distribution ratio, and V is the interstitial volume of the column. Table 1 represents a comparison of these values for the MR resin with those for the conventional resin. The separation of isomers was attempted with two columns. The elution of the first column for a mixture of *iso*- and *tert*-butanol is shown in Fig. 3. Another elution was performed by using a column much larger than the first (Fig. 4). The curves overlapped so badly that a satisfactory separation could not be achieved. The position of the peak was estimated from Eq. 2, and the value of D was obtained from the first column. The calculated values of U for *tert*-, *sec*-, and *iso*-butyl alcohol were 23.1, 29.5, and 31.2 ml respectively. The agreement between the calculated and observed values seems reasonable, though the peaks overlap (Fig. 4). The elution required 30 hr for the completion of a run. The separation might be made more completely with a column of a higher height. It seems that the MR resin as the stationary phase is inadequate for the salting-out chromatography of isomeric butyl alcohols.

The authors wish to express their thanks to Miss Shima Miura, who carried out part of the experimental work.

Properties of Water in Macromolecular Gels. V. Anomalous Temperature Dependence of the Nuclear Magnetic Resonance Line-width of Water in Macromolecular Gels

Masuo AIZAWA, Shuichi SUZUKI, Teruo SUZUKI,* and Hiroshi TOYAMA*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo

**Japan Electron Optics Laboratory Co., Ltd., Akishima, Tokyo*

(Received March 22, 1972)

The line-width of the nuclear magnetic resonance (NMR) signal gets narrow, in general, with an increase in the temperature. In contrast, the NMR line-width of the water proton in agarose gels was found to increase with an increase in the temperature up to about 30°C. As for the other polysaccharide gels, such as curdlan-type polysaccharide, and κ- and λ-carrageenan gels, the NMR line-width of water increases with an increase in the temperature. The anomalous temperature dependence of the line-width was most marked in agarose gels than in other polysaccharide gels. The close relationship between the gel network, which consists of small cavities (microspace) of the micelle, and the magnitude of the anomality was revealed, this anomalous effect was named the "Micro-Space Effect."

The line-width of the nuclear magnetic resonance (NMR) signal is known to become narrow as a result of the activation of molecular movement with an increase in the temperature, namely, motional narrowing.[1] In contrast, the present authors have found that the NMR line-width of the water proton in agarose gels containing more than 30% of water became wide with an increase in the temperature. Thus, the molecular motion seems to get bounded with an elevation in the temperature.

It was shown in previous papers[2-3] that water in polysaccharide gels is markedly affected by the three-dimensional framework of the polymer. The thermal expansion of water, for example, was found to be extremely obstructed in gels. The double-helix model, in which the two chains of each pair are parallel and are twisted around each other, has been proposed for the possible structure of such polysaccharides as agarose and carrageenan. The proposed model[4-5] suggests a mechanism for the formation of gels when dilute aqueous solutions of these polysaccharides are cooled: chain segments associate in double helices to crosslink the chains in a three-dimensional framework which is then responsible for the shape and strength of the gel. Subsequently or simultaneously, the double helices could combine into larger aggregates. There is much evidence in support of such mechanism. Furthermore, the effect of structural variations on gel properties may be explained in terms of the model for junction zones. Therefore, the temperature effect on the properties of water may depend on the properties of the junction zones and the framework. The small cavities in the three-dimensional framework of polysaccharide gels can be called the micro-space. Water is included in this micro-space. Therefore, the three-dimensional framework in gels was presumed to be responsible for the anomalous temperature dependence mentioned above. In other words, the anomalous temperature effect was supposed to be related with the micro-space in gels.

Agarose gels are known to be quite different from other polysaccharide gels, such as κ-carrageenan, λ-carrageenan, and curdlan-type polysaccharide gels, in their gel properties. A different anomalous temperature dependence of the NMR linewidth can be expected for these polysaccharide gels. The NMR linewidth was measured for these polysaccharide gels compared with agarose gels in the temperature range from 0 to 60°C.

Experimental

Materials. The agarose, κ-carrageenan, λ-carrageenan and curdlan-type polysaccharide gels used in this study were prepared with distilled water treated with ion-exchanger resins, and were sealed in a standard NMR sample tube (5 mm O.D.). Curdlan-type polysaccharide,[6] a bacterial gel-forming β-1, 3-glucan, which was supplied by Takeda Chemical Industrials, Ltd., was obtained from a culture filtrate of a mutant strain (NTK-U, IFO 13140) of *Alcaligenes faecalis var. myxogenes strain* 10C 3K. These samples were assayed for their ash content by the atomic absorption method. The analytical results on the ash content are shown in Table 1. The water content of the sample was measured by drying it at 105°C for 24 hr and by that then weighing the dried matter after the NMR measurement.

NMR Spectra. The proton NMR spectra were obtained using a JNM-C-60HL high-resolution NMR spectrometer with an external-lock system. Since the signals were wider than those normally seen in high-resolution measurement, it

was necessary to operate at the optimum rf power levels, just below signal saturation. The spectrometer was equipped with a variable-temperature controller which maintained the sample within ± 0.5°C of the desired temperature.

The temperature of a sample was calibrated by means of a copper-constantan thermo-couple placed inside the sample tube. The linewidth of the spectra is expressed in terms of half linewidth, *i.e.*, the linewidth at half of the maximum peak height.

Results

(1) Agarose Gels. The signal of the agarose proton is much wider than that of the water proton, as has been shown previously by broad-line NMR. Therefore, the proton signal in the high-resolution NMR spectra of agarose molecule can be distinguished from that of water.

The temperature dependence of the linewidth of the water proton in agarose gels was investigated in the range from 0 to 60°C at intervals of 5°C by high-resolution NMR. The spectra are illustrated for an agarose gel containing 92% of water at 10, 29, and 53°C in Fig. 1. The line shape remains evidently unchanged in the above temperature range, though the linewidth varies.

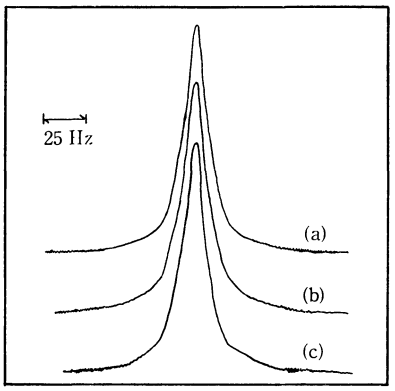

Fig. 1. NMR spectra of agarose gel containing 92% of water at (a) 53°C, (b) 29°C, and (c) 10°C.

The temperature dependence of the linewidth of the water proton in an agarose gel containing 92% of water is shown in Fig. 2. The linewidth was found to increase with an elevation of the temperature in the range from 0 to 35°C. In contrast, at temperatures higher than in the above range, the linewidth decreases as the temperature increases.

The linewidth temperature curves for agarose gels containing 79 and 72% of water are shown in Figs. 3 and 4. An anomalous temperature dependence was observed similar to that of the agarose gel containing 92% water.

(2) κ-Carrageenan and Curdlan-type Polysaccharide Gels. The gel properties of κ-carrageenan and curdlan-type polysaccharide gels are quite different from those of agarose gels. κ-Carrageenan and curdlan-type polysaccharide gels are very flexible, though the gel is weak in its gel strength. If the above anomalous temperature dependence of the line-width in agarose gels is related with the gel framework, different temperature dependences can be expected.

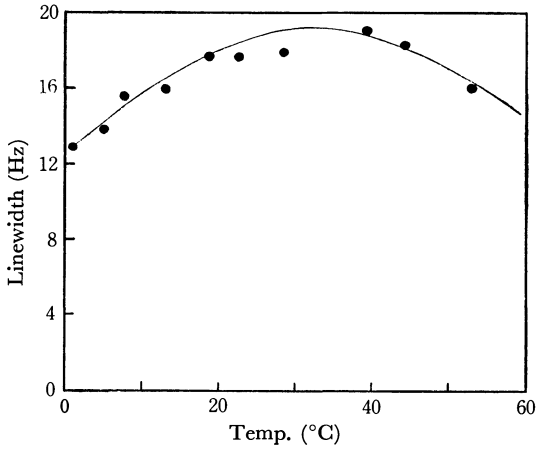

Fig. 2. Temperature dependence of the linewidth for agarose gel containing 92% of water.

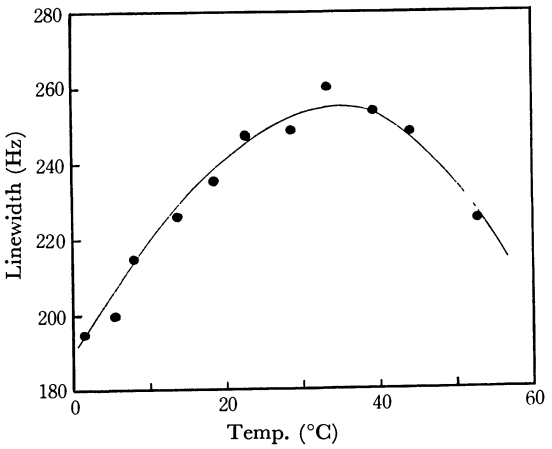

Fig. 3. Temperature dependence of the linewidth for agarose gel containing 79% of water.

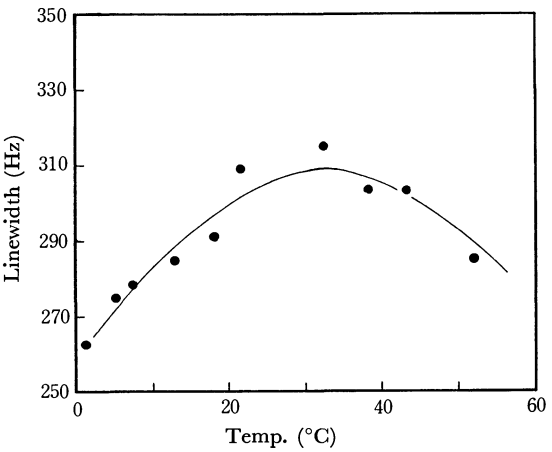

Fig. 4. Temperature dependence of the linewidth for agarose gel containing 72% of water.

The temperature dependence of the line-width for κ-carrageenan gels are illustrated in Fig. 5. For the gel containing 90.5% of water, the linewidth is not so dependent on the temperature as that of agarose gels. The linewidth, however, does not decrease with an increase in the temperature. Therefore, an anomalous temperature dependence was observed in such a

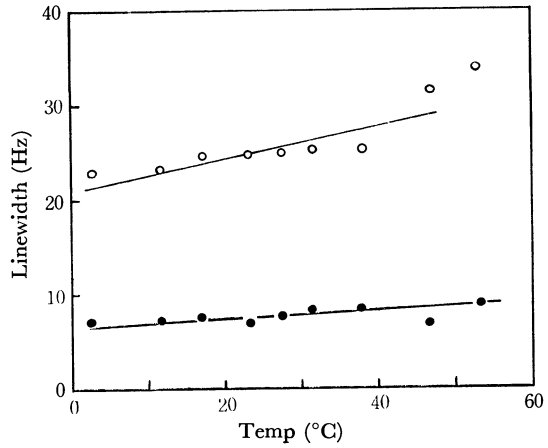

Fig. 5. Temperature effect on the linewidth of κ-carrageenan gel containing 85% of water (-○-) and 90.5% (-●-).

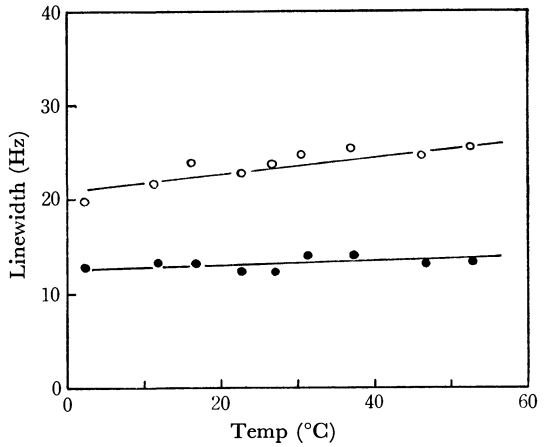

Fig. 6. Temperature effect on the linewidth of curdlan type polysaccharide gels containing 89.5% of water (-○-) and 91.8% (-●-).

gel. The κ-carrageenan gel containing 85% of water exhibited an evident anomalous temperature dependence of the linewidth, but it was, not so marked as in the agarose gels.

Figure 6 presents the temperature dependence of the NMR linewidth of the water proton in curdlan-type polysaccharide gels. The gels containing both 91.8 and 89% of water showed an anomalous temperature dependence similar to that of κ-carrageenan gels.

As was expected, the anomalous temperature dependence was confirmed in the κ-carrageenan gels and curdlan-type polysaccharide gels, though it was not so pronounced as in agarose gels. In addition, the maximum point in the linewidth *vs.* temperature curve, which was observed for agarose gels, was not detected for either κ-carrageenan gels or curdlan-type polysaccharide gels.

(3) λ-Carrageenan Gels. The gel strength of λ-carrgeenan gels is known to be not so strong as that of κ-carrageenan gels. The temperature dependence of the linewidth is postulated for the λ-carrageenan gels containing 93.5 and 88% of water in Fig. 7. These λ-carrageenan gels show a decrease rather than an increase in the linewidth with an elevation of the temperature. The anomalous temperature dependence

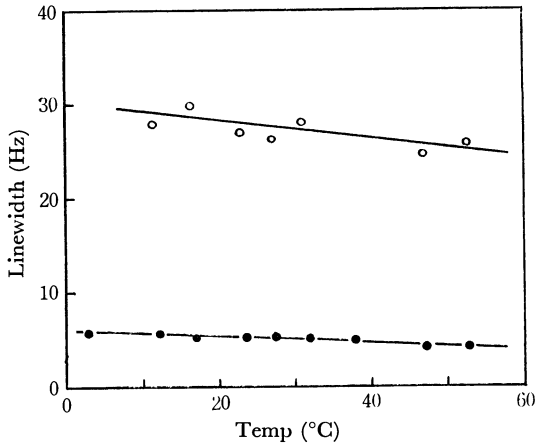

Fig. 7. Temperature effect on the linewidth of λ-carrageenan gel containing 88% of water (-○-) and 93.5% (-●-).

was not so enormous as that of the other gels.

Agarose, κ-carrageenan, curdlan-type polysaccharide, and λ-carrageenan gels exhibited an anomalous temperature dependence of the NMR linewidth of their water proton. The magnitudes of the anomalities were in the order; agarose>κ-carrageenan, curdlan type polysaccharide>λ-carrageenan gels. As was expected, this new finding regarding the anomalous temperature dependence of the line-width is closely related with the gel network. Agarose gels which have a strong network give the most marked anomality.

Discussion

Anomalous temperature effects on the nuclear magnetic resonance linewidth of the water proton in gels were found not only in agarose gels, but also in κ-carrageenan and curdlan-type polysaccharide, λ-carrageenan gels. The effect was the most prominent in the agarose gels.

The linewidth change depends not only on the motional state of the proton, but also on the so-called exchange association, the impurities, and so on. As is shown in Fig. 1, the line-shape of water in gels may be Lorentzian in the upper part and rather Gaussian in the lower part. The line shape remains unchanged in the temperature range surveyed. Proton exchange is estimated to be so rapid as to show no splitting in this system. Therefore, if the exchange association occurs, the linewidth can be expected to be narrowed. The impurities which influence the nuclear magnetic resonance are negligible, as is shown in Table 1. Therefore, the factors other than the motional state of the proton cannot explain those anomalous phenomena.

In view of the motional state of the proton, we assumed that this anomality can be explained by the relationship between the gel strength and the motional state of the water proton. Agarose gels are endowed with a high gel strength and elasticity, though κ-carrageenan and curdlan-type polysaccharide gels are flexible in texture. λ-carrageenan gels have a low gel strength. The magnitude of the anomality decreased with a decrease in the gel strength. The anomalous temperature effect was found to be related

with the strength of the gel network.

Gels, in general, are constructed of a macromolecular network consisting of a number of small cavities. Gels can enclose a large amount of water inside these cavities. Such cavities may be called "micro-space." The dimensions of the micro-space are estimated to be in the order from several Å to 10^2 Å. The properties of the micro-space, depend of course, on the steric properties of the network polymer. For instance, water inside the micro-space constructed of a rigid network may be markedly prevented from thermally expanding, because the expansion coefficient of the network polymer is much smaller than that of water, as was shown previously.[3] In other words, the motional state of water in a gel is closely related with the properties of the micro-space. Therefore, the above anomalous temperature effect on the linewidth of water can be explained in connection with the properties of the micro-space.

The important points regarding the behavior of water in gels are that the lower water contents of agarose gel containing less than 30% show no anomality in their temperature dependence, and that such an anomality is observed only above the transition points in the range from 0 to −20°C, as is shown in Fig. 8. At least three states of water, such as W_1, W_2, and W_3, can be considered for the behavior of water molecules in macromolecular gels, as was proposed previously, where W_1 and W_3 correspond to the so-called free water and bound water respectively.[2,3] The agarose gels containing less than 30% of water are dominated mainly by the specific state which corresponds to W_3. Therefore, most of the water in such gels may be stuck so tight by hydroxyl groups of agarose that it behaves just like the network polymer, even in thermal expansion. That is why no anomality was observed in such lower-water-content agarose gels.

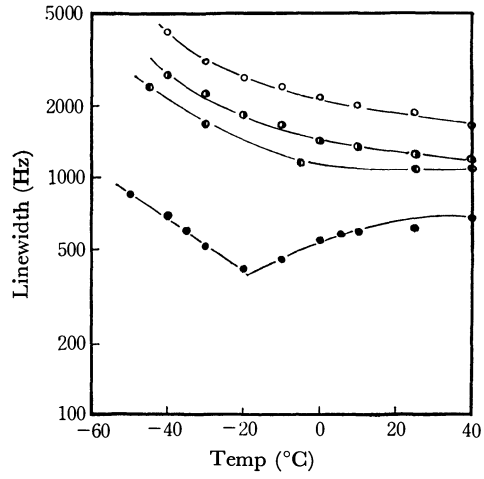

Fig. 8. NMR linewidth changes between −60°C and 40°C for varied water contents of agarose gel. -○- 10%, -◑- 19%, -◐-21.3%, -●- 43%.

Agarose gels containing a large amount of water gave an anomalous temperature dependence of the linewidth. The network polymer of the gel has not only hydrophylic sites, but also hydrophobic sites. Supposed that such hydrophobic sites expel water molecules in the micro-space, water molecules may lose their freedom.

Another important point is that the maxima were seen in the curve of the linewidth against the temperature for agarose gels, though the other gels gave no maxima. Though the gel-sol transition point of agarose gels is approximately 80°C, agarose gels soften around the above maxima. Such a softening is not so obvious in the other polysaccharide gels. In gels, a tremendous difference in thermal expansion coefficient can be supposed between the network polymer and entrapped water, as was indicated previously. The thermal expansion of enclosed water may be supposed on the basis of the network polymer. The thermal expansion of gels should be determined at the balance of the expansions of the network polymer and enclosed water. When the network polymer, however, cannot restrict the expansion of water, in other words, the nodes of the network polymer are relaxed with an increase in the temperature, the thermal expansion coefficient of the gels increases and the enclosed water becomes rather mobile. The maxima in the curve of the linewidth against the temperature for agarose gels can be attributed to such a point. Therefore, agarose gels should soften and the linewidth of water decreases with an increase in the temperature above this point.

On the basis of these results and discussion, the new finding regarding the anomalous temperature dependence can be explained by attributing it to the effect of the micro-space. The restriction of the motional state appears when the extreme difference between the framework of the micro-space, *i.e.*, the network polymer, and the enclosed molecules, *i.e.*, water, is in the physicochemical properties, such as the thermal expansion coefficient.

Brey[7] calculated the activation energy of water adsorbed on lysozyme through the temperature dependence of the NMR linewidth. As a lysozyme containing 488 mg/g of water showed a negative activation energy, he eliminated its activation energy from the other results without any discussion, though the temperature dependence was persented. These anomalous phenomena can be explained by the micro-space effect.

Summary

An anomalous temperature dependence of the NMR linewidth was found for water in macromolecular gels. In other words, the linewidth of the water proton increased with an elevation in the temperature.

The magnitude of this anomality was in the following order: agarose gels>κ-carrageenan, curdlan-type polysaccharide gels>λ-carrageenan gels. The gel with a rigid network gave an extinct anomality compared with the flexible network of the gel. This new-found anomality was explained by the "Micro-Space Effect."

Effects of Pressure on the Chemical Properties of Solid Surface. VI. The Surface Acidity of the Compressed Zinc Sulfate

Takeshi KAWAKAMI, Akira USUI, and Yoshisada OGINO

Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai

(Received June 24, 1971)

In order to clarify the mechanism of the acidity change due to compression, zinc sulfate was compressed under various pressures, ranging from 0 to 7000 kg/cm², and the surface acidity was measured and compared with the data of the structural change in the sample. According to the experimental results, the surface acidity varied on compression. At lower compacting pressures ($P\sim2500$ kg/cm²), the content of weak acid ($H_0=1.5$—3.3) was high and that of the strong acid was poor. These facts were explained by the higher content of anion-water, or heptahydrate, in the sample. In the pressure region of $P=2500<5500$ kg/cm², the acidity-pressure curve showed a maximum at 4500 kg/cm². Further, in this pressure range, the acidity-pressure curve paralleled well the respective curves of the X-ray peak width of hexahydrate pressure, the relative intensity of the IR $\nu_1(SO_4^{2-})$-pressure, and the half width of the IR $\nu_3(SO_4^{2-})$-pressure. It was considered that the acidity change in this pressure range is caused by the change in the content of the distorted structural unit of hexahydrate in the sample. In the highest pressure range, the content of weak acid was found to increase, whereas the content of strong acid was found to decrease. These results were discussed by considering the increased inclusion of tetrahydrate in the sample.

It has been revealed by the earlier works of the present authors[1-3] that the surface acidity of a solid varies on compression, and in the immediately preceding work[4] the authors have attemped to clarify the mechanism of the acidity change in aluminum sulfate. It has been demonstrated that the acidity change can be explained in terms of a microscopic structural change of the sample.

The purpose of the present work is to investigate whether or not the same mechanism as for the acidity change in aluminum sulfate is applicable to the acidity change in zinc sulfate. The details of the experimental results, including the acidity change, as well as the structural change in the sample will be described in this paper. Further, the validity of the previously-proposed mechanism of the acidity change will be demonstrated in the discussion.

Experimental

Material. The zinc sulfate heptahydrate was purified by means of recrystallization, and the resulting sulfate was used as the raw material for the sample.

Preparation of the Compressed Sample. The raw sulfate was compressed by the procedures described in the previous papers.[1-4] Briefly, the compression was carried out over a 10 min period under various pressures, ranging from 0 to 7000 kg/cm² and at a temperature of 20°C. The resulting cylindrical pellet, 6 mm in diameter and 2 mm in height, was pulverized in a mortar, and the powdered material was subjected to drying in a vacuum for 45 min at a temperature of 18°C. Then the powder served as a sample for the desired measurement. In order to minimize the effects of the change in ambient conditions, the following operations, *i.e.*, compressions, pulverizings, dryings, and weighings, were carried out in an air-conditioned room.

For the sake of convenience, the respective samples which were compressed under 0, 2500, 4500, 5500, and 7000 kg/cm² were defined as P_0, P_{2500}, P_{4500}, P_{5500}, and P_{7000}.

Surface Acidity. The surface acidity was determined by Benesi's method[5] with the following four indicators: dicinnamalacetone ($pK_a=-3.0$), crystal violet ($pK_a=0.8$), benzeneazodiphenylanmie ($pK_a=1.5$), and *p*-diphenylamino-azobenzene ($pK_a=3.3$). The acidity measurements were also carried out in an air-conditioned room.

Qualitative Tests for Lewis Acid. The identification of the Lewis acid center on the sample surface was carried out by the procedures used in a previous work.[4]

Surface Areas. The specific surface area of the sample evaluated by applying the BET thory to the adsorption data of nitrogen at −195°C.

Differential Thermal Analysis(DTA) and Thermogravimetric Analysis(TGA). DTA and TGA runs were carried out on a Rigaku Denki unit. The DTA curves and TGA curves were obtained at a temperature programming rate of 5°C/min.

X-Ray Diffraction. Powder X-ray diffraction patterns of the sample were obtained with a Shimadzu GX-1 X-ray Diffractometer. The Cu$K\alpha$ radiation (Ni filter) at 30 KV and 15 mA was used.

Infrared Spectroscopy. The infrared spectra for a 400~4000 cm^{-1} wave number range were obtained with a Perkin-Elmer Model 125 Infrared Spectrophotometer. In this work, a Nujol technique was employed.

Results

Surface Acidity. In Fig. 1, the acidity values of a given H_0 value are plotted against the compacting pressure. As can be seen in this figure, the acidity of $H_0=-3.0\sim0.8$ and the acidity of $H_0=0.8\sim1.5$ both increase with an increase in the compacting pressure and reach a maximum at a compacting pressure of 4500 kg/cm²; a further increase in the compacting pressure results in a decrease in the surface acidity. On the other hand, the pressure dependence of the content of weak acid ($H_0=1.5\sim3.3$) showed a com-

plicated behavior. Further, none of the samples showed any sign positive to the existence of Lewis acid.

Water Content. The water contents in samples compressed under various pressures are given in Table 1.

Table 1. Water Contents of the Samples compressed under Various Pressures

Compacting Pressure (kg/cm²)	0	2500	4500	5500	7000
Water Content (mol-H_2O/mol-$ZnSO_4$)	6.33	6.13	6.11	6.12	6.16

DTA and TGA. The DTA curves for various samples are given in Fig. 2. As can be seen in this figure, dehydration from the compressed sample occurred at 50, 98, and 240°C, while the dehydration from the uncompressed sample occurred at various temperatures. The TGA experiment and the chemical analysis

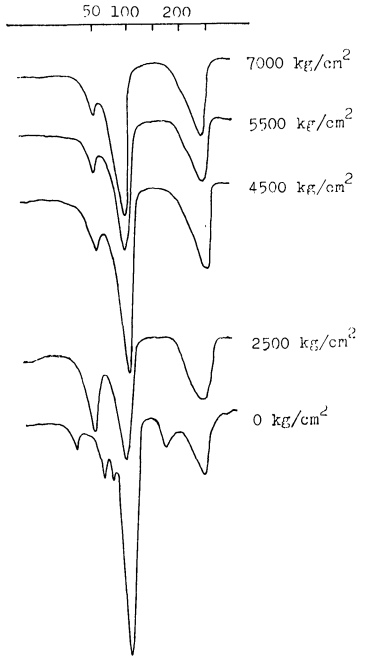

Fig. 2. D.T.A. curves for the samples compressed at various pressures.

Table 2. Amount of Dehydration at 50°C and 98°C

Samples	50°C	98°C
P_{2500}	1.7 mol-H_2O/mol-$ZnSO_4$	3.6 mol-H_2O/mol-$ZnSO_4$
P_{4500}	1.9 mol-H_2O/mol-$ZnSO_4$	3.2 mol-H_2O/mol-$ZnSO_4$
P_{5500}	1.9 mol-H_2O/mol-$ZnSO_4$	3.3 mol-H_2O/mol-$ZnSO_4$
P_{7000}	2.0 mol-H_2O/mol-$ZnSO_4$	3.3 mol-H_2O/mol-$ZnSO_4$

gave the corresponding amounts of dehydration at 50 and 98°C. The results are summarized in Table 2. The data given in this table show that the endothermic DTA peak appearing at 50°C for the compressed samples may be attributed to the dehydration;

$$ZnSO_4 \cdot 6H_2O \longrightarrow ZnSO_4 \cdot 4H_2O + 2H_2O$$

and that the peak appearing at 98°C may be attributed to the dehydration;

$$ZnSO_4 \cdot 4H_2O \longrightarrow ZnSO_4 \cdot H_2O + 3H_2O$$

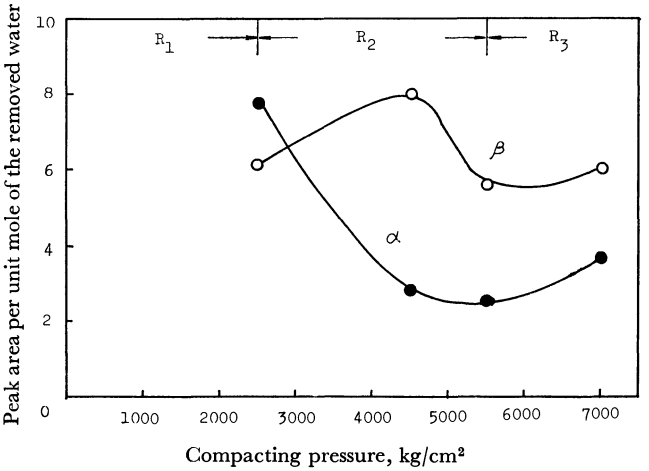

Fig. 3. Relations between the compacting pressure and the area of the endothermic peaks appaered at 50°C (-●-) and at 98°C (-○-).

The value of the endothermic DTA peak area per unit mole of removed water is given in Fig. 3. The area of the peak appearing at 50°C varied on compression and reached a minimum at a compacting pressure of 4500~5500 kg/cm². On the contrary, the area of the peak appearing at 98°C increased with an increase in the compacting pressure and reached a maximum at a compacting pressure of 4500 kg/cm². A further increase in the compacting pressure resulted in a decrease in this peak area.

As can be seen in Fig. 2, there is a marked difference between the DTA curve of the uncompressed sample and that of the compressed sample. The DTA curve for the former sample has many more endothermic peaks than the DTA curve for the latter sample. This means that the uncompressed sample contains many kinds of crystallization water. As can be seen in the next section, the compressed sample contains both zinc sulfate heptahydrate and zinc sulfate hexahydrate, whereas the compressed sample contains mainly hexahydrate. (The possibility of the coexistence of a small amount of heptahydrate can not be excluded. Further, the coexistence of tetrahydrate $ZnSO_4 \cdot 4H_2O$ is also seen at pressures higher than 5500 kg/cm²). Thus,

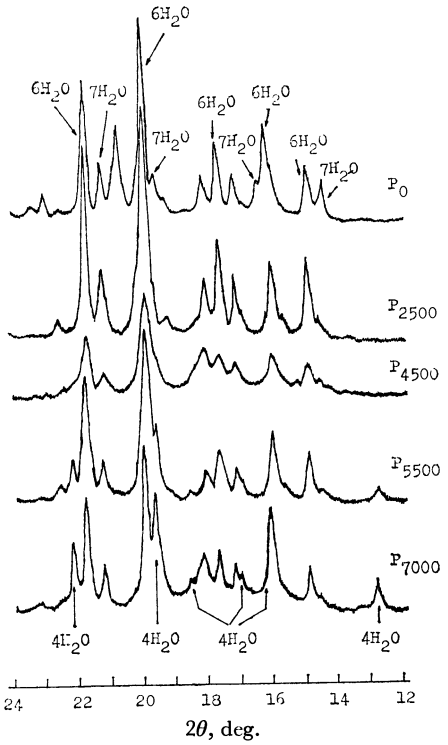

Fig. 4. X-ray diffraction patterns for various samples.

the complex DTA curve for the uncompressed sample may be attributed to the co-existence of hexahydrate and heptahydrate.

X-Ray Diffraction. Powder X-ray diffraction patterns for the various samples are igven in Fig. 4. From these patterns, it can be understood that the zinc sulfate used in this study consisted of crystals of heptahydrate[6] and hexahydrate.[7] Up to the compacting pressure of 4500 kg/cm^2, the line intensity of the heptahydrate decreased, and that of the hexahydrate increased, with an increase in the compacting pressure. However, this trend was reversed at compacting pressures higher than 4500 kg/cm^2.

Further, the degree of the broadening of the diffraction line for the hexahydrate increased with an increase in the compacting pressure from 0 to 4500 kg/cm^2, then it decreased at higher compacting pressures. In addition, diffraction peaks for tetrahydrate ($ZnSO_4 \cdot 4H_2O$) were found to appear (Fig. 4) in the diffraction pattern for the samples compressed at pressures higher than 5500 kg/cm^2.

Infrared Spectra. The infrared spectra for the sample compressed under various pressures are given in Fig. 5. Among the absorption bands in this figure, the bands assigned to ν_{OH} (3400 cm^{-1}), ν_{wag} (540 cm^{-1}),[8] and ν_{SO_2} (985 cm^{-1}) seemed to vary on compression. In view of the general difficulties in the comparison of the IR data for the polycrystalline hydrate, the following IR data are thought to include some ambiguities; they

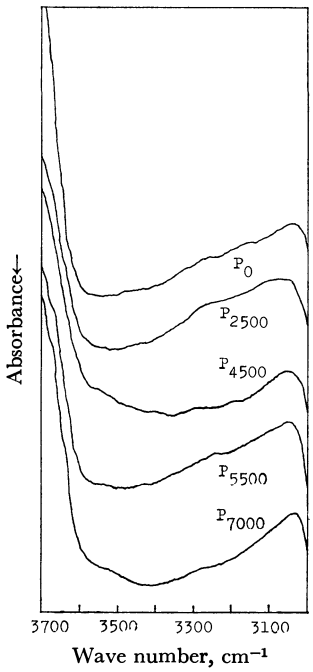

Fig. 5 A. Infrared spectra for various samples.

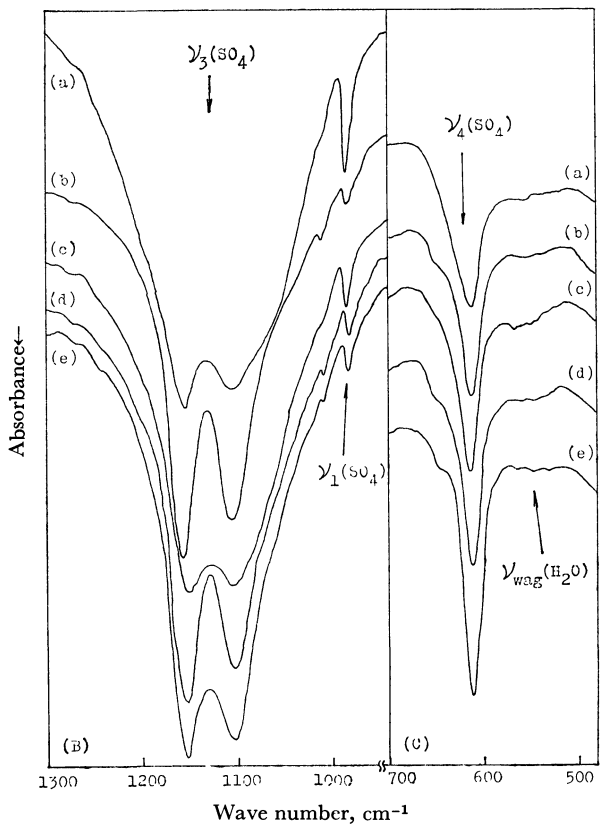

Fig. 5-B,C. Infrared spectra for the samples compressed at various pressures: (a) P_0; (b) P_{2500}; (c) P_{4500}; (d) P_{5500}; (e) P_{7000}.

must be regarded as qualitative data even if they are expressed by numerical values (*e.g.*, the intensity or the relative intensity):

i) The shape of the absorption band appearing at 2800~3600 cm^{-1}, which was assigned to the OH stretching vibration, seemed to vary on compression,

6) "Index to the Powder Diffraction Fill," ed. by J. V. Smith, ASTM Publications (1965), 9-395.

7) *Ibid*, 1-0352.

8) I. Nakagawa and T. Shimanouchi, *Spectrochimica Acta*, **20**, 429 (1964).

especially at 4500 kg/cm². From this fact, it was suspected that the absorption band for the P_{4500} sample shifted to somewhat lower wave numbers. However, this is only a suspicion. Because of the broad absorption band, the exact peak position could not be determined.

ii) The absorption appearing at 985 cm^{-1} was assigned to the ν_1 vibration of sulfate ions in the sample. The relative intensity[9] of this absorption against the intensity of the absorption for the ν_4 vibration of the sulfate ion (656 cm^{-1}) is given in Fig. 6. As can be seen in this figure, the relative intensity varied on compression.

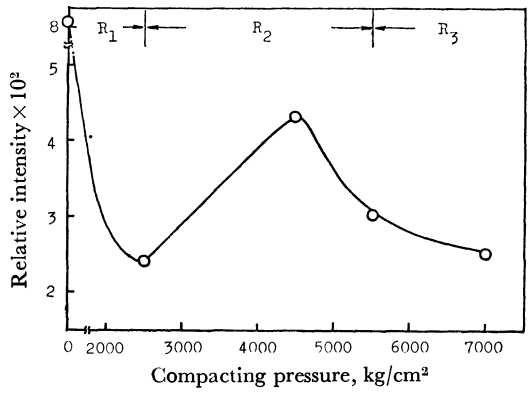

Fig. 6. Relations between the compacting pressure and the relative intensity of the ν_1 absorption against the ν_4 absorption for the sulfate ion.

iii) The absorption appearing at 540 cm^{-1} was assigned to the wagging vibration of the coordinated water in the sample. As can be seen in Fig. 5, the intensity[10] of this absorption seemed to increase with an increase in the compacting pressure, reaching a maximum at the compacting pressure of 4500 kg/cm², while it seemed to decrease at higher compacting pressures. Unfortunately, however, the reliability of this pressure-dependence for the H_2O wagging libration is not high enough because the absorption band at 540 cm^{-1} is broad and weak.

Discussion

Acidity Change on Compression and Related Data. Much as with the surface acidity of the other sulfates,[1-4] the surface acidity of zinc sulfate hydrate was found to vary on compression.

Generally speaking, the observed acidity change should be related to the structural change of the sample. However, as can be seen in Fig. 1, the surface acidity per unit surface area varied on compression. Therefore, the acidity change observed in the present study could not be attributed to the change in the surface area. Other factors must be related to the acidity change. It may be suspected that the dehydration from the sample might be directly causing the acidity change. However, efforts to correlate the acidity change with the degree of dehydration were not successful. It is difficult to derive any meaning from the small differences among the water contents of the various compressed samples (Table 1). In addition, approaches of this type seem to give little information about the microscopic cause of the acidity change.

In discussing the mechanism of the acidity change, the fact that the sample did not show any sign positive to Lewis acid must be taken into consideration. This fact and the experimental results given in Fig. 1 indicate that the acid which was found on the sample surface should be identified as Brönsted acid, which has a strength of $3.3 \geq H_0 \geq -3.0$. Therefore, the mechanism of the acidity change may be considered to include changes in the interaction among ions constituting the sample. From this point of view, the changes in the ionic arrangement in the sample must be compared with the acidity change.

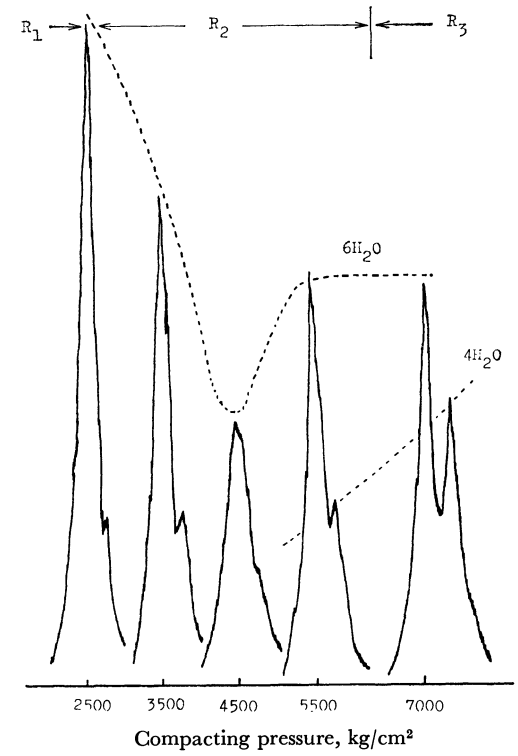

Fig. 7. Changes in the X-ray diffraction peak height (2θ= 20.2°).

On this point, information obtained from the X-ray diffraction study is useful. As can be seen in Fig. 7, the height of the X-ray diffraction peak at 2θ=20.2°, reached a minimum at the compacting pressure of 4500 kg/cm². Further, as can be seen in Fig. 8, the half-width of the diffraction peak reached its maximum at 4500 kg/cm². If these two figures are compared with Fig. 1, which shows the maximum acidity at 4500 kg/cm², an intimate relation between the acidity change and the change in the crystal structure becomes evident. However, the anomalously high acidities of H_0=1.5~3.3 for both samples of P=0 and P=7000 kg/cm² do not conform with the relation between the X-ray half-width (2θ=20.2°) and the compacting pressure (Fig. 8). These facts seem to indicate that factors other than the change in the X-ray peak at 2θ=20.2°

9) Defined by the ratio of the peak area.
10) Defined by the peak area.

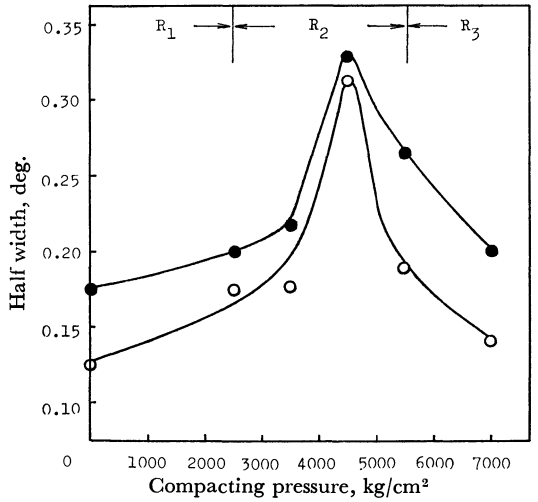

Fig. 8. Relations between the compacting pressure and the half-width of the X-ray diffraction peak for zinc sulfate hexahydrate: -●- $2\theta=20.2°$, -○- $2\theta=15.0°$.

(*i.e.*, the change in the crystal structure of hexahydrate) must be taken into consideration in order to discuss the acidities of the samples of $P=0$ and $P=7000$ kg/cm^2.

On the basis of the above discussion, the following discussion may be divided into three parts corresponding to three pressure regions-R_1, R_2, and R_3; R_1 ($P=0$ kg/cm^2) is a region where the anomalously high content of weak acid does not conform with the smaller half-width of the X-ray peak at $2\theta=20.2°$; R_2 ($P=2500\sim5500$ kg/cm^2) is a region where the acidity change conforms well with the change in the X-ray peak width, and R_3 ($P=5500$—7000 kg/cm^2) is a region where the existence of tetrahydrate becomes evident and the higher content of weak acid does not conform with the smaller X-ray half-width of hexahydrate ($2\theta=20.2°$).

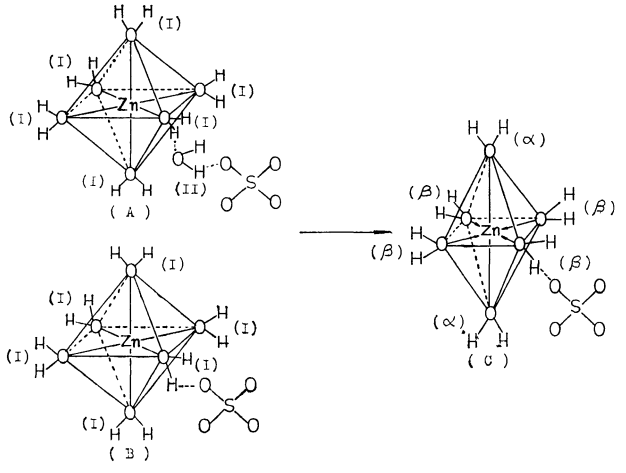

Fig. 9. Models of structural unit of zinc sulfate: (A) heptahydrate, (B) hexahydrate (not distorted), (C) hexahydrate (distorted).

Acidity Change and Structural Change in R_1. As can be seen in Fig. 1, the amount of weak acid ($H_0=1.5\sim3.3$) in the uncompressed sample was considerably great. On the other hand, the water content of this sample was also high compared with the other samples (Table 1). Further, the X-ray diffraction pattern for the uncompressed sample indicated rather strong peaks for heptahydrate. Therefore, it seems probable that the higher content of the weak acid in the uncompressed sample may be due to the higher content of anion-water (*cf.* Fig. 9-A) or to the presence of a heptahydrate.

In connection with the above discussion, it must be made clear that the relative intensity of the IR $\nu_1(SO_4^{2-})$ spectrum and the half-width of the $\nu_3(SO_4^{2-})$ spectrum were quite high for the uncompressed sample (Figs. 6, and 10). These facts may be ascribed to the higher content of anion-water. That is, it was considered that the anion-water may act to reduce the symmetry around sulfate ions in the sample.

The above view is rather crude, and more detailed discussions are desirable. Unfortunately, however, this is not possible at present. From a rather complicated feature appearing in the DTA chart for the uncompressed sample (Fig. 2), it is thought that the water molecules in this sample behave in a complex manner. Further, the easier dehydration observed at lower compacting pressures suggests that the uncompressed sample has an unstable structure. Thus, it is thought that the mechanism of the acidity change at compacting pressures lower than 2500 kg/cm^2 (in R_1) might be complex; more precise experimental work than the present experiments seem to be required to clarify the mechanism. For these reasons, detailed discussions of the acidity change in R_1 were not carried out in this paper.

One more point to be mentioned here is the low acidity for the strong acid ($H_0\leq1.5$) in this region (Fig. 1). Judging from the fact that the peak height for the X-ray diffraction of the uncompressed sample was generally high, both heptahydrate and hexahydrate seem to have their regular structural units. Therefore, there are few factors to strengthen the acid in the uncompressed sample. A higher content of anion-water may be an important factor in exhibiting the appearance of the strong acid. Thus, it may be possible to consider that the existence of heptahydrate is unfavorable for the appearance of strong acid.

Acidity Change and Structural Change in R_2.[11] As was mentioned in the previous section, the acidity change in this region was found to parallel well the change in the X-ray peak height or peak width for hexahydrate. Therefore, the acidity change in this region (R_2) may be related intimately to the change in the crystal structure of hexahydrate. Further, considering from the X-ray diffraction data (Fig. 4) and water content (Table 1), it may be estimated that the dominant species existing in the samples in the R_2 region are hexahydrate and that the existence of other species (heptahydrate and tetrahydrate) would have little effect on the acidity change because the contents of the latter species are considered to be small.

Under the provisions described above, the following discussions may be applicable to the acidity change in R_2. When changes in the crystal of hexahydrate occur, some changes in the structural unit constituting

11) It must be noted that all the figure referred to in this part should be confined to the pressure region of 2500—5500 kg/cm^2.

the crystallite of hexahydrate may be expected to occur. Therefore, the intimate relation between the acidity change in R_2 and the change in the X-ray diffraction peak for hexahydrate seems to mean that the acidity change may be caused by the change in the structural unit of hexahydrate. This view is in accord with the results obtained in the preceding work.[4] In order to aid the following discussions, models of the structural units of zinc sulfate hydrate,[8] including the model of hexahydrate, are given in Fig. 9.

The structural unit of $ZnSO_4 \cdot 6H_2O$ contains 6 moles of the coordinated water. However, the DTA data shown in Fig. 2 indicate that the coordinated water in the compressed sample is not equivalent. Further, the TGA data showed that 2 moles of the coordinated water were removed by the heating at ~50°C, and that the remaining coordinated water was removed by heating at higher temperatures. Therefore, it may be plausible to consider that the compressed sample contains two sorts of coordinated water. Thus, the 2 mol of coordinated water which were removed at 50°C were defined as α, and the other coordinated water was defined as β. The 4 mol of β may be considered to consist of 3 mol of β_1 and 1 mol of β_2. The respective dehydration temperatures of β_1 and β_2 are 98 and 240°C. Unfortunately, however, it is not possible to decide which one of the four coordinated water specimen is β_2.

There are many reasons to consider that the interactions between the central Zn^{2+} ion and the coordinated water vary on compression. As can be seen in Fig. 3, the DTA endothermic peak area per unit of mole of the removed water varied on compressing the sample. The peak area for the dehydration of α-water decreased on compression and reached its minimum at the compacting pressure of 4500~5500 kg/cm^2. On the contrary, the peak area for the dehydration of β_1-water reached its maximum at 4500 kg/cm^2. These facts indicate that the interaction between Zn^{2+} and β_1 reached its maximum at 4500 kg/cm^2, while the interaction between Zn^{2+} and α reached its minimum in the vicinity of this compacting pressure.

As has been mentioned in the experimental section, the interpretation of the IR data for such polycrystalline hydrates as are used in the present work involves many difficulties. Therefore, the following discussions of the IR data should be regarded as crude and approximate. The purpose of the present discussion is to show that the results of the IR experiments exhibit qualitative parallelisms with the other experimental data, *i.e.*, the surface acidity, the X-ray diffraction, and the DTA.

As has been mentioned in connection with the experimental results, the IR absorption band at 3400 cm^{-1} (OH stretching) for the P_{4500} sample was suspected to shift toward lower wave numbers (Fig. 5A, P=2000~5500 kg/cm^2). If this suspicion was not imaginary, the IR data in Fig. 5A (P=2000~5500 kg/cm^2) would support the theory that the strongest interaction of Zn^{2+} with β occurred at P=4500 kg/cm^2. Further, the IR absorption for the H_2O wagging libration (540 cm^{-1}) seemed to be most intensified at P=4500 kg/cm^2 (Fig. 5C). Although the reliability of this spectral change was not high enough, the strongest interaction of Zn^{2+} with β at P=4500 kg/cm^2 seems to be suggested.

In addition to the above-mentioned changes in the infrared spectra for water, Fig. 5 shows that the infrared spectra for the sulfate ion varied also on compression. The changes in the half-widths of the ν_3 vibration of the sulfate ion and the relative intensity of the ν_1 vibration of the sulfate ion are given in Fig. 10 (P=2500~5500 kg/cm^2). It can be seen that the largest change appeared at the compacting pressure of 4500 kg/cm^2. These facts seem to indicate that the interaction between the sulfate ion and its environments varied on compression. In view of the model of the structural unit, such changes as have been described above may be thought to occur easily. Presumably, the increased ν_1 absorption of SO_4^{2-}, which is originally inactive in the infrared absorption, may result from an increased interaction between the oxygen in the sulfate ion and the hydrogen in the coordinated water, β.

The acidity changes observed in the R_2 region seem to be explainable in terms of the structural unit of $ZnSO_4 \cdot 6H_2O$. The existence of two sorts of coordinated water, *i.e.*, α and β, means that the octahedron around the Zn^{2+} ion is distorted in the manner shown in Fig. 9-C (the distances between Zn^{2+} and H_2O (α) are extended and the distances between Zn^{2+} and H_2O (β) are shortened); moreover as has been mentioned in the previous section, the change in the interaction between the central Zn^{2+} and the coordinated water, β, may result from the change in the compacting pressure. The change in the interaction between Zn^{2+} and H_2O (β) may result in a change in the degree of the polarization of the H_2O (β) molecule in the following way:

$$Zn^{2+}\cdots O\begin{matrix}H\\ \\ H\end{matrix} \longrightarrow Zn^{2+}\cdots {}^{-\delta}O\begin{matrix}H^{\delta+}\\ \\ H\end{matrix}$$

Thus, the quantity of the protonic-acid center around the octahedral structural unit will vary. According to this mechanism, the acidity will become larger as the interaction between Zn^{2+} and H_2O (β) is increased.[12]

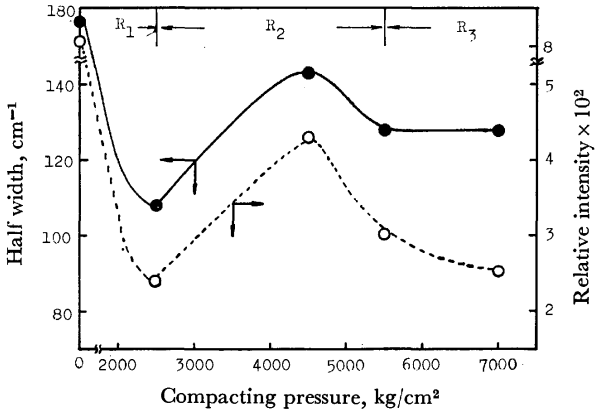

Fig. 10. Relations between the compacting pressure and the half width of the ν_3 absorption band of the sulfate ion (-○-), and the changes in the relative intensity of the ν_1 absorption against the ν_4 absorption for the sulfate ion (-●-).

12) G. Zundel, "Hydration and Intermolecular Interaction," Academic Press, New York (1969).

The parallelism between the acidity change (Fig.1) and the change in the dehydration peak area (Fig. 3) seems to indicate the validity of the above-mentioned mechanism for the acidity change. Further, the crude parallelism between the acidity change (Fig. 1) and the IR data for the OH stretching (Fig. 5A) and H_2O wagging libration (Fig. 5C) seems to be consistent with the proposed mechanism for the acidity change.

The interaction between the sulfate ion and the coordinated water (β) may also contribute to the acidity change. As has been mentioned in the previous section, the infrared spectra (Figs. 5 and 10) revealed that this interaction also varies on compression; the acidity change (Fig. 1) also paralleled the changes in the infrared spectra for the ν_1 and ν_3 vibrations of the sulfate ion (Fig. 10). Presumably, the compression resulted in a displacement of the sulfate ion nearer to the octahedral structural unit, and this promoted the polarization of the H_2O (β) molecule. Further support for this mechanism is given in Fig. 11. As can be seen in this figure, the relative intensity of the ν_1 absorption of SO_4^{2-} has a straight-line relationship to the acidity change.

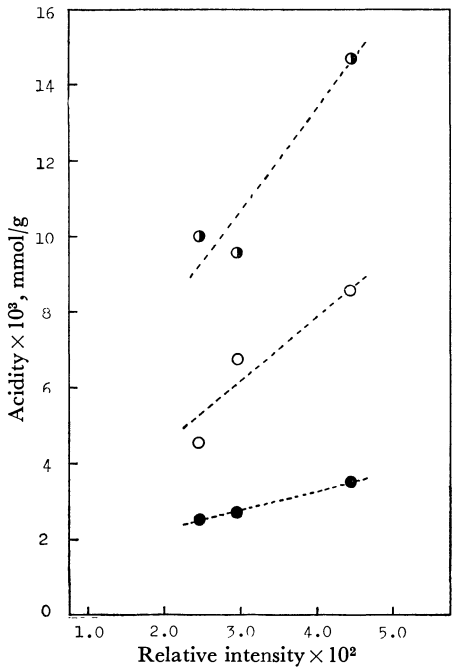

Fig. 11. Relations between surface acidity ($H_0=-3.0\sim 0.8$, -●-; $H^0=-3.0\sim 1.5$, -○-; $H^0=-3.0\sim 3.3$, -◑-) and the relative intensity of ν_1 absorption against the ν_4 absorption for the sulfate ion.

The pressure range of $P=4500\sim 5500$ kg/cm² seems to be a special region, though this pressure range was considered to belong to R_2. In this pressure range, the acidity was found to decrease despite the increasing pressure. As has been mentioned in the previous paragraphs, the decreasing acidity in R_2 is attributable to the decreasing distortion of the structural unit of hexahydrate. This decreasing distortion of the structural unit seems to be ascribable to the appearance of tetrahydrate. The X-ray diffraction data given in Fig. 4 show that the peak for tetrahydrate appears at 5500 kg/cm². It is probable that a part of the supplied energy of compression was consumed to produce tetrahydrate. Therefore, the energy to distort the structural unit may be reduced. Thus, the smaller content of the distorted structural unit and the smaller surface acidity may result. Of course, the formation of tetrahydrate would result in a decrease in the content of hexahydrate (probably accompanied by the formation of heptahydrate). However, judging from the rather weak diffraction peaks of tetrahydrate in R_2, other effects of tetrahydrate on the acidity change in R_2 may be considered to be small and negligible.

Acidity Change and Structural Change in R_3. As can be seen in Fig. 4, when the compacting pressure exceeds 5500 kg/cm² (especially at 7000 kg/cm²), the peaks for tetrahydrate ($ZnSO_4\cdot 4H_2O$) became evident. On the other hand, the content of weak acid ($H_0=1.5\sim 3.3$, R_3 in Fig. 1) and the DTA peak area (β_1, R_3 in Fig. 3) increased in this region, R_3. Therefore, it is not unlikely that these changes are related directly to the existence of tetrahydrate. Unfortunately, however, direct evidence for this view is lacking at present. Whether the higher content of weak acid ($H_0=1.5\sim 3.3$) in the sample compressed at 7000 kg/cm² is due directly to the existence of tetrahydrate, or to the somewhat increased content of heptahydrate, is not certain. (Considering from the fairly constant water content in the compressed sample of $P\geq 2500$ kg/cm², the formation of tetrahydrate may proceed through a disproportionation of hexahydrate. Thus, the formation of tetrahydrate may accompany the formation of heptahydrate. According to the discussion in Part I, the existence of heptahydrate may be a cause of the appearance of weak acids.)

The behavior of the strong acid ($H_0=-3.0\sim 1.5$) in this region (R_3) is also interesting. In spite of the increase in the X-ray diffraction peaks for tetrahydrate, the acidity of $H_0\leq 1.5$ tended to decrease beyond $P=5500$ kg/cm². Therefore, it may be said at least that the existence of tetrahydrate does not result in a marked increase in the content of strong acid. However, in view of the rather complicated structure and composition of the sample in this region (R_3), the possibility that the appearance of tetrahydrate might affect the acidity change (strong acid) in a complicated manner can not excluded.

One important role played by tetrahydrate in the acidity change (strong acid in R_3) seems to be the reduction of the compression energy which is available to distort the structural unit. In the pressure range where the appearance of tetrahydrate is more favorable, the energy of compression may be consumed mainly to form tetrahydrate; in that case, only a part of the energy would be consumed to distort the structural unit. Therefore, a great reduction in the content of strong acid may result. In addition, the formation of tetrahydrate would reduce the content of hexahydrate in the sample. That is, hexahydrate would be consumed and tetrahydrate and heptahydrate, both of which are considered to be ineffective for the appearance of strong acid, might be accumulated in the sample. These factors may also contribute to a reduction in the acidity of the lower H_0 values (strong acid).

Effects of Pressure on the Chemical Properties of Solid Surfaces. VII. Surface Basicities of Some Compressed Carbonates and Related Compounds

Shoe BABA and Yoshisada OGINO

Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai

(Received June 28, 1971)

In order to investigate the effect of the compacting pressure on the surface basicities of solids, experiments were carried out by employing various carbonates, hydroxides, and oxides of alkali metals and alkaline earth metals as samples. That is, compacting pressures ranging from 0 to 15000 kg/cm^2 were applied to these samples, and the changes in the surface basicities were observed using an indicator method. It was observed that the surface basicities of various solid vary on compression. Further, the respective basicity change in cadmium carbonate, calcite, and aragonite could be explained by the change in the surface area of each of these samples. On the other hand, the basicity changes of both strontium carbonate and barium carbonate could be explained thus only with difficulty. From the results of the X-ray-diffraction study and the electron-diffraction study, the changes in the crystal structures of these samples were suspected of causing the basicity changes due to compressions. According to the results of infrared spectroscopic studies, changes in the symmetry around carbonate ions in the sample crystals were considered to be the cause of the basicity changes in strontium cabonate and barium carbonate.

It has been revealed by previous works[1-4] of this laboratory that the surface acidities of various solids including metal sulfates vary on compression. Considering from the conjugate characters of the acid and the base and from the findings in the previous works,[1-4] we can expect the surface basicity of a solid will also vary on compression.

The purpose of the present work is to confirm the above expectation. It will be demonstrated in this paper that the surface basicities of various solids vary on compression. Further, some additional experimental results which serve to explain the change will also be included in this paper.

Experimental

Materials. The following solids served as samples for the qualitative experimental works to disclose the pressure effect on the surface basicity:

Carbonates: $CaCO_3$(calcite), $SrCO_3$, $BaCO_3$, $KHCO_3$, K_2CO_3, $NaCO_3$, $NaCO_3 \cdot H_2O$, $(NH)_4CO_3$

Hydroxides: $Mg(OH)_2$, $Ca(OH)_2$, $Sr(OH)_2 \cdot 8H_2O$, $Ba(OH)_2 \cdot 8H_2O$

Oxides: BeO, MgO, CaO, ZnO, BaO

They were all obtained commercially as reagent-grade materials, except for the magnesium oxide, which was obtained by pyrolyzing a commercial magnesium hydroxide at 700°C. In addition, the following carbonates served as samples for the quantitative measurements of the basicity change as well as the structural change;

$CaCO_3$(calcite), $CdCO_3$: sodium nitrate structure

$CaCO_3$(aragonite), $SrCO_3$, $BaCO_3$: potassium nitrate structure

These materials were all obtained commercially as reagent-grade materials, except for the aragonite, which was prepared by drying precipitate obtained by mixing an aqueous calcium chloride solution with an aqueous sodium carbonate solution at 90～100°C.

Preparation of the Sample. The compression of the raw materials was carried out by essentially the same procedures as have been described in the preceding papers.[1-4] That is, the material was gently pulverized in an agate mortar, and then about 0.1 g of the powder was packed into the sample room of a piston-cylinder device. A desired pressure, ranging from 0 to 15000 kg/cm^2, was applied to the powder for 10 min at room temperature.[5] After compression, the resulting cylindrical pellet (1—2 mm in height and 6 mm in diameter) was pulverized in a mortar. The pulverized material was subjected to drying in a vacuum over a 1 hr period at room temperature. The resulting dry material served as a sample for a desired experiment.

Surface Basicity. The qualitative effect of pressure on the surface basicity was observed by the following procedures: by manipulation in a dry box, a given amount of the powder of the compressed sample was transferred to a 50 ml conical flask containing 10 ml of purified benzene. Then, several drops of a 0.1% phenolphtalein ($pK_a=9.3$) solution in benzene were added, and after 1 hr the surface color of the sample was observed. At the same time, a similar observation was carried out by using as uncompressed sample. The difference between the colors of the two samples was then recorded.

The quantitative determination of the surface basicity of the carbonate sample was carried out by employing the following method: by manipulation in a dry box, a given amount (0.05 g) of the sample powder was transferred to each of a a series (usually ten) of 50 ml conical flasks each containing 10 ml of purified benzene. Then enough 1/500 or 1/1000N benzoic acid in benzene was added to each of these ten samples so as to bracket the expected titer. After the samples had then stood for 20 hr. several drops of the indicator solution, *i.e.*, a 0.1% phenolphthalein solution in benzene, were added to each flask. The bracketed titer, *i.e.*, the titer of benzoic acid required to neutralize the surface base, could be determined easily by the observation of the surface color of each sample.

Surface Area. The specific surface area of the carbo-

5) Exceptionally, pressure was applied at a temperature of 100°C.

nate samples were evaluted by applying the BET theory to the absorption data of nitrogen at −195°C.

X-ray Diffraction. Powder X-ray diffraction patterns of carbonates which have a potassium nitrate structure were obtained with a Shimadzu GX-1 X-ray Diffractometer. The Cu$K\alpha$ radiation (Ni filter) at 30 KV and 20 mA was used.

Infrared Spectroscopy. The infrared spectra (600—1200 cm^{-1} wave number range) of carbonates which have a potassium nitrate structure were obtained with Perkin-Elmer Model 337 Infrared Spectrophotometer. A Nujol mull technique was employed in every case.

Electron Diffraction. Phtographs of the Debye-Scherrer rings of the strontium carbonate sample and the barium carbonate sample were obtained with an electron-diffraction apparatus (JEM-ADF) attached to a JEOLCO JEN-50 Electron Microscope. The operation was carried out at 50 KV and about 5 μA.

Results

Surface Basicity. The surface colors of the various samples are summarized in Table 1. As can be seen in this table, the compression at 4500 kg/cm² resulted in an increase in the surface color for about 2/3 of all the samples. In other words, the surface basicities of these samples increased on compression.

The results of the quantitative determination of the surface basicity are given in Fig. 1 (a, b), wherein the surface basicities of the samples with a sodium nitrate structure as well as the basicities of the samples with a potassium nitrate structure are both expressed as functions of the compacting pressure. As can be seen in this figure, the basicity of every carbonate increased considerably on compression, though the shape of the basicity-*vs.*-pressure curve was different from carbonate to carbonate. For example, the basicity of calcite, whose original basicity was nearly zero, increased monotonously with an increase in the compacting pressure and reached about 1.6×10^{-2} mmol/g at 15000 kg/cm². In contrast with this, the pressure-*vs.*-basicity curve for cadmium carbonate had a maximum at a pressure of about 7000 kg/cm², and the basicity at this pressure was about twice the original value.

Table 1. Effect of the compacting pressure on the surface basicities of various solids

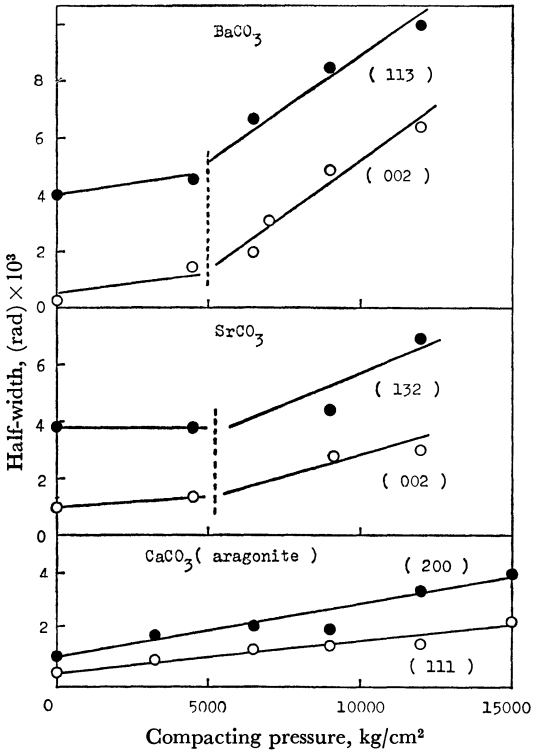

Fig. 3. Relations between the half-widths of the X-ray diffraction peaks and the compacting pressure.

the specific surface areas of every carbonate also varried on compression, though the shape of the surface area-*vs.*-pressure curve was different from carbonate to carbonate.

X-Ray Diffraction. Except for an increase in the halfwidth of the diffraction peak, no appreciable changes in their X-ray diffraction patterns resulted from the compressions of aragonite, strontium carbonate, and barium carbonate. The plots of the half-width against the compacting pressure are given in Fig. 3. Although the evaluation of the lattice distortion by applying Hall's method[6] to the broadening of the X-ray diffraction peaks was not possible, Fig. 3 reveals an interesting aspect of the pressure dependence of the half-width. The half-width of the diffraction peak for aragonite increased monotonously on an increase in the compacting pressure, whereas the half-width of both strontium carbonate and barium carbonate increased abruptly at a compacting pressure of about 5000 kg/cm².

Infrared Spectra. Examples of the infrared spectra for the samples with a potassium nitrate structure (aragonite, strontium carbonate, and barium carbonate) are given in Fig. 4. Two absorption bands, expressed as ν_1 and ν_2 in these spectra were assigned to the totally symmetric stretching vibration of the carbonate anion (CO_3^{2-}) and the out-of-plane deformation vibration of the same anion respectively. Further, the intensities[7] of the ν_1 absorptions of both strontium carbonate and barium carbonate were found to diminish at higher compacting pressures, while the intensities of the ν_2 absorptions of these samples varied little.[8] This behavior is depicted in Fig. 5. As can be seen in this figure, the $S\nu_1/S\nu_2$ ratio, where $S\nu_1$ is the intensity of the ν_1 absorption and $S\nu_2$ is the intensity of the ν_2 absorption, diminished pronouncedly at higher compacting pressures than 5000 kg/cm². In contrast with the pressure-dependent behaviors of the $S\nu_1/S\nu_2$ ratios

—·—: literature value for (111) plane

for strontium carbonate and barium carbonate, the Sv_1/Sv_2 ratio for aragonite was found to be independent of the compacting pressure (Fig. 5).

Electron Diffraction. On the basis of the photographs obtained from the electron-diffraction studies for strontium carbonate and barium carbonate, the lattice distances of the crystals of these samples were calculated. As is illustrated in Fig. 6, the lattice distances for the (111) planes of these samples diminished slightly with the increase in the compacting pressure. Considering the lager scattering of the experimental data shown in Fig. 6, a statistical treatment was applied on the data. The results are given in Table 2. It may be concluded from this table that the decrease in the lattice distance is appreciable.

Discussion

Basicity Change on Compression. As can be seen in Table 1, the present work revealed that the surface basicities of many solid substances vary on compression. Generally speaking, the change in the surface basicity may be caused by the change in the structure of the sample. However, care must be taken to select suitable samples so as to obtain unambiguous structural data for the discussion of the basicity change. It was found by preliminary experiments that carbonates are suitable for this purpose. Thus, only discussions of the basicity changes in carbonates will be described in this paper.

For the sake of simplicity, the basicity changes in calcite and cadmium carbonate will be considered first. By comparing Fig. 1 (a) with Fig. 2 (a), it can easily be understood that the curves representing the basicity *vs.* pressure relations parallel the cruves representing the surface area-*vs.*-pressure relations. Therefore, the changes in the surface areas are supsected of causing the basicity changes in these samples. In fact, as can be seen in Fig. 7 (a), the surface basicity per unit of surface area for each of the two samples was independent of the compacting pressure. This verifies the validity of the suspicion.

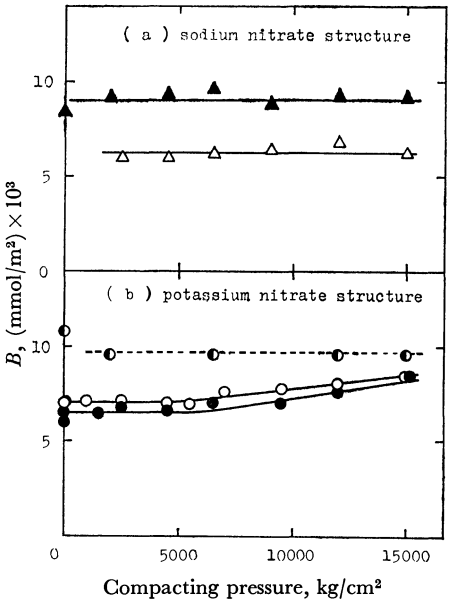

Fig. 7. Relations between B (the basicity per unit of surface area) and the compacting pressure.
△: $CaCO_3$ (calcite), ▲: $CdCO_3$, ◐: $CaCO_3$ (aragonite), ●: $SrCO_3$, ○: $BaCO_3$

In contrast with the above-mentioned simple behavior of the samples with the sodium nitrate structure, the samples with the potassium nitrate structure behaved somewhat complicatedly. That is, as can be seen in Fig. 7 (b), the basicity per unit of surface area of aragonite was found to be independent of the compacting pressure, whereas the surface basicity per unit of surface area of each of the other two samples (strontium carbonate and barium carbonate) showed a pressure dependence. This pressure dependence was small at pressures lower than 5000 kg/cm², but it tended to increase beyond this pressure. In the pressure range of 5000~15000 kg/cm², the pressure dependence was evaluated to be about 30%/1000 kg/cm².

Considering the facts described above, the basicity change in aragonite may be ascribed to the change in the surface area of this sample. That is, the reason for the basicity change in aragonite may be considered to be the same as for that in calcite or in cadmium

carbonate. However, the pressure dependences of the surface basicities of both strontium carbonate and barium carbonate can not be attributed to the cahnges in the surface areas. In order to explain the basicity changes in the strontium carbonate and barium carbonate samples, some other factors must be taken into consideration.

Crystal-structure Change upon Compression. The results of the X-ray diffraction study seem to give some information about the basicity changes in strontium carbonate and barium carbonate. As can be seen in Fig. 3, the half-width of the X-ray diffraction peak for each of these samples tended to increase at ~5000 kg/cm^2. The same tendency is observable in Fig. 7 (b), where the change in the basicity per unit of surface area for each of these two samples is depicted. These facts seem to suggest that the deformation of the crystallites resulted in the increases in the number of basic sites on the surfaces of the samples. Further, the electron-diffraction studies in the present work have revealed that the compression resulted in a decrease in the lattice distances ((111) plane) of strontium carbonate and barium carbonate. These facts also suggest the existence of an intimate relation between the respective basicity change of these samples and the deformation of the crystal structure in each of these samples. Unfortunately, however, because of the existence of larger scatterings in the X-ray diffraction data as well as in the electron-diffraction data, further discussions based on the changes in the crystal structure were not possible.

For the purposes of the present discussion, the infrared-absorption data appears to be more useful than the X-ray-diffraction data. That is, by comparing Fig. 5 with Fig. 7 (b), it can easily be seen that a close relation between the basicity change and the change in the Sv_1/Sv_2 ratio exists. Corresponding to the samll change in the basicity per unit of surface area of the aragonite sample, the Sv_1/Sv_2 ratio of this sample showed little pressure dependence. This fact supports the previous consideration that the observed basicity change (Fig. 1 (b)) of aragonite must result solely from the change in the surface area. On the other hand, the Sv_1/Sv_2 ratios of both strontium carbonate and barium carbonate varied considerably on compression, this tendency seems to correspond to the basicity changes in these samples (Fig. 7 (b)). Thus, in Fig. 8, the basicity changes, B/B_0[9] are plotted against the Sv_1/Sv_2 ratios. As can be seen in this figure, the B/B_0 *vs.* Sv_1/Sv_2 relations for both strontium carbonate and barium carbonate can be expressed by a single curve. This fact seems to indicate that the change in the ν_1 vibration of the carbonate ion in these samples is directly related to the basicity change.

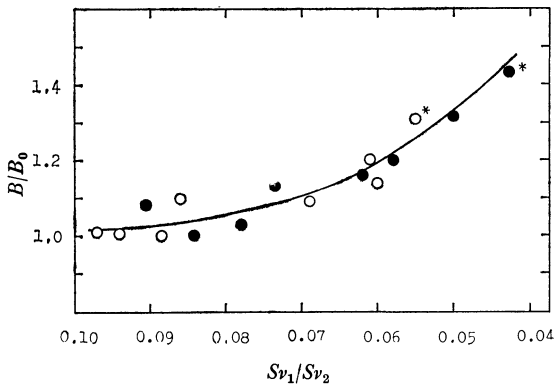

Fig. 8. The relation between the basicity change (B/B^0) and the change in the relative intensity of ν_1 vibration (Sv_1/Sv_2). ●: $SrCO_3$, ○: $BaCO_3$. (The mark * means the value obtained by using the sample compressed under the pressure of 15000 kg/cm^2 and at a temperature of 100°C.)

Analysis of IR Data. It is known that the ν_1 vibration of the carbonate ion becomes inactive for the infrared absorption when the ion is placed in site of D_{3h}, D_3, or C_{3h} symmetry.[10] However, when the site symmetry changes to C_{3v}, C_{2v}, C_3, C_2, or C_s, the ν_1 vibration becomes active for the infrared absorption. The crystal structures of calcium carbonate (aragonite), strontium carbonate, and barium carbonate are of the potassium-nitrate type and belong to the space group D_{16}^{2h}, and the site symmetry is C_s. Therefore, the ν_1 vibration of the carbonate ion becomes active for the infrared absorption. Thus, the observed invariance of the ν_1 absorption spectra of calcium carbonate means either that the original D_{2h} structure of this sample is preserved even in the compressed state or that the original site symmetry varied to C_{3v}, C_3, or C_2. However, few changes in the crystal structure (for example, a change to the calcite structure) were detected from the X-ray-diffraction data and the electron-diffraction data given above. Therefore, the possibility of change in the site symmetry in the calcium carbonate sample may be ignored. Thus, it seems probable to consider that the original crystal structure, D_{2h}, is preserved.

On the contrary, the pressure-dependent behavior of the infrared spectra of both strontium carbonate and

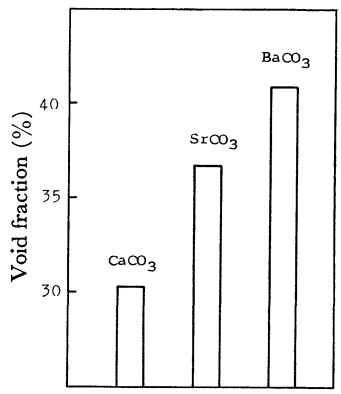

Fig. 9. The void fraction.
The void fractions were approximated by the following equation.
void fraction (%) $=(1-(v/V))\times 100$
v: sum of the volume of metal ions (4π(ionic radius)^3/3) and carbonate ions ($3\times 4\pi$(ionic radius of O^{2-})^3/3) in a unit cell
V: volume of a unit cell

9) B_0 was defined as the original basicity per unit of surface area, and B was defined as the basicity per unit of surface area of the compressed sample.

10) K. Nakamoto, "Infrared Spectra of Inorganic and Coordination Compounds," John Wiley & Sons. New York (1970), p. 61.

barium carbonate mean that the original D_{2h} structures of these samples varied on compression to direction where the symmetry of the crystal increases, *i.e.*, from C_s to D_{3h}, D_3, or C_{3h}.

Presumably, the structural changes being considered accompany contractions, for pressure acts to reduce the volume of a sample. As can be seen in Fig. 9, the void fraction of aragonite is considerably smaller than that of strontium carbonate or of barium carbonate. Therefore, it seems reasonable to consider that the smaller void fraction of aragonite hinders the contraction of this sample and that the original D_{2h} structure is preserved in the compressed state. On the contrary, the larger void fractions of strontium carbonate and barium carbonate may provide spaces to be contracted by the compression.[11]

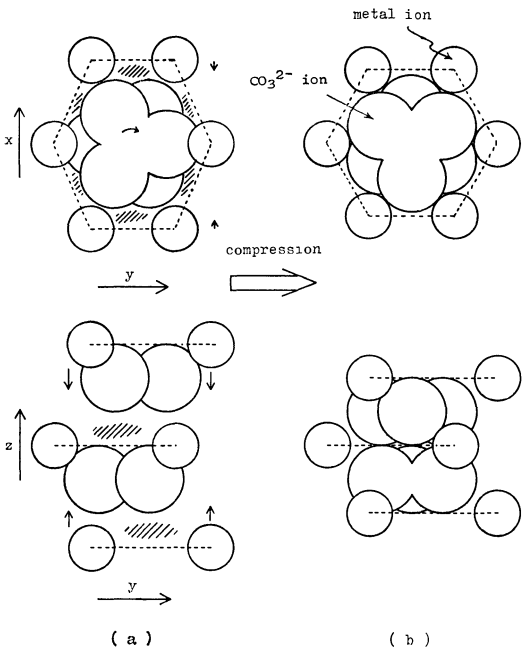

Fig. 10. The expected structural changes of strontium carbonate and barium carbonate due to compression.

The expected structural changes in strontium carbonate and barium carbonate are depicted in Fig. 10. The shaded areas in this figure are the spaces to be contracted by the compression. When these spaces are contracted, the following three changes may occur: (i) the original distorted hexagonal network, which is perpendicular to the z-axis constituted by metal ions, is transformed into a perfect hexagonal network; (ii) around the respective carbon atom, each carbonate ions rotates horizontally (parallel with the xy-plane), 30° from the original position, and (iii) each horizontal plane on which the center of the carbonate ion is located is brought to the hypothetical horizontal plane existing at the center of two nighboring hexagonal networks.

On the basis of the above mentioned discussion, a more precise model for the structural change was

11) If the compressibility of a solid is proportional to the void fraction, it may be expected that the change in the infrared spectra of barium carbonate will be larger than that of strontium carbonate because the former sample has a larger void fraction. However, the compressibility of a solid is affected by many factors, *i.e.*, the void fraction, the ionic radius, the crystal structure, *etc.*, and is not neceassarily propotional to the void fraction. Therefore, the fact the extents of the changes in the infrared spectra for both samples were nearly equal (Fig. 5) is not always in conflict with the different void fractions of the two carbonate samples. Although the details of the mechanisms of the compression are not clear, the more complete hexagonal structure of the barium carbonate crystal might reduce the degree of the contraction of void. Generally, a crystal of a higher symmetry, *i.e.*, regular cubic or hexagonal, is less compressible than a crystal of lower symmetry.

constructed to give Fig. 11. This figure was used as a basis for the factor group analysis designed to clarify selection rules for the infrared absorption. The results of the conventional-factor group analysis[12] are give in Table 3. This table indicates that both ν_1 vibration of the carbonate ions in the unit cell of the compressed sample (Fig. 11 (b)), which belong to the A_1 and B_1 or B_2 species, are inactive for the infrared absorption. Thus, it became clear that the intensity of the infrared ν_1 absorption diminishes as the symmetry of the sample crystal changes from the original D_{2h} type in the direction of the final D_6 type. The observed pressure-dependent spectral changes of strontium carbonate and barium carbonate may be considered to be examples of such cases as have been described above.

The authors wish to express their gratitude to Professor Koyo Aida, Faculty of Engineering, Tohoku University, for his permission to use the infrared spectrophotometer.

This paper is a part of a dissertation submitted by one of the authors (Shoe Baba) in partial fulfillment of the requirements for the degree of Doctor of Engineering in Tohoku University.

Effects of Pressure on the Chemical Properties of Solid Surface. VIII. The Surface Acidity of the Compressed Magnesium Sulfate

Takeshi KAWAKAMI, Hiroyoshi BANBA, and Yoshisada OGINO

Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai

(Received September 13, 1971)

In order to clarify the mechanism of the acidity change due to compression, magnesium sulfate was compressed under various pressures ranging from 0 to 12000 kg/cm^2, the surface acidities, the powder X-ray diffraction patterns, the DTA data, and infrared spectra of the compressed samples were thus obtained. According to the experimental results, the surface acidity of the sample did not vary upon the compression of low pressures (0—6000 kg/cm^2), and a further increase in the compacting pressure resulted in an increase in the surface acidity. From the results of the X-ray diffraction studies, infrared, and far infrared absorption studies and the DTA studies, the relations between the acidity change and the structural changes of the samples were discussed. As a result of this work, the observed acidity change was explained in terms of the distortion of the structural unit of magnesium sulfate.

In our previous studies[1-5] of the effects of pressure on the surface acidity of aluminum sulfate and zinc sulfate, explanations were given for the acidity change due to compression.

The present work has been undertaken to examine whether or not the same explanations are applicable to the acidity change of magnesium sulfate hydrate. The purpose of the present paper is to describe the details of the experimental results and to discuss the mechanism of the acidity change.

Experimental

Materials. Commercial magnesium sulfate heptahydrate was purified by means of recrystallization,[6] and the resulting sulfate was used as the raw material of the sample.

Preparation of the Compressed Sample. The raw sulfate was compressed by the procedures described in the previous papers.[1-5] The compression was carried out under various pressures ranging from 0 to 12000 kg/cm^2 and at a temperature of 20°C. Pressure was applied over a 10 min period. The resulting cylindrical pellet, 6 mm in diameter and 2 mm in height, was pulverized in an agate mortar, and the powdered material was subjected to drying in a vacuum over a 60 min period at a temperature of 18°C. Then, the powder served as a sample for the desired measurment. In order to minimize the effects from the change in ambient conditions, all the operations were carried out in an air-conditioned room.

For the sake of convenience, the respective samples which were compressed under 0, 2000, 4000, 6000, 8000, 10000, and 12000 kg/cm^2 were defined as P_0, P_{2000}, P_{4000}, P_{6000}, P_{8000}, P_{10000}, and P_{12000}.

Surface Acidity. The surface acidity was determined by Benesi's method[7] with the following two indicators: *p*-diphenylaminobenzene ($pK_a=3.3$) and phenylazonaphthylamine ($pK_a=4.0$). The acidity measurements were also carried out in an air-conditioned room.

Qualitative Tests for Lewis Acid. The Lewis-acid center on the sample surface was identified by the procedures used in a previous work[4] (color tests with phenolphthalein or trithylchloride).

Surface Areas. The specific surface area of the sapmle was evaluated by applying the BET theory to the adsorption data of nitrogen at −195°C.

Differential Thermal Analysis (DTA) and Thermogravimetric Analysis (TGA). The DTA and TGA runs were carried out on a Rigaku Denki unit. The DTA curves and the TGA curves were obtained at a temperature-programming rate of 2°C/min.

X-Ray Diffraction. The powder X-ray diffraction patterns[8] of the sample were obtained with a Shimadzu GX-1 X-ray Diffractometer. The Cu-$K\alpha$ radiation (Ni filter) at 30 KV and 15 mA was used.

Infrared Spectroscopy. The infrared spectra (IR) for a 400—4000 cm^{-1} wave number range were obtained by means of Perkin-Elmer Model 125 Infrared Spectrophotometer. In these works, a Nujol technique was employed. To minimize the interferences from the air moisture, a sample which had been compressed and evacuated was kept in the vessel containing dry nitrogen. Then, immediately before the IR experiment, the sample was withdrawn from vessel and mixed with nujol as quickly as possible.

Results

Surface Acidity. The surface acidities (H_0=3.3—4.0) of samples compressed under various pressures are given in Fig. 1. The acidity values in this figure are given by *n*-butylamine titers per unit of the surface area. As can be seen in Fig. 1, the acidity did not vary of compressions of 2000—6000 kg/cm², but a further increase in the compacting pressure resulted in an increase in the surface acidity.

Further, additions of phenolphthalein or trithylchloride to the sample showed no sign positive to the existence of Lewis acid on the sample surface. Thus, the acid appearing on the sample could be identified as protonic acid.

Water Content. The water contents of the samples compressed under various pressures are given in Fig. 2. From this figure, it can be understood that the samples compressed at pressures higher than 6000 kg/cm² contain 6 mol of water per mole of $MgSO_4$.

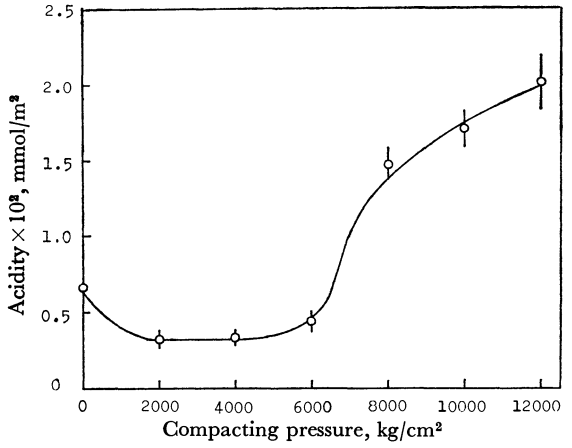

Fig. 1. Relations between the compacting pressure and the surface acidity (H_0=3.3—4.0).

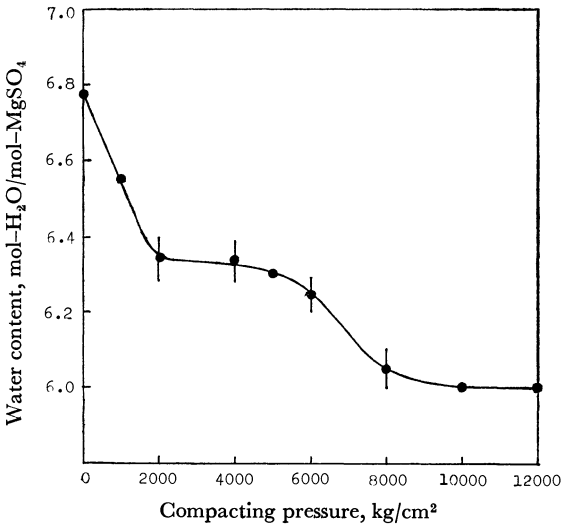

Fig. 2. Relations between the compacting pressure and the water contents.

X-Ray Diffraction. The powder X-ray diffraction patterns of the samples compressed under various pressures are given in Fig. 3. From these patterns, it can be understood that the sample consists of crystallites of magnesium heptahydrate[9] and hexahydrate.[10]

The half-widths of the diffraction peak for the heptahydrate (2θ=21.0°) and that of the hexahydrate

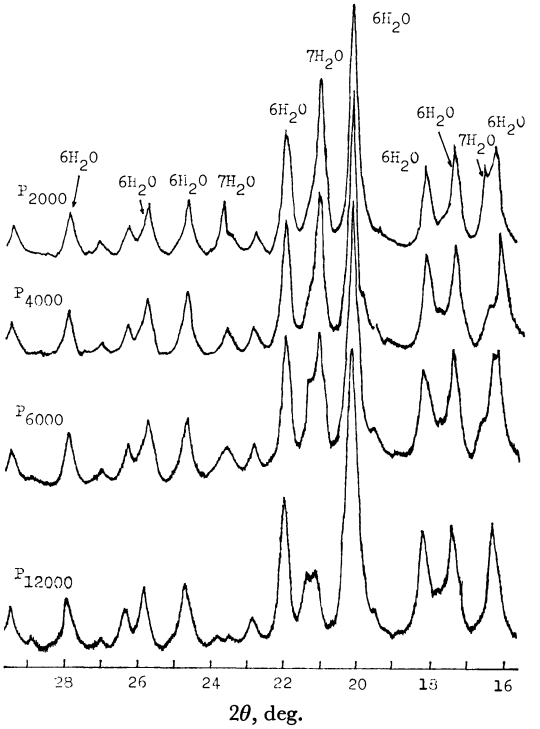

Fig. 3. X-ray diffraction patterns for various samples.

8) In the X-ray diffraction studies for some metal sulfates, e.g. $Al_2(SO_4)_3 \cdot 18H_2O$, it was found that the diffraction pattern varies from time to time. This phenomenon is due to the interference of air moisture, it was avoided by covering the compressed and evacuated sample with collodion. However, in the case of the samples used in the present study, the X-ray diffraction pattern did not vary with the time. Therefore, the collodion treatment was not carried out.

10) *Ibid.*, 1-0356.

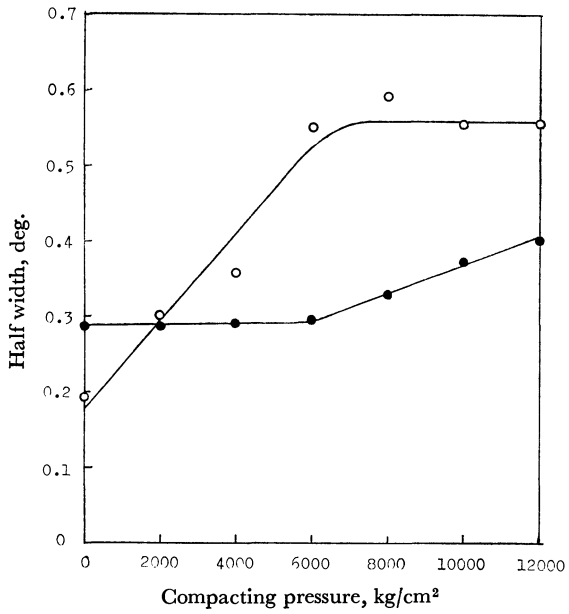

Fig. 4. Relations between the compacting pressure and the half widths of the X-ray diffraction peaks for magnesium sulfate heptahydrate (-○-, $2\theta=21.0°$) and for magnesium sulfate hexahydrate (-●-, $2\theta=20.2°$).

($2\theta=20.2°$) were found to vary on compression (Fig. 4). From this figure, it may be considered that the crystallites of heptahydrate were destroyed by the compression at pressures lower than 6000 kg/cm², while the crystallites of hexahydrate were little affected in this pressure range. The change in the half-width of the diffraction peak of hexahydrate was observed only at compacting pressures higher than 6000 kg/cm².

The relation between the compacting pressure and the relative intensity of the diffraction peak of heptahydrate ($2\theta=21.0°$) against the peak of hexahydrate ($2\theta=20.2°$) is given in Fig. 5. This seems to show that the relative content of heptahydrate to hexahydrate in the sample remained constant in the range of 2000—6000 kg/cm² and that the transition from heptahydrate to hexahydrate occurred somewhat above 6000 kg/cm². Such a discontinuous transition may be suggested by a rather discontinuous change in the water content in the sample (Fig. 2).

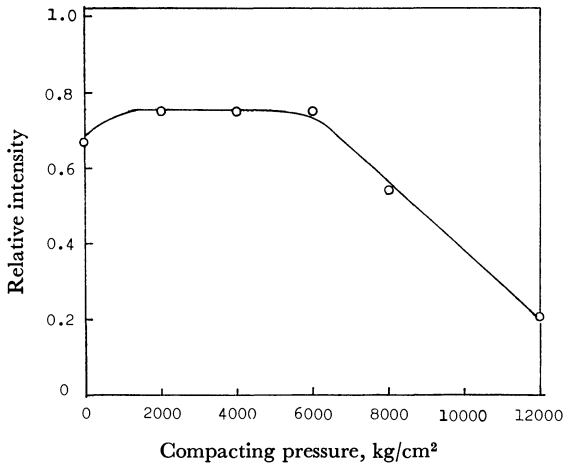

Fig. 5. Relations between the compacting pressure and the relative intensity of the X-ray diffraction peak of heptahydrate against the peak of hexahydrate.

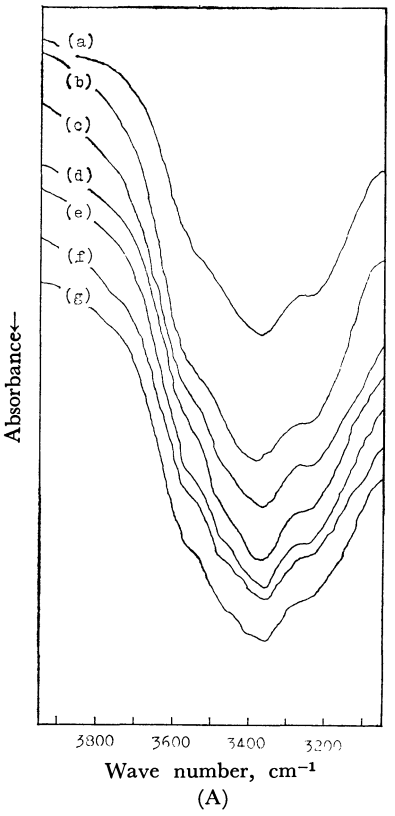

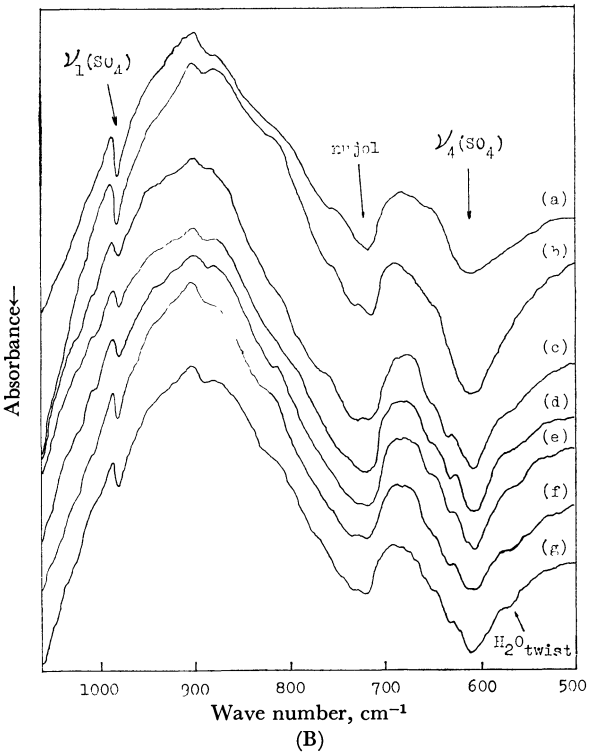

Fig. 6. Infrared spectra for the samples compressed at various pressures: (a) P_0; (b) P_{2000}; (c) P_{4000}; (d) P_{6000}; (e) P_{8000}; (f) P_{10000}; (g) P_{12000}.

Infrared Spectra. The infrared (IR) spectra of the samples compressed under various pressures are given in

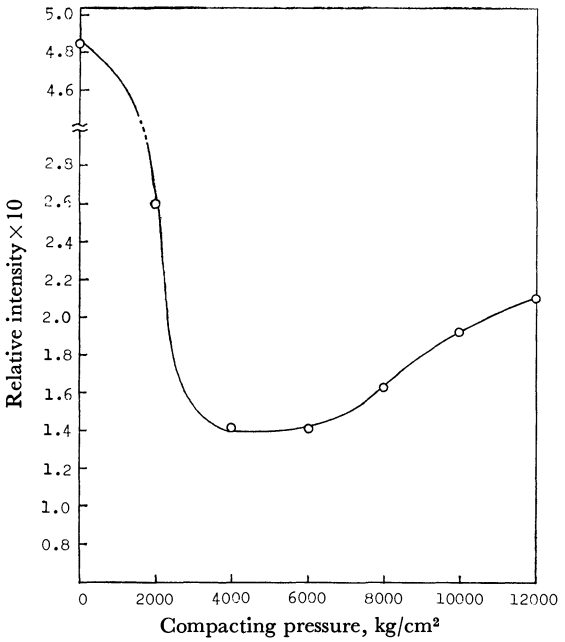

Fig. 7. Relations between the compacting pressure and the relative intensity of the ν_1 absorption against the ν_4 absorption for sulfate ion.

Fig. 6. The IR data may be summarized as follows;[11]

i) A broad band ranging from 3000 to 3600 cm^{-1} was assigned to the OH stretching vibration.[12] On compressing the sample at pressures higher than 6000 kg/cm^2, this band appeared to shift slightly toward lower wave numbers (Fig. 6-A). However, this is somewhat ambiguous because of the uncertainty of the exact peak position of the broad absorption band.

ii) An absorption band appearing at 985 cm^{-1} (Fig. 6-B) was assigned to the ν_1 vibration of the sulfate ion.[13] The relation between the compacting pressure and the relative intensity[14] of the ν_1 absorption against the ν_4 vibration for the sulfate ion (610 cm^{-1}) is given in Fig. 7. As can be seen in this figure, the relative intensity increased with an increase in the compacting pressure ranging from 6000—12000 kg/cm^2, while the relative intensity varied little at compacting pressures lower than 6000 kg/cm^2.

DTA and TGA. The DTA curves for various samples are given in Fig. 8. As can be seen in this figure, endothermic peaks appeared at various temperatures, and Peak I[15] can be attributed to the dehydration:[6]

$$MgSO_4 \cdot 7H_2O \longrightarrow MgSO_4 \cdot 6H_2O + H_2O$$

On the other hand, Peak II was attributed to the dehydration:

$$MgSO_4 \cdot 6H_2O \longrightarrow MgSO_4 \cdot 5H_2O + H_2O$$

According to the results of the TGA experiment, the

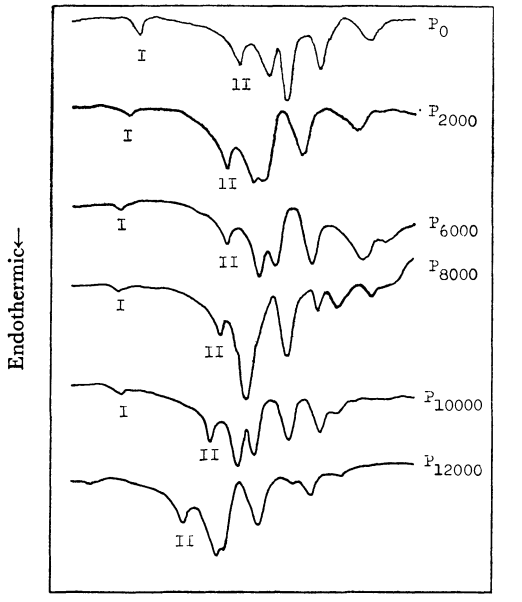

Fig. 8. DTA curves for the samples compressured at various pressures.

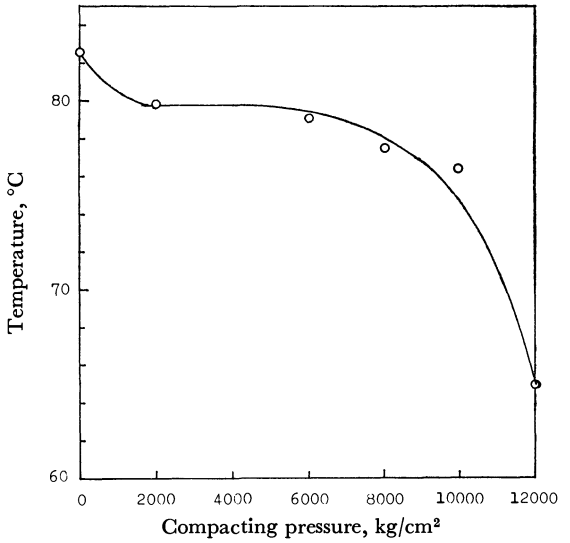

Fig. 9. Relations between the compacting pressure and the temperature of the DTA endothermic peak II.

11) The peak for H_2O_{rock} seemed to be overshadowed by a strong Nujol absorption and could not be detected on the IR chart. Further, the peak for H_2O_{twist} seemed to exist as a shoulder of the absorption peak of $\nu_4(SO_4)$. Since the shoulder peak was weak and broad, the existence of the peak is somewhat ambiguous and the effect of pressure on this peak could not be investigated. The peaks for ν(Mg-O) and for H_2O_{wag} could not be detected.

12) I. Gamo, This Bulletin, **34**, 760 (1961).

13) P. Krishnamurti, *Indian J. Phys.*, **5**, 183 (1930).

14) Approximated by the ratio of the peak height for ν_1 to that for ν_4. A precise determination of the peak area for the ν_4 was difficult because of the existence of a shoulder peak. Therefore, the ratio of the peak heights was used as a measured of the intensity ratio.

15) As can be seen in Fig. 8, the intensity of Peak I was very weak (especially for the compressed sample) compared with that of Peak II. This seems to mean that the phase change I requires far less energy than the phase change II. This view seems plausible because I is the dehydration of anion water and II is the dehydration of coordination water. Further, the compressed samples contain less anion water than 0.4 mol/mol-$MgSO_4$ (P=2000—12000 kg/cm^2). This would make the DTA peak I of the compressed sample smaller. Because of the instrumental limits, a quantitative comparison of the peak heights (I) of the different samples and the quantitative comparison of the peak height (I) with the water content (Fig. 2) were not possible.

amount of dehydration corresponding to the DTA endothermic peak II was found to be nearly one mole per unit mole of $MgSO_4$ for all of the samples.

Discussion

Acidity Change and X-Ray Diffraction Data. As can be seen in Fig. 1, the acidity values which varied upon compression were the values per unit of the surface area. Therefore, the acidity change can not be explained in terms of the change in the surface area. The acidity change due to compression must be attributed to structural changes other than that in the surface area.

A suggestion about the cause of the acidity change was derived from the information about the nature of the acid point. As was stated in the previous section, the acid point appearing on the surface of the compressed sample could be regarded as a protonic acid because the sample did not show any sign positive to the Lewis acid. Usually, the protonic-acid center and the water of crystallization are thought to be interrelated. Therefore, information about the change in the water of crystallization would be expected to throw some light on the cause of the acidity change.

X-Ray diffraction data revealed interesting aspects of the change in the crystallites of the sample hydrate. By a comparison of Fig. 4 with Fig. 1, it became evident that, in the pressure range of 2000—6000 kg/cm², where few changes in the surface acidity were observed, the half-width of the X-ray diffraction peak of hexahydrate was fairly constant, whereas the half-width of heptahydrate increased monotonously. Further, in the pressure range of 6000—12000 kg/cm², where the surface acidity was found to increase on compressing the sample, the half-width of the diffraction peak of hexahydrate increased, while that of the diffraction peak of heptahydrate varied little.[16] These facts strongly suggest that the disintegrations or distortions of hexahydrate crystallites play an important role in the acidity change, whereas the acidity change in the crystal of heptahydrate has little influence on the acidity change.

Probably, the change occurring in the hexahydrate crystallites is a distortion of the structural unit. Here, it must be pointed out that the X-ray diffraction data (Fig. 3) indicate the existence of heptahydrate even in the sample of P_{12000}, whereas the data on water content (Fig. 2) indicate 6 mol-H_2O/mol-$MgSO_4$ in this sample. Further, the DTA data (Fig. 8) indicate the existence of anion water in the P_{10000} sample, whose water content was also 6 mol-H_2O/mol-$MgSO_4$. A part of the cause of this discrepancy may be ascribed to the experimental error or to differences in the manner of sample handling in the different experiments. However, other factors must also be taken into consideration. For instance, the possibility that some lower hydrate may be contained in the sample could not be excluded. If the content of the lower hydrate is small or if the lower hydrate is in an amorphous state, its existence can not be detected by X-ray diffraction. Therefore, the water contents expected from the X-ray data would become larger than the true value. If the existence of the lower hydrate is true, posibilities that this hydrate may affect the acidity value arise. However, as can be seen in Fig. 2, the water content was fairly constant in the pressure range of 8000—12000 kg/cm². Therefore, it may be supposed that the content of the lower hydrate might also be constant in this pressure range. Thus, it is more plausible to consider that the acidity change in this pressure range is due to the distortion of the hexahydrate structure.

Structural Unit of Magnesium Sulfate Hydrate. As in the preceding works,[4,5] to serve for the discussion of the mechanism of the acidity change, models of the structural unit of magnesium sulfate hydrate[17] are given in Fig. 10. In this figure, A, B, and C are the models for heptahydrate, hexahydrate, and a distorted hexahydrate respectively. As can be seen in the figure, the central metal ion (Mg^{2+}) is coordinated by six water molecules, each of which is located on an apex of a hypothetical octahedron. In the structural unit of heptahydrate, one water molecule is located apart from the octahedron; this water may be regarded as anion water.

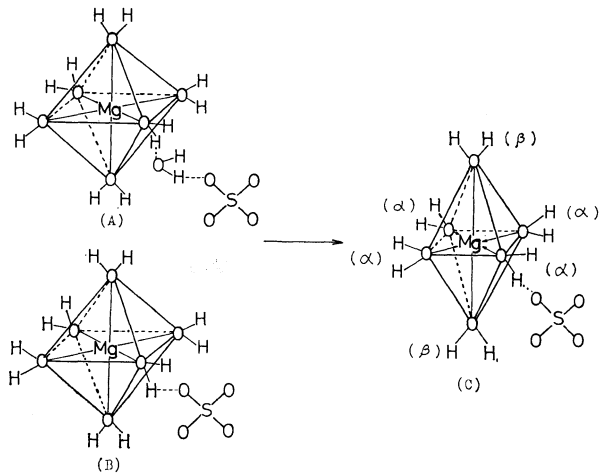

Fig. 10. Models of structural unit of magnesium sulfate: (A) heptahydrate, (B) hexahydrate (not distorted), (C) hexahydrate (distorted).

Changes in the Structural Unit of Heptahydrate. At pressures lower than 6000 kg/cm², only the changes in the structural unit of heptahydrate were taken into consideration, for the X-ray diffraction data (Fig. 4) indicated an invariance of hexahydrate structural unit in the samples compressed under low pressures.

Probably, the change occurring in the heptahydrate crystal is a liberation of the anion water (*cf.* Fig. 2). The coordinated water in heptahydrate would remain

16) At first sight, the X-ray data given in Fig. 3 (the decrease in the peak intensity and the splitting of the diffraction peak of heptahydrate at $2\theta=21°$) may give the impression that the distortion of the crystallites of heptahydrate occurred upon the compression of 6000—12000 kg/cm². However, this impression is erroneous; it is due to the abbreviation of the diffraction patterns of the P_{8000} and P_{10000} samples in the figure. It can be seen clearly in Fig. 4 that the half-width of the diffraction peak of heptahydrate is fairly constant in the pressure range of 6000—12000 kg/cm².

17) R. W. G. Wyckoff, "Crystal Structures," Interscience Publishers, Inc., New Yrok, (1960).

unaffected by the compression because those two elements are thought to be coordinated in the same manner as in the hexahydrate structural unit, which is considered not to vary at low pressures. Since anion water is not directly coordinated to the central Mg^{2+} ion, its liberation might have little effect on the ionization states of Mg^{2+} or of the coordinated water. Therefore, the observed invariance of the acidity of the sample compressed under low pressures is acceptable.

Changes in the Structural Unit of Hexahydrate. As has been stated in the previous sections, evidence that the change in the structural unit of hexahydrate occurred only at pressures higher than 6000 kg/cm^2 is presented by the X-ray peak broadenings (Fig. 4). Since the water content did not vary at pressures higher than ~6000 kg/cm^2, one possible change in the structural unit may be a distortion of the octahedron.

In the present research, a distorted octahedron structural unit, as is shown in Fig. 10-C, was considered. In this model, the distances between Mg^{2+} and H_2O (α) are shortend and the distances between Mg^{2+} and H_2O (β) are stretched. In such a distorted structural unit, interactions between Mg^{2+} and the coordinated water should differ in character from those in the normal structural unit (Fig. 10-B).

The results of the DTA experiments also support the idea that the octahedron structural unit is distorted at high pressures. As can be seen in Fig. 9, the dehydration temperature of the coordinated water decreases with an increase in the compacting pressure. This fact supports the idea that a part of the coordinated water, presumably H_2O (β), becomes unstable. In the distorted octahedral coordination, H_2O (β) may be weakly bound by the central Mg^{2+} ion because the distance between H_2O (β) and Mg^{2+} is stretched.

In connection with the change in the structural unit, the behavior of the sulfate ion against the compression should be taken into consideration. The IR spectra gave interesting information about the behavior of the sulfate ion. As can be seen in Fig. 7, the relative intensity of the IR ν_1 absorption against ν_4 absorption for the sulfate ion varied on compression. This fact seems to indicate that interaction between the sulfate ion and its environment varies on compression.

The decrease in the relative intensity of the $\nu_1(SO_4)$ absorption at lower compacting pressures (0—2000 kg/cm^2) may be related to the dehydration of anion water from the heptahydrate crystal (*cf.* Figs. 2 and 4). Presumably, the symmetry of the crystal field around the sulfate ion would be reduced by the existence of anion water and the ν_1 vibration (which is originally inactive for the infrared absorption) becomes active for the infrared absorption. As the releasing of anion water proceeds, the symmetry of the crystal field may recover and the peak of the ν_1 vibration may become weaker.

On the contrary, the increase in the relative intensity of the $\nu_1(SO_4)$ absorption at compacting pressures higher than 6000 kg/cm^2 may be related to the increased interaction between oxygen in the sulfate ion and hydrogen in the OH group of the coordinated water (α). Approaches of the sulfate ion to the octahedral structural unit become easier at higher compacting pressures. Further, at higher compacting pressures, anion water, which may hinder the approach of the sulfate ion to the octahedron, no longer exists.

Mechanism of the Acidity Change. The small influence of the change in the heptahydrate structure on the surface acidity is made obvious by a comparison of Fig. 1 with Figs. 2, 4, 5, and 7. Therefore, the following discussions will be confined to the acidity change as well as to the structural change at pressures higher than 6000 kg/cm^2.

The observed acidity change of magnesium sulfate hydrate seems to be explainable in terms of the change in the structural unit of $MgSO_4 \cdot 6H_2O$. That is, because of the distortion of the octahedral structure (Fig. 10-C), distances between the central Mg^{2+} ion and each coordinated water may vary; *i.e.*, the lengths of the four Mg^{2+}–H_2O (α) bonds are shortened and the lengths of the two Mg^{2+}–H_2O (β) bonds are stretched. Consequently, the degree of the interaction between Mg^{2+} and H_2O (α) may increase and the increased polarization of H_2O (α) may result. Thus, the polarized coordinated water can have a protonic acid property.

As has been discussed in the previous section, changes in the octahedral structural unit were considered to occur only at compacting pressures higher than 6000 kg/cm^2. Further, it was considered that the changes in the structural unit increase with an increase in the compacting pressure. Therefore, in the pressure range of 6000—12000 kg/cm^2, an increase in the compacting pressure may be considered to result in an increase in the content of polarized water (α). In other words, the compression at high pressures may result in an increase in the acidity of the sample.

The interaction between the sulfate ion and coordinated water (α) seems to contribute also to the acidity change. When the hydrogen-bridge donor property of the coordinated water (α) in the distorted structural unit increases, the hydrogen bond between the sulfate ion and the coordinated water (α) may be strengthened. Then, the distorted octahedral structural unit may be brought to a quasi-stable state by the aid of this strengthened hydrogen bond. Thus, the presence of the sulfate ion, which may be displaced nearer to the octahedron by the compression, seems to contribute to the acidity change. As has been discussed in the previous section, approaches of the sulfate ion to the octahedron were considered to be possible only at pressures higher than 6000 kg/cm^2, above which point the acidity change was observed.

The above-mentioned mechanism of the acidity change seems to be supported also by the linear relationship between the acidity change and the relative intensity of the IR ν_1 absorption for sulfate (Fig. 11).

Comparisons to the Acidity of Other Sulfates. The present mechanism for the acidity change in the compressed magnesium sulfate hydrate is almost identical with those proposed for the acidity changes in aluminum sulfate hydrate[4] and zinc sulfate hydrate.[5] In the acidity changes in these metal sulfates, including magnesium sulfate, interactions between the central cation and the octahedrally-coordinated water were thought

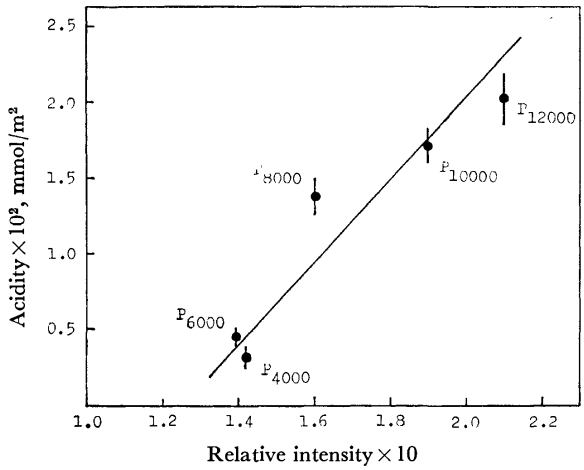

Fig. 11. Relations between surface acidity and the relative intensity of ν_1 absorption against ν_4 absorption for sulfate ion.

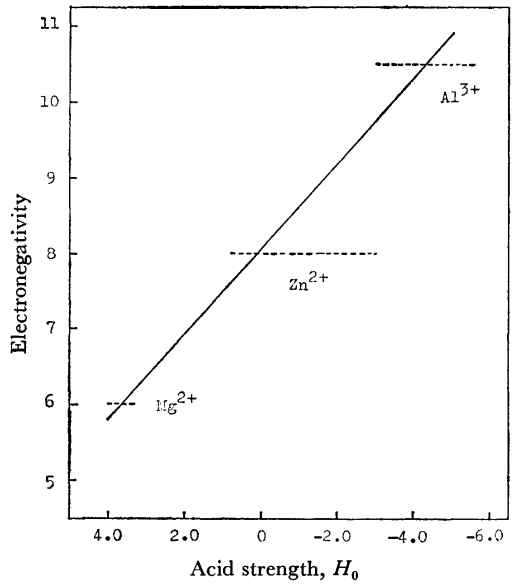

Fig. 12. Relations between electronegativities of some cations and the acid strength of the compressed sulfates containing the corresponding cations.

to play the most important roles. A question arises, therefore, if any differences among the acidic properties of these sulfates exist, for different cations (Al^{3+}, Zn^{2+}, Mg^{2+}) would yield differences in the strength of the cation field, which affects the degree of polarization in H_2O (α). Thus, the electronegativities of these cations[18] were compared with the observed values of the acid strength (H_0 values) of the corresponding sulfates (Fig. 12). As can be seen in this figure, an approximate linear relationship was obtained. The existence of such a simple relationship as above seems to support the validity of the common mechanism of the acidity changes for various metal sulfates.

In summarizing the published works of this series, the following point should be emphasized. The samples treated in these works were subjected to compression and evacuation. Further, it must be taken into consideration that the compacting pressure was released after the compression of the sample during a given period. Therefore, the observed pressure effects should be regarded as indirect ones. Some pressure effects might be relaxed by the release of the compacting pressure, and some other effects might be amplified or modified by the evacuation-dehydration. It must be remembered that the term "pressure effects" which is used in the works of this series means that the differences in the degree of compression induce diffrences in the effects of the other operations which follow the compression.

It seems to be important to study the details of the effects of evacuation as well as the effects of the pressure releasing. Measurements under pressure are also necessary in order to ascertain the direct effect of pressure. All of these works require special techniques and include many experimental difficulties, however, and so they were not included in the works of this series.

ESR Studies of the Negative Ions of Biphenyl Derivatives. IV. Conformation of 4,4′-Polymethylenebiphenyl Anion Radicals

Kazuhiko ISHIZU, Fujito NEMOTO, Hideo HASEGAWA,* Koji YAMAMOTO,** and Masao NAKAZAKI**

Department of Chemistry, Faculty of Science, Ehime University Bunkyo-cho, Matsuyama
**Japan Electron Optics Laboratory, Akishima, Tokyo*
***Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka*

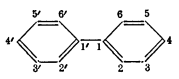
(Received December 8, 1971)

The electron spin resonance has been observed for anion radicals of 4,4′-polymethylene bridged biphenyls which have various lengths of the polymethylene chain, from the carbon number of $n=11$ to that of $n=16$. The relation between the chain length of the methylene bridge and the ring-proton splitting were studied in order to see how the polymethylene span brings on a strain in the biphenyl ring. The geometrical structures of the sp^3-hybrid bond of the β-carbons were investigated on the basis of the observed values of the β-proton splitting in each derivative. In the cases of both pentadeca and hexadeca derivatives, the magnitude of both the *ortho*- and the *meta*-ring proton splitting are comparable with those of the 4,4′-diethylbiphenyl anion radical, the open-chain model of the present derivatives. A rotation of the β-methylene sp^3-bond is forbidden in this case, however, and the coupling constants of the β-methylene protons no longer exhibit an equivalent value; that is, two of these C–H bonds are placed on a coplanar biphenyl plane, but the others are twisted out by about 30° from the $2p_z$ axis of the ring-carbon atom. When the number of the methylene groups is reduced from thirteen to twelve, the magnitude of the *ortho*-ring proton coupling constant is greatly reduced. The HMO calculations of the spin density were carried out. The observed tendency of the ring-proton splitting can be qualitatively understood on the assumption that the coplanar biphenyl ring may be modified by twisting the phenyl groups about the central 1-1′ bond rather than by slanting them together against the original aromatic plane. A strong beam of the polymethylene chain also causes a modification of the geometrical structure of the β-methylene sp^3 bond and results in a reduction of the β-proton coupling constant to a large extent.

Polymethylenebiphenyls in which a suitable length of the polymethylene chain is bridged at the 2,4′-, 3,4′-, or 4,4′-positions have recently been synthesized, and their conformation have been studied by UV and NMR absorption spectroscopy.[1-3]

In the cases of the 4,4′-polymethylene derivatives, a molecular model suggests that at least thirteen methylene carbon atoms are necessary to set the bridge across the 4,4′-positions of the biphenyl ring without resulting in a strain in the molecule.

If the number of the methylene carbon atom is less than thirteen, the biphenyl ring is hard to held in the coplanar fashion. In this study, ESR observation has been carried out for the anion radicals of 4,4′-polymethylenebiphenyl, which have various numbers of polymethylene groups, from 11 to 16. The hyperfine coupling constants of either β-methylene or the ring proton are determined in order to elucidate the steric structure of these derivatives. The degree of the strain effected in the biphenyl ring could be estimated by a comparison of the values of the ring-proton splitting with those of 4,4′-diethyl biphenyl, an open-chain model of the present derivatives. The geometrical structure of the β-methylene carbons may be investigated on the basis of the measurement of the β-proton hyperfine coupling constant and its temperature dependence. The general structure of 4,4′-polymethylene biphenyl is given below;



Experimental

The materials used in this studies were synthesized by a process previously established before. The physico-chemical indexes of the materials are listed in Table 1.

TABLE 1. PHYSICO-CHEMICAL INDEXES OF THE MATERIALS

Number of polymethylene carbon *n*	11	12	13	14	15	16
Mp(°C)	86—88	116—117	101—102.5	112.5—114.5	128—129	110—111

4,4′-Diethylbiphenyl (mp 82.5°C) was synthesized by an Ullman reaction on *p*-iodo-ethylbenzene. The anion radicals were prepared in dimethoxyethane (DME) by reduction with a potassium mirror kept in an acetone–dry ice bath.

The green-colored paramagnetic solution gave a strong ESR absorption, and the anion radicals were stable enough for the observation of the ESR spectra at room temperature. The ESR spectra were recorded by a JEOL ME-3X spectrometer operating with a 100 kHz magnetic field modulation. The magnetic field was calibrated by a perylene cation radical prepared in concentrated sulfuric acid.[4]

Results and Discussion

The Analysis of the ESR Spectra. The ESR spectrum of the 4,4′-hexadecabiphenyl anion radical recorded at −20°C is given in Fig. 1(a). One may easily determine the *ortho*- and the *meta*-proton hyperfine coupling constants (a^H_2 and a^H_3) by referring to those of the 4,4′-diethyl biphenyl anion radical, which have

already been reported.[5]

As for the β-proton splitting (a_4^H), however, neither the line intensity nor the total width of the spectrum were adequately explainable unless the non-equivalent values of the β-proton splitting were assumed; that is, a triplet splitting ($a_4^{H_A}$) arises out of the two methylene protons, but that of the others ($a_4^{H_B}$) vanishes to the order of the line width (200 m gauss).

The hyperfine coupling constants thus estimated are: $a_4^{H_A}=7.00$, $a_4^{H_B}<0.20$, $a_2^H=2.62$, and $a_3^H=0.46$ gauss. These values were confirmed by the computer calculation of the line intensity, as is shown in Fig. 1(b).[6] As the temperature is gradually elevated, the hyperfine structures began to change; the spectrum shown in Fig. 1(c) was recorded at room temperature. In this case, another triplet splitting, $a_4^{H_B}$ was recognized in addition to $a_4^{H_A}$, and the hyperfine structure could be understood well using the following hyperfine coupling components; $a_4^{H_A}=6.51$, $a_4^{H_B}=0.47$, $a_2^H=2.60$, and $a_3^H=0.47$ gauss. The computer-calculated spectrum shown in Fig. 1(d) also gives a good agreement with the observed spectrum. A similar temperature dependence of the β-proton splitting was observed for the 4,4′-pentadecamethylene derivative ($n=15$). When the number of the methylene group was reduced to $n=14$, the a_2^H value began to decrease, but the a_3^H value showed a slight increase. The triplet splitting of $a_4^{H_B}$ was hidden in the line-width, and it was not possible to observe the temperature dependence in this case for the temperature range of $-50\sim+50$°C. In the case of $n=13$, a further decrease in the $a_4^{H_A}$ value was noted, while either the a_2^H or the a_3^H values were almost comparable with those of tetradecamethylene biphenyl ($n=14$). Therefore, the critical length of the polymethylene chain for making a bridge between the 4,4′-position of the biphenyl without a strain resulting may be concluded to be $n=14$. The hyperfine coupling constants of both the *ortho*- or β-protons were strongly suppressed if the number of the methylene carbon atoms reduced to $n=12$, and further for the derivative of $n=11$.

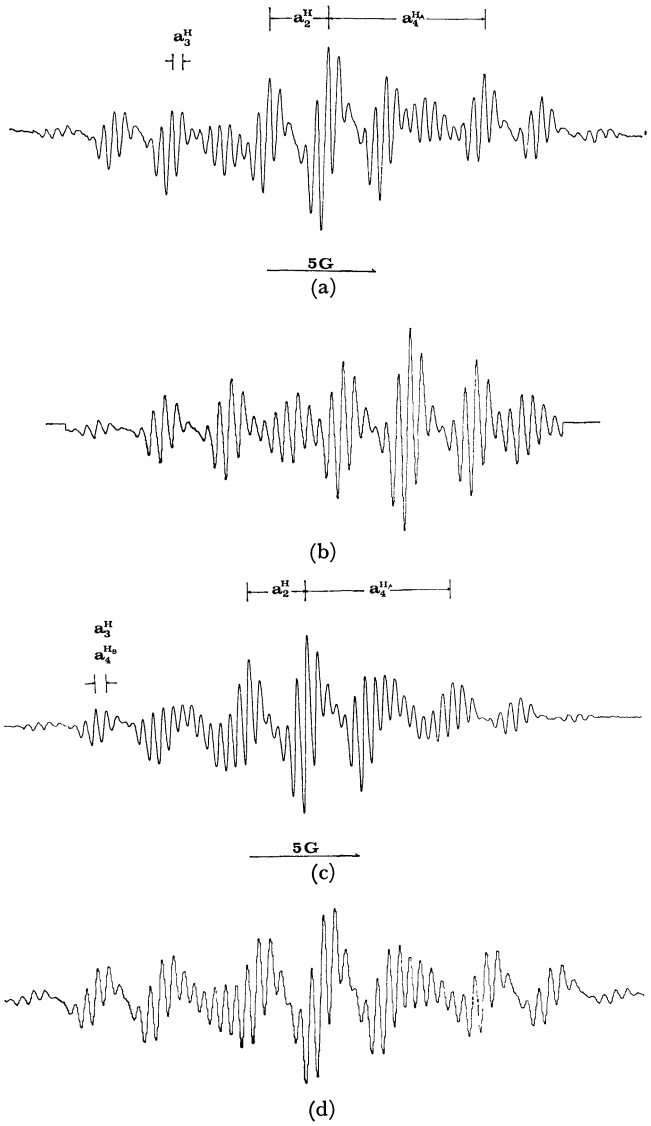

Fig. 1. 4,4′-Hexadecamethylenebiphenyl
a) ESR spectrum recorded at −20°C. b) computer simulated spectrum of (a). c) ESR spectrum recorded at room temperature. d) computer simulated spectrum of (c). A line shape is assumed to be as a Lorentzian with line width 0.2 gauss.

In Fig. 2(a), we show the ESR spectrum of 4,4′-dodecamethylenebiphenyl anion radical. The computer simulation of the spectrum again confirmed that the triplet splitting of $a_4^{H_B}$ came to have the same magnitude of the line-width, as is shown in Fig. 2(b). The hyperfine coupling constants of the 4,4′-polymethylene biphenyl anion radical thus determined are summarized in Table 2. The relations between the hyperfine coupling constants and the number of polymethylene carbon atoms are plotted in Fig. 3.

The Ring-proton Splitting. It can be seen from Table 2 and Fig. 3 that the polymethylene strain actually serves to reduce the a_2^H, accompanied by a

slight increase in the a_3^H.

In order to explain the present results qualitatively, HMO calculations of the spin density were carried out on the assumptions that the polymethylene span modifies the structure of the coplanar biphenyl at the central 1-1′ bond and that the axis of the $2P_z$ AO of each 1,1′ ring carbon is either slanted (θ) or twisted (γ), as is shown in Fig. 4.

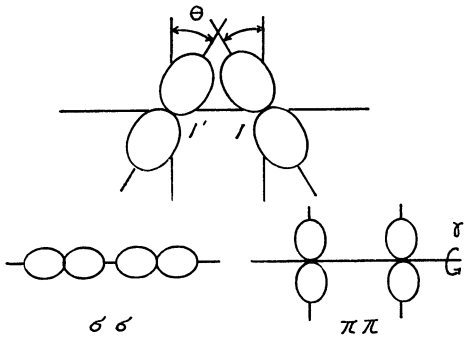

Fig. 4. $2P_z$ AO of the central 1, 1′ ring carbons slanted or twisted by the polymethylene bridge.

The resonance integral between the 1-1′ bond, $\beta_{11'}$, was calculated from the overlap integral, $S_{11'}$, as a function of both θ and γ; it may be expressed as follows.[7]

$$\beta_{11'} = \frac{S_{11'}/(1+S_{11'})}{S_{\pi\pi}/(1+S_{\pi\pi})}$$

$$\beta_{11'} = S_{\sigma\sigma}\sin^2\theta + S_{\pi\pi}\cos^2\theta\cos\gamma$$

The values of both the $S_{\sigma\sigma}$(0.3326) and $S_{\pi\pi}$(0.2186) integrals were used, referring to Kopineck's calculation,[8] where the bond distance of the C_1–C_1' bond was taken to be 1.539 Å.

For the sake of simplicity, the inductive parameter of the polymethylene group was rounded off to $\delta=-0.2$, taking into account that for methyl;[9] that is, the Coulomb integral of the *para*-position was estimated to be $\alpha_4=\alpha_4'=\alpha-0.2\beta$.

In Fig. 5, we show the relations between the theoretical spin density on the ring carbon atoms (ρ_i^π) and the twisting angle (γ), where the slanting angle (θ) is tentatively assumed to be 0, 15, and 30°.

As may be seen in Fig. 5, the spin density on the *ortho*-positions (ρ_2^π) shows a gradual increase, and that for the *meta*-positions (ρ_3^π), a decrease, with an increase in θ, contrary to the observed tendency of the spin density.

On the other hand, however, the HMO calculation gives an adequate explanation of the observed results, when the effect of the twisting of the phenyl rings (γ) is taken into account.

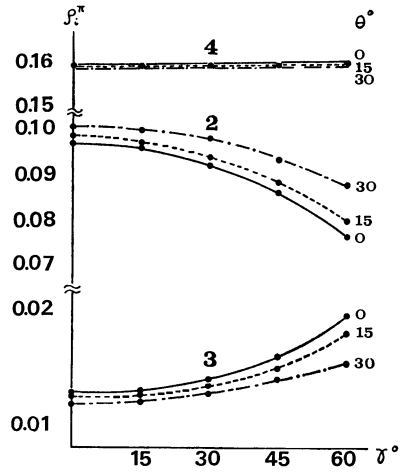

Fig. 5. Dependence of HMO spin density on the strain caused at the central 1-1′ bond of the biphenyl ring.

It is noteworthy here that the spin density on the *para*-positions is not affected everywhere. Based on the present calculation, one may speculate that the polymethylene bridge causes a strain in the molecule by twisting the phenyl rings rather than inclining them against the original aromatic plane.

The Methylene Proton Splitting. The β-proton coupling constant has been calculated by the following equation, expressed as a function of the angle between the carbon-hydrogen bond and the axis of the ring carbon $2P_z$ orbital:

9) A. Streitwieser, Jr. "Molecular orbital theory for organic chemists" John Wieley & Sons, Inc. New Yorkk (1961), p. 131.

$$a_i^H = \langle Q \rangle \rho_i^\pi,\ Q = B_0 + B\cos^2\varphi.^{10)}$$

In the case of the methyl derivative, the free rotation of the methyl group will average out the cosine term to $\langle\cos^2\phi\rangle = 1/2$, thus, the methyl-proton splitting is directly proportional, to the spin density, ρ_i^π, of the adjacent ring carbon atom, where the B_0 term is regarded as small in comparison with $B \approx 50$ gauss. According to this model, the ethyl proton splitting can also be well understood, assuming that $\langle Q \rangle$ is suppressed by about 25% by a restricted rotation of the ethyl group.

Recently, however, the fact of an exceptional hindered internal rotation of the alkyl group was demonstrated for the *n*-propyl derivative,[11] where it was recognized that a normal quintet splitting of the four β-protons fell into two sets of triplet splitting.

In the cases of the present derivatives, one may thus expect that a rotation of the β-methylene residue would be largely restricted not only by the large mass of the polymethylene chain, but also by its strong strain. This is indeed true, because the temperature dependence of the β-proton coupling constant has been found to be negligible for the derivatives of $n = 11$—13, and the lack of the two-methylene-proton splitting in the observed spectra suggests that one of the CH bond is tightly fixed on the aromatic plane.

When the length of the polymethylene chain increases, the biphenyl ring recovers its coplanar fashion and the β-proton coupling constants can be calculated in the same manner as was used for the open-chain derivative. McLachlan's calculation ($\lambda = 1.0$) of the spin density was carried out for the open-chain derivative; ρ_4^π was thus estimated to be 0.195, taking the Coulomb integral of the *para*-positions to be $\alpha_4 = \alpha_4' = \alpha - 0.2\beta$. The β-proton coulping constants, $a_4^{H_A}$ and $a_4^{H_B}$, were calculated to be 7.30 gauss and zero respectively, when the β-methylene residue takes the conformation ($\varphi = 30°$), as is illustrated in Fig. 6.

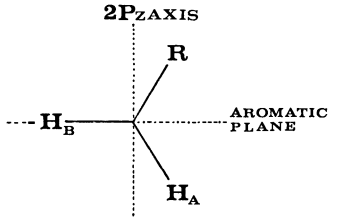

Fig. 6. The probable conformation of the β-methylene sp^3-bond in hexadecabiphenyl anion radical.

This must also be the case with the hexadecamethylenebiphenyl anion observed at −20°C. The occurrence of a small triplet splitting ($a_4^{H_B}$) observed at room temperature suggests that the torsional oscillation of the β-methyl residue is accelerated by thermal activation and that the sp^3-lobes of methylene group take a new equilibrium conformation.

Of interest is the magnitude of the β-proton splitting, which is lowered by the reduction of the chain length, for the MO calculation predicts that the spin density at the *para*-position will not be affected by a modification of the biphenyl ring.

The probably means that the polymethylene beam alters the conformation of the β-methylene sp^3 bond so as to reduce the orbital overlap between this hybrid orbital and $2P_z$ atomic orbital of the ring carbon atom. The beam is so strong that the freedom of the segment movement of the polymethylene is greatly suppressed, and the temperature dependence of the β-proton splitting is no longer observed in this case.

Thermal Decomposition Reactions of Metal Oxalato Complexes in the Solid State. II.[1] Evolved Gas Analyses of Metal Oxalato Complexes

Kenzo NAGASE

Department of Chemistry, Tohoku University, Kawauchi, Sendai

(Received January 31, 1972)

The thermal decomposition reactions of a number of metal oxalato complexes in the solid state were studied by an EGA method in a helium atmosphere. As regards the decomposition stage of an anhydrous complex, the complexes investigated could be divided into three groups: the complexes of Mn(III), Fe(III), Co(III), Rh(III), Cu(II), Pd(II), and Pt(II), this first group giving only CO_2 as a gaseous product, decomposed by electron transfer from an oxalato ligand to a central metal ion; the complexes of Al(III) and Zn(II), this second group giving CO and CO_2 in the molar ratio of 1: 1, decomposed by C–O bond breaking to form a metal oxide with no change in the oxidation number of a central metal; and the complexes of V(III) and Cr(III), this third group giving CO_2 and a smaller amount of CO, decomposed through both the processes, electron transfer and C–O bond breaking. The subsequent decomposition reactions of the bivalent metal oxalato complexes formed upon heating the corresponding trivalent metal oxalato complexes were divided into two types: one is associated with further reduction of a central metal ion, while the other is associated with C–O bond breaking.

The thermal decomposition reactions of metal oxalato complexes have been studied by several techniques, and the stoichiometries for several complexes have been examined on the basis of their gaseous and solid products.

Broadbent *et al.*[2] have studied the thermal decomposition of $K_3[Fe(ox)_3]$ in a nitrogen atmosphere and found $K_2C_2O_4$ and a chalky yellow solid at 260°C, and, beyond 460°C, a mixture of K_2CO_3 and free iron, by a method of X-ray diffraction identification.

Wendlandt and Simmons[3,4] have suggested that the bivalent metal complexes formed upon heating $K_3[Mn(ox)_3]$ and $K_3[Co(ox)_3]$ below 200°C in a nitrogen atmosphere can be represented by the $K_2[Mn(ox)_2]$ and $K_2[Co(ox)_2]$ formulae on the basis of their reflectance spectra. Tanaka and Sato[5] have assigned the chalky yellow compound, which had been found by Broadbent,[1] to $K_2[Fe(ox)_2]$ on the basis of the infrared and reflectance spectra.

Bancroft *et al.*[6] have also examined the thermal decomposition of $K_3[Fe(ox)_3]$ and suggested the presence of $K_6[(C_2O_4)_2Fe(OX)Fe(C_2O_4)_2]$ (OX=quadridentate oxalato group) on the basis of the infrared spectrum; this differs from the conclusions reported by Broadbent[2] and Tanaka.[5]

Broadbent *et al.*[7] have reported that $K_3[Al(ox)_3]$ decomposes in two stages upon heating above 375°C and that the residue contains Al_2O_3, K_2CO_3, and K_2O, as determined by X-ray diffraction identification.

The studies mentioned above, however, are incomplete, particularly in gaseous products. In the present study, the thermal decomposition reactions of the metal oxalato complexes were studied by a method of EGA (evolved gas analysis) in the temperature range of 25—600°C, and on the basis of the gaseous products, the stoichiometries of the thermal reactions were reexamined; moreover, the stoichiometries for the other metal oxalato complexes will be newly presented.

Experimental

Materials. The complexes used in this study were prepared according to the literature. Analyses of the complexes have been reported in the preceding paper.[1]

Measurements of EG Curves. Evolved gas (EG) curves were obtained with an apparatus consisting of a Shimadzu GC-1C gas chromatograph and a Shimadzu PYR-1A pyrolyzer in a helium atomosphere, at a flowing rate of 50 ml/min. With the rearrangement, the exit line from a pyrolysis chamber is directly connected to a thermal conductivity detector, without passing through a column. The procedure is as follows: about a 3-milligram sample in a platinum boat is introduced into a pyrolysis chamber. After the air is swept out, the temperature of the sample is raised to 600°C at a heating rate of 5°C/min. Changes in the thermal conductivity by the evolved gas are recorded as a function of the temperature of the sample.

Analyses of Gaseous Products. Analyses of gaseous products were performed by the use of the above apparatus equipped with a column, composed of 2-meter-long and 3-millimeter-indiameter stainless steel tubing, packed with 60—80 mesh activated charcoal. The temperature of the detector and the column were maintained at 200°C and 150°C respectively. The procedure was as follows: the temperature at which a peak maximum is observed on a EG curve, and then a sample was introduced into the furnace and it was maintained at that temperature for about 5 min while helium carrier gas was routed through the bypass by means of a two-way valve. By changing the valve, carrier gas is routed through the pyrolysis chamber and gaseous products are carried into the chromatographic column. The retention times are 1.5 min for CO and 3.0 min for CO_2 under the conditions employed in this study.

Results and Discussion

The evolved gas (EG) curves of the metal oxalato

complexes and potassium oxalate in the temperature range of 25—600°C are given in Figs. 1—3. These curves show that the complexes investigated decomposed in 3 or 4 stages. Gas analyses of each decomposition stage are sammarized in Table 1.

Dehydration (Stage I). All of the complexes immediately lost hydrated waters upon heating at about 100°C. Except for $K_3[Mn(ox)_3]\cdot 3H_2O$, the complexes showed the corresponding anhydrous plateaus on the EG curves. The dehydration of $K_3[Mn(ox)_3]\cdot 3H_2O$ took place with the decomposition of the anhydrous complex. For the complexes of Al(III), V(III), Cr(III), Fe(III), and Co(III), the peak corresponding to the dehydration splits into two or three, suggesting that water molecules are not held in the crystal lattice in an identical manner. On the other hand, the peaks of Rh(III), Pd(II), and Pt(II) are smooth, with no shoulder, water molecules being held equally in the crystal lattice.

Decomposition of Anhydrous Complexes (Stage II). In contrast to the dehydration, there are big variations in the temperatures at which the anhydrous complexes begin to decompose. Most of the complexes investigated decomposed in one step, but the complexes of Mn(III), Co(III), and Pd(II), which showed no anhydrous plateau, or only a short one, decomposed in two steps. The reason for this difference is not yet clear.

In Table 1, it should be noticed that the complexes can be divided into three groups: the complexes of Mn(III), Fe(III), Co(III), Rh(III), Cu(II), Pd(II), and Pt(II), giving only CO_2, belong to the first group; the complexes of Al(III) and Zn(II), giving CO and CO_2 in the molar ratio of 1: 1, belong to the second group; and the complexes of V(III) and Cr(III), giving CO_2 and a smaller amount of CO, belong to the third group.

The giving of only CO_2 suggests that electron transfer takes place from an oxalate to a central metal ion. The stoichiometries for the complexes in the first group may be represented by the following equations:

$$K_3[M^{III}(ox)_3] \longrightarrow K_2[M^{II}(ox)_2] + 1/2K_2C_2O_4 + CO_2 \quad (M=Mn, Fe, and Co)$$

$$K_3[M^{III}(ox)_3] \longrightarrow M + 3/2K_2C_2O_4 + 3CO_2 \quad (M=Rh)$$

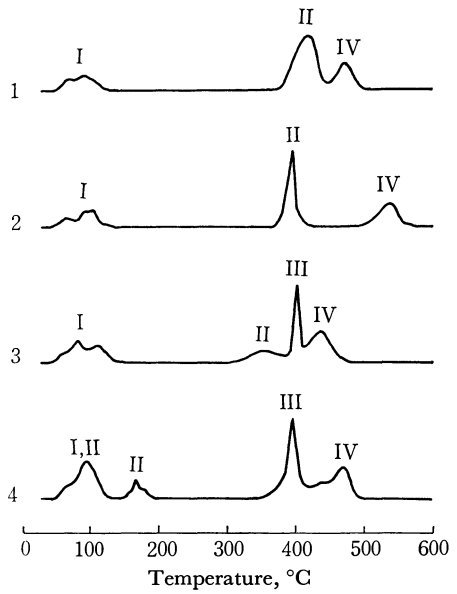

Fig. 1. EG curves of (1) $K_3[Al(ox)_3]\cdot 3H_2O$, (2) $K_3[V(ox)_3]\cdot 3H_2O$, (3) $K_3[Cr(ox)_3]\cdot 3H_2O$, and (4) $K_3[Mn(ox)_3]\cdot 3H_2O$ in a helium atmosphere.

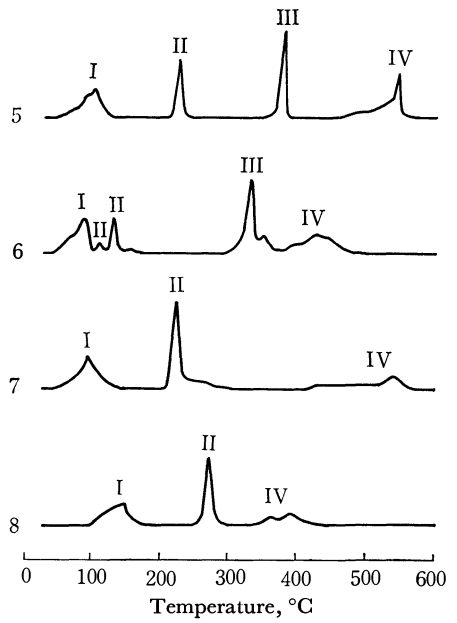

Fig. 2. EG curves of (5) $K_3[Fe(ox)_3]\cdot 3H_2O$, (6) $K_3[Co(ox)_3]\cdot 3H_2O$, (7) $K_3[Rh(ox)_3]\cdot 4.5H_2O$, and (8) $K_2[Cu(ox)_2]\cdot 2H_2O$ in a helium atmosphere.

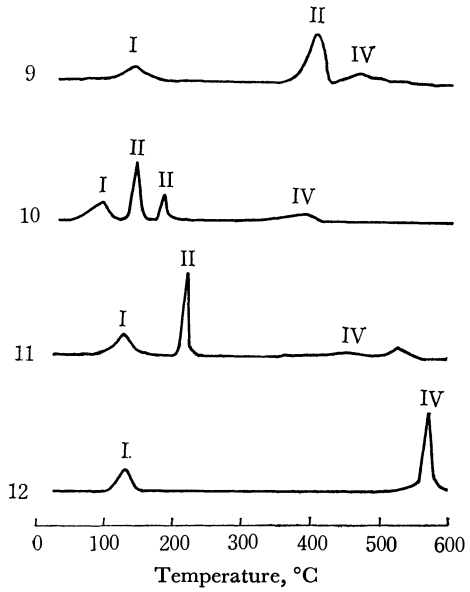

Fig. 3. EG curves of (9) $K_2[Zn(ox)_2]\cdot 2H_2O$, (10) $K_2[Pd(ox)_2]\cdot 3H_2O$, (11) $K_2[Pt(ox)_2]\cdot 2H_2O$, and (12) $K_2C_2O_4\cdot H_2O$ in a helium atmosphere.

$$K_2[M^{II}(ox)_2] \longrightarrow M + K_2C_2O_4 + 2CO_2$$
(M=Cu, Pd, and Pt)

The results from the TG and the DSC, which have been reported in the preceding paper, are consistent with these equations.

For the complexes in the second group, the following equations are possible:

$$K_3[Al(ox)_3] \longrightarrow 1/2Al_2O_3 + 3/2K_2C_2O_4 + 3/2CO + 3/2CO_2$$

$$K_2[Zn(ox)_2] \longrightarrow ZnO + K_2C_2O_4 + CO + CO_2$$

In this case, the decomposition of the complexes may be initiated by C–O bond breaking, thus forming a metal oxide with no change in the valency of the central metal. In fact, Dollimore *et al.* have confirmed the formation of Al_2O_3 upon the thermal decomposition of $K_3[Al(ox)_3]$. The results from the TG and the DSC, which have reported in the preceding paper, also support the above equations.

The decreasing order of the redox potentials of metal ions forming aquo ions is as follows:

Co(III)>Mn(III)>Pt(II)>Pd(II)>Rh(III)>Fe(III)
Cu(II)>V(III)>Cr(III)>Zn(II)>Al(III)

The complexes involving the metal ions listed on the left-hand side of Cu(II) in this series caused an electron transfer from an oxalate to a central metal upon heating, while the complexes of Al(III) and Zn(II), with the most negative potential, did not cause the electron transfer. The metal ions, V(III) and Cr(III) in reducibility, exist in the critical region. In view of the reducibility, in addition to the observation that the CO/CO_2 ratio was considerably smaller than 1, it may be supposed that the complexes of V(III) and Cr(III) in the third group decompose through both the processes, electron transfer and C–O bond breaking.

Subsequent Decomposition (Stage III). The decomposition of the bivalent metal oxalato complexes, probably $K_2[Cr(ox)_2]$, $K_2[Mn(ox)_2]$, $K_2[Fe(ox)_2]$, and $K_2[Co(ox)_2]$, which were formed by heating the corresponding trivalent complexes, can be divided into two types. One may be represented by the equation:

$$K_2[M^{II}(ox)_2] \longrightarrow M + K_2C_2O_4 + 2CO_2$$
(M=Fe and Co)

which involves electron transfer from an oxalate to a central metal ion, while the other may be represented by the equation:

$$K_2[M(ox)_2] \longrightarrow MO + K_2C_2O_4 + CO + CO_2$$
(M=Cr(II) and Mn(II))

which involves C–O bond breaking.

This division is supported by the reducibility of a bivalent metal ion as well as by the analyses of gaseous products. The decreasing order of the redox potentials of bivalent metal ions forming aquo ions is as follows:

Pt(II)>Pd(II)>Cu(II)>Co(II)>Fe(II)>
Zn(II)>Mn(II)

Subsequent Decomposition (Stage IV). The decomposition of the $K_2C_2O_4$ formed on the thermal decomposition of the complexes was the final decomposition stage in the temperature range of 25—600°C. From the EG curves, the peak maximum corresponding to the decomposition of $K_2C_2O_4$ appears at a lower temperature than that of pure $K_2C_2O_4$. This suggests that an included metal or a metal oxide may act as a catalyzer.

The analyses of the gaseous products in Table 1 show that the peak corresponding to the decomposition of $K_2C_2O_4$ involved CO and CO_2, which suggests that the decomposition of $K_2C_2O_4$ can be represented by the following equations:

$$K_2C_2O_4 \xrightarrow{I} K_2CO_3 + CO$$
$$K_2C_2O_4 \xrightarrow{II} K_2O + CO + CO_2$$
$$K_2C_2O_4 \xrightarrow{III} K_2O + 1/2C + CO_2$$

where Process I may be the main one for most of the complexes investigated, since CO is the main product for these complexes. The formations of K_2CO_3 and K_2O have been confirmed, by X-ray diffraction identification,[7] upon the thermal decomposition of $K_3[Al(ox)_3]$. The residue obtained by heating $K_3[Al(ox)_3]$ at 500°C was white, but the residue of pure $K_2C_2O_4$ at 600°C was gray. This difference suggests that Process III is possible for the decomposition of pure $K_2C_2O_4$, but impossible for the $K_2C_2O_4$ formed on the thermal decomposition of $K_3[Al(ox)_3]$. The $2CO \rightarrow CO_2+C$ reaction which has been suggested by several workers, may not occur under the conditions employed in this work, since carbon was not always formed upon heating the complexes at 600°C. The details of this stage will be reported later on the basis of analyses of solid products.

The author wishes to thank Professor Nobuyuki Tanaka, Tohoku University, for his valuable advice.

Polarographic Studies of the Anodic Oxidation of Mercury. I. Anodic Waves of Ammonia and Several Amines in *N,N*-Dimethylformamide

Yoshihisa MATSUI, Yukio KUROSAKI,* and Yoshio DATE
Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue
(Received April 17, 1972)

The behavior of ammonia and several amines at the dropping mercury electrode was studied in *N,N*-dimethylformamide containing 0.10M Et_4NClO_4 by means of DC polarography and amperometric titration. Ammonia gave a diffusion-controlled anodic wave, which was attributed to the reversible oxidation of mercury to the 1:2 complex of mercury(II) with ammonia. A dilute solution of methylamine or dimethylamine gave a diffusion-controlled anodic wave similar to that of ammonia. A concentrated solution of each amine gave a prewave due to the adsorption of the electrolysis product, $Hg(am)_2^{2+}$, on the electrode surface. Trimethylamine also gave an anodic wave, but it was attributed to the oxidation of the amine itself to the corresponding cation radical. Ethylenediamine and 1,2-diaminopropane each gave a well-defined anodic wave over the concentration range examined. The wave was diffusion-controlled and was attributed to the reversible oxidation of mercury to the chelate compound of the $Hg(diam)_2^{2+}$ type. No adsorption phenomena were observed in this case. Aromatic amines such as aniline and β-naphthylamine gave no anodic waves. The overall stability constants of the 1:2 complexes of mercury(II) with ammonia, methylamine, dimethylamine, ethylenediamine, and 1,2-diaminopropane were evaluated by the analyses of the waves to be $10^{16.9}$, $10^{17.1}$, $10^{15.0}$, $10^{23.5}$, and $10^{24.0}M^{-1}$ respectively.

When the dropping mercury electrode is polarized anodically in a solution containing an ion or a compound which can form a stable complex with mercury(I) or mercury(II), an anodic diffusion current is observed at a potential less positive than the potential at which the anodic current due to the free dissolution of mercury flows. This is due to the electrolytic oxidation of mercury to the mercury complex; such polarographic behavior make it possible not only to determine the complexing agents quantitatively, but also to investigate the chemical and physicochemical properties of both complexing agents and their mercury complexes. Among them, the halide, cyanide, thiocyanate, sulfide, and thiosulfate ions, the compounds containing the thiol group, and their mercury complexes have often been studied in aqueous and nonaqueous solutions.[1,2] The compounds containing an amino group are also known to form considerably stable complexes with mercury.[3] Nevertheless, their electrochemical behavior on the dropping mercury electrode has rarely been examined,[4-6] probably because amines are in general such strong bases that, in a dilute aqueous solution, they react with water to form the corresponding ammonium and hydroxide ions. On the other hand, amines are in the free state in aprotic solvents; this must be favorable for a polarographic study of free amines. Thus, Coetzee and Kolthoff[6] have reported that some amines give well-defined anodic waves in acetonitrile. However, they gave no details of the electrode reactions.

The present investigation was undertaken in order to survey the anodic behavior of amines on the dropping mercury electrode in detail by means of DC polarography and amperometric titration. Among amines, ammonia (NH_3), methylamine ($MeNH_2$), dimethylamine (Me_2NH), trimethylamine (Me_3N), ethylenediamine, 1,2-diaminopropane, aniline, and β-naphthylamine were chosen for the present study. *N,N*-dimethylformamide (DMF) was used as a solvent, for it is aprotic and is frequently used in polarography.

Experimental

Materials. The DMF obtained commercially was dried over potassium carbonate for several days and then distilled under reduced pressure in the presence of a few lumps of calcium hydride. The tetraethylammonium perchlorate (Et_4NClO_4) used as a supporting electrolyte was prepared as has been described by Fujinaga *et al.*[7] The NH_3, $MeNH_2$, Me_2NH, and Me_3N were obtained commercially in aqueous solutions; their concentrations were 28, 30, 40, and 30% respectively. They were diluted with DMF in order to prepare cell solutions of the amines without the removal of water.[8] The concentration of each amine was determined by titration with an aqueous hydrochloric acid. The other amines studied were commercially obtained and were used without further purification. A solution of mercuric perchlorate in DMF was prepared as has been described previously.[9]

Apparatus. The DC polarography was carried out at 25°C with a Shimadzu polarograph, model RP-50. An H-type cell was used for the polarography. The bridged

8) The amount of water introduced into the cell solutions with the amines was thought to be too small (below 0.04%) to affect the polarographic behavior of the amines. In fact, it was found for $MeNH_2$ that the anodic waves measured in the presence of water up to 0.40% were essentially the same as that measured after the removal of water.

saturated calomel electrode proposed by Takaoka[10] was used throughout as a reference electrode. All the potentials were corrected automatically for the IR-drop across the electrolysis cell with a Shimadzu automatic potential corrector, model AIC-50. No cell solution was degassed, since some amines are so volatile that degassing would change the amine concentrations. The cathodic wave of oxygen appears at a potential too negative to influence the anodic wave of mercury. The current-time curves (*i-t* curves) were measured by means of the polarograph described above, with a minimum damping of amplitude and with a maximum chart speed of the recorder (160 mm/min). The response of the recorder was not very fast, but it was fast enough to observe qualitative features.

Results and Discussion

Anodic Waves of NH_3, $MeNH_2$, and Me_2NH. In polarographic behavior NH_3, $MeNH_2$, and Me_2NH are essentially similar to one another. Figures 1, 2, and 3 show their polarograms at various concentrations. Each of these depolarizers gave a single well-defined anodic wave at concentrations lower than 0.5 mM. At higher concentrations, $MeNH_2$ and Me_2NH gave

prewaves, while NH_3 did not. For each depolarizer, as is shown, for example, in Tables 1 and 2 with respect to $MeNH_2$, the total limiting current (i_d) was virtually proportional to the bulk concentration of the depolarizer, and also to the square root of the effective pressure (h_{corr}) on the mercury drop; these facts indicate that the total limiting current is diffusion-controlled. On the other hand, the height (i_p) of each prewave of $MeNH_2$ and Me_2NH was virtually independent of the bulk concentration of the depolarizer and was proportional to h_{corr}; these facts indicate that the prewave

is characteristic of an adsorption current.

The composition of the mercury-amine complexes, which were considered to be formed during the electrode processes of the amines, was examined by the amperometric titration of the simple mercury(II) ion with each amine. The results for all three amines were virtually the same; as an example, the results of $MeNH_2$ are shown in Fig. 4. The simple mercury(II) ion gave a cathodic wave (accompanied by a maximum). The cathodic limiting current decreased with the amount of the amine added. At the same time, a second cathodic wave appeared at a less positive potential. The wave height increased in proportion to the amount of the amine added. When the quantity of the amine added was more than double that of mercury(II), the first cathodic wave disappeared, whereas an anodic limiting current appeared on the second wave. After that, the cathodic current of the second wave became virtually constant or decreased only slightly, while the anodic current increased in proportion to the excess amount of the amine. These results evidently show that the mercury(II) ion reacts with the amine (am) to form a complex of the $Hg(am)_2^{2+}$ type and that the complex is reduced at a potential corresponding to the second cathodic wave. The half-wave potential of this wave is approximately equal to that of the anodic wave of $MeNH_2$ shown in Fig. 2; this indicates that the electrode process is reversible. Thus, the electrode reaction can be expressed by the following equation:

$$Hg + 2am \rightleftarrows Hg(am)_2^{2+} + 2e \qquad (1)$$

Although Coetzee and Kolthoff[6] attributed the anodic waves of NH_3 and some amines in acetonitrile to the formation of salts of the $HgNH_2ClO_4$ type, this is implausible, at least in the case of the electrode process in DMF.

The diffusion coefficients of NH_3, $MeNH_2$, Me_2NH, and their mercury(II) complexes were evaluated by using the Ilkovic equation. The results are shown in Table 3, together with those for the other amines and their mercury(II) complexes. Compared with the data that the diffusion coefficient of NH_3 in water is 14.6×10^{-6} cm²/s (20°C)[11] and that of the simple mercury(II) ion in DMF is 3.92×10^{-6} cm²/s (25°C),[9] the values here obtained seem to be reasonable.

Table 3. Diffusion coefficients of amines and their complexes with mercury (II) in DMF at 25°C

Compound	$D_a\times10^{6}$ a) (cm²/s)	$D_c\times10^{6}$ b) (cm²/s)
NH_3	19.9	3.68
$MeNH_2$	18.8	4.01
Me_2NH	18.9	2.76
Ethylenediamine	15.0	5.59
1,2-Diaminopropane	12.9	4.83

a) Diffusion coefficient of amine.
b) Diffusion coefficinet of the 1:2 complex of mercury (II) with amine.

If the electrode process (1) is reversible, the equation of the wave should be expressed by:

$$E = E_0 - (RT/2F)\ln\beta_2 + (RT/2F)\ln k_0^2/k_2 + (RT/2F)\ln i/(i_d-i)^2 \qquad (2)$$

In this equation, E_0 represents the standard potential of the mercury-mercury(II) half-cell; β_2, the overall stability constant of the $Hg(am)_2^{2+}$ complex, and k_0 and k_2, the Ilkovic equation constants for the amine and $Hg(am)_2^{2+}$ respectively. Since the first three terms on the right-hand side of this equation are constant, a plot of $\log i/(i_d-i)^2$ *vs.* E should give a straight line, with a reciprocal slope of 0.030 V at 25°C. The results for the waves of 0.66 mM NH_3, 0.52 mM $MeNH_2$, and 0.24 mM Me_2NH are shown in Fig. 5. For each compound, a straight line with a reciprocal slope of about 0.030 V was obtained at the more positive potentials of the wave, whereas the plot deviated from the line at the less positive potentials of the wave. Similar plots were obtained for the waves of 0.33—1.32

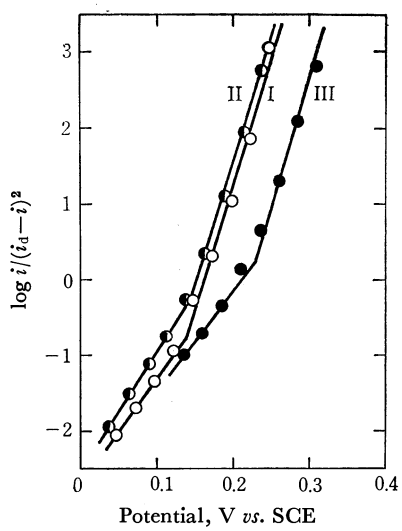

Fig. 5. The plots of $\log i/(i_d-i)^2$ *vs.* potential for the waves of 0.66 mM NH_3 (I), 0.52 mM $MeNH_2$ (II), and 0.24 mM Me_2NH (III).

11) D. M. Himmelblau, *Chem. Rev.*, **64**, 527 (1964).

mM NH_3, 0.10—0.66 mM $MeNH_2$, and 0.11—0.53 mM Me_2NH. The deviation of the plots can be attributed either to the partial formation of the higher amine complex, $Hg(am)_3^{2+}$, or to the adsorption of the electrolysis product, $Hg(am)_2^{2+}$, on the electrode surface. However, it was found that no equation derived by taking into account the formation of the higher complex[12] can explain the shape of the wave measured. Thus, at the less positive potentials of the wave a large part of the electrolysis product may be adsorbed on the electrode surface, and this may be responsible for the flowing of the extra anodic current. At the more positive potentials of the wave, the complex formed may cease to be adsorbed, and the polarographic curve may come to agree with that expressed by Eq. (2).

If Eq. (2) holds at the more positive potentials of each wave the value of β_2 can be estimated. For example, the potential at which the $\log i/(i_d-i)^2$ of the NH_3 wave equaled zero was graphically estimated to be 0.163 (average) V *vs.* SCE, E_0 is 0.557 V *vs.* SCE,[9] and the k_0 of NH_3 and the k_2 of $Hg(NH_3)_2^{2+}$ were 4.37×10^3 and 3.06×10^3 μA/M respectively. Consequently, β_2 was evaluated to be $10^{16.9}M^{-1}$. This value is comparable to that in water, that is, $10^{17.5}M^{-1}$.[13] The results of the other amines are listed in Table 4.

TABLE 4. OVERALL STABILITY CONSTANTS OF THE 1:2 COMPLEXES OF MERCURY (II) WITH AMINES IN DMF AT 25°C[a]

Compound	β_2, M^{-1}
NH_3	$10^{16.9}$
$MeNH_2$	$10^{17.1}$
Me_2NH	$10^{15.0}$
Ethylenediamine	$10^{23.5}$
1,2-Diaminopropane	$10^{24.0}$

a) Ionic strength: 0.10M

Furthermore, from Eq. (2) the following equation can easily be derived:

$$E_{1/2} = K - (RT/2F)\ln c_0 \qquad (3)$$

where $E_1/_2$ and c_0 are the half-wave potential and the bulk concentration of each amine respectively, and where K is a constant. The observed $E_1/_2$'s of the NH_3 waves are plotted in Fig. 6. When the concentration of NH_3 was less than 2 mM, the $E_1/_2$ was shifted, exactly in accordance with Eq. (3), to the less positive potential with an increase in the concentration. This indicates that Eq. (2) is valid in the low concentration range. However, when the concentration exceeded 2 mM, the $E_1/_2$ was shifted to the more positive potential with an increase in the concentration. Similar plots were obtained for $MeNH_2$ and Me_2NH, too. These may be well explained in terms of the inhibition of the anodic process by the electrolysis product adsorbed on the mercury electrode. That is, the concentration of each depolarizer may be so high that the surface

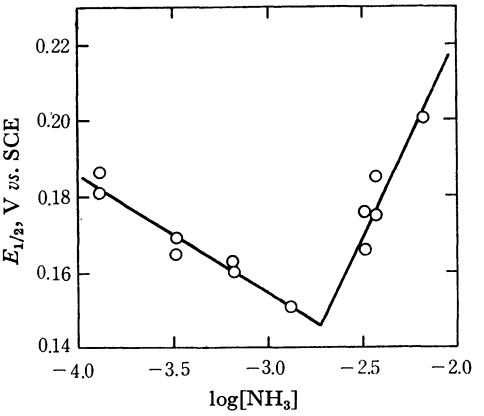

Fig. 6. Relation between the concentration of NH_3 and its half-wave potential.

of the mercury electrode may be completely covered by the film of the electrolysis product, which may then continue to inhibit the further diffusion of the depolarizer to the electrode until the complex is desorbed from the electrode at the more positive potential.

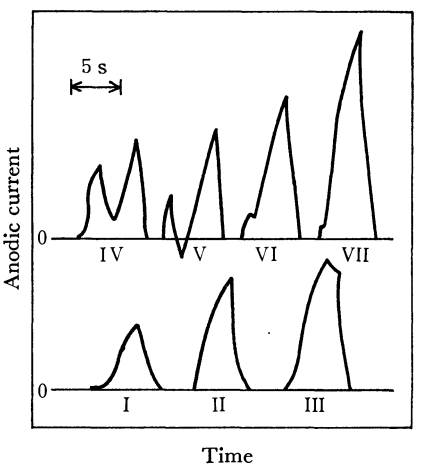

Fig. 7. The current-times curve of 1.5 mM Me_2NH at various potentials (25°C). Potential (V *vs.* SCE): I, 0.10; II, 0.15; III, 0.20; IV, 0.25; V, 0.30; VI, 0.40; VII, 0.50.

The inhibition of the electrode process by the adsorption was also observed by the measurement of the *i-t* curve during the growth of each mercury drop, especially in the case of Me_2NH (Fig. 7). In this case, the anodic current increased with the growth of a mercury drop at the potential of +0.15 V *vs.* SCE, corresponding to the mid-point of the Me_2NH prewave; this is characteristic of a diffusion-controlled process. On the other hand, at the potential of +0.20 V *vs.* SCE corresponding to the plateau of the prewave, the anodic current decreased somewhat before the dropping of mercury. At more positive potentials, the anodic current abruptly decreased in the course of the growth of a mercury drop. This is characteristic of an adsorption current and indicates that the electrode process is inhibited by the adsorbate layer. Similar results were observed in the case of $MeNH_2$, although that decrease in the current was not so great as in the case of Me_2NH.

If the adsorption of the mercury complexes obeys the

13) L. G. Sillen and A. E. Martell, "Stability Constants of Metal-Ion Complexes," Special. Publ. **17**, Chem. Soc., London (1964), p. 155.

Langmuir isotherm, the maximum amount of the adsorbate per unit area (Z) can be evaluated by the following equation:[14]

$$Z = i_p/(knFm^{2/3}t^{-1/3}) \quad (4)$$

$$k = 0.85\ \mathrm{cm^2g^{-2/3}}\ \text{at } 25°\mathrm{C}$$

where n is the number of the electrons participating in the electrode process. For example, in the case of $MeNH_2$ n is equal to 2, and the mean value of i_p, measured when m and t are equal to 1.546 mg/s and 4.67 s respectively, is 1.85 μA. Therefore, Z is equal to 1.41×10^{-9} mol/cm^2, which indicates that one adsorbate molecule occupies an area of 11.8 Å^2 of the electrode surface. The value of Z for Me_2NH was 1.59×10^{-9} mol/cm^2 (10.4 Å^2/molecule).

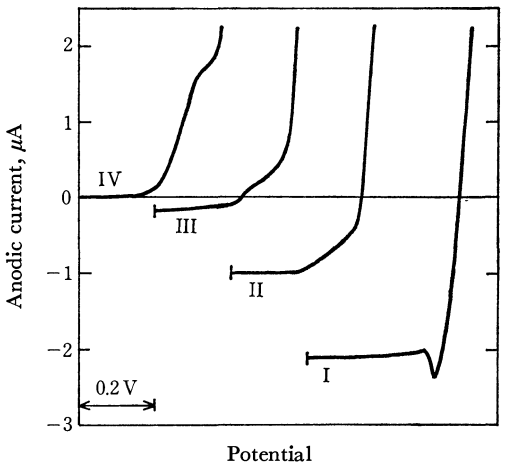

Fig. 8. The amperometric titration of 0.50 mM Hg(II) with Me_3N at 25°C. Each polarogram was recorded from +0.10 V *vs.* SCE toward the more positive potential. The concentration of Me_3N added: I, 0.00 mM; II, 0.50 mM; III, 1.00 mM; IV, 1.50 mM.

Anodic Wave of Me_3N. The polarogram of Me_3N was similar to that of $MeNH_2$. The wave height was virtually proportional to the bulk concentration of Me_3N and also to the square root of the effective pressure on the mercury drop; these facts indicate that the wave is diffusion-controlled (I_d=1.31 μA·mM^{-1} mg$^{-2/3}$s$^{1/2}$). However, the results of the amperometric titration of the simple mercury(II) ion with Me_3N were different from those with $MeNH_2$ and Me_2NH (Fig. 8). Although the height of the wave of the simple mercury(II) ion decreased with the increase in the amount of Me_3N, no reduction wave of the mercury complex appeared. The reduction wave of the simple mercury(II) ion almost disappeared when the concentration of the amine added exceeded twice that of the mercury(II) ion. It was also observed that the mercury(II) solution changed from colorless to a yellowish brown as the amine was added. These results indicate that the simple mercury(II) ion is chemically reduced by the amine to metallic mercury and the cation radical of the amine, which may then be liable to decompose to electro-inactive products. Thus, the anodic wave of Me_3N may not be due to the oxidation of mercury to its complex with the amine, but to the oxidation of the amine itself to the corresponding cation radical.

14) K. Hasebe and T. Kambara, *Rev. Polarog.* (Kyoto), **15**, 37 (1968).

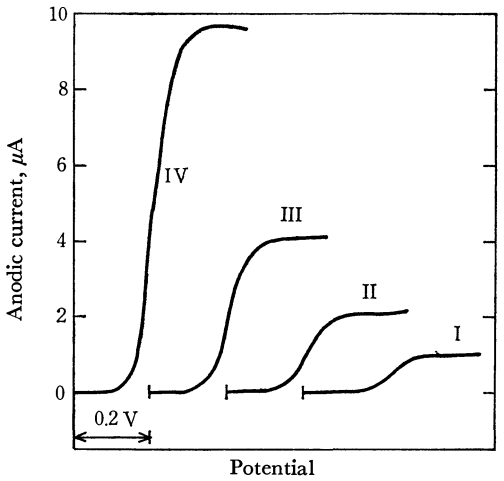

Fig. 9. DC polarograms of ethylenediamine in DMF at 25°C. Each polarogram was recorded from −0.25 V *vs.* SCE toward the positive potential. I, 0.25 mM; II, 0.51 mM; III, 1.01 mM; IV, 2.53 mM.

Anodic Waves of Ethylenediamine and 1,2-Diaminopropane. The polarographic behavior of ethylenediamine and that of 1,2-diaminopropane were similar to one another, but different from that of the monoamines examined above. Figure 9 shows the polarograms of ethylenediamine at various concentrations. Each diamine gave a well-defined anodic wave even in a concentrated solution. The height of the wave of each diamine was proportional to the bulk concentration of the diamine and also to the square root of the effective pressure on the mercury drop; these facts indicate that the wave is diffusion-controlled. The results of the amperometric titration of the simple mercury(II) ion with each diamine clearly indicated that the mercury(II) ion reacts with each diamine to form a complex of the $Hg(diam)_2^{2+}$ type.

If the anodic wave of each diamine is due to the formation of the 1:2 complex in a reversible process, Eq. (2) should hold. The plots of $\log i/(i_d-i)^2$ *vs.* potential were linear, in good accordance with Eq. (2), over the entire potential range of the anodic wave of each diamine. This is different from the results obtained for NH_3, $MeNH_2$, and Me_2NH and suggests that the mercury(II) complex with each diamine is not adsorbed on the electrode. This argument was supported by the measurements of the *i-t* curve and of the electrocapillary curve of each diamine. The absence of adsorption may be related to the formation of the chelate complex of mercury(II) with each diamine. A plot of $E_{1/2}$ *vs.* the logarithmic concentration of each diamine was virtually linear, in accordance with Eq. (3), over the whole range of concentration studied. The diffusion coefficients of each diamine and its mercury(II) complex, and the overall stability constants of the 1:2 complex, are listed in Tables 3 and 4 respectively.

It was found that the mercury(II) complexes of the diamines are more stable than those of the mono-

amines by a factor of about 10^7. It was also found that the values of β_2 in DMF are very close to those in water ($10^{23.42}M^{-1}$ for ethylenediamine and $10^{23.53}M^{-1}$ for 1,2-diaminopropane in 0.10N KNO_3 at 25°C[4]); this suggests that solvents have little effect on the stability of the complexes.

Anodic Behavior of Aromatic Amines. Although Coetzee and Kolthoff[6] have reported that aniline gives a well-defined anodic wave in acetonitrile, it gives no anodic wave in DMF. β-Naphthylamine also gives no anodic wave in DMF. These results are in clear contrast to those of the aliphatic amines. The complexing ability of the aromatic amines with mercury(II) may be lower than that of the aliphatic amines, just as the basicity of the former is lower than that of the latter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 152—156 (1973)

The Synthesis of Crystalline Rare Earth Carbonates

Kozo Nagashima, Hisanobu Wakita,* and Akihiko Mochizuki

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Bunkyo-ku, Tokyo 112

(Received April 20, 1972)

The factors which influence the crystallization of rare earth carbonates were studied. Crystalline rare earth carbonates were precipitated at various temperatures from aqueous solutions by using sodium carbonate, sodium bicarbonate, trichloroacetic acid, and urea as precipitants. The crystal parameters, compositions, and factors concerning the formations of various carbonates, such as lanthanite-type $Ln_2(CO_3)_3 \cdot 8H_2O$(Ln=La, Ce), tengerite-type $Ln_2(CO_3)_3 \cdot nH_2O$(Ln=Nd, Sm, Gd, Dy, Ho, Er, and Y, n=2—3), monoxocarbonate-type $Ln_2O(CO_3)_2 \cdot nH_2O$(Ln=La, Ce, Nd, and Sm, n=1—2) and a hydrated double carbonate of rare earth and sodium (rare earth= La, Ce, Nd, Sm, Gd, Dy, and Y) were determined by chemical analysis and X-ray powder diffractometry.

Rare earth carbonates of various compositions have been reported as a result of numerous syntheses and thermal analyses.[1-9] Many of the results reported and the accompanying discussions are, however, contradictory. The inconsistencies are due in part to preparatory difficulties and to a lack of structural data.

The carbonates of most metals are prepared by the following two common procedures: the precipitation of the compounds by alkali carbonates or bicarbonates from solutions containing the metal salt, and by passing carbon dioxide through an aqueous suspension of metal hydroxides. However, pure crystalline carbonates of the rare earth elements are difficult to prepare by these methods.

Crystalline rare earth carbonates are generally obtained by the hydrolysis of trichloroacetates of rare earth elements, but the precipitates of heavier lanthanoids prepared by other techniques usually appear amorphous when examined by X-ray powder diffractometry.[10]

Katsurai and Uda[11] prepared pure crystalline siderite, $FeCO_3$, by autoclaving a solution of ferrous ammonium sulfate in the presence of urea. The present authors have now successfully used this procedure in preparing the crystalline rare earth carbonates.

In general, the principal factors which influence the crystallization of scarcely-soluble compounds from aqueous solution are: (1) the nature of the precipitant, (2) the temperature and pressure, (3) the concentrations of the metal ion and the precipitant, and (4) the aging period. These factors have been repeated vaguely in almost all studies concerned with the synthesis of crystalline rare earth carbonates. To be considered in this investigation are the natures of the carbonates of lanthanum, cerium(III), neodymium, samarium, gadolinium, holmium, erbium, ytterbium(III), yttrium, and scandium, essentially even-atomic-numbered lanthanoids, as they are affected by the above conditions during the preparation.

Experimental and Results

Synthesis. *(1) Alkali Carbonate and Bicarbonate as Precipitant*: Similar results were obtained with sodium carbonate and sodium bicarbonate, but usually the bicarbonate gave a superior crystalline product. Crystalline carbonates of lanthanum, cerium(III), neody-

a) All crystalline precipitates gave the tengerite type X-ray powder patterns.

mium, samarium, gadolinium, dysprosium, erbium, and ytterbium were produced by this method, whereas ytterbium and scandium gave only amorphous carbonates.

Procedure: To a constantly-stirred 10 ml portion of a 0.1M rare earth chloride solution contained in a beaker, we added a solution of twice the molar equivalent of sodium bicarbonate (or carbonate). The procedure was then repeated at various temperatures from 20 to 80°C. The total volume of the mixed solution was adjusted to 100 ml and was maintained at the desired temperature for one week. The precipitates were then filtered off, washed with water repeatedly, air-dried and subjected to microscopy, chemical analysis, X-ray powder diffractometry, and thermal analysis. The results for the precipitates obtained at higher temperatures agreed with those obtained by the other methods.

(2) Trichloroacetic Acid as the Precipitant: This is the most popular method for obtaining crystalline rare earth carbonates. Not only light lanthanoids, but also yttrium and heavy lanthanoids except for ytterbium, gave crystalline carbonates.[10)] Crystalline carbonates of the elements mentioned in (1) have been obtained in the temperature range from 40 to 120°C. Below 40°C, the rate of the hydrolysis of trichloroacetate was too slow for us to prepare sufficient amounts of carbonates.

Procedure: To a 10 ml portion of a 0.1M rare earth chloride solution contained in a beaker or flask, we added 5 ml of a 2.0 M trichloroacetic acid solution. The solution was adjusted with ammonia to pH 5—6, and the volume was adjusted to 100 ml. Beakers or flasks were placed in thermostatically-controlled baths at temperatures ranging from 40 to 120°C, at ten-degree intervals, for one week. For temperatures over 100°C, the flasks were equipped with reflux condensers, or sealed glass ampoules were used. The precipitates were then filtered off, washed with water, and air-dried.

(3) Urea as the Precipitant: A mixture of 10 ml of a 0.1M rare earth solution and 10 ml of a 0.2M urea solution was autoclaved for one week at various temperatures from 50 to 150°C. As has been mentioned by Head and Holley,[2)] the autoclaving of rare earth carbonates appears to produce good crystallization. The precipitates were filtered off, washed with water repeatedly, air-dried, and subjected to analysis.

In the case of yttrium, the formation reaction is expressed as:

$$3(NH_2)_2CO + 2YCl_3 + (6+n)H_2O \longrightarrow Y_2(CO_3)_3\cdot nH_2O + 6NH_4Cl.$$

(4) Factors Which Influence Crystallization: The following experiments were carried out for the purpose of studying the various factors which influence the crystallization of rare earth carbonates, such as the temperature, the concentration of metal ions and the aging period of the precipitates.

Experiment: 2-, 5-, 10-, and 20-ml portions of 0.1M rare earth chloride solutions were placed in beakers, and 1-, 2.5-, 5-, and 10-ml portions of a 2.0M trichloroacetic acid solution were added respectively. Then the pH values of mixed solutions were adjusted to 5—6 with ammonia and the volumes were adjusted to 100 ml. The beakers were placed in a thermostatically-controlled bath maintained in the temperature range of 50 to 70°C. After several days, the precipitates were filtered off, washed with water, air-dried, and subjected to microscopy and X-ray powder diffractometry. The results for the experiment using yttrium are summarized in Table 1.[12)] It can be seen that longer aging periods and lower concentrations of the metal ion produce larger crystals. It was also revealed that varying the concentration of metal ion does not change the structure of rare earth carbonates within the concentration range of the present work. In all cases, the tengerite structure was obtained.

Chemical Analyses and X-Ray Powder Diffractometry. Chemical analyses were carried out on the rare earth

carbonates prepared by the prescribed methods. The carbonates were classified into five types according to their compositions. It was found that the compositions were affected by the temperature, but were not dependent on the method of preparation. The results of the chemical analyses of typical samples are shown in Table 2. The types of rare earth carbonates obtained at various temperatures are illustrated in Fig. 1. Rare earth elements on a horizontal axis are shown according to their ionic radii. The X-ray powder diffractions of the synthesized samples were recorded on a Rigaku Denki Geigerflex Diffractometer, applying Ni-filtered Cu$K\alpha$ radiation and employing metallic silicon as the internal standard.

By chemical and X-ray analyses, the natures of the following carbonates were determined.

(A) Monoxocarbonate Type (shown by open circles in Fig. 1). Experimental formula: $Ln_2O_3 \cdot 2CO_2 \cdot nH_2O$($n$=1—2)——Table 2. Carbonates of lanthanum, cerium(III), neodymium, and samarium prepared at 90°C and higher are of this type. The X-ray powder data for the lanthanum compound of this type are given in the third column of Table 3. So far as we can discover in the literature surveyed, this is the first report on the X-ray powder data for rare earth monoxocarbonate. Though a possibility still exists that the compound is a hydroxocarbonate, this type of carbonate was classified as monoxocarbonate $Ln_2O(CO_3)_2 \cdot nH_2O$ (n=1—2) through thermal analysis and a study of its infrared spectrum.

B) Lanthanite Type (shown by solid squares in Fig. 1). Lanthanum and cerium(III) ions, the largest two of the lanthanoid ions, form this type of carbonate in the temperature range from 20 to 80°C. This type of carbonate has the composition of $Ln_2(CO_3)_3 \cdot 8H_2O$ (Table 2) and gives an X-ray-powder-diffraction pattern (Table 3) identical with that of lanthanite,[8] a very rare, hydrated, rare earth carbonate mineral.

(C) Tengerite Type (shown by open squares in Fig. 1). Neodymium (40—70°C), samarium (30—80°C), gadolinium, dysprosium, yttrium, and erbium form this type of carbonate, with the formula of $Ln_2(CO_3)_3 \cdot nH_2O$(n=2—3)[10] (Table 2). Because of the experimental difficulty, the central area of Fig. 1 remains incomplete at present. It may be said, however, that the formation of the tengerite-type carbonate is characteristic of the heavier lanthanoids, excluding ytterbium. The X-ray diffraction data listed in Table

3 coincide well with those of natural tengerite.[10] In the table, the indices and cell edges as well as the d values and intensities for the lanthanite-type lanthanum carbonate and those for the tengerite-type yttrium carbonate are listed.

(D) Double Carbonate (shown by the solid circle in Fig. 1). The double carbonate was obtained when sodium carbonate was used as the precipitant at lower temperatures. Lanthanum (20°C), cerium(III) (20—50°C), neodymium, samarium, gadolinium, dysprosium, and yttrium (20—30°C) form this double carbonate. In the cases of lanthanum and cerium(III), either the lanthanite type or the double carbonate forms, depending on minor variations in the preparation process. The composition of this double carbonate may be expressed as a hydrated double carbonate of rare earth and sodium. Further study is necessary, however, to determine the compositions of the compounds. The X-ray powder data for the double carbonate of gadolinium are listed in the last column of Table 3.

With ytterbium, a crystalline carbonate was not formed by these procedures within the given temperature range; only an amorphous basic carbonate was obtained. Scandium, however, formed a crystalline hydroxide upon the hydrolysis of trichloroacetate or urea. The X-ray data of the respective monoxocarbonates (La, Ce, Nd, Sm) are listed in Table 4. In the table, it can clearly be seen that d values of carbonates of this type increase linearly with an increase in the ionic radii of rare earth elements.

Thermal Analysis of Monoxocarbonates. The thermal decomposition study of the monoxocarbonates was performed with a Choryo Keiki Thermobalance modified to record the thermogravimetric analysis (TGA), differential thermal analysis (DTA), and differential thermogravimetric analysis (DTG) curves simultaneously. The measurements were made in air at a heating rate of 5.4°C/min, using approximately 100 mg samples. The results of the TGA, DTA, and DTG analyses of lanthanum and neodymium monoxocarbonates are shown in Figs. 2 and 3. The decomposition processes of cerium and samarium monoxocarbonate were similar to that of neodymium. On the TGA curve for the lanthanum compound, there is initially a loss of water, leading to the plateau, which corresponds to the step of the anhydrous monoxocarbonate. The stability of this compound in one of the bases for assuming the formula of the initial compound to be hydrated monoxocarbonate. This plateau is prominent for the lanthanum compound. On the TGA curve for the neodymium compound, the temperature rise leads to dehydration and decarbonatation at the same time. The difference observed in the TGA curves was also observed in the DTA curves. The DTA curve in Fig. 2 shows that the exothermic effects in the 250—400°C range corresponds to the formation of the anhydrous monoxocarbonate. The continuous raising of the temperature leads to the formation of some intermediate phases, shown in the following processes, (1) and (2):

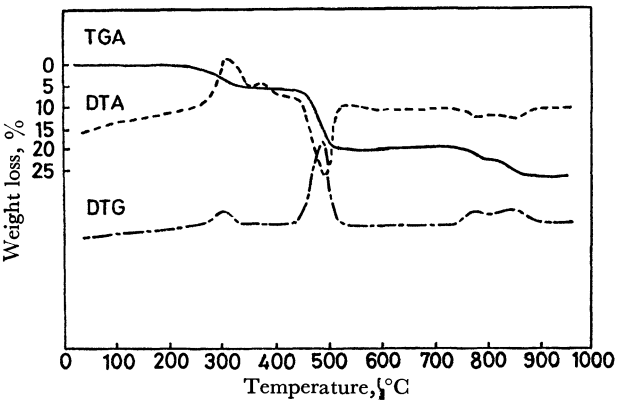

Fig. 2. TGA, DTA, and DTG curves of $La_2O(CO_3)_2 \cdot 1.4H_2O$

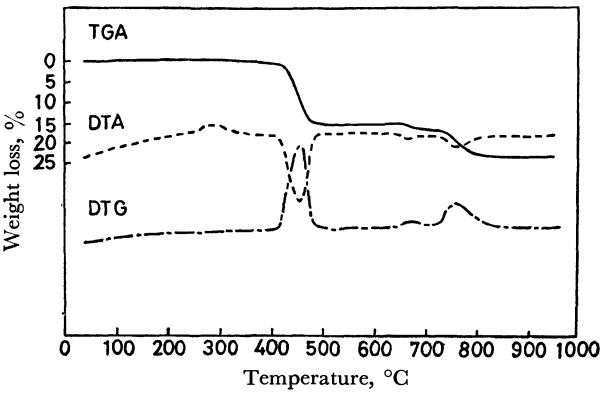

Fig. 3. TGA, DTA, and DTG curves of $Nd_2O(CO_3)_2 \cdot 1.5H_2O$

Infrared Spectroscopy. Herzberg[13] gave the frequencies for the four modes of the free carbonate ion: ν_1, 1063 cm^{-1}; ν_2, 879 cm^{-1}; ν_3, 1415 cm^{-1}; and ν_4, 680 cm^{-1}, when the ν_3 and ν_4 modes degenerate. The ν_1 symmetrical streching mode is infrared-inactive for the free ion, but it may become active in the crystalline stage. Its presence and the splitting of degenerate modes indicate the presence of a dipole within the carbonate group. The D_{3h} symmetry of the free carbonate ion is thus lowered either to C_{2v} or to C_s symmetry. The splitting of the non-degenerate bands is generally an indication of nonequivalent carbonate groups in a given structure.[14]

The infrared spectra of the rare earth carbonates obtained in this work are shown in Fig. 4. The multiple splittings of all modes for the crystalline rare earth carbonates (lanthanite-type, tengerite-type, monoxocarbonate-type, and double carbonate) must be caused by several types of carbonate ions situated at crystallographically non-equivalent site.

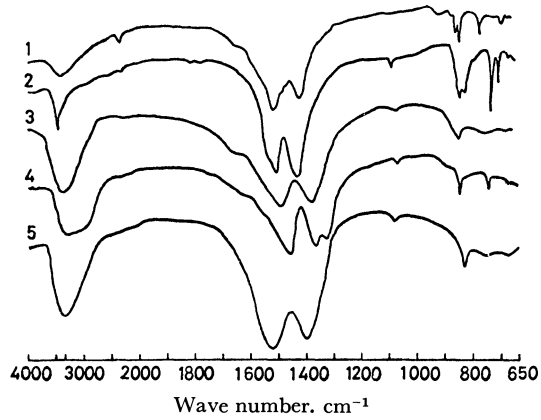

Fig. 4. Infrared absorption spectra of rare earth carbonates (in KBr disk).
1: tengerite type (Y), 2: monoxocarbonate type (Sm), 3: double carbonate (Sm), 4: lanthanite type (La), 5: amorphous carbonate (Yb).

The minerals —shortite, huntite, and parisite— which contain two nonequivalent CO_3^{2-} groups show similar spectra, with the splittings of all modes.[15]

Conclusion

It was found in this study that crystalline rare earth carbonates may be classified into several phases according to the ionic radii of rare earth elements and the preparation temperatures, and that the concentrations of the rare earth ion and the aging periods affect mainly the crystallization.

The preparation and the structure of lanthanite-type rare earth carbonates were previously studied by Shinn and Eick,[8] and the preparation and cell parameters of tengerite-type rare earth carbonates were described by Wakita and Nagashima.[10] The present investigation was clarified the formation temperature range for lanthanite-type and tengerite-type carbonates and the elements which form those carbonates.

The formation of rare earth monoxocarbonates through the decomposition of hydrated rare earth carbonates or oxalates has been reported by many investigators. The formation of crystalline substances in those cases is doubtful, however, because of the procedures used, and none of the investigators have referred to the formation of monoxocarbonate from an aqueous solution.

A rare earth double carbonate is indicated by the results of X-ray powder analyses, chemical analyses, infrared spectrometry, and thermal analyses. This appears to be the first time that such a rare-earth double-carbonate compound has been reported; further investigation of this class of rare earth carbonates is desirable.

The Viscosities of Aqueous Solutions Containing Metal Complexes. III. Iminodiacetato and Methyliminodiacetato Complexes[1]

Kiyoshi MIZUTANI and Motoo YASUDA

Department of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 21, 1972)

The viscosities of aqueous solutions containing a metal chelate formed with iminodiacetic acid (H_2ida) or *N*-methyliminodiacetic acid (H_2mida) were measured with Cannon-Fenske capillary viscometers. Measurements were made in a Shibata viscosity bath maintained at 25±0.01°C. The Jones-Dole viscosity *B*-coefficient of each bis-ida chelate is lower than that of the corresponding bis-mida chelate, as may be expected. The *B*-coefficients for the mono-ida and mono-mida chelates were not determined accurately and will not be reported here. The *B*-value of *cis*(*N*)-[Co(ida)$_2$]$^-$ is higher than that of the *trans*-isomer. This is probably associated with the fact that the *cis*-isomer interacts with the solvent more strongly than the *trans*-isomer.

In the previous papers of this series, the viscosities of the luteo-type Co(III) and Co(II) complexes and the ethylenediaminetetraacetato (edta^{4-}) complexes[2a] and *trans*-1,2-cyclohexanediaminetetraacetato (cydta^{4-}) complexes were reported.[2b] The results showed, above all, that the *B*-coefficient of the Co(III) chelate formed with edta^{4-} or cydta^{4-} was much lower than those of the corresponding divalent metal chelates, and suggested that there might be a marked difference between the structures of [CoL]$^-$ and [ML]$^{2-}$ (L: edta^{4-} or cydta^{4-}; M: divalent metal ion). In order to study this problem in more detail, a viscosity study was made of aqueous solutions of metal chelates formed with iminodiacetic acid and *N*-methyliminodiacetic acid.

Experimental

Measurements. The viscosity *B*-coefficients of Co(III) and six divalent metal chelates were determined by means of Cannon-Fenske capillary viscometers with efflux times of ca. 520 and 600 sec respectively for distilled water. The viscosities and densities of the solutions were measured in a Shibata viscosity bath maintained at 25±0.01°C. The efflux times, measured with stopwatches to 0.1 sec, were easily reproducible to 0.2 sec.

Chelating Agents. Dotite H_2ida and Aldrich H_2mida were used. The analytical results for the C, H, and N contents showed these agents to be satisfactorily pure.

Complexes. The *cis*(*N*)- and *trans*(*N*)-potassium bis(iminodiacetato)cobaltates(III) were prepared following the method in the literature.[3] Divalent metal chelates of H_2ida and H_2mida were not isolated as crystals. Instead, solutions of these chelates were made up using metal nitrate (or chloride) and the K_2ida or K_2mida stock solutions.

Calculation. For each of the chelates studied, the relative viscosity, η/η_0, of aqueous solutions was expressed by the Jones-Dole equation:[4]

$$\frac{\eta}{\eta_0} = 1 + A\sqrt{c} + Bc \qquad (1)$$

where η and η_0 are the viscosities of the solution and of water respectively, and where c is the molar concentration of the solute. The coefficients, A and B, which are constants characteristic of the solute, were fully discussed by Gurney.[5] The *B*-coefficient was evaluated by a plot of $((\eta/\eta_0)-1)/\sqrt{c}$ *vs.* $\sqrt{c}$. A straight line was obtained for each case studied at concentrations below 0.06 mol/l. The slope of the resulting straight line gives the value of the *B*-coefficient for the solute. Because it has been shown to be true, for a wide variety of solutions, that B is composed additively of contributions from each of the solute species present in a solution, the *B*-value of the complex ion is obtained by subtracting a relatively small correction for the co-existing ionic species.

Results and Discussion

As both H_2ida and H_2mida are tridentate chelating agents, two kinds of chelates are formed following these equations:

$$M + L \rightleftarrows ML \qquad (2)$$

$$ML + L \rightleftarrows ML_2 \qquad (3)$$

where M is a metallic cation and where L is ida^{2-} or mida^{2-}. Accordingly, there are two kinds of viscosity *B*-coefficients, B_{ML} and B_{ML_2}, to be measured. Though we tried to obtain both of them, only the latter was determined accurately. Concerning the coefficient, B_{ML}, for the mono-chelate, only a rough value could be estimated because of several difficulties involved. For instance, in the lower pH range the dissociation of the chelate ML, that is, the reverse reaction of Eq. (2), occurs. This might tend to increase the viscosity of the solution. Next, in the higher pH range hydroxo-complexes, which might be formed by base hydrolysis, should be taken into account, and the chelate ML_2 must be considered to be present in the solution following Eq. (3), even though the solution contains stoichiometrical quantities of the metal ion and ligand. Furthermore, the B_{ML}-value is lower than the B_{ML_2}-value, and so more concentrated solutions should be used for the viscosity measurements of the mono-chelate. However, because of the low solubility of ML, which has no ionic charge, accurate measurements were impossible.

The *B*-coefficients of the bis-chelate ML_2 studied here are listed in Table 1. The pH value of each solution

Pb^{+2+}	0.75	—
Co^{3+}	*cis* 0.49	—
	trans 0.42	—

used for viscosity measurement was between 7~9; the higher pH range was used for the chelate with a lower stability constant. Since the ida^{2-} and $mida^{2-}$ chelates have rather large stability constants, it may be assumed that there is no appreciable change in the viscosity of the solution due to the dissociation of the chelate in the pH range studied.

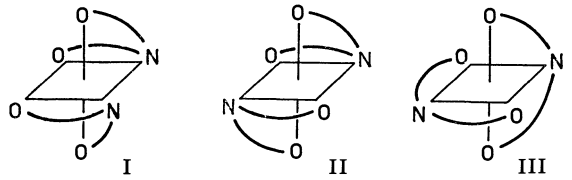

Fig. 1. The three possible geometric isomers of $[M(ida)_2]^{n-}$.

Three geometrical isomers are possible for the bis-chelate, $[M(ida)_2]^{n-}$ or $[M(mida)_2]^{n-}$, as is shown in Fig. 1. Two of them are *trans*(*N*)-forms, while the third is the *cis*(*N*)-form. However, only two isomers are isolated for Co(III)-ida chelates; one is *cis*(*N*) and the other is *trans*(*N*). The latter was assigned to Structure II by Hidaka *et al.* from the bond angles of a nitrogen atom of the ligand.[3] Later Cooke[6] tried several times to get the meridional *trans*-isomer (isomer III) by the elution of a mixture of the isomers from a Dowex 2-X8 anion-exchange resin in the chloride form, using NH_4Cl as the eluting agent. However, in no case was any evidence for a second *trans* isomer obtained. As he stated, the existence of this chelate can not be ruled out, and yet it is not considered that this chelate may be present appreciably. On the other hand, in the case of the bis-mida complexes of Co(III) the *trans*(*N*)-isomer alone is isolated.[6] The absence of the *cis*-isomer in this case and the dominance of the *trans*-isomer in the Co(III)-ida chelates were attributed to the presence of steric interactions between the amine groups in the *cis*-isomer. The values listed in Table 1 are, therefore, with the exception of Co(III) complexes, those for a mixture of *cis*- and *trans*-isomers which might be present in the solutions, although the values for the mida-chelates are considered to be practically those for the *trans*-isomers.

As may be seen from Table 1, the Jones-Dole viscosity *B*-coefficient of each ida-chelate is lower than that of the corresponding mida-chelate, as may be expected. The differences in *B*-values caused by the introduction of the methyl group on the amino nitrogen atom of ida^{2-} are 0.11~0.12 for Cu^{2+}, Ni^{2+}, and Co^{2+} complexes, and 0.08 for Zn^{2+}. That is, the differences are very much the same, except for the Zn^{2+} complex. However, as has been mentioned above, the differences may be caused by the *cis-trans* geometric effects as well as by the effect of the methyl group. Therefore, the lower value for the Zn^{2+} chelate can not be discussed easily. It is clear that there exists a definite difference between *cis*- and *trans*-$[Co(ida)_2]^-$. The higher value found for the *cis*-isomer is probably associated with the fact that this species interacts with the solvent more strongly than does the *trans*-isomer, evidently as a result of the permanent dipole moment associated with the *cis*-configuration.

The viscosity *B*-values for the edta- and cydta-chelates have been reported by Charles[7] and by one of the present authors[2] respectively. The order of the *B*-values for each divalent metal is as follows:

$$[M(ida)_2]^{2-} < [M(mida)_2]^{2-} \sim [Medta]^{2-} < [Mcydta]^{2-}$$

This meets our expectations. Now, it may be noted that the bis(mida)-chelates have very much the same values as the corresponding edta-chelates. While the edta-chelates have an enforced *cis*(*N*)-configuration about the metal, the mida-chelates probably have the *trans*-configuration. Therefore, it may be supposed that each mida-chelate has a lower *B*-coefficient than the corresponding edta-chelate, because the $edta^{4-}$ anion is practically equivalent to two anions of $mida^{2-}$ from the standpoint of molecular size. Therefore, the equality in *B*-values between the edta- and bis(mida)-chelates might be explained as follows; for the divalent metal chelates, which are much less stable than the corresponding Co(III)-chelate, there is not so large a difference in *B*-values between the *cis*- and *trans*-configurations, or the special stability of the edta-complex, compared with that of the mida-complex, plays a part, or some other factors, for example, the geometric configuration, are related to it. In connection with the second point mentioned above, metals with a greater affinity for the ligand generally form chelates with smaller *B*-values, as has been reported previously.[2] This applies also to the ida- and mida-chelates, as may be seen from Fig. 2; the ordinates are the *B*-values of

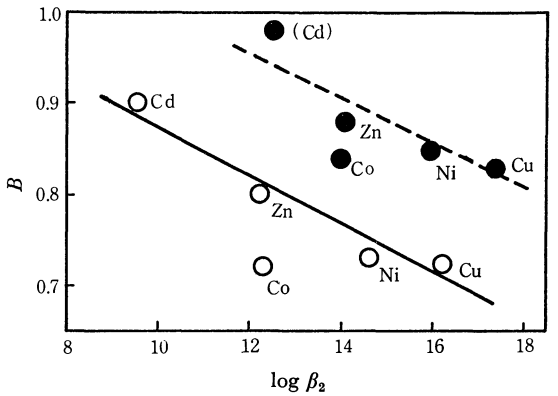

Fig. 2. Relation between the *B*-coefficient and the stability constant β_2: —○— ida-complex, —●— mida-complex.

7) R. G. Charles, *J. Amer. Chem. Soc.*, **78**, 3946 (1956).

the ida- or mida-chelates,[8] and the abscissas are the stability constants of these chelates.[9]

Finally, the *B*-coefficients of the Co(III) chelates will be discussed. The Co(III)-mida chelate, *trans*-K[Co(mida)$_2$], was prepared in a fashion analogous to that used for the *trans*-ida chelate, using an appropriate amount of H_2mida. However, its low solubility did not allow viscosity measurements. The *B*-values of the Co(III)-ida chelates are much lower than that of any of the divalent metal ida-chelates studied, as in the cases of the edta- and cydta-chelates. The solution of the *cis*-isomer showed no appreciable change in viscosity for at least 24 hr; thereafter the viscosity gradually decreased, probably because of the conversion of the *cis*- to the *trans*-configuration. It was unexpected that Co(III)-ida chelates have higher *B*-values than the Co(III)-edta chelate. This cannot be explained esaily, but we consider, at present, that the smaller *B*-value of the Co(III)-edta chelate might be caused by the extraordinary stability of the chelate, because chelates having higher stability constants have, in general, lower *B*-values, as has been mentioned above.

8) The *B*-value of the $[Cd(mida)_2]^{2-}$ anion (and also of $[Pb(mida)_2]^{2-}$) was not obtained because of its low solubility. Hence the value of $[Cdedta]^{2-}$ is plotted instead in Fig. 2, because $[M(mida)_2]^{2-}$ and $[Medta]^{2-}$ have very much the same *B*-coefficients for the divalent metal chelates studied.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 159—162 (1973)

The Absolute Configuration of the $(-)_{589}$-Oxalatobis(ethylenediamine)-cobalt(III) Ion as Determined by X-Ray Structure Analysis

Tadashi AOKI, Keiji MATSUMOTO, Shun'ichiro OOI, and Hisao KUROYA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received May 29, 1972)

The absolute configuration of $(-)_{589}$-[Co ox en_2]$^+$ has been determined by the X-ray diffraction method. The crystals of $(-)_{589}$-[Co ox en_2]Br·H_2O are orthorhombic, with the space group $P2_12_12_1$, and the unit cell dimensions are: $a=16.67(1)$Å, $b=12.40(1)$Å, $c=6.183(7)$Å, and $Z=4$. The crystal structure was solved by the conventional Patterson and Fourier methods, and refined by the least-squares procedure to an R factor of 9.97%. The cobalt atom has an octahedral coordination, being chelated by an oxalate anion and two ethylenediamine molecules which are of the *ob-lel* conformation. The absolute configuration of the complex cation can be denoted as $\Delta(\delta\lambda)$.

In previous papers, the crystal structures of $(+)_{589}$-[$CoCl_2en_2$]Cl·H_2O[1] and $(+)_{589}$-[$Co(CN)_2en_2$]Cl·H_2O[2] have been reported. The absolute configurations of the complex cations in these compounds are consistent with those assigned spectroscopically.[3-7] As a part of our X-ray studies of the absolute configurations of cobalt(III) complexes with C_2-symmetry, we have now determined the absolute crystal structure of $(-)_{589}$-[Co ox en_2]Br·H_2O (ox=oxalate anion).[8]

Experimental

The red plate-like crystals of $(-)_{589}$-[Co ox en_2]Br·H_2O were kindly provided by Dr. Jinsai Hidaka of Osaka University.

The unit cell dimensions were obtained by the least-squares refinement, using the θ values from zero-layer Weissenberg photographs on which powder lines of sodium chloride were super-imposed for calibration.

The crystal data are: FW=365.0; orthorhombic, $a=16.67(1)$Å, $b=12.40(1)$Å, $c=6.183(7)$Å; $Z=4$, $\mu=79.4$ cm^{-1} (for Ni$K\alpha$); space group $P2_12_12_1$ from systematic absences.

The intensities were estimated visually from the Weissenberg photographs of the $hk0$—$hk3$ and $h0l$—$h6l$ layers taken by means of the multiple-film and equi-inclination techniques. After they had been corrected for the Lp-factor, spot-shape,[9] and absorption, they were placed on a common arbitrary scale by internal correlation. A total of 1185 reflections were obtained; however, 91 of these were too weak to be observed and were assumed to be zero. The crystal specimens used for the data collection were cylinders 0.35 mm in diameter, the cylindrical axes being parallel to the b and c axes respectively.

Determination of the Crystal Structure

The initial coordinates for the cobalt and bromine atoms were deduced from a three-dimensional Patterson function. From the first Fourier synthesis phased on

a) In order to represent the correct absolute configuration, the atomic coordinates in Table 1 should be set up in the left-handed system.

these two heavy atoms, all the non-hydrogen atoms were located. The structure was initially refined by four cycles of block-diagonal-matrix least-squares to an R factor of 12%, with an assumption of isotropic temperature factors, equal weights being employed for all reflections. The function minimized was $\sum w(|F_o|-|F_c|)^2$.

In the subsequent refinement, anisotropic thermal parameters were used. The weighting scheme employed was as follows:

$$w = 0.3 \quad \text{for } F_o < 6.1$$
$$w = 1.0 \quad \text{for } 30.6 \geq F_o \geq 6.1$$
$$w = 30.6/F_o \quad \text{for } F_o > 30.6$$

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[10] The real part of the dispersion correction was applied for the cobalt atom.[11] The three cycles of the least-squares calculation improved the R factor to 9.97%. In the last cycle, the shifts in the atomic coordinates were less than $(1/10)\sigma$ for heavy atoms and less than $(1/8)\sigma$ for light atoms. A difference synthesis of the electron density computed at this stage confirmed the crystal structure, though no peaks corresponding to any of the hydrogen atoms were yielded. The final atomic coordinates, the temperature factors, and their e.s.d.'s are given in Table 1. A complete list of the calculated and observed structure factors is preserved by the Chemical Society of Japan.[12]

In order to determine the absolute configuration of the complex cation, the oscillation photographs were taken with Cu$K\alpha$ radiation about the c axis. Some

Bijvoet pairs, indicative of appreciable anomalous intensity differences, are listed in Table 2, together with the observed inequality relationships. The right-handed coordinate system for the reciprocal lattice was carefully used throughout the present work. The values of F_c^2 shown in Table 2 were calculated on the basis of the set of atomic coordinates given in Table 1. A comparison of the observed inequality relationships with the calculated ones indicates that the model used in the calculations is a mirror image of the absolute structure of the crystal.

Discussion

The crystal structure viewed along the c axis is shown in Fig. 1. The crystal is composed of $(-)_{589}$-[Co ox en_2]$^+$ complex cations, bromide anions, and water molecules, these being held together mainly by ionic forces. The hydrogen bonds are summarized in Table 3. One of the hydrogen atoms in the NH_2 groups involving N_1, N_2, and N_3, and both of the H atoms

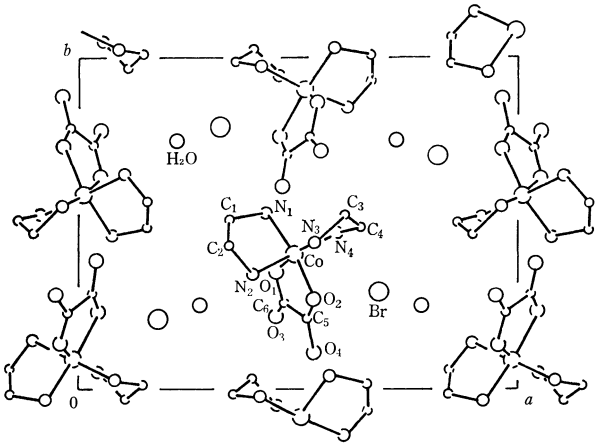

Fig. 1. The structure viewed along the *c* axis.

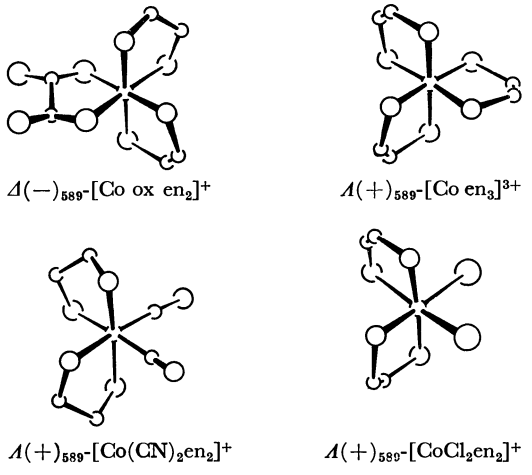
TABLE 3. POSSIBLE N-H···B HYDROGEN BONDS

The positions of the hydrogen atoms in the NH_2 groups were calculated on the assumption that the N-H bond length is 1.03Å.

N···B		N···B	H···B	∠N-H-B
N_1	$O(1-x, 1/2+y, 1/2-z)$	2.92Å	2.01Å	146°
N_2	$H_2O(1/2-x, 1-y, 1/2+z)$	3.01	2.02	160
N_3	Br	3.41	2.47	151
N_4	Br	3.47	2.46	167
N_4	$O_3(1-x,1/2+y, 1/2-z)$	3.02	2.11	146
Br	$H_2O(1-x, -1/2+y, 1/2-z)$	3.44		

linked to N_4, participate in the hydrogen bonding, in which the oxygen atom ($O_{(H_2O)}$) or $O_{(C=O)}$) or the bromide ion takes part as the base of the hydrogen bonds. Similarly, one of the water hydrogen atoms participates in the O-H—Br^- hydrogen bond, while the other appears to remain indifferent to any hydrogen bonding.



$\Delta(-)_{589}$-[Co ox en_2]$^+$ $\Delta(+)_{589}$-[Co en_3]$^{3+}$

$\Delta(+)_{589}$-[$Co(CN)_2en_2$]$^+$ $\Delta(+)_{589}$-[$CoCl_2en_2$]$^+$

Fig. 2. The absolute configurations of the complex ions.

The absolute configuration of the complex ion is depicted in Fig. 2. It is in accordance with that assigned before by several workers[3-7] and should be denoted as $\Delta(\delta\lambda)$. In the figure, the absolute configurations of $(+)_{589}$-[$Co(CN)_2en_2$]$^+$,[2] $(+)_{589}$-[$CoCl_2en_2$]$^+$,[1] and $(+)_{589}$-[Co en_3]$^{3+}$ [13] are also shown as references. The oxalate ion is planar, while the ethylenediamine molecules assume the "gauche" form and are disposed in the conformation of the *ob-lel* type.

By analogy with the trisethylenediamine complex,[14] the intramolecular potential energy of the bisethylenediamine complex increases in the order of *lel-lel*<*ob-lel*<*ob-ob*.[15] However, since the potential energy difference between the least stable and the most stable conformers may be about 0.2 kcal/mol in the case of [Co ox en_2]$^+$,[16] this complex could more readily assume less stable conformations than in the case of the trisethylenediamine complex. Although the hydrogen bonds in which the hydrogen atoms of NH_2 groups participate play an important role in stabilizing the

14) E. J. Corey and J. C. Bailar, Jr., *J. Amer. Chem. Soc.*, **81**, 2620 (1959).

15) In this paper we have discussed the relative instability of the respective conformer of bisethylenediamine complex on the basis of the instability order *lel-lel-lel*<*ob-lel-lel*<*ob-ob-lel*<*ob-ob-ob*, for trisethylenediamine complex given by Corey and Bailar. However, Hawkins *et al.* have recently pointed out that this instability order should be revised to *lel-lel-lel*≃*ob-lel-lel*<*ob-ob-lel*<*ob-ob-ob* (*Inorg. Chem.*, **9**, 576 (1969)).

16) F. P. Dwyer, T. E. McDermott, and A. M. Sargeson, *J. Amer. Chem. Soc.*, **85**, 661 (1963).

less stable conformers of $[Cr\ en_3]^{3+}$,[17] this is not likely to be the case for the bisethylenediamine complex, as has been stated elsewhere.[1,2] Thus, the specific conformation of the bisethylenediamine complex might be mainly due to the crystal packing.

The projections and elevations of the three chelate rings are illustrated in Fig. 3. Although the oxalate chelate ring is nearly planar, the (O_1, C_6, O_3) plane is slant against the (O_2, C_5, O_4) plane by 4.3°, which is considerably less than the value (17°, on average) found in $K_2[Cu\ ox_2]\cdot 2H_2O$.[18] The plane of the oxalate ion is bent away from the (Co, O_1, O_2) plane by 6.4°. Probably this also comes from the crystal packing. The bond length of C_5–C_6 (1.60 Å) is considerably longer than that for the usual $C(sp^2)$–$C(sp^2)$ but it is comparable to that found in $K_2C_2O_4\cdot 2H_2O$ (1.573 Å).[19] In each of the two ethylenediamine chelate rings, one carbon atom is disposed above, and the other, below, the plane defined by the cobalt and two nitrogen atoms. The bond lengths and angles within the chelate rings are quite normal (Table 4).

The authors wish to express their thanks to Mr. Ken Hirotsu and Mr. Masayuki Hinamoto, who adapted the HBLS-4 and the RSSFR-3 computer programs to the FACOM 270-30 computer at Osaka City University. Studies on Actinoid Elements. V. The Determination of the Np(V)/Np(IV) Ratio in an Aqueous Solution by Means of the Partition Method

Akira OHYOSHI and Tsuneo KAWAMURA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto

(Received May 31, 1972)

The distribution study of neptunium ions in an aqueous solution containing Np(IV) and Np(V) was made using the metal chelate extraction system, TTA-benzene, or HDEHP-benzene at room temperature. The results obtained by this method were then compared with those obtained by spectrophotometry. In each system, a linear relationship was obtained between the fraction of the Np(V) ion and $1/(D+1)$, where D is the distribution ratio of neptunium. This analysis was performed with an accuracy of $\pm 5\%$ and was established within one minute in the case of the HDEHP-benzene system. The results obtained by this method were in good agreement with those obtained by spectrophotometry.

When a solution contains metal ions of different oxidation states, its composition is usually determined by spectrophotometry, potentiometry, *etc.* However, these methods, in which an appreciable concentration of the sample is required for measurement, appear not to be suitable for a nuclide like ^{239}Np, which is difficult to supply in so great a quantity which is difficult to handle because of its radioactivity.

In this experiment, we have attempted to use a radiochemical method, *i.e.*, a liquid-liquid partition of Np(IV) and Np(V) ions, to determine the oxidation state of neptunium.

Experimental

Reagents. Neptunium-237 oxide obtained from the Radiochemical Center, Amersham, was dissolved in nitric acid. The solution was then evaporated to dryness, and the residue was dissolved in 0.1M hydrochloric acid. This solution served as the stock solution of neptunium. The neptunium-239 was prepared from neutron-irradiated uranium dioxide by the thenoyltrifluoroacetone(TTA) extraction method.[1,2] The radiochemical purities of ^{237}Np and ^{239}Np were confirmed by studying the γ-ray spectra with a $2''\phi \times 2''$ NaI(Tl) detector connected to a TMC 400-channel pulse-height analyzer. The chemical purity of ^{237}Np was also checked by spectrophotometry. The tributyl phosphate (TBP) and di(ethylhexyl)phosphoric acid (HDEHP) were purified from commercial chemicals by the usual method.[3,4] The other reagents used were of a G.R. grade.

The sample solution of tetravalent neptunium-239 was prepared by a TTA-extraction method,[2,5,6] and by oxidizing this solution with a warm perchloric acid solution, the neptunium-239 was changed to the pentavalent state. Both sample solutions were freshly prepared before each experiment.

Apparatus. The γ-activity of the neptunium-239 was measured with a $5''\phi \times 5''$ well-type NaI(Tl) scintillation counter. A Hitachi EPS-2U spectrophotometer was used to determine the absorption spectra of the neptunium-237. The sample (about 1 ml) was transferred into a quartz cell with a 1 cm path length. A Hitachi-Horiba pH meter, model M-5, was used for the pH measurement.

Procedures. *Liquid-liquid Partition Study*: After 4 ml of 1.0M perchloric acid and a 0.5M TTA benzene solution (4 ml) or a 0.16M HDEHP benzene solution (4 ml) had been transferred into the centrifuge tubes, sample solutions (50 μl each) of different Np(V)/Np(IV) ratios were added to the mixture. The air in the tubes was displaced with nitrogen gas. Then the tubes were shaken mechanically for 10 min at room temperature because it was already known by preliminary experiments that this period was sufficient to equilibrate the partition of Np(IV) and Np(V) ions. In the case of the 0.16M HDEHP/benzene extraction system, since the pre-equilibration was made between the organic and aqueous phases, the partition was accomplished within 1 min. After the shaking and the centrifugation, an aliquot (2 ml) of each phase was transferred into a polyethylene tube and the γ-activity was measured in order to determine the distribution ratio, D. The hydrogen-ion concentration of the aqueous phase was determined by a titration method after the γ-activity measurements.

Spectrophotometry and Partition Study. In the course of the reduction reaction, the changes in the oxidation states were simultaneously measured by spectrophotometry and the partition method. Into a spectrophotometer cell containing a solution of citric acid and pentavalent neptunium, a pentavalent neptunium-239 solution was added. The mixture was then irradiated with the light of a tungsten lamp, and the cell was kept in a thermostat maintained at 20°C. The reactions were followed at the same time by spectrophotometry and by radiometry, with a partition between 0.16M HDEHP/benzene and the 1.0M perchloric acid solution.

Results and Discussion

Calculation of the Neptunium(V) Fraction from the Partition Data. As is already known, in a liquid-liquid partition system of neptunium species, the distribution ratio, D, is represented by Eq. (1):

$$D = [\mathrm{Np}]_{org}/[\mathrm{Np}]_{aq} = \frac{\gamma\text{-activity of } ^{239}\mathrm{Np/ml \text{ of organic phase}}}{\gamma\text{-activity of } ^{239}\mathrm{Np/ml \text{ of aqueous phase}}} \quad (1)$$

The fraction of pentavalent neptunium, X, is expressed as follows:

$$X = \frac{[\mathrm{Np(V)}]}{[\mathrm{Np(IV)}]+[\mathrm{Np(V)}]} \quad (2)$$

If we assume that there is no change in the oxidation states of neptunium in the extraction procedure, the net distribution ratio can be defined as follows:

$$D = \frac{[\mathrm{Np(IV)}]_{org}+[\mathrm{Np(V)}]_{org}}{[\mathrm{Np(IV)}]_{aq}+[\mathrm{Np(V)}]_{aq}} \quad (3)$$

The distribution ratios of the respective neptunium species are:

$$D^{IV} = [\mathrm{Np(IV)}]_{org}/[\mathrm{Np(IV)}]_{aq} \quad (4)$$

$$D^{V} = [\mathrm{Np(V)}]_{org}/[\mathrm{Np(V)}]_{aq} \quad (5)$$

A new function, Y, is defined by the following equation:

$$Y = 1/(1+D) \quad (6)$$

The material balance equation can be thus expressed concerning the pentavalent neptunium:

$$[\mathrm{Np(V)}]_{aq} + [\mathrm{Np(V)}]_{org} = [\mathrm{Np(V)}] \quad (7)$$

By introducing Eq. (5) into Eq. (7), Equation (8) is obtained:

$$[\mathrm{Np(V)}]_{aq} = 1/(1+D^{V})\cdot X/(1-X)\{[\mathrm{Np(IV)}]_{aq} + [\mathrm{Np(IV)}]_{org}\} \quad (8)$$

From Equations (3), (4), and (8), Eqs. (9) and (10) are obtained:

$$1/D = 1/D^{IV}\{1+(1+D^{IV})/(1+D^{V})\cdot X/(1-X)\} \quad (9)$$

$$1 + D = (1+D^{IV})\{(1+D^{V})-D^{V}X\}/\{(1+D^{V}) + (D^{IV}-D^{V})X\} \quad (10)$$

Since the $D^{V}X$ term is sufficiently small compared to unity, Equation (10) can be simplified and the Y function can be expressed as follows:

$$Y = 1/(1+D^{IV}) + [(D^{IV}-D^{V})/(1+D^{IV})(1+D^{V})]\cdot X \quad (11)$$

When the partition process is performed under constant experimental conditions, the distribution ratios, D^{IV} and D^{V}, are both constant; therefore, it can be expected that Y can be expressed as a linear function of X.

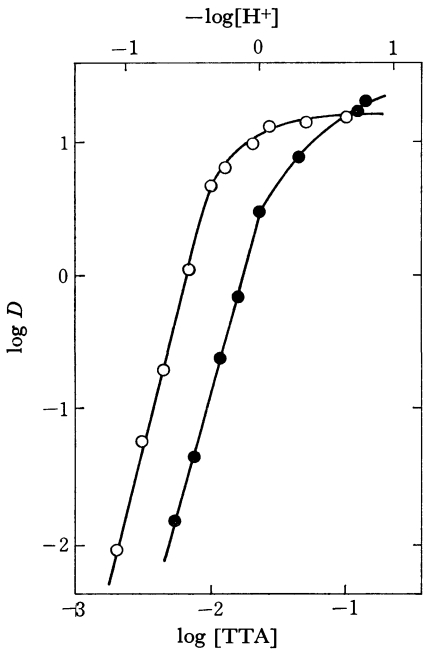

Fig. 1. Plots of log D *vs.* −log[H+] (●) and log D *vs.* log-[TTA] (○).

The Confirmation of the Valency State of the Neptunium Ion in the Sample Solution. The TTA extraction of the tetravalent neptunium ion was carried out in order to verify its valency state in a perchloric acid solution. The effect of the hydrogen ion concentration on the extraction was examined by using a 0.05M TTA benzene solution. As Fig. 1 shows, the relationship between log D and −log [H+] is linear, with a slope of 3.8, over the −log [H+] range from −0.6 to 0.0. The relationship between the TTA concentration and the distribution ratio was examined in 0.1M perchloric acid. As is shown in Fig. 1, the log-log plot of the distribution

Table 1. Distribution ratio of ^{239}Np for sample solution (D) and tetravalent state (D^{IV})

Partition system	Distribution ratio	
	D	D^{IV}
0.16M HDEHP -1M $HClO_4$	0.01±0.01	4.2±0.2
0.5M TTA -1M $HClO_4$	0.001±0.001	55 ±4

ratio and the TTA concentration shows a good linearity, with a slope of 4.0, over the TTA concentration range from 0.002 to 0.01M. These results indicate that the neptunium ion is tetravalent during the procedures.

The pentavalent neptunium ion was also confirmed by the partition method. The distribution ratio of ^{239}Np in the sample solution was measured with 0.16M HDEHP/benzene and 0.5M TTA/benzene *vs.* a 1M perchloric acid solution. The results obtained are given in Table 1, where the distribution ratios of Np(IV), D^{IV} are also shown as examples. These are mean values for three measurements. The differences between D^{IV} and D, 4×10^2 and 5×10^4, show that the neptunium exists in the form of an unextractable species. Since the hexavalent neptunium is extractable from the highly acidic solution,[1] the neptunium in the sample solution indicating such small D values may be considered to be in a pentavalent state, NpO_2^+.

The Rate of the Partition of Neptunium Ions. The partition rate of the neptunium ion between two phases may depend on various experimental conditions, such as the contact time, the way of shaking and the extracting reagent. Tests were made for tetra- and pentavalent neptunium ions using the two kinds of extractants, 0.50M TTA/benzene and 0.16M HDEHP/benzene, under constant shaking conditions and at a constant temperature. Same typical results are presented in Fig. 2. In the case of the TTA system, the partition was fairly rapid and gave reproducible data, while in the case of the HDEHP system, a pre-equilibration was necessary between an organic and an aqueous phase because the partition rate was appreciably small and the observed D value was not reproducible. As the contact time, 1 and 10 min were selected for the HDEHP and TTA systems respectively.

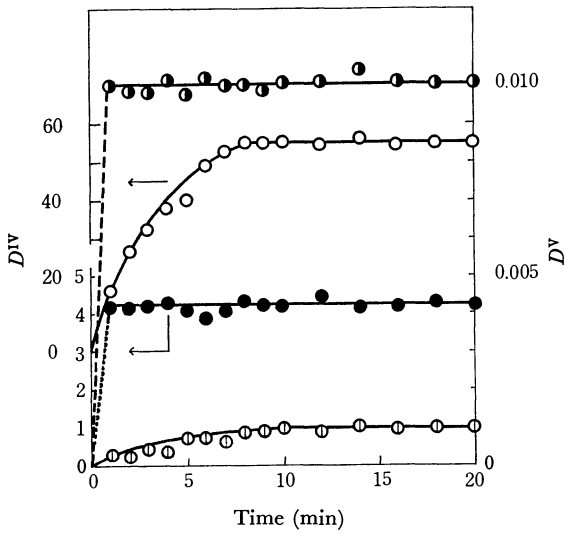

Fig. 2. The plot of D^{IV} or D^{V} *vs.* extraction time.
D^{IV}: ○ TTA, ● HDEHP, D^{V}: ◐ TTA, ◑ HDEHP

Determination of the Pentavalent Neptunium Fraction, X, from the Partition Data. The results are shown in Figs. 3 (TTA-benzene system) and 4 (HDEHP-benzene system) as plots of Y *versus* X. As has been expected, the plots indicate a good linear relationship between Y and X in both cases. However, it was found that the air on the extractant should be removed because the oxygen caused a transformation from Np(IV) to Np(V) during the shaking for 10 min, as is indicated by the closed circles in Fig. 3. On the other hand, since the shaking time is only one minute for the HDEHP system, the variation between the two oxidation states might be sufficiently small,

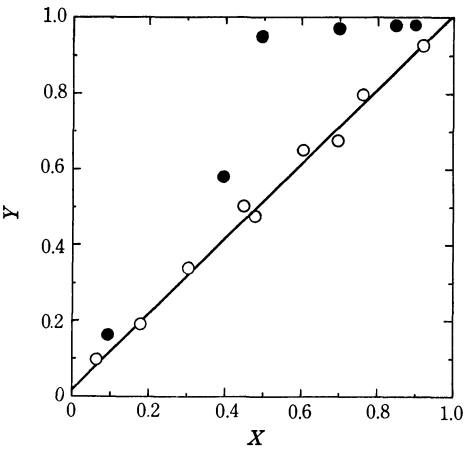

Fig. 3. The plot of $Y=1/1+D$ *vs.* X for TTA/benzene perchloric acid system.
○: Air replaced, ●: Unreplaced.

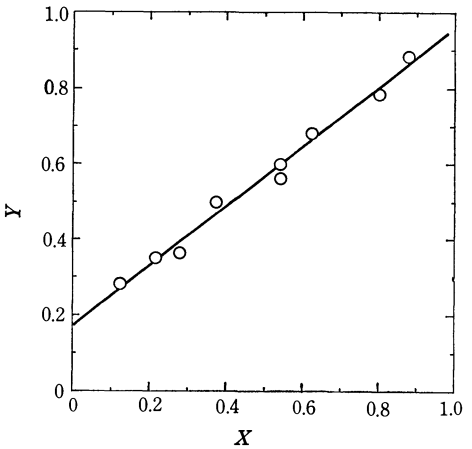

Fig. 4. The plot of $Y=1/1+D$ *vs.* X for HDEHP/benzene perchloric acid system.

The empirical equations were determined by a least-squares method as follows:

$Y=(0.015\pm0.003)+(0.983\pm0.001)\cdot X$; 0.50M TTA-benzene/1.0M $HClO_4$

$Y=(0.18\pm0.01)\pm(0.78\pm0.01)\cdot X$; 0.16M HDEHP-benzene/1.0M $HClO_4$.

Comparison of the Results from Two Different Analyses of Neptunium Ions. The spectrophotometry of neptu-

○: Spectrophotometry, ●: Partition method.

nium ions was carried out in order to compare the results with those from the partition method in the course of the kinetic run. A photochemical reduction of pentavalent neptunium ions was employed in this attempt. A mixture of $^{237}NpO_2^+$, $^{239}NpO_2^+$, and citrate ions was placed under the tungsten lamp and irradiated by visible light. The reduction of NpO_2^+ then proceeded *via* some photochemical processes. The details of this reaction will be reported elsewhere.

The changes in the absorbance due to the neptunium-237 and the changes in the distribution ratio of the neptunium-239 in the reacting solution were simultaneously measured at appropriate intervals.

Figure 5 shows the changes in the absorption spectra of neptunium with the reaction time during the course of reduction; the absorbances at 617 and 980 mμ corresponding to Np(V) decrease, while those at 723 and 960 mμ corresponding to Np(IV) simultaneously increase. The logarithmic plots of the Np(V) fraction *versus* the reaction time are shown in Fig. 6, using the data from spectrophotometry (○) and those from the partition method (●). This figure, where the open circles and the closed circles are observed on the same line, confirms that the results from these two methods are essentially the same. From the good linear relationship obtained, the reaction can be said to obey first-order kinetics.

Thus, the partition method can be used to determine the pentavalent neptunium fraction in a mixture of Np(V) and Np(IV) ions, especially when their concentrations are in a tracer scale. Furthermore, it may be used in studying the kinetics of a reaction between penta- and tetravalent neptunium ions.

The Ultraviolet Absorption Spectra and Hydrolysis of Bis(acetylacetonato)nickel(II) in Dichloromethane

Kiyoshi ISOBE, Yukio NAKAMURA, and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received June 2, 1972)

The ultraviolet spectrum of $Ni(acac)_2$ in dichloromethane shows two maxima, at 265 and at 300 nm. The intensity ratio of these two bands is very sensitive to the water content of the solvent, the high-energy band decreasing and the low-energy band increasing with the water content. It is thus suggested that the trimeric $Ni(acac)_2$ might have only one absorption band, at 265 nm, in dichloromethane completely free from donor impurities. The UV spectrum of $Ni(acac)_2$ in dichloromethane changes with time due to the hydrolytic reaction. Even in the solvent containing 4.54×10^{-3}M water, acetylacetone was freed from the complex in the yield of 34.4% after 48 hours' standing. A minute amount of the residual complex was isolated; its tetrameric structure is suggested on the basis of its UV spectrum in methanol.

The ultraviolet spectra of thirty-one metal acetylacetonates were measured by Holm and Cotton[1] in chloroform and/or absolute ethanol in the 240—400 nm region, and were grouped into three classes. Bis(acetylacetonato)nickel(II) is present in ethanol entirely as the solvated species $Ni(acac)_2\cdot2EtOH$, and shows an absorption maximum at 294 nm ($\varepsilon=23700M^{-1}cm^{-1}$), accompanied by a shoulder on the longer-wavelength side. Similar absorption spectra were also observed for all other metal complexes except Cu(II), Fe(III), Co(III), Cr(III), and alkali metal acetylacetonates,[1] and are thought to be due to a π-π^* type transition.[2]

In chloroform, however, $Ni(acac)_2$ exhibits a very different spectrum than that in ethanol, having two maxima at 265 nm ($\varepsilon=15200$) and at 296 nm ($\varepsilon=12400$).[1] It is well established that $Ni(acac)_2$ exists as an octahedral trimer in crystals[3] and also in non-coordinating solvents.[4] The anomalous spectrum found in chloroform was explained by Cotton and Fackler[5] as due to the presence of both nonbridging and bridging chelate rings in the trimer. The former were presumed to give rise to the low-energy band at nearly the same wavelength as that of the absorption band observed in alcohol. On the other hand, the latter bridging rings were thought to cause the high-energy band, which disappears in donor solvents because of the depolymerization of the trimer.

In the course of our investigation of the reaction of $Ni(acac)_2$ with dry hydrogen bromide in dichloromethane,[6] the ultraviolet spectra of $Ni(acac)_2$ and other related compounds have been carefully examined. In this paper we will report the results we have obtained, which are different from those of Cotton and his co-workers.[1,5]

Experimental

Preparation of Complexes. *Anhydrous bis(acetyacetonato)-nikel(II), Ni(acac)$_2$*: Bis(acetylacetonato)diaquonickel(II) was prepared according to the Charles method,[7] recrystallized three times from methanol, and dehydrated by heating at 100°C *in vacuo* for 4 hr (Found: Ni, 22.82; C, 46.23; H, 5.54%).

Bis(acetylacetonato)dimethanolnickel(II), Ni(acac)$_2$(CH$_3$OH)$_2$: $Ni(acac)_2$ (2 g) was dissolved in 100 ml of light petroleum, and the mixture was refluxed for 30 min. To this solution we then added 30 ml of dry methanol and refluxed it for 30 min. The solution was then evaporated to about 40 ml and kept in a desiccator at room temperature. Sky-blue crystals were thus obtained. Found: Ni, 18.21; C, 44.43; H, 6.95%. Calcd for $C_{12}H_{22}O_6Ni$: Ni, 18.29; C, 44.90; H, 6.91%.

Bis(acetylacetonato)bis(pyridine)nickel(II), Ni(acac)$_2$py$_2$: Following the method of Hashagen and Fackler,[8] the direct reaction of $Ni(acac)_2$ with pyridine was conducted to obtain $Ni(acac)_2py_2$. Found: Ni, 14.46; C, 57.59; H, 5.87; N, 7.02%. Calcd for $C_{20}H_{24}N_2O_4Ni$: Ni, 14.14; C, 57.81; H, 5.78; N, 6.74%.

Tetrameric Complex [Ni(acac)(OCH$_3$)(CH$_3$OH)]$_4$: This compound was prepared according to the directions of Bertrand and Caine.[9] Found: Ni, 26.54; C, 37.53; H, 6.58%. Calcd for $C_7H_{14}O_4Ni$: Ni, 26.59; C, 38.58; H, 6.48%.

Presumably Tetrameric Complex Ni(acac)(OH)(H$_2$O)$_2$: $Ni(acac)_2(H_2O)_2$ (3 g, 1.02×10^{-2} mol) was dissolved in 300 ml of water, and to the mixture we added an aqueous solution (300 ml) of KOH (0.56 g, 1.00×10^{-2} mol); the resulting precipitate was separated and dried. Found: Ni, 28.35; C, 27.53; H, 5.61%. Calcd for $C_5H_{12}O_5Ni$: Ni, 27.84; C, 28.48; H, 5.74%.

Purification of Solvents. Dichloromethane and methanol were purified and dried by the standard methods.[10] The water contents of the dried solvents were determined by the Karl Fischer method to be 4.54×10^{-3} and 2.6×10^{-3}M respectively. Appropriate amounts of water was added to prepare solvents of various water contents up to 0.12M and 0.3M respectively.

Measurements. The ultraviolet absorption spectra were measured at room temperature on a Hitachi recording spectrophotometer, EPS-3T, using 1-cm quartz cells in the 210—

340 nm region. Freshly-distilled solvents were used to prepare $\sim 10^{-5}$ M solutions. The molar absorption coefficients of polymeric complexes are expressed on the basis of the gram-atom of nickel(II).

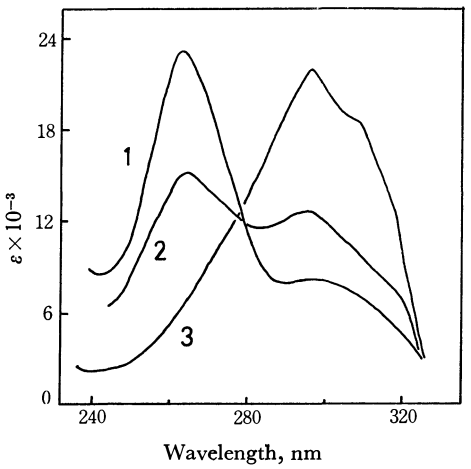

Fig. 1. Ultraviolet spectra of bis(acetylacetonato)nickel(II) in dichloromethane (curve 1), in chloroform (curve 2, ref. 5) and in methanol (curve 3).

Results and Discussion

Ultraviolet Spectra of $Ni(acac)_2$. Curve 1 in Fig. 1 represents the absorption spectrum of $Ni(acac)_2$, which was measured before 10 min after dissolution in dichloromethane containing 4.54×10^{-3}M water. The spectrum is very different from Curve 2 determined by Cotton and Fackler[5] in chloroform. The high-energy band at 265 nm is much larger (ε=23650), and the low-energy band at 300 nm is much smaller (ε=8450). This discrepancy is due not to the nature of the solvent employed, but to the difference in the water content. The peak-height ratio of the 265 and 300 nm bands decreases as the water content of dichloromethane is increased. The spectra of $Ni(acac)_2$ in dichloromethane containing 8.0×10^{-3}M water or 1.2×10^{-2}M methanol are quite similar to Curve 2 in Fig. 1. On the other hand, the peak-height ratio of the two absorption bands became even larger when dichloromethane was dried over calcium hydride for 2 days, and a $Ni(acac)_2$ solution was prepared in a vacuum system and measured in a sealed cell without exposure to air. It seems very probable that the low-energy band at 300 nm will not be observed for a dichloromethane solution containing no trace of water or other donor impurity. Thus, the 265 nm band may be concluded to be the only absorption by trimeric $Ni(acac)_2$ and the 300 nm band may be concluded to be caused by the donor impurity.

An aqueous solution of $Ni(acac)_2(H_2O)_2$ and a methanolic solution of $Ni(acac)_2(CH_3OH)_2$ both exhibit only one absorption maximum, at around 300 nm, with ε=21000 and 22000 respectively. In dry dichloromethane, however, both solvated complexes show the same spectra as that of the anhydrous trimer, indicating that the following trimerization equilibria are quickly attained and are favorable for the trimer under these conditions:

$$Ni(acac)_2L_2 \rightleftarrows \frac{1}{3}[Ni(acac)_2]_3 + 2L \quad (1)$$

The concentrations of the complexes, and hence of the coordinated solvents ($\sim10^{-5}$M), are nearly negligible compared to that of water ($\sim10^{-3}$M) contained *a priori* in dichloromethane. This situation seems to be the reason why $Ni(acac)_2(H_2O)_2$ and $Ni(acac)_2(CH_3OH)_2$ show no spectral difference from the anhydrous trimer. On the contrary, the spectrum of $Ni(acac)_2py_2$ in dichloromethane resembles that in methanol, showing an absorption band due to the acetylacetonate ligand only at 300 nm. It is thus certain that $Ni(acac)_2py_2$ is much more stable in dichloromethane and that Equilibrium (1) is favorable for the monomer adduct.

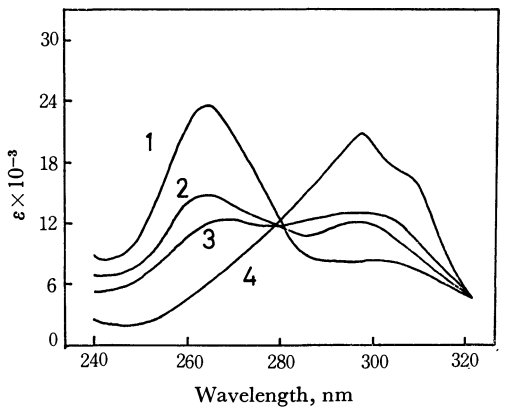

Fig. 2. Ultraviolet spectra of bis(acetylacetonato)nickel(II) in dichloromethane (curve 1), in dichloromethane containing methanol at the concentration of 1.2×10^{-2}M (curve 2) and 1.8×10^{-2}M (curve 3), and in methanol (curve 4). $[Ni(acac)_2]=1.776\times10^{-5}$M.

As is illustrated in Fig. 2, the peak-height ratio of the 265 and 300 nm bands decreases with an increase in methanol added to the dichloromethane solution of $Ni(acac)_2$, showing a gradual shift of Equilibrium (2)

$$Ni_3(acac)_6 + 6CH_3OH \rightleftarrows 3Ni(acac)_2(CH_3OH)_2 \quad (2)$$

$$K = \frac{[Ni(acac)_2(CH_3OH)_2]^3}{[Ni_3(acac)_6][CH_3OH]^6} \quad (3)$$

to the monomer side. Unfortunately, no absorption data in dichloromethane completely free from water are available, and so the determination of the equilibrium constant (3) is not possible. However, the concentrations of the trimer and the monomer are comparable, both lying in the region of 10^{-5}M when $\sim10^{-2}$M methanol is involved in dichloromethane. We can thus estimate K to be in the order of magnitude of 10^2M^{-4}.

Fackler[11] found that the reaction of bis(acetylacetonato)nickel(II) with pyridine in benzene proceeds *via* the intermediate $Ni_2(acac)_4py$, and estimated the equilibrium constants for the two steps by the spectrophotometric method:

$$2Ni_3(acac)_6 + 3py \rightleftarrows 3Ni_2(acac)_4py,$$

$$K_1 = \frac{[Ni_2(acac)_4py]^3}{[Ni_3(acac)_6]^2[py]^3} = ca.\ 10^{10}\ \text{M}^{-2}$$

11) J. P. Fackler, Jr., *J. Amer. Chem. Soc.*, **84**, 24 (1962).

$$Ni_2(acac)_4py + 3py \rightleftarrows 2Ni(acac)_2py_2,$$

$$K_2 = \frac{[Ni(acac)_2py_2]^2}{[Ni_2(acac)_4py][py]^3} = 2.7\times10^5\ M^{-2}$$

From these data, the equilibrium constant for the overall reaction (Eq. 4) is calculated to be $K=(K_1K_2^3)^{1/2}=ca.\ 10^{13}M^{-4}$:

$$Ni_3(acac)_6 + 6py \rightleftarrows 3Ni(acac)_2py_2 \qquad (4)$$

This value is very much larger than that (3) for the methanol adduct, conforming to the qualitative observation that $Ni(acac)_2py_2$ is quite stable and does not dissociate in dichloromethane.

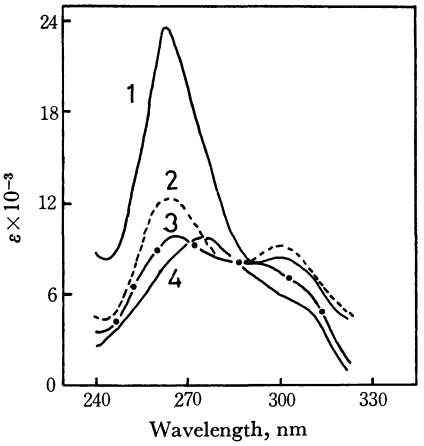

Fig. 3. Ultraviolet spectra of bis(acetylacetonato)nickel (II) in dichloromethane containing 4.54×10^{-3}M water at 10 min (curve 1), 1 hr (curve 2), 8 hr (curve 3) and 48 hr (curve 4) after dissolution.

The Hydrolysis Reaction of Ni(acac)$_2$ in Dichloromethane. Figure 3 represents the change with time of the ultraviolet spectra of $Ni(acac)_2$ in dichloromethane containing 4.54×10^{-3}M water. One hour after the dissolution, the high-energy peak was quite remarkably diminished, and it continued to decrease further with time. A new band gradually appeared in turn at 274 nm. Solutions of $Ni(acac)_2(H_2O)_2$ and $Ni(acac)_2(CH_3OH)_2$ in dry dichloromethane showed quite the same spectral change. When dichloromethane saturated with water (0.12M) was employed as the solvent, the 265 nm peak was not observed, but the 274 nm band appeared from the outset. The band position coincides with that of free acetylacetone, and suggests the occurrence of some hydrolytic reaction of $Ni(acac)_2$, thus liberating acetylacetone molecules. To confirm this possibility, a $Ni(acac)_2$ solution in dry dichloromethane was kept standing for 48 hr (Curve 4 in Fig. 3); the solvent was then distilled under reduced pressure. Acetylacetone in the distillate corresponded to 34.4% of the entire ligand.

In order to investigate the other hydrolysis product, a $Ni(acac)_2$ solution in water-saturated dichloromethane was kept standing for five days. A white, fuzzy precipitate resulted. The solvent was distilled under reduced pressure, and the residue was repeatedly washed with dichloromethane and then dried. This compound was soluble in methanol and exhibited the spectrum as shown by Curve 1 in Fig. 4. The yield of the compound was so minute that elemental analysis and other

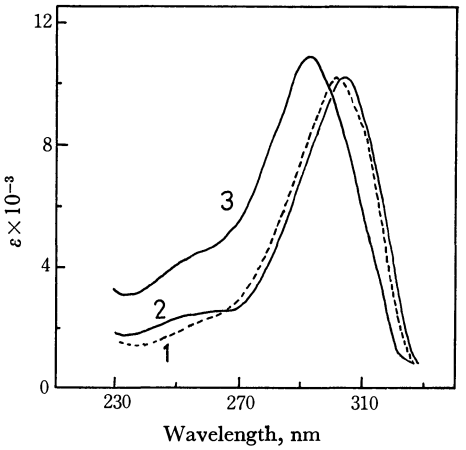

Fig. 4. Ultraviolet spectra in methanol of the hydrolysis product of bis(acetylacetonato)nickel(II) in dichloromethane (curve 1), $Ni(acac)(OH)(H_2O)_2$ (curve 2) and $[Ni(acac)(OCH_3)(CH_3OH)]_4$ (curve 3).

physical measurements were not possible, so a model compound was prepared for comparison.

Bertrand and his co-laborators synthesized a green compound $Ni(acac)(OCH_3)(CH_3OH)$ by the reaction of $Ni(acac)_2$ with equimolar potassium hydroxide in refluxing methanol.[9] The compound is tetrameric in chloroform and isostructural with $[Co(acac)(OCH_3)(CH_3OH)]_4$, which was shown by X-ray analysis to have a cubane-type structure.[12] The ultraviolet and infrared spectra of $[Ni(acac)(OCH_3)(CH_3OH)]_4$ were measured; they are shown in Figs. 4 and 5 respectively. As has been described in the Experimental section, an analogous hydroxo compound was prepared by the reaction of $Ni(acac)_2$ with potassium hydroxide in water. This compound, $Ni(acac)(OH)(H_2O)_2$, retains two molecules of solvent per nickel atom, and exhibits a very broad band in the O–H stretching region (Curve 1 in Fig. 5), a band which is sharpened by heating at

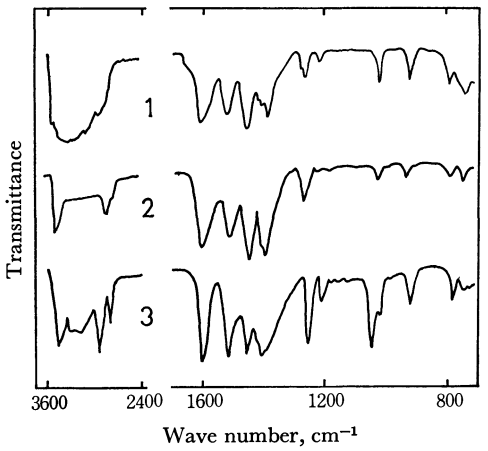

Fig. 5. Infrared spectra in Nujol (lower-frequency region) and in hexachlorobutadiene (higher-frequency region) of $Ni(acac)(OH)(H_2O)_2$ (curve 1), the same compound after heating at 100°C *in vacuo* (curve 2) and $[Ni(acac)(OCH_3)(CH_3OH)]_4$ (curve 3).

12) J. A. Bertrand, A. P. Ginsberg, R. I. Kaplan, C. E. Kirkwood, R. L. Martin, and R. C. Sherwood, *Inorg. Chem.*, **10**, 240 (1971).

100°C *in vacuo* (Curve 2 in Fig. 5). The infrared spectrum of $Ni(acac)(OH)(H_2O)_2$ bears a close resemblance to that of $[Ni(acac)(OCH_3)(CH_3OH)]_4$, and the former might also have a tetrameric structure similar to that of the latter, involving an excess H_2O molecule as the water of crystallization.

In Fig. 4 are reproduced the ultraviolet spectra of the tetrameric methoxo complex (Curve 2) and the presumably tetrameric hydroxo complex (Curve 3). They are very similar except that the latter is located in a little longer wavelength region than the former. It should be noted that the spectrum of the hydrolysis product of $Ni(acac)_2$ in dichloromethane (Curve 1) shows a striking resemblance to that of the synthesized hydroxo complex (Curve 2), suggesting an essential similarity between their structures.

If the hydrolysis of Ni $(acac)_2$ in dichloromethane proceeds according to Eq. (5), the yield of the freed acetylacetone will be 50% of the total acetylacetone contained in the starting complex. Cotton and

$$Ni_3(acac)_6 + 3nH_2O = \frac{3}{4}[Ni(acac)(OH)(H_2O)_{n-1}]_4 + 3acacH \quad (5)$$

Winquist[13] prepared a hexameric complex, $Ni_6(tfac)_{10}(OH)_2(H_2O)_2$ by drying a light green solid, presumably $Ni(tfac)_2(H_2O)_2$, at 108°C *in vacuo* for 24 hr; the solid had been obtained by a reaction between nickel(II) carbonate and trifluoroacetylacetone in refluxing benzene. If a similar hexameric complex is derived from $Ni(acac)_2$ in the present case, the yield of the freed acetylacetone will be 16.7%.

The observed yield of acetylacetone (34.4%) is higher than the value calculated for the above hexameric product (16.7%) and lower than that for the tetrameric product (50%). Although the tetrameric formulation seems preferable on the spectral basis, further detailed studies are desirable in order to establish the structure of the hydrolysis product of $Ni(acac)_2$ in dichloromethane.

The mechanism of the hydrolysis of bis(acetylacetonato)nickel(II) in dichloromethane containing more or less water is not certain as yet. However, it seems quite probable that the hydrolysis reaction of $Ni(acac)_2$ liberating an acetylacetone molecule does not proceed *via* $Ni(acac)_2(H_2O)_2$. If this is the case, the 300 nm band should rise with time at the expense of the 265 nm band. The observed results in Fig. 3 clearly obviate this possibility. Even when $Ni(acac)_2(H_2O)_2$ was dissolved in dichloromethane containing 4.54×10^{-3}M water, the spectrum was the same as that of a solution of anhydrous $Ni(acac)_2$, indicating a trimerization according to Eq. (1), and then it changed with time in the same fashion as shown in Fig. 3. Thus, the hydrolysis reaction of $Ni(acac)_2$ in question can be considered to start from the trimeric molecule.

The authors are grateful to the Ministry of Education for its financial assistance and also to the Daicel Co., Ltd. for the supply of acetylacetone.

Derivatographic Studies on Transition Metal Complexes. IX.[1] Thermal CN-Bridging Reaction of Double Complex Salts in Solid Phase[2]

Ryokichi TSUCHIYA, Shigeo NAKAGAWA,* Akira UEHARA, and Eishin KYUNO

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

**Department of Chemical Engineering, Faculty of Technology, Kanazawa University, Kanazawa*

(Received June 3, 1972)

It was found by derivatography and spectral measurements that the double complex salts, $[Co(H_2O)_2N_4][Co(CN)_6]\cdot nH_2O$, where N_4 is $4NH_3$, two moles of ethylenediamine (en) or one mole of triethylenetetramine (trien), $[Co(NH_3)_2trien][Co(CN)_6]\cdot 2H_2O$, $[Co(NH_3)tepa][Co(CN)_6]\cdot 2H_2O$, where tepa is tetraethylenepentamine, and $[Co(H_2O)_2trien][Cr(CN)_6]\cdot 2H_2O$ underwent deaquation- or deammonation-CN-bridging formation reaction upon heating. The general tendency was observed to be as follows: the more stable the structural configuration of the coordination sphere, the higher the activation energy. In the case of the complex containing hexacyanochromate(III) as an anion, the activation energy for the bridging formation reaction is especially high as a result of possible flipping in CN bridging groups.

It is known that the hexaammine or aquopentaammine complexes of transition metals such as $[M(NH_3)_6]X_3$ or $[M(H_2O)(NH_3)_5]X_3$ liberate a part of ammonia or water by deammonation- or deaquation-anation upon heating, producing the corresponding acidopentaamine complexes as expressed by the fol-

1) Part VIII in this series: see R. Tsuchiya, M. Suzuki, and E. Kyuno, This Bulletin, **45**, 3105 (1972).

2) Presented at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April (1970).

lowing reactions:

$$[M(NH_3)_6]X_3(s) \xrightarrow{\Delta} [MX(NH_3)_5]X_2(s) + NH_3(g)$$

$$[M(H_2O)(NH_3)_5]X_3(s) \xrightarrow{\Delta} [MX(NH_3)_5]X_2(s) + H_2O(g),$$

where M is Co[3-6] or Cr[6,7] and X is halogens.

Thermal bridging reaction can be expected when X in the complexes of the above types is replaced by the relevant complex anions of the type $[M'X_6]^{3-}$ containing a ligand X which can form a bridge over two metals, *i.e.*, heating of some double complex salts will give the binuclear complexes as expressed by the following reactions:

$$[MA_nB_{6-n}][M'X_6] \xrightarrow{\Delta} [B_{6-n}M\text{-}X_n\text{-}M'X_{6-n}] + nA,$$

where M and M′ are central metal atoms, A is a volatile neutral ligand, B the ligand which can not be expelled by heating, X the ligand which can form the bridge between M and M′, and n the number of ligand A contained in the starting complexes.

It can be expected that the binuclear complexes produced have one, two or three bridges between two metals in the respective cases where n is 1, 2, or 3, the coordinated atoms forming two octahedrons holding a point, an edge or a face in common, respectively, as shown in Fig. 1.

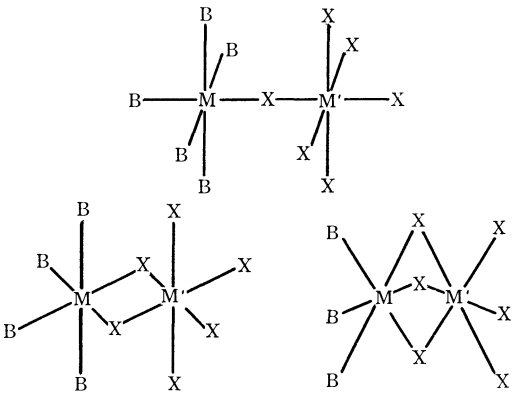

Fig. 1. Three possible types of bridged binuclear complexes.

No reports have been found on the above thermal reactions except for a study in which the complex $[(NH_3)_5Co\text{-}NC\text{-}Co(CN)_5]$ was prepared by isothermal heating and characterized by physical methods.[8]

We prepared a series of double complex salts containing water or ammonia as a volatile ligand A and CN^- as bridging group X, and examined the possibility of occurrence of these bridging formation reactions.

Experimental

Preparation of Double Complex Salts. *1)* cis-*Diaquotetraamminecobalt(III) Hexacyanocobaltate(III) Monohydrate,* cis-$[Co(H_2O)_2(NH_3)_4][Co(CN)_6]\cdot H_2O$ *(I).* To a 100 ml aqueous solution of 3.7 g of *cis*-diaquotetraamminecobalt(III) nitrate, *cis*-$[Co(H_2O)_2(NH_3)_4](NO_3)_3$,[9] a 100 ml of 3.3 g of potassium hexacyanocobaltate(III) $K_3[Co(CN)_6]$[10] was added. After a few minutes of stirring, red crystals were precipitated. After being filtered off, they were washed with water, ethanol and ether in turn and air dried.

Found: C, 18.16; H, 4.33; N, 35.89%. Calcd for $[Co(H_2O)_2(NH_3)_4][Co(CN)_6]\cdot H_2O$: C, 18.50; H, 4.66; N, 36.00%.

2) cis-*Diaquobis(ethylenediamine)cobalt(III) Hexacyanocobaltate(III) Trihydrate,* cis-$[Co(H_2O)_2en_2][Co(CN)_6]\cdot 3H_2O$ *(II).* When a solution of 4.9 g of *cis*-diaquobis(ethylenediamine)cobalt(III) bromide dihydrate, *cis*-$[Co(H_2O)_2en_2]Br_3\cdot 2H_2O$[11] in 20 ml of 1 N HNO_3 and a solution of 3.3 g of $K_3[Co(CN)_6]$ in 20 ml were mixed together and kept standing at room temperature for one day, fine red crystals were precipitated. They were treated and dried in a similar way to that described for 1).

Found: C, 24.77; H, 5.13; N, 29.13%. Calcd for $[Co(H_2O)_2en_2][Co(CN)_6]\cdot 3H_2O$: C, 24.80; H, 5.41; N, 28.91%.

3) cis-α-*Diaquotriethylenetetraminecobalt(III) Hexacyanocobaltate(III) Dihydrate,* cis-α-$[Co(H_2O)_2trien][Co(CN)_6]\cdot 2H_2O$ *(III).* The complex was obtained as pink crystals precipitated from a mixture of the two solutions, one containing 0.01 mol of *cis*-α-diaquotriethylenetetraminecobalt(III) salt, *cis*-α-$[Co(H_2O)_2trien]^{3+}$, and the other containing 3.3 g of $K_3[Co(CN)_6]$ in a similar manner to that for salt I, the former being prepared by the reaction of *cis*-α-carbonatotriethylenetetraminecobalt(III) perchlorate monohydrate, *cis*-α-$[CoCO_3trien]ClO_4\cdot H_2O$[12] (3.7 g) with 20% $HClO_4$ solution.

Found: C, 29.55; H, 5.25; N, 28.66%. Calcd for $[Co(H_2O)_2trien][Co(CN)_6]\cdot 2H_2O$: C, 29.28; H, 5.32; N, 28.45%.

4) cis-β-*Diaquotriethylenetetraminecobalt(III) Hexacyanocobaltate(III) Dihydrate,* cis-β-$[Co(H_2O)_2trien][Co(CN)_6]\cdot 2H_2O$ *(IV).* The double complex salt was prepared from 3.7 g of *cis*-β-$[CoCO_3trien]ClO_4$[12] as the starting complex cation in the same way as descrybed in 3). It was orange.

Found: C, 28.84; H, 5.13; N, 27.53%. Calcd for $[Co(H_2O)_2trien][Co(CN)_6]\cdot 2H_2O$: C, 29.28; H, 5.32; N, 28.45%

5) cis-β-*Diamminetriethylenetetraminecobalt(III) Hexacyanocobaltate(III) Dihydrate,* cis-β-$[Co(NH_3)_2trien][Co(CN)_6]\cdot 2H_2O$ *(V).* *cis*-β-diamminetriethylenetetraminecobalt(III) chloride, *cis*-β-$[Co(NH_3)_2trien]Cl_3$[13] and $K_3[Co(CN)_6]$ were used as starting materials for the preparation. The product was yellow crystals.

Found: C, 30.05; H, 5.68; N, 34.28%. Calcd for $[Co(NH_3)_2trien][Co(CN)_6]\cdot 2H_2O$: C, 29.37; H, 5.68; N, 34.28%.

6) *Amminetetraethylenepentaminecobalt(III) Hexacyanocobaltate(III) Dihydrate,*$[Co(NH_3)tepa][Co(CN)_6]\cdot 2H_2O$ *(VI).* One of the starting complexes, amminetetraethylenepentaminecobalt(III) bromide, $[Co(NH_3)tepa]Br_3$, was prepared from the corresponding bromo complex, $[CoBr\ tepa]Br_2$[14] in

liquid ammonia. The aqueous solution containing 5.0 g of $[Co(NH_3)tepa]Br_3$ was mixed with a solution of 3.3 g of $K_3[Co(CN)_6]$ and cooled with ice in a similar manner to that described above. Yellow crystals were obtained and then treated as mentioned in 1).

Found: C, 32.18; H, 5.38; N, 31.75%. Calcd for $[Co(NH_3)tepa][Co(CN)_6]\cdot 2H_2O$: C, 32.54; H, 5.85; N, 32.53%.

7) cis-α-Diaquotriethylenetetraminecobalt(III) Hexacyanochromate(III) Dihydrate, cis-α-$[Co(H_2O)_2trien][Cr(CN)_6]\cdot 2H_2O$ *(VII).* The double complex salt was prepared from 3.7 g of *cis*-α-$[CoCO_3trien]ClO_4\cdot H_2O$[12] and 3.3 g of $K_3[Cr(CN)_6]$[15] in the same way as in the case of 3). The product was pink crystals.

Found: C, 30.72; H, 5.40; N, 28.98%. Calcd for $[Co(H_2O)_2trien][Cr(CN)_6]\cdot 2H_2O$: C, 29.70; H, 5.40; N, 28.86%.

8) μ-Cyanoaquobis(ethylenediamine)pentacyanodicobalt(III,III) Pentahydrate, $[(H_2O)en_2Co\text{-}NC\text{-}Co(CN)_5]\cdot 5H_2O$ *(VIII).* When one gram of *cis*-$[Co(H_2O)_2en_2][Co(CN)_6]\cdot 3H_2O$ was stirred in 400 ml of water, the compound gradually dissolved giving orange coloration. After being kept standing at room temperature for about a day, orange needle crystals appeared, which were dried after filtration.

Found: C, 23.86; H, 5.57; N, 27.87%. Calcd for $[Co_2en_2(H_2O)(CN)_6]\cdot 5H_2O$: C, 23.80; H, 5.60; N, 27.76%.

9) μ-Dicyanotriethylenetetraminetetracyanodicobalt(III,III) Pentahydrate, $[trien\ Co\text{-}(NC)_2\text{-}Co(CN)_4]\cdot 5H_2O$ *(IX).* When one gram of *cis*-α-$[Co(H_2O)_2trien][Co(CN)_6]\cdot 2H_2O$ was suspended in 200 ml of water and heated on a water bath, the double complex salt was completely dissolved with yellow color. The solution was concentrated to about half its volume on a water bath and kept standing at room tempetature, yellow crystals being precipitated. The complex was dried in a similar manner to that described above.

Found: C, 28.49; H, 5.46; N, 27.80%. Calcd for $[Co_2trien(CN)_6]\cdot 5H_2O$: C, 28.25; H, 5.53; N, 27.45%.

Derivatographic Measurements. The derivatograms were obtained with a MOM Derivatograph Typ-OD-102. All the measurements were carried out in a constant flow of nitrogen under the heating rate of 1°C/min. 0.4 or 0.5 g of sample was used in each run. The activation energies (E_a) and enthalpy changes (ΔH) were calculated by analysis of the DTA curves in the derivatograms.

Spectral Measurements. In order to examine the structural change during the course of the thermal reaction, the electronic spectra and IR spectra were measured with a Hitachi EPS and EPU-2A Spectrophotometers in both solution and powdered state and with a JASCO Model IR-E Spectrophotometer in mull state, respectively.

Isothermal Measurements. Isothermal determination of the deaquation or deammonation accompanied by bridging reaction was carried out by use of a Shimadzu TM-1A Thermobalance in static air at the desired temperature.

Results and Discussion

Derivatography. It was found that most of the salts do not show any distinct evidence for the bridging formation in the TG curve, except for some salts. As an example, the double complex salt, $[Co(H_2O)(NH_3)_5][Co(CN)_6]$, the simplest compound anticipated to give the binuclear complex, decomposed at 190°C without giving any plateau in the TG curve suggesting the bridging formation, as shown in Fig. 2.

15) J. H. Bigelow and J. C. Bailar, Jr., "Inorganic Syntheses," Vol. 2, (1946), p. 203.

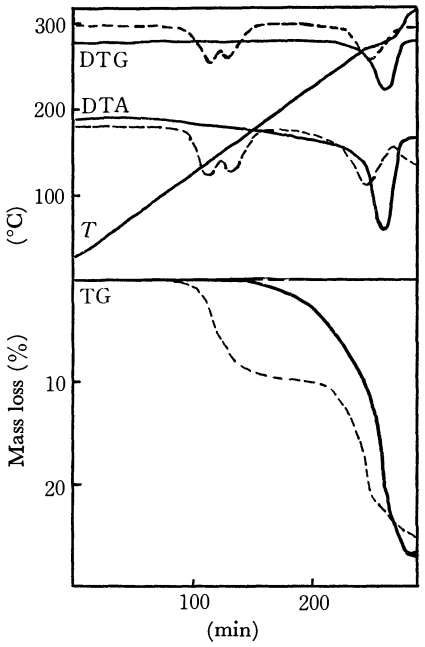

Fig. 2. Derivatograms of the double complex salts, $[Co(H_2O)(NH_3)_5][Co(CN)_6]$ (——) and I (----).

In several salts, however, distinct thermal reactions for the formation of the stable complexes containing CN bridges between two central metal atoms were found by the presence of one or two steady steps of the liberation of neutral ligands involved. The derivatograms of the diaquotetraammine-type double complex salt I, the diaquobis(ethylenediamine)-type one II. and the diaquotriethylenetetramine-type one III are shown in Figs. 2, 3, and 4, respectively.

In the double complex salt I, the DTA and DTG curves split into two peaks are observed in the temperature range 90—150°C, where the mass loss corresponding to two moles of water or to the sum of one mole of water and one mole of ammonia appears in

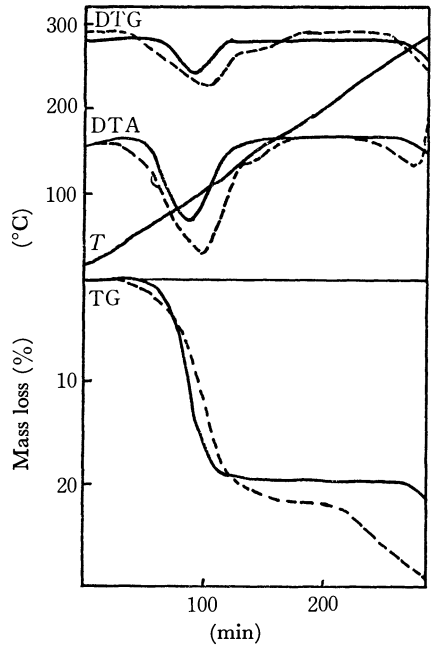

Fig. 3. Derivatograms of II (——) and VIII (----).

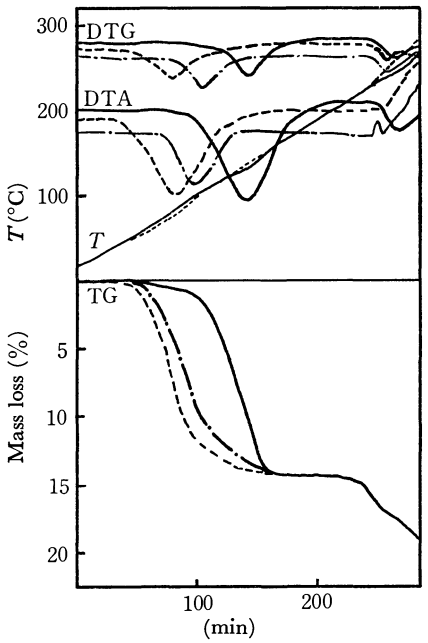

Fig. 4. Derivatograms of III (——), IV (----) and VII (---)

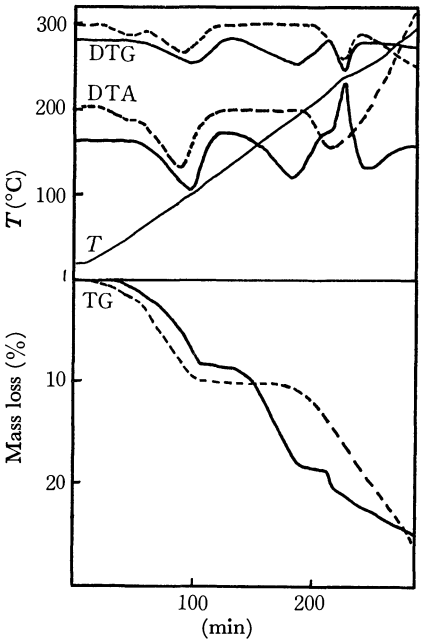

Fig. 5. Derivatograms of V (——) and VI (----).

the TG curve. However, since the ammonia evolution was not sufficient for detection in this step, the mass loss might be attributed to one mole of lattice water and one mole of coordinated water.

Salt II showed the mass loss corresponding to five moles of water in the region 50—120°C, and after that the weight of the sample remained constant till 260°C. The elemental analysis for the salt taken out from the furnace at 150°C was as follows: Found: C, 30.22; H, 4.90; N, 35.58%. Calcd for $[en_2Co_2(CN)_6]$: C, 30.47; H, 4.90; N, 35.53%. Thus, the thermal reaction product seems to be a binuclear complex containing two CN bridges as $[en_2Co(CN)_2Co(CN)_4]$.

The derivatogram of complex VIII which has one CN bridge is also included in Fig. 3. It is seen from the DTA and DTG curves that five moles of the lattice water are liberated from 60 to 120°C and then one mole of the coordinated water is continuously expelled to 160°C. Despite the loss of the coordinated water in complex VIII, the binuclear complex having the same two CN bridges as those obtained from complex II could not be found, the reason being not clear.

Salts III, IV, and VII give similar derivatograms to each other irrespective of the difference of the initiation dehydration temperatures, 90°C for III, 45°C for IV, and 75°C for VII, respectively, as seen in Fig. 4: two steps of the mass losses corresponding to two moles of the lattice water and to two moles of the coordinated water can not be distinguished from each other both in DTA and DTG curves. We also see that the *cis*-β-form double complex salt IV undergoes CN-bridging formation more easily than the corresponding *cis*-α-form one III and the complex containing $[Cr(CN)_6]^{3-}$ VII gives more readily the bridging formation than the corresponding cobaltate(III), III.

The derivatograms of the two double complex salts V and VI containing ammine as the labile ligand against heating are shown in Fig. 5.

Salt V shows two steps of mass losses at 50—120°C and 140—190°C, and then decomposes at 220°C. From the results of IR spectra and detection of ammonia, the first step is due to the liberation of two moles of the lattice water and the second to the deammonation reaction accompanied by the two CN-bridging formation.

Salt VI loses one mole of ammonia at 100—170°C, giving a complex containing one CN-bridge.

Electronic Spectra. On heating these double complex salts in the solid phase, the deaquation-bridging reaction accompanied by a distinct color change from red to yellow was observed, but scarcely in the deammonation-bridging reaction.

In the double complex salts, the first absorption bands of the complex cations $[Co(H_2O)_2N_4]^{3+}$ give a maximum in the neighborhood of 500 nm, whereas those of the complex anions $[Co(CN)_6]^{3-}$ and $[Cr(CN)_6]^{3-}$ give a maximum at 311 and 300 nm, respectively. Since the bands resulting from the hexacyanometallate anions are situated in the near-ultraviolet region, they scarcely affect the visible bands of the complex cations contained in the double complex salts. Therefore, the first absorption maxima of the cations constituting the double complex salts are considered to be those of the complexes themselves.

The numerical values for the first absorption bands of all the complexes prepared in the experimental section and those heated are listed in Table 1. The spectra of salts III and IV and those heated at 170°C, including VII heated at 170°C, are shown as representatives in Fig. 6, the spectra being measured by the diffuse reflectance method.

As seen in Table 1, the absorption bands of the double complex salts, when heated, are found to shift to the higher frequency region except for salts V and VI, *e.g.*, those of the complexes II, III, and IV are shifted to the neighborhood of 470 nm, which is almost similar

Table 1. Change of the absorption maxima upon heating of the double complex salts

Salts	λ_{max} (nm)	$\xrightarrow{\Delta}$	λ_{max} (nm)
I	510		485
II	504		467
III	505		472
IV	486		472
V	476		472
VI	476		474
VII	505		420
VIII	480		468
IX	462		

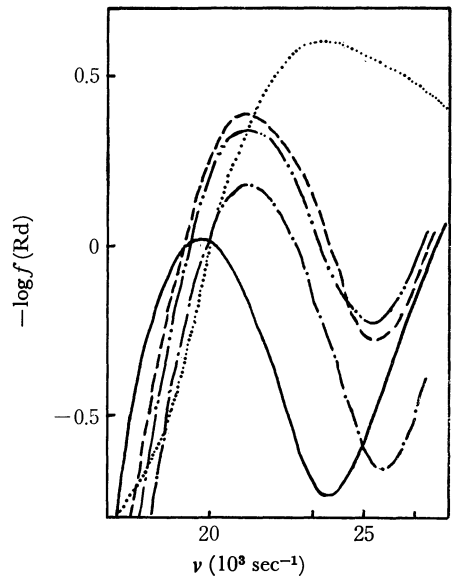

Fig. 6. Absorption spectra by the diffuse reflectance method of III at room temperature (——), III heated at 170°C (– – –), IV at room temperature (— · —), IV heated at 170°C (— · · —), and VII heated at 170°C (·····).

to that of hexaamminecobalt(III) complex, and above all, the wavenumber of the band of the thermal product from III is approximately close to that of IX. It is obvious that complex III undergoes the two-CN-bridging formation reaction upon heating to be converted into the binuclear complex IX.

Salt I liberates two moles of water upon heating, and the absorption band is shifted to 485 nm. Complex VIII has an absorption band at 480 nm, both bands coinciding with the band of aquopentaamminecobalt(III) complex. It seems that both the complex formed by heating I and complex VIII have one CN-bridge between two central metals and the cationic part has CoN_5O-type coordination. Complex VIII was found to give the absorption peak at 468 nm after the liberation of one mole of the coordinated water. The peak is close to that of the thermal bridging product of II. This suggests that complex VIII is converted into the two CN-bridging complex of CoN_6-type.

Only a slight shift of the band can be observed in V and VI (Table 1). It is obvious that in their thermal bridging reaction product, N atoms in CN^- bridges are coordinated to cobalt in the cationic part and C atoms participate in cobalt in anionic part; *i.e.*, the cationic part consists of CoN_6-type coordination, giving similar spectra to that of hexaamminecobalt(III) complex.

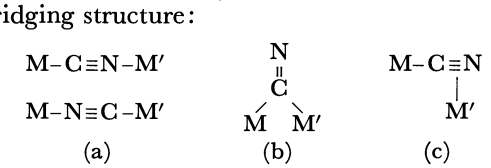
Complex VII heated at 170°C gives a broad absorption band in the wavelength region 430—390 nm in contrast to the case of Co–CN–Co type salts as shown in Fig. 6. It suggests that in contrast to the Co–CN–Co type salts which consist of CoN_6- and CoC_6-type coordination spheres combined with CN-bridges, the Co–CN–Cr type salt thermally obtained from VII consists of CoC_2N_4- and CrC_4N_2-type coordination spheres formed by the flipping of CN-bridges[8,16] and the overlap of their spectra appearing at 410 and 405 nm gives a broad band.

IR Spectra. IR spectra of the double complex salts we prepared except for those of VIII and IX show, in the frequency region of ν_{CN} stretching, one clear band at 2143—2149 or 2130 cm^{-1}, which is assigned to the terminal CN stretching vibration in $[Co(CN)_6]^{3-}$ or $[Cr(CN)_6]^{3-}$, respectively. With the progress of deaquation- or deammonation-anation, a new band whose extinction increases gradually appears at *ca.* 2190 cm^{-1} in addition to the original peak due to terminal-CN stretching. This is assigned to the stretching of CN bridging. The IR spectral data concerned with ν_{CN} for all the double complex salts and those heated are given in Table 2. As a typical example for the change of ν_{CN} bands, the spectra in the neighborhood of 2100—2200 cm^{-1} of salt IV at several steps of heating are shown in Fig. 7.

Table 2. Change of ν_{CN} in IR spectra of the double complex salts

Salts	ν_{CN}	$\xrightarrow{\Delta}$	ν_{CN}
I	2143		2143, 2190
II	2143		2143, 2190
III	2149		2149, 2196
IV	2149		2149, 2196
V	2143		2143, 2196
VI	2143		2143, 2190
VII	2130		2130, 2170
VIII	2143, 2220		
IX	2143, 2212		

The following three possible modes are considered for bridging structure:



(a) would be the most possible mode, because the frequency of CN stretching vibration in both (b) and (c) should be lower than that of the terminal CN group in $[M(CN)_6]^{3-}$ and the possibility of the flipping reaction was observed as shown in the section of electronic spectra. However, if mode (a) is accepted, the complexes containing two CN-bridges in *cis* position

produced by the thermal reaction would not be binuclear but have the structure of either tetramer or polymer, since the bond M–C≡N–M′ or M–N≡C–M′ should be linear.

On the other hand, X-ray diffraction for the single crystal of $[(NH_3)_5Co\text{–}N{\equiv}C\text{–}Co(CN)_5]\cdot H_2O$[17] shows that the angle of Co–C–N is 172.4° and that of Co–N–C 159.8°. Thus, it is not unreasonable to consider the possibility of the presence of the binuclear complexes having structure (a) with bending M–C≡N–M′ or M–N≡C–M′ bonds in *cis* position, not (b) or (c). However, the presumption could not be verified, since the molecular weight determination could not be made because of the small solubility of the salts in many solvents.

Thermochemical Data. The data of the enthalpy changes ΔH and the activation energies E_a for the thermal reaction of the double complex salts are summarized in Table 3, the former being estimated from the analysis of DTA and the latter from the analysis of DTA or DTG curve in a similar manner to that described previously.[7]

The values of the enthalpy change for these thermal reactions of I through V are close to those for the general deaquation- or deammonation-anation reactions, but those for VI, VII, and VIII are remarkably small. This may be due to the large contribution of exothermic bridging formation throughout the reactions. It is found that the activation energies for the liberation of two neutral molecules increase in the order, IV<II<III<V<VII. This sequence can be explained as follows.

1. The α-trien chelate stabilizes the complex to a greater extent than ethylenediamine chelate, so that the coordinated water in salt III is not so easily liberated as in salt II.
2. Since β-trien chelate has a larger strain than α-trien chelate, the former expels the coordinated water more easily than the latter, making the activation energy in IV lower than in III.
3. The activation energy of V is larger than that of IV, which may be due to the greater difficulty of evolution of ammonia than water.
4. Salt VII has a larger activation energy than salt III. This might be due to the possibility of the flipping reaction in VII.

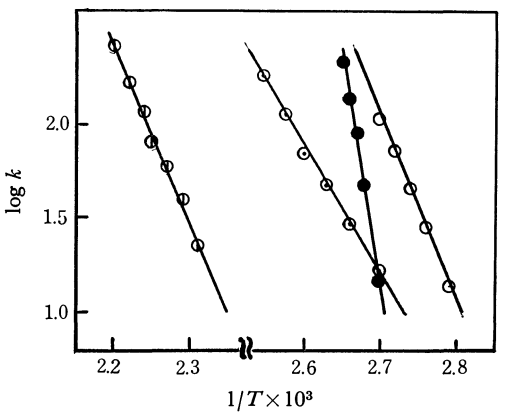

Fig. 8. Arrhenius plots for the bridging reaction of the double complex salts: I (●—●), III (⊙—⊙), V (◑—◑) and VII (○—○).

17) O. Hassel and J. R. Salvesen, *Z. Phys. Chem.*, **128**, 345 (1927).

Isothermal Measurements and Reaction Mechanism. The Arrhenius plots, $\log k$ *vs.* $1/T$, estimated by the isothermal measurements of the thermal bridging formation reactions of salts I, III, V, and VII are shown in Fig. 8, where k is the rate constant of the reaction calculated on the basis of the presumption of the first order. The activation energies obtained from the plots are also given in Table 3. They are in fairly good agreement with those obtained by derivatography except for I.

Taking into account the results from derivatography, isothermal measurements and the UV and IR absorption spectral measurements, it was concluded that, in the thermal bridging formation reaction of Co–Co double complex salts, the CN groups in the anionic part coordinate to cobalt in cationic part with *N*-atoms, but in that of Co–Cr salts, they coordinate to cobalt with C-atom as a result of CN flipping.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 175—178 (1973)

Polarographic Studies of Some Lanthanoids(III) in *N,N*-Dimethylacetamide

Makoto AIHARA and Seizo MISUMI
Inorganic Chemistry Laboratory, Faculty of Science, Kyushu University, Fukuoka
(Received June 6, 1972)

Polarographic behaviour of some lanthanoids(III) has been studied in *N,N*-dimethylacetamide. La(III), Pr(III), and Nd(III) showed irreversible, three-electron reduction wave and the other lanthanoids(III), Gd(III), Tb(III), Dy(III), Ho(III), Er(III), Tm(III), and Lu(III) except Sm(III), Eu(III), and Yb(III), gave irreversible, three-electron reduction wave with a pre-wave. The kinetic parameters for La(III), Pr(III), and Nd(III) were determined by means of Koutecky's method. Sm(III), Eu(III), and Yb(III) showed two-step reduction waves, the first wave being a reversible, one-electron reduction wave. These solvated lanthanoids(III) were investigated also by cyclic voltammetry.

The polarographic studies of Pb(II), Cd(II), *etc.*,[1] and alkali and alkaline earth metal[2] in *N,N*-dimethylacetamide (DMA) have been reported. However, lanthanoid(III) (Ln(III)) has not yet been investigated. It is interesting to compare the polarographic behaviour of each Ln(III), in particular the half-wave potential in DMA, with that in other non-aqueous solvents.

Important kinetic parameters for irreversible waves are transfer coefficient (α) and standard rate constant (k_s). There are few investigations of the rate constant of Ln(III) in non-aqueous solvents. Gaur and Zutshi[3] reported on the polarographic reduction of Eu(III) in formamide.

In this work polarographic and cyclic voltammetric studies and the kinetic parameters of some lanthanoids-(III) in DMA are presented.

Experimental

Materials. DMA was fractionally distilled three times from calcium hydride *in vacuo* (10 mmHg) under nitrogen and finally distilled in the absence of calcium hydride. Moisture in DMA was determined by Karl-Fischer titration to be 0.04%. Lanthanoid(III) perchlorates were prepared by dissolving the oxides in perchloric acid and drying at 60°C *in vacuo*. Tetraethylammonium perchlorate (TEAP) was used as the supporting electrolyte. All other reagents were of extra pure grade.

Apparatus. The electrolysis cell consists of three electrodes.[4] The reference electrode was an SCE with a salt bridge:

$$\left(\frac{0.5\text{M TEAP}}{\text{DMA}}\middle|\frac{1\text{M NaClO}_4}{\text{H}_2\text{O}}\middle|\frac{1\text{M NaCl}}{\text{H}_2\text{O}}\middle|\frac{1\text{M KCl}}{\text{H}_2\text{O}}\right).$$

DME was used for DC polarography ($m^{2/3}t^{1/6}=1.25$ mg$^{2/3}$/sec. in 0.1M TEAP-DMA medium at -2.4 V *vs.* SCE) and HDME (area of HDME; 0.051 cm^2) was used for cyclic voltammetry as thework ing electrode. Other apparatus were as described previously.[4]

Procedure. A sample solution of 0.1M TEAP-DMA containing 0.3~2.0 mM $Ln(ClO_4)_3$ of the final concentration was taken into a cell. After dried nitrogen gas was passed through it for 20 min., a polarogram was recorded. The junction potential was measured by using an SCE with a slowly flowing-type aqueous saturated KCl salt bridge and found to be 25 mV. All experiments were carried out at 25.0±0.1°C.

Results and Discussion

Polarograms of 0.3 mM Ln(III) except for Sm(III), Eu(III), and Yb(III) in DMA are shown in Fig. 1.

Each reduction wave of La(III), Pr(III), and Nd-(III) was single and irreversible in the concentration range 0.3~1.0 mM for Ln(III), whereas that of other lanthanoids(III) (Gd(III), Tb(III), Dy(III), Ho(III), Er(III), Tm(III), and Lu(III)) was single and irreversible with a pre-wave, the main wave becoming ill-defined with increasing concentration of Ln(III).

Polarographic data are shown in Table 1-1. The

electrode reaction was found to be irreversible, of three-electron reduction and diffusion-controlled (Table 2-1). The diffusion current of the main wave decreased and the half-wave potential was shifted to a more negative value with decreasing ionic radius of Ln(III), the total wave height remaining nearly constant.

The effect of increasing concentration of water to DMA on the reduction wave was investigated. Typical polarograms of Pr(III) and Er(III) in water-DMA medium are shown in Fig. 2. The values of half-wave potential and wave-height for Pr(III) did not change with addition of water, but the reduction wave for Er(III) became a single wave even with 1% addition of water. It was observed that the half-wave potential of this wave was shifted toward a more positive value with increasing concentration of water.

Eu (III) (1st wave)	0.166±0.003	(2nd)	0.073~0.060[b]
Yb (III) (1st wave)	0.186±0.002		

a) Temperature coefficient: 5.5~9.5%.
b) Temperature coefficient: 6.5~9.0%.

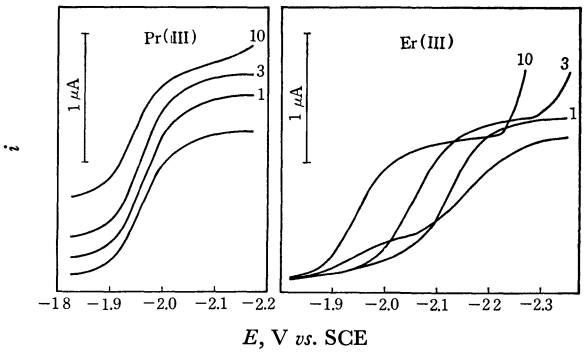

Fig. 2. Typical polarograms of 0.3 mM Pr(III) and Er(III) in water-DMA medium.
Numbers on curves refer to per-cent water added to the solution.

Cyclic voltammograms are shown in Fig. 3. No pre-wave was seen for La(III), Pr(III), and Nd(III) but one was observed for the other lanthanoids(III) such as Gd(III) and Tb(III). The height of the pre-wave also increased with decreasing radius of Ln(III). No anodic waves could be observed at this sweep rate because of the irreversibility of electrode reaction.

Polarograms for Sm(III), Eu(III), and Yb(III) are shown in Fig. 4. Sm(III) and Eu(III) showed two-step reduction waves but the second wave of Yb(III) was observed to overlap the residual current of the supporting electrolyte. Polarographic data are shown

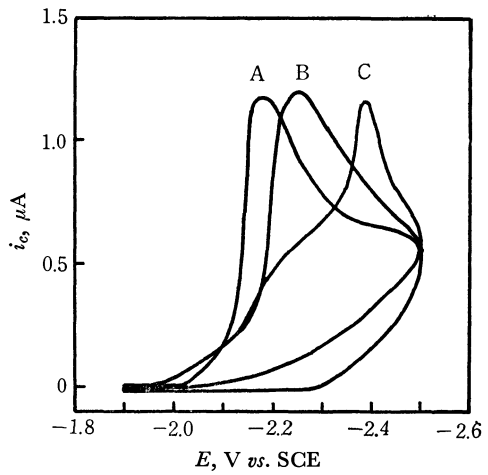

Fig. 3. Cyclic voltammograms of 0.3 mM Ln(III) in DMA.

E, V *vs.* SCE

Fig. 4. Polarograms of 1.0 mM Sm(III), Eu(III) and Yb(III) in water-DMA medium.
Number on curves refer to per-cent water added to the solution.

in Table 1-2. The electrode reaction for the first wave is diffusion-controlled but the value of $i_l/\sqrt{h_{corr.}}$ for the second wave decreased with increasing mercury pressure (Table 2-2). The value of temperature coefficient was in the range 5~9%.

The value of reciprocal slope for the first wave is 54, 59, and 61 mV for Sm(III), Eu(III), and Yb(III), respectively. It was found that its electrode reaction is reversible and of one-electron reduction. The ratio of current for the first wave to that for the second wave is 0.84 for Sm(III) and 0.49 for Eu(III). The effect of water on the reduction wave is shown in Fig. 4. The half-wave potential for the first wave is shifted toward a more negative value and that for the second wave toward a more positive value with increasing concentration of water. The height of the second wave increases with the addition of water.

It is supposed that La(III), Pr(III), and Nd(III) would form a stable solvate species with DMA and these species would not be affected by the adidtion of water. The electrode reaction is assumed to be as follows.

$$[Ln(DMA)_x]^{3+} + yH_2O \rightleftarrows [Ln(DMA)_{x-y}(H_2O)_y]^{3+} + y(DMA)$$

$$[Ln(DMA)_x]^{3+} + 3e^- \longrightarrow Ln^0 + x\text{DMA} \quad (1)$$

$$[Ln(DMA)_{x-y}(H_2O)_y]^{3+} + 3e^- \longrightarrow Ln^0 + (x-y)\text{DMA} + yH_2O \quad (2)$$

Equations 1 and 2 correspond to the electrode reactions of the main wave and the pre-wave, respectively.

The half-wave potentials of the main waves corrected for the rubidium scale in three kinds of solvents (the donor numbers of DMA, *N,N*-dimethylformamide (DMF) and acetonitrile (AN) are 27.8, 26.6, and 14.1, respectively) are listed in Table 3. Values of the half-wave potentials are in the order AN[5]>DMF[6]>DMA. A comparison of these values shows that the half-wave potential is related to donor number and metal ion-solvent interaction depends on the polarographic overvoltage.

Table 3. Half-wave potential of Ln(III) in different solvents in volts *vs.* the half-wave potential of Rb^+

Ln(III)	Solvent		
	DMA	DMF	AN
La	−0.09	−0.05	0.45
Pr	0.00	−0.05	0.45
Nd	−0.05	−0.05	0.45
Gd	−0.14	−0.14	0.45
Tb	−0.16	−0.14	
Dy	−0.18	−0.16	
Ho	−0.21	−0.18	
Er	−0.23	−0.19	
Tm	−0.23		
Lu	−0.27		

The half-wave potential of the first wave for Sm(III) and for Eu(III) in water[5] was more negative than that in DMA. This explains the negative shift of half-wave potential caused by the addition of water. The electrode reaction of the first wave is reversible and of one electron reduction, but that of the second wave differs from that in other solvents (*e.g.* Eu(II)→Eu(0) in acetonitrile[5]).

The kinetic parameters for the reduction of La(III), Pr(III), and Nd(III) were calculated by means of Koutecky's method[7] and the values of E_s (standard electrode potential) were obtained by Hale and Parson's method.[8]

For the reaction where $k_s \leq 5 \times 10^{-4}$ cm/sec, there is a region near the top of the wave in which $\exp\{nF(E-E_s)/RT\} \ll 1$. Under these conditions Koutecky's equations can be simplified as follows.

$$i/i_d = F(\chi) \quad (3)$$

$$\chi = (12t/7D_0)^{1/2}k_f \quad (4)$$

where $F(\chi)$[9] is a power series in the variable (χ) and k_f is the rate constant for the forward reaction. k_f is related to the standard rate constant by the equation.

$$(k_s): k_f = k_s e^{-\alpha nF(E-E_s)/RT} \quad (5)$$

k_f and α can be determined from Eqs. (3), (4) ,and (5). When E equals E_s, $\exp\{nF(E-E_s)/RT\}$ becomes 1 and Koutecky's equations become

$$i/i_d = F(\chi)/2 \quad (6)$$

$$\chi = 2(12t/7D_0)^{1/2}k_f \quad (7)$$

By plotting $\log(F(\chi)/2)$ *vs.* $\log(\chi/2)$ and $\log(i/i_d)$ *vs.* $\log(12t/7D_0)^{1/2}k_f$, the intersection gives the point k_s.

$$k_f = k_s e^{-\alpha nF(E-E_s)/RT} = k_s$$

The values of α for La(III), Pr(III), and Nd(III) were determined also by plotting $\log \chi$ *vs.* E. The

values were in agreement with those obtained by log-plot analysis. The results of the determination of $(k_s)_{ms}$ are given in Fig. 5 and kinetic parameters in Table 4, where $(\alpha_c)_{ms}$ and $(k_f)_{ms}$ mean the parameters determined directly from the experimental data without any theoretical correction.

Table 4. Data for parameters of reduction of La(III), Pr(III) and Nd(III) in DMA

	$(E_{1/2})_{irr}$ V *vs.* SCE	$(E_{1/2})_r$ V *vs.* SCE	$(\alpha_c)_{ms}$	$(k_s)_{ms}$ cm/sec
La	-2.04_0	-2.00_3	0.24	2.0×10^{-4}
Pr	-1.95_6	-1.93_7	0.49	2.2×10^{-4}
Nd	-2.00_8	-1.98_4	0.43	2.4×10^{-4}

On the other hand, the value of k_f^0 (the forward rate constant of the electron transfer at zero volt *vs.* NHE) was obtained by cyclic voltammetry. The value of k_f^0 (5.3×10^{-27} cm/sec) for La(III) is nearly identical with that (3.0×10^{-27} cm/sec) obtained by using k_s, but in the case of Pr(III) and Nd(III) the values of k_f^0 do not coincide with those obtained by using k_s, because of very small values of k_f^0.

The authors are grateful for financial support given by the Ministry of Education for this work. They are indebted to Miss E. Kamiunten for her help in the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 178—183 (1973)

Racemization Reactions of Cobalt(III) Complexes of Ethylenediaminetetraacetate and Trimethylenediaminetetraacetate

Hiroshi OGINO, Masatake TAKAHASHI, and Nobuyuki TANAKA
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai

(Received June 6, 1972)

The kinetics of racemization reactions of ethylenediaminetetraacetatocobaltate(III), $Co^{III}edta^-$, and trimethylenediaminetetraacetatocobaltate(III), $Co^{III}trdta^-$, were investigated in acid solutions. The rate law for the racemization of $(+)_{546}Co^{III}edta^-$ is:

$$\frac{d[(+)_{546}Co^{III}edta^-]}{dt} = -2\frac{k_{r1}K_a + k_{r2}[H^+]}{K_a + [H^+]}[(+)_{546}Co^{III}edta^-]$$

where K_a is the equilibrium constant of the reaction:

$$(+)_{546}Co^{III}(H_2O)Hedta \rightleftarrows (+)_{546}Co^{III}edta^- + H^+$$

The values of k_{r1} and k_{r2} at 120°C and at an ionic strength of 0.53 are 2.0×10^{-5} sec^{-1} and 5.6×10^{-4} sec^{-1} respectively. The rate law for the racemization of $(+)_{589}Co^{III}trdta^-$ is:

$$\frac{d[(+)_{589}Co^{III}trdta^-]}{dt} = -2k'_{r2}[H^+][(+)_{589}Co^{III}trdta^-]$$

The value of k'_{r2} at 120°C and at an ionic strength of 0.53 is 1.9×10^{-5} l mol^{-1} sec^{-1}. It is known that the rate of the racemization reaction of optically-active $Co^{III}edta^-$ is accelerated by the presence of $Co^{II}edta^{2-}$ because of the electron-exchange reaction between these two species. In this paper, the electron-exchange reaction between $Co^{III}trdta^-$ and $Co^{II}trdta^{2-}$ is also investigated by the utilization of the optical activity. This reaction proceeds faster than the reaction between $Co^{III}edta^-$ and $Co^{II}edta^{2-}$.

Bailar[1] proposed a trigonal twist mechanism for the racemization reaction of the optically-active $Co^{III}edta^-$ complex. Cooke, Im, and Busch[2] investigated this reaction in the pH range from 2 to 4 and supported Bailar's proposal on the basis of the facts that this reaction gives a very large and positive entropy of activation and that the reaction rate is insensitive to the pH within the range studied. In this paper, the reaction of the racemization of $Co^{III}edta^-$ and $Co^{III}trdta^-$ will be investigated in solutions containing

2) D. W. Cooke, Y. A. Im, and D. H. Busch, *Inorg. Chem.*, **1**, 13 (1962).

hydrogen ions in concentrations of more than 0.05M, and the mechanisms will be discussed.

Im and Busch[3] investigated the kinetics of the electron-exchange reaction between $Co^{III}edta^-$ and $Co^{II}edta^{2-}$ by the utilization of optical activity. In this work, the kinetics of the electron-exchange reaction between $Co^{III}trdta^-$ and $Co^{II}trdta^{2-}$ was followed by a procedure similar to that of Im and Busch.[3] The results will also be presented in this paper.

Experimental

Optically-active $K[Co^{III}edta]\cdot 2H_2O$[4] and $K[Co^{III}trdta]\cdot 2H_2O$[5] were prepared by the procedures described in the literature. The ionic strength of the solutions was adjusted with potassium nitrate. The visible absorption spectra were recorded with a Hitachi EPS-3 pen-recording spectrophotometer. A JASCO model ORD/UV-5 spectrophotometer with a CD attachment was used for the kinetic studies of $Co^{III}edta^-$. In most cases, the rotations were measured at 550 nm. A JASCO model DIP-SL automatic polarimeter was used for the studies of $Co^{III}trdta^-$; the rotation was measured at the sodium D line unless otherwise stated.

The kinetics of the racemization reaction of $Co^{III}edta^-$ or $Co^{III}trdta^-$ was studied in potassium nitrate–nitric acid media. Sealed ampules filled with a solution containing an optically-active cobalt(III) complex, nitric acid, and potassium nitrate were placed in a thermostated oil-bath. The ampules were withdrawn at intervals from the oil-bath and cooled immediately. The solutions were then transferred to optical cells and submitted to measurements of the optical rotations. The kinetic stiudes of the electron-exchange reaction between $Co^{II}trdta^{2-}$ and optically-active $Co^{III}trdta^-$ were carried out at 90°C. To avoid the evaporation of the solution, the reaction vessel shown in Fig. 1 was employed.

in an oil-bath of a given temperature. Portions of the solution were removed at intervals from the reaction vessel by opening the stopcock, A, and collected in a vessel, B. The solutions were then transferred to optical cells and submitted to measurements of the optical rotations. The pH of the solution was maintained with an acetate buffer. A Hitachi-Horiba F-5 pH meter was used for the measurement of the pH of the solution. It was found that $Co^{II}trdta^{2-}$ was slowly oxidized at 90°C. Therefore, air was expelled from the solution by passing through a stream of nitrogen gas before it was placed in a reaction vessel.

Results and Discussion

Racemization Kinetics of $Co^{III}edta^-$. The rate constants of the racemization reaction of $Co^{III}edta^-$ were determined by this equation:

$$-\log\left(\frac{\alpha_t}{\alpha_0}\right) = \frac{2}{2.303}k_r t \qquad (1)$$

where α_t and α_0 represent the optical rotations at time t and at time zero respectively. k_r denotes the observed rate constant of the racemization reaction. An example of the plots of $-\log(\alpha_t/\alpha_0)$ *vs.* time is shown in Fig. 2.

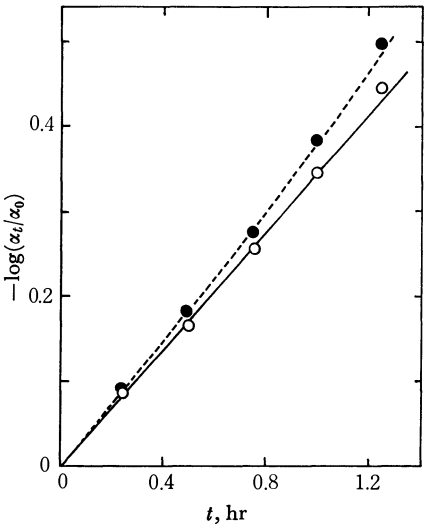

Fig. 2. Relation between $-\log(\alpha_t/\alpha_0)$ and t(solid circles). Open circles represent the values of $-\log(\alpha_t/\alpha_0)$ plotted after correction for the decreases in Co^{III} $edta^-$ by the decomposition reaction. Experimental condition: $[H^+]$= 0.421M, μ=0.53, 120°C.

It is apparent that the plots do not give a linear relation. The measurements of the visible spectra showed that the cobalt ions in $Co^{III}edta^-$ were gradually reduced to the divalent state with time. The decrease in the concentrations of $Co^{III}edta^-$ by this decomposition reaction was determined by the measurement of the visible absorption spectra, and the values of $-\log(\alpha_t/\alpha_0)$ were corrected. The values thus corrected were plotted against the time. The plots gave a straight line, as shown by the solid line in Fig. 2. The rate constant of the racemization, k_r, was calculated from the slope of this straight line. The values of k_r increased with the hydrogen ion concentrations.

It has been known that $Co^{III}edta^-$ is converted into

$Co^{III}(H_2O)Hedta$ in acid solutions.[6] Shimi and Higginson showed the formation of $Co^{III}(H_2O)Hedta$ by the measurement of the visible spectra of $Co^{III}edta^-$ in acid solutions.[7] The equilibrium constant of the reaction:

$$Co^{III}(H_2O)Hedta \rightleftarrows Co^{III}edta^- + H^+ \quad (2)$$

was determined to be 1.28 at 25°C and at an ionic strength of 1.0.[6,8] The formation of $Co^{III}(H_2O)Hedta$ is also shown on the circular dichroism curves (CD curves). In Fig. 3, a CD curve of $(+)_{546}Co^{III}edta^-$ measured in 4.21M HNO_3 (Curve A) is given and is compared with that of $(+)_{546}Co^{III}edta^-$ measured in a neutral solution (Curve B). Curve A is clearly different from Curve B.

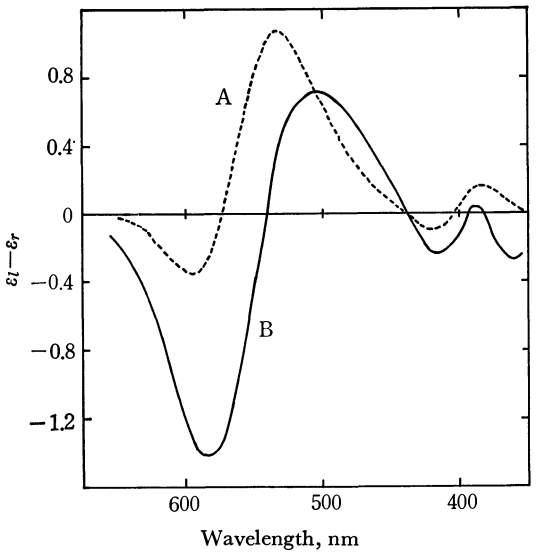

Fig. 3. CD curves of $(+)_{546}$ Co^{III} edta$^-$ in 4.21M HNO_3 (Curve A) and in water (Curve B).

The change in the k_r value with the hydrogen ion concentrations may be explained by considering the formation of $Co^{III}(H_2O)Hedta$ as follows:

$$(+)_{546}Co^{III}(H_2O)Hedta \rightleftarrows (+)_{546}Co^{III}edta^- + H^+ \quad (3)$$

$$(+)_{546}Co^{III}edta^- \xrightarrow{k_{r1}} (-)_{546}Co^{III}edta^- \quad (4)$$

$$(+)_{546}Co^{III}(H_2O)Hedta \xrightarrow{k_{r2}} (-)_{546}Co^{III}(H_2O)Hedta \quad (5)$$

In this reaction mechanism, k_r can be expressed as:

$$k_r = \frac{k_{r1}K_a + k_{r2}[H^+]}{K_a + [H^+]} \quad (6)$$

where K_a represents the equilibrium constant of Reaction (3). The plot of k_r $(K_a + [H^+])$ *vs.* $[H^+]$ is given in Fig. 4, which shows a linear relation. The values of k_{r1} and k_{r2} were determined from the intercept and the slope of the straight line respectively. The K_a values used here were calculated from the data reported by Dyke and Higginson.[6] The kinetic parameters are summarized in Table 1.

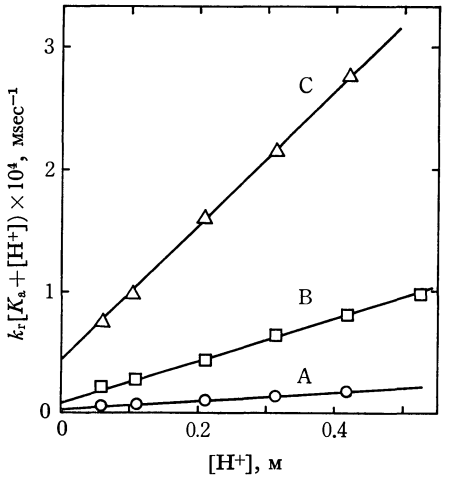

Fig. 4. Relation between $k_r(K_a+[H^+])$ and hydrogen ion concentration for $(+)_{546}$ Co^{III} edta$^-$. Temperature: 100°C (A), 110°C (B), and 120°C (C).

Table 1. Kinetic parameters of the racemization reaction of Co^{III} EDTA complex (μ=0.53 (KNO_3))

	k_{r1} sec^{-1}	k_{r2}, sec^{-1}
100°C	1.9×10^{-6}	3.9×10^{-5}
110°C	6.1×10^{-6}	1.6×10^{-4}
120°C	2.0×10^{-5}	5.6×10^{-4}
ΔH^*(kcal/mol)	32.9	38.5
ΔS^*(e.u.)	3.1	3.9

Cooke *et al.*[2] reported 3.9×10^{-6} sec^{-1} as the rate constant of the racemization reaction of $Co^{III}edta^-$ at 100°C, which corresponds to the k_{r1} in this work. They also reported that the activation energy and the entropy of activation were 40.6 kcal/mol (ΔH^*=39.9 kcal/mol) and 20.6 e.u. respectively. There is a significant discrepancy between the kinetic parameters determined in this work and those reported by Cooke *et al.* It should be recognized, however, that the gradual decomposition of $Co^{III}edta^-$ was not considered in the studies by Cooke *et al.*

Recently, it was found in this laboratory that the decomposition of $Mn^{III}edta^-$ in an aqueous solution led to the formation of $Mn^{II}edta^{2-}$, $Mn^{II}edtra^-$, Mn^{II}-edda, and some other products,[9] where edtra and edda denote $(^-O_2CH_2C)_2NCH_2CH_2NH(CH_2CO_2^-)$ and $(^-O_2CH_2C)NHCH_2CH_2NH(CH_2CO_2^-)$ respectively. It is not unreasonable that the decomposition products of $Co^{III}edta^-$ contain $Co^{II}edta^{2-}$, $Co^{II}edtra^-$, $Co^{II}edda$, and some other products similar to the decomposition products of $Mn^{III}edta^-$. In this work, the concentration of the hydrogen ion is kept higher than 0.05M. Under this experimental condition, divalent cobalt ions produced during the reaction are present in the form of aquo ions, Co^{2+}, so that the contribution of the electron-exchange reaction to the racemization reaction of $Co^{III}edta^-$ can be neglected. As Cooke *et al.* studied the racemization reaction in the pH range from 2 to 4,

6) R. Dyke and W. C. E. Higginson, *J. Chem. Soc.*, **1960**, 1998.
7) I. A. W. Shimi and W. C. E. Higginson, *ibid.*, **1958**, 260.
8) In this work, the determination of the equilibrium constant was repeated. The constant was found to the 1.31 at 25°C and at an ionic strength of 2.0 ($NaClO_4$), which is in good agreement with the value reported by Dyke and Higginson.[6]
9) H. Ogino, T. Shirakashi, and N. Tanaka, presented at the 24th Annual Meeting of the Chemical Soceity of Japan, Osaka (Apr. 1971).

the electron-exchange reaction between $Co^{III}edta^-$ and decomposition products might have accelerated the racemization reaction. Therefore, the kinetic parameters given in Table 1 seem to be more reliable than those reported by Cooke *et al.*

Although the entropy of activation for Reaction (4) is not a large positive value, this value may suggest that the acid-independent racemization of $Co^{III}edta^-$ proceeds through the trigonal twist mechanism, because it is expected that a dissociative mechanism will give a negative value for the entropy of activation.[2,7,10] Furthermore, it is unlikely that the acid-independent path is detectable in the range of hydrogen ion concentrations employed in this work (0.05—0.5M), because this mechanism requires the breaking of at least two Co–O bonds without protonation in an acid solution and rapid recombination after the inversion reaction. A similar situation exists even for the acid-dependent path. The entropy of activation of k_{r2} is a very large positive value. Therefore, it seems reasonable to say that the racemizations of $Co^{III}edta^-$ and $Co^{III}(H_2O)$-Hedta proceed through the trigonal twist mechanism. The values given in Table 1 indicate that $Co^{III}(H_2O)$-Hedta racemizes from 20 to 28 times faster than Co^{III}-$edta^-$. This implies that the decrease in the number of chelate rings in the EDTA complex makes the twist easier.

The Rây and Dutt mechanism[11] has been known to be an intramolecular racemization mechanism. It should be noted that, when the Rây and Dutt mechanism is applied to at least $Co^{III}edta^-$ and related complexes, this mechanism is identical with the mechanism proposed by Bailar.[1]

Racemization Kinetics of $Co^{III}trdta^-$. The reaction was followed by the procedure described for the Co^{III}-$edta^-$ complex. The plots of $-\log(\alpha_t/\alpha_0)$ *vs.* time after correction for the decomposition of $Co^{III}trdta^-$ with time gave a good linear relation. The plots of k_r *vs.* $[H^+]$ indicate linear dependencies, as shown in Fig. 5. The intercepts of the plots are essentially zero at all temperatures. Therefore, k_r can be expressed as:

$$k_r = k'_{r2}[H^+] \quad (7)$$

If $K_a \gg [H^+]$ is assumed, this relation can be formally derived from Eq. (6).

The visible spectra and CD cruves of $Co^{III}trdta^-$ did not show any changes with the increase in the hydrogen ion concentration up to 5M of nitric acid. This is quite different from the behavior of $Co^{III}edta^-$ in an acid solution. That is, the formation of $Co^{III}(H_2O)$-Htrdta is very unfavorable.

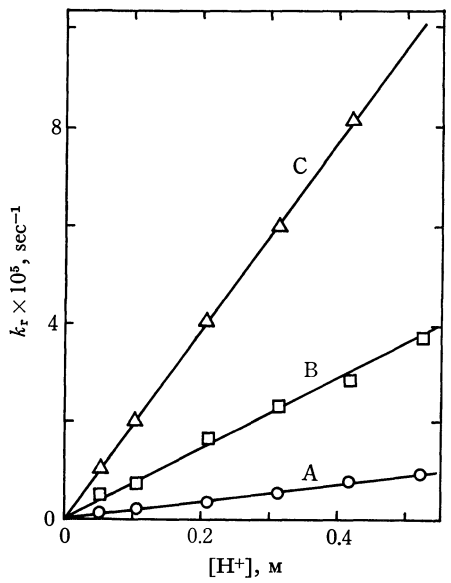

Fig. 5. Relation between k_r and hydrogen ion concentration for $(+)_{546}Co^{III}trdta^-$. Temperature: 120°C (A), 130°C (B), and 140°C (C).

Table 2. Kinetic parameters of the racemization reaction of Co^{III} TRDTA complex (μ=0.53 (KNO_3))

	k'_{r2}, 1 mol^{-1} sec^{-1}
120°C	1.9×10^{-5}
130°C	6.7×10^{-5}
140°C	2.0×10^{-4}
ΔH^*(kcal/mol)	37.5
ΔS^*(e.u.)	14.8

The values of k'_{r2}, the enthalpy of activation, and the entropy of activation are given in Table 2. The racemization reaction of $Co^{III}trdta^-$ is characterized by the facts that an acid-independent path is absent and that the over-all reaction rate is much smaller than that of $Co^{III}edta^-$. As the value of the acid dissociation constant of $Co^{III}(H_2O)Htrdta$ is not known, a comparison between the k'_{r2} value for $Co^{III}trdta^-$ and the k_{r2} value for $Co^{III}edta^-$ is not possible. Figure 5 shows that the acid-independent racemization reaction is extremely slow. One reason for this may be that, if $Co^{III}edta^-$ and $Co^{III}trdta^-$ racemize through the trigonal twist mechanism, the diamine chelate rings must be inverted, as shown in Fig. 6. The absolute configurations of $(-)_{546}Co^{III}edta^-$ [12] and $(-)_{546}Co^{III}$-

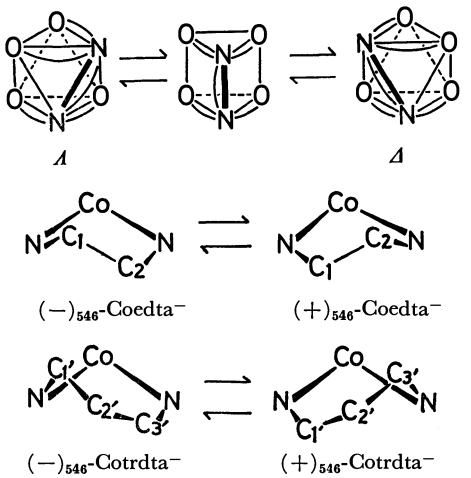

Fig. 6. Racemization processes of $Co^{III}edta^-$ and $Co^{III}trdta^-$ by the trigonal twist mechanism.

10) M. L. Morris and D. H. Busch, *J. Phys. Chem.*, **63**, 340 (1959).
11) P. Rây and N. K. Dutt, *J. Indian Chem. Soc.*, **20**, 81 (1943).
12) T. E. MacDermott and A. M. Sargeson, *Aust. J. Chem.*, **16**, 334 (1963).

trdta$^-$ [5] have been determined to be *A*. In a previous paper,[5] it was shown that the conformation of the trimethylenediamine chelate ring is a twist form. That is, the cobalt(III) ion, two nitrogen atoms, and one central carbon atom of trimethylenediamine ($C_{2'}$ in Fig. 6) lie on the same plane and there is a two-fold axis through the cobalt(III) ion and $C_{2'}$. In the racemization of $(-)_{546}Co^{III}edta^-$, the carbon atom, C_1, above the N–Co–N plane moves downward, while C_2, below the N–Co–N plane moves upward, as shown in Fig. 6. In the case of $(-)_{546}Co^{III}trdta^-$, the $C_{1'}$ above the N–Co–N plane moves downward and $C_{3'}$ below the N–Co–N plane, moves upward. In addition, the $C_{2'}$ atom must be fixed in the N–Co–N plane during the inversion process. Therefore, in the transition state, the cobalt(III) ion, two nitrogen atoms, $C_{1'}$, $C_{2'}$, and $C_{3'}$ must exist on the same plane. It is quite natural that this situation is sterically hindered and leads to the absence of an acid-independent path for $Co^{III}trdta^-$.

Electron-exchange Reaction between $Co^{II}trdta^{2-}$ and Co^{III}-trdta$^-$. The electron-exchange reaction between $Co^{II}trdta^{2-}$ and optically-active $Co^{III}trdta^-$ was followed by measurements of the decrease in optical rotation with the time. As the intramolecular racemization of optically-active $Co^{III}trdta^-$ is negligible under these experimental conditions, the reaction can be expressed as follows:

$$Co^{II}trdta^{2-} + \text{optically-active } Co^{III}trdta^- \xrightarrow{k_e} \text{racemic } Co^{III}trdta^- + Co^{II}trdta^{2-} \quad (8)$$

From Reaction (8), these relations:

$$-\log\left(\frac{\alpha_t}{\alpha_0}\right) = \frac{k_{obs}}{2.303}t \quad (9)$$

$$k_{obs} = k_e[Co^{II}trdta^{2-}] \quad (10)$$

can be derived. Figure 7 shows some examples of these plots, the slopes of which correspond to $k_{obs}/2.303$. The values of k_{obs} were found to be dependent

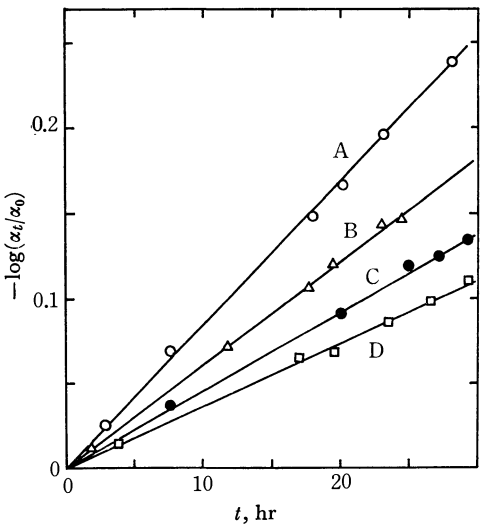

Fig. 7. Relation between $-\log(\alpha_t/\alpha_0)$ and t.
Experimental conditions: $[Co^{II}trdta^{2-}]$=13.45mM (A), 22.97 mM (B), 13.77 mM (C), and 13.80 mM (D); pH=3.04 (A), 3.58 (C), and 3.86 (B) and D)

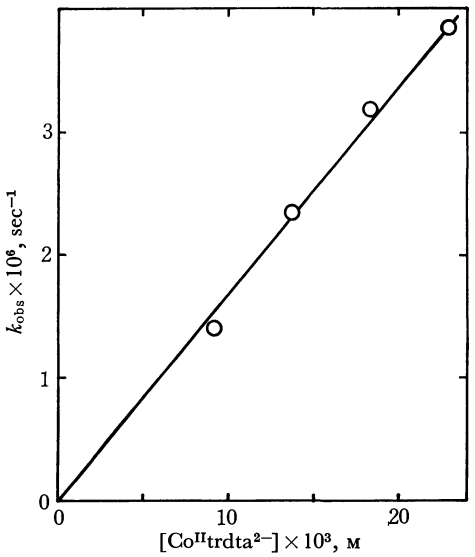

Fig. 8. Relation between k_{obs} and $[Co^{II}trdta^{2-}]$. pH=3.86

on both $[Co^{II}trdta^{2-}]$ and $[H^+]$. When the hydrogen ion concentration is kept constant, the k_{obs} values are proportional to $[Co^{II}trdta^{2-}]$, as shown in Fig. 8. The slope of the straight line which is shown in Fig. 8 corresponds to the rate of the electron-exchange reaction, k_e. The k_e values were determined at several pH values; the results are given in Table 3.

TABLE 3. RATE CONSTANTS OF THE ELECTRON-EXCHANGE REACTION OF Co-TRDTA SYSTEM AT μ=0.2 (KNO_3) AND 90°C

pH	k_e, 1 mol^{-1} sec^{-1}
3.86	1.55×10^{-4}
3.58	1.99×10^{-4}
3.04	3.74×10^{-4}

It is known that $Co^{II}trdta^{2-}$ is in equilibrium with $Co^{II}Htrdta^-$ as follows:[13]

$$Co^{II}Htrdta^- \rightleftharpoons Co^{II}trdta^{2-} + H^+ \quad (11)$$

Therefore, the electron-exchange reaction between Co^{II}-trdta^{2-} and $Co^{III}trdta^-$ can be expressed by this mechanism:

$$Co^{II}trdta^{2-} + \text{optically-active } Co^{III}trdta^- \xrightarrow{k_{e1}} \text{racemic } Co^{III}trdta^- + Co^{II}trdta^{2-} \quad (12)$$

$$Co^{II}Htrdta^- + \text{optically-active } Co^{III}trdta^- \xrightarrow{k_{e2}} \text{racemic } Co^{III}trdta^- + Co^{II}Htrdta^- \quad (13)$$

On the basis of this mechanism, the rate law can be derived as:

$$k_e = \frac{k_{e1}K^H + k_{e2}[H^+]}{K^H + [H^+]} \quad (14)$$

where K^H represents the equilibrium constant of Eq. (11). By use of the data given in Table 3 and Eq. (14), the values of k_{e1}, k_{e2}, and K^H were calculated. The results are given in Table 4, along with the data

Table 4. Rate constants of electron-exchange reaction for Co-TRDTA and Co-EDTA systems (μ=0.2)

	Temp., °C	k_{e1}, l mol^{-1} sec^{-1}	k_{e2}, l mol^{-1} sec^{-1}	K^H, mol/l	Ref.
Co-TRDTA system	90	1.0×10^{-4}	1.1×10^{-3}	2.4×10^{-3}	This work
Co-EDTA system	90	8.1×10^{-5}	2.8×10^{-4}	1.1×10^{-3}	3

reported for the Co-EDTA system.[3]

The reactions proceed faster than the reaction between $Co^{II}edta^{2-}$ and $Co^{III}edta^{-}$ for both the acid-independent and the acid-dependent paths.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 183—186 (1973)

Studies on Nitrogen-Phosphorus Compounds. XXII.[1] The Synthesis and Properties of Phosphoric Aniline Diamide

Etsuro KOBAYASHI

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo

(Received February 3, 1972)

In order to develop fireproof materials, a new compound, phosphoric aniline diamide, was prepared by employing phosphorus oxychloride, aniline, and ammonia as the starting materials. The conditions for the synthesis and the characteristics of the product have been investigated. Phosphoric aniline diamide can be prepared in the following way: 2 moles of aniline are added to 1 mole of phosphorus oxychloride diluted with chloroform, and the precipitate of aniline hydrochloride, a by-product, is separated from the solvent by filtration. A mixture of phosphoric amide and ammonium chloride is formed by the reaction between an excess of gaseous ammonia and the above filtrate at −10—20°C, and is then separated from the mother liquor. Crude phosphoric amide is extracted from the mixture with ethanol, and subsequent re-extraction with acetone yields the pure product with the formula $PONHC_6H_5(NH_2)_2$. The product thus obtained is composed of a white crystalline powder, soluble in water, ethanol and acetone but insoluble in various organic solvents. The compound shows its own characteristic X-ray diffraction pattern and IR absorption bands. Upon heating, the product melts at about 140°C; condensation occurs by de-ammoniation above 170°C, and conversion into insoluble condensed amidophosphates takes place.

Inorganic compounds with P–N bonds are of interest because of their covalency and the possibility of introducing different substituents into the phosphorus atom, and also because most of the compounds polymerize at moderate temperatures. As typical P–N compounds, phosphoric amides, the following types are known: $PO(OH)_2NH_2$, $POOH(NH_2)_2$, $PO(NH_2)_3$, $PONR_2(NH_2)_2$, $PO(OR)_2NH_2$, $POOR(NH_2)_2$, and $PONHR(NH_2)_2$. Some of these compounds have already been prepared by a reaction between the corresponding phosphoric chloride and ammonia at low temperatures.[2-4]

The author has also synthesized the phosphoric amides of $PONR_2(NH_2)_2$ type.[5] In this work, phosphoric aniline diamide, which is expected to have an excellent flame resistance because it contains an aromatic radical in its molecule, was initially formed by a reaction between phosphorus oxychloride, aniline, and ammonia in chloroform as the reaction medium. The pure product was then isolated from ammonium chloride by using ethanol and acetone as extractive solvents. In this paper an experimental study of the preparation and properties of this new compound is described.

Experimental

Synthesis. The flow sheet for the synthesis of phosphoric aniline diamide is shown in Fig. 1. The phosphoric amide can be prepared in the following way: 0.1 mole (15.3 g) of phosphoric oxychloride was placed in a three-necked flask and diluted with 100ml of chloroform. To this was added a solution containing 0.2 mol (18.6 g) of aniline in 80 ml of chloroform at room temperature. The precipitate of aniline hydrochloride (R·1) was separated by filtration from a solution containing phosphoric aniline dichloride. The above filtrate (SR1) was then added, drop by drop, into another three-necked fiask containing some ammoniacal chloroform at −15—20°C, simultaneously the reactant in the flask was vigorously stirred while a moderate basicity was maintained by passing gaseous ammonia into it. Thus, a mixture (R2) of phosphoric amide and ammonium chloride was precipitated. This was kept standing overnight and was then separated from the mother liquor (SR2). R2 was put into a stoppered Erlenmeyer flask containing 300 ml of ethanol and stirred. Thus, phosphoric amide and a portion of ammonium chloride contained in R2 were dissolved in ethanol, and the residue (R3) of ammonium chloride was isolated from the ethanol solution (SR3). Crude

phosphoric amide (R4) including ammonium chloride as an impurity was obtained by the vacuum distillation of SR3. A large amount of acetone was poured into R4, and the mixture was stirred for several hours at 35°C. Thus, phosphoric aniline diamide alone was dissolved in acetone. The resulting residue (R5) of ammonium chloride was isolated from the acetone solution (SR5). When the above extractions was incomplete because of the low solubility of phosphoric aniline diamide in acetone, it was necessary to use acetone for the reextraction. Pure phosphoric aniline diamide (R6) was precipitated fron an acetone solution concentrated by vacuum distillation at 40°C: R6 was separated by filtration from the mother liquor (SR6) and finally vacuum-dried over phosphorus pentoxide.

Analysis. A sample solution for determining the phosphorus, total nitrogen, and chlorine was prepared as follows: 0.2—0.8 g of a solid sample was weighed exactly and dissolved in water, the volume of the solution being adjusted to 250 ml.

The phosphorus content was determined gravimetrically as magnesium pyrophosphate. The total nitrogen content was determined by Kjeldahl's method. The chlorine content was determined gravimetrically as silver chloride.

The molecular weight of the product was determined with a Mechrolab model 301A vapor-pressure osmometer. The powder diffraction pattern was obtained by using a Rigaku-Denki model 2001 diffractometer with Ni-filtered Cu$K\alpha$ radiation, with 20 KVP and 5 mA. The infrared absorption spectrum was measured with a Hitachi model EPI-S2 infrared spectrophotometer applying the method of KBr disks. The differential thermal analysis (DTA) and thermogravimetric measurements (TGA) were performed simultaneously in a nitrogen atmosphere and at a heating rate of 5°C/min with a Rigaku-Denki model DC-Cl-S thermal analyser.

Results and Discussion

Synthesis of $PONHC_6H_5(NH_2)_2$. The results of the synthesis and analysis of phosphoric amides are summarized in Table 1.

Reaction between Phosphorus Oxychloride and Aniline. Phosphoric aniline dichloride and aniline hydrochloride are formed by the reaction of 1 mol of phosphorus oxychloride with 2 mol of aniline as follows.

$$POCl_3 + 2C_6H_5NH_2 \longrightarrow PONHC_6H_5Cl_2 + C_6H_5NH_2 \cdot HCl \quad (1)$$

$$POCl_3 + 4C_6H_5NH_2 \longrightarrow PO(NHC_6H_5)_2Cl + 2C_6H_5NH_2 \cdot HCl \quad (1')$$

$$POCl_3 + 6C_6H_5NH_2 \longrightarrow PO(NHC_6H_5)_3 + 3C_6H_5NH_2 \cdot HCl \quad (1'')$$

Chloroform was chosen as the medium for the reaction because it does not react with phosphorus oxychloride. Further, chloroform dissolves phosphoric aniline dichloride, but aniline hydrochloride is insoluble in it. Carbon tetrachloride used for the previous synthesis of phosphoric amides[4,5] was not suitable, since phosphoric aniline dichloride is insoluble in carbon tetrachloride.

For a mole ratio of 2: 1 of $C_6H_5NH_2$ to $POCl_3$, 11.7—14.1 g of R–1 was obtained. These typical results approached the theoretical yield (12.9 g) of aniline hydrochloride. The analytical values of R–1 also agreed with the calculated values of each component in the $C_6H_5NH_2 \cdot HCl$, so that confirmation of Eq. (1) might be expected. However, in the experiments at mole ratios of 4: 1 and 6: 1, it was found that Eqs. (1)′ and (1)″ respectively are not invariably completed.

Reaction between SR1 and Ammonia. A mixture (R–2) of phosphoric amide and ammonium chloride was precipitated by a reaction between the filtrate SR1 containing phosphoric aniline dichloride and ammonia as shown by

$$PONHC_6H_5Cl_2 + 4NH_3 \longrightarrow PONHC_6H_5(NH_2)_2 + 2NH_4Cl \quad (2)$$

In this case, a large amount of R–2 was obtained with a mole ratio of 2: 1 of $C_6H_5NH_2$ to $POCl_3$. The high yield of crude phosphoric amide extracted from the above R2 with ethanol was expected as a matter of course. The yield of R2, however, decreased with an increase in the mole ratio of $C_6H_5NH_2$ to $POCl_3$, and the yield of R8 as a by-product increased. It is conceivable that the reaction product (R8) dissolves in chloroform because of non-polarity with the excess of combined aniline, since, on the synthesis of this phosphoric amide, the mole ratio of 2: 1 of $C_6H_5NH_2$ to $POCl_3$ was just what was expected. When the effects of the reaction temperatures on the yields of R2 and R8 were observed, no apparent difference was recognized at −15—20°C. However, it is evident that the polymerization by deammoniation of phosphoric amides is prevented when Reaction (2) takes place at low temperatures and when diffusion of the heat of reaction is kept smooth, and consequently, a high yield of orthophosphoric amide might be expected. At reaction temperatures above 20°C, there is a probability of the formation of condensed products. The resulting product is reddish-brown, a color which frequently appears in aniline salts.

Extraction of Crude Phosphoric Amide from R2. The R2 product consists of phosphoric amide and ammonium chloride. The two compounds cannot be easily separated because their reactions with various solvents resemble each other; that is, both materials are soluble in water and methanol, and insoluble in such organic solvents as chloroform, carbon tetrachloride, petroleum ether, and benzene. The author therefore chose ethanol and acetone as the solvents because they have a suitable polarity for the extraction of phosphoric amide from R2. Acetone does not dissolve ammonium chloride, but phosphoric amide is a little soluble in it, so that the direct extraction of phosphoric amide, by using acetone is not an efficient treatment. Thus, ethanol which also dissolves a small amount of ammonium chloride was used in the first extraction of phosphoric amide from R4. The residue R4 was a light yellowish-brown powder, containing 13—15% P, 20—23% N, and 3—8% Cl, as shown in Table 1. It is soluble in water, the solution being almost neutral. The P: N: Cl atomic ratios of the products were 1.0: 3.0—3.6: 0.0—0.6, in which the values of Cl correspond to the values of nitrogen which exceed 3.0. It might be understood that crude phosphoric amide R4 is contaminated with ammonium chloride.

Extraction of Phosphoric Aniline Diamide. In the preliminary experiments, it was confirmed that phosphoric aniline diamide is slightly soluble in acetone, but not ammonium chloride. Therefore, the pure phosphoric aniline diamide R6 was obtained from R4 by a previous method. However, because of the low solubility of phosphoric aniline diamide in acetone, a tendency for this compound to remain in the R5 residue was often observed in the chemical analysis of R5 and on the basis of X-ray diffraction data. An efficient extraction of phosphoric aniline diamide may also be expected by using a solvent in which 2—5 vol% of ethanol is added to acetone.

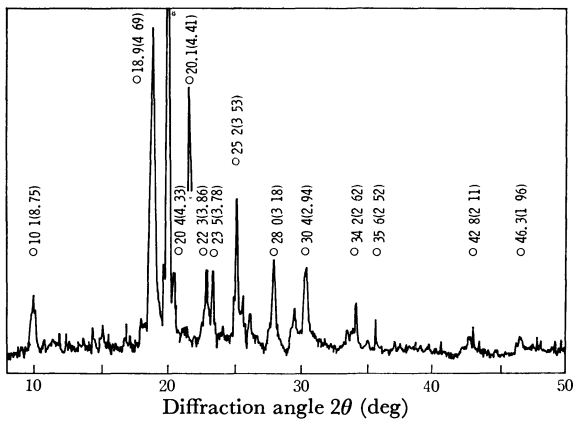

Fig. 2. X-ray diffraction spectrum of phosphoric aniline diamide. Numerals near peaks indicate distances (Å) between planes in crystals.

Properties of $PONHC_6H_5(NH_2)_2$. X-Ray Diffraction: Phosphoric aniline diamide is a white, crystalline powder. Each crystal is a tetragonal plate 5—30 μ in size, as determined by means of microphotography. The X-ray diffraction pattern is shown in Fig. 2. Three strong diffraction lines at 4.69, 4.41, and 3.53 Å can be used for identification. So far, single crystals of phosphoric aniline diamide of a suitable size have not been obtained, and an accurate interpretation of the X-ray data is not possible.

Solubility with Various Solvents. Compound $PONHC_6H_5 \cdot (NH_2)_2$ is soluble in water; its solubility is 3.49% at 0°C, and 5.66% at 25°C, and the pH of a 1% aqueous solution is 4.5. This compound is insoluble in such organic solvents as chloroform, carbon tetrachloride, petroleum ether, and benzene, but soluble in polar solvents such as methanol and ethanol, the solubility in the latter being 1.36% at 0°C and 2.39% at 25°C. The compound is slightly soluble also in acetone, the solubility being 0.23% at 0°C and 0.28% at 25°C. Therefore, on the complete extraction of R6 from R4, a large excess acetone is necessary for the treatment of R4.

Analysis of Purified Products. The percentage of each component in R6 agreed with that of the formula $PONHC_6H_5(NH_2)_2$. The P: N atomic ratios almost reached 1: 3, as shown in Table 1. The molecular weight of R6, as measured in the ethanol solution, was close to the calculated value (171.14) for this formula.

In the cases of Nos. 7 and 8, where the $C_6H_5NH_2/POCl_3$ mole ratios are 4: 1 and 6: 1, respectively, small amounts of R6 are obtained; the products can actually be denoted by $PONHC_6H_5(NH_2)_2$. The following process seems to take place: when 2 or 3 mol of aniline replace chlorine atoms in phosphorus oxychloride in Reactions (1) and (2), the part of which amount is greater than that of a connecting C_6H_5NH radical is replaced by NH_2 radical from ammonia giving rise to the formation of $PONHC_6H_5(NH_2)_2$.

Infrared Absorption Spectra. Previously, the infrared absorption spectra of $PO(NH_2)_3$ had been investigated by Stenger,[6] and those of $PON(C_2H_5)_2(NH_2)_2$ (crude) by the author,[5] but not the IR of $PONHC_6H_5(NH_2)_2$. The results are shown in Fig. 3.

In this spectrum, the absorption bands may be assigned as follows: There are N–H stretching vibrations at 3350 and 3220 cm^{-1}, the C–C stretching vibrations in aromatic compounds at 1600 and 1489 cm^{-1}, the C–N stretching vibrations in aromatic secondary amines at 1407 cm^{-1}, the N–H bending mode in secondary amines or the C–N stretching vibrations at 1291 and 1238 cm^{-1}, and the P–O stretching vibration at 1140 cm^{-1}, while the absorption bands in the range

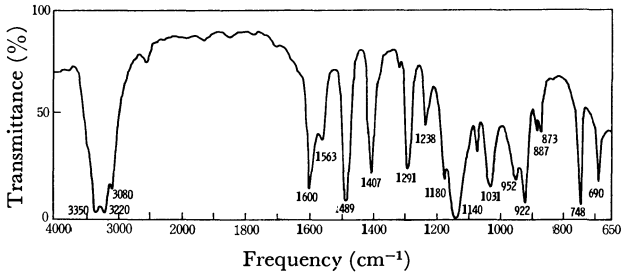

Fig. 3. Infrared spectrum of phosphoric aniline diamide.

of 1075 and 873 cm^{-1} are related to the NH_2 radicals. The assignment of the absorptions at 748 and 690 cm^{-1} is difficult. However, because though these peaks can be generally considered to represent the P–N stretching vibrations, the characteristic peaks of aniline as a raw material have also appeared at the same locations.

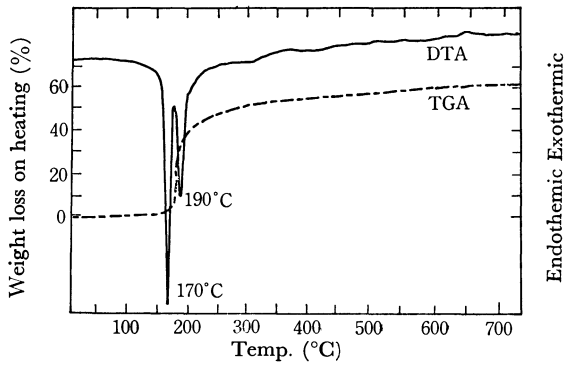

Fig. 4. DTA and TGA curves for phosphoric aniline diamide. Sample; 100 mg, Heating rate; 5°C/min, Current gas; Nitrogen 0.3l/min

Change in Product by Heating. When phosphoric aniline diamide is used in fireproof material its effect can be expected. In fact, both paper and fiber immersed in aqueous solutions of R4 or R6 exhibited a remarkable fireproof character. Both R4 and R6 reacted with formalin to form resinous products which are insoluble in water and fireproof. Upon heating, the $PONHC_6H_5(NH_2)_2$ melted at about 140°C and commenced condensation with deammoniation. The compound bubbled above 170°C after it formed a fire-resistant film.

The DTA and TGA curves for $PONHC_6H_5(NH_2)_2$ are shown in Fig. 4. Two endothermic peaks resulting from melting and condensation in the heated product appeared at 170 and 190°C, respectively. In this case condensation was recognized by the loss in weight shown by the TGA curve. Conversion of the phosphoric amide into the insoluble condensed phosphates was also confirmed by paper chromatography.

The Stability of Fused Rings in Metal Chelates. IX. Copper(II) and Nickel(II) Complexes of Schiff Bases Derived from Salicylaldehyde and Dipeptides Containing Glycine and/or β-Alanine

Yasuo NAKAO and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received April 24, 1972)

Copper(II) and nickel(II) complexes of Schiff bases derived from salicylaldehyde(Sal) and dipeptides containing glycine and/or β-alanine have been prepared. It has been found that Schiff base ligands containing glycylglycine (Gly·Gly), glycyl-β-alanine (Gly·β-Ala) or β-alanylglycine (β-Ala·Gly) as the peptide moieties give rise to square-planar, quadridentate copper(II)- and nickel(II)-chelates, while the *N*-salicylidene-β-alanyl-β-alanine (Sal=β-Ala·β-Ala) does not form the same type of copper(II)- or nickel(II)-chelate. It is concluded on the basis of spectrophotometric, polarographic and other measurements that the stability decreases in the order 6-5-5-([Cu(Sal=Gly·Gly)])≧6-5-6-([Cu(Sal=Gly·β-Ala)])≧6-6-5-([Cu(Sal=β-Ala·Gly)])≫6-6-6-([Cu(Sal=β-Ala·β-Ala)])fused-ring system.

In a previous paper,[1] it was reported as the result of a comparative study on copper(II) complexes of Schiff bases derived from 2-acetylpyridine or 2-pyridinecarbaldehyde and some dipeptides that the stability of fused-ring systems in metal Schiff base chelates decreases in the order 5-5-6-≃5-6-5->5-5-5->5-6-6-membered ring system.[2] As an extension of our previous investigations we have studied the copper(II) and nickel(II) complexes of Schiff bases produced from salicylaldehyde and dipeptides such as glycylglycine, glycyl-β-alanine, β-alanylglycine, and β-alanyl-β-alanine. Structural formulas of these chelates are shown in Fig. 1, (Ia—V'). In this paper we describe the relationship between the structures of the chelates and their relative stabilities.

Copper(II) Complexes of the Schiff bases Derived from Salicylaldehyde and Glycylglycine, Glycyl-β-alanine, β-Alanylglycine or β-Alanyl-β-alanine (Ia—IVa). The sodium and potassium salts of *N*-salicylideneglycylglycinatocuprate(II) (Ia) were reported in detail.[3] In the present study we have newly prepared copper(II) chelates of Schiff bases obtained from salicylaldehyde and glycyl-β-alanine, β-alanylglycine, or β-alanyl-β-alanine (IIa, IIIa, and IVa, respectively). The chelates were prepared by reactions of each dipeptide with bis(salicylaldehydato)copper(II) in the pH range 9—11. Of these IIa and IIIa have been isolated as either potassium, calcium, or barium salts. The color of these salts is violet, and their IR spectra revealed that the structure of each complex is essentially the same as that in Ia regardless of the kind of cation. On the other hand, preparation of the copper(II) chelate of *N*-salicylidene-β-alanyl-β-alanine by the same method has resulted in the formation of a bright green complex. The decomposition temperature, absorption maximum for the *d-d* transition band and the half-wave

potentials for the reduction of copper(II) at the dropping mercury electrode of a green complex are given in Table 1, together with those of three violet complexes, Ia—IIIa. A comparison of some properties in Table 1 shows that the structure of the green complex may differ from that of the three violet complexes which have similar properties to each other. Since

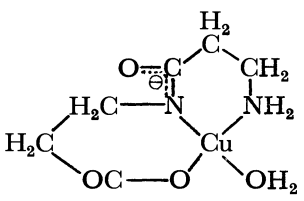
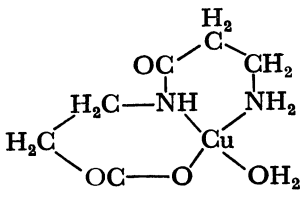
a) pH	$\bar{\nu}_{max}$($\times 10^3$)cm^{-1}	b) pH	$E_{1/2}^{(1)}$	$E_{1/2}^{(2)}$
6.5	15.2	6.3	−0.16V	−0.42V
8.4	16.4	7.9	−0.16	−0.42
10.3	16.8	8.7	−0.18	−0.43
11.2	16.8	9.4	−0.20	−0.43
		10.0	−0.21	−0.43
		11.4		−0.43

such properties as the color and decomposition temperature of the crystals and the absorption maximum for the *d-d* band in the 20% dimethyl sulfoxide aqueous solution are similar to those of *N*-salicylideneaminoacidatoaquocopper(II),[4] the green complex seems to be better explained by the structure V or V' rather than by IVa. The result of elemental analysis also supports the presumption. We have recently demonstrated from a pH-titration study that the deprotonation of amide >NH to CuL from $CuHL^+$ in the β-alanyl-β-alanine-Cu(II) chelate is more difficult than that in copper(II) chelate with glycylglycine, glycyl-β-alanine, or β-alanylglycine.[5] The difficulty in isolating copper(II) chelate of IVa-structure can be explained as due to the result described above and the increasing steric strain in 6-6-6-fused-ring system. Thus it can be concluded that the copper(II) complex IVa is less stable than complexes Ia—IIIa.



CuL



$CuHL^+$

From the decomposition temperatures, the absorption maxima of *d-d* transition bands and the polarographic half-wave potentials (nearly constant in the pH range 6—10) corresponding to the reduction of copper(II) in the chelates Ia—IIIa (Table 1), we see that the stability of the three copper(II) complexes differs only slightly. On the other hand, the polarographic behavior of the bright green complex is entirely different from that of the other violet complexes Ia—IIIa. The polarograms of the green complex corresponding to various pH values are given in Fig. 2. The reduction wave for the green complex consists of two steps, in which the ratio of the wave-height of the first and

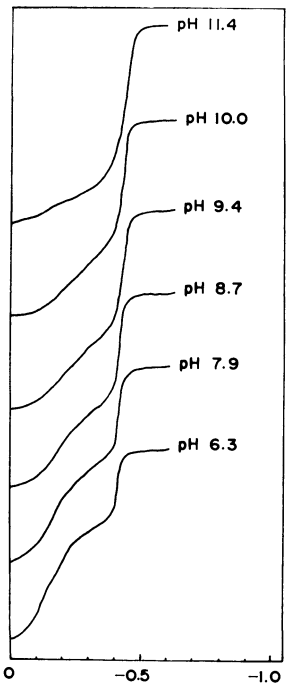


Fig. 2. Polarograms of salicylaldehyde-β-alanyl-β-alanine-copper(II) in various pH-values.

second reduction wave varies with pH values. The wave-height of the first reduction wave decreases but that of the second reduction wave increases with the rise in pH, the total wave-heights remaining unchanged. Thus, it is considered that two kinds of complexes exist in the pH range 6—11, and the ratio of their abundance changes with pH. The second wave on the polarogram can be estimated as the reduction wave due to the species IVa, as judged from the value of the half-wave potential and the increase of its wave-height with the rise in pH. On the other hand, the first wave is considered to be the reduction wave for the green complex V (or V'). The effect of pH on the *d-d* absorption band for the green complex was also examined. The results are shown in Table 1. We see that the *d-d* absorption band is hypsochromically shifted with increasing pH values. The absorption maximum at pH 6.5 is almost the same as those of *N*-salicylideneaminoacidatoaquocopper(II) complexes.[4]

4) Y. Nakao, K. Sakurai, and A. Nakahara, This Bulletin, **40**, 1536 (1967).

5) O. Yamauchi, Y. Hirano, Y. Nakao, and A. Nakahara, *Can. J. Chem.*, **47**, 3441 (1969).

In the pH region 10.3—11.2 the absorption maximum is observed at 16.8×10^3 cm^{-1}, showing the formation of a structure similar to that of copper(II) chelates Ia—IIIa. Thus, it can be considered that the most predominant structure of chelate in aqueous solution at around pH 11 should be the one represented by IVa. The reason why the species IVa cannot be isolated in the preparation of salicylaldehyde-β-alanyl-β-alanine-copper(II) chelate in aqueous solution in the pH range 9—11 was found to be as follows: V (or V') are preferentially separated from the solution because of its comparatively poor solubility when the equilibrium V (or V')⇋IVa takes place in an alkaline solution. From a comparison of the easiness of preparation and of the numerical data in Table 1, it may be concluded that the relative stability in the copper(II) chelates Ia—IVa decreases in the order: Ia(6-5-5)≧IIa-(6-5-6)≧IIIa(6-6-5)≫IVa(6-6-6). It is of interest to note that the chelate produced from copper(II), β-alanyl-β-alanine and 2-pyridinecarbaldehyde or 2-acetylpyridine (instead of salicylaldehyde) can easily be isolated as stable crystals,[1] but not IVa. This contrast is understood by taking the increasing strain in the 6-6-6-fused-ring system into consideration.

Nickel(II) Complexes of the Schiff Bases Derived from Salicylaldehyde and Glycylglycine, Glycyl-β-alanine, β-Alanylglycine or β-Alanyl-β-alanine (Ib—IVb). Nickel(II) complexes of Schiff bases derived from salicylaldehyde and dipeptides (Gly·Gly, Gly·β-ala, β-Ala·Gly, and β-Ala·β-Ala) were prepared. The nickel(II) complex Ib containing glycylglycine residue was isolated as potassium, calcium or barium salts. Their IR spectra showed no essential difference and were in good agreement with those for the corresponding salts of *N*-salicylideneglycylglycinatocuprate(II). From these IR-studies and the elemental analyses, it is evident that the structure of nickel(II) complex produced from salicylaldehyde, glycylglycine, and nickel(II) is of Ib. Similar findings were confirmed also for nickel(II) complexes of *N*-salicylidene-glycyl-β-alaninate and -β-alanylglycinate. Hence, the structures of those chelates are concluded to be of IIb and IIIb, respectively. The nickel(II) complex of Schiff base derived from salicylaldehyde and β-alanyl-β-alanine could not be isolated. During the course of preparation of nickel(II) complexes Ib—IIIb the original green solution turned orange with the rise in pH, giving orange crystals. The visible and ultraviolet absorption spectra for nickel(II) chelates Ib—IIIb in dimethyl sulfoxide-water (1: 1 by volume) are shown in Fig. 3. The absorption curves resemble those observed for nickel(II) complexes which are considered to have a square-planar structure.[6] In the case of salicylaldehyde-β-alanyl-β-alanine-nickel(II) complex, the color of reaction solution does not change during the course of preparation regardless of pH (5—11). Thus, all efforts to obtain the complex in crystal were unsuccessful. However, it may be considered from the absorption spectrum of the reaction solution diluted with water that the nickel(II) complex of *N*-salicylidene-β-alanyl-β-alaninate in solution have an octahedral structure.[6] This suggests that the complex is more stabilized in high-spin form (sp^3d^2) than in square-planar form. This is because of the rather weak ligand field of *N*-salicylidene-β-alanyl-β-alaninate, which contains a considerable strain in 6-6-6-fused-ring system IVb.

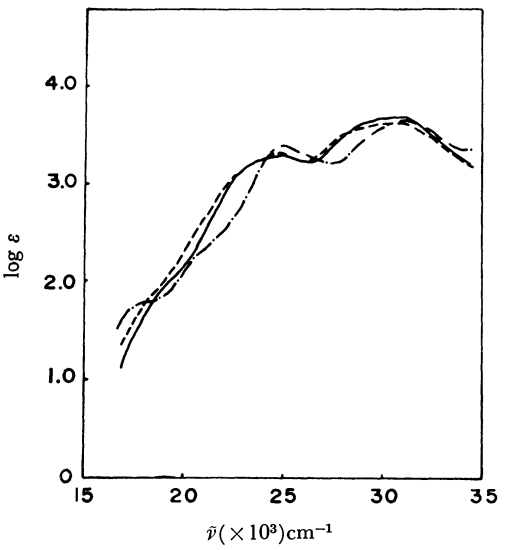

Fig. 3. VIS-UV spectra of Ba/2[Ni(Sal=Gly•Gly)]•H_2O (—), Ba/2[Ni(Sal=Gly•β-Ala)]•$3H_2O$ (--), and Ba/2[Ni (Sal=β-Ala•Gly)]•$2H_2O$ (——).

Experimental

Dipeptides[1] and Bis(salicylaldehydato)copper(II)[7] were prepared according to the directions described previously.

Bis(salicylaldehydato)nickel(II) was obtained by the same method as that for the corresponding copper(II) complex, using nickel acetate instead of copper acetate. *Potassium N-salicylideneglycylglycinatocuprate(II)* was prepared by the known method.[3] *Potassium* N-*salicylideneglycylglycinatonickelate-(II), Ib.* Into 15 ml of a water: ethanol mixture (2:1 by volume) were dissolved 0.34 g of glycylglycine and 0.78 g of bis(salicylaldehydato)nickel(II). The resulting mixture was adjusted to pH 9—10 by 1N-KOH solution and stirred at 25°C for an hour. The reaction product was deposited as orange powders and was recrystallized from water-ethanol. The results of elemental analyses are shown in Table 2.

Barium Salts of Copper(II) Chelates of Schiff Bases Derived from Salicylaldehyde and Dipeptides(Ia—IIIa), and Copper(II) Chelate Containing β-alanyl-β-alanine as Dipeptide Moiety (V or V'). *Method A*: To a mixture of 0.0025 mol of each dipeptide and 15 ml of water: ethanol (2: 1 by volume) was added 0.0025 mol of bis(salicylaldehydato)copper(II). The pH-values of each reaction solution were adjusted to 9—11 by using 1N-KOH solution. After it had been stirred at 25°C for an hour, the reaction mixture was filtered. The filtrate was passed through a column of the cation exchanger Amberlite IR-120B (Ba form). The column was washed with water, and the violet crystalline product adsorbed on the resin layer was extracted by hot water. The solution which had passed through the cation exchanger and the extracted aqueous solution were combined and concentrated *in vacuo* until violet crystals were considerably deposited. This was recrystallized from hot water (90°C). In the case of reaction system containing β-alanyl-β-alanine as dipeptide, the solution

which had passed through a column was evaporated to dryness *in vacuo*. The green products were recrystallized from water-acetone. Its aqueous solution gave no white precipitate by the addition of dilute sulfuric acid. Analytical data of the violet complexes are given in Table 3. Analytical data of the green complex are as follows: Found: C, 45.54; H, 4.70; N, 8.19%. Calcd for Cu($C_{13}H_{14}N_2O_4$)·H_2O: C, 45.41; H, 4.70; N, 8.15%.

Method B. Almost the same procedure as that in Method A was applied. After filtration of reaction mixture, the saturated solution of barium chloride (0.63 g) was added to the filtrate. Upon cooling the solution violet crystals were deposited, which were filtrated by suction and recrystallized from hot water (90°C).

Calcium Salts of Copper(II) Chelates of Schiff Bases Derived from Salicylaldehyde and Dipeptides (glycylglycine, glycyl-β-alanine) Ia—IIa. These complexes were obtained in a similar manner to method B using calcium chloride instead of barium chloride. Recrystallization from water or water-ethanol gave violet crystals, whose analytical data are given in Table 2.

Barium Salts and Calcium Salts of Nickel(II) Chelates of Schiff Bases Derived from Salicylaldehyde and Dipeptides (glycylglycine, glycyl-β-alanine, β-alanycine) Ib—IIIb. The same method of preparation as that for copper(II) complexes was employed. The results of elemental analyses are shown in Table 2 and 3.

Measurements. The VIS-UV absorption spectra were obtained with a Shimadzu spectrophotometer QR-50 at room temperature. The solvent used was 20% or 50% dimethyl sulfoxide aqueous solution. The IR spectra were recorded with a Hitachi EPI-2 infrared spectrophotometer. The measurements were carried out at room temperature using the pressed KBr disk technique in the wave number range 700—4000 cm^{-1} with a rock-salt prism. Polarographic measurements were carried out by the same method as already described.[1] Water was used as solvent. Concentration of the copper(II) chelates used was 5×10^{-4}M. The supporting electrolyte and the maximum suppressor used were 0.1M-KNO_3 and Triton X-100 (0.0018%), respectively. The pH-value of each solution was adjusted by KOH solution.

Sterically Controlled Syntheses of Optically Active Organic Compounds. XVII. Asymmetric Syntheses of Amino Acids by Addition of Benzoyl Cyanide to the Azomethine Compounds[1]

Kaoru HARADA and Tadashi OKAWARA

Institute for Molecular and Cellular Evolution and Department of Chemistry, University of Miami, Coral Gables, Florida, 33134 U.S.A.

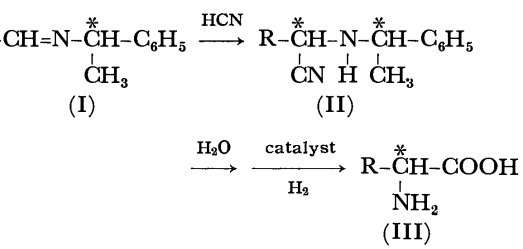
(Received June 6, 1972)

The addition reactions of benzoyl cyanide to the Schiff's bases prepared from several aliphatic aldehydes with optically active benzylic amines were studied. The adioditn products were hydrolyzed and hydrogenolyzed to form optically active amino acids. The synthetic yields of optically active amino acids were in a range 15 to 57% and the optical purities were in a range 15—37%. When *S*-α-alkylbenzylamines were used, *S*-amino acids were obtained.

Addition reactions to the cabon-nitrogen double bonds have been studied.[2,3] Carbon-nitrogen double bonds react with hydrogen cyanide to form α-aminonitriles.[4-12] Hydrolysis of the aminonitriles yielded α-amino acids.

Partially optically active *N*-alkyl-α-aminopropionitrile (II) was prepared from optically active α-methylbenzylamine, acetaldehyde, and hydrogen cyanide[13] or from the same amine with lactnitrile.[14] *N*-α-Methylbenzyl aminoacetonitrile (II) was hydrolyzed and hydrogenolyzed to form optically active alanine. From the reaction mixture, highly optically active alanine (optical purity 85—98%) was isolated by crystallization in which fractionation of optical isomers would take place.[15]

Recently Patel and Worsley[16] reported an asymmetric synthesis of α-amino acids (mostly unnatural) by addition of hydrogen cyanide to the carbon-nitrogen double bond of the Schiff's base that was prepared from optically active α-methylbenzylamine and various aldehydes. The optical purities of amino acids they reported were very high (98—99%). The high optical purities have resulted from fractionation during the crystallization and washing procedures employed in the synthesis.[17]



In this investigation, the addition reactions of benzoyl cyanide to azomethine compounds prepared from various optically active benzylic amines and aliphatic aldehydes were studied as shown in Scheme 1. The amines used were benzylamine, *S*-(−)-α-methylbenzylamine, *R*(+)-α-methylbenzylamine, *S*(−)-α-ethylbenzyl amine, and *S*(−)-α-(1-naphthyl)ethylamine. The aldehydes used were acetaldehyde, propionaldehyde, isobutyraldehyde, and isovaleraldehyde.

The addition reactions of benzoyl cyanide to the various azomethine compounds were carried out at room temperature in ether solution for 20—24 hrs. The

resulting reaction products that contained *N*-benzoyl-*N*-alkylaminonitrile were hydrolyzed with 6N hydrochloric acid under reflux. The resulting *N*-alkylamino acids were separated by the use of a Dowex 50 ion exchange column. A part of the *N*-benzylamino acids was recrystallized from water and ethanol. The melting points and analytical data for the *N*-benzylamino acids are shown in Table 1. The *N*-alkylamino acids were then hydrogenolyzed with palladium on charcoal. The racemic amino acids prepared by the use of benzylamine were recrystallized for elemental analyses. The results are shown in Table 2.

The syntheses of optically active amino acids by addition reaction of benzoyl cyanide to Schiff's bases which are composed of optically acitve amines were carried out in a similar way. However, in order to remove the *N*-α-alkylbenzyl group, palladium hydroxide on charcoal instead of palladium on charcoal was used. A part of the resulting amino acids were converted to their corresponding DNP derivatives. The resulting DNP derivatives were then purified by the use of a Celite column,[18] without fractionation of optical isomers.[19] These DNP derivatives were used

to measure the optical purities of resulting amino acids. The specific rotations, optical purities, and synthetic yields of amino acids are listed in Table 3. However, DNP-leucine is difficult to crystallize and the elimination of dinitrophenol from the DNPylated reaction mixture by sublimation before celite column chromatography is probably not complete. Therefore, the specific rotations and optical purities of leucine listed in Table 3 are thought to be lower than those of the actual values. The other part of amino acids were recrystallized from water and alcohol for elemental analyses. Some of the elemental analyses of optically active amino acids prepared from *S*(−)-α-methylbenzylamine are shown in Table 4.

Table 4. Elemental analyses of optically active amino acids using *S*(−)-α-methylbenzylamine

	Formula	Calcd (Found)		
		C	H	N
S-Alanine	$C_3H_7NO_2$	40.44 (40.33)	7.92 (7.87)	15.72 (15.69)
S-Butyrine	$C_4H_9NO_2$	46.59 (46.83)	8.86 (8.81)	13.58 (13.70)
S-Valine	$C_5H_{11}NO_2$	51.62 (50.87)	9.46 (9.34)	11.96 (11.68)
S-Leucine	$C_6H_{13}NO_2$	54.94 (55.10)	9.99 (9.89)	10.68 (10.43)

The overall yield of amino acid is in a range of 20—60%. The yield of alanine is the highest; however, the yields decrease as the size of the alkyl group of the aldehyde increases. In all cases the yields of racemic α-amino acids prepared from sterically least hindered benzylamine are the highest. When *S*(−)-amine and *R*(+)-amine were used, the configurations of the resulting amino acids were (*S*)- and (*R*)- respectively. The facts agree with the results obtained in the related Strecker type asymmetric synthesis.[13-17] The optical purities are in a range of 15—39%. The effect of optically active amines on the resulting amino acids is not clear, except in the case of valine synthesis. The optical purity of (*S*)-valine prepared by the use of *S*(−)-α-(1-naphthyl)ethylamine was 39% compared with less than 20% of optical purity prepared by α-methyl- or α-ethylbenzylamine.

Experimental

All hydrogenolysis reactions were carried out by the use of Paar 3910 shaker type hydrogenation apparatus. All optical activity measurements were carried out on a JASCO-ORD-UV 5 spectropolarimeter.

The specific rotations of optically active amines were:
R(+)-α-methylbenzylamine, $[\alpha]_D^{25}+41.5°$ (benzene)
S(−)-α-methylbenzylamine, $[\alpha]_D^{25}-42.3°$ (benzene)
S(−)-α-ethylbenzylamine, $[\alpha]_D^{25}-21.0°$ (benzene)
S(−)-α-(1-naphthyl)ethylamine, $[\alpha]_D^{25}-86.5°$ (benzene)

Preparation of the Schiff's Base (VI). To the solution of benzylic amine (0.01 mol) in 15 m*l* of anhydrous benzene was added a solution of an aldehyde (0.01 mol) in 15 m*l* of benzene under ice cooling. The solution was kept in ice water for five minutes under occasional shaking. Then the solution was kept at room temperature for twenty minutes. To the mixture, 5.0 g of anhydrous sulfate was added to remove precipitated water. The benzene solution was kept for another 12 hr at room temperature. The mixture was filtered to remove sodium sulfate and the filtrate was evaporated under reduced pressure at a temperature below 45°C using a water bath. The pale yellow syrup (Schiff's base) was used for addition without further purification.

Preparation of N-*Benzoyl*-N-*alkylaminoacetonitrile (VII).* Freshly distilled benzoyl cyanide (1.30 g, 0.01 mol) in anhydrous ether (15 m*l*) was added to a solution of the Schiff's base (0.01 mol) in 15 m*l* of anhydrous ether. The reaction mixture was allowed to stand for 20 hr at room temperature. Then the ether was evaporated and the residue was used for further hydrolysis.

N-*Alkylamino Acids (VIII).* The crude *N*-benzoyl-*N*-alkyl-aminoacetonitrile (VII) was refluxed with 6N HCl (30 m*l*) for 6 hr. After the hydrolysis was over, the hydrochloric acid was removed under reduced pressure. To the residue, water (20 m) was added and the evaporation procedures were repeated 3 times to minimize the residual hydrochloric acid. The residue was dissolved in a small amount of water and was applied to a Dowex 50 column (H^+ form, 19×2.3 cm). The column was washed with water and then the column was eluted with 1.5N aqueous ammonia. The fractions containing *N*-alkylamino acid were combined and were evaporated to dryness under reduced pressure. In the *N*-benzylamino acid preparation, the residue was divided into two portions. A part was recrystallized from water and ethanol for elemental analysis and the remaining part was used for further hydrogenolysis. The melting points and elemental analyses of racemic *N*-benzylamino acids prepared by the use of benzylamine are listed in Table 1.

Amino Acids (IX). The *N*-alkylamino acid was dissolved in a mixture (60 m*l*) of water and ethanol (1:1 in volume). The solution was mixed with 0.8 g of palladium hydroxide on charcoal (in the case of *N*-benzylamino acid, 5% palladium on charcoal was used), and was hydrogenolyzed for 12 hr. After hydrogenolysis was over, the catalyst was removed by filtration. Free amino acid was obtained by evaporation of the solvent. A part of the amino acid was recrystallized from water and ethanol for elemental analysis. The elemental analyses of racemic amino acid prepared by the use of benzylamine are listed in Table 2. The elemental analyses of optically active amino acid prepared from *S*(−)-α-methylbenzylamine are shown in Table 4. The optically active amino acids were converted to DNP-amino acids in the usual way,[20] and the resulting DNP-amino acids were purified by the use of a Celite column treated with pH 7 citrate–phosphate buffer.[18] The specific rotations, optical purities, and overall yields are shown in Table 3.

This work was supported by Grant NGR 10-007-052 from the National Aeronautics and Space Administration. The authors wish to express their thanks to Dr. Kazuo Matsumoto for valuable discussions. Thanks are extended also to Mr. Charles R. Windsor for amino acid analyses.

The Tautomeric Equilibria of 4-(Dialkylamino)azobenzene Derivatives

Shunzo YAMAMOTO, Norio NISHIMURA, and Shigeo HASEGAWA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received February 21, 1972)

The tautomeric equilibrium constants, K_t=[ammonium ion]/[azonium ion], of the first conjugate acids of 4-dialkylaminoazobenzene derivatives were estimated by the spectrophotometric method. The K_t values increase in this order: pyrrolidino- <dimethylamino- <diethylaminoazobenzenes. The effects of *N*-alkyl groups on the base strength of the amino and azo nitrogens were examined in order to explain the effects on the tautomeric equilibrium. The base strength of azo nitrogens is governed by the degree of the resonance interaction between the amino group and the rest of the molecule. For dimethylamino- and pyrrolidinoazobenzenes, the base strength of the amino nitrogen can also be explained in terms of the resonance effects, but the amino nitrogen of diethylaminoazobenzenes exhibits an anomalously high base strength, arising from the steric inhibition of the hydrogen bonding in the free base. The above order of K_t can be explained in terms of these cumulative resonance and steric effects.

The structures of the first conjugate acids of 4-aminoazobenzene derivatives have been the subject of much discussion.[1-4] Some authors[1,2] have identified the ammonium structure as the exclusive one of the conjugate acids of 4-dimethylaminoazobenzene. Others,[3,4] on the other hand, have concluded that the conjugate acid has the azonium structure.

Recently it has become clear, however, that there is a tautomeric equilibrium between the ammonium and the azonium forms.[5-8] The tautomeric equilibrium constants have been determined by several workers.[7-9] Jaffé *et al.*[7] determined the constants for a series of substituted derivatives of 4-dimethylaminoazobenzene by various methods, and found that the constants follow the Hammett equation.

A number of attempts[10-12] have been made to explain the structural effects on the basicities of alkylanilines. The base strength of *N,N*-dialkylaniline derivatives in 50% aqueous ethanol are in this order: *N*-phenylpyrrolidine< dimethylaniline< diethylaniline.[11] It has been proposed that solvation on the alkaline side of the ionization equilibrium lowers the free energy of *N*-phenylpyrrolidine and dimethylaniline, and that it is, therefore, base-weakening. The steric inhibition of solvation occurs with diethylaniline and is base-strengthening. It can be expected, therefore, that for 4-dialkylaminoazobenzenes the basicity of the amino nitrogen atom is similarly influenced by the alkyl groups, but the basicity of the azo nitrogen atoms is not so much influenced. As far as we know, there has been no study of the effect of *N*-substituents on the tautomeric equilibrium. The purpose of the present paper is to examine to what extent the tautomeric equilibrium of the first conjugate acids of 4-dialkylaminoazobenzene derivatives is influenced by a change in the alkyl groups.

Experimental

Compounds. The 4-dimethylamino- and 4-diethylaminoazobenzene derivatives were prepared by procedures described in a previous paper.[13] The 4-pyrrolidinoazobenzene derivatives were prepared by diazotizing aniline derivatives and by coupling the resulting diazonium salt with *N*-phenylpyrrolidine, which had been prepared by the methods given in the literature.[14] These azo compounds were purified by dissolving them into benzene, passing them through an alumina column, and then crystallizing them from benzene. The *N,N,N*-trimethyl-*p*-phenylazoanilinium chlorides were prepared by procedures described by Jaffé and Isaks.[7]

Measurements. The dipole moments and the absorption spectra of the bases were measured by the methods described in a previous paper.[13] The absorption spectra of unbuffered solutions were measured in *ca.* 50% aqueous ethanol (25 ml of the solution contained 12.5 ml of commercial 99% ethanol) with various concentrations of acids. The concentrations of all the azo compounds were about 3×10^{-5}M. The pH of the solutions was measured by means of a Hitachi-Horiba pH meter, Model M-5, calibrated with standard buffer solutions at 25±0.5°C. The dissociation constants, pK_a, were calculated by a standard method. The average deviations for all the compounds were within ±0.05 pH units.

Results

The spectra of some 4-dialkylaminoazobenzene derivatives in *ca.* 1N hydrochloric acid (50% aqueous ethanol), the acidity of which is necessary for the complete formation of the first conjugate acid, are given in Fig. 1. The A band at about 320 nm has been attributed to the conjugation band of the species of the ammonium form (II), while the C band at about 510 nm has been ascribed to that of the azonium form (III).[5-8] The spectra show that the first conjugate acids of 4-dialkylaminoazobenzene derivatives are equilibrium mixtures of II and III, as has been proposed by earlier workers.[5-8] It seems that the $\varepsilon_a/\varepsilon_c$ ratio gives a crude idea of the tautomeric equilibrium. The ε_a value is the apparent molar extinction coefficient at the wavelength maximum of the A band, and the ε_c value is that at the wavelength maximum of the C band. The $\varepsilon_a/\varepsilon_c$ ratio for various substituted

4-dialkylaminoazobenzenes are shown in Table 1.

As is shown in Table 1, $\varepsilon_a/\varepsilon_c$ varies widely from compound to compound. This shows that the tautomeric equilibrium is sensitive to *N*-substituents; especially for 4-pyrrolidinoazobenzene derivatives the equilibrium greatly shifts to the azonium form.

It has been shown for 4-aminoazobenzene derivatives that ε_c increases, and that, simultaneously, ε_a decreases, with an increase in the sulfuric acid concentration.[9] In a very concentrated sulfuric acid (>12N), both bands, A and C, disappear, and at the same time a

new band appears at about 410 nm; this latter band has been assigned to the diprotonated form.[7,8] Figure 2 shows a plot of ε_a and ε_c against the sulfuric acid concentration. As is shown in Fig. 2, for 4-dimethylamino- and 4-diethylaminoazobenzene derivatives ε_c increases and ε_a decreases with an increase in the sulfuric acid concentration. For 4-pyrrolidinoazobenzene, however, ε_a and ε_c are almost uninfluenced by the change in the acid concentration. This shows that, for dimethylamino- and diethylaminoazobenzenes, the tautomeric equilibrium shifts from the ammonium to the azonium form with an increase in the sulfuric acid concentration,[9] while for pyrrolidinoazobenzene the equilibrium does not change, since it has almost completely shifted to the azonium form even at lower concentrations of sulfuric acid. The molar extinction coefficient of the azonium form at *ca.* 510 nm (Band C) for dimethylamino- and diethylaminoazobenzenes cannot be obtained by direct photometric measurement, since they exist in both the azonium and ammonium forms. However, since pyrrolidinoazobenzenes exist exclusively in the azonium form, the ε_c values can be regarded as true molar extinction coefficients. If the molar extinction coefficients of the azonium forms (Band C) are the same for these three types of compounds with the same 4′-substituents, the tautomeric equilibrium constants can be estimated in the following way:

$$\text{Fraction of III} = \frac{\varepsilon_c}{\varepsilon_c^0}$$

$$\text{Fraction of II} = 1 - \frac{\varepsilon_c}{\varepsilon_c^0}$$

Therefore,
$$K_t = \frac{[\text{II}]}{[\text{III}]} = \frac{\varepsilon_c}{\varepsilon_c^0} - 1 \qquad (1)$$

where ε_c^0 is the ε_c value of 4-pyrrolidinoazobenzene derivatives.

According to Gerson and Heilbronner,[8] the equilibrium in question can be expressed as in the following chart:

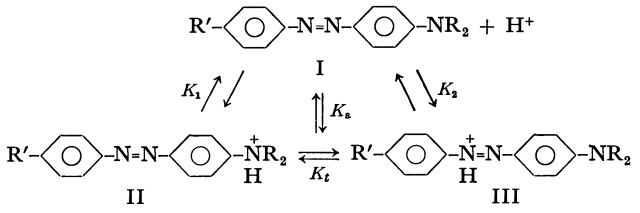

Chart 1.

In this case, the following equations may hold:

$$\begin{aligned} \varepsilon_a C &= \varepsilon_a^{\text{II}}[\text{II}] + \varepsilon_a^{\text{III}}[\text{III}] \\ \varepsilon_c C &= \varepsilon_c^{\text{II}}[\text{II}] + \varepsilon_c^{\text{III}}[\text{III}] \\ C &= [\text{II}] + [\text{III}] \end{aligned} \qquad (2)$$

where $\varepsilon_a^{\text{II}}$ and $\varepsilon_a^{\text{III}}$ are the molar extinction coefficients of II and III at the wavelength maximum of the A band, where $\varepsilon_c^{\text{II}}$ and $\varepsilon_c^{\text{III}}$ are those of II and III at the wavelength maximum of the C band, where [II] and [III] represent the concentrations of II and III respectively, and where C is the concentration of the free base added. Since $\varepsilon_a^{\text{III}}$ is small compared with $\varepsilon_a^{\text{II}}$, and since $\varepsilon_c^{\text{II}}$ is nearly zero, the tautomeric equilibrium constant, K_t, may be expressed as:

$$K_t = \frac{[\text{II}]}{[\text{III}]} = \frac{\varepsilon_c^{\text{III}}}{\varepsilon_a^{\text{II}}} \frac{\varepsilon_a}{\varepsilon_c} \qquad (3)$$

Gerson and Heilbronner[8] assumed that the value of the $\varepsilon_c^{\text{III}}/\varepsilon_a^{\text{II}}$ ratio for 4-dimethylaminoazobenzene is 3 on the basis of the data of Isaks and Jaffé, and that this value is valid for other 4-dimethylaminoazobenzene derivatives as well.

In the present case, however, $\varepsilon_c^{\text{III}}/\varepsilon_a^{\text{II}}$ was estimated in a different manner. From Eq. (2), it follows that

$$\varepsilon_c = \left(\frac{\varepsilon_c^{\text{II}} - \varepsilon_c^{\text{III}}}{\varepsilon_a^{\text{II}} - \varepsilon_a^{\text{III}}}\right)\varepsilon_a + \frac{\varepsilon_c^{\text{III}}\varepsilon_a^{\text{II}} - \varepsilon_c^{\text{II}}\varepsilon_a^{\text{III}}}{\varepsilon_a^{\text{II}} - \varepsilon_a^{\text{III}}}$$

Since $\varepsilon_a^{\text{II}} \gg \varepsilon_a^{\text{III}}$, and $\varepsilon_c^{\text{II}} \approx 0$,

$$\varepsilon_c = -\frac{\varepsilon_c^{\text{III}}}{\varepsilon_a^{\text{II}}}\varepsilon_a + \varepsilon_c^{\text{III}} \qquad (4)$$

According to Eq. (4), there should be a linear relationship between ε_c and ε_a. Various sets of ε_c and ε_a were obtained by changing the sulfuric acid concentrations; they were then plotted according to Eq. (4). A representative one is given in Fig. 3, which shows the validity of Eq. (4). The values of $\varepsilon_c^{\text{III}}/\varepsilon_a^{\text{II}}$ and $\varepsilon_c^{\text{III}}$ were obtained from the slope and the intercept of the line in Fig. 3. These values are given in Table 2. In Table 2, $\varepsilon_a^{\text{IV}}$ denotes the molar extinction coefficinet of *N,N,N*-trimethyl-*p*-phenylazoanilinium chlorides (IV) at the wavelength maximum of the band corresponding to that of the ammonium form (II).

Since the electronic effect of the $-\overset{+}{N}(CH_3)_3$ group on the **A** band may be similar to that of the $-\overset{+}{N}H(CH_3)_2$ group, it should be $\varepsilon_a^{II} \approx \varepsilon_a^{IV}$. As expected, the agreement is quite satisfactory (Table 2), indicating again the validity of Eq. (4).

As is shown in Table 2, the $\varepsilon_c^{III}/\varepsilon_a^{II}$ ratio varies slightly from compound to compound. The tautomeric equilibrium constants calculated according to Eq. (3) are shown in Table 3. These values are in fair agreement with the corresponding values obtained according to Eq. (1). According to Jaffé and Yeh,[7] the molar extinction coefficient at *ca.* 320 nm of the azonium form is about 2000. In this case, therefore, ε_a is the sum of the contributions of both the ammonium and azonium forms. When ε_a is sufficiently large, as in the cases of dimethylamino- and diethylaminoazobenzenes, the contribution of the azonium form to ε_a can be neglected. However, as is shown in Table 1, ε_a is so small for pyrrolidinoazobenzenes as not to permit us to neglect the contribution of the azonium form. Therefore, the value (0.14) for pyrrolidinoazobenzenes obtained by Eq. (3) must be overestimated.

The values for 4-dimethylaminoazobenzene and the 4′-methyl and 4′-chloro derivatives are in good agreement with the values given by Gerson and Heilbronner,[8] but they differ from those obtained by Isaks and Jaffé,[7] as is shown in Table 3. This large discrepancy is due to the difference in the composition of the solvent. The present values were obtained in *ca.* 1N hydrochloric acid, whereas Isaks and Jaffé obtained theirs in much more acidic solutions. In their case, therefore, the equilibrium must have shifted to the azonium form, for the reason mentioned above.

Discussion

The tautomeric equilibrium constant, K_t, is a measure of the difference between the basicity of the amino nitrogen (pK_1) and that of the azo nitrogens (pK_2). Hence, an examination of the effects of *N*-alkyl groups on both pK_1 and pK_2 is necessary in order to interpret the effects on K_t. The values of K_1 and K_2 were calculated according to the following equations:

$$\frac{1}{K_2} = \frac{1}{K_a}\frac{1}{1+K_t}$$

$$\frac{1}{K_a} = \frac{1}{K_1} + \frac{1}{K_2} \qquad (5)$$

where K_1 and K_2 are the acid dissociation constants of the ammonium and the azonium ions respectively, and where K_a is the apparent acid dissociation constant of the first conjugate acid (Chart 1). All the pK_a values were determined by using a standard spectrophotometric method.[14] These values are listed in Table 4.

d) Obtained according to Eq. (5) using K_t values in the fourth column.
e) Obtained according to Eq. (3).
f) Obtained according to Eq. (5) using K_t values in the seventh column.

For all three groups in Table 4, pK_1 increases in this order: pyrrolidino-<dimethylamino-<diethylaminoazobenzenes. On the other hand, pK_2 increases in this order: dimethylamino-<diethylamino-<pyrrolidinoazobenzenes. The difference in pK_2 is rather smaller than that in pK_1.

The dipole moments of these compounds were measured in order to examine the electronic effect of the *N*-alkyl groups on both pK_1 and pK_2. As may be seen in Table 5, the dipole moments increase step-by-step in this order: dimethylamino-<diethylamino-<pyrrolidinoazobenzenes in each group. The increment is too large to ascribe to the inductive effect of these substituents.

Nash *et al.*[11] have shown, from comparisons of the ^{13}C chemical shifts, the ultraviolet spectra, and the molar refractions of *N*,*N*-dialkylaniline derivatives, that the degree of resonance interaction between the lone-pair electrons on nitrogen and the π-electrons of the

14) In order to obtain pK_a, the absorption spectra of the compounds were measured in various hydrochloric acid concentrations up to *ca.* 1N. For all of the compounds, three isosbestic points were observed in the range from 240 to 600 nm. This indicates that K_t is constant over these acid concentrations. Therefore, the standard method can be used for the determination of pK_a.

benzene ring increases in this order: dimethylaniline< diethylaniline≈*N*-phenylpyrrolidine. In the case of dialkylaminoazobenzene derivatives, if it is assumed that the degree of resonance interaction between the amino group and the rest of the molecule increases in this order: dimethylamino-<diethylamino-<pyrrolidinoazobenzenes— if, that is to say, the degree of the contribution of the type

is the greatest for pyrrolidinoazobenzene and the smallest for dimethylaminoazobenzene— it can account for the order of the dipole moments. If the above proposal is reasonable, the transition energy of the conjugation band of these free bases should decrease and the molar extinction coefficient should increase in this order: dimethylamino-<diethylamino-<pyrrolidinoazobenzenes. An inspection of the data for B band in Table 1 supports this idea.

The order of pK_2 is the same as that of the dipole moments, as is shown in Tables 4 and 5. The basicity of azo nitrogens is hardly subject to inductive and steric effects of the alkyl groups, for the alkyl groups are apart from the azo group. Thus, the factor governing pK_2 must be the same as in the case of the dipole moments, since the greater the extent of the contribution of the above type, the greater the negative charge on one of the azo nitrogens.

An inhibition of the resonance decreases the potitive charge on the amino nitrogen and results in an increase in the base strength of the amino nitrogen, all other factors being equal. Therefore, pK_1 should increase in this order: pyrrolidino-<diethylamino-<dimethylaminoazobenzenes, but actually it increases in this order: pyrrolidino-<dimethylamino-<diethylaminoazobenzenes, as is shown in Table 4. This latter order is the same as that for *N,N*-dialkylaniline derivatives given by Nash and Maciel.[11] They have suggested that the alkyl groups in free diethylaniline produce so cluttered a situation in the vicinity of the nitrogen atom that the hydrogen bonding between hydroxylic solvent molecules and the nitrogen atom is inhibited. The resulting loss of solvation energy increases the free energy of the free base, reduces the energy gap between *N,N*-diethylaniline and its anilinium ion, and correspondingly increases the base strength of the former relative to dimethylaniline. Most of their discussion holds in our case as well, thus accounting for the anomalously high base strength of the amino nitrogen of diethylaminoazobenzenes.

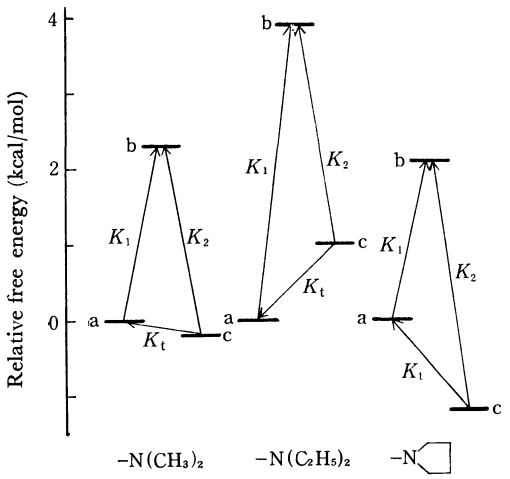

Fig. 4. The diagram of free energy.
a: ammonium ion, b: base + H^+, c: azonium ion.

On the basis of the data in Table 4, a diagram of the free energy was obtained by assuming that the ammonium ions of dimethylamino-, diethylamino-, and pyrrolidinoazobenzenes have equal free energies,[11] the energy of the ammonium ions being taken as the standard. As may be seen in Fig. 4, the free energy gaps between the ammonium ions and the azonium ions, $\Delta G = G(\text{ammonium ion}) - G(\text{azonium ion})$, increase in this order: diethylamino-<dimethylamino-< pyrrolidinoazobenzene; hence, the K_t values decrease in this same order.

The authors are deeply grateful to Miss Hiromi Ohtani for her elemental analysis.

Synthesis and Halochromism of 4- and 6-Styryl-2-aminotropones

Kimiaki IMAFUKU and Hisashi MATSUMURA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto

(Received March 2, 1972)

The methylation of 4-styryltropolones with diazomethane afforded two isomers, 2-methoxy-4-styryltropones and 2-methoxy-6-styryltropones. Their reactions with ammonia gave the corresponding 2-amino-4-styryltropones and 2-amino-6-styryltropones, respectively, by normal nucleophilic substitution. Infrared and ultraviolet absorption spectra were measured. The halochromism of 2-aminotropones was also examined, the halochromic shifts being found to be linearly correlated with the Hammett substituent constants.

Investigations have been carried out by Nozoe,[1,2] Haworth,[3] Tarbell,[4,5] and Kuraoka[6] on styryltropolones with particular interest in them as a potential intermediate in the synthesis of colchicine and its analogues.

The chemical reactivities of 4- and 6-styryl-substituted 2-methoxytropones,[7] 2-chlorotropones,[7] and 2-tosyloxytropones[8,9] towards nucleophilic reagents such as ammonia, amines, and hydroxide ion were studied by one of us (H. M.). More quantitative treatments of the reactivity of the styryltropolones[10,11] were made by measuring their dissociation constants and by correlating them to the Hammett substituent constants. Thus, it was established that the electronic effects of the substituents in the benzene ring can be transmitted through an ethylenic linkage to the tropolone nucleus. The dissociation constants of 4- and 6-styryl-2-aminotropones were measured and found to obey the Hammett equation.[12]

This communication deals with the synthesis of 4- and 6-styryl-2-aminotropones, which are used for the measurements of the dissociation constants of their conjugate acids.[12] The infrared and ultraviolet absorption spectra of 2-methoxytropones and 2-aminotropones were also measured, and the halochromism of 2-aminotropones is discussed quantitatively.

Results and Discussion

Synthesis. The starting materials, 4-styryltropolones (Ia—Ih) having substituent in the benzene ring, were prepared by the condensation of the corresponding benzaldehyde with 3-carboxy-4-carboxymethyltropolone[13] obtained from purpurogallin[14] and the decarboxylation of the condensation products.[15]

4-Styryltropolone (Ia) was methylated with diazomethane in ether to afford two isomers of methyl ether, 2-methoxy-4-styryltropone (IIa) and 2-methoxy-6-styryltropone (IIIa).[5,16] Similarly, seven 4-styryltropolone methyl ethers (IIb—IIh) and seven 6-styryltropolone methyl ethers (IIIb—IIIh) were obtained from seven 4-(substituted styryl)tropolones (Ib—Ih). These isomers could be readily and perfectly separated by means of preparative thin layer chromatography. The yields, melting points and analytical data are summarized in Table 1. The melting points of 6-isomers are higher than those of the corresponding 4-isomers.

Ammonolysis of 2-methoxy-4-styryltropone (IIa) and 2-methoxy-6-styryltropone (IIIa) with ammonia in absolute ethanol in a sealed tube afforded the corresponding 2-amino-4-styryltropone (IVa) and 2-amino-6-styryltropone (Va), respectively, by normal nucleophilic substitution.[7] 4-Styryl (IIb—IIh) and 6-styryl isomers (IIIb—IIIf) having substituent in the benzene ring were also aminated with ammonia to afford the corresponding seven 2-amino-4-styryltropones (IVb—IVh) and five 2-amino-6-styryltropones (Vb—Vf), re-

spectively. However, the ammonolysis of both 2-methoxy-6-(*p*- and *m*-nitrostyryl)tropones (IIIg and IIIh) did not give the corresponding 2-aminotropones (Vg and Vh). The yields, melting points and analytical data are summarized in Table 2. In contrast to the case of methyl ethers, it was found that the melting points of 4-isomers are higher than those of the corresponding 6-isomers except for 2-aminotropones having *m*-chloro substituent.

These 2-aminotropones were hydrolyzed in alkali solution to give the corresponding original 4-styryltropolones.

Infrared Absorption Spectra. The infrared absorption spectra of the 2-methoxytropones (IIa—IIh and IIIa—IIIh) and 2-aminotropones (IVa—IVh and Va—Vf) were measured in chloroform. As characteristic bands, both of them have $\nu_{C=O}$ and δ_{CH} (in *trans* –CH=CH–) bands. 2-Aminotropones exhibit two ν_{NH} bands. These data are listed in Tables 3 and 4.

The geometry of the ethylenic linkage is *trans*, since the δ_{CH} bands are observed at 955—960 cm^{-1}. The carbonyl stretching bands of 6-isomers are observed in a lower wave number band than those of 4-isomers by *ca.* 10 cm^{-1}, if examined in detail. This might be due to the fact that the distance between the carbonyl group and the styryl group, which may conjugate with the former, is smaller in 6-isomers than in 4-isomers. It is found that, similar to 4-styryltropolones,[15] the $\nu_{C=O}$ bands of both 2-methoxytropones and 2-aminotropones are little affected by the substituents in the benzene ring.

Ultraviolet Absorption Spectra. The ultraviolet absorption spectra of 4- and 6-styryl-substituted 2-methoxytropones (IIa—IIh and IIIa—IIIh) and 2-aminotropones (IVa—IVh and Va—Vf) were measured in methanol, and are shown in Tables 3 and 4, respectively.

There is a remarkable difference between the spectra of 4-styryl- and 6-styryl-2-methoxytropones. On the other hand, the spectra of 4- and 6-styryl-2-aminotropones are very similar and hardly distinguishable, as shown in Fig. 2. However, when these 2-aminotropones are dissolved in acidic medium, they show different patterns. The spectra of 4- and 6-styryl-2-

aminotropones are shown in Fig. 2, as an example. Although their visible absorption bands show hypsochromic shifts, the 4-isomers show stronger shifts than the 6-isomers. The positions of the longest absorption bands in neutral and in acidic media are shown in Table 5, in terms of λ_B and λ_{BH^+} values, respectively.

The effects of the substituents in the benzene ring on the spectra can be seen from Tables 3 and 4. In general, the visible bands are shifted toward longer wavelength by *para* substituents, and the effect is roughly proportional to the Hammett substituent constants with the exception of electron-donating methoxy group. However, *meta* substituents cause little or none. A similar substituent effect is found in 4-aminostilbenes,[17] since the 2-aminotropone ring can be regarded as a non-benzenoid analogue of aniline and the spectroscopic properties of styryl-substituted 2-aminotropones can be directly compared with aminostilbenes. The longest absorption bands of the protonated ions are

a) Numbers refer to those given in Figs. 3 and 4.

also sensitive to substituent effects in a manner parallel to the neutral species.

Halochromism and Substituent Effects. Rapoport *et al.*[18] measured the absorption spectra of 4-substituted 2-nitrophenols in neutral and in alkaline solutions, and showed theoretically that the difference between the longest absorption bands in two media are quantitatively related with the dissociation constants. These wavenumber shifts are also proportional to the Hammett substituent constants. This phenomenon is well-known in a number of azobenzene series such as 4-phenylazophenols[19] and 4-phenylazoanilines[20] as halochromism. It was found to hold in 5-phenylazotropolones which are non-benzenoid aromatic compounds.[21] The degree of halochromism of a compound can be defined as the frequency difference between the visible bands of the neutral and its conjugate acid or base.

We measured absorption spectra of 4- and 6-styryl-2-aminotropones in 50% aqueous methanol (pH *ca.* 6) and in 50% aqueous methanol containing hydrochloric acid (pH *ca.* 1). That only one species exists in each solution was checked by the pH changes of solution. The longest absorption spectra of both of these 2-aminotropones are shifted to shorter wavelength. The degree of shifts is larger in 4-styryl than in 6-styryl isomers as mentioned above. The wavelengths and wave numbers are listed in Table 5 as λ_B and ν_B for the neutral species and λ_{BH^+} and ν_{BH^+} for the protonated species, respectively. The $\Delta\nu$ values in the same Table give the difference between ν_B and ν_{BH^+} values. The dissociation constants (pK_a)[12] of these 2-aminotropones are also shown in Table 5.

When the $\Delta\nu$ values of 4- and 6-styryl-2-aminotropones are plotted against their pK_a values, the plots define the two lines for 4- and 6-isomers as shown in Fig. 3. The following equations are obtained by the least square method.

$$\text{(4-styryl)}\quad \Delta\nu = 12868 - 3891pK_a \quad (r=0.905)$$

$$\text{(6-styryl)}\quad \Delta\nu = 6434 - 2211pK_a \quad (r=0.961)$$

The magnitude of the pK_a values for suitable equilibria in phenyl derivatives is directly proportional to the Hammett substituent constants of substituent in the benzene ring. Thus, the $\Delta\nu$ values should be proportional to the substituent constants. Several examples of this type of correlation have been reported.[18-27]

When the $\Delta\nu$ values are plotted against the σ constants, two lines for 4- and 6-styryl-2-aminotropones are obtained as shown in Fig. 4. However, the $\Delta\nu$

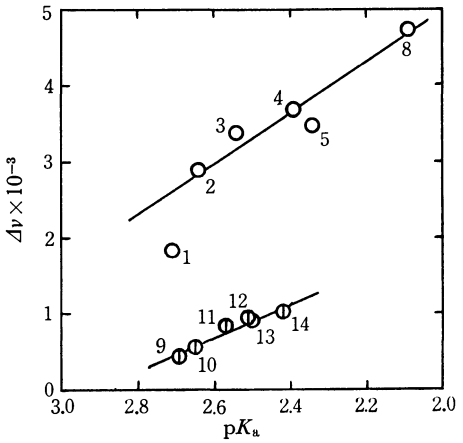

Fig. 3. The relationship between $\Delta\nu$ and pK_a.

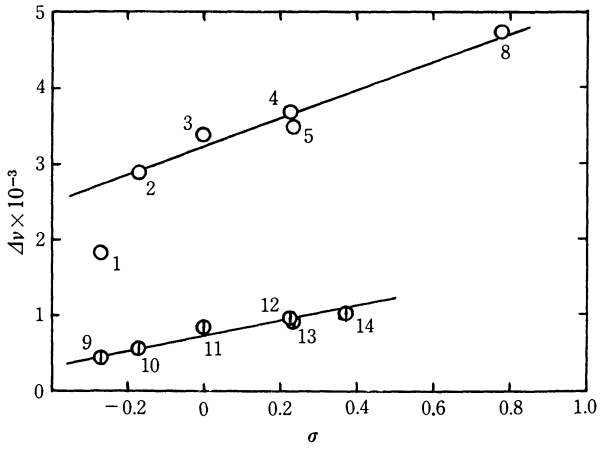

Fig. 4. The relationship between $\Delta\nu$ and σ.
○: 2-Amino-4-styryltropones
ⓘ: 2-Amino-6-styryltropones

value for 2-amino-4-(*p*-methoxystyryl)tropone having strongly electron-donating group considerably deviates from the regression line. The value is, therefore, not included in a calculation of the regression line. When an electrophilic substituent constants[28] ($\sigma^+ = -0.778$ for *p*-methoxy) is introduced, the plot of *p*-methoxy group is found to lie on the line. The regression equations are as follows.

$$\text{(4-styryl)}\quad \Delta\nu = 1879\sigma + 3235 \quad (r=0.984)$$

$$\text{(6-styryl)}\quad \Delta\nu = 882\sigma + 724 \quad (r=0.963)$$

The effect of substituents in the benzene ring on the electronic spectra is larger in 4-styryl than in 6-styryl isomers. This is consistent with the Hammett type analysis of both their dissociation constants.[12] Thus, it is found that the effect of resonance should not be neglected in the 4-isomers, since the effect in 4-isomers is about twice as much as in 6-isomers and σ^+ value fits better than the unmodified σ value for electron-donating *p*-methoxy group.

The excellent linear correlation between $\Delta\nu$ and pK_a or σ for 4- and 6-styryl-2-aminotropones suggests that similar relationships should hold for the other types of equilibria in troponoids having styryl group.

28) H. C. Brwon and Y. Okamoto, *ibid.*, **80**, 4980 (1958).

Experimental

All the melting points were measured on a Yanagimoto micro-melting point apparatus and uncorrected. The infrared and ultraviolet absorption spectra were taken on a JASCO IRA-1 and a Hitachi EPS-3T spectrophotometer, respectively.

4-Styryltropolones (Ia—Ih). The starting materials, 4-(substituted styryl) tropolones (Ia—Ih), were prepared according to a previous work.[15]

The corresponding benzaldehydes were treated with 3-carboxy-4-carboxymethyltropolone[13] obtained from purpurogallin[14] by sodium iodate oxidation, to give 3-carboxy-4-styryltropolones. The latter were sublimed at elevated temperature to afford 4-styryltropolones (Ia—Ih) with the elimination of carbon dioxide.

2-Methoxy-4-styryltropones (IIa—IIh) and 2-Methoxy-6-styryltropones (IIIa—IIIh). An excess of diazomethane in ether was added to a solution of 4-styryltropolones (Ia—Ih) (1 g, 3.3—4.2 mmole) in chloroform (20 ml), and the mixture was allowed to stand in a refrigerator (at *ca.* 5°C). After two days, the solvent was evaporated off under reduced pressure. The residue was dissolved in a small amount of chloroform and separated on silica gel plates (Wakogel B-10) with ethyl acetate as a developing solvent. Two bands of isomers of methyl ethers from 4-styryltropolones appeared. Each band was scraped out and extracted with chloroform. 2-Methoxy-4-styryltropones (IIa—IIh) and 2-methoxy-6-styryltropones (IIIa—IIIh) were obtained from the upper and the lower bands, respectively. Each methyl ether was recrystallized from benzene.

2-Amino-4-styryltropones (IVa—IVh) and 2-Amino-6-styryltropones (Va—Vf). A solution of 4- and 6-styryl-2-methoxytropones (IIa—IIh and IIIa—IIIh) (200 mg, 0.7—0.9 mmol) in absolute ethanol (10 ml), saturated with ammonia at ice-cooled temperature, was heated in a sealed tube for 3 hr at 100°C. The dark red solution was evaporated to give a reddish oil. The residue was crystallized by treating with a small amount of chloroform to afford 4- and 6-styryl-2-aminotropones (IVa—IVh and Va—Vf), respectively. These 2-aminotropones were recrystallized from either benzene or ethanol.

The Estimation of the Electronic Effects of Cyclopropyl and 2,2-Dichlorocyclopropyl Groups

Yoshiaki KUSUYAMA and Yoshitsugu IKEDA
Department of Chemistry, Wakayama University, Masagocho, Wakayama
(Received March 30, 1972)

The normal substituent constant, σ^0, and the resonance substituent constant, $\Delta\bar{\sigma}_R^+$, in the Yukawa and Tsuno treatment of cyclopropyl and 2,2-dichlorocyclopropyl were determined by the ionization of *m*-, *p*-substituted phenylacetic acids in 50% aqueous ethanol and by the solvolysis of α-(*m*-, *p*-substituted phenyl) ethyl chlorides in 80% aqueous acetone. For cyclopropyl, the obtained σ^0 value indicates an inductive electron-attracting behavior, while the $\Delta\bar{\sigma}_R^+$ value indicates a marked enhancement of the electron-releasing resonance effect on the electron deficient reaction center compared with alkyl groups. A minor resonance contribution was observed for the 2,2-dichlorocyclopropyl group.

It is well known that cyclopropane derivatives are remarkably different in their chemical properties compared with other cycloalkanes and alkanes. Of particular interest is the fact that the cyclopropane ring may enter into conjugated systems. Since Walsh[1] concluded, from his molecular orbital caluculations, that the cyclopropane ring posessed properties of a π bond character, numerous spectroscopic[2,3] and kinetic studies[4–11] have been carried out to examine the electronic properties of the cyclopropane ring. However, the influence of the cyclopropane ring is complicated by steric, inductive, and resonance effects. In order to attain a better understanding of the chemical behavior of the cyclopropane ring, it appeared to be of interest to estimate strictly the electronic contribution of the cyclopropyl group, using a system in which the steric factor is neglected.

The purpose of the present work has been to evaluate the electronic effect of the cyclopropyl group on the basis of a linear free-energy relationship. The σ^0-values[12–14] of cyclopropyl and 2,2-dichlorocyclopropyl have been determined from the dissociation of *m*-, *p*-substituted phenylacetic acids in 50% aqueous alcohol at 25°C, while the $\Delta\bar{\sigma}_R^+$ value in the Yukawa and Tsuno equation[14] has been determined from the solvolysis of α-(*m*-,*p*-substituted phenyl) ethyl chlorides in 80% aqueous acetone at 45°C.

Experimental

Materials. The materials were identified by means of spectroscopic and gas-chromatographic measurements and by elemental analyses. The NMR spectra were measured on a JEOL JMN-C-60HL (60MHz) spectrometer in CCl_4, with tetramethylsilane as the internal standard.

The unsubstituted and *p*-nitrophenylacetic acids were obtained commercially. The *m*-nitro derivative was obtained by the hydrolysis of the appropriate nitrile. The other phenylacetic acid derivatives were prepared by a modified Willgerodt reaction, using sulfur and morpholine, from the appropriate acetophenones. The acids were purified by recrystallization. The melting points are listed in Table 1. The syntheses of cyclopropylbenzene derivatives will be described below.

2,2-Dichlorocyclopropylbenzene. Sodium *t*-butoxide (145g) was vigorously stirred into a solution of styrene (73 g) and chloroform (167 g) in 500 ml of *n*-hexane cooled in water bath. The reaction mixture was then hydrolyzed by being added to 500 ml of ice-water. The hexane layer and hexane extracts were combined and dried with silica gel pellets, and the hexane was removed under reduced pressure. The product was distilled through a Widmer column fitted with a glass spiral core. Yield 92 g (70% from styrene). Bp 120°C/20 mmHg, NMR: δ 1.53—2.02 (2H, multiplet), 2.60—2.95 (1H, triplet), 7.15 (5H, singlet).

Cyclopropylbenzene. To a solution of 2,2-dichlorocyclo-

propylbenzene (50 g) in 2-propanol (100 g), sodium metal (23 g) was added. A vigorous exothermic reaction then occurred. The mixture was allowed to stand overnight and then hydrolyzed by the addition of ice water. Cyclopropylbenzene was obtained by the hexane extraction and distillation of the dried hexane extract. Yield, 18 g (67%). Bp 77°C/30 mmHg, NMR: δ 0.50—1.00 (4H, multiplet), 1.53—2.03 (1H, multiplet), 6.71—7.37 (5H, complicated).

p-*Cyclopropylacetophenone.* Cyclopropylbenzene was acetylated in accordance with the procedure given in the literature. Pure *p*-cyclopropylacetophenone (GLC analysis) was obtained by fractional distillation. Bp 130°C/7 mmHg (lit, bp 114—119°C/2.5—2.9 mmHg,[15] 142°C/12 mmHg,[16] 142—145°C/9 mmHg,[17] Mp 36°C (lit, 35—36°C,[15] 36°C[16,17]) NMR: δ 0.60—1.25 (4H, multiplet), 1.62—2.21 (1H, multiplet), 2.40 (3H, singlet), 6.86—7.73 (two 2H doublets, J= 8 Hz).

p-*Cyclopropylphenylacetic Acid.* *p*-Cyclopropylacetophenone (32 g), morpholine (30 g) and sulfur (11.2 g) were refluxed for 14 hr. Ethanol (99%, 130 ml) was then added. The mixture was heated to 80°C and filtered while hot. *p*-Cyclopropylphenylthioacetomorpholide was crystallized spontaneously on cooling in the filtrate. Yield, 44 g (85%). Mp 107—108°C.

The morpholide was refluxed with 300 ml of 15% potassium hydroxide for 12 hr. The alkaline solution was then acidified, and the precipitate was recrystallized from benzene. Yield, 24 g (83%). Mp 84—85°C, Found: C, 74.84; H, 6.86%. Calcd: C, 74.98; H, 6.86%.

Ethyl ester: Bp 145°C/10 mmHg, NMR: δ 0.50—0.95 (4H, multiplet), 1.17 (3H, triplet, J=8 Hz), 1.55—2.02 (1H, multiplet), 3.40 (2H, singlet), 4.02 (2H, quartet, J=7 Hz), 6.80—6.87 (4H, complicated).

p-*2,2-Dichlorocyclopropylacetophenone.* 2,2-Dichlorocyclopropylbenzene was converted to *p*-2,2-dichlorocyclopropylacetophenone in chloroform, using aluminum chloride and acetyl chloride at 10°C. Bp 153°C/23 mmHg, NMR: δ 1.93 (1H, doublet, J=9 Hz), 1.96 (1H, doublet, J=9 Hz), 2.50 (3H, singlet), 2.92 (1H, triplet, J=9 Hz), 7.19—7.93 (two 2H doublets, J=8 Hz).

p-*2,2-Dichlorocyclopropylphenylacetic Acid.* *p*-2,2-Dichlorocyclopropylacetophenone (48 g), morpholine (30 g), and sulfur (11.2 g) were refluxed gently for 20 hr. 99% Ethanol (40 ml) was then added, and the mixture was cooled with an ice bath. However, morpholide was not precipitated, but a pasty mass. To this, a 15% sodium hydroxide solution (400 ml) was added, and the mixture was refluxed for 7 hr. The mixture was filtered rapidly while hot with suction and acidified with diluted hydrochloric acid. Attempts to crystallize the resultant precipitate were unsuccessful. Methyl *p*-2,2-dichlorocyclopropylphenylacetate (9 g) was obtained by refluxing a mixture of the precipitate, methanol (50 ml), and concentrated sulfuric acid (5 ml) for 6 hr. Bp 122°C/2 mmHg. NMR: δ 1.68—2.05 (2H, multiplet), 2.62—2.98 (1H, triplet), 3.50—3.64 (2H, one doublet, 3H singlet), 7.20 (4H, singlet). The ester (6.5 g) was converted to the appropriate acid by alkaline hydrolysis. Yield, 4 g. Mp 110—111°C. Found: C, 54.05; H, 4.03; Cl, 29.14%. Calcd: C, 53.90; H, 4.11; Cl, 28.83%.

*α-(*p-*Cyclopropylphenyl)ethyl Alcohol.* *p*-Cyclopropylacetophenone (10 g) was converted to α-(*p*-cyclopropylphenyl)-ethyl alcohol (7 g) by $LiAlH_4$ (0.8 g) reduction according to the usual procedure. Bp 109°C/3.5 mmHg. Found: C, 81.53%; H, 8.70%. Calcd: C, 81.43%; H, 8.69%. NMR: δ 0.40—1.12 (4H, multiplet), 1.20—1.40 (3H, doublet, J= 6 Hz), 1.58—2.02 (1H, multiplet), 4.04—4.13 (1H, singlet), 4.38—4.78 (1H, quartet, J=8 Hz), 6.75—7.20 (4H, complicated).

*α-(*p-*Cyclopropylphenyl)ethyl Chloride.* Hydrogen chloride was passed over a solution of 7 g of α-(*p*-cyclopropylphenyl)-ethyl alcohol in 30 ml of dichloromethane for ten minutes. The mixture was then treated with anhydrous calcium chloride after which hydrogen chloride was again passed over for ten minutes. The reaction mixture was then filtered rapidly, and the dichloromethane and dissolved hydrogen chloride was removed under a reduced nitrogen pressure. The product was utilized for the rate measurement without further purification. Found: C, 72.88; H, 7.46; Cl, 19.44%. Calcd: C, 73.12; H, 7.24; Cl, 19.62%. NMR: δ 0.44—1.08 (4H, multiplet), 1.55—2.08 (1H, multiplet), 1.60—1.80 (3H, doublet, J=7 Hz), 4.72—5.13 (1H, quartet, J=7 Hz), 6.60—7.35 (4H, two doublets, J=8 Hz, further splits).

*α-(*m-*Cyclopropylphenyl)ethyl Alcohol.* The Grignard reagent from *m*-bromocyclopropyl benzene (15 g)[8] and magnesium (1.95 g) was treated with acetaldehyde (3.5 g). The mixture was then decomposed with a saturated ammonium chloride solution. Subsequent work-up by the usual method gave α-(*m*-cyclopropylphenyl) ethyl alcohol. Yield, 11 g. Bp 103°C/1 mmHg. NMR: δ 0.58—1.21 (4H, multiplet), 1.35—1.56 (3H, doublet, J=7 Hz), 1.70—2.20 (1H, multiplet) 2.96—3.20 (1H, singlet), 4.55—4.95 (1H, quartet, J=7 Hz), 6.80—7.35 (4H, complicated).

*α-(*m-*Cyclopropylphenyl)ethyl Chloride.* α-(*m*-Cyclopropylphenyl)ethyl alcohol (10 g) was converted to the appropriate chloride (7 g) by the method described above for the synthesis of α-(*p*-cyclopropylphenyl)ethyl chloride. Bp 78°C/3 mmHg. Found: C, 72.79; H, 7.20; Cl, 19.49%. Calcd: C, 73.13; H, 7.25; Cl, 19.62%. NMR: δ 0.45—1.16 (4H, multiplet), 1.47—2.13 (1H, multiplet), 1.71—1.80 (3H, doublet, J=6 Hz), 4.75—5.15 (1H, quartet, J=6 Hz), 6.70—7.30 (4H, multiplet).

*α-(*p-*2,2-Dichlorocyclopropylphenyl)ethyl Alcohol.* The treatment of *p*-2,2-dichlorocyclopropylacetophenone (10 g)

with $LiAlH_4$ in ether gave α-(*p*-2,2-dichlorocyclopropylphenyl)ethyl alcohol (7.5 g). Bp 145°C/2.5 mmHg. Mp *ca* 35°C. Found: C, 57.18; H, 5.09; Cl, 30.68%. Calcd: C, 57.16; H, 5.23; Cl, 30.68%. NMR: δ 1.18—1.40 (3H, doublet, J=6.5 Hz), 1.65—2.05 (2H, multiplet), 2.58—3.00 (1H, triplet, J=9.5 Hz), 3.75—3.88 (1H, singlet), 4.40—4.82 (1H, quartet, J=6.5 Hz), 6.76—7.40 (4H, multiplet).

α-(p-2,2-Dichlorocyclopropylphenyl)ethyl Chloride. α-(*p*-2,2-Dichlorocyclopropylphenyl)ethyl alcohol (7 g) was converted to α-(*p*-2,2-dichlorocyclopropyl) ethyl chloride (5 g) with hydrogen chloride in dichloromethane. The dichloromethane and dissolved hydrogen chloride were removed under reduced pressure. The product was then used directly for the rate measurement without any further treatment. Found: C, 54.02; H, 4.15; Cl, 42.83%. Calcd: C, 52.93; H, 4.40; Cl, 42.62%. NMR: δ 1.20—2.10 (2H, multiplet), 1.70—1.90 (3H, doublet, J=7 Hz), 2.63—3.02 (1H, triplet, J=9.5 Hz), 4.82—5.20 (1H, quartet, J=7 Hz), 7.00—7.53 (4H, complicated).

Measurements of pK_a. The pK_a values of the phenylacetic acids were determined by the potentiometric titration of the acid with sodium hydroxide in 50% (v/v) ethanol, using a pH meter (Hitachi Horiba F-5) with glass and with reference electrodes. The titration cell was a flat-bottomed, 100 ml beaker equipped with a water jacket maintained at 25.00±0.02°C. The base was added from the titration buret graduated to 0.01 ml. The sample was stirred magnetically. The pH meter and electrodes were standardized before each run against a pH 7 buffer (a neutral phosphate standard solution) and checked against a pH 4 buffer (a phthalate standard solution). Each new batch of commercial buffer was compared with previous sample before use. The electrodes were kept immersed in the solvent for a day before the measurements. The solvent was prepared in a large quantity. A sample of each acid was weighed and dissolved in the solvent (9.0×10^{-3}mol/l). A 25 ml portion of the solution was pipetted out and transferred into the titration, cell. After the cell had been equilibrated thermally, the acid solution was titrated with a 0.02N carbonate free sodium hydroxide solution in the same solvent. The pH was measured after each small addition of the base until pH 11. The measurements were repeated two or three times. The pK_a calculations were carried out by the method described in the literature.[8,18] Identical pK_a values were obtained from the pH at one-fourth and three-fourths neutralization. No correction was made for the liquid-junction potential.

Kinetic Measurements. The rates of the solvolysis of α-phenylethyl chlorides were determined in an 80% (v/v) aqueous acetone solution.[19] An accurately-weighed amount of chloride was made up to volume in a volumetric flask (150 ml, 0.02 mol/l). The mixture was then transferred to a reaction vessel immersed in a thermostated bath. Kinetic runs below 45°C were conducted in a 200 ml flask. When the solution had reached the temperature of the thermostat, a 10 ml portion was pipetted out, transferred into 50—100 ml of cold dry acetone (to stop the reaction) and free hydrogen chloride titrated with 0.02N sodium hydroxide, using bromocresol purple as the indicator. For the runs at 55°C and 65°C, the sealed-ampule technique was used. The reactions were continued until at least 70% completion. The rate constants were calculated from the integrated form of the first-order rate equation. The rate constants from different runs agreed within 1%.

Results and Discussion

Normal Substituent Constants of Cyclopropyl and 2,2-Dichlorocyclopropyl Groups. It is desirable to determine the σ^0 from the dissociation of phenylacetic acids in water, as well as the σ from that of benzoic acid in water.[13] The substituent effect is, however, too small in these equilibria in water for us to obtain precise σ^0 values.[13,14] 50% ethanol was chosen as the medium, because in this solvent substituents influence the acid dissociation by a factor of 1.5 more than in water.[18,20] It was hoped that this solvent would result in a uniform deviation from the thermodynamic pK_a values and offer the advantage of the solubility of the acids. The ionization constants thus measured are given in Table 2. It is noteworthy that *p*-cyclopropylphenylacetic acid is measurably stronger than the *p*-alkyl derivatives.

Table 2. Apparent dissociation constants of phenylacetic acids in 50% ethanol at 25°C

Substituent	pK_a (±0.01)	Substituent	pK_a (±0.01)
H	5.63	*p*-C_6H_5O	5.60
p-C_2H_5	5.78	*p*-NO_2	5.01
p-CH_3	5.74	*m*-Br	5.40
p-*c*-C_3H_5	5.72	*p*-Br	5.38
p-*c*-(2,2-Cl_2-C_3H_3)	5.60	*m*-NO_2	5.11

The effects of substituents can be correlated linearly with those on the dissociation of phenylacetic acids in water,[21] as is illustrated in Fig. 1. As would be anticipated, a precisely linear correlation is observed for σ^0, with a ρ value of 0.775 (correlation coefficient,

d) Present study.

The obtained σ^0 value for cyclopropyl (Table 3) shows more electron-withdrawing behavior than in other p-alkyl groups. This is inconsistent with Pews and Ojha's report, in which the σ^0 values for the cyclopropyl and ethyl groups, determined from the ^{19}F NMR chemical shift of fluorobenzenes,[3] are nearly identical. The tendency observed in present study, however, is in agreement with that of σ_m[8] and the kinetic results of the solvolysis, where the direct conjugative interaction between substituent and reaction site makes no contribution.[7,8,10] The relative electron-withdrawing effect of cyclopropyl is attributable to the inductive-electron attracting effect of the three-membered ring, which is constructed with a slightly increased electronegative carbon atom compared with the alkyl groups. This result is a proof of the proposed molecular orbital structures of cyclopropane,[1,22] in which the exo orbital of cyclopropane possesses considerably more s orbital character than sp^3. The σ^0 values of 2,2-dichlorocyclopropyl show a considerably strong inductive effect of the group caused by the highly electronegative chlorine atom. This is incompatible with the σ^* values[11] calculated from the pK_a of 2,2-dichlorocyclopropylacetic acid. The σ^0 values are useful for the estimation of the resonance effect of cyclopropyl and 2,2-dichlorocyclopropyl groups.

Resonance Effect of Cyclopropyl and 2,2-Dichlorocyclopropyl Groups. Considerable interest has been shown in the solvolysis of cyclopropyl carbinyl derivatives,[4] in which the cyclopropyl group exhibits large rate accelerations. In the cyclopropyl carbinyl system, however, the interpretation of the effect of the group is complicated by the immediate proximity of the positive reaction center. In order to estimate the electronic effects of cyclopropyl, the substituent constant,[23] σ^+, has been determined by several workers.[5,7,8,24] Each derived value, however, is more different than the general error in σ^+ values.

Thus, in order to probe the interaction mechanism of cyclopropyl with a cationic center more precisely, it was felt that substituent constants should be derived from the representative solvolysis reaction, in which experimental errors has been minimized. The solvolysis of α-phenylethyl chlorides[25] in 80% aqueous acetone was selected for this study because, in this reaction, the relative rates may be calculated from

b) Present work.

only Arrhenius equation and because the results previously obtained have been sufficient to elucidate the substituent effects.[13,14]

The observed rate constants are listed in Tables 4 and 5. The solvolysis of the *p*-cyclopropyl derivative is 353 times faster than that of the parent phenylethyl chloride and 234 times faster than the *m*-cyclopropyl derivatives (45°C). This marked exaltation of the *p*-cyclopropyl group is consistent with the results of other experimental studies of cyclopropyl systems[5,7,8] and indicates the strong contribution of the resonance effect to the transition state.

In the *para* position, some rate accelerations of *p*-alkyl groups have been observed, usually in electrophilic reactions; these accelerations have been attributed to hyperconjugation.[26] However, the exaltation of cyclopropyl in this study is remarkably larger than this effect. The *p*-cyclopropyl derivative is 10 times faster than the *p*-isopropyl homologue.

The solvolysis rate is depressed by a factor of 0.036 on 2,2-dichloro substitution on the *p*-cyclopropyl group. The relative rate of the *p*-2,2-dichlorocyclopropyl derivative for unsubstituted α-phenylethyl chloride is 1.24. No marked participation in the *gem*-dichlorocyclopropyl carbinyl chloride solvolysis has been observed in Robinson's work,[11] and it has been described as anomalous in comparison with other substituted cyclopropyl carbinyl solvolyses. The inductive effect of cyclopropyl increases upon the substitution of a more negative chlorine atom, and this decreases the solvolysis rate. However, the inductive effect may be decreased by the transmission of the cyclopropyl; if so, it will be impossible for it to affect the reaction center strongly. The observed results described above indicate the major importance of the resonance effect for the cyclopropyl and the depression of the effect for the 2,2-dichlorocyclopropane ring.

Product studies of α-(*p*-cyclopropylphenyl) and α-(*p*-2,2-dichlorocyclopropylphenyl)ethyl chloride solvolysis were conducted by means of an NMR examination. Only α-(*p*-cyclopropylphenyl) and α-(*p*-2,2-dichlorocyclopropylphenyl)ethyl alcohol respectively were detected.

The resonance effect of the substituents may be evaluated strictly in terms of the following linear free-energy relationship, presented by Yukawa and Tsuno:[13,14]

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^+) \quad (1)$$

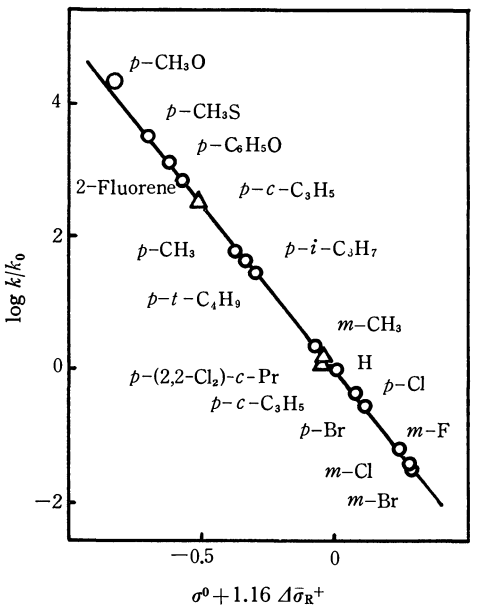

Fig. 3. Application of Eq. (1) to the solvolysis of α-phenylethyl chlorides.

where r is a constant depending on the resonance requirement of the reaction and where $\Delta\bar{\sigma}_R^+$ measures the capacities of the substituents to supply electrons by resonance. The application of the equation to the solvolysis of α-phenylethyl chlorides gave an excellent correlation,[25] with a correlation coefficient of 0.999, as is shown in Fig. 3.

$$\log k/k_0 = -4.95(\sigma^0 + 1.16\Delta\bar{\sigma}_R^+) \quad (2)$$

On the basis of this correlation, the resonance contributions of cyclopropyl and 2,2-dichlorocyclopropyl were estimated using σ^0 values obtained as has been described above (Table 3).

The $\Delta\bar{\sigma}_R^+$ for cyclopropyl indicates a marked contribution of the resonance effect. The magnitude relative to the alkyl groups is about twofold and shows the ability for a strong interaction with an electron-deficient center without ring opening. Thus, the striking exaltation in the cyclopropyl carbinyl systems is partly attributable to the behavior of the cyclopropane ring itself, although ring-opening products were generally produced. The perturbation of cyclopropyl over the hyperconjugative effect of alkyl groups may be evaluated by substructing the $\Delta\bar{\sigma}_{R\,i\text{-Pr}}^+$ from the $\Delta\bar{\sigma}_{R\,c\text{-Pr}}^+$. Thus, the value thus obtained (−0.226) indicates a remarkable ring-closure effect and an extra-delocalization of the intra-cyclic orbital of the cyclopropane ring. This situation is compatible with the two proposed molecular orbital models of cyclopropane.[1,22] The structure suggests that intra bonds possess considerable p orbital character and that they interact with the extra p orbitals of groups linked to the ring. Therefore, the mode of the contribution is different from the exalted hyperconjugation[27] and/or the σ-π vertical stabilization.[28]

27) J. D. Roberts and R. H. Mazur, *J. Amer. Chem. Soc.*, **73**, 2509 (1951).

28) T. G. Traylor, W. Hanstein, H. J. Berwin, N. A. Clinton, and R. S. Brown, *ibid.*, **93**, 5715 (1971).

The contribution of the resonance of 2,2-dichlorocyclopropyl is minor. The decrease in the contribution of the resonance ($\Delta\bar{\sigma}_{R\ p\text{-}c\text{-}Pr} - \Delta\bar{\sigma}_{R\ p\text{-}(2,2\text{-dichloro-}c\text{-}Pr)}$) is found to be two times that of the inductive effect ($\sigma^0_{p\text{-}c\text{-}Pr} - \sigma^0_{p\text{-}(2,2\text{-dichloro-}c\text{-}Pr)}$). The low reactivity of *p*-2,2-dichlorocyclopropyl is attributable mainly to the depression of the resonance effect by substitution with the chlorine atom. The decrease in the resonance is nearly identical with the ring-closure effect described above. It appears that, in the cyclopropyl, the developing charge was delocalized over the ring. However, in the 2,2-dichlorocyclopropyl, the chlorine atom interacts with the cyclopropane ring and the internal cyclopropane bond scarcely interacts at all with the reaction center. The exact interaction mechanism remains to be elucidated.

The solvolysis of the *m*-cyclopropyl derivative is slower than that of the *m*-methyl derivative. This fact fits previous evidence that cyclopropyl exhibits electron-attracting behavior in a system to which direct interaction with the reaction center cannot contribute as much as alkyl groups.[7,8,10,29]

The authors wish to thank Professor Yasuhide Yukawa and Yuho Tsuno for their many helpful discussions and suggestions during this work.

Polyether-amides from the Condensation of ω-(*p*-Carboxyphenoxy)-alkanoic Acids with Aliphatic Diamines

Taketoshi KITO, Tsutomu FUJIMOTO, Ryuzo MIKAMI, and Ichiro HIRAO*

Department of Chemical Engineering, Kyushu Institute of Technology, Tobata-ku, Kitakyushu
**Laboratory of Industrial Chemistry, Kyushu Institute of Technology, Tobata-ku, Kitakyushu*

(Received April 27, 1972)

Polyether-amides were prepared by the polycondensation of ω-(*p*-carboxyphenoxy)alkanoic acids (CPAA) and such aliphatic diamines as ethylenediamine, hexamethylenediamine, and piperazine. The polymers with higher intrinsic viscosities and moderate melting temperatures (200—240°C) were obtained from CPAA and hexamethylenediamine. The polymers from both CPAA and ethylenediamine or piperazine generally have low intrinsic viscosities; the former melted at higher temperatures than did the polyether-amides with hexamethylenediamine, while the latter melted at lower ones.

There are various types of polymers on the market in which polyamide, polyester, polyacrylonitrile, *etc.* are included. In addition, poly *p*-(2-hydroxyethoxy)benzoate, which can be classified as a type of polyether-ester, has been found to have some excellent characteristics as a fiber. Other polymers with an ether linkage in the main chain have been prepared from ω-(*p*-carboxyphenoxy)alkanoic acids by many authors. Izard[2] has prepared polyether-esters from ω-(*p*-carboxyphenoxy)alkanoic acids. Kawai and his co-worker[3] have prepared a polyether-ester from *p*-carboxyphenoxyacetic acid and ethylene glycol, and a polyanhydride from *p*-carboxyphenoxyacetic acid. The former melts at 90—93°C and has an intrinsic viscosity of 0.26 (in *m*-cresol at 30°C). Sofue and his co-worker[4] have reported resins prepared from ω,ω-bis(2-methoxy-4-carboxyphenoxy)alkanes and aliphatic diamines. They have inherent viscosities of more than 0.5 (0.5 g/100 ml of *m*-cresol, at 30°C) and melt at 160—230°C.

In connection with the synthesis of ω-(*p*-carboxyphenoxy)alkanoic acids, which we have already reported,[5] we attempted to prepare some polyether-amides by polycondensation from ω-(*p*-carboxyphenoxy)alkanoic acids and aliphatic diamines. They also have a phenyl nucleus and a phenyl-alkyl ether linkage and, in addition, have an amide linkage in the main chain in a repeating unit.

Results and Discussion

Nylon Salt. Nylon salts were prepared from ω-(*p*-carboxyphenoxy)alkanoic acids and aliphatic diamines, and the melting point of each salt was deter-

mined by differential thermal analysis (DTA). The results are listed in Table 1. The melting point of 66-salt was determined by this method to be 198°C (lit,[6] 196—197°C). Of these salts, however, all attempts to prepare the nylon salts of SE2, SE5, SP3, and SP5 (for the symbols of SEn, SHn, and SPn, see Table 1) were unsuccessful because their analytical values of nitrogen deviated largely from the calculated values. SHn and SPn melted at higher temperatures than did SEn, and SEn and SPn melted with a loss of water, while the two endothermic peaks, that is, the melting and dehydration peaks, of SHn and 66-salt were distinguishable.

Polymerization. Seventeen polyether-amides were prepared by polycondensation. The physical properties and other characteristics are summarized in Tables 2 and 3. The polymerization consists of two steps. From the first step, the prepolymer is obtained by heating nylon salt in an autoclave for several hours, while raising the temperature gradually. From the second-step, a higher polymer is obtained by heating the prepolymer while stirring it under reduced pressure (0.1—0.5 mmHg). By this method, such ploymers as E6, H1, H3, H4, H5, H6, P4, and P6 (for the symbols of En, Hn, and Pn, see Table 2) were prepared, but E1, E3, E4, H2, P1, and P2 were prepared only by the first-step polymerization because H2 was a rubber-like polymer and we failed to raise the viscosities of E1, E3, E4, P1, and P2 by the second step polymerization. The prepolymers of E5, P3, and P5 were prepared by mixing equivalent amounts of diacid and diamine in a sealed glass-tube and by then heating it according to the procedure described in the first step polymerization.

TABLE 3. SOLUBILITY OF POLYMER IN ORGANIC SOLVENTS

Solvent	Solubility[a] (±)	Solubility[a] (−)
Acetic acid[b]	E1, E4, E6, H1, H4, P4—P6	E3, E5, H3, H5, H6, P1
Benzyl alcohol	E4, E6, H1, H3—H6, P3—P6	E1, E3, E5, P1
Dimethyl-formamide	E6, P3, P5	E1, E3—E5, P1, P4, P6

a) (±); soluble at 100°C. (−); insoluble even at 100°C
b) P3 was soluble in acetic acid at room temperature.

6) W. R. Sorenson and T. W. Campbell, "Kobunshi Gosei Zikkenho," Tokyo Kagakudozin, Tokyo (1963). p. 54.

(a) Melting Point (T_m): Although the Tm of Pn and Hn were evaluated by DTA as endothermic peaks, Pn showed no remarkable endothermic peak. Therefore, the Tm of Pn was determined as the point at which a sample reached a completely molten state.

The alternating character of the melting point associated with the methylene number was also observed in these polyether-amides, and it was found that the polymer containing an odd-numbered methylene group shows a higher melting point than that containing an even-numbered one. As is shown in Table 1, the melting points of nylon salt decreased in the order of SHn≒SPn>SEn, while, on the contrary, the melting points of polyether-amide decreased in the order of En>Hn>Pn. Especially, Pn melted at an appreciably lower temperature than did En and Hn, this being probably due to the structure of *N*-alkyl polyamide.

It is well known that the introduction of a phenyl nucleus into the main chain raises the melting point of the polymer, while the introduction of an ether linkage decreases it. For example, it has been reported that the polyamides from hexamethylenediamine and azelaic acid or sebacic acid melt at 205 and 209°C[7] respectively, while the polyamide from hexamethylenediamine and 1,4-bis(2-carboxyethyl)benzene, HOOC-CH_2CH_2-  -CH_2CH_2COOH, melts at 295°C,[7] the difference being about 85°C. On the other hand, the polyamide from hexamethylenediamine and 3-(*p*-carboxymethoxyphenyl)propionic acid softens at 218°C (vicat penetrometer).[8] For the sake of comparison, a nylon salt (SK1) and polyamide (K1) analogous to SH1 and H1 respectively were prepared by us from hexamethylenediamine and 3-(*p*-carboxyphenyl)propionic acid, the latter being a diacid with an ether linkage of *p*-carboxyphenoxyacetic acid replaced by a methylene group. As a result, it was proved that K1 melted 27°C higher than H1 in spite of the fact that SK1 melted 29°C lower than SH1. The melting points of SK1 and K1 are also listed in Tables 1 and 2. The lower melting point of K1 compared with that of polyamide from 1,4-bis(2-carboxyethyl)benzene may be due to the fact that 3-(*p*-carboxyphenyl)propionic acid is an unsymmetrical diacid.

(b) Glass Transition Temperature (T_g): The glass transition temperatures of En and Hn were generally higher than that of nylon 66 or 6, but there was no such remarkable regularity between the Tg and the methylene number as was seen in Tm.

(c) Decomposition Temperature (T_d): The Td of Hn lay in the range from 360 to 410°C, while those of En and Pn were below 360°C except for P5. Under similar conditions, the weight loss of nylon 66 occurred at 361°C, which is nearly comparable to the value of H1—H4. The difference between Td and Tm was large for Hn and Pn, but small for En. The small difference for En may cause a lower intrinsic viscosity, because the polymerization was carried out in a molten state.

(d) Intrinsic Viscosity: The intrinsic viscosities of most polymers were less than 0.5; only H4, H5, H6, and P5 showed high values. In addition, it was proved that phosphoric acid was not an effective catalyst for these polymerizations. Thus, high polymers which have intrinsic viscosities of more than 1.0 were prepared in the absence of phosphoric acid.

(e) Fiber-forming Property: En did not have a fiber-forming property. Hn and Pn formed fibers when a glass rod was inserted into the molten polymer and then drawn up at a moderate rate, but only weak fibers were formed from En. H2 and P2 were rubber like and viscous materials respectively, both incapable of being formed into fibers.

Experimental

ω-(p-Carboxyphenoxy)alkanoic Acid. It was prepared according to a procedure described before.[5]

3-(p-Carboxyphenyl)propionic Acid. (a) 4-Carboxycinnamic Acid (I): A mixture of 104 g of pyridine, 2 g of piperidine, 25 g of malonic acid, and 19 g of methyl *p*-formylbenzoate was heated while being stirred for 2 hr on a water bath and was then refluxed for 30 min after 200 ml of water had been added. The reaction mixture was acidified with hydrochloric acid, and the resulting precipitate was collected on a filter and washed with water. Yield, 95%. Mp 207—208°C. Found: C, 63.90; H, 4.80%. Calcd for $C_{11}H_{11}O_4$: C, 64.06; H, 4.90%.

(b) Dimethyl Ester of (I): Twenty-six grams of (I) were esterified by refluxing for 8 hr with 200 ml of methanol and 4 ml of sulfuric acid. Yield 82%. Mp 124—124.5°C (AcOMe); lit,[9] 125.5—126.5°C. Found: C, 65.20; H, 5.48%. Calcd for $C_{12}H_{12}O_4$: C, 65.44; H, 5.50%.

(c) Methyl 3-(p-Methoxycarbonylphenyl)propionate (II): In 150 ml of methyl acetate, a 2.5 g portion of the methyl ester of (I) was dissolved. Palladium charcoal (containing 5% of palladium, 0.15 g) was added, and the mixture was hydrogenated between 50—60°C for 4 hr (the initial pressure of hydrogen was 20 kg/cm²). Yield 87%. Mp 27—28°C (aq. EtOH); lit,[10] 29—31°C (hexane). Found: C, 64.55; H, 6.21%. Calcd for $C_{12}H_{14}O_4$: C, 64.84; H, 6.36%. The IR absorption at 1644 cm^{-1} which was observed in the methyl ester of (I) disappered.

(d) 3-(p-Carboxyphenyl)propionic Acid: A mixture of 15 g of (II) and 540 ml of 5% aq. sodium hydroxide was refluxed for 2 hr. The mixture was then acidified with hydrochloric acid, and the precipitate was collected and washed with water. Yield 90%. Sublimes at about 280°C (water); lit,[10] melts at 286—289°C (AcOH). Found: C, 61.62; H, 5.16%. Calcd for $C_{10}H_{10}O_4$: C, 61.85; H, 5.19%.

Nylon Salt. (a) SE1, SH1, and SP1: Nylon salt was precipitated from an aqueous solution containing *p*-carboxyphenoxyacetic acid and an equivalent amount of diamine by dilution with methanol, and was then collected. Then, the salt was washed with ether and dried in a vacuum.

(b) SE3, SE4, SE6, SH2, SH3, SH4, SH6, SP2, SP6, and SK1: A solution of diamine in ethyl alcohol was added, drop by drop, to a boiling solution of an equivalent amount of diacid in ethyl alcohol. The salt was then filtered and recrystallized from aqueous methanol.

(c) SH5: This was prepared by the method (b), but the ethyl alcohol was replaced with *n*-propyl alcohol.

Polymerization. (a) First-step Polymerization: A mixture

of 10 g of nylon salt, 0.25 g of phosphoric acid, and 1.0 g of water was charged in a glass tube open at the top, and then the glass tube was placed in an autoclave. After the air had been replaced by nitrogen, the salt was heated to afford the prepolymer. The heating conditions were as follows: PE3; 150—200°C (8 hr), 200(12). PE4; ~150(3), ~180(3), ~200(2), 200(10), ~230(3). PE6; ~160(3), 160(3), ~250(2), 250(1). PH1; 150—200(2.5), ~250(5). PH2; ~150(2), ~180(1.5), ~200(2), 200(2). PH3; 150—180(2.5), ~200(4.5). PH4—1; 150—200(5), ~230(5). PH4—2(heated in the absence of phosphoric acid); ~180 (3), ~200(1.5), ~230(2), ~250(1), 250(2). PH5—1, PH5—2(see PH4—2) and PH6—1; 150—180(3), ~200(2), ~230(3.5). PH6—2(see PH4—2); 150—180(2.5), ~200 (1.5), ~250(1), 250(2). PP1; 180—200(4), ~230(6). PP2; 150—180(5). PP4; 150—180(2.5), ~200(5), PP6; 150—180(2), ~200(5.5). PK1; ~150(1), ~180(1.5), ~200(1.5), 200(1.5), ~230(3), ~250(1), 250(2). The first letter, P, in PEn, PHn, PPn, or PK1 indicates the "Prepolymer" of En, Hn, Pn, or K1.

(b) First-step Polymerization in a Sealed Tube: When nylon salt could not be prepared, a diamine and an equivalent amount of a diacid were sealed in a glass tube, and the polymerization was run according to the procedure described in (a). The heating conditions were as follows: PE5; 150—250°C (9hr), 250(10). PP3; 150—180(3.5), ~200(4.5). PP5; 150—180(2.5), ~200(3), ~250(5). However, the prepolymer of E1 was obtained by heating SE1 in a sealed tube as follows: 150—200(6), ~250(5), 250(12).

(c) Second-step Polymerization: The prepolymer was placed in a round-bottomed flask equipped with a side arm, which connected to a vacuum pump; the flask was then equipped with a mechanical air-tight stirrer and gradually brought to a high vacuum (0.5—0.1 mmHg) with heating and stirring. The heating conditions were as follows: E6; 250—265°C(6 hr). H1; 190—240(5.5). H3; 220—230(1.5). H4–1(prepared from PH4–1); 210—260(7). H4–2(from PH4–2); 220—250(5). H5–1(from PH5–1); 240—250(6). H5–2(from PH 5–2); 250—260(1). H6–1(from PH6–1); 220—270(2). H6–2 (from PH6–2); 220—270(2). P3; 200—240(5). P4; 200—230(6). P5; 210—280(6). P6; 200—260(6.5).

Melting Point (T_m) and Decomposition Temperature (T_d). The Tm was determined by observing the point at which the sample reached a completely molten state (for Pn) or by DTA (for En and Hn) (Rigaku Denki, cat. No. 8001MS; heating rate, 10°C/min). In the latter method, the Tm was defined as the intersecting point of a base line and a tangent line of the peak on the lower-temperature side. The Td was measured by TGA (Cho Keiryoki, TRDA$_1$-L; heating rate, 2.8°C/min in N_2) and was defined as the temperature at which the weight loss began to occur.

Glass Transition Temperature (T_g). The Tg was measured by means of a dilatometer.

Intrinsic Viscosity. The specific viscosity was measured in *m*-cresol at 25°C with an Ubbelohde viscometer, plotted *versus* the concentration, and extrapolated to zero.

Solubility in a Solvent. A mixture of 0.1 g of a sample and 3 ml of a solvent was allowed to stand for 24 hr at room temperature, with occasional shaking. If a clear solution was obtained by this treatment, the plus sign (+) was given. When some solid mass remained insoluble in a solution, the mixture was kept at about 100°C for 10 min with shaking; the plus-minus sign (±) was given when the solution became clear, and the minus sign (−), when some solid mass still remained insoluble.

Peptide Synthesis *via* *N*-Acylated Aziridinone. I. The Synthesis of 3-Substituted-1-benzyloxycarbonylaziridin-2-ones and Related Compounds[1)]

Muneji MIYOSHI

Department of Synthetic Chemistry, Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., Kashima-cho, Higashiyodogawa-ku, Osaka

(Received April 27, 1972)

Optically-active 3-substituted-1-benzyloxycarbonylaziridin-2-ones were synthesized from the corresponding benzyloxycarbonyl L-amino acids by the use of a dehydrating agent, such as phosgene, thionyl chloride, or phosphorus oxychloride. The reaction was carried out in THF at −20——30°C using triethylamine to neutralize the reaction solution exactly. Among the other *N*-protecting groups used in peptide chemistry, *p*-bromobenzyloxycarbonyl and *p*-chlorobenzyloxycarbonyl amino acids also gave the corresponding aziridinones quantitatively. Some of these *N*-acylated aziridinones were obtained in the crystalline form. A reaction mechanism was also described.

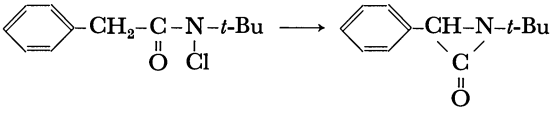
In 1908, Leuchs[2)] proposed aziridinone as a reactive intermediate when his *N*-carboxy-α-amino acid anhydride (NCA) rapidly lost carbon dioxide on heating to form polypeptide. Since then, aziridinone has been suggested as a possible reactive intermediate in peptide synthesis, though it has never been isolated from either amino acid or peptide derivatives.

In 1961, in the course of his studies of the Favorskii-

1) A part of this study has been reported in a preliminary communication. This Bulletin, **43**, 3321 (1970). Also presented at the 8th Symposium on Peptide Chemistry, Osaka, Nov. 1970, and at the 24th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1971.

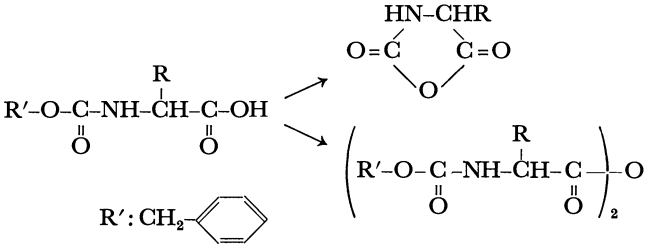
2) H. Leucks and W. Geiger, *Ber.*, **41**, 1721 (1908).

type rearrangement of *N*-*t*-butyl-*N*-chloroamide, Baumgarten[3] first detected an aziridinone as the intermediate; though it could not be isolated in a pure form, it showed a carbonyl band at 1847 cm^{-1} in IR spectra. One year later, he[4] succeeded in isolating *N*-*t*-butyl-3-phenyl-aziridinone.

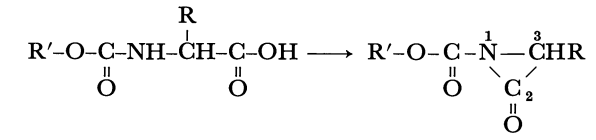


Recently, some of the aziridinones have been synthesized and their physical and chemical properties have also been clarified[5-9] to some extent. The typical synthetic routes reported so far are attributed to the dehydrohalogenation of either *N*-haloamides or α-haloamides, and it has been revealed that the *N*-substituent decisively influences the ease of ring formation and the stabilization of the corresponding aziridinone. All the aziridinones synthesized to date have the *N*-substituent, which is an electron-donating and sterically bulky alkyl group. Among them, *N*-*t*-butyl and *N*-adamantyl aziridinones have both been isolated in the pure form.

On the other hand, the reaction of an amino acid with phosgene ($COCl_2$) or thionyl chloride ($SOCl_2$) has been widely studied since Leuchs first obtained NCA. In 1950, Katchalski and Ben-Ishai[10] reported an improved route of synthesizing NCA by the use of benzyloxycarbonyl L-amino acid (Z-AA) and excess $SOCl_2$ at 40—60°C. One year later, Wieland and Bernhard[11] reported that Z-AA reacted with $COCl_2$ at 0°C in the presence of a *t*-amine to form Z-amino acid anhydride. The variety of products formed in each reaction depends upon both the reaction temperature and the presence or absence of the *t*-amine.



In the present paper, I wish to report a new synthesis of *N*-acylated aziridinones, which have an optically-active asymmetric carbon at *C*-3, from the corresponding L-acylamino acid. Some of them are isolated in the crystalline form.



Results and Discussion

Synthesis of 3-Substituted-1-benzyloxycarbonylaziridin-2-ones. Z-AA dissolved in tetrahydrofuran (THF) did not react with an equivalent $COCl_2$ under stirring at −20——30°C during the first 30 minutes. As an equivalent triethylamine (TEA) in ether was added drop by drop, triethylamine hydrochloride (TEA–HCl) was formed, and a thin-layer chromatograph (tlc) developed in the buffer solution ($CHCl_3$: AcOEt: AcOH, 85: 15: 3) showed a new spot (R_f 0.4), which was detected by ninhydrin. When another equivalent TEA was added, drop by drop, to the mixture at the same temperature and the reaction solution was neutralized exactly, a different spot (R_f 0.9) appeared almost quantitatively. The IR spectra of the reaction solution at each reaction step are summarized in Table 1.

Table 1. IR of the reaction solution

Reaction solution	R_f	IR (cm^{-1})
Z-AA	0.5	$\nu_{C=O}$ 1715, 1690 ν_{NH} 3300
After adding an eq. TEA	0.4	$\nu_{C=O}$ 1790, 1720 ν_{NH} 3200
After adding two eq. TEA	0.9	$\nu_{C=O}$ 1840, 1690 ν_{NH} —

In order to isolate the final product of this reaction, ether was added to the reaction mixture at −20°C, the mixture was then quickly filtered to remove the TEA–HCl formed, and the filtrate was evaporated under reduced pressure on an ice-bath. Then to the residue were added ether and petroleum ether, and the mixture was kept in a refrigerator overnight. A small amount of the remaining Z-AA and the TEA–HCl precipitated was filtered off, and the filtrate was evaporated again. This procedure was repeated a few times, until the tlc of the solution showed a single spot at R_f 0.9. Attempts to crystallize the oil obtained after concentration did not succeed in most cases, though the oil in each case was rather stable at low temperatures.

Fortunately, when Z-L-phenylalanine (Z-Phe) was treated in the same manner, the product was obtained in the crystalline state in a refrigerator; it was subsequently recrystallized from ether and petroleum ether to afford colorless needles with mp of 73.0—73.5°C. $[\alpha]_D^{20}$ −36.0° (*c* 1, THF). IR: $\nu_{C=O}$; 1840, 1690 cm^{-1}. The results of elementary analysis agreed with the dehydration product of Z-Phe, and its structure was confirmed to the 3-benzyl-1-carbobenzoxyaziridin-2-one (I) from these results and other observations, which will be discussed later.

From a further study of this dehydration reaction, it was found that 3-substituted-1-benzyloxycarbonyl-

aziridin-2-ones were also synthesized by the same treatment using $SOCl_2$ or phosphorus oxychloride ($POCl_3$) instead of $COCl_2$. When Z-Phe was used as the starting material, the corresponding crystalline aziridinone was obtained; it was identified with the specimen afforded above.

When $SOCl_2$ was used as the dehydrating agent, one more equivalent TEA was required for the neutralization of the reaction solution to form a brown-colored SO_2–TEA complex.[12]

Synthesis of Other N-*Acylated Aziridinones.* Various *N*-protecting groups commonly used in peptide chemistry were examined by the treatment and reaction conditions used for Z–AA. A remarkable difference among them was observed.

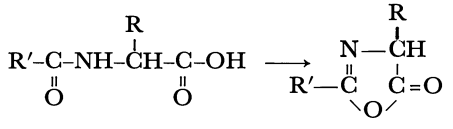
Ring formation to the aziridinone proceeded when *p*-bromobenzyloxycarbonyl (Br–Z) and *p*-chlorobenzyloxycarbonyl (Cl–Z) amino acids were used. The dehydration of Br-Z-L-phenylalanine and Cl-Z-L-phenylalanine was carried out successfully, with the aid of equivalent $COCl_2$ in THF at −20°C, by the dropwise addition of two equivalent TEA in the way described above. Then the corresponding *N*-acylated aziridinones were obtained in the respective crystalline forms. The analytical data of these aziridinones are listed in Table 2.

When tosyl amino acid was used, considerable amounts of the corresponding *N*-acylated aziridinone were isolated, but it failed to crystallize.

On the contrary, in the case of the *p*-methoxybenzyloxycarbonyl group (PMZ), which is sterically very similar to the analogous carbobenzoxy groups mentioned above, the ring formation of PMZ amino acid proceeded with little detection.

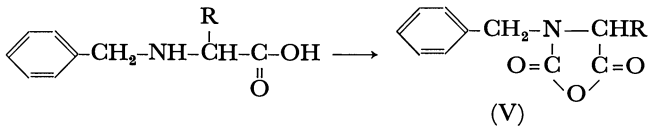
In the cases of the *t*-butyloxycarbonyl (BOC) and *t*-amyloxycarbonyl (AOC) groups, which are widely used in solid-phase peptide synthesis, the corresponding expected aziridinones could not be detected.

When other acyl groups, such as benzoyl and acetyl, were used for the *N*-protection of amino acids, the ring compounds resulting from the treatment described above were found not to be aziridinone, but azlactone. From benzoyl-L-phenylalanine and acetyl-L-phenylalanine, the corresponding 2-substituted-4-benzyl-azlactones were obtained in good yields.



R′: CH_3, C_6H_5 (IV)

If *N*-benzyl L-amino acid was used as the starting material, optically-active benzylamino-*N*-carboxyanhydrides (*N*-Bzl-NCA) were synthesized under the same reaction condition; some of them were obtained in the crystalline form.

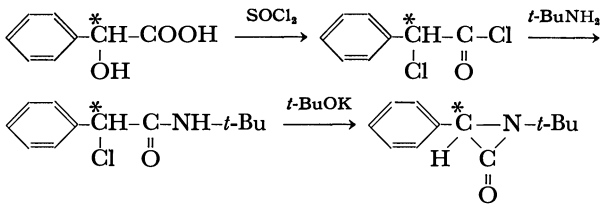


(V)

In any case, it is interesting to note that the *N*-substituents of amino acids leading to the formation of the corresponding *N*-acylated aziridinones are limited in some urethan-type groups (Z, Br–Z, Cl–Z) and the tosyl group investigated so far in this study.

Retention of Optical Activity. The aziridinones obtained to date have been synthesized by the dehydrohalogenation of *N*-haloamides or α-haloamides. Besides this type of reaction, the only optically-active aziridinone obtained *via* the optically-active α-haloamide was reported by Baumgarten[5] *et al.*

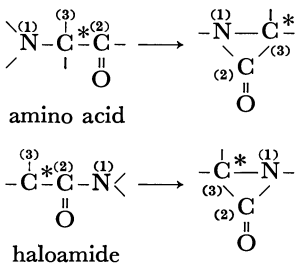
In the above route, a chance of partial racemization still remains during the abstraction of the chlorine atom on the asymmetric carbon at *C*-3.



On the contrary, the new route to synthesize the *N*-acylated aziridinone reported here may be carried out by intramolecular dehydration between carboxyl and amino groups in L-acylamino acids. This new route involves no abstraction on the asymmetric carbon during the cyclization reaction, because the atomic sequence of the starting material in this study is in

12) L. C. Bateman, E. D. Hughes, and C. K. Ingold, *J. Chem. Soc.*, **1944**, 243.

striking contrast to that of haloamide.



amino acid

haloamide

Accordingly, there is every possibility of retaining the whole optical activity in this new route. This fact is confirmed by deriving the aziridinones to the known optically-active amino acid derivatives.

Spectral Assay. Sheehan and Beeson[6] reported that *N*,3-di-*t*-butylaziridinone showed a carbonyl absorption band at 1835 cm^{-1} in the IR spectra. Later, the same band for *N*,3-di-adamantylaziridinone was observed at 1830 cm^{-1} by Talaty *et al.*[9]

All the *N*-acylated aziridinones obtained in this study show a carbonyl band due to the ring at 1840 cm^{-1} and the acyl carbonyl at 1690 cm^{-1}, and no amino band is detected in the range of 3100—3300 cm^{-1}. The IR spectra of II and III, which are typical examples of these aziridinones, are shown in Fig. 1.

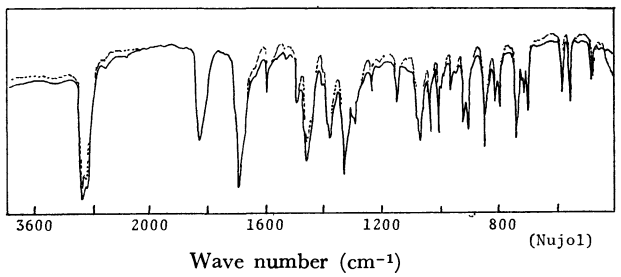


Fig. 1. IR spectra of aziridinones
—— II; ——III

The NMR data of the three crystalline aziridinones and Z-Phe which is the starting material of I, are shown in Table 3 and Fig. 2.

The triplet of the methine proton on the *C*-3 of I at 4.55 (δ) is caused only by the AB-type coupling with the methylene proton of the benzyl group. On the contrary, the methine proton of Z-Phe shows a quartet at 4.67 (δ) due to the adjacent amino proton.

The mass spectrum of the parent molecular ion of

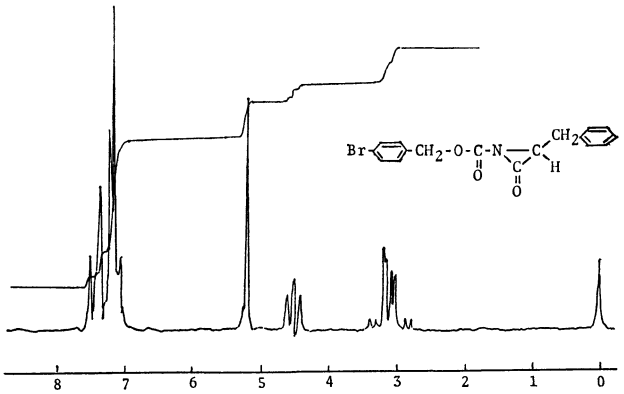

Fig. 2. NMR spectrum of II

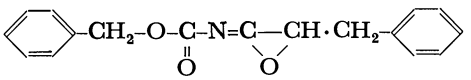
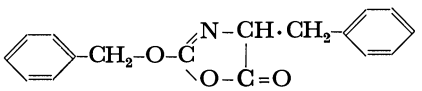
I shows *m/e* 281 ($C_{17}H_{15}NO_3$). The *m/e* 253, which is derived from the fisson of the aziridinone ring, and *m/e* 238, 209, 192, 181, 162, 146, 128, 118, 117, and 91 ions are observed. Some of these assignments are shown in Scheme 1.

The mass spectra of II and III show M^+ 362 ($C_{17}H_{14}NO_3 \cdot Br$) and 315 ($C_{17}H_{14}NO_3 \cdot Cl$) respectively; the *m/e* ion values observed can also probably be identified with that of I mentioned above.

Isomeric Structures. The other possible isomeric structures, such as an epoxide (VI) and an azlactone must be taken into consideration with regard to the dehydration product from Z-Phe.



(VI)



(VII)

With regard to VI, Sheehan and Beeson[6] reported the thermal decomposition of *N*,3-di-*t*-butylaziridinone at 175°C; they discussed the isomerization of the aziridinone to epoxide in order to explain the formation of pivalaldehyde and *t*-butyronitrile as the main products.

Azlactone would be another isomeric structure, though it has never yet been synthesized. Siemion

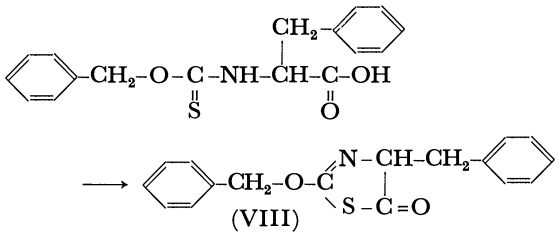
et al.[13] reported the only example of thiourethan-type azlactone (VIII), which was derived from benzyloxythiocarbonyl-L-phenylalanine; it was completely optically-inactive as had been expected. The IR spectra showed 1630 cm^{-1} ($\nu_{C=N}$) and 1720 cm^{-1} ($\nu_{C=O}$).



It has widely been accepted that the racemization during the peptide-coupling reaction must be caused by the formation of an azlactone.[14] Therefore, along with the results observed by the spectral assay, the retention of the whole optical activity in the dehydration product from Z–AA strongly supports that its structure should be the *N*-acylated aziridinone. To confirm the structure definitely, an X-ray analysis of Br-Z-aziridinone (II) is now in progress.

Reaction Mechanism. In the present study, dehydration of Z–AA to form 3-substituted-1-benzyloxycarbonylaziridinones took place by the use of $POCl_3$ as well as $COCl_2$ and $SOCl_2$, which contain two reactive halogen atoms in the molecule. Therefore, the pathway of this reaction may be partially similar to that of "the phosphorus oxychloride method" reported by Wieland and Heinke.[15]

A mechanistic approach was carried out using $SOCl_2$ as the dehydrating agent. In this case, three equivalent TEA are required to neutralize the reaction mixture exactly, because one more TEA is consumed for the neutralization of SO_2, as has been described earlier. The SO_2–TEA complex formed in the course of the reaction is brown and is insoluble in the THF–ether contained in the reaction system. Accordingly, by cutting off the reaction at each step when the addition of every equivalent TEA is over, the entire reaction may be divided into three steps. The TEA–HCl or SO_2–TEA complex precipitated at the end of each step of the reaction is collected by filtration.

It was found that an equivalent TEA–HCl was recovered almost quantitatively at the end of the first step, and that during this step the tlc of the reaction solution showed no aziridinone at R_f 0.9. At the end of the second step, when another equivalent TEA was added, the mass collected by filtration was rather small in amount and was still colorless, while tlc showed that the reaction proceeded about a half. A mixture of the rest of the TEA–HCl and an equivalent SO_2–TEA complex, which was brown in color, was obtained quantitatively in the last step of the reaction, when the reaction solution was neutralized exactly and the formation of the aziridinone was accomplished.

It is evident that $SOCl_2$ does not act as a chlorinating agent, but as a dehydrating one, at the lower temperatures treated in this study, and that the reaction proceeds *via* a mixed anhydride resulting from dehydrohalogenation between Z–Phe and $SOCl_2$ with the aid of TEA.

It should be noted that the use of ethylchloroformate or benzenesulfonyl chloride, commonly used as the mixed anhydride reagents in peptide chemistry, did not cause the ring closure under the above reaction conditions. Thus, another halogen atom containing in the intermediate mixed anhydride formed from Z–Phe and $SOCl_2$ must play an essential role as an effective leaving group in forming such a strained aziridinone. The abstraction of the hydrogen atom from the amino

nitrogen may take place by TEA, accompanied by the formation of TEA–HCl. Consequently, the nucleophilic attack of nitrogen to the carbonyl carbon would lead to the formation of an aziridinone ring.

The ease of abstraction of the hydrogen atom in the amino nitrogen may also be connected with the electronegativity of the nitrogen atom itself caused by the effect of *N*-substituents. The fact that PMZ–AA gave scarcely any of the corresponding aziridinone may be attributed to the relatively greater electronegative property of the urethan oxygen of the PMZ group in comparison with that of the Z group. The above electronegativity of the urethan oxygen of the PMZ group would affect the electron density of the amino nitrogen enough to prevent the abstraction of the hydrogen atom under the circumstances used in this study. It is well known that PMZ–AA is cleaved much more easily than Z–AA under mild acidic conditions. Similarly, in the cases of BOC–AA and AOC–AA, which are also easily cleaved under the same acidic conditions, the corresponding aziridinones were not obtained.

Experimental

The melting points are uncorrected. Thin-layer chromatography (tlc) was performed with silica gel G (Merck), and the spots were detected by ninhydrin on heating at 100°C after developing in a buffer solution ($CHCl_3$: AcOEt: AcOH, 85: 15: 3). The IR spectra were obtained using a Shimadzu IR-27G apparatus. The NMR spectra were recorded at 60 MHz in $CDCl_3$ with TMS as the internal standard using a Hitachi R-20A apparatus. The mass spectra were obtained by means of a Hitachi RMS-4 mass spectrometer. The optical rotations were measured with a Yanagimoto OR-100 apparatus.

The THF, ether and petroleum ether used throughout this experiment were dried over sodium metal wire after distillation. The $COCl_2$ gas was absorbed in dry ether to prepare the $COCl_2$–ether solution which was then stored in a refrigerator. The $SOCl_2$, $POCl_3$, and TEA were purified by distillation before use.

3-Benzyl-1-benzyloxycarbonylaziridin-2-one (I). (a) To a solution of Z-Phe (14.95 g, 0.05 mol) in 200 ml of THF was added $COCl_2$–ether solution (25 ml, containing 0.05 mol of $COCl_2$) at −20°C. TEA (7 ml, 0.05 mol) in 15 ml of ether was then added drop by drop to the solution over a period of 30 min, with stirring at −20°C. Tlc showed a spot at R_f 0.4. After 30 min, TEA (7 ml, 0.05 mol) in 15 ml of ether was added again to the reaction mixture under the same conditions as above. A spot appeared at R_f 0.9 on tlc. After an additional 30 min of stirring, 200 ml of ether was added to the reaction mixture. The TEA-HCl thus precipitated in a quantitative yield was removed by filtration, and the filtrate was evaporated under reduced pressure on an ice-bath. To the residue were added ether (200 ml) and petroleum ether (100 ml), then the mixture was stored in a refrigerator overnight. After the removal of a small amount of precipitate by filtration, the filtrate was evaporated again in the same manner as above. Then, ether (100 ml) and petroleum ether (300 ml) were added to the residue, which was then crystallized in a refrigerator for three days. The crude products thus formed were collected by filtration to afford 10.2 g (73%). For recrystallization, to the crude product was added 100 ml of ether at 0°C. After the removal of a small amount of undissolved material by filtration, petroleum ether (200 ml) was added to the filtrate, which was stored again in a refrigerator for several days to afford colorless needles (6.74 g, 48%). Recrystallization was then repeated once more in the same manner to give an analytical sample.

(b) Freshly distilled $SOCl_2$ (5.95 g, 0.05 mol) in 30 ml of ether was added to a solution of Z-Phe (14.95 g, 0.05 mol) in 200 ml of THF at −30°C. To the solution was added TEA (14 ml, 0.1 mol) in 30 ml of ether, drop by drop, over a period of 1 hr with stirring. Tlc showed two spots, at R_f 0.4 and 0.9. Then TEA (7 ml, 0.05 mol) in 15 ml of ether was added drop by drop to the reaction mixture at the same temperature. The reaction mixture gradually turned brown. After an additional 30 min, ether was added to the mixture; the mixture was subsequently filtered to romove quantitative yields of the TEA-HCl and SO_2-TEA complex thus precipitated; the yellowish filtrate, which showed a spot at R_f 0.9 on tlc, was then worked up in the manner described in (a). Subsequent recrystallization from ether and petroleum ether gave colorless needles (3.5 g, 25%), which were identified with those afforded by (a).

*3-Benzyl-1-*p*-bromobenzyloxycarbonylaziridin-2-one (II).* Br-Z-Phe[16] was prepared by a Schotten-Baumann reaction with L-phenylalanine and *p*-bromobenzyloxycarbonyl chloride. Mp 107—109°C. $[\alpha]_D^{20}$ −8.9° (*c* 1, MeOH). To a solution of Br-Z-Phe (7.56 g, 0.02 mol) in 50 ml of THF was added the $COCl_2$–ether solution (10 ml, containing 0.02 mol of $COCl_2$) at −20°C. TEA (5.6 ml, 0.04 mol) in 12 ml of ether was then added over a period of 1.5 hr to neutralize the reaction mixture at −20°C in the same manner as had been described above. Colorless prisms of II (3.2 g, 44%) were obtained after recrystallization.

*3-Benzyl-1-*p*-chlorobenzyloxycarbonylaziridine-2-one (III).* Cl-Z-Phe was synthesized with L-phenylalanine and *p*-chlorobenzyloxycarbonyl chloride in the same manner as Br-Z-Phe. Mp 80.5—82.0°C. $[\alpha]_D^{20}$ −7.5° (*c* 1, MeOH). To a solution of Cl-Z-Phe (6.66 g, 0.02 mol) in 50 ml of THF was added the $COCl_2$–ether solution (10 ml, containing 0.02 mol of $COCl_2$) at −20°C; TEA (5.6 g, 0.04 mol) in 12 ml of ether was subsequently added in the same manner as above to afford III as colorless needles (2.3 g, 37%) after recrystallization.

4-Benzyl-2-phenyl-5-oxazolone (IV). To a solution of benzoyl-L-phenylalanine (26.9 g, 0.1 mol) in 200 ml of THF was added the $COCl_2$–ether solution (50 ml, containing 0.1 mol of $COCl_2$) at −30°C. TEA (28 ml, 0.2 mol) in 80 ml of ether was then added dropwise over a period of 1.5 hr in order to completely neutralize the reaction mixture at the same temperature. A 200 ml portion of ether was then added to the reaction mixture, which was subsequently filtered to remove the TEA-HCl precipitated; the filtrate was evaporated *in vacuo* on an ice-bath. To the residue was added 300 ml of ether; the mixture was washed with an ice-cold 5% sodium bicarbonate aqueous solution and dried over magnesium sulfate. The organic layer was evaporated to about half its volume, and 150 ml of petroleum ether was added to the solution, which was then stored in a refrigerator overnight to afford 19.4 g of IV (73.3%). Recrystallization from ether and petroleum ether gave colorless needles (14.7 g, 58.6%). Mp 72—74°C. IR $\nu_{C=O}$ 1830, 1815 cm^{-1}. $\nu_{C=N}$ 1655 cm^{-1}. NMR (δ) 7.27 (bs, 5H), 7.69 (m, 4H), 4.68 (t, 1H), 3.42 (dd, 2H), 3.13 (dd, 2H). Found: C, 76.13; H, 5.18; N, 5.38%. Calcd for $C_{16}H_{13}NO_2$: C, 76.47; H, 5.22;

16) D. M. Channing, P. B. Turner, and G. T. Young, *Nature*, **167**, 487 (1951).

N, 5.57%. $[\alpha]_D^{20}$ 0° (*c* 1, THF).

3-Benzyl-4-phenyl-2,5-oxazolidinedione (V). A Schiff base from L-phenylglycine and benzaldehyde was reduced by catalytic hydrogenation to afford *N*-benzyl-L-phenylglycine. Mp 222—224°C. $[\alpha]_D^{20}$ +92.4° (*c* 1, AcOH). To a solution of *N*-benzyl-L-phenylglycine (4.8 g, 0.02 mol) in 15 ml of THF was added the $COCl_2$–ether solution (10 ml, containing 0.02 mol of $COCl_2$) at −30°C. TEA (5.6 ml, 0.04 mol) in 12 ml of ether was then added, drop by drop, in the manner described above. After the removal of the TEA–HCl precipitated by filtration, the filtrate was evaporated *in vacuo* on an ice-bath. To the residue was then added 300 ml of ether, and the mixture was washed with an ice-cold 5% sodium bicarbonate aqueous solution and dried over magnesium sulfate. Crystallization from ether and petroleum ether (1 : 2) gave 2.6 g of V. Mp 120—122°C. IR $\nu_{C=O}$ 1850, 1760 cm^{-1}. NMR (δ) 7.04—7.55 (m, 10H), 4.90 (s, 1H), 4.44 (q, 2H). Found: C, 71.79; H, 5.08; N, 5.28%. Calcd for $C_{16}H_{13}NO_3$: C, 71.90; H, 4.90; N, 5.24%. $[\alpha]_D^{20}$ +124.0° (*c* 1, THF).

The author wishes to express his hearty gratitude to Dr. S. Sakakibara for his guidance and to Professor I. Murata for his valuable advice on the spectral assay. Acknowledgement is made to Dr. T. Takayanagi and Dr. I. Chibata of Tanabe Seiyaku Co., Ltd., for their encouragement. Thanks are extended to Mr. H. Tamura for his assistance in the experimental work.

Syntheses of Isoprenoids by Telomerizations. VIII.[1,2] Anionic Telomerizations of Isoprene with Secondary Amines

Kunihiko TAKABE, Takao KATAGIRI, and Juntaro TANAKA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received January 11, 1972)

The anionic telomerizations of isoprene with secondary amines in the presence of alkali-metal catalysts were investigated under several conditions. The $n=2$ telomers were found to contain *N,N*-dialkyl(3,7-dimethyl-2,6-octadienyl)amine (**2A**) and *N,N*-dialkyl(2-isopropenyl-5-methyl-4-hexenyl)amine (**2B**) as the main components, $n=1$ and $n=3$ telomers were also identified. On the basis of these results, the mechanism of this anionic telomerization and the reactivity of the carbanions connected with this reaction were discussed.

It has been known that the naturally-occurring monoterpenes have 4,1-(geranyl-, neryl-, linalyl-, and terpinyl-) mainly and 4,3-(lavandulyl) coupled skeletons of isoprene. Many investigations have been made of the syntheses of these terpenes by means of the telomerizations of isoprene, but the C_{10} telomers obtained by cationic[3-5] or radical-initiated[6] telomerizations contain many products, and the yield of acyclic monoterpenes is low.

No studies of the synthesis of the terpenoids by anionic telomerization[7] have been carried out. Therefore, the anionic telomerizations[8] of isoprene with secondary amines were studied in detail. In this paper, we wish to report on the structures of the telomers, the reaction scheme, and the reactivity of the carbanions connected with this reaction.

Results and Discussion

The Structure of the Telomers. The structures of the telomers obtained were identified by means of IR, NMR, and the mass spectra; they are summarized in Tables 1 and 2.

Reaction Scheme. The yields of the telomers and the ratios of **1A/1B** obtained under various conditions are shown in Table 3. When the molar ratio of isoprene to diethylamine was 1/2, the $n=2$ telomers were not formed. The order of the catalytic activity was K>Na>Li, but the ratio of **1A/1B** was the reverse. Table 4 shows that the ratio of **1A/1B** was not influenced by the reaction time, and was nearly constant.

Therefore, the mechanism of this reaction is similar to that of alkali metal-catalyzed reactions of isoprene with alkylaromatics[9] and can be formulated as follows;

1) A part of this work was presented at the Annual Meeting of the Chemical Society of Japan, Osaka, April, 1971.

2) Part VII of this series: K. Takabe, T. Katagiri, and J. Tanaka, This Bulletin, **45**, 2662 (1972).

3) J. Tanaka, T. Katagiri, and T. Takeshita, *Nippon Kagaku Zasshi*, **89**, 65 (1968).

4) T. Asahara, M. Toyoda, and H. Kise, *Kogyo Kagaku Zasshi*, **72**, 1530 (1969).

5) K. Takabe, T. Katagiri, and J. Tanaka, *ibid.*, **74**, 1162 (1971).

6) T. Katagiri, K. Takabe, K. Ono, and J. Tanaka, *Nippon Kagaku Zasshi*, **91**, 393 (1970).

7) The anionic telomerizations of styrene with some *sec*-amines have been investigated in detail by Asahara *et al.* [T. Asahara, M. Seno, S. Tanaka, and N. Den, This Bulletin, **42**, 1996, 2337 (1969).]

8) The addition reactions of isoprene with some secondary amines have already been reported by Martirosyan *et al.* [G. T. Martirosyan, E. A. Grigoryan, and A. T. Bahayan, *Arm. Khim. Zh.*, **20**, 423 (1967); *Chem. Abstr.*, **68**, 48940 (1968).]

9) H. Pines and N. C. Shi, *J. Org. Chem.*, **30**, 280 (1965); W. M. Stalic and H. Pines, *ibid.*, **35**, 422 (1970).

Table 1. The structural formulas of the telomers

$n=1$		(**1A**) *N,N*-dialkyl(3-methyl-2-butenyl)amine
		(**1B**) *N,N*-dialkyl(2-methyl-2-butenyl)amine
$n=2$		(**2A**) *N,N*-dialkyl(3,7-dimethyl-2,6-octadienyl)amine
		(**2B**) *N,N*-dialkyl(2-isopropenyl-5-methyl-4-hexenyl)-amine
		(**2H**) myrcene
$n=3$		(**3B**) *N,N*-dialkyl(6-isopropenyl-3,9-dimethyl-2,8-decadienyl)amine
		(**3C**) *N,N*-dialkyl(2-isopropenyl-5,9-dimethyl-4,8-decadienyl)amine
		(**3D**) *N,N*-dialkyl(2,4-diisopropenyl-7-methyl-6-octenyl)amine
		(**3H**) 6-isopropenyl-9-methyl-3-methylene-1,8-decadiene

Table 2. Characterization of the telomers

Telogen	Products (Mass; M^+)	IR (cm^{-1})	NMR (τ)
Me_2NH	**1A** (113)	1680, 817 (a trisubstituted double bond), 1020, 1040, (C–N), 2810, 2765, 2725 (R–NMe_2).	8.37(3H, s, –(CH_3)C=), 8.28 (3H, s, –(CH_3)C=), 7.90 (6H, s, CH_3–N⟨), 7.23(2H, d, J=7.2 Hz, =CH–CH_2–N⟨), 4.80 (1H, t, J=7.2 Hz, ⟩C=CH–).
	1B (113)	1680, 817 (a trisubstituted double bond), 1020, 1040 (C–N), 2810, 2765, 2725(R–NMe_2).	8.21—8.54 (6H, m, –(CH_3)C=), 7.96(6H, s, CH_3–N⟨), 7.36(2H, s, =C–CH_2–N⟨), 4.50—5.01 (1H, m, ⟩C=CH–).
	2A (181)	1665, 818 (trisubstituted double bonds), 1015, 1040 (C–N), 2815, 2760, 2720(R–NMe_2).	8.23—8.48(9H, m, –(CH_3)C=), 7.92(6H, s, CH_3–N⟨), 7.90—8.13(4H, m, =C–CH_2–CH_2–C=), 7.24 (2H, d, J=7.0 Hz, =CH–CH_2–N⟨), 4.70—5.15 (2H, m, ⟩C=CH–).
	2B (181)	1645, 883 (an end methylene group), 1670, 840 (a trisubstituted double bond), 1040 (C–N), 2815, 2760, 2720(R–NMe_2).	8.25—8.50(9H, bs, –(CH_3)C=), 7.91(6H, s, CH_3–N⟨), 7.69—8.08(5H, m, –CH_2–, ⟩CH–), 5.38 (2H, bs, ⟩C=CH_2), 5.03(1H, t, J=7.0 Hz, ⟩C=CH–).
	3B (249)	1645, 886 (an end methylene group), 1670, 830 (trisubstituted double bonds), 1040, 1015(C–N), 2815, 2760, 2725(R–NMe_2).	8.25—8.51(12H, m, –(CH_3)C=), 7.92(6H, s, CH_3–N⟨), 8.20—8.70(2H, m, –CH_2–), 7.75—8.12 (5H, m, =C–CH_2–, =C–CH⟨), 7.25(2H, d, J=7.0 Hz, =CH–CH_2–N⟨), 5.35(2H, bs, ⟩C=CH_2), 4.76—5.10 (2H, m, ⟩C=CH–).
	3C (249)	1645, 886 (an end methylene group), 1675, 840 (trisubstituted double bonds), 1040 (C–N), 2815, 2765, 2725(R–NMe_2).	8.20—8.53 (12H, bs, –(CH_3)C=), 7.90(6H, s, CH_3–N⟨), 7.70—8.18 (9H, m, –CH_2–N, =C–CH_2–, =C–CH⟨), 5.35(2H, bs, ⟩C=CH_2), 4.75—5.10(2H, m, ⟩C=CH–).
	3D (249)	1645, 885(end methylene groups), 1670, 843 (trisubstituted double bonds), 1040 (C–N), 2810. 2775, 2725(R–NMe_2).	8.25—8.52 (12H, bs, –(CH_3)C=), 7.92(6H, s, CH_3–N⟨), 8.50—8.80 (2H, m, –CH_2–), 7.80—8.12 (6H, m, –CH_2–N⟨, =C–CH_2–, =C–CH⟨), 5.38(4H, bs, ⟩C=CH_2), 4.90—5.10(1H, m, ⟩C=CH–).
Et_2NH	**1A** (141)	1670, 835 (a trisubstituted double bond), 1055, 1170, 1200 (C–N).	9.04(6H, t, J=7.1 Hz, CH_3–CH_2–N⟨), 8.39 (3H, s, –(CH_3)C=), 8.29(3H, s, –(CH_3)C=), 7.61 (4H, q, J=7.1 Hz, CH_3–CH_2–N⟨), 7.09 (2H, d, J=6.8Hz, =CH–CH_2–N⟨), 4.86(1H, t, J=6.8Hz, ⟩C=CH–).
	1B (141)	1670, 850 (a trisubstituted double bond), 1050, 1170, 1195(C–N).	9.03(6H, t, J=7.0 Hz, CH_3–CH_2–N⟨), 8.25—8.60 (6H, m, –(CH_3)C=), 7.61(4H, q, J=7.0 Hz, CH_3–CH_2–N⟨), 7.18(2H, s, =C–CH_2N⟨), 4.50—4.90 (1H, m, ⟩C=CH–).

TABLE 3. REACTIONS OF ISOPRENE WITH DIETHYLAMINES[a]

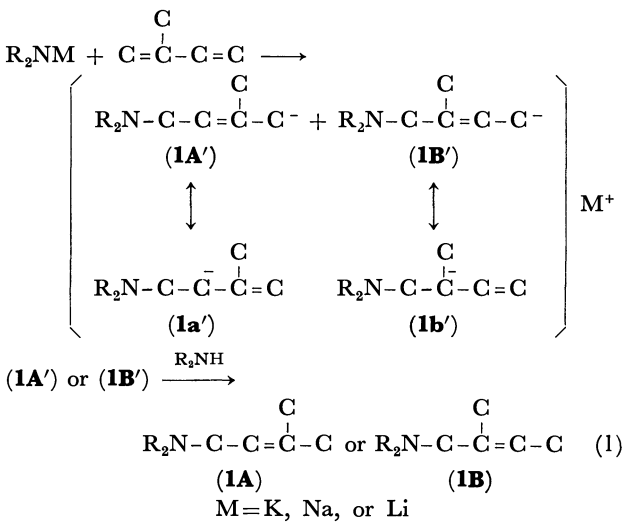
Cation	(g)	Temperature (°C)	Yield[b] of $n=1$ telomer (%)	Composition (%) (1A)	Composition (%) (1B)	(1A)/(1B)
Na	(0.2)	0—3	33	88	12	7.1
		40	64	84	16	5.4
		70	72	79	20	3.9
K	(0.3)	0—3	62	75	25	3.0
		40	80	71	18	3.9
Li	(0.1)	0—3	2	78	3	26
		40	12	95	5	20

a) Reaction condition; isoprene 6.8 g, isoprene/Et_2NH=1/2 (molar ratio), reaction time 1 hr.
b) Yields were calulated on the basis of isoprene added.

TABLE 4. REACTIONS OF ISOPRENE WITH DIETHYLAMINE[a]

Time (min)	Cat. Na Yield (%)[b]	Cat. Na (1A)/(1B)	Cat. K Yield (%)[b]	Cat. K (1A)/(1B)
15	2	6.5	51	2.7
30	43	6.8	85	2.8
60	59	6.5	89	2.9
120	82	6.4		
150	91	6.1	91	2.5

a) Reaction condition; isoprene 6.8 g, isoprene/Et_2NH=1/2 (molar ratio), cat. 0.2 g, reaction temperature 0—2°C.
b) Yields of $n=1$ telomers were calculated on the basis of isoprene.



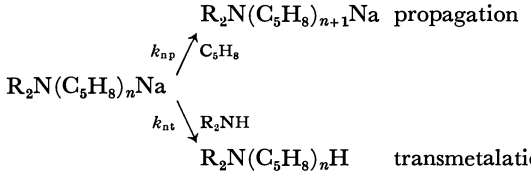
(1)

The preferential formation of **1A** over **1B** is likely to be due mainly to the difference in the stabilities of the carbanions **1A′** and **1B′** (*prim↔sec vs. prim↔tert*) and only a small extent to a steric interaction between the R group of R_2NM and the methyl group of isoprene on addition.

The effect of the molar ratio of isoprene to dimethylamine is shown in Table 5. The $n\geq 2$ telomers and a small amount of **2H** and **3H**[10] were formed as the reaction proceeded, as is shown in Table 6.

From these results, the schemes of the formation of the $n=2$ and 3 telomers are considered to be as is shown in Fig. 1.

Reactivity of Carbanions. It seems that such organosodium compounds (a) as **1A′**, **1a′**, **2A′**, **2a′**, **2B′**, **2b′**, **3A′**, **3B′**, **3C′**, and **3D′** react with isoprene or secondary amine; that is, propagation and transmetalation reactions occur competitively as follows:



As is shown in Fig. 1 and Eq. (1), the telomers (**1A**, **1B**, **2A**, **2B**, **3A**, **3B**, **3C**, and **3D**) confirmed in this telomerization might be formed by the transmetalation of the primary carbanions (**1A′**, **1B′**, **2A′**, **2B′**, **3A′**, **3B′**, **3C′**, and **3D′**), the telomers formed by the transmetalation of the secondary carbanions (**1a′**, **2a′**, and **2b′**) were not confirmed, but it seems that these secondary carbanions react with isoprene to give the primary carbanions (**2B′**, **3B′**, and **3D′**) *i.e.*, propagation occurs.

From these results, the reactivity of the carbanions in this telomerization is considered to be as follows:

$k_{nt}[R_2NH] \approx k_{np}[C_5H_8]$ for the primary carbanions

$k'_{nt}[R_2NH] < k'_{np}[C_5H_8]$ for the secondary carbanions

TABLE 5. EFFECT OF MOLAR RATIO (ISOPRENE/Me_2NH) ON COMPOSITIONS OF TELOMERS

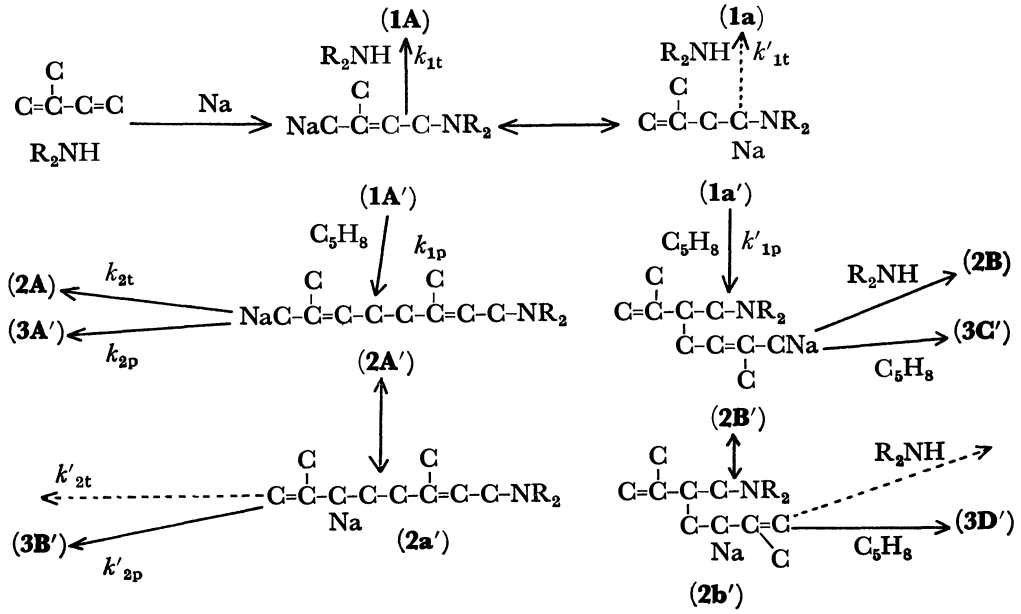

Fig. 1. Anionic telomerizations of isoprene with *sec*-amines.

Experimental

Materials. The secondary amines were commercial products of the purest grade, they were distilled and checked by glc. The isoprene was dried over anhydrous sodium sulfate and distilled in the presence of hydroquinone. The inorganic compounds were also commercial materials.

The Anionic Telomerization of Isoprene with Secondary Amine. For example, a mixture of dimethylamine (1.8 g) and isoprene (13.6 g) was placed in a pressure bottle. Then lumps of sodium (0.1 g) were added, and the mixture was allowed to react at 40°C for 3 hr while being stirring under a nitrogen atmosphere. After the reaction, the reaction mixture was cooled and treated with 10 ml of ethanol to decompose the sodium and organosodium compounds. Then the mixture was washed three times with a saturated sodium sulfate aqueous solution, and the organic layer was dried over anhydrous sodium sulfate. After the removal of the unreacted isoprene and dimethylamine under reduced pressure, the products were obtained (11.0 g). They included the $n=1$ telomer (0.3 g, bp 55—58°C/86 mmHg), and the $n=2$ telomer (3.0 g, bp 80—86°C/10 mmHg), the $n=3$ telomer (3.0 g, bp 80—90°C/1.5 mmHg), and the $n\geq 4$ telomers (4.7 g, residue), each telomer was analyzed by IR, NMR, and mass spectra after glc fractionation.

Measurements. All the products were analyzed after glc fractionation (15% Apiezone grease L/Celite 455, 4 mmϕ × 2.5 m, H_2: 50 ml/min). The IR spectra were recorded with a Perkin Elmer Model 337 spectrometer in a liquid film. The mass spectra were determined on a Hitachi RMU-7L spectrometer, and the NMR data, on a Hitachi-Perkin Elmer Model R-20 (60 MHz) spectrometer in carbon tetrachloride. The product ratios were determined by glc.

Syntheses of Isoprenoids by Telomerizations. IX.[1] Stereoselectivity of Telomers and the Effect of Telogens in Anionic Telomerizations Using Secondary Amines

Kunihiko TAKABE, Takao KATAGIRI, and Juntaro TANAKA
Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu
(Received January 20, 1972)

The stereoselectivity of the telomers and the effect of the telogens in the anionic telomerizations of isoprene with secondary amines were investigated. Dimethyl-, diethyl-, di-*n*-propy-l, diisopropyl-, and methylphenyl-amines, pyrrolidine, morpholine, and piperidine were used as the telogens. The ratio of *N,N*-dialkyl(3,7-dimethyl-2,6-octadienyl)amine(**2A**) to *N,N*-dialkyl(2-isopropenyl-5-methyl-4-hexenyl)amine(**2B**), which were obtained in these reactions, was varied with the sort of secondary amines, the yield of the telomers was found to be dependent on the acidity of the secondary amines. Moreover, **2A**, which was the main component of the $n=2$ telomers, was confirmed to have a *cis*-configuration—that is, *N,N*-dialkylnerylamine. However, the $n=1$ telomer of myrcene with secondary amine was *N,N*-dialkylgeranylamine. These results were interpreted in terms of the stability of the cyclic intermediate of the carbanions.

In the preceding paper,[1] it was reported that the anionic telomerizations of isoprene with secondary amines gave mainly *N,N*-dialkyl(3,7-dimethyl-2,6-octadienyl)amine(**2A**) and *N,N*-dialkyl(2-isopropenyl-5-methyl-4-hexenyl)amine (**2B**) as the $n=2$ telomers.

In this paper, the stereoselectivity of the telomers and the effect of the telogens in the telomerizations using several secondary amines will be discussed, and the intermediate carbanions will be presumed on the basis of these results.

Results and Discussion

Stereoselectivity of the Telomers. *N,N*-Diethyl(3,7-dimethyl-2,6-octadienyl)amine (**2A**) has two stereoisomers, *cis* and *trans*—that is, *N,N*-diethylnerylamine and *N,N*-diethylgeranylamine. The structure of the telomer (**2A**) was identified as *N,N*-diethylnerylamine from IR, mass,[2] NMR,[3] and glc analyses.[4]

On the other hand, *N,N*-diethylgeranylamine was obtained quantitatively by the anionic telomerization of myrcene (3-methylene-7-methyl-1,6-octadiene) with diethylamine.

These anionic telomerizations can be formulated by the equations shown in Figs. 1 and 2. The stereoselectivity of the telomers can be interpreted in terms of the intramolecular solvation[5,6] (coordinate metal-nitrogen bond[7]), as with **1a'** and **1Ms'** (the stability

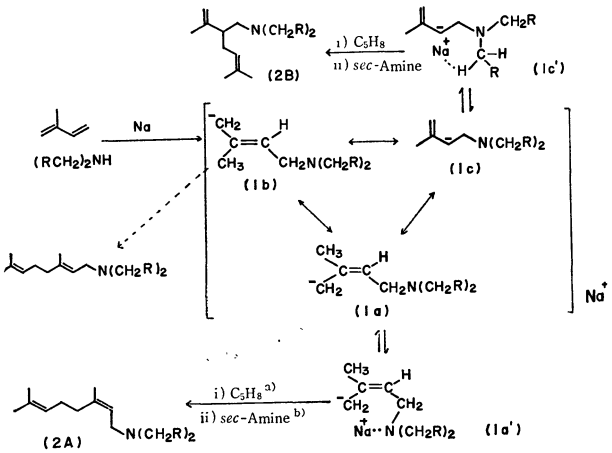

Fig. 1. Telomerization scheme of isoprene.
a) Propagation, b) Transmetalation

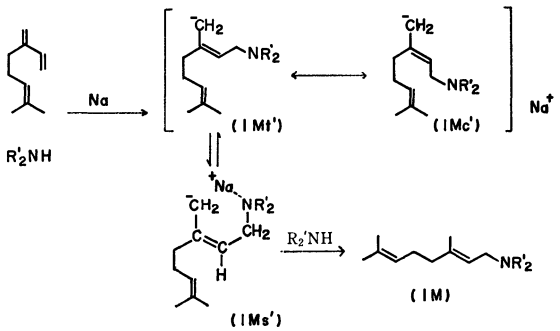

Fig. 2. Telomerization scheme of myrcene

of the carbanions: **1a'**>**1a**, **1b**, and **1Ms'**>**1Mt'**,**1Mc'**). Thus, it seems that the more stable carbanions (**1a'** and **1Ms'**) react with isoprene and the telomers (**2A** and **1M**) are formed stereoselectively.

The Effect of the Telogens. Dimethyl-, diethyl-, di-*n*-propyl-, and methylphenyl-amines were used as the telogens. The effects of these secondary amines on the yields and the compositions of the telomers are shown in Tables 1 and 2. The yields of the telomers varied with the sort of the secondary amines, they were in the following order: $Me_2NH > Et_2NH \approx (n\text{-propyl})_2NH > (\text{isopropyl})_2NH > C_6H_5NH(CH_3)$. It is possible

1) Part VIII of this series: K. Takabe, T. Katagiri, and J. Tanaka, This Bulletin, **46**, 218 (1973).

2) The data of the IR and mass spectra of **2A** agreed very closely with those of authentic *N,N*-diethylgeranylamine, which was synthesized from geranyl chloride and diethylamine.

3) Slight difference between the NMR spectrum of **2A** and that of *N,N*-diethylgeranylamine were observed in the shapes of the signals of τ 7.90—8.10(=CH-C**H**$_2$-C**H**$_2$-C=) and 8.25—8.46 (CH_3-C=).

4) The retention times of **2A** and *N,N*-diethylgeranylamine were 10.8 and 11.7 min respectively under the same glc conditions (15% Apiezon grease L/Celite 545, 2.5 m, 150°C, H_2: 50 ml/min).

d) Na 0.1 g,reaction time 6 hr.

to explain these results by considering the acidity of the secondary amines[8] in the step of the transmetalation.

The ratios of **2A/2B**, which were obtained in these reactions, varied with the sort of the secondary amines as is shown in Tables 1 and 2. These ratios seems to correspond to the yields of the telomers. In the case of the cyclic secondary amines (pyrrolidine, piperidine, and morpholine), however, the ratios of **2A/2B** were nearly constant, as is shown in Table 3. This phenomenon may be interpreted by presuming the presence of the cyclic intermediate (**1c'**)[9] as is shown in Fig. 1.

The difference in the **2A/2B** ratio among these secondary amines—that is, the facility of the formation of **1c'**—seems to be dependent on the steric factor of the R group in **1c'**. For example, the formation of **1c'** may become more difficult in the case of di-*n*-propylamine than in the case of dimethylamine. The very preferential formation of **2B** over **2A** (**2A/2B**= 0.2) in the reaction using dimethylamine may be interpreted by considering the effect of the hyperconjugation of the methyl group. The result in the case of the cyclic secondary amines seems to be due to the lack of any steric difference in the formation of **1c'** among them.

Thus, the ratios of **2A/2B** are considered to be dependent on the degree of the formation of the stable carbanions, **1a'** and **1c'**.

Experimental

Materials. The secondary amines were commercial products of the purest grade, they were distilled and checked by glc. The isoprene and myrcene were dried over anhydrous sodium sulfate and distilled in the presence of hydroquinone. The inorganic compounds were also commercial materials.

Reaction Procedure. In a typical reaction, a mixture of isoprene (8.2 g) and morpholine (3.0 g) was allowed to

8) This has been reported in detail by Asahara *et al.* in relation to the acidity of the amines and reactivity in anionic telomerizations: T. Asahara, M. Senō, and S. Tanaka, *Seisan Kenkyu*, **23**, 304, 353, 356 (1971).

9) If so, the secondary carbanion (**1c**) should convert into a more stable carbanion (**1c'**), and **2B** should increase.

react in the presence of sodium (0.1 g) at 40°C for 3 hr while being stirred in a pressure bottle by the method described in the preceding paper.[1] The reaction products (5.9 g) included the n=1 telomer (bp 62.5—64.0°C/6 mmHg, 1.4 g), the n=2 telomer (bp 91.0—97.5°C/1.5 mmHg, 1.7 g), and the $n\geq 3$ telomer (residue, 2.6 g).

Reaction of Myrcene with Diethylamine. A mixture of myrcene (9.9 g) and diethylamine (3.6 g) was allowed to react in the presence of sodium (0.1 g) at 40°C for 3 hr, as has been described in the preceding paper.[1] The reaction products (8.0 g) included the n=1 telomer (bp 85—87°C/2 mmHg, 7.7 g) and the $n\geq 2$ telomers (residue, 0.2 g). The n=1 telomer was found by glc analyses to consist 90% of the compound **1M** (*N,N*-diethylgeranylamine).

Synthesis of N,N-*Diethylgeranylamine.* *N,N*-Diethylgeranylamine was prepared from geranyl chloride by a modification of Sandler's method.[10] Mass (*m/e*); 209(M^+), IR(cm^{-1}, liquid film); 1200, 1165, 1050(C-N), 1660, 830 (trisubstituted double bond). NMR (τ, CCl_4); 9.04 (6H, t, J=7.0 Hz, CH_3-CH_2-), 8.25—8.46 (9H, m, CH_3-C=), 7.89—8.09 (4H, m, =CH-CH_2-CH_2-C=), 7.62 (4H, q, J=7.0 Hz, CH_3-CH_2-N-), 7.09 (2H, d, J=6.6 Hz, =CH-CH_2-N◯), 4.69—5.18 (2H, m, -Ċ=C**H**-).

Identification of the Telomers. Glc (15% Apiezon grease L/Celite 545, 2.5 m, H_2) was used for the determination of the compositions of the telomers. The IR, NMR, and mass spectra were measured by the use of Perkin Elmer Model 337, Hitachi-Perkin Elmer Model R-20 (60 MHz), and Hitachi RMU-7L spectrometers respectively. The characterizations of the telomers which were obtained using secondary amines are shown in Tables 4 and 5.

The financial support for this work by the Ministry of Education, Japanese Government, is gratefully acknowledged.

Synthesis and Biological Activity of Peptides Related to Eledoisin. I. Hexapeptide Amides Containing α-Hydroxy Acids[1,2]

Hiroshi SUGANO,[3] Ko HIGAKI, and Muneji MIYOSHI

Department of Synthetic Chemistry, Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd. 962 Kashima-cho, Higashiyodogawa-ku, Osaka

(Received April 27, 1972)

A new series of eledoisin-like depsipeptides was synthesized in order to obtain some information about the relationship between the structure of the peptide backbone of eledoisin and the biological activity. Specific amino acids in the biologically-active hexapeptide analog of eledoisin, H-Lys-Phe-Ile-Gly-Leu-Met-NH_2 (**1**), were replaced by the corresponding α-hydroxy acids. The biological activities of these analogs were then compared with that of the standard one (**1**). On the blood pressure in rabbits, H-Lys-Phe-Ile-Glyc-Leu-Met-NH_2 (**4**) and H-Lys-Phlac-Ile-Gly-HyIc-Met-NH_2 (**6**) possessed a substantial activity, though lower than **1**, and H-Lys-Phlac-Ile-Gly-Leu-Met-NH_2 (**2**) and H-Lys-Phe-Ile-Gly-HyIc-Met-NH_2 (**5**) were almost as active as **1**. On the other hand, H-Lys-Phe-HyMeV-Gly-Leu-Met-NH_2 (**3**) exhibited much less activity. The results indicate that the amide bond between the phenylalanine residue and the isoleucine residue is essential for the hypotensive activity.

Eledoisin, Pyroglu-Pro-Ser-Lys-Asp-Ala-Phe-Ile-Gly-Leu-Met-NH_2, was isolated by Erspamer from extracts of salivary glands of *Eledone moshata* and *Aldrovandi*.[4] Its pharmacological action includes the induction of acute arterial hypotension and the stimulation of smooth muscles.[5]

Since the primary structure of eledoisin was elucidated and confirmed by synthesis,[6] a large number of analogs in which amino acids are replaced by other amino acids or in which the peptide chains are shortened have been synthesized.[7] These synthetic studies have given us much information about the sequence and specific amino acid residues required for pharmacological activity. That is, the *C*-terminal hexapeptide analog, H-Lys-Phe-Ile-Gly-Leu-Met-NH_2 (**1**), obtained by the replacement of alanine with lysine possesses a high biological activity.[8] The exchange of the phenylalanine residue and the isoleucine residue almost always leads to the formation of compounds with lower activity. It is, however, relatively harmless to exchange the glycine residue. The exchange of the methionine residue produces inactive compounds almost exclusively.[7]

However, there is no knowledge about the relationship between the structure of the peptide backbone and the specific biological activity of eledoisin. In order to obtain some information about the role of the peptide chain of eledoisin, especially about the necessity of the presence of an amide group for the compound to manifest its biological properties, the present authors synthesized several hexadepsipeptides in which phenylalanine, isoleucine, glycine, and leucine in the compound **1** were replaced with the corresponding α-hydroxy acids and assayed for eledoisin-like activity. The compound **1** was chosen as the model peptide of eledoisin in this study because it had been reported that the *C*-terminal pentapeptide, H-Phe-Ile-Gly-Leu-Met-NH_2, was needed in order to have an appreciable activity of eledoisin[7] and the compound **1** was almost as active as natural eledoisin.

Shemyakin *et al.* attempted to exchange the amide groups by ester groups in the biologically-active peptides, such as glutathione, opthalmic acid, and bradykinin.[9] However, no systematic studies of depsipeptide analogs of eledoisin have ever been performed.

We synthesized such depsipeptides as H-Lys-Phlac-Ile-Gly-Leu-Met-NH_2 (**2**), H-Lys-Phe-HyMeV-Gly-Leu-Met-NH_2 (**3**), H-Lys-Phe-Ile-Glyc-Leu-Met-NH_2 (**4**), H-Lys-Phe-Ile-Gly-HyIc-Met-NH_2 (**5**), and H-Lys-Phlac-Ile-Gly-HyIc-Met-NH_2 (**6**).

Optically active α-hydroxy acids were prepared from the corresponding amino acids by the method reported by Winitz *et al.*[10] The acids were converted into benzyl esters by refluxing them with benzyl alcohol in benzene in the presence of a catalytic amount of sulfuric acid or *p*-toluenesulfonic acid. In the synthesis of the depsipeptides, an ester bond was formed with the aid of benzenesulfonyl chloride in pyridine according to the method of Shemyakin *et al.*[11] All the

hexadepsipeptide amides obtained as dihydrochloride were found to be homogeneous by the criteria of paper chromatography, paper electrophoresis, thin-layer chromatography, and elemental analysis. The presence of the ester bond was confirmed by IR, which showed an ester carbonyl band near 1750 cm^{-1}.

The syntheis of H–Lys–Phlac–Ile–Gly–Leu–Met–NH_2 (**2**) was carried out according to Scheme 1:

di-BOC–Lys–OH + H–Phlac–OBzl (**7**)
↓ $C_6H_5SO_2Cl$/Pyridine
di-BOC–Lys–Phlac–OBzl (**8**)
↓ H_2/Pd
di-BOC–Lys–Phlac–OH (**9**) + H–Ile–Gly–Leu–Met–NH_2
↓ EtOCOCl/Et_3N
di-BOC–Lys–Phlac–Ile–Gly–Leu–Met–NH_2 (**10**)
↓ HCl in AcOH
H–Lys–Phlac–Ile–Gly–Leu–Met–NH_2·2HCl (**2**)

Scheme 1.

The di-*t*-butyloxycarbonyl(BOC)-didepsipeptide ester (**8**), obtained in a crystalline form, was converted to the acid (**9**) by hydrogenolysis. The di-BOC-hexapeptide amide (**10**), obtained by the mixed anhydride (MA) method, was treated with 2.5N hydrogen chloride in acetic acid to get the hygroscopic amorphous dihydrochloride (**2**).

Subsequently, H–Lys–Phe–HyMeV–Gly–Leu–Met–NH_2 (**3**) was synthesized as is shown in Scheme 2:

BOC–Phe–OH + H–HyMeV–OBzl (**11**)
↓ $C_6H_5SO_2Cl$/Pyridine
BOC–Phe–HyMeV–OBzl
↓ H_2/Pd
BOC–Phe–HyMeV–OH (**12**) + H–Gly–Leu–Met–NH_2
↓ EtOCOCl/Et_3N
BOC–Phe–HyMeV–Gly–Leu–Met–NH_2 (**13**)
↓ i) HCl in Dioxane ii) di-BOC-Lys-ONP (**14**)
di-BOC–Lys–Phe–HyMeV–Gly–Leu–Met–NH_2 (**15**)
↓ HCl in AcOH
H–Lys–Phe–HyMeV–Gly–Leu–Met–NH_2·2HCl (**3**)

Scheme 2.

The oily BOC-didepsipeptide benzyl ester, obtained through column chromatography on silica gel, was hydrogenolyzed with palladium on charcoal to yield the corresponding acid (**12**). **12** was coupled with glycyl-leucyl-methionine amide by the MA method to yield the amorphous BOC-pentapeptide amide (**13**) in a good yield. The protected hexapeptide amide (**15**) was prepared from the di-BOC-lysine *p*-nitrophenyl ester (**14**) and the pentapeptide amide which had been obtained after the removal of the protecting group of **13**.

H–Lys–Phe–Ile–Glyc–Leu–Met–NH_2 (**4**) was synthesized as is shown in Scheme 3:

BOC–Ile–OH + $ClCH_2COOBzl$
↓ Et_3N in AcOEt
BOC–Ile–Glyc–OBzl
↓ H_2/Pd
BOC–Ile–Glyc–OH (**16**) + H–Leu–Met–NH_2
↓ EtOCOCl/Et_3N
BOC–Ile–Glyc–Leu–Met–NH_2 (**17**)
↓ i) HCl in Dioxane ii) BOC-Phe-ONP (**18**)
BOC–Phe–Ile–Glyc–Leu–Met–NH_2 (**19**)
↓ i) HCl in Dioxane ii) di-BOC-Lys-ONP (**14**)
di-BOC–Lys–Phe–Ile–Glyc–Leu–Met–NH_2 (**20**)
↓ HCl in AcOH
H–Lys–Phe–Ile–Glyc–Leu–Met–NH_2·2HCl (**4**)

Scheme 3.

The benzyl ester of BOC-isoleucyl-glycolic acid was prepared by the reaction of BOC-isoleucine with benzyl chloroacetate in the presence of an equimolar amount of triethylamine. The ester was hydrogenolyzed to produce BOC-didepsipeptide acid (**16**). BOC-tetradepsipeptide amide (**17**) was synthesized by the MA method. Di-BOC-hexapeptide amide (**20**) was obtained by the stepwise elongation method.

H–Lys–Phe–Ile–Gly–HyIc–Met–NH_2 (**5**) was synthesized as follows (Scheme 4):

BOC–Gly–OH + H–HyIc–OBzl (**21**)
↓
BOC–Gly–HyIc–OBzl
↓ H_2/Pd
BOC–Gly–HyIc–OH (**22**) + H–Met–NH_2
↓ EtOCOCl/Et_3N
BOC–Gly–HyIc–Met–NH_2 (**23**)
↓ HCl in Dioxane
AOC–Phe–Ile–N_2H_3 (**24**) + H–Gly–HyIc–Met–NH_2·HCl (**25**)
↓ HNO_2
AOC–Phe–Ile–Gly–HyIc–Met–NH_2 (**26**)
↓ i) HCl in Dioxane ii) di-BOC-Lys-ONP (**14**)
di-BOC–Lys–Phe–Ile–Gly–HyIc–Met–NH_2 (**27**)
↓ HCl in AcOH
H–Lys–Phe–Ile–Gly–HyIc–Met–NH_2·2HCl (**5**)

Scheme 4.

The BOC-dipeptide benzyl ester was hydrogenolyzed to yield an acid (**22**), which was then coupled with methionine amide to afford the crystalline BOC-tripeptide amide (**23**). The condensation of the azide derived from AOC-dipeptide hydrazide (**24**) with tripeptide amide (**25**) gave an acylpentapeptide amide (**26**).

H-Lys-Phlac-Ile-Gly-HyIc-Met-NH_2 (**6**) was synthesized according to Scheme 5:

BOC-Ile-OH + H-Gly-HyIc-Met-NH_2 (**25**)
↓ EtOCOCl/Et_3N
BOC-Ile-Gly-HyIc-Met-NH_2 (**28**)
↓ HCl in Dioxane
di-BOC-Lys-Phlac-OH (**9**) + H-Ile-Gly-HyIc-Met-NH_2
↓ EtOCOCl/Et_3N
di-BOC-Lys-Phlac-Ile-Gly-HyIc-Met-NH_2 (**29**)
↓ HCl in AcOH
H-Lys-Phlac-Ile-Gly-HyIc-Met-$NH_2 \cdot 2HCl$ (**6**)

Scheme 5.

The BOC-tetradepsipeptide amide (**28**) was obtained by acylating tripeptide amide (**25**) by a mixed anhydride of BOC-isoleucine. The di-BOC-hexapeptide amide (**29**) was obtained from **9** and the tetradepsipeptide amide by the MA method. The removal of the BOC group lead to the desired depsipeptide amide dihydrochloride (**6**).

TABLE 1. PHARMACOLOGICAL RESULTS ON THE BLOOD PRESSURE IN RABBITS.

Compound	Relative activity[a)]
H-Lys-Phe-Ile-Gly-Leu-Met-NH_2 (**1**)	100
H-Lys-Phlac-Ile-Gly-Leu-Met-NH_2 (**2**)	90
H-Lys-Phe-HyMeV-Gly-Leu-Met-NH_2 (**3**)	10
H-Lys-Phe-Ile-Glyc-Leu-Met-NH_2 (**4**)	30
H-Lys-Phe-Ile-Gly-HyIc-Met-NH_2(**5**)	120
H-Lys-Phlac-Ile-Gly-HyIc-Met-NH_2(**6**)	30

a) Compared on the basis of the dose which caused fall of 20 mmHg of the blood pressure

A biological comparison of the five depsipeptide analogs to the standard compound (**1**) is given in Table 1. In the study of rabbit blood pressure, **2** and **5** were almost identical with **1**, and **4** and **6** possessed substantial activity, though it was lower than that of the parent hexapeptide, while **3** showed much less activity. These results show that the amide bond between the phenylalanine residue and the isoleucine residue play an important role in manifesting the hypotensive activity. Thus, it was found that, in the case of the replacement of the amide bond in the compound **1** by the ester bond, with no change in the amino acid side chain, the potency of the biological activity was strictly dependent upon the position replaced. To clarify this point, more precise investigations are required; such studies will be reported in the near future.

Experimental

All the melting points are uncorrected.

H-Phlac-OBzl (7). A solution of β-phenyllactic acid[10] (60 g, 360 mmol), *p*-toluenesulfonic acid monohydrate (5.5 g), and benzyl alcohol (180 ml) in benzene (360 ml) was refluxed in a Dean and Stark apparatus[12] for 30 min. The solution was washed with water, 4% sodium bicarbonate, and again water, dried over magnesium sulfate, and fractionated. A fraction boiling at 165—170°C/1 mmHg was collected; yield, 30 g (32.5%); $[\alpha]_D^{25}$ −13.0° (*c* 1, MeOH); $[\alpha]_D^{25}$ −10.9° (*c* 1.5, EtOH).

Di-BOC-Lys-Phlac-OBzl (8). To a solution of di-BOC-Lys-OH (34.6 g, 100 mmol) in a mixture of pyridine (100 ml) and tetrahydrofuran (100 ml), was added with stirring benzenesulfonyl chloride (19.5 g, 110 mmol) at −10°C over a period of 10 min. After 10 min, a solution of compound **7** (25.6 g, 100 mmol) in pyridine (40 ml) was added to the solution. The mixture was then allowed to stand at 0°C for 1 hr and at room temperature for 8 hr, and subsequently poured into water (1000 ml). The oil separated was extracted with ether. The extract was washed repeatedly with 2% hydrochloric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The solvent was distilled off *in vacuo*, and crude product obtained as crystals was recrystallized from ether-*n*-hexane; yield, 57 g (85%); mp 60—62°C; $[\alpha]_D^{25}$ −28.1° (*c* 1, MeOH). Found: C, 65.73; H, 7.59; N, 4.48%. Calcd for $C_{32}H_{44}O_8N_2$: C, 65.73; H, 7.59; N, 4.79%.

Di-BOC-Lys-Phlac-OH (9). Compound **8** (5.84 g, 10 mmol) was dissolved in methanol (50 ml) and hydrogenolyzed in the presence of 10% palladium on charcoal. The filtrate from the catalyst was evaporated to dryness; yield of oil, 4.9% (100%).

Di-BOC-Lys-Phlac-Ile-Gly-Leu-Met-NH_2 (10). To a solution of **9** (4.5 g, 8 mmol) and triethylamine (1.2 ml) in chloroform (40 ml), was added ethyl chloroformate (880 mg, 8 mmol) at −15——10°C. After 15 min, there was added a solution of H-Ile-Gly-Leu-Met-$NH_2 \cdot HCl$[13] (4.3 g, 8 mmol) and triethylamine (1.2 ml) in dimethylformamide (100 ml) at −15——10°C, and this mixture was allowed to stand at room temperature overnight. The mixture was poured into cold water (1000 ml), and the resulting solid was extracted with ethyl acetate. The extract was washed successively with 1% hydrochloric acid, 4% sodium bicarbonate, and water. The solvent was then evaporated *in vacuo*, and the crude product was recrystallized from ethyl acetate-methanol-petroleum ether; yield, 4.6 g (62%); mp 190—192°C; $[\alpha]_D^{20}$ −35.6° (*c* 0.5, MeOH). Found: C, 57.43; H, 7.89; N, 10.53; S, 3.75%. Calcd for $C_{44}H_{73}O_{11}N_7S \cdot H_2O$: C, 57.08; H, 8.10; N, 10.59; S, 3.45%.

H-Lys-Phlac-Ile-Gly-Leu-Met-$NH_2 \cdot 2HCl$ (2). Compound **10** (200 mg) was dissolved in 2N hydrogen chloride in acetic acid (5 ml), and the solution was allowed to stand at room temperature for 20 min. The product was precipitated by adding dry ether, and the precipitate was collected by filtration, washed well with ether, and dried over sodium hydroxide *in vacuo*. It was dissolved in 60% methanol (4 ml), and an insoluble material was filtered off. The filtrate was con-

centrated to dryness over phosphorus pentoxide *in vacuo* to obtain the product; yield, 170 mg; mp 160—165°C $[\alpha]_D^{25}$ −48.1° (*c* 0.305, H_2O); R_f, 0.70.[14] Found: C, 50.83; H, 7.92; N, 12.36; S, 4.44; Cl, 8.84%. Calcd for $C_{34}H_{57}O_7N_7S \cdot 2HCl \cdot H_2O$: C, 51.12; H, 7.64; N, 12.28; S, 4.01; Cl, 8.89%. The amino acid ratios in the acid hydrolyzate were Lys 1.00, Ile 1.03, Gly 1.05, Leu 1.00, and Met 0.91.

H-HyMeV-OBzl (11). This was obtained from α-hydroxy-β-methylvaleric acid[10] (52.8 g, 400 mmol), benzyl alcohol (200 ml), and sulfuric acid (2 ml) as described for the preparation of **7**; yield of oil, 62 g (70%); bp 122—125°C /1 mmHg; $[\alpha]_D^{25}$ −12.7° (*c* 1.9, EtOH).

BOC-Phe-HyMeV-OH (12). BOC-Phe-OH (26.5 g, 100 mmol) was condensed with **11** (24.5 g, 110 mmol) by the benzenesulfonyl chloride method to yield an oil (33.8 g, 72%); this oil was then hydrogenolyzed in the presence of 10% palladium on charcoal; yield of oil, 24.6 g (64%).

BOC-Phe-HyMeV-Gly-Leu-Met-NH_2 (13). This compound was obtained from **12** (6.4 g, 16.8 mmol) and H-Gly-Leu-Met-$NH_2 \cdot HCl$[13] (6.9 g, 19 mmol) as described for the preparation of **10**; yield, 7.5 g (66%); mp 165—168°C; $[\alpha]_D^{25}$ −39.5° (*c* 1, MeOH). Found: C, 58.34; H, 7.89; N, 10.41; S, 4.81%. Calcd for $C_{33}H_{53}O_8N_5S$: C, 58.29; H, 7.85; N, 10.30; S, 4.71%.

Di-BOC-Lys-Phe-HyMeV-Gly-Leu-Met-NH_2 (15). Compound **13** (5.4 g, 8 mmol) was dissolved in 3N hydrogen chloride in dioxane (70 ml) at room temperature. After 20 min, the solution was evaporated to dryness in *vacuo*. The pentadepsipeptide amide hydrochloride thus obtained was dissolved in dimethylformamide (40 ml) and then neutralized with triethylamine (1.2 ml). Di-BOC-Lys-ONP (**14**)[15] (4.2 g, 9 mmol) was added to the solution, and the mixture was allowed to stand at room temperature for 20 hr. Water was added to the reaction mixture to precipitate the product, which was then collected by filtration, washed well with 2% hydrochloric acid, N ammonia, and water, and dried. Recrystallization from ethyl acetate-petroleum ether gave 4.4 g (60%) of a product; mp 192—195°C; $[\alpha]_D^{25}$ −37.8° (*c* 0.5, MeOH). Found: C, 58.13; H, 8.03; N, 10.57; S, 3.62%. Calcd for $C_{44}H_{73}N_7O_{11}S$: C, 58.19; H, 8.10; N, 10.79; S, 3.53%.

H-Lys-Phe-HyMeV-Gly-Leu-Met-$NH_2 \cdot 2HCl$ (3). This compound was obtained from **15** (200 mg) as described for the preparation of **2**; yield, 170 mg; mp 60—80°C; $[\alpha]_D^{25}$ −35.2° (*c* 0.25, H_2O); R_f, 0.72.[14] Found: C, 51.05;H, 7.83; N, 12.05; S, 4.25; Cl, 9.05%. Calcd for $C_{34}H_{57}O_7N_7S \cdot 2HCl \cdot H_2O$: C, 51.12; H, 7.64; N, 12.28; S, 4.01; Cl, 8.89%. The amino acid ratios in the acid hydrolyzate were Lys 0.98, Phe 0.96, Gly 1.00, Leu 1.00, and Met 0.76.

BOC-Ile-Glyc-OH (16). A solution of BOC-Ile-OH (15 g, 60 mmol), triethylamine (8 ml), and benzyl chloroacetate[16] (10.5 g, 60 mmol) in ethyl acetate (150 ml) was refluxed for 5 hr. The solution was washed with 2% hydrochloric acid, 4% sodium bicarbonate and water, dried over magnesium sulfate, and concentrated to dryness. The resulting oil (16 g) was dissolved in methanol (80 ml) and hydrogenolyzed in the presence of 5% palladium on charcoal. The solvent was distilled off *in vacuo*, and the crude acid was dissolved in 4% sodium bicarbonate, washed with ether, and acidified with 1% hydrochloric acid. The oil thus separated was extracted into ether. The ether was removed under reduced pressure; yield of oil, 7.7 g (60%).

BOC-Ile-Glyc-Leu-Met-NH_2 (17). This was obtained from **16** (7 g, 24.2 mmol) and H-Leu-Met-$NH_2 \cdot HCl$[13] (8.3 g, 25 mmol) as described for the preparation of **10**. The crude product was recrystallized from ethyl acetate-petroleum ether; yield, 8.7 g (68%); mp 171—177°C; $[\alpha]_D^{25}$ −39.0° (*c* 1, MeOH). Found: C, 54.01; H, 8.13; N, 10.82; S, 6.47%. Calcd for $C_{24}H_{44}N_4O_7S$: C, 54.13; H, 8.27; N, 10.52; S, 6.01%.

BOC-Phe-Glyc-Leu-Met-NH_2 (19). Compound **17** (4 g, 8 mmol) was dissolved in 3N hydrogen chloride in dioxane (60 ml) at room temperature. After 20 min, the solution was evaporated to dryness under reduced pressure. The tetradepsipeptide amide hydrochloride thus obtained was dissolved in dimethylformamide (30 ml), neutralized with triethylamine (1.1 ml), and then subjected to a reaction with BOC-Phe-ONP (**18**)[15] (3.1 g, 8 mmol). After standing overnight at roomt emperature, the solution was diluted with ethyl acetate (350 ml), washed with 2% hydrochloric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The solvent was distilled off under reduced pressure, and the solid material was recrystallized from ethyl acetate-petroleum ether; yield, 4 g, (75%); mp 156—158°C; $[\alpha]_D^{25}$ −25.3° (*c* 1, MeOH). Found: C, 56.73; H, 7.97; N, 10.06; S, 4.84%. Calcd for $C_{33}H_{53}O_8N_5S \cdot H_2O$: C, 56.81; H, 7.89; N, 10.04; S, 4.59%.

Di-BOC-Lys-Phe-Ile-Glyc-Leu-Met-NH_2 (20). Compound **19** (1.3 g, 2 mmol) was treated with 3N hydrogen chloride in dioxane. The pentadepsipeptide amide hydrochloride thus obtained was dissolved in dimethylformamide (10 ml), neutralized with triethylamine (0.28 ml), and then subjected to a reaction with compound **14** (1 g, 2.1 mmol). The mixture was then treated as described for the preparation of **15**; yield, 1.5 g (80%); mp 146—149°C; $[\alpha]_D^{25}$ −36.0° (*c* 1, MeOH). Found: C, 57.39; H, 8.25; N, 10.29; S, 3.36%. Calcd for $C_{44}H_{93}O_{11}N_7S \cdot H_2O$: C, 57.08; H, 8.10; N, 10.59; S, 3.45%.

H-Lys-Phe-Ile-Glyc-Leu-Met-$NH_2 \cdot 2HCl$ (4). This compound was obtained from **20** (200 mg) as described for the preparation of **2**; yield, 170 mg, mp 65—80°C; $[\alpha]_D^{25}$ −26.7° (*c* 0.5, H_2O); R_f, 0.68.[14] Found: C, 51.05; H, 7.82; N, 12.13; S, 3.53; Cl, 9.13%. Calcd for $C_{34}H_{57}O_7N_7S \cdot 2HCl \cdot H_2O$: C, 51.12; H, 7.64; N, 12.28; S, 4.01; Cl, 8.89%. The amino acid ratios in the acid hydrolyzate were Lys 1.08, Phe 0.98, Ile 1.12, Leu 1.00, and Met 0.85.

H-HyIc-OBzl (21). This compound was obtained from α-hydroxyisocaproic acid[10] (25.4 g, 200 mmol), benzyl alcohol and sulfuric caid as described for the preparation of **7**; yield of oil, 26 g (60%); bp 113—115°C/1 mmHg; $[\alpha]_D^{25}$ −16.0° (*c* 2.1, EtOH).

BOC-Gly-HyIc-OH (22). Benzenesulfonyl chloride (17.7 g, 100 mmol) was added to a solution of BOC-Gly-OH (17.5 g, 100 mmol) in a mixture of tetrahydrofuran (200 ml) and pyridine (100 ml) at −10°C. Then compound **21** (22.2 g, 100 mmol) was added. The product was isolated and purified by column chromatography. The resulting oil (38 g) was hydrogenolyzed in the presence of 5% palladium on charcoal; yield of oil, 17 g (60%).

BOC-Gly-HyIc-Met-NH_2 (23). To a solution of **22** (18.86 g, 65 mmol) and triethylamine (9.2 ml) in chloroform (200 ml), was added ethyl chloroformate (7.6 g, 70 mmol) at −12——10°C. After 15 min, a solution of H-Met-$NH_2 \cdot HCl$[17] (12.8 g, 70 mmol) and triethylamine (9.8 ml) in dimethylformamide (50 ml) was added to the solution. The mixture was stirred at room temperature for 2 hr and then poured into water (500 ml), and the oil thus separated was

14) Paper chromatography was carried out on Toyo Roshi No.50 with *n*-butanol–acetic acid–water (4: 1: 1).

extracted with chloroform. The extract was washed with 1% hydrochloric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The solvent was distilled off under reduced pressure, and the product was recrystallized from ethyl acetate–petroleum ether; yield, 17 g (73%); mp 148—150°C; $[\alpha]_D^{25}$ −34.5° (*c* 1.25, MeOH). Found: C, 51.71; H, 8.04; N, 9.53; S, 7.66%. Calcd for $C_{18}H_{33}O_6N_3S$: C, 51.54; H, 7.93; N, 10.02; S, 7.63%.

AOC-Phe-Ile-NHNH$_2$ (24). A solution of AOC-Phe-Ile-OEt (8.4 g, 20 mmol) and hydrazine hydrate (10 g, 200 mmol) in methanol (20 ml) was refluxed for 48 hr. After ocoling, the crystal thus precipitated out was filtered, washed well with water, and recrystallized from methanol–water; yield, 6.4 g (78%); 171—172°C; $[\alpha]_D^{20}$ −45.9° (*c* 1, AcOH). Found: C, 62.16; H, 8.43; N, 13.53%. Calcd for $C_{21}H_{34}O_4N_4$: C, 62.04; H, 8.43; N, 13.78%.

AOC-Phe-Ile-Gly-HyIc-Met-NH$_2$ (26). Compound **23** (3 g, 7.1 mmol) was dissolved in 3N hydrogen chloride in dioxane (50 ml) at room temperature. After 30 min, the solvent was distilled off under reduced pressure, and the residue was triturated with ether. The product was dried *in vacuo* over sodium hydroxide; yield, 2.5 g (99%). This material (**25**) was used in the following reaction without further purification. To a solution of **24** (2.85 g, 7 mmol) in a mixture of 3N hydrochloric acid (11.2 ml) and dimethylformamide (280 ml), was added with stirring a chilled solution of sodium nitrite (483 mg, 7 mmol) in water (3 ml) at −18—−15°C. After 20 min, the solution was neutralized with triethylamine and there was added a solution of **25** (2.5 g, 7 mmol) obtained above and triethylamine (0.98 ml) in dimethylformamide (35 ml) at −15—−10°C. After the mixture had been stirred at room temperature for 3 hr, it was treated as described for the preparation of **10**; yield, 3.5 g (73%); mp 191—192°C; $[\alpha]_D^{25}$ −47.0° (*c* 1, MeOH). Found: C, 58.63; H, 8.14; N, 10.13; S, 4.40%. Calcd for $C_{34}H_{55}O_8N_5S$: C, 58.87; H, 7.93; N, 10.10; S, 4.61%.

Di-BOC-Lys-Phe-Ile-Gly-HyIc-Met-NH$_2$ (27). Compound **26** (1 g, 1.4 mmol) was treated with 3N hydrogen chloride in dioxane for 30 min at room temperature. The solvent was distilled off under reduced pressure. The product, which corresponded to H-Phe-Ile-Gly-HyIc-Met-NH_2·HCl, was added to a solution of **14** (700 mg, 1.5 mmol) in dimethylformamide (7 ml), together with triethylamine (0.2 ml); the mixture was then treated as described for the preparation of **15**; yield, 1 g, (77%); mp 199—201°C; $[\alpha]_D^{25}$ −44.4° (*c* 0.5, MeOH). Found: C, 57.48; H, 8.45; N, 10.36; S, 3.35%. Calcd for $C_{44}H_{73}O_{11}N_7S\cdot H_2O$: C, 57.08; H, 8.10; N, 10.59; S, 3.45%.

H-Lys-Phe-Ile-Gly-HyIc-Met-NH$_2$·2HCl (5). This compound was obtained from **27** (200 mg) as described for the preparation of **2**; yield, 180 mg; mp 230—233°C; $[\alpha]_D^{25}$ −28.8° (*c* 0.25, H_2O); R_f, 0.68.[14] Found: C, 50.84; H, 7.93; N, 12.59; S, 3.67; Cl, 9.25%. Calcd for $C_{34}H_{57}O_7N_7S\cdot 2HCl\cdot H_2O$; C, 51.12: H, 7.64; N, 12.28; S, 4.01; Cl, 8.89%. The amino acid ratios in the acid hydrolyzate were Lys 0.97, Phe 1.01, Ile 1.00, Gly 1.04, and Met 0.85.

BOC-Ile-Gly-HyIc-Met-NH$_2$ (28). To a solution of BOC-Ile-OH (1 g, 4 mmol) and triethylamine (0.56 ml, 4 mmol) in chloroform (50 ml), was added ethyl chloroformate (0.44 g, 4 mmol) at −12—−10°C. After 15 min, there was added a solution of H-Gly-HyIc-Met-NH_2·HCl (**25**) obtained from **23** (1.5 g, 3.6 mmol) and triethylamine (0.5 ml) in dimethylformamide (20 ml); the mixture was then stirred at room temperature for 3 hr. Then it was poured into water (100 ml), and the solid thus precipitated was extracted with ethyl acetate. The extract was washed with 1% hydrochloric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The solvent was distilled off *in vacuo*, and the crude product was recrystallized from ethyl acetate–petroleum ether; yield, 1.25 g (59%); mp 140—142°C; $[\alpha]_D^{25}$ −46.0° (*c* 1, MeOH). Found: C, 53.68; H, 8.28; N, 10.78; S, 6.06%. Calcd for $C_{24}H_{44}O_7N_4S$: C, 54.12; H, 8.33; N, 10.52; S, 6.00%.

Di-BOC-Lys-Phlac-Ile-Gly-HyIc-Met-NH$_2$ (29). Compound **28** (1.7 g, 3.2 mmol) was dissolved in 3N hydrogen chloride in dioxane at room temperature. After 40 min, the solvent was distilled off *in vacuo*, and the residue, which corresponded to H-Ile-Gly-HyIc-Met-NH_2·HCl, was used in the following reaction without further purification. To a solution of compound **9** (2 g, 4 mmol) and triethylamine (0.56 ml) in chloroform (50 ml), was added ethyl chloroformate (440 mg, 4 mmol) at −10—−8°C. Then, a solution of the tetradepsipeptide amide hydrochloride obtained above in dimethylformamide (16 ml) was added and the mixture was treated as described for the preparation of **10**; yield, 1.9 g (52%); mp 148—150°C; $[\alpha]_D^{25}$ −50.0° (*c* 0.5, MeOH). Found: C, 57.26; H, 7.97; N, 9.25; S, 3.76%. Calcd for $C_{44}H_{72}O_{12}N_6S\cdot H_2O$: C, 57.01; H, 7.99; N, 9.07; S, 3.45%.

H-Lys-Phlac-Ile-Gly-HyIc-Met-NH$_2$·2HCl (6). This compound was obtained from **29** (200 mg) as described for the preparation of **2**; yield, 180 mg; mp 155—160°C; $[\alpha]_D^{25}$ −52.3° (*c* 0.285, H_2O): R_f, 0.75.[14] Found: C, 51.17; H, 7.70; N, 10.79; S, 4.23; Cl, 8.76%. Calcd for $C_{34}H_{56}O_8N_6S\cdot 2HCl\cdot H_2O$: C, 51.05; H, 7.56; N, 10.50; S, 4.00; Cl, 8.86%. The amino acid ratios in the acid hydrolyzate were Lys 0.93, Ile 1.00, Gly 1.05, and Met 0.83.

Pharmacological Assay. White male rabbits (2—3 kg) were anesthetized subcutaneously with 1.2 g/kg of urethane. Anesthesia was maintained with additional doses as needed. The arterial blood pressure was measured from a canulated carotid artery and recorded on a Kymograph by means of a mercury manometer. All the peptides were dissolved in physiological saline and injected into the femoral vein. Each dose was tested on five animals and always checked against the reference standard material, **1**. The activity of the peptides was compared on a weight basis. The data were obtained with five animals per group.

The authors wish to thank Professor N. Izumiya of Kyushu University and Director Dr. I. Chibata of Tanabe Seiyaku for their encouragement in the course of this study.

Synthesis and Biological Activity of Peptides Related to Eledoisin. II.[1] Hexapeptide Amides Containing *N*-Methylamino Acids[2,3]

Hiroshi SUGANO,[4] Ko HIGAKI, and Muneji MIYOSHI

Department of Synthetic Chemistry, Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd. 962 Kashima-cho, Higashiyodogawa-ku, Osaka

(Received May 20, 1972)

Eledoisin-like hexapeptides were synthesized in order to obtain longer-lasting hypotensive analogs. A part of the amino acid of the standard peptide, H–Lys–Phe–Ile–Gly–Leu–Met–NH_2 (**1**), was replaced by *N*-methylamino acid. It was found, in these syntheses, that when the *C*-terminal amino acid of a carboxy component was an *N*-methylamino acid, a system of dicyclohexylcarbodiimide plus 1-hydroxybenzotriazole was a useful coupling agent. With regard to the hypotensive effect in rabbits, H–Lys–Phe–MeIle–Gly–Leu–Met–NH_2 (**2**) and H–Lys–Phe–Ile–Gly–MeIle–Met–NH_2 (**6**) show much less activity; H–Lys–MePhe–Ile–Gly–Leu–Met–NH_2 (**3**) and H–Lys–MePhe–Ile–Gly–MeLeu–Met–NH_2 (**7**) show a substantial activity, though weaker than the standard one. On the other hand, H–Lys–Phe–Ile–Gly–MeLeu–Met–NH_2 (**5**) and H–Lys–Phe–Ile–Sar–Leu–Met–NH_2 (**4**) show a higher activity than **1**. These results indicate that, in some cases, the replacement of an amide bond by an *N*-methylamide bond without any change in the side chain of amino acid would have an important influence on the activity. The duration of the action of *N*-methypeptildes synthesized was unexpectedly of the same order of magnitude as that of **1**.

In the preceding paper,[1] we described the synthesis and the biological activity of several hexadepsipeptide analogs of eledoisin, in which the amide bond was replaced with the ester bond in order to avoid cleavage by the proteolytic enzyme of the organism and, consequently, in order to obtain a longer-lasting compound. However, the duration of the depsipeptides synthesized was unexpectedly of the same order of magnitude as that of the standard peptide, H–Lys–Phe–Ile–Gly–Leu–Met–NH_2 (**1**). This shows that the ester bond would be hydrolyzed by the enzyme as readily as the original peptide bond and that, in order to produce a longer-lasting action, the peptide bond must be replaced by some other bond which can not be attacked by the enzyme.

Andreatta and Scheraga recently reported that a peptide involving *N*-methylamino acid was not attacked by the protease.[5] Thus, the His–MeAla bond in [Val[5], MeAla[7]]-angiotensin II is totally resistant to the aminopeptidase. Baldwin also showed that a peptide bond involving methylated arginine could not be hydrolyzed by trypsin.[6]

In the present investigation, from this point of view, the authors synthesized several hexapeptides, H–Lys–Phe–MeIle–Gly–Leu–Met–NH_2 (**2**), H–Lys–MePhe–Ile–Gly–Leu–Met–NH_2 (**3**), H–Lys–Phe–Ile–Sar–Leu–Met–NH_2 (**4**), H–Lys–Phe–Ile–Gly–MeLeu–Met–NH_2 (**5**), H–Lys–Phe–Ile–Gly–MeIle–Met–NH_2 (**6**), and H–Lys–MePhe–Ile–Gly–MeLeu–Met–NH_2 (**7**). In these peptides, a part of the amino acid of the standard peptide **1** was replaced with *N*-methylamino acid, and their biological activity was compared with that of **1**.

In compounds **2**, **3**, **4**, **5**, and **7**, none of the amino-acid side chains are altered, whereas the amino-acid side chain of compound **6** is different from the reference standard in the part of leucine.

Synthesis

Optically active *N*-methylamino acids were prepared by the method reported previously by Quitt *et al.*[7]

H–Lys–Phe–MeIle–Gly–Leu–Met–NH_2 (**2**) was synthesized according to Scheme 1. *t*-Amyloxycarbonyl (AOC)-phenylalanine was condensed with the *N*-methylisoleucine methyl ester (**8**) with dicyclohexylcarbodiimide (DCC) to yield the AOC-phenylalanyl-*N*-methylisoleucine methyl ester. The ester did not crystallize and was converted into AOC-dipeptide acid (**9**) by

AOC–Phe–OH + H–MeIle–OMe (**8**)
↓ DCC
AOC–Phe–MeIle–OMe
↓ NaOH
AOC–Phe–MeIle–OH (**9**) + H–Gly–Leu–Met–NH_2
7% ↓ EtOCOCl/Et_3N
AOC–Phe–MeIle–Gly–Leu–Met–NH_2 (**10**)
↓ i) HCl in Dioxane ii) di-BOC-Lys-ONP
di-BOC–Lys–Phe–MeIle–Gly–Leu–Met–NH_2 (**11**)
↓ HCl in AcOH
H–Lys–Phe–MeIle–Gly–Leu–Met–NH_2·2HCl (**2**)

Scheme 1.

saponification, which did not proceed smoothly because of the bulkiness of the side chain and, in addition, that of the *N*-methyl group of *N*-methylisoleucine. The acid (**9**) was coupled with glycyl-leucyl-methionine amide to produce AOC-pentapeptide amide in a rather poor yield. This low yield may also be due to the bulky *C*-terminal amino acid in the carboxy component.

Di-*t*-butyloxycarbonyl (BOC)-hexapeptide amide (**11**) was prepared from the di-BOC-lysine *p*-nitrophenyl ester and the pentapeptide amide which had been obtained from AOC-pentapeptide amide (**10**) using 2N hydrogen chloride in dioxane. The BOC group was removed from compound **11** using 2N hydrogen chloride in acetic acid.

The route of synthesizing H–Lys–MePhe–Ile–Gly–Leu–Met–NH_2 (**3**) is shown in Scheme 2:

A)

di-BOC–Lys–OH + H–MePhe–OBzl (**12**)

↓ DCC

di-BOC–Lys–MePhe–OBzl

↓ H_2/Pd

di-BOC–Lys–MePhe–OH (**13**) + H–Ile–Gly–Leu–Met–NH_2

20% ↓ $EtOCOCl/Et_3N$

di-BOC–Lys–MePhe–Ile–Gly–Leu–Met–NH_2 (**15**)

B)

di-BOC–Lys–MePhe–OH (**13**) + H–Ile–Gly–Leu–Met–OMe

75% ↓ DCC/HOBt

di-BOC–Lys–MePhe–Ile–Gly–Leu–Met–OMe (**14**)

↓ NH_3 in MeOH

di-BOC–Lys–MePhe–Ile–Gly–Leu–Met–NH_2 (**15**)

↓ HCl in AcOH

H–Lys–MePhe–Ile–Gly–Leu–Met–$NH_2 \cdot 2HCl$ (**3**)

Scheme 2.

Compound **13**, obtained from the di-BOC-lysyl-*N*-methylphenylalanine benzyl ester by hydrogenolysis, was coupled with *C*-terminal tetrapeptide amide by the mixed anhydride method to afford the protected hexapeptide amide (**15**) in a low yield, accompanied by a considerable amount of ethoxycarbonyl-isoleucyl-glycyl-leucyl-methionine amide.

On the other hand, using DCC together with the 1-hydroxybenzotriazole (HOBt) developed by König and Geiger,[8] the di-BOC-hexapeptide ester (**14**) was obtained in a good yield from compound **13** and the tetrapeptide ester. No acylurea was detected on thin-layer chromatography.[9] Thus, the DCC–HOBt is recommendable for a coupling agent if the *C*-terminal amino acid of a carboxy component is a bulky *N*-methyl-amino acid.

Hexapeptide, H–Lys–Phe–Ile–Sar–Leu–Met–NH_2 (**4**), was synthesized in the following way (Scheme 3):

BOC–Ile–OH + H–Sar–OBzl (**16**)

↓ DCC

BOC–Ile–Sar–OBzl

↓ H_2/Pd

BOC–Ile–Sar–OH (**17**) + H–Leu–Met–OMe

↓ HCl in AcOH

H–Lys–Phe–Ile–Sar–Leu–Met–$NH_2 \cdot 2HCl$ (**4**)

Scheme 3.

BOC-isoleucyl-sarcosine, which was prepared by allowing BOC-isoleucine to react with the sarcosine benzyl ester by the DCC method, followed by hydrogenolysis over palladium on charcoal, was coupled with the leucyl-methionine ester by DCC–HOBt. Amidation followed by two successive stepwise elongations using the *p*-nitrophenyl ester and subsequent deprotection afforded the desired compound (**4**).

H–Lys–Phe–Ile–Gly–MeLeu–Met–NH_2 (**5**) and H–Lys–Phe–Ile–Gly–MeIle–Met–NH_2 (**6**) were synthesized according to Scheme 4:

BOC–Gly–OH + H–X–OMe (**22**) or (**8**)

Scheme 4. X=MeLeu or MeIle

BOC-dipeptide acids (**23a** and **23b**) were obtained as crystals and were coupled with the methionine ester by the use of HObt and DCC. The BOC-tripeptide esters (**24a** and **24b**) thus obtained were amidated and deprotected to give tripeptide amide hydrochlorides. They were converted into AOC-pentapeptide amides (**26a** and **26b**) by the azide method. Deprotection and subsequent reaction with the di-BOC-lysine *p*-nitrophenyl ester afforded di-BOC-hexapeptide amides (**27a** and **27b**), which were then subjected to acidolysis to yield the desired compounds (**5** and **6**).

Further, H–Lys–MePhe–Ile–Gly–MeLeu–Met–NH_2 (**7**) was synthesized as follows:

BOC–Gly–MeLeu–Met–OMe (**23a**)

↓ i) HCl in MeOH ii) BOC-Ile-OH $EtOCOCl/Et_3N$

BOC–Ile–Gly–MeLeu–Met–OMe (**28**)

↓ i) HCl in MeOH ii) di-BOC-Lys-MePhe-OH (**13**) DCC/HObt

di-BOC–Lys–MePhe–Ile–Gly–MeLeu–Met–OMe (**29**)

↓ NH_3 in MeOH

di-BOC–Lys–MePhe–Ile–Gly–MeLeu–Met–NH_2 (**30**)

↓ HCl in AcOH

H–Lys–MePhe–Ile–Gly–MeLeu–Met–NH_2·2HCl (**7**)

Scheme 5.

Compound **23a** was used as the starting material (Scheme 5). Thus, **23a** was deprotected and was condensed with a mixed anhydride of BOC-isoleucine to afford the BOC-tetrapeptide ester (**28**). After the removal of the BOC group, compound **28** was coupled with di-BOC-dipeptide acid (**13**) with the aid of HObt and DCC. Amidation and deprotection gave the desired hexapeptide amide dihydrochloride (**7**).

None of the protected hexapeptide amides reported here, except di-BOC–Lys–Phe–Ile–Gly–MeIle–Met–NH_2 (**27b**), crystallized; they were purified by column chromatography on silica-gel. Compound **27b** was recrystallized from ethyl acetate. The hexapeptide amide dihydrochlorides were all amorphous and were shown to be homogeneous by paper chromatography, paper electrophoresis, and elemental analysis.

Results

The pharmacological results concerning rabbit blood pressure are summarized in Table 1.

The time of 50% recovery as well as that of 100% recovery shows that the duration of action of the *N*-methylpeptides synthesized here is of the same order of magnitude as that of the reference standard, **1**. These results suggest that the *N*-methylpeptide bond would be cleaved by the proteolytic enzyme of the organism as fast as the usual peptide bonds, or that other factors, as yet unknown, would participate in the deactivation of the peptides. As regards this point, a more precise study will be reported in a following paper.

Table 1 also shows that compound **2** and compound **6** have much less activity and that compounds **3** and **7** possess a substantial activity, though weaker than the standard one, **1**. On the other hand, compound **5** and compound **4** show a higher activity than **1**. It is reasonable that **6** exhibits a marked decrease in activity, because it has a different amino-acid side chain in the part of leucine which has been reported to be essential for activity.[10] Though the other compounds, **2**, **3**, **4**, **5**, and **7**, have the same side chains as **1**, they vary in the degree of biological activity. As may be seen in the case of depsipeptide analogs,[1] these results suggest that, in some cases, the replacement of an amide bond by an *N*-methylamide bond would have an important influence on the activity. To clarify this point, a more precise investigation is required; studies are currently in progress.

Experimental

All the melting points are uncorrected. Column chromatography was carried out on silica gel (Merck, 70—325 mech). The amino acid analysis was performed by the method reported by Kono *et al.*,[11] in which the acid hydrolysate was converted into the *t*-butyl ester of trifluoroacetylamino acid and the composition was determined by gas chromatography. The pharmacological assay was carried out as had been described previously.[1]

H–MeIle–OMe·HCl (8). Thionyl chloride (83 g, 0.7 mol) was stirred into methanol (120 ml) at −2—2°C. To this solution, *N*-methyl-L-isoleucine (18 g, 0.124 mol) prepared by the procedure developed by Quitt *et al.*[7] ($[\alpha]_D^{25}$ +29.0° (*c* 1, H_2O) was added; the solution was stirred at room temperature for 1 hr, and then refluxed for 3 hr. After evaporation, this procedure was repeated two times. The oily residue thus obtained was dissolved in water (50 ml), and the solution was basified with sodium bicarbonate and repeatedly extracted with ether. The ethereal solution was washed with a saturated sodium chloride solution and dried over magnesium sulfate. Into the filtered solution, dry hydrogen chloride was bubbled, and the white crystals thus obtained were collected and recrystallized from methanol–ether; yield, 15.7 g (65%); mp 156—157°C; $[\alpha]_D^{25}$ +40.1° (*c* 1, ethanol) [lit,[12] mp 154—155°C; $[\alpha]_D^{25}$ +39° (*c* 1, ethanol)]. (Found: C, 49.47; H, 9.30; N, 7.16; Cl, 17.95%).

AOC–Phe–MeIle–OH (9). Into a solution of *t*-amyloxycarbonyl-L-phenylalanine dicyclohexylammonium salt[13]

(50 g, 0.11 mol) and **8** (20 g, 0.1 mol) in chloroform (300 ml), DCC[14] (22.7 g, 0.11 mol) was stirred at −5°C. After this mixture had been stirred overnight at room temperature, the dicyclohexylurea and dicyclohexylammonium chloride were filtered off. The filtrate was washed successively with 4% sodium bicarbonate, N hydrochloric acid, and water, and then dried over magnesium sulfate. The filtrate was evaporated *in vacuo* to yield an oil (31 g), which contained the acylurea[9] in some degree. This oil (30 g) was dissolved in a mixture of methanol (100 ml) and 4N sodium hydroxide (30 ml), and the solution was stirred for 20 hr at 0—5°C. After the dicyclohexylurea originating from the acylurea had been filtered off, the methanol was distilled off under reduced pressure below 40°C. The aqueous solution was washed with ether, acidified with N hydrochloric acid, and repeatedly extracted with ether. The combined ether extracts were washed with water and dried over magnesium sulfate. Evaporation gave crude crystals, which were recrystallized from ethyl acetate–petroleum ether; yield, 24 g (60%); mp 115—116°; $[\alpha]_D^{25}$ −61.9° (*c* 1, methanol). Found: C, 65.49; H, 8.47; N, 7.10%. Calcd for $C_{22}H_{34}O_5N_2$: C, 65.00; H, 8.43; N, 6.89%.

*AOC-Phe-MeIle-Gly-Leu-Met-NH_2 (**10**).* To a solution of **9** (8 g, 20 mmol) and triethylamine (3.1 ml) in chloroform (100 ml), ethyl chloroformate (2.4 g, 22 mmol) was added over a 15 min period at −12——10°C. After 15 min, a solution of glycyl-leucyl-methionine amide hydrochloride[15] (8 g, 22 mmol) and triethylamine (3.1 ml) in dimethylformamide (100 ml) was added, after which the solution was stirred overnight at room temperature. Then, it was poured into water (600 ml) and extracted with ethyl acetate. The ethyl acetate solution was washed successively with N hydrochloric acid, 4% sodium bicarbonate, and water, and then dried over magnesium sulfate. The filtrate was evaporated *in vacuo*, and the crude product was recrystallized from ethyl acetate–petroleum ether; yield, 1 g (7.05%); mp 204—206°C; $[\alpha]_D^{25}$ +22.1° (*c* 1, methanol). Found: C, 58.16; H, 8.41; N, 11.45; S, 4.65%. Calcd for $C_{35}H_{58}N_6O_7S\cdot H_2O$: C, 58.01; H, 8.28; N, 11.60; S, 4.42%.

*Di-BOC-Lys-Phe-MeIle-Gly-Leu-Met-NH_2 (**11**).* Compound **10** (400 mg, 0.6 mmol) was dissolved in 3N hydrogen chloride in dioxane (10 ml), and the solution was allowed to stand at room temperature for 30 min. The solvent was then distilled off *in vacuo*, and the residue was treated with ether. The pentapeptide amide hydrochloride thus obtained was dissolved in dimethylformamide (3 ml), neutralized with triethylamine (0.1 ml), and then subjected to a reaction with the di-BOC-lysine *p*-nitrophenyl ester[1] (400

14) J. C. Sheehan and G. P. Hess, *J. Amer. Chem. Soc.*, **77**, 1067 (1955).

15) K. Lübke, E. Schröder, R. Schmiechen, and H. Gibian, *Ann. Chem.*, **679**, 195 (1964).

mg, 0.85 mmol). After standing overnight at room tempetature, the solution was diluted with ethyl acetate (200 ml), washed successively with N hydrochloric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The solvent was distilled off *in vacuo*, and the residue was precipitated as an amorphous powder from ethyl acetate–petroleum ether; yield, 420 mg (75%); mp 196—197°C; $[\alpha]_D^{25}$ −5.0° (*c* 0.5, methanol). Found: C, 57.98; H, 8.39; N, 11.73; S, 3.35%. Calcd for $C_{45}H_{76}O_{10}H_8S \cdot H_2O$: C, 57.50; H, 8.30; N, 11.92; S, 3.40%.

H–Lys–Phe–MeIle–Gly–Leu–Met–NH$_2$·2HCl (2) Compound **11** (200 mg) was dissolved in 2N hydrogen chloride in acetic acid (5 ml), and the solution was allowed to react at room temperature for 20 min. The product was precipitated by adding ice-cold dry ether (20 ml), and the precipitate was collected by filtration, washed well with ether, and dried over sodium hydroxide *in vacuo*. The product was dissolved in 60% methanol (4 ml), and an insoluble material was filtered off. The filtrate was concentrated to dryness over phosphorus pentoxide *in vacuo* to obtain the final product; yield, 170 mg; mp 159—164°C; $[\alpha]_D^{25}$ +27.3° (*c* 0.52, water); R_f, 0.79;[16] amino acid ratios in the acid hydrolyzate: Lys, 1.09; Phe, 1.01; Gly, 0.925; Leu, 1.00; Met, 0.99.[17] Found: C, 50.65; H, 7.99; N, 13.38; S, 3.48%. Calcd for $C_{35}H_{60}O_6N_8S \cdot 2HCl \cdot 2H_2O$: C, 50.66; H, 7.96; N, 13.51; S, 3.86%.

H–MePhe–OBzl–Tos–OH (12). A solution of *N*-methyl-L-phenylalanine[7] (18 g, 0.1 mol), *p*-toluenesulfonic acid monohydrate (21 g, 0.1 mol), and benzyl alcohol (100 ml) in benzene (100 ml) was refluxed in a Dean and Stark apparatus[18] for 48 hr. Ether (100 ml) was added to the solution, and it was kept at −20°C for 10 hr. The product, precipitated as crystals, was collected and recrystallized from methanol–ether; yield, 36 g (82%); mp 110—113°C; $[\alpha]_D^{25}$ +1.2° (*c* 1, ethanol). Found: C, 65.49; H, 6.09; N, 3.09; S, 7.21%. Calcd for $C_{24}H_{27}O_5NS$: C, 65.29; H, 6.16; N, 3.17; S, 7.25%.

Di-BOC–Lys–MePhe–OH (13). Into a solution of di-BOC-L-lysine dicyclohexylammonium salt[13] (28 g, 50 mmol) and **12** (22 g, 50 mmol) in chloroform (250 ml), DCC was stirred at −5°C. After it had been allowed to stand overnight, the dicyclohexylurea and dicyclohexylammonium chloride were filtered off. The filtrate was washed successively with 4% sodium bicarbonate, N hydrochloric acid, and water, and then dried over magnesium sulfate. The filtrate was evaporated *in vacuo* to yield an oil (25 g). This oil (25 g) was dissolved in methanol (300 ml) and was subjected to hydrogenolysis in the presence of 5% palladium on charcoal. After the filtration and evaporation of the solvent, the crude material was dissolved in 4% sodium bicarbonate, extracted with ether, acidified with N hydrochloric acid, and extracted into ether. The ether was then removed *in vacuo*, leaving a colorless, clear oil; yield, 20 g (80%); $[\alpha]_D^{25}$ −52.9° (*c* 1.55, methanol).

Di-BOC–Lys–MePhe–Ile–Gly–Leu–Met–OMe (14). Into a solution of **13** (5 g, 10 mmol) and HOBt[8] (1.4 g, 10 mmol) in tetrahydrofuran (50 ml), DCC was stirred (2.1 g, 10 mmol) at −5°C. After stirring for 1 hr at −5—5°C and then for 1 hr at room temperature, a solution of isoleucyl-glycyl-leucyl-methionine methyl ester hydrochloride[15] (4.8 g, 10 mmol) and triethylamine (1.4 ml) in tetrahydrofuran (20 ml) was added. After the mixture had then been allowed to stand overnight at room temperature, the dicyclohexylurea was filtered off. The filtrate was evaporated *in vacuo*, and the remaining oil was dissolved in ethyl acetate (200 ml). The ethyl acetate solution was washed successively with 1% hydrochloric acid, N sodium bicarbonate, and water, and dried over magnesium sulfate. The filtrate was evaporated to dryness under reduced pressure, and the crude product obtained was purified by column chromatography, being eluted with a mixture of ethyl acetate–benzene (1: 1); yield, 7.2 g (75%); $[\alpha]_D^{25}$ − 25.7°(*c* 1, methanol). Found: C, 58.29; H, 8.12; N, 10.25; S, 3.20%. Calcd for $C_{46}H_{77}O_{11}N_7S \cdot H_2O$: C, 57.89; H, 8.34; N, 10.27; S, 3.36%.

Di-BOC–Lys–MePhe–Ile–Gly–Leu–Met–NH$_2$ (15). a) To a solution of **13** (4 g, 8 mmol) and triethylamine (1.2 ml) in chloroform (100 ml), ethyl chloroformate (0.95 g, 8.8 mmol) was added over a 15 min period at −12—−10°C. After 15 min, a solution of isoleucyl-glycyl-leucyl-methionine amide hydrochloride[15] (3.8 g, 8 mmol) and triethylamine (1.2 ml) in dimethylformamide (20 ml) was added, and the solution was stirred overnight. Then, it was poured into water (200 ml) and extracted with chloroform. The chloroform extract was washed successively with 1% hydrochloric acid, 4% sodium bicarbonate, and water, dried over magnesium sulfate, and evaporated to dryness. The product was recrystallized from ethyl acetate–methanol–petroleum ether to yield ethoxycarbonyl-isoleucyl-glycyl-leucyl-methionine amide; yield, 2.3 g (58%); mp 247—249°C. Found: C, 52.10; H, 8.10; N, 13.65%. Calcd for $C_{22}H_{41}N_5O_6S$: C, 52.47; H, 8.21; N, 13.91%. From the mother liquor, the desired compound, **15**, was obtained; 1.5 g (20%); mp 180—182°C; $[\alpha]_D^{25}$ +14.6° (*c* 1, methanol). Found: C, 57.60; H, 8.28; N, 11.58; S, 3.18%. Calcd for $C_{45}H_{76}O_{10}N_8S \cdot H_2O$: C, 57.50; H, 8.30; N, 11.92; S, 3.40%.

b) A solution of **14** (4.7 g, 5 mmol) in methanol (100 ml) was saturated with dry ammonia gas at 0°C, and the solution was allowed to stand for 24 hr at room temperature. The reaction mixture was then concentrated to dryness under reduced pressure, and the residue was crystallized from ethyl acetate–methanol–petroleum ether; yield, 3.8 g (82%); mp 181—183°C; $[\alpha]_D^{25}$ +14.8° (*c* 1, methanol).

H–Lys–MePhe–Ile–Gly–Leu–Met–NH$_2$·2HCl (3). This was obtained from **15** (200 mg) by the method described for the preparation of **2**; yield, 180 mg; mp 103—105°C; $[\alpha]_D^{25}$ −19.1° (*c* 0.2, water), R_f, 0.77;[16] amino acid ratios in the acid hydrolyzate; Lys, 1.15; MePhe,1. 10; Ile, 1.08; Gly, 1.15; Leu, 1.00; Met, 0.85. Found: C, 51.06; H, 8.01; N, 13.60; S, 4.08%. Calcd for $C_{35}H_{60}O_6N_8S \cdot 2HCl \cdot 2H_2O$: C, 50.66; H, 7.96; N, 13.51; S, 3.86%.

H–Sar–OBzl·HCl (16). A solution of sarcosine (50 g, 0.6 mol), *p*-toluenesulfonic acid monohydrate (125 g, 0.66 mol) and benzyl alcohol (600 ml) in benzene (600 ml) was treated as described for the preparation of **12**. The crude product precipitated as *p*-toluenesulfonate was dissolved into water (100 ml), and the solution was basified with sodium bicarbonate and extracted with ethyl acetate. The extract was washed with a saturated sodium chloride solution and then dried over magnesium sulfate. To the filtered solution, 3N hydrogen chloride in dioxane (200 ml) was added, and the solution was evaporated *in vacuo* to dryness. The remaining crystal was recrystallized from methanol–ether; yield, 93 g (72%); mp 174—176°C. Found: C, 55.20; H, 6.58; N, 6.56; Cl, 16.46%. Calcd for $C_{10}H_{13}NO_2 \cdot HCl$: C, 55.68; H, 6.49; N, 6.49; Cl, 16.47%.

16) Paper chromatography was carried out on Toyo Roshi No.50 with *n*-butanol–acetic acid–water (4: 1: 1).

17) MeIle was present but not determined. Its presence was proved by paper chromatography of the acid hydrolysate [*n*-butanol–acetic acid–water (4: 1: 1) system] in which MeIle was perfectly separated from the other slower moving amino acids.

18) J. P. Greenstein and M. Winitz, "Chemistry of the Amino Acids," John Wiley & Sons, Inc., New York and London (1961), p. 940.

BOC-Ile-Sar-OH (17). This was obtained from BOC-isoleucine[13] and **16** (21 g, 100 mmol) as described for the preparation of **13**; yield of oil, 19.2 g (64%); $[\alpha]_D^{25}$ −31.0° (*c* 1.3, methanol).

BOC-Ile-Sar-Leu-Met-OMe (18). This was obtained from **17** (9.1 g, 30 mmol), HObt (4 g, 30 mmol), DCC (6.8 g, 33 mmol), and leucyl-methionine methyl ester hydrochloride[15] (9.5 g, 30 mmol) as described for the preparation of **14**. The crude product was purified by column chromatography on silica-gel, being eluted with ethyl acetate; yield of oil, 15.5 g (92%); $[\alpha]_D^{25}$ −51.3° (*c* 1.25, methanol).

BOC-Ile-Sar-Leu-Met-NH_2 (19). A solution of **18** (11.2 g, 20 mmol) in methanol (300 ml) was saturated with dry ammonia gas at 0°C, after which the solution was allowed to stand for 40 hr at room temperature. The reaction mixture was concentrated to dryness under reduced pressure, and the residual crystal was recrystallized from ethyl acetate-petroleum ether; yield, 9 g (80%); mp 188—191°C; $[\alpha]_D^{25}$ −55.0° (*c* 1, methanol). Found: C, 55.08; H, 8.44; N, 12.77; S, 6.06%. Calcd for $C_{25}H_{47}O_6N_5S$: C, 55.04; H, 8.62; N, 12.84; S, 5.87%.

BOC-Phe-Ile-Sar-Leu-Met-NH_2 (20). Compound **19** (5.5 g, 10 mmol) was dissolved in 3N hydrogen chloride in dioxane (100 ml), and the solution was allowed to stand at room temperature for 40 min. The solvent was then distilled off *in vacuo*, and the residue was triturated with ether. The tetrapeptide amide hydrochloride thus obtained was dissolved in dimethylformamide (40 ml), neutralized with triethylamine (1.6 ml), and then subjected to a reaction with the BOC-phenylalanine *p*-nitrophenyl ester (5.2 g, 13 mmol). The solution was treated as described for the preparation of **11**, and the crude product was recrystallized from ethyl acetate-methanol-petroleum ether; yield, 4.9 g (90%); mp 162—167°C; $[\alpha]_D^{25}$ −54.1° (*c* 1, methanol). Found: C, 58.47; H, 7.70; N, 11.85; S, 4.35%. Calcd for $C_{34}H_{56}O_7N_6S$: C, 58.95; H, 8.09; N, 12.13; S, 4.62%.

Di-BOC-Lys-Ile-Sar-Leu-Met-NH_2 (21). This was obtained from the di-BOC-lysine *p*-nitrophenyl ester (700 mg, 1.5 mmol) and the pentapeptide amide derived from compound **20** (1 g, 1.4 mmol) as described for the preparation of **11**; yield, 825 mg (63%); mp 154—160°C; $[\alpha]_D^{25}$ −57.3° (*c* 1, methanol). Found: C, 57.46; H, 8.30; N, 11.59; S, 3.26%. Calcd for $C_{45}H_{76}O_{10}N_8S\cdot H_2O$: C, 57.50; H, 8.30; N, 11.92; S, 3.40%.

H-Lys-Phe-Ile-Sar-Leu-Met-$NH_2\cdot 2HCl$ (4). This was obtained from **21** (200 mg) as described for the preparation of **2**; yield, 170 mg; mp 80—90°C; $[\alpha]_D^{25}$ −33.8° (*c* 0.5, water); R_f, 0.73;[16] amino acid ratios in the acid hydrolyzate; Lys, 1.07; Phe, 1.05; Ile, 1.05; Sar, 1.15; Leu, 1.00; Met, 0.94. Found: C, 51.64; H, 7.79; N, 13.62; S, 3.83%. Calcd for $C_{35}H_{60}O_6N_8S\cdot 2HCl\cdot H_2O$: C, 51.78; H, 7.89; N, 13.81; S, 3.94%.

H-MeLeu-OMe·HCl (22). This was obtained from *N*-methyl-L-leucine[7] as described for the preparation of **8**; yield (77%); mp 126.5—127°C; $[\alpha]_D^{25}$ +31.4° (*c* 1, ethanol) (lit,[12] mp 127—128°C; $[\alpha]_D^{25}$ +30° (ethanol)). (Found: C, 49.32; H, 9.21; N, 7.19; Cl, 18.17%).

BOC-Gly-MeLeu-OH (23a). Into a solution of BOC-glycine[13] (17.5 g, 100 mmol) **22** (20 g, 100 mmol), and triethylamine (14 ml) in chloroform (300 ml), DCC was stirred at −5°C. After the mixture had been allowed to stand overnight at room temperature, the dicyclohexylurea was filtered off and the filtrare was treated as described for the preparation of **9**. The crude product was recrystallized from ether-*n*-hexane; yield, 10.6 g (35%); mp 93—95°C; $[\alpha]_D^{25}$ −24.6° (*c* 1, methanol). Found: C, 55.46; H, 8.82; N, 9.18%. Calcd for $C_{14}H_{26}O_5N_2$: C, 55.61; H, 8.67; N, 9.27%.

BOC-Gly-MeIle-OH (23b). This was obtained from BOC-glycine (17.5 g, 100 mmol) and **8** (20 g, 100 mmol) as described above. The crude product was recrystallized from ethyl acetate-petroleum ether; yield, 10.2 g (33.8%); mp 139.5—140°C; $[\alpha]_D^{25}$ −1.1° (*c* 2, methanol). Found: C, 55.76; H, 8.53; N, 9.41%. Calcd for $C_{14}H_{26}O_5N_2$: C, 55.61; H, 8.67; N, 9.27%.

BOC-Gly-MeLeu-Met-OMe (24a). This compound was obtained from **23a** (20 g, 67 mmol), HObt (9.1 g, 67 mmol), DCC (16 g, 80 mmol), methionine methyl ester hydrochloride (14 g, 70 mmol), and triethylamine (9.8 ml, 70 mmol) as described for the preparation of **14**. The crude oil was purified by column chromatography on silica gel being eluted with a mixture of benzene and ethyl acetate (7: 3); yield of oil, 27 g (90%); $[\alpha]_D^{25}$ −9.2° (*c* 1, methanol).

BOC-Gly-MeIle-Met-OMe (24b). This was obtained from **23b** (9 g, 30 mmol), HObt (4 g, 30 mmol), DCC (6.6 g, 33 mmol), methionine methyl ester hydrochloride (6.6 g, 33 mmol), and triethylamine (4.6 ml, 33 mmol) as described above; yield of oil, 11.6 g, (87%); $[\alpha]_D^{25}$ +11.0° (*c* 1, methanol).

BOC-Gly-MeLeu-Met-NH_2 (25a). A solution of **24a** (16.5 g, 37 mmol) in methanol (300 ml) was saturated with dry ammonia gas at 0°C, and the solution was treated as described for the preparation of **19**; yield of oil, 13.2 g (84%); $[\alpha]_D^{25}$ −6.2° (*c* 1, methanol).

BOC-Gly-MeIle-Met-NH_2 (25b). This was obtained from **24b** (4.5 g, 10 mmol) as described for the preparation of **19**; yield of oil, 3.6 g (80%); $[\alpha]_D^{25}$ −17.8° (*c* 1, methanol).

AOC-Phe-Ile-Gly-MeLeu-Met-NH_2 (26a). Into a solution of *t*-amyloxycarbonyl-phenylalanyl-isoleucine hydrazide[1] (4 g, 10 mmol) in a mixture of 2N hydrochloric acid (20 ml, 40 mmol) and dimethylformamide (200 ml), a chilled solution of sodium nitrite (700 mg, 10 mmol) in water (1 ml) was stirred over a 15 min period at −15——13°C. After 20 min, the solution was neutralized with triethylamine; then a solution of triethylamine (1.4 ml) and the glycyl-*N*-methylleucyl-methionine amide hydrochloride obtained from **25a** (4.3 g, 10 mmol) in dimethylformamide (20 ml) was added at −10——5°C. After the reaction mixture had been stirred at room temperature for 3 hr, it was poured into water (1000 ml) and extracted with ethyl acetate. The extract was washed successively with N hydrochloric acid, 4% sodium bicarbonate, and water, dried over magnesium sulfate, and evaporated *in vacuo*. The oily residue (6.6 g) was purified by column chromatography on silica gel (Merck 0.2—0.5 mm) being eluted with a mixture of ethyl acetate and methanol (8: 2); yield of oil, 5.8 g (80%); $[\alpha]_D^{25}$ −23.9° (*c* 1, methanol). Found: C, 58.33; H, 8.14; N, 11.62; S, 4.24%. Calcd for $C_{35}H_{58}O_7N_6S\cdot H_2O$: C, 58.01; H, 8.28; N, 11.60; S, 4.42%.

AOC-Phe-Ile-Gly-MeIle-Met-NH_2 (26b). To a solution of the azide derived from *t*-amyloxycarbonyl-phenylalanyl-isoleucine hydrazide (4 g, 10 mmol) in dimethylformamide (200 ml), a solution of the glycyl-*N*-methylisoleucyl-methionine amide hydrochloride obtained from **25b** (4.3 g, 10 mmol) and triethylamine (1.4 ml) in dimethylformamide (20 ml) was added. The crude product was obtained as described above and was purified by column chromatography on silica-gel, being eluted with a mixture of ethyl acetate and methanol; yield of oil, 5.9 g (82%); $[\alpha]_D^{25}$ −15.8° (*c* 1, methanol). Found: C, 58.38; H, 8.25; N, 11.40; S, 4.23%. Calcd for $C_{35}H_{58}O_7N_6S\cdot H_2O$: C, 58.01; H, 8.28; N, 11.60; S, 4.42%.

Di-BOC-Lys-Phe-Ile-Gly-MeLeu-Met-NH_2 (27a). This was obtained from the di-BOC-lysine *p*-nitrophenyl ester (2.3 g, 5 mmol) and the pentapeptide amide derived from compound **26a** (3 g, 4.4 mmol) as described for the preparation of **11**. The crude product was purified by column chromatography on silica-gel, being eluted first with ethyl

acetate and then with a mixture of ethyl acetate and methanol (8: 2); yield of oil, 3 g (72%); $[\alpha]_D^{25}$ −26.5° (*c* 1, methanol). Found: C, 57.82; H, 8.18; N, 11.73; S, 3.18%. Calcd for $C_{45}H_{76}O_{10}N_8S \cdot H_2O$: C, 57.50; H, 8.30; N, 11.92; S, 3.40%.

Di-BOC-Lys-Phe-Ile-Gly-MeIle-Met-NH$_2$ (27b). This was obtained from the di-BOC-lysine *p*-nitrophenyl ester (1.9 g, 4 mmol) and the pentapeptide amide derived from compound **26b** (2.7 g, 3.8 mmol). The crude product was dissolved in ethyl acetate, and the product was precipitated gradually as crystals; yield, 2.1 g (61%); mp 212—213°C; $[\alpha]_D^{25}$ +8.3° (*c* 1, methanol). Found: C, 57.97; H, 8.18; N, 11.90; S, 3.36%. Calcd for $C_{45}H_{76}O_{10}N_8S \cdot H_2O$: C, 57.50; H, 8.30; N, 11.92; S, 3.40%.

H-Lys-Phe-Ile-Gly-MeLeu-Met-NH$_2$·2HCl (5). This was obtained from **27a** (200 mg) as described for the preparation of **2**; yield, 180 mg; mp 107—112°C; $[\alpha]_D^{25}$ −7.3° (*c* 0.3, water); R_f, 0.70;[16] amino acid ratios in the acid hydrolyzate: Lys, 1.14; Phe, 1.05; Ile, 1.00; Gly, 1.05; MeLeu, 1.02; Met, 0.99. Found: C, 50.42; H, 7.94; N, 13.65; S, 3.48%. Calcd for $C_{35}H_{60}O_6N_8S \cdot 2HCl \cdot 2H_2O$: C, 50.66; H, 7.96; N, 13.51; S, 3.86%.

H-Lys-Phe-Ile-Gly-MeIle-Met-NH$_2$·2HCl (6). This was obtained from **27b** (200 mg) as described for the preparation of **2**; yield, 170 mg, mp 85—100°C; $[\alpha]_D^{25}$ +34.0° (*c* 0.2, water); R_f, 0.70;[16] amino acid ratios in the acid hydrolyzate: Lys, 0.92; Phe, 0.99; Ile, 1.00; Gly, 0.97; Met, 0.98.[17] Found: C, 50.95; H, 8.11; N, 13.46; S, 3.93%. Calcd for $C_{35}H_{60}O_6N_8S \cdot 2HCl \cdot 2H_2O$: C, 50.66; H, 7.96; N, 13.51; S, 3.86%.

BOC-Ile-Gly-MeLeu-Met-OMe (28). Into a solution of BOC-isoleucine (2.3 g, 10 mmol) and triethylamine (1.4 ml) in chloroform (50 ml), ethyl chloroformate (1.1 g, 10 mmol) was stirred over a 15 min period at −11——10°C. After 15 min, there was added a solution of triethylamine (1.4 ml) and the glycyl-*N*-methylleucyl-methionine methyl ester hydrochloride derived from **23a** (4.5 g, 10 mmol) in chloroform (30 ml), the reaction mixture was then stirred at room temperature overnight. It was washed successively with N hydrochloride acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The filtered solution was evaporated to dryness under reduced pressure to yield the product; yield of oil, 4.9 g (88%); $[\alpha]_D^{25}$ −23.0° (*c* 1, methanol).

Di-BOC-Lys-MePhe-Ile-Gly-MeLeu-Met-OMe (29). This was obtained from **13** (7.6 g, 15 mmol), HOBt (2 g, 15 mmol), DCC (3.5 g, 17 mmol), and the isoleucyl-glycyl-*N*-methylleucyl-methionine methyl ester derived from **28** (8.2 g, 15 mmol) as described for the preparation of **14**. The crude oil was purified by column chromatography on silica-gel, being eluted with ethyl acetate; yield of oil, 10.6 g (77%); $[\alpha]_D^{25}$ −30.8° (*c* 1, methanol). Found: C, 58.01; H, 8.32; N, 10.33; S, 3.51%. Calcd for $C_{47}H_{79}O_{11}N_7S \cdot H_2O$: C, 58.32; H, 8.37; N, 10.13; S, 3.30%.

Di-BOC-Lys-MePhe-Ile-Gly-MeLeu-Met-NH$_2$ (30). A solution of compound **29** (9.7 g, 10 mmol) in methanol was saturated with ammonia gas at 0°C, after which the solution was allowed to stand for 24 hr at room temperature. The reaction mixture was then concentrated to dryness under reduced pressure, and the residue was dissolved in ethyl acetate and chromatographed on silica-gel, being eluted first with ethyl acetate and then with a mixture of ethyl acetate and methanol (8: 2); yield of oil, 7.7 g (81%); $[\alpha]_D^{25}$ −30.2° (*c* 1, methanol). Found: C, 57.56; H, 8.25; N, 11.28; S, 3.27%. Calcd for $C_{46}H_{78}O_{10}N_8S \cdot H_2O$: C, 57.98; H, 8.40; N, 11.76; S, 3.36%.

H-Lys-MePhe-Ile-Gly-MeLeu-Met-NH$_2$·2HCl (7). This was obtained from **30** (200 mg) as described for the preparation of **2**; yield, 180 mg; mp 109—115°C; $[\alpha]_D^{25}$ −22.7° (*c* 0.1, water); R_f, 0.74;[16] amino acid ratios in the acid hydrolyzate: Lys, 0.89; MePhe, 0.93; Ile, 1.00; Gly, 0.95; MeLeu, 1.06; Met, 0.92. Found: C, 51.02; H, 8.09; N, 13.26; S, 3.42%. Calcd for $C_{36}H_{62}O_6N_8S \cdot 2H_2O$: C, 51.24; H, 8.06; N, 13.28; S, 3.79%.

The authors wish to thank Professor N. Izumiya of Kyushu University, and Director Dr. I. Chibata of Tanabe Seiyaku for their encouragement in the course of this study.

Photochemical Reactions of Aromatic Compounds. XI[1] The Photochemical Cycloaddition of Vinyl Ethers to α-Naphthonitrile

Chyongjin PAC, Taizo SUGIOKA, Kazuhiko MIZUNO, and Hiroshi SAKURAI
The Institute of Scientific and Industrial Research, Osaka University, Suita-shi, Osaka
(Received April 28, 1972)

The photochemical reactions of α-naphthonitrile with vinyl ethers gave two stereo-isomeric (2+2) cycloadducts, *trans*-1-cyano-8-alkoxy-2,3-benzobicyclo[4.2.0]octa-2,4-diene **1** and the *cis* isomer, **2**, in 80—90% yields. From the results of fluorescence measurements and kinetic analysis, the photocycloaddition was established to occur from the lowest excited singlet state of α-naphthonitrile.

Recently much attention has been paid to the photocycloaddition of unsaturated bonds to aromatic rings. Although the photocycloaddition to the benzene ring has been well investigated,[2] the cycloaddition to the naphthalene ring has been less investigated; only a few examples have been studied, the (2+2) addition of acrylonitrile[3] or diarylacetylenes[4] to naphthalene, the (2+2+2) addition of dimethyl acetylenedicarboxylate to naphthalene,[5] the (4+4) addition of acyclic dienes to naphthalene,[6] and the (4+4) addition of furan to α-naphthonitrile.[7]

The present paper will describe the photochemical (2+2) cycloaddition of alkyl vinyl ethers to α-naphthonitrile (α-NN) and will suggest that the photocycloaddition takes place *via* an exciplex generated from the lowest excited singlet state of α-NN.

Results

Irradiation-results and Structural Assignment of Products. The irradiation of a mixture of α-NN and a large excess of methyl vinyl ether in methanol or benzene with a high-pressure mercury arc at room temperature through a Pyrex glass (>300 nm) and under a nitrogen atmosphere gave two isomeric 1:1-adducts, **1a** and **2a**, in 80—90% yields when 90—95% of α-NN was consumed. The formation-ratio of **1a** to **2a** was dependent on the solvent used; it was *ca.* 1 for a benzene solution and 2—3 for methanolic and acetonitrile solutions, though the total yields of the products did not change with the solvents used.

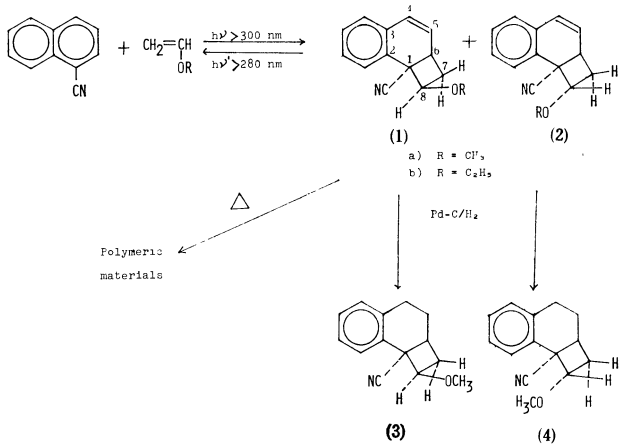

Chart 1.

The **1a** adduct, mp 86—87°C, was separated from **2a** by chromatography on the silica gel of the photolysate. On the other hand, **2a** could not be obtained in a pure form, since the chromatographic separation of **2a** from **1a** was incomplete and preparative vpc was not suitable because of the thermal instability of the adducts. Since **2a** was found to be thermally more stable than **1a** (*vide infra*), the photolysate from a benzene solution was subjected to thermolysis at 180—200°C; we thus obtained a mixture enriched with **2a**. The repeated chromatography of that mixture afforded **2a** containing only a small amount of **1a**.

The structure of the adducts was determined by IR, UV, and NMR analyses and by studying the mass spectroscopic data. The mass spectra of both adducts exhibit a weak parent peak at *m/e* 211, a strong peak at *m/e* 153 (α-NN), and a moderate peak at *m/e* 58 (C_3H_6O), along with other, far less important peaks. This fragmentation pattern strongly suggests the structure of 1:1-cycloadduct for the adducts. The two adducts have similar IR spectra, which show bands at 3040, 3020 (aromatic and olefinic C–H), 2990, 2930 (aliphatic C–H), 2210 (C≡N), 1640 (C=C), and 1140 cm^{-1} (C–O–C). The UV spectra, λ_{max}^{MeOH} (ε) 265 (7.6×10^3) and 300 nm (1.17×10^3) for **1a** and 265 (5.2×10^3) and 300 nm (sh) for **2a**, show that both adducts have a

	$J_{4,5}=9$,	$J_{5,6}=4$,	$J_{6,7}=11$,	$J_{6,7'}=3$,	$J_{7,8}=J_{7',8}=8$, and	$J_{7,7'}=11$	

a) NMR spectra were taken for CCl_4 solutions using TMS as an internal standard and aromatic protons showed the signals at δ 6.9—7.5 as multiplets.

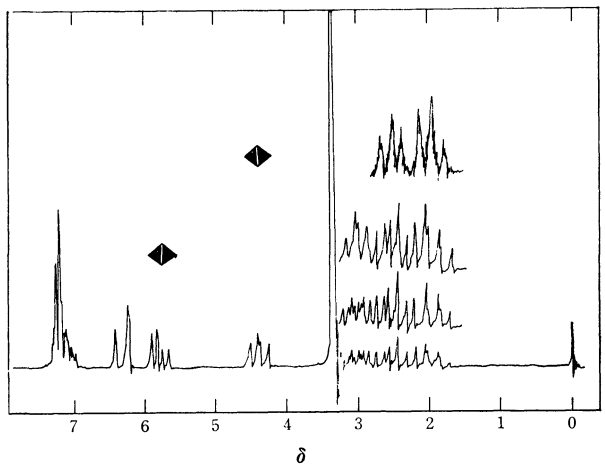

Fig. 1. NMR spectrum of **1a** in CCl_4.

1,2-dihydronaphthalene-chromophore.[8] From these spectral data, the structures of substituted napthhalene and the (2+4) cycloadduct can be safely eliminated.

The NMR spectra of the two adducts are similar (Table 1). The chemical shifts and the coupling constants are determined by first-order analysis of the spectra and a spin-decoupling method. The integral of signals shows that both **1a** and **2a** have four aromatic protons, two vinyl protons, two methine protons, two methylene protons, and three methoxy protons. Figure 1 shows the NMR spectrum of **1a** and the results of the spin-decoupling experiment. Irradiation at δ 5.77 changes the octet at δ 2.84—3.22 (C_6–H) into a quartet with the coupling constants of 9 and 10 Hz. Thus, it is confirmed that the two vinyl protons (C_4– and C_5–H) and the C_6-methine proton form an ABX-spin system ($J_{AX}\sim 0$ Hz) and that the X-part couples further with the adjacent unequivalent methylene protons (C_7– and $C_{7'}$–H). The quartet at δ 4.40 are clearly due to the C_8-proton. On irradiation at this position, the complex signal in the methylene region collapses into two triplets at δ 1.95 and 2.51, with a coupling constant of *ca.* 10 Hz. This result unambiguously shows, that the C_8-methine proton couples with the $C_{7,7'}$-methylene protons in an ABX type of coupling. Thus, these data establish the ring skeleton of **1a** to be 1-cyano-8-methoxy-2,3-benzobicyclo[4.2.0]octa-2,4-diene.

The similarity of the IR, UV, and NMR spectra between **1a** and **2a** strongly suggests that **2a** has the same ring skeleton as **1a**. Especially, the NMR data support the structure. The triplet at δ 4.09 and the ABX-type of signal pattern in the olefinic region cannot be resonably interpreted by the other possible structures of (2+2) cycloadducts. On irradiation at δ 4.09, the multiplet due to methylene protons collapses into a triplet with a coupling constant of 11 Hz at δ 2.71 and a quartet with coupling constants of 3 and 11 Hz at δ 2.34. These results unambiguously show that **2a** has the same spin system as **1a**, though the signal pattern of C_6–H of **2a** cannot be firmly established on account of the overlapping of the signal with that of the methoxy protons.

Therefore, the structural difference between **1a** and **2a** occurs from the stereochemical difference, the *cis* or *trans* configuration of the methoxy group to the cyano group, *i.e.*, the *endo*- or *exo*-location of the C_8-proton in relation to the benzene ring. In the case of benzo-polycyclic compounds, it is well known that an *endo*-proton is more shielded than an *exo*-proton.[9,10] Therefore, it is important to note that the signal of the C_8-proton of **2a** appears 0.31 ppm higher in field than that of the proton of **1a**. This fact requires the *endo*-location of the proton of **2a**. In the case of the dihydro isomers, **3** and **4** obtained by the catalytic hydrogenation of **1a** and **2a**, this type of anisotropic effect can be expected to be more evident for the C_8-proton, since the molecular models indicate that the C_8-proton of **4** is more closely located over the benzene ring than that of any other isomer. For the same reason, the methoxy protons of **3** must be most shielded. In fact, **4** shows the signal of the C_8-proton at a higher field (δ 3.67) than any other isomer, while the methoxy protons of **3** have the signal at the highest field (δ 3.21)

Table 2. Comparison of chemical shifts of C_8-proton and methoxy protons between **1a**, **2a**, **3**, and **4**

Protons	Compounds Chemical shift (δ)			
	1a	**2a**	**3**	**4**
C_8–H	4.40	4.09	4.27	3.67
OCH_3	3.35	3.30	3.21	3.35

Table 3. NMR data of **1b** and **2b**[a)]

Compounds	δ(Multiplicity)/Coupling constants (Hz)					
	C_4–H	C_5–H	C_6–H	$C_{7'}$–H	C_7–H	C_8–H
1b	6.28	5.75	2.99	1.92	2.50	4.45
	(d)	(q)	(oct)	(complex)		(q)
	$J_{4,5}=10$,	$J_{5,6}=6$,	$J_{6,7}=10$,	$J_{6,7'}=8$,	$J_{7,8}=9$,	$J_{7',8}=8$, and $J_{7,7'}=10$
2b	6.3	5.75	3.1—3.3	2.32	2.55	4.16
	(d)	(q)	(m)	(complex)		(t)
	$J_{4,5}=10$,	$J_{5,6}=4$,	$J_{6,7}=9$,	$J_{6,7'}=3$,	$J_{7,8}=J_{7',8}=8$, and $J_{7,7'}=11$	

a) The adduct **1b** exhibited the signal of ethoxy group at δ 1.1 (t, CH_3, $J=7$ Hz) and 3.55 (q, OCH_2) and aromatic protons at δ 6.8—7.4 (m), and **2b** showed the signals at δ 1.18 (t, CH_3, $J=8$ Hz), 3.43 (q, OCH_2), and 6.8—7.5 (m, aromatic protons).

among the four isomers (see Table 2). Thus, these NMR data clearly establish that **1a** and **3** require the *exo*-location of the C_8-proton, *i.e.*, the *trans*-configuration between the cyano and methoxy groups, whlie **2a** and **4** have the *cis*-configuration.

Both **1a** and **2a** are thermally as well as photochemically unstable. When the adducts are subjected to vpc analyses by changing the temperature of the inlet-part, the peaks of **1a** and **2a** decrease over 180 and 230°C respectively. However, the peak of α-NN does not so increase, even upon the complete decomposition of **1a** and **2a**. When **1a** and **2a** are heated at 180°C and over 250°C respectively, brownish polymeric materials are mostly yielded, along with a small amount of α-NN. In contrast to the thermolysis, the irradiation of both adducts by a light longer than 280 nm affords α-NN in a quantitative yield. This result indicates that the photoaddition is competitive with the retro-reaction when both α-NN and the adducts absorb the incident light. However, the retro-reaction may be less important when methyl vinyl ether is present in an excess.

The photocycloaddition of ethyl vinyl ether to α-NN is also efficient in giving **1b** and **2b** in good yields. The relative ratio of **1b** to **2b** is again dependent on the solvent used and is similar to that of **1a** to **2a**. The structural determination of **1b** and **2b** was carried out by means of elemental analyses and spectroscopic data. The NMR data are listed in Table 3. On the other hand, vinyl acetate and isobutylene react only slowly with α-NN, and the products can not be isolated in a pure form. Although the photocycloaddition of acrylonitrile to naphthalene has been reported,[3)] the irradiation of α-NN in the presence of acrylonitrile affords no adducts, but only polymers. Moreover, the photoreaction of naphthalene with vinyl ethers results in the quantitative recovery of naphthalene upon irradiation for a longer time, though vpc analyses indicate the formation of at least four products in trace amounts.

Quantum Yield. On the irradiation of a dilute cyclohexane solution of α-NN containing ethyl vinyl ether at 313 nm, there appear an isosbestic point at 279 nm and new absorption maxima similar to those of **1b** and **2b** (Fig. 2). Therefore, the quantum yields for the disappearance of α-NN can be determined by monitoring the decrease in the absorbance at 307 nm, using a potassium ferroixalate actinometer. The reciprocals of the quantum yields are linearly changed

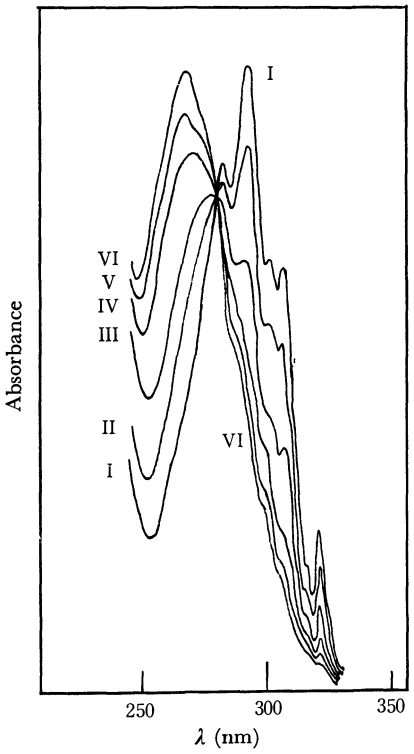

Fig. 2. Spectral change of a cyclohexane solution containing 1.5×10^{-4}M of α-NN and 0.93M of ethyl vinyl ether with time (min); I(0), II(1.5), III(5.0), IV(10.0), V(20.0), and VI(40.0). Absorbance is in an arbitary unit.

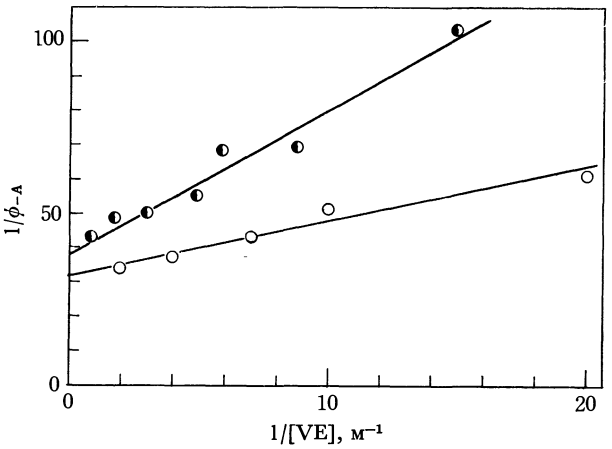

Fig. 3. The plots of $1/\phi_{-A}$ *vs.* 1/[VE] for degassed (-○-) and air saturated (-◐-) cyclohexane solutions, [α-NN]$=1.38\times10^{-4}$M.

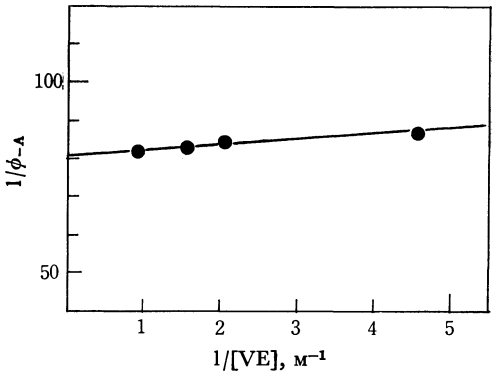

Fig. 4. The plots of $1/\phi_{-A}$ *vs.* 1/[VE] for air saturated methanolic solution, [α-NN]$=1.38\times10^{-4}$M.

with the reciprocals of the concentrations of ethyl viny ether; thus, the slopes and intercepts are determined to be 1.6M and 32 for degassed cyclohexane solutions, 4.1M and 39 for air-saturated cyclohexane solutions, and 1.5M and 82 for air-saturated methanolic solutions (Figs. 3 and 4).

Quenching of Fluorescence. A dilute cyclohexane or methanolic solution of α-NN emits a fluorescence with the maxima at 320—340 nm. The fluorescence is quenched by ethyl vinyl ether without any change in the shape of the spectra, and linear Stern-Volmer plots are obtained (Fig. 5). The slopes of the Stern-Volmer plots are determined to be 19M^{-1} for degassed cyclohexane solutions, 10.3M^{-1} for air-saturated cyclohexane solutions, and 51M^{-1} for air-saturated methanolic solutions.

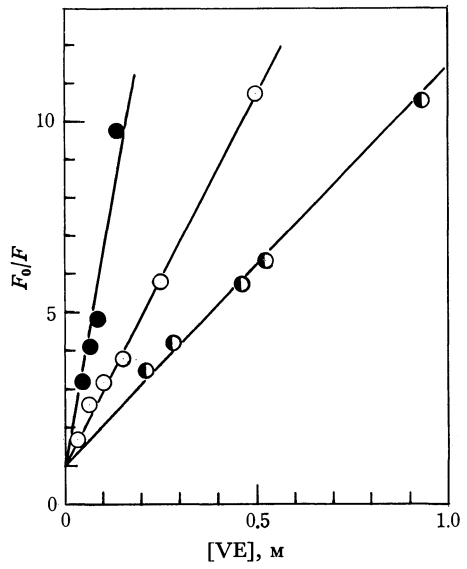

Fig. 5. The Stern-Volmer plots for the quenching of α-NN fluorescence with ethyl vinyl ether; degassed cyclohexane solutions (-○-), air saturated cyclohexane solutions (-◐-), and air saturated methanolic solutions (-●-). [α-NN]$=1.38\times10^{-4}$M.

On the other hand, acrylonitrile does not appreciably quench the fluorescence of α-NN. The fluorescence quenching with vinyl acetate is quite ineffective, as 0.8M of vinyl acetate causes only a *ca.* 10% decrease in the fluorescence.

Discussion

The effective fluorescence-quenching by ethyl vinyl ether indicates that the photochemical cycloaddition of ethyl vinyl ether to α-NN takes place from the lowest excited singlet state of α-NN (^{1}A). Moreover, benzophenone does not sensitize the photocycloaddition, though the photoreduction of benzophenone with benzhydrol is effectively quenched by α-NN. Therefore, a triplet mechanism can be safely eliminated.

$$F_0/F = (1+k_r[VE])/(k_d+k_o[O_2]) \quad (7)$$

$$1/\phi_{-A} = \left(1+\frac{k_d+k_o[O_2]}{k_r[VE]}\right)\left(1+\frac{k_n}{k_c}\right) \quad (8)$$

Scheme 1.

In Scheme 1, therefore, a simplified singlet mechanism is described, from which the Stern-Volmer expression for fluorescence-quenching (7) and the rate equation (8) are derived. In the equations, let ϕ_{-A}, F_0, and F denote the quantum yield for the disappearance of α-NN and the fluorescence intensities in the absence and in the presence of ethyl vinyl ether (VE) respectively. The (2) process indicates all the unimolecular decay of ^{1}A involving radiative and nonradiative processes. In the case of air-saturated runs, the oxygen-quenching process (3) should be taken into account, whereas it can be neglected for degassed runs.

From the intercepts and the slopes in Figs. 3 and 4, the intercept-to-slope ratios can be calculated to be 20M^{-1} for degassed cyclohexane solutions, 9.5M^{-1} for air-saturated cyclohexane solutions, and 54.7M^{-1} for air-saturated methanolic solutions; these ratios are in good agreement with the slopes of the Stern-Volmer plots for the respective solutions in Fig. 5. This agreement, especially for the air-saturated runs, clearly shows that the photocycloaddition takes place in the lowest excited singlet state of α-NN, since both the intercept-to-slope ratio and the slope of the Stern-Volmer plots represent the same rate term, k_r/k_d for degassed runs or $k_r/(k_d+k_o[O_2])$ for air-saturated runs.

The fluorescence decay life of a degassed cyclohexane solution of α-NN was determined to be 17 nsec by the use of a TRW nsec flashspectrophotometer. The oxygen-quenching method,[11] using an L_0/L value ($=1+k_o[O_2]/k_d=1.77$), gave a similar decay life. From this value of the decay life, k_r can be calculated to be 1.1×10^9M^{-1}sec^{-1}, very close to the diffusion rate in-

11) I. B. Berlman, "Handbook of Fluorescence Spectra of Aromatic Molecules," Academic Press, New York and London (1965), p. 36.

cyclohexane (*ca.* 5×10^{9}M^{-1}sec^{-1}). Unfortunately, not many kinetic studies of the cycloaddition of π,π^*-singlet species to olefins have been reported,[3,12] and the rate constant, k_r, has not yet been given.

On the other hand, kinetic investigations of electronically-excited carbonyl compounds have been intensively carried out. In the n,π^*-triplet state, the oxetane-formation takes place through 1,4-biradicals, with rate constants of 5×10^{7}—10^{8}M^{-1}sec^{-1}.[13] In the present case, therefore, it is not suitable to suggest that a 1,4-biradical or 1,4-dipolar intermediate, **5**, is directly generated by the attack of ^{1}A on VE in a near diffusion rate, since ^{1}A might be considered to be less electrophilic than the n,π^*-triplet carbonyl compounds, which have been well established to have a high electrophilic character.

On the other hand, it has been reported that the photocycloaddition of acetone to dicyanoethylene[14] and that of propionaldehyde to cyclohexadiene[15] afford oxetanes by way of the exciplexes generated from the excited singlet state of the carbonyl compounds in a diffusion-controlled rate.[16] In many cases, the exciplex formation is well established to occur in a diffusion-controlled rate from the excited singlet state.[17] In the present case, therefore, the large value of k_r can be reasonably interpreted by assuming an exciplex intermediate. The inefficiency of acrylonitrile and the less effective nature of vinyl acetate in the fluorescence-quenching and the photoreaction may also suggest an exciplex intermediate with a charge-transfer character; ethyl vinyl ether is known to be an electron-rich olefin, whereas vinyl acetate has less of a donor-ability and acrylonitrile is an acceptor rather than a donor.

The rate constant for fluorescence-quenching, $k_r/(k_d+k_o[O_2])$, is about five times greater in methanol than in cyclohexane. This reflects the solvent-dependence of k_r, since the fluorescence intensity of α-NN was found to be similar both in air-saturated methanolic and cyclohexane solutions. In the exciplex-formation, polar solvents have been known to enhance the rate of fluorescence-quenching[7,18,19] and the reaction rate,[7,18] at least in some cases. Moreover, since an exciplex is a special case of well-known charge-transfer complexes, the solvation of exciplexes can occur and, in polar solvents, leads to species with configurations different from those of the exciplexes in non-polar solvents.[20] If this is the case, the solvent-dependent results of k_n/k_c and the product ratio are consistent with the exciplex mechanism. However, the solvent-dependence can possibly be explained as being caused by the solvation of the 1,4-biradical, **5**, generated from an exciplex, since solvent effects have been observed in the Norrish-type II photoelimination, which has been well established to proceed *via* a 1,4-biradical.[21] However, a discrete 1,4-dipolar intermediate is not a likely reaction intermediate, since the photoreaction in methanol gave neither a solvolytic nor an inserted product such as **6** or **7**, even under acidic and basic conditions.

Chart 2

Experimental

General. The spectroscopic analyses of the products were carried out as follows; the NMR spectra using a Hitachi Perkin-Elmer R-20 spectrophotometer, the IR spectra using a Hitachi EPI-S2 spectrophotometer, the UV spectra using Hitachi 124 spectrophotometer, the fluorescence spectra using a Hitachi MPF-2A spectrofluorometer, and the mass spectra using a Hitachi RMU-6E spectrometer. The yields and the product ratios were determined by vpc with a Shimadzu GC-3AF using a column of SE-30 (5% on Shimalite W, 1m) at 160°C. The thermal behavior of **1** and **2** was checked by vpc with a Shimadzu GC-2C equipped with a flame-ionization detector, by changing the temperature of the inlet-part. The solvents were purified as usual. The ethyl vinyl ether, vinyl acetate, and acrylonitrile were distilled over calcium chloride under a nitrogen stream before use. The methyl vinyl ether was distilled from a gas cylinder before use. The α-NN was purified by vacuum distillation.

Quantum Yields. The solutions were prepared by dissolving α-NN (1.38×10^{-4}M) and ethyl vinyl ether into cyclohexane or methanol. Monochromatic light at 313 nm was isolated through a Toshiba UV-D25 glass filter and a filter solution (0.2 g potassium chromate made up to 1 *l* with distilled water), with a path length of 10 mm from resomance lines of a high-pressure mercury arc. The light intensity (I^0) was determined by potassium ferrioxalate actinometry[22] to be 1.42×10^{-6} mol/cm^{2}min. Sample solutions placed in cuvettes (10 mm × 10 mm × 45 mm) were irradiated by the 313 nm light, and the decrease in the absorbance at 307 nm (κcd) was monitored in order to determine the quantum yields for the disappearance of α-NN (ϕ_{-A}). When natural logarithms of ($e^{\kappa cd}-1$) were plotted against the time (t, min), straight lines were obtained. The quantum yields (ϕ_{-A}) were obtained from the slopes of the lines by applying

this equation; $\ln(e^{\kappa cd}-1)=-1000\phi_{-A}I_0t+$ Constant, where κ is the molar extinction coefficient at 307 nm (5.39×10^3 l/mol cm).

Photochemical Reaction in Preparative Scale. a) The photochemical reaction of α-NN with methyl vinyl ether will be described as a typical run, since the procedures were identical in every case. The results of the elemental analyses of the adducts **1**—**4** are listed in Table 4. A methanolic solution (300 ml) containing 1 g of α-NN and 20 ml of methyl vinyl ether in a Pyrex doughnut-type vessel was irradiated for 20 hr with a high-pressure mercury arc at an ambient temperature. The unreacted vinyl ether and methanol were then distilled off *in vacuo*, and the residue was chromatographed on silica gel. After 0.1 g of α-NN had been eluted with a mixture of benzene (30%) in hexane, elution with 300 ml of benzene gave *ca.* 1 g of **1a** containing a small amount of **2a**, which solidified on standing overnight; it was recrystallized from methanol (mp 86—87°C). Further elution with benzene gave a mixture of **1a** and **2a** (0.1 g).

b) In a similar manner, a benzene solution containing 1 g of α-NN and 15 ml of methyl vinyl ether was irradiated for 15 hr. After the unchanged vinyl ether and benzene had been distilled off *in vacuo*, the residue was heated at 180—200°C for 20 min; the subsequent vacuum distillation of the pyrolysate gave an oil (bp 105—113°C/10^{-3}mmHg). The chromatographic treatment of the oil on silica gel gave 0.2 g of α-NN and 0.4 g of a mixture containing **2a** and a small amount of **1a**. The further chromatography of the latter fraction led to a decrease in the content of **1a** to a trace amount. The vacuum distillation of this fraction gave an oil (bp 102°C/10^{-3}mmHg), which did not solidify, even on storage in a refrigerator.

Hydrogenated Adducts, 3 and 4. An ethanolic solution containing 0.2 g of **1a** and **2a** was hydrogenated over Pd-charcoal (5%) at an ambient temperature for 2 hr. The complete hydrogenation was checked by vpc analyses. The filtration of the Pd-charcoal, followed by the evaporation of the ethanol, left an oil, which was then chromatographed on a short column of silica gel. In the case of **4**, it solidified on storage in a refrigerator overnight and was then recrystallized from methanol (mp 65—65.5°C). On the other hand, **3** did not solidify, even on storage in a refrigerator over several weeks.

Pyrolyses of 1a and 2a. The pyrolyses of crystalline **1a** (0.1 g) at 180—200°C for 1 hr gave a brownish glassy material, which was then chromatographed on silica gel. Elution with 500 ml of benzene gave less than 50 mg of α-NN; further elution with a mixture of ether and benzene (1: 9) afforded brownish glassy materials which could not be identified. Pyrolyses of **2a** at 250—260°C gave similar results, while heating at 180—200°C resulted in no appreciable change in the **2a**.

Photolyses of 1a and 2a. A methanolic or benzene solution of **1a** or **2a** (0.1 g/4 ml) in a Pyrex tube was irradiated with a high-pressure mercury are for 20 hr. During the course of the irradiation, vpc analyses of the photolysate were carried out at 1 hr intervals for the initial 5 hr; it was found that α-NN increased linearly with the disappearance of the adduct. Irradiation for about 10 hr resulted in the complete decomposition of the adduct, and further irradiation for 10 hr gave no additional change. After the irradiation, removal of a solvent left a solid, which was identified as α-NN by studing its IR, and mass spectra, and by a mixed-melting-point determination.

The authors wish to express their hearty thanks to Professor Masaharu Kawanishi and Dr. Naruhiro Owaki, The Institute of Scientific and Industrial Research, Osaka University, for their useful advice and kind guidance in determining the decay life of the fluorescence of α-NN with a TRW nsec spectrophotometer.

Studies of Organosulfur Compounds. IX. The Preparation of Organometal IVb Esters of Aromatic Thio Acid

Shinzi KATO, Wataru AKADA, Masateru MIZUTA, and Yoshio ISHII*

Faculty of Engineering, Gifu University, Kagamihara, Gifu

(Received May 1, 1972)

It was found that the reactions of potassium salts of aromatic thio acid with chlorotrimethylsilane gave the corresponding thionoacyloxysilanes [$ArC(S)OSi(CH_3)_3$]. On the other hand, the reactions with chlorotrimethylgermanes or -stannane gave the corresponding thiol esters [$ArC(O)SM(CH_3)_3$, M: Ge, or Sn] containing the sulfur-metal (IVb) linkage in almost quantitative yields.

During the last decade, a number of reports[1-3] of organometallic sulfur compounds containing silicon, germanium, tin, and lead have been published. However, there have been very few reports[4-6] on any compounds containing the ≡M–S–CO–C≡ (M: IVb element) linkage except the tin compounds; further, many of the reported compounds (mainly tin compounds) have been described in patents [7g-r] without any characterization or description of their physical constants.

In this paper, the results of the reactions of potassium salts of aromatic thio acid with trimethylmetal IVb chlorides will be disclosed in the expectation that the corresponding thiolacyloxy-sialnes, -germanes, and -tins will be obtained.

Results and Discussion

When an equimolar amount of chlorotrimethylsilane was added to a suspension of potassium thiobenzoate in petroleum ether; the color of the reaction mixture changed from colorless to yellow, the subsequent vacuum distillation of the petroleum ether soluble parts gave orange yellow oil with a definite boiling point in almost quantitative yields. Surprisingly, the IR spectrum of this oil showed no absorption band of ν C=O; instead, the absorption bands at 1590 (ν C=C, aromatic), 1250 (δ CH_3, scissoring), 1238 (ν C=S), and 953 cm^{-1} (δ CH_3, rocking) were observed. The NMR peaks appeared at 9.54 τ ($SiCH_3$, s, 9H) and 1.90—3.20 τ (aromatic, m, 5H). In the visible spectrum, the maximum band at 437 mμ (ε 75) was observed. These results, together with the analytical results, indicate that the liquid is thionobenzoyloxylsilane with the Ic structure (Eq. (1)). By the similar treatment of other

$$C_6H_5\overset{O}{\overset{\|}{C}}S^-K^+ + (CH_3)_3SiCl \xrightarrow[-KCl]{rt} C_6H_5\overset{S}{\overset{\|}{C}}OSi(CH_3)_3 \quad (1)$$
Ic

substituted potassium thiobenzoates with chlorotrimethylsilane, the corresponding thionobenzoyloxysilanes were obtained in excellent yields, as is shown in Table 1. Gornowicz and Ryan[8] reported two methods for the preparation of thionoacyloxysilanes (Eqs. (2) and (3)).

$$[(CH_3)_3Si]_2NH + 3CH_3\overset{O}{\overset{\|}{C}}SH \longrightarrow 2(CH_3)_3SiO\overset{S}{\overset{\|}{C}}CH_3 + (NH_4)^+(AcS)^- \quad (2)$$

$$Ph_3SiCl + PhC(O)SH \xrightarrow{Et_3N} Ph_3SiO\overset{S}{\overset{\|}{C}}Ph + Et_3N\cdot HCl \quad (3)$$

However, the method reported in this paper is more useful than the method in the literature them because we could avoid using thio acids, which are generally unstable and unpleasant to work with.

The formation of the thion esters (I) might be derived from the strong affinity of silicon to the oxygen atom.

Contrary to the reactions with chlorotrimethylsilane, potassium thiobenzoate reacted readily with chlorotrimethylstannane at 45°C to give the expected (benzoylthio)trimethylstannane (IIIg) as a colorless oil in 98% yield (Eq. (4)). The IIIg structure could be

$$C_6H_5\overset{O}{\overset{\|}{C}}S^-K^+ + (CH_3)_3SnCl \xrightarrow[-KCl]{rt} C_6H_5\overset{O}{\overset{\|}{C}}SSnMe_3 \quad (4)$$

assigned by elemental analysis and spectral data: intensive absorption bands at 1631 (ν C=O) and 775 cm^{-1} (δ $SnCH_3$) in the IR spectrum, and at 9.43 τ (Sn–CH_3, s, 9H), 1.98—2.50 τ (aromatic, m, 5H), $J_{^{119}Sn-C-H}=59$ Hz, $J_{^{117}Sn-C-H}=56$ Hz in NMR spectrum. The analogous treatment of other potassium-substituted thiobenzoate with chlorotrimethylstannane gave the corresponding (benzoylthio)trimethylstannanes (IIIa—f and h—l) respectively in quantitative yields (Table 2). The formation of the stannyl esters, III, can be explained by the strong affinity of tin to sulfur atom.

The results obtained above encouraged us to investigate the reactions with chlorotrimethylgermane, bacause germanium is situated between silicon and tin in the peridical table. However, the analogous treatment of potassium thiobenzoate with chlorotrimethylgermane gave (benzoylthio)trimethylgermane (IIg)

$$C_6H_5\overset{\overset{O}{\|}}{C}SK + (CH_3)_3GeCl \xrightarrow[-KCl]{rt} C_6H_5\overset{\overset{O}{\|}}{C}SGe(CH_3)_3 \quad (5)$$
IIg

(Eq. 5). The IIg structure was established by elemental analysis and studies of the IR and NMR spectra. In the IR spectrum, intensive absorption bands at 1648 (ν C=O) and 829 cm^{-1} (δ $GeCH_3$) were observed. The NMR spectrum showed peaks at 9.33 τ ($GeCH_3$, s, 9H), and 1.00—2.78 τ (aromatic, m, 5H). By the analogous treatment of other potassium-substituted thiobenzoates with chlorotrimethylgermane, the corresponding (benzoylthio)trimethylgermanes (IIa—f and h—l) were obtained in excellent yields (Table 3). Germanium would be considered to have a higher affinity to the sulfur atom rather than the oxygen atom.

The silyl thion esters (I) thus obtained were readily hydrolyzed by moisture in air to give hexamethyldisiloxane and the corresponding thiobenzoic acid in almost quantitative yields. However, the germyl thiol esters (II) were fairly stable against moisture and were very slowly hydrolyzed to give hexamethyldigermoxane and the corresponding thiobenzoic acid. On the other hand, the trimethylstannyl thiol esters (III) were a very stable oil or crystals which could be recrystallized

from alcohols.

Spectral Data. *a) IR Spectra*: The IR spectra of thionobenzoyloxy trimethylsilane (Ic), (benzoylthio)-trimethylgermane (IIg), and -stannane (IIIg) are shown in Fig. 1 as typical examples. Bak *et al.*[9] reported that the two frequencies (*ν* C=S and C–S) obtained by a simplified force constant calculation must be looked for in the vicinity of 1200 (C=S) and 700 cm^{-1} (C=S), and that the absorption bands of the C=S band in a series of twenty-one carboxymethyl-dithio esters were observed between 1190—1225 cm^{-1}. Bellamy and Rogasch[10] have reported some results of dithio acid in a variety of solvents. The silyl esters (II) obtained showed necessarily two characteristic strong absorption bands near 1280 and 1240 cm^{-1} on both sides on the absorption band at 1250 cm^{-1} (δ $SiCH_3$). However, it is difficult to assign the former band to the *ν* C=S band because it is situated at a far higher frequency. Further, no the absorption band around 1240 cm^{-1} on (selenobenzoyloxy)trimethylsilane[11] was observed. For these reasons, the absorption band near 1240 cm^{-1} may be considered to be due to the

C=S stretching band on the silyl esters (I). This result also fits well with the assignment given by Bak *et al.*[9] and Bellamy.[10] In Table 4 the IR absorption bands at near 1240 cm^{-1} are shown.

Gilman and Lichtenwalter[4] reported that the ν C=O of (benzoylthio)triphenylsilanes appeared at 1690 cm^{-1}. The ν C=O values of the obtained trimethylgermyl (II) and -stannyl esters (III) were observed in the 1645—1677 and 1612—1645 cm^{-1} ranges respectively. These results indicate that the ν C=O on the esters with a ≡M–S–CO–C≡ linkage (M: Metal IVb) would have a lower frequency shift with an increase in the atomic number of the metal (IVb). These lower frequency shifts are probably caused by either the heavy atomic effect or the higher electron donating properties of IVb elements.

b) UV and Visible Spectra: The absorption spectra of (thionobenzoyloxy)trimethylsilane (Ic), (benzoylthio)trimethylgermane (IIg), and stannane (IIIg) are reproduced in Fig. 2, along with the absorption maxima (λ_{max}) in Table 4. As is shown in Fig. 2 and Table 4, (thionobenzoyloxy)trimethylsilanes have three cha-

racteristic maximum bands at 240—260 (ε 5000—10000), 288—305 (ε 7000—15000), and 426—443 mμ (ε 75—230). The former two bands may be ascribed to $\pi \rightarrow \pi^*$ with the latter are $n \rightarrow \pi^*$ transitions of the thiocarbonyl group. On the other hand, the (substituted-benzoylthiotrimethyl)germanes and -stannanes except for those with substituents in the *ortho* position and with a methoxy group in the *para* position, all showed two characteristic maximum absorption bands at 240—260 and 260—290 mμ with of molecular extinction coefficients over 8000.

Experimental[12)]

Materials. The potassium salts of substituted thiobenzoic acid were prepared by the method described by the literature;[13)] the chlorotrimethylsilane was distilled before use. Chlorotrimethylgermane[14)] and -tin[15)] were prepared similarly.

All the reactions were carried out under nitrogen. Some typical procedures are shown below, while the data are summarized in Tables 1—4.

Reaction of Potassium Thiobenzoate with Chlorotrimethylsilane. An equimolar amount of chlorotrimethylsilane was added to a suspension of 1.77 g (0.01 mol) of potassium thiobenzoate in petroleum ether (bp below 45°C), after which the mixture was stirred for 15 min at room temperature. After the removal of the insoluble parts by filtration, the evaporation of the solvent from the filtrate and the vacuum distillation of the residue gave 2.0 g of (benzoylthio)trimethylsilane (Ic).

Reaction of Potassium Thiobenzoate and Chlorotrimethylgermane. A solution of an equimolar amount of chlorotrimethylgermane (1.70 g, 0.011 mol) and potassium thiobenzoate in petroleum ether (bp below 45°C) (10 ml) was stirred for 1 hr at room temperature. After the insoluble parts were filtered, the vacuum removal of the solvent and the excess of chlorotrimethylgermane gave 2.37 g of chemically pure (benzoylthio)trimethylgermane (IIg).

Reaction of Potassium p-*Nitrothiobenzoate and Chlorotrimethyltin.* A solution of an equimolar amount of chlorotrimethyltin (2.08 g, 0.01 mol) and potassium *p*-nitrothiobenzoate (2.22 g, 0.01 mol) in petroleum ether (bp below 45°C) was refluxed for 1 hr. After the separation of the insoluble parts and the solvent, the recrystallization of the residue from ether–*n*-hexane gave 3.6 g of (*p*-nitrobenzoylthio)trimethyltin (IIIa) as colorless crystals.

The Polymerization of Vinyl Monomers in the Presence of Surface Active Agents. III. The Rate of the Polymerization of Styrene

Teruzo ASAHARA, Manabu SENŌ, Shinsaku SHIRAISHI, and Yoshikazu ARITA

Institute of Industrial Science, University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received May 1, 1972)

Styrene polymerized in the presence of sodium tetrapropylenebenzenesulfonate in an aqueous system without any ordinary initiators. The rate of the polymerization was dependent on the concentration of the surfactant and on the initial monomer concentration. The apparent activation energy of the polymerization was about 13.9 kcal/mol. The polymerization was inhibited by adding hydroquinone to the reaction system.

Imoto and Takemoto[1] have reported the homo- and graft polymerization of methyl methacrylate (MMA) onto fibers with hydroxylic pendant groups, especially onto cellulose. In their paper, they have also described that styrene (St) polymerized only with difficulty under the same reaction conditions. We ourselves have previously reported that the polymerization of MMA in the presence of anionic surface active agents, such as sodium tetrapropylenebenzenesulfonate and 2-dodecylbenzenesulfonate, in an aqueous system without any ordinary initiators gave a stable emulsion of poly(methyl methacrylate) (PMMA) with an unusually high molecular weight, and that the resultant polymer was recovered in a good yield.[2,3] During the course of the investigation, we found that styrene also polymerized in the presence of sodium tetrapropylenebenzenesulfonate about three times or more as much as in the case of MMA in an aqueous medium.

In this paper, we will describe the kinetic study of the polymerization of styrene; we will also consider the reaction in some detail.

Experimental

Materials. Styrene and acrylonitrile (AN) were purified by usual methods. Sodium tetrapropylenebenzenesulfonate (ABS) was purified according to the procedure described in our previous paper.[2]

Polymerization. In a four-necked, 100 ml, flat-bottomed flask equipped with a condenser, a dropping funnel, a nitrogen inlet tube, and a rubber stopper, given amounts of deionized water and ABS were placed; the mixture was then preheated to the reaction temperature (80°C except otherwise stated) for 40 min, during which period a slow stream of nitrogen was introduced into the mixture. A definite amount of a monomer was then added to the mixture through the dropping funnel and allowed to polymerize. For a kinetic experiment, 2 g portions of the reaction mixture were withdrawn by means of a syringe at definite time intervals, weighed accurately, and poured into 10 ml of methanol in order to precipitate the polymer formed. The polymer was collected by filtration, thoroughly washed with methanol, dried at 60°C under a vacuum, and weighed. The rate of polymerization was determined from the time-conversion curves. The molecular weight, $\overline{M}$, of the polystyrene thus obtained was determined from the intrinsic viscosity, $[\eta]$, by using this equation:[4]

$$[\eta] = 1.2\times10^{-5}\,\overline{M}^{0.71}.$$

The viscosity of the polymer solutions in toluene was measured according to an ordinary method at 30°C.

Determination of Number of Particles. For particle-size determination, a sample of about 1 g was taken from the reaction mixture and diluted 10 times by water containing 0.01% of hydroquinone to minimize any further change. It was deposited onto a collodion substrate in minute droplets approximately 2 microns in radius. The specimen was directly photographed by using a JEM-5Y electron microscope of 9800 magnification at 80 kV. A photograph was enlarged in length as much as 2 times. The diameter of the particles was measured by a Scale Lupe of 5 magnification on 50 to 100 particles on the enlarged photograph, and the average diameter was calculated. The number of particles in the reaction mixture was calculated from the average diameter and the density of the particles, which was approximated as 1.0.

Results and Discussion

As has been reported previously,[2] we have found that MMA polymerized in the presence of ABS in an aqueous system without any ordinary initiators. The initiation mechanism, however, has not yet been elucidated. Knowledge of whether or not this polymerization technique is applicable to other monomers may throw some light on the problem; thus, we attempted the polymerization of St in a manner similar to that used for MMA. It was found that St polymerized in an aqueous system in the presence of ABS as much three times or more as in the case of MMA. The polymerization reaction of St was inhibited by adding hydroquinone. This result shows that the polymerization reaction of St proceeds *via* a free radical mechanism.

The relationship between the rate of polymerization of St and the concentration of ABS was investigated. As is shown in Fig. 1, an approximately linear relation was found between the rate of polymerization, R_p, and the ABS concentration, [ABS], in the range studied.

$$R_p \propto [\mathrm{ABS}] \qquad (1)$$

Equation (1) did not agree with either the equation of the polymerization of MMA or that of the Smith-Ewart theory, but it was consistent with the equation

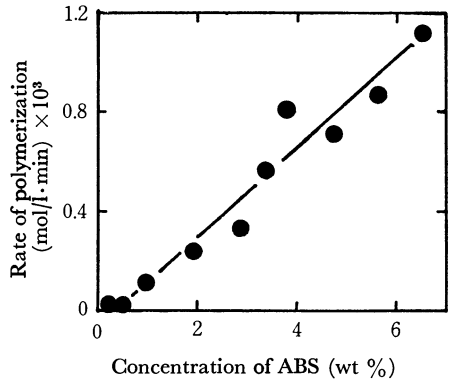

Fig. 1. Dependence of polymerization rate (mol/l·min) on ABS concentration (wt%).

of Medvedev,[5] as will be shown below.

Medvedev argued that the surface area was the most important parameter of the emulsion polymerization and developed a kinetic expression; in which R_P was proportional to the emulsifier concentration when primary radicals were formed in adsorbed emulsifier layers.

Therefore, the surface area may in a sense be one of the important parameters of the present polymerization system. Furthermore, the number of micelles may be considered to be another important parameter,because the number of micelles increases with an increase in the ABS concentration. Supposing that the radicals are generated only on the surface of the micelle, the number of radicals may increase with an increase in the number of micelles in our system.

In the case of AN, the polymerization did not occur even at higher concentration of ABS as is shown in Table 1. The solubility of AN in water, higher than that of St, is responsible for this behavior. This result, together with the fact reported before[2] that the polymerization of MMA did not occur in the medium of organic solvents, suggests that the formation of micelles may be essential for the polymerization in the present system.

Table 1. Polymerization of acrylonitrile

ABS (g)	AN (g)	Temp. (°C)	Time (hr)	Yield (%)
1.0	10.0	80	2	0
1.0	10.0	70	2	0
1.0	20.0	70	3	trace

3.0	10.0	75	2	0

water 100 g; under nitrogen atmosphere.
a) water 90 g and benzen 10 g under nitrogen atmosphere

The number of polymer molecues was calculated from the yields and the molecular weights of the polymers. The effects of the concentrations of ABS and St and of the reaction temperature on the number of polymer molecules are shown in Figs. 2 and 3 and in Table 2. It was noticeable that the number of polymer molecules increased with an increase in the concentration of ABS and a rise in the reaction temperature, but were nearly independent of the concentration of the monomer in the range above 1.5 mol%. This result suggests that the number of initiation species increased with an increase in the concentration of ABS and the reaction temperature.

Table 2. Effect of reaction temperature on polymerization rate, *DP* and number of polymer molecules

Reaction temperature (°C)	Polymerization rate (mol/l·min) ×10³	*DP* ×10⁻⁴	Number of polymer molecules (ml^{-1}) ×10⁻¹⁵
70	0.74	4.22	1.04
80	1.14	2.82	2.43
85	1.14	2.44	2.76
90	2.30	2.61	5.16
100	3.50	2.20	11.3

St 10g/100g aqueous phase, ABS 1wt% under nitrogen atmosphere.

The reaction mixture was observed by means of an electron microscope, and the particle sizes were determined at reaction times of 30, 60, and 120 min at ABS concentrations of 1 and 3 wt%. The results are shown in Table 3. The particle sizes were nearly constant, most of them lying in the range from 300 to 400 Å, independent of the concentration of ABS and the reaction time. The maximum particles were from 1000 to 1200 Å in size, and new particles with smaller radii appeared at each reaction time, as is shown in Fig. 4. The number of polymer particles per unit of volume was about 1×10^{15}, which is of the same order as the number of polymer molecues esti-

mated previously. These results can be explained from the following considerations. The loci of the polymerization reaction are the interfaces between the micelles and the continuous medium; the radicals generated at the interface enter into the micelle, and hence the polymerization occurs.

By assuming that one polymer is formed in one micelle, the number of micelles can be calculated by:

$$N = (W/\bar{M}) \times 6 \times 10^{23},$$

where W is the yield of the polymer in grams and where $\bar{M}$ is the average molecular weight of the polymer.

The number of particles was about $(0.7 \text{ to } 4.0)\times 10^{15}$ ml^{-1} of the solution; this value was of the same order as in the general emulsion polymerization.[6]

From the above discussion, it can be concluded that the formation of micelles is an important factor in the generation of radicals and that the radicals do not enter into the particle from the water phase, but are generated only in the micelle. The ABS concentration was thought to be a factor in the production of radicals, and it was quantitatively understood that the relationship between the ABS concentration and the number of polymer particles was linear.

The rate of emulsion polymerization was usually independent of the initial monomer concentration and proportional to the monomer concentration in the polymer particles or micelles, but in our system the relationship between the rate of polymerization and the initial monomer concentration, $[M]_0$, defined in mol% calculated from the composition in the initial reaction mixture, was as is shown in Fig. 5. The dependence of R_p on $[M]_0$ was more remarkable than in the case of MMA. The apparent relationship can be written by:

$$R_p \propto [St]_0^{0.64}.$$

However, the dependence of R_p on the initial monomer concentration was small compared with that on the ABS concentration, as R_p may be considered to be almost independent of the initial monomer concentration in the range above 0.85 mol%, as is shown in Fig. 5.

These results may be well understood by suposing the following relation:

$$R_p \propto [M]_0[ABS]/([M]_0+[ABS]).$$

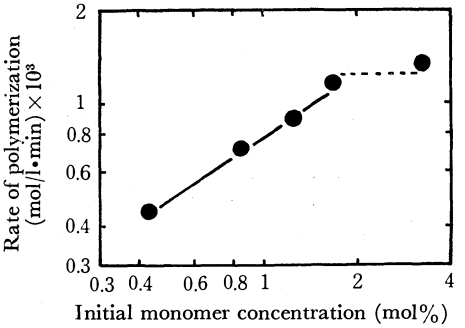

Fig. 5. Dependence of polymerization rate (mol/l•min) on initial monomer concentration (mol%).
ABS 1 wt%, 80°C under nitrogen atmosphere.

6) P. J. Flory, "Principles of Polymer Chemistry" Princeton Univ. Press (1953), p. 215.

When the experiment is conducted under the condition of $[M]_0 \gg [ABS]$, R_p is apparently expressed by $R_p \propto [ABS]$. On the other hand, when [ABS] is constant, R_p is almost constant in the range of $[M]_0 \gg [ABS]$, but R_p is slightly dependent on $[M]_0$ in the range where $[M]_0$ is not sufficiently larger than [ABS]. This explains the apparent relationship of $R_p \propto [St]_0^{0.64}$. The plot of R_p *vs.* $[ABS]/([M]_0+[ABS])$ also gave a straight line (Fig. 7); this shows a better linearity than the plot of R_p *vs.* [ABS].

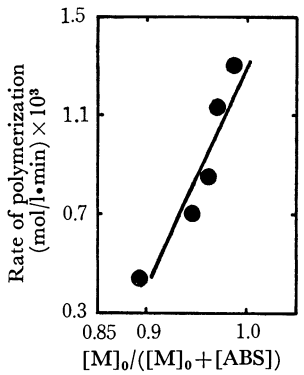

Fig. 6. Dependence of polymerization rate (mol/l•min) on $[M]_0/([M]_0+[ABS])$
ABS 1 wt%, 80°C under nitrogen atmosphere.

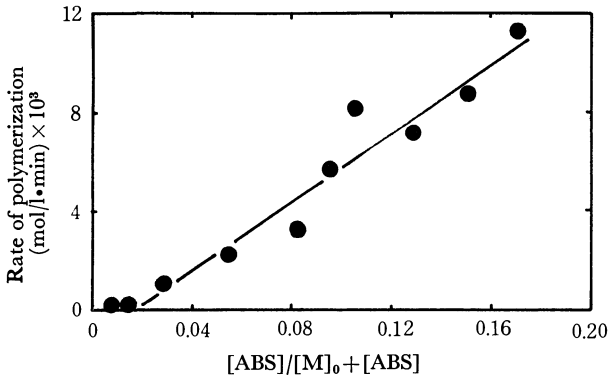

Fig. 7. Dependence of polymerization rate (mol/l•min) on $[ABS]/([M]_0+[ABS])$
St 10 g/aqueous phase 100 g, 80°C under nitrogen atmosphere.

From the relation between the polymerization rate and the reaction temperature shown in Table 2, the activation energy was calculated to be about 13.9 kcal/mol. This value is somewhat smaller than that of ordinary radical polymerization.

The average degree of polymerization, *DP*, calculated from the intrinsic viscosity was plotted against the ABS concentration, the initial monomer concentration, and the reaction temperature. As is shown in Figs. 2, 3, and 8, *DP* increases with an increase in the ABS concentration, and it is nearly independent of the concentration of the monomer, but decreases with the rise of the reaction temperature. *DP* is expressed by:

$$DP = R_p/(R_t+R_{tr}) = R_p/R_i$$

where R_p, R_t, R_{tr}, and R_i are the rates of the propagation reaction, the termination reaction, chain transfer to the monomer, and the initiation reaction respectively. Therefore, the activation energy derived from the temperature dependence of the *DP*, E_{DP}, is expressed as

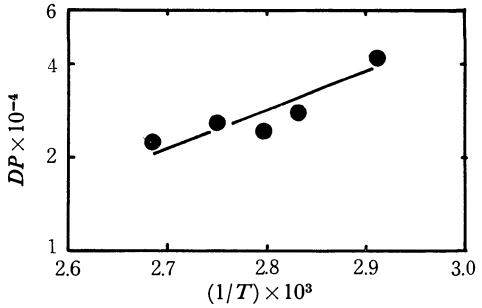

Fig. 8. Dependence of *DP* on $1/T$.
St 10 g/aqueous phase 100 g, ABS 1 wt%, 2 hr, under nitrogen atmosphere.

follows:

$$E_{DP} = E_p - E_i,$$

where E_p and E_i are the activation energies of propagation and initiation respectively. In general, E_i is larger than E_p, and therefore *DP* decreases with a rise in the reaction temperature, as is shown in Fig. 8. As is shown in Fig. 8, the activation energy of *DP* was calculated to be about −5.2 kcal/mol. On the other hand, the E_p of the emulsion polymerization of St was found by Morton[7] to be 7.4 kcal/mol. Using the values of E_{DP} and E_p mentioned above, E_i was calculated to be 12.6 kcal/mol, which is considerably smaller than those values found for the thermal polymerization or polymerization by radical initiators. The reason for the difference is not clear, but it may be attributed to the effect of the surfactant added to the polymerization system. Hohenstein and Mark investigated the polymerization of St in the presence and in the absence of soap; they found that, in the case of emulsion polymerization by potassium persulfate, E_i is about 17 kcal/mol, about 8 kcal/mol smaller than the value in the case of polymerization without soap.[8]

If this value, 8 kcal/mol, is applied to our system, the activation energy of the initiation of St in the absence of soap is 20.6 kcal/mol, which almost agrees with the activation energy of the thermal initiation of the St polymerization calculated by Tobolsky.[9]

It has been shown that, in the case of thermal and radical polymerization, the overall activation energy, *E*, can be calculated by the following equation:[10]

$$E = (1/2)E_i + [E_p - (1/2)E_t],$$

where E_t is the activation energy of termination. By this equation, $[E_p-(1/2)E_t]$ is calculated to be 7.6 kcal/mol because *E* is calculated to be 13.9 kcal/mol, as has been mentioned above. This value agrees with Tobolsky's value of about 6.3 kcal/mol,[11] which was found for the ordinary radical polymerization of St.

The authors are indebted to Mr. Toshihiro Shibata for his helpful technical assistance.

(Received May 16, 1972)

In order to elucidate the effect of basicities of amidines on their reactions with 2-dimethoxymethyl-3-methoxypropiononitrile (**1**), the reaction of **1** with benzamidine was studied. Products are similar to those from the reaction of **1** with acetamidine. The minor pathway in the reaction with acetamidine (Route B in Chart 1) was the major one in the reaction with benzamidine. This remarkable difference could be explained in terms of the electronic effect of 2-substituents of the intermediates (**4a** and **4b**) in both reactions and of basicities of acetamidine and benzamidine.

α-Formylpropiononitrile derivatives,[3] *e.g.*, 2-dimethoxymethyl-3-methoxypropiononitrile (**1**) and 2-dimethoxymethylacrylonitrile (**2**), are important building blocks for heterocyclic compounds.[4,5] When treated with acetamidine, **1** and **2** afford 2,7-dimethyl-5,6-dihydropyrimido[4,5-*d*]pyrimidine (**8a**), which is an important intermediate for thiamine since it is easily hydrolyzed to 2-methyl-4-amino-5-acetamidomethylpyrimidine (**9a**).[4] In previous papers we proposed a detailed pathway for the reactions as shown in Chart 1.[1,6] The pathway involves the major process **1**→**2**→**3a**→**4a**→**5a**→**6a**→**7a**→**8a** and minor ones **1**→**13**→**14a** and **6a**→**10a**→**11a** (=**8a**). Among the proposed intermediates, the key intermediate **4a** was successfully isolated in a fairly good yield but the others were not under usual reaction conditions.[1] To extend the scope of these reactions, the reaction of **1** with benzamidine was attempted. Since the basicities of reaction media were thought to play an important role for some steps of the reaction,[1] studies with less basic benzamidine[7] seemed necessary.

The reaction of **1** with benzamidine is expected to

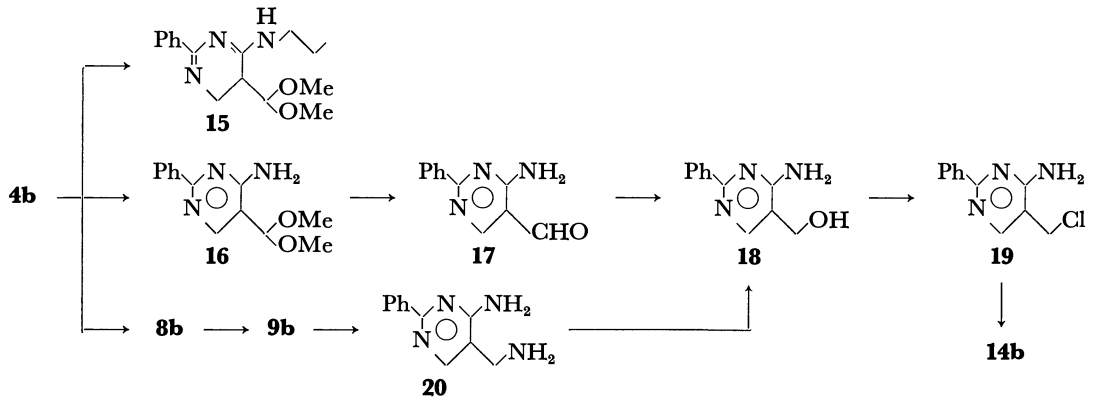

Chart 2.

proceed *via* the same pathway as that with acetamidine. When **1** with benzamidine was heated in methanol at 40°C for 6 hr, three products, **4b** (11%), **8b** (2.5%), and **10b** (6.8%), were obtained along with the recovery of 68% of **1**.

Compound **4b** showed an absorption band similar to that of 2-phenyl-4-amino-5,6-dihydropyrimidine in the UV spectrum.[6,8] **4b** was therefore tentatively characterized as 2-phenyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine, which corresponds to **4a**. The NMR spectrum supported the structure; *viz.*, it showed the signals of an ABXY system, in which H_6 and $H_{6'}$ constitute an AB part, H_5 an X part, and the methine proton of the acetal group a Y part, and of a 6-proton singlet due to two methoxy groups. When treated with *n*-propylamine, **4b** was easily converted into 4-*n*-propylamino analog of **4b** (**15**). This facile transamination suggested the existence of 4-aminodihydropyrimidine moiety.[1]

Unequivocal proof of the structure of **4b** was provided by its conversion into 2-phenyl-4-amino-5-methoxymethylpyrimidine (**14b**), an authentic sample of which was obtained from **13** and benzamidine in a way similar to the preparation of **14a** from **13** and acetamidine.[9] Treatment of **4b** with chloranil gave a pyrimidine (**16**), which was readily hydrolyzed to 5-formylpyrimidine (**17**). Reduction of **17** with sodium borohydride yielded 5-hydroxymethylpyrimidine(**18**), which was converted into **14b** *via* a 5-chloromethyl compound (**19**). The spectral and elementary analytical data supported the presence of the above intermediates **16**, **17**, and **18**.

The pathway **1**→**2**→**3b**→**4b**[1,6] was supported by the isolation of **4b**. When **2** was treated with benzamidine in 1,2-dimethoxyethane, the formation of **3b** was confirmed at the initial stages of the reaction. Although **3b** could not be isolated in a pure state because of its rapid cyclization to **4b**, its structure was supported by the IR and UV spectra which showed the presence of non-conjugate nitrile[1,6] and benzamidino groups.

Compound **8b**, $C_{18}H_{14}N_4$, showed the absorption maximum at 350 nm in the UV spectrum. It was also obtained by the further reaction of **4b** with benzamidine. Thus, **8b** should be the final product corresponding to **8a**. Hydrolysis of **8b** gave **9b**, which was further hydrolyzed to 2-phenyl-4-amino-5-aminomethylpyrimidine (**20**). Treatment of **20** with sodium nitrite gave the above-described 5-hydroxymethylpyrimidine **18**. These series of reactions and the NMR spectrum supported the structure of **8b**.

Compound **10b**, which gave a correct analysis for **8b** plus one mole of ammonia, was easily converted into **11b** (=**8b**) on heating and showed an absorption band similar to that of **9b** in the UV spectrum. Thus, **10b** was confirmed to be 2-phenyl-4-amino-5-benzamidinomethylpyrimidine corresponding to the intermediate of the minor pathway (Route B in Chart 1) in the reaction of **1** with acetamidine.

Formation of **8b** suggests that the second step of the reaction **4b**→**8b** also proceeded *via* the same pathway as that of the reaction with acetamidine **4a**→**8a**. However, it was somewhat surprising that the yield of **10b**, *viz.*, the contribution of Route B (see Chart 1), was much higher than in the case of the reaction of **1** with acetamidine.

To obtain the contribution ratio of Routes A (**6**→**7**→**8**) to B (**6**→**10**→**11**), the reaction of **4b** and *p*-toluamidine was examined. Treatment of **4b** with *p*-toluamidine in methanol followed by hydrolysis afforded a mixture of 2-phenyl-5-*p*-toluamidomethyl- (**12c**) and 2-*p*-tolyl-5-benzamidomethyl-4-aminopyrimidine (**9c**). The former pyrimidine **12c** was the product *via* Route B and the latter **9c** *via* Route A. Their structures were identified by comparison with those of authentic samples. The authentic **12c** was prepared by the reaction of **20** with *p*-toluchloride and **9c** by the reaction of **1** with *p*-toluamidine as outlined in Chart 3.

a) Containing a samll amount of sodium methoxide, since exact neutralization of the hydrochlorides of **4** and amidine was difficult.

The B/A ratio in the reaction of **4b** with *p*-toluamidine was determined by the integration of the respective singlets due to the methyl groups of *p*-tolyl moieties of **12c** and **9c** in the NMR spectrum of the product. The results are summarized in Table 1. The maximum yield of total pyrimidines was observed in the presence of some amount of benzamidine hydrochloride. On the other hand, the contribution of Route B increased with the decrease of the amidine hydrochloride; Route B became a major pathway in the absence of the hydrochloride. These interesting results prompted us to reinvestigate the reaction of **4a** with propioamidine under similar conditions. The ratio of two products, **12f** *via* Route B and **9f** *via* Route A, was determined by means of gas chromatography. The results are shown in Table 1. The maximum yield of total pyrimidines **12f** and **9f** was similarly observed in the presence of a similar amount of amidine hydrochloride, and the relative ratio of Route B increased with the decrease of the amidine hydrochloride. However, the contribution of Route B, *i.e.* the yield of **12f**, was always very low.

The remarkable contribution of Route B in the reaction of **4b** with benzamidines as compared with the reaction of **4a** with acetamidines can be explained in terms of the electronic effect of 2-substituents of possible intermediates **6a** and **6b**, and of the basicities of amidines.

The reactions of **4a** with benzamidine and of **4b** with acetamidine were carried out. Hydrolyzed products from the former reaction were **12d** (=**9e**) *via* Route B and **9d** (=**12e**) *via* Route A, and from the latter **12e** (=**9d**) *via* Route B and **9e** (=**12d**) *via* Route A. The structure of **9d** (=**12e**) was identified by its conversion into **9b** and that of **9e** (=**12d**) by comparison with an authentic sample prepared by the benzoylation of 2-methyl-4-amino-5-aminomethylpyrimidine (**24**).[10] The results were similar to those of the reaction of **4a** with propioamidine as shown in Table 1; Route B was always a minor pathway and the maximum yields of total pyrimidines were observed in the presence of suitable amounts of amidine hydrochlorides.

Table 1 shows that the relative ratio of Route B increases with the decrease of amidine hydrochloride. Route B proceeds by the abstraction of C_6 proton (H_6) of a possible intermediate **6** by an amidine base. Thus, it is reasonable that more basic conditions such as the absence of amidine hydrochlorides favors Route B.

For the abstraction of H_6 of **6**, the existence of an electron-attracting group such as the 2-phenyl group is more desirable. This is supported by the fact that the heating of a mixture of one mole each of **4a** and **4b** with sodium methoxide gave **14a** and **14b** in 1 : 10 ratio. The electronic effect can explain the fact that Route B was always minor in the reaction of **4a**. However, the yield of **12e** in the reaction of **4b** with acetamidine being lower than that of **12c** in the reaction of **4b** with *p*-toluamidine cannot be explained. Thus, Route B was expected to be favored in the former reaction since acetamidine is a stronger base than benzamidine.[7]

We considered the difference between the two reactions of **4b** to be caused by the faster cyclization of **6e**→**7e** than of **6c**→**7c**, and examined model reactions **10a**→**11a** (=**8a**) and **10b**→**11b** (=**8b**) for confirmation. Kinetic measurement for the reactions was carried out by following the increases of respective products. They showed first-order kinetics, the rate of **10a**→**11b** being higher than that of **10b**→**11b** at reflux temperature. By analogy, the cyclization of **6e**→**7e** would proceed faster than that of **6c**→**7c**. Therefore, two factors in **6c**, its slow cyclization to **7c** and the higher acidity of its C_6 position, favor Route B in the reaction of **4b** and *p*-toluamidine.

The appearance of maximum in the yields of total pyrimidines in the reaction of **4** and amidines (Table 1) may be accounted for as follows. As amidine hydrochloride catalyzes the elimination of methanol at the step **4**→**5**,[1] a higher concentration of amidine hydrochloride is desirable (see Chart 4). On th other

10) H. Andersag and K. Westphal, *Ber.*, **70**, 2035 (1937); R. Grewe, *Z. Phys. Chem.*, **242**, 89 (1936).

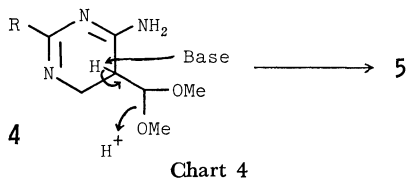

Chart 4

hand, a higher concentration of amidine is required for the step **5**→**6**. When the total amount of amidine and amidine hydrochloride is constant, both requirements can not be satisfied at the same time. Therefore, the maximum in yield appears at an appropriate ratio of amidine and amidine hydrochloride.

In conclusion, the reaction of **1** with benzamidine proceeds *via* the same pathway as that with acetamidine. The yields of the products depend on the amount of amidine hydrochlorides for both reactions. However, Route B, the minor pathway in the reaction with acetamidine, was observed as a major one in the reaction with benzamidine under the reaction conditions. The remarkable difference was essentially caused by the difference in electronic effect between phenyl and methyl groups.

Experimental

All the melting points were recorded on a Kofler block and have not been corrected. The NMR spectra were taken with a Varian A-60-A spectrometer, using tetramethylsilane as an internal reference. The chemical shifts were expressed in terms of δ values (s: singlet, d: doublet, t: triplet, q: quartet, m: multiplet). The molecular weights were determined by means of a vapor-pressure osmometer in acetone. The UV and IR spectra are shown in nm and cm^{-1}, respectively. The solvents used were removed under reduced pressure. The percentages of solutions of base and acid are given in w/w.

Reaction of 2-Dimethoxymethyl-3-methoxypropiononitrile (1) with Benzamidine. A solution of **1** (4.77 g) and benzamidine (3.87 g) in methanol (13 ml) was stirred at 40°C for 6 hr, and then evaporated to dryness. The residue was separated by alumina chromatography (Wakogel; 50 g). After removal of fraction 1 eluted with benzene (50 ml), fraction 2 was eluted with a mixture of benzene (25 ml) and ether (25 ml), and then the solvents were removed. A mixture of crystals, 2,7-diphenyl-5,6-dihydropyrimido[4,5-*d*]pyrimidine (**8b**), and an oil, **1**, was obtained. The crystals (199 mg; 2.5%) were collected by filtration, and **1** (3.8 g; 68%) was recovered from the filtrate. Recrystallization from acetonitrile gave columns of **8b** (35 mg). Fractions 3, eluted with ether (50 ml) and 4, eluted with a mixture of ether (96 ml) and ethanol (4 ml), gave 2-phenyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**4b**) (818 mg, 11%), which was purified by recrystallization from acetonitrile. The yield of pure **4b** was 198 mg (cubics). Fraction 5, further eluted with the above mixture (100 ml), gave 2-phenyl-4-amino-5-benzamidinomethylpyrimidine (**10b**) (570 mg, 6.8%), which was purified by recrystallization from acetonitrile. The yield of pure **10b** was 37 mg (cubics). **8b**: Mp 210.5—211.5°C. UV (CH_3CN) 254 (ε 72800), 312 (ε 13800), 350 (ε 9700). Found: C, 71.61; H, 5.51; N, 22.99%; mol wt, 293. Calcd for $C_{18}H_{17}N_5$: C, 71.26; H, 5.65; N, 23.09%; mol wt, 303.

Reaction of 2-Phenyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (4b). (1) Reaction with n-*Propylamine*: A mixture of **4b** (0.7 g) and *n*-propylamine (7 g) in a sealed tube was heated at 100°C for 2 hr. After evaporation of *n*-propylamine, the residue was recrystallized from benzene. Columns of 2-phenyl-4-*n*-propylamino-5-dimethoxymethyl-5,6-dihydropyrimidine (**15**) were obtained (430 mg). Mp 116—117°C. UV (EtOH) 248 (ε 10800), 281 (ε 7100); (+HCl) 258. 290, 305 (shoulder). IR(KBr) 1110, 1065 (acetal). NMR ($CDCl_3$) 8.2—7.2 (m, 5H, phenyl), 3.43—3.77 (m, 3H, H_5, H_6), 4.35 (d, 1H, J 8 Hz, C<u>H</u>$(OMe)_2$), 3.37 (s, 3H) 3.38 (s, 3H) (CH$(O\underline{Me})_2$), 2.37 (q, 2H, $-HN-C\underline{H}_2-CH_2-$), 1.58 (m, 2H, $-CH_2-C\underline{H}_2-CH_3$), 1.00 (t, 3H, $-CH_2-C\underline{H}_3$), 5.9 (m, 1H, NH). Found: C, 66.53; H, 7.79; N, 14.43%; mol wt, 279.8. Calcd for $C_{16}H_{23}N_3O_2$: C, 66.41; H, 8.01; N, 14.52%; mol wt, 289.4.

(2) Reaction with Benzamidine: (a) A solution of **4b** (1.3 g) and benzamidine (0.7 g) in 1,2-dimethoxyethane (20 ml) was refluxed for 18 hr. The solvent was evaporated to dryness. The residue was recrystallized from methanol to give **8b** (1.14 g, 80%). (b) A solution of **4b** (2.47 g) and benzamidine (1.2 g) in methanol (7 ml) was heated at 50°C for 5 hr. The solution was evaporated to dryness and the residue was recrystallized from benzene to give crude **8b** (600 mg). The mother liquor was evaporated to dryness and the residue was separated by alumina chromatography (Wakogel; 50 g). Fractions 1, eluted with benzene (100 ml), and 2, eluted with a mixture of benzene (45 ml) and ether (5 ml), afforded a mixture of **8b** and **10b** (876 mg). Recrystallization of the mixture from acetonitrile gave **8b** (403 mg). The mother liquor was evaporated to dryness. Recrystallization of the residue gave **10b** (166 mg).

(3) Dehydrogenation: A mixture of **4b** (269 mg) and chloranil (270 mg) in benzene (40 ml) was refluxed for 3 hr and then separated by decantation from the precipitates. The benzene solution was washed with 4% sodium hydroxide solution (20 ml), dried over magnesium sulfate and evaporated to dryness. Recrystallization of the residue from benzene gave 2-phenyl-4-amino-5-dimethoxymethylpyrimidine (**16**) (needles; 35 mg). Mp 117—118°C. UV (CH_3CN) 240 (ε 29400), 260 (shoulder), 282 (ε 12000), 296 (ε 11000); (+HCl) 252. IR (Nujol) 3400, 3240 (NH_2), 1095, 1050 (acetal). NMR ($CDCl_3$) 8.54—7.31 (m, 5H, phenyl), 8.42 (s, 1H, H_6), 6.47 (s, 1H, C<u>H</u>$(OMe)_2$), 3.47 (s, 6H, CH$(O\underline{Me})_2$). Found: C, 63.43; H, 6.30; N, 17.02%; mol wt, 246. Calcd for $C_{13}H_{15}N_3O_2$: C, 63.66; N, 6.16; H, 17.13%; mol wt, 245.27.

2-Phenyl-4-amino-5-formylpyrimidine (17). A mixture of 2-phenyl-4-amino-5-dimethoxymethylpyrimidine (**16**; 485 mg), acetic acid (1.7 g), and water (2.7 ml) was heated at 100°C for 5 min. After cooling, crystals (342 mg) obtained were collected by filtration. Recrystallization of the crystals from methanol gave **17** (needles; 146 mg). Mp 180—180.5 °C. IR (Nujol) 2750, 1670 (CHO). NMR (DMSO-d_6) 7.4—8.5 (m, 5H, phenyl), 8.88 (s, 1H, H_6), 9.94 (s, 1H, CHO). Found: C, 66.20; H, 4.66; N, 20.88%. Calcd for $C_{11}H_9N_3O$: C, 66.32; H, 4.52; N, 21.10%.

2-Phenyl-4-amino-5-hydroxymethylpyrimidine (18). (i) Sodium borohydride (35 mg) was added to a methanol solution (10 ml) of **17** (200 mg), and the solution was stirred at room temperature for 30 min. After subsequent heating at 40—50°C for 30 min, the solvents was removed and the residue was extracted with acetone. The acetone extract was recrystallized from a mixture of acetone and benzene. Plates of **18** (107 mg) were obtained. Mp 134—135.5°C. IR (Nujol) 3440, 3300, 3200 (NH_2, OH). NMR ($CDCl_3$) 8.47—7.33 (m, 5H, phenyl), 8.07 (s, 1H, H_6), 4.60 (s, 2H, $-CH_2-$), 6.47 (2H, NH_2). Found: C, 65.65; H, 5.48; N, 20.71%. Calcd for $C_{11}H_{11}N_3O$: C, 65.67; H, 5.51; N, 20.88%.

(ii) A mixture of crude **20** (1.88 g), concd. hydrochloric acid (980 mg), and water (25 ml) was heated on a boiling-water bath, and sodium nitrite (650 mg) was added to the mixture. After heating for 2.5 hr, an additional amount of sodium nitrite (0.63 g) was added, and the solution was further heated for 2 hr on a boiling-water bath. Resinous substances which appeared were eliminated by decantation, the solution was neutralized with sodium carbonate, extracted with chloroform (150 ml), and then the chloroform was removed. Recrystallization of the residue from a mixture of benzene and acetone afforded **18** (456 mg).

2-Phenyl-4-amino-5-methoxymethylpyrimidine (14b). (i) Under cooling, **18** (402 mg) was added to phosphorous oxychloride (1.224 g) and the solution was heated at 85°C for 3 hr. After cooling, methanol (1 ml) was added to the solution which was left at room temperature overnight. Crystals (**19**) obtained were collected by filtration, and washed with methanol and then with benzene (1 ml). They were dissolved in methanol (3 ml) containing sodium methoxide, which had been prepared from sodium (150 mg) and methanol (5 ml). After being left standing at room temperature overnight, the solution was filtered from precipitated sodium chloride and then evaporated to dryness. Recrystallization of the residue from benzene gave **14b** (leaflets; 63 mg). Mp 130°C. UV (CH_3CN) 238 (ε 21600), 258 (shoulder, ε 14700), 281 (ε 8800), 286 (shoulder, ε 8600), 297 (ε 8300). IR (Nujol) 3480, 3300 (NH_2), 1085 (OMe). NMR ($CDCl_3$) 8.5—7.4 (m, 5H, phenyl), 8.23 (s, 1H, H_6), 4.43 (s, 2H, $-CH_2-$), 3.33 (s, 3H, OMe). Found: C, 66.95; H, 6.05; N, 19.38%; mol wt, 218. Calcd for $C_{12}H_{13}N_3O$: C, 66.95; H, 6.09; N, 19.52%; mol wt, 215.25.

(ii) To a solution of benzamidine (1.5 g) in 1,2-dimethoxyethane (50 ml), **13** (1.5 g)[11] was added in portions. After the solution was refluxed for 4.5 hr, the solvent was removed. Recrystallization of the residue from benzene gave **14b** (1.53g).

Reaction of 2-Dimethoxymethylacrylonitrile (2) with Benzamidine. To a stirred solution of benzamidine (18 g) in 1,2-dimethoxyethane (15 ml), **2** (22.7 g) was added at such a rate, as to keep the reaction temperature below 23°C within about 30 min. The solution was kept at room temperature. After 10 min a spot due to **3b** appeared in the tlc (a silica-gel plate; acetone, R_f 0.9—0.5). Isolation of **3b** in a pure state was unsuccessful. [**3b**: IR (Film) 2280 (non-conjugate CN). UV (CH_3CN) 225 (benzamidine moiety)]. After 1 day, crystals of 2-phenyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**4b**) appeared, which were collected by filtration. Recrystallization from acetonitrile yielded pure **4b** (15.4 g).

2-Phenyl-4-amino-5-benzamidomethylpyrimidine (9b). A mixture of 2,7-diphenyl-5,6-dihydropyrimido[4,5-*d*]pyrimidine (**8b**; 100 mg), potassium hydroxide (180 mg), ethanol (5 ml), and water (0.2 ml) was refluxed for 3 hr, and the solution was evaporated to dryness. The residue was recrystallized from a mixture of water and ethanol to give **9b** (leaflets; 64 mg). Mp 228—229.5°C. UV (CH_3CN) 210 (ε 11700), 298 (ε 12000); (+HCl) 254. IR (Nujol) 1613 (CONH). NMR (DMSO-d_6) 8.42—7.30 (m, 10H, phenyl), 8.17 (s, 1H,H_6), 4.35[s] (2H, $-CH_2-$). Found: C, 69.06; H, 5.21; N, 17.81%. Calcd for $C_{18}H_{16}N_4O \cdot \frac{1}{2}H_2O$: C, 68.93; H, 5.10; N, 17.87%.

2-Phenyl-4-amino-5-aminomethylpyrimidine (20). A mixture of **9b** (5.9 g), ethanol (35 ml), potassium hydroxide (12 g), ethanol (35 ml) and water (20 g) was refluxed for 30 hr and the solution was evaporated to dryness. Water (25 ml) was added to the residue. A brown oil appeared, which was extracted with chloroform (100 ml). The chloroform solution was dried over magnesium sulfate and then the solvent was removed. A brown oil (crude **20**; 4.03 g) was obtained. Concentrated hydroiodic acid was added to a part of the brown oil (187 mg), and crystals (**20**, hydroiodide) appeared. They were collected by filtration, washed with ethanol and recrystallized from methanol. The yield was 107 mg. Mp 268—272°C (decomp.). Found: C, 29.25; H, 3.14; N, 12.24%. Calcd for $C_{11}H_{12}N_4 \cdot 2HI$: C, 28.96; H, 3.09; N, 12.28%.

Cyclization of 2-Phenyl-4-amino-5-benzamidinomethylpyrimidine (10b). A solution of **10b** (40 mg) in methanol (4 ml) was refluxed for 6 hr and then evaporated to dryness. Recrystallization of the residue from acetonitrile gave 2,7-diphenyl-5,6-dihydropyrimido[4,5-*d*]pyrimidine (**8b**; 20 mg).

Reaction of 2-Phenyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (4b) with p-*Toluamidine. General Procedure*: A mixture of **4b** (3 g), *p*-toluamidine and its hydrochloride in methanol (20 g) was refluxed for 14 hr. 48% Sodium hydroxide solution (10 g) and water (10 ml) were added to the solution and then refluxed for 3 hr. After cooling, the solution was diluted with water (50 ml). A powder appeared was collected by filtration. The filtrate was evaporated to dryness and water (60 ml) was added to the residue. An insoluble powder was collected by filtration. The two powders were combined (**9c**+**12c**). The relative ratio was determined by means of NMR spectroscopy using the integration of methyl singlets of **9c** (2.26 δ) and **12c** (2.18 δ) in pyridine-d_5. The data are shown in Table 1. (i) When the molar ratio of **4b**, *p*-toluamidine and *p*-toluamidine hydrochloride was 1:1:1, the combined powder was recrystallized from methanol. 2-Phenyl-4-amino-5-toluamidomethylpyrimidine (**12c**; 600 mg) was obtained as leaflets. The mother liquor was evaporated to dryness. Recrystallization of the residue from methanol gave 2-*p*-tolyl-4-amino-5-benzamidomethylpyrimidine (**9c**), but its purification was unsuccessful because a small amount of contaminated **12c** could not be eliminated. (ii) When the molar ratio of **4b** and *p*-toluamidine was 1:3, the combined powder was worked up in a procedure similar to that for (i). Pure **9c** was obtained (289 mg).

*2-*p*-Tolyl-4-amino-5-benzamidomethylpyrimidine (9c).* A mixture of 2-*p*-tolyl-4-amino-5-*p*-toluamidomethylpyrimidine (**22**; 120 mg), potassium hydroxide (12 g), ethanol (7 ml) and water (20 g) was refluxed for 34 hr. The solution was concentrated to 25 g and then water (50 ml) was added. By extraction with chloroform (50 ml), a syrup was obtained (crude **23**). Benzoyl chloride (100 mg) was added to a solution of the syrup (57 mg) in pyridine (700 mg) and left at room temperature. After 1 day, a mixture of water (10 ml), a 48% sodium hydroxide solution (500 mg) and methanol (5 ml) was added to the solution. The solution was heated at 100°C for 10 min, concentrated and poured into water (50 ml). Crystals obtained were collected by filtration and then recrystallized from methanol. Twenty miligrams of

11) Contained about 15% of **1** (determined by means of gas chromatography).

9c were obtained. Mp 236—237°C. UV (EtOH) 208 (ε 15300), 250 (ε 12500), 263 (shoulder), 282 (ε 6400), 297 (shoulder); (+HCl) 205, 258, 278 (shoulder). IR (KBr) 1613 (CONH). NMR (pyridine-d_5) 8.27 (s, 1H, H_6), 4.80, 4.67 (s, 1H+s, 1H, $-CH_2-$), 2.26 (s, 3H, Me). Found: C, 71.66; H, 5.45; N, 17.75%. Calcd for $C_{19}H_{18}N_4O$: C, 71.67; H, 5.70; N, 17.60%.

*2-Phenyl-4-amino-5-*p*-toluamidomethylpyrimidine (**12c**).* To a solution of 2-phenyl-4-amino-5-aminomethylpyrimidine (**20**; 400 mg) in pyridine (2 ml), *p*-toluchloride (400 mg) was added at 0°C and the solution was left at room temperature for 1 day. To the solution, a mixture of water (20 ml), 48% sodium hydroxide solution (1 g) and methanol (5 ml) was added. The solution was left at room temperature for 1 hr and then evaporated to dryness. Water (30 ml) was added to the residue. Crystals obtained were collected by filtration. Recrystallization from methanol gave **12c** (270 mg). Mp 235—236.5°C. UV (MeOH) 206 (ε 15600), 240 (ε 16400), 257 (shoulder), 281 (ε 5000), 295 (shoulder); (+HCl) 205, 252. NMR (pyridine-d_5) 8.27 (s, 1H, H_6), 4.77, 4.65 (s, 1H, s, 1H, $-CH_2$), 2.18 (s, 3H, CH_3-). Found: C, 71.91; H, 5.87; N, 17.86%. Calcd for $C_{19}H_{18}N_4O$: C, 71.67; H, 5.70; N, 17.60%.

*2-*p*-Tolyl-4-amino-5-*p*-toluamidomethylpyrimidine (**22**).* A solution of 2-dimethoxymethyl-3-methoxypropiononitrile (**1**; 500 mg), *p*-toluamidine (700 mg) in methanol (3 ml) was refluxed for 8 hr (formation of **21**), and 15% sodium hydroxide solution (2 g) was added. The solution was refluxed for 1 hr, poured into water (50 ml), and the precipitates (574 mg) were collected by filtration. Recrystallization of precipitates gave **22** (needles; 91 mg). Mp 235—239°C. UV (MeOH) 205 (ε 16600), 242 (ε 14700), 260 (shoulder), 282 (ε 6400), 296 (shoulder); (+HCl) 204, 256, 286 (shoulder). IR (KBr), 1614 (CONH). NMR (pyridine-d_5) 8.28 (s, 1H, H_6), 4.80, 4.67 (s, 1H + s, 1H, $-CH_2-$), 2.27 (s, 3H, Me), 2.20 (s, 3H, Me). Found: C, 72.45; H, 5.89; N, 17.50%. Calcd for $C_{20}H_{20}N_4O$: C, 72.27; H, 6.07; N, 16.86%.

*Reaction of 2-Methyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**4a**) with Propioamidine. General Procedure:*[1] Hydrochlorides of propioamidine (651 mg) and **4a** (443 mg) was added to methanolic sodium methoxide which had been prepared from an appropriate amount of sodium and methanol (6 ml). The solution was refluxed for 5 hr, filtered from precipitated sodium chloride and then evaporated to dryness. To the residue was added water (8 ml) and the aqueous solution was heated on a boiling-water bath for 1 hr. Removal of the water gave syrupy crystals. The total yield and relative ratio of **9f**[1] and **12f**[1] in the syrupy crystals were determined by means of UV spectroscopy and gas chromatography,[1] respectively. The data are shown in Table 1.

*Reaction of 2-Methyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**4a**) with Benzamidine. General Procedure:* Hydrochlorides of **4a** (443 mg) and benzamidine were added to methanolic sodium methoxide which had been prepared from an appropriate amount of sodium and methanol (6 ml). The solution was refluxed for 5.5 hr and then evaporated to dryness. The residue was dissolved in 40% acetic acid solution (5 ml) and then heated on a boiling-water bath for 7 hr. The solution was concentrated and the residue was neutralized with a saturated bicarbonate solution and then diluted with water (20 ml). Crystals of a mixture of **9d** and **12d** were collected by filtration. The relative ratio of **9d** and **12d** in the crystals was determined by means of NMR spectroscopy using the integration of the methyl singlets of **9d** (1.98 δ) and **12d** (2,40 δ) in methanol-d_4. Recrystallization of the above crystals from acetonitrile gave **9d** in a pure state. When molar ratio of **4a**, benzamidine and benzamidine hydrochloride was 1:2:1, the yield of isolated **9d** was 212 mg. Mp 199—200°C (leaflets). UV (MeOH) 242 (ε 21000), 290 (ε 7500); (+HCl) 255. IR (Nujol) 1655 (CONH). NMR (CD_3OD) 1.98 (s, 3H, MeCONH), 8.01 (s, 1H, H_6), 4.40 (s, 2H, $-CH_2-$), 7.3—8.3 (m, 5H, phenyl). Found: C, 64.19; H, 5.93; N, 22.36%. Calcd for $C_{13}H_{14}N_4O$: C, 64.44; H, 5.82; N, 23.13%.

*The Conversion of **9d** into **9b**.* A mixture of 2-phenyl-4-amino-5-amidomethylpyrimidine (**9d**, 430 mg), 48% sodium hydroxide (25 g) solution, and ethylene glycol (20 ml) was refluxed for 5 hr, and then evaporated to dryness. A yellow syrup (**20**) was obtained by extraction with chloroform (50ml). The syrup was dissolved in pyridine (4 ml) and then benzoyl chloride (320 mg) was added to the solution at 0°C. The solution was left in a refrigerator for 4 hr and then poured onto ice-water. Crystals obtained were collected by filtration and recrystallized from acetonitrile. The yield was 210 mg.

*2-Methyl-4-amino-5-benzamidomethylpyrimidine (**9e**=**12d**).* To a mixture of 2-methyl-4-amino-5-aminomethylpyrimidine (500 mg) and pyridine (4 g) was added benzoyl chloride (2 g) at 0°C. The solution was kept at room temperature overnight, and then evaporated to dryness. 10% Sodium hydroxide solution (50 ml) was added to the residue. The solution was evaporated to dryness and washed with cold water (10 ml). Recrystallization of the residue from methanol gave **9e** (225 mg). Mp 232—234°C (columns). UV (EtOH) 231 (ε 21700), 275 (ε 6700); (+HCl) 237. IR (KBr) 1675 (CONH). NMR (CD_3OD) 2.40[s] (3H, 2-Me), 7.98 (s, 1H, H_6), 4.42 (s, 2H, $-CH_2-$), 7.93—7.40[m] (5H, phenyl). Found: C, 64.35; H, 5.97; N, 23.30%. Calcd for $C_{13}H_{14}N_4O$: C, 64.44; H, 5.82; N, 23.13%.

*Reaction of 2-Phenyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**4b**) with Acetamidine. General procedure:* Hydrochlorides of **4b** (741 mg) and acetamidine (850 mg) were added to methanolic sodium methoxide which had been prepared from appropriate amounts of sodium and methanol (10 ml), and the solution was refluxed for 5 hr. 80% Acetic acid (5 ml) was added to the solution which was refluxed for 1.5 hr and then extracted with chloroform (100 ml). The chloroform layer was washed with a saturated sodium bicarbonate solution (10 ml) and then water (10 ml) and dried, and the chloroform was removed. Crystals of a mixture of **9e** and **12e** were obtained. The relative ratio of **9e** and **12e** in the crystals was determined by means of NMR spectroscopy using the integration of methyl singlets of **9e** (2.40 δ) and **12e** (1.98 δ) in methanol-d_4. The data are shown in Table 1. Recrystallization of the above crystals from methanol gave **9e**. When the molar ratio of **4b**, acetamidine, and acetamidine hydrochloride was 1:2:1, the yield of **9e** was 358 mg.

*Reaction of 2-Phenyl-4-amino-5-dimethoxymethyl-5,6-dihydropyrimidine (**4a**) with Sodium Methoxide.* To a mixture of **4a** hydrochloride (443 mg) and **4b** (493 mg) was added a sodium methoxide solution which had been prepared from sodium (138 mg) and methanol (15 ml). The solution was refluxed for 4 hr, filtered from precipitated sodium chloride and then evaporated to dryness. Extraction of the residue with chloroform gave a syrup (458 mg), which was a mixture of 2-phenyl-4-amino-5-methoxymethylpyrimidine (**14b**) and 2-methyl-4-amino-5-methoxymethylpyrimidine (**14a**). The ratio of **14b** and **14a** was determined to be 91.4:8.6 by means of gas chromatography (Apiezon grease L 30%, 1 m; column temperature, 234.5°C; carrier gas, He, flow rate, 90 ml/min; retention time, **14a**: 2.2 min, **14b**: 36.9 min). The syrup was chromatographed over alumina (Wakogel 10 g) with benzene (40 ml) and, subsequently, with a mixture of benzene

(30 ml) and ethyl acetate (30 ml). One hundred and sixty-three milligrams of **14b** was obtained.

*Cyclization Rates of 2-Methyl-4-amino-5-acetamidinomethylpyrimidine (**10a**) and 2-Phenyl-4-amino-5-benzamidinomethylpyrimidine (**10b**).* The rate constants for the two reactions were determined spectrophotometrically with a Perkin Elmer 139 spectrophotometer by following the increase of the absorbance at 310 nm due to **8a** in the reaction of **10a**, and that at 350 nm due to **8b** in the reaction of **10b** at reflux temperature (64.5°C).

*(1) The Decrease of **10a** (k_a)*: The hydrochloride of **10a** (6 mg) was dissolved in methanol in a 200 ml volumetric flask. The methanol solution was exactly neutralized with a dilute solution of potassium hydroxide in methanol and then the flask was filled to the mark with methanol at 26°C. $k_a = 7.3 \times 10^{-2} \mathrm{min}^{-1}$.

*(2) The Decrease of **10b** (k_b)*: Fourteen milligrams of **10b** was dissolved in methanol and then messed up to 200 ml at 26°C. $k_b = 4 \times 10^{-3} \mathrm{min}^{-1}$.

The authors express their deep gratitude to Professor Toshihiko Okamoto, the University of Tokyo, for his interest in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 259—263 (1973)

Intramolecular Interaction between the Hydroxyl Group and the Oxirane Ring[1]

Michinori Ōki and Tetsuo Murayama

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received May 23, 1972)

The intramolecular interaction between the hydroxyl group and the oxirane ring has been detected by means of studying the infrared spectra in the 3μ region of various hydroxyalkyloxiranes. The O–H stretching absorptions of several compounds which have limiting structures in the sence of the conformational preference have been closely examined. The results indicate that the intramolecular interaction takes place between the hydroxyl group and the electron orbitals involved in the formation of the C–O bond, while that involving the electrons of the C–C bond can be neglected.

It has been established that the cyclopropane ring interacts with the hydroxyl group, the former acting as a proton acceptor.[2] This property of the cyclopropane ring is, of course, attributable to the strain of the bonds or to the low ionization potential of the electrons. Since the oxirane ring is an oxygen analog of the cyclopropane, it can naturally be expected that the oxirane ring will behave similarly; the study of the intramolecular interaction between the hydroxyl group and the oxirane ring is thus undertaken as an extension of the previous work.

Since the oxirane ring contains an oxygen atom, the three bent bonds of the ring, namely one C–C and two C–O bonds, are not equal. Because of the high electronegativity of the oxygen atom, oxirane has been reported to have a dipole moment (1.91 D)[3] which is slightly larger than those of tetrahydrofuran (1.63 D)[3] or dimethyl ether (1.29 D).[4] Thus, the electron densities of the bent bonds of the ring are clearly not equal, that of the C–C bond being tenuous.[5] It may be postulated, therefore, that the electron orbitals involved in the C–O bond formation, rather than the C–C bond of the oxirane ring, will interact with the hydroxyl group, if any O–H···oxirane interaction does exist.

This paper will deal with the detection of such an intramolecular interaction and with the dynamic stereochemistry which is necessary in establishing the interaction in detail. It will also seek to determine if the above expectation as to the site of the interaction is really correct.

Experimental

Spectral Measurements. The infrared absorption spectra in the 3μ region were measured on a Perkin-Elmer 112G single-beam grating spectrophotometer, the slit width being 0.8 cm^{-1} in this region. The apparent absorption curves were graphically separated into symmetrical curves.

Wako special-grade carbon tetrachloride was used in making up the solutions of alcohols. The concentrations of the solutions were *ca.* 0.003 mol/l. A quartz optical cell 2 cm thick was used.

The NMR spectra were taken on a JNM 3H-60 spectrometer.

Materials. All the alcohols except *erythro*-3,4-epoxy-4-methylpentan-2-ol (VIII) were prepared by the epoxidation of the appropriate unsaturated alcohols with perbenzoic acid. The acids were removed with calcium hydroxide during the reaction in order to avoid isomerization as much as possible.[6]

The epoxidation of 4-methyl-3-penten-2-ol gave *threo*-3,4-epoxy-4-methylpentan-2-ol (VII); bp 67—68°C/15 mmHg, $n_D^{16.5}$ 1.4270. This compound was identical with the one obtained by the isomerization of *cis*-2-methyl-3,4-epoxypentan-2-ol.[7] (lit. bp 75—76°C/20 mmHg, n_D^{25} 1.4238). NMR (δ from TMS in CCl_4): 1.15 (3H, d, J=6 Hz), 1.26 (3H, s), 1.27 (3H, s), 3.20—2.80 (1H, m), 2.62 (1H, d, J=8 Hz), 4.10 (OH).

erythro-3,4-Epoxy-4-methylpentan-2-ol (VIII) (bp. 68.5—69°C/10 mmHg, $n_D^{16.5}$ 1.4271) was obtained by the isomerization of *trans*-2-methyl-3,4-epoxypentan-2-ol.[7] NMR (δ from TMS in CCl_4): 1.25 (3H, d, J=6 Hz), 1.30 (6H, s), 2.48 (1H, d, J=8.5 Hz), 3.48 (1H, m), 3.81 (OH).

Table 1. ν_{O-H} data of epoxy alcohols

Compound	ν_{max} (cm^{-1})	$A\times10^{-3}$[a] (mol·l·cm)	Relative intensity

Results and Discussion

The spectral data of the O–H stretching absorptions (ν_{O-H}) of several 2,3-epoxypropan-1-ol derivatives are given in Table 1. Some representative curves are also given in Fig. 1.

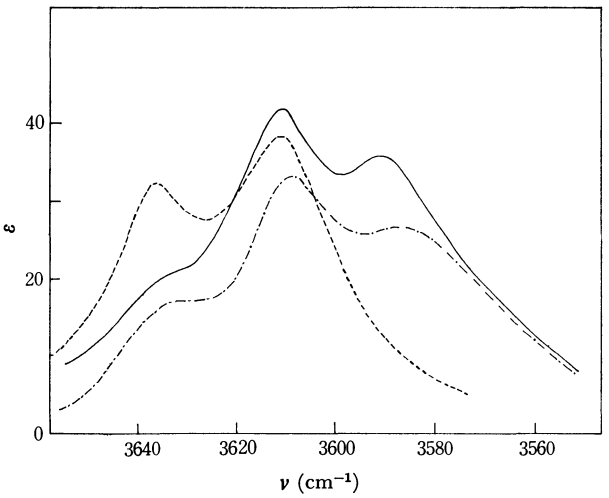

Fig. 1. ν_{O-H} absorption bands of 2,3-epoxypropan-1-ol (I: ——), 2,3-epoxy-3-methylbutan-1-ol (II: ------), and *trans*-2,3-epoxybutan-1-ol (III: —·—).

The ν_{O-H} curve of glycidol (I) apparently has three absorption peaks. One of the three maxima can certainly be assigned to the hydroxyl group which is hydrogen-bonded to the oxygen atom of the oxirane ring. In order to establish this assignment, the ν_{O-H} absorptions of several alcohols with a similar situation have been measured: tetrahydrofurfuryl alcohol and 2-hydroxymethyloxane[8] show their O–H···O bonded ν_{O-H} at 3602 and 3597 cm^{-1} respectively. It is then found that the band at the lowest frequency, 3590 cm^{-1}, is most probably the intramolecularly O–H···O-bonded band. The band at the highest wave number, 3638 cm^{-1}, can be assigned to the free OH group of the primary alcohol, because other primary alcohols are known to give rise to an absorption at *ca.* 3636 cm^{-1} [9]

Table 2. ν_{O-H} data of RCH_2OH

R	ν_{max} (cm^{-1})	$A\times10^{-3}$ (mol^{-1} l cm^{-2})	A_l/A_h[a]	Ref.
CH_3	3637.3	2.8	0.56	9
	3627	1.6		
$(CH_3)_2CH$	3641.5	3.6	0.50	9
	3628	1.8		
	3633.7	2.3	1.1	2b
	3619	2.6		

a) A_l and A_h denote integrated intensities of the bands at lower and higher frequencies, respectively.

8) S. A. Barker, J. S. Brimacombe, A. B. Foster, D. H. Whiffen, and G. Zweifel, *Tetrahedron*, **7**, 10 (1959).

9) M. Ōki and H. Iwamura, This Bulletin, **32**, 950 (1959).

(see Table 2). The third band, 3611.8 cm^{-1}, is located at too low a frequency to be assigned to a second rotamer of the primary alcohol, which usually gives the absorption near 3625 cm^{-1} and which is located at a lower frequency than the intramolecularly O–H··· cyclopropane interacting band (see Table 2). Thus, the last band is attributable to the O–H···oxirane interacting species.

2,3-Epoxy-3-methylbutan-1-ol (II), which carries two methyl groups at the C_3 of the ring, failed to show absorptions below 3600 cm^{-1}. However, when we removed the methyl group at C_3 which is *cis* to the hydroxymethyl group, the absorption band below 3600 cm^{-1} reappeared: the spectrum of *trans*-2,3-epoxybutan-1-ol (III) has a band at 3583 cm^{-1}, as is shown in Fig. 1 and Table 1.

These results may be interpreted as follows. In order to establish the intramolecular hydrogen bond between the hydroxyl group and the oxygen of the oxirane, the hydroxyl group must approach one of the lone-pair orbitals of the oxygen which are directed up and down in relation to the ring. However, if that conformation is taken in 2,3-epoxy-3-methylbutan-1-ol, the repulsive interaction between the *cis*-methyl and hydroxyl groups will be severe. Thus, the conformation is not favored in the case of compound II. Compound III, which lacks the *cis*-methyl group, has no severe interaction which would prevent the approach, and the O–H···O hydrogen bond is favored to show a band at 3583 cm^{-1}.

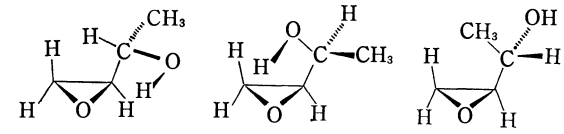
Although the band below 3600 cm^{-1} is lacking for compound II, a band is still observed at 3612.4 cm^{-1} which is attributable to the intramolecularly O–H··· oxirane interacting species. This fact offers support to the idea that the O–H···oxirane interaction takes place if the OH group approaches the ring within the plane of the ring, as was the case in O–H···cyclopropane interaction.[2] That is, edge-interaction is the favored process.

The absorption frequency (3590 cm^{-1}) of the intramolecularly O–H···O hydrogen-bonded species of glycidol (I) is higher by *ca.* 10 cm^{-1} than those of the glycidols (III, IV) which carry methyl groups. On the other hand, *trans*-2,3-epoxy-3-phenylpropan-1-ol (V), which is a phenyl-substituted glycidol, shows an absorption at almost the same frequency as glycidol itself. These results certainly reflect the electronic effect of the substituents.

The absorption frequencies (*ca.* 3610 cm^{-1}) due to the intramolecularly O–H···oxirane interacting species of glycidol and its homologs are apparently lower than those of the O–H···cyclopropane species.[2] This means that the electron density at the site in the acceptor is higher than that of cyclopropane, because the conformational situations are quite analogous. It can, then, be suggested that the interacting electron orbitals are not of the C–C bond, but of the C–O bond of the ring, because it is the C–O bond, not the C–C, which has a higher electron density than the C–C bond of the cyclopropane.

As to the substituent effect, there is another interesting phenomenon in connection with 3,4-epoxybutan-2-ol (VI), which is believed to be of steric origin. That is, this compound shows no band due to the free OH group. Instead, two bands are observed at 3573 and 3607.0 cm^{-1}; the former can be attributed to the O–H···O bonded species, and the latter, to the O–H··· oxirane interacting species. To understand why this compound does not show any free OH, the conformational consideration is very helpful. Since this alcohol contains two asymmetric carbons, there are a pair of racemates. The method of preparation, *i.e.*, the epoxidation of 3-buten-2-ol with perbenzoic acid, suggests that the alcohol which is under investigation is the *threo* isomer, since it is known that the application of the same procedure to 4-methyl-3-penten-2-ol gives rise to a *threo* isomer of 3,4-epoxy-4-methylpentan-2-ol (VII), as will be discussed later. Therefore, there are three conformations (VIa, VIb, and VIc) to be considered with respect to the rotation about the C_2–C_{OH} bond.

The H-inside conformation (VIa) has nothing unfavorable about it, because the repulsive interaction between hydrogens at C_3 and α to the hydroxyl group should be small. In addition, VIa can be stabilized because of the interaction between the hydroxyl group and the oxirane ring.



VIa VIb VIc

The OH-inside conformation (VIb) is unfavorable because of the steric interference between the hydrogen at C_3 and the OH group. However, this conformation can be stabilized due to the O–H···O bond formation.

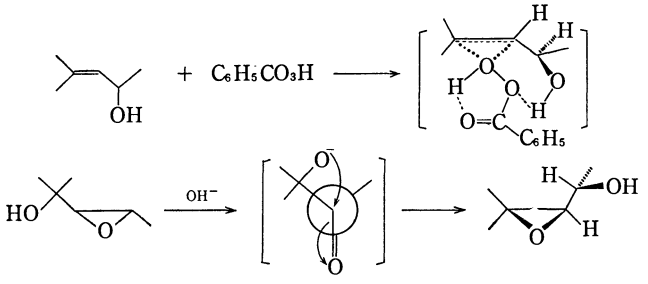
On the other hand, the CH_3-inside conformation (VIc) is unfavorable because of the repulsion between the hydrogen at C_3 or the lone pair of the oxygen atom of the ring and the methyl group, and there is nothing to favor the conformation; it could be considered that the intramolecular interaction between the hydroxyl group and the electrons of the C–C bond in oxirane can take place, but this interaction would be of a very weak nature, if it existed at all, judging from a theoretical consideration of the electron density and the experimental evidence which will be given later.

Thus, the population of the VIc conformation must be small and O–H-free conformations within the skeletal frames of VIa and VIb must also be scarce, thus reducing the intensity of the free O–H band.

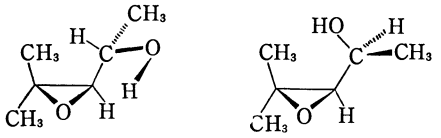
These results, together with the theoretical background, forced us to search for possible experimental evidence which clearly shows that the electron density at the C–C bond of the oxirane ring is really low. Thus, another approach has been undertaken: compounds which involve more severe steric requirements have been sythesized and their spectra examined.

The *threo* and the *erythro* isomers of 3,4-epoxy-4-methylpentan-2-ol (VII and VIII) have been selected as examples to study because the methyl group at C_3 exerts a severe steric effect and any conformational preference will thus be sharper than with compound

VI. The *threo* isomer (VII) has been obtained by the epoxidation of 4-methyl-3-penten-2-ol with perbenzoic acid. A consideration of the transition state of the epoxidation leads to the conclusion that the *threo* isomer is the main product, since it is a well-known fact that the peroxy acids attack the olefinic bond from the *cis* side of the hydroxyl group, probably because of the stabilization due to hydrogen-bond formation. This tentative conclusion is supported by the identity of the physical properties of the isolated product with those of the known *threo* isomer, which can be prepared by the isomerization of *cis*-3,4-epoxy-2-methylpentan-2-ol with the base.[7] The *erythro* isomer has been prepared by the isomerization of *trans*-3,4-epoxy-2-methylpentan-2-ol with the base.[7]



In the *threo* isomer VII, the H-inside conformation (VIIa) is the most stable, because the steric repulsion between the $CH_3CH(OH)$ group and the methyl group at C_3, which is *cis* to the $CH_3CH(OH)$ group, is the least. In addition, this conformation favors the intramolecular O–H···oxirane interaction. On the other hand, the O–H inside conformation (VIIb), which has the OH group above the ring, suffers from a severe steric interaction between the OH group and the methyl group at C_3, although this conformation may be stabilized due to the formation of the O–H···O bond. Thus, it can be concluded that the VIIb conformation is less stable than the VIIa conformation. The CH_3-inside conformation may be disregarded because its inner strain is high.



VIIa VIIb

The absence of any absorption below 3600 cm^{-1} and the presence of two ν_{O-H} bands at 3607.4 and 3628 cm^{-1} (Fig. 2 and Table 1) for Compound VII support the above discussion. The absorption at the higher frequency, which is assigned to the free OH group, is weak, and the band at the lower frequency is strong, also suggesting that the O–H···oxirane interaction is an exothermic process to a considerable extent.

In the *erythro* isomer VIII, if the hydroxyl group is to interact with the C–O of the oxirane ring, the methyl-inside conformation (VIIIa) must be taken. This conformation is, however, apparently unfavorable because of the severe interaction between the methyl group at C_3 and the $CH_3CH(OH)$ group. On the other hand, such a repulsive interaction will be less when H-inside conformation (VIIIb) is taken. In the VIIIb conformation, the O–H group may approach the C–C bond of the oxirane ring, but it is impossible for it to approach the C–O of the ring.

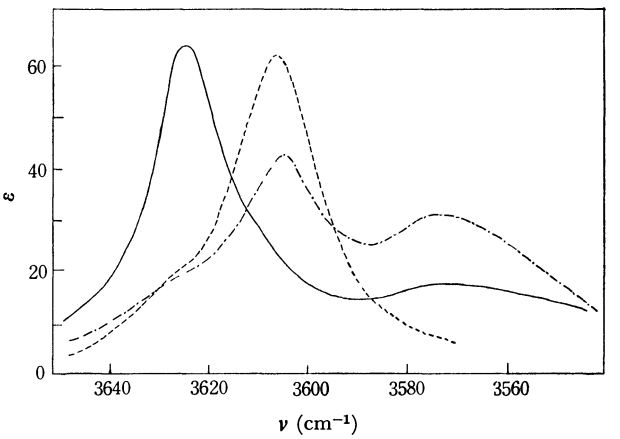


Fig. 2. ν_{O-H} absorption bands of *threo* (VII; ------) and *erythro* (VIII; ——) isomers of 3,4-epoxy-4-methylpentan-2-ol, and *trans*-3,4-epoxypentan-2-ol (IX; —·—).

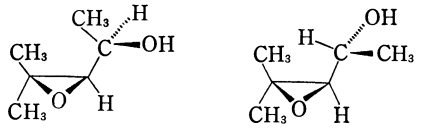


VIIIa VIIIb

In reality, the ν_{O-H} spectrum of VIII shows absorptions at 3623.6 and 3567 cm^{-1}, the former being by far the strongest band. Besides, the presence of a weak band at 3612 cm^{-1} is suggested by the separation of the observed band into symmetrical component bands. The results indicate that the intramolecular interaction between the OH group and the orbitals involved in the C–C bond is a very weak one, if there is any at all. If the C–C bond is really interacting, then Compound VIII should also have shown a strong band attributable to the O–H···oxirane interaction.

The discussions of the stable conformations of the diastereomers given above are also supported by the NMR spectra. The vicinal coupling constants (J_{vic}) of the ring proton with the α-protons of the *threo* and *erythro* isomers were 8.0 and 8.5 Hz respectively. The larger values of J_{vic} suggest that the average torsional angles made by the two $H-C_{methine}$ bonds are large;[10] that is, the populations of the H-inside conformers, VIIa and VIIIb, are large.

The steric effects of the *cis*-methyl group are clear from the spectrum of the *threo* isomer of *trans*-3,4-epoxypentan-2-ol (IX), which corresponds to a compound in which the *cis*-methyl group of the *threo*-3,4-epoxy-4-methylpentan-2-ol (VII) has been removed. IX shows a strong O–H···O-bonded band (Fig. 2), in contrast to the absence of the O–H···O bond in VII.

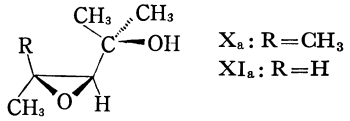
In view of the above discussions, it seemed that it would be interesting to examine the case where there were no small groups at the α-position of the alcoholic hydroxyl group. Thus, the ν_{OH} spectrum of 3,4-epoxy-

10) K. Tori, T. Kameno, and T. Nakagawa, *J. Org. Chem.*, **29**, 1136 (1964).

2,4-dimethylpentan-2-ol (X) was measured; it gave absorptions at 3617 and 3559.4 cm^{-1}. Apparently the band at the higher frequency can be assigned to the free hydroxyl group,[9] and that at the lower frequency, to the O–H···O bonded form. On the other hand, *trans*-3,4-epoxy-2-methylpentan-2-ol (XI), which lacks the methyl group *cis* to the $C(CH_3)_2OH$, showed absorptions at 3598 and 3566.4 cm^{-1}. Thus, compound X can be regarded as existing as both free and O–H···O interacting species, whereas compound XI exists as both the O–H···oxirane-interacting and the O–H···O-bonded species.

In addition to the fact that the OH-inside conformation of compounds X and XI can be stabilized by forming an O–H···O hydrogen bond, the CH_3-inside conformation (Xa and XIa) is the least stable, because the van der Waals radius of oxygen is smaller than that of the methyl. Thus, in both cases, the O–H···O bonded species exist as the major components.

The cause of the presence of the O–H···oxirane interacting species in XI may be the relative bulkiness



X_a: R=CH_3
XI_a: R=H

of the methyl group and hydrogen. Although the methyl-inside conformations (Xa and XIa) are more unstable than the OH-inside, such a confomration is not prohibitive if R is a hydrogen. If such a conformation is present, the O–H···oxirane interaction can be expected to occur to some extent. The Xa conformation is, however, almost prohibited because of the severe steric repulsion between the two methyl groups.

All the results presented above are explainable if the following two points are assumed: 1) the O–H···oxirane ring interaction takes place between the hydroxyl group and the C–O bond of the oxirane, but the interaction involving the C–C bond of the oxirane is negligible, and 2) the interaction takes place when the OH group approaches the oxirane ring within the plane of the ring.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 263—265 (1973)

Macro Rings. V.[1] Syntheses of Tetraoxaparacyclophanes Containing Two Biphenyl Nuclei

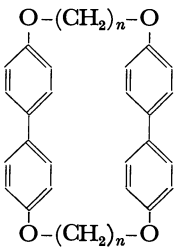
Joji NISHIKIDO,[2] Takahiko INAZU,* and Tamotsu YOSHINO

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka

(Received May 25, 1972)

Three new tetraoxaparacyclophanes containing two biphenyl nuclei connected with oxypolymethyleneoxy bridges in the respective 4,4′-positions, such as 1,5,18,22-tetraoxa[5.0.5.0]paracyclophane I_3, 1,6,19,24-tetraoxa-[6.0.6.0]paracyclophane I_4, and 1,7,20,26-tetraoxa[7.0.7.0]paracyclophane I_5, were synthesized. The UV, IR, and NMR spectra of these paracyclophanes were compared with those of the corresponding open-chain compound, IV_3.

Three paracyclophanes, I_3, I_4, and I_5, in which the 4,4′-positions of two biphenyl molecules are connected with five-, six-, and seven-membered bridges respectively, were synthesized. The IR, UV, and NMR spectral properties of these compounds, I's, and of the corresponding open-chain compounds, IV_3, will be discussed.



I_3: $n=3$, I_4: $n=4$, I_5: $n=5$.

Fig. 1. Tetraoxaparacyclophanes

The synthetic routes are shown in Schemes 1, 2, and 3. Three portions of a potassium salt of 4,4′-biphenyldiol were treated, respectively, with ethylene-, trimethylene-, and tetramethylene-chlorohydrins to give diols, II's, which were then treated with phosphorous tribromide to give dibromides, III's. The dibromides, III's, were also prepared in considerable yields by the condensation of 4,4′-biphenyldiol with polymethylene dibromides in the presence of potassium carbonate.[3] The dibromides, III's, were reduced with lithium aluminum hydride to IV′ compounds. These compounds were synthesized as reference compounds, which served as open-chain models of the cyclic compounds, I's, in a comparison of their spectra.

Most macrocyclic ethers, known as ansa compounds, are diethers which are generally prepared by the intramolecular condensation of compounds with a

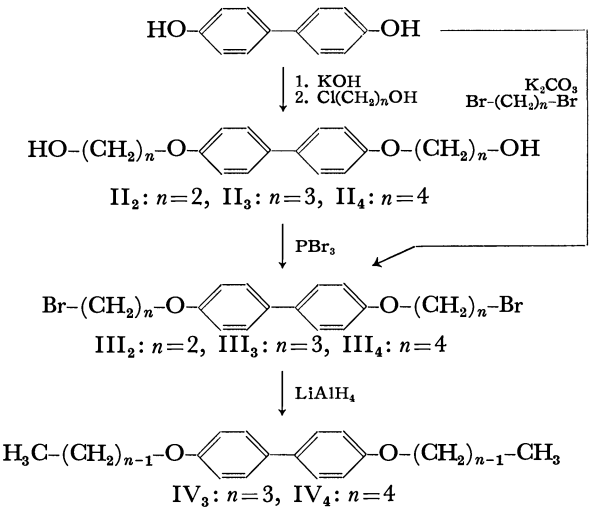
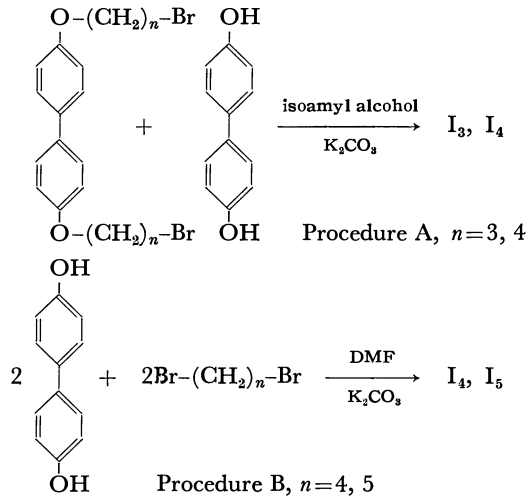


Scheme 1.

phenolic hydroxyl group and a long-chain ω-haloalkyloxy group.[3] Since the compounds to be synthesized in this investigation are tetraethers, though, it was difficult to use this method without alteration in the syntheses of tetraethers. Therefore, as is shown in Scheme 2, the intermolecular double condensation (Procedure A) and the one-step quadruple condensation (Procedure B) were adopted.

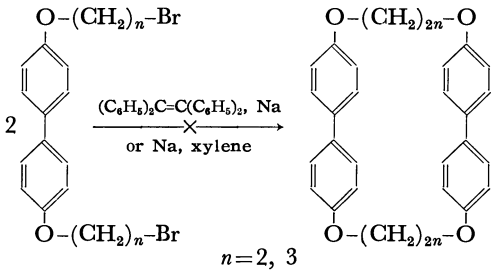


Scheme 2.

In Procedure A, paracyclophanes (I_3, I_4) were synthesized by allowing an equimolar mixture of 4,4′-biphenyldiol and 4,4′-bis(ω-bromoalkyloxy)biphenyl III's to react under high dilution condition. This reaction was carried out by dropping an isoamyl alcohol solution containing the respective reactant into a stirred suspension of anhydrous potassium carbonate in isoamyl alcohol[4] for over 80 hr.

In Procedure B, paracyclophanes (I_4, I_5) were synthesized by dropping, over a 30 hr period, a dimethylformamide solution containing 4,4′-biphenyldiol and polymethylene dibromide into a stirred mixture of anhydrous potassium carbonate in dimethylformamide; the products were thus obtained as crystalline solids. The yields of the cyclic compounds in both procedures were very low, but, unexpectedly, the yields of the products in the procedure B were appreciably higher than those in Procedure A.

In the hope of obtaining the tetraoxa[6.0.6.0]- and tetraoxa[8.0.8.0]paracyclophanes shown in Scheme 3, the intermolecular Wurtz reaction of 4,4′-bis(ω-bromoalkyloxy)biphenyl (III_3, III_4) was attempted under a nitrogen atmosphere both in the presence of a sodium adduct of tetraphenylethylene in tetrahydrofuran at room temperature and in the presence of molten sodium in boiling xylene, but no paracyclophane was obtained in either case.



Scheme 3.

The cyclic structures of I_3, I_4, and I_5 were confirmed by their IR, UV, and NMR spectra, by elementary analyses, and by a molecular-weight determination. In the infrared spectra, the absorptions of the cyclic compounds, I's, were more complicated than that of the open-chain model, IV_3, in the 800—900 cm^{-1} region. These bands were used as a diagnosis[5] for the cyclic structure.

The NMR spectra suggest that the conformation of the two biphenyl nuclei in the macro ring may not be fixed rigidly, but may be flexible in a solution at room temperature. The peaks for benzene protons were found to shift upfield by 0.2—0.6 ppm from those of open-chain models, IV's. Among the paracyclophanes, I_3, I_4, and I_5, the peaks for benzene protons exhibited to shift to a higher field with a decrease in the methylene numbers in the oxypolymethyleneoxy bridges. These upfield shifts are due to the shielding by the biphenyl nuclei on the opposite side of the macro ring. The close resemblance of UV spectra of paracyclophanes, I's, to those of the corresponding open-chain models, IV's, reveals that the aromatic rings of I's are planar and that there is no strain in the macro rings.

The problem whether or not other small molecules are included in the empty space of the macrocyclic rings is also interesting; studies of these adducts are now in progress.

Experimental

All the melting points are uncorrected. The ultraviolet spectra were measured on a Hitachi ESP-3T spectrophotometer. The infrared spectra were measured on a Hitachi EPI-S2 spectrophotometer. The NMR spectra were recorded on Hitachi R-20 photometer, using tetramethyl silane as the internal standard and deuterochloroform as the solvent.

4) H. Stetter and E. E. Roos, *Chem. Ber.*, **87**, 566 (1954).

5) D. J. Cram and H. Steinberg, *J. Amer. Chem. Soc.*, **73**, 5961 (1951).

The molecular weights were measured by means of a Hitachi Perkin-Elmer 115 molecular weight apparatus, using benzene as the solvent.

4,4'-Bis(2-bromoethoxy)biphenyl, III_2. A mixture of 2 g (0.011 mol) of 4,4'-biphenyldiol, 8.27 g (0.044 mol) of ethylene bromide, 20 ml of acetone, 2 ml of water, and 5 g of potassium carbonate was refluxed with stirring on a steam-bath for 15 hr, after which an additional 1.75 g of potassium carbonate was added and stirring and refluxing was continued for 20 hr. The acetone was then distilled off with stirring to prevent bumping. The reaction mixture was then washed with water and recrystallized from a dioxane–ethanol mixture. White needles, mp 175—176°C; yield, 1.0 g (24%). Found: C, 48.22; H, 4.14%. Calcd for $C_{16}H_{16}Br_2O_2$: C, 48.03; H, 4.03%.

4,4'-Bis(3-bromopropoxy)biphenyl, III_3. A mixture of 10 g (0.054 mol) of 4,4'-biphenyldiol, 50 g (0.270 mol) of trimethylene dibromide, 40 ml of acetone, 6.7 ml of water, and 36 g of potassium carbonate was stirred and refluxed on a steam-bath for 40 hr. At the end of this period, the acetone was removed, and the reaction mixture was shaken with water. The product was recrystallized from a dioxane–ethanol mixture; white crystals, mp 127—128°C; yield, 13.8 g (60%). Found: C, 52.47; H, 4.94%. Calcd for $C_{18}H_{20}Br_2O_2$: C, 50.49; H, 4.67%.

4,4'-Bis(4-bromobutoxy)biphenyl, III_4. This was prepared in the same way as the corresponding 4,4'-bis(3-bromopropoxy)biphenyl, III_3. From 5 g (0.027 mol) of 4,4'-biphenyldiol, 25 g (0.107 mol) of tetramethylene dibromide, 15 ml of acetone, 3.4 ml of water, and 18 g of potassium carbonate, 8 g (65%) of a product was obtained; white crystals, mp 136°C. Found: C, 52.37; H, 5.26%. Calcd for $C_{20}H_{24}Br_2O_2$: C, 52.66; H, 5.30%.

4,4'-Dipropoxybiphenyl, IV_3. A suspension of 500 mg of the III_2 dibromide in 100 ml tetrahydrofuran was stirred, and then the solution was added, drop by drop, into a mixture of excess lithium aluminum hydride in 50 ml of tetrahydrofuran at room temperature; after stirring for an additional 1.5 hr, the mixture was refluxed for 6 hr. After cooling, the mixture was treated with water and extracted with benzene. The removal of the benzene under reduced pressure gave a white powder, which was recrystallized from an ethanol–benzene mixture to give 170 mg (55% yield) of a white crystalline powder; mp 156—158°C. NMR; 7.23 ppm (8H, quartet, aromatic), 3.955 (4H, triplet, O-**CH_2**), 1.85 (4H, quintet, O-CH_2-**CH_2**-CH_3), 1.05 (6H, triplet, O-CH_2-CH_2-**CH_3**). IR; 1609 cm^{-1} (m, ν_{ip} C=C), 1501 (s, ν_{ip} C=C), 1242 (s, ν_{as} C-O-C), 824 (s, δ_{op} H-C_{arom}). UV; λ_{max} 267 nm, $\varepsilon_{max}=5.9\times10^3$.

4,4'-Dibutoxybiphenyl, IV_4. This compound was prepared in exactly the same manner as the 4,4'-dipropoxybiphenyl, IV_3. The product was white crystals; mp 145—146°C. Yield, 60%.

1,5,18,22-Tetraoxa[5.0.5.0]paracyclophane, I_3. Into a 3 liter, four-necked reaction flask of the high-dilution apparatus, we placed 650 ml of dry isoamyl alcohol and 8 g of finely-powdered, anhydrous potassium carbonate which had been heated in an open dish over a free flame for 30 min. A solution of 2.997 g (0.007 mol) of 4,4'-bis(3-bromopropoxy)-biphenyl III_3 and 1.303 g (0.007 mol) of 4,4'-biphenyldiol in 850 ml of dry isoamyl alcohol was then introduced into a boiling alcohol–potassium carbonate mixture over an 85 hr period. A current of nitrogen was run through the circulatory system in order to minimize any oxidation of the 4,4'-biphenyldiol which might take place. After having been stirred and heated for an additional hour, the reaction mixture was allowed to cool, filtered to remove the inorganic salts present, and evaporated under diminished pressure on a water pump until only traces of the isoamyl alcohol remained. The dark, viscous material remaining was placed in a Soxhlet extractor and partially extracted with petroleum ether for 18 hr. A pale yellow mass remaining in the Soxhlet extractor was recrystallized form benzene to give white needles. Mp above 280°C; yield, 22 mg (0.7%). NMR; 6.80 ppm (16H, quartet, aromatic), 4.25 (8H, triplet, O-**CH_2**), 2.05 (4H, multiplet, O-CH_2-**CH_2**-CH_2-O). IR; 1609 cm^{-1} (m, ν_{ip} C=C), 1497 (s, ν_{ip} C=C), 1224 (s, ν_{as} C-O-C), 817 (s, δ_{op} H-C_{arom}). UV; λ_{max} 263 nm, $\varepsilon_{max}=1.1\times10^4$. Found: C, 79.76; H, 6.37%; mol wt, 452.1. Calcd for $C_{30}H_{28}O_4$: C, 79.62; H, 6.24%; mol wt, 452.5.

1,6,19,24-Tetraoxa[6.0.6.0]paracyclophane, I_4. *Method A*: This compound was prepared in the same way as the corresponding cyclic ether, I_3. In the reaction flask we placed 650 ml of dry isoamyl alcohol and 7 g of powdered potassium carbonate which had been heated to a red heat for 30 min. A solution of 3.194 g (0.007 mol) of 4,4'-bis(4-bromobutoxy)-biphenyl, III_4, and 1.303 g (0.007 mol) of 4,4'-biphenyldiol in 850 ml of dry isoamyl alcohol was then added to the boiling alcohol–potassium carbonate mixture over an 80 hr period. The product consisted of white prisms. Mp 235—236°C; yield, 13 mg (0.4%). NMR; 6.87 ppm (16H, quartet, aromatic), 4.16 (8H, multiplet, O-**CH_2**), 1.90 (8H, multiplet, O-CH_2-**CH_2**-**CH_2**-CH_2-O). IR; 1607 cm^{-1} (m, ν_{ip} C=C), 1496 (s, ν_{ip} C=C), 1245 (s, ν_{as} C-O-C), 820 (s, δ_{op} H-C_{arom}). UV; λ_{max} 264 nm, $\varepsilon_{max}=1.3\times10^4$. Found: C, 79.96; H, 6.74%; mol wt, 488.8. Calcd for $C_{32}H_{32}O_4$: C, 79.97; H, 6.71%; mol wt, 480.6.

Method B: A solution of 3.30 g (0.018 mol) of 4,4'-biphenyldiol and 3.82 g (0.018 mol) of tetramethylene dibromide in 800 ml of dimethylformamide was added, from a dropping funnel and over a 30 hr period, to a suspension of 30 g of potassium carbonate in 600 ml of dimethylformamide, the temperature being kept at 130°C. After stirring and heating for an additional hour, the reaction mixture was cooled, filtered to remove the inorganic salts, and then concentrated to about 400 ml. It was then placed in an ice box and allowed to stand overnight. Crystals were deposited. The material was crystallized from dimethylformamide to give white prisms. Yield, 320 mg (3.8%). The IR and NMR spectra of this compound were in accord with those of the cyclic compound, I_4, prepared by Method A.

1,7,20,26-Tetraoxa[7.0.7.0]paracyclophane, I_5. A solution of 4.66 g (0.0025 mol) of 4,4'-biphenyldiol and 5.75 g (0.025 mol) of pentamethylene dibromide in 800 ml of dimethylformamide was added, through a dropping funnel and over a 30 hr period, to a suspension of 30 g of potassium carbonate in 700 ml of dimethylformamide, the temperature being kept at 130°C. After stirring and heating for an additional hour, the reaction mixture was cooled, filtered to remove the inorganic salts, and concentrated to about 400 ml. It was then placed in the ice box and allowed to stand overnight. Crystals were deposited. The material was crystallized from dimethylformamide to give white needles. Mp 236°C; yield, 200 mg (3.1%). NMR: 6.98 ppm (16H, quartet, aromatic), 4.05 (8H, multiplet, O-**CH_2**), 1.75 (12H, multiplet, O-CH_2-**CH_2**-**CH_2**-**CH_2**-CH_2-O). IR; 1600 cm^{-1} (m, ν_{ip} C=C), 1495 (s, ν_{ip} C=C), 1227 (s, ν_{as} C-O-C), 812 (s, δ_{op} H-C_{arom}). UV; λ_{max} 265 nm, $\varepsilon_{max}=1.4\times10^4$. Found: C, 80.70; H, 7.30%; mol wt, 471.8. Calcd for $C_{34}H_{36}O_4$: C, 80.28; H, 7.13%; mol wt, 508.6.

Syntheses of L-Threose and Methyl Di-*O*-acetyl-L-threuronate from *dextro*-Tartaric Acid

Gen NAKAMINAMI, Haruo EDO, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, 560

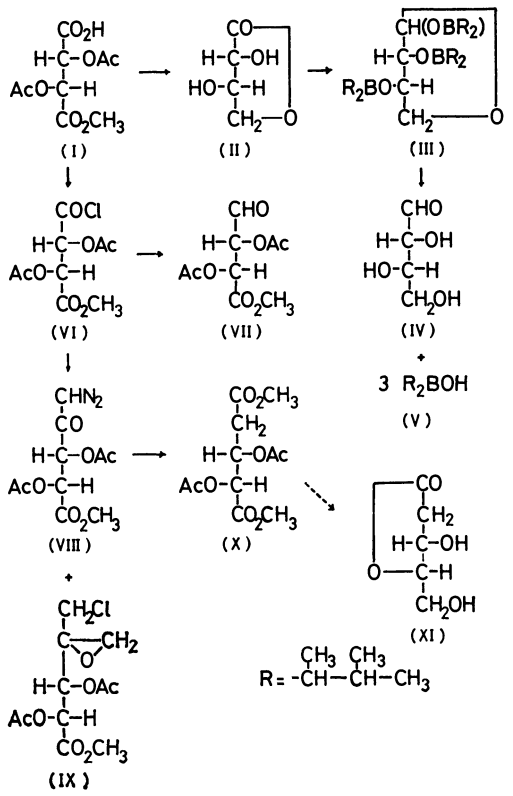
(Received June 2, 1972)

Reduction of methyl hydrogen di-*O*-acetyl-*dextro*-tartrate (I) with sodium borohydride in water afforded L-threono-γ-lactone (II). L-Threose (IV) was obtained on treatment of the γ-lactone (II) with an excess of disiamylborane. Reduction of ester chloride of di-*O*-acetyl-*dextro*-tartaric acid (VI) with tri-*n*-butyltin hydride yielded methyl di-*O*-acetyl-L-threuronate (VII). Attempts to reduce 2-deoxy-pentarate ester (X) derived from ester chloride (VI) *via* diazoketone (VIII) with sodium borohydride to give 2-deoxy-*threo*-pentono-γ-lactone (XI) gave unsatisfactory results. Formation of methyl L-*threo*-2,3-di-*O*-acetyl-5-chloro-5-deoxy-4-*C*-hydroxymethyl-4,4′-anhydropentonate (IX) in addition to diazoketone (VIII) was observed when ester chloride (VI) was treated with an excess of diazomethane. On the basis of the observed (—)-Cotton effect in the 290 nm region of ORD and CD spectra of L-threose (IV) and D-erythrose, possibility of the presence of an open chain non-hydrated *aldehyde*-form of aldotetrose in water was discussed.

dextro-Tartaric acid has been used widely as a starting material for syntheses of carbohydrates and their derivatives. L-Threuronate derivative (VII) was prepared by the Rosenmund reduction of ester chloride of *dextro*-tartaric acid derivative (VI).[1] Further reduction of VII with sodium amalgam afforded L-theritol *via* L-threonic acid.[1] Syntheses of L-threonolactone (II) and L-threuronate derivative (VII) have been achieved by the reduction of VI with tri-*tert*-butoxyaluminohydride.[2] The conversion of *dextro*-tartaric acid into L-apiose has been reported by Weygand and Scmiechen.[3]

We describe here some experiments to synthesize sugars and derivatives starting from *dextro*-tartaric acid carried out with the purpose of exploring the utility of complex hydride in carbohydrate chemistry.

It has been recognized that uronate esters could be reduced with sodium borohydride, in contrast to the failure of reduction of usual esters.[4] Treatment of monoethyl ester of *dextro*-tartaric acid with a large excess of sodium borohydride in anhydrous ethanol resulted in a partial recovery of the monoester accompanied by *dextro*-tartaric acid, hydrolysate of the ester. However, methyl hydrogen di-*O*-acetyl-*dextro*-tartrate (I) could be reduced to L-threono-γ-lactone (II) on treatment with sodium borohydride in water. The product obtained by the reaction of I (1 mol) with sodium borohydride (3.5 mol) in water was hydrolyzed without isolation with potassium hydroxide. Distillation of the hydrolysate *in vacuo* yielded crystalline L-threono-γ-lactone (II) in a 74% yield. Reduction of I could not be observed with the hydride in ethanol. The hydride in a mixture of ethanol and water afforded II in a low yield (47%). Facile reduction of I can reasonably be attributed to an enhanced electrophilicity of methoxycarbonyl funciton caused by the introduction



of electron withdrawing acetyl groups.[5] The present procedure of reduction of *dextro*-tartaric acid derivative (I) is more convenient and more practical than the older procedures[1,2] and L-threono-γ-lactone (II) can be obtained in a much higher yield.

Sodium borohydride reduction of aldono-γ-lactone to aldose proposed by Wolfrom and his co-workers[6] has been applied successfully to various aldonic acid lactones.[7] Usually, the reduction is performed in a weakly acidic buffer solution to avoid hydrolysis of the lactone ring. The reduction of II with an excess of

sodium borohydride (2–12 equivalents) in the presence of boric acid or boric acid and Amberlite IR 120 (H^+)[8] gave unsatisfactory results. Although the formation of L-threose (IV) could only be detected by a weak spot on tlc, predominent formation of by-products was observed in the case of a large excess of the reducing agent and a large amount of II was recovered in the case a slight excess of the hydride. Bis(1,2-dimethylpropyl)borane (disiamylborane) has been used in the reduction of γ-lactones to γ-hydroxyaldehydes.[9] In view of the success of reduction of 2-deoxy-*erythro*-pentono-γ-lactone to 2-deoxy-*erythro*-pentose with the same borane,[10] the reaction of II with an excess of disiamylborane in tetrahydrofuran was performed at room temperature. After borinate ester (III) formed had been hydrolyzed on addition of water, disiamylborinic acid (V) was removed by extraction with ether. L-Threose (IV) was obtained from the aqueous layer as a syrup in a quantitative yield. No crystalline D- or L-threose has so far been obtained, and the crystalline D-threose reported by Freudenberg[11] which showed positive specific rotation appears to be in error.[12] The specific rotation of syrupy L-threose (IV) thus obtained and the melting point of its benzoylhydrazone agreed with the reported values (Table 1). The overall yield of L-threose (IV) from *dextro*-tartaric acid was found to be 46%. The present method seems to be superior to the reported methods in view of the simplicity of procedure and the high yield. The Wohl degradation of L-xylose derivative obtained from sorbitol to give L-threose (IV) requires several steps[16] and the glycol-cleavage of 1,3-benzylidene-L-arabitol derived from L-arabinose affords L-threose (IV) in a lower yield (36% based on L-arabinose).[15,17,18b]

Table 1. Specific rotations of IV and melting point of benzoylhydrazone of IV

		+13.1°[16]
Mp of benzoylhydrazone	167.5—169.0°C	L-form: 167—168°C (decomp.)[14]

Reduction of ester chloride (VI) with tri-*n*-butyltin hydride which proved to be an useful reagent in the conversion of acid chloride into aldehyde[19] afforded methyl di-*O*-acetyl-L-threuronate (VII) as a liquid. Although attempts to crystallize VII by means of vacuum distillation or chromatography on silica gel or alumina failed, liquid VII gave crystalline 2,4-dinitrophenylhydrazone in a 38% yield based on VI.

As stated previously, introduction of the acetoxyl group into a position adjacent to the alkoxycarbonyl group facilitates sodium borohydride reduction of the alkoxycarbonyl group to the hydroxymethyl group. Consequently, it was anticipated that 2-deoxy-pentarate ester (X) which could be derived from ester chloride (VI) *via* diazoketone (VIII) by a photochemical rearrangement[3] might afford 2-deoxy-*threo*-pentono-γ-lactone (XI) by a preferential reduction of the methoxycarbonyl group at 5-position. However, the reaction of X (1 mol) with various amounts of sodium borohydride (2.5—5.0 mol) in different solvents (water, methanol, tetrahydrofuran, or 2-propanol) gave unsatisfactory results. Only removal of acetyl groups was observed in the case of methanol solution. Treatment of X in tetrahydrofuran with the hydride resulted in a recovery of X. The reaction product obtained on treatment of X with the hydride in water or 2-propanol gave syrupy material after deacetylation by the ester-exchange reaction followed by hydrolysis of methyl ester groups. The syrup gave a weak spot corresponding to an authentic specimen of XI together with several spots of by-products. Since crystalline diazoketone (VIII), precursor of 2-deoxy-pentarate ester (X), could be scarcely obtained when the reaction of diazomethane with ester chloride (VI) had been carried out according to the reported method,[3] ester chloride (VI) was treated with an excess of diazomethane. The product was subjected to chromatography on silica gel which resulted in the separation of diazoketone (VIII) and another crystalline compound. The structure of epoxide ester (IX) could be assigned to the crystalline compound on the basis of elemental analysis and IR and NMR spectroscopic data. The NMR spectrum of IX in deuteriochloroform exhibited singlets at δ 2.91 (2H) and δ 3.73 (5H) which could be assinged to methylene protons of the epoxide ring, and protons of methyl in the ester and chloromethyl groups, respectively. The NMR spectrum of IX measured in benzene afforded more confirmative evidence, *i.e.*, methylene protons in the epoxide ring exhibited AB quartet [centered at δ 1.84 and 1.92 (J=10.2 Hz)], and protons of the chloromethyl group also split in AB quartet [centered at δ 2.88 and 2.93 (J=12.4 Hz)]. IX also gave a positive test for sodium thiosulfate-phenolphthalein reagent[20] indicating the presence of epoxide ring. The epoxy-ester (IX) may be formed by the reaction of diazoketone (VIII) with

hydrogen chloride liberated[21] and another mole of diazomethane.[22]

Finally we wish to give some remarks on the optical rotatory properties of some compounds related to aldotetrose. L-Threono-γ-lactone (II) exhibited a negative Cotton effect in the ORD and CD spectra in agreement with the general rule proposed by Okuda, Harigaya, and Kiyomoto.[23] They concluded that the sign of the Cotton effect of aldonolactones is governed by the configuration of carbon atom at 2-position, *i.e.*, (*R*)- and (*S*)-configurations at 2-position gave negative and positive Cotton effects, respectively. The observed negative Cotton effect of L-threono-γ-lactone (II) is consistent with the (*R*)-configuration at 2-position.

An aqueous solution of L-threose (IV) obtained by the disiamylborane reduction of II showed a small negative Cotton effect at *ca.* 290 nm. Cantor and Peniston carried out polarographic studies on aqueous solution of carbohydrates and pointed out the presence of species reducible at dropping mercury cathode and estimated the amount of the reducible form.[24] They considered that the reducible species should be of *aldehydo*-form or its hydrated species of carbohydrates.[24] It was revealed later that the ORD spectra of aqueous solution of aldopentoses and aldohexoses usually exhibit a simple curve in a wavelength region longer than 210 nm and no Cotton effect can be observed in the region of $n\rightarrow\pi^*$ transition of carbonyl of aldehyde group.[25] In spite of the high content of the reducible form,[24] D-ribose also showed no Cotton effect in the region of carbonyl $n\rightarrow\pi^*$ transition. Thus, complete hydration of the free aldehyde group in open chain form of aldopentose or aldohexose was concluded.[26] L-Threose (IV) obtained by acid hydrolysis of an authentic 2,4-*O*-benzylidene-L-threose[18b] also showed a negative Cotton effect at *ca.* 290 nm. This indicates that the negative Cotton effect observed in L-threose (IV) derived from II can not be ascribed to the presence of any carbonyl containing impurity, but is an inherent property of IV (Fig. 1 and Table 2). The signal at δ 9.44 (singlet) in the NMR spectrum of L-threose (IV) in deuterium oxide can presumably be attributed to the proton of the free aldehyde group. Recently, the presence of a weak Cotton effect in the CD spectrum of D-erythrose in water was briefly reported.[27] This was confirmed by the present authors employing a syrupy D-erythrose obtained by the hydrolysis of crystalline 2,4-*O*-ethylidene-D-erythrose[18a] (Fig. 1 and Table 2). *glycero*-Tetrulose appears to be the most probable impurity of these aldotetroses. Rearrangement of L-threose or D-erythrose should result in L- or D-*glycero*-tetrulose, respectively. However, studies on *glycero*-tetrulose revealed that the L-isomer exhibits a positive and the D-isomer a negative Cotton effect in their ORD spectra.[28] Consequently, the negative Cotton effect of L-threose can not be attributed to the presence of L-*glycero*-tetrulose as an impurity. 2,4-*O*-Ethylidene-D-erythrose, starting material for the preparation of D-erythrose, shows a weak negative Cotton effect ($\Delta\varepsilon$ — 0.021) at 293 nm in water. Therefore, we can not hold the presence of a small amount of 2,4-*O*-ethylidene-D-erythrose as an impurity to be responsible for most of the observed negative Cotton effect of D-erythrose.

Tetrose may contain more of the open chain form than pentose and hexose in the ring-chain equilibrium, because furanose, the cyclic form of aldotetrose, is known to be less stable than pyranose. The observed Cotton effect in the region of $n\rightarrow\pi^*$ transition of the carbonyl group seems to indicate that some part of the open chain form of aldotetrose exists in non-hydrated *aldehydo*-form.

Experimental

The melting points were measured on a Mettler FP2 apparatus and uncorrected. The IR spectra were obtained on a Hitachi EPI-2 Spectrophotometer, the ORD and CD spectra on a Yanagimoto ORD-185, a JASCO ORD/UV-5 and a Roussel-Juan Dichrograph and the NMR spectra on a Varian A-60 or T-60 spectrometer using tetramethylsilane or sodium 2,2-dimethyl-2-silapentane-5-sulfonate as an internal standard, unless otherwise stated. Commercial silica gel (E. Merck, Darmstadt, Germany, 70—325 mesh) was immersed in 60% aqueous acetic acid and kept standing overnight. The gel was collected by suction filtration and washed thoroughly with water until the filtrate gave neutral test, and dried at 120°C for 15 hr. The silica gel thus treated was used in chromatography.

L-Threono-γ-lactone (II). To an ice-cooled and stirred solution of sodium borohydride (991 mg, 28.3 mmol) in water (15 ml) was added dropwise a solution of half-ester of di-*O*-acetyl-*dextro*-tartaric acid[1] (I, 2.0 g, 8.06 mmol) in water (23 ml). After the mixture had been stirred for 4 hr at room temperature, 2N hydrochloric acid (20 ml) was added and the water was removed under reduced pressure. Methanol was added to the residue and concentrated under reduced pressure. The procedure was repeated 3 times to complete the removal of boric acid as its methyl ester. Extraction of the residue with acetone gave an oily material (1.54 g), which was dissolved in methanol (15 ml) and mixed with potassium hydroxide (2.5 g, 45 mmol) in water (5 ml). The mixture was kept at room temperature for 15 min and then refluxed for 1 hr. 2N Hydrochloric acid (22 ml) was added to the cooled reaction mixture. The residue obtained by evaporating the water *in vacuo* was extracted with ethyl acetate. The oily material (998 mg) obtained from the extract was subjected to a vacuum distillation (0.088 mmHg). The fraction obtained from *ca.* 148°C (bath temp.) crystallized on standing. The crystals were washed with a small amount of ethyl acetate to yield fairly pure II (700 mg, 74%). Recrystallization from the same solvent afforded pure II, mp 67—69°C (lit. values: mp 65—68°C[29]; mp 61—64°C[2]), IR (Nujol mull): 3400 (O–H), 1770 (C=O) cm^{-1}, $[\alpha]_D^{17}=+46.7°$ (*c*, 1.54, CH_3OH) (lit. values: $[\alpha]_D^{21}=+47.0°$[29]; $[\alpha]_D^{19}=+51.2°$[30]), $[\phi]_{min}=-5210°$ (239.5 nm), $\Delta\varepsilon_{max}=-3.59$ (222.5 nm) (*c*, 2.11×10^{-3} mol/l, CH_3OH).

Found: C, 40.59; H, 5.14%. Calcd for $C_4H_6O_4$: C, 40.68; H, 5.12%.

Phenylhydrazide. Colorless plates, mp 153—157°C (lit. value: mp 161—161.5°C[29]).

Found: C, 52.98; H, 6.35; N, 12.16%. Calcd for $C_{10}H_{14}N_2O_4$: C, 53.09; H, 6.24; N, 12.38%.

L-Threose (IV). A solution of disiamylborane in tetrahydrofuran was prepared according to the usual method from a solution of 2-methyl-2-butene (4.275 g, 61.1 mmol) in the same solvent (15 ml) and a stock solution of diborane (34.2 ml, 0.445 mmol/ml, 15.2 mmol). To this was added dropwise under ice-cooling a solution of γ-lactone (II, 300 mg, 2.54 mmol) in the same solvent (12 ml) in nitrogen atmosphere. After the mixture had been kept at room temperature for 18 hr, water (1 ml) was added under stirring to the ice-cooled reaction mixture to decompose the excess of disiamylborane. It was then mixed with a further amount of water (60 ml) and stirred for 30 min at room temperature to hydrolyze borinate ester (III). The mixture was extracted with ether (25 ml×3) to remove disiamylborinic acid (V). The ethereal extract was washed with water (25 ml). The combined aqueous layer and washing were concentrated under reduced pressure. The residue was mixed with methanol and the solvent was removed *in vacuo*. After the procedure had been repeated 3 times, the residue was dried in an evacuated desiccator containing phosphorus pentoxide to give an almost colorless syrup (325 mg, $[\alpha]_D^{20}=+12.2°$ (initial)→ $+12.6°$ (after 3 days) (*c*, 2.55, H_2O)). The syrup was converted into crystalline benzoylhydrazone according to the reported method.[14] Syrupy L-threose (IV, 48 mg) gave 60 mg (63%) of benzoylhydrazone. Recrystallization from ethanol gave pure hydrazone as colorless fine needles, mp 167.5—169.0°C. IR (Nujol mull): 3500, 3360, 3240 (O–H, N–H); 1647 (amide-I): 1551 (amide-II) cm^{-1}.

Found: C, 55.44; H, 6.01; N, 11.74%. Calcd for $C_{11}H_{14}N_2O_4$: C, 55.45; H, 5.92; N, 11.76%.

Methyl Di-O-acetyl-L-threuronate (VII). A solution of acid chloride (VI,[3] 2.30 g, 8.63 mmol) in tetrahydrofuran (16 ml) was added to tri-*n*-butyltin hydride[31] (2.64 g, 9.07 mmol) over a period of 15 min. After stirring for 100 min, the solvent was removed under reduced pressure. The residue was mixed with petroleum benzine and water and the aqueous layer was washed twice with petroleum benzine. The combined benzine solution was washed with water. The combined aqueous layer was concentrated under reduced pressure to *ca.* 50 ml. The concentrated solution was treated with active charcoal–celite (1:1) and the filtrate was evaporated under reduced pressure. The residue was dried in an evacuated desiccator over phosphorus pentoxide to afford almost colorless syrup (1.57 g). A mixture of the syrup (116 mg), 2,4-dinitrophenylhydrazine (98 mg) and ethanol (3 ml) was refluxed for 3 hr. The crude crystals deposited were dissolved in benzene and the solution was passed through a short column of alumina. The crystals (99 mg, 38% based on acid chloride (VI)) were recrystallized from ethanol to give an analytical specimen, aggregate of yellow needles, mp 146.5—148.0°C (lit. value:[1] 148°C).

Found: C, 43.83; H, 3.94; N, 13.73%. Calcd for $C_{15}H_{16}N_4O_{10}$: C, 43.69; H, 3.91; N, 13.59%.

Methyl L-threo-*2,3-Di-O-acetyl-5-chloro-5-deoxy-4-C-hydroxymethyl-4,4'-anhydro-pentonate (IX).* Acid chloride (VI,[3] 0.0353 mol) was treated with diazomethane (0.107 mol) according to the reported method.[3] Crystalline diazoketone (VIII) obtained by evaporating the solvent under reduced pressure was filtered. Syrupy filtrate was dissolved in benzene–ethyl acetate (8: 2) and chromatographed on silica gel. Epoxy compound (IX) obtained from early fractions crystallized immediately (mp 63—79°C). Farther elution with the same mixed solvent afforded an additional diazoketone (VIII). Change of melting point of IX could not be observed after recrystallization from diisopropyl ether, ethyl acetate, or ether–petroleum benzine. IX gave immediate red coloration for cold sodium thiosulfate-phenolphthalein reagent[20] indicating the presence of the epoxide ring.

Found: C, 45.05; H, 5.08; Cl, 11.95%. Calcd for $C_{11}H_{15}O_7Cl$: C, 44.83; H, 5.13; Cl, 12.03%.

Hetera-*p*-carbophanes. I. Hetera-*p*-carbophanes Containing Two Amide Groups

Kazuhiko SAKAMOTO and Michinori ŌKI[1)]

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 9, 1972)

Several hetera-*p*-carbophanes containing two amide groups in the ansa chain were synthesized by the high-dilution method. Those which have shorter ansa chains than 15 atoms show no sign of the internal rotation of the benzene ring, even at higher temperatures, whereas that which has the ansa chain of 16 atoms shows no sign of the freezing of the motion, even at lower temperatures. The infrared spectra of these compounds suggest that the amide groups in these compounds exist as the *s-cis* conformation.

The restricted rotation of an aromatic ring in paracyclophanes was first demonstrated by the optical resolution of oxygen-containing hetera-*p*-carbophanes[2)] by Lüttringhaus.[3)] Later, Cram and his co-worker succeeded in resolving a [2.2]paracyclophane derivative,[4)] and Blomquist *et al.* reported the first resolution of carbo-*p*-carbophanes in 1961.[5)] A faster but still hindered rotation can, of course, be observed by the dynamic nuclear magnetic resonance technique. Thus, Cope *et al.* published a paper on the hindered rotation of an olefinic cyclophane (I) using the nonequivalence-collapse of the aromatic and aliphatic protons.[6)] On the other hand, Nakazaki *et al.* studied the nonequivalence of protons of an XCH_2 group which is attached to the benzene ring of a paracyclophane (II).[7)]

In general, paracyclophanes should have nonequivalent benzylic methylene protons, provided that the aromatic ring is unsymmetrically substituted and the rotation of the ring is slow enough on the NMR time scale. Actually, Cope *et al.* pointed out that the benzylic protons of I were nonequivalent.[6)] In the compounds of the type of II, the conformational distribution will, in principle, vary with the temperature because the stabilities of three rotamers concerned with the internal rotation about the C_{arom}–C_{CH_2X} bond are different. Thus, it is the authors' opinion that much more study is needed to clarify the various effects on the rate of the rotation of the aromatic ring in paracyclophanes and in order to discuss the effect of the variation in the population of the rotamers on the apparent barriers to the internal rotation.

This paper will deal with the syntheses and some spectroscopic properties of 10 hetera-*p*-carbophanes (III and IV) as the first probe of a series. The reason for the selection of these compounds is the simplicity of the analysis of the line shape. The rigidity and the mobility of these compounds as revealed by NMR spectroscopy will be reported.

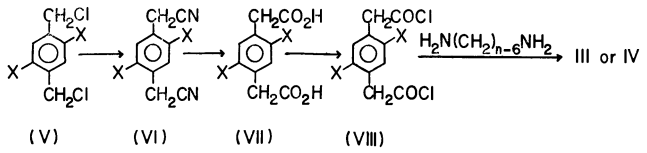
IV_n X=Me (n=12—16)

Experimental

Syntheses. The hetera-*p*-carbophanes, III_n and IV_n,[8)] were synthesized by the high-dilution method from the corresponding 1,4-phenylenediacetyl dichloride and α,ω-diamines. The routes of the syntheses of the former are depicted in Scheme 1, while the latter compounds were of commercial origin.



(V) (VI) (VII) (VIII)

Scheme 1.

All the melting points are uncorrected.

α^1,α^4-Dichlorodurene (V, X=Me). A mixture of 53 g (0.5 mol) of *p*-xylene, 106 g (1.3 mol) of 37% formaline, and 530 g of concentrated hydrochloric acid was heated at 60—70°C for 7—15 hr with stirring and while introducing dry hydrogen chloride. The resulting crystals were filtered, and the filtrate was extracted with ether. The crystals and the ether extract were combined and were thoroughly washed with a saturated aqueous solution of sodium bicarbonate and then with a sodium chloride solution. After drying over magnesium sulfate, the solvent and some α^2-chloro-1,2,4-trimethylbenzene were evaporated to yield the crude α^1,α^4-dichlorodurene. Recrystallization from ether gave 65 g of the pure compound; mp 128—129°C (lit, mp 133°C).[9)]

α^1,α^4-Dicyanodurene (VI, X=Me). A mixture of 50 g (0.25 mol) of the dichloride (V, X=Me), 37 g (0.75 mol) of powdered sodium cyanide, 800 ml of ethanol, and 150 ml of water was refluxed for 30 hr. The subsequent working-up of the reaction mixture in the usual manner gave 37 g (80%) of the crude dicyanide (mp 136—138°C), which was directly

a) The numerical data in the upper column are those found and those in lower column are the calculated values.
b) The reaction was carried out at the boiling point of tetrahydrofuran without adding triethylamine.

used for the preparation of 2,5-dimethyl-1,4-phenylenediacetic acid. IR(KBr): 2240 cm^{-1} (ν_{CN}). NMR ($CDCl_3$, δ from internal TMS): 2.31 (6H, s); 3.62 (4H, s); 7.20 (2H, s).

α^1,α^4-Dicyano-p-*xylene (VI, X=H)* was obtained similarly in an 89% yield; mp 95.5—96.5°C (lit, mp 96°C).[10] IR (KBr); 2250 cm^{-1} (ν_{CN}). NMR ($CDCl_3$, δ from internal TMS): 3.76 (4H, s); 7.36 (4H, s).

2,5-Dimethyl-1,4-phenylenediacetic Acid (VII, X=Me). A mixture of 37 g (0.2 mol) of the dicyanide (VI, X=Me), 60 ml of concentrated sulfuric acid, and 80 ml of water was refluxed for 3 hr. The reaction mixture was then poured into ice–water after cooling to yield 20 g (39%) of the crude product. The sample, after purification, melted at 257—261°C with decomposition. IR(KBr); 1700 cm^{-1} (ν_{CO}).

1,4-Phenylenediacetic acid (VII, X=H) was prepared similarly in a 49% yield. Mp 227—230°C (decomposition) (lit, mp 240—241°C).[11] IR(KBr): 1710 cm^{-1} (ν_{CO}).

2,5-Dimethyl-1,4-phenylenediacetyl Dichloride (VIII, X=Me). A mixture of 10 g (38 mmol) of the dicarboxylic acid (VII, X=Me), 20 g (180 mmol) of thionyl chloride, and 120 ml of absolute ether was refluxed for 5 hr. The unreacted dicarboxylic acid was removed by filtration, and the exess thionyl chloride and the solvent were evaporated under reduced pressure to give 8 g (68%) of yellow crystals. The crude dichloride was used for the next reaction without further purification.

1,4-Phenylenediacetyl dichloride was obtained similarly in a 69% yield.

Syntheses of Hetera-p-*carbophanes (III and IV).* These compounds were prepared by two general methods. Method A was used for the compounds which were soluble in a benzene–toluene mixture. For the compounds which were sparingly soluble in a benzene–toluene mixture, the use of method B was preferable. The method of preparation, the melting points, the analytical data, and the solvents of recrystallization for each compound are summarizd in Table 1.

Method A. This method will be described by taking the case of 14,17-dimethyl-3,10-diaza-2,11-dioxo[12]paracyclophane (IV_{12}) as an example.

A solution of 3.4 g (13 mmol) of 2,5-dimethyl-1,4-phenylenediacetyl dichloride in 350 ml of a 1:1 (v/v) benzene–toluene mixture was slowly added to a vigorously-stirred mixture of 4.0 g (40 mmol) of triethylamine, 2.3 g (20 mmol) of hexamethylenediamine, and 500 ml of 1:1 (v/v) benzene–toluene over a period of 40 hr. The mixture was freed from any solid material by filtration and then evaporated *in vacuo* to give 0.5 g (13%) of pale yellow crystals. The recrystallization of the product from methanol afforded colorless, granular crystals; mp 237.5—238.5°C.

Method B. This method will be exemplified by the preparation of 3,13-diaza-2,14-dioxo[15]paracyclophane (III_{15}).

A solution of 1.65 g (7 mmol) of 1,4-phenylenediacetyl dichloride in 100—150 ml of tetrahydrofuran was slowly added to a vigorously-stirred and refluxing mixture of 1.5 g (15 mmol) of triethylamine and 1.1 g of nonamethylenediamine in 600—800 ml of tetrahydrofuran over a period of 25 hr, employing a high-dilution apparatus. After the solvent has then been removed, the residue was extracted with 100 —200 ml of dichloromethane. The extract was washed with dilute hydrochloric acid and then with saturated aqueous sodium chloride, and dried over magnesium sulfate. The evaporation of the solvent, after filtration, gave 0.5 g (18%) of pale yellow crystals which were recrystallized several times from methanol or dichloromethane. The pure compound consisted of colorless crystals; mp 269.0—270.0°C.

N,N'-Dipropyl-2,5-dimethyl-1,4-phenylenediacetamide (XV). To a solution of 3 g (31 mmol) of propylamine and 3 g of (30 mmol) of triethylamine in 50 ml of tetrahydrofuran, was added a solution of 2.6 g (10 mmol) of 2,5-dimethyl-1,4-phenylenediacetyl dichloride in 50 ml of tetrahydrofuran,

10) A. F. Titly, *J. Chem. Soc.*, **1926**, 515.
11) F. S. Kipping, *ibid.*, **56**, 21 (1888).

while the temperature was maintained below 5°C. The resulting solid was collected by filtration, washed with water, and recrystallized from methanol. The compound (mp 230.0—231.0°C), was thus obtained in a 1.5 g (50%) yield. IR (KBr): 3300 (ν_{NH}); 1640 (amide I); 1545 (amide II). Found: C, 71.23; H, 9.44; N, 8.96%; mol wt, 304 (M^+). Calcd for $C_{18}H_{28}N_2O_2$: C, 71.02; H, 9.27; N, 9.20%; mol wt, 304.

N,N'-Dipropyl-1,4-phenylenediacetamide (XIV) (mp 225.0—226.0°C) was similarly obtained in a 64% yield. IR(KBr): 3260 (ν_{NH}); 1635 (amide I); 1555 cm^{-1} (amide II). Found: C, 69.56; H, 8.86; N, 9.90%; mol wt, 276 (M^+). Calcd for $C_{16}H_{24}N_2O_2$: C, 69.53; H, 8.75; N, 10.14%; mol wt, 276.

1,8-Diaza-9,18-dioxocyclooctadecane (XVI). This compound was prepared in a manner similar to that described for the preparation of hetera-*p*-carbophanes (Method A) from decanedioyl dichloride and hexamethylenediamine. The compound melted at 216.0—218.0°C after recrystallization from dimethylformamide. IR (Nujol mull): 3300 (ν_{NH}); 1640 (amide I); 1545 (amide II). Found: C, 67.53; H, 10.59; N, 9.53%; mol wt, 282 (M^+). Calcd for $C_{16}H_{30}N_2O_2$: C, 68.04; H, 10.71; N, 9.92%; mol wt, 282.

Measurement of the Spectra. The infrared spectra were recorded on either a Hitachi EPI-G2 grating infrared spectrophotometer or a Perkin-Elmer 112G grating spectrophotometer. The NMR spectra were measured on a Hitachi R-20B spectrometer, and the mass spectra, on a Hitachi RMU-6L spectrometer.

Results and Discussion

Internal Rotation of the Aromatic Ring. The observed NMR spectra of III_{12} and IV_{12}—IV_{16} in a deuteriochloroform solution at 34°C are illustrated in Fig. 1. The high-resolution spectra of III_{13}—III_{16} could not be obtained because of their poor solubilities in the appropriate solvents.

It can be pointed out generally that the shapes of the signals of the bridge methylene protons in IV_n reflect the rigidity of the molecule: the compounds with the smaller ring give the complex spectra, while those of the larger ring, give the rather smooth spectra. The chemical shifts of the methylenes of the smaller ring are located in the high magnetic field, suggesting the anisotropy effect of the benzene ring.

The benzylic protons of III_{12} and IV_{16} gave signals of the A_2 type at 3.58 and 3.51 ppm respectively from the internal TMS, whereas those of IV_{12}, IV_{13}, IV_{14}, and IV_{15} gave signals of the AB type at *ca.* 3.54 ppm.

Considerations of the conformations of III_n and IV_n reveal that there are three conformations possible, the isomerism of which is caused by the rotation about the C_{CO}–C_{benzyl} bond: *syn*, *anti*, and *syn'* in Fig. 2.[12]

The Newman projections of these conformations, as separated forms for the two benzylic parts, are given in Fig. 3.

Since these molecules are rather rigid, the exchange among these conformations might be slow on the NMR time scale. However, looking at the data of III_{12}, the possibility that the slow exchange is the cause of the appearance of the AB signals can be rejected: if such were the case, III_{12} should also have

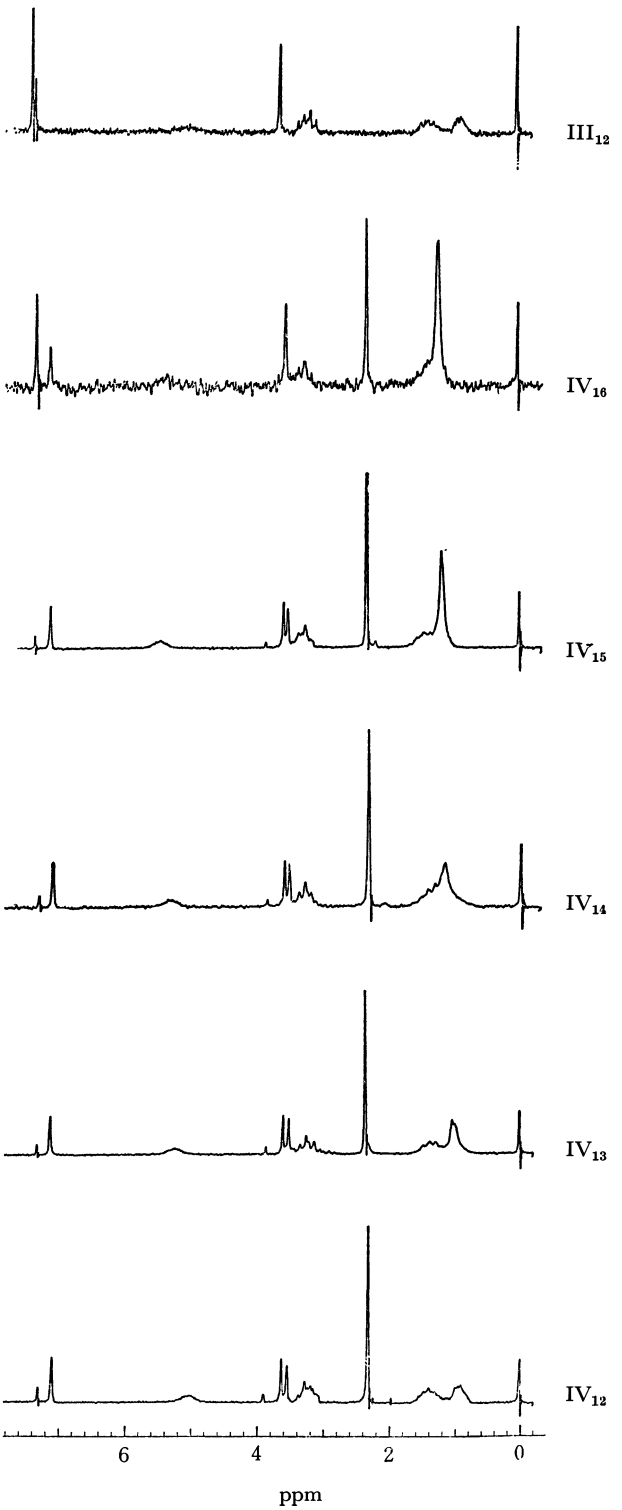

Fig. 1. NMR spectra III_{12} and IV_{12}—IV_{16} in $CDCl_3$ (δ from internal TMS).

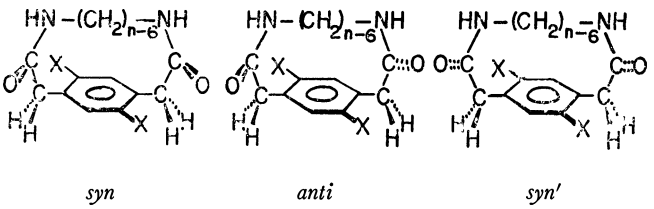

Fig. 2. Rotational isomerism about the C_{CO}–C_{benzyl} bond.

12) We are assuming that no isomerization is possible about the amide moiety. See the discussions below.

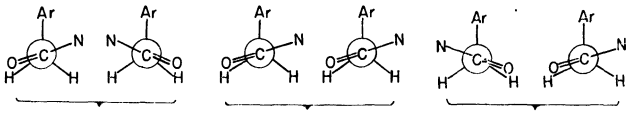

Fig. 3. Newman projections of rotational isomers about the C_{CO}–C_{benzyl} bond.

shown the AB signal for the benzylic protons. Thus, the slow internal rotation of the unsymmetrically-substituted benzene ring is the sole possible cause of the AB-type signals.

At least, at room temperature, the signals suggest that the internal rotation of the dimethylbenzene ring in IV_{15} is slow while that in IV_{16} is fast, on the NMR time scale. The temperature dependence of these spectra was thus studied in an attempt to obtain the kinetic data of the internal rotation: IV_{15} in 1,1,2,2-tetrachloroethane at higher temperatures (34—170°C) and IV_{16} in deuteriochloroform at lower temperatures (34—−50°C). To our suprise, however, the changes in signal shape according to the temperature change are so small that it is impossible to obtain the expected data.

The minimum and maximum free energies of activation may be obtained by applying this equation:[13]

$$\Delta G_c^* = 4.57 T_c\{9.97 + \log_{10}(T_c/\sqrt{\delta\nu^2 + 6J^2})\}$$

provided that the chemical shifts and the coupling constants are the same for both compounds when the internal rotation is slow enough and that the coalescence temperature (T_c) in the above equation is transferable to any temperature desired. Thus, since the AB quartet of the benzyl methylenes in IV_{15} did not colapse at 443°K, the minimum free energy of activation is obtained as 22.3 kcal/mol. Similarly, since the benzyl methylene signals of IV_{16} did not change in shape even at 223°K,[14] the free energy of activation for the internal rotation must be less than 10.8 kcal/mol. Therefore, the difference in barriers to the internal rotation of the benzene ring is at least 11.5 kcal/mol for these compounds. This large difference in the barriers by changing the number of bridge methylenes by only one is not without precedent. *trans*-Cyclodecene is known to have the barrier of 10.7 kcal/mol[15] by the dynamic NMR, and *trans*-cyclononene, one of 20 kcal/mol by the conventional kinetic technique.[16]

It is noteworthy that, although the coupling constants

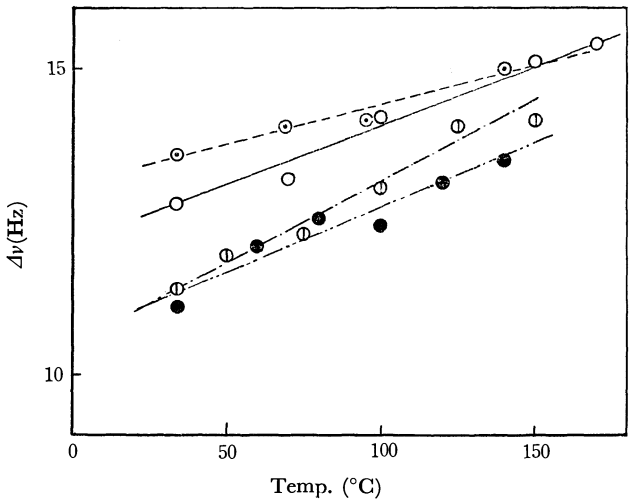

Fig. 4. Temperature dependence of the chemical shift difference between the benzylic methylene protons in IV_{12}—IV_{15}.
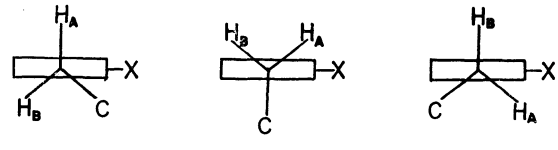
—○—; IV_{12}, ---⊙---; IV_{13}, —◑—; IV_{14}, ---●---; IV_{15}

did not change, even the benzylic methylene protons change their chemical shifts due to the temperature variation. This is a rather unexpected phenomenon, because no reason for the change can be deduced from the first approximation. The relation between the chemical shifts and the temperature are shown in Fig. 4. The chemical shifts show small but definite changes within the range of 1.5—3.0 Hz at the temperature of 34—*ca.* 150°C. The change in chemical shifts is linearly correlated with the temperature.

Such a temperature dependence may, in general, be attributed to solvation effects or the population effects. If the reasons for the temperature dependence of the spectra are attributed to the population effect, there will be two cases to be considered. The first is the isomeric conformations caused by the rotation about the C_α–C_{CO} bond, and the second is the change in the populations of the conformers (IX, X, and XI) formed by the rotation about the C_{ar}–C_α bond.



However, the change in population is not the likely cause of the change in chemical shifts. The change in population of the conformers on raising the temperature causes the averaging tendency of the signals, since the more unstable conformers increase in their populations. The data in Fig. 4 show, however, that the chemical shift differences between the A and B protons, rather, increase at higher temperatures.

Thus, the solvation effect becomes a more likely reason. Since, at lower temperatures, the solvated molecules reside close to the solute molecule for a longer time, the protons suffer from the anisotropy effects of various bonds and atoms. However, at higher temperatures, the effects will be more or less averaged out because of the faster motion of the molecules. These

14) The apparent singlet signal may be the results of the accidental identity of the chemical shifts of the two benzylic protons in this solution system. Since the attempts to obtain spectra at low temperatures in other solvent systems have failed due to the poor solubility of the compound, we tentatively assume that the apparent singlet signal shows the fast exchange of the two ptorons. Incidentally, the corresponding diester compound has shown the splitting tendency of the singlet signal into a quartet at *ca.* −50°C in CH_2Cl_2–$CDCl_3$ (an unpublished work).

differences should be able to cause the variation in chemical shifts to some extent.

The Conformations of the Amide Groups. It has been well documented that some amides exist as *s-cis* (XII) and *s-trans* (XIII) isomers. Lactams of the small rings cannot take the *s-trans* conformation due to the ring strain and exist solely as the *s-cis* conformation, whereas the open-chain amide is the most stable when the *s-trans* conformation is taken. In view of these facts, it will be interesting to study whether the amide groups in these hetera-*p*-carbophanes take the *s-cis* or the *s-trans* conformation. Thus, the N–H stretching absorption spectra, which have been extensively employed for the diagnosis of the conformation in question, have been examined in detail. The results obtained with dilute chloroform solutions are shown in Table 2, together with the data of the open-chain analogs (XIV and XV) and a simpler cyclic amide (XVI).

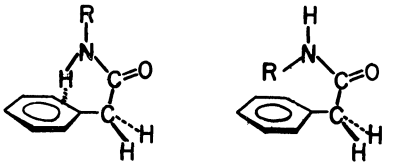
XVI	3453 (252)	

a) Graphically resolved.

As may be seen in the table, the hetera-*p*-carbophanes examined all show only one N–H stretching absorption, as does the dilactam (XVI), whereas the open-chain analogs (XIV and XV) show two ν_{NH} absorptions. The absorption of the dilactam (3453 cm^{-1}) corresponds to the frequencies of the well-documented *s-trans* conformation, and this compound is believed to exist as a bis-*s-trans* conformer.

The absorption frequencies of the hetera-*p*-carbophanes are rather low and are in the region of the *s-cis* conformation. However, the phenylacetamide derivatives are known to possess an internal N–H···π interaction[17] which causes a lowering of the absorption frequencies, even though the conformation is *s-trans*. Indeed, the N–H absorptions of the open-chain analogs at the lower frequencies must be attributed to the N–H···π interacting species, since the absorption coefficients of the lower band are too large to assign to the *s-cis* conformation.



N–H···π intracting (*s-trans*) *s-cis*

Then a problem arises: why does the absorption appear at lower frequencies for the hetera-*p*-carbophanes? Is this a sign of an *s-cis* conformation or of N–H···π interaction? We would like to attribute the phenomena to the *s-cis* conformation of the amide groups for the following three reasons.

The first reason is the rigidity of the scale models. In the smaller ring compounds, although it is possible to make a model involving two *s-trans* conformations, this model tends to collapse when the support is removed, suggesting that this conformation has a high energy. It is also possible to make up a model involving *s-cis* and *s-trans* conformations. However, all the III_n and IV_n give only one absorption at about the same wave number, a number which is within the region attributable to the *s-cis* conformation. Therefore, a conformation involving the two *s-cis* amides is the more likely possibility.

The second reason is the consideration of the N–H···π interaction. The most favorable conformation for the interaction is the one in which the C_α–C_{CO} bond is perpendicular to the benzene ring (X); in this conformation, the N–H group approaches the π-lobe of the benzene ring from the top, and this gives the maximum overlap of the orbitals concerned. If the other conformations (*e.g.*, IX and XI) are taken and the overlap of the orbitals is decreased, the compound should show other N–H absorptions; these may be either free or interacting to a lesser extent. However, none of the hetera-*p*-carbophanes shows a second N–H band. Therefore, although this evidence is negative in nature, this can be taken as supporting the absence of the *s-trans* conformation.

The third reason is the evidence obtained by NMR spectroscopy. If there is an exchange between the *s-cis* and N–H···π interacting *s-trans* conformations, then there will be a change in the chemical shifts of the CH_2 protons, α to the nitrogen atom, since it is a well-

17) I. Suzuki, M. Tsuboi, and T. Shimanouchi, *Spectrochim. Acta*, **16**, 467 (1960).

known fact that the *s-cis* and *s-trans* amides give signals characteristic of their conformations and that, even though these conformations are not detected by NMR because of the fast rate of exchange, there should yet appear a change in the chemical shifts. However, in reality, no change in the chemical shifts of the CH_2N signals was observed.

The presence of the *s-cis* conformation only for III_n and IV_n, in contrast to the presence of *s-trans* for the dilactam XVI, is undoubtedly a reflection of the rigidity of the benzene ring in III and IV, which limits the conformation of the molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 275—279 (1973)

The Peracid-oxidation of Tetraphenylallene: The Formation of Hydroxyindanone and Its Oxidative Transformation

Akira OKU, Kojiro SHIMADA, and Fujio MASHIO

Department of Chemistry, Kyoto Institute of Technology, Matsugasaki, Sakyo-ku, Kyoto, 606

(Received June 17, 1972)

The oxidation of tetraphenylallene (**1**) with *m*-chloroperbenzoic acid has been reported. Under acidic conditions, 1-hydroxy-1,3,3-triphenyl-2-indanone (**2**) was isolated in 45% yield, along with benzophenone (**3**) and the *m*-chlorobenzoate of **2** as minor products. In the presence of sodium carbonate, the oxidation products were 2,2,4,4-tetraphenyloxetanone (**6**), **3**, and 1,3,3-triphenyl-2,3-dihydro-5*H*-indene-2,5-dione (**5**). The prolonged oxidation of **2** with peracetic acid yielded α,α-diphenylphthalide (**9a**). The alkaline hydrolysis of **2** induced ring cleavage to give *o*-benzhydrylbenzilic acid (**15b**), whereas acid hydrolysis in ethanol or methanol gave the corresponding ethers, **16a** and **16b** respectively.

The intermediacy of allene oxides has attracted our attention in terms of olefin-epoxidation and valence tautomerism with cyclopropanone.[1] Vorlander[2] was the first to report the synthesis of tetraphenylallene dioxide by the cromic-acid oxidation of tetraphenylallene, but it was proved later[3] that the product was tetraphenyloxetanone instead of the dioxide. Recently Crandall and his co-workers[4] have reported extensive work on the isolation of allene dioxides, cyclopropanones, and oxetanones in the peracid oxidation of alkyl-substituted allenes. More significantly, Greene and Camp[5] have isolated 1,3-di-*tert*-butylallene oxide by using *m*-chloroperbenzoic acid as the effective reagent.

In the present study, we wish to report the peracid oxidation of tetraphenylallene (**1**), where the product formation is largely dependent on the pH of the oxidation mixture. Analogously to the earlier studies,[4] the intermediacy of tetraphenylallene oxide (**7**) and its corresponding spiro-dioxide (**8**), though not isolated, has been demonstrated. On the other hand, however, cationic alkylation on a benzene ring of substrates has taken place predominantly under acidic conditions to give 1-hydroxy-1,3,3-triphenyl-2-indanone (**2**),[6] while under the conditions buffered with sodium carbonate, 2,2,4,4-tetraphenyloxetanone (**6**) and 1,3,3-triphenyl-2,3-dihydro-5*H*-indene-2,5-dione (**5**) have been obtained instead of the indanone (**2**). It has also been found while examining the oxidative susceptibility of the indanone (**2**) to peracids that **2** undergoes a novel Baeyer-Villiger transformation involving the elimination of the benzoyloxy group.

Results and Discussion

Oxidation of Tetraphenylallene. The treatment of tetraphenylallene (**1**) with 2 equivalents of *m*-chloroperbenzoic acid in methylene chloride for 20 hr at 1—3°C (peracid consumption 60%) afforded a yellow

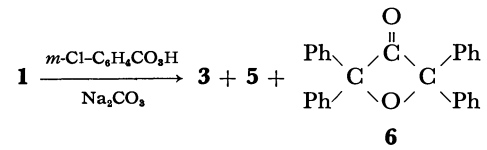
product mixture, which was then chromatographed to give four products: **2** (45%), **3** (3%), **4** (1%), and **5** (<1%), besides the unreacted allene (**1**) (25%).[7]

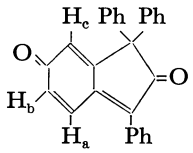
The structure of the main product (mp 160°C) was determined to be 1-hydroxy-1,3,3-triphenyl-2-indanone (**2**)[8] by the following analyses and by the chemical behavior to be described in the last section of the present paper. The infrared spectrum showed carbonyl (1760 cm^{-1}, indicative of a cyclic five-membered ketone) and hydroxyl (3560 cm^{-1}) absorptions. The NMR spectrum showed only a complex multiplet of aromatic protons. The elemental analysis ($C_{27}H_{20}O_2$) indicates that the allene ($C_{27}H_{20}$) was oxidized by two atoms of oxygen. Several possible structures other than **2** were also examined, but were ruled out. For example, tetraphenyloxetanone (**6**)[9] was the most expected product by analogy with Crandall's result, but it should show a much higher frequency of $\nu_{C=O}$ than that observed (for the oxetanone (**6**), see the next paragraph). The indanone (**2**) did not form hydrazone with 2,4-dinitrophenylhydrazine nor did it react with hydroxylamine.[10] A similar low reactivity has also been reported for 3-hydroxy-1,3-diphenyl-2-indanone.[11] The second product **3** was identified as benzophenone by comparison with authentic sample. The third product, **4** (mp 216°C), obtained in a low yield, turned out to be $C_{34}H_{23}O_3Cl$. An examination of its infrared spectrum, which shows two carbonyl absorptions at 1770 (strong) and 1730 cm^{-1} (stronger), indicates that a mixed structure with cyclic ketone and *m*-chlorobenzoate functions is preferable to other structures, such as acid anhydrides. The NMR spectrum showed only a complex multiplet of aromatic ring protons and no signal in the other regions. From these data, **4** is assumed to be the *m*-chlorobenzoate of **2**, as has been indicated above. In fact, the formation of **2** was confirmed in the acid hydrolysis of **4**. The minor product **5** was obtained in a trace; its structural determination will be described in the next paragraph.

In order to minimize the influence of *m*-chlorobenzoic acid in the reaction, an excess amount of finely-powdered sodium carbonate was added to the reacting mixture. In this buffered reaction, three products, **3** (10%), **5** (3%), and **6** (5%), were isolated, besides the unreacted allene (48%), after a reaction for 20 hr at 1—3°C (peracid consumption, 46%).



6

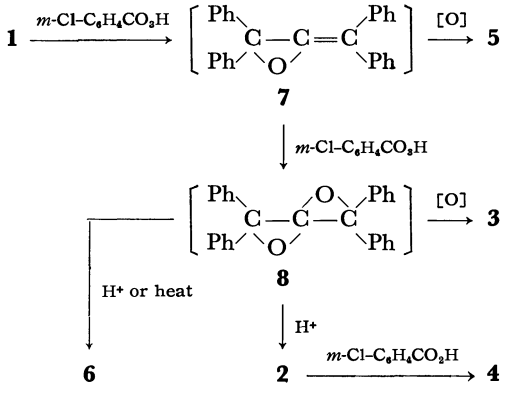
No appreciable formation of any other products was detected, although the isolated yields of the above products were low. It should be noted that the indanone (**2**) was not detected here, but that, instead, tetraphenyloxetanone (**6**) was formed. This implies that the formation of **2** occurred only under acidic conditions. The **6** product (mp 201°C) showed a carbonyl absorption at 1805 cm^{-1} (strained C=O) in its infrared spectrum, and the NMR spectrum showed only the existence of aromatic ring protons. The **5** product (mp 220°C), obtained as orange-yellow crystals, was found to be $C_{27}H_{18}O_2$ by the elemental analysis as well as a study of its mass spectrum (M^+ *m/e* 374). The infrared spectrum showed two carbonyl absorptions, at 1725 (s) and 1640 (vs) cm^{-1}. The ultraviolet spectrum showed two absorptions, at 367 nm (log ε 4.7) and 260 nm (log ε 4.5), characteristic of the multi-conjugated system involving carbonyl functions, such as *o*-quinone or fuchsone.[12] Its rather distinct NMR signals at τ 2.13 (1H, d, J=10 Hz), 3.41 (1H, a pair of doublet, J_1=10 Hz, J_2=1.5 Hz), and 3.68 (1H, d, J=1.5 Hz), in addition to the multiplets of aromatic hydrogens, are quite characteristic of the cyclic conjugating systems with a three-proton arrangement of $-CH_a=CH_b-C=CH_c-$ or $-CH_a=CH_b-CO-CH_c=$.[13] The structural elucidation of this product, based on an analysis of the above data, suggests a cross-conjugated diketone structure depicted below rather than any other available structures:



5

In this structure, *i.e.*, 1,3,3-triphenyl-2,3-dihydro-5*H*-indene-2,5-dione, the three protons on the quinone ring well account for the observed NMR spectrum, in which H_a is shifted downfield due to the diamagnetic anisotropy of the *peri*-phenyl group.

Scheme 1 illustrates the reaction route to accommodate these results. As has been proposed[4] the initial step in this sequence is the formation of allene



Scheme 1

oxide (**7**), which is then further oxidized to form **8**. Both oxides are unisolated intermediates, but are likely sources of the isolated products. The failure to isolate the **7** and **8** intermediates can be attributed to the substituent effect of the phenyl group, which is in contrast to that of alkyl homologs.[4,5] Thus, tetraphenylallene is less reactive than the alkyl homologs toward the peracid, as may be seen in the imcomplete and slow conversion of the peracid and the allene (**1**). On the other hand, the **7** and **8** intermediates are much more susceptible to the acid-catalyzed (or thermal) transformation, probably because of the delocalization of cationic species by phenyl groups. The formation of the indanone (**2**) under acidic conditions clearly demonstrates the cationic alkylation of a phenyl ring *via* one of the few possible reaction paths. This route, however, is almost completely suppressed in a buffered reaction, and the oxetanone (**6**) is formed instead. This clear-cut distinction indicates an important role of pH in the product control, regardless of whether **6** is formed thermally or by acid catalysis. The formation of benzophenone, probably closely analogous to the formation of acetone from tetramethylallene,[4] cannot be interpreted well. The most likely precursor, however, seems to be the spirodioxide (**8**), which undergoes further oxidation to give **3** as was observed in the oxidation of **8** with cromic acid.[2] The formation of the *m*-chlorobenzoate (**4**) can be reasonably explained in terms of an acid-catalyzed esterification between **2** and *m*-chlorobenzoic acid. The formation of the diketone (**5**), observed more in the buffered reaction than in the acidic oxidation, reasonably rules out the possible intermediacy of the indanone (**2**) as a precursor of **5**. A plausible explanatory reaction sequence consists of an oxidative ring-hydroxylation of the allene oxide (**7**), followed by some cationic ring-formation and oxidation. However, sufficient evidence is not yet available to support this sequence.

Reaction of 1-Hydroxy-1,3,3-triphenyl-2-indanone (2). The stability of the indanone (**2**) in relation to *m*-chloroperbenzoic acid rules out the possibility that this material is the precursor of **3**, **5**, or **6**. The oxidation of **2** with peracetic acid after a prolonged reaction, however, afforded only one product. Its infrared spectrum showed a carbonyl absorption at 1775 cm^{-1}, and both its mass spectrum and elemental analysis ($C_{20}H_{14}O_2$, *m/e* 286) proved it to be either **9a** or **9b**.[14] Compound **9a** has been prepared from phthalic anhydride and phenyllithium,[15] whereas **9b** has been prepared from benzil and phenol.[16] As a result, it has been found that the product was α,α-diphenylphthalide (**9a**)

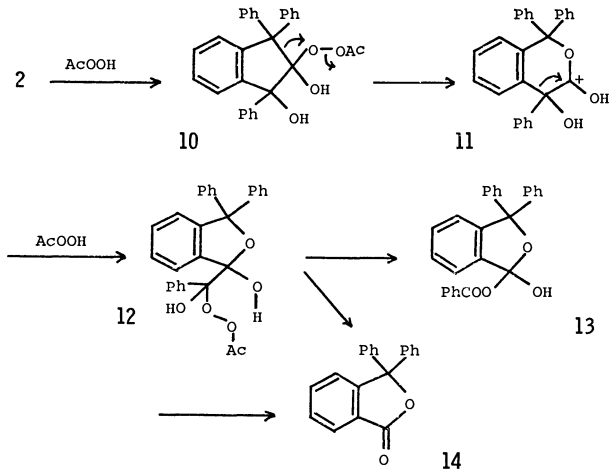
(15%); this presents us with a possible reaction scheme in which a novel Baeyer-Villiger-type transformation of α-hydroxyketone is involved (Scheme 2). Additionally, the fact that benzophenone was not formed in this reaction excludes any transformation in which the indanone (**2**) can be the precursor of benzophenone.



Scheme 2

Some supplemental reactions of the indanone (**2**) were carried out in order to determine the structure and reaction behavior of **2** in the oxidation system. The hydrolysis of **2** in aqueous potassium hydroxide gave a white solid of a potassium carboxylate (**15a**). This material was then acidified to yield its free acid (**15b**). The infrared spectrum and the NMR spectrum of **15b** are in good agreement with the structure of *o*-benzhydrylbenzilic acid,[8] and its formation can be interpreted in terms of a hydroxy-anion attack on the carbonyl function, followed by ring cleavage to form the trityl anion.

17

The treatment of **2** with ethanolic hydrochloric acid yielded 1-ethoxy-1,3,3-triphenyl-2-indanone (**16a**) in a good yield. The NMR spectrum of **16a**, however, showed a pair of quartets of the ethoxy methylene signal slightly split (by about 3 Hz), whereas the ethoxy methyl appeared unsplit. With the aid of a molecular model, this may be accounted for by a steric inhibition of the free rotation in this rather crowded molecule. Similarly, the methoxy derivative (**16b**) was obtained from a methanolic hydrochloric acid solution in a 73% yield. Somewhat related to the formation of the *m*-chlorobenzoate (**4**), the ether formation may be indicative of a possible nucleophilic displacement on

the position adjacent to the carbonyl. In addition, the tertiary hydroxy group of **2** was readily reduced by treating **2** with hydriodic acid and sodium bisulfite,[17] thus giving 1,1,3-triphenyl-2-indanone (**17**).

Experimental

Melting points are uncorrected. Infrared spectra were recorded on a JASCO IRA-1 grating spectrophotometer, NMR spectra were taken on a JEOL 4H-100 spectrometer (100 MHz) unless otherwise stated. Chemical shifts are relative to internal TMS and are given on τ scale. Mass spectra were obtained with a Shimadzu LKB-9000 mass spectrometer. Combustion analyses were performed by the Microanalytical Laboratory, Kyoto University.

m-Chloroperbenzoic Acid. The preparation of *m*-Cl-perbenzoic acid[18] on a laboratory scale was performed starting with *m*-toluidine according to the method indicated in the literatures.[19]

Tetraphenylallene (1).[20] Starting with diphenylmethyl bromide (120 g) and 1,1-diphenylethylene (88 g), and after several experimental procedures directed by the literature,[21] a pure solid of **1** (28.5 g, mp 165°C) was obtained.

Oxidation of 1 with m-Chloroperbenzoic Acid. To a solution of **1** (13.8 g, 0.04 mol) in methylene chloride (100 ml) was added a solution of 86% *m*-Cl-perbenzoic acid (16.6 g, 0.08 mol) in methylene chloride (250 ml) and the mixture was stirred for 20 hr at 1—3°C (peracid consumption 60%).[22] Then the mixture was washed three times with 10% aqueous sodium carbonate and two times with saturated aqueous sodium chloride. After the organic solution has been dried over anhyd magnesium sulfate, the solvent was removed by flash evaporation to give a yellow oil. Tlc showed two major spots, plus several (mainly three) minor spots. The crude oil was chromatographed on silica gel (Merck 70—325 mesh), first with carbon tetrachloride and then with chloroform. The first eluting fraction contained unreacted **1** (4.1 g, 25% recovery). The second fraction gave a colorless solid of 1,3,3-triphenyl-2-oxodihydro-1-indenyl *m*-Cl-benzoate (*4*), 0.2 g (1%); mp 216°C (ethanol); IR (CCl_4) 1770 (strong) and 1730 (stronger) cm^{-1} (both C=O); NMR (CCl_4) τ 2.7—3.2 (m).

Found: C, 79.54; H, 4.59%. Calcd for $C_{34}H_{23}O_3Cl$: C, 79.29; H, 4.50%.

The saponification of **4** with hot hydrochloric acid in dioxane, followed by the removal of the solvents, yielded a crude solid, which showed a tlc spot identical with that of indanone (**2**). The third fraction gave a viscous oil which gradually solidified on standing. The solid was recrystallized from diethyl ether to give 0.4 g (3%) of benzophenone (**3**). The fourth fraction was a viscous yellow oil, from which the diketone (**5**) was isolated (<1%). The physical data of **5** will be given in the next experimental paragraph. The fifth fraction consisted mainly of 1-hydroxy-1,3,3-triphenyl-2-indanone (**2**), which was purified by recrystallization from toluene to give 6.7 g (45%) of **2** as colorless needles; mp 161°C; IR 3560 (OH), 1760 cm^{-1} (C=O); UV $\lambda_{max}^{cyclohexane}$ 320 nm (log ε 2.5), 278 (3.56), 270 (3.34), 263 (3.31); NMR (CCl_4) τ 2.62—3.02 (m); *m/e* 376 (M^+).

Found: C, 86.34; H, 5.32%. Calcd for $C_{27}H_{20}O_2$: C, 86.15; H, 5.36%.

Oxidation of 1 with m-Chloroperbenzoic Acid in the Presence of Sodium Carbonate. To a solution of **1** (13.8 g, 0.04 mol) in methylene chloride (100 ml), we added 100 g of finely-pulverized sodium carbonate. To this suspension was then added 17.2 g (0.08 mol) of *m*-Cl-perbenzoic acid (assay 83%) dissolved in methylene chloride (250 ml), after which the mixture was stirred at 1—3°C for 20 hr (peracid consumption 45%). The inorganic salts were filtered out, and the filtrate was washed three times with 10% aqueous sodium carbonate and two times with saturated aqueous sodium chloride, and dried over anhyd. magnesium sulfate. The solvent was then removed by flash evaporation to give a yellow oil (4 tlc spots, but none of **2**, on a silica gel plate). The oil was chromatographed (silica gel, carbon tetrachloride and chloroform eluent). The first eluting fraction contained unreacted **1** (6.7 g, 48%). The second fraction consisted mainly of 2,2,4,4-tetraphenyloxetanone (**6**); 0.8 g (5%); mp 198—201°C (diethyl ether); IR (CCl_4) 1805 cm^{-1} (C=O); NMR (CCl_4) τ 2.77 (m).

Found: C, 86.05; H, 5.46%. Calcd for $C_{27}H_{20}O_2$: C, 86.14; H, 5.35%.

The third fraction was proved to consist mainly of **3**, as in the previous experimental paragraph. The fourth fraction was a deep yellow oil, the same component as the third chromatographed fraction obtained in the preceding experimental paragraph. This was purified by preparative tlc (silica gel), followed by recrystallization from ethanol, to give orange-yellow crystals of 1,3,3-triphenyl-2,3-dihydro-5*H*-indene-2,5-dione (**5**); 0.5 g (3%); mp 219 —220°C; IR (CCl_4) 1725 and 1640 cm^{-1} (C=O); NMR (THF) τ 2.13 (1H, d, J=10 Hz), 2.32 (2H, m), 2.50 (3H, m), 2.73 (10H, m), 3.41 (1H, q, J_1=10 Hz, J_2=1.5 Hz), 3.68 (1H, d, J=1.5 Hz); UV $\lambda_{max}^{cyclohexane}$ 367 nm (log ε 4.7), 260 (4.5); *m/e* 374 (M^+).

Found: C, 86.06; H, 4.81%. Calcd for $C_{27}H_{18}O_2$: C, 86.60; H, 4.85%.

Oxidation of 2 with Peracetic Acid. Peracetic acid was prepared by adding 90% hydrogen peroxide (10.8 ml, 0.40 mol) to a cold solution of acetic anhydride (44.9 g, 0.44 mol) in methylene chloride (100 ml); the mixture was then kept overnight in a refrigerator (peracid concentration 1.8×10^{-3} mol/g[22]). About 20 ml (40 mmol) of the above peracid solution and **2** (0.75 g, 2 mmol) dissolved in chloroform (30 ml) were mixed, and this mixture was stirred at 10—15°C for 11 days (peracid consumption 15%). The organic mixture was then washed three times with 10% aqueous sodium carbonate and two times with saturated aqueous sodium chloride, and then dried over anhyd. magnesium sulfate. The solvents were removed by flash evaporation to give a crude solid, which was chromatographed (silica gel, carbon tetrachloride eluent) to give **9a** (0.08 g, 15%) in addition to the unreacted **2** (0.5 g, 70% recovery). **9a**: colorless prismen crystal (diethyl ether); mp 117—118°C; mmp (with an authentic sample, see below) 117°C; IR (CCl_4) 1775 cm^{-1} (C=O); NMR (CCl_4) 2.46 (4H, m), 2.73 (10H, m).

α,α-Diphenylphthalide (9a). To a warm ethereal solution of phenyllithium prepared from lithium metal (9.36 g, 1.35 mol) and bromobenzene[14] (101 g, 0.64 mol), was added a solution of phthalic anhydride (20 g, 0.135 mol) in anhyd.

dioxane (150 ml) over a 2 hr period. After the mixture has been heated for another hour, the mixture was hydrolyzed by 100 ml of water and the organic layer was dried over anhyd magnesium sulfate. The flash evaporation of the solvent then afforded a crude oil, which was distilled *in vacuo* to give a yellow oil; bp 200°C/4 mmHg. The treatment of the oil in hot ethanol separated **9a** (colorless crystals), 2 g (6%); mp 117°C; IR (CCl_4) 1775 cm^{-1} (C=O).

*Preparation of 3,3-Diphenylcoumaran-2-one (**9b**).* A mixture of benzil (50 g), phenol (50 g), and zinc chloride (50 g) was treated according to a procedure previously reported.[15] After following the work-up procedure, an oily material (*ca.* 1 g) was obtained. IR (liq. film) 1805 cm^{-1} (C=O).

*o-Benzhydrylbenzilic Acid (**15b**).* Compound **2** (1.1 g, 3 mmol), dissolved in ethanol (20 ml), was heated with 20% aq potassium hydroxide (2 ml) under a solvent reflux for 5 hr. On cooling, a white solid separated; this was recrystallized from ethanol to give potassium *o*-benzhydrylbenzilate (**15a**); 1.2 g (95%); mp 297°C; IR (nujol dispersion) 3570 and 3350 (OH), 1605 cm^{-1} (COOK).

Found: C, 70.66; H, 5.22%. Calcd for $C_{27}H_{21}O_3K$ (1.47 H_2O): C, 70.65; H, 5.25%.

An aqueous solution of **15a** was acidified with concd hydrochloric acid to give a precipitate of **15b**; 0.95 g (85%); mp 188°C (ethanol); IR (nujol dispersion) 3530 and 1695 cm^{-1} (COOH); NMR (acetone-d_6) τ 2.53 (2H, m), 2.90 (15H, m), 3.31 (2H, m), 3.86 (1H, s).

Found: C, 82.53; H, 5.52%. Calcd for $C_{27}H_{22}O_3$: C, 82.21; H, 5.62%.

*1-Ethoxy-1,3,3-triphenyl-2-indanone (**16a**).* A mixed solution of **2** (1.1 g, 3 mmol) and concd hydrochloric acid (5 ml) in ethanol (20 ml) was heated under reflux for 5 hr. After cooling, a white solid of **16a** separated from the solution; 0.9 g (73%); mp 166°C (cyclohexane); IR (CCl_4) 1760 (C=O) and 1085 cm^{-1} (C–O); NMR (CCl_4) τ 2.96 (19H, m), 6.74 and 6.76 (2H, a pair of q, $J=7$ Hz), 8.86 (3H, t).

Found: C, 86.70; H, 5.98%. Calcd for $C_{29}H_{24}O_2$: C, 86.11; H, 5.95%.

*1-Methoxy-1,3,3-triphenyl-2-indanone (**16b**).* A treatment of **2** (1.1 g, 3 mmol) with methanol similar to the above-described procedure used for **16a** gave **16b** (0.9 g, 78%); mp 168°C; IR (CCl_4) 1760 (C=O) and 1085 cm^{-1} (C–O); NMR ($CDCl_3$, 60 MHz) τ 2.90 (19H, m), 6.82 (3H, s).

Found: C, 86.41; H, 5.47%. Calcd for $C_{28}H_{22}O_2$: C, 86.13; H, 5.68%.

*1,3,3-Triphenyl-2-indanone (**17**).* A solution of **2** (1.1 g, 3 mmol) and 47% hydriodic acid (4 ml) in glacial acetic acid (15 ml) was heated for 1 min under solvent reflux.[16] After cooling, the solution was decolorized with 5% aq sodium bisulfite to give a colorless precipitate of **17**; 0.7 g (65%); mp 133—134°C (diethyl ether); IR (CCl_4) 1760 cm^{-1} (C=O); NMR (CCl_4, 60 MHz) τ 2.85 (19H, m), 5.33 (1H, s).

Found: C, 89.67; H, 5.69%. Calcd for $C_{20}H_{20}O$: C, 89.97; H, 5.59%.

The authors wish to thank Mr. Takeda of the Shimadzu Co. for his help in taking the mass spectra. Thanks are also due to Mr. Takayuki Kida for the NMR measurement.

(Received June 29, 1972)

The catalytic homogeneous hydrogenation of 1,4-androstadiene-3,17-dione (I) with dichlorotris(triphenylphosphine)ruthenium has been investigated in the presence of basic additives. The rate of hydrogenation increased with respect to added amines in the order pyridine<none<butylamine<aniline<diethylamine≅triethylamine. The hydrogenation was also promoted by the addition of calcium carbonate, but slightly retarded by that of sodium carbonate. The amount of triethylamine required for obtaining the maximum rate of hydrogenation has been determined. Addition of triethylamine also reduced the formation of 5α-androstane-3,17-dione produced by a different pathway from that for the formation of 4-androstene-3,17-dione (II), resulting in an increased selectivity for the formation of II. I was also hydrogenated with the ruthenium complexes having *p*-methoxy-, *p*-methyl-, and *p*-fluoro-substituted triphenylphosphines as ligands. The catalytic activity of the ruthenium complex was greatly enhanced by *p*-methoxyl and *p*-methyl groups and reduced by *p*-fluoro group when the catalyst was used in the presence of triethylamine.

In a previous paper[1] we showed that 3-oxo-1,4-diene steroids are selectively hydrogenated to the corresponding 3-oxo-4-enes with dichlorotris(triphenylphosphine)-ruthenium as a catalyst. Hydrogenation with the ruthenium complex also yielded small amounts of saturated 5α-ketones which were formed by a different pathway from that for the formation of 3-oxo-4-enes.

1) Part I: S. Nishimura and K. Tsuneda, This Bulletin, **42**, 852 (1969).

This was in contrast to the hydrogenation with chlorotris(triphenylphosphine)rhodium,[2,3] where saturated ketones were all formed consecutively *via* the intermediate 3-oxo-4-enes. It was also shown that the ratio of 3-oxo-4-ene to the saturated 5α-ketone formed increases with increasing hydrogen pressure and decreasing reaction temperature. Thus, with the ruthenium complex catalyst, high yields of 3-oxo-4-enes were obtained by hydrogenating the corresponding 3-oxo-1,4-dienes at a relatively low temperature and under a high hydrogen pressure.

In this study we have investigated the effects of added basic substances and of *para* substituents in the triphenylphosphine ligand on the hydrogenation of 1,4-androstadiene-3,17-dione (I) with the ruthenium complex as catalyst.

The Effects of Basic Additives. It is known that bases promote the formation of the hydrido complex of ruthenium, the active species in hydrogenation, according to the equation[4]

$$RuCl_2(PPh_3)_3 + H_2 + \text{base} = RuClH(PPh_3)_3 + \text{base}\cdot HCl \quad (1)$$

We have therefore studied the effect of the addition of various basic substances in the hydrogenation of I in benzene. We see from Table 1 that the rate of hydrogenation increased with respect to the added amines in the order pyridine<none<butylamine<aniline<diethylamine≅triethylamine. The hydrogenation was also effectively promoted by the addition of calcium carbonate, but retarded slightly by the addition of sodium carbonate. Figure 1 shows the effect of the varying amount of added triethylamine on the rate of hydrogenation of I. It is seen that the maximum rate is obtained when triethylamine is added in a slightly greater amount than that required by Eq. (1) and addition of the amine in further excess ureslts in the decrease in rate.

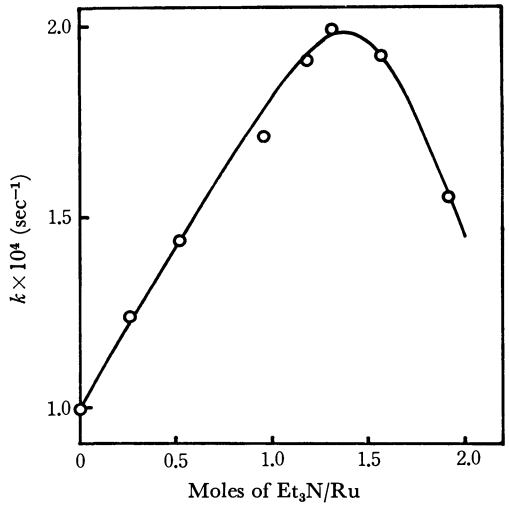

Fig. 1. Effect of the varying amount of added triethylamine on the rate of hydrogenation of I. I (500 mg) was hydrogenated with 50 mg of $RuCl_2(PPh_3)_3$ in 10 ml benzene at 50°C and 100 kg/cm² H_2.

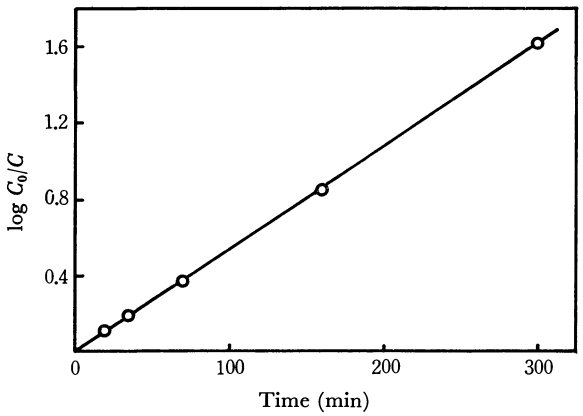

Fig. 2. First-order dependence of the rate of hydrogenation on the concentration of I. I (500 mg) was hydrogenated with 50 mg (0.052 mmol) of $RuCl_2(PPh_3)_3$ and 6.9 mg (0.068 mmol) of triethylamine in 10 ml benzene at 50°C and 100 kg/cm² H_2.

TABLE 1. EFFECT OF BASIC ADDITIVES ON THE HYDROGENATION OF 1,4-ANDROSTADIENE-3,17-DIONE (I) WITH DICHLOROTRIS-(TRIPHENYLPHOSPHINE)RUTHENIUM[a]

Additive[b]	Conversion of I, %
Triethylamine	95.4
Diethylamine	95.4
Butylamine	86.5
Aniline	88.1
Pyridine	62.7
Calcium carbonate	95.2
Sodium carbonate	73.0
None	76.0

a) I(500 mg) was hydrogenated with 50 mg of $RuCl_2(PPh_3)_3$ in 10 ml benzene at 40°C under a hydrogen pressure of 130—135 kg/cm² for 6 hr.

b) The amines were added in the stoichiometric amounts required by Eq. (1). Calcium and sodium carbonates were added in the amounts 21 and 22 mg (four times of the amounts required by Eq. (1)), respectively.

The rate of hydrogenation is strictly of first order in the concentration of I as shown in Fig. 2. This kinetic dependence of the rate on concentration is also in contrast to the hydrogenation of I with the rhodium complex where the rate obeys the Langmuir type equation in the same region of the concentration of I.[5]

Variations in the amounts of products during hydrogenation are shown in Fig. 3. Since the reaction pathways for the formation of saturated ketones (IIIα and IIIβ) are considered to be as shown in Scheme 1, the variation in concentration of 4-androstene-3,17-dione (II) can be expressed as a function of the concentration of I by the equation[6]

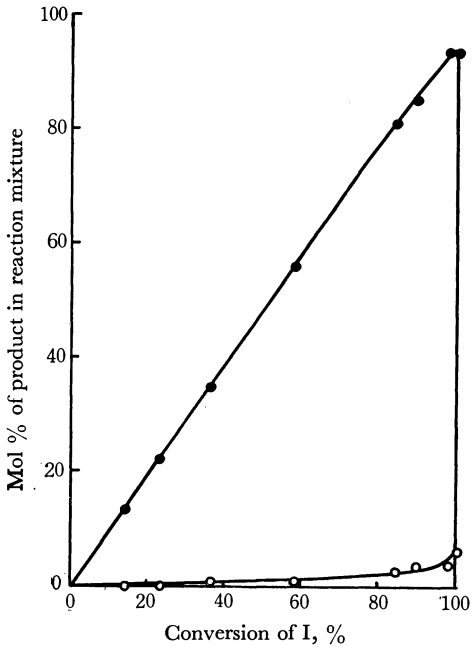

Fig. 3. Variations in the amounts of II (●) and III (○) in the reaction mixture as a function of the conversion of I. The points indicate individual experiments. Full lines give theoretical curves showing the variations in the amounts of II and III when f=0.983 and K=1/90 in Eq. (2). The reaction conditions are the same as in Fig. 2.

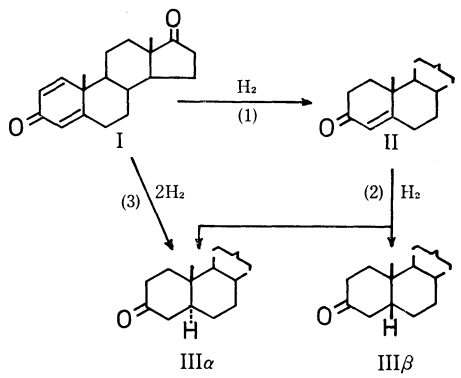
$$C_{II} = \frac{f}{K-1}(C_I - C_I^K) \qquad (2)$$

where $f=k_1/(k_1+k_3)$, $K=k_2/(k_1+k_3)$, and k_i's are the first-order rate constants for the corresponding reaction paths shown in Scheme 1. C_I and C_{II} are the concentrations of I and II, respectively, when the initial concentration of I is taken as unity. It follows from Eq. (2) that the variation in concentration of added IIIα and IIIβ is given by $1-C_I-f(C_I-C_I^K)/(K-1)$. By applying this relation to the observed change in the amount of IIIα and IIIβ, we obtain f=0.983 and K=1/90 as a most satisfactory set of values. This implies that the amount of IIIα formed by the reaction path (3) was depressed to the extent of only 1.7% in the presence of added triethylamine as compared with 10.5% for that in the absence of the amine.[1] On the other hand, the result indicates that hydroganetion of



Scheme 1. Hydrogenation pathways of 1,4-androstadiene-3,17-dione.

II to IIIα and IIIβ, which practically did not take place in the absence of base,[1] occurs very slowly in the presence of triethylamine. The ratio of IIIα to IIIβ formed decreases toward the end of hydrogenation, indicating increasing contribution of the saturated ketones formed *via* II with the extent of hydrogenation.[7] The maximum yield of II is given by $f\times K^{K/(1-K)}$ and calculated to be 93.5% at 98.9% conversion of I from the obtained values of f and K.

The Effect of para *Substituents in the Triphenylphosphine Ligand.* It has been reported that the catalytic activity of chlorobis(triphenylphosphine)rhodium is enhanced by electron-releasing *para* substituents in the triphenylphosphine ligand, as observed in the hydrogenation of olefins.[8] As regards the ruthenium complex, the use of tri-*p*-tolyl- and tri-*p*-fluorophenylphosphines as ligands has recently been described in a patent.[9] We prepared the ruthenium complexes

7) Small amounts of IIIβ and an alcohol, possibly 3-hydroxy-5α-androstan-17-one, appear to be formed also by the reaction path (3). The ratio of IIIβ to IIIα, however, was much smaller than that in the products formed through II.

8) S. Montelatici, A. van der Ent, A. Osborn, and G. Wilkinson, *J. Chem. Soc. A*, **1968**, 1054; C. O'Connor and G. Wilkinson, *Tetrahedron Lett.*, **1969**, 1375.

9) J. P. Candlin, J. R. Jennings, and P. F. Todd, Brit. Pat. 1246123 (1971); *Chem. Abstr.*, **75**, 129935 m (1971).

9a) Note Added in Proof. After this manuscript was submitted to publication, preparations of *para*-substituted triphenylphosphineruthenium complexes and their use in an isomerization reaction have been described by Blum and Becker [*J. Chem. Soc. Perkin II*, **1972**, 982].

with tri-*p*-methoxyphenyl-, tri-*p*-tolyl-, and tri-*p*-fluorophenylphosphines as ligands and compared their catalytic activities in the hydrogenation of I.[9a] The results are summarized in Table 2. It is seen that the activity of the ruthenium complex is also enhanced by the electron-releasing *p*-methoxyl and *p*-methyl groups and decreased by the electron-withdrawing *p*-fluoro group. The effects of the *para* substituents seem to be more pronounced than in the case of the rhodium complex (see Table 2). It is to be noted that their electronic effects are observed in a proper order only in the presence of triethylamine.

The results show that the activity as well as the selectivity of dichlorotris(triphenylphosphine)ruthenium in the hydrogenation of I are greatly improved by the addition of an optimal amount of triethylamine. The activity of the ruthenium complex is further enhanced by the electron-releasing *p*-methoxyl and *p*-methyl groups in the triphenylphosphine ligand. Thus the hydrogenation of 3-oxo-1,4-diene steroids under these conditions might be useful for the preparation of the corresponding 3-oxo-4-enes. Typical examples of the preparation of II using the ruthenium complexes are given (see Experimental).

Experimental

Material. 1,4-Androstadiene-3,17-dione (I) was obtained from the Kikkoman Shoyu Co., Ltd., and used without further purification. Mp 142.5—143.5°C.[10]

Catalysts. Dichlorotris(triarylphosphine)ruthenium was prepared by refluxing ruthenium chloride trihydrate with six-fold excess of the triarylphosphine in ethanol for about 1 hr (for 2.5 hr in the case of tri-*p*-fluorophenylphosphine).

Dichlorotris(triphenylphosphine)ruthenium. Found: C, 66.93; H, 4.92%. Calcd for $C_{54}H_{45}Cl_2P_3Ru$: C, 67.64; H, 4.74%.

Dichlorotris(tri-*p*-methoxyphenylphosphine)ruthenium. Found: C, 60.92; H, 5.26%. Calcd for $C_{63}H_{63}Cl_2O_9P_3Ru$: C, 61.56; H, 5.18%.

Dichlorotris(tri-*p*-tolylphosphine)ruthenium. Found: C, 69.47; H, 5.38%. Calcd for $C_{63}H_{63}Cl_2P_3Ru$: C, 69.72; H, 5.86%.

Dichlorotris(tri-*p*-fluorophenylphosphine)ruthenium. Found: C, 57.94; H, 3.93%. Calcd for $C_{54}H_{36}Cl_2F_9P_3Ru$: C, 57.87; H, 3.24%.

Hydrogenation. The hydrogenation was performed in a 30 ml bomb equipped with a magnetic stirrer. The bomb was immersed in an oil bath maintained at a constant temperature.

Analysis of Product. The product was analyzed by gas chromatography (2% OV-17 at 250°C or 1.5% QF-1 at 220°C) after evaporation of the solvent followed by extraction with methylcyclohexane.

Examples of the Preparation of 4-Androstene-3,17-dione (II).

a) By Hydrogenation of I with Dichlorotris(triphenylphosphine)ruthenium. I (500 mg) was hydrogenated with 50 mg (0.052 mmol) of the ruthenium catalyst and 5.3 mg (0.052 mmol) of triethylamine in 10 ml benzene at 40°C under a hydrogen pressure of 130 kg/cm² for 8 hr. The benzene solution was passed through alumina followed by elution with benzene–ether. Evaporation of the solvent gave 498 mg of a solid residue. Recrystallization from acetone–hexane gave 447 mg of colorless needles (89% yield). Mp 169.5—171°C (98% purity by glpc analysis) (reported mp: 173—174°C[11]).

*b) By Hydrogenation of I with Dichlorotris(tri-*p*-tolylphosphine)ruthenium.* I (500 mg) was hydrogenated with 28 mg (0.026 mmol) of the ruthenium catalyst and 3.4 mg (0.034 mmol) of triethylamine in 10 ml benzene at 50°C under a hydrogen pressure of 100 kg/cm² for 2 hr. Treatment of the benzene solution in the same way as above gave 506 mg of a solid residue. Recrystallization from acetone–hexane gave 452 mg of light brown needles (90% yield). Mp 168.5—171°C (97.5% purity by glpc analysis).

*c) By Hydrogenation of I with Dichlorotris(tri-*p*-methoxyphenylphosphine)ruthenium.* I (2.0 g, recrystallized from ethanol–hexane, mp 144—145°C) was hydrogenated with 32 mg (0.026 mmol) of the ruthenium catalyst and 3.4 mg (0.034 mmol) of triethylamine in 10 ml benzene at 50°C under a hydrogen pressure of 100 kg/cm² for 2.5 hr. Treatment of the benzene solution in the same way as above gave 2.02 g of a solid residue. Recrystallization from acetone–hexane gave 1.82 g of colorless needles (90% yield). Mp 170—171°C (98.5% purity by glpc analysis).

The authors are grateful to Dr. Motohiko Kato of the Kikkoman Shoyu Co. and to Drs. Masanobu Sawai and Hiromu Mori of the Teikoku Hormorne Manufacturing Co. for their valuable suggestions.

Compounds Related to Acridine. X.[1] The Reaction of 9-Ethynylacridine with Active Methylene Compounds

Otohiko Tsuge[2] and Akiyoshi Torii*

Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka, 812
**Department of Industrial Chemistry, Kurume Technical College, Komorino, Kurume, 830*

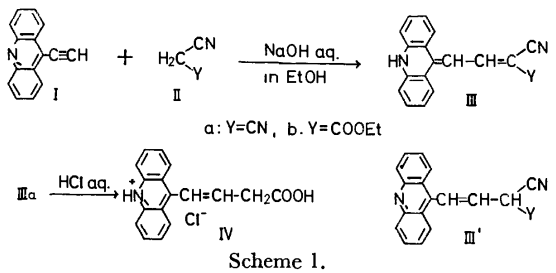
(Received June 28, 1972)

In the presence of aqueous sodium hydroxide, 9-ethynylacridine (I) reacts with malononitrile and with ethyl cyanoacetate to yield the corresponding 1,1-disubstituted 3-(9-acridanylidene)propenes III. A similar reaction of I with diethyl malonate affords a 2:1 adduct VI and a 1:2 adduct VII. On the other hand, I reacts with acetylacetone to give 3-acetyl-5-(9-acridanylidene)-1-(9-acridinyl)pent-1,3-diene (IX). In this context, the reaction of 9-chloroacridine (XI) with active methylene compounds has been reinvestigated; XI reacts with malononitrile and with ethyl cyanoacetate to afford products XII with an acridane structure, while with diethyl malonate XI gives 9-di(ethoxycarbonyl)methylacridine (XIII), as has been reported previously.

Little is known about the reaction of heteroaromatics having an ethynyl group. Recently, we have reported[3] a convenient method of the preparation of 9-ethynylacridine (I) and some of its reactions.[3,4] Our previous studies[3,4] suggested that the acetylene I would react easily with active methylene compounds to form 2-substituted 1-(9-acridinyl)ethylenes. We will now report on the novel reaction of the acetylene I with active methylene compounds. In this connection, the present paper will also deal with the reaction of 9-chloroacridine with active methylene compounds.

Results and Discussion

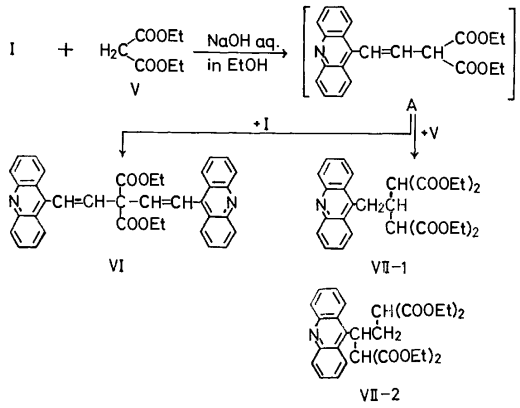
The reaction of the acetylene I with malononitrile (IIa) in the presence of aqueous sodium hydroxide in ethanol at room temperature afforded a 1:1 adduct IIIa as violet prisms in an excellent yield. The spectral data of IIIa indicated that IIIa was not the expected 1-(9-acridinyl)-3,3-dicyanopropene (III'), but rather 3-(9-acridanylidene)-1,1-dicyanopropene (Scheme 1).



Scheme 1.

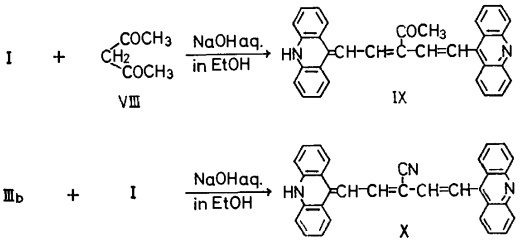
Similarly, the acetylene I reacted with ethyl cyanoacetate (IIb) to give the corresponding acridanylidene derivative IIIb. The hydrolysis of IIIa with hydrochloric acid afforded hydrochloride of 4-(9-acridinyl)-but-2-enoic acid (IV), whose structure was confirmed by the spectral data as well as by the results of microanalysis.

On the other hand, the reaction of acetylene I with diethyl malonate (V) under similar conditions afforded a 2:1 adduct VI and a 1:2 adduct VII of I and V, respectively, both as pale yellow prisms, in 36 and 4% yields respectively. On the basis of their spectral data, VI and VII were deduced to be 1,5-di(9-acridinyl)-3,3-di(ethoxycarbonyl)pent-1,4-diene, and either 1,1,3,3-tetra(ethoxycarbonyl)-2-(9-acridinylmethyl)propane (VII-1) or 1,1,4,4-tetra(ethoxycarbonyl)-2-(9-acridinyl)-butane (VII-2), respectively. The structures of VI and VII correspond to those of 1:1 Michael-type adducts of A to the acetylene I and to V respectively (Scheme 2).



Scheme 2.

The reaction of the acetylene I with acetylacetone (VIII) yielded a product IX, whose molecular formula corresponded to that of the compound derived from a 2:1 adduct of I and VIII under the elimination of an acetyl group. From the inspection of its spectral data, IX was identified as 3-acetyl-5-(9-acridanylidene)-1-(9-acridinyl)pent-1,3-diene.



Scheme 3.

The two products VI and IX correspond to the compounds obtainable from two moles of the acetylene I and one mole of an active methylene compound.

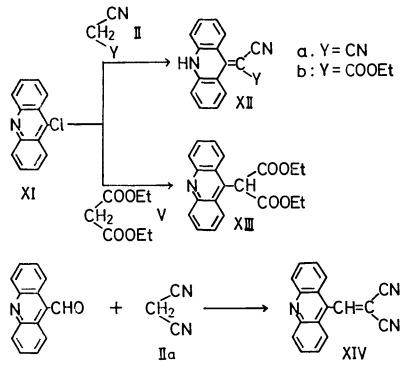
1) Part IX of this series: O. Tsuge and A. Torii, *Org. Prep. Proced. Int.*, in press (1972).
2) To whom inquiries should be directed.
3) O. Tsuge and A. Torii, This Bulletin, **43**, 2920 (1970).
4) O. Tsuge and A. Torii, *Org. Prep. Proced. Int.*, in press (1972).

Therefore, the 1: 1 adduct would be expected to react with the acetylene I to give compounds of the VI or IX type.

Although IIIa did not react with the acetylene I, the reaction of IIIb with I afforded 5-(9-acridanylidene)-1-(9-acridinyl)-3-cyanopent-1,3-diene (X), whose structure corresponds to that of the compound derived from a 1: 1 adduct by decarbethoxylation. The structure of X was confirmed by the spectral data as well as by the results of microanalysis. The pathway for the formation of IX and X is not yet clear, however.

In view of the formation of the acridane-like compound III, it is conceivable that the products from the reaction of 9-chloroacridine (XI) with active methylene compounds have acridane-like structures. Investigations on the reaction of XI with active methylene compounds have been reported by several workers. Most of them[5-7] have reported the products to be derivatives of 9-methylacridine. Only Kröhnke and Honig[8] discussed the possibility of an equilibrium between acridine and acridane structures.

We investigated the reaction of XI with active methylene compounds in order to determine whether or not the products had the acridane structure. The reaction of XI with malononitrile (IIa) and with ethyl cyanoacetate (IIb) afforded products of the acridane type, XIIa and XIIb, while XI reacted with diethyl malonate (V) to give 9-di(ethoxycarbonyl)methylacridine (XIII), as has been reported in the literature.[5]



Scheme 4.

The UV spectra of the acridanylidene compounds, III, X, and XII, exhibited absorption bands in a longer-wavelength region. The UV spectrum of XIIa showed a strong band at 480 nm, while an absorption band appeared at 366 nm in the spectrum of 1-(9-acridinyl)-2,2-dicyanoethylene (XIV). This can be explained by the longer conjugation of the acridanylidene structures.

Experimental

All the melting points are uncorrected. The IR spectra were measured as KBr pellets, and the UV spectra were determined in ethanol solutions. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV, while the NMR spectra were determined at 60 MHz with a Hitach-R-20 NMR spectrometer, with TMS as the internal reference. The microanalyses were performed by Miss M. Akita of our laboratory.

Reaction of the Acetylene I with Malononitrile (IIa). A solution of 0.3 g of I, 0.1 g of IIa, and one drop of an aqueous saturated sodium hydroxide solution in 5 ml of ethanol was stirred at room temperature for 1 hr; during this time crystals were deposited. Filtration gave 0.36 g (91%) of violet crystals which, on recrystallization from ethanol, afforded 3-(9-acridanylidene)-1,1-dicyanopropene (IIIa), mp 280—281 °C, as violet prisms.

Found: C, 80.49; H, 3.95; N, 15.36%. Calcd for $C_{18}H_{11}N_3$: C, 80.28; H, 4.12; N, 15.61%.

(12H, sextet, CH_3), 4.0 (13H, multiplet, CH_2 (10H) and CH (3H)), 8.0 (8H, multiplet, aromatic protons). Mass spectrum *m/e*: 523 (M^+), 450 ($M^+-COOEt$), 363 ($M^+-CH_2(COOEt)_2$), 204 ($363^+-CH(COOEt)_2$).

Reaction of the Acetylene I with Acetylacetone (VIII). To a solution of 0.5 g of I and 0.2 g of VIII in 10 ml of ethanol was added two drops of an aqueous sodium hydroxide solution; the reaction mixture was then stirred at room temperature for 15 hr. After it had been allowed to stand overnight, filtration gave 0.16 g (22%) of crystals. Recrystallization from dioxane afforded 3-acetyl-5-(9-acridanylidene)-1-(9-acridinyl)pent-1,3-diene (IX), mp 223—224°C, as violet prisms.

Found: C, 85.13; H, 5.38; N, 5.82%. Calcd for $C_{33}H_{24}N_2O$: C, 85.32; H, 5.21; N, 6.03%.

IR cm^{-1}: ν_{NH} 3280, $\nu_{C=O}$ 1620. UV λ_{max} nm (log ε): 249 (5.1), 346 (4.1), 525 (4.3). Mass spectrum *m/e*: 464 (M^+), 421 (M^+-COCH_3), 286 (M^+—acridinyl), 260 (M^+—9-ethynylacridine), 217 (260^+-COCH_3), 204 (9-ethynylacridine$^+$), 193 (base peak), 179 (acridine$^+$).

Reaction of the Acetylene I with the Acridanylidene Derivative IIIb. A solution of 0.15 g of I and 0.2 g of IIIb in 5 ml of ethanol was stirred at room temperature for 4.5 hr; during this time crystals were deposited. Filtration and recrystallization from dioxane gave 0.2 g (71%) of 5-(9-acridanylidene)-1-(9-acridinyl)-3-cyanopent-1,3-diene (X), mp 264—265°C, as violet prisms.

Found: C, 85.92; H, 4.56; N, 9.06%. Calcd for $C_{32}H_{21}N_3$: C, 85.88; H, 4.73; N, 9.39%.

IR cm^{-1}: ν_{NH} 3300, $\nu_{C\equiv N}$ 2220. UV λ_{max} nm (log ε): 250 (4.9), 318 (4.0), 570 (4.5). Mass spectrum *m/e*: 447 (M^+), 268 (M^+—acridine), 243 (M^+—9-ethynylacridine), 217 (243^+-CN), 204 (9-ethynylacridine$^+$), 193 (base peak), 179 (acridine$^+$).

Reaction of 9-Chloroacridine (XI) with Malononitrile (IIa). To a solution of 0.5 g of XI[9] and 0.5 g of IIa in 5 ml of ethanol was added four drops of an aqueous sodium hydroxide solution; the reaction mixture was then stirred at room temperature for 1.5 hr; during which time crystals were precipitated. Filtration gave 0.34 g (60%) of reddish orange crystals. Recrystallization from nitrobenzene afforded the 9-acridanylidene derivative XIIa, mp 339°C (lit,[7] mp 342°C), as reddish orange prisms.

IR cm^{-1}: ν_{NH} 3280, $\nu_{C\equiv N}$ 2215. UV λ_{max} nm (log ε): 240 (4.3), 294 (4.0), 480 (4.1). NMR (DMSO-d_6) δ ppm: 7.2—8.8 (8H, complicated, aromatic protons), 12.5 (1H, broad, NH, exchanged with D_2O).

Similarly, XI reacted with ethyl cyanoacetate (IIb) to give a 60% yield of the 9-acridanylidene derivative XIIb, mp 218°C (lit,[6] mp 222—224°C), as violet prisms.

IR cm^{-1}: ν_{NH} 3280, $\nu_{C\equiv N}$ 2210, $\nu_{C=O}$ 1660. UV λ_{max} nm (log ε): 247 (4.7), 293 (4.1), 480 (3.9). NMR (DMSO-d_6) δ ppm: 1.19 (3H, triplet, CH_3), 4.20 (2H, quartet, CH_2), 7.2—8.4 (8H, multiplet, aromatic protons), 12.40 (1H, broad, NH, exchanged with D_2O).

On the other hand, the reaction of XI with diethyl malonate (V) according to the reported method[5] gave the 9-methylacridine derivative XIII, mp 102—103°C (lit,[5] mp 100—102°C), as pale yellow prisms, as has been reported previously.

1-(9-Acridinyl)-2,2-dicyanoethylene (XIV). A solution of 1.0 g of acridine-9-carboxaldehyde[10] and 0.32 g of IIa in 10 ml of ethanol containing one drop of an aqueous sodium hydroxide solution was stirred at 60°C for 5 min. After the reaction mixture had been cooled, filtration gave 1.2 g (97%) of yellow crystals. Recrystallization from benzene afforded XIV, mp 181—182°C (decomp.), as yellow plates.

Found: C, 80.11; H, 3.65; N, 16.53%. Calcd for $C_{17}H_9N_3$: C, 79.98; H, 3.55; N, 16.46%. UV λ_{max} nm (log ε): 248 (4.9), 366 (3.8).

Studies of Enamines. II.[1] The Reaction of 4-(1-Piperidyl)- and 4-(1-Pyrrolidinyl)-3-penten-2-ones with Aryl Isocyanates

Otohiko TSUGE[2] and Akitaka INABA

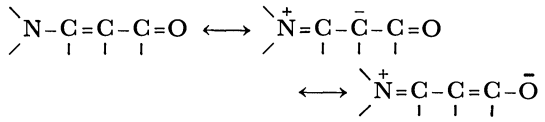
Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka, 812

(Received July 1, 1972)

The reaction of aryl isocyanates with enamino ketones, derived from acetylacetone and secondary amines such as piperidine and pyrrolidine, has been investigated. At room temperature, enamino ketones react with phenyl, *p*-chlorophenyl and *p*-tolyl isocyanate to give 1:2 adducts, 3,5-diarylcarbamoyl derivative. In solution, these adducts exist in general as a mixture of two tautomers, 3-penten-2-one and 4-penten-2-one, the ratio depending on the solvent. Under reflux in benzene, the reaction of enamino ketones with phenyl isocyanate gives 4-amino-6-methyl-1-phenyl-5-phenylcarbamoylpyrid-2-one and its 3-phenylcarbamoyl derivative; the former is also obtained by heating the 1:2 adduct. On the other hand, 4-(1-pyrrolidinyl)-3-penten-2-one reacts with 1-naphthyl isocyanate to afford the 1:1 adduct, 5-(1-naphthylcarbamoyl)-4-penten-2-one.

Many investigations have been carried out on the reactions of enamines with isocyanates. Products of different types are formed depending on the structures of the enamines and on the reaction conditions. For example, the reaction of *β*-disubstituted enamines with phenyl isocyanate at low temperature gives *β*-amino-*β*-lactams,[3,4] while the reaction with two equivalents of the isocyanate at high temperature affords hydrouracils, the 1:2 cycloadducts.[5] On the other hand, enamines having *β*-hydrogen react with isocyanates to give the corresponding carboxamides.[6,7]

Although a few reports are available on the reactions of enamino ketones with electrophiles,[8-11] the reaction of enamino ketones with isocyanates has not been investigated. On the basis of previous studies,[8-11] the chemical behavior of enamino ketones can be understood in terms of the following mesomeric forms.



It thus appeared of interest to investigate the reaction of enamino ketones with isocyanates. We report on a new reaction of enamino ketones derived from acetylacetone with aryl isocyanates.

Results and Discussion

Reaction at Room Temperature. When 4-(1-piperidyl)-3-penten-2-one (Ia) was treated with two equivalents of phenyl isocyanate (IIa) in benzene at room temperature for 5 hr, a 1:2 adduct IIIa of Ia and IIa was obtained in 91% yield. Even when Ia was employed in excess, the 1:1 adduct was not formed and the 1:2 adduct IIIa was again obtained albeit in low yield.

The IR spectrum of IIIa showed bands ascribable to ν_{NH} and $\nu_{C=O}$ at 3390 and 1635 cm^{-1} respectively. The NMR spectrum in deuteriochloroform ($CDCl_3$) displayed signals at δ 2.0 (3H, CH_3), 4.08 (2H, CH_2), 11.58 and 11.96 ppm (each 1H, NH), besides piperidyl and aromatic protons. The 1:2 adduct was thus confirmed to be 3,5-di(phenylcarbamoyl)-4-(1-piperidyl)-3-penten-2-one (IIIa).

Scheme 1.

Similarly, the reaction of 4-(1-pyrrolidinyl)-3-penten-2-one (Ib) with phenyl (IIa), *p*-chlorophenyl (IIb), and *p*-tolyl isocyanate (IIc) in benzene gave the corresponding 1:2 adducts IIIb—IIId, respectively (Scheme 1).[12] The NMR spectra showed that the adducts III exist as a mixture of two tautomers, 3-penten-2-one and 4-penten-2-one.

Hydrolysis of both IIIa and IIIb with 18% hydrochloric acid gave IV. In view of the spectral data and identification with an authentic sample prepared from dimethyl *β*-ketoglutarate and aniline, IV was confirmed to be 1,3-di(phenylcarbamoyl)acetone; a singlet assignable to an olefinic proton at δ 5.88 ppm in its NMR spectrum suggests that IV exists in its

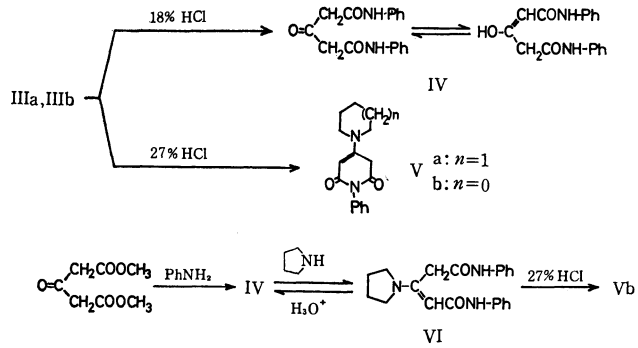
12) The product isolated from Ib and IIa was, however, a complex of IIIb and benzene, which on treatment with ethanol afforded pure IIIb.



Scheme 2.

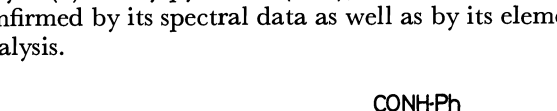
enol form in $CDCl_3$.

Treatment of IIIb with 27% hydrochloric acid afforded a new product Vb as reddish brown plates, whose molecular formula ($C_{15}H_{16}N_2O_2$) corresponded to that of a compound derived from IIIb by the elimination of both an acetyl and an anilino group. The IR spectrum of Vb displayed two crabonyl bands at 1645 and 1694 cm^{-1}. The NMR spectrum exhibited singlets at δ 3.60 (2H, C**H**$_2$) and 5.0 ppm (1H, =C**H**), besides pyrrolidinyl (8H) and phenyl protons (5H). These spectral data suggested V to be 1-phenyl-4-(1-pyrrolidinyl)-1,2,6-trihydropyridine-2,6(5H)-dione; Vb was indeed identical with an authentic sample prepared by the treatment of dianilide VI with 27% hydrochloric acid (Scheme 2).

A similar treatment of IIIa gave a mixture of IV and Va, identified by its spectral properties. However, Va could not be isolated in pure form.

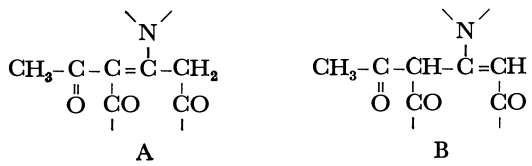
Although the exact pathway for the hydrolysis of III is not clear, it can be considered to arise from the initial formation of dianilide VI, followed by hydrolysis or deanilination depending on the strength of hydrochloric acid.

The reaction of IIIa and IIIb with hydrazine hydrate afforded 3(5)-phenylcarbamoylmethyl-4-phenylcarbamoyl-5(3)-methylpyrazole (VII), whose structure was confirmed by its spectral data as well as by its elemental analysis.



VII

Tautomerism of III. The NMR spectrum of IIIa indicated that it exists as the 3-penten-2-one of type A in $CDCl_3$. However, it has been clarified that all adducts of type III exist in general as a mixture of the 3-penten-2-one (type A) and 4-penten-2-one (type B) in solution, *e.g.*,



A B

As illustrated in Fig. 1 the NMR spectrum of IIIb in pyridine-d_5 can be understood as that of a 1:1 mixture of the corresponding A and B of IIIb.

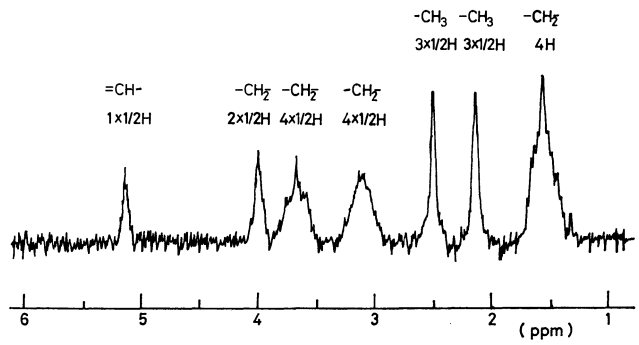


Fig. 1. NMR spectrum of IIIb in pyridine-d_5

The ratios of A to B in all III in solutions were similarly calculated; the results are summarized in Table 1.

Table 1. Ratio of A to B in III

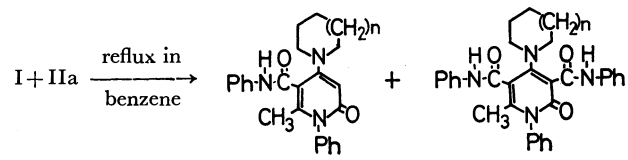
III	A:B	Solvent
IIIa	1:0	$CDCl_3$
IIIa	2:3	DMSO-d_6
IIIa	1:1	Pyridine-d_5
IIIb	3:2	$CDCl_3$
IIIb	1:1	Pyridine-d_5
IIIb	1:2	DMSO-d_6
IIIc	1:2	$CDCl_3$
IIId	3:2	$CDCl_3$

On heating, IIIa and IIIb (but not IIIc) easily underwent elimination of water to give VIIIa and VIIIb.

Reaction under Reflux in Benzene. When Ia was treated with two equivalents of isocyanate IIa in refluxing benzene for 5 hr, two products VIIIa and IXa were obtained, but not IIIa.

The molecular formula of the major product VIIIa corresponded to that of the compound derived from a 1:2 adduct with loss of water. The IR spectrum of VIIIa exhibited bands assignable to ν_{NH} and $\nu_{C=O}$ at 3280 and 1645, 1663 cm^{-1}, and the NMR spectrum in $CDCl_3$ displayed singlets at δ 2.13 (3H, C**H**$_3$), 5.97 (1H, =C**H**), and 8.64 ppm (1H, N**H**), besides piperidyl (10H) and aromatic protons (10H). VIIIa was thus deduced to be 6-methyl-1-phenyl-5-phenylcarbamoyl-4-(1-piperidyl)pyrid-2-one. The mass spectrum supported the proposed structure for VIIIa.

The minor product IXa corresponded to a compound derived from a 1:3 adduct of Ia and IIa with loss of water. The IR spectrum of IXa was very similar to that of VIIIa showing bands ascribable to ν_{NH} and $\nu_{C=O}$ at 3300 and 1630, 1650 cm^{-1}. Its NMR spectrum in deuteriodimethylsulfoxide (DMSO-d_6) dis-



VIII IX

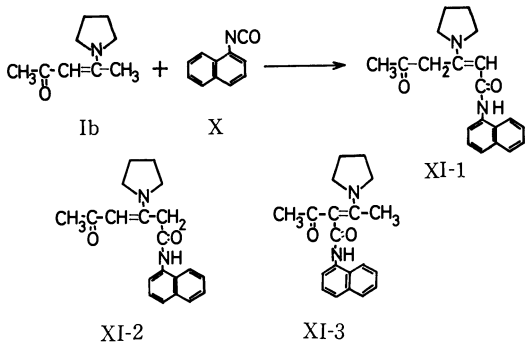
a: n=1, b: n=0

played singlets at δ 1.95 (3H, C**H**$_3$), 10.28 and 10.56 ppm (each 1H, N**H**), together with piperidyl (10H) and aromatic protons (15H). The results leave little doubt that IXa is 3,5-di(phenylcarbamoyl)-6-methyl-1-phenyl-4-(1-piperidyl)pyrid-2-one.

Under similar conditions, the reaction of Ib with IIa in refluxing benzene afforded 3,5-di(phenylcarbamoyl)-4-(1-pyrrolidinyl)pyrid-2-one IXb and a 2:1 complex of 5-phenylcarbamoyl-4-(1-pyrrolidinyl)pyrid-2-one VIIIb and *s*-diphenylurea. On heating with hydrochloric acid–acetic acid mixture, the 2:1 complex decomposed into its components VIIIb and *s*-diphenylurea.

As mentioned above, the structure of VIII corresponds to that of the compound obtainable from 1:2 adduct III with concurrent dehydration. When an ethanol solution of IIIa or IIIb was refluxed for 5 hr, the corresponding product VIIIa or VIIIb was obtained.[13] The formation of VIII under reflux in benzene can therefore be considered to proceed by the initial formation of 1:2 adduct III, followed by dehydration. On the other hand, VIII did not react with phenyl isocyanate (IIa); the pathway for the formation of IX has not yet been elucidated.

The reaction of enamino ketone Ib with 1-naphthyl isocyanate (X) at room temperature did not occur, but under reflux in benzene a 1:1 adduct XI was obtained in a small amount, together with *s*-di(1-naphthyl)urea and 1-(1-naphthyl)-2-(1-pyrrolidinyl)-urea; neither 1:2 adduct nor the product resulting from loss of water was formed.



Scheme 3.

The IR spectrum of XI showed bands assignable to ν_{NH} and $\nu_{C=O}$ at 3000 and 1690 cm^{-1}. The NMR spectrum exhibited singlets at δ 2.21 (3H, C**H**$_3$), 4.20 (2H, C**H**$_2$), 5.15 (1H, =C**H**), and 10.96 ppm (1H, N**H**) besides pyrrolidinyl (8H) and aromatic protons (7H). Thus, it seems that XI is 4-(1-pyrrolidinyl)-5-(1-naphthylcarbamoyl)pent-4-en-2-one (XI-1) rather than XI-2 or XI-3 (Scheme 3).

Experimental

All melting points are uncorrected. The IR spectra were measured as KBr pellets on a Nippon Bunko IR-S spectrophotometer; the NMR spectra were determined at 60 MHz on a Hitachi R-20 NMR spectrometer with TMS as internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV. The elemental analyses were performed by Miss M. Akita.

Materials. *4-(1-Piperidyl)-3-penten-2-one (Ia)*: A solution of 5.0 g (0.05 mol) of acetylacetone and 8.5 g (0.1 mol) of piperidine in 700 ml of dry benzene was refluxed until a theoretical amount of water was distilled out (about 15 hr). The reaction mixture was concentrated to leave a residue. The distillation of the residue gave yellow viscous liquid (bp 122—123°C/7 mmHg), which on standing solidified. Recrystallization from petroleum ether (bp 30—45°C) afforded 6.5 g (78%) of Ia, mp 47—47.5°C (decomp.), colorless prisms.

Found: C, 71.76; H, 10.55; N, 8.43%. Calcd for $C_{10}H_{17}NO$: C, 71.86; H, 10.42; N, 8.38%.

4-(1-Pyrrolidinyl)-3-penten-2-one (Ib) was prepared according to the published procedure.[14] Mp 114—115°C (decomp.), (lit,[14] mp 115—116°C). Phenyl (IIa), *p*-chlorophenyl (IIb), *p*-tolyl (IIc) and 1-naphthyl isocyanate (X) were obtained commercially.

Reaction of 4-(1-Piperidyl)-3-penten-2-one (Ia) with Phenyl Isocyanate (IIa). *i) At Room Temperature*: A solution of 1.67 g (0.01 mol) of Ia and 2.38 g (0.02 mol) of IIa in 50 ml of benzene was stirred at room temperature for 5 hr, during which time crystals precipitated. Filtration gave crystals, which on recrystallization from ethanol below 50°C afforded 3.7 g (91%) of 3,5-di(phenylcarbamoyl)-4-(1-piperidyl)-3-penten-2-one (IIIa), mp 168.5—169°C (decomp.), as colorless needles.

Found: C, 71.17; H, 6.83; N, 10.42%. Calcd for $C_{24}H_{27}N_3O_3$: C, 71.09; H, 6.71; N, 10.36%.

NMR (in $CDCl_3$) δ ppm: 1.70 (6H, multiplet, C**H**$_2$), 2.0 (3H, singlet, C**H**$_3$), 3.87 (4H, multiplet, C**H**$_2$), 4.08 (2H, singlet, C**H**$_2$), 7.0—8.0 (10H, multiplet, aromatic protons), 11.58, 11.96 (each 1H, singlet, N**H**).

Similarly, the reaction of 4-(1-pyrrolidinyl)-3-pentene-2-one (Ib) with IIa, *p*-chlorophenyl (IIb) and *p*-tolyl isocyanate (IIc) gave the corresponding 1:2 adducts IIIb, IIIc, and IIId respectively. However, the product isolated from the reaction of Ib with IIa was a 2:1 complex of IIIb and benzene, which on treatment with ethanol afforded pure IIIb.

The 2:1 complex of IIIb and benzene: mp 131—132°C (decomp.), colorless needles.

Found: C, 72.91; H, 6.35; N, 9.68%. Calcd for $(C_{23}H_{25}N_3O_3)_2 \cdot C_6H_6$: C, 72.56; H, 6.51; N, 9.79%.

IR cm^{-1}: ν_{NH} 3280, 3230; $\nu_{C=O}$ 1706, 1640. Mass spectrum *m/e*: 373 (IIIb$^+$—H_2O), 78 ($C_6H_6^+$).

Recrystallization of the complex from ethanol below 50°C gave 1:2 adduct IIIb, mp 165—166°C (decomp.), as colorless needles. Yield, 65%.

Found: C, 70.29; H, 6.32; N, 10.72%. Calcd for $C_{23}H_{25}N_3O_3$: C, 70.57; H, 6.44; N, 10.74%.

IR cm^{-1}: ν_{NH} 3390, 3345; $\nu_{C=O}$ 1650. NMR (in $CDCl_3$) δ ppm: 1.89 (4H, multiplet, C**H**$_2$), 1.95 (3×2/5H, singlet, C**H**$_3$), 2.22 (3×3/5H, singlet, C**H**$_3$), 3.40 (4×2/5H, multiplet, C**H**$_2$), 3.57 (4×3/5H, multiplet, C**H**$_2$), 3.98 (2×3/5H, singlet, C**H**$_2$), 4.85 (1×2/5H, broad, =C**H**), 6.8—7.8 (10H, multiplet, aromatic protons), 9.80 (1H, broad, N**H**), 10.56 (1H, singlet, N**H**).

1:2 Adduct IIIc: mp 162—163°C, colorless needles. Yield, 40%.

13) When a solution of IIIa or IIIb in ethanol was gently heated below 50°C for a long time, their isomers IIIa′, mp 257—260°C (decomp.), and IIIb′, mp 179—180°C (decomp.), respectively, were formed. However, their structures have not yet been elucidated.

14) N. J. Leonard and J. A. Adamcik, *J. Amer. Chem. Soc.*, **81**, 595 (1959).

Found: C, 60.07; H, 5.13; N, 9.06%. Calcd for $C_{23}H_{23}N_3O_3Cl_2$: C, 60.00; H, 5.00; N, 9.13%.

IR cm^{-1}: ν_{NH} 3320; $\nu_{C=O}$ 1650, 1630. NMR (in $CDCl_3$) δ ppm: 1.90 (4H, multiplet, CH_2), 2.0 ($3\times2/3$H, singlet, CH_3), 2.18 ($3\times1/3$H, singlet, CH_3), 3.39 ($4\times1/3$H, multiplet, CH_2), 3.73 ($4\times1/3$H, multiplet, CH_2), 3.95 ($2\times1/3$H, singlet, CH_2), 5.41 ($1\times2/3$H, singlet, =CH), 6.9—7.7 (8H, multiplet, aromatic protons), 9.8 (1H, singlet, NH), 10.25 ($1\times1/3$H, singlet, NH), 10.70 ($1\times2/3$H, singlet, NH). Mass spectrum *m/e*: 463, 461, 459 (M^+).

1:2 Adduct IIId: mp 138—140°C, colorless crystals. Yield, 49%.

Found: 72.06; H, 7.10; N, 9.72%. Calcd for $C_{25}H_{29}N_3O_3$: C, 71.57; H, 6.97; N, 10.02%.

IR cm^{-1}: ν_{NH} 3245, 3180; $\nu_{C=O}$ 1695, 1630. NMR (in $CDCl_3$) δ ppm: 1.90 (4H, multiplet, CH_2), 1.99 ($3\times2/5$H, singlet, CH_3), 2.24 ($3\times3/5$H, singlet, CH_3), 2.30 (6H, singlet, CH_3), 3.40 ($4\times2/5$H, multiplet, CH_2), 3.68 ($4\times3/5$H, multiplet, CH_2), 3.96 ($2\times3/5$H, singlet, CH_2), 5.50 ($1\times2/5$H, singlet, =CH), 6.9—7.8 (8H, multiplet, aromatic protons), 9.37 ($1\times2/5$H, broad, NH), 9.6 (1H, broad, NH), 10.52 ($1\times3/5$H, broad, NH).

ii) Under Reflux in Benzene: A solution of 1.67 g (0.01 mol) of Ia and 2.38 g (0.02 mol) of IIa in 50 ml of benzene was refluxed for 5 hr. After cooling, filtration gave crystals, which on recrystallization from ethanol afforded 0.97 g (25%) of 6-methyl-1-phenyl-5-phenylcarbamoyl-4-(1-piperidyl)-pyrid-2-one (VIIIa), mp 266—268°C (decomp.), as colorless needles.

Found: C, 74.22; H, 6.78; N, 10.63%. Calcd for $C_{24}H_{25}N_3O_2$: C, 74.39; H, 6.50; N, 10.85%. Mass spectrum *m/e*: 387 (M^+).

The benzene filtrate was concentrated *in vacuo* to leave a residue. The residue was washed with ethanol to give crystals, which on recrystallization from benzene afforded 0.2 g (6%) of 3,5-di(phenylcarbamoyl)-6-methyl-1-phenyl-4-(1-piperidyl)-pyrid-2-one (IXa), mp 280—281°C, as colorless needles.

Found: C, 73.89; H, 6.00; N, 10.75%. Calcd for $C_{31}H_{30}N_4O_3$: C, 73.49; H, 5.97; N, 11.06%.

Similarly, the reaction of 1.53 g (0.01 mol) of Ib with 2.38 g (0.02 mol) of IIa gave 1.60 g (43%) of a 2:1 complex of VIIIb and *s*-diphenylurea, mp 228°C (decomp.), and 0.27 g of IXb, mp 272°C (decomp.), as both colorless prisms.

The complex; Found: C, 73.89; H, 5.72; N, 11.88%. Calcd for $(C_{23}H_{23}N_3O_2)_2\cdot C_{13}H_{12}N_2O$: C, 73.83; H, 6.04; N, 11.90%.

IR cm^{-1}: ν_{NH} 3290; $\nu_{C=O}$ 1700, 1674, 1636. NMR (in DMSO-d_6) δ ppm: 1.85 (4H, multiplet, CH_2), 1.88 (3H, singlet, CH_3), 3.40 (4H, multiplet, CH_2), 5.42 (1H, singlet, =CH), 7.0—8.0 (15H, multiplet, aromatic protons), 8.75, 10.75 (each 1H, singlet, NH). Mass spectrum *m/e*: 273 ($VIIIb^+$).

Compound IXb; Found: C, 73.34; H, 6.03; N, 11.19%. Calcd for $C_{30}H_{28}N_4O_3$: C, 73.15; H, 5.73; N, 11.38%.

IR cm^{-1}: ν_{NH} 3320; $\nu_{C=O}$ 1656, 1634. NMR (in DMSO-d_6) δ ppm: 1.75 (4H, multiplet, CH_2), 1.88 (3H, singlet, CH_3), 3.50 (4H, multiplet, CH_2), 6.9—7.8 (15H, multiplet, aromatic protons), 10.62, 10.82 (each 1H, singlet, NH). Mass spectrum *m/e*: 492 (M^+).

A solution of 1.0 g of the complex in 50 ml of concentrated hydrochloric acid–acetic acid mixture (1:1 vol/vol) was refluxed for 20 hr. After cooling, filtration gave 0.12 g of *s*-diphenylurea. The filtrate was concentrated *in vacuo* to leave a residue, which on several recrystallizations from ethanol afforded 0.25 g of pure VIIIb, mp 248—250°C (decomp.), as colorless prisms.

Found: C, 73.63; H, 6.50; N, 11.03%. Calcd for $C_{23}H_{23}N_3O_2$: C, 73.97; H, 6.21; N, 11.25%.

IR cm^{-1}: ν_{NH} 3265; $\nu_{C=O}$ 1660, 1645. NMR (in $CDCl_3$) δ ppm: 1.91 (4H, multiplet, CH_2), 2.08 (3H, singlet, CH_3), 3.47 (4H, multiplet, CH_2), 5.43 (1H, singlet, =CH), 7.0—7.7 (10H, multiplet, aromatic protons), 9.60 (1H, singlet, NH). Mass spectrum *m/e*: 273 (M^+).

Hydrolysis of 1:2 Adduct III. A solution of 1.0 g of IIIa in 10 ml of 18% hydrochloric acid was stirred at room temperature for 6 hr. Water was added to the reaction mixture and then the precipitated solid was filtered. Recrystallization from ethanol–petroleum ether mixture afforded 0.2 g (27%) of 1,3-di(phenylcarbamoyl)acetone (IV), mp 151—152°C (lit,[15] mp 155°C), as colorless plates.

Found: C, 68.98; H, 5.30; N, 9.30%. Calcd for $C_{17}H_{16}N_2O_3$: C, 68.90; H, 5.44; N, 9.46%.

IR cm^{-1}: ν_{NH} 3270; $\nu_{C=O}$ 1720, 1650. NMR (in pyridine-d_5) δ ppm: 3.8 (4H, broad, CH_2), 6.8—7.9 (19H, multiplet, aromatic protons), 10.8 (2H, broad, NH). Mass spectrum *m/e*: 296 (M^+).

Similarly, hydrolysis of IIIb gave IV in 30% yield. Compound IV was identical with an authentic sample prepared from dimethyl β-ketoglutarate and aniline.

1-Phenyl-4-(1-pyrrolidinyl)-1,2,6-trihydropyridine-2,6(5H)-dione (Vb). i) A solution of 1.0 g of IIIb in 15 ml of 27% hydrochloric acid was stirred at room temperature for 20 hr. The reaction mixture was poured into water and the precipitated solid was filtered. Recrystallization from ethanol–petroleum ether afforded 0.2 g (30%) of Vb, mp 214—216°C (decomp.), as reddish brown plates.

Found: C, 70.08; H, 6.26; N, 10.88%. Calcd for $C_{15}H_{16}N_2O_2$: C, 70.29; H, 6.29; N, 10.93%. Mass spectrum *m/e*: 256 (M^+).

ii) A solution of 5.92 g of IV and 10 ml of pyrrolidine in 50 ml of benzene was stirred at room temperature for 15 hr and then 30 ml of petroleum ether was added to the reaction mixture. Filtration afforded 6.50 g (93%) of dianilide VI, mp 174—175°C, as colorless needles.

Found: C, 72.29; H, 6.73; N, 12.15%. Calcd for $C_{21}H_{23}N_3O_2$: C, 72.18; H, 6.63; N, 12.03%.

IR cm^{-1}: ν_{NH} 3310; $\nu_{C=O}$ 1675. NMR (in $CDCl_3$) δ ppm: 1.79 (4H, multiplet, CH_2), 3.38 (4H, multiplet, CH_2), 4.54 (1H, singlet, =CH), 6.8—7.7 (11H, multiplet, aromatic protons and NH), 11.11 (1H, singlet, NH). Mass spectrum *m/e*: 349 (M^+).

Treatment of 1.0 g of VI with 10 ml of 27% hydrochloric acid gave 0.15 g of Vb. Hydrolysis of VI with 18% hydrochloric acid also afforded IV quantitatively.

Reaction of 1:2 Adduct IIIa with Hydrazine Hydrate. A solution of 1.0 g of IIIa and 5 ml of hydrazine hydrate in 20 ml of ethanol was stirred at room temperature for 5 hr. The reaction mixture was concentrated *in vacuo* to leave a residue, which on recrystallization from ethanol afforded 0.25 g (31%) of pyrazole derivative VII, mp 239—240°C, as colorless needles.

Found: C, 68.09; H, 5.27; N, 16.64%. Calcd for $C_{19}H_{18}N_4O_2$: C, 68.24; H, 5.42; N, 16.76%.

IR cm^{-1}: ν_{NH} 3240; $\nu_{C=O}$ 1650, 1630. NMR (in $CDCl_3$) δ ppm: 2.50 (3H, singlet, CH_3), 3.95 (2H, singlet, CH_2), 7.0—8.0 (11H, multiplet, aromatic protons and NH), 10.55, 11.07 (each 1H, singlet, NH). Mass spectrum *m/e*: 334 (M^+).

Reaction of Enamino Ketone Ib with 1-Naphthyl Isocyanate (X). A solution of 1.53 g (0.01 mol) of Ib and 1.69 g (0.01 mol) of X in 50 ml of benzene was refluxed for 16 hr. After cooling, filtration gave 0.34 g of a mixture of *s*-di(1-naphthyl)urea and 1-(1-naphthyl)-2-(1-pyrrolidinyl)urea. Fractional recrystal-

15) E. Besthorn and E. Garben, *Ber.*, **33**, 3443 (1900).

lization from ethanol afforded pure *s*-di(1-naphthyl)urea, mp 268—270°C (decomp.) (lit,[16] mp 270—314°C (decomp.)), and 1-(1-naphthyl)-2-(1-pyrrolidinyl)urea, mp 134—135°C. Both ureas were identical with authentic samples prepared from 1-naphthyl isocyanate and 1-naphthylamine or pyrrolidine, respectively.

16) J. W. Boehmer, *Rec. Trav. Chim. Pays-Bas*, **55**, 379 (1936).

The filtrate was concentrated *in vacuo* to leave a residue, which was washed with petroleum ether. Recrystallization of the insoluble solid from ethanol–petroleum ether afforded 0.32 g of 1: 1 adduct XI, mp 165—166°C (decomp.), as colorless needles.

Found: C, 74.39; H, 6.60; N, 8.60%. Calcd for $C_{20}H_{22}N_2O_2$: C, 74.51; H, 6.88; N, 8.69%. Mass spectrum *m/e*: 322 (M^+).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 290—291 (1973)

Preparation of *p*-Nitrophenyl 2-*O*-Acetyl-β-D-glucopyranoside and *N*-Acetyl-β-D-glucosaminidase Activity toward It. (Essential Requirement of 2-Acetamide Group of Substrate for *N*-Acetyl-β-D-glucosaminidase Hydrolysis)

Kazuhiko YAMAMOTO

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received April 11, 1972)

Paranitrophenyl 2-*O*-acetyl, and 2,3-di-*O*-acetyl-β-D-glucopyranoside (VI, VII) were synthesized in order to investigate the effect of the substitution of the amide-nitrogen of the substrate by oxygen on the *N*-acetyl-β-D-glucosaminidase hydrolysis. Paramethoxybenzylidene was used as an *O*-blocking group for the preparation, and it was found that this blocking group could be easilly removed without the destruction of *p*-nitrophenyl glycoside. The evidence that VI could not be hydrolysed with this enzyme indicated the essential requirement of the amide-nitrogen of the substrate for the enzyme action.

Several *p*-nitrophenyl 2-acylamino-2-deoxy-β-D-glucopyranosides containing several *N*-acyl substituents were synthesized recently in order to investigate the *N*-acyl specificity of *N*-acetyl-β-D-glucosaminidase [EC. 3. 1. 2. 30]. The *N*-acyl specificity of this enzyme was fairly well clarified in a previous study.[1] An attempt to investigate the effect of replacing the amide-nitrogen of the substrate with oxygen on the enzyme action led to the synthesis of 2-*O*-acetyl-β-D-glucopyranoside.

The present report will describe the preparation of *p*-nitrophenyl 2-*O*-acetyl-β-D-glucopyranoside (VI) and *p*-nitrophenyl 2,3-di-*O*-acetyl-β-D-glucopyranoside (VII) as the reference derivative, and the susceptibilty of VI toward the enzymic hydrolysis. *para*-Nitrophenyl glycoside was chosen as a consequence of the previous investigation. The greater reactivity of the 2-hydroxyl group as compared to the other secondary hydroxyl groups has been noted.[3] Therefore, it is most probable that the 2-*O*-acetyl derivative of II results in the reaction of II with a limited amount of acetic anhydride. The selective 2-*O*-acetylation of *p*-nitrophenyl 4,6-*O*-(*p*-methoxybenzylidene)-β-D-glucopyranoside (II) under limited conditions and the chromatographic purification of debenzylidenated products gave a pure *p*-nitrophenyl 2-*O*-acetyl-β-D-glucopyranoside (VI). The location of the acetyl group was confirmed by periodate-oxidation analysis. *para*-Methoxybenzylidene as the *O*-blocking group was used for the preparation because *p*-nitrophenyl glycoside was usually very acid-labile. This new blocking group, which has been reported to be smoothly cleaved under mild acidic conditions,[4] was removed more easily without the destruction of glycoside. The product III substituted with di-*O*-(*p*-methoxybenzylidene) was found in the case of the prolonged treatment.

The synthetic scheme and the compounds synthesized are shown in Fig. 1.

With regard to the enzymic hydrolysis, this sub-

strate VI was not affected by *N*-acetyl-β-D-glucosaminidase. This evidence suggests that the –NH– group of the amide bond of 2-acetamide-2-deoxy-D-glucopyranoside is essential for the action of this enzyme.

Experimental

The melting points were determined by a micro-melting-point apparatus (Yanagimoto MFG.), and the optical rotations were measured by means of a recording spectropolarimeter (Yanagimoto MFG, ORD-185).

para-*Nitrophenyl 4,6-O-(p-methoxybenzylidene)-β-D-glucopyranoside (II).* To 50 ml of dimethylformamide solution of (I)[2] (1.0 g) we added 3 ml of anisaldehyde, 6 ml of ethylorthoformate, and 2 ml of trifluoroacetic acid.[4] After the reaction had continued for 8 hr at room temperature, the reaction mixture was evaporated *in vacuo* to dryness. The residue, suspended in a cold sodium bicarbonate solution, was collected by filtration. The crystallization of the dried raw product from toluene afforded a crystalline (II) (1.1 g, 79%); mp 190—192°C $[\alpha]_{589}^{20}=-21.7°$ (C, 0.773 in dimethylformamide) Found: C, 57.17; H, 5.08; N, 3.30%. Calcd for $C_{20}H_{21}O_9N$: C, 57.28; H, 5.05; N, 3.34%.

The same reaction mixture as above was kept for 20 hr. at room temperature and subsequently treated in the same manner. The first crystallization of the dried raw products from toluene and methanol gave 0.51 g (27%) of a crystalline product (III), and the mother liquor of III afforded 0.42 g of II upon further crystallization. Mp 288—289°C, $[\alpha]_{589}^{20}=+13.7°$ (*C*, 1.47 in dimethylformamide) Found: C, 62.68; H, 5.14; N, 2.61%. Calcd for $C_{28}H_{27}O_{10}N$: C, 62.56; H, 5.06; N, 2.61%.

para-*Nitrophenyl 2,3-di-O-Acetyl-4,6-O-(p-methoxybenzylidene)-β-D-glucopyranoside (V).* Five hundred and fifty mg of II were acetylated with 10 ml of acetic anhydride in 60 ml of pyridine. The evaporated residue of the reaction mixture was then crystallized from ethanol, thus giving 530 mg (88%) of V. Mp 252—253°C $[\alpha]_{589}^{20}=-5.82°$ (*C*, 0.923 in dimethylformamide). Found: C, 57.49; H, 5.05; N, 2.81%. Calcd for $C_{24}H_{25}O_{11}N$: C, 57.25; H, 5.01; N, 2.78%.

para-*Nitrophenyl 2,3-di-O-Acetyl-β-D-glucopyranoside (VII).* A 400 mg portion of V, dissolved in 45 ml of 66% acetic acid, was heated for 5 min in boiling water, and then the acetic acid solution was evaporated *in vacuo* to a heavy syrup. The crystallization of the heavy syrup from ethanol gave 190 mg (62%) of VII. Mp 183—185°C $[\alpha]_{589}^{20}=-24.9°$ (*C*, 0.553 in dimethylformamide). Found: C, 49.75; H, 5.04; N, 3.62%. Calcd for $C_{16}H_{19}O_{10}N$: C, 49.87; H, 4.97; N, 3.63%. The concentration of the mother liquors gave a further 90 mg (29%) of (VII). Mp 182—183°C.

Selective O-Acetylation of II and Preparation of (VI). A chloroform–pyridine solution (1: 1, 60 ml) of II (460 mg) was cooled to −10°C, and to this solution we added 230 mg of acetic anhydride in 10 ml of chloroform, drop by drop, over a 10 hr period. The residue, after the evaporation of the reaction mixture, showed three spots on a thin-layer chromatogram. As the fastest of them corresponded to V and the slowest to II, the middle spot was assumed to be the mono-*O*-acetylated product(IV). The residue was debenzylidenated in 66% acetic acid for 5 min at 100°C; the subsequent evaporation of the hydrolysate gave a heavy syrup. The chromatographic purification of VI from the contaminants was performed on a Bio-gel-P-2 column (2.0×200 cm). The heavy syrup, which had been washed three times with ether, was dissolved in 45 ml of water and then applied to a Bio-gel column (2.0×200 cm) and eluted with 0.01M acetic acid. The effluent was monitored by measuring the absorbance at 300 mu. The main peak, which was assumed to be VI from the thin-layer chromatographic identification, was collected and dried by lyophillization. It afforded 120 mg (33%) of the amorphous solid, which showed $[\alpha]_{589}$ and the following elemental analytical result; $[\alpha]_{589}^{20}=-36.9°$ (*C*, 0.430 in dimethylformamide). Found: C, 48.17; H, 4.99; N, 4.00%. Calcd for $C_{14}H_{17}O_9N$: C, 48.98; H, 4.99; N, 4.08%.

In the periodate oxidation, which was performed in 10 mM of sodium periodate (pH 5.5) at room temperature by measuring the amount of periodate consumed acording to Avigad's method.[5] VI Consumed 1 mole equivalent periodate; its analytical data are shown in Table 1. This evidence indicates that the specimen had the structure of VI.

Table 1. Periodate-oxidation analysis for VI

Compound	Amount for analysis (mol)	$NaIO_4$-Consumption: Moles of $NaIO_4$ consumed	Molar equivalent: observed	Molar equivalent: calculated
VI	2.15×10^{-6}	2.11×10^{-6}	0.98	1.00
	1.07×10^{-6}	1.18×10^{-6}	1.10	1.00
VII	2.08×10^{-6}	0.12×10^{-6}	0.058	0.00
	1.04×10^{-6}	0.00	0.00	0.00

N-Acetyl-β-D-glucosaminidase Activity toward VI. The enzyme specimen and the analytical procedure were the same as that of the previous report.[1]

Two mM of VI in a pH 4.5-citrate buffer were incubated with the enzyme (concentration from 0.5 ppm to 50 ppm) at 37°C for 24 hr. No *p*-nitrophenol liberated from VI could be detected.

The author wishes to thank Professor Y. Matsushima (Faculty of Science, Osaka University) for his continued interest and support during this work and Dr. K. Shingu (Faculty of Science, Osaka University) for his kind operation of recording spectropolarimeter.

Studies on Nitrile Salts. I. Dimerization of Nitriles Having α-Hydrogen in the Presence of Hydrogen Chloride

Shozo YANAGIDA, Tetsuo FUJITA, Masataka OHOKA, Ichiro KATAGIRI, and Saburo KOMORI

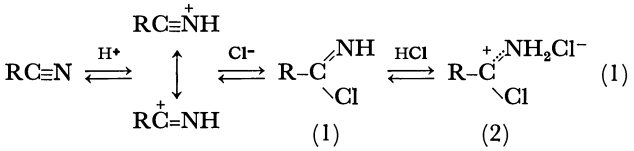
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received February 9, 1972)

The compositions and structures of several stable nitrile-HCl salts previously reported were reinvestigated. Most of them have been found to have the composition of $2RC{\equiv}N\cdot 2HCl$ and have been identified as *N*-(α-chloroalkenyl)alkylamidine hydrochlorides (**3**) by mass and NMR spectra analyses. However, the 2:3 adduct from chloroacetonitrile was confirmed to be *N*-(α,α,β-trichloroethyl)chloroacetamidine hydrochloride. The scope and limitations of the dimerization reaction of nitriles having α-hydrogen with HCl were studied. Most nitriles having α-hydrogen react with HCl to give *N*-(α-chloroalkenyl)alkylamidine hydrochlorides (**3**). Their hydrolysis to diacylamines (**4**) was also investigated.

Since Gautier[1] first reported the reaction of propionitrile with hydrogen chloride in 1866, the reactions of nitriles with hydrogen halides have been well documented.[2-6]

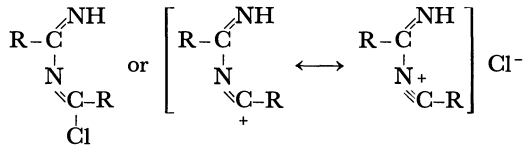
It is now believed that nitriles react with HCl at a low temperature to form various salt-like species which are in equilibrium with each other, as is shown in Eq.1:



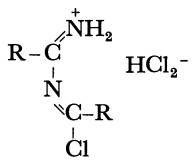
(1)

In addition, it has recently been ascertained,[7] on the basis of neutron-diffraction analysis, that the addition product prepared from acetonitrile and HCl at a low temperature has the structure of **2**($R=CH_3$), as was proposed by Allainstein and Schmidt.[8] On the other hand, there have been some reports concerning the addition products assigned to Structure **1**; Michael and Wing[9] assigned the nitrile salt prepared from propionitrile and HCl according to the method of Gautier[1] to propionimidoyl chloride (**1**, $R=C_2H_5-$) on the basis of the reaction with aniline. Similarly, a U. S. Patent[10] has claimed that 2-chloropropionitrile and 2-chlorobutyronitrile react with HCl in ether to give the corresponding imidoyl chloride (**1**, $R=CH_3CHCl-$, CH_3CH_2CHCl-).

In addition to the simple imidoyl chloride salts (**1** or **2**), some nitriles are known to form isolable dimeric hydrochlorides. Grudmann *et al.*[11] reported that some α-chloronitriles reacted with HCl in ether to give dimeric salts with the composition of $2RC{\equiv}N\cdot HCl$ and proposed the following structures on the basis of their salt-like properties:



Zil'berman *et al.*,[12] however, reported that α-haloacetonitriles gave dimeric salts with the composition of $2RC{\equiv}N\cdot 3HCl$ under the same conditions and assumed the following dihydrochloride structure:



Recently we reported that the reaction of chloroacetonitrile with HCl gave the 2:2 adduct.[13] Hinkel and Treharne.[14] has also reported that, on standing, the unstable acetimidoyl chloride (**2**, $R=CH_3-$) changed slowly to *N*-(α-chloroethylidene)acetamidine hydrochloride, which has the composition of $2CH_3C{\equiv}N\cdot 2HCl$.

Similar dimeric salts of nitriles have also been postulated as intermediates in the reactions of nitriles in the presence of HCl.[2,4,13,15,16]

In view of the uncertainties surrounding the composition of stable nitrile-HCl salts, we have now undertaken a complete reinvestigation of the reactions of nitriles with HCl.

b) Molecular ion peaks corresponding 2,4,6-triethyl-*s*-triazine was also observed.
c) Ratio 8: 10: 5.

Results and Discussion

Reinvestigation of Stable Nitrile Salts Previously Reported. In order to clarify the discrepancies in the results of the reaction of chloroacetonitrile and HCl, we first undertook a careful reinvestigation of the addition product.

As was reported previously,[13] the melting point of the adduct varied in several repeated experiments. It has now been found, on the basis of analyses of the chlorine content and the IR spectra, that the adduct freshly prepared in ether below 0°C is quite different from that prepared by heating in a sealed tube using a solvent such as chlorobenzene, and that, on standing, the former gradually changes to the latter. The analysis of the chlorine content indicated that the former has the composition of $2ClCH_2C{\equiv}N\cdot 3HCl$, and the latter, the composition of $2ClCH_2C{\equiv}N\cdot 2HCl$. The hydrolysis of the both adducts gave bis(chloroacetyl)-amine (**4g**), indicating that both have a dimeric structure. The mass spectrum of the latter salt also supported the dimeric structure (Table 1). In their IR spectra (Nujol), the absorptions in the region of 1500 to 1700 cm^{-1} are quite similar, but only the former has the characteristic absorption at 1750 cm^{-1}.[17]

However, when the latter salt was left standing in drying pistol at 50°C under reduced pressure, the chlorine content decreased to 59.0%; this corresponds to the composition of $2ClCH_2C{\equiv}N\cdot HCl$, as was analyzed by Grundmann *et al.*[11] The mass spectrum showed not only the fragment ion peaks due to the dimer salt with the composition of $2ClCH_2C{\equiv}N\cdot 2HCl$, but also the molecular ion and fragment ion peaks due to 2,4,6-tris(chloromethyl)-*s*-triazine, suggesting that the salt suffered from degradation.[18]

In view of the above facts, we concluded that the initially-formed salt, $2ClCH_2C{\equiv}N\cdot 3HCl$ is gradually transformed to a more stable dimer salt, $2ClCH_2C{\equiv}N\cdot 2HCl$ (**3g**), which is then further transformed to 2,4,6-tris(chloromethyl)-*s*-triazine with a loss of HCl.[19]

The reinvestigation has now been extended to the addition products prepared by the reactions of dichloroacetonitrile, 2-chloropropionitrile, or propionitrile with HCl.

An analogous treatment of dichloroacetonitrile and 2-chloropropionitrile with HCl in ether readily gave the white addition products, as were previously reported.[10,11] The elemental analyses of these adducts (**3t** and **3u** in Table 2) indicated that they all had the empirical formula $R^1R^2CHC{\equiv}N\cdot HCl$. Their IR spectra in the region from 1500 to 1700 cm^{-1} were similar

17) We assumed that this absorption might be assigned to the cation $>C{=}N^+H-$, although the imminium bands were not observed clearly. B. Witkop, *Experientia.*, **10**, 420 (1954).

18) In its IR spectrum, the characteristic absorption was observed at 1760 cm^{-1}.

19) The formation of the *s*-triazines is under study in our group.

enough for us to assume that they all had the same structure as the dimer salt, $2ClCH_2C{\equiv}N{\cdot}2HCl$ (**3g**), although sometimes their IR spectra showed a weak absorption around 1750 cm^{-1} as well as the precursor of **3g** described above.

On the other hand, the addition product from propionitrile was prepared by reacting propionitrile with excess HCl in a sealed glass tube at 60—65°C. The resulting addition product (**3b**) was found, on the basis of elemental analysis and the melting point, to be

identical with a substance which had already been obtained by Gautier[1] and Michael.[9] Its IR spectrum did not show the absorption around 1750 cm^{-1} and indicated the same structure as the other adducts, **3g**, **3t**, and **3u**. Generally, the adducts obtained by heating in a sealed tube did not show the IR absorption around 1750 cm^{-1}.

As is shown in Table 1, their mass spectra exhibited the fragment ion peaks corresponding to M^+–HCl, M^+–HCl—Cl, $R^1R^2CHC{\equiv}\overset{+}{N}H$, and $R^1R^2CHC{\equiv}N$. Thus, all the addition products (**3b**, **3t**, and **3u**) have been confirmed to be dimer salts with the composition of $2R^1R^2CHC{\equiv}N\cdot 2HCl$. Further proof was obtained by the hydrolysis of the addition products to diacylamine **4** or **5**, as will be discussed below.

Dimerization of Other Nitriles Having α-Hydrogen with HCl. Nitriles were generally allowed to react with an excess of dry HCl in a sealed glass tube at 60—65°C until the reaction mixture became viscous enough (Table 2). In two cases, those of isobutyronitrile and 2,3-dichloropropionitrile, the whole reaction mixture solidified at the end of the reaction. In the other cases, when the viscous product was treated with dry ether or was left standing with ether in a refrigerator, the white or pale yellow product crystallized or solidified. Most of the adducts thus obtained were analytically pure, as is shown in Table 2. The addition product from acetonitrile was very hygroscopic, as was the dimeric product reported by Hinkel and Treharne.[14] On the basis of the data in Tables 1 and 2, and the hydrolysis to the corresponding diacylamines (**4**) (see next section), all of the addition products were identified as dimer salts with the composition of $2R^1R^2CHC{\equiv}N\cdot 2HCl$. It is worth pointing out that, in some of their mass

21) Shand[10] reported that water converted the salt from 2-chloropropionitrile to 2-chloropropionamide.

22) Grundmann *et al.*[2] reported that the treatment of the dimeric salt having the formula $(CHCl_2C{\equiv}N)_2HCl$, with water gave bis(dichloroacetyl)amine (**4t**).

spectra, the molecular-ion and degradation-ion peaks due to the *s*-triazine with the composition of $(R^1R^2CHC{\equiv}N)_3$ were observed instead of the degradation peaks due to the dimer salts (**3**).[19]

The reaction seems to proceed quantitatively. Especially, an excess of HCl and a prolonged reaction time seem to be beneficial for the reaction. Heating is not always necessary. Some α-chloronitriles quantitatively dimerize in ether under cooling, and isobutyronitrile reacts with a large excess of HCl at room temperature, although slowly, giving a quantitative yield of the salt (**3m**). A higher reaction temperature (100°C) did not favor the reaction (see **3m** in Table 2).

All attempts to prepare the solid dimer salts from methoxyacetonitrile, 3-alkoxypropionitriles, ethyl cyanoacetate, and diphenylacetonitrile were in vain (see Experimental Section).

Hydrolysis of the Dimer Salts (3) to Diacylamines (4). When most of the dimer salts (**3**) thus obtained were treated with water or with aqueous acetone or methanol, the corresponding diacylamines (**4**) were formed without being contaminated with other products (see Eq. 3). The yields and analytical data of the diacylamines (**4**) thus obtained are summarized in Table 3.[20]

It should be noted, however, that these dimer salts, **3b**, **3m**, and **3u**, were unreactive to water; they were recovered unchanged after the removal of water under reduced pressure. They were readily hydrolyzed by aqueous alkali to give these diacylamines, **4b**, **4m**, and **4u** respectively, as had been expected. However, the freshly-prepared ones were in part readily hydrolyzed by only cold water to give the corresponding diacylamines; this may be ascribed to the initial formation of unstable salts, such as 2: 3 adducts (see next section).

20) Diacylamines (**4**) were reported obtainable by the reaction of nitriles with carboxylic acids or acid chlorides. But the reaction conditions were very drastic (reaction temp. 100—250°C) and probably the yields may be low. (R. Otto and J. Troger, *Chem. Ber.*, **23**, 760 (1890)). This reaction provides a facile one-step synthesis of diacylamines (**4**).

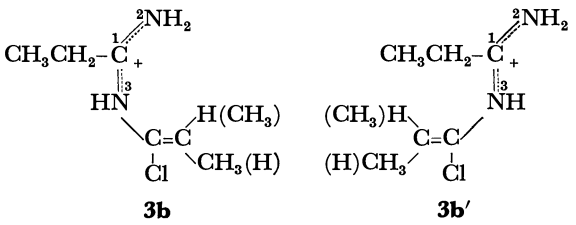
As is shown in Table 3, the similar treatment of the dimer salts **3r** and **3t** with water gave anomalous products. The former afforded *N*-(3-chloro-2-methylpropionyl)-*N*-methacryloylamine (**6**), which must be formed by the further but partial dehydrochlorination of bis(3-chloro-2-methylpropionyl)amine (**4r**) during work-up, while the latter gave a partially-hydrolyzed product, *N*-(1, 2, 2-trichlorovinyl) dichloroacetamide (**5**).[25]

Structure of the Dimer Salts (3). The mass spectra of the dimer salts (**3**) indicated that one mole of HCl in the salts was intrinsically bonded and that another mole of HCl was present in the ionic form. The analysis of the ionic chlorine content also supported this fact.

The most interesting problem was to determine the structure of the protonated amidine function in these dimer salts (**3**). In view of the above interest, we undertook an NMR investigation of their structures.

The NMR spectra of **3b** measured in the range from −60 to 20°C using liquid SO_2 as the solvent show two sets of quartets for the vinyl proton at τ 3.79 and 3.81 in almost the same ratio, and two sets of doublets for the methyl protons attached to the vinyl group at τ 8.08 and 8.11 in the same ratio; both the quartets and the doublets are coupled to each other (J=6.7 Hz), suggesting the presence of a propenyl group as a mixture of *cis* and *trans* in almost equal proportions.

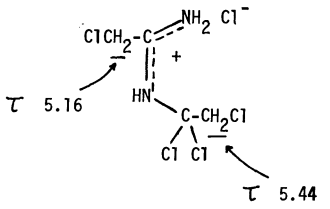
The NH protons give rise to three broad signals at 20°C. As the temperature is lowered, a narrowing of the signals and slight shift to higher magnetic fields are observed. Below −35°C, the two upfield peaks were split, giving new, small, broad signals at τ *ca.* 1.77—1.93 and *ca.* 2.44—2.47 respectively. The simplest interpretation of these data is that the upfield signals are due to $>C^1{=}N^2H_2$, with a hindered rotation about the C^1N^2 bond because of its partial double-bond character, and that the low-field signal is due to a highly acidic proton on the nitrogen, N^3. The behavior of the upfield N^2H_2 protons at low temperatures may unambiguously be ascribed to the internal rotation of the α-chloroalkenyl group about the C^1N^3 bond with the partial double-bond character, as is shown in Eq. (2):



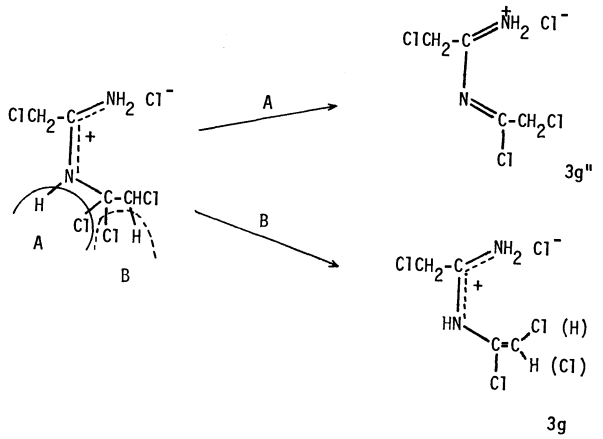
(2)

However, no splitting of the low-field N^3H signal was observed. The IR absorption patterns of **3b** in the region from 1500 to 1700 cm^{-1} are absolutely identical both in the solid state and in solution (in methanol).

The NMR spectrum of the 1: 1 adduct from chloroacetonitrile, however, was not reproducible in any solvent such as DMSO-d_6, CF_3COOH, and liquid SO_2. Taking into account its instability, the freshly-isolated adduct, $2ClCH_2C{\equiv}N\cdot 3HCl$, was analyzed instantly with a 100 MHz NMR spectrometer. The NMR spectrum (Fig. 1) suggests that the adduct has the following structure:



On the other hand, when the adduct was left standing under reduced pressure overnight, signals due to two pairs of methylene protons were deformed and signals attributable to the olefinic proton (*cis* and *trans*) appeared in its NMR spectrum (Fig. 2). These changes in the spectrum indicate the occurrence of partial dehydrochlorination, which may follow both A and B paths as follows:



Accordingly, the lack of reproducibility of the NMR spectrum of the 2: 2 adduct from chloroacetonitrile was ascertained to be attributable to the indefinite contamination with **3g''** or the 2: 3 adduct.

Table 3 summarizes the NMR spectra of the 2: 2 adducts measured in this investigation. The data

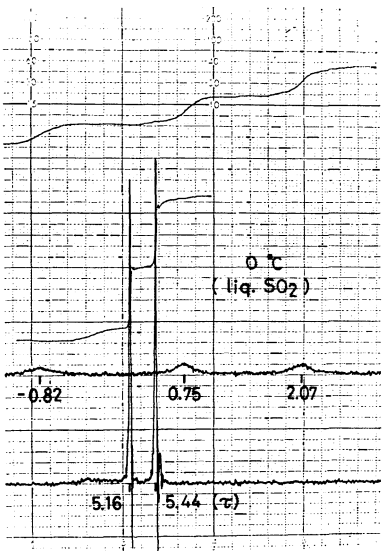


Fig. 1.

25) L. Hellerman, M. L. Cohn, and R. E. Hoen, *J. Amer. Chem. Soc.*, **50**, 1725 (1928).

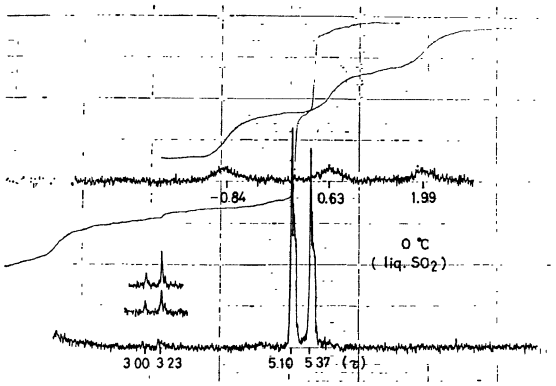

Fig. 2.

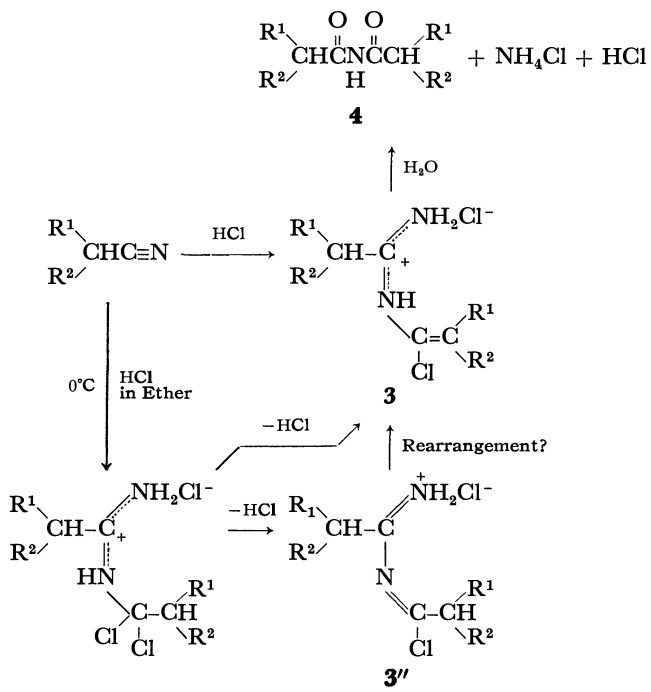
supported the general formula **3** as the structure of the dimer salts.

The reaction described above can now be presented as follows:



Extensive chemistry based on nitrile salts is now in progress in our group and will be described elsewhere.

Experimental

All the melting points were determined on a Yanagimoto micro-melting point apparatus and were corrected. The IR spectra were measured on a JASCO IR-E spectrometer; the NMR spectra, on JEOL JNM-G-60 and JNM-PS-100 spectrometers, with tetramethylsilane as the internal standard, and the mass spectra, on a Hitachi RMU-6E spectrometer.

General Procedure. In a 30 ml glass tube we placed 2—5 g of nitrile. The tube was then immersed in a mixture of ice and water, and dry HCl was allowed to be absorbed in it as much as possible. During that time, a white, crystalline solid, probably imidoyl chloride hydrochloride (**2**), was precipitated in some cases. The tube was stoppered, cooled in Dry Ice-acetone, sealed carefully, and heated to 60—65°C in a water bath until the reaction mixture was judged viscous enough. Table 2 lists the molar ratio of HCl to nitrile and the length of time. After the end of the reaction, the reaction tube was chilled in Dry Ice-acetone and opened carefully. After the removal of the HCl by warming, the stirring-in of dry ether caused the dimer salt to precipitate. When no solid precipitate appeared by this procedure, the mixture was then stored in a refrigerator for 24 hr or more, during which time the product was slowly crystallized and precipitated. Scratching the flask was sometimes beneficial for the solidification. The solid product was filtered, washed with dry ether, and dried under reduced pressure. In this manner, analytically-pure dimer salts were obtained and analyzed (Table 1). However, some salts (**3h, 3i, 3u,** and **3y**) required further purification. No attempt to find a good purification method was made.

Some reactions using ether as a solvent under cooling were carried out according to the methods previously reported.

The reaction of methoxyacetonitrile with HCl according to the general procedure, however, gave a black, hygroscopic substance. Ethyl cyanoacetate also gave a black, hygroscopic substance. The analogous treatment of 3-methoxypropionitrile or 3-butoxypropionitrile with HCl did not give the expected viscous reaction mixtures, and the starting nitriles were recovered. A small amount of the precipitated product consisted of ammonium chloride.

In the case of diphenylacetonitrile, di-*n*-butyl ether was employed as the solvent since the nitrile is solid. However, the resulting precipitate was identified as diphenylacetamide on the basis of following analytical results; mp 172—174°C (lit,[25] 167.5—168.5°C). Mass (M^+) 211. IR(KBr) 3380, 3180, 1650 cm^{-1}. Found: C, 79.59; H, 6.03; N, 6.67%. Calcd for $C_{14}H_{13}NO$: C, 79.59; H, 6.21; N, 6.63%. The formation of the amide is probably due to the degradation of di-*n*-butyl ether by HCl.

Preparation of the 2: 3 Adduct from Chloroacetonitrile. According to the method of Grundmann *et al.*,[11] chloroacetonitrile was allowed to react with HCl in ether under cooling. The resulting crystalline product was filtered by suction, left standing under reduced pressure for about 1 hr, and stored in a desiccator. Within 12 hr the white powder thus obtained was subjected to analysis. Found: Cl, 68.17%. Calcd for $C_4H_7N_2Cl_5$: Cl, 68.02%. Ionic chlorine content: Found: 40.56%. Calcd: 40.85%. The NMR tube containing the sample dissolved in liquid SO_2 was stored in a Dry Ice-acetone bath before measurement.

Hydrolysis of Dimer Salts (3). The dimer salt (**3**) (0.2—0.5 g) was dissolved in water (2—20 g). When the salt did not dissolve readily in cold water, the mixture was heated slightly, or methanol or acetone was added until the amidine salt dissolved. After a while, the diacylamine (**4**) was precipitated without being contaminated by other compounds, but in most cases several hours were required to observe the precipitation of diacylamines (**4**). Then, after the mixture had been allowed to stand overnight at room temperature, the diacylamine (**4**) formed was filtered with suction and dried. The diacylamines (**4**) thus obtained have a sufficient purity for synthetic use, but were further purified by sublimation and analyzed (Table 3).

When the amidines are resistant to hydrolysis in water, aqueous Na_2CO_3 was added until the mixture became alkali enough. Diacylamines **4** thus formed were treated in the same way.

In the hydrolysis of salt **3t**, after the filtration of **5**, the filtrate was extracted with ether. On evaporation, **5** was also obtained, but the further hydrolyzed product, bis(dichloroacetyl)amine (**4t**), was not isolated.

The authors wish to thank Mr. H. Moriguchi for

the mass spectra measurement, Mrs. M. Sakurai for the NMR measurement, and Miss J. Maenaka and Mr. and Mrs. Muneishi for elemental analyses. This work was supported in part by a grant-in-aid from Kokusan Gijutsu Shinkokai. We wish to express our thanks to the founder, the late Mr. Chikara Kurata.

Studies on Nitrile Salts. II.[1] A Facile One-step Synthesis of the Pyrimidine Nucleus

Shozo YANAGIDA, Tetsuo FUJITA, Masataka OHOKA, Reiji KUMAGAI, and Saburo KOMORI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received March 18, 1972)

The reaction of *N*-(α-chloroalkenyl)alkylamidine hydrochlorides (**1**) with phosgene was studied. The amidine hydrochlorides (**1a**—**h**) which were prepared from nitriles with more than two α-hydrogens reacted with phosgene at 100—105°C to give good yields of 4,6-dichloro-2,5-disubstituted-pyrimidines (**3a**—**h**). The amidine hydrochlorides (**1j**—**t**), which were obtained from nitriles with only one α-hydrogen, afforded 2-alkylidene-4,6-dichloro-5,5-disubstituted-2,5-dihydropyrimidines (**5j**—**t**) in good yields. The amidine hydrochloride **1i**, however, gave 2-dichloromethylidene-2,5-dihydro-5,5,6-trichloro-4(3*H*)-pyrimidinone (**4i**) under comparable conditions.

In our previous papers,[2-4] it was shown that the reaction of aliphatic nitriles or amides with phosgene and HCl gave good yields of 6-chloro-2,5-disubstituted-4(3*H*)-pyrimidinones (**2**), with traces of 4,6-dichloro-2,5-disubstituted-pyrimidines (**3**), and that arylacetonitriles gave 1,3-dichloroisoquinoline derivatives with the corresponding pyrimidinones (**2**) and pyrimidines (**3**). Further, we recently showed that most nitriles having α-hydrogen reacted with HCl to give *N*-(α-chloroalkenyl)alkylamidine hydrochlorides (**1**) almost quantitatively.[1]

On the basis of the reaction mechanism proposed for the formation of the pyrimidine derivatives (**2**) and (**3**),[2] the reaction of the amidine hydrochlorides (**1**) with phosgene may be expected to provide a convenient and facile one-step synthesis of the pyrimidine nucleus.

This paper will report the synthesis of pyrimidine derivatives, mainly **3** and **5**, based on this concept.

Results and Discussion

When *N*-(α-chloropropenyl)propioamidine hydrochloride (**1b**) was allowed to react with excess phosgene in chlorobenzene for 260 hr using a sealed glass tube at 60°C, 6-chloro-2-ethyl-5-methyl-4(3*H*)-pyrimidinone (**2b**) was obtained in a 60% yield, as had been expected (Scheme 1). However, the similar treatment of *N*-(α-chlorostyryl)phenylacetamidine hydrochloride (**1e**) with phosgene resulted in the recovery of the starting materials unchanged. Upon continued heating at 100—105°C for a period of 24 hr, 4,6-dichloro-2-benzyl-5-phenylpyrimidine (**3e**) was produced in a 75% yield. It is worth pointing out that 1,3-dichloroisoquinoline, which is the main product in the direct reaction of phenylacetonitrile with phosgene and HCl at 100°C,[4] was not formed. 6-Chloro-2-benzyl-5-phenyl-4(3*H*)-pyrimidinone hydrochloride, a precursor of **2e**,[2] first formed must be converted into **3e** by phosgene because of its strong electrophilicity at high temperatures (Scheme 1.).

a) 70 eV. b) Values in parentheses are calculated ones. c) Identified by comparison with authentic sample.[2,4] d) By glpc. e) Nujol. f) Measured in $CDCl_3$. g) Lit,[4] 136.0—138.0°C. h) KBr disk. i) Shoulder. j) 6.67(m, 4H), 5.63(s, 2H), 2.60—7.00(complex peaks, 10H) in CF_3COOH.

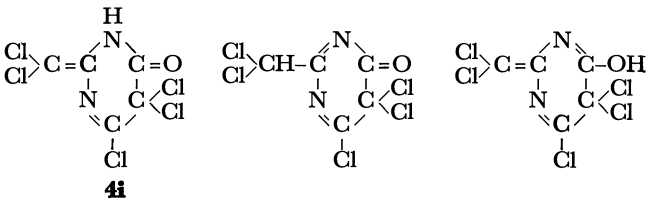
In view of the above facts, the reaction was extended to other amidines **1a**—**h**, employing 100°C as the reaction temperature. The expected dichloropyrimidines **3a**—**h** were obtained in good yields. (Scheme 1). It should be noted that the pyrimidine **3h** was obtained in a satisfactory yield by this reaction. As has been reported previously,[2] the direct reaction of 3-chloropropionitrile with phosgene in the presence of HCl gave a polymeric substance, and neither the pyrimidinone **2h** nor the pyrimidine **3h** was isolated.[5]

These pyrimidines **3** were confirmed on the basis of their physical properties and by elemental analysis, as is summarized in Table 1.

The NMR spectra of the pyrimidine **3f** are of particular interest. As is shown in Table 1, in CCl_4 the signals due to two pairs of methylene protons of the 2-phenethyl group were observed as a singlet, indicating that the phenyl ring of the 2-phenethyl group and the pyrimidine ring in **3f** are magnetically equivalent. A similar spectrum was also obtained in benzene. In CF_3COOH, however, this singlet signal was observed as an A_2B_2 pattern centered at τ 6.67, the signal due to methylene protons of the 5-benzyl group shifted to a lower field, and the signals of both phenyl ring protons, which were observed as a singlet in CCl_4, changed to a complex series of lines. The spectrum complexity is probably due to the protonation at the pyrimidine nitrogen.

We assumed that the driving forces of this cyclization reaction are the nucleophilicity of the β-carbon of a kind of enamino group [–NH–CCl=CHR] in the amidines **1** (Scheme 1)[6] and the prototropy of the hydrogen on the β-carbon. In view of these assumptions, the amidine hydrochlorides **1i**—**t** prepared from nitriles with only one α-hydrogen were expected to react with phosgene under comparable conditions to give a new type of pyrimidine derivative.

The treatment of the amidine hydrochloride **1i**, where both R and R′ are Cl, with phosgene under the same conditions as above led to a colorless compound, which was analyzed well for $C_5HON_2Cl_5$. The IR spectrum, taken in CCl_4, showed absorption bands at 3070, 2970, 2880 (NH), 1690 (C=O), 1590 (C=N), and 1530 (C=C) cm^{-1}. The series of absorption bands in the NH region were thought to be too low to assign to the NH stretching band. However, the NMR spectrum, measured in CCl_4, showed only a broad signal attributable to the NH proton at τ −2.85. In addition, the IR spectra in the region below 1700 cm^{-1} are quite identical both in the solid state and in solution (CCl_4). On the basis of these spectral analytic results, the compound was formulated as 2-dichloromethylidene-2,5-dihydro-5,5,6-trichloro-4(3*H*)-pyrimidinone (**4i**) rather than the following alternative structures:



4i

5) It has been found in our laboratory that 3-chloropropionitrile reacts with phosgene and HCl in chlorobenzene at 100—105°C to give 1,3-dichloropropenyl isocyanate in a moderate yield, which fact will be reported eslewhere in the very near future.

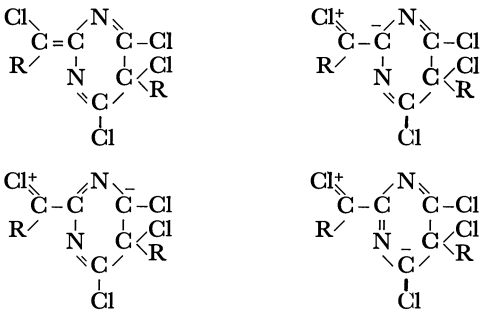
Scheme 2.

It is apparent that the pyrimidines **5** are formed through the chlorination of the initially-formed pyrimidinones **4** by phosgene, and that the pyrimidinone **4i** must be unreactive to phosgene under the reaction conditions employed.

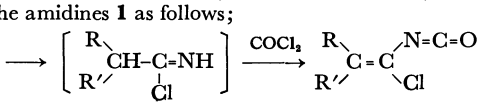
The structures of **5j—o** were confirmed on the basis of their physical properties and by elemental analysis (Table 2). Attempts to isolate analytically-pure pyrimidines **5p—t** were unsuccessful. They were characterized by IR and mass spectra (see Experimental section).

It should be noted that, as is shown in Table 2, the IR absorptions attributable to the C=N and C=C stretching vibrations of **5j—m** are shifted to frequencies lower by about 100 cm^{-1} compared with those of the other pyrimidines **5o—t**. These large shifts may be explained by considering the following structures, based on the mesomeric effect:



The IR spectra of the crude products from the amidines **1p—t** showed weak bands around 1750 cm^{-1} and medium bands attributable to the N=C=O stretching vibration around 2260 cm^{-1}, indicating the formation of by-products with a COCl group and/or an N=C=O group.[7] Accordingly, the crude products from **1p** and **1t** were treated with aniline, unexpectedly giving dimethylmalonoanilide and butylmethylmalonoanilide in 9 and 25% yields, respectively, based on the starting amidines. This fact suggests the formation

7) As noted in Ref. 6, some nitriles have been found to react with phosgene at high temperature to give α-chloroalkenyl isocyanates. In view of this fact, we assumed the compounds having N=C=O group to be corresponding isocyanates, which are probably produced through imidoyl chlorides formed by the degradation of the amidines **1** as follows;



of disubstituted malonyl chlorides as by-products, we assumed that they were produced through the further reaction of the pyrimidines **5p—t** with phosgene.[8] However, no urea derivatives, which were thought to be derived from compounds with an N=C=O group, were isolated.[9]

Further studies of the reactivity of the pyrimidines **5** are now in progress in our laboratory.

Experimental

The melting points were determined on a Yanagimoto micro melting point apparatus and were corrected. The boiling points were uncorrected. The NMR spectra were obtained using a Model JNM-G-60 spectrometer (Japan Electronic Optics Laboratory Co.); the solvent was carbon tetrachloride, except where otherwise noted, with tetramethylsilane as the internal reference. The IR spectra were recorded with a Japan Electroscopic IR-E spectrophotometer, the mass spectra, with a Hitachi mass spectrometer, Model RMU-6E, and the UV spectra, with a Shimadzu double-beam spectrophotometer, UV-200.

Materials. *N*-(α-Chloroalkenyl)alkylamidine hydrochlorides (**1a—t**) were prepared according to the method reported previously.[1]

Reaction of the Amidine Hydrochlorides (1) with Phosgene. General Procedure: In a 150 ml glass tube we placed 1.6—3.0 g (*ca.* 20 mmol) of the amidine hydrochloride (**1**) and 20 ml of chlorobenzene. The tube was then immersed in a mixture of ice and water, and 6.2—7.4 g (*ca.* 75 mmol) of phosgene was bubbled into the mixture. The tube was stoppered, cooled in a Dry Ice–acetone mixture, sealed carefully, and heated to 100—105°C in an oil bath for 24 hr. The reaction tube was then chilled in the Dry Ice–acetone mixture and opened carefully. After the removal of the phosgene and chlorobenzene under reduced pressure, the resulting products were purified by recrystallization or distillation, if necessary, after column chromatographic separation, as is shown in Tables 1 and 2. The column chromatography was always done using silica gel, and all the products were eluted with petroleum ether.

In the cases of the pyrimidines **5p—t**, repeated distillations after column chromatography did not give the analytically-pure pyrimidines. They were all confirmed in the basis of their IR spectra. The mass spectra also supported the structure of **5**. The crude yields, boiling points, and IR absorption bands attributable to the C=N and C=O streching vibrations are as follows: **5p**: 1655 and 1620 cm^{-1}; **5q**: 58%, *ca.* 85.0—86.0°C/2 mmHg, 1655 and 1615 cm^{-1}; **5r** 52%, 130.0—130.5°C/2 mmHg, 1655 and 1610 cm^{-1}; **5s**: 45%, 1655 and 1610 cm^{-1}; **5t**: 63%, *ca.* 105°C/1 mmHg, 1660 and 1620 cm^{-1}.

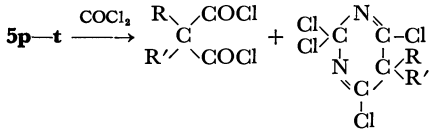
Of particular interest is the fact that **5p** is very sensitive to moisture and that the purification of crude **5p** by column chromatography resulted in the unexpected isolation of 5,5-dimethylbarbituric acid (82% yield). An attempt to explain this formation is now under way.

Isolation of Disubstituted Malonoanilides. A typical procedure was as follows: a crude product (0.77 g) obtained from **1p** was mixed with aniline (1.5 g) in 1,2-dichloroethane (10 ml). The mixture was then allowed to stand overnight at room temperature. After the aniline hydrochloride precipitated had been filtered out with suction, the filtrate was concentrated under reduced pressure. The residue was chromatographed on silica gel; chloroform eluted 0.25 g of dimethylmalonoanilide (9% yield based on the amidine **1p**). It was recrystallized from dichloroethane–ether and analyzed as follows: mp 209.0—210.0°C (lit,[10] 205°C). IR (KBr disk) 3260, 3120, 1645, 1600 cm^{-1}. Mass spectrum (70eV) 282 (M^+). NMR ($CDCl_3$–CF_3COOH) (τ) 8.28 (s, 6H), 2.51—2.86 (m, 10H). Found: C, 72.23; H, 6.25; N, 9.78%. Calcd for $C_{17}H_{18}O_2N_2$: C, 72.32; H, 6.43; N, 9.92%.

Similarly, butylmethylmalonoanilide was isolated in a 25% yield based on the starting amidine **1s**, and was analyzed after recrystallization from ethanol as follows: mp 198.5—199.0°C, IR (KBr disk) 3340, 3240, 1660, 1600 cm^{-1}. Mass spectrum (70 eV) 324 (M^+). NMR (CF_3COOH) (τ) 8.95 (t, 3H), 8.46 (m, 4H), 8.02 (s, 3H), 7.67 (t, 2H), 2.57 (s, 10H), 0.15 (s, 2H). Found: C, 74.20; H, 7.29; N, 8.64%. Calcd for $C_{20}H_{24}O_2N_2$: C, 74.04; H, 7.46; N, 8.64%.

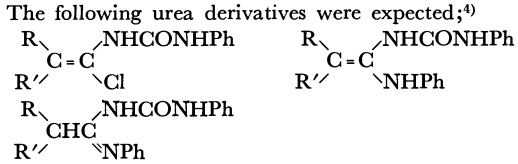
The authors wish to thank Mr. H. Moriguchi for the mass spectrum measurement, Mrs. M. Sakurai for the NMR measurement, and Miss J. Maenaka and Mr. and Mrs. Muneishi for elemental analysis. This work was supported in part by a grant-in-aid from Kokusan Gijutsu Shinkokai. We wish to express our thanks to the founder, the late Mr. Chikara Kurata.

8) In view of the formation of disubstituted malonyl chlorides, the following reaction can be considered;



However, latter products have not been identified yet.

9) The following urea derivatives were expected;[4]



However, more polar solvent eluted only black tarry substance.

Studies on Nitrile Salts. III.[1] Dimerization of Nitriles Having No α-Hydrogen with Hydrogen Chloride

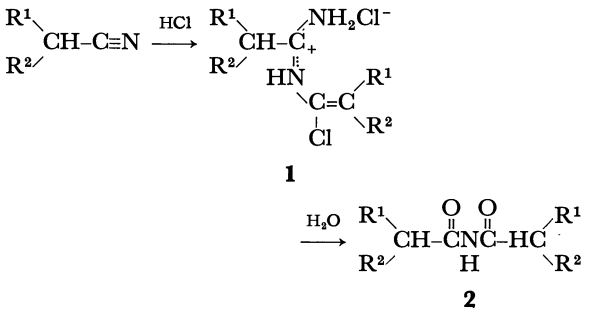
Shozo YANAGIDA, Tetsuo FUJITA, Masataka OHOKA, Ichiro KATAGIRI, Mikio MIYAKE, and Saburo KOMORI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received May 1, 1972)

The reaction of nitriles having no α-hydrogen, such as aromatic nitriles and thiocyanates, with hydrogen chloride was investigated. Benzonitrile, *p*-tolunitrile, *m*-tolunitrile and some thiocyanates gave analytically pure 2:2 adducts in their reactions with HCl in a sealed glass tube at 30—60°C. The structure of the adducts was elucidated on the basis of NMR analysis and the mechanism of the generalized dimerization of nitriles was discussed.

In this laboratory,[2] it was shown that nitriles having α-hydrogen reacted with HCl to give *N*-(α-chloroalkenyl)alkylamidine hydrochlorides (**1**), and that the amidines (**1**) are readily hydrolyzed in water giving diacylamines (**2**) as follows:



1

2

Our interest not only in extending this dimerization reaction to other cyano compounds but also in seeking an explanation for the reaction mechanism, prompted us to investigate the reaction of nitriles having no α-hydrogen with HCl.

Attempts to dimerize trichloroacetonitrile[3] or pivalonitrile with HCl have failed. However, it has now been found that some aromatic nitriles and thiocyanates undergo dimerization.

This paper reports their dimerization reaction, the structure of the resulting 2:2 adducts and the mechanism of the dimerization of nitriles.

Results and Discussion

Reaction of Aromatic Nitriles with HCl. It was so far believed[4] that some aromatic nitriles react with HCl at a low temperature (below 0°C) to give arylimidoyl chloride hydrochlorides, which are stable only in the atmosphere of HCl but decompose to the starting materials in the air. It has now been found that the treatment of benzonitrile with dry HCl in a sealed glass tube at a higher temperature (30—60°C) leads to the isolation of the white addition product having the empirical formula C_7H_6NCl, which is stable in the air. When this salt-like adduct was dissolved in water and allowed to stand overnight at room temperature, dibenzoylamine was formed in 44% yield. The hydrolysis of the adduct with aqueous alkali unexpectedly gave *N*-benzoylbenzamidine contaminated with a small amount of 2,4,6-triphenyl-*s*-triazine. These facts indicate that the product is a 2:2 adduct. However, the mass spectrum and melting point of the adduct were found essentially identical with those of 2,4,6-triphenyl-*s*-triazine, suggesting that pyrolysis of the adduct produces 2,4,6-triphenyl-*s*-triazine.

Similarly, *m*- and *p*-tolunitrile gave the corresponding adducts (Table 1). In the case of *o*-tolunitrile, *p*-nitrobenzonitrile, and *p*-chlorobenzonitrile, ethyl ether was employed as a solvent to increase the solubility of HCl, since the nitriles dissolve less amount of HCl or the nitriles are solid in some cases. However, the reaction resulted in the formation of the corresponding amides.[5]

Reaction of Thiocyanates with HCl. Allenstein and Quis[8] reported that methyl thiocyanate reacted with HCl at 0°C giving methyl thioimidoyl chloride hydrochloride. However, the reaction at a higher temperature was not studied. We have found that the reaction of ethyl thiocyanate with excess HCl in a sealed glass tube at 60°C affords a dimeric 2:2 adducts, the structure of which was supported by the IR and mass spectra, and hydrolysis to bis(ethylthioformyl)amine.

The reaction was extended to methyl, propyl, butyl, octyl, and benzyl thiocyanates. Their IR spectra indicate the formation of the corresponding 2:2 adducts, but their mass spectra showed molecular and fragment ion peaks due to the corresponding 2,4,6-tris(alkylthio)-*s*-triazines. Hydrolysis of these adducts did not give the expected bis(alkylthioformyl)amines but unidentified oily or tarry substances. In addition, the isolation of analytically pure adducts was unsuccessful except for the case of octyl thiocyanate.

2) S. Yanagida, T. Fujita, M. Ohoka, I. Katagiri, and S. Komori, This Bulletin, **46**, 292 (1973).

3) Grundmann *et al.* reported the formation of the 2:1 adduct in the reaction of trichloroacetonitrile with HCl. C. Grundmann, G. Weisse, and S. Seide, *Ann. Chem.*, **577**, 77 (1952).

4) E. N. Zil'berman, *Russ. Chem. Rev.*, **31**, 615 (1962).

5) Especially *p*-chlorobenzamide was formed in 50% yield. The cleavage of ether linkage by hydrogen halides to an alcohol and a halide is well-known.[6] Thus the amide must be formed through imidates from nitriles, HCl and ethyl alcohol formed by the degradation of ethyl ether used as solvent.[7]

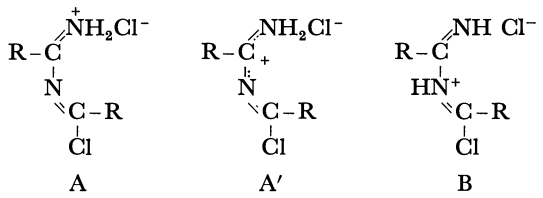
Structure of the 2:2 Adducts. Taking into account the basicity of nitrogen atoms of the conjugate base, the dimeric adducts from aromatic nitriles or thiocyanates were expected to have structure A rather than B. In addition, in view of the possible resonance structures of A, the structure may well be expressed by the delocalized structure A'. In fact, the NMR spectra support structure A' rather than A or B.



A A' B

In the NMR spectrum of the 2:2 adduct from benzonitrile measured at −33°C in liquid SO_2, two distinct signals attributable to NH protons were observed (Fig. 1a).

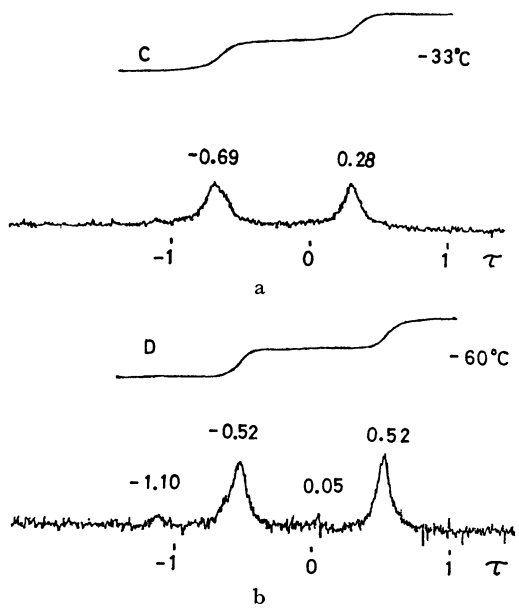


Fig. 1. NH_2 Signals in NMR Spectra of the 2:2 Adduct from Benzonitrile.

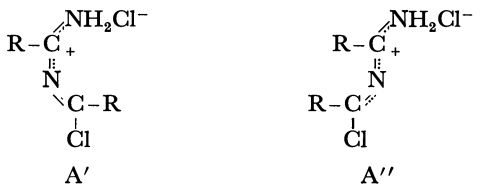
An increase in temperature led to broadening and coalescence of the signals. The adduct from ethyl thiocyanate also exhibited a similar spectral change (see Experimental). These observations indicate the presence of NH_2 group in the adducts. The nonequivalence of the two amino protons may be accounted for by the hindered rotation about the CN bond owing to its partial double bond character. In addition, two pairs of phenyl ring protons and two pairs of methylene protons of the ethylthio groups have almost the same chemical shift. If the adducts took either structure A or B, one pair of the protons should have been greatly deshielded by the localized positive charge. The appearance of new small signals in Fig. 1b is probably ascribed to the presence of the following geometrical isomer A'':



A' A''

Formation Mechanism of Dimeric Adducts. Some mechanisms for the dimerization of nitriles were proposed by several investigators[4,9,10] but they were still open to question.

von Braun *et al.*[11] and Prajsnar[12] reported that some N-substituted imidoyl chlorides having α-hydrogen, generated *in situ* from N-substituted amides, underwent dimerization, giving amidine derivatives as exemplified

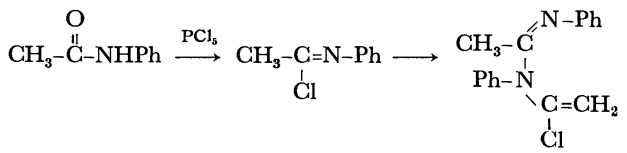
9) W. Ruske, "Friedel-Crafts and Related Reactions," Vol. 3. Part 1. G. A. Olah, Ed., Interscience Publishers, New York, N. Y. (1964), p. 398.

10) F. Johnson and R. Madronero, "Advances in Heterocyclic Chemistry," Vol. 6, A. R. Katrizky, Ed., Academic Press, New York, N. Y. (1966), p. 95.

11) J. von Braun, F. Jostes, and H. Heymons, *Chem. Ber.*, **60**, 92 (1927).

12) B. Prajsnar, *Roczniki Chem.*, **36**, 1449 (1962); *Chem. Abstr.*, **59**, 5139 (1963).

by the following equation:[13]



The reaction is quite comparable to the dimerization of nitriles in the presence of HCl.

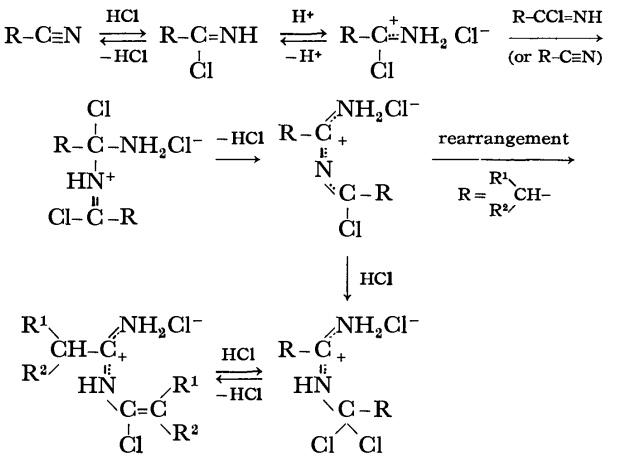
In order to get spectral evidence of the dimeric products and to seek an explanation for the mechanism of the dimerization of imidoyl chlorides, we reinvestigated the reaction of acetanilide with PCl_5 or phosgene.

The reaction of acetanilide with PCl_5, followed by neutralization with aqueous ammonia, gave *N,N'*-diphenyl-*N*-(α-chlorovinyl)amidine as reported, which was confirmed on the basis of NMR analysis.[14] Phosgene also gave the identical amidine. These facts suggest that HCl formed during the reaction plays an important role in the dimerization.[15] Accordingly it may be concluded that imidoyl chlorides, especially having at least one α-hydrogen and free from steric hindrance around α-carbon atom, readily dimerize giving *N*-(α-chloroalkenyl)amidine derivatives.[16]

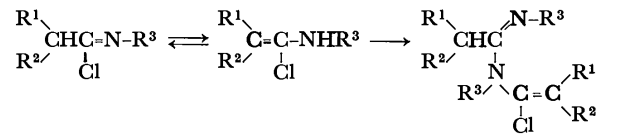
Recently Speziale and Freeman[17] showed that *N,N*-diethyl-1,2,2-trichlorovinylamine reacts with an amine giving a *N,N*-diethyl-*N'*-substituted dichloroacetamidine through the addition-elimination mechanism rather than the usual S_N2 mechanism.

In addition, it is claimed by a U. S. patent[18] that dimethyl cyanamide reacts with HCl to give *N,N*-dimethylaminoimidoyl chloride hydrochloride and that, on heating to 100°C, the hydrochloride dimerizes giving the 2: 2 adduct.

In view of these considerations and the facts gained through a series of these studies,[2] we propose the following sequence as a mechanism of the dimerization of nitriles with HCl:



13) Braun proposed a mechanism involving a rearrangement to the enamine as follows:



However, in view of the success in dimerization of nitriles which never undergo rearrangement to the enamine structure due to the absence of α-hydrogen, a similar mechanism for the dimerization of nitriles is unlikely.

The dimerization of *N*-substituted imidoyl chlorides,[11,12] the Pinner synthesis of imidates and the intramolecular amination of nitriles in the presence of HCl[19] may be interpreted in a similar manner, that is, displacement of chloride ion from imidoyl chloride hydrochloride by the nucleophilic imidoyl chloride, alcohol or amine.

Experimental

Melting points were determined on a Yanagimoto micro melting point apparatus and were corrected. The NMR spectra were obtained using a Model JNM-G-60 spectrometer (Japan Electronic Optics Laboratory Co.) with tetramethylsilane as an internal reference. The IR spectra were recorded with a Japan Electroscopic IR-E spectrophotometer, and the mass spectra with a Hitachi mass spectrometer Model RMU-6E.

Dimerization of Aromatic Nitriles or Thiocyanates with HCl. A typical procedure is as follows: Dry HCl was bubbled into benzonitrile (3 g, 29.1 mmol) in 30 ml glass tube under cooling in an ice bath (1.02 g, 28.0 mmol of HCl was absorbed). The glass tube, after being sealed, was placed in a water bath maintained at 60°C for 93 hr. As the reaction proceeded, the reaction mixture became viscous. The tube was opened carefully and excess HCl was removed. Addition of dry ether into the reaction mixture caused precipitation of the 2: 2 adduct, which was filtered with suction, dried and analyzed (Table 1) (1.0 g, 12.8% yield).

The reaction conditions and yields for the other cases are shown in Table 1. It should be noted that the longer the reaction time, the higher the yield.

The mass spectrum of the adduct from ethyl thiocyanate shows the following fragment ion peaks (70 eV): *m/e* (rel intensity) 181 (19) [$C_2H_5SC(=NH)N=CClS^+$], 175 (10) [$C_2H_5SC(=NH)N=C^+-SC_2H_5$], 149 (100) [$C_2H_5SC(=NH)N=C^+-Cl$]. NMR ($SO_2$) at −30°, τ 0.43 (bs, 1H), 0.86 (bs, 1H), 6.81 (q, 4H, J=7.5 Hz), 8.54 (t, 3H, J=7.5 Hz), and 8.59 (t, 3H, J=7.5 Hz); at −62°C, τ 0.55 (bs, 1H), 1.10 (bs, 1H), 6.82 (q, 4H, J=7.5 Hz), 8.55 (t, 3H, J=7.5 Hz), and 8.60 (t, 3H, J=7.5 Hz).

Hydrolysis of the 2: 2 Adduct from Benzonitrile or Ethyl Thiocyanate. According to the procedure reported previously,[2] 4 g of the adduct from benzonitrile was dissolved in 50 ml of water and left standing at room temperature overnight. The resulting precipitate was filtered with suction, dried and identified as dibenzoylamine on the basis of the following analysis (1.58 g, 44%): mp 149—152°C (lit,[20] 147—148°C).

Analogous treatment of the adduct from ethyl thiocyanate

14) Braun determined the structure on the basis of elemental analysis and hydrogenation to *N,N'*-diphenyl-*N*-ethylacetamidine.

Isolation of N-*Benzoylbenzamidine.* The aqueous solution of the adduct from benzonitrile (1 g in 20 ml of water) was made basic to litmus with aqueous Na_2CO_3, causing rapid precipitation of a brown crystal. The IR spectrum indicated that it was a mixture of *N*-benzoylbenzamidine and a small amount of triphenyl-*s*-triazine. The product was recrystallized from petroleum ether giving pure *N*-benzoylbenzamidine: mp 98°C (lit,[21] 98°C). IR (KBr) 1603 (C=O) 1563 (C=N) cm^{-1}. Mass spectrum (70 eV) *m/e* (rel intensity) 224 (46) [M^+], 208 (t) [M^+-NH_2], 147 (46) [$M^+-C_6H_5$], 105 (100) [$C_6H_5CO^+$], 77 (86)[$C_6H_5^+$], 51 (34).

Reaction of Acetanilide with PCl_5. According to the same procedure as that of Braun *et al.*,[9] powdered acetanilide (27 g) was allowed to react with powdered PCl_5 (43.5 g), followed by neutralization with aqueous ammonia, giving crude *N,N'*-diphenyl-*N*-(α-chlorovinyl)acetamidine (16 g). Extraction with petroleum ether using a Soxhlet extractor, concentration and recrystallization from hexane gave an analytically pure amidine: mp 106—108°C (lit,[9] 119°C), IR (KBr) 1650, 1630, 1595 cm^{-1}. Mass spectrum (70 eV) *m/e* (rel intensity) 270 (15) [$M^+ + 1$], 269 (15) [M^+], 118 (100) [$CH_3C^+=N-C_6H_5$], 93 (44) [$C_6H_5NH_2^+$], 77 (59) [$C_6H_5^+$]. NMR ($CDCl_3$) τ 8.12 (s, 3H), 4.68 (d, 1H) (J=3 Hz), 4.61 (d, 1H) (J=3 Hz), *ca.* 2.5—3.4 (m, 10H).

The NMR signals at τ 4.68 and τ 4.61, which are attributable to olefinic protons, support the *N*-(α-chlorovinyl)structure.

Reaction of Acetanilide with Phosgene. In a 200 ml four necked flask fitted with a thermometer, a condenser, a mechanical stirrer and a gas inlet tube, 27 g of acetanilide and 100 ml of benzene were placed and heated to 60—70°C. With stirring, phosgene was bubbled into the mixture. At first a yellow precipitate was formed. Upon continued heating and bubbling phosgene, the precipitate dissolved, giving a red brown transparent mixture which was cooled and left standing overnight. After filtration, the filtrate was concentrated with rotary evaporator, giving 18.5 g of a red brown oily substance. 5.1 g of this was dissolved in 300 ml of water and insoluble substance was removed by filtration. The filtrate was made basic by adding 28% aqueous ammonia, affording 2.68 g of red-yellow viscous material which gradually solidified on standing. Extraction with petroleum ether and concentration gave 0.6 g of *N,N'*-diphenyl-*N*-(α-chlorovinyl)actamidine.

The authors wish to thank Mr. H. Moriguchi for the mass spectrum measurement, Mrs. M. Sakurai for the NMR measurement, and Miss J. Maenaka and Mr. and Mrs. Muneishi for elemental analysis. This work was supported in part by a grant-in-aid from Kokusan Gijutsu Shinkokai. We wish to express our thanks to the founder, the late Mr. Chikara Kurata.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 306—310 (1973)

Studies on Nitrile Salts. IV.[1] Trimerization of Nitriles to 1,3,5-Triazines by the Combined Catalyst PCl_5–HCl

Shozo YANAGIDA, Masaaki YOKOE, Ichiro KATAGIRI, Masataka OHOKA, and Saburo KOMORI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka

(Received June 8, 1972)

The combined catalyst PCl_5–HCl shows effective catalysis in the trimerization of some aromatic nitriles or trichloroacetonitrile to *s*-triazines (III). The scope and limitation of the trimerization, in comparison with other Lewis acids, and its mechanism were studied. It was confirmed that PCl_5 is effective both in the formation of an intermediate, nitrile–HCl 2:2 adduct, and in the reaction of the 2:2 adduct with another nitrile to *s*-triazine.

According to U.S. patents[2,3] aromatic nitriles can be trimerized to produce 2,4,6-triaryl-*s*-triazines (III) by heating at *ca.* 200—500°C in the presence of metal halides or the combined catalyst, $AlCl_3$–HCl. Wakabayashi *et al.* reported that 2-substituted-4,6-bis(trichloromethyl)-*s*-triazines are obtainable by the cotrimerization of trichloroacetonitrile with some nitriles in the presence of the combined catalyst, Lewis acids–HCl.[4] However, they did not study the combined catalyst PCl_5–HCl.

While reports have been made concerning the reactions of PCl_5 with some cyano compounds under various conditions, no reactions with aromatic nitriles have been studied yet.[5,6]

In the course of our studies on the reactions of nitriles in the presence of HCl, it has been found that the combined catalyst PCl_5–HCl is quite effective in the trimerization of aromatic nitriles to *s*-triazines (III) under mild reaction conditions.

In the preceding paper[1] we reported that some aromatic nitriles (I) react with HCl in a sealed tube to afford the 2:2 adducts (II). Our desire to find an explanation for the trimerization of nitriles (I) prompted us to investigate the reaction of the 2:2 adducts (II) with aromatic nitriles (I) in the presence of PCl_5.

This paper reports the scope and limitation of catalysis of the PCl_5–HCl system in the trimerization of nitriles (I), in comparison with other Lewis acid–HCl systems, and a possible mechanism.

Results and Discussion

When benzonitrile (Ia) was allowed to react with PCl_5 in the presence of HCl in a sealed glass tube at 100—105°C, the reaction mixture solidified in 24 hr. The resulting solid product was identified as 2,4,6-triphenyl-*s*-triazine (IIIa) on the basis of its IR spectrum and elemental analysis. No product containing phosphorus atom was formed.

In order to know the role of PCl_5 in this reaction, we have studied the effect of varying the molar ratios of PCl_5 to benzonitrile from 0: 10 to 3: 10 on the yield under comparable conditions. An almost quantitative yield was obtained with a ratio 1: 10 or greater. A ratio 1: 50 was also effective, giving 60% yield of *s*-triazine (IIIa). In the absence of PCl_5, only a trace amount of IIIa was formed. When HCl was not used in the reaction,[7] 40% yield of IIIa was obtained after a period of 240 hr.

It is well-known that some Lewis acids catalyze the trimerization of aromatic nitriles.[2,3,8] However, the effectiveness of the combined catalyst Lewis acid–HCl has not been fully studied yet. From this point of view, some Lewis acid–HCl systems were examined.

Table 1. Catalysis of lewis acid–HCl in the trimerization of benzonitrile[a]

Catalyst[b]	Yield (%)
PCl_5–HCl	98
$SbCl_5$–HCl	62
PBr_3–HCl	20
$AlCl_3$–HCl	18
$SnCl_4$–HCl	21
$ZnCl_2$–HCl	13
$FeCl_3$–HCl	13

a) Reaction conditions: Procedure A (see Experimental), reaction temp. 24 hr.
b) Molar ratio of benzonitrile to Lewis acid, 10: 1.

We see from Table 1 that superior catalysis of PCl_5–HCl system was established. $SbCl_5$–HCl was also found effective, but the resulting *s*-triazine was contaminated with considerable amounts of further chlorinated *s*-triazines and required purification. Compared with the results of the U.S. patent using the combined catalyst $AlCl_3$–HCl,[3] the procedure using a closed vessel under milder reaction conditions is favorable for an increase in the yield.

The reaction using the combined catalyst PCl_5–HCl was extended to several other aromatic nitriles. When nitriles were solid, nitrobenzene was used as a solvent. Most nitriles trimerized to give the corresponding *s*-triazines (III) in satisfactory yields (Table 2). In the cases of *s*-triazines from *m*-tolunitrile and β-naphthonitrile, their mass spectra showed molecular ion peaks corresponding to *s*-triazines having one chlorine atom, indicating that the contamination with small amounts of monochlorinated *s*-triazines resulted from chlorination by PCl_5.

In the cases of *o*-tolunitrile, α-naphthonitrile and phthalonitrile, the expected triazines were not isolated; the former two were recovered unchanged, and when the reaction mixture from phthalonitrile was treated with water, only phthalimide was isolated.

The reaction was further extended to trichloroacetonitrile and 1,1,2-trichloropropionitrile, which have

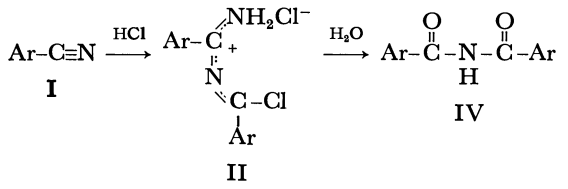
no α-hydrogen susceptible to chlorination by PCl_5. Only trichloroacetonitrile gave 82% yield of 2,4,6-tris(trichloromethyl)-*s*-triazine by the reaction at room temperature for 240 hr.[13]

Mechanism. Some mechanisms for the trimerization of nitriles to *s*-triazines in the presence of acidic reagents have been proposed, but they still lack concrete evidences.[14]

Recently we found that some aromatic nitriles react with HCl, giving *N*-(α-chloroarylmethylidene)arylamidine hydrochlorides (II), and that their hydrolysis affords diaroylamines (IV) as follows;[1]



I II IV

On treatment of the reaction mixture obtained in the trimerization of benzonitrile using the combined catalyst PCl_5–HCl with water, dibenzoylamine (IVa) was formed. The yield of IVa was much greater than that in the absence of PCl_5 (Table 3). When $AlCl_3$ or $SnCl_4$ was used instead of PCl_5, dibenzoylamine (IVa) could also be isolated in the same way. The results indicate that the 2:2 adduct (II) is an intermediate to *s*-triazine (III) and that PCl_5 is effective in the dimerization of nitriles to II in the presence of HCl.

Table 3. Effect of lewis acids–HCl on the yields of dibenzoylamine (IVa) and the *s*-triazine IIIa[a]

Lewis acid	Yield of IVa (%)	Yield of IIIa (%)
None	12(18[b])	0
PCl_5	45	11
$AlCl_3$	24[c]	3
$SnCl_4$	11[c]	3

a) Reaction conditions: molar ratios, PhC≡N: HCl: PCl_5=1: 0.9: 0.1; reaction temp., 30°C; reaction time, 110 hr.
b) The yield of IIa.
c) Reaction time: 140 hr.

We observed that the pyrolysis of adducts (II) gives 2,4,6-triphenyl-*s*-triazines (III).[1] In order to estimate the sequence of this pyrolysis, differential thermal analysis of *N*-(α-chlorobenzylidene)benzamidine hydrochloride (IIa) was carried out (Fig. 1). On the basis of the decrease in weight and the analysis of the products, we estimated that two moles of amidine IIa reacts at 123°C, giving one mole of *s*-triazine IIIa, one mole of benzonitrile and four moles of HCl presumably through the following sequence;

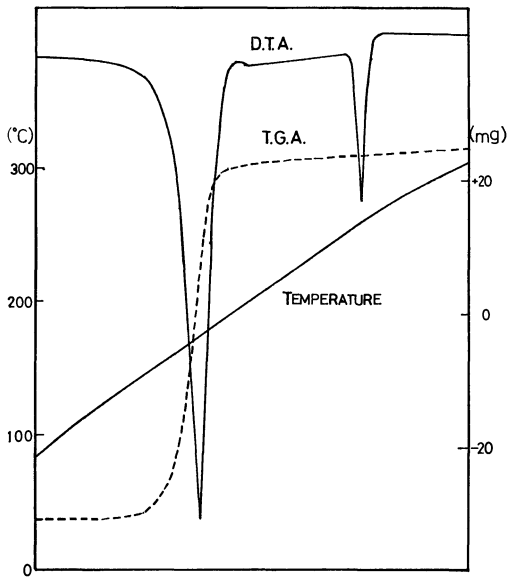


Fig. 1. Differential thermal and thermal gravimetrical analysis of *N*-(α-chlorobenzylidene)benzamidine hydrochloride (IIa).
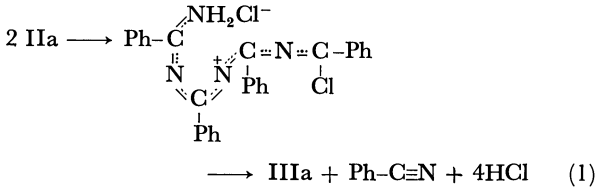
Conditions for measurement: standard sample, α-Al_2O_3; amount of sample, 103.1 mg; sensitivity of gravimetry, ±50 mg; sensitivity of thermocouple, ±50 μV; heating rate, 2.5°C/min; circumstance, N_2: thermocouple, Pt–PtRh (13%); decrease of the weight (between 123—179°C), 52.0 mg (50.4%).



IIIa + Ph-C≡N + 4HCl (1)

For the purpose of obtaining further proof for the catalysis of PCl_5, the reaction of the 2:2 adducts (II) with other aromatic nitriles was effected under various conditions. In view of the pyrolysis of the adduct II, all the reactions were made at 30°C for 12 days.

The reaction of the 2:2 adduct IIa from benzonitrile with *p*-tolunitrile in the presence of PCl_5 and HCl gave, although in low conversion, a mixture of *s*-triazines consisting of 2,4-diphenyl-6-*p*-tolyl-*s*-triazine (IIIa′) and 2,4,6-tris(*p*-tolyl)-*s*-triazine (IIIb) as major products, and 2,4,6-triphenyl-*s*-triazine (IIIa) and 2-phenyl-4,6-bis(*p*-tolyl)-*s*-triazine (IIIb′) as minor products. Without PCl_5, however, only traces were obtained even at 60°C for 5 days. Analogous treatment of the 2:2 adduct IIb from *p*-tolunitrile with benzonitrile resulted in the major formation of IIIb′ and IIIa as expected.

Formation of IIIa and IIIb in these reactions apparently results from homotrimerization of benzonitrile and *p*-tolunitrile, respectively. In order to suppress the homotrimerization, the 2:2 adduct IIa was made to react with *p*-tolunitrile only in the presence of PCl_5, giving IIIa′ exclusively, although in a low conversion.

PCl_5 is believed to have an ionic character on the basis of X-ray analysis and its IR spectra in solution, no complexes of PCl_5 with nitriles being re-

13) Kornuta *et al.* reported that trichloroacetonitrile reacts with PCl_5 at 140—145°C giving pentachloroethylphosphorimidic trichloride. P. P. Kornuta, V. I. Schevchenko, and A. V. Kirsanov, *J. Gen. Chem. USSR.*, **37**, 2657 (1967).

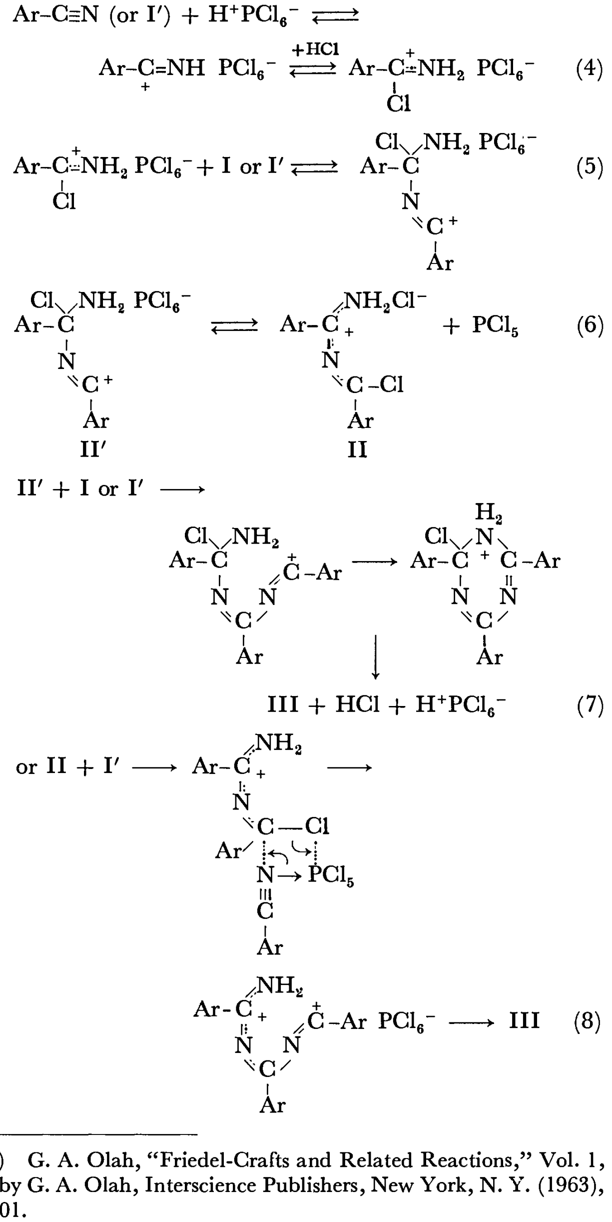
14) a) M. Lora-tamayo and R. Madronero, "1,4-Cycloaddition Reactions", ed. by J. Hamer, Academic Press, New York, N. Y. (1967), p. 132. b) A. I. Meyers and J. G. Sircar, "The Chemistry of the Cyano Groups," ed. by Z. Rapoport, Interscience Publishers, New York, N. Y. (1970), p. 341.

cognized.[5,6,15,16] However, it was reported that its homologue $SbCl_5$ reacts with nitriles giving the 1:1 adduct R–C≡N·$SbCl_5$, which readily reacts with HCl or alkyl chlorides to give nitrilium salts.[17,18] Accordingly PCl_5 can be expected to act as a weak Lewis acid.[15] Lewis acids are known to polarize the cyano group and to increase not only the electrophilic character of carbon but also the nucleophilic character of nitrogen.[14a,19]

In view of these facts and the proposed mechanism for the dimerization of nitriles,[1] the trimerization can be explained as involving the following sequences.

$$\underset{\text{I}}{\text{Ar–C}\equiv\text{N}} + PCl_5 \rightleftarrows \underset{\text{I}'}{\text{Ar–C}\equiv\text{N}\ PCl_5} \qquad (2)$$

$$HCl + PCl_5 \rightleftarrows H^+PCl_6^- \qquad (3)$$



At a high reaction temperature, sequence 1 (pyrolysis of II) can not be neglected. The failure of *o*-tolunitrile, phthalonitrile and α-naphthonitrile to trimerize is probably due to the steric hindrance of *ortho* groups in the sequences 4 and 7 or 8. Formation of phthalimide implies the exclusive intramolecular dimerization of the two cyano groups induced by the combined catalyst PCl_5–HCl.[20]

To our knowledge, the trimerization reported here is the first example of the catalysis of PCl_5 as a Lewis acid.

Experimental

Melting points were determined on a Yanagimoto micro melting point apparatus and were corrected. The IR spectra were recorded with a Japan Electroscopic IR-E spectrophotometer, and the mass spectra with a Hitachi mass spectrometer Model RMU-6E. Thermal gravimetrical and differential analyses were carried out with a Rigaku Denki Thermoflex, and glpc analysis with a Yanagimoto G-8 apparatus.

General Procedure. *A. Without Solvent*: Aromatic nitrile (30—50 mmol) and Lewis acid (3—5 mmol) (molar ratio 10:1) were placed in a 30 ml glass tube. Dry HCl (15—25 mmol) was bubbled into the mixture under cooling. The tube was stoppered, cooled in Dry Ice–acetone, sealed carefully and heated to 100—105°C in an oil bath for an appropriate time. After the end of the reaction, the tube was chilled in Dry Ice–acetone and opened. The reaction mixture was poured into water and insoluble *s*-triazine was filtered with suction and dried. The *s*-triazine was recrystallized from a suitable solvent (acetone, nitrobenzene or acetic acid) when necessary for analysis.[8] The analytical results are summarized in Tables 1 and 2.

B. In Nitrobenzene: Into a mixture of aromatic nitrile (20—30 mmol), PCl_5 (3.3—3.8 mmol) (Molar ratio 10:1) and nitrobenzene (5—10 g), was bubbled dry HCl (12—18 mmol). The tube was sealed and heated to 100—105°C for an appropriate time. When the tube was opened and the reaction mixture was degassed on standing, a precipitate was formed except for the case of *p*-methoxybenzonitrile. The resulting precipitate was filtered with suction, washed with some appropriate solvents having low solubility for *s*-triazine (ether, alcohol and acetone), and dried. In the case of *p*-methoxybenzonitrile, the mixture was condensed under reduced pressure and the residue was treated with water and extracted with ether. The extract was evaporated, giving *s*-triazine IIIg.

Isolation of Phthalimide. The reaction mixture obtained from phthalonitrile according to procedure B was poured into aqueous acetone and allowed to stand at room temperature for 3 days. The mixture was then extracted with ether, and the extract was evaporated to give a small amount of precipitate, which was confirmed as phthalimide on the basis of the following analyses; mp 236—238°C (lit,[21] 238) IR (Nujol) 3230, 2775, 1745, 1312, 1055, and 715 cm^{-1}.

Isolation of Dibenzoylamine (IVa). The reaction mixture obtained from benzonitrile according to procedure A was poured into 50 ml of water. After filtration of the

s-triazine IIIa, the filtrate was extracted with ether to remove unreacted benzonitrile. The resulting aqueous phase was left standing at room temperature overnight. The needle-like crystal formed was filtered, washed with water and dried under reduced pressure. The product was confirmed by direct comparison with an authentic sample.[1)]

Reaction of II with Aromatic Nitriles in the Presence of PCl_5. A typical procedure is as follows. The 2:2 adduct IIa (1.02 g, 3.66 mmol), *p*-tolunitrile (4.10 g, 35 mmol) and PCl_5 (0.30 g, 1.44 mmol) were placed in a 30 ml glass tube. Dry HCl (0.68 g, 18.6 mmol) was bubbled into the mixture under cooling. The tube was sealed and placed in a thermostat at 30°C for 12 days. Ether was added to the reaction mixture, giving a crystalline product which was confirmed to be a mixture of IIa and IIb by IR spectrum analysis (1.78 g) The filtrate was mixed with water (30 ml) and extracted with 50 ml of ether. The extract was dried with $MgSO_4$ and evaporated, giving a precipitate. The viscous residue was triturated with methanol giving an additional precipitate. Both precipitates were combined together (0.2 g) and analyzed. IR and mass spectra indicated that the product is a mixture of 2,4-diphenyl-6-*p*-tolyl-*s*-triazine (IIIa′), 2,4,6-tris(*p*-tolyl)-*s*-triazine (IIIb), 2-phenyl-4,6-bis(*p*-tolyl)-*s*-triazine (IIIb′), and 2,4,6-triphenyl-*s*-triazine (IIIa). Their ratios were determined to be roughly 56:38:2:4 by glpc by assuming that the sensitivity is proportional to their weight percentages.

Glpc was performed with a column of silicon gum SE, 10% on Diasolid L (60—80 mesh, 3 mmϕ × 1 m column, 300°C, hydrogen carrier gas, 30 ml/min).

A similar reaction of the 2:2 adduct IIb from *p*-tolunitrile with benzonitrile in the presence of PCl_5–HCl gave a mixture of IIIb′, IIIa, IIIa′, and IIIb in an approximate ratio 22:74: trace: 4.

The reaction of IIa (1.05 g) with *p*-tolunitrile (4.30 g) only in the presence of PCl_5 (0.30 g) yielded a mixture (0.27 g) of IIIa′, IIIb, IIIb′, and IIIa in an approximate ratio 88:4:2:6.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 310—313 (1973)

The Alkylation of 3,5-Dimethylisoxazole

Choji KASHIMA, Shinji TOBE, Noboru SUGIYAMA, and Makoto YAMAMOTO
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received June 26, 1972)

3,5-Dimethylisoxazole (**1**) was alkylated with sodium amide in liquid ammonia to give 3-methyl-5-alkylisoxazoles. By di- and tri-alkylation reactions using excess sodium amide, isoxazoles having secondary and tertiary alkyl groups at 5-position could be obtained. The hydrogenolysis and hydrolysis of these isoxazoles were also studied.

The reaction of β-diketones with hydroxylamine hydrochloride gives isoxazoles[1] which are regenerated to β-diketones by hydrogenolysis and hydrolysis,[2] showing that the formation and cleavage of isoxazoles is useful for the protection of β-diketones.

Few papers have reported on the alkylation of 3,5-dimethylisoxazoles. The 5-methylisoxazoles having the electron-withdrawing group at 4-position condense with benzaldehyde to give 4-substituted 5-styrylisoxazoles in the presence of amine or sodium methoxide as a catalyst.[3-5] Micetich reported[6] that the 5-methyl group of 3,5-dimethylisoxazole (**1**) is lithiated by butyl lithium in tetrahydrofuran. The lithio derivative reacts with benzyl chloride to give 3-methyl-5-phenylethylisoxazole (**5**). In both cases, the methyl group at 3-position of 3,5-dimethylisoxazoles does not react. Since it is well-known that the methyl group attached to such heterocyclic compounds as picoline[7] or quinaldine[8] is alkylated by sodium amide in liquid ammonia as a catalyst, alkylation on the methyl group at 5-position of **1** is expected.

We have studied the alkylation of 3,5-dimethylisoxazole (**1**) and obtained isomerically pure mono-, di-, and tri-alkylated isoxazoles by using an appropriate amount of sodium amide in liquid ammonia. Generation of β-diketones from these alkylated isoxazoles has also been carried out. The results are given in this paper.

Results and Discussion

3,5-Dimethylisoxazole (**1**) is expected to react at three reaction sites, 3-methyl, 5-methyl, and 4-position, in the electrophilic substitution reaction. For determination of the reaction site, **1** was treated with methyl iodide in the presence of equimolar sodium amide in liquid ammonia. The reaction product (yield, *ca.* 70%) showed methyl protons at δ 2.18, methine proton at δ 5.68 and ethyl protons at δ 2.68 and 1.26 in NMR.

From these data, the product was identified as 3-methyl-5-ethylisoxazole (**2**).[9] But neither 3-ethyl-5-methylisoxazole nor 3,4,5-trimethylisoxazole could be detected by NMR and vpc. Similarly, **1** was treated with ethyl bromide, *n*-propyl bromide, benzyl bromide and allyl bromide in the presence of sodium amide to give the corresponding products (**3**, **4**, **5**,[6] and **6**) alklated on 5-methyl position. Isopropyl bromide, one of the secondary alkyl halides, also gave 3-methyl-5-isobutylisoxazole (**7**). Similarly, **1** was reacted with 1,2-epoxybutane to give 3-methyl-5-(3-hydroxy)pentylisoxazole (**8**), which was easily oxidized to ketone (**9**) with chromic anhydride.

Fig. 1.

When **1** was treated with a half molar α,ω-dibromoalkane (**10**, n=3, 4, 5), the corresponding α,ω-di(3-methyl-5-isoxazolyl)alkanes (**11**, n=3, 4, 5) were obtained. In the case of 1,2-dibromoethane (**10**, n=2), the anomalous reaction product 1,2-di(3-methyl-5-isoxazolyl)ethane (**11**, n=0) was obtained.[6] When **1** was treated with sodium amide in liquid ammonia in the absence of **10** (n=2) followed by hydrolysis with ammonium chloride, the starting material was recovered. Thus, 1,2-dibromoethane (**10**, n=2) apparently acted as an oxidative reagent in this anomalous reaction.

For di- and tri-alkylation of the 5-methyl group, we tried the reaction of **1** with excess amounts of sodium amide and methyl iodide. When 2 molar sodium amide and 2 molar methyl iodide were used, the products were 3-methyl-5-ethylisoxazole (**2**), 3-methyl-5-isopropylisoxazole (**12**) and 3-methyl-5-*t*-butylisoxazole (**13**). **2** was identified with the authentic sample by means of NMR and vpc. The structures of **12** and **13** were deduced from IR, NMR, and elemental analysis. When 3 molar sodium amide and 3 molar methyl iodide were used, **2**, **12**, and **13** were also obtained. When of 4 molar sodium amide and 4 molar methyl iodide were used, **13** was the sole product, and none of **2**, **12**, 3-ethyl-5-*t*-butylisoxazole and 3,4-dimethyl-5-*t*-butylisoxazole could be detected by NMR and vpc. The product ratios in these reactions are summarized in Table 1. Similarly, **1** was treated with 2 molar sodium amide and 2 molar benzyl bromide to give di-alkylation product, 3-methyl-5-(1,3-diphenyl-2-propyl)isoxazole (**14**). The reaction of **5** with benzyl bromide also gave **14**. The structure of **14** was confirmed by means of IR, NMR, and elemental analysis. In the NMR spectrum, the 3-methyl protons at δ 2.01 were deshielded by the sterically crowded phenyl groups.

Table 1. Product ratios in the reaction of **1** with methyl iodide

Molar ratio			Total yield	Product ratio		
1 :	CH_3I :	$NaNH_2$	(%)	2%	12%	13%
1	1	1	58	100	0	0
1	2	2	68	33	57	10
1	3	3	59	9	62	29
1	4	4	51	0	0	100

We see from these results that the di- and tri-alkylation reactions were accomplished in one step. They occurred on the same reaction site at 5-methyl group of **1**, and were controlled by the amount of sodium amide. Thus, 3-methyl-5-cycloalkylisoxazoles (**15**) were expected in the case of α,ω-dibromoalkane (**10**) and **1** in the presence of 2 molar sodium amide. When, 1,3-dibromopropane (**10**, n=3) was treated with equimolar **1** and 2 molar sodium amide, 1,5,9-tri(3-methyl-5-isoxazolyl)nonane (**16**, n=3) was obtained together with 1,5-di(3-methyl-5-isoxazolyl)pentane (**11**, n=3), but no 3-methyl-5-cyclobutylisoxazole (**15**, n=3). Similarly, 1,6,11-tri(3-methyl-5-isoxazolyl)undecane (**16**, n=4) and 1,6-di(3-methyl-5-isoxazolyl)hexane (**11**, n=4) were obtained from 1,4-dibromobutane (**10**, n=4), but no 3-methyl-5-cyclopentylisoxazole (**15**, n=4).

If two different alkyl halides are used in the presence of 2 molar sodium amide, 3-methyl-5-*sec*-alkylisoxazoles might be obtained. When **1** was treated with methyl iodide followed by ethyl bromide, 3-methyl-5-*sec*-butylisoxazole (**17**) was obtained as well as 5-ethyl- (**2**), 5-*n*-propyl- (**3**), and 5-isopropyl-3-methylisoxazole (**12**).

e) Isox is 3-methylisoxazolyl f) KBr.

These isomerically pure isoxazoles produced by alkylation on the 5-methyl group of **1** were hydrogenated by platinum oxide in ethanol. The structures of the hydrogenated products were confirmed to be 2-amino-2-alkene-4-one (**18**) by means of IR, NMR, and elemental analysis. Furthermore, 2,12-diaminotrideca-2,11-diene-4,10-dione (**19**, $n=3$), hydrogenated product from **11** ($n=3$), was hydrolyzed by dilute hydrochloric acid in ethanol to give the corresponding ketone, tridecane-2,4,10,12-tetraone (**20**, $n=3$).[10]

Thus, it is possible to alkylate the methyl group at the 5-position of isoxazole with sodium amide and alkyl halides in liquid ammonia. By di- and trialkylation reactions using excess sodium amide, the isoxazoles having secondary and tertiary alkyl groups at the 5-position can be obtained. Hydrogenolysis of these isoxazoles gave the 5-alkylated 2-amino-2-pentene-4-ones (**18**). By hydrolysis of **18**, the γ-alkylation products of β-diketones were obtained in good yields. These procedures enable the 1,1-di- and 1,1,1-trialkylation reactions to take place, it being much more difficult for them to do so by the direct γ-alkylation of 2,4-diketones.[11,12]

Experimental

3,5-Dimethylisoxazole (1). By the method of Lampe,[1] a mixture of acetylacetone (34.3 g), hydroxylamine hydrochloride (35.4 g) and potassium carbonate (34.5 g) was refluxed for 4 hr. After washing the mixture with water, the organic layer was distilled, bp 49—50°C/29 Torr. Yield 45%.

General Procedure for Mono-alkylation. A solution of sodium (1.15 g) in liquid ammonia (*ca.* 300 ml) was oxidized to sodium amide catalyzed with ferric chloride. To this sodium amide suspension was added **1** (5.00 g) in anhydrous ether (30 ml). After stirring for 1.5 hr under nitrogen stream, alkyl halide (0.05 mol) in anhydrous ether (30 ml) was added. Stirring was continued for another 3 hr. After the mixture was neutralized with ammonium chloride, ammonia was removed at room temperature. The residual ether solution was acidified with dilute hydrochloric acid. The ether extract was concentrated and purified by preparative vpc, fractional distillation and/or silica gel column chromatography.

3-Methyl-5-ethylisoxazole (2). Purified by the preparative vpc on polyethylene glycol succinate (1 m stainless steel column) at 103°C, yield 70%. The NMR spectrum was superimposable on that of the authentic sample.[9]

*3-Methyl-5-*n*-propylisoxazole (3).* Purified by fractional distillation, yield 45%.

Found: C, 67.27; H, 8.97; N, 11.00%. Calcd for $C_7H_{11}NO$: C, 67.17; H, 8.86; N, 11.19%.

*3-Methyl-5-*n*-butylisoxazole (4).* Purified by fractional distillation, yield 61%.

Found: C, 68.96; H, 9.44; N, 10.05%. Calcd for $C_8H_{13}NO$: C, 69.03; H, 9.41; N, 10.06%.

3-Methyl-5-phenylethylisoxazole (5). Purified by silica gel column chromatography with benzene–ethyl acetate mixture and fractional distillation, yield 70%. The NMR spectrum was superimposable on that of the authentic sample.[6]

3-Methyl-5-(3-butenyl)isoxazole (6). Purified by preparative vpc on polyethylene glycol succinate at 120°C, yield 44%.

Found: C, 69.27; H, 7.99; N, 10.05%. Calcd for $C_8H_{11}NO$: C, 70.04; H, 8.08; N, 10.21%.

3-Methyl-5-(3-hydroxypentyl)isoxazole (8). 1,2-Epoxybutane was used instead of alkyl halide and purified by fractional distillation and silica gel chromatography with benzene–ethyl acetate mixture, yield 15%.

Found: C, 63.63; H, 8.85; N, 8.30%. Calcd for $C_9H_{15}NO_2$: C, 63.88; H, 8.94; N, 8.28%.

1,5-Di(3-methyl-5-isoxazolyl)pentane (**11**, n=3). Purified by silica gel chromatography with benzene–ethyl acetate mixture, yield 84%.

Found: C, 66.35; H, 7.90; N, 11.86%. Calcd for $C_{13}H_{18}N_2O_2$: C, 66.64; H, 7.74; N, 11.96%.

1,6-Di(3-methyl-5-isoxazolyl)hexane (**11**, n=4). Purified by silica gel chromatography with benzene–ethyl acetate mixture and recrystallization from *n*-hexane, yield 77%.

Found: C, 67.81; H, 8.12; N, 11.09%. Calcd for $C_{14}H_{20}N_2O_2$: C, 67.71; H, 8.12; N, 11.28%.

1,7-Di(3-methyl-5-isoxazolyl)heptane (**11**, n=5). Purified by recrystallization from *n*-hexane, yield 70%.

Found: C, 68.31; H, 8.66; N, 10.57%. Calcd for $C_{15}H_{22}N_2O_2$: C, 68.67; H, 8.45; N, 10.68%.

1,2-Di(3-methyl-5-isoxazolyl)ethane (**11**, n=0). 1,2-Dibromoethane (**10**, *n*=2) used instead of alkyl halide and purified by recrystallization from *n*-hexane, yield 39%. The product was identified by the superimposable NMR and mp 92—94°C.[6]

General Procedure for Di-(tri-)alkylation. As described above, **1** (1.00 g) was treated with 0.02 mol (0.04 mol) of alkyl halide in the presence of 0.02 mol (0.04 mol) of sodium amide in liquid ammonia (*ca.* 50 ml).

3-Methyl-5-isopropylisoxazole (**12**). Purified by preparative vpc on Apiezon L (1 m stainless steel column) at 103°C and fractional distillation, yield 37%.

Found: C, 66.86; H, 9.04%. Calcd for $C_7H_{11}NO$: C, 67.17; H, 8.86%.

3-Methyl-5-t-butylisoxazole (**13**). Purified by fractional distillation, yield 51%.

Found: C, 68.93; H, 9.34; N, 10.14%. Calcd for $C_8H_{13}NO$: C, 69.03; H, 9.41; N, 10.06%.

3-Methyl-5-(1,3-diphenyl-2-propyl)isoxazole (**14**). Purified by silica gel chromatography with benzene–ethyl acetate mixture, yield 35%.

Found: C, 82.68; H, 6.85; N, 5.05%. Calcd for $C_{19}H_{19}NO$: C, 82.28; H, 6.91; N, 5.05%.

1,5,9-Tri(3-methyl-5-isoxazolyl)nonane (**16**, n=3). Purified by silica gel chromatography with *n*-hexane–ether mixture, yield of **16** (*n*=3) 12% and **11** (*n*=3) 25%.

Found: C, 67.07; H, 7.97; N, 10.95%; mol wt (mass), 371. Calcd for $C_{21}H_{29}N_3O_3$: C, 67.90; H, 7.87; N, 11.32%; mol wt, 371.47.

1,6,11-Tri(3-methyl-5-isoxazolyl)undecane (**16**, n=4). Purified by silica gel chromatography with *n*-hexane–ether mixture, yield of **16** (*n*=4) 15% and **11** (*n*=4) 19%. Found: C, 70.49; H, 8.43; N, 10.02%; mol wt (mass), 399. Calcd for $C_{23}H_{33}N_3O_3$: C, 69.14; H, 8.33; N, 10.52%; mol wt, 399.52.

3-Methyl-5-sec-butylisoxazole (**17**). To a mixture of sodium amide (790 mg) and 3,5-dimethylisoxazole (1.00 g) in liquid ammonia (*ca.* 50 ml) was added methyl iodide (1.43 g) in anhydrous ether (15 ml) with stirring. After 1.5 hr, ethyl bromide (1.11 g) in anhydrous ether (15 ml) was added to the reaction mixture. Stirring was continued for another 2.5 hr at −50°C. The products were purified by preparative vpc on Apiezon L at 130°C, yields **2**, 47%; **12**, 8%; **3**, 7%; **17**, 12%. Found: C, 68.91; H, 9.58; N, 9.86%. Calcd for $C_8H_{13}NO$: C, 69.03; H, 9.41; N, 10.06%.

Oxidation of **8**. A mixture of **8** (100 mg), chromic anhydride (600 mg) and pyridine (1.5 g) in dichloromethane (30 ml) was stirred for 30 min at 5°C. The dichloromethane extract from the reaction mixture was washed with aqueous sodium carbonate, dilute hydrochloric acid and water. Product (**9**) was purified by silica gel chromatography with benzene–ethyl acetate mixture, yield 50%. Found: C, 63.96; H, 7.96; N, 8.40%. Calcd for $C_9H_{13}NO_2$: C, 64.65; H, 7.84; N, 8.38%.

Hydrogenation of Isoxazoles. About one gram of isoxazoles was hydrogenated in ethanol (20 ml) catalyzed by platinum oxide (100 mg) at room temperature under ordinary pressure. After the catalyst was filtered off, the filtrate was concentrated and the corresponding products were recrystallized from *n*-hexane.

2-Amino-2-heptene-4-one (**18**, *R*=n-*Pr*). Yield 42%, mp 47.5°C. Found: C, 66.31; H, 10.32; N, 11.06%. Calcd for $C_7H_{13}NO$: C, 66.10; H, 10.30; N, 11.01%.

2-Amino-6-phenyl-2-hexene-4-one (**18**, *R*=$(CH_2)_2Ph$). Yield 95%, mp 103°C. Found: C, 76.09; H, 8.08; N, 7.06%. Calcd for $C_{12}H_{15}NO$: C, 76.15; H, 7.99; N, 7.40%.

2,12-Diaminotrideca-2,11-diene-4,10-dione (**19**, n=3). Yield 72%, mp 109°C. Found: C, 65.77; H, 9.36; N, 11.76%. Calcd for $C_{13}H_{22}N_2O_2$: C, 65.51; H, 9.31; N, 11.76%.

2,13-Diaminotetradeca-2,12-diene-4,11-dione (**19**, n=4). Yield 76%, mp 150°C. Found: C, 66.39; H, 9.67; N, 10.88%. Calcd for $C_{14}H_{24}N_2O_2$: C, 66.63; H, 9.59; N, 11.10%.

2,9-Diaminodeca-2,8-diene-4,7-dione (**19**, n=0). Yield 70%, mp 165°C. Found: C, 61.40; H, 8.39; N, 14.25%. Calcd for $C_{10}H_{16}N_2O_2$: C, 61.20; H, 8.22; N, 14.28%.

Hydrolysis of **19** (n=3). **19** (*n*=3) was dissolved in ethanol acidified to pH 4 with hydrochloric acid and the mixture was stirred for 10 hr at room temperature. After being neutralized with potassium carbonate, the mixture was extracted with ether. The residue from the extract was recrystallized from *n*-hexane, yield 52%, mp 67°C. The product was identified with the authentic sample[10] by IR and NMR spectra and mp.

Carbon Products Prepared from Variant Pitch Materials. VIII. The Preparation of Isotropic Pitch Carbon with a High Density

Sugio OTANI and Asao OYA

Faculty of Technology, Gunma University, Kiryu, Gunma

(Received June 7, 1972)

The present works were undertaken in order to prepare the isotropic Pitch Carbon with a high density and with a desired degree of graphitization. The tablets were prepared by pressing some kinds of variant pitch materials and were then heat-treated below 2600°C in N_2 gas. Isotropic Pitch Carbon with a high density and with a low degree of graphitization can be readily prepared by pressing the non-graphitizable variant pitch material under high pressure. On the other hand, for the purpose of preparating isotropic Pitch Carbon with a high density and with a high degree of graphitization, a graphitizable variant pitch material with a low softening point, —in other words, with a good ability of sintering— was pressed into tablets under low pressure. The typical properties of the Pitch Carbon thus obtained (H.T.T. 2600°C) were as follows: Bacon Anisotropic Factor: 1.01; Bulk density: 1.79 g/cc; d_{002}: 3.40 Å; Lc: 210 Å.

The high-temperature gas-cooled reactor (HTGR) has lately attracted considerable attention, simultaneously, the isotropic carbon products with a high density have been required as one of the most important materials for the reactor.[1,2]

It was previously reported by the present authors that carbon rods or tablets could be prepared from specific variant pitch materials instead of coke powder and pitch binder. The carbon articles prepared by this method were referred to as Pitch Carbon.[3] From the previous results, it was been found that the properties of Pitch Carbon can be changed greatly by choosing variant pitch materials and/or conditions of heat-treatment. These facts suggest the possibility of thus preparing a carbon product for the reactor use.

The present experiments were undertaken to prepare an isotropic Pitch Carbon with a high density and with various degrees of graphitization.

Experimental

In order to prepare the variant pitch materials, coal tar pitch was distilled at 500°C for 30 min by bubbling N_2 gas through it. The resulting variant pitch materials (to be referred to as variant pitch material-N) did not clearly exhibit its softening point (S.P.) by the penetration method[4] (heating rate: 30°C/min), but it was sintered to an appreciable extent after the measurement. This variant pitch material was crushed to under 100 mesh and was used in preparing the Pitch Carbon. This variant pitch material was then pressed into tablets 10 mm in diameter and about 10 mm thick. The tablets were pre-heated in air up to 300°C at about 1.5°C/min to prevent their deformation at the subsequent heating stage, and were then heat-treated in N_2 gas at a temperature below 2600°C for 10 min. In addition, four kinds of variant pitch materials (A,[5] C,[6] L,[7] Al[8]) were used in preparing Pitch Carbons with various degree of graphitizability. The details of their methods of preparation have been reported elsewhere. Unless otherwise noted, however, the variant pitch material used was variant pitch material-N.

As first, the relationships between the preferred orientation of graphite crystallite in Pitch Carbon and the following factors were examined: the graphitizability, the particle size of the variant pitch material, the heat-treatment temperature (H.T.T.), and the addition of natural graphite or needle cokes. Furthermore, the preferred orientation of Pitch Carbon was compared with those of the other carbon materials. For the representation of the preferred orientation of graphite crystallite, the Bacon Anisotropic Factor (BAF)[9] was measured from the orientation diagram which was obtained by using the X-ray transmission technique reported by Noda and Inagaki.[10] The value of BAF is 1.00 for the completely isotropic carbon product, and it increases with a lowering of its isotropy. Carbon sections about 0.5 mm thick were cut with their planes parallel to or vertical to the pressing direction of Pitch Carbon.

The interlayer spacing, d_{002}, and the crystallite thickness, Lc, of carbon specimens were calculated according to a method previously described.[4] Some carbon specimens gave composite (002) diffraction profiles. These profiles were separated into two symmetrical components, and the X-ray parameters of each component were calculated. Moreover, the properties such as the density and the porosity were measured, and the internal structure was observed according to a method previously described.[4]

Results and Discussion

1. The Preferred Orientation of the Graphite Crystallite in the Pitch Carbon. For all the carbon sections cut with their planes vertical to the pressing direction, the values of BAF were nearly 1.00. Therefore, the values for these sections will not be presented in this report; only the values for sections cut with their planes parallel to the pressing direction will be shown.

graphitization of Pitch Carbon which were represented by d_{002} and Lc decreased, the values of BAF gradually decreased also. The Pitch Carbon which was prepared from the variant pitch material-L was completely isotropic; that is, the value of BAF was 1.00. From these results, it was found that the isotropic Pitch Carbon could easily be prepared from non-graphitizable variant pitch materials.

Table 2. The effect of the moulding pressure

a) Crushed by ball mill for 8 hr.

1.3. The Effect of the Particle Size of Variant Pitch Materials (Table 3). The variant pitch material-N (under 100 mesh) was further crushed by the use of a ball mill for 8 hr and was then pressed into tablets. The tablets were then heat-treated in the way described above. It seems that the preferred orientation of Pitch Carbon generally falls off as the particle size of the variant pitch material decreases. However, the preferred orientation of the Pitch Carbon which was prepared from such fine pitch powder was scarcely affected by the moulding pressure.

1.4. The Effect of Heat-treatment Temperature (Table 4). The degree of the graphitization of Pitch Carbon was gradually increased by raising the temperature between 1400 and 2400°C. The values of BAF, on the whole, increased with the increase of H.T.T.

Table 4. The effect of heat-treatment temperature

Variant pitch materials	Moulding pressure (kg/cm²)	HTT (°C)	d_{002} (Å)	Lc (Å)	BAF
N	400	2600	3.41	270	1.11

N	400	1000	3.42	25	1.05

Table 5. The effect of the addition of needle cokes or natural graphite

Additives	Moulding pressure (kg/cm²)	HTT (°C)	d_{002} (Å)	Lc (Å)	BAF
—	400	2600	3.41	270	1.11
25 wt% of needle cokes	400	2600	3.39	480	1.24
25 wt% of natural graphite	400	2600	3.35 3.40	1000 190	1.44
50 wt% of natural graphite	400	2600	3.35 3.40	1000 230	1.99

1.5. The Effect of the Addition of Needle Cokes or Natural Graphite (Table 5). The values of BAF were increased considerably by the addition of 25 wt% of natural graphite (under 100 mesh, Madacascar flaky graphite) or of needle cokes (under 100 mesh) which were very lamellar in shape. The further addition of natural graphite increased more remarkably the value of BAF for the resulting Pitch Carbon.

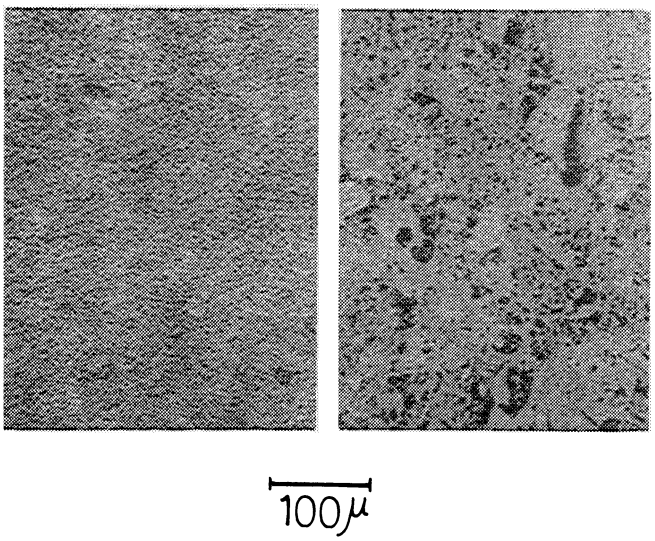
Table 6. The comparison with the other carbon materials

Carbon materials	Moulding pressure (kg/cm²)	HTT (°C)	d_{002} (Å)	Lc (Å)	BAF
Pitch carbon	400	2600	3.41	270	1.11
Carbon electrode	—	2600	3.38	480	1.18
Pyrolytic carbon	—		3.42	210	4.16
Vitro carbon	—	2600	3.45	27	1.02

1.6. The Comparison with Other Carbon Materials (Table 6). In order to evaluate the preferred orientation of the Pitch Carbon which was prepared from the variant pitch material-N, the values of BAF of the other carbon materials were measured. For the carbon electrode or Vitro Carbon,[11] the thin section was cut with its plane parallel to the pressing- or depositing-direction. Pyrolytic carbon exhibited an extremely remarkable preferred orientation, while, on the contrary, Vitro Carbon was almost isotropic. Pitch Carbon and the carbon electrode exhibited values of BAF intermediate between those of pyrolytic carbon and Vitro Carbon.

2. The Relationships between the Moulding Pressure and Some Properties of Pitch Carbon. Figure 1 shows microscopic photographs of Pitch Carbon which was

11) H. Honda, Y. Sanada, and T. Furuta, *Tanso*, No. 46, 2 (1966).



(a) Before heating (b) After heating

Fig. 1. Internal structures of pitch carbon pressed at 1600 kg/cm² (variant pitch material-N)

prepared from the variant pitch material-N by pressing at 1600 kg/cm². Large pores or grains were not observed in the tablet before the heat treatment. After the tablet had been heat-treated at 2600°C, on the other hand, large pores or grains were developed in it. From the above photographs, it is clear that these changes were caused by the coalescence and/or shrinkage of variant pitch particles at the heating stage.[6] This fact shows that the variant pitch material-N has a good ability of sintering. The internal structures of the other tablets (moulding pressure: 100 and 400 kg/cm²) before the heat treatment were similar to that shown in Fig. 1(a), and 2600°C-specimens gave less dense and less homogeneous structures than that shown in Fig. 1(b). Such differences are probably due to the difference in moulding pressure. The formation of cross-linkages among the molecules included in the pitch and the resulting elevation of the S.P. of pitch materials depended mainly on the progress of the oxidation reaction in the pre-heat treatment process in air. The oxygen is difficult to diffuse into closely-packed tablets. Therefore, these tablets tend to become semi-fused, thus having more mobility than in the solid state in this oxidation stage. As a result, a high moulding pressure accelerates sintering among particles of variant pitch materials.[6] A similar tendency of becoming semi-fused and accelerating the sintering can also be expected in the use of an oxidation temperature in the first stage lower than 300°C.[5]

The relationships between the bulk density of Pitch Carbons and the moulding pressure were as follows; 100 kg/cm²: 1.60 g/cm³, 400 kg/cm²: 1.64 g/cm³, 1600 kg/cm²: 1.83 g/cm³. For the Pitch Carbons pressed at 100 and 400 kg/cm², their bulk density were analogous in spite of the differences in the moulding pressure and in the values of BAF (r.f. 1.2).

3. Possibility of Isotropic Pitch Carbon with a High Density and with Various Degree of Graphitization.

According to the results described above, it seems that the preferred orientation of Pitch Carbon increases with a rise in the graphitizability of the variant pitch material used, but changes only slightly with an increase in the degree of graphitization upon heat treatment. These facts suggest that the preferred orientation of the final products is mainly determined at the moulding stage. In addition, the moulding pressure has scarcely no effect on the degree of graphitization of the resulting Pitch Carbon, but has a remarkable effect on the preferred orientation as well as the graphitizability of the variant pitch materials. The preferred orientation gradually became isotropic with a decrease in the moulding pressure. On the other hand, there were two methods for the preparation of Pitch Carbon with a high density. One is the use of the high moulding pressure described above, and the other is the acceleration of the sintering by using raw variant pitch materials with low S.P. and/or by applying a low oxidation temperature at the first stage.[6] The high-moulding-pressure-method is useful in the preparation of the isotropic Pitch Carbon with a low degree of graphitization which is prepared from non-graphitizable variant pitch materials such as chlorinated pitch.[6] It is clear that this method can not, however, be used for the preparation of isotropic Pitch Carbon with a high degree of graphitization, the other method would be better for this purpose. Since the degree of graphitization of Pitch Carbon is not affected by the moulding pressure, but is essentially affected by the graphitizability of the raw variant pitch, our purpose can be accomplished in the following manner. At first, graphitizable variant pitch materials with a low S.P. are moulded into tablets under a pressure lower than 100 kg/cm², and then the tablets are oxidized at as low temperature as possible within the limits required to prevent their deformation at the subsequent heating stage. By this treatment, the graphitizability of the product generally deteriorates to some extent. Therefore, even when this procedure is used, it is unavoidable that there is some limit to the improvement in the degree of graphitization of the resulting products.

4. Attempt to Make Isotropic Pitch Carbon with a High Density and with a High Degree of Graphitization.

When the tablet from material-N was heated under N_2 gas, it was deformed. From this fact, it seemed that the S.P. of the material-N was sufficiently low for this purpose. Therefore, the acceleration of the sintering was attempted by the control of the oxidation temperature in air. Moreover, for the improvement of the preferred orientation, a moulding pressure smaller than 100 kg/cm² was applied. The variant

TABLE 7. TYPICAL PROPERTIES OF ISOTROPIC PITCH CARBON WITH HIGH DENSITY

Pitch carbon	d_{002} (Å)	Lc (Å)	BAF
dia. 20 mm	3.39	210	1.02
dia. 40 mm	3.40	210	1.01

App. density (g/cm³)	Bulk density (g/cm³)	App. porosity (%)
2.12	1.75	17.3
2.12	1.79	15.4

pitch material-N (under 100 mesh) was pressed into tablets (diameter: 20 and 40 mm; thickness: about 10 mm) at 80 kg/cm^2. Then, the tablets were heated at the rate of 0.15°C/min up to 210°C in air, followed by heat-treatment at 2600°C in N_2 gas.

Some properties of the Pitch Carbon thus obtained are shown in Table 7. Both Pitch Carbons were almostly isotropic and were considerably improved in density in comparison with the other Pitch Carbons. In addition, their degrees of graphitization were considerably improved.

As a result, it seems reasonable to conclude that an isotropic carbon product with a high density, in addition to an improved degree of graphitization, can be prepared by the use of the method of preparing Pitch Carbon without any other techniques.

The Determination of the Iodine Affinity of Poly(vinyl acetate)

Sadao HAYASHI, Masayuki KISHIBE, and Nobumasa HOJO
Faculty of Fiber Science and Technology, Shinshu University, Tokiiri, Ueda

(Received February 16, 1972)

In a previous paper, in which the complex between poly(vinyl acetate)(PVAc) and iodine in the presence of potassium iodide has been investigated, we have reported that the potentiometric titration curve for a PVAc suspension with iodine is of the same type as that for amylose.[1] However, it was found from the results of many experiments that the iodine affinity of PVAc (grams of iodine consumed by 100 g of PVAc) varies widely with the measurement conditions, because the reaction system between PVAc suspended in an aqueous solution and iodine is heterogeneous. Therefore, in the present paper, we wish to attempt a more accurate estimation of the iodine affinity of PVAc in an apparent homogeneous system.

Experimental

Materials. The PVAc samples used here were prepared by the solution polymerization of vinyl acetate in methanol and by the suspension polymerization of vinyl acetate, using benzoyl peroxide and potassium persulfate respectively. The degree of polymerization of the PVAc prepared by solution polymerization was about 500. The iodine, potassium iodide, and sodium thiosulfate were reagents of a guaranteed grade.

Measurements. A methanol solution (1 ml) containing PVAc (1.5×10^{-3}g) prepared by solution polymerization and iodine, the content of which was varied from 0.80×10^{-7} to 20.8×10^{-7} mol, was added to 40 ml of an aqueous solution of potassium iodide (6.42×10^{-3} mol), and the total volume was exactly adjusted 50 ml by adding water.[2] The mixture instantly showed a red-violet color. The colored solution was kept in a water bath thermostated at 15°C for an hour; then the absorbance and the potential values of the solution were measured by the use of a Hitachi-Horiba M-5 pH-meter and a Hitachi 101 spectrophotometer respectively.

The films of PVAc were prepared by casting a methanol solution of PVAc obtained by the solution polymerization and a PVAc suspension produced by the suspension polymerization on the polyethylene film. The films of PVAc thus obtained were dried in a vaccum, dipped in 100 ml of a 0.1N iodine solution (iodine/potassium iodide=1/4 by wt.) for 24 hr at 15°C, and then washed with water for two weeks. The amount of iodine reacted with PVAc was determined by the following method: the film reacted with iodine was dissolved by methanol (50 ml), and then it was titrated with a 0.1N sodium thiosulfate solution.

Results and Discussion

When the mixture of PVAc and iodine in methanol was added to an aqueous solution of potassium iodide, a red-violet complex was immediately formed. This complex was rapidly destroyed by adding sodium thiosulfate, and at that time the solution was transparent, after which it gradually became turbid because of the precipitation of PVAc. It is evident from this finding that, in the method used here, the reaction system of PVAc with iodine is apparently homogeneous.

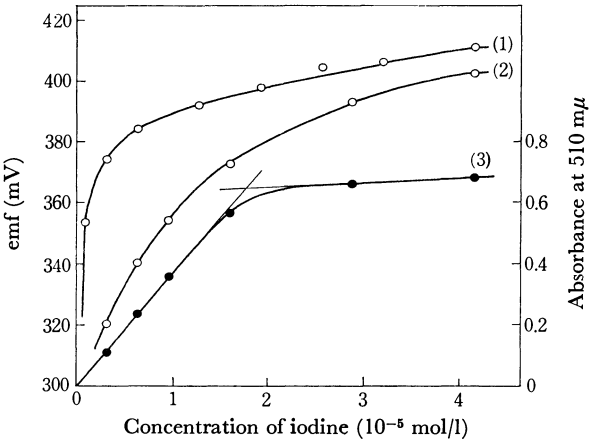

Fig. 1. Plots of emf (○) and absorbance (●) at 510 mμ versus concentration of iodine. PVAc concentration: 0.03 g/l.
(1) Curve of emf in the absence of PVAc,
(2) Curve of emf in the presence of PVAc,
(3) Curve of absorbance at 510 mμ in the presence of PVAc.

The potential values *versus* the concentration of iodine in the apparent homogeneous system are shown in Fig. 1, in which the potential values in solution increased with an increase in the concentration of iodine. This result has some similarity to that for the partially-saponified PVAc, which is easily soluble in water and which reacts with iodine to produce the red-violet complex.[1,3]

In a previous paper,[1] we could see a horizontal part in the potentiometric titration curve for the PVAc with iodine, where the potential values in solution remained constant upon the addition of iodine because the iodine added was consumed in the complex formation with PVAc suspended as particles in water.

Consequently, it is confirmed that the potentiometric titration curve for PVAc with iodine varies with the reaction conditions. On the basis of these data, we can explain the potentiometric titration curves for PVAc with iodine as follows: the fact that the titration curve for PVAc suspended in water is similar to that for

amylose indicates a heterogeneous reaction based on the diffusion of iodine into the PVAc particles suspended in water, without regard to the formation of a helical complex of a polymer with iodine postulated in the case of amylose.[4]

The relationship between the absorbance and the concentration of iodine in the apparent homogeneous system is shown in Fig. 1. When the amount of PVAc was kept constant, the maximum absorption was obtained by adding more than about 2.5×10^{-5} mol/l of iodine for 3.48×10^{-4} mol/l of monomer units in PVAc. This shows that PVAc has a stoichiometric relation with iodine. According to Bates *et al.*,[5] results of Fig. 1 show the iodine affinity of PVAc to be 12.2. This value is considerably larger than the value of 7.3 obtained in the heterogeneous system.[1] Furthermore, from Fig. 1, the molecular extinction coefficient of iodine in the complex was estimated to be 42200 l/mol·cm.

The iodine affinities of PVAc in film are summarized in Table 1. The swelling of a film began as soon as the film assumed a red-violet color; eventually it grew to several times the original film. When a thin film was used as a sample, it was observed that some of the polymers disperse into water from the film as the complex forms during a period of washing. On the other hand, when a thick film was used as a sample, no loss of polymers was observed, and the iodine affinities of PVAc were about the same. This indicates that, if the reaction conditions, such as the reaction time and the concentration of iodine, are given satisfactorily, the iodine affinities of PVAc are almost all the same, independent of the properties of the PVAc originating from the polymerization conditions. Consequently, the largest cause for the error in the iodine affinity of PVAc found by the potentiometric titration in the heterogeneous system[1] appears to be the insufficiency of the reaction conditions in its system. The average value of the iodine affinities of PVAc in film, except for the thin films, was 13.5. This value is in good agreement with that found from Fig. 1. Accordingly, the iodine affinity of PVAc obtained in the apparent homogeneous system is thought to be reasonable.

The stoichiometry indicates that one molecule of iodine reacts with about 24 vinyl acetate units in PVAc. However, in the absence of direct evidence, the arrangement of iodine molecules in the complex between PVAc and iodine can not be illustrated. Further work is now in progress.

Phase Transition and Spin-exchange Interaction in Ion Radical Salts. Some Information Derived from ESR Measurements

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received March 14, 1972)

The prominent magnetic properties of solid ion radical salts have been the subject of many theoretical and experimental investigations over the past several years.[1-7] In certain ion radical salts, the extra electrons on the ion radical molecules appear to be paired by means of an exchange interaction.[1-7] In this case, the paramagnetic contribution to the susceptibility of these materials at any temperature, T, can be fitted approximately to the expression:

$$\chi_p = (2Ng^2\mu_B^2/3kT)\left(1+\frac{1}{3}e^{J/kT}\right)^{-1}, \quad (1)$$

which corresponds to an assembly of N quasimolecules with a singlet ground state and a triplet state lying an energy, J, above the ground state.

The intensity of the electron-spin-resonance (ESR) absorption, I, is known to be proportional to the value of χ_p. Therefore, since a plot of ln (IT) *versus* T^{-1} yields an approximately straight line, the singlet-triplet energy separation, J, can be estimated from the slope value of this straight line.[1,2,4]

If these ion radical salts undergo first-order phase transitions, an abrupt change in the singlet-triplet energy separation should be associated with the phase transition.[4-7] The J values in the low- and high-temperature phases have both been estimated by using this slope method. However, the slope method is not applicable when the intensity measurements cannot be made over a wide temperature range. In this case, the relative intensity ratio of the ESR absorptions at the transition temperature is useful for the determination of the J values below or above the transition temperature.

At the transition temperature, T_c, in the lower and higher temperature ranges, the singlet-triplet energy separations are represented by J and J', while the ESR absorption intensities are represented by I and I'. It is assumed, in Eq. (1), that only a change in the singlet-triplet energy separation is involved; that is, the value of N, g, or μ_B in the lower temperature range is assumed to be equal to the corresponding one in the higher temperature range. On this assumption, we obtain:

$$\frac{I'}{I} = \frac{3+\exp(J/kT_c)}{3+\exp(J'/kT_c)}. \quad (2)$$

Therefore, if the values of (I'/I), J, and T_c are known experimentally, the value of J' can be estimated by means of:

$$J' = kT_c \ln\left\{3\left(\frac{I'}{I}-1\right)+\frac{I'}{I}\exp(J/kT_c)\right\}. \quad (3)$$

We shall apply this method, for example, to the phase transition of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$, one of the anion radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ).

Several years ago, we examined the ESR spectra of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ and its variation with the temperature.[6] For this anion radical salt, the paramagnetism due to the excited triplet state has been established from the anisotropic zero-field splitting in the ESR absorption at low temperatures.[1] The phase transition takes place at T_c=315.7K,[8] where the intensity of the ESR absorption increases abruptly in the higher temperature range by a factor of (I'/I)= 1.9.[6] Although the singlet-triplet energy separation in the low-temperature phase, J, is known to be 0.065 eV by Kepler's susceptibility measurements,[5,9] there have been no experimental data on the value in the high-temperature phase. If J=0.065 eV in the low-temperature phase holds at the transition temperature, the singlet-triplet energy separation in the high-temperature phase, J', can be determined to be 0.039 eV by putting those values into Eq. (3). The appreciable reduction of the singlet-triplet energy separation in the high-temperature phase is found to be caused by the phase transition. On the other hand, the J' value estimated from the slope method is 0.03 eV or less, which is somewhat smaller than that estimated from the relative intensity-ratio method. However, since the observation of the ESR absorption intensities in the high-temperature phase was done over a limited temperature range,[6] the slope value for the singlet-triplet splitting in the high-temperature phase should be taken as only an indication.

The present intensity-ratio method in ESR absorption can be applied, in general, to the phase transitions of ion radical salts which possess a magnetic system composed of a singlet ground state and a triplet excited state. In some cases, this method gives more accurate information on the singlet-triplet energy separation than does the slope method.

9) Rigorously speaking, the J value was found to depend slightly on the temperature. However, the variation in J with the temperature is not observed in the ESR measurements, because one measures only the relative intensity. The ESR intensity, I, is proportional to $\exp(-J/kT)$, and if J varies as $J_0+\alpha T$, the linear term in T will appear only as a constant and, therefore, not show up in relative intensity measurements. By using the slope method of the ESR intensity, Chesnut and Phillips reported the J value to be 0.062 eV,[1] while Iida *et al.* reported it to be 0.08 eV.[6]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 321—322 (1973)

A Study of Catalytic Partial Oxidation of Hydrocarbons. XIII. The Effect of Bi_2O_3 Content in MoO_3-Bi_2O_3-P_2O_5 Catalysts on the Dehydration of Isopropyl Alcohol

Mamoru Ai and Sadao Suzuki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 25, 1972)

The present authors have recently reported the effect of the Bi_2O_3 content in the MoO_3–Bi_2O_3–P_2O_5 ternary catalyst system on the oxidation of olefins, furan, and maleic anhydride.[1,2] It has been considered that, with an increase in the Bi_2O_3 content, the acidity of the catalysts changes; accordingly, the affinity, *i.e.*, the adsorptive action, of the catalysts for such basic compounds as olefins and furan, and that for such electron-acceptor-type compounds as carboxylic acid and oxygen, varies. We should measure directly the acidity of the catalyst system in order to cofirm those results. However, it is hard to measure the acidity by means of the conventional titration method, because both the acidity and the surface area are very small; moreover, the catalysts are dark—the low Bi_2O_3 content catalyst, for instance, is black. However, it is well known that there are good correlations between the acidic properties and activities of catalysts for many acid-catalyzed reactions,[3] so it seems appropriate to adopt the activity for the dehydration of alcohols as a measure reflecting the acidity of the catalyst.

In the present work, the dehydration of alcohols, especially that of isopropyl alcohol (IPA), was performed over a series of MoO_3–Bi_2O_3–P_2O_5 catalysts with various Bi/Mo ratios in order to study the dependency of the acidity on the Bi_2O_3 content and the relationship between the acidity and the activities for oxidation and isomerization reactions.

Experimental

The vapor-phase dehydration of alcohols, such as ethyl and isopropyl alcohols, was carried out over a series of MoO_3–Bi_2O_3–P_2O_5 catalysts with various Bi/Mo ratios (P/Mo=0.2 atomic ratio) in an ordinary continuous-flow-type reaction system.[4] The concentration of alcohol was about 2.2 mol% in nitrogen or air, and the flow rate was kept at 1.0 l/min (STP). The amount of the catalyst used was 20 ml (contact time=1.2 sec). The reaction temperature was varied from 160 to 300°C.

The reaction products were analyzed by gas chromatography; for propylene and ethylene: activated alumina and a 6 m column at 80°C; for alcohols and other oxygen-containing compounds: PEG20M and a 6 m column at 80°C. The other experimental procedures were similar to those employed in earlier works.[1-3]

The catalysts used in these experiments were the same as those used in previous works.[1,2] The surface area of these catalysts was 0.6 ± 0.3 m²/g, as determined by the BET method, using nitrogen at −195°C as the adsorbate, and their packing density was within the limits of 0.75—0.80 g/ml. Taking the experimental error into account, the dependence of these values upon the catalyst composition (Bi/Mo ratio) was obscure.

Results and Discussion

Dehydration of Ethyl Alcohol. Only a trace amount of ethylene was produced, even at about 300°C, over the entire range of Bi/Mo ratios. This shows that the acid strength of the catalyst is too weak to catalyze the dehydration of normal alcohol.[5]

Dehydration of Isopropyl Alconol. The effect of the reaction temperature on the conversion of isopropyl alcohol into propylene was studied over the MoO_3–Bi_2O_3–P_2O_5 catalysts in atmospheres both of nitrogen and of air. The results in nitrogen are shown in Fig. 1. Apart from propylene, only di-isopropyl ether and acetone were found in the product. The acetone formation, *i.e.*, the dehydrogenation, was very little in nitrogen—less than 1%. It was more appreciable in air, especially at high temperatures. Propylene was the main product in the dehydration above 180°C. The portion of propylene in the products decreased with a decrease in the temperature, and below 160°C, ether was predominant. The rate of propylene forma-

tion was almost of a zero order in isopropyl alcohol. No loss of activity was observed within 4—5 hr, even in the nitrogen atmosphere.

The value of the conversion to propylene at 185°C was adopted as a measure of the dehydration activity; the data are plotted as a function of the Bi_2O_3 content in Fig. 2. The value of the conversion to acetone in air at 185°C is also shown in Fig. 2. With an increase in the Bi_2O_3 content of the catalyst, the dehydration activity increases at first, passes through a maximum at the Bi/Mo atomic ratio of 0.1—0.2, and then decreases to the value of the pure Bi_2O_3 catalyst, which is extremely inactive. Although the shapes of the curves are almost the same, the activity in the air seems to be lower than that in nitrogen. Further investigation is necessary to clarify the effect of the atmosphere.

Discussion. If the dehydration activity really represents the acidity of a catalyst, it can be concluded from the results shown in Fig. 2 that a new acidic site is produced by adding Bi_2O_3 up to Bi/Mo= 0.1, that the acidity passes through a maximum at Bi/Mo=0.1—0.2, and that it then decreases sharply upon the further addition of Bi_2O_3.

If the acidity of the catalyst plays an important role in the oxidation and isomerization of olefin, a linear relation between the activities for these reactions and that for the dehydration must be obtained. The characters of the curves in Fig. 2 are quite similar to those of olefin oxidation.[1,2] Figure 3 shows the relationship between the dehydration activity for isopropyl alcohol and the oxidation and isomerization activities for butene. Both the oxidation and isomerization activities for butene increase steadily with an increase in the dehydration activity for IPA. Those results show that both the oxidation and isomerization activities are closely related to the acidities of the catalysts, which may support our explanation of the oxidation mechanism being based on the acid-base nature of the reactant and the catalyst.[1,2]

The Effect of the Addition of γ-FeOOH Nuclei at the Initial Stage of Oxidation on the Formation of γ-FeOOH

Masao KIYAMA, Nariyasu JIKUHARA,* and Toshio TAKADA
Institute for Chemical Research, Kyoto University, Kyoto
(Received April 24, 1972)

The presence of green rusts has been considered to be indispensable for the formation of γ-FeOOH. Bernal *et al.* proposed, from a crystallochemical point of view, that γ-FeOOH was topotactically formed by the surface oxidation of the green rusts.[1] We recently reported that γ-FeOOH can be obtained not only from the green rusts in ferrous salt solutions, but also from acidic solutions containing ferrous ions, by selecting the oxidizing conditions.[2] It was found that, under the conditions where γ-FeOOH was formed together with α-FeOOH, the γ-FeOOH content in the oxidation product was affected by slight differences in the treatment before oxidation. The γ-FeOOH content may be determined by the ratio of the α-FeOOH nuclei to the γ-FeOOH nuclei formed at the initial stage of oxidation. In order to prove this assumption, an attempt has been made to change this ratio variously by adding very fine particles of α-FeOOH and γ-FeOOH to the solutions. The experimental results will be reported here.

Experimental and Results

The chemicals used in the present study were of a reagent grade. The fine particles of α-FeOOH used as nuclei were prepared by the hydrolysis of a ferric nitrate at 40°C for 50 hr, while those of γ-FeOOH were prepared *via* a green rust (I) by the oxidation of $Fe(OH)_2$ below 10°C in a ferrous chloride solution. The precipitates formed by hydrolysis and oxidation were filtered, washed with water, and then diluted with water to obtain turbid solutions containing 0.05 mol of the nuclei per liter. The particles of α-FeOOH were superfine (below 0.02 μ in size), while those of γ-FeOOH were flaky (about 0.3 μ in length).

Varying quantities of the turbid solutions were added to 3 l of a mixture of 0.21M-$FeCl_2$ and 1.44M-NaI solutions, and the resultant solutions were subjected to oxidation. The procedures of the oxidation and identification of the samples thus obtained were the same as have been described in a previous paper.[2] The contents of α-FeOOH, β-FeOOH, and γ-FeOOH were determined by comparing the relative intensities of the X-ray diffraction lines of α-FeOOH d(110) 4.18 Å, β-FeOOH d(110) 7.40 Å, and γ-FeOOH d(020) 6.3 Å.

Air was bubbled into the mixtures with and without 10 ml of the turbid solution of γ-FeOOH (containing 0.5 mmol of γ-FeOOH) at the rate of 300 l/hr for 20 hr at various temperatures for oxidation. The contents of three forms of FeOOH in the oxidation product thus obtained are plotted against the oxidizing temperature in Figs. 1 and 2. The γ-FeOOH content increases with the temperature and attains, at temperatures between 60 and 70°C, the maximum value, which is 40% when no turbid solution of γ-FeOOH has been added and 80% when it has been added.

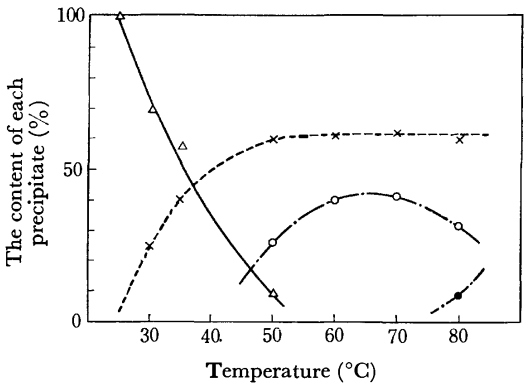

Fig. 1. The content of each precipitate in the oxidation products formed at various temperatures in a mixture of 0.21M-$FeCl_2$ and 1.44M-NaI solutions.

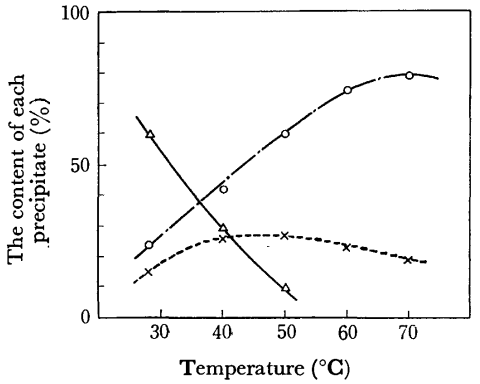

Fig. 2. The content of each precipitate in the oxidation products formed at various temperatures in the mixture containing 0.5 mmol of γ-FeOOH nuclei.
×: α-FeOOH, △: β-FeOOH, ○: γ-FeOOH

Varying quantities of the turbid solutions were added to 3 l portions of the mixture, and the resultant solutions were oxidized at 60°C for 20 hr. About 7 g (87 mmol) of an oxidation product was obtained from each solution, and the product consisted of only α-FeOOH, only γ-FeOOH, or their mixture. The γ-FeOOH content of the products is plotted against the amount of α-FeOOH or γ-FeOOH added in Fig. 3. When 2.5 mmol or more of γ-FeOOH was added to the mixture, only γ-FeOOH was formed, whereas when

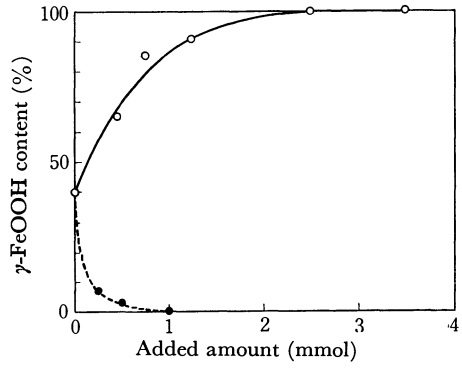

Fig. 3. The γ-FeOOH content of the oxidation products formed at 60°C in the mixtures containing different amounts of α-FeOOH and of γ-FeOOH nuclei.
●: α-FeOOH nuclei, ○: γ-FeOOH nuclei

1 mmol or more of α-FeOOH was added to it, only α-FeOOH was formed as the oxidation product. The effect of the addition of the nuclei on their formation may depend upon the particle size of the nuclei.

On oxidation, γ-FeOOH was not obtained from the $FeSO_4$ and $FeCl_2$ solutions, but other precipitates, such as α-FeOOH and β-FeOOH, were obtained. A turbid solution (100 ml) containing 5 mmol of γ-FeOOH was added to 3 l portions of these solutions containing 0.21 M-ferrous ions, and the resultant mixtures were oxidized at 60°C for 20 hr. The oxidation products thus obtained consisted of α-FeOOH only (when these solutions containing no γ-FeOOH nuclei were oxidized under the same conditions as above, too, only α-FeOOH was formed).

By oxidation, a hydroxo ferric complex which has H_2O and OH^- ligands may be formed together with other ferric complexes which have halogen ligands besides H_2O and OH^- ligands. The concentration of the hydroxo ferric complex depends on the conditions, such as the concentration of the halogen ions and the temperature. The precipitation of β-FeOOH may be due to the hydrolysis of the halo ferric complexes, while that of α-FeOOH and γ-FeOOH may be due to the hydrolysis of the hydroxo ferric complex. Which is formed, α-FeOOH or γ-FeOOH, presumably depends upon whether or not an epitaxial reaction occurs between the γ-FeOOH nucleus and the hydroxo ferric complex. The hydroxo ferric complexes may be epitaxially deposited on the γ-FeOOH nucleus to give a precipitate of γ-FeOOH. The formation of the γ-FeOOH nuclei and their growth on the nuclei may be influenced by the rate of formation of the hydroxo ferric complex.

The Kinetics of Proton-transfer Reaction in an Aqueous Solution of *n*-Butylamine by Means of Ultrasonic Absorption

Sadakatsu NISHIKAWA, Tetsuya NAKAMOTO, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received April 25, 1972)

Various mechanisms associated with the ultrasonic absorptions in aqueous solutions of amines have previously been proposed.[1-4] Some problems relating to the elucidation of the mechanisms seem, however, to be still in question. On the other hand, the clarification of the dynamic properties of aqueous solutions of amines may provide useful and fundamental information on the kinetics and mechanisms associated with the conformational changes of the protein molecules.

The purpose of the present investigation is to confirm the mechanism of the excess absorption in a dilute aqueous solution of *n*-butylamine in detail by measuring the ultrasonic absorption.

Experimental

The chemical used in the present experiment were of a guaranteed reagent grade. The *n*-butylamine was purified by distillation, and its purity was confirmed by the gas-chromatographic method to be higher than 99.9%. The pH of the solution was adjusted to the desired values using either NaOH or $HClO_4$. The ultrasonic absorptions were measured at the odd harmonic frequencies of 5 MHz and 20 MHz X-cut quartz crystals by the pulse technique.[5] The frequency range of the measurement was from 15 to 220 MHz. Since the aqueous solution of amine is highly basic, the cell was made air-tight, and nitrogen gas was passed over the solution to prevent the contamination of specimens by the oxidation with air. The sing-around method was employed at 1.92 MHz to measure the sound velocity. The pH values of the solutions were measured by a Hitachi-Horiba F-5 type pH meter. All the measurements were made at 20°C.

Results and Discussion

Figure 1 shows an example of the ultrasonic absorption spectra of aqueous solutions of *n*-butylamine. These

spectra can be represented by the formula of a single relaxation as follows:

$$\alpha/f^2 = \frac{A}{1+(f/f_r)^2} + B \qquad (1)$$

where α is the absorption coefficient; f, the frequency; f_r, the relaxation frequency, and A and B, constants. The values of these constants were determined so as to obtain the best fit of the data to Eq. (1). The ultrasonic parameters and densities thus obtained are listed in Table 1. If these excess absorptions are due to hydrolysis, the reaction scheme is given by the following equation:

$$R\text{-}NH_3^+ + OH^- \underset{k_b}{\overset{k_f}{\rightleftharpoons}} R\text{-}NH_2 + H_2O. \qquad (2)$$

The reciprocal relaxation time is related to the rate constants and concentrations as follows:

$$1/\tau = 2\pi f_r = k_f[[R\text{-}NH_3^+]+[OH^-]]\Pi\gamma_i + k_b. \qquad (3)$$

where τ is the relaxation time, k_f and k_b are the forward and backward rate constants respectively, and γ_i is the activity coefficient. If the activity coefficients and concentrations of the $R\text{-}NH_3^+$ ion are equal to those of the OH^- ion at each concentration, Eq. (3) can be rewritten as:

$$1/\tau = 2\pi f_r = 2k_f\gamma^2[OH^-] + k_b \qquad (4)$$

The relationship between the ionic strengths and the activity coefficients of monoamine and OH^- ions has been given by almost the same curve.[6] Assuming that the relationship also holds for *n*-butylamine, the appropriate activity coefficients can be obtained graphically.

Figure 2 shows the plot of $2\pi f_r$ *vs.* $\gamma^2[OH^-]$. The linearity of the plot confirms that the mechanism of excess absorption is associated with hydrolysis. The forward and backward rate constants were calculated from the slope and intercept respectively of the plots. The standard volume change, ΔV, of the reaction can be determined in the following manner. The excess absorption per wavelength shows a maximum at the $f=f_r$ frequency and can be written as:

$$(\alpha\lambda)_{max} = \frac{1}{2}Af_rc \qquad (5)$$

where $(\alpha\lambda)_{max}$ is the maximum excess absorption per wavelength, and c, the velocity of sound. For a chemical process of the type represented by Eq. (2), the maximum excess absorption per wavelength can be represented by:

$$(\alpha\lambda)_{max} = \frac{1}{2}\pi\rho c^2\frac{(\Delta V)^2}{RT}\Gamma_c \qquad (6)$$

where ρ is the density and where $\Gamma_c=[1/[OH^-]+1/[R\text{-}NH_3^+]+1/[R\text{-}NH_2]]^{-1}$. In Table 2 the rate constants and the mean standard volume change associated with the hydrolysis of *n*-butylamine are tabulated, together with the results for other amines obtained by Eigen and his co-workers.[4,7,8]

a) This work

In addition, in order to confirm that the absorption mechanism is due to the perturbation of the equilibrium represented by Eq. (2), the ultrasonic absorptions at a constant concentration of *n*-butylamine were measured at various pH's. The theoretical dependences of $(\alpha\lambda)_{max}$ and f_r on pH can be calculated from Eqs. (3) and (6) respectively. In Fig. 3, the calculated variation of Γ_c with the pH is shown, together with the $(\alpha\lambda)_{max}$ obtained; the value of the equilibrium constant, $K=k_b/k_f$, in the literature[9)] was used to calculate the concentration terms in Eqs. (3) and (6) because large and serious errors usually occur in determining them from ultrasonic data. A reasonable dependence of f_r on pH was observed. This information also provides confirmation that the perturbation of the proton-transfer equilibrium is the origin of the excess absorption.

As a result, the value of the rate constant, k_f, for a diffusion-controlled reaction obtained in this study agrees very closely with the results obtained experimentally and theoretically for other compounds.[4,7,8,10,11)] The value of k_f obtained is, however, slightly different from those for other amines obtained by Eigen and his co-workers. This difference may be due to the fact that they have employed an equation, $1/\tau=2k_f\sqrt{KC_0}+k_b$, which is derived from Eq. (2) as an approximate form, where $C_0=[R\text{-}NH_2]+[R\text{-}NH_3^+]$.

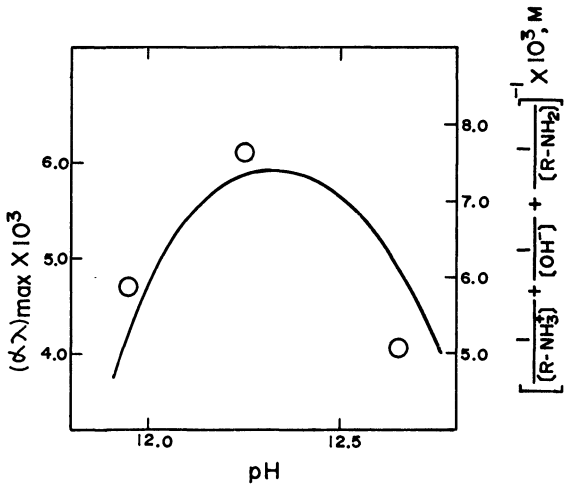

Fig. 3. The variation of $(\alpha\lambda)_{max}$ and Γ_c with pH in 0.537M *n*-butylamine. The solid line represents the predicted behavior of Γ_c. The circles are the experimental points of of $(\alpha\lambda)_{max}$.

As has been proposed by Eigen and his co-workers[8)] the recombination process of the OH^- ion with an acid in an aqueous solution might not be as simple as that described in Eq. (3). The process probably proceeds through the complex state expressed by next equations:

$$R\text{-}NH_3^+ + OH^- \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} R\text{-}NH_3^+ \cdots OH^- \underset{k_{23}}{\overset{k_{32}}{\rightleftharpoons}} R\text{-}NH_2 + H_2O \quad (8)$$

where the complex state is formed by the hydrogen bond. Therefore, the rate constants obtained should be given by:

$$k_f = k_{12}, \quad k_b = k_{21}\cdot\frac{k_{32}}{k_{23}} \quad (9)$$

Consequently, the value of k_f depends on the collision frequency of reactant partners, $R\text{-}NH_3^+$ and OH^-. In the case of relatively small molecules, as is shown in Table 2, the values of k_f are probably constant within the limits of experimental error.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 327—328 (1973)

Photochromism of *N*-3-Pyridylsydnone

Akio MITSUI* and Nozomu EBARA

Department of Chemistry, College of General Education, University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received May 26, 1972)

Except for a few qualitative studies[1-4] the photochromism (PC) of *N*-3-pyridylsydnone (3PS) has been little investigated, the only mechanism proposed thus far being that of Mill *et al.*[3] who assumed the formation of a color center. However, the experiments described seem somewhat inexact and the mechanim has several drawbacks. The substance is very liable to decompose and available information is scanty. The present note attempts to contribute to the understanding of the PC of 3PS.

Radiolysis of 3PS. Mill's mechanism requires that the electron in the color center should be supplied from the molecule and leaves a $3PS^+$ cation radical. It is known that 3PS acts as an electron donor to form complexes with Cu^{2+}, Ni^{2+} or I_2.[5,6] This, however, does not necessarily mean that 3PS ionizes easily to form a cation radical. To clarify the mode of ionization of 3PS, γ-radiolysis was tried in a rigid matrix at 77°K.[7] It gave only $3PS^-$ (Fig. 1) and no cation radical was formed. This is against the color center mechanism.

Flash Photolysis of Solutions. Metz[2] has concluded from a solution experiment by steady irradiation that the PC of 3PS was restricted only to solid state. Solutions of 3PS (10^{-2} to 10^{-5} mol/l) in various solvents were subjected to flash photolysis (500 J, 5 μsec) in either the presence or absence of addenda (NaCl, KBr, O_2 or TCNE) which might affect the stability of 3PS ionic structures. In all cases no PC was observed down to the lifetime of 5 μsec. There were no effects of temperature, solvent polarity, solvent viscosity or presence of any electron acceptor. As the solution PC due to unimolecular reactions usually has a much longer lifetime under similar conditions, it is hard to regard PC of 3PS as an intramolecular process. Experiments in PVA or polystyrene also failed to show the PC.

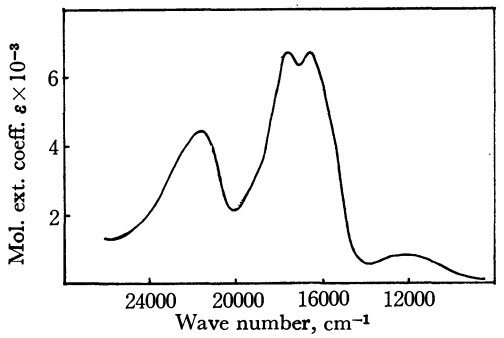

Fig. 1. Spectrum of $3PS^-$ in 2-methyltetrahydrofuran (Courtesy of Dr. T. Shida)

However, the effect of TMPD in an ethanol solution was remarkable. Although the solution showed no PC, 3PS seemed to stabilize in its stead the $TMPD^+$ radical. It was found that for a 4.0×10^{-4} mol/l TMPD solution, the presence of either 5.1×10^{-5} or 4.0×10^{-4} mol/l 3PS made 48.9 or 100%, respectively, of the recombination of $TMPD^+$ take place by way of electronated 3PS. Hence, the acceptor property of 3PS seemed to be manifest.

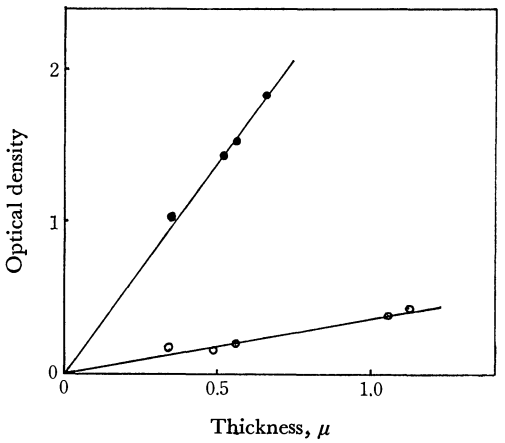

Fig. 2. Plots of OD against the thickness of the film (in μ): ○ at 605 nm, ● at 290 nm

PC in Crystal Films. Tien[1] could not decide whether the PC was confined to the surface of the crystals or it extended to within. We thus measured the maximum absorption intensity of the blue form obtained by constant irradiation of the oxygen-free evaporated crystal film. The thickness was determined from the interference pattern. The good linearity in Fig. 2 shows that the PC is distributed almost uniformly within the crystal entity. The plots were compared with those for the absorption by 3PS itself at 290 nm. Assuming tentatively that the extinction coefficient of the blue absorption was 10000 (double the value at 290 nm), the extent to which the PC took place amounted to 7.5%.

The dielectric constant of the crystal film was also measured. It did not change on irradiation until decomposition took place.

kinds of sample film, one evaporated in a vacuum and the other precipitated from a nitromethane solution, are shown in Fig. 3. They differ considerably, which seems to be due to the preferred orientation in the crystal films rather than to polymorphism, since there is no indication of the latter. Assuming that the crystals mainly have their axes of growth (assigned later to the *b* axis) almost perpendicular to the quartz plate in an evaporated film, as is often the case, but parallel or at random in a precipitated film, the difference may be accounted for in terms of the factor group splitting. Comparison of the spectra of 3PS with the corresponding spectra of *N*-phenylsydnone (PhS), which is non-photochromic, shows that the splitting in the former is far more greater (1700 cm^{-1} compared with 750 cm^{-1} of PhS for the lowest band), and that the direction of the splitting is reversed (see arrows in Fig. 3).

The anisotropy in the blue band is astonishingly large. A single crystal was placed under a polarizing microscope and was observed visually. It was blue when the polarizer was perpendicular to the *b* axis, but pale yellow-green when the polarizer was parallel to the *ac* plane.

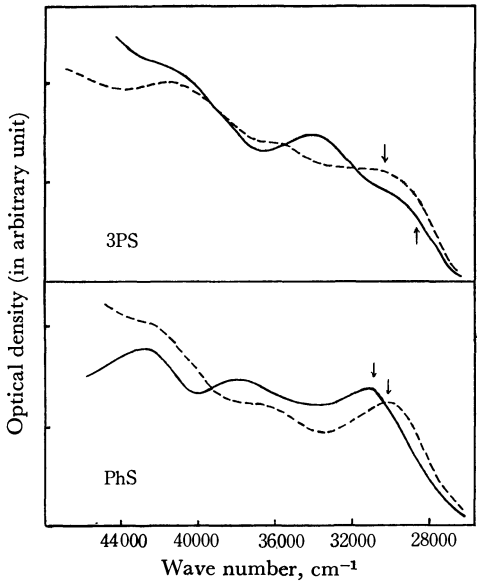

Fig. 3. Crystal spectra of 3PS and PhS.
——: evaporated film, ------: precipitated film.

Crystal Structure. In view of the large anisotropy in the crystal spectrum and the failure of observing solution PC, the crystal analysis of 3PS was carried out. The crystal of 3PS has orthorhombic structure with $a=22.9$, $b=7.0$, $c=8.6$ Å and $Z=8$. Three space groups conformed to the extinction rule, $P2_1ma$, Pm2a, and Pmma. Comparison with the crystal of PhS[8] ($P2_1/a$, $a=22.06$, $b=3.75$, $c=9.58$, $\beta=103°10'$, and $Z=4$) suggests that the space group of 3PS is possibly Pm2a (or Pmma) and that both structures do not differ greatly except that the crystal of 3PS consists of molecular layers stacked along the *b* axis, whereas in the crystal of PhS the molecules are stacked alternatively by a screw axis.

Discussion. Under suitable conditions every kind of organic PC except for that of 3PS was found to take place in solution. The absence of solution PC in 3PS suggests that it is not a unimolecular process such as ionization, isomerization or dissociation. Absence of an ESR signal in oxygen-free samples[4] shows that it does not involve radical formation. The marked polarization of the blue band in the *ac* plane suggests that the absorption is an intermolecular transition which is of CT type in nature, and that the interaction took place between the molecules in the same layer. The homoionic structure and the donor-acceptor property of sydnones seem to favor the complex formation. If this is the case, the formation of the complex may be invoked by some change in the molecular structure or in the molecular disposition in the crystal, which is induced photochemically. Metz[2] reported that the blue form was bleached by the application of e.m.f. Mill[3] observed that a surge of electric current occurred when the blue crystal was thermally bleached. Although the observations do not seem to be exact, they conform to the present mechanism.

The Migration of the Exciton in the Radiolysis of Alkanes

Tetsuo MIYAZAKI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received May 29, 1972)

A number of studies of the exciton migration in molecular crystals have been mostly concerned with aromatic crystals. Though the energy transfer in the γ-irradiated aromatic crystal has been interpreted in terms of the excitation transfer,[1] the possibility of the excitation transfer in the solid alkane has been ignored in radiation chemistry; only the energy transfer *via* an ionic process, such as a charge transfer, an ion-molecular reaction, or an electron capture, has been emphasized. Recently, however, Miyazaki *et al.* have found phenomena which suggest the migration of the exciton in the radiolysis of isobutane,[2] neopentane,[3] and 2,3-dimethylbutane.[4]

The theoretical treatment of the migration of the exciton in the alkanes has not been undertaken previously. In order to obtain some information on whether or not the electronic excitation transfer is possible in solid alkane, the theoretical treatment of irradiated aromatic materials[5] will be applied here to alkanes.

In order to occur at all, excitation transfer requires some interaction between excited and unexcited molecules. The interaction energy (u) can be approximated as the interaction between the transition dipoles of molecules. Since the transition dipoles can be represented by the experimentally-available oscillator strength (f), the interaction energy is given by:

$$u = -3f(ea_0)^2 \frac{R}{\Delta E} \frac{\Omega}{r} \qquad (1)$$

where a_0 is the first Bohr radius; R, the Rydberg energy; ΔE, the excitation energy; Ω, the geometric factor, depending upon the orientation of the transition dipole moments, and r, the distance between nearest neighboring molecules.

The oscillator strengths (f) of isobutane, neopentane, and 2,3-dimethylbutane were obtained by the integration of the absorption spectra;[6] they are shown in Table 1. The distances (r) between adjacent molecules of isobutane, neopentane, and 2,3-dimethylbutane were obtained from the densities at 77K; they are 5.3, 6.7, and 6.7 Å respectively. As for the geometric factor of transition dipole moments (Ω), the optimum condition is here considered to be that in which the transition dipoles are directed along the line joining the molecular centers. In this case, $\Omega=2$. The interaction energies calculated from Eq. (1) are shown in Table 1.

One can estimate roughly the migration distance of the exciton from the interaction energy by means of the following equation:[7]

$$u \simeq \frac{h\Delta n}{t}$$

where h denotes Planck's constant and Δn, the number of molecules through which the exciton migrates during its lifetime (t). The calculated distances of the exciton migration are shown in Table 1.

The interaction energies of isobutane, neopentane, and 2,3-dimethylbutane range from 0.01 to 0.1 eV (Table 1). These values are not small as compared with those of benzene calculated by Voltz.[5]

TABLE 1. CALCULATED VALUES OF THE TRANSITION DIPOLE-DIPOLE INTERACTION ENERGIES AND THE DISTANCES OF EXCITON MIGRATION IN IRRADIATED ALKANES

Compound	Excitation energy ΔE eV	Oscillator strength f	Interaction energy u, eV	Distance corresponding to different lifetimes, Δn[a]	
				10^{-8}—10^{-9} sec	10^{-11}—10^{-13} sec
Isobutane	(1st) 7.7	0.03

a) Unit is the number of molecules through which exciton migrates.
b) M. Kato, T. Miyazaki, Y. Saitake, and Z. Kuri, to be presented at the 15th Japanese Conference of Radiation Chemistry, Oct. 1972, Osaka, Japan.

From the measurements of the fluorescence of liquid alkanes, the lifetimes of the lowest singlet-excited states were obtained: *n*-hexane (2×10^{-9} sec), cyclohexane (7×10^{-9} sec), *etc.*[8] Therefore, the lifetimes of the lowest singlet-excited state of neopentane and 2,3-dimethylbutane are probably 10^{-8}—10^{-9} sec. It is expected from the calculated values shown in Table 1 that the excitons of these alkanes in the lowest excited states can migrate through 10^4—10^3 molecules during their lifetimes. It is interesting to note that the distance obtained experimentally by the measurements of luminescence from solid 2,3-dimethylbutane containing toluene lies in the range expected from this calculation (Table 2).

In the solid-radiolysis of isobutane or neopentane containing other alkanes, it was suggested that the excitation transfer may occur *via* highly excited states.[3] Since the internal conversion from the highly excited states occurs very fast, the lifetime of the highly excited state may be extremely small as compared with that of the lowest singlet-excited state. An exact estimation of the lifetime of the highly excited state is currently impossible; from indirect theoretical and experimental evidence, however, it may be expected to lie between 10^{-11}—10^{-13} sec.[5,9] The calculated results in Table 1 show that the excitons in the highly-excited states of isobutane and neopentane migrate through 200—1 molecules during their lifetimes. It is interesting to note that the distances obtained experimentally in the radiolysis of isobutane and neopentane are 7—8 and 40—85 molecules respectively, which lie in the range expected from this calculation.

The author wishes to express his appreciation to Professor Noriaki Ito and Dr. Kenji Fueki of Nagoya University for their fruitful discussions and to Professor Zen-ichiro Kuri of Nagoya University for his encouragement.

The d→d Absorption Spectra of Potassium Tris(8-quinolinolato)-nickelate(II) in Methanol-Chloroform Mixtures

Yoshinori YAMAMOTO

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi

(Received July 4, 1972)

The d→d absorption spectra of $K[NiQ_3]\cdot EtOH$,[1] which was prepared in our laboratory, in MeOH–$CHCl_3$ mixtures have been observed to vary greatly with the change in the ratio of the volume of $CHCl_3$ to that of MeOH. Such a large change in the spectrum cannot be attributed to normal solvent effects, in view of the fact that the absorption spectra of $Al(III)Q_3$ or $Fe(III)Q_3$ in various pure and mixed solvents are practically the same.[2]

In the present study, this spectral change was examined with the intention of exploring the basis for this change.

Results and Discussion

The spectra of $K[NiQ_3]\cdot EtOH$ in MeOH and MeOH–$CHCl_3$ mixtures are shown in Fig. 1.[3] The presence of the isosbestic points in Fig. 1 indicates that two species coexist at equilibrium and that normal solvent effects are negligibly small. The plot of the absorbance at 950 nm *vs.* the vol% of $CHCl_3$ shown in Fig. 2 indicates that the complex exists predominantly in one form (Species A) in MeOH, and in another form (B) in 80 vol% or more of $CHCl_3$. The absorption data summarized in Table 1, compared[4] with

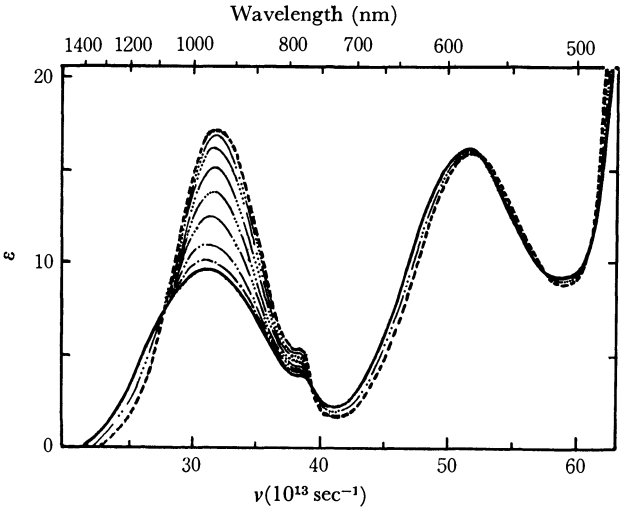

Fig. 1. Absorption spectra of $K[NiQ_3]\cdot EtOH$ in MeOH–$CHCl_3$ mixture. Concentration of the complex, $1.21_8\times 10^{-2}$M. Vol% of $CHCl_3$: ——, 0; —·—, 10; —··—, 20; —···—, 30; —····—, 40; —·····—, 50; —·····—, 60; —·····—, 70; ————, 80%.

that[5] of $K[Ni(gly)_3]$, suggest that both species, A and B, are six-coordinated (3 O and 3 N atoms of three 8-quinolinolate ligands) complexes.

As is shown in Table 1, with the change from A to B the second band shows little change in either intensity or the position, while the first band shows a small blue shift and a significant increase in intensity. This trend of the spectral change shows a striking resemblance to that of the spectral changes attended by the steric changes from the *mer*-$[Co(O,N)_3]$ complexes to the *fac* isomers, which are described in the literature.[6] In DMSO the configuration of MQ_3, where M is Al(III), Co(III), or Rh(III), has been reported by Baker and Sawyer to be a *mer* structure.[7] The same configuration can be expected for the NiQ_3^- ion in MeOH. These facts suggest that the A species has a *mer* structure and that, accordingly, B has a *fac* structure.

The conversion to the *fac* form from the *mer* form may be explained in terms of the ion-pair formation. It is well known that, in the $[Co(en)_2Cl_2]^+$ system, in various dipolar solvents the ratio of the concentration of the *cis* and *trans* ions varies with the chloride-ion concentration, since the dipolar *cis* ion is stabilized by the ion-pair formation.[8] The *fac*-NiQ_3^-, whose three

c) This work.

anionic O atoms are concentrated around the c_3 axis, is expected to have a larger net dipole moment than the *mer* ion, and the formation of the ion pair K^+, NiQ_3^- in MeOH–$CHCl_3$ mixtures with dielectric constants lower than that of MeOH may not be negligible.

Experimental

Reagents and Solvents. All the chemicals used were of a guaranteed reagent quality. The solvents were from freshly-opened bottles of a G. R. quality.[9]

Preparation of Potassium Tris(8-quinolinolato)nickelate(II) Monoethanolate, $K[Ni(C_9H_6ON)_3]\cdot(C_2H_6O)$. A 10.0 g portion of KOH(86%) was suspended (almost dissolved) in 70 ml of EtOH, and the supernatant solution was added to 70 ml of EtOH containing 12.0 g of 8-quinolinol (0.083 mol),[10] after which the mixture was filtered out through a filter paper. To this filtrate, warmed about 70°C, a hot solution of 4.0 g of nickel(II) acetate tetrahydrate (0.016 mol) in 100 ml of EtOH was slowly added without stirring; the resultant clear, deep green, mixed solution was allowed to stand for two days. The fine, deep green crystals obtained were washed with EtOH several times, and dried at room temperature *in vacuo*. The yield, based on the nickel acetate, was 90% (8.3 g).

Found: C, 59.64; H, 4.06; N, 7.39; Q^-, 74.7%. Calcd: C, 60.44; H, 4.20; N, 7.29; Q^-, 75.0%.

The solvent of crystallization (EtOH) was released by heating at 175°C for 6 hr: the complex decomposed slightly. (Found: 8.07%. Calcd: 7.99%).

The complex was recrystallized from MeOH by adding ethanolic KOH, but it was sufficiently pure without recrystallization.

Measurement of Absorption Spectra. A 5.00 ml volume of the $6.09_1\times10^{-2}$M $K[NiQ_3]\cdot EtOH$ methanolic solution and an appropriate volume of $CHCl_3$ were placed in each of a series of 25 ml volumetric flasks, and then each solution was diluted to the mark with MeOH. Each reference solution, containing all the components except the complex, was prepared in a similar manner. After one hour's standing after the initial mixing, each solution was placed in a 1 cm quartz cell and its components determined by means of a Shimadzu MPS-50L spectrophotometer, the transmittance being read at room temperature. No spectral change with time was observed after one day's standing.

Other Systems. In a manner similar to that in the case of $CHCl_3$, the spectra of $K[NiQ_3]\cdot EtOH$–MeOH–S systems, where S is benzene, dioxane, diethyl ether, acetone, EtOH, KBr, KI, CH_3COOK, KOH, NaOH, *etc.*, were examined. In all cases, the shape of the maximum near 950 nm varied from a rounded hump for the complex–MeOH system to a sharp peak in the presence of S. In the present study, $CHCl_3$ as S was chosen for its greater ability to vary the spectra and for the higher solubility of the complex in this system, though the complex is scarcely soluble in pure $CHCl_3$.

The spectra of the complex–MeOH–KOH system are shown in Fig. 3.

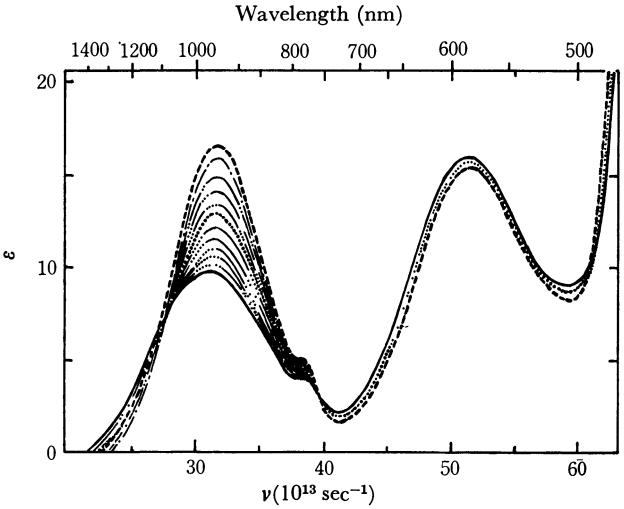

Fig. 3. Absorption spectra of $K[NiQ_3]\cdot EtOH$ in MeOH containing varying amounts of KOH. Concentration of the complex, $1.21_8\times10^{-2}$M. Concentrations of KOH: ——, 0; —·····—, 1.84×10^{-2}; —·····—, 3.68×10^{-2}; —·····—, 9.20×10^{-2}; —·····—, 1.47×10^{-1}; —·····——, 2.30×10^{-1}; ·····3.68×10^{-1}; —···—, 5.52×10^{-1}; —···—, 9.20×10^{-1}; —··—, 1.47; —·—, 2.30; ------, 3.68M.

The author is indebted to Professor Shinsuke Takei of Ibaraki University for his useful suggestions and encouragement.

9) $KNiQ_3$ in the commercially obtained dehydrated MeOH gave an identical spectrum with that of G. R. MeOH solution.
10) Experimentally, excess KOH and HQ gave fine crystals.

The Reductive Coupling Reactions of Some Chloromethylbenzene Derivatives with Iron(II) Complexes. II. Reduction by Anhydrous Iron(II) Chloride and Lithium Chloroferrate(II)

Kazuhiko ONUMA, Junzo YAMASHITA,* and Harukichi HASHIMOTO*

Department of Synthetic Chemistry, The University of Tokyo, Bunkyo-ku, Tokyo
**Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai*

(Received March 7, 1972)

Previously we reported[1] that ferrous chloride tetrahydrate reduces polyhalomethylbenzene derivatives to give coupling products.[2] Though some chelating ligands such as ethylenediamine can increase the yield of coupling products considerably,[1] hydrolysis by the water of crystallization or solvolysis by the ethanol solvent of the organic halides is unavoidable in these reactions, and this limits, in some cases, the synthetic usefulness of this reaction.[1,2]

To inhibit the side reactions, therefore, we prepared anhydrous ferrous chloride and lithium chloroferrate(II)—$LiFe^{II}Cl_3$—in acetonitrile as will be described in the Experimental Section[3] and investigated the reaction with organic halides.

TABLE 1. REDUCTIVE COUPLING OF BENZOTRICHLORIDE BY FERROUS CHLORIDE AND LITHIUM CHLOROFERRATE(II) IN ACETONITRILE

$FeCl_2$: 1.0×10^{-2} mol, $LiFeCl_3$: 2.0×10^{-2} mol, CH_3CN: 60 ml

Fe(II)	$PhCCl_3$: Fe	Temp. °C	Time hr	Product[a] (%) $PhCCl_2$-CCl_2Ph	Product[a] (%) $PhCCl$=$CClPh$
$FeCl_2$	1:1	80	5	51	—
	1:2	80	5	77	—
$LiFeCl_3$	1:1	50	5	74	—
	1:2	80	4	—	87[b]

a) Yield based on $PhCCl_3$ used.
b) Isomer ratio is *trans*: *cis*=33: 67.

TABLE 2. REDUCTIVE COUPLING OF DIPHENYLDICHLOROMETHANE BY FERROUS SALTS

$FeCl_2$: 1.0×10^{-2} mol, $LiFeCl_3$: 2.0×10^{-2} mol, CH_3CN: 60 ml

Fe(II)	Ph_2CCl_2: Fe	temp. °C	time hr	Product[a] (%) Ph_2CCl-$CClPh_2$	Product[a] (%) Ph_2C=CPh_2
$FeCl_2$	1:1	20	22	51[b]	—
	1:2	80	5	—	64[b]
$LiFeCl_3$	1:2	80	4	—	93

a) Yield based on Ph_2CCl_2 used.
b) Benzophenone and unreacted diphenyldichloromethane were recovered. The former is the product by hydrolysis of the latter during the after-treatment of the reaction mixture.

TABLE 3. REDUCTIVE COUPLING OF BENZAL CHLORIDE BY FERROUS SALTS

$FeCl_2$: 1.0×10^{-2} mol, $LiFeCl_3$: 2.0×10^{-2} mol, CH_3CN: 60 ml

Fe(II)	$PhCHCl_2$: Fe	Temp. °C	Time hr	product[a] (%) PhCHCl-CHClPh	product[a] (%) *trans*-PhCH=CHPh
$FeCl_2$	1:1	80	4	3[b]	6[c]
	1:2	80	24	—	28[c]
$LiFeCl_3$	1:1	30	24	5[b]	6[c]
	1:2	80	7	—	81

a) Yield based on $PhCHCl_2$ used.
b) *meso*-Isomer.
c) Benzaldehyde and unreacted benzal chloride were recovered. See the footnote b) in Table 2.

The results are tabulated in Tables 1—3. We wish to point out that reductive coupling products are obtainable in good yields without any competing side reactions. The use of the anhydrous salt is evidently superior to the use of the tetrahydrate; in the latter case, some additives are needed for good results.[1] In addition, anhydrous lithium chloroferrate(II) has been revealed to be the more powerful reductant. Thus, tolan tetrachloride is obtained from benzotrichloride by $FeCl_2$, but if $LiFeCl_3$ is employed (Fe(II)/$PhCCl_3\geq2$), benzotrichloride is further reduced to tolan dichloride, with a shorter reaction time than the $FeCl_2\cdot4H_2O$–DMSO system.[2]

Tetraphenylethylene is generally attained from diphenyldichloromethane by the use of ferrous salt under ordinary conditions (Table 2), and tetraphenyldichloroethane has been thought to be formed only intermediately. Reaction at a low temperature with $FeCl_2$, however, gave tetraphenyldichloroethane in a considerable yield.[4] Thus, it is seen that the highly selective reductive coupling of benzotrichloride and of diphenyldichloromethane is possible by the use of $FeCl_2$ or $LiFeCl_3$ in acetonitrile.

As may be seen in Table 3, the attempt to obtain stilbene dichloride from benzal chloride in a good yield failed (only 3% by $FeCl_2$ and 5% by $LiFeCl_3$). However, *trans*-stilbene was obtained in a high yield by employing $LiFeCl_3$ as the reductant. It should be

1) K. Onuma, J. Yamashita, and H. Hashimoto, This Bulletin, **43**, 836 (1970).
2) Similar results were reported in T. Shirafuji, Y. Yamamoto, and H. Nozaki, *ibid.*, **44**, 1994 (1971).
3) M. Asscher and D. Vofsi, *J. Chem. Soc., B*, **1968**, 947.
4) This attempt failed in previous studies because of the hydrolysis of the organic halide by the water of crystallization in $FeCl_2\cdot4H_2O$. The $FeCl_2\cdot4H_2O$–DMSO system gave also tetraphenyldichloroethane in a good yield at a low temperature with a smaller $FeCl_2\cdot4H_2O/Ph_2CCl_2$ mole ratio.[2]

noted that the $FeCl_2 \cdot 4H_2O$–CH_3CN[1] or –DMSO system[2] failed to obtain *trans*-stilbene from benzal chloride. All these reductions are thought to proceed step by step as follows;

$$Ph(R)CCl_2 \xrightarrow{2Fe(II)} Ph(R)CCl\text{–}CCl(R)Ph \xrightarrow{2Fe(II)} Ph(R)C{=}C(R)Ph$$

(R=Ph, Cl, H)

The reduction of benzyl chloride by $LiFeCl_3$ was also attempted, but only 4% of bibenzyl resulted. Benzyl bromide was converted to benzyl chloride under the same conditions.

As may be seen, the reactivity of lithium chloroferrate(II) is obviously superior to that of ferrous chloride. This may be partly due to the fact that $FeCl_4^-$ ion is very stable in acetonitrile.[5]

Experimental

Materials. The anhydrous ferric chloride and iron powder were used directly. The benzotrichloride, benzal chloride, benzyl chloride, and diphenyldichloromethane were distilled under reduced pressure and then used. The purification of acetonitrile was done in the following manner: it was distilled first from potassium permanganate and sodium carbonate, second from phosphorous pentoxide, and at last carefully under nitrogen from calcium hydride after reflux. The lithium chloride was dehydrated *in vacuo* at 150°C for several days.

Preparation of the Ferrous Solution. To a solution of anhydrous ferric chloride (2.6 g) and, if necessary, lithium chloride (1.02 g) in acetonitrile (70 ml), iron powder (1.8 g) was added under an atmosphere of nitrogen according to the Asscher and Vofsi method.[3] After standing for several hours, the solution was filtered and introduced into the reaction vessel. The concentration of the solution was determined by ceric titration just before the reaction. The concentration of chloride ions in the lithium chloroferrate solution was determined by Volhard's method. The $FeCl_2$ solution is almost colorless or slightly yellow, and the $LiFeCl_3$ solution is faintly violet. As these iron salts are very sensitive to air, they should be treated carefully in a nitrogen atmosphere.

Reaction Procedure. In a four-necked, 100 ml flask equipped with a nitrogen inlet, a thermometer, a magnetic stirrer, and a condenser, a 60 ml portion of a ferrous solution was introduced ($FeCl_2 = 1 \times 10^{-2}$: $LiFeCl_3 = 2 \times 10^{-2}$ mol/l): the reaction was then initiated by adding organic halide at the required temperature under nitrogen. After the completion to the reaction, 150 ml of water was poured in and then extracted with benzene. The benzene solution was then condensed, and the coupling products were isolated. The resinous by-products were removed through column chromatography (300 mesh alumina). All the products were recrystallized and identified by mp, IR NMR, and elemental analysis.[1]

Mixture of *cis*- and *trans*-tolan dichloride were separated by means of the difference in their solubility to alcohol, and the separated isomers were again recrystallized from alcohol. The melting point of the *trans* isomer is 145.0—146.0°C, while that of the *cis* isomer is 59.0—62.0°C. The melting point of tetraphenyldichloroethane is 161—167°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 335—336 (1973)

A Fluorescence Study of a β-Structural 1-Dimethylamino-naphthalene-5-sulfonyl Poly-L-lysine Conjugate

Takayoshi Iio

Department of Physics, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received May 31, 1972)

An α-helical poly-L-lysine (PLy) is irreversibly transformed in its conformation to a β-structure when the temperature of the solution is raised to 50°C.[1] It is agreed that the β-structure is stabilized by the hydrophobic bond between the side chains in addition to the hydrogen bond between the main-chain peptide groups. The intensity of the observed emission light of the 1-dimethylaminonaphthalene-5-sulfonate (DNS) bound to PLy is increased as the conformation of the DNS–PLy conjugate is changed from the α-helix to the β-structure (Fig. 1). On the other hand, the optical

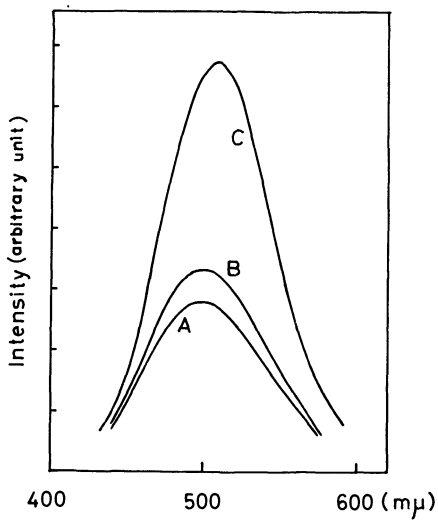

Fig. 1. Observed emission spectra of DNS-PLy conjugate in 0.01N KCl solutions at 20°C. Wavelength of excitation light was 350 mμ. A: Random coil (pH 5.8), B: α-Helix (pH 12.4), C: β-Structure (after heating the α-helical solution at 50°C for 30 min, then cooled to 20°C).

density of the conjugate at the wavelength of the excitation light scarcely changes during the conformational transition. The increase in the relative fluorescence intensity in the β-structural conjugate may be a reflection of the change in the environment around the DNS group. The DNS group may come in contact with the solvent molecules in the case of the α-helix; on the other hand, it may be incorporated in the hydrophobic region and surrounded by the hydrophobic residues when the conjugate takes the β-structure. As a support to this conclusion, we can offer the fact that the quantum yield of DNS is increased from 0.29 to 0.71 when the solvent is changed from water to *n*-butanol at 20°C.[2]

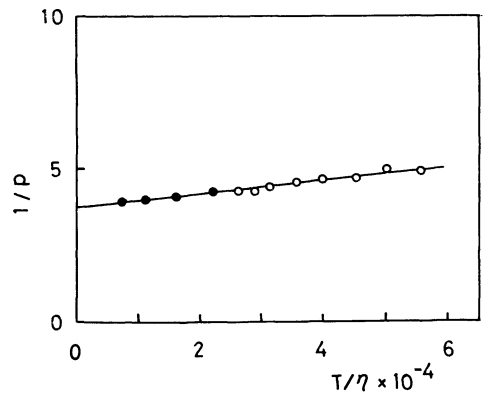

Fig. 2. Depolarization curve of β-structural DNS-PLy conjugate in 0.01N KCl (open circles) and in mixture of water and glycerine containing 0.01N KCl at 20°C (filled circles). Wavelength of excitation light and that of emission light were 350 mμ and 500 mμ, respectively.

We desire to obtain information on the rotational motion of the DNS group which is incorporated into the hydrophobic region. This information can be obtained from the depolarization curve[3,4] of the β-structural conjugate (Fig. 2). The isothermal plot (filled circle) and the heating plot (open circle) give the same straight line. From this plot, we can obtain the rotational relaxation time (ρ_h) at a particular temperature (T) of the DNS group bound to the β-structural PLy according to Eq. (1);

$$\rho_h = \left(\frac{1}{p_0} - \frac{1}{3}\right) \cdot \frac{3\tau}{\text{the slope}} \cdot \left(\frac{\eta}{T}\right)_T \qquad (1)$$

where p_0 is an intrinsic polarization, τ is the lifetime of the lowest excited state of the DNS group, and η is the viscosity of the solvent. The τ value is proportional to the relative fluorescence intensity,[5] so the τ value is obtained according to Eq. (2);

$$\tau_\beta = \tau_{coil} \cdot \frac{F_\beta}{F_{coil}} \cdot \frac{OD_{coil}}{OD_\beta} \qquad (2)$$

where F is the fluorescence intensity and OD is the optical density of the conjugate at the wavelength of the excitation light. The magnitude of F is calculated as follows: the corrected emission spectra which is obtained by calibrating the observed emission spectra (Fig. 1) for the detector system is plotted on graph paper, and the magnitude of F is determined by calculating the area beneath the curve. As the τ_{coil} value, we adopt 1.2×10^{-8} sec, this value is an average

of the measurements of three different DNS-protein conjugates in the neutral pH region.[6] The τ value for the β-structural conjugate is determined as 2.7×10^{-8} sec. Then we obtained $\rho_h=38.2\times10^{-8}$ sec for the β-structural conjugate at 20°C; this value is larger than that of the conjugate in the other conformations (see Ref. 7). The large value of ρ_h means that the rotational motion of the DNS group in the β-structural conjugate is extremely suppressed. The value of $\rho_h=38.2\times10^{-8}$ sec corresponds to the rotational relaxation time of a sphere with a radius of 50 Å, showing that the DNS group is incorporated in a very large β-structural region.

In the course of this experiment, we found a very interesting fact: the $1/p$ value of the β-structural conjugate do not depend on the wavelength of the excitation light (λ^{ex}). On the contrary, the $1/p$ values of the conjugate in the other conformations depend on the λ^{ex} value (Fig. 3). The DNS-protein conjugates show the same $1/p-\lambda^{ex}$ relationship as do the α-helical and random coiled conjugates.[8] The reason for these results is unknown at this stage; we wish to leave it for future investigation.

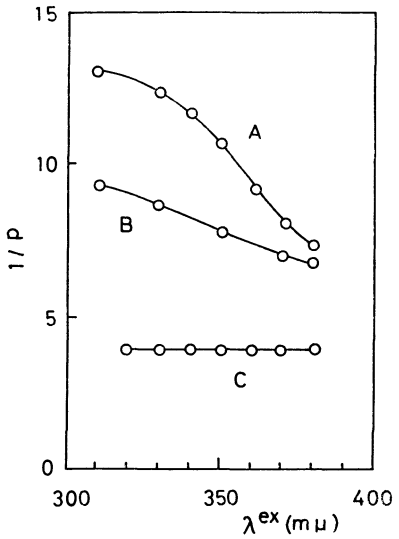

Fig. 3. Effect of wavelength of excitation light (λ^{ex}) on degree of polarization (p) of 500 mμ emission light in DNS-PLy conjugate. Measurements were performed in 0.01N KCl at 20°C. Slit width for excitation light was 6 mμ. Marks are the same as Fig. 1.

Experimental

DNS-Cl was bound to PLy (molecular weight, 30000) according to the method reported by Weber.[9] The molar ratio of the bound DNS to the L-lysyl residue was 1:48.5. All the fluorescence measurements were performed in a concentration of 3.5×10^{-6} mmol of DNS per ml. The fluorescence spectra and polarization of fluorescence were measured with a grating-type Hitachi Fluorescence Spectrophotometer MPF-2A. The degree of polarization (p) was calculated according to Eq. (3):

$$P=\frac{I_{vv}-GI_{hv}}{I_{vv}+GI_{hv}} \tag{3}$$

where I_{vv} and I_{hv} are, respectively the fluorescence intensity of vertically-polarized light and that of horizontally-polarized light when the solution is excited with vertically-polarized light, and where $G=I_{vh}/I_{hh}$ is a correction factor which is needed when the P value is measured using a grating-type fluorometer; here I_{vh} and I_{hh} are, respectively the fluorescence intensity of vertically-polarized light and that of horizontally-polarized light when the solution is excited with horizontally-polarized light. The depolarization curve was obtained by plotting the reciprocal of the polarization of the fluorescence ($1/p$) as a function of the temperature divided by viscosity (T/η in degree·poise^{-1}).

The author wishes to express very many thanks to Dr. K. Mihashi, and Dr. Y. Kawasaki (Nagoya University) and to Dr. S. Takahashi (Kyoto University) for their encouragement and discussions.

The Synthetic Reactions of Aliphatic Nitro Compounds. VII.[1] The Synthesis of α-Amino Acids from the Nitroacetic Ester[2]

Eisuke KAJI and Shonosuke ZEN

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo

(Received February 14, 1972)

As a short communication,[3] we previously reported the synthesis of DL-aspartic acid and DL-glutamic acid *via* the *C*-alkylation of nitroacetate[4] with halo esters. In this investigation, several neutral and basic amino acids were prepared by the same procedure.

Method (i), $R^1X + NaO_2N{=}CHCO_2Me$

Method (ii), $R^1X + O_2NCH_2CO_2Me + CHO_3Na$

$\xrightarrow{-NaX}$ $R^1{\cdot}CHR^2CO_2R^3$ **1**: $R^2{=}NO_2$; $R^3{=}CH_3$ **2**: $R^2{=}NH_2$; $R^3{=}CH_3$ **3**: $R^2{=}NH_2$; $R^3{=}H$

Chart 1.

This procedure is carried out by the reaction of the halides either with the sodium salt of nitroacetate (Method i) or with nitroacetate and sodium methylate (Method ii) in dipolar aprotic solvents, as is shown in Chart 1. When methyl bromoacetate, methyl β-bromopropionate, methyl iodide, isopropyl iodide, benzyl bromide, *N*-(β-iodoethyl)-phthalimide, *N*-(γ-iodopropyl)-phthalimide, and *N*-(δ-iodobutyl)-phthalimide were used as the halogeno compounds in the above reaction, dimethyl nitrosuccinate[3] (**1a**), dimethyl α-nitroglutarate[3] (**1b**), methyl α-nitropropionate[2] (**1c**), methyl α-nitroisovalerate[2,11] (**1d**), methyl α-nitro-β-phenylpropionate[2] (**1e**), methyl α-nitro-γ-phthalimidobutyrate (**1f**), methyl α-nitro-δ-phthalimidovalerate (**1g**), and methyl α-nitro-ε-phthalimidocaproate (**1h**) respectively resulted as the corresponding *C*-alkylated products. They could be obtained as crystalline diethylammonium or ammonium salts.

Furthermore, by the catalytic hydrogenation of the nitroesters (**1**) and the subsequent hydrolysis of the corresponding amino esters (**2**), DL-aspartic acid (**3a**), DL-glutamic acid (**3b**), DL-alanine (**3c**), DL-valine (**3d**), DL-phenylalanine (**3e**), DL-α,γ-diaminobutyric acid (**3f**), DL-ornithine (**3g**), and DL-lysine (**3h**) were obtained. These results are summarized in Tables 1 and 2.

Only when bromoacetate and sodium salt of nitroacetate were used was trimethyl β-nitrotricarballylate obtained as a by-product (in a 16.4% yield) in addition to the expected product, **1a**.

It has been found that the *C*-alkylation reaction of nitroacetate with the halides takes place only in dipolar aprotic solvents, as is shown in Table 3. As for the influence of the variation in halogen atoms, the reaction is found to be promoted in the order of I>Br>Cl.

All new compounds reported above (in Table 2) gave satisfactory results in C, H, and N analyses.

Table 3. Solvent effect on the yields of dimethyl α-nitrosuccinate (**1a**)

Solvent	Yield (%) of **1a**
Ethanol, methyl acetate, or dioxane	0
N-Methylacetamide	30
Dimethylformamide	57
Dimethylacetamide	66
Dimethyl Sulfoxide	55
Hexamethylphosphoramide	51

Experimental

Dimethyl α-Nitrosuccinate[5] *(**1a**) (A Typical Example of the General Procedure).* Method (i): Sodium salt of methyl nitroacetate (2.0 g, 14.2 mmol) was added to a solution of methyl bromoacetate (2.17 g, 14.2 mmol) in 50 ml of dimethylacetamide. This suspension was stirred overnight at room temperature. The reaction mixture was then added to 150 ml of water and extracted with benzene. The extract was concentrated, and the resultant syrup was subjected to fractional distillation under reduced pressure to give **1a** (0.63 g) in a 23% yield; IR (liquid film): 1745 (ester CO), 1565 and 1380 (C–NO_2) cm^{-1}, UV: λ_{max}^{MeOH} 275 mμ (ε 290). When the product was allowed to stand, a crystalline trimethyl β-nitrotricarballylate separated. Colorless prismatic crystals (0.30 g) were collected; 16.4% yield; mp 88.5—89.5°C (from ether–isopropyl ether); IR (KBr): 1730 (ester CO), 1560 and 1370 (C–NO_2) cm^{-1}; UV: λ_{max}^{MeOH} 283 mμ (ε 36). Found: C, 40.60; H, 4.68; N, 5.20%. Calcd for $C_9H_{13}NO_8$: C, 41.06; H, 4.94; N, 5.32%. An equimolar mixture of diethylamine and **1a** gave a diethylammonium salt of **1a** as a solid. Recrystallization from ethanol–ether gave needles; mp 103—104°C. Found: C, 44.90; H, 7.50; N, 10.11%.
Calcd for $C_{10}H_{20}N_2O_6$: C, 45.45; H, 7.58; N, 10.61%.

Method (ii): Sodium methylate (1.03N, 22.8 ml) in methanol was added to a solution of 3.1 g (26.1 mmol) of methyl nitroacetate and 4.0 g (26.1 mmol) of methyl bromoacetate in dimethylacetamide (100 ml). The mixture was stirred overnight at room temperature. The reaction mixture was then treated in a manner similar to that described in Method (i) to give a yellow syrup. After distillation, 3.3 g of **1a** were obtained. Yield, 66%.

*Amino Esters (A Typical Procedure for the Catalytic Reduction of α-Nitroesters, **1a**—**h**).* A solution of **1a** (1.0 g, 5.24 mmol) in methanol (50 ml) was hydrogenated for 1 hr with 2 ml of the Raney Nickel T-1[6] catalyst at room temperature under 40—50 *psi* of hydrogen in a Parr low-pressure hydrogenator.[7] The filtrate from the nickel was evaporated *in vacuo* to dryness to give the product (**2a**, 0.17 g) in a 90% yield. The amino esters, **2a**—**h**, were prepared by the same procedure, **1a**—**e** were thus proved to be identical with the authentic samples prepared by the esterification of the corresponding standard DL-amino acids.

α-Amino Acids (A Typical Procedure for the Hydrolysis of the Amino Esters). A mixture of 200 mg of **2a** and 6 ml of 6N hydrochloric acid was heated in a sealed tube at 110°C for about 16 hr (or under reflux for about 16 hr). The solution was then evaporated to dryness, and the residual syrup was washed with ether and acetone to obtain a colorless powder of the HCl salt of DL-aspartic acid (**3a**) in a 94% yield. This product was found to be identical with the authentic sample in its melting point, the result of elementary analysis, the IR, the R_f value, and in the corresponding *N*-2,4-dinitrophenyl derivative[8]. **3b**—**h** were prepared in the same way as **3a** from the corresponding aminoesters (**2b**—**h**).[9] The results are shown in Table 1.

The authors wish to thank Misses Keiko Yuhki and Kazuko Shibuya and Mr. Kotaro Uchida for their technical assistance.

Reaction of Troponoid with Ylide. IV.[1] A Conversion of Tropone into Cyclooctatrienone

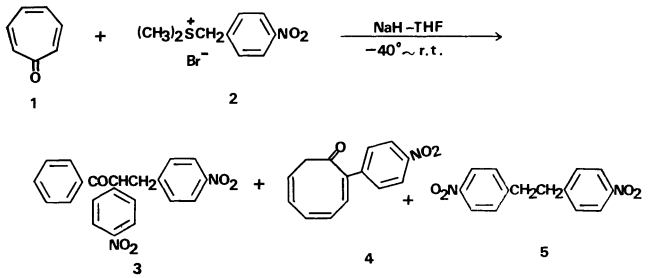
Yukio SUGIMURA, Nobuo SOMA, and Yukichi KISHIDA
Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo

(Received March 13, 1972)

We have studied the reaction of tropone with various ylides and found a convenient one-step synthesis of 2,3-homotropones by the reaction of tropone with stable sulfonium ylide.[2] It has been reported that benzylsulfonium ylide is stable in solution at −70°C under a nitrogen atmosphere, but when treated with sodium hydroxide at 60°C, in an aqueous medium *p*-nitrobenzyldimethylsulfonium tosylate, it is converted quantitatively into a mixture of *cis* and *trans*-4,4′-dinitrostilbene.[3]

We attempted the reaction of tropone with *p*-nitrobenzyldimethylsulfonium bromide pretreated with sodium hydride at −40°C for five minutes, and obtained the products 2,3-di-*p*-nitrophenylpropiophenone (**3**, 44%), 2-*p*-nitrophenylcycloocta-2,4,6-trien-1-one (**4**, 6%), and 4,4′-dinitrodibenzyl[4] (**5**, 34%). The structural assignments of **3** and **4** were given by spectroscopic data. **3**: mp 110°C, $C_{21}H_{16}O_5N_2$ (elemental analysis and high resolution mass spectrum); IR: $\nu_{C=O}$ (Nujol) 1680 cm^{-1}; NMR (in $CDCl_3$, δ ppm): 3.20 (1H, d of d, J=14.0 and 7.5 Hz), 3.70 (1H, d of d, J=14.0 and 7.5 Hz), 5.02 (1H, t, J=7.5 Hz), 7.2—7.6 (7H, m), 7.8—8.2 (6H, m). **4**: pale yellow oil, $C_{14}H_{11}O_3N$ (elemental analysis and mass spectrum); IR: $\nu_{C=O}$ (liquid) 1660 cm^{-1}; NMR and NMDR (in $CDCl_3$, δ ppm, Fig. 1): 3.20 (2H, d, J=8.3 Hz, H-8). 5.87 (t of d, J=8.3 and 10 Hz, H-7), 6.46 (d of d of d, J=10, 4.5 and 2.0 Hz, H-6), 6.48 (d of d of d, J=12.0, 7.5 and 2.0 Hz, H-4), 6.71 (d of d, J=12.0 and 4.5 Hz, H-5), 7.03 (d of d, J=7.5 and 1.0 Hz, H-3), 7.45 (2H, A_2B_2), 8.13 (2H, A_2B_2).

A plausible mechanistic path for the formation of **3** and **4** is shown in Fig. 2. From the reaction of tropone with stable sulfur ylide[2] whose carbanion attacked the 2-position of tropone to give homotropone,



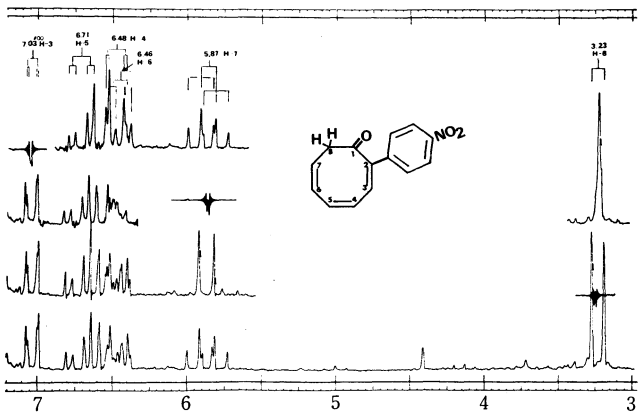


Fig. 1. NMR and NMDR of eight-membered ring protons of 2-*p*-Nitrophenylcycloocta-2,4,6-trien-1-one (**4**).

it is considered that the carbanion of the benzylsulfonium ylide attacked the 1-position of tropone. The ring enlargement of tropone to cyclooctatrienone in the reaction of tropone with diazoalkane has been reported by Franck-Neumann,[5] but the reaction proceeded *via* cycloaddition to the 2-, 3-positions of tropone (Δ^1-pyrazoline). For our present reaction, an intermediacy of carbene would be denied, because dinitrostilbene was not isolated and the isolation of the dibenzyl, **5**, suggests an intervention of radical mechanism.[6]

Chloroform eluate: 3.16 g of the starting tropone.

We are grateful to Prof. T. Nozoe for his helpful discussion.

X-Ray Photoelectron Spectroscopic Study for the Reaction of Evaporated Iron with O_2 and H_2O

Kosaku KISHI and Shigero IKEDA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received February 1, 1972)

Reactions of evaporated iron with O_2 and H_2O have been investigated by X-ray photoelectron spectroscopy. Binding energies of $Fe2p_{3/2}$ and Ols electrons were measured during the course of reactions and their variation was discussed in terms of the positive and negative charges of the iron and oxygen of the surface oxide formed, respectively, assuming a simple charge-chemical shift relation. They are compared with the binding energies of the Ols in SiO_2, Al_2O_3, Fe_2O_3, $Cd(OH)_2$, KOH, and $Ni(OH)_2$ and those of $Fe2p_{3/2}$ in various iron compounds. High reactivity of the surface oxide with H_2O and the resulting hydroxyl group formation were observed. A rough estimation of the Fe to O atomic ratio of the surface oxide was also carried out from the ratio of the Fe and O peak areas.

Dissolution and corrosive reactions of metals are largely influenced by the presence of oxygen. In our UV absorption study[1] for acetylacetone adsorption on oxygen-treated metals, two or more chemical states have been observed for the oxygen on the metal surfaces.

X-Ray photoelectron spectroscopy,[2] giving information on the surface and semisurface of solids, seems to be useful for studying the variation in the charge of the atom in question and in the valence band during the course of surface reaction. Application of the spectroscopy for catalysis research has been reviewed recently.[3]

Two kinds of oxygen were observed for the surface oxide of nickel by X-ray photoelectron spectroscopy.[4] We report here on variations in the $2p_{3/2}$ binding energy of iron and the ls of oxygen in an evaporated iron exposed to O_2 and H_2O. The core binding energy shifts were correlated to the charges of the atoms and compared with those of metal oxides, hydroxide and various iron compounds in order to investigate the chemical states and reactivity of the surface oxide.

Experimental

The apparatus for metal evaporation and reaction is illustrated in Fig. 1. Chamber (g) was evacuated for several hours at 10^{-6} Torr. The thin iron foil wound by tungsten filament (f) was then degassed by heating electrically and the metal was finally evaporated on copper plate (a). The iron sample was inserted (within 1 min) into chamber (c) for photoelectron measurement through a gate valve (d) without exposing the sample to air by use of rubber O-ring (e). The vacuum of (c) was 10^{-7} Torr. After recording the spectrum for the metal, the sample was pulled out to the reaction chamber and exposed to the gases to be studied. The sample plate was again inserted for spectral measurement on the surface species obtained.

Photoelectron spectra were measured with 0.1 eV step scan on a KEC-X2000 (Kokusai Electric Co.) electron

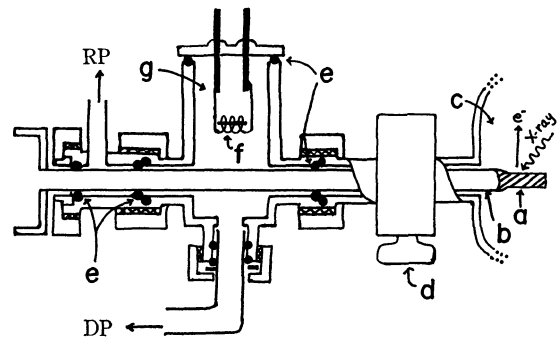

Fig. 1. Diagram of reaction chamber. (a): sample holder, (b): sample shaft, (c): photoemission chamber, (d): gate valve, (e): rubber O-ring, (f): tungsten filament, (g): reaction chamber.

spectrometer using $AlK\alpha_{1,2}$ X-ray line as an excitation source. The reproducibility of $Fe2p_{3/2}$ and Ols peak positions was within 0.2 eV.

Water was distilled and degassed in a vacuum. Commercial oxygen was led into a vacuum system and was dried with liquid nitrogen cooled trap. The purity of iron was 99.99%.

SiO_2(Mallinckrodt Chemical Works) and Al_2O_3(alumina activated for chromatography, Nakarai Pure Chemicals) were heated in a crucible at 600°C for 2 hr and after being left standing for 15 hr in the air, their photoelectron spectra were measured for the powder sample pressed on an adhesive aluminum tape. Fe_2O_3 was obtained in two ways, by heating ferric oxalate in a crucible at 500°C for 5 hr or at 700°C for 3 hr. $Ni(OH)_2$ and $Cd(OH)_2$ were produced by the reaction of $Ni(NO_3)_2$ and $CdCl_2$, respectively, with aq. KOH solution. Photoelectron spectra of $K_4Fe(CN)_6$, $K_3Fe(CN)_6$, $Fe_2(SO_4)_3(NH_4)_2SO_4 \cdot 24H_2O$, and KOH(Nakarai Pure Chemicals) were measured in powder without further purification.

Results

The $Fe2p_{3/2}$ and Ols photoelectron lines from the evaporated iron exposed to O_2 are shown in Fig. 2. Binding energies have been calculated using the value of 285.0 eV for Cls line of a contaminant observed in the background spectrum of evaporated fresh iron. For the fresh iron, the $Fe2p_{3/2}$ peak is located at 708.2 eV and the Ols at 532.4 and 530.6 eV (case a). The metal was then exposed to O_2 in succession (b, 0.01

a) The intensities are obtained from the respective peak areas and normalized with respect to the area of $Fe2p_{3/2}$ in fresh iron (100).
b) Chemical shifts from genuine Fe are given in parentheses.

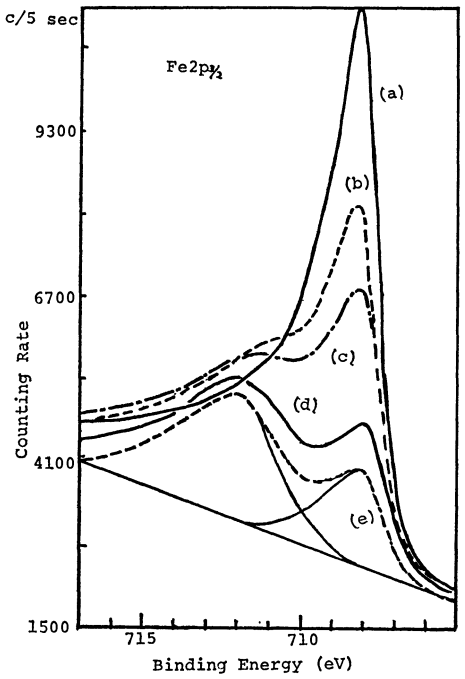

Fig. 2-(i). $Fe2p_{3/2}$ photoelectron lines from evaporated iron exposed to O_2 in succession. (a): fresh iron, (b): 0.01 Torr O_2; 1 min, (c): 0.5 Torr; 1 min, (d): 10 Torr; 5 min, (e): 100 Torr; 30 min.

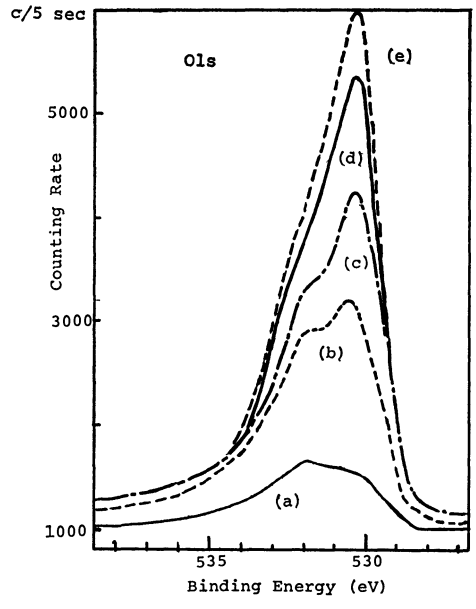

Fig. 2-(ii). Ols photoelectron lines from evaporated iron exposed to O_2 in succession.

Torr, 1 min; c, 0.5 Torr, 1 min; d, 10 Torr, 5 min; e, 100 Torr, 30 min). The genuine Fe peak was depressed and another peak appeared at high energy side. The chemical shift of this peak from the genuine one varied from +3.2 eV in case b to +4.0 eV in case e. With O peak, two peaks were observed and the low energy one increased mainly in intensity after oxidation, showing no shift in binding energy. These results of chemical shift and intensity are summarized in Table 1, with the corresponding chemical shifts

of various compounds for comparison. Each peak area was estimated by resolving roughly the two peaks graphically as exemplified by case e. In the case of $Fe2p_{3/2}$ peaks, the two peaks were resolved on considering the shape of fresh metal and bulk oxide peaks. However, the maximum peak positions and the peak area of the surface oxide could not be accurately determined, especially in the case of (b), because of their unsymmetrical profiles. Approximate values for Fe peaks are listed in Table 1.

Figure 3 shows the $Fe2p_{3/2}$ and the Ols peaks from the evaporated iron exposed to H_2O in succession (a, fresh iron; b, 1 Torr, 1 min; c, 15 Torr, 30 min; d, 15 Torr, 2 hr). As an example, the second Fe appeared at +3.2 eV from the genuine Fe in case d. With Ols, the high energy peak is larger in intensity than the other, unlike the cases for oxidation with O_2.

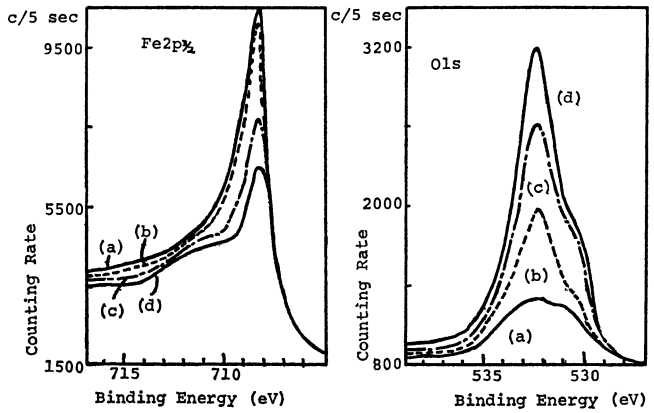

Fig. 3. $Fe2p_{3/2}$ and Ols photoelectron lines from evaporated iron exposed to H_2O in succession. (a): fresh iron, (b): 1 Torr H_2O; 1 min, (c): 15 Torr; 30 min, (d): 15 Torr; 2 hr.

Figure 4 shows the spectra of $Fe2p_{3/2}$, and Ols electrons. The $Fe2p_{3/2}$ for the surface oxide (case a, after exposing the metal to 200 Torr O_2 for 30 min) shifted 0.6 eV to low energy after the reaction with H_2O (15 Torr) for 1 hr (case b). The low energy Ols was depressed and the high energy one enhanced.

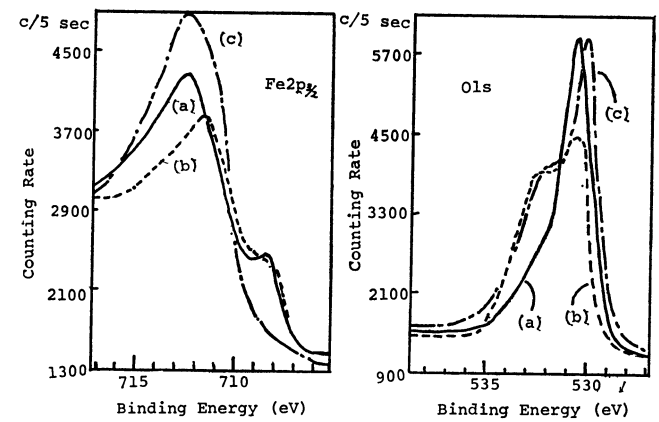

Fig. 4. Reaction of surface oxide with H_2O. $Fe2p_{3/2}$ and Ols photoelectron lines from, (a): iron metal exposed to 200 Torr O_2 for 30 min, (b): the surface oxide exposed to 15 Torr H_2O for 1 hr, (c): Fe_2O_3. (Counting rate unit for Fe_2O_3 is arbitrary.)

When Fe_2O_3 (case c, obtained by heating ferric oxalate at 700°C for 3 hr) was treated with H_2O for 2 hr, only a slight change was observed for the Ols peaks and none at all for the $Fe2p_{3/2}$.

Discussion

The high energy Ols peak for fresh iron is likely to be assigned to a contaminant or absorbed species except for the oxide since the low energy peak increased mainly in intensity (after exposing the metal to O_2). Measurable carbon and oxygen peaks due to a contaminant were also reported for prereduced Pt foil.[3] The peak area ratio of the high energy Ols to the Cls due to a contaminant, however, differs from that of fresh iron and gold, the ratio being larger considerably for iron. This suggests that on iron surface the active gases such as CO, CO_2, H_2O adsorbed with strong chemical force and hydrocarbons predominate on gold.

The low energy Ols for fresh iron can be assigned to the oxygen on the metal with a small amount of surface oxide under the pressure of 10^{-6}—10^{-7} Torr. The corresponding $Fe2p_{3/2}$ peak, however, could not be detected because of the broad tailing of the peak of high energy side. After reaction of the fresh iron with O_2, the second $Fe2p_{3/2}$ peak appeared, followed by the enhancement of the low energy Ols being shifted +3.2 eV (case b, c), +3.7 eV (d), and +4.0 eV (e) to high energy from the genuine Fe, as shown in Fig. 2. When the fresh iron was exposed immediately to 200 Torr O_2 for 30 min, the Fe shifted +4.2 eV, the same binding energy as for Fe_2O_3. The chemical shifts of Fe3p electrons of various iron compounds have been reported;[5] K_2FeO_4 (+5.3 eV from Fe metal), K_3FeF_6 (+5.3 eV), $K_3Fe(CN)_6$ (+2.6 eV) and Fe_2O_3 (+2.5 eV). If we assume that the localized positive charges on iron atoms are 3 and 0 in K_3FeF_6 and Fe metal, respectively, and that the Fe3p binding energies reflect only the charge of the metal and have a linear dependence on the charge, the positive charge of Fe in Fe_2O_3 is estimated to be 1.4.[6] In our results with $Fe2p_{3/2}$, the corresponding chemical shifts for all compounds measured are larger than those with the above 3p electrons (Table 1) and the shift of Fe_2O_3 is larger than that of $K_3Fe(CN)_6$. Assuming the positive charge of 1.5 for Fe_2O_3 giving the 4.2 eV shift of $Fe2p_{3/2}$, the iron atom in the surface oxide is considered to transfer, on the average, about 1.1 and 1.5 electrons to oxygen atoms when the chemical shift of the iron atom is +3.2 eV and +4.2 eV, respectively, after exposure to O_2. The localized charges

6) In order to treat the relation of charge-chemical shift more strictly, a correction due to crystal potential effect should be included. However, there are several findings indicating that the expected differences in crystal potentials do not appear in the measured values. For example, the observed Nls binding energies are almost the same for the nitrates, $NaNO_3$ (407.4 eV), NH_4NO_3 (407.2 eV), and $[Rh(NH_3)_6](NO_3)_3$ (407.3 eV) (W. L. Jolly, *et al.*, *Inorg. Chem.* **8**, 2642 (1969). There are also no differences in the Al2p spectra for kaolinite (Al: 6-coordinate), microcline (4-coordinate), and sillimanite (half, 4-coordinate; half, 6-coordinate),[3]

on Fe in these oxides are not so large as in $Fe_2(C_2O_4)_3 \cdot 6H_2O$ (estimated charge, +2.0) and $Fe_2(SO_4)_3(NH_4)_2SO_4 \cdot 24H_2O$ (+2.2). In the latter, the number of H_2O is uncertain because of release of H_2O on evacuation. As an example, the dark green $[Cr(H_2O)_4Cl_2]Cl$ turned purple-red after photoelectron measurement, the coloration being immediately restored after exposure to air. This indicates that the H_2O is released from the complex on evacuation.

The Fe to O atomic ratio of the surface oxide was estimated roughly as follows. The peak area ratio of low energy Ols to $Fe2p_{3/2}$ and to Fe3p in Fe_2O_3 were approximately 1.3 and 1.9, respectively. These values, however, can not be used directly for the estimation of the Fe to O ratio of the surface oxide since electrons of low kinetic energy can only escape from near the surface, whereas electrons of high kinetic energy can escape from deeper inside the material, as illustrated in Figure 5. The kinetic

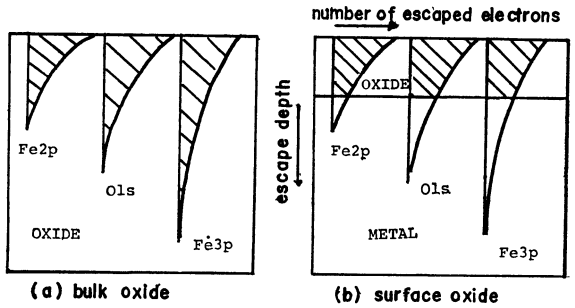

Fig. 5. Intensity-oxide depth relation for $Fe2p_{3/2}$, Ols, and Fe3p lines from surface oxide.

energy of electrons ejected from the Ols orbital (*ca.* 950 eV) is larger than that from the $Fe2p_{3/2}$ (*ca.* 770 eV), the escape depth thus being deeper for the former. Therefore, for the surface oxide where the genuine metal peak remains, the apparent peak area ratio ($Ols/Fe2p_{3/2}$) becomes smaller, as shown by the difference in the shaded parts of (a) and (b) in Fig. 5. This situation is reversed on the Ols to Fe3p (kinetic energy: *ca.* 1430 eV). In fact, the peak area ratio of metal-iron to oxide-iron was larger in the observation of the Fe3p electrons than in the $Fe2p_{3/2}$. For the surface oxide obtained after exposure to 200 Torr O_2 for 30 min, the observed peak area ratios of the Ols to the $Fe2p_{3/2}$ and to the Fe3p are about 1.0 and 1.9, respectively. This indicates that the Fe to O ratio is between about 1 : 1.2 and 1 : 1.5. On considering the differences in the kinetic energies (Ols–$Fe2p_{3/2}$: 180 eV, Fe3p–Ols: 480 eV), the Fe to O ratio is expected to be near 1 : 1.3. For the surface oxide $Fe_{1.0}O_{1.3}$, the negative charge of the oxygen is evaluated as about 1.1 using the positive charge of 1.5 for iron atom. The total area of the $Fe2p_{3/2}$ peaks decreased during the oxidation reaction. This might be due to the dilution of iron atoms with oxygen atoms (ionic radii: O^{2-}, 1.40 Å; Fe^{3+}, 0.64 Å) and the different mean escape depth between iron metal and oxide. For the surface oxide after exposure to 0.01 Torr O_2 for 1 min, the Fe to O ratio is approximately 1 : 0.7 and their estimated charges are +1.1 and −1.6 on Fe and O atoms, respectively. However, the binding energy difference was not observed for the oxygen atoms with the negative charges −1.1 and −1.6. This may be due to an inaccurate estimation of Fe to O peak area ratio in case b (Fig. 2).

The binding energy of Ols of the surface oxide is smaller than that of SiO_2 and Al_2O_3 by 3.7 and 1.7 eV, respectively, and larger than that of Fe_2O_3 by 0.3 eV. Although it is concluded from the chemical shift of $Fe2p_{3/2}$ that the surface oxide shows a larger covalent bonding than in other oxygen-coordinating compounds in the above discussion, of the metal oxides the surface oxide of iron exhibits larger ionicity than SiO_2 or Al_2O_3 as shown from the binding energy of Ols electrons. The linearity of the chemical shift-charge relation of the Ols peak is not so good as for the Nls or the Cls, but the negative charge of 0.5 corresponds roughly to the 3.5 eV shift.[7] The Ols binding energy of SO_4^{2-} is about 2.5 eV larger than that of Fe_2O_3 and the negative charge of oxygen in SO_4^{2-} was evaluated to be 0.83 from the positive charge of sulfur.[2] The 2.5 eV shift leads to the negative charge of about 1.18 for the oxygen in Fe_2O_3. The value is near that obtained from the positive charge of iron atom, 1.0, although the above relation could not be applied to the energy difference between the surface oxide and Fe_2O_3. In spite of larger negative charge the Ols binding energy of the surface oxide is larger by 0.4 eV than that of Fe_2O_3. We could not explain this although the Cls binding energy can not be taken as the same value for the two oxides as energy reference.

When the surface oxide was treated with H_2O, the low energy Ols was depressed followed by the enhancement of the high energy one (Fig. 4). The Ols main peak is also the high energy one when the fresh iron was exposed to H_2O (Fig. 3). The high energy Ols (532.6 eV) is located between the Ols binding energies of $Cd(OH)_2$ (532.7 eV) and KOH or $Ni(OH)_2$ (531.9 eV). This suggests that the hydroxyl group was formed on the reaction of the fresh iron or the surface oxide with H_2O. In the former, the reaction may be caused by a mixture of H_2O and O_2 remaining due to incomplete removal. When one oxide-oxygen was displaced by $2OH^-$, the total area of low and high energy Ols peaks should increase by the same amount with the decreased area of the low energy peak after reaction compared with the total area before reaction. In the spectrum the increase in the total area is actually indicated but the increased amount is somewhat smaller than expected. This is probably due to the depression of the Ols peaks caused by the increase of a contaminant hydrocarbon on the surface.

Fadley and Shirley[8] measured the photoelectron peaks of Fe foil heated in 10^{-2} Torr H_2 atmosphere and observed two oxygen peaks. The low energy Ols disappeared first at 360°C and was suggested to be assigned to more weakly adsorbed oxygen-containing

gases. The high energy Ols, remaining even at 600°C, was assigned to the oxygen of the surface oxide. From the present study, the low energy one is more accurately assigned to the surface oxide-oxygen, and the disappearance of this peak after heating in the hydrogen stream can, therefore, be explained by the reduction of the oxide-oxygen with H_2 and consequent formation of hydroxyl group giving the high energy Ols peak. The hydroxyl group formation on iron surface will be also expected for the iron metal immersed in an aqueous solution. Experiments on the degree of depression of the low energy peak after reaction with H_2O suggested the hydroxyl group formation to be easier for the iron metal with fewer oxide layer. As an extreme case, Fe_2O_3 showed no such formation of hydroxyl group even after being exposed to H_2O for 2 hr although the high energy Ols peak may be due in part to the hydroxyl group formed already during the production of the Fe_2O_3. Such behavior was also observed for the acetylacetone adsorption on oxygen treated metal by UV absorption spectra.[1] Acetylacetone adsorption was accelerated after iron or manganese film was exposed to oxygen (1 Torr) for 1 min, but not detected on the metal oxide obtained by heating the metal film in the air at 200°C for 1.5 hr.

Hydrogen bonding is explained by the formation of molecular complex where partial electron transfer occurs from the proton-accepting species to the antibonding orbital of, for example, O–H bond of the proton donating species,[9] the O–H dissociation being an extreme case. The above hydroxyl group formation on the iron surface is also expected to occur followed by electron transfer from oxygen of the surface oxide to the antibonding orbital of H_2O. Thus, a higher reactivity to H_2O will be expected for the iron metal with a slight oxidation, where the oxygen atom has more localized orbital, donating electrons to H_2O, than for one in bulk oxide because of incomplete formation of the bulk oxide structure.

The $Fe2p_{3/2}$ chemical shift to low energy on reaction with H_2O suggests that the Fe–O bond became more covalent in the hydroxide.

Iron surface is easily oxidized to give approximately 20 Å of oxide under the conditions of 10^{-4} Torr oxygen and room temperature.[10] This oxide layer increased to about 25 Å at 760 Torr O_2. Under the present oxidation conditions of 100 Torr O_2, 30 min, and room temperature, the iron surface is expected to be oxidized approximately to the same depth. The peak area of low energy Ols for fresh iron has 1/9 area of the corresponding one obtained after oxidation with 100 Torr O_2 for 30 min. Assuming 25 Å thickness of the latter surface oxide, the oxide layer for fresh iron is estimated to be thinner than 3 Å. However, a relatively rapid formation of four oxide layers has been reported under the condition of 2×10^{-7} to 5×10^{-6} Torr and 24°C.[11] On the other hand, assuming the four oxide layers for the present fresh iron, a thickness larger than 100 Å is derived for the surface oxide after exposing to 100 Torr O_2. Further attempts are necessary for a quantitative discussion on the depth of the oxide layers. The escape depth of electrons for the above metal with the surface oxide is slightly larger than the thickness of the oxide layer obtained after reaction with 100 Torr O_2 for 30 min, since the genuine Fe peak still can be detected but with weak intensity. Estimated range of escape depth: 8 Å for 362 eV electrons in case of Ag[12] and *ca.* 100 Å for 860 eV electrons in that of iodostearic acid.[2] In the case of Au, an escape depth of 22 Å has been observed for 1200 eV electrons.[13] From these results and the dependence of the depth on the kinetic energy of electrons and on the atomic number of materials, the depth of the oxide for the fresh iron seems to be thinner than four oxide layers.

The above photoelectron data indicate the important role of oxygen in the dissolution reaction of metals into aqueous solution; in this case for iron, the formation of a transient oxide to bulk oxide with high reactivity to H_2O was revealed.

The authors wish to thank Dr. Y. Yokoyama and Mr. I. Watanabe, Osaka University, for assistance and suggestions in carrying out the experiment.

Energetic Reactions of ^{80}Br Activated by (I. T.) Process in C_3H_8–C_2H_6 and C_3H_8–CH_3Br Systems

Kenshi NUMAKURA* and Enzo TACHIKAWA

Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received February 21, 1972)

In order to examine the relative importance of the thermal ionic process in the reactions of ^{80}Br from the (I. T.) process with C_3H_8, we chose C_2H_6 or CH_3Br as diluents. Some assumptions have made in estimating the yield-variation of products from the diluents: 1) the rate of the reduction of the yields of the products from C_3H_8 caused by the addition of the diluent is the same for all of the products and 2) the ionic yield is zero over the whole range of concentrations of C_3H_8. With these assumptions, the analysis of the results shows that the contribution of the thermal ionic process in these binary systems has only minor importance; the products are, essentially, formed *via* energetic processes. It is also found that the ratio of n-$C_3H_7{}^{80}Br/i$-$C_3H_7{}^{80}Br$ per bond basis seems to decrease from 1.1 ± 0.1 on the addition of the diluent. This indicates that the formation of i-$C_3H_7{}^{80}Br$ is a lower energy process, relative to that of n-$C_3H_7{}^{80}Br$ in the present reaction system.

In recoil ^{80}Br chemistry, the method commonly used to distinguish excess kinetic energy processes from others consists of the addition to the reaction system of an inert gas as a kinetic-energy moderator.[1-6] However, when a reactant molecule is diluted with an inert gas having a higher ionization potential (IP) than that of Br, the charge distribution, and the energy distribution of ^{80}Br are both influenced. Thus, the moderator curve obtained must be carefully analyzed in order to ascertain the real nature of the reactions involved. For example, the limiting yield at 1.0 m. f. of a moderator simply means that the yield is due to the thermal processes in the moderactor atmosphere and does not necessarily indicate the thermal yield in the reactant atmosphere.

In the previous paper we examined the nature of the reacting ^{80}Br activated by the isomeric transition in ethane,[6] which has a lower IP than that of Br, and speculated about it principally as a kinetically-excited atom, probably with on charge, on the basis of the assumption that the isotopic variation in the products is significant only when the products are formed *via* energetic processes.

The present paper will deal with the reactions of ^{80}Br with C_3H_8 in the binary system; C_2H_6 and CH_3Br were chosen as counterparts. All of these molecules have lower IP values than that of Br. Thus we can expect that the thermal ionic processes of ^{80}Br are not important in these systems if the above speculations are generally true. The conclusion drawn from the present results is that ^{80}Br reacts principally *via* the energetic processes in these binary systems; this supports the assumptions that the relative IP of the atmosphere is a major controlling factor in determining the relative important of the thermal ionic processes of ^{80}Br.

An attempt has also been made to compare the reactivity of two kinds of C–H bonds in C_3H_8, since corrections for the ^{80}Br spectrum are not required except for the secondary decomposition of the primary products.

Experimental

The general experimental procedure is the standard one for recoil Br atom reactions,[4] involving the formation of ^{80}Br from the ^{80}Br(I. T.)^{80}Br nuclear reaction and the subsequent analysis of the radioactive products by radio gas chromatography. The total pressure was usually 700 ± 10 Torr except in the pressure-effect experiments. The ratio of Br_2 relative to the reactant was 0.02 ± 0.01 throughout the work.

Materials. The ethane and propane were supplied by the Takachiho Chemical Co. with nominal purities of 99.9% and 99.7%; they were used after washing with concentrated sulfuric acid and after purification by vacuum distillation. Methyl bromide from the Tokyo Kasei Co. was purified several times by vacuum distillation.

Addition of O_2. Initially many runs were made without the addition of O_2 to the reaction systems. The values of the yields of the products from the reaction of ^{80}Br with C_3H_8, particularly that for the yield of i-$C_3H_7{}^{80}Br$, were not reproducible. This was probably due to the reaction of the C_3H_6 present in C_3H_8 as an impurity with the irradiated Br_2. However, reproducible results were obtained when 65 Torr of O_2 was added to the reaction mixture at the beginning of the reactions.

Percent Yields. The propane used in the present work contains very little C_3H_6, but even this amount of propylene interferes with the measurement of the total organic yield from the systems containing C_3H_8 as a reactant. Thus the absolute yield has been measured only from the ^{80}Br-C_2H_6-$O_2(3.2\pm0.1\%)$ and ^{80}Br-CH_3Br-$O_2(2.5\pm0.1\%)$ systems by a solvent extraction method. Individual radioactivity yields have been obtained by dividing the activities in the radio gas chromatogram by the total ^{80}Br activity, as measured with a G–M counter 2 hr after sampling the gases. The relative yields have been normalized to the percentage yields using a correction factor determined from the sum of the relative yields and from the total organic yield found in the above systems. The radio gas chromatograms were analyzed on a FACOM 230—60 computor in order to obtain the relative yields of the products, using the BOB 7 series program[7] corrected for the background and for the radio-activity decay of nuclides.

Results and Discussion

The five chief organic products observed from the reactions of (I. T.)-activated ^{80}Br with C_3H_8 were $CH_3{}^{80}Br$, n-$C_3H_7{}^{80}Br$, $C_2H_5{}^{80}Br$, i-$C_3H_7{}^{80}Br$, and $CH_2{}^{80}BrBr$. Table 1 summarizes the yields of the individual products obtained from the Kr-moderated systems. The yields of $C_2H_5{}^{80}Br$, n-$C_3H_7{}^{80}Br$, and $CH_2{}^{80}BrBr$ decreased with the increase in the m. f. of Kr, and could be extrapolated to zero at 1.0 m. f. of Kr. However, the $CH_3{}^{80}Br$ and i-$C_3H_7{}^{80}Br$ yields were extrapolated to 0.6±0.1% and 0.05±0.02% respectively. If one simply assigns these limiting yields at 1.0 m. f. of Kr as the thermal ionic yields, both $CH_3{}^{80}Br$ and i-$C_3H_7{}^{80}Br$ are found to be formed by two processes. One involves an excess kinetic energy, and the other, thermal ionic processes. The other products are principally formed *via* energetic processes of ^{80}Br. This simple assignment does not necessarily indicate the true reaction processes involved in the reactions of ^{80}Br in the C_3H_8 atmosphere, as has been discussed in our previous paper.[6] Since the IP of Kr is considerably higher than that of Br, the presence of the large amount

of Kr in the reaction system influences the charge neutralization as well as the energy degradation of ^{80}Br; thus, the charge and the kinetic energy distribution of ^{80}Br in the reaction energy range is different from those of a system with no additives. Thus, the results shown in Table 1 can firm that fractions of $CH_3{}^{80}Br$ and $i\text{-}C_3H_7{}^{80}Br$ are formed *via* thermal ionic processes in a highly Kr-moderated system.

As an alternative approach to the true reaction processes involved in the C_3H_8 atmosphere, one can study a binary system, using C_2H_6 or CH_3Br as a counterpart. The IP's of the constituents are 11.21 eV for C_3H_8, 11.65 eV for C_2H_6, and 10.6 eV for CH_3Br, compared to 11.84 eV for Br.[8] If the identity of the reacting ^{80}Br is primarily controlled by the IP of the constituents of the reaction systems, it is seems that the thermal ionic processes are of only minor importance in these binary systems. Thus, the yields of the products from one of the constituents will decrease with an increase in the m. f. of the other and can be extrapolated to zero at 1.0 m. f. of the latter. However, if this is not the case, the yields, as a function of the diluent, will reflect the thermal ionic processes.

Table 2 summarizes the yield-variation of products from various mixtures of C_3H_8 and C_2H_6, and from those of C_3H_8 and CH_3Br. *Iso-* and $n\text{-}C_3H_7{}^{80}Br$ were formed only from the reaction of ^{80}Br with C_3H_8, and their yields decreased smoothly from 0.20 ± 0.02 and 0.67 ± 0.07 respectively with the addition of the diluent to zero percent. However, in the C_3H_8–C_2H_6 mixtures, $CH_3{}^{80}Br$, $C_2H_5{}^{80}Br$, and $CH_2{}^{80}BrBr$ were formed from the reactions with either constituent and the sum of the yields was the same as the observed yields of these products. Similarly, in the C_3H_8–CH_3Br mixture, $CH_3{}^{80}Br$ and $CH_2{}^{80}BrBr$ were products from both constituents.

A separation of the observed yield at any m. f. of C_3H_8 into the yields originating from the individual constituents can be performed on two assumptions; one, that the thermal ionic yield is zero over the whole range of m. f. of C_3H_8, and the other, that the relative yield distribution among the products from the reactions with C_3H_8 is constant over the range of m. f. of C_3H_8. The first assumption is rather probable in view of the IP's of the constitutents involved. The second assumption, however, is a crude one, since the ratio of $n\text{-}C_3H_7{}^{80}Br/i\text{-}C_3H_7{}^{80}Br$ tends to vary slightly with the m. f. of the diluents(see below). However, the variation is only significant at a small m. f. of C_3H_8, where the yields of products from C_3H_8 are small. This amount of variation in the yield distribution, thus, will have only a minor influence on the subsequent discussion.

With these assumptions, the yields of these products at any m. f. of C_3H_8 can be calculated by multiplying the percentage yield of $n\text{-}C_3H_7{}^{80}Br$ by 1.8 for $CH_3{}^{80}Br$, by 0.85 for $C_2H_5{}^{80}Br$, and by 0.70 for $CH_2{}^{80}BrBr$. The solid curves in Figs. 1 and 2 indicate the calculated yields of these products from the reactions with C_3H_8.

The dotted curves in the same figures are simply obtained from the difference between the calculated yields and the experimentally-determined yields at each measureing point and are assigned to the yield curves from the reactions with C_2H_6 or CH_3Br.

These results show that the yields of products which originated from either C_2H_6 or CH_3Br decreased zero upon the addition of C_3H_8, and that it is rather difficult to detect any interference of possible thermal ionic process in the yield variation. This implies that the thermal ionic process is not important in the present binary systems (see Appendix).

The oxygen added to suppress the radical formations of organic compounds amounts to roughly 9% of the reaction mixture. The IP of O_2 is intermediate between the first and the second IP of Br. Thus, its presence possibly influences the ^{80}Br spectrum towards preferring the formation of the thermal $^{80}Br^+$ ion. However, the influence will be smaller than that to be expected simply from its mole fraction judging from the point of the collision cross section for the ^{80}Br-O_2 and ^{80}Br-reactant molecule collisions. The analysis of the results (see Figs. 2 and 3) shows no positive evidence for the contribution of the thermal ionic process. Thus, it is conclusive that ^{80}Br reacts principally *via* the energetic processes to form organic compounds in the C_3H_8, C_2H_6, and CH_3Br atmospheres. However, when these reactants are diluted with a sufficiently large excess of Kr having a IP of 14.00 eV, the energy degradation and the charge neutralization of ^{80}Br are controlled through its collision with Kr. The thermal $^{80}Br^+$ was eventually obtained,[9] and its reaction became important. Those conclusions are consistent with the previous speculation[6] that the thermal ionic processes of ^{80}Br are almost negligible in a reaction system with a lower IP than that of Br.

Reactivity of Primary and Secondary C–H Bonds in C_3H_8. In the recoil atom reactions, the chemical factors often play an important role in controlling the reactivity of various bonds. Two main difficulties have usually confronted such experiments: 1) the attainment of the "equivalent experimental conditions" for the comparison of the various chemical bonds, and 2) the failure of all of the molecules formed in the primary reactions to survive long enough to be measured.[10] The most important problem in trying to equalize conditions for an inter- or intra-comparison of different samples is in controlling the number and distribution *vs.* the energy of the hot collisions potentially available to an energetic atom prior to thermalization.[11–13] The cumulative absolute yield from a particular hot atom reaction is a function not only of the other hot reactions available to the energetic atom at all energies, but also of the rate of energy loss for the atom in nonreactive collisions. The measurement of the relative yields in an intramolecular system, however, ensures that each hot atom sums over the identical recoil atom spectrum and is free from the problem.

Propane includes both primary and secondary C–H bonds in a molecule, thus permitting a direct comparison of the reactivities of these C–H bonds toward the energetic ^{80}Br atom. The ^{80}Br *for H* reaction gives n- and i-$C_3H_7{}^{80}Br$, depending upon which kind of C–H bond is attacked. The bond dissociation energies are 4.23±0.04 eV for primary, and 4.1± 0.02 eV for secondary, C–H bonds.[14] If the chemical characteristics, including the bond strength, have some correlation with the reactivity toward the energetic ^{80}Br, it may appear in the relative yields of n- and i-$C_3H_7{}^{80}Br$.

Figure 3 shows the variation in the n-$C_3H_7{}^{80}Br/i$-$C_3H^{80}Br$ per bond basis as function of $C_3H_8/(C_3H_8+$ diluent) in the mixed system with C_2H_6 or CH_3Br. One can discuss the results without any correction for the ^{80}Br-spectrum, but they must be corrected for the decomposition reactions of the primary products. The most probable decomposition pathway both for n- and i-$C_3H_7{}^{80}Br$ is the elimination of $H^{80}Br$ to form

C_3H_6. Such unimolecular reactions can be conveniently investigated through pressure variation experiments; the present pressure-dependent data are shown in Table 3. The yields of both *n*- and *i*-$C_3H_7{}^{80}Br$ increased with an increase in the pressure. The ratio between them also increased, with a preference toward *n*-$C_3H_7{}^{80}Br$, at the beginning, but tended to be constant at 1.1 ± 0.1 over a total pressure of 600 Torr. However, this value does not necessarily indicate the real yield ratio of the primary reactions, since the correct estimation must be based on measurements of their secondary decomposition products, measurements are not possible in this type of experiment. In the present semiquantitative consideration, no correction has been made for the secondary decompositions of the primary products, since no a priori basis for estimating a correction factor exists. Recent theoretical knowledge indicates that more than one chemical bond is involved in the substitution reaction of an energetic atom.[15] Furthermore, the intramolecular distribution of the excitation energy is attained within a few vibrations. Thus, even if the secondary decomposition of the primary products still occur at pressures higher than 600 Torr, the yield ratio of *n*-$C_3H_7{}^{80}Br$/*i*-$C_3H_7{}^{80}Br$ should be much less sensitive to the applied pressure.

With these allowances, one can notice a positive dependence of the ratio on the concentration of C_3H_8, although the points deviate considerably. The ratio is 1.1 ± 0.1 with no dilution, and seems to decrease with the diluent. This qualitatively implies that the difference in reactivities of two kinds of C–H bonds for ^{80}Br is not significant in the distribution spectrum of the ^{80}Br controlled by collisions, principally with C_3H_8, but that the reactivity of secondary C–H bonds relative to primary C–H bonds increases with the dilution. While the effects on energy moderation by an inert gas are relatively simple to evaluate, the effects of dilution by a second reagent are much more complex, since such a reagent influences the ^{80}Br-spectrum through both kinetic-energy moderation and reactive collisions. The total organic yields from systems variously diluted with a second reagent, however, are always very small, as may be seen in Table 2; this, the elimination of ^{80}Br through reactions with the diluent cannot be important in the present qualitative discussion. As dilution with the diluent proceeds, the kinetic energy spectrum of ^{80}Br available for the reactions with C_3H_8 tends to shift to the lower-energy end and the lower-energy process becomes preferred over the high-energy process. Thus, one can tentatively conclude that the formation of *i*-$C_3H_7{}^{80}Br$ is a lower energy process than the formation of *n*-$C_3H_7{}^{80}Br$.

The efficiency of the kinetic energy moderation varies depending upon the additive used in the binary systems. Thus, the rate of decrease in the *n*-$C_3H_7{}^{80}Br$/*i*-$C_3H_7{}^{80}Br$ ratio with dilution should be correlated with the additives used. Unfortunately, the scattering of the results exceeds the possible variation in the ratio due to the different moderating efficiency of the diluent.

The relative position of the energy range of the reactions with two kinds of C–H bonds is consistent with the pressure dependence of the yields of the reaction products. The failure of the billiard-ball type of approximation in the recoil atom reaction implies that the internal excitation energy of the primary substitution reaction products is a good guide for the average kinetic energy of the recoil atom at the time of reaction.[16–18] As the total pressure rises, the stabilization of the excited products become more probable. Thus, an increase in the *n*-$C_3H_7{}^{80}Br$/*i*-$C_3H_7{}^{80}Br$ ratio with the pressure will be reflected in the fact that *i*-$C_3H_7{}^{80}Br$ is less excited and has a longer life-time, than *n*-$C_3H_7{}^{80}Br$.

The present results thus furnish evidence that the secondary C–H bond is more subject to the *^{80}Br for H* reaction than is the primary C–H bond under kinetic-energy-moderated conditions. Although this is consistent with the C–H bond strength effect involving the higher reactivity of the weaker C–H bond than that of the stronger C–H bond, no definite impormation has been obtained here concerning the identity of the chemical nature affecting the reactivities of two kinds of C–H bonds.

The trend toward higher yields for reactions with less sterically obstructed C–H would favor a higher yield for *n*-$C_3H_7{}^{80}Br$ than that for *i*-$C_3H_7{}^{80}Br$, this is not supported by the experimental observations. If such a steric factor is also opperative in the present experiment, the assessment of the importance of the chemical nature must be increased by an equivalent counterbalancing factor.

Appendix

The kinetic theory for energetic atom reactions was developed by Wolfgang *et al.*[10,20] and has since been applied to various systems.[21] The assumptions involved in its application to the reaction systems of ^{80}Br have been discussed by Milman.[22] Success depends on the assumptions that neither S nor α is a function of the recoil atom energy, or that, if they are, the energy variations are slight and the function smooth. Another important assumption is that the initial energy of the recoil atom is sufficiently high for the atoms to have made a number of collisions in order to attain the statistical distribution of energies for the atoms in the reaction range. The average kinetic energy of the Br atom achieved from the molecular explosion of Br_2 can be estimated to be up to 100 eV, based upon the Coulombic interaction energy. Since our knowledge about the kinetic energy spectrum of Br is not yet complete, we assume this

to be reasonably justified in our case.

The developed equation for the yields of individual products from energetic reactions with a reactant in the moderated system, P_1, is:

$$P_1 = \frac{f_1}{\alpha} I_1 - \frac{f_1^2}{\alpha^2} K_1 + \frac{f_1^3}{\alpha^3} L_1 - \quad (1)$$

where f and α have their usual meanings.

Unless the total reactivity of the system is very high, the series will converge rapidly. In systems of a very low reactivity, as in the present case, only the first may be sufficient.

Table 4. Relative α-values in the ^{80m}Br-C_3H_8-C_2H_6 and ^{80m}Br-C_3H_8-CH_3Br systems

In C_3H_8-C_2H_6 system compound	intercept $\alpha(R)/I_1$	slope $\alpha(M)/I_1$	$\frac{\alpha(C_3H_8)}{\alpha(C_2H_6)}$
i-$C_3H_7{}^{80}Br$ from C_3H_8	4.0	4.0	1.0
n-$C_3H_7{}^{80}Br$ from C_3H_8	1.4	1.3	1.1
$CH_3{}^{80}Br$ from C_2H_6	0.66	0.68	1.0
$C_2H_5{}^{80}Br$ from C_2H_6	0.78	0.84	1.1
$CH_2{}^{80}BrBr$ from C_2H_6	2.4	3.7	1.5
			av. 1.1±0.2
In C_3H_8-CH_3Br system compound	intercept $\alpha(R)/I_1$	slope $\alpha(M)/I_1$	$\frac{\alpha(C_3H_8)}{\alpha(CH_3Br)}$
i-$C_3H_7{}^{80}Br$ from C_3H_8	4.8	6.3	0.76
n-$C_3H_7{}^{80}Br$ from C_3H_8	1.8	2.6	0.69
$C_2H_5{}^{80}Br$ from C_3H_8	2.1	2.6	0.81
$CH_3{}^{80}Br$ from CH_3Br	0.56	0.47	0.83
$CH_2{}^{80}BrBr$ from CH_3Br	1.2	0.88	0.74
			av. 0.77±0.06

Table 5. ^{80}Br recoil energies resulting from coulombic repulsion of $^{80m}BrBr$

Original charge on bromine	^{80}Br recoil energies (eV)
+2	3.2
+4	9.6, 12.9
+6	16.1, 25.8, 29.0
+8	22.4, 38.5, 48.2, 51.4
+10	29.0, 51.4, 68.0, 77.0, 80.4
+12	35.3, 64.3, 86.7, 102.7, 115.6

Thus, in a moderated system Eq. (1) may be modified to this equation:

$$\frac{1}{P_1} = \frac{\alpha(R)}{I_1} + \frac{\alpha(M)}{I_1}\left[\frac{f(M)+Af(O_2)}{f(R)}\right] \quad (2)$$

where $A=\alpha(O_2)/\alpha(M)$; when M is C_2H_6, $A=0.72$ was obtained using the results in Ref. 6). When we plot $1/P$ *vs.* $[f(M)+Af(O_2)]/f(R)$, the slope is $\alpha(M)/I_1$ and the intercept is $\alpha(R)/I_1$. The ratio of these gives $\alpha(M)/\alpha(R)$.

The results shown in Figs. 1 and 2 have been used for the kinetic treatment according to Eq. (2). Table 4 summarizes the $\alpha(M)/I_1$, $\alpha(R)/I_1$, and $\alpha(M)/\alpha(R)$ thus obtained. In the present kinetic analysis two important requirements are not fully satisfied. One of these is that, because the initial kinetic energy is relatively low (see Table 5) the equilibrium distribution of ^{80}Br can not be attained in the reaction energy range. The other is the exclusion of the energetic-$H^{80}Br$ yield from the considerations, which will introduce a serious error if we ignore the higher terms in Eq. (1). Despite these difficulties, reasonably consistent values are obtained for both $\alpha(M)/\alpha(R)$ values. These, in turn, indicate that the above assumptions are reasonably satisfied and that the present kinetic analysis is justified within our limits of experimental accuracy.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 351—354 (1973)

A New Catalyst for Ethylene Polymerization Containing Nickel Oxide

Ken-ichi MARUYA and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo

(Received February 23, 1972)

A new catalyst for ethylene polymerization $NiO–NiSO_4$, was found from a study of $NiO–SiO_2$, and $NiCl_2$ catalysts. The $Ni–NiSO_4$ catalyst prepared from mixtures of formate and sulfate is much less active than $NiO–NiSO_4$ prepared from mixtures of hydroxide and sulfate. Poisoning behavior of carbon monoxide and water is quite similar to $NiO–SiO_2$ catalyst. An equimolar mixture of $NiO–NiSO_4$ gives maximum activity. The active species is postulated to be hydroxy sulfate of nickel. The structure of the active site is discussed.

Nickel oxide-silica is known to be effective for the dimerization of ethylene at room temperature.[1] As an extention of the study on its active site various nickel salts were tested for their activity in dimerization. It was found that nickel chloride could be activated for dimerization, when it was evacuated at above 230°C after a preevacuation at 140°C.[2] Both catalysts have common features. (1) Isotopic mixing in ethylene [1,3] and isomerization of *n*-butene[4,5] simultaneously take place over these catalysts. (2) They are poisoned by a small amount of CO for dimerization but not for isomerization. (3) The rate

of dimerization decreases with the increase in carbon number of olefin.[4,6] This similarity in catalytic properties suggests that an essentially identical active site is responsible for the dimerization over nickel oxide-silica and nickel chloride.

It has been suggested that the active site for dimerization is formed by an interaction of a nickel ion of low valency with an acid site.[1] The characteristic reaction on the low valent nickel is the chemisorption of CO and the isotopic mixing in ethylene. The acid site is characterized by butene isomerization.[5] It was shown that nickel oxide alone is activated for the isotopic mixing in ethylene by evacuation above 300°C, but it is inactive for the dimerization.[3] This is possibly due to the fact that no acid site can be developed on pure nickel oxide. An acid nature of nickel oxide silica has been shown.[1,5] Other catalyst systems for dimerization could thus be obtained by incorporating low valent nickel with acid component. This view was examined by combining nickel formate or hydroxide expected to give reduced nickel or nickel oxide after decomposition, with a number of sulfates which are known to be acidic.[7] In this way a new catalyst system of NiO–$NiSO_4$ was found for the polymerization of ethylene.

Experimental

Preparation. Catalysts containing nickel formate were prepared by evaporating mixed aqueous solutions of nickel formate and sulfate. Although nickel formate was deposited during the course of evaporation, the mixture was evaporated to dryness with stirring. The product thus obtained was green powder. The catalysts contianing nickel hydroxide were prepared by evaporating mixtures of nickel sulfate solution and the nickel hydroxide freshly prepared from nickel nitrate by precipitation with aqueous ammonia.

Procedure. The rate of polymerization of ethylene was determined at 30°C with an initial pressure of 45 cmHg, measuring pressure decrease in a constant volume static system, utilizing an oil manometer for less active catalysts. Reaction products were analyzed by gas chromatography using ODPN or pola-pack column. The rate of isomerization of 1-butene was estimated by conversion within 15 min at room temperature.

Results

Nickel Formate-based Catalyst (Catalyst I). Six sulfates (Mg^{2+}, Al^{3+}, Fe^{3+}, Co^{2+}, Ni^{2+}, and Cu^{2+}) were tested for their effectiveness as co-catalysts to nickel in the ethylene polymerization by combining each with nickel formate. It was found that only nickel sulfate was effective for the purpose.

Different mole ratios of nickel formate-nickel sulfate mixtures were evacuated at 300°C for 3 hr and tested for their activities. The rates of polymerization were so low that the pressure change was followed by an oil manometer. The pressure change with time is exemplified in Fig. 1. There is an induction period

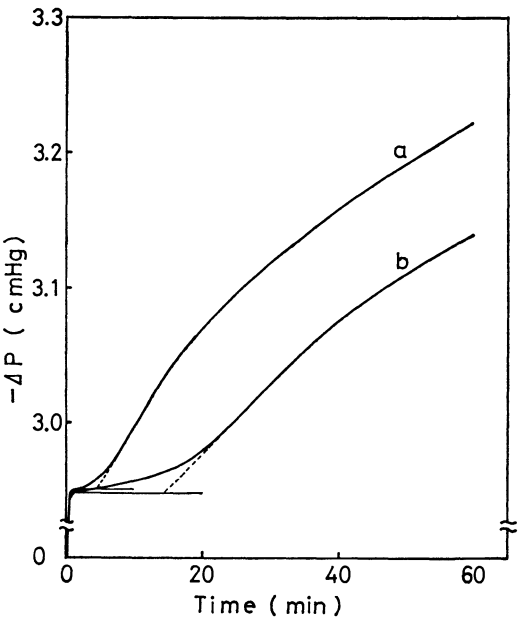

Fig. 1. Typical time course of ethylene polymerization over catalyst I.
$Ni(HCOO)_2/NiSO_4$=1 in a, 1/10 in b

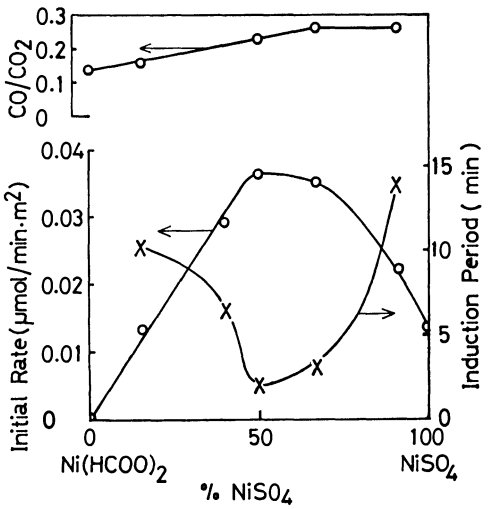

Fig. 2. Variations of induction period, initial rate of ethylene consumption and CO/CO_2 ratio in the decomposition product of $Ni(HCOO)_2$–$NiSO_4$ mixture with composition.

for the pressure change after a rapid initial change due to adsorption. The initial rates of ethylene consumption and the induction periods obtainable by the extrapolation shown in Fig. 1, are given in Fig. 2 as a function of catalyst composition. It can be seen that the maximum rate is obtained at around equimolar composition accompanied by minimum induction period, and that nickel sulfate itself has a small activity.

The product obtained from the gas phase was exclusively *n*-butenes.

The rate of ethylene consumption by the equimolar mixture was drastically reduced to about one seventh by 0.5 μmol/g of preadsorbed CO, or by 50 μmol/g of preadsorbed H_2O. However, in the case of pure nickel sulfate no effect of CO was observed.

7) K. Tanabe and T. Takeshita, *Advan. Catal.*, **173**, 15 (1967).

The nature of decomposition product of nickel formate was examined by the reaction of C_2H_4 and D_2 on a catalyst rich in nickel sulfate ($Ni/NiSO_4=1/10$) at 30°C for 2 hr. Neither exchange nor hydrogenation was detected, suggesting that no metallic phase of nickel exists at least on the surface. The ratio of CO/CO_2 in the gaseous decomposition product from the catalyst mixtures is shown in Fig. 2 as a function of catalyst composition. It can be seen that the ratio increases with the concentration of nickel sulfate.

The decomposition of nickel formate has been described by several authors[8,11] in terms of the following two simultaneous reactions

$$Ni(HCOO)_2 \longrightarrow \begin{cases} Ni + H_2 + 2CO_2 & (a) \\ Ni + H_2O + CO + CO_2 & (b) \end{cases}$$

although the relative importance of each reaction seems to depend on reaction condition and particle size of the sample.[12] According to Kornienko,[13] however, about 10% of nickel is transformed into NiO in the absence of H_2 and CO. It was found in the present case that 3.4 (ml S. T. P.) of hydrogen was absorbed for 3 hr at 300°C by the decomposition product from 1 g of $Ni(HCOO)_2 \cdot 2H_2O$. It was suggested that the nickel formate was partly transformed into nickel oxide instead of metallic nickel. The presence of nickel sulfate appeared to enhance the formation of nickel oxide. Thus the question arose of whether the real catalyst might not be a composite of nickel oxide and nickel sulfate. This led to the following study of $NiO–NiSO_4$ system.

Nickel Hydroxide-based Catalyst (Catalyst II). An equimolar mixture of nickel hydroxide and nickel sulfate was evacuated at 300°C for 1 hr and tested for its activity in the ethylene polymerization at 30°C. The pressure change with time is shown in Fig. 3. It is obvious that ethylene is rapidly consumed with no induction period. The rate of consumption is about 30 times that by equimolar catalyst I. Figure 3 also shows another run in which 1 μmol/g of CO was preadsorbed. It is clear that the pressure change stops after the initial rapid decrease which should be due to adsorption process. This shows that carbon monoxide effectively poisons this catalyst also.

Since the initial decrease due to adsorption is nearly over within the first one minute, it is better to estimate the initial rate of ethylene consumption after this period. Thus the initial rates are obtained from the pressure change in the period 1—3 min and plotted against the temperature of evacuation (Fig. 4). It can be seen that the activity appears above 200°C reaching a maximum at 350°C. It is remarkable

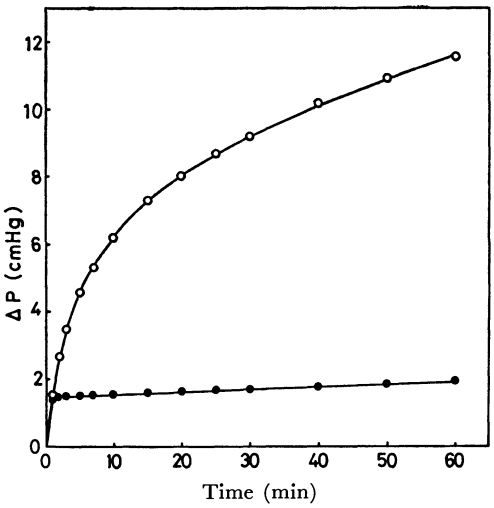

Fig. 3. Time course of ethylene polymerization at 30°C over $NiO–NiSO_4$ (1/1) catalyst evacuated at 300°C 1 hr. Solid circle shows the run with preadsorbed CO of 1 μmol/g.

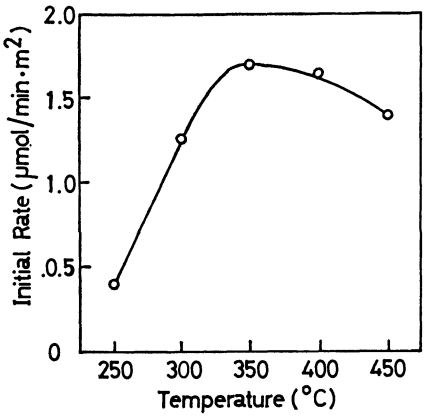

Fig. 4. Variation of initial rate with the evacuation temperature. $NiO/NiSO_4=1$.

that the acidity of nickel sulfate attains a maximum by the heat treatment at 350°C.[7]

The effect of composition on the initial rate per surface area was examined where the catalysts were evacuated at 250°C. As shown in Fig. 5, the maximum activity is obtained at equimolar composition. Another series of runs were made to study the effect of composition on isomerization of butene on this catalyst system. The result is also shown in Fig. 5. Since nickel sulfate is known to be acidic and to catalyze the isomerization of butene and since nickel oxide is known to be inactive, it can be expected that the activity of a mechanical mixture of the two components for the isomerization of butene increases with the content of nickel sulfate. In this respect the result shown in Fig. 5 is remarkable. The activity for isomerization also attains a maximum at the equimolar composition. This is not due to the change in surface area as shown in Fig. 5. The result, as well as that on the rate of polymerization, suggests that the mixture is not merely a mechanical mixture and the equimolar composition is significant as regards the active site.

The nature of the active site for isomerization was

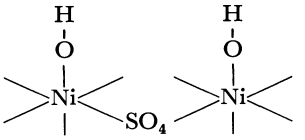
examined by the effect of preadsorbed carbon monoxide. It was found that 1 μmol/g. cat. of carbon monixide gave no effect on the extent of isomerization, although the amount of carbon monixide was enough to inhibit the polymerization. The result is reasonable when the active site for isomerization is an acid one.

Discussion

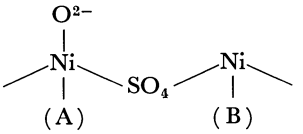
The postulate for the active site could develop a new catalyst system formed by the interaction of nickel oxide with nickel sulfate. However, the postulate should be corrected on the basis of the present results. The term "low valent nickel" originated from the fact that the NiO–SiO_2 catalyst was drastically poisoned by carbon monoxide, since a low-valent nickel is favorable to chemisorb carbon monoxide.[1] Catalyst I of the present study was adopted to test the idea "low valent". That catalyst I was much less active than catalyst II shows that the metallic state of nickel is inadequate to form the active site. A slight activity observed in catalyst I can be ascribed to a small amount of nickel oxide formed in the decomposition of nickel formate. It is to be noted that the NiO–SiO_2 catalyst is remarkably deactivated by hydrogen reduction to Ni–SiO_2.[14] Even in Ni–SiO_2 catalyst we can assume unreduced nickel, because oxide reacted with silica gel is hardly reducible.[15]

An essential feature common to NiO–SiO_2 and NiO–$NiSO_4$ is the fact that both catalysts are activated by dehydration from the surface, forming a carbon monoxide-sensitive site. This is also observed with nickel oxide alone, although the dehydrated nickel oxide is not active for dimerization, but active for isotopic mixing in ethylene[3] and hydrogenation of ethylene.[16] The active site for dimerization has been postulated to be formed by an interaction of the carbon monoxide sensitive site of the nickel oxide with an acid site. In fact, the expected activity was obtained by incorporating nickel sulfate which is known to provide an acid site. However, it is to be noted that none of the other sulfates known to be acidic could give activity by incorporation with nickel formate. In view of this fact, it is interesting that the acidic component in NiO–SiO_2 is formed by the reaction between nickel hydroxide and silica gel, as observed in the SiO_2–Al_2O_3 system. It seems that nickel ion is involved in the acidic component to cause an effective interaction between the carbon monoxide sensitive site and the acid component.

We found that an equimolar mixture of $Ni(OH)_2$ and $NiSO_4$ gives a maximum activity. The equimolar mixture may be regarded as a hydroxy nickel sulfate $Ni_2(OH)_2SO_4$. Although the structure of hydroxy sulfate of nickel is unknown, there can be pairs of –Ni(OH) groups which are separated by sulfate ions as



When the hydroxy sulfate is subjected to heat treatment, –Ni(OH) would be dehydrated forming two types of sites (A) and (B).



Since both (A) and (B) are coordinatively unsaturated, such pairs of nickel ion would disappear upon rearrangement at higher temperature. However, at intermediate temperature, pairs of (A) and (B) are likely to exist as an intermediate metastable state, being separated from each other by the sulfate ion. If this presumption is correct, site (A) may have a higher electron density than (B) owing to high electron density in the attached oxide anion. The observed poisoning by CO is reasonable on the type (A) site. It has been noted that CO poisons both the ethylene dimerization and the isotopic mixing in ethylene but not the isomerization of butene over the same catalyst.[1] This was confirmed with this catalyst system. The view is reasonably interpreted as selective occupation of type (A) site by CO, type (B) site being unoccupied. (B) is essentially an acid site and can act as a site for the butene isomerization.

The activation by heating in a vacuum followed by degradation at higher temperature is also reasonable as dehydration to form the pair of nickel ions followed by structural rearrangement. It is interesting that the activation of NiO–$NiSO_4$ reaches a maximum by heat treatment at 350°C at which the acidity of $NiSO_4$ reaches a maximum.[7] This coincidence would be reasonable if the basic structure is similar in both systems so that the maximum is determined by the temperature at which the structural rearrangment begins.

Generalized Method for Calculating Löwdin Orbitals

Kazuya Suzuki, Shinsaku Maruyama, and Kunio Araki

Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki

(Received March 9, 1972)

A generalized method for numerically calculating Löwdin orbitals is proposed, the method being an application of Frobenius' theorem in algebra. Löwdin transformation matrix $\mathbf{T}=\mathbf{S}^{-1/2}$ ($\mathbf{S}$ is overlap matrix) is calculated as $\mathbf{T}=\mathbf{U}\mathbf{S}_0^{-1/2}\mathbf{U}^t$, where $\mathbf{S}_0$ is a diagonal matrix whose diagonal elements are eigen values of $\mathbf{S}$, $\mathbf{U}$ is a matrix whose column vectors are eigen vectors of $\mathbf{S}$ and $\mathbf{U}^t$ is the transposed matrix of $\mathbf{U}$. It is proved that the eigen values of the overlap matrix of $\mathbf{S}$ are always positive for any choice of linearly independent atomic orbitals and that $\mathbf{S}^{-1/2}$, the inverse square-root of $\mathbf{S}$, exists within the range of real numbers. This method is useful for computer calculation by applying Jacobi's method.

Theoretical

Löwdin's method is used for orthonormalizing a given set of atomic orbitals and the transformed orbitals, Löwdin orbitals are useful for zero differential overlap approximation[1] (ZDO). However, for the numerical calculation of the Löwdin transformation matrix $\mathbf{T}=\mathbf{S}^{-1/2}$, only an expansion formula was shown[2,3] as

$$\mathbf{S}^{-1/2} = \mathbf{I} - 1/2\mathbf{D} + 3/8\mathbf{D}^2 - 5/16\mathbf{D}^3 + \cdots\cdots \quad (1)$$

where $\mathbf{S}$ is overlap matrix and an element of $\mathbf{S}$, s_{ij} is defined by

$$s_{ij} = \int x_i(v)x_j(v)\mathrm{d}v$$

x_i, x_j are atomic orbitals
$\mathbf{I}$; unit matrix
$\mathbf{D} = \mathbf{S} - \mathbf{I}$

If the value of the overlap integral s_{ij} is large, the convergence of Eq. (1) is not good. Generally, the value of overlap integral of pi orbitals is 0.20—0.30 and that of sigma orbitals 0.20—0.60. Thus, Eq. (1) is not considered to be sufficiently accurate for a detailed calculation on sigma orbitals. For other cases, in applying group theory, basic AO's are transformed into symmetry orbitals and the overlap integrals are inevitably large, if the orbitals belong to the same irreducible representation. Thus, a method for accurate calculation on the transformation matrix $\mathbf{T}=\mathbf{S}^{-1/2}$ is necessary.

In algebra, the regular matrix $\mathbf{S}$ is solved into the product of three factors:

$$\mathbf{S} = \mathbf{U}\mathbf{S}_0\mathbf{U}^t \quad (2)$$

where the matrices $\mathbf{U}$, $\mathbf{S}_0$, and $\mathbf{U}^t$ are as follows.

$$\mathbf{U} = \begin{pmatrix} u_{11} & u_{12} & \cdots\cdots & u_{1m} \\ u_{21} & u_{22} & \cdots\cdots & u_{2m} \\ \cdots & \cdots & \cdots\cdots & \cdots \\ \cdots & \cdots & \cdots\cdots & \cdots \\ u_{m1} & u_{m2} & \cdots\cdots & u_{mm} \end{pmatrix}$$

The column vector of $\mathbf{U}$, $\mathbf{u}_j(u_{1j},u_{2j},\cdots\cdots,u_{mj})$, is an eigen vector of $\mathbf{S}$. ($j=1,2,\cdots\cdots,m$)

$$\mathbf{S}_0 = \begin{pmatrix} s_1 & & 0 \\ & s_2 & \\ & & \ddots \\ 0 & & s_m \end{pmatrix}$$

The diagonal element of $\mathbf{S}_0$, s_j is an eigenvalue of $\mathbf{S}$ ($j=1,2,\cdots\cdots,m$).

$\mathbf{U}^t$; transposed matrix of $\mathbf{U}$

As the matrix $\mathbf{U}$ is unitary, $\mathbf{U}^t=\mathbf{U}^{-1}$, $\mathbf{U}\mathbf{U}^t=\mathbf{I}$ and $\mathbf{U}^t\mathbf{U}=\mathbf{I}$. By means of Eq. (2), we can calculate the matrix $\mathbf{D}$ of Eq. (1):

$$\mathbf{D} = \mathbf{S} - \mathbf{I} = \mathbf{U}(\mathbf{S}_0-\mathbf{I})\mathbf{U}^t$$
$$\mathbf{D}^2 = \mathbf{U}(\mathbf{S}_0-\mathbf{I})^2\mathbf{U}^t$$
$$\mathbf{D}^3 = \mathbf{U}(\mathbf{S}_0-\mathbf{I})^3\mathbf{U}^t$$
$$\cdots\cdots\cdots\cdots$$
$$\mathbf{D}^n = \mathbf{U}(\mathbf{S}_0-\mathbf{I})^n\mathbf{U}^t$$

Substituting these values for those of Eq. (1), we obtain the following equation.

$$\begin{aligned}\mathbf{S}^{-1/2} &= \mathbf{I} - 1/2\mathbf{U}(\mathbf{S}_0-\mathbf{I})\mathbf{U}^t + 3/8\mathbf{U}(\mathbf{S}_0-\mathbf{I})^2\mathbf{U}^t \\ &\quad - 5/16\mathbf{U}(\mathbf{S}_0-\mathbf{I})^3\mathbf{U}^t + \cdots\cdots \\ &= \mathbf{U}[\mathbf{I} - 1/2(\mathbf{S}_0-\mathbf{I}) + 3/8(\mathbf{S}_0-\mathbf{I})^2 \\ &\quad - 5/16(\mathbf{S}_0-\mathbf{I})^3 + \cdots\cdots]\mathbf{U}^t \\ &= \mathbf{U}[\mathbf{I} + (\mathbf{S}_0-\mathbf{I})]^{-1/2}\mathbf{U}^t \\ &= \mathbf{U}\mathbf{S}^{-1/2}\mathbf{U}^t\end{aligned}$$

The matrix $\mathbf{S}_0$ is diagonal, and we have

$$\mathbf{S}^{-1/2} = \mathbf{U} \cdot \begin{pmatrix} s_1^{-1/2} & & 0 \\ & s_2^{-1/2} & \\ & & \ddots \\ & & s_m^{-1/2} \end{pmatrix} \cdot \mathbf{U}^t \quad (3)$$

This is an exact and generalized expression for Löwdin transformation matrix $\mathbf{T}=\mathbf{S}^{-1/2}$, which is known in algebra as Frobenius' theorem;

Eigenvalues of matrix $F(\mathbf{A})$ are $F(\alpha_1),F(\alpha_2),\cdots\cdots,F(\alpha_m)$, where $\alpha_1,\alpha_2,\cdots\cdots,\alpha_m$ are eigenvalues of the matrix $\mathbf{A}$ and $F(x)=x^{-1/2}$.

It is proved that the eigenvalues $s_1,s_2,\cdots\cdots,s_m$ are always positive, not zero or negative. If one of the eigen values s_j is zero, the determinant of $\mathbf{S}$, Det $\mathbf{S}$ is zero (the matrix $\mathbf{S}$ is singular) and $\mathbf{S}^{-1}$, the inverse matrix of $\mathbf{S}$, does not exist. If the eigen value s_j is negative, the value of $s_j^{-1/2}$ is complex. It will be shown that no such cases exist.

1) J. A. Pople and G. A. Segal, *J. Chem. Phys.* **43**, S136, (1965)
2) P. O. Löwdin, *J. Chem. Phys*, **18**, 365, (1950).
3) P. O. Löwdin, *ibid.*, **21**, (1953).

The element of overlap matrix **S** is defined by

$$s_{ij} = \int x_i(v)x_j(v)\mathrm{d}v$$

and determinant of such a matrix is Gram's determinant (Gramian), which is transformed as follows.

$$\mathrm{Det}\,\mathbf{S} = 1/m\,!\iint\cdots\int \begin{Vmatrix} x_1(v_1) & x_2(v_1) & \cdots & x_m(v_1) \\ x_1(v_2) & x_2(v_2) & \cdots & x_m(v_2) \\ \cdots & \cdots & \cdots & \cdots \\ x_1(v_m) & x_2(v_m) & \cdots & x_m(v_m) \end{Vmatrix}^2 \mathrm{d}v_1\mathrm{d}v_2\cdots\mathrm{d}v_m$$

The atomic orbitals $x_1(v)$, $x_2(v)$, $\cdots$, $x_m(v)$ are linearly independent and then Det **S** is always positive.

$$\mathrm{Det}\,\mathbf{S} > 0$$

From Eq. (2), we have

$$\begin{aligned}\mathrm{Det}\,\mathbf{S} &= \mathrm{Det}\,(\mathbf{US_0U}^t) \\ &= \mathrm{Det}\,\mathbf{S}_0 \qquad (\mathbf{UU}^t=\mathbf{I}) \\ &= s_1s_2\cdots\cdots s_m\end{aligned}$$

then $s_1s_2\cdots\cdots s_m>0$

Thus it is proved that no one of the eigenvalues $s_1, s_2, \cdots\cdots s_m$ is zero and the matrix **S** is regular.

Next, it is shown all of them are positive. Considering the integral

$$Q = \int\left\{\sum_{j=1}^{m} p_jx_j(v)\right\}^2\mathrm{d}v$$

we find that Q is positive for arbitrary real numbers $p_1, p_2, \cdots\cdots, p_m$, except that the atomic orbitals $x_1(v)$, $x_2(v), \cdots\cdots, x_m(v)$ are linearly dependent (it is assumed that all the parameters p_j's are not zero). The integral Q is transformed into quadratic form:

$$\begin{aligned}Q &= \sum_{i,j=1}^{m}\int p_ip_jx_i(v)x_j(v)\mathrm{d}v \\ &= \sum_{i,j=1}^{m} p_ip_js_{ij} \\ &= (\mathbf{S}\boldsymbol{p}, \boldsymbol{p})\end{aligned}$$

where **S** is overlap matrix and $\boldsymbol{p}$ is non-zero vector $\boldsymbol{p}(p_1,p_2,\cdots\cdots p_m)$. Substituting **S** of Eq. (2), we obtain the following equation.

$$\begin{aligned}Q &= (\mathbf{US_0U}^t\boldsymbol{p}, \boldsymbol{p}) \\ &= (\mathbf{S}_0\mathbf{U}^t\boldsymbol{p}, \mathbf{U}^t\boldsymbol{p})\end{aligned}$$

here we introduce the parameter $\boldsymbol{q}(q_1,q_2,\cdots\cdots, q_m)$, which is transformed from the former parameter $\boldsymbol{p}(p_1, p_2 \cdots\cdots, p_m)$ as $\boldsymbol{q}=\mathbf{U}^t\boldsymbol{p}$.

$$\begin{aligned}Q &= (\mathbf{S}_0\boldsymbol{q}, \boldsymbol{q}) \\ &= s_1q_1^2 + s_2q_2^2 + \cdots\cdots + s_mq_m^2\end{aligned}$$

As the integral Q is also positive for real numbers $q_1, q_2, \cdots\cdots, q_m$, all the coefficients $s_1, s_2, \cdots\cdots, s_m$ are positive *i.e.* Q is positive definite quadratic form.

$$s_1 > 0,\ s_2 > 0, \cdots\cdots s_m > 0$$

Thus, Eq. (3) is always consistent for arbitrary functional systems $x_1(v)$, $x_2(v), \cdots\cdots, x_m(v)$, except for the case in which these functions are linearly dependent, in which case at least one of the eigenvalues of overlap matrix is zero and $\mathbf{S}^{-1/2}$, the inverse square-root matrix of **S**, does not exist.

Application of Eq. (3) to computer calculation is simple. In order to solve the secular equation of symmetric matrix **H** (Hamiltonian) or **F** (Hartree-Fock matrix), usually Jacobi's method is used. It is often preliminarily arranged as a subprogram. By using this, we can obtain the transformation matrix **T** as follows; eigen values and eigen vectors of **S** are calculated by Jacobi's method and then the diagonal elements $s_1, s_2, \cdots\cdots, s_m$ are substituted in Eq. (2) for the inverse square-root $s_1^{1/2}, s_2^{-1/2}\cdots\cdots, s_m^{-1/2}$. The process is easy programming. We might find the order of eigen values and eigen vectors, obtained by Jacobi's method, is indefinite and variable, depending on the diagonalizing operations. Nevertheless, the product of the matrices $\mathbf{S}=\mathbf{US_0U}^t$ and $\mathbf{S}^{-1/2}=\mathbf{US_0}^{-1/2}\,\mathbf{U}^t$ are uniquely determined. In other words, the matrices **S** and $\mathbf{S}^{-1/2}$ are invariable against the permutation of arbitrary eigenvalues and eigenvectors of **S**.

We have for an element of **S**, s_{pq}

$$\begin{aligned}s_{pq} &= \sum_{i,j=1}^{m} u_{pi}\delta_{ij}s_ju_{qj} \\ &= \sum_{j=1}^{m} u_{pj}s_ju_{qj}\end{aligned}$$

and similarly, for an element of $\mathbf{S}^{-1/2}$,

$$(\mathbf{S}^{-1/2})_{pq} = \sum_{j=1}^{m} u_{pj}s_j{}^{-1/2}u_{qj}$$

$$\mathbf{U} = \begin{array}{c} \\ \\ \\ p> \\ \\ q> \\ \\ \end{array}\begin{pmatrix} & & & \boldsymbol{u}_j & & \boldsymbol{u}_i & \\ u_{11} & u_{12} & \cdots & u_{1j} & \cdots & u_{1i} & \cdots \\ u_{21} & u_{22} & \cdots & u_{2j} & \cdots & u_{2i} & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ u_{p1} & u_{p2} & \cdots & u_{pj} & \cdots & u_{pi} & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \\ u_{q1} & u_{q2} & \cdots & u_{qj} & \cdots & u_{qi} & \cdots \\ \cdots & \cdots & \cdots & \cdots & \cdots & \cdots & \cdots \end{pmatrix}$$

As the summation is taken over all the elements of p-th row and q-th row, the total sum is invariant against permutation of arbitrary eigenvafues s_i, s_j and the corresponding column vectors u_i, u_j. Thus, the matrices **S** and $\mathbf{S}^{-1/2}$ are invariable against the change of the order of eigenvalues and eigenvectors.

Combination with group theory is also simple.[4] The basic AO's are at first transformed into symmetry orbitals and then ortho-normalized by the Löwdin transformation.

$$\begin{aligned}&\boldsymbol{x}_s = \mathbf{O}\boldsymbol{x}_a \quad (\boldsymbol{x}_s, \boldsymbol{x}_a, \text{ column vectors}) \\ \text{or}\quad &\boldsymbol{x}_s = \boldsymbol{x}_a\mathbf{O}^t \quad (\boldsymbol{x}_s, \boldsymbol{x}_a, \text{ row vectors}) \\ &\boldsymbol{x}_L = \boldsymbol{x}_s\mathbf{S}^{-1/2}\end{aligned}$$

where **O** is a unitary matrix determined from the symmetry of molecules. The vectors $\boldsymbol{x}_a$, $\boldsymbol{x}_s$, and $\boldsymbol{x}_L$ are the array of basic AO's, symmetry orbitals and ortho-normalized orbitals, respectively. The merit of these transformations lies in the invariability of the Hamiltonian and Hartree-Fock matrix.

4) J. A. Pople, D. P. Santry, and G. A. Segal, *J. Chem. Phys*, **43**, S 129, (1965).

Examples

Some examples of the Löwdin transformation matrix $\mathbf{T}=\mathbf{S}^{-1/2}$ are given as follows.

Ex. (1). *Pi Orbitals of Ethylene.*

C_1—C_2 the distance C_1—C_2; 1.34Å the value of overlap integral

$2p_{z1}$ $2p_{z2}$ $s_{12}=0.270$

The overlap matrix is as follows.

$$\mathbf{S}=\begin{bmatrix}1 & s\\ s & 1\end{bmatrix} \qquad s_{12}=s_{21}=s$$

By applying Eq. (2), the matrix **S** is transformed as

$$\mathbf{S}=\begin{bmatrix}1/\sqrt{2} & 1/\sqrt{2}\\ -1/\sqrt{2} & 1/\sqrt{2}\end{bmatrix}\begin{bmatrix}1+s & 0\\ 0 & 1-s\end{bmatrix}\begin{bmatrix}1/\sqrt{2} & -1/\sqrt{2}\\ 1/\sqrt{2} & 1/\sqrt{2}\end{bmatrix}$$

Then, by means of Eq. (3), we obtain

$$\mathbf{S}^{-1/2}=\begin{bmatrix}1/\sqrt{2} & 1/\sqrt{2}\\ -1/\sqrt{2} & 1/\sqrt{2}\end{bmatrix}\begin{bmatrix}1/\sqrt{1+s} & 0\\ 0 & 1/\sqrt{1-s}\end{bmatrix}\begin{bmatrix}1/\sqrt{2} & -1/\sqrt{2}\\ 1/\sqrt{2} & 1/\sqrt{2}\end{bmatrix}$$

Substituting s=0.270,

$$\mathbf{S}^{-1/2}=\begin{bmatrix}1.029 & -0.141\\ -0.141 & 1.029\end{bmatrix}$$

The same values are obtained also by Eq. (1).

Ex. (2). *Pi Orbitals of Allyl Radical.*

C_1 C_2 C_3 the distance C_1-C_2; 1.39Å
$<C_1C_2C_3=120°$

$2p_{z1}$ $2p_{z2}$ $2p_{z3}$ $s_{12}=0.246$
$s_{13}=0.035$

The overlap matrix **S** is as follows.

$$\mathbf{S}=\begin{bmatrix}1.000 & 0.246 & 0.035\\ 0.246 & 1.000 & 0.246\\ 0.035 & 0.246 & 1.000\end{bmatrix}$$

From C_{2v} symmetry of allyl radical the symmetry orbitals are obtained as $\Gamma=A_2+2B_1$

A_2; $1/\sqrt{2}\cdot 2p_{z1}-1/\sqrt{2}\cdot 2p_{z3}$

B_1; $2p_{z2}$, $1/\sqrt{2}\cdot 2p_{z1}+1/\sqrt{2}\cdot 2p_{z3}$

The overlap matrices of the symmetry orbitals are calculated to be

$$\mathbf{S}_{A2}=0.965$$

$$\mathbf{S}_{B1}=\begin{bmatrix}1.035 & 0.348\\ 0.348 & 1.035\end{bmatrix}$$

Then, the transformation matrices are obtained as follows.

$$\mathbf{S}_{A2}^{-1/2}=1.018$$

$$\mathbf{S}_{B1}^{-1/2}=\begin{bmatrix}1.030 & -0.183\\ -0.183 & 1.030\end{bmatrix}$$

The transformation matrix of AO basis is calculated by Eq. (3) as follows.

$$\mathbf{S}^{-1/2}=\begin{bmatrix}1.024 & -0.130 & 0.006\\ -0.130 & 1.048 & -0.130\\ 0.006 & -0.130 & 1.024\end{bmatrix}$$

The radical $CH_3\cdot$ is assumed to be planar of C_{3v} symmetry.

The overlap matrix is as follows.

	$2p_z$	$2s$	$2p_x$	$2p_y$	$1s_1$	$1s_2$	$1s_3$
$2p_z$	1.000	0.000	0.000	0.000	0.000	0.000	0.000
$2s$	0.000	1.000	0.000	0.000	0.576	0.576	0.576
$2p_x$	0.000	0.000	1.000	0.000	0.233	−0.456	0.233
$2p_y$	0.000	0.000	0.000	1.000	0.403	0.000	−0.403
$1s_1$	0.000	0.576	0.233	0.403	1.000	0.256	0.256
$1s_2$	0.000	0.576	−0.465	0.000	0.256	1.000	0.256
$1s_3$	0.000	0.576	0.233	−0.403	0.256	0.256	1.000

The symmetry orbitals are determined to be $\Gamma=3A_1+2E$.

A_1; $2p_z$

$2s$

$1/\sqrt{3}\ (1s_1+1s_2+1s_3)$

E; $2p_x$

$1/\sqrt{6}\ (1s_1-2s_2+1s_3)$

$2p_y$

$1/\sqrt{2}\ (1s_1-1s_3)$

and their overlap matrices are calculated as

$$\mathbf{S}_{A1}=\begin{bmatrix}1.000 & 0.000 & 0.000\\ 0.000 & 1.000 & 0.998\\ 0.000 & 0.998 & 1.512\end{bmatrix}$$

$$\mathbf{S}_{E}=\begin{bmatrix}1.000 & 0.570 & 0.000 & 0.000\\ 0.570 & 0.744 & 0.000 & 0.000\\ 0.000 & 0.000 & 1.000 & 0.570\\ 0.000 & 0.000 & 0.570 & 0.744\end{bmatrix}$$

Using Eq. (3), we can obtain the following transformation matrices.

$$\mathbf{S}_{A_1}^{-1/2} = \begin{bmatrix} 1.000 & 0.000 & 0.000 \\ 0.000 & 1.563 & -0.699 \\ 0.000 & -0.699 & 1.204 \end{bmatrix}$$

$$\mathbf{S}_{E}^{-1/2} = \begin{bmatrix} 1.233 & -0.505 & 0.000 & 0.000 \\ -0.505 & 1.460 & 0.000 & 0.000 \\ 0.000 & 0.000 & 1.233 & -0.505 \\ 0.000 & 0.000 & 0.505 & 1.460 \end{bmatrix}$$

As for the transformation matrix of AO basis, the following result is obtained.

$$\mathbf{S}^{-1/2} = \begin{array}{c} \\ 2p_z \\ 2s \\ 2p_x \\ 2p_y \\ 1s_1 \\ 1s_2 \\ 1s_3 \end{array} \begin{array}{c} \begin{array}{ccccccc} 2p_z & 2s & 2p_x & 2p_y & 1s_1 & 1s_2 & 1s_3 \end{array} \\ \begin{bmatrix} 1.000 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 & 0.000 \\ 0.000 & 1.564 & 0.000 & 0.000 & -0.405 & -0.405 & -0.405 \\ 0.000 & 0.000 & 1.232 & 0.000 & -0.205 & 0.411 & -0.205 \\ 0.000 & 0.000 & 0.000 & 1.232 & -0.356 & 0.000 & 0.356 \\ 0.000 & -0.405 & -0.205 & -0.356 & 1.373 & -0.083 & -0.083 \\ 0.000 & -0.405 & 0.411 & 0.000 & -0.083 & 1.373 & -0.083 \\ 0.000 & -0.405 & -0.205 & 0.356 & -0.083 & -0.083 & 1.373 \end{bmatrix} \end{array}$$

From the three examples, we see that the transformation matrix deviates largely from unit matrix, especially in the case of sigma orbital (Ex. 3). Thus, it seems necessary to examine the parameters used in NDO method. As an example, Hartree-Fock matrix **F** and core Hamiltonian **H** are transformed as follows by the Löwdin transformation.

$$\mathbf{F}' = \mathbf{S}^{-1/2}\mathbf{F}\mathbf{S}^{-1/2}$$

$$\mathbf{H}' = \mathbf{S}^{-1/2}\mathbf{H}\mathbf{S}^{-1/2}$$

Usually, the symbol β_{ij} is used for i, j element of H'_{ij} which is determined from the spectroscopic data. By means of Eq. (3), one can calculate the value of β_{ij} and compare it with experimental one.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 358—363 (1973)

The Polymerization of α-Naphthylmethylvinylether and 3-Pyrenylmethylvinylether and Electrical Conductivity of Their Polymers

Shigeki Yoshimoto,* Kenichi Okamoto,** Hirotaka Hirata,*** Shigekazu Kusabayashi,** and Hiroshi Mikawa

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka

(Received March 17, 1972)

A new vinylmonomer with a large pendant π-electron group was synthesized. α-Naphthylmethylvinylether and 3-pyrenylmethylvinylether were polymerized in good yields, although their polymers have fairly low molecular weights. Both polymers have a fairly high isotacticity. Poly-3-pyrenylmethylvinylether showed a large photocurrent in its absorption region and a small photocurrent even above 500 to 1000 mμ. The doped TCNE significantly sensitized its photoconductivity.

Polycyclic aromatic hydrocarbons have been much studied as organic photoconductors.[1] The conductivity of polymers with a large aromatic ring as a side chain has also been studied because of the practical interest in their ability to form a photoconductive film. Poly-*N*-vinylcarbazole is one of the most photoconductive polymers which have ever been reported and used as material for electrophotography.[2] It has been suggested that the high photoconductive property of poly-*N*-vinylcarbazole is associated with the crystallinity.[3] Poly-3-vinylpyrene is the polymer with the largest aromatic ring as a side chain which has ever been synthesized.[4] Although the polymer is ordinarily poorly crystalline, spherulite is observed in the polarizing hot-stage after heat annealing, and it is also photoconductive.[4] The relationship between the conductivity and the crystallinity has also been found in other polymers.[5]

Many studies have been done on the stereoregular polymerization of vinylethers. As has been reported in connection with the polymerization of both tri-

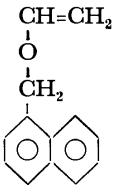
methylsilylvinylether and benzylvinylether,[6] a vinylether with a large side-chain group is expected to give an isotactic polymer by cationic polymerization in nonpolar solvents.

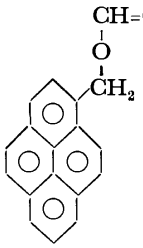
In the present paper, the authors will report on the polymerization of α-naphthylmethylvinylether (NVE) and of 3-pyrenylmethylvinylether (PVE) as well as on the high isotacticities and the electrical conductivity of their polymers.

Experimental

Synthesis.



NVE



PVE

NVE. NVE was prepared according to the method reported by Watanabe and Conlon.[7] The crude material was purified by means of column chromatography (basic alumina, ligroin) and high vacuum distillation (bp 95°C/0.03 mmHg).

PVE. 3-Pyrenylaldehyde[4] was reduced to 3-pyrenylmethanol by the following procedures. A 25-g portion of 3-pyrenylaldehyde was dissolved in 800 cc of methanol with 4 g of $NaBH_4$, and the mixture was heated at about 40°C for 6 hr with stirring. After the excess $NaBH_4$ had then been decomposed by dilute acetic acid, most of the solvent was distilled away and the reaction product was extracted with benzene. The benzene solution was washed several times with water and dried over anhydrous potassium carbonate. The benzene was distilled away, and the resulting precipitate, 3-pyrenylmethanol, was washed several times with a benzene-ligroin mixture and recrystallized three times from ligroin. Yield, 15 g (60%); mp 126—127°C. Found: C, 88.27; H, 5.19%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.17%.

3-Pyrenylmethanol was transformed to 3-pyrenylmethylvinylether by the procedures similar to those used in the case of naphthylmethylvinylether.[7] The reaction mixture of 3-pyrenylmethanol (20 g), isobutylvinylether (500 cc), and $Hg(OCOCH_3)_2$ (1.8 g) was refluxed for a day; then another 1.0 g of $Hg(OCOCH_3)_2$ was added and reflux was continued for one more day. The reaction mixture was then washed with water, and the isobutylvinylether was removed by distillation. After being purified by column chromatography (basic alumina, ligroin), PVE was recrystallized three times from ligroin. Yield, 3.33 g (15%); mp 77—78°C. Found: C, 88.28; H, 5.46%. Calcd for $C_{19}H_{14}O$: C, 88.34; H, 5.17%. Its NMR signal consisted of a multiplet (ring protons) at 1.9—2.5 τ, a quartet (internal vinyl hydrogen) at 3.2—3.6 τ, a singlet (Py-CH_2-O-) at 4.8 τ, and a multiplet (terminal vinyl hydrogens) at 5.5—6.6 τ.

Polymerization. The polymerization conditions are summarized in Tables 1 and 2. The solvents were purified by ordinary methods. The initiators were distilled prior to use and were kept as a toluene solution under nitrogen. Polymerization was carried out in a vacuum sealed tube. Methanol was used as the precipitating agent.

Preparation of Poly-3-pyrenylmethylvinylether (PPVE) Doped with Tetracyanoethylene (TCNE). A certain amount of TCNE was added into a benzene solution of PPVE. After being stirred for an hour, the mixture was poured into a large amount of methanol or ligroin and the precipitate was washed with methanol or ligroin and dried *in vacuo*. The content of TCNE was estimated from the results of elementary analysis.

Measurement of the Electrical Conductivity. Both polymers were purified as much as possible by repeated precipitations before the measurement. As a thin film (10 μ thick) of poly-α-naphthylmethylvinylether (PNVE) could be formed on a nesa quartz plate by the cast method, its electrical conductivity was measured in an Au-PNVE-Nesa sandwich-type cell. As it was not possible to make thin films

of both PPVE and PPVE doped with TCNE because of the low molecular weight of PPVE, the powder of the polymer was compressed into a disk under a pressure of 7000 kg/cm², upon which a pair of comb-type gold electrodes were evaporated under 10^{-5} mmHg. The surface-type cell thus obtained (distance between the electrodes, 0.02 cm; electrode length, 5 cm) was used for the electrical measurement of PPVE. Dark- and photocurrents were measured in a high vacuum (10^{-4}—10^{-5}mmHg) or in the air by the DC method with a Takedariken TR81 vibrating-reed electrometer. The monochromatized light from a 500 W xenon lamp was used, its intensity being controlled by neutral filters. The voltage was applied up to about 10000 V/cm. The measurements were carried out in the range from −10° to 70°C.

Results and Discussion

Polymerization. The polymerization results are shown in Tables 1 and 2. Both polymers, PNVE and PPVE, were obtained in good yields, although the molecular weight was fairly low. The difficulties in the chain growth of the monomers, especially in that of PVE, might be due to the steric effect of the large substituent groups under these catalytic conditions.

The polymerization of NVE proceeded rapidly within half an hour, but the polymer yield increased very slowly thereafter. The effect of both temperature and solvent on the polymer yield were very small.

PPVE was fractionated according to the solubility, as is shown in Table 3. Each fraction showed the same elementary composition. The main differences between fractions are found in the molecular weight, the melting point, and the IR absorption spectrum. The IR spectrum of each fraction is shown in Fig. 1. The most significant difference in the IR absorption observed at 1060 and 1135 cm^{-1}. The difference in the solubility must be due to the difference in the

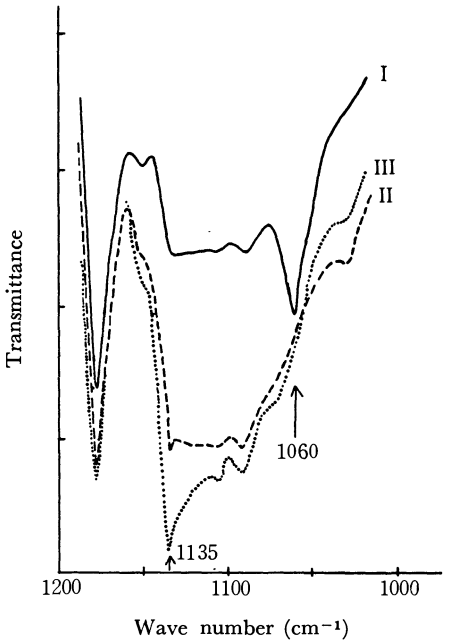

Fig. 1. IR spectra of each fraction of PPVE. Fractions I, II, and III.

molecular weight of the polymer. Fraction I, insoluble both in tetrahydrofuran and in benzene, has the highest melting temperature and probably the highest molecular weight. Fractions II and III have lower melting points and lower molecular weights. It is not clear whether these differences are due to the difference in crystallinity and/or to that in tacticity.

The tacticity of PNVE was studied by means of the IR spectrum of the polyvinylalcohol (PVA) led from the polymer. Dry HBr gas was bubbled into a toluene solution of PNVE with stirring at room temperature. The resulting precipitate, PVA, was washed with toluene and dried in a vacuum. The IR spectrum of

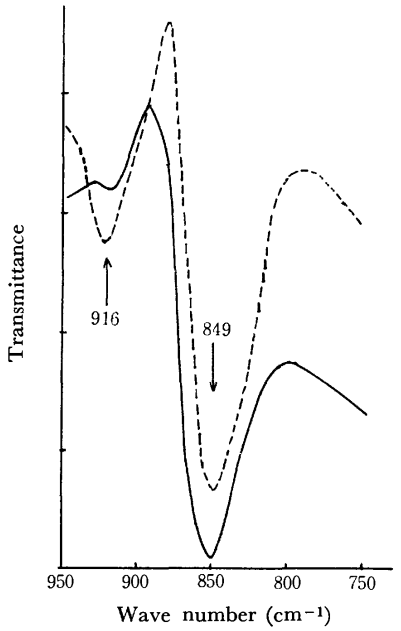

Fig. 2. IR spectrum of PVA.
solid line: PVA obtained from PNVE (No. 15 in Table 1), broken line: commercial atactic PVA.

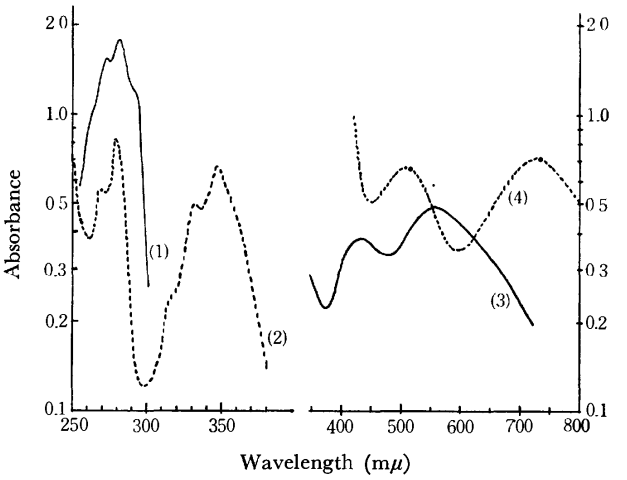

Fig. 3. UV absorption spectra of PNVE, PPVE and their CT complexes with TCNE in methylene chloride.
(1) PNVE (2.40×10^{-4} mol/l); (2) PPVE (8.8×10^{-4} mol/l); (3) PNVE (4.60×10^{-2} mol/l) and TCNE (8.2×10^{-3} mol/l); (4) PPVE (1.0×10^{-2} mol/l) and TCNE (7.0×10^{-2} mol/l).

PVA thus obtained was measured in a film; it is shown in Fig. 2. The absorbance ratio of 916 to 849 cm^{-1}, D_{916}/D_{849}, was reported to be a measure of the syndiotacticity of PVA.[8] The D_{916}/D_{849} ratio was found to be 0.03 for PVA from PNVE. This value corresponds to an isotacticity of 80—90%. The PNVE obtained by the above-mentioned procedure is, therefore, highly isotactic. The high isotacticity seems to result from the effect of the large substituent group on the polymerization.

PPVE was treated by a similar method, but the difficulty in cleaving this polymer to PVA hindered us from obtaining a clear answer as to the polymer tacticity. PPVE, however, might be safely said to have a fairly high isotacticity because of the effect of the bulky substituent group, which is larger than those of the polybenzyl- and polynaphthylmethyl-vinylethers.

PNVE is amorphous judging from the X-ray diffraction pattern, although it has a high isotacticity. An appropriate heat-treatment did not improve its crystallinity.

UV Absorption Spectra. Figure 3 shows the absorption spectra of the polymers and their charge-transfer complexes (CT complex) in methylene chloride. The CT complex of PNVE showed the same spectrum as did the CT complex of naphthylmethylethylether. The equilibrium constants for the CT complexes were calculated by means of the Benesi-Hildebrand equation. The equilibrium constant for the PNVE-TCNE complex was found to be 1.5 l/mol at 20°C in methylene chloride. This was much smaller than that for the naphthylmethylethylether-TCNE complex (4.5 l/mol at 20°C in methylene chloride). Similar results have been reported for the CT complexes of poly-*N*-vinylcarbazole and *N*-ethylcarbazole.[9] It may be noted that the steric effect on the equilibrium is considerable, even for the polymer such as PNVE, in which the side-chain group is separated from the main chain by the $-O-CH_2-$ bond.

Dark Conductivity. The dark current of PPVE was too small to be observed with a surface-type cell ($i_d \ll 10^{-15}$ A under 10000 V/cm). The sandwich-type cell of PNVE showed an ohmic dark current (specific conductivity at 50°C, $\sigma_{50}=10^{-18}\ \Omega^{-1}\ cm^{-1}$) whose activation energy was 1.9 eV in a high vacuum.

Photoconductivity. PNVE showed only a small photocurrent in the wavelengths shorter than 350 mμ.

Fractions II and III of PPVE in Table 3 were used for the measurements, no difference in electrical conductivity being observed between these fractions. The data to be presented below were obtained from Fraction III.

PPVE showed a large photoresponse, as is shown in Fig. 4. The photocurrent was proportional both to the applied voltage and to the light intensity at every wavelength, as is shown in Figs. 4 and 5. No appreciable photovoltaic current was observed. Figure 6 shows the spectral dependence of the photocurrent and the diffuse reflectance spectra. The diffuse reflectance spectra were measured using potassium bromide powder as a standard and are plotted using the Kubelka-Munk function, $f(R)=(1-R)/2R$, where R is the reflectance. The long-wavelength absorption peak was observed at 380 mμ in the solid state. This corresponds to the long-wavelength and low-intensity band of the pyrene ring, which has been observed at 376 mμ for 3-ethylpyrene and poly-3-vinylpyrene in a THF solution.[10] A maximum in the photocurrent

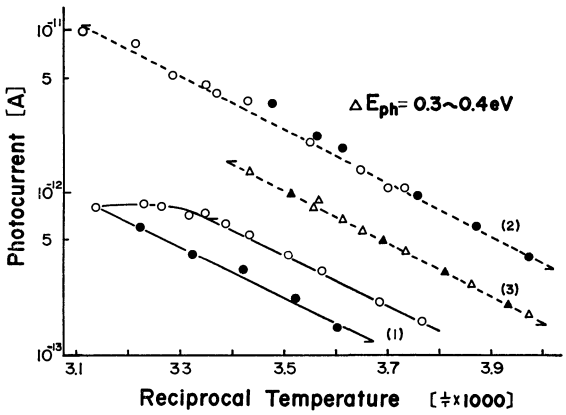

Fig. 7. Temperature dependence of photocurrent of PPVE.
(1) 420 mμ illumination in high vacuum, (2) 420 mμ illumination in air, (3) 600 mμ illumination in air, under 2500 V/cm. The values in the line (1) are 1/10 of the observed ones.

was observed at about 410 mμ, at a little longer wavelength than the absorption peak. A similar shift of the maximum in the photocurrent from the absorption peak has been also observed in poly-*N*-vinylcarbazole.[5] A small photocurrent was observed even above from 500 mμ to 1000 mμ, where PPVE has no absorption. The activation energy of the photocurrent, ΔE_a, in the equation; $i \propto \exp(-\Delta E_a/kT)$ was 0.3—0.4 eV at every wavelength in a vacuum or in air (Fig. 7). The magnitude of the photo-current was larger by two factors in air than in a high vacuum. This suggests that the majority carrier in PPVE is a hole rather than an electron. This sign of the carrier is the same as that in other polymers with large π-electron systems, such as poly-*N*-vinylcarbazole.[5]

Generally, polymers have many impurities which act as trapping centers. In many cases,[5,11] a re-excitation of the carriers trapped in the centers by

Table 4. Sensitization factors of dark- and photoconductivities of PPVE by doped TCNE

TCNE Content mol%	Darkconductivity[a]	Photoconductivity[a]			
		700 mμ	550 mμ	450 mμ	410 mμ
1	larger than 10^2	36	35	5.3	1.3
10	larger than 5×10^3	186	250	40	5

a) The currents were measured under 2500 V/cm in a high vacuum at room temperature.

illumination creates the photocurrent which is sensitive to visible or IR light. PPVE showed this behavior; that is, even after the cell had been kept for many hours under no applied voltage in the dark at room temperature the photocurrent was observed for a while when the cell was illuminated with visible light under no applied voltage. This suggests that PPVE also has many deep traps, which may be the origin of the photocurrent in the visible and near IR regions.

Sensitization of the Conductivity of PPVE. The doping of TCNE sensitized both the dark- and photoconductivities of PPVE. The degree of sensitization increased with the doping amount, as is shown in Table 4. The sensitized dark- and photocurrents were ohmic. The sensitized photocurrent showed a sublinear dependence (0.8 power) on the light intensity, as is shown in Fig. 5.

Figure 8 shows the temperature dependence of the sensitized dark- and photocurrents. The activation energies for the dark- and photocurrents were 1.1 eV and 0.18—0.25 eV respectively, both *in vacuo* and in air. Doped TCNE decreased the activation energy for photocurrent of PPVE. A similar effect has been reported for other polymers.[13]

Its spectral dependence was not, however, consistent with the absorption spectrum of PPVE-TCNE system in the solid state, as is shown in Fig. 6. A maximum and a shoulder in the photocurrent were observed at about 450 mμ and in the 550—650 mμ region (the CT absorption region) respectively. Doped TCNE apparently caused the large increase in the photocurrent in the CT bands, especially in the shorter wavelength CT band. The CT excitation with a higher energy will generate the carriers more easily:

$$(D\cdots A) \xrightarrow{h\nu_{CT}} (D^+\cdots A^-)^* \longrightarrow D^+ + A^- \qquad (1)$$

In addition to the spectral sensitization mentioned above, the chemical sensitization was also observed. Doped TCNE enhanced the photocurrent in the absorption region of PPVE by a factor of 1.5—2.0 in the case of 1 mol% (doping amount) and by a factor of 5 in the case of 10 mol%. Similar behavior was observed in the photoconductivity of poly-*N*-vinylcarbazole; it can be explained in terms of both the field-assisted thermal dissociation of an excited CT complex and the excitation of the donor, A^-, by singlet excitons.[12] The same mechanism is applicable for the chemical sensitization of the photocurrent of PPVE by doped TCNE; that is,

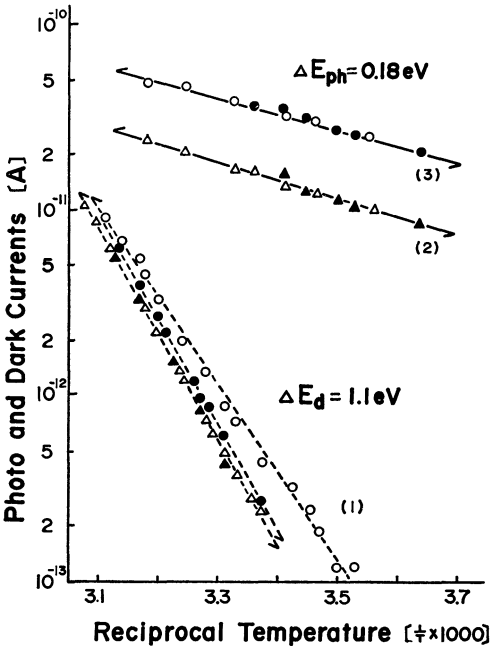

Fig. 8. Temperature dependence of photo- and dark- currents of PPVE sensitized with TCNE.
(1) dark current (○; 1-st heating, ●; 1-st cooling, △; 2-nd heating, ▲; 2-nd cooling), (2) photocurrent under 420 mμ illumination, (3) photocurrent under 600 mμ illumination, in high vacuum 2500 V/cm.

$$D \xrightarrow{h\nu} D^* \qquad (2),$$

$$D^* + A \longrightarrow (D^+\cdots A^-)^* \longrightarrow D^+ + A^- \qquad (3),$$

$$A^- + D^* \longrightarrow A + D^- \qquad (4),$$

where D is a donor molecule; D*, an excited singlet state of the donor; A, an acceptor molecule; $(D^+\cdots A^-)^*$, an excited CT complex; D^+ and D^-, ion radicals of the donor (mobile charge carriers), and A^- the anion radical of the acceptor (immobile). The gaseous electron affinity (EA_G) of TCNE and pyrene are 2.2 eV[14] and 0.58 eV[15] respectively. On the assumptions that the EA_G value of PPVE is equal to the value of pyrene, and that the polarization energy due to $PPVE^-$ is equal to that due to $TCNE^-$ in a pellet of PPVE doped with TCNE, the energy required for the excitation of an electron from $TCNE^-$ to the conduction level of PPVE is estimated to be 1.6 eV. As the energy of the singlet exciton (~3.2 eV) is larger than this value, Process (4) is probable.

(Received April 21, 1972)

The viscosities of aqueous solutions of sodium alkylsulfate and alkyltrimethylammonium bromide have been measured at various temperatures from 5 to 55°C. The viscosity data have been interpreted in terms of the Jones-Dole equation, and the viscosity B coefficients for the alkylsulfate and alkyltrimethylammonium ions at various temperatures have been calculated. The B values for these ions are all positive; they decrease with an increase in the temperature and increase linearly with an increase in the alkyl-chain length. The increment of B is found to be 0.076/-CH_2- at 25°C. The energy and the entropy of activation for the viscous flow at 25°C have been calculated for these ions; they increase with an increase in the alkyl-chain length. This behavior of the B coefficient, and the energy and the entropy of activation for the viscous flow may be interpreted by saying that the longer-chain ions promote the hydrogen-bond structure of water around the hydrocarbon chain of these ions, while shorter-chain ions, *e.g.*, ethylsulfate and ethyltrimethylammonium ions, behave instead as structure breakers because of the predominance of the disordering effect on the water around the ionic head. The viscosities of micellar solutions have also been measured. The volume of micelles as a hydrodynamic moving unit in solution has been estimated.

The viscosities of aqueous surfactant solutions have been measured by many investigators in order to obtain information about the micelle-forming properties.[1]

Gurney,[2] Kaminsky,[3] and Nightingale[4] have emphasized that the B coefficients of the Jones-Dole equation of viscosity[5] provide significant informations about the nature of ion-solvent interaction. The division of the B value of electrolytes into individual ionic values has been attempted by Gurney.[2] Kaminsky has extended this treatment to a wide temperature range.[3] Further, Nightingale[4] has indicated that the influence of strong electrolytes upon the viscosity of the solvent can be interpreted as a rate process, and that the energy and entropy of activation for a viscous flow can be estimated for a number of ions; on the basis of such estimates, he has discussed the nature of the ion-solvent interaction.

Having a molecule composed of a hydrophilic ionic head and a hydrophobic long-chain tail is a characteristic of an ionic surfactant. With respect to the hydrophobic interaction between water and a hydrocarbon chain, there have been many experimental and theoretical studies, especially by Nemethy and Scheraga.[6]

In this paper, the interaction between long-chain ions and solvent water will be discussed on the basis of the ionic B coefficients and the energy and entropy of activation for the viscous flow of two homologues of surface-active substances, sodium alkylsulfates and alkyltrimethylammonium bromides.

Experimental

Materials. The homologous series of *n*-alkanols and *n*-alkylbromides used in the preparation of sodium *n*-alkylsulfates and *n*-alkyltrimethylammonium bromides with 2 to 12 carbon atoms were all found by gas chromatography to be pure. All the salts gave correct elemental analyses.

Sodium Alkylsulfates: The reaction mixture obtained by treating *n*-alkanols with chlorosulfonic acid was extracted with ether and then neutralized with sodium hydroxide. The longer-chain compounds were obtained from the ether layer, and the shorter compounds, from the water layer. The sodium alkylsulfates thus obtained were recrystallized from an acetone-methanol mixture.

Alkyltrimethylammonium Bromides: These compounds were prepared by the reaction of the corresponding *n*-alkylbromides with trimethylamine. They were purified by recrystallization from acetone.

The critical micelle concentrations (CMC) of surfactants with an alkyl chain from 8 to 12 carbon atoms were determined by means of surface-tension and electric-conductivity measurements; the CMC's obtained by both methods were in good agreement with those from other sources.[7] The surface tension *vs.* concentration curves did not exhibit a minimum in the vicinity of the CMC.

Measurement of Viscosity. All the measurements of viscosity were carried out at a constant temperature between 5 and 55°C (±0.01°C). All the solutions were prepared on a molal basis. Two Geist-Cannon type viscometers with a flow time of *ca.* 500 s for water at 25°C were employed. The viscometers were carefully cleaned, rinsed with distilled water and methanol, and dried before they were filled with a solution and immersed in a thermostat. The solutions were filtered before being introduced into the viscometers in order to remove dust, *etc.* The error in the flow time was 0.1 s. Two viscometers were calibrated with pure water and 20% and 30% sucrose solutions by means of Eq. (1):

$$\frac{\eta}{\rho} = Kt - \frac{L}{t} \quad (1)$$

where η is the absolute viscosity, ρ is the density, and t is the flow time. The characteristic constants of the viscometers, K and L, were 1.592×10^{-5} and 1.36×10^{-2} for one, and 1.613×10^{-5} and 0.75×10^{-2} for the other, respectively. For the absolute viscosities of water, and 20% and 30% sucrose solutions at 25°C, we used 0.008903, 0.01701, and 0.02741 poise[8] respectively. The densities are 0.99707, 1.07940, and 1.12512 g/ml[9] respectively. The densities of the solutions were measured at a given temperature with *ca.* 6-ml pycnometer; the error of measurement was within ±0.0001 g/ml.

Results and Discussion

The viscosities of the solutions were computed by means of Eq. (1). It was found that the $\rho=\rho_0(1+\alpha m)$ equation held for the densities of aqueous solutions of sodium alkylsulfate and alkyltrimethylammonium bromide over a wide range of concentrations and temperatures, where m is the molal concentration; ρ_0, the density of pure water, and α, a constant.

The viscosity data have been analyzed by means of the Jones-Dole equation[10]:

$$\eta_r = 1 + A\sqrt{m} + Bm \quad (2)$$

where $\eta_r(=\eta/\eta_0)$ is the relative viscosity of a solution and where A and B are constants characteristic of the solute electrolyte. Eq. (2) can, then, be rewritten as:

$$\frac{(\eta_r-1)}{\sqrt{m}} = A + B\sqrt{m} \quad (3)$$

The A coefficient represents the contribution from interionic electrostatic force.[11] The B coefficient is said to be a measure of the effective hydrodynamic volume of the solvated ions,[12] and to denote the order or disorder introduced by the ions into the solvent structure.

Plots of $(\eta_r-1)/\sqrt{m}$ *vs.* $\sqrt{m}$ for aqueous solutions of sodium alkylsulfate and alkyltrimethylammonium bromide at 25°C are given in Fig. 1. The A intercepts obtained were small in every case; at most they amounted to 0.01 in the aqueous solutions studied. The plots of Eq. (3) were found to be linear up to concentrations of 0.1 molality for solutions of salts with hydrocarbon chains shorter than the octyl compound, and up to the CMC for solutions of micelle-forming salts with a hydrocarbon chain of from 8 to 12 carbon atoms. The B coefficients obtained at various temperatures are presented in Table 1.

Viscosity B Coefficient. For a satisfactory discussion of the temperature dependence of the viscosity B coefficients, the individual B values of the component ions are needed. The division of the B coefficients into individual ionic values is a rather arbitrary process, because there is no quantity corresponding to the transport numbers used in ionic mobility assignments. Gurney[2] has computed the ionic B coefficients in aqueous solutions by equating the contributions of the K^+ and Cl^- ions to the B coefficient of KCl at 25°C. Kaminsky has extended this treatment to the temperature range from 15 to 45°C,[3] and obtained ionic values in good agreement with those reported by Cox and Walfenden[13] that were based on the mobility difference for the Li^+ and IO_3^- ions. We have followed Kaminsky's procedure and have used his data for the Na^+ and Br^- ions. The ionic B coefficients for the alkylsulfate and alkyltrimethylammonium ions thus obtained are given in Table 2.

B coefficients for the relatively small alkali and halide ions in an aqueous solution decrease with an

increase in the ionic size, often to negative values, and in such cases B increases with an increase in the temperature.[2] These ions are known as structure breakers. On the other hand, large molecular ions such as the tetraalkylammonium ions have large and positive B values.[14,15] Assuming that the viscosity of an electrolytic solution at a constant temperature can be interpreted by Einstein's equation[16]:

$$\eta_r = 1 + 2.5\phi \tag{4}$$

where ϕ is the volume fraction of the salts, and by combining with Eq. (2), Eq. (4) becomes:

$$2.5\phi = A\sqrt{m} + Bm \tag{5}$$

The $A\sqrt{m}$ term can safely be neglected in comparison with Bm in the present solution. Since also $\phi = C\overline{V}$ $(=C\sum\bar{v}_i)$, where C is the molarity, $\overline{V}$ and $\bar{v}_i$ are the partial molar volumes of the solute electrolyte and the i-th ions in solution respectively, and since $C \simeq m$, we obtain:

$$2.5\,\overline{V} = B \tag{6}$$

$$2.5\,\bar{v}_i = B_i \tag{7}$$

where: $$\sum B_i = B \tag{8}$$

Therefore, if the viscosity of an electrolytic solution can be explained by Einstein's equation, the viscosity B coefficient should be approximately linear with the partial molar volume of the solute, *i.e.*, the ionic size. A plot of B *vs.* $\overline{V}$ for sodium alkylsulfate and alkyltrimethylammonium bromide is found to be linear, as is shown in Fig. 2, where the partial molar volumes of the long-chain salts used are given in Table 3. The slopes of these straight lines, however, are not equal to 2.5, but are about two times it. The B coefficient decreases with the increase in the temperature, as will be mentioned later, whereas $\overline{V}$ slightly increases with

perature, and the longer the alkyl chain length, the larger the negative temperature coefficient of B values, as is shown in Fig. 3. This tendency is similar to that for the tetraalkylammonium ions.[14,15] On the other hand, the B coefficient of a strong inorganic electrolyte increases with an increase in the temperature.[2] Therefore, the decrease in the B coefficient of these long-chain ions can be attributed to the interaction between the solvent water and the hydrocarbon part of the chain ions. The negative temperature coefficient of the B for the chain ion may be explained by the fact that these long-chain ions cause the water around the hydrocarbon part to become more ice-like than normal water,[18,19] and that this "ice-likeness" or "iceberg"[6] melts as the temperature is raised, causing the ionic B coefficient to be lowered.

The variation in the ionic B coefficient with the alkyl chain length is shown in Fig. 4. The ionic B

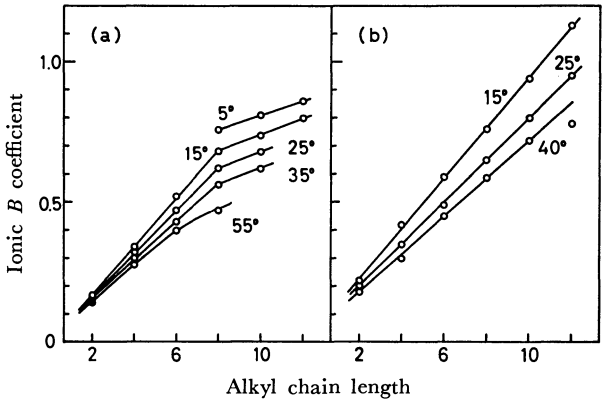

Fig. 4. Ionic B values at various temperature as a function of alkyl chain length. (a): alkylsulfate ions, (b): alkyltrimethylammonium ions.

coefficients of two homologous salts increase with an increase in the chain length at each temperature. This increase can be attributed to the Einstein effect of the additional methylene group and to the highly ordered "iceberg" structure around the hydrocarbon tail of the long-chain ions. The increase in the ionic B coefficient with the chain length is linear at 15 and 25°C except for alkylsulfate with carbon atoms larger than 8; the increments per methylene group are 0.076 for the alkylsulfate ion and 0.075 for the alkyltrimethylammonium ion at 25°C. At 15°C they are 0.085 and 0.091 respectively. Thus, these values are independent of the ionic heads of long-chain ions at a constant temperature. The plots of B values *vs.* the chain length for the alkylsulfate ion are found to be bent suddenly at the carbon number of 8, as is shown in Fig. 4, whereas this is not observed for the alkyltrimethylammonium ion.

Energy and Entropy of Activation for the Viscous Flow. The energy of activation for the viscous flow, $E^{\neq}$, according to the theory of absolute reaction rates presented by Eyring *et al.*,[20] is given by:

$$E^{\neq} = R\frac{\mathrm{d}\ln\eta}{\mathrm{d}(1/T)} \tag{9}$$

For an associated liquid such as water, the plot of ln η *vs.* $1/T$ is not linear; *i.e.*, $E^{\neq}$ varies with the temperature. By substituting Eq. (2) into Eq. (9), and by neglecting the $A\sqrt{m}$ term in Eq. (2), it follows that:

$$E^{\neq} = R\frac{\mathrm{d}\ln\eta_0}{\mathrm{d}(1/T)} + \frac{R}{1+Bm}\frac{\mathrm{d}(1+Bm)}{\mathrm{d}(1/T)} \tag{10}$$

where the first term of the right-hand side is identical with the energy of activation for the solvent water, $E_0^{\neq}$. Assuming that the difference between the activation energy of a solution and a solvent is equal to the activation energy for the flow of the solute, $\Delta E^{\neq}$, it follows that:

$$\Delta E^{\neq} = E^{\neq} - E_0^{\neq} = \frac{R}{1+Bm}\frac{\mathrm{d}(1+Bm)}{\mathrm{d}(1/T)} \tag{11}$$

The free energy of activation for the viscous flow is given by:

$$\Delta G^{\neq} = RT\ln\frac{\eta V}{hN} \tag{12}$$

where h is the Planck constant, N is the Avogadro number, and V is the molar volume of the moving unit. Subtracting the activation free energy for the solvent, $\Delta G_0^{\neq}$, from Eq. (12), the activation free energy for the flow of the solute is given by:

$$\Delta\Delta G^{\neq} = \Delta G^{\neq} - \Delta G_0^{\neq} = RT\ln\frac{\eta V}{\eta_0 V_0} \tag{13}$$

Since the activation enthalpy can safely be assumed not to differ appreciably from the activation energy, the entropy of activation of the solute, $\Delta\Delta S^{\neq}$, may also be calculated as:

$$\Delta\Delta S^{\neq} = \frac{\Delta E^{\neq} - \Delta\Delta G^{\neq}}{T} \tag{14}$$

Nightingale[4] has shown that the activation quantities of the solute can be represented by the following formulae:

$$\Delta E^{\neq} = \sum \nu_i \Delta E_i^{\neq},\ \Delta\Delta S^{\neq} = \sum \nu_i \Delta\Delta S_i^{\neq} \tag{15}$$

where $\Delta E_i^{\neq}$ and $\Delta\Delta S_i^{\neq}$ are the energy and the entropy of activation for the ionic components, and where ν_i is the number of ions per molecule of salt. He further assumed, in a manner similar to that in the evaluation of the ionic B coefficients, that the activation energy for the flow of the K^+ ion in solutions was approximately equal to that of the Cl^- ion. Following Nightingale's procedure, and using his data for the Na^+ and Br^- ions, the energies and entropies of activation for the flow of alkylsulfate and alkyltrimethylammonium ions were determined to be as is shown in Table 4.[21] It can be seen from Table 4 that the activation energies for the ions under consideration are all positive, that they in-

crease with the increase in the chain length of ions, and that, unlike those for ethylsulfate and butylsulfate, the activation entropies for the other ions considered are positive. These results confirm the interpretation of the negative temperature coefficient of ionic B values. That is, those ions which have a positive activation energy and a positive viscosity B coefficient increase the viscosity of water by increasing the ice-like structure apo-surface.[22] However, the ethylsulfate ion, which has a negative activation entropy, is weakly peri-surface hydrated and scarcely increases the B value at all because of the order-destroying effect of the ionic head. These results, when considered along with the temperature dependence of the B values, indicate that the alkylsulfate and alkyltrimethylammonium ions with longer alkyl chains are structure makers and that ethylsulfate and ethyltrimethylammonium ions are structure breakers, while for the butylsulfate ion the two effects appear to cancel each other out.

Viscosity of Micelles Solutions. It seems likely that, in dilute aqueous solutions of association colloides, the micelles are reasonably spherical. The viscosity of these solutions may be represented by Einstein's equation. The concentration of micelles composed of n molecules, C_m(mol/l), is given by:

$$C_m = \frac{C-\mathrm{CMC}}{n} \tag{16}$$

The hydrodynamic volume of the micelle, V_m (l/mol), is given by:

$$V_m = \frac{n(\bar{v}_m + n_h v_h)}{1000} \tag{17}$$

where $\bar{v}_m$ (ml/mol) is the partial molar volume of the surfactant in the micellar state; v_h(ml/mol), the molar volume of water hydrated, and n_h, the number of moles of the hydrated water per mole of the surfactant.

22) Literally—away from the surface on the ion. While peri-surface means at and round-about the ionic surface. Ref. 10.

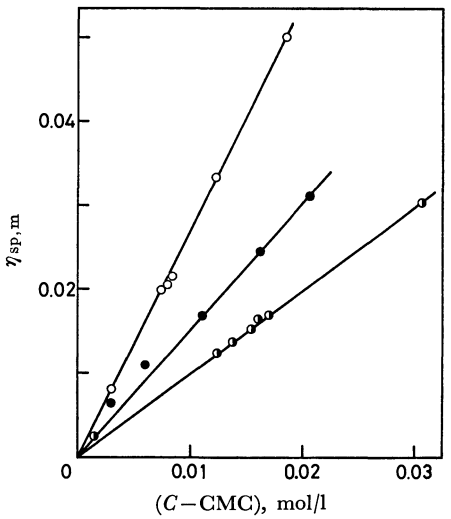

Fig. 5. Plots of $\eta_{sp,m}$ *vs.* (C−CMC) for the micellar solution at 25°C; sodium decylsulfate (●), sodium dodecylsulfate (○), decyltrimethylammonium bromide (◑).

TABLE 5. HYDRODYNAMIC VOLUME FOR MICELLES

Surfactant	$\bar{v}_m + n_h v_h$	$\bar{v}_m$[17]	n_h
$C_{10}Me_3NBr$	397	262.3	7—8
$C_{10}SO_4Na$	604	212.5	21—22
$C_{12}SO_4Na$	1108	246.2	47—48

In a micellar solution the viscosity of the solvent, η_0, should be replaced by the viscosity of the solution at the CMC η_m^0; then Eq. (4) becomes:

$$\eta_{sp,m} = \frac{\eta}{\eta_m^0} - 1 = \frac{\bar{v}_m + n_h v_h}{400}(C-\mathrm{CMC}) \tag{18}$$

A plot of $\eta_{sp,m}$ *vs.* (C-CMC) gives a straight line, as is shown in Fig. 5. The hydrodynamic volume of the micelle may be estimated from these slopes. The values of V_m thus obtained are presented in Table 5, together with the values of $\bar{v}_m$ and n_h. It can be seen from Table 5 that, in a homologous series, the longer the chain length, the larger the hydration number. However, n_h is larger than one would expect. Because the micelles of these ionic surfactants carry an electric charge in aqueous solutions, an electroviscous effect is always included as part of the measured intrinsic viscosity. Parker and Wasik[23] have shown that the intrinsic viscosities for sodium dodecylsulfate (SDS) in water and 0.2 M sodium chloride should differ by a factor of 2.3. Courchene,[24] with correction for the electroviscous effect, estimated 12 as the number of water for each surfactant molecule in the micelle. In this paper, the hydration number of SDS micelles in water is calculated to be about 13—14 from a similar correction for the electroviscous effect; this is in fair agreement with Courchene's value.

Electrochemiluminescence of 9,10-Dichloroanthracene at Low Temperatures

Tamotsu MATSUMOTO, Masanori SATO, and Satoshi HIRAYAMA

Laboratory of Analytical Chemistry, Faculty of Textile Science, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto

(Received May 29, 1972)

The electrochemiluminescence (ECL) of 9,10-dichloroanthracene in methylene chloride was investigated at temperatures as low as −60°C. The cation was quite stable and the anion was unstable at room temperature. The anion, however, increased its stability as the temperature decreased and below *ca.* −40°C it was essentially stable. Temperature was also found to have great influence on the relative intensity of the two spectral components of the ECL of 9,10-dichloroanthracene. By lowering the temperature the components at the longer wavelength increased strongly compared with the other component. When the ECL was observed by applying a rectangular potential, the intensities of the two components decayed exponentially with the same decay constant. Therefore, it was concluded that the emission at the longer wavelength originated not from the products of electrolysis but from the excimer and that the primary process to produce these two emissions was the same.

It is well known that in aprotic solvents numerous aromatic compounds often show luminescence at the surface of an electrode to which an alternating potential is applied. This phenomenon, electrochemiluminescence (ECL), is mainly attributed to the annihilation of generated cations and anions. The first observation on ECL of many aromatic compounds was reported by Hercules.[1] Since then, detailed investigations on ECL have been carried out chiefly by Chandross *et al.*,[2,3] Zweig[4], Bard *et al.*[5,6] and Hercules *et al.*[7] and the various mechanisms of ECL have been postulated.

It is recognized that the observed ECL spectra sometimes contain longer wavelength emission which is not assignable to the corresponding fluorescence. The longer wavelength emission is often attributed to i) excimer fluorescence, ii) phosphorescence, or iii) fluorescence of the electrolytic products excited by energy transfer from excited molecules of the parent compound.

The following reaction scheme (A=aromatic) is considered to be appropriate to explain the phenomenon cited above, although a preannihilation mechanism[8] is not included.

$$\left.\begin{aligned} &A + e \longrightarrow A^-, \text{ cathodic process} \\ &A - e \longrightarrow A^+, \text{ anodic process} \end{aligned}\right\} \quad (1)$$

$$A^- + A^+ \rightleftharpoons {}^1(A\cdots A)^* \rightleftharpoons {}^1A^* + A, \quad (2)$$

$$A^- + A^+ \rightleftharpoons {}^3(A\cdots A) \longrightarrow {}^3A + A, \quad (3)$$

$${}^3A + {}^3A \rightleftharpoons {}^1(A\cdots A)^* \quad (4)$$

$${}^1A^* \longrightarrow A + h\nu_1, \text{ fluorescence} \quad (5)$$

$${}^1(A\cdots A)^* \longrightarrow 2A + h\nu_2, \text{ excimer fluorescence} \quad (6)$$

$${}^3A \longrightarrow A + h\nu_3, \text{ phosphorescence} \quad (7)$$

$${}^1A^* + B \longrightarrow A + {}^1B^*, \text{ B: electrolytic product} \quad (8)$$

$${}^1B^* \longrightarrow B + h\nu_4, \text{ fluorescence} \quad (9)$$

We consider here two mechanisms to produce an excimer, one of which is due to the triplet-triplet annihilation and the other involving direct formation through cation-anion annihilation. To reveal the emitting species of the observed ECL and to elucidate in detail the mechanism to produce them are of great value both in the study of emission spectroscopy and in the study of electron transfer reactions associated with a large change in enthalpy of reaction.

For the mechanism of ECL to be established, it is necessary to re-examine rigorously the electrochemical systems. For example, the character of the solvents has great influence on the electrochemical reactions. We have observed that dimethylformamide (DMF), frequently used for the study of ECL, is not suitable, because in this solvent most cations of aromatic molecules are not stable on account of DMF's strong nucleophilic property. For that reason the ECL processes (8) and (9) in which electrolytic products take part cannot be excluded from the plausible mechanisms of ECL. This has made the detailed discussion on the mechanism of ECL more complicated.

Therefore, it is essential to observe ECL spectra under the conditions where both anions and cations can exist stably. One of the best ways is to observe ECL spectra at low temperatures where undesirable reactions of ion radicals with solvent or impurities are greatly or completely retarded.

For rigorously quantitative treatment, electrochemical studies of aromatic compounds in aprotic solvents at low temperatures often involve difficulties in the choice of solvents, supporting electrolytes and a reference electrode, and through investigations have not been made until Van Duyne and Reilly's recent studies[9]. Only two investigations of ECL were done at low temperatures, one by Parker and Short[10] and the other by Weller and Zachariasse[11]. Although interest-

ing results were obtained by Parker and Short, they did not examine precisely their electrochemical system. On the other hand the latter authors' work concerned only with ECL spectra produced by the annihilation between the ion radicals of the two different molecules. By lowering the temperature not only the anion and the cation but also excimers will increase their stability, so that the observation of ECL spectra at low temperatures will become a useful means to study the mechanism of ECL involving excimer formation.

In order to elucidate the mechanism of the ECL of 9,10-dichloroanthracene (9,10-di-Cl-A), whose ECL spectrum had already been reported to be composed of the two components[12], electrochemical examinations of the ECL of this compound were performed at low temperatures. Large temperature effect was found not only on the ion radical stability but also on the ECL spectrum of 9,10-di-Cl-A. From the results obtained we will discuss the primary process of the observed ECL of 9,10-di-Cl-A.

Experimental

Materials. 9,10-di-Cl-A was synthesized by the method reported earlier[12] and purified by sublimation after recrystallization from carbon tetrachloride. Methylene chloride of guaranteed grade was further purified by distillation, dried over Molecular Sieve Linde 5A, and transferred to an electrolysis cell *in vacuo*. Dry tetrabutylammonium perchlorate (TBAP) or potassium perchlorate was used as a supporting electrolyte. Its concentration was *ca.* 0.05 M throughout the experiments.

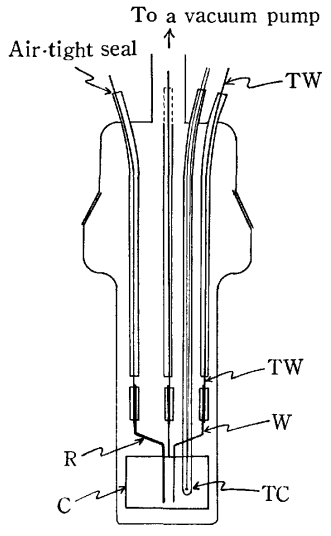

Fig. 1. Electrolysis cell.

Apparatus. A Pyrex glass electrolysis cell is shown in in Fig. 1. The working electrode, W, is of Pt wire (0.05—0.08 cm diameter, 3 cm length); R is a reference electrode of Ag wire (0.1 cm diameter); and C is a counter electrode of Pt plate (1.5 cm×2.0 cm and 0.02 cm in thickness). These electrodes are connected to the outside leads through tungsten wires.

——: ECL (7×10^{-4} M), ----: fluorescence (7×10^{-4} M),
——: filters: (a) V-VIA, (b) V-051 (Similar ECL spectra were also observed in methylene chloride and acetonitrile.)

Aliquot amounts of 9,10-di-Cl-A and a supporting electrolyte were weighed into the electrolysis cell which was then evacuated by using an oil diffusion pump. The solvent was transferred into the cell *in vacuo* and the solution was degassed by repeating a freeze-pump-thaw cycle. The cell was then sealed off from the vacuum line and its cylindrical part was inserted into a transparent Dewar vessel made of Pyrex glass. By circulating cold nitrogen gas into the Dewar vessel, constant low-temperature was maintained. Temperatures were measured with a copper-constantan thermocouple.

Controlled potential electrolysis using a three-electrode configuration was performed by employing a potentiostat. Cyclic voltammograms were recorded on a Yokogawa *X–Y* Recorder Type 3077 at various temperatures. For the separate measurements of the intensities of two components of the ECL of 9,10-di-Cl-A (Fig. 2), Toshiba glass filters V-VIA and V-051 were used. Transmittance curves of these filters are also shown in Fig. 2. The light transmitted through each filter was measured with a Hamamatsu R136 photomultiplier and recorded on the *X–Y* recorder or on a Matsushita VP-541A oscilloscope. The observed light intensities should be proportional to the intensities of the corresponding emissions, so that the change in the ratio of these two intensities with temperature was thought to give us informations about the spectral change with temperature.

Results

Cyclic Voltammogram. The cyclic voltammograms of 9,10-di-Cl-A are presented in Figs. 3 and 4. In DMF both the anion and the cation are unstable at the room temperature. As the temperature decreases the re-oxidation current of the anion comes to be observed, corresponding to an increase of the stability of the anion radical. The cation, however, was still unstable at low temperature on account of the strong nucleophilic property of DMF.[9] In methylene chloride, known as a good solvent for cation radicals, the cation of 9,10-di-Cl-A was stable[14] but the anion was unstable. When the potential was reversed after producing the anion, near +0.9 V *vs.* Ag the oxidation current (probably due to secondary products

of electrolysis) was observed (arrow in Fig. 4). Upon lowering the temperature this current finally disappears. In both cyclic voltammograms in Figs. 3 and 4 the difference between the anodic and cathodic peak potentials are larger than that of an ideal reversible wave. The peak current ratio for the anion radical couple was, however, close to unity even at a slow sweep rate of potential of 32 mV/s if the temperature was lower than *ca.* −40°C.[15] This shows almost complete stability of the anion at low temperatures. Similar results were obtained in acetonitrile.

In Fig. 5 the relationship between the applied potential and the observed emission intensity is shown. Light intensities were measured by using the photomultiplier without glass filters. This figure shows that as temperature decreases, the emission intensity becomes stronger and the emission lasts longer. Curiously the emission was observed only in the negative potential region even at low temperatures where both radical ions were considered to be stable. This phenomenon was independent of the direction of the potential sweep. From the results it is clear that the preannihilation mechanism is not suitable for the ECL of 9,10-di-Cl-A. In order to simulate the ECL-potential relationship, preliminary computer calculation was carried out by assuming that both ion radicals are completely stable and that the emission is observable only when the annihilation occurs be-

tween an anion and a cation.[16] The theoretical emission-potential curve differs from the observed curves in that the emission is observable both in the negative and positive potential regions.

Temperature Effect on ECL. When a rectangular potential having an amplitude a little larger than the difference between the reduction and the oxidation potentials shown in Fig. 4 was applied to the working electrode, an emission, whose intensity decays with time, was observed every time when the sign of the potential changed. This differs from the situation found in the case of a triangular potential. For the decay curves observed when the potential changed from positive (cation) to negative (anion), a log I_0/I *vs.* time plot was carried out as illustrated in Fig. 6, where I_0 corresponds to the maximum light intensity and the time corresponding to this point was put equal to zero. The results were shown for the two cases, one for the decay observed through the glass filter V–VIA and the other through the glass filter V–051. Both decay curves are seen to follow approximately exponential decay. The apparent decay

[9,10-di-Cl-A]10^{-3} M

constants for both curves are the same at the same temperature and diminish with a decrease in temperature. This is probably because the diffusion coefficients of molecules become smaller and stabilities of ion radicals increase as the temperature decreases.

The ratio of the peak heights of the two decay curves corresponding to the two emission components, designated by (I_0(excimer)/I_0(fluorescence)), is plotted against temperature in Fig. 7. The ratio continuously increases as the temperature decreases.

The emission from the excimer of 9,10-di-Cl-A by photo-excitation was observed by Chandross[17] in softened methylcyclohexane at low temperatures. In the same concentration region of 9,10-di-Cl-A, where its ECL was observed and at temperature as low as −60°C, no excimer emission was detected in either methylene chloride or DMF by photo-excitation.

In order to know the effect of concentration on the ECL spectra of 9,10-di-Cl-A, the ratio of the ECL intensity at 550 nm (excimer) to that at 450 nm (fluorescence) was measured in the concentration range of 10^{-3} to 10^{-4} M. As a measure of the fluorescence intensity, the light intensity at 450 nm was chosen in order to get rid of the effect of re-absorption of the fluorescent component at the shorter wavelength. The ratio showed a little increase as concentration increases, but its effect on ECL did not seem to have such a large effect as temperature had.

Discussion

Concerning the mechanism of the ECL of 9,10-di-Cl-A, it appears that the anion-cation annihilation process is indispensable and that this process occurs mostly in the bulk solution away from the working electrode. This is because we could not observe ECL when the electrolysis was carried out by applying triangular or rectangular potential in the region where only one type of ion was produced.

When we compare the emission *vs.* potential curve with the current *vs.* potential curve shown in Fig. 5, it is easily seen that the potential where ECL becomes observable almost coincides with the potential where the cathodic current begins to flow and that the potential where the ECL intensity reaches a maximum nearly corresponds with the cathodic peak potential. These results are compatible with the results of computer simulation.[16] ECL is still observable in the small negative potential region where a faradaic current is almost zero. This trend becomes more remarkable with the decrease of temperature as shown in Fig. 5. We can explain this in terms of the increased viscosity and stability of ion radicals at low temperatures. These facts indicate that ECL originates from the annihilation of ion radicals which have diffused away from the electrode.

There remains, however, an important question why the ECL could not be observed near the peak current potential where the cation was produced with a triagular potential. The results of computer simulation of the ECL based on the annihilation of the stable anion and cation radicals indicate that the ECL should be observed strongly in the two separate regions which correspond to the peak current potentials for reduction and oxidation. As far as the cyclic voltammetry concerns, both ion radicals are quite stable below −40°C,[15] so that we cannot find an pertinent explanation for the finding.

From the experiments at low temperatures it has also been assured that, of the two components of the ECL spectra of 9,10-di-Cl-A, the one at the longer wavelength corresponds to the emission from the excimer. The other possibility that the longer wavelength component is due to the secondary products of electrolysis is easily excluded,[6] because the emission intensity of this component increases as the anion increases its stability. The fact that an excimer is stabilized at low temperatures should also be noted. Combined with other experimental facts previously reported,[12] these new findings are thought to confirm our previous interpretation.

The primary process to produce two components of the ECL of 9,10-di-Cl-A is considered to be the same because the emission decay curves for the two components are the same at any temperature. However, it is not clear from the present work alone whether the mechanism to form the excimer is produced from reaction (2) or from reactions (3) and (4). The latter possibility, *i. e.*, the participation of the triplet state, has been pointed out by Weller and Zachariasse[11], and Freed and Faulkner[19] in an "energy deficient" ECL system. In our case, if we estimate roughly the enthalpy change in the anion-cation annihilation by the equation $\Delta H = E^{ox} - E^{red}$, where E^{ox} and E^{red} are the peak current potentials[20] for oxidation and reduction, respectively, the value of ΔH is of the same order as the energy of the lowest excited signlet state

of 9,10-di-Cl-A[21]. In addition the energy required to form the excimer is smaller than that of the excited singlet state. Therefore, we cannot eliminate the the possibility of the direct excimer formation by the simple consideration of energy balance alone. The simplest and most reliable way to ascertain experimentally the participation of the triplet state in ECL would be to observe the T–T′ absorption of the molecule in the triplet state, using an optically transparent electrode (OTE) as a working electrode.[22] With the aid of OTE, the transient absorption due to the anion or the cation generated near OTE has been measured.[15] If the mechanism of ECL is primarily based on the reaction Schemes (3) and (4), the local concentration of the triplet state molecules is expected to be as high as that of the ion radicals, which will permit us to measure its absorption with OTE.

As has been discussed hitherto, no conclusion can be drawn as to the mechanism of ECL except that the primary process of the ECL of 9,10-di-Cl-A is the annihilation of the anion and cation. It should be noted, however, that the excimer emission observed in the ECL is much stronger than that observed by photo-excitation. In fact at a concentration as low as 5×10^{-4} M, no excimer emission was observed by photo-excitation even at *ca.* −60°C. Change in concentration did not have large effect on ECL. These results are considered to indicate either (i) the excimer is directly formed by the anion-cation annihilation, or (ii) the local concentration in the neighbourhood of the excited molecule (singlet or triplet) is quite high because the excited molecule which has been produced as a result of the electron transfer reaction between two ions — anion and cation — will always have its counterpart in its close vicinity. If the mechanism (i) is working in our case, it is quite interesting since it entails an efficient energy dissipation process in electron transfer reactions which are accompanied by a large change in reaction enthalpy.

Photoelectron Spectra and Orbital Structures of Higher Alkyl Chlorides, Bromides, and Iodides

Katsumi KIMURA, Shunji KATSUMATA, Yohji ACHIBA, Hiroshi MATSUMOTO,* and Saburo NAGAKURA**

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo

**Japan Spectroscopic Co., Ltd., Hachiohji, Tokyo*

***The Institute for Solid State Physics, The Universtiy of Tokyo, Roppongi, Minato-ku, Tokyo*

(Received June 19, 1972)

High-resolution photoelectron spectra of alkyl halides RX (R=ethyl, *n*-propyl, and *n*-butyl; X=Cl, Br, and I) were measured with the 584 Å line of helium. In the region below about 17 eV, six bands were observed for each of the ethyl halides, eight bands for each of the *n*-propyl halides, and ten bands for each of the *n*-butyl halides. All the observed vertical ionization energies were plotted against Pauling's electronegativity of the halogen atom, indicating that there are approximate linear relationships. Assuming Koopmans' theorem, total and partial sums of experimental orbital energies were calculated using the observed ionization energies for the individual alkyl halides and found to be well reproduced by calculating the sums of empirical orbital-energy values for several localized orbitals such as $n(X)$, $n'(X)$, $\sigma(C\text{–}X)$, $\sigma(C\text{–}C)$, $\pi(CH_3)$, $\pi'(CH_3)$, and $\pi(CH_2)$. From a comparison of the experimental and calculated partial orbital-energy sums, assignments of the photoelectron bands to the localized molecular orbitals were made for each of the alkyl halides.

It is known in photoelectron spectroscopy that removal of a lone-pair electron gives rise to the first ionization with a sharp band distinguishable from other types of electrons such as π and σ electrons. As a result, the ionization energies of the lone pair electrons can be accurately determined, thus attracting attention to the photoelectron spectra of various compounds containing halogen atoms.

With respect to alkyl halides, several photoelectron studies[1–6,8] have been carried out with high-resolution photoelectron technique during the last few years. Turner[1] first succeeded in measuring high-resolution photoelectron spectra for many compounds including some halogen-containing compounds. Ragle

et al.[2] reported on the photoelectron spectra of many halomethanes including methyl halides and interpreted each of the observed bands in terms of molecular orbital structure from a comparative study of the spectra. For a series of alkyl bromides, Hashmall and Heilbronner[4] reported an interesting comparison of their first ionization energies obtained from the high-resolution photoelectron spectra, and concluded that the first ionization energy is reduced by 0.2 eV by methyl substitution on the α-position and by 0.09 eV on the β-position.

Photoelectron spectra of methyl iodide and several alkyl iodides have been studied by Baker *et al.*[5] together with other halogen-containing compounds from an analytical point of view, indicating that there is a correlation between the first ionization energies and the Taft σ values of the alkyl groups.

The "lone pair" bands of the series of the alkyl iodides as well as alkyl bromides have been studied theoretically in detail by Brogli and Heilbronner[6] in terms of the spin-orbit coupling. The photoelectron bands associated with ionization from the formally non-bonding p orbitals of the halogen atoms in various halomethanes have been interpreted by Dixon *et al.*,[7] in terms of a pseudo one-electron hamiltonian.

Photoelectron data of *n*-butyl iodide except for the first-ionization band has not so far been found in literature. Several photoelectron studies of alkyl halides mentioned above are available, but no systematic and comparative photoelectron studies covering higher alkyl chlorides, bromides and iodides have been published yet.

We have carried out a systematic and comparative study of not only the first but also the higher ionization energies of ethyl, *n*-propyl and *n*-butyl halides by means of a high-resolution photoelectron technique, with the aim first to deduce some correlations of ionization energies of alkyl halides with carbon chain and electronegativity of the halogen atom, and secondly to clarify valence orbital structures of the series of normal alkyl halides up to the butyl halides.

Experimental

Commercial alkyl halides were used after purification. Measurements of photoelectron spectra were carried out with a JASCO PE-1 high-resolution photoelectron spectrometer, containing an electrostatic semispherical analyzer, using helium 584 Å (21.22 eV) resonance line. Detection of photoelectrons was made with an electron multiplier coupled to an amplifier, discriminater and rate meter. The typical working resolution of this spectrometer was 20—25 meV. Calibration of an ionization-energy scale from the analyzer voltage was carried out using known ionization energy values of Ar and Xe as standard substances.

Results and Discussion

Photoelectron Spectra and Ionization Energies. Observed photoelectron spectra for ethyl, *n*-propyl and *n*-butyl halides (X=Cl, Br, and I) are shown in Figs. 1—3. General aspects of these spectra differ from those of the corresponding methyl halides except for the first bands, the spectrum becoming successively complicated as the alkyl group is ascended.

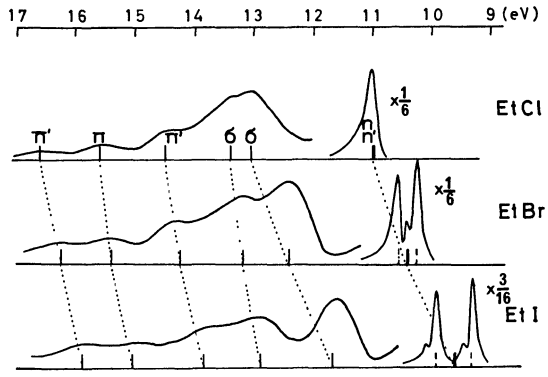

Fig. 1. Photoelectron spectra of ethyl halides.

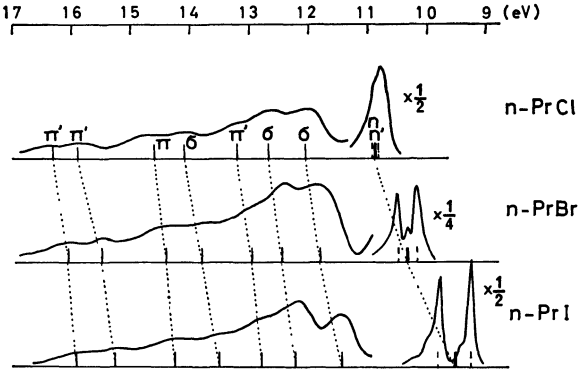

Fig. 2. Photoelectron spectra of *n*-propyl halides.

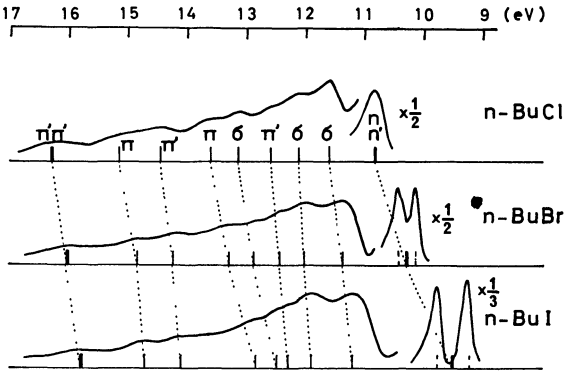

Fig. 3. Photoelectron spectra of *n*-butyl halides.

A comparative and systematic study is of merit for determining ionization energies from the photoelectron spectra.

First a brief review of the spectral features of methyl halides (CH_3X)[2,3] will provide a basis for interpreting electronic structures and photoelectron spectra of higher alkyl halides. In the methyl halides four photoelectron bands ascribed to different orbitals have been observed below *ca.* 22 eV. The first bands accompany spin-orbit splittings and vibrational structures are assigned to ionization of the non-bonding orbitals. The second bands ascribed to the C–X bonding orbitals show relatively broad maxima without any structure, and the third bands due to the pseudo

π orbitals of CH_3 are composed of double maxima due to the Jahn-Teller splitting. The fourth band appearing at *ca.* 20 eV has tentatively been assigned to the C 2s orbital.[3]

Spectral features observed for the higher alkyl halides are as follows.

Ethyl Halides. As seen from Fig. 1, a total of six bands appear for the individual ethyl halides, the first bands with structures very similar in spectral shape to those of the corresponding methyl halides. A slight shoulder appearing on high energy side of the second band of ethyl chloride is considered to be an independent band corresponding to the third inner orbital. Mean vertical ionization energies obtained from the maxima or shoulders of their photoelectron spectra are summarized in Table 1, the values obtained from the shoulders being shown in parentheses.

In order to find some correlation among the ethyl-halide data, we plotted the observed ionization energies against Pauling's electronegativities of the halogen atoms (Fig. 4) in which six kinds of observed ionization energies correspond well to each other. Such correlation diagrams are also drawn for other series of the alkyl halides in Fig. 4. In Fig. 5, the first and second ionization-energy plots of the ethyl halides are compared with those of the other higher halides.

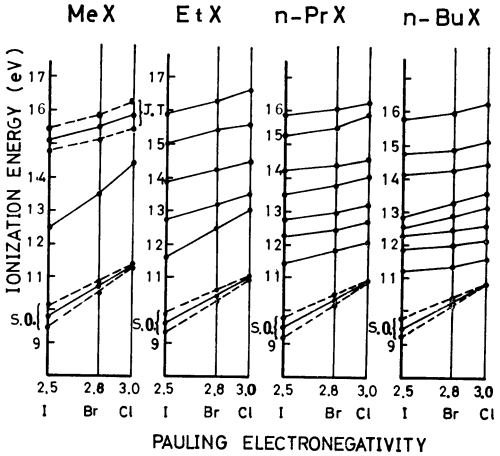

Fig. 4. Plots of ionization energies against Pauling's electronegativities of the halogen atoms. Corresponding points are connected by lines. (J. T. and S. O. denote the splittings of Jahn-Teller effect and spin-orbit coupling, respectively.)

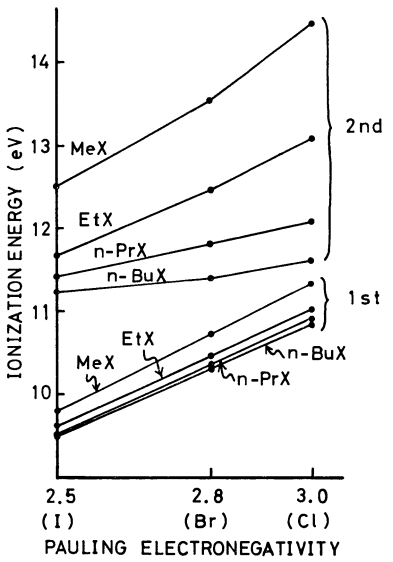

Fig. 5. Comparison of the first and second ionization-energy plots for the alkyl halides.

n-Propyl Halides. The photoelectron spectra of the series of the *n*-propyl halides are compared in Fig. 2. For these compounds a total of eight bands are distinguishable from the overall spectra. The resulting ionization energies are summarized in Table 2. Here also slight shoulders appear at *ca.* 13.2 eV for *n*-PrCl and *ca.* 12.9 and 13.8 eV for *n*-PrBr.

Seven ionization energy values have already been reported for *n*-PrI by Baker *et al.*,[5] whereas we identified a total of eight bands including the 13.5 eV band which appears as only a slight shelf. Good correlations were obtained for the observed ionization energies among the *n*-propyl halides as in the case of the ethyl halide series.

n-Butyl Halides. In the *n*-butyl halides the situation is much more complicated with overlapping bands in the photoelectron spectra. However, we can identify a total of at least ten bands from the observed spectra of the *n*-butyl halides by the aid of the correlation diagram (Fig. 4). The resulting values are given in Table 3.

Some literature values, though incomplete, are available for comparison with the present data, as

shown in Tables 1—3. For the alkyl chlorides except methyl chloride, no photoelectron data are available for comparison. For a series of alkyl bromides, no higher ionization energies have been reported previously. The first ionization energies including spin-orbit splittings reported by Hashmall and Heilbronner[4] were essentially in agreement with our corresponding data. Furthermore, in alkyl iodides, ethyl, *n*-propyl and *n*-pentyl iodides have been studied by photoelectron spectroscopy by Baker *et al.*,[5] but *n*-butyl iodide has not been included. As far as comparison is possible, excellent agreements were obtained.

Alkyl Substituent Effect on First Ionization. In Fig. 6, variations in the first mean ionization energies are shown for the alkyl halides from the methyl to *n*-butyl halides. Their higher normal homologues can be expected to tend to converge to nearly constant values.

It has been pointed out that the mean first ionization energies of the alkyl bromides are reduced by 0.2 eV per α-methyl substituent and by 0.09 eV per β-methyl substituent.[4] It is interesting to note that in the series of the alkyl chlorides, bromides and iodides, the ionization energy variation due to the methyl substitution on γ-position still amounts to as much as 0.02—0.05 eV.

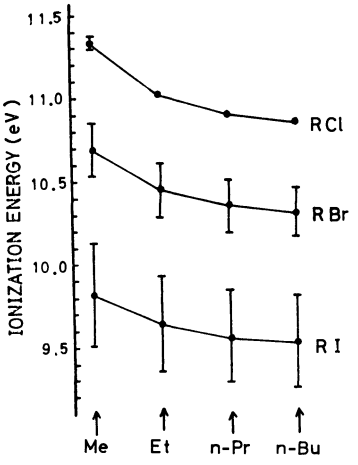

Fig. 6. The effect of carbon chain on the mean first ionization energies for the alkyl chlorides, bromides and iodides. Magnitudes of the spin-orbit splittings are also shown.

Correlation with Pauling's Electronegativity of Halogen Atom. It is interesting to examine how halogen atoms depend on ionization energies. The available ionization energies for the methyl halides are plotted for comparison (Figs. 4—6). As seen from Fig. 5, there are more or less linear relationships for many sets of ionization energy. Baker *et al.*[8] have pointed out that such a linear relationship is found for the first ionization energies of methyl halides. A similar correlation has now been found for the higher alkyl halides.

The gradient of the lines plotted in the correlation diagram is considered to express a measure of contribution from the halogen atoms. It is expected that the greater the contribution of the halogen atom, the steeper the line.

Let us consider the first ionization of the series of alkyl halides. The lowest straight lines corresponding to the first ionization show almost parallel relationships but become slightly less steep as the series ascends. The gradient of these lines may roughly be related to the magnitude of contribution of halogen p orbital by the following consideration. Assuming Koopmans' theorem, the lone-pair orbital ε_1 can be given by

$$\varepsilon_1 = c_x^2 F_{xx} + \sum_{\nu} c_{1x} c_{1\nu} F_{x\nu} + \cdots \quad (1)$$

where F_{xx} is a Hamiltonian element expressed in terms of the halogen p atomic orbitals. Since the molecular orbitals associated with the first ionization are expected to be largely contributed by the halogen p orbitals, coefficient c_x in the first term should be predominantly large. In the CNDO/2 approximation,[9] F_{xx} can be expressed by

$$F_{xx} = -\frac{1}{2}(I_x + A_x) + \cdots \quad (2)$$

It should be noticed that the first term in Eq. 2 is equivalent to Mulliken's electronegativity, which is in turn proportional to Pauling's electronegativity

$$\frac{1}{2}(I+A) = \chi\,(\text{Mulliken}) \propto \chi\,(\text{Pauling}) \quad (3)$$

Assuming that the rest of the terms in Eq. (1) be independent of the halogen atoms, the linearity and parallelism obtained for the lowest lines suggest that coefficients c_x have a nearly constant value for all the alkyl halides in spite of different kinds of halogen and alkyl group.

However, we see from Fig. 5 that the plots of the second ionization energies show no parallelism, the line slope becomes rapidly gentle as the series ascends. In *n*-propyl and *n*-butyl halides, in particular it is interesting to note that the second lines are considerably flat.

Total Orbital Energies. Since the total sum of eigenvalues of a secular equation is mathematically equal to its diagonal sum, total orbital energies should be unchanged before and after taking orbital interaction into account. Assuming Koopmans' theorem, this

a) Obtained on the assumption of Koopmans' theorem using all the ionization energies observed for individual ethyl, *n*-propyl, and *n*-butyl halides (Tables 1—3). For the methyl halides, the ionization-energy values reported in Ref. 2 were used.
b) Calculated by substituting the orbital energies given in Table 5 into Eqs. (4)—(7).

sum rule may be applied to our ionization energy problem. For the individual alkyl halides we calculated total orbital energies using $-\{2(I_1)_{av}+I_2+I_3+\cdots\}$ in the energy range studied. The resulting total energies thus obtained are shown in Table 4.

In interpreting these experimental total orbital energies, we considered that the orbitals under study are composed of several localized orbitals such as n(X), σ(C–X), σ(C–C), $\pi(CH_3)$, $\pi(CH_2)$, schematically shown in Fig. 7, and found that empirical values given in Table 5 are very suitable for these assumed orbitals. Total orbital energies were calculated with these values using the following equations

$$E(\text{MeX}) = 2\varepsilon^0(n, \text{X}) + \varepsilon^0(\sigma, \text{C-X}) + 2\varepsilon^0(\pi, CH_3) \quad (4)$$

$$E(\text{EtX}) = E(\text{MeX}) + \varepsilon^0(\sigma, \text{C-C}) + \varepsilon^0(\pi, CH_2) \quad (5)$$

$$E(n\text{-PrX}) = E(\text{MeX}) + 2\varepsilon^0(\sigma, \text{C-C}) + 2\varepsilon^0(\pi, CH_2) \quad (6)$$

$$E(n\text{-BuX}) = E(\text{MeX}) + 3\varepsilon^0(\sigma, \text{C-C}) + 3\varepsilon^0(\pi, CH_2) \quad (7)$$

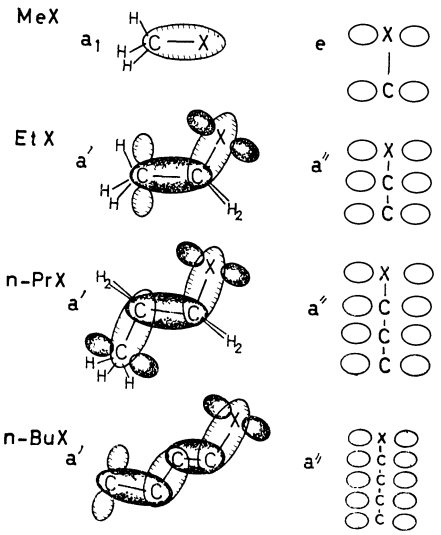

Fig. 7. Localized molecular orbitals used for the interpretation of the photoelectron data of the alkyl halides.

Table 5. Assumed orbital energies (in eV)

ε^0 (n, Cl) = −12.78[a]	ε^0 (σ, C-Cl) = −14.45[b]
ε^0 (n, Br) = -11.83_5[a]	ε^0 (σ, C-Br) = −13.52[b]
ε^0 (n, I) = -10.71_5[a]	ε^0 (σ, C-I) = −12.50[b]
ε^0 (σ, C-C) = −11.75	
ε^0 (π, CH_3) = ε^0 (π, CH_2) = −14.32	

a) Taken from the $(I_1)_{av}$ of the corresponding hydrogen halides reported in Ref. a) in Table 6.
b) Taken from the I_2 of the corresponding methyl halides reported in Ref. 2.

The calculated results are compared with the experimental ones in Table 4. It is interesting to see that the calculated total orbital energies are in good agreement with the experimental ones, strongly indicating that the molecular orbitals under consideration interact very slightly with inner orbitals such as C 2s and X *n*s orbitals.

The above agreements obtained for the total energy sums seem to support the existence of the concealed bands, whose ionization energy values are shown in parentheses in Tables 1—3.

As regards our estimation of the empirical energy values given in Table 5, the halogen non-bonding orbital energies were taken from the first mean ionization energies of molecules HX, shown in Table 6, since there is very little interaction between the non-bonding orbitals of these simplest halides and other valence orbitals. For C–X bands, their assumed unperturbed orbital energies were taken from orbital-energy values estimated from the second ionization energies of the methyl halides (Table 6), since the σ(C–X) orbitals belonging to a_1 symmetry do not interact with the n(X) and $\pi(CH_3)$ orbitals belonging to e symmetry and are considered to interact very slightly with inner orbitals of the same symmetry.

The $\pi(CH_3)$ orbital energy can not be determined directly from photoelectron spectra, since it always interacts with other orbitals to a considerable extent. However, from a comparison of the HX and MeX spectra, we can estimate the energy level of $\pi(CH_3)$

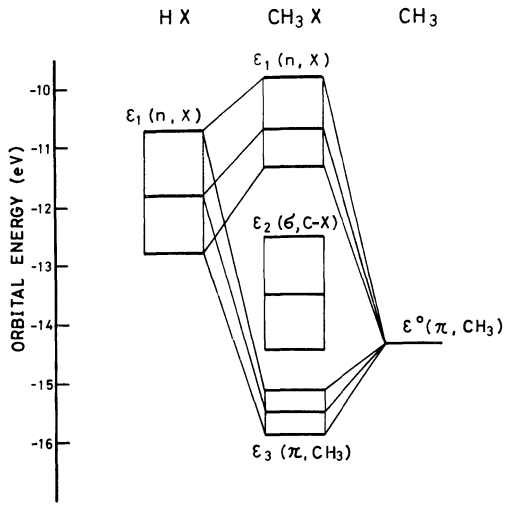

Fig. 8. Orbital energy levels of CH_3X (X=Cl, Br, and I), showing interactions of the n(X) and $\pi(CH_3)$ orbitals.

by considering that the first and third photoelectron bands result from an interaction of the halogen nonbonding and the CH_3 orbitals as shown in Fig. 8. Thus, assuming that

$$\{-I_1(CH_3X)\}_{av} + \{-I_3(CH_3X)\}_{av} = \{-I_1(HX)\}_{av} + \varepsilon^0(\pi, CH_3) \quad (8)$$

and using available data of ionization energy in the cases of X=Cl, Br, and I (see Table 6), we have $\varepsilon^0(\pi, CH_3) = -14.41$, -14.36 and -14.21 eV, respectively, with an average value of -14.32 eV.

The orbital energy of $\pi(CH_2)$ was assumed to be the same as that of $\pi(CH_3)$ for simplicity.

As shown in Fig. 9, the unperturbed C–C bonding

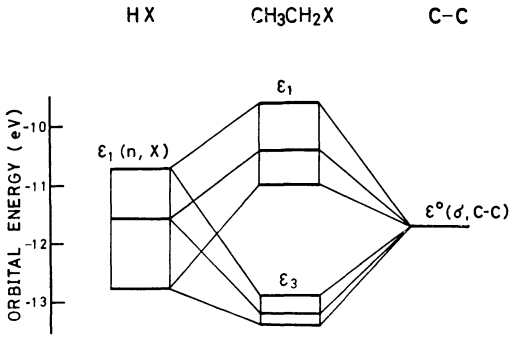

Fig. 9. Orbital energy levels ε_1 and ε_3 of C_2H_5X (X=Cl, Br, and I), showing interactions of the n(X) and σ(C–C) orbitals.

orbital energy $\varepsilon^0(\sigma, C–C)$ was estimated by taking the interaction between the C–C bonding and the halogen n'(X) orbitals of the ethyl halides into account. From the approximate equation

$$\{-I_1(EtX)\}_{av} + \{-I_3(EtX)\}_{av} = \{-I_1(HX)\}_{av} + \varepsilon^0(\sigma, C–C) \quad (9)$$

and with the available ionization energies, we obtained $\varepsilon^0(\sigma, C–C)$ values of -11.63, -11.80, and -11.82 eV in the cases of X=Cl, Br, and I, respectively, an average value of 11.75 eV being obtained.

From the agreements of the experimental and the calculated total orbital energies, we may conclude that our data of ionization energies shown in Tables 1—3 covers all the valence orbitals existing in the range higher than *ca.* -17 eV.

Assignments of Photoelectron Spectra. Orbital structures of the methyl halides are well understood and expressed approximately by[1-3]

$$\cdots e(\pi, CH_3)^4 a_1(\sigma, C–X)^2 e(np\pi, X)^4$$

in decreasing order of ionization energy. We found that the lower-energy shifts of the first bands of methyl halides compared with those of hydrogen halides can well be interpreted in terms of the interactions between the n(X) orbital and the $\pi(CH_3)$ orbital which is assumed to possess an orbital energy of about -14.3 eV (Fig. 8). Calculated and experimental sums for the methyl halides are shown in Table 7, indicating a validity of the selection of the $\pi(CH_3)$ energy values.

Ethyl halides are of symmetry C_s, so that molecular orbitals are divided into two species a′ and a″. As shown in Figs. 9 and 10, interactions in species a′ are considered to occur mainly between n(X) and σ(C–C) and between σ(C–X) and $\pi(CH_3)$, while in species a″ the n'(X), $\pi'(CH_3)$ and $\pi'(CH_2)$ orbitals considerably mix with one another (see also Fig. 6).

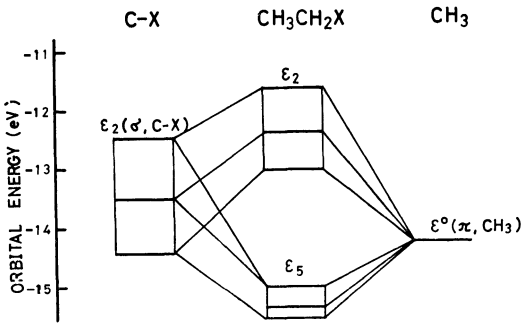

Fig. 10. Orbital energy levels ε_2 and ε_5 of C_2H_5X (X=Cl, Br, and I), showing interactions of the σ(C–X) and $\pi(CH_3)$ orbitals.

Using the sum rule mentioned before and the empirical energy values given in Table 5, it was found that the partial orbital-energy sums of $\{n$(X) and σ(C–C)$\}$, $\{\sigma$(C–X) and $\pi(CH_3)\}$ and $\{n'$(X), $\pi'(CH_3)$, and $\pi'(CH_2)\}$ are approximately equal to $-(I_1+I_3)$, $-(I_2+I_5)$ and $-(I'_1+I_4+I_6)$, respectively (Table 7). Good agreement of the partial sums of the calculated and experimental orbital energies makes it possible to assign the observed photoelectron bands of the ethyl halides. It might be concluded that I_2 and I_3 correspond to σ(C–X) and σ(C–C), respectively, with large contributions from $\pi(CH_3)$ and n(X), respectively. I_4, I_5, and I_6 can be assigned to $\pi'(CH_3)$, $\pi(CH_3)$ and $\pi'(CH_2)$, respectively. From the shapes of the first bands with spin-orbit splittings, it is not possible to distinguish the two bands corresponding to n(X) and n'(X) from each other which probably overlap closely.

For *n*-propyl halides, it is known that in gaseous phase there exist two types of rotational isomers, a *trans* form (symmetry C_s) and a *gauche* form (no symmetry).

a) Used the values reported in Ref. 2.

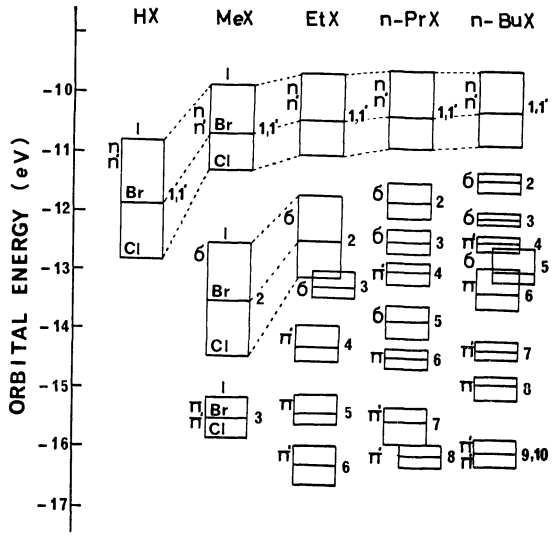

Fig. 11. Energy level diagram of the alkyl halides estimated from their photoelectron spectra, showing the effect of the successive methyl substitution.
In each block, the top line denotes RI, the middle line RBr and the bottom line RCl. Numbers 1,1',2,3,..... correspond to the orbitals starting from the highest occupied orbital to the inner orbitals successively. Letters n, n', σ, π, and π' indicate the assignments for the orbitals (see Table 7 for more details).

In the *trans* configuration, molecular orbitals of these compounds are divided into species a′ and a″, and those belonging to species a′ are expected to separate roughly into two minor groups, as shown in Table 7, one composed of σ(C_2–C_3) and σ(C–X), and the other of n(X), σ(C_1–C_2), and π(CH_3). The *gauche* form was neglected in the present discussion for simplicity. The a″ species includes the n'(X), π'(CH_3), and two π'(CH_2) orbitals (Fig. 7). The present ionization-energy data of the series of *n*-propyl halides were well interpreted in terms of the orbital interactions summarized in Table 7, good agreement being obtained for the partial sums of the calculated and experimental orbital energies.

We obtained results for the *n*-butyl halides from a similar analysis (Table 7). Here, a *trans* configuration was again assumed for these compounds, so that molecular orbitals are divided into two species a′ and a″. The orbitals belonging to a′ can be expected to separate further into two minor groups with little interaction, one composed of n(X), σ(C_3–C_4), and σ(C_1–C_2), and the other of σ(C_2–C_3), σ(C–X), and π(CH_3). Other orbitals, n'(X), π'(CH_3) and three π'(CH_2) are easily seen to belong to a″. Calculated partial sums for these groups are in good agreement with the corresponding experimental sums as shown in Table 7. From the investigation mentioned above, the following assignments were concluded.

EtX a′: $(I_1, I_3) \rightarrow \{n(\mathrm{X}), \sigma(\mathrm{C\text{-}C})\}$

$(I_2, I_5) \rightarrow \{\sigma(\mathrm{C\text{-}X}), \pi(\mathrm{CH_3})\}$

a″: $(I_1', I_4, I_6) \rightarrow \{n'(\mathrm{X}), \pi'(\mathrm{CH_3}), \pi'(\mathrm{CH_2})\}$

n-PrX a′: $(I_2, I_5) \rightarrow \{\sigma(\mathrm{C_2\text{-}C_3}), \sigma(\mathrm{C\text{-}X})\}$

$(I_1, I_3, I_6) \rightarrow \{n(\mathrm{X}), \sigma(\mathrm{C_1\text{-}C_2}), \pi(\mathrm{CH_3})\}$

a″: $(I_1', I_4, I_7, I_8) \rightarrow \{n'(\mathrm{X}), \pi'(\mathrm{CH_3}), 2\pi'(\mathrm{CH_2})\}$

n-BuX a': $(I_1, I_3, I_5) \rightarrow \{n(X), \sigma(C_3\text{-}C_4), \sigma(C_1\text{-}C_2)\}$

$(I_2, I_6, I_8) \rightarrow \{\sigma(C_2\text{-}C_3), \sigma(C\text{-}X), \pi(CH_3)\}$

a'': $(I_1', I_4, I_7, I_9, I_{10}) \rightarrow \{n'(X), \pi'(CH_3), 3\pi'(CH_2)\}$

All the experimentally determined levels are shown in Fig. 11.

From the present study the second ionization in the n-propyl and n-butyl halides can be assigned to the $\sigma(C_2\text{–}C_3)$ orbital rather than the σ(C–X) orbital, although these orbitals are mixed considerably. It should be pointed out that this fact is reflected on the slope of the second lines shown in the correlation diagram in Fig. 5, whereas the slope of the corresponding lines of the methyl and ethyl halides are much steeper, indicating large contributions from the σ(C–X) orbitals.

We are thus able to infer the possible assignments of all the observed photoelectron bands to orbitals which can be interpreted in terms of the localized molecular orbitals schematically shown in Fig. 7. We may say in general that the total or partial sum of appropriate ionization energies gives an important clue to spectral assignment in photoelectron studies.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 380—384 (1973)

The Polarized Absorption Spectra of Some β-Substituted Anthraquinones

Hiroyasu INOUE, Toshihiko HOSHI*, Junko YOSHINO*, and Yoshie TANIZAKI**

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama

**Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo*

***Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Meguro-ku, Tokyo*

(Received June 24, 1972)

The polarized absorption spectra of 2-hydroxy-, 2-amino-, and 2,3-diaminoanthraquinones were measured in stretched PVA sheets below 47 kK, and semiempirical ASMO-SCF-CI calculations, including the variable β method, were carried out for these compounds. By a comparison of the observed and the calculated results, the π–π* bands of these compounds were assigned. Each of these compounds has six bands in the observed wave number region, four of which correspond to those of anthraquinone; the other two bands can be assigned to the intramolecular charge-transfer transitions.

In a previous paper,[1] we measured the polarized absorption spectra of the α-aminoanthraquinones and discussed the assignment of the electronic bands of these compounds. For instance, it has been found that 1-aminoanthraquinone has five absorption bands, at 20.4, 31.8, 35.5, 40.3, and 42.6 kK, in a PVA sheet. From the comparison of the observed and calculated results, the latter four bands have been found to correspond to those of anthraquinone,[2] and the band at 20.4 kK has been assigned to the intramolecular charge-transfer transition associated with a charge migration from the amino group to the carbonyl groups. The polarization direction of the charge-transfer transition was found to be along the C=O bond axis.

Also, in the case of β-substituted anthraquinone with a hydroxyl or amino group, the intramolecular charge-transfer transition is expected to occur. However, its polarization direction may be different from that of the corresponding α-substituted anthraquinone.

In the present paper, the electronic absorption spectra of 2-hydroxy-, 2-amino-, and 2,3-diaminoanthraquinones are studied by means of the polarized absorption spectra and theoretical calculations.

Experimental

Materials. The anthraquinone derivatives used here were kindly presented to us by Dr. Mitsuhiko Hida of The University of Tokyo. The PVA sheets were prepared from the commercially-available powder (mean degree of polymerization, 1500).

Measurements of the Polarized Absorption Spectra and Notations. The methods of the determination and analysis of the polarized absorption spectra were the same as have been described elsewhere.[3] The notations used in the figures are as follows:

$D_{\parallel}$ and $D_{\perp}$: Absorbances measured for incident light polarized parallel to and perpendicular to the stretched direction of the PVA sheet respectively.

R_d: Ratio between $D_{\parallel}$ and $D_{\perp}$, $D_{\parallel}/D_{\perp}$.

R_s: Degree of stretching of the PVA sheet.

θ: Orientation angle for a transition moment of a band, which can be calculated from the values of R_d and R_s; it indicates an angle between the transition moment and the orientation axis of a molecule.

Method of MO Calculation

We have used the semiempirical ASMO–SCF–CI method[4,5] with the variable β approximation.[6] The

resonance integrals, β_{rs}'s, were adjusted at every iteraction of the SCF calculations by using the following equations:

$$\beta_{CC} = -1.84 - 0.51\,P_{CC}$$
$$\beta_{CN} = -2.02 - 0.53\,P_{CN}$$
$$\beta_{CO} = -2.20 - 0.56\,P_{CO}$$

where P_{rs} is a π bond order between the r and s atoms. The one-center repulsion integrals were evaluated by use of the following valence-state ionization potentials (I_p(r)) and the electron affinities (E_a(r)):

I_p(C) = 11.42 eV, E_a(C) = 0.58 eV
I_p(N) = 25.00 eV, E_a(N) = 10.00 eV
I_p(O) = 17.32 eV, E_a(O) = 2.65 eV.

The two-center repulsion integrals were obtained from the Nishimoto-Mataga equation.[7] All singly-excited configurations associated with the transitions between each of the five highest occupied levels and each of the five lowest vacant levels were taken into account in the CI calculations.

Results and Discussion

Figure 1 shows the absorption spectra of 2-hydroxy-, 2-amino-, and 2,3-diaminoanthraquinones in ethanol solutions. The spectrum of anthraquinone is also shown for comparison. By comparing each spectrum of the β-substituted anthraquinones with that of anthraquinone, we can find an additional band in the visible region for the β-substituted anthraquinone. Moreover, an additional band may exist also in the near-ultraviolet region, because the absorption curve in this region is intricate in shape compared with the absorption curve of anthraquinone. In contrast with the present cases, α-aminoanthraquinones have one additional band in the visible region.[1]

I: 2-Hydroxyanthraquinone, II: 2-Aminoanthraquinone, III: 2,3-Diaminoanthraquinone, IV: Anthraquinone

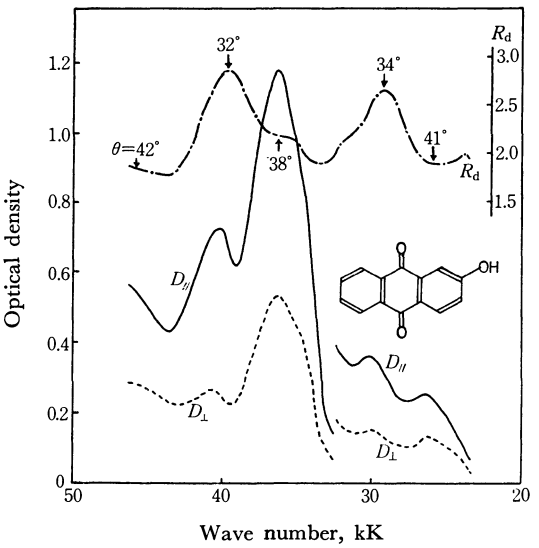

Fig. 2. The polarized absorption spectrum of 2-hydroxyanthraquinone. (R_s=5.8)

Figure 2 shows the polarized absorption spectrum of 2-hydroxyanthraquinone. From the features of the R_d and absorption curves, it is found that the compound has six absorption bands, at 26.3, 30.0, 34.5 (shoulder), 36.2, 40.3, and around 46 kK.

The observed results are compared with the calculated results in Table 1. A band corresponding to the calculated II transition is not found in the polarized absorption spectra. In the case of anthraquinone,[2] the corresponding band is observed around 32 kK. The calculated polarization directions of the III, V, and VI transitions are nearly along the X-axis of the molecule, and that of the IV transition is nearly along the Y-axis (Fig. 3). These results explain well the polarized absorption spectrum of this molecule. As in the cases of anthraquinonesulfonates and α-aminoanthraquinone,[1,2] a band polarized along the long axis of a molecule should have relatively large R_d values. Therefore, it is considered that the 30.0, 36.2, and 40.3 kK bands, with large R_d values, are polarized nearly along the X-(long) axis of the molecule, and that the 26.3, 34.5, and 46 kK bands, with small R_d values, are polarized along the Y-(short) axis.

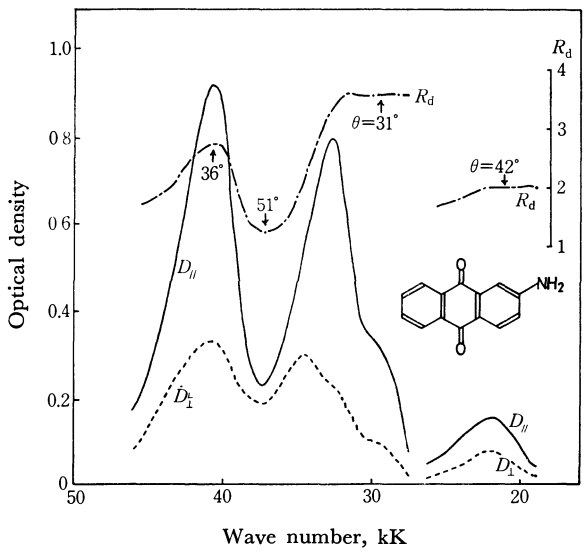

Fig. 4. The polarized absorption spectrum of 2-aminoanthraquinone. (R_s=9.0)

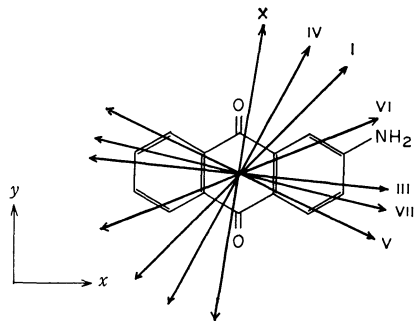

Fig. 5. The calculated polarization directions for 2-aminoanthraquinone.

Judging from the above-mentioned band positions, polarization directions, and relative intensities, the bands at 30.0, 34.5, 40.3, and 46 kK may correspond to the bands of anthraquinone at 30.8, 36.8, 39.7, and 43.4 kK respectively. The corresponding bands have also been found in each spectrum of the α-aminoanthraquinones.

Figure 4 shows the polarized absorption spectrum of 2-aminoanthraquinone. The bands corresponding to those of anthraquinone appear at 29.6, 34.6 (the absorption maximum appears only in the $D_\perp$ curve), 40.7, and around 46 kK (estimated from the R_d curve). The experimental results are summarized in Table 2 and compared with the results of the calculation. Figure 5 shows the calculated polarization directions. We can discuss the polarization directions of the two

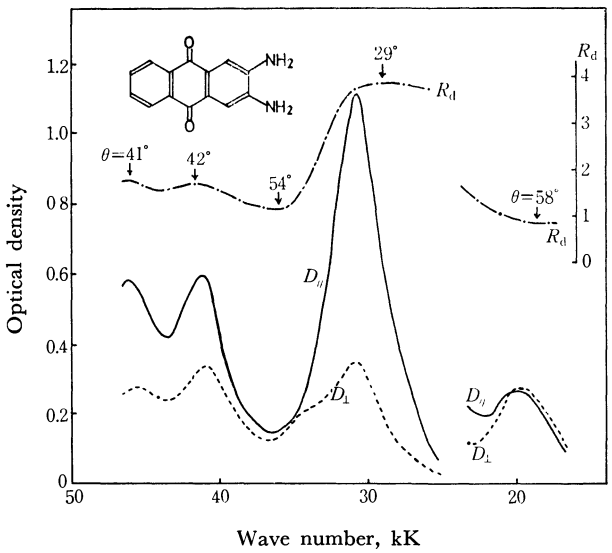

Fig. 6. The polarized absorption spectrum of 2,3-diaminoanthraquinone. (R_s=5.5)

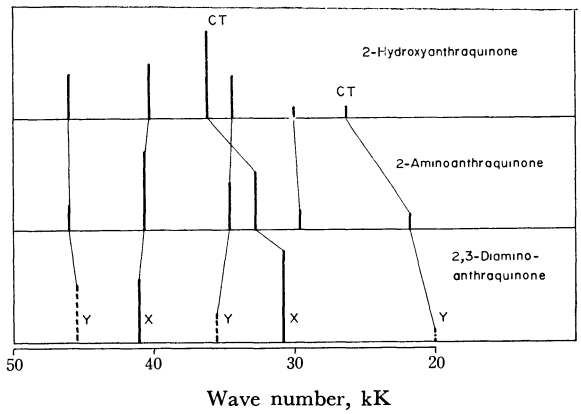

Fig. 7. Correlation diagram of the observed results.

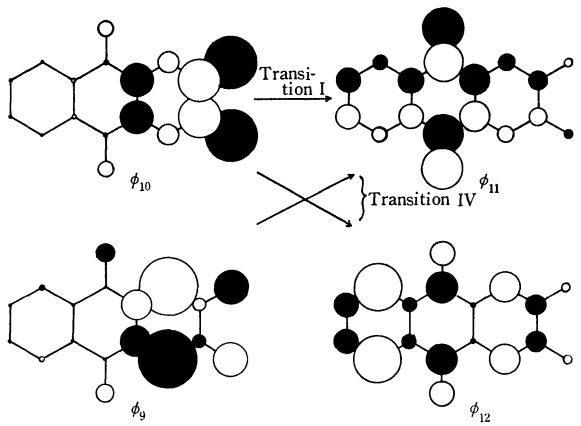

Fig. 8. Coefficients of the wave functions for 2,3-diaminoanthraquinone.

extra bands quantitatively, since the 21.7 kK band is isolated from the other bands and since the 32.7 kK band is not influenced in its polarization direction, because the intensities of the adjacent bands are very weak. The relative polarization direction of the 21.7 kK band with respect to that of the 32.7 kK band can be evaluated from the orientation angles as either 11° (=42°−31°) or 73° (=42°+31°). As has been shown above, the theoretical calculation shows the latter angle to be more reasanable.

The polarized absorption spectrum of 2,3-diaminoanthraquinone is shown in Fig. 6. The compound is assumed to belong to the C_{2v} point group; hence, the polarization direction of each band should be along the X- or Y-axis of the molecule. The extra bands of compound are found at 30.7 and 20.0 kK, and their orientation angles are 29° and 58° respectively. These bands are polarized perpendicularly to each other, because the sum of the orientation angles are approximately a right angle (29°+58°=87°). Since the

compound seems to orient in a manner similar to the cases of anthraquinonesulfonates and α-aminoanthraquinones,[1,2] that is, since the molecule orients its X-axis preferentially along the stretching direction of the sheet, the 30.7 kK band, with relatively large R_d values, is considered to be polarized along the X-axis, and 20.0 kK band, along the Y-axis. The experimental results obtained above are compared with the theoretical results in Table 3.

The results for the three compounds are compared in Fig. 7 as a correlation diagram. As may be seen from the figure, both of the two extra bands shift to the lower wave numbers with an increase in the electron-donating power of the substituent (OH→ NH_2) or with an increase in the number of the substituents. On the other hand, the positions of bands corresponding to the bands of anthraquinone are not significantly affected by the substitution. These tendencies can also be seen in the calculated results.

Table 4 presents the first and fourth excited state wave functions, which correspond to the two extra bands for 2,3-diaminoanthraquinone. The ψ_I is approximately represented by $\psi_{10,11}$ and the ψ_{IV}, by $\psi_{9,11}$ and $\psi_{10,12}$. The coefficients of the wave functions associated with the excitations are shown pictorially in Fig. 8. As may be seen from the figure, the charge migration from the amino to the carbonyl groups takes place in these excitations. Therefore, the I and IV transitions may be assigned to the intramolecular charge-transfer types. Similar results were obtained for 2-hydroxy- and 2-aminoanthraquinones.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 384—387 (1973)

Molecular Structure of *N*-Methylacetamide as Studied by Gas Electron Diffraction

Mitsuo KITANO, Tsutomu FUKUYAMA and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 29, 1972)

The bond distances (r_g) and angles (r_α) in *N*-methylacetamide have been determined by gas electron diffraction as follows: C–C=1.520±0.005 Å, N–C (methyl)=1.469±0.006 Å, N–C (carbonyl)=1.386±0.004 Å, C=O=1.225±0.003 Å, C–H (average)=1.107±0.005 Å, ∠N–C=O=121.8±0.4°, ∠C–N–C=119.7±0.8°, ∠C–C–N=114.1±1.5°, ∠H–C–H(average)=110.4±2° and ∠H–N–C(carbonyl)=110±5°. In comparison with the molecular structure in the crystal, the N–C(carbonyl) bond is about 0.10 Å longer, whereas the C–C and C=O bonds are about 0.02 and 0.01 Å shorter, respectively. The two methyl groups are in the *trans* conformation about the N–C (carbonyl) bond, no other conformer being observed.

N-Methylacetamide (Fig. 1) has frequently been taken as one of the simplest models of a polypeptide chain.[1] Previous studies of infrared, Raman and ultraviolet spectra,[2,3] the dipole moment,[2] and X-ray diffraction data[4] revealed the existence of the *trans* conformer in regard to the methyl groups about the C_2–N bond in all phases, whereas an infrared band (*ca.* 3429 cm^{-1}) observed by Russell and Thompson[5] in a dilute solution of carbon tetrachloride was tentatively assigned to the N–H stretching vibration of a *cis* conformer with an estimated abundance ratio of about 5%. The structure of this molecule in the gas phase was first investigated by the visual method of electron diffraction by Kimura and Aoki,[6] who estimated the N–C_3 distance and the C–N–C angle and also favored

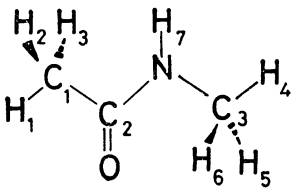

Fig. 1. *N*-methylacetamide.

the *trans* conformation. The rest of the structural parameters were transferred from those of acetamide determined by the same authors. In view of the importance of this molecule in chemistry and biochemistry, the present study was undertaken to determine its structure in the gas phase with higher accuracy.

Experimental

A commercial sample purified by vacuum distillation was heated to about 160°C by a high-temperature nozzle,[7] and diffraction photographs were taken with 40 kV electrons at camera distances of 111.80 mm (short) and 248.47 mm (long).[8] The scale factors of the diffraction patterns were

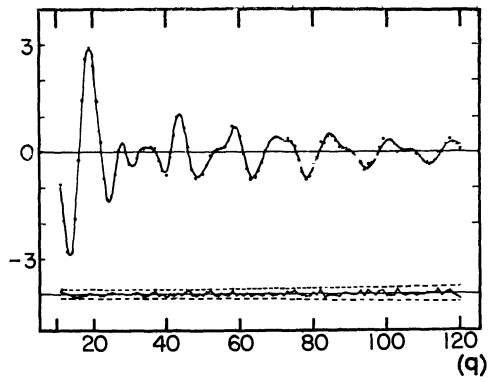

Fig. 2. Experimental and theoretical molecular intensities for *N*-methylacetamide. Typical observed $qM(q)$ values are shown in dots, and the best-fit theoretical is shown in the solid curve. The indices of resolution for long and short intensities are 0.950 and 0.763, respectively. The lower solid and broken curves represent the residuals and the error limits in the $qM(q)$ to a fractional error of 1×10^{-3} of the original photocurrent, respectively.

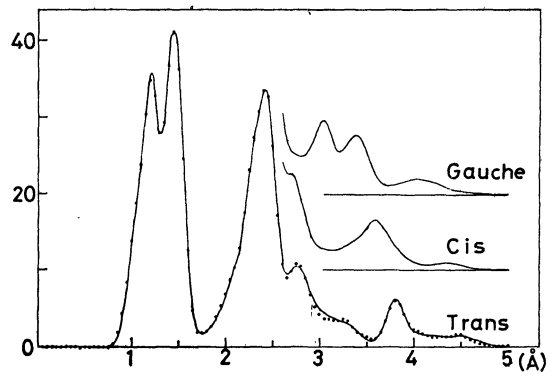

Fig. 3. Experimental (dots) and theoretical radial distribution curves. A damping factor, $\exp(1.599\times 10^{-4}q^2)$, is used.

calibrated to within 0.10% with reference to the r_a(C–O) distance of carbon dioxide (1.1646 Å)[8] for the short camera distance and to the r_a(N–N) distance of nitrogen (1.1007 Å)[9] for the long camera distance. The densities of four plates taken at each camera distance were measured by a digital microphotometer.[10]

Molecular intensities in the ranges $q=7$—50 and 30—120 Å^{-1} were obtained from the long and short distance data, respectively.[11] Since they agreed with each other in the overlapping region within experimental error (about 0.1 in the absolute $qM(q)$ scale), they were joined at 41 Å^{-1} (Fig. 2). The corresponding radial distribution curve shown in Fig. 3 has confirmed that the dominant conformer has *trans* methyl groups. Most of the calculations were carried out on a HITAC-5020E in the Computer Center of the University of Tokyo.

Analysis

The molecular intensity was analyzed under the following assumptions:

1) The molecule has a symmetry plane.
2) The two methyl carbon atoms are in the *trans* conformation about the C_2–N axis.
3) The *N*-methyl group is in the staggered conformation with the C_2–N bond.
4) One of the hydrogen atoms in the *C*-methyl group is in the eclipsed position with the C=O bond.
5) The methyl groups have local C_{3v} symmetry.
6) All the C–H distances are equal.
7) The r_α(N–H) distance is equal to the corresponding r_s(N–H) distance in formamide,[12] 1.002 Å.

The mean amplitudes of vibration and the vibrational corrections for the shrinkage effect[13] (r_a-r_α listed in Table 1) were calculated from a set of modified Urey-Bradley force constants determined by Itoh[14,15] from frequencies observed in the liquid phase. In the calculation of the vibrational corrections, contributions from the skeletal and methyl torsions, for which a conventional approximation of infinitesimal amplitudes breaks down,[16] were estimated by a high barrier

approximation.[17-20] The skeletal torsion around the C_2–N axis was assumed to obey the potential function, $V=(1/2)V_2(1-\cos 2\phi)$, where V_2 is 20 kcal/mol as estimated by Warshel *et al.*[21] The contributions from this motion to the r_a-r_α for the skeletal atom pairs were −0.0040 Å for C_1–C_3 and 0.0053 Å for O–C_3. The contributions from the skeletal torsion to the corrections for other atom pairs involving hydrogen were ignored, since they are obscured by much larger contributions from the methyl torsions. The effects of the methyl torsions on the nonbonded pairs indicated as b) in Table 1 were estimated from threefold potential barriers of 1 and 2 kcal/mol for the *C*-methyl and *N*-methyl torsions,[22] respectively, whereas those on the bonded and next-to-bonded pairs were assumed to be independent of the torsional motion. Uncertainties equal to 100% of the values calculated above were included in the limits of error of the structural parameters. The uncertainties from this origin are practically negligible except for the H–C–H angle.

The asymmetry parameters κ for the bonded C–H and N–H distances were assumed to be[23] 1.8×10^{-5} Å^3, and the rest of the κ parameters were ignored.

The r_g distances and r_α angles[13,24] derived from least-squares analyses[25] are listed in Table 2 with their limits of error estimated from the internal consistency and reproducibility of the parameters with additional account of systematic errors.[25-27] The error matrix is given in Table 3. The theoretical molecular intensity and radial distribution curves based on this structure are compared in Figs. 2 and 3, respectively, with the corresponding observed curves.

The experimental radial distribution and molecular intensity curves were further examined in detail in order to corroborate the above-mentioned assumptions 2—4) concerning the skeletal and methyl conformations. As for the skeletal conformation, the observed molecular intensity curves (q=11 to 40) were analyzed by the least-squares method on the assumption that the system is composed of *trans* (with a dihedral angle of 180°), *cis* (0°) and *gauche* (60°) conformers. Their frame structures were assumed to be identical, and the abundance ratios were the only variable parameters. The analysis gave 98±5, 0±5, and 2±4%, respectively. Analyses of the radial distribution curve and the background functions[28-30] were

not more sensitive than the least-squares analysis and also limited the concentration of conformers other than *trans* to less than 5%. The staggered conformation of the *N*-methyl group with respect to the C_2–N bond resulted in significantly better agreement with experiment than the eclipsed conformation. On the other hand, the conformation about the *C*-methyl group is less definitive, because both the eclipsed and staggered models gave acceptable radial distribution curves within experimental error. The most probable parameters derived from a least-squares analysis based on the staggered model are essentially equal to those given in Table 2, except that the N–C_2=O angle is 121.5°.

Discussion

The present structure is compared in Table 2 with those determined in previous studies[4,6)] and in Table 4 with those for related molecules. The most remarkable difference in the structural parameters in the gas and solid phases is seen in the C_2–N bond distance (*ca.* 0.10 Å). The C_2=O and C_1–C_2 bonds are found to be slightly shorter in the gas phase (*ca.* 0.01 and 0.02 Å, respectively) than in the solid phase. The presence of intermolecular hydrogen bonds (N–H···O) in the crystal[4)] seems to be the principal origin of these differences. The C_3–N distance, on the other hand, is nearly equal to that in the crystal and is about 0.08 Å longer than the C_2–N distance. Since the C_3–N distance is also nearly equal to those in methylamine[31)] and ethylenediamine,[30)] this bond can be regarded as a normal C–N single bond.

In comparison with the structure of acetone,[32,33)] *N*-methylacetamide has a very similar C–C bond distance but a slightly (*ca.* 0.01 Å) longer C=O bond and a slightly (*ca.* 2°) larger C–C=O angle. The C–N–C angle in *N*-methylacetamide is larger than that in dimethylamine[34,35)] by more than 7°, and the C–C–N angle is larger than that in ethylenediamine[30)] by more than 3°.

The authors are indebted to Dr. Yasushi Koyama of Kwansei Gakuin University and to Professors Masao Kimura and Takao Iijima of Hokkaido University for helpful discussions.

The Distribution of 2-Thenoyltrifluoroacetone between Several Organic Solvents and an Aqueous Solution and Its Extraction of Sodium(I) into Methyl Isobutyl Ketone

Tatsuya SEKINE, Yoshihiro TAKAHASHI, and Naohiko IHARA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 29, 1972)

Aqueous solutions containing sodium hydroxide and sodium perchlorate at various mixing ratios, 1 M Na(OH, ClO_4), were equilibrated with several organic solvents containing 2-thenoyltrifluoroacetone (TTA) at 25°C. From the measurements of the hydrogen-ion concentration of the aqueous phase, the $(K_D+1)K_a^{-1}$ values, where K_D is the distribution constant and K_a is the acid dissociation constant of TTA, were obtained; they were, $10^{7.17}$ (hexane), $10^{7.74}$ (CCl_4), $10^{8.01}$ (C_6H_6) and $10^{8.17}$ ($CHCl_3$). From the values of K_D obtained in another study, the value of K_a was determined to be $10^{-6.28}$. However, a much lower value than that expected was obtained for the MIBK system; this was due to the extraction of sodium(I) with TTA. The extraction was also confirmed by the distribution experiments of sodium(I). The extraction constant, $K_{ex}=[NaA]_{org}/[Na^+][A^-]$ (where A^- is the TTA anion), was found from these results to be $10^{0.86}$ in 1 M $NaClO_4$ and $10^{0.79}$ at an infinite dilution.

The solvent extraction of alkali metal ions with chelating extractants is usually poor except for that of lithium(I).[1-4] However, it was pointed out by Healy[3] that the extraction of alkali metal ions with 2-thenoyltrifluoroacetone (TTA)[3] and dibenzoylmethane[4] is very much enhanced by adduct formation (synergism); thus, even sodium(I) can be extracted to some extent with these chelating reagents if a neutral adduct-forming ligand, such as trioctylphosphine oxide, triphenylphosphine oxide, tributylphosphate, N,N-dibutylacetamide, ethylhexyl alcohol or nitromethane, is added.

The present authors have made a series of studies of the acid dissociation and two-phase distribution of several β-diketones. When the organic phase was nonpolar solvent, the chemical behavior of these reagents agreed with that statistically expected. However, when the solvent was methyl isobutyl ketone (MIBK), a deviation from the statistical expectation was found.

After an analysis, it was concluded that the above deviation is due to an extraction of the sodium(I) with TTA. This was also confirmed from the distribution ratio of sodium(I), measured by using a radioactive tracer.

Experimental

The sodium-24 tracer was obtained from the Japan Atomic Energy Research Institute as a sodium chloride solution. The TTA and MIBK were obtained from the Dojindo & Co. and the Tokyo Kasei Co., Ltd., respectively. The MIBK was washed several times with 0.1 M perchloric acid and with water, and then washed several times with 0.1 M sodium hydroxide and again with water. The sodium perchlorate was prepared from sodium carbonate and perchloric acid and was recrystallized three times from water. The other reagents were of an analytical grade. The sodium hydroxide solution was prepared by the dilution of its 50% aqueous solution with decarbonated water. A weighed portion of TTA was dissolved in an organic solvent, stored at least one day before the experiment, and then used as the stock solution.

All of the procedures were carried out in a thermostatted room at 25±0.3°C. Twenty-ml glass-stoppered tubes were used to equilibrate the two phases. A 5-ml portion of the TTA solution of an organic solvent, and a 5-ml portion of an aqueous solution which contained the 1 M sodium ion, and perchlorate and hydroxide ions at a certain molar ratio, 1 M Na(OH, ClO_4), were placed in the tubes. In the MIBK system, the two phases in the tube were placed on a rotating framework (20 rpm), agitated for three hr, and then centrifuged. In the other systems, the two phases were vigorously shaken for several minutes and then centrifuged. The hydrogen-ion concentration (in stoichiometric units) of the aqueous phase were determined potentiometrically with a glass electrode.

The experiment with the radioactive tracer was carried out as follows. The initial aqueous phase contained various amounts of sodium hydroxide and the sodium tracer. A 5-ml portion of this aqueous phase and a 5-ml portion of the MIBK solution, which contained an amount of TTA equivalent to the sodium hydroxide in the aqueous phase were placed in the tubes. The two phases were vigorously shaken for 3 min and then centrifuged. A 2-ml portion was pipetted from each phase and transferred into a small test tube. The γ-radioactivity of the sample was determined with a well-type scintillation counter (NaI). The distribution ratio was calculated as follows;

$$D = \frac{\gamma\text{-count-rate per ml of the org. phase}}{\gamma\text{-count-rate per ml of the aq. phase}}$$

Statistical

The acid dissociation constant and the two phase-distribution constants of a weak acid, HA, can be written as;

$$HA \rightleftharpoons H^+ + A^-$$

$$K_a = [H^+][A^-][HA]^{-1} \quad (1)$$

$$HA \rightleftharpoons HA_{(org)}$$

$$K_D = [HA]_{org}[HA]^{-1} \quad (2)$$

The ratio of these two values can be determined by a two-phase titration method[5] or by measurements of

4) T. V. Healy, *ibid.*, **31**, 499 (1969).
5) D. Dyrssen, *Svensk. Kem. Tidskr.*, **64**, 213 (1952),

the hydrogen-ion concentration of the aqueous phase, which initially contained various amounts of hydroxide ions and which were equilibrated with an organic phase containing an excess of the acid to the hydroxide ion.[6]

The statistical treatment for the latter method is as follows. In the following equations, the initial concentration of the acid in the organic phase will be denoted by $C_{HA(org)}$, and that of sodium hydroxide in the aqueous phase, by C_{OH}. The volumes of the two phases are always the same, and we assume no complex formation in the aqueous phase.

When no extraction of sodium salt occurs, the following equations can be obtained from Eqs. (1) and (2):

$$C_{HA(org)} = [A^-] + [HA] + [HA]_{org} = [A^-](1 + (K_D+1)K_a^{-1}[H^+]) \quad (3)$$

If $-\log [H^+]$ is not very high (*e.g.*, if $-\log [H^+]$ is below 11), it can be regarded that $C_{OH}=[A^-]+[OH^-]\simeq[A^-]$. Then, C_{OH} can be introduced into Eq. (3) instead of $[A^-]$ and we obtain:

$$C_{HA(org)}C_{OH}^{-1} - 1 = (K_D+1)K_a^{-1}[H^+] \quad (4)$$

On the other hand, when the sodium salts are extracted, the extraction equilibrium can be written as;

$$Na^+ + A^- \rightleftharpoons NaA_{(org)}$$

$$K_{ex} = [NaA]_{org}[Na^+]^{-1}[A^-]^{-1} \quad (5)$$

The initial concentration can then be written as (the other species in the organic phase, such as the dimer, are neglected):

$$C_{HA(org)} = [A^-] + [HA] + [HA]_{org} + [NaA]_{org} + [A^-]_{org} \quad (6)$$

When no dissociation in the organic phase is assumed, Eq. (6) can be rewritten as:

$$C_{HA(org)} = [A^-] + [NaA]_{org} + (K_D+1)K_a^{-1}[A^-][H^+] \quad (7)$$

Furthermore, when the concentration of the sodium ion can always be regarded as unity and when $-\log [H^+]$ is not very high (*e.g.*, when $[OH^-]<10^{-3}$, in other words, $[Na^+]_{initial}-[NaA]_{org}\simeq 1$ M):

$$C_{OH} = [A^-] + [NaA]_{org} = [A^-](1+K_{ex}) \quad (8)$$

From Eqs. (7) and (8), the following equation is obtained:

$$C_{HA(org)}C_{OH}^{-1} - 1 = (K_D+1)K_a^{-1}(K_{ex}+1)^{-1}[H^+] \quad (9)$$

Since the $C_{HA(org)}$ and C_{OH} values are known, and since the $[H^+]$ value can be determined by potentiometry, the $(K_D+1)K_a^{-1}(K_{ex}+1)^{-1}$ value can be determined from a set of experimental data, and when the values of K_D and K_a can be obtained by separate experiments, the K_{ex} value can be determined.

The distribution data of the second experiments, which were carried out by using a radioactive tracer, were treated as follows. Since the initial amount of sodium hydroxide is equivalent to that of the weak acid, TTA, in these systems, the $[Na(I)]_{org,total}=[TTA]_{org,total}$, and $[Na(I)]_{total}=[TTA]_{total}$ relations are always established. Provided that there is no dissociation of the species in the organic phase and no association of those in the aqueous phase, and furthermore, provided that the amount of the TTA in the HA form produced by the hydrolysis of A^- in the aqueous phase is much smaller than that of A^-, the following equations can be obtained:

$$[Na(I)]_{org,total} = [NaA]_{org} \quad (10)$$

$$[Na(I)]_{total} = [Na^+] = [A^-] \quad (11)$$

$$D = [NaA]_{org}[Na^+]^{-1} \quad (12)$$

From the above equations and Eq. (5):

$$K_{ex} = D[A^-]^{-1} = D[Na^+]^{-1} \quad (13)$$

When the distribution ratio is determined by radiometry, the value of $[Na^+]$ can be obtained as:

$$[Na^+] = C_{OH}(D+1)^{-1} \quad (14)$$

and from this value of $[Na^+]$, K_{ex} can be obtained by means of Eq. (13).

Results

Distribution Measurements. Table 1 gives the results of the distribution measurements. As may be seen from Eq. (13), the distribution ratio decreases with the decrease in $[Na^+]$ (and, at the same time, with that in C_{OH}). Since the ionic strength in the aqueous phase is not controlled in these systems, the extraction constants determined cannot be directly compared with each other. However, from these results, the following conclusions can be reached: (i) Part of the sodium (I) in the aqueous phase is extracted into MIBK with TTA. (ii) The value of K_{ex} increases with the decrease in the aqueous sodium-ion concentration and reaches a definite value. Thus, the K_{ex} at an infinite dilution can be estimated to be $10^{0.79}$.

Another series of distribution measurements were also carried out in systems where the electrolyte concentration in the aqueous phase was kept at 1 M by using sodium perchlorate. However, since sodium perchlorate is also to some extent extractable into the organic

Table 1. Distribution of sodium(I) between MIBK and aqueous phase containing sodium salt of TTA (no perchlorate) determined by radiometry[a]

$C_{OH}(=C_{HA(org)})$	log D	log $[Na^+]$	log K_{ex}[b]
2.0×10^{-1}	−0.45	−0.83	0.38
1.0×10^{-1}	−0.62	−1.09	0.47
5.0×10^{-2}	−0.77	−1.37	0.60
3.0×10^{-2}	−0.93	−1.57	0.64
2.0×10^{-2}	−1.07	−1.74	0.67
1.0×10^{-2}	−1.33	−2.02	0.69
8.0×10^{-3}	−1.36	−2.12	0.76
6.0×10^{-3}	−1.48	−2.24	0.76
4.0×10^{-3}	−1.62	−2.41	0.79
2.0×10^{-3}	−1.92	−2.70	0.78

a) The total amount of sodium ion is equivalent to TTA and the ionic strength in the aqueous phase is not controlled.
b) $\log D - \log [Na^+]$. Since the ionic strength in the aqueous phase changes, direct comparison of these data to each other is not suitable, especially in the higher $[Na^+]$ region.

$K_{ex}=[NaA]_{org}[Na^+]^{-1}[A^-]^{-1}$ $K_{ex_0}=[NaA]_{org}[H^+][Na^+]^{-1}[HA]_{org}^{-1}$
a) The equilibrium constant $\log(K_D+1)K_a^{-1}(K_{ex}+1)^{-1}$ is concluded to be 7.68.
From this value and the value of $(K_D+1)K_a^{-1}$ for this MIBK system determined in another study[8], the following extraction constants were obtained; $K_{ex}=10^{0.86}$, $K_{ex_0}=10^{-7.73}$.

phase,[7] a correction for this effect was necessary. In this case, as the accuracy of the experiments was not satisfactorily enough to make such a correction, no difinite value of K_{ex} could be obtained from these experiments.

Potentiometric Measurements. The value, $(K_D+1)K_a^{-1}$, obtained by introducing the values of $C_{HA(org)}$, C_{OH}, and $[H^+]$ into Eq. (4) agreed with the value computed by using the K_D and K_a^{-1} values experimentally obtained when the solvent was hexane, carbon tetrachloride, benzene, or chloroform. Thus we concluded that there was no extraction of sodium (I) with TTA into these solvents. Table 2 shows the values of $-\log[H^+]$ at equilibrium against the initial concentration of sodium hydroxide in the aqueous phase, C_{OH}, when the initial concentration of TTA in the organic phase, $C_{HA(org)}$, is 1.00×10^{-1} M. Table 2 also shows the $(K_D+1)K_a^{-1}$ values calculated by means of Eq. (4). Although a slight increase in $(K_D+1)\times K_a^{-1}$ with the decrease in C_{OH} is observed, it may be concluded that the values are nearly constant in each system.

The distribution constants of TTA in these systems were determined in another study in the authors' laboratory by the spectrophotometric method.[8] The values obtained were $10^{0.85}$, hexane; $10^{1.43}$, carbon tetrachloride; $10^{1.73}$, benzene; and $10^{1.89}$, chloroform With these distribution constants and the $(K_D+1)\times K_a^{-1}$ value obtained for each solvent in Table 2, the values of K_a were calculated to be $10^{-6.27}$, $10^{-6.30}$,

7) T. Sekine and T. Ishii, This Bulletin, **44**, 275 (1971).

8) Y. Hasegawa, *et al.*, unpublished work.

$10^{-6.28}$, and $10^{-6.27}$, from the results in the hexane, carbon tetrachloride, benzene, and chloroform systems, respectively. The acid dissociation constant of TTA in the 1 M sodium perchlorate solution at 25°C was thus estimated to be $10^{-6.28}$ as the average of these values.

The distribution constant of TTA between MIBK and 1 M sodium perchlorate had also been determined separately[8] to be $10^{2.31}$, and from the values of this K_D and the above K_a value, the log $(K_D+1)K_a^{-1}$ value in this system was expected to be $10^{8.59}$. However, as may be seen from Table 2, the value experimentally obtained, $10^{7.65}$ is about one-tenth of the expected value. The deviation may well be explained by the extraction of sodium with TTA which had already been demonstrated by the tracer experiments. Table 3 gives the values of $-\log [H^+]$ at equilibrium against the initial concentration of sodium hydroxide in the aqueous phase when the initial TTA concentrations in MIBK, $C_{HA(org)}$, are 0.05, 0.1, and 0.2 M and the values of the equilibrium constant, $(K_D+1)K_a^{-1}\times(K_{ex}+1)^{-1}$. The value of K_{ex} in Eq. (5) was calculated from this constant, and from the above $(K_D+1)\times K_a^{-1}$ value for the MIBK system, to be $10^{0.86}$.

The constant for metal extraction with chelating extractants is usually given by the following equation:

$$Na^+ + HA_{(org)} \rightleftharpoons NaA_{(org)} + H^+$$

$$K_{ex_0} = [NaA]_{org}[H^+][Na^+]^{-1}[HA]^{-1}{}_{org} \quad (15)$$

From Eqs. (5) and (15), the following relation can be obtained;

$$K_{ex_0} = K_{ex}\, K_a\, K_D^{-1} \quad (16)$$

Thus, K_{ex_0} in Eq. (15) can be calculated, from the constants cited above, to be $10^{-7.73}$.

Discussion

In order to make an analysis of the chemical equilibria in metal extraction system with a chelating extractant, the $(K_D+1)K_a^{-1}$ (when $K_D \gg 1$, $K_DK_a^{-1}$ can be used) is very important.[9] This value can be obtained naturally if the values of K_a and K_D can be found in the literature. However, these values are different when the ionic concentration in the aqueous phase is different, and the latter constant, K_D of course, is different in different solvents.

Although the two-phase titration method[5] seems to be applicable to such determinations of $(K_D+1)K_a^{-1}$, the simplified method demonstrated in this study also seems to be very useful for such a purpose, as has already been pointed out.[6] The usefulness of this method may be concluded from the fact that the values of K_a of TTA in 1 M sodium perchlorate calculated from the results of the four series of independent experiments using the different solvents shown in Table 2 are identical with each other.

It is well known that MIBK is a very good solvent for the TTA extraction of several metal ions, because the extraction is much enhanced by the use of this solvent over that using various non-polar solvents. For example, the extraction of alkaline earth ions with TTA is very effective when the solvent is MIBK, as was first reported by Kiba and Mizukami.[10] This enhancement has been quantitatively explained, in terms of adduct TTA chelate formation.[6]

The fact found in this study, that sodium(I) is extracted with TTA only when the solvent is MIBK, seems to indicate that the extraction of sodium with TTA due to an adduct formation of the chelate complex with MIBK, as in the case of the extraction of sodium(I) with TTA in benzene containing various neutral adduct-forming ligands.[3] Healy pointed out that two molecules of the adduct-forming ligand combine with one TTA sodium(I) chelate. In the present study, this solvation number could not be determined.

The value of the extraction constant, K_{ex_0}, in Eq. (5), $10^{-7.73}$, is not large, although it is much larger than that when the solvent is pure benzene, $10^{-11.16}$.[3] Thus, as has been described, the determination of K_{ex} from the distribution data when the aqueous phase is 1 M sodium perchlorate was not successful. On the other hand, it is very remarkable that the deviation of the hydrogen-ion-concentration data of the extraction experiments is quite large (one pH unit); thus, a reasonable extraction constant could be determined from the data.

The authors are very grateful to Dr. Yuko Hasegawa and Messrs. Yu Komatsu and Jun-ichi Yumikura of the present laboratory for their very helpful discussions. They are also grateful to Misses Etsuko Yamaguchi, Masumi Okamoto and Mr. Takaaki Shiokawa of the laboratory for their experimental aids.

The Calculation of the π-Electron Orbital Energies of the Allyl Cation, Butadiene, and Cyclic Polyenes by Means of Green's Function Method

Katsumi SHIMADA, Sadao OKIDO, and Osamu TANIMOTO

Department of Applied Physics, Faculty of Engineering, Osaka City University, Sumiyoshi, Osaka

(Received June 29, 1972)

Green's function matrix method for the calculation of the orbital energies of π-electron systems, which has been discussed in previous papers, is applied to the allyl cation, butadiene, rectangular cyclobutadiene, and cyclic polyenes with various molecular lengths. The higher-order correction for the Hartree-Fock orbital energies are calculated, and in the case of butadiene the theoretical value of the ionization potential is discussed in comparison with the experimental data. The relation between the higher-order correction effect and the molecular length is illustrated in the cases of the cyclic polyenes. In particular, the breakdown of perturbation calculation based on the Hartree-Fock orbitals occurs in the case of the $C_{30}H_{30}$ molecule.

In our previous papers,[1,2] Green's function matrix method for π-electron system was discussed using several examples. These examples were of cases where the self-consistent-field (SCF) Green's function matrices can easily be calculated by the analytical method. In the present article, our method is applied to the allyl cation, butadiene, rectangular cyclobutadiene, and cyclic polyenes for the purpose of investigating the relation between the higher-order correction effect and the molecular length.

As is shown in References 1) [to be referred to as I] and 2), we are concerned with the calculation of the one-particle Green's function matrix $G(\omega)$, because the poles of $G(\omega)$ give the orbital energies. Using the perturbation method based on the Hartree-Fock orbitals, the one-particle Green's function matrix is given as follows:

$$G(\omega) = [g(\omega)^{-1} - \Sigma(\omega)]^{-1}, \tag{1}$$

where:

$$g(\omega) = [(\omega+\mu)I - (\alpha+\beta+\chi)]^{-1}. \tag{2}$$

The $g(\omega)$ matrix is Hartree-Fock Green's function matrix. (see Eq. (I.38)) The 'chemical potential', μ, is fixed at a certain value between the highest occupied level and the lowest unoccupied one. The α and β matrices are core integrals. In the following, we put:

$$\alpha_{ll} = -u - \sum_{l \neq m} \gamma_{lm}, \tag{3}$$

where u represents the ionization potential of a carbon atom in its valence state. Using the Pariser, Parr, and Pople's Hamiltonian, the elements of the Hartree-Fock field matrix, χ, are given by the following equations (from Eq. (I.31)):

$$\left.\begin{aligned} \chi_{ll} &= -i\int \frac{d\omega}{2\pi} e^{-i\omega(0^-)}\{\gamma_{ll}g_{ll}(\omega) + 2\sum_{p\neq l}\gamma_{lp}g_{pp}(\omega)\}, \\ \chi_{lm} &= i\gamma_{lm}\int \frac{d\omega}{2\pi} e^{-i\omega(0^-)}g_{lm}(\omega) \quad (l \neq m). \end{aligned}\right\} \tag{4}$$

The self-energy part, Σ, represents the correction of higher-order effects to the Hartree-Fock orbital energies:

$$\begin{aligned} \Sigma_{lm} = \sum_{pq}\gamma_{lp}\gamma_{mq}\int\frac{d\omega_1}{2\pi}\int\frac{d\omega_2}{2\pi} \\ \times\{2g_{pq}(\omega_1)g_{qp}(\omega_2)g_{lm}(\omega-\omega_1+\omega_2) \\ -g_{lq}(\omega_1)g_{qp}(\omega_2)g_{pm}(\omega-\omega_1+\omega_2)\}. \end{aligned} \tag{5}$$

(see Eq. (I.32))

The Allyl Cation

In the case of the allyl cation, the unperturbed Green's function matrix is given by:

$$g(\omega) = \begin{pmatrix} \omega+\mu-\alpha_{11}-\chi_{11} & -\beta_{12}-\chi_{12} & -\beta_{13}-\chi_{13} \\ -\beta_{12}-\chi_{12} & \omega+\mu-\alpha_{22}-\chi_{22} & -\beta_{12}-\chi_{12} \\ -\beta_{13}-\chi_{13} & -\beta_{12}-\chi_{12} & \omega+\mu-\alpha_{11}-\chi_{11} \end{pmatrix}^{-1}. \tag{6}$$

The residue of the (lm) element of the Green's function matrix is denoted as R_{lm}:

$$R_{lm} = \frac{1}{2\pi i}\int d\omega e^{-i\omega(0^-)}g_{lm}(\omega). \tag{7}$$

It can easily be seen that R_{lm} have the following relations:

$$\left.\begin{aligned} &2R_{11} + R_{22} = 1, \\ &R_{13} = R_{11}, \\ &R_{11}R_{22} = R_{12}^2 \end{aligned}\right\} \tag{8}$$

and

$$(\alpha_{11}-\alpha_{22}+\beta_{13}+\chi_{13})R_{12} = (\beta_{12}+\chi_{12})(1-2R_{22}).$$

The self-consistency conditions (4) are, then, written as:

$$\left.\begin{aligned} &(4\gamma_{12}-\gamma_{11}-2\gamma_{13})R_{22} = 2\chi_{11} - \gamma_{11} - 2\gamma_{13}, \\ &-\gamma_{12}R_{12} = \chi_{12}, \\ &(\gamma_{11}-2\gamma_{12})R_{22} = \chi_{22} - 2\gamma_{12}, \\ &\gamma_{13}R_{22} = 2\chi_{13} + \gamma_{13}. \end{aligned}\right\} \tag{9}$$

From these relations, the following algebraic equation is obtained:

$$\begin{aligned} A_1^2R_{22}^4 + A_1(2A_2-A_1)R_{22}^3 + \{A_2(A_2-2A_1)+8\beta_{12}^2\}R_{22}^2 \\ - (A_2^2+8\beta_{12}^2)R_{22} + 2\beta_{12}^2 = 0, \end{aligned} \tag{10}$$

where:

$$\left.\begin{aligned} A_1 &= -\frac{3}{2}\gamma_{11} + 2\gamma_{12} - \frac{1}{2}\gamma_{13}, \\ A_2 &= \alpha_{11} - \alpha_{22} + \frac{1}{2}\gamma_{11} - \gamma_{12} + \frac{1}{2}\gamma_{13} + \beta_{13}. \end{aligned}\right\} \tag{11}$$

Using the solution for R_{22} in the above equation (10), the Hartree-Fock field, χ, is obtained from Eq. (9). The orbital energies, ω_1, ω_2 and ω_3 ($\omega_1<\omega_2<\omega_3$), in the SCF approximation are easily obtained by the use of Eq. (2); they are listed in Table 1. The element of the SCF Green's function matrix is represented as;

1) O. Tanimoto and K. Shimada, *Mol. Phys.*, **23**, 745 (1972).
2) K. Shimada and O. Tanimoto, *ibid.*, **23** 765 (1972).

Table 1. The orbital energies of the allyl cation (in eV)

	Semi-empirical[3]	Löwdin orbitals(1)	Löwdin orbitals(2)
γ_{11}	10.84	17.62	
γ_{12}	7.52	8.92	
γ_{13}	5.63	5.57	
β_{12}	−2.85	−2.68	
β_{13}	−0.45	0	−0.45
u	11.42	11.54	
ω_3	−5.860 (−5.651)	−4.281 (−3.192)	−4.399 (−3.469)
ω_2	−9.761 (−9.659)	−8.933 (−8.519)	−8.493 (−8.080)
ω_1	−21.31 (−21.23)	−20.18 (−19.69)	−20.47 (−19.97)

The values in the bracket are the result of the SCF calculation. (1) As the values of the coulomb-integrals, those in the case of benzene[4] are adopted. (2) The value of β_{13} is used that of semi-empirical case.

Table 2.

(lm)	A_{lm}	B_{lm}	C_{lm}
11	A_{11}	0.5	$0.5-A_{11}$
22	$1-2A_{11}$	0	$2A_{11}$
12	A_{12}	0	$-A_{12}$
13	A_{11}	−0.5	$0.5-A_{11}$

$$g_{lm}(\omega)=\frac{A_{lm}}{\omega-\omega_1-i\delta}+\frac{B_{lm}}{\omega-\omega_2+i\delta}+\frac{C_{lm}}{\omega-\omega_3+i\delta}, \quad (12)$$

where A_{lm}, B_{lm}, and C_{lm} are certain constants simply related to one another, as is shown in Table 2. From the theorem of residues:

$$\begin{aligned}&\int\frac{d\omega_1}{2\pi}\frac{d\omega_2}{2\pi}g_{ij}(\omega_1)g_{kl}(\omega_2)g_{mn}(\omega-\omega_1+\omega_2)\\&=\frac{A_{ij}B_{kl}A_{mn}}{\omega-2\omega_1+\omega_2}+\frac{A_{ij}C_{kl}A_{mn}}{\omega-2\omega_1+\omega_3}+\frac{B_{ij}A_{kl}B_{mn}}{\omega+\omega_1-2\omega_2}\\&+\frac{B_{ij}A_{kl}C_{mn}+C_{ij}A_{kl}B_{mn}}{\omega+\omega_1-\omega_2-\omega_3}+\frac{C_{ij}A_{kl}C_{mn}}{\omega+\omega_1-2\omega_3}. \quad (13)\end{aligned}$$

$$g(\omega)=\begin{pmatrix}\omega+\mu-\alpha_{11}-\chi_{11} & -\beta_{12}-\chi_{12} & -\beta_{13}-\chi_{13} & -\beta_{14}-\chi_{14}\\ -\beta_{12}-\chi_{12} & \omega+\mu-\alpha_{22}-\chi_{22} & -\beta_{23}-\chi_{23} & -\beta_{13}-\chi_{13}\\ -\beta_{13}-\chi_{13} & -\beta_{23}-\chi_{23} & \omega+\mu-\alpha_{22}-\chi_{22} & -\beta_{12}-\chi_{12}\\ -\beta_{14}-\chi_{14} & -\beta_{13}-\chi_{13} & -\beta_{12}-\chi_{12} & \omega+\mu-\alpha_{11}-\chi_{11}\end{pmatrix}^{-1}. \quad (14)$$

For even alternant hydrocarbons, the theorem proved by Pople[6] states that:

$$P_{rr}=2\frac{1}{2\pi i}\int d\omega\, e^{-i\omega(0^-)}g_{rr}(\omega)=1. \quad (15)$$

From the above theorem, the following relation is obtained:

$$\alpha_{rr}+\chi_{rr}=\text{constant}\equiv\mu, \quad (16)$$

where the chemical potential, μ, is set at the center of the level scheme. The relation:

$$\beta_{13}+\chi_{13}=0 \quad (17)$$

is derived from the pairing theorem.[7] Using these relations, the elements of the SCF Green's function can be written thus:

$$\begin{aligned}g_{lm}(\omega)=&\frac{a_{lm}}{\omega-\beta_+-i\delta}+\frac{b_{lm}}{\omega+\beta_++i\delta}\\&+\frac{c_{lm}}{\omega-\beta_--i\delta}+\frac{d_{lm}}{\omega+\beta_-+i\delta}, \quad (18)\end{aligned}$$

where, assuming that $\beta_{12}=\beta_{13}\equiv\beta$ and $\beta_{14}=0$:

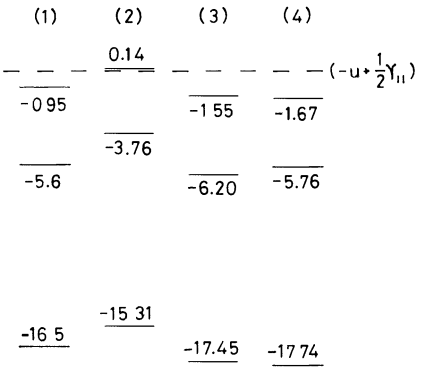

Fig. 1. The orbital energies of the allyl cation measured from the standard $-u+1/2\,\gamma_{11}$.
Case (1) is the result that is in the Salem's text and cases (2), (3) and (4) correspond to the first, second and third column in Table 1, respectively.

Using Eqs. (13) and (5), the orbital energies including the correlation effect were calculated from the secular equation (1); they are shown in Fig. 1, along with the results in Salem's text.[5] The orbital energies are measured from the standard $-u+\gamma_{11}/2$. In the case of the semi-empirical parameters, unlike the other cases, the highest energy level appears above the origin of the energy level. With regard to the electron-density distribution, we have the following relations:

$$q_{22}>2q_{11} \quad \text{(Case (2) in Fig. 1)}$$

and:

$$q_{22}<2q_{11} \quad \text{(Cases (1), (3) and (4) in Fig. 1)}$$

as q_{ii} is the electron-occupation number at the carbon atom, i. It shows the feature of the semi-empirical parameters that the correction for the Hartree-Fock orbital energies is smaller than that in other cases.

Butadiene

In the case of butadiene, the SCF Green's function matrix is given by:

6) J. A. Pople, *Trans. Faraday Soc.*, **49**, 1375 (1953).

7) A. D. McLachlan, *Mol. Phys.*, **4**, 49 (1961).

TABLE 3.

(lm)	a_{lm}	b_{lm}	c_{lm}	d_{lm}
11	a_{11}	a_{11}	a_{22}	a_{22}
22	a_{22}	a_{22}	a_{11}	a_{11}
12	a_{12}	$-a_{12}$	a_{12}	$-a_{12}$
13	a_{12}	a_{12}	$-a_{12}$	$-a_{12}$
14	a_{11}	$-a_{11}$	$-a_{22}$	a_{22}
23	a_{22}	$-a_{22}$	$-a_{11}$	a_{11}

$$\left.\begin{aligned}\beta_+ &= -\frac{1}{2}[\{(\beta+\chi_{23}-\chi_{14})^2+4(\beta+\chi_{12})^2\}^{1/2} \\ &\quad -\beta-\chi_{14}-\chi_{23}], \\ \beta_- &= -\frac{1}{2}[\{(\beta+\chi_{23}-\chi_{14})^2+4(\beta+\chi_{12})^2\}^{1/2} \\ &\quad +\beta+\chi_{14}+\chi_{23}].\end{aligned}\right\} \quad (19)$$

The relations among the coefficients, a_{lm}, b_{lm}, c_{lm}, and d_{lm}, in Eq. (18) are given in Table 3, and

$$\left.\begin{aligned}a_{11} &= \frac{1}{4}[1+(\beta+\chi_{23}-\chi_{14})\{(\beta+\chi_{23}-\chi_{14})^2 \\ &\quad +4(\beta+\chi_{12})^2\}^{-1/2}], \\ a_{22} &= \frac{1}{2}-a_{11}, \\ a_{12} &= -\frac{1}{2}(\beta+\chi_{12})\{(\beta+\chi_{23}-\chi_{14})^2 \\ &\quad +4(\beta+\chi_{12})^2\}^{-1/2}=\sqrt{(a_{11}a_{22})}.\end{aligned}\right\} \quad (20)$$

From these equations and Eq. (4), the following equations can easily be obtained:

$$\left.\begin{aligned}\chi_{11} &= \frac{1}{2}\gamma_{11}+\gamma_{12}+\gamma_{13}+\gamma_{14}, \\ \chi_{22} &= \frac{1}{2}\gamma_{22}+\gamma_{12}+\gamma_{13}+\gamma_{23}, \\ \chi_{12} &= 2\beta\gamma_{12}\chi_{23}/(\beta\gamma_{23}-A\chi_{23}), \\ \chi_{14} &= -(\gamma_{14}/\gamma_{23})\chi_{23}\end{aligned}\right\} \quad (21)$$

and

$$4A^2\chi_{23}^4-8\beta\gamma_{23}A\chi_{23}^3+(20\beta^2-A^2)\gamma_{23}^2\chi_{23}^2 +2\beta\gamma_{23}^3A\chi_{23}-\beta^2\gamma_{23}^4=0, \quad (22)$$

where:

$$A=2\gamma_{12}-\gamma_{23}-\gamma_{14}. \quad (23)$$

Eq. (22) has two real solutions. We choose the solution which satisfies the condition:

$$\beta+\chi_{23}<0. \quad (24)$$

The orbital energies, including the correlation effect, are obtained and the numerical results are listed in Table 4, together with the SCF orbital energies. In other to compare the present results with the experimental results, the ionization potential is calculated. Using Slater orbitals, the ionization potential of *trans*-butadiene is calculated as below:

$$I_{\text{calc}}=u-\frac{1}{2}\gamma_{11}-\omega=9.01\text{ eV}\quad(8.80\text{ eV})$$

where ω is the energy of the higher occupied orbital given in Table 4 and where $u=11.54$ eV is used.

TABLE 4. NUMERICAL RESULTS OF π-ELECTRON ORBITAL ENERGIES IN BUTADIENE MOLECULE

	Slater orbitals[8]		Hall orbitals[9]
	cis-	*trans*-	*trans*-
γ_{11}	16.93		17.26
γ_{22}	16.93		17.56
γ_{12}	9.24		9.03
γ_{23}	8.69		8.63
γ_{13}	5.52		5.48
γ_{14}	4.68	3.83	3.78
β	−2.68		−2.68
χ_{12}	−4.37	−4.39	−4.28
χ_{23}	−1.42	−1.35	−1.37
χ_{14}	0.763	0.595	0.598
ω^{SCF}	±5.79 ±9.12	±5.72 ±9.16	±5.62 ±9.06
ω	±6.04 ±9.02	±5.93 ±8.99	±5.92 ±8.92
Δ	±0.25	±0.21	±0.30
$(\Delta=\omega-\omega^{\text{SCF}})$	∓0.10	∓0.17	∓0.14

The value in brackets is the result of the SCF calculation. The experimental value was given by Price and Walsh[10] as:

$$I_{\text{expt}}=9.07\text{ eV}.$$

Thus, our result is in good agreement with the experimental value. The effect of orbital reorganization during the ionization process was investigated by Devaquat and Salem.[11] Using the perturbation theory, they found only a small correction to the I_{SCF} value for the ionization potential in the SCF scheme; the correction is about 0.1 eV for closed-shell systems, such as the allyl cation or butadiene. On the other hand, the correlation energies obtained with our method are 0.2—0.5 eV, except for the semi-empirical parameters. Hence, the deviations in the orbital energies from the SCF values are determined by the correlation effect rather than by the orbital-distortion effect.

The Rectangular Cyclobutadiene

Here we will derive the equations for the orbital energies of the rectangular cyclobutadiene. From the SCF Green's function matrix:

$$g(\omega)=\begin{pmatrix}\omega & -\beta-\chi_{12} & 0 & -\beta'-\chi_{14} \\ -\beta-\chi_{12} & \omega & -\beta'-\chi_{14} & 0 \\ 0 & -\beta'-\chi_{14} & \omega & -\beta-\chi_{12} \\ -\beta'-\chi_{14} & 0 & -\beta-\chi_{12} & \omega\end{pmatrix}^{-1}. \quad (25)$$

we obtain the following self-consistency conditions:

$$\left.\begin{aligned}\chi_{11} &= \frac{1}{2}\gamma_{11}+\gamma_{12}+\gamma_{13}+\gamma_{14}, \\ \chi_{12} &= -\frac{1}{2}\gamma_{12}, \\ \chi_{13} &= \chi_{14}=0.\end{aligned}\right\} \quad (26)$$

We also obtain the orbital energies, $\omega_{\text{SCF}}=\pm\beta_\pm$,

8) R. G. Parr and R. S. Mulliken, *J. Chem. Phys.*, **18**, 1338 (1950).
9) G. G. Hall, *Trans. Faraday Soc.*, **50**, 773 (1954).
10) W. C. Price and A. D. W. Walsh, *Proc. Roy. Soc.*, Ser. A, **174**, 220 (1940).
11) A. Devaquet and L. Salem, *J. Chim. Phys.*, **62**, 1267 (1965).

where:

$$\beta_{\pm} = \beta \pm \beta' - \frac{1}{2}\gamma_{12}. \tag{27}$$

The matrix element of the self-energy part is given by:

$$\Sigma_{lm} = \frac{a}{4}\left(\frac{1}{\omega+3\beta_+} + \frac{(-1)^{l+m}}{\omega-3\beta_+} + \frac{\alpha_{lm}}{\omega+3\beta_-} + \frac{(-1)^{l+m}\alpha_{lm}}{\omega-3\beta_-}\right) + \frac{b}{4}\left(\frac{1}{\omega+\beta_++2\beta_-} + \frac{(-1)^{l+m}}{\omega-\beta_+-2\beta_-} + \frac{\alpha_{lm}}{\omega+2\beta_++\beta_-} + \frac{(-1)^{l+m}\alpha_{lm}}{\omega-2\beta_+-\beta_-}\right), \tag{28}$$

where:

$$\left.\begin{aligned} a &= \frac{1}{16}\{(\gamma_{11}-\gamma_{12})^2-(\gamma_{11}-\gamma_{13})^2+(\gamma_{11}-\gamma_{14})^2 \\ &\quad +(\gamma_{12}-\gamma_{13})^2+(\gamma_{13}-\gamma_{14})^2-(\gamma_{12}-\gamma_{14})^2\}, \\ b &= \frac{1}{16}\{3(\gamma_{11}-\gamma_{12})^2+(\gamma_{11}-\gamma_{13})^2-(\gamma_{11}-\gamma_{14})^2 \\ &\quad -(\gamma_{12}-\gamma_{13})^2+7(\gamma_{13}-\gamma_{14})^2+(\gamma_{12}-\gamma_{11})^2\} \end{aligned}\right\} \tag{29}$$

and

$$\alpha_{11} = \alpha_{12} = -\alpha_{13} = -\alpha_{14} = 1. \tag{30}$$

The orbital energies, $\omega=\pm\omega_{\pm}$, are given by the following equations:

$$\omega_+ = \beta_+ + \frac{a}{\omega_++3\beta_+} + \frac{b}{\omega_++\beta_++2\beta_-} \tag{31}$$

and

$$\omega_- = \beta_- + \frac{a}{\omega_-+3\beta_-} + \frac{b}{\omega_-+2\beta_++\beta_-}. \tag{32}$$

The Cyclic Polyenes

For the purpose of investigating the relation between the correlation energies and the molecular length, we will discuss the cyclic polyenes here. The systems of $4n+2$ π-electrons are considered in the following discussion. For the sake of simplicity, only the nearest-neighbour interactions are taken into account. The SCF Green's function, $g_{4n+2}(\omega)$, is given as below:

$$g_{4n+2}(\omega) = \begin{pmatrix} \omega & d & 0 & \cdots & d \\ d & \omega & d & \cdots & 0 \\ 0 & d & \omega & \cdots & 0 \\ \cdot & \cdot & \cdot & & \cdot \\ \cdot & \cdot & \cdot & & \cdot \\ d & 0 & 0 & \cdots & \omega \end{pmatrix}^{-1}, \tag{33}$$

where we put $\mu=\alpha+\chi_{ll}$ and $d=-\beta-\chi_{l,l\pm1}$. The poles of this Green's function matrix are given by:[12]

$$\det|g_{4n+2}(\omega)^{-1}| = -4d^{4n+2}\sin^2(2n+1)\theta = 0, \tag{34}$$

where:

$$\omega = -2d\cos\theta. \tag{35}$$

The solutions of the above equation are:

$$\theta_r = \frac{r}{2n+1}\pi, \tag{36}$$

where:

$$\left.\begin{aligned} &r = 0,\ 2n+1 \\ &r = 1, 2, \cdots, 2n \text{ (doubly degenerated levels).} \end{aligned}\right\} \tag{37}$$

12) C. Coulson, *Proc. Roy. Soc., Ser. A*, **164**, 383 (1938).

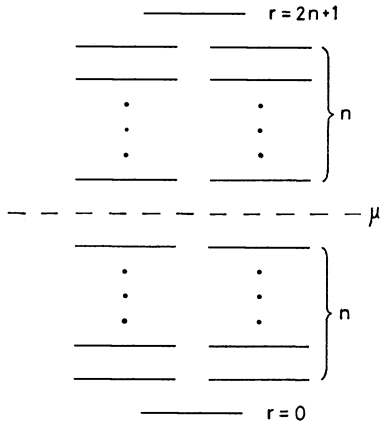

Fig. 2. The schematic orbital energies of the cyclic polyenes with $4n+2$ π-electrons.

The $4n+2$ suffix in $g_{4n+2}(\omega)$ will be disregarded hereafter for the sake of simplicity. The (lm) element of $g(\omega)$ is obtained thus:

$$g_{lm}(\omega) = \frac{\cos(2n+1+l-m)\theta}{2d\sin\theta\sin(2n+1)\theta}. \tag{38}$$

On the other hand, as is shown in Fig. 2, $g_{lm}(\omega)$ is written in the following form:

$$g_{lm}(\omega) = \sum_{r=0}^{n}\frac{a_{lm;r}}{\omega-\omega_r-i\delta} + \sum_{r=n+1}^{2n+1}\frac{b_{lm;r}}{\omega-\omega_r+i\delta}. \tag{39}$$

The transformation of the variables, ω to θ, is convenient for the following evaluation. Then, the contour on the complex plane is distorted to that shown in Fig. 3.

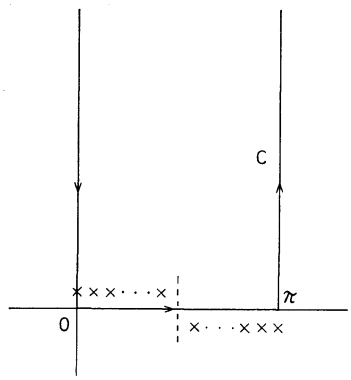

Fig. 3. The contour in the complex θ plane.
The mark × denotes the poles of the one-particle Green's function.

The residues are given by:

$$\begin{aligned} a_{lm;r} &= \lim_{\omega\to\omega_r}(\omega-\omega_r)\sum_j\frac{a_{lm;j}}{\omega-\omega_j} \\ &= \lim_{\theta\to\theta_r} w_r(\theta-\theta_r)\frac{\cos(2n+1+l-m)\theta}{\sin(2n+1)\theta} \\ &= \frac{w_r}{2n+1}\cos\frac{(l-m)r}{2n+1}\pi, \end{aligned} \tag{40}$$

$$b_{lm;r} = a_{lm;2n+1-r} = (-1)^{l-m}a_{lm;r}, \tag{41}$$

where, as the pole, $r=0$, exists on the contour, c, and as the other poles are included within c, we have:

$$w_0 = 1/2, \text{ and } w_r = 1 \text{ for } 1 \leqq r \leqq n. \tag{42}$$

Using Eq. (4) and the relations:

$$\left.\begin{aligned}&\sum_r \alpha_{ll;r} = \sum_{r=0}^{n} \frac{w_r}{2n+1} = \frac{1}{2n+1}\left(n+\frac{1}{2}\right) = \frac{1}{2}\\ &\text{and}\\ &\sum_r a_{l,l\pm1;r} = \frac{1}{2n+1}\left(\sum_{r=0}^{n} \cos\frac{r\pi}{2n+1} - \frac{1}{2}\right),\end{aligned}\right\} \quad (43)$$

we obtained the self-consistency conditions:

$$\left.\begin{aligned}&\chi_{ll} = \frac{1}{2}\gamma_0 + 2\gamma_1,\\ &\chi_{l,l\pm1;r} = -\frac{1}{2n+1}\frac{\cos\dfrac{n\pi}{2n+1}}{1-\cos\dfrac{\pi}{2n+1}}\end{aligned}\right\} \quad (44)$$

where $\gamma_0=\gamma_{ll}$ and $\gamma_1=\gamma_{l,l\pm1}$. Hence, we obtain the next relations:

$$\left.\begin{aligned}&\mu = \alpha + \chi_{ll} = \alpha + \frac{1}{2}\gamma_0 + 2\gamma_1 = -u + \frac{1}{2}\gamma_0,\\ &d = -\beta + \frac{\gamma_1}{2n+1}\frac{\cos\dfrac{n\pi}{2n+1}}{1-\cos\dfrac{\pi}{2n+1}}.\end{aligned}\right\} \quad (45)$$

The SCF orbital energies are obtained by using $\omega_r^{SCF}=-2d\cos\theta_r\equiv\beta_r$. The (lm) element of $\Sigma(\omega)$ can easily be obtained:

$$\Sigma_{lm}(\omega) = \sum_{rst} B_{rst}(lm)\left[\frac{1}{\omega+\beta_r+\beta_s+\beta_t} + \frac{(-1)^{l+m}}{\omega-\beta_r-\beta_s-\beta_t}\right], \quad (46)$$

where the coefficient, $B_{rst}(lm)$, is given by:

$$B_{rst}(lm) = \sum_{pq} \gamma_{lp}\gamma_{mq}(-1)^{p+q}[2a_{pq;r}a_{qp;s}a_{lm;t} - a_{lq;r}a_{qp;s}a_{pm;t}]. \quad (47)$$

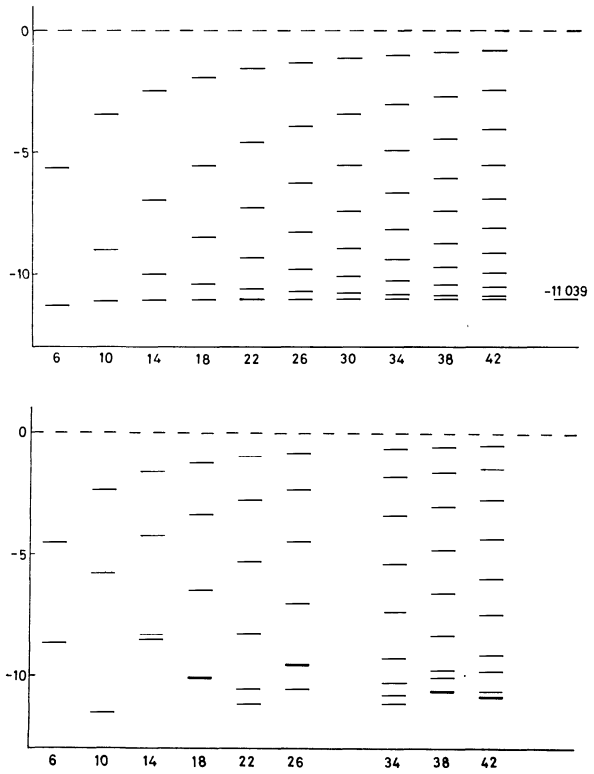

Fig. 4. The orbital energies of the cyclic polyenes of the SCF method and these including the correlation effect.

										±10.85

13) The Löwdin orbital parameters for benzene in Ref. 4 are used.

In the nearest-neighbour-interaction approximation, Eqs. (34) and (35) hold if ω and d are transformed to $\omega-\Sigma_{11}(\omega)$ and $d-\Sigma_{12}(\omega)$ respectively; that is,

$$-4[d-\Sigma_{12}(\omega)]^{4n+2}\sin^2(2n+1)\theta = 0. \quad (48)$$

Therefore,

$$\omega_r - \Sigma_{11}(\omega_r) = -2[d-\Sigma_{12}(\omega_r)]\cos\theta_r \quad (49)$$

is obtained, where θ_r is given by Eq. (36). Using these parameters[13];

$$\gamma_0 = 17.62\,\text{eV} \text{ and } \gamma_1 = 8.92\,\text{eV},$$

the numerical calculations are executed. The numerical results for $n=1-10$ are listed in Table 5 and are illustrated in Fig. 4.

In the case of the Hartree-Fock approximation, the energy of the $r=0$ level (the lowest occupied orbital), as measured from the center of the level scheme, monotonously increases as the π-electron number, $m=4n+2$, increases. At the limit, $m\to\infty$, the value of the lowest orbital energy approaches -11.039 eV in the case of the above-mentioned parameters. However, the orbital energies of occupied levels belonging to the other quantum number, r, monotonously decrease. By including the higher-order correction, these monotonous properties are broken down (see Fig. 4). The extremely close levels appear in the lower part of the level scheme. Furthermore, at $m=30$, the relation:

$$\omega_2 = \omega_5 + \omega_6 + \omega_7$$

is accidentally satisfied and the perturbation calculation is not adequate. The deviations from the Hartree-Fock orbital decrease as m increases, and the orbital energies approach the Hartree-Fock levels.

Solubility of Alkyl Bromides in Aqueous Polymer Solutions

Tsuneo Okubo, Shou-Xyng Chen, and Norio Ise
Department of Polymer Chemistry, Kyoto University, Kyoto

(Received July 4, 1972)

The solubility of alkyl bromides (alkyl : ethyl, *n*-propyl, *n*-butyl and *n*-amyl) in aqueous solutions of neutral polymers and polyelectrolytes was measured and discussed. The polymers used were polyacrylamide (PAAm), polyvinylalcohol(PVA), polyethyleneglycol(PEG), polyvinylpyrrolidone(PVP), polyethylenimine(PEI) and polyacrylic acid(PAA) and its salts. The solubility of alkyl bromide increased linearly with concentration of neutral polymer in the order PAAm>PVP~PEI>PEG>PVA~PAA. Sodium salt of PAA decreased the solubility of alkyl bromide, but organic salts of PAA such as tetraalkylammonium salts increased it. Using the equation $\ln (S_0/S)=km_2$, the limiting Setchénow constant k was obtained for these systems. The results were accounted for in terms of the hydrophobic structural modifications of water and the direct dipole and/or hydrophobic interactions between solute and cosolute.

In a previous paper,[1] the solubility of non-polar solutes, *i.e.*, naphthalene and biphenyl, in aqueous polymer solutions was reported. It was revealed that solvent-solute interactions, *viz.*, the structural effects of polymers on water, were most influential in determining the solubility. The cosolute-cosolute interactions or the solute-cosolute interactions except for those mediated by solvent water molecules were found to be negligible. In this paper we report on attempts to estimate the comparative strength of the solute-cosolute or cosolute-cosolute interactions and that of the solvent-solute interactions in polymer solution when cosolute is polar by measurements of the solubility of alkyl bromides. Studies on the solubility of the polar cosolute in polymer solutions have been carried out,[2] but the cosolutes were complicated compared with the alkyl bromids we used.

Experimental

Materials. Neutral polymers used as solutes were polyacrylamide (PAAm, degree of polymerization ($\overline{DP}$= 1800), polyvinylalcohol (PVA, $\overline{DP}$=1200, fractionated sample), polyethyleneglycol (PEG, $\overline{DP}$=140) and polyvinylpyrrolidone (PVP, $\overline{DP}$=220). Polyelectrolytes also used as solutes were sodium, tetramethylammonium (Me_4N–), tetraethylammonium (Et_4N–), tetra-*n*-propylammonium (Pr_4N–) and tetra-n-butylammonium (Bu_4N–) polyacrylates (PAA) obtained by neutralization of a polyacrylic acid(a product of Toa Gosei Chemicals Co., Nagoya, Japan, $\overline{DP}$= 640) with the corresponding hydroxide. Polyethylenimine (PEI, a product of Sumitomo Chemicals Co., Osaka, Japan, $\overline{DP}$=100) and unneutralized polyacrylic acid(PAA) were also used. Low molecular weight solutes were urea, tetramethylammonium bromide, tetraethylammonium bromide, tetra-*n*-propylammonium bromide and tetra-*n*-butylammonium bromide. Except for high molecular weight compounds, all the materials used were commercially available (Guaranteed reagent grade). Water was deionized by cation- and anion-exchange resins. Ethyl bromide (EtBr), *n*-propyl bromide (PrBr), *n*-butyl bromide (BuBr) and *n*-amyl bromide (AmBr) used as cosolute were further purified by distillation, and washed three times with water before use.

Solubility measurements. Excess cosolute was introduced into 20 ml test tubes containing 5 ml pure water or polymer solution with known concentration, wchich were sealed with stopper, shaken vigorously at first and placed for two to four days in a mechanical shaker in a thermostat at 25°C.

2) Cf. e. g., J. Eliassaf, F. Eriksson, and F. R. Eirich, *J. Polymer Sci.*, **47**, 192 (1960).

After equilibration, a small portion of the homogeneous layer was taken out with a syringe and analyzed by gas chromatography. The apparatus used was GCG-550T with a thermal conductivity detector of Yanagimoto Mfg. Co., Kyoto. The column used was 2.2 m×3 mm ϕ. The stationary phase is Tide with carrier Neopak 1 A (mesh 60—80, products of Nishio Industry Co. Tokyo). The carrier gas was helium. The injection and detector temperatures were 125—135°C and 110°C, respectively. For ethyl bromide, *n*-pyropyl bromide, *n*-butyl bromide and *n*-amyl bromide, the column temperatures were 103, 100, 98 and 96°C, the helium flow rates 15, 20, 22.5 and 25 ml/min. and the bridge currents 100, 130, 150 and 200 mA, respectively. The solubilities of ethyl, n-propyl, n-butyl and n-amyl bromide are estimated to be 8.3×10^{-2}, 1.9×10^{-2}, 4.3×10^{-3} and 7.9×10^{-4} mol/l, respectively, at 25°C.

Rusults and Discussion

The solubilization[3] of *n*-butyl bromide in various neutral polymer solutions is shown in Fig. 1, in which

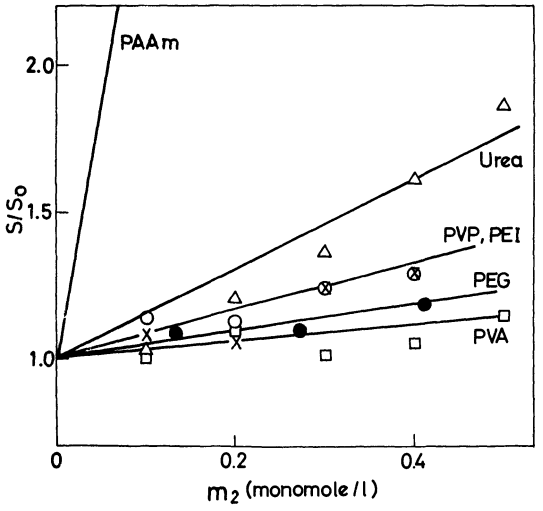

Fig. 1. Solubilization factor (S/S_0) of BuBr in various neutral polymer solutions at 25°C. ○: PVP, ×: PEI.

S_0 and S are the solubilities in pure water and in polymer solution, respectively, and m_2 is the polymer concentration. It is seen that S/S_0 becomes larger with increasing polymer concentration in the order:

$$\text{PVA} < \text{PEG} < \text{PVP} \sim \text{PEI} \ll \text{PAAm} \qquad (1)$$

On the other hand, the order for the non-polar hydrocarbons such as naphthalene and biphenyl was[1]

$$\text{PAAm} < \text{PVA} < \text{PEG} < \text{PEI} < \text{PVP} \qquad (2)$$

which was accounted for in terms of the iceberg enforcing effects. In other words, when an iceberg enhancing polymer is dissolved in water, a cage of water molecules is formed around the polymer solute, and the cosolute can then be incorporated within the same cage as the polymer. Thus, the solubility of the cosolute can be expected to be enhanced by the presence of iceberg enhancing polymers. The fact that

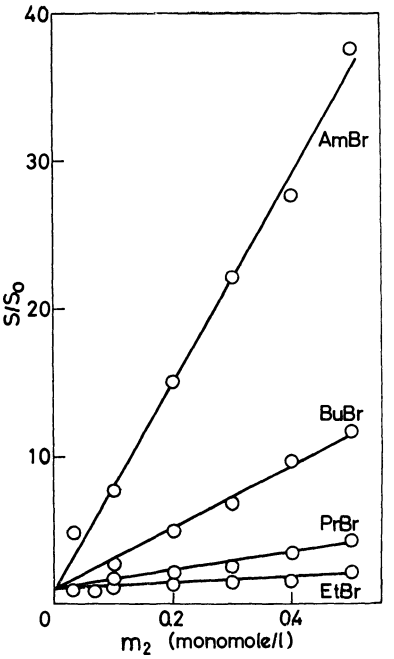

Fig. 2. Solubilization factor (S/S_0) of various alkyl bromides in polyacrylamide solution at 25°C.

the order (1) coincides with (2) except for PAAm indicates that the iceberg enforcing effect is still a main factor for the solubilization of polar cosolute as in the case of non-polar cosolute. Thus, the solute-solvent interactions are stronger than those between solute and cosolute or cosolute and cosolute. It should be recalled that PAAm solubilized most weakly non-polar cosolutes, whereas it solubilized most strongly polar cosolutes. This suggests that PAAm cannot greatly increase the solubility of polar cosolute by iceberg formation (carbamoyl groups of PAAm interfere with the formation) and some kind of complex formation of PAAm with alkyl bromide should exist. Solubilization of n-butyl bromide by urea is less strong than by PAAm, but fairly stronger than by other polymers. Thus, the carbamoyl groups contained both in PAAm and urea can be considered to interact strongly with butyl bromide by dipole-dipole interactions. The extent of the solubilization of butyl bromide by PVP, PEI, PEG and PVA is similar to that for naphthalene or biphenyl.

Figure 2 gives the solubilization of various alkyl bromides by PAAm. The solubility increases with the order:

$$\text{EtBr} < \text{PrBr} < \text{BuBr} < \text{AmBr} \qquad (3)$$

In other words, the larger the molecular weight of the cosolute, the more remarkable the solubilization. We see that the solubility increases linearly with the concentration of PAAm in the concentration region 0—0.5 monomol/l.

The solubilization effect by various water-soluble polymers is demonstrated in the following. Figures 3, 4 and 5 show the solubility of EtBr, PrBr, BuBr and AmBr in the presence of PVP PEI and PEG, respectively. The solubility increases in the order shown by the relation (3) but not that of EtBr by addition of

3) In this paper the term "solubilization" refers to the solubility increase by addition of the third substances. The correct term is "hydrotropy".[4]

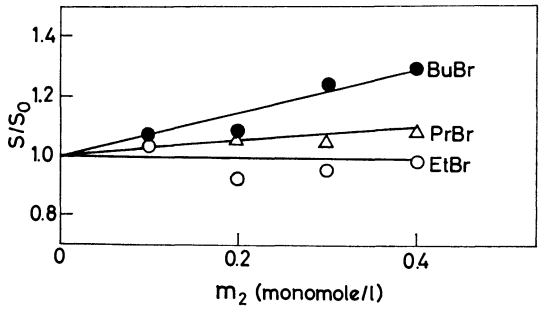

Fig. 4. Solubilization factor (S/S_0) of various alkyl bromides in polyethylenimine solution at 25°C,

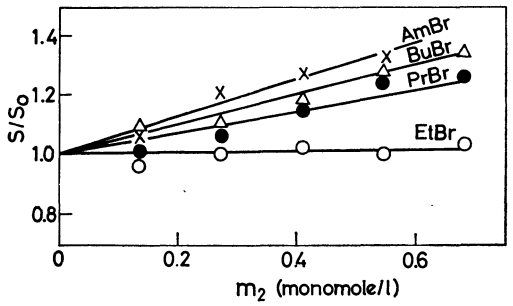

Fig. 5. Solubilization factor (S/S_0) of various alkyl bromides in polyethyleneglycol solution at 25°C.

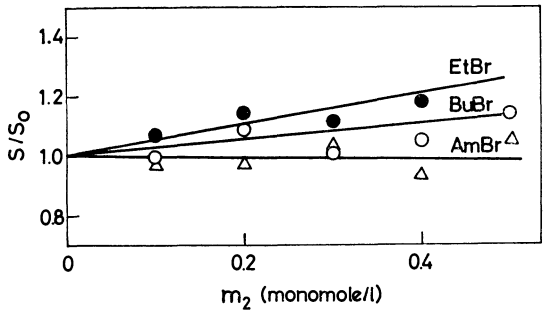

Fig. 6. Solubilization factor (S/S_0) of various alkyl bromides in polyvinylalcohol solution at 25°C.

these neutral polymers. Order (3) can be understood by the concept of the iceberg enforcing effect since it is known that the larger the volume of cosolute, the stronger the solubilizing effects.[1,4,5] Inequality (1) appears to hold also for PrBr. The specific interactions between polymer and cosolute such as dipole-dipole interactions do not seem to be significant in these polymers.

Figure 6 gives the experimental data for PVA. Solubilization is not so remarkable as in the case for naphthalene[1], and is in the order

$$\text{EtBr} > \text{BuBr} > \text{AmBr} \quad (4)$$

This indicates that the iceberg enforcing effect is unimportant on account of the interfering effect of OH groups with the iceberg formation,[1,6] and the interactions of the OH groups of PVA with polar cosolute (solute-cosolute interactions) certainly exist.

The Setchénow equation was reported to be valid for non-polar cosolute in various polymer solutions in dilute concentration regions, and the Setchénow constant, k, derived from the following equation was discussed in detail.[1]

$$\ln (S_0/S) = km_2 \quad (5)$$

For BuBr, $\ln(S_0/S)$ in various polymer solutions linearly decreased with increasing polymer concentration below 0.4 monomol/l except for PAAm solution. In the case of PAAm, deviation from linearity was found over 0.1 monomol/l, and the linearity between S/S_0 [not $\ln(S/S_0)$] and m_2 holds in the range 0—0.5 monomole/l (Fig. 2). The limiting Setchénow constants ($k/2.303$) derived for BrBu were −5.0, −0.31, −0.22, −0.21, −0.14 and −0.05 for PAAm, PVP, PEI, PEG, PAA and PVA, respectively.

Figure 7 shows the solubilization of BuBr in the presence of mixtures of PAAm and PVP. PAAm solubilized strongly BuBr whereas PVP did only weakly (Fig. 1). If no specific interaction exists between PAAm and PVP, the solubility should change as shown by the broken line. However, the solubility decreases at first with increasing PAAm and increases through a minimum. The decrease in solubilizing forces by mixing of PAAm and PVP may reflect that the polar carbamoyl groups of PAAm, which can solu-

bilize alkyl bromide, combine with the polar side chain groups of PVP and the effective carbamoyl groups decrease. It is probable that complex formation takes place between PAAm and PVP. The behaviour of the desolubilization of the mixture of PVP and PAAm seems to be specific since the cosolute is more strongly solubilized by mixing of solutes than by individual solute.[7,8,9]

Figure 8 gives the solubility of BuBr in the presence of polyacrylic acid or its salts. The sodium polyacrylate and sodium chloride salt-out, whereas tetraalkylammonium salts show salting-in effects. It is seen that the solubility increases with increasing number of carbon atoms in organic gegenions, or with increasing hydrophobicity. The tendency has been observed for naphthalene and biphenyl.[1] The results indicate that the salting-in effect on the polar cosolute is also mainly determined by the hydrophobic interactions of solute with water molecules. The Setchénow constants ($k/2.303$) of BuBr were 0.54, −0.14, −0.49, −0.49, −0.88 for NaPPA, Me_4NPAA, Et_4NPAA, Pr_4NPAA and Bu_4NPAA, respectively.

Extensive study has been carried out on low molecular weight tetraalkylammonium salts.[6,10–14] We studied the solubilization effect for alkyl bromides by tetraalkylammonium bromide. Figure 9 shows the influence of the bromide on BuBr. The solubilization becomes stronger in the order

$$Me_4NBr < Et_4NBr < Pr_4NBr < Bu_4NBr \qquad (6)$$

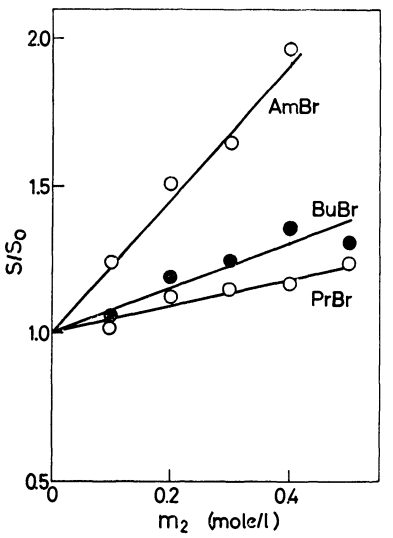

Fig. 10. Solubilization factor (S/S_0) of various alkyl bromides in tetraethylammonium bromide solution at 25°C.

This order was also found for tetraalkylammonium polyacrylates, but the strength of the solubilization is weaker by the bromide than by polyacrylate. Order (6) is the same as that found by Wen an Hung[6] for butane. This also indicates that hydrophobic interactions between the salts and water are the main factor determining the solubility of polar cosolutes (alkylbromide) as was the case for non-polar cosolute.

Figure 10 gives the solubilization data of n-propyl, n-butyl, and n-amyl bromides by tetraethylammonium bromide. The S/S_0 value is larger for larger alkyl groups. This is easily understood by the McDevit and Long equation,[15] which shows that the Setchénow coefficient is a linear function of the volume of the cosolute.

Diffusion Coefficients of Bolaform Electrolytes in Aqueous Solution

Hisashi UEDAIRA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama

(Received July 1, 1972)

The diffusion coefficients of sodium salts of *m*-benzene disulfonate, 1,5-naphthalenedisulfonate, 1,2-ethanedisulfonate, and 1,4-butanedisulfonate in aqueous solutions were measured at 25°. The concentration dependence of the diffusion coefficients for sulfonates decreased with increasing charge distance and was smaller than that of the corresponding ordinary 2 : 1 electrolytes. The concentration dependence of diffusion coefficient for sodium *m*-benzenedisulfonate was the largest. It is shown that bolaform electrolytes behave like normal 1 : 1 electrolytes in the concentration range where the ion atmosphere around each charged group is independent.

Bolaform electrolytes are a peculiar type of 2 : 1 electrolyte and the physico-chemical properties of their aqueous solutions are unusual. However, the cause of this peculiarity is not yet clarified. It was shown by Atkinson, Yokoi and Hallada[1] that the electrolytic conductances of bolaform electrolytes (*m*-benzenedisulfonate, 4,4′-biphenyl-disulfonate *etc.*) in aqueous solutions were interpreted by means of the Fuoss-Onsager equation. According to them, these behave as a spherical 2 : 1 strong electrolyte, irrespective of the position of sulfonic groups and the distance between them. Thomson, Rice and Nagasawa[2] found that the diffusion coefficients of potassium salts of *p*-benzene and 4,4′-biphenyldisulfonates in aqueous solutions show no concentration dependence. In contrast to their behavior in conductance, the diffusion coefficients of bolaform electrolytes are not explained by the theory of the ordinary strong electrolyte.

Bonner and Rogers,[3] and Bonner, Rushing and Torres[4] obtained the osmotic and activity coefficients for several bolaform electrolytes in which two sulfonic groups were separated by varying distance. They found that the thermodynamic properties of bolaform electrolytes markedly differed from those of normal electrolytes, especially in dilute solutions.

Thus, it is expected that the diffusion coefficients of bolaform electrolytes depend on the distance between the ionized groups and their positions. For the sake of confirmation, the diffusion coefficients were measured for sodium salts of *m*-benzenedisulfonate (*m*-Na_2BDS), 1,5-naphthalenedisulfonate (Na_3NDS). 1,2-ethanedisulfonate (Na_2EDS) and 1,4-buthanedisulfonate (Na_2BuDS) in aqueous solutions at 25°.

Experimental

The purification of sulfonates has been described elsewhere.[5]

The diffusion experiments were performed at 25±0.01° using a Spino Model-diffusion apparatus a Rayleigh interferometer. The standard 11 ml cell was used. For a typical run, nine photographic exposures were made at intervals ranging from 15 min. to 3 hr. Kodak type M glass photographic plates (4 in. by 5 in.) were used. The concentration difference in the solution on both sides of the diffusion boundary was so adjusted that the total number of Rayleigh fringe was 50 or 60. The procedure was the same as already reported.[6]

Deionized water was employed as the solvent for these systems. All the solutions were prepared by weight. Weighing was corrected to vacuum. The molar concentrations of solutions were calculated by means of the solution densities, which were mesurred with a 30 ml sprengel pycnometer at 25±0.01°.

To obtain the limiting diffusion coefficients, the conductances of the solutions were measured. The procedure was the same as that described.[5]

Results and Discussion

The mean concentration of each diffusion experiment and the corresponding value of diffusion coefficient are given in the Table. The diffusion coefficient for each salt at infinite dilution was calculated from the limiting mobility by the Nernst equation.

The values of the limiting equivalent conductances, λ°, of aqueous Na_2EDS and Na_2BuDS solutions determined from the plots of equivalent conductance against $(\text{normality})^{1/2}$, are 114.0 and 103.2 $cm^2\ ohm^{-1}\ equiv^{-1}$, respectively. It is not necessary to take into account the formation of ion-pair for the sulfonates. The values of λ° for *m*-Na_2BDS and Na_2NDS were taken from the works of Atkinson, Yokoi and Hallada,[1] and Eloworthy,[7] respectively.

The diffusion coefficient of 2 : 1 type electrolyte in an aqueous solution can be written in the form[8]

$$D = (D_0 + \Delta_1)\left(1 + c\frac{\mathrm{d}\ln y}{\mathrm{d}c}\right) \tag{1}$$

where D_0 is the Nernst limiting value of the diffusion coefficient, c the molarity, and y the activity coefficient in the molarity scale. Δ_1 is the first-order electrophoretic term and is expressed by the following equation for aqueous solutions at 25°

$$\Delta_1 = -8.07\times10^{-6}\frac{(z_1\lambda_2^0 + z_2\lambda_1^0)^2}{\lambda_0^2 z_1 z_2}\cdot\frac{\sqrt{I}}{1+0.3291\ a\sqrt{I}} \tag{2}$$

where I is the ionic strength, λ_1 and λ_2 are the limiting

	16.3539	0.911_1

mobilities of cation and anion, respectively, and z_1 and z_2 are the valencies of cation and anion, respectively. a is the parameter and its value is determined from the activity coefficient data.[8]

The values of the molal activity coefficients were obtained experimentally only for *m*-Na_2BDS and Na_2EDS.[3,4] In general, the activity coefficient of an electrolyte with a large ionic radius is not given by the Debye-Hückel formula. We used the following expression of the rational activity coefficient for 2 : 1 electrolyte solutions at 25°.[8]

$$\ln f = -\frac{4.08\sqrt{c}}{1+0.57\,a\sqrt{c}} + bc \qquad (3)$$

where a and b are the constants adjustable to fit the experimental curve.

Using the molal activity coefficient data,[3,4] and the densities, we obtain the following equation of the rational activity coefficients:

$$\ln f = -\frac{4.08\sqrt{c}}{1+3.899\sqrt{c}} + 0.0089\,c \quad (c<0.5\ \text{mol/l}) \qquad (4)$$

for *m*-Na_2BDS solution, and

$$\ln f = -\frac{4.08\sqrt{c}}{1+2.256\sqrt{c}} + 0.335\,c \quad (c<0.5\ \text{mol/l}) \qquad (5)$$

for Na_2EDS solution. An HITAC 8400 computer was used to apply the least square method to the data. The values of a in Eq. (3) for *m*-Na_2BDS and Na_2EDS are 6.84 and 3.96 A, respectively. Thus the theoretical equation for the diffusion coefficient of *m*-Na_2BDS in aqueous solution is

$$D\times10^5 = \left(1.089-\frac{1.480\sqrt{c}}{1+3.899\sqrt{c}}\right) \times\left[1+0.0089\,c-\frac{2.04\sqrt{c}}{(1+3.899\sqrt{c})^2}\right] \qquad (6)$$

Similarly, the equation for the diffusion coefficient of Na_2EDS in aqueous solution is

$$D\times10^5 = \left(1.121-\frac{1.448\sqrt{c}}{1+2.256\sqrt{c}}\right) \times\left[1+0.335\,c-\frac{2.04\sqrt{c}}{(1+2.256\sqrt{c})^2}\right] \qquad (7)$$

The theoretical curves of diffusion coefficients for *m*-Na_2BDS and Na_2EDS are given in Figs. 1 and 2. For the sake of comparison, the experimental curves of diffusion coefficients for *m*-Na_2BDS and Na_2EDS are included in the Figures. In both cases, the

experimental values of diffusion coefficients are larger than the calculated values. That is, the concentration dependencies of the experimental values are remarkably smaller than those expected from Eqs. (6) and (7). A similar situation is expected also for Na_2NDS and Na_2BuDS.

From Eqs. (1), and (2), and (3), the concentration depedence of the diffusion coefficient decreases with increasing ionic radius, since parameter a is proportional to the ionic radius. Fig. 3 shows the relation $(D-D_0)/D_0$ against $c^{1/2}$ for various sulfonates in aqueous solutions. The ionic radius dependence of the diffusion coefficient holds for the aromatic and the aliphatic homologues, but the concentration dependence of the diffusion coefficient of Na_2EDS is smaller than that of Na_2NDS.

The experimental diffusion coefficients for these sulfonates show a tendency to approach constant values (Fig. 3), in contrast to normal electrolytes. The concentrations (c_t) at which the diffusion coefficints become constant are in the region 0.09~0.16 mol/l. The value of c_t for *m*-Na_2BDS is the largest.

As Eqs. (4) and (5) well reproduce the experimental values of activity coefficients, the chief discrepancy between the experimental and calculated values of the diffusion coefficients is caused by the overestimation of electrophoretic effect in Eq. (1).

On the assumption that the center of negative charge of a sulfonic group is located at the sulphur atom, the distance between two sulfonic groups are found to be 4.6 for Na_2EDS and *m*–Na_2BDS, and 7 A for Na_2BuDS and Na_2NDS. Only at an extreme dilution where $1/\kappa > R$, it is appropriate to assume that the bolaform ion is divalent and that the ion atmosphere is spherically symmetric. R is the charge distance of sulfonate ion and κ has the usual meaning. Atkinson, Yokoi and Hallada[1] explained the electrolytic conductances of *m*-Na_2BDS in aqueous solution by means of the Fuoss-Onsager equation for the spherical 2 : 1 strong electrolyte. The concentration range of their experiments was $0 \sim 45 \times 10^{-4}$ mol/l. At the concentration 45×10^{-4} mol/l, $1/\kappa$ is 26 A, thus $1/\kappa > R$. However, under experimental conditions of most diffusion measurements, we have $1/\kappa < R$, as the concentration range is 0,01~0,2 mol/l (the concentrations corresponding to 4.6 and 7 A are 0.145 and 0.0629 mol/l, respectively). Under these conditions, Eq. (1) does not hold. Thus, it is a reasonable to assume that the ion atmosphere about each charge is almost independent. Rice[9] showed that the electrophoretic effect for a bolaform ion was just twice that for an oridnary ion. The absolute value of this additional retarding effect increases with increasing concentration. However, Figs. 1 and 2 show that the effect of Δ_1 in Eq. (1) is overestimated. Thus Rice's theory not hold either, in which the retarding effect based on the asymmetry of the ion atmosphere is added to Δ_1 of Eq. (1).

In the diffusion of a single electrolyte, cation and anion should diffuse with the same final velocity. When the ion atmosphere about each ionized group is almost independent at the concentration $1/\kappa < R$, the motion of bolaform electrolyte approximates that of 1 : 1 electrolyte. Therefore, it is postulated that the electrophoretic effect on the bolaform electrolyte is the same as that on 1 : 1 electrolyte. For 1 : 1 electrolyte, this effect is expressed by the following relation.

$$\Delta_1 = -8.07 \times 10^{-6} \frac{(\lambda_1^0 - \lambda_2^0)^2}{\lambda_0^2} \cdot \frac{\sqrt{c}}{1+\kappa a} \qquad (8)$$

Thus, Δ_1 of the right hand side in Eq. (1) should be expressed by Eq. (8) under the condition $1/\kappa < R$.

Generally, the absolute value of Δ_1 for 1 : 1 electrolyte is small.[8] As an example, the value of λ_2^0 is 49.0 cm^2 ohm^{-1} $equiv^{-1}$ for methanesulfonate ion,[10] of which EDS ion consists, and the value of Δ_1 for sodium methanesulfonate (NaMS) is in the order of 10^{-10} from Eq. (8). Under the condition $1/\kappa < R$, the values of Δ_1 for the other sulfonates will be in the same order as that of NaMS, and can be neglected in comparison with D_0 in Eq. (1) (the value of D_0 is in the order of 10^{-5}). Thus Eq. (1) becomes the following Nernst-Hartley equilation.

$$D = D_0\left(1 + c\frac{\mathrm{d}\ln y}{\mathrm{d}c}\right) \qquad (9)$$

We see from Figs 1 and 2 that the values calculated from Eq. (9) lie nearer the experimental values than that of Eq. (1). The calculated value for *m*–Na_2BDS agrees with the experimental value. Thus it is clear that the concentration dependence of diffusion coefficient of bolaform electrolyte with long R is smaller than that of bolaform electrolyte with short R, as κ^2 is proportional to the concentration of electrolyte.

The frictional coefficient of non-spherical molecule depends on the size and shape. In the case of bolaform ion, the frictional coefficient is also affected by the ionic atmosphere. A rod like bolaform ion such as aliphatic sulfonate ion behaves like a monovalent ion, under the conditions where the ion atmosphere about each charge is almost independent. Therefore, the frictional coefficient of bolaform ion decreases, and the value of D_0 in Eq. (9) increases. Hence, the calculated value from Eq. (9) approaches

more closely the experimental value. Due to the bulkiness of molecule the frictional coefficient of aromatic sulfonate ion is little affected by the asymmetry of the ion atmosphere. The difference between Fig. 1 and 2 is thus accounted for.

The diffusion coefficient of a bolaform electrolyte will always be larger than the diffusion coefficient of a corresponding ordinary 2 : 1 electrolyte not in line with Rice's theory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 404—407 (1973)

The Molecular Structure of Antimony Trichloride as Determined by Gas-electron Diffraction[1)]

Shigehiro KONAKA and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 11, 1972)

The molecular structure and mean amplitudes of $SbCl_3$ have been determined, by the sector-microphotometer method of gas-phase electron diffraction, to be as follows: r_g(Sb–Cl)=2.333±0.003 Å, r_g(Cl–Cl)=3.50±0.02 Å, θ_α=97.2°±0.9°, l(Sb–Cl)=0.063±0.004 Å, and l(Cl–Cl)=0.147±0.014 Å. The zero-point average structure derived from the diffraction results by the use of the estimated potential constants is consistent with the rotational constants, B_z, derived from the B_0 of microwave measurements. The joint use of the ED and MW data has given a value of 2.326±0.001 Å for r_z(Sb–Cl).

Some regularities exist among the molecular structures of trihalides of the Vb-group elements.[2–5)] That is, the experimental bond length is generally shorter than the sum of the covalent radii by an amont which can be related to the difference between the electronegativities of the central atom and the halogen. Valence angles increase with a decrease in the electronegativities of halogens relative to the Vb-group atom.

The molecular structure of antimony trichloride was previously investigated by the visual method of electron diffraction (ED)[6,7)] and by microwave spectroscopy (MW)[8)] (Table 1). The reported uncertainties in the MW structure are much smaller than those in the visual ED data. However, the bond angle given by MW seems to be too large by 2 or 3 degrees, whereas the bond length is reasonable, as judged from the trend found in the structures of many trihalides of the Vb-group atoms (see Figs. 3 and 4 of Ref. 4).

TABLE 1. PREVIOUS RESULTS ON THE MOLECULAR STRUCTURE OF $SbCl_3$

	r(Sb–Cl)	θ(ClSbCl)
ED(visual)[a)]	2.37 ±0.02 Å	104° ±2°
ED(visual)[b)]	2.37 ±0.02 Å	96° ±4°
MW[c)]	2.325±0.005 Å	99.5°±1.5°

a) Ref. 6 b) Ref. 7 c) Ref. 8

The present study was undertaken in order to determine the geometry of this molecule more accurately by the sector-microphotometer method of ED. At just the same time, Matsumura[9)] reinvestigated the microwave spectra and obtained the rotational constants, B_0, for $^{121}Sb^{35}Cl_3$ and $^{123}Sb^{35}Cl_3$, which were very close to the previous values, and also the B_0 values for $^{121}Sb^{37}Cl_3$ and $^{123}Sb^{37}Cl_3$, which had not been measured before. The structure determined from these rotational constants is: r_0(Sb–Cl)=2.323±0.005 Å and θ(ClSbCl)=96°50′±30′.[9)] The bond length is essentially equal to the previous MW value, but the angle is not. This structure is in fair agreement with the existing regularities in relation to the structures of related molecules.

In the present report, an electron-diffraction determination of the thermal average structure will be described. Furthermore, the consistency between the ED and MW data will be examined and the zero-point average structure will be derived by the joint use of both sets of data.

Experimental

A sample of antimony trichloride (over 99% pure) obtained from Wako Pure Chemical Industries, Inc., was used without further purification. Electron-diffraction photographs were

taken with a diffraction unit employing an r^3-sector[10] and a high-temperature nozzle made of stainless steel[11] under the following conditions: camera length, 12.39 cm; accelerating voltage, about 42 kV; exposure time, 3—4 minutes; electron-beam current, about 0.24 μA and nozzle temperature, about 70°C. The pressure in the diffraction chamber during exposures was about 7×10^{-5} Torr. Diffraction patterns of CS_2 molecules were taken at the same nozzle temperature just after taking the sample patterns in order to measure the scale factor accurately.[12]

Photographs were recorded on Fuji process hard plates and were developed at 20°C for 5 min with a FD-131 developer diluted twice. The photographic densities were measured with a digital microphotometer at intervals of 1/3 mm.[4] The densities were converted to intensities by using the relation[4] $E=D(1+0.03D)$; they were also corrected for the imperfection of the sector opening from an ideal r^3-shape. Seven plates, four for $SbCl_3$ and three for CS_2, taken in the same sequence of exposures, were selected for structure analysis.

Analysis of Data

The intensities were leveled by the theoretical backgrounds calculated by the use of the elastic and inelastic scattering factors taken from the literature.[13-15] The experimental backgrounds and molecular intensities were determined by using the criterion that there should appear no ghost peak in the range of $r\leqq1.05$ Å in the radial distribution curve, which was itself calculated in a manner described elsewhere.[4]

The interatomic distances, r_a(Sb-Cl) and r_a(Cl-Cl), the mean amplitudes, l(Sb-Cl) and l(Cl-Cl), and the index of resolution, k, were determined by a least-squares fitting of the experimental molecular intensities to the following theoretical expression:

$$qM(q) = k\sum_{i\neq j} A_{ij}\mu_{ij}\cos\Delta\eta_{ij}\exp\left\{-\frac{1}{2}\left(\frac{\pi}{10}q\right)^2 l_{ij}^2\right\} \times\sin\left\{\frac{\pi}{10}q\left(r_{aij}-\left(\frac{\pi}{10}q\right)^2\kappa_{ij}\right)\right\} \quad (1)$$

Here, all the notations follow usual usage.[16] The asymmetry parameter, κ_{Sb-Cl}, was estimated to be 1.2×10^{-5} Å^3 by the diatomic approximation[17] and was fixed in the least-squares analysis. The κ_{Cl-Cl} was ignored. The thermal average distances, r_g, were obtained as sums of r_a and l^2/r_a.

The experimental molecular intensity and the theoretical one calculated from the best-fit parameters are shown in Fig. 1.[18] The least-squares results are listed in Table 2. An error matrix is given in Table 3.

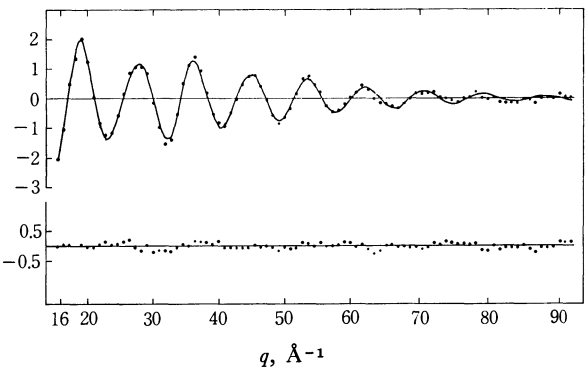

Fig. 1. Molecular intensity (dots for observed values and the solid curve for the best-fit theoretical intensity) and the residuals.

Table 2. Results of the least-squares analysis

	Average[a]	σ_1[b]	σ_2[b]
k	0.882	0.014	0.006
r_a(Sb-Cl)	2.3307	0.0010	0.0003
l(Sb-Cl)	0.0632	0.0017	0.0004
r_a(Cl-Cl)	3.4926	0.0072	0.0034
l(Cl-Cl)	0.1467	0.0054	0.0014

a) The averages of the results from four plates are listed.
b) The definitions of σ_1 and σ_2 are given in Ref. 19.

Table 3. Error matrix[a]

	k	r_a(Sb-Cl)	l(Sb-Cl)	r_a(Cl-Cl)	l(Cl-Cl)
k	231	9	72	66	71
r_a(Sb-Cl)		16	−1	2	7
l(Sb-Cl)			29	19	22
r_a(Cl-Cl)				118	9
l(Cl-Cl)					89

a) $\sigma_{ij}=\mathrm{sgn}[(\boldsymbol{B}^{-1})_{ij}][|(\boldsymbol{B}^{-1})_{ij}|\cdot\boldsymbol{V}^*\boldsymbol{P}\boldsymbol{V}/(n-m)]^{1/2}$, where the notations follow Ref. 19. Units for r_a and l are 10^{-4} Å and the index of resolution, k, is dimensionless.

Results and Discussion

The final results are summarized in Table 4, along with the limits of error estimated in the procedure described in a previous paper.[4] In order to derive a bond angle with a physically clear meaning,[20] the r_g distances were converted to the r_a distances by the following relation:[21,22]

$$r_a = r_g - \frac{\langle\Delta x^2\rangle+\langle\Delta y^2\rangle}{2r_e} - \delta r_{\mathrm{rot}} \quad (2)$$

TABLE 4. MOLECULAR PARAMETERS OF ANTIMONY TRICHLORIDE DETERMINED BY ED[a] (r AND l IN Å UNIT)

	Sb-Cl		Cl-Cl
r_g	$2.332_8 \pm 0.003_3$		3.499 ± 0.019
l	0.063 ± 0.004		0.147 ± 0.014
r_α	$2.328_7 \pm 0.003_3$		3.494 ± 0.019
θ_α(ClSbCl)		$97.2 \pm 0.9°$	
r_z	$2.324_8 \pm 0.004_2$		
θ_z(ClSbCl)		$97.2 \pm 1.0°$	

a) All parameters except for r_z and θ_z are given values at 343°K.

The stretchings due to the perpendicular thermal vibrations, $(\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle)/2r_e$, were calculated to be 0.0028 Å and 0.0020 Å for Sb–Cl and Cl–Cl respectively by using the harmonic potential constants estimated below.[22] The centrifugal stretchings, δr_{rot}, were evaluated to be 0.0013 Å and 0.0030 Å for Sb–Cl and Cl–Cl respectively.[23] The r_α-structure thus obtained is also given in Table 4.

The general quadratic potential field of a pyramidal XY_3-type molecule can be defined by using the following six potential constants associated with the internal symmetry coordinates, as has been described in a previous paper:[22]

$$\begin{aligned} F_{11} &= f_r + 2f_{rr}, \\ F_{12} &= f_{r\theta'} + 2f_{r\theta}, \\ F_{22} &= f_\theta + 2f_{\theta\theta}, \\ F_{33} &= f_r - f_{rr}, \\ F_{34} &= f_{r\theta'} - f_{r\theta}, \\ F_{44} &= f_\theta - f_{\theta\theta}. \end{aligned} \tag{3}$$

Since not all the potential constants can be determined uniquely from four vibrational frequencies, the experimental mean amplitudes were used as supplementary information. The fundamental frequencies measured in the liquid state[24] were used because those for the gas phase were not available. A sufficiently large number of sets of mean amplitudes were calculated from the potential fields compatible with the frequencies and compared with the observed mean amplitudes. The potential constants were then estimated to be as is shown in Table 5. The theoretical values of the mean amplitudes corresponding to the estimated potential constants were 0.062±0.006 Å and 0.134±0.008 Å for l(Sb–Cl) and l(Cl–Cl) respectively.

TABLE 5. POTENTIAL CONSTANTS OF $SbCl_3$ ESTIMATED FROM THE OBSERVED MEAN AMPLITUDES AND VIBRATIONAL FREQUENCIES (IN md/Å UNIT)

A_1 species		E species	
F_{11}	$2.0_6{}^{+0.2}_{-0.4}$[a]	F_{33}	$1.5_0{}^{-0.2}_{+0.1}$
F_{12}	-0.1 ± 0.2	F_{34}	0.2 ± 0.1
F_{22}	$0.22^{-0.02}_{+0.10}$	F_{44}	$0.20^{+0.07}_{-0.03}$

a) The uncertainties take the upper and lower signs in the same order.

The molecular structure given in Table 4 is very close to the r_0-structure determined by a recent microwave study.[9] However, this may not necessarily indicate that both the MW and the ED data are consistent, for different definitions of the molecular parameters were used. In order to see the consistency of the data, the r_α-structure measured by ED was converted to the zero-point average structure (r_z) and the rotational constants observed by MW were reduced to the rotational constants, B_z, corresponding to the r_z-structure. The observed ground-state rotational constants are given in Table 6.

TABLE 6. GROUND-STATE ROTATIONAL CONSTANTS AND ZERO-POINT AVERAGE ROTATIONAL CONSTANTS (IN MHz UNIT)

	$^{121}Sb^{35}Cl_3$	$^{123}Sb^{35}Cl_3$	$^{121}Sb^{37}Cl_3$	$^{123}Sb^{37}Cl_3$
B_0[a]	1753.6_0	1750.0_4	1670.3_5	1667.0_0
B_z	1751.4_3	1747.8_7	1668.3_2	1664.9_7

a) Determined by Matsumura.[9]

The following relations were used for deriving r_z(Sb–Cl) from r_α(Sb–Cl):[21]

$$r_z \simeq r_\alpha - (\langle \Delta z \rangle_T - \langle \Delta z \rangle_0) \tag{4}$$

$$\langle \Delta z \rangle \simeq \langle \Delta r \rangle - \frac{\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle}{2r_e} \simeq \frac{3}{2} a_3 \langle \Delta z^2 \rangle - \frac{\langle \Delta x^2 \rangle + \langle \Delta y^2 \rangle}{2r_e} \tag{5}$$

The Morse parameter, a_3, was assumed to be 2 Å^{-1}. The parallel and perpendicular mean amplitudes were computed from the estimated potential constants, and the correction term, $\langle \Delta z \rangle_T - \langle \Delta z \rangle_0$, was evaluated to be $0.003_9 \pm 0.002_5$ Å. On the other hand, the difference in bond angles, $(\theta_z - \theta_\alpha)$, was simply assumed to be $0 \pm 0.3°$.[25,26] The zero-point average structure thus estimated is also shown in Table 4.

The B_z values were derived from the B_0's as:[5]

$$B_z = B_0 - \delta B_{vib} - \delta B_{cent} \tag{6}$$

The sums of δB_{vib} and δB_{cent} were estimated, according to the theory of rotation-vibration interaction,[27,28] to be 2.17±0.11 MHz and 2.03±0.10 MHz for (^{121}Sb, ^{123}Sb)$^{35}Cl_3$ and (^{121}Sb, ^{123}Sb)$^{37}Cl_3$ respectively. The B_z values are also listed in Table 6.

In Fig. 2, the relation between r_z(Sb–Cl) and θ_z(ClSbCl), constrained by zero-point average rotational constants, are shown by four lines. The rectangle denotes the limits of the molecular structure determined by ED. The average structure corresponding to the crossing point of the MW lines is: $r_z = 2.324_8$ Å and $\theta_z = 96.2°$. This is slightly different from the r_0-structure,[9] $r_0 = 2.323 \pm 0.005$ Å and $\theta = 96°50' \pm 30'$. The MW bond angle appears to be about 1° smaller

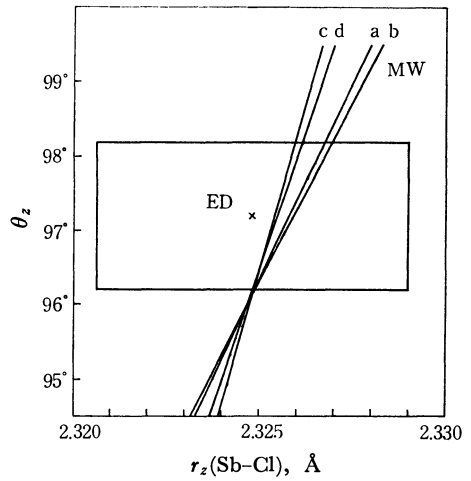

Fig. 2. The zero-point average structure obtained by ED and the relations given by the MW rotational constants (a): $^{121}Sb^{35}Cl_3$, (b): $^{123}Sb^{35}Cl_3$, (c): $^{121}Sb^{37}Cl_3$, (d): $^{123}Sb^{37}Cl_3$.

than the diffraction value, while the bond lengths from the two sets of data are in perfect agreement. However, it should be noted that the above MW structure is sensitive to a systematic error due to unknown isotopic shifts of the r_z-structure.[5] That is, the crossing point of the MW lines in Fig. 2 may shift remarkably even as a result of an isotope effect of r_z as small as 0.0003 Å. Since all the microwave lines pass near the center of the ED rectangle, we may conclude that the ED and MW data are consistent. By combining the ED valence angle with the MW lines, we can determine r_z(Sb–Cl) to be $2.325_9 \pm 0.001_1$ Å, which may be regarded as much more reliable and precise than the ED value. The corresponding r_g distance is 2.334± 0.003 Å.

The authors wish to thank Professor Takao Iijima for his helpful discussion and Mr. Makoto Ogasawara for his help in operating the high temperature nozzle. Numerical computations were performed on a FACOM 230—60 of the Hokkaido University Computing Center, to which the authors' thanks are also due.

Electron Diffraction Study of Dimethylmercury

Kuniaki KASHIWABARA,* Shigehiro KONAKA, Takao IIJIMA, and Masao KIMURA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 26, 1972)

Electron scattering by dimethylmercury has been studied for 42 keV electrons. The theoretical scattering factors currently used have shown satisfactory conformity to the observed scattering intensity, with the following distance parameters: r_g(Hg–C)=2.083±0.005 Å, r_g(Hg···H)=2.71±0.02 Å, and r_g(C–H)=1.106 Å (assumed). A comparison of the background functions has revealed that the scattering factors based on the relativistic Hartree-Fock-Slater potential are better than those based on the Thomas-Fermi-Dirac and Thomas-Fermi potentials. The zero-point average distance determined from the spectroscopic data has shown significant inconsistency with the diffraction result. The diffraction value is shorter than the spectroscopic one by 0.015 Å.

The phase-shift of complex atomic scattering factors in gas-phase electron diffraction has been a long-lasting topic in both theoretical and experimental studies.[1] For almost all the molecules investigated so far, theoretical predictions of the cut-off points have been in reasonable agreement with the experimental results, although the conclusions have sometimes been obscured by large experimental errors. However, a recent study of tetramethyllead has claimed that there was considerable inconsistency between the experimental results and the theory,[2] not only in the cut-off point but also in the background intensity. To prove or disprove the possibility that the inconsistency is inherent in the heaviest members of the atoms, dimethylmercury was chosen for the present study as a practically usable compound which showed closest kinship to tetramethyllead. The present study has disproved the possibility mentioned above, in accordance with the results of a similar study of mercuric chloride.[3]

The vibrational[4] and rotational spectra[5] indicate that the present molecule has a linear structure. As for the Hg–C bond length, Rao *et al.* have derived an r_0 value of 2.094±0.005 Å from the rotational constants,[5] whereas an earlier electron-diffraction study by Gregg *et al.* gave a value of 2.23±0.04 Å.[6] The present paper will, then, present a more accurate Hg–C distance determined by means of the current electron-diffraction technique.

The rotational constants obtained by Raman spectroscopy[5] were corrected for the vibrational effect, and the zero-point structure was compared with the diffraction results. There was a disparity in the Hg–C distances, which, unfortunately, was left unsettled.

Diffraction Experiment and Analysis

The sample of dimethylmercury was purchased from the K&K Co., Inc., U. S. A., and was used without further purification. The diffraction experiment and the data analysis were carried out by our routine procedure of the sector-microphotometer method.[7] The experimental conditions were as follows: accelerating voltage,~42 kV; camera length, 244.3 mm; electron beam current, ~0.07 μA; sample pressure, 40 Torr, and exposure times, 20—30 sec. The photographs were taken at room temperature. Carbon disulfide was used as the reference substance to calibrate the scale factor. The data covered the range of q= 8—63.

Background Intensities. Two sets of scattering factors for mercury were used in the analysis:

a) The Thomas-Fermi-Dirac(TFD)-based elastic scattering factors[8] and the Thomas-Fermi(TF)-based inelastic scattering factors.[9]

b) The relativistic Hartree-Fock-Slater(RHFS)-based elastic and Hartree-Fock(HF)-based inelastic scattering factors.[10]

For carbon and hydrogen atoms, the HF-based elastic[8] and inelastic scattering factors[11] were used.

The total intensities leveled by the theoretical background function are shown in Fig. 1.[12] The overall consistency between the theoretical and observed background intensities may be regarded as satisfactory, irrespective of the scattering factors employed. However, a close examination in the smaller q region reveals that the discrepancy between the theoretical and observed intensities is much less for the set b than for the set a. This improvement due to the use of the set b was more markedly observed in the region of still smaller q, $q \leqq 8$, by means of a counting method. The small angle scattering by dimethylmercury and other molecules containing heavy atoms will be reported in a forthcoming paper.[13]

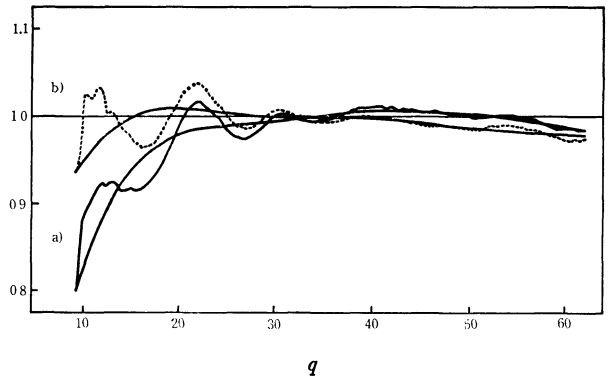

Fig. 1. The leveled total intensity. a): The set a of scattering factors was used, b): The set b was used. (see Text)

Molecular Structure. The bond distances were determined by a least-squares adjustment for the molecular intensity. Since the scattering power of the mercury atom is predominant, it is impracticable to determine the bond distances between light atoms. Thus, only the Hg–C and Hg···H distances were adjusted. The C–H distances were assumed to be 1.100 Å in r_a, and the other non-bonded distances, C···C, intramethyl H···H, and C···H, were constrained in r_α-parameters by assuming a linear structure. The intermethyl H···H distances were ignored, as the large mean amplitude caused by the nearly free rotation of the methyl tops[14] in addition to the small scattering power of hydrogen, makes the contribution from these terms less significant.

All the mean amplitudes were fixed at the values shown in Table 1, which were calculated by the use of the force constants determined by Miles *et al.*[15] The perpendicular amplitudes and the shrinkage corrections were also calculated as listed in Table 1. The calculated values of the parallel mean amplitudes are consistent with those given by Bribes and Gaufrès.[16] The torsional motion was neglected in these calculations. The r_α-values should, therefore, be interpreted as representing the average configuration where the torsional motion is frozen. The asymmetry parameters, κ, was estimated in the same way as in the previous paper.[2]

The results of the least-squares adjustment for the four best plates are summarized in Table 2. The indices of resolution were in the range of 0.86—1.05.

Table 2. Bond distances of dimethylmercury (in Å units)

	r_g	σ_1	σ_2	Limit of error
Hg–C	2.083	0.004	0.002	0.005
Hg···H	2.712	0.014	0.003	0.018
C–H	1.106	(assumed)		

The results shown in Table 2 were obtained by the use of the RHFS and HF scattering factors (set b), since they were considered to be better expressions of the true scattering factors, because of the better agreement of the experimental background with the theoretical one as well as the theoretical sophistication of the atomic potential itself. The best-fit theoretical molecular intensity is shown in Fig. 2, along with the observed values and the residuals. The agreement is satisfactory.

The use of the set a instead of the set b produced longer Hg–C and Hg···H distances by 0.005 Å and 0.009 Å respectively, with standard deviations similar to those for the set b. The indices of resolution were 0.94—1.13.

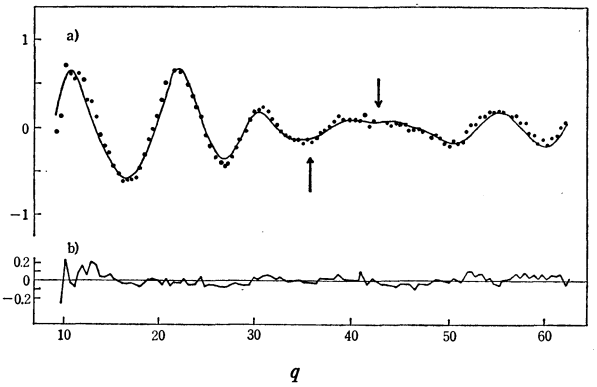

Fig. 2. a) The molecular intensity calculated by the best-fit model (solid curve). Dots are the observed values. The arrows indicate the theoretical cut-off points, $q^c_{Hg\cdots H}=35.8$ and $q^c_{Hg-C}=42.8$.

Zero-point Average Structure

The rotational constants of the normal and fully-deuterated species were observed by Rao *et al.*[5] The moments of inertia were corrected for the vibrational effect by the one-top formalism, which was reported elsewhere.[17] The effective and zero-point moments of inertia are listed in Table 3. The vibrational correction is relatively small for the *b*-constant of this molecule.

The zero-point average distance, r_z(Hg–C), was determined from the zero-point moments of inertia to be 2.095±0.006 Å. A relation between r_z(C–H) and ϕ_z(HCH) was also obtained, although neither of them can be determined separately. If, for instance, r_z(C–H) is assumed to be 1.096 Å, ϕ_z(HCH) can then be evaluated as 109°20′. The r_z(Hg–C) is insensitive to the possible isotope effect in the structure parameters of the methyl top as long as the effect is confined within reasonable limit.

Table 3. Moments of inertia of dimethylmercury (in amu Å² units)

	I_b^{eff} a)	ΔI_b b)	$I_b^{(z)}$ c)
Normal	145.06±0.13	0.17	145.23
d_6-species	184.83±0.20	0.21	185.04

a) Observed by Rao *et al.* Ref. 5. b) Vibrational corrections. c) Zero-point moments of inertia.

The r_g distance obtained by the diffraction experiment was converted to the r_α^0 distance which can be compared with the r_z value.[18] The value of r_α^0 thus obtained was 2.080±0.005 Å, which shows a significant difference from the spectroscopic r_z value. This is equivalent to the fact that the B_0(ED) is larger than B_0(Raman) by about 1%. A similar amount of disparity in B_0 was observed by Tanimoto *et al.*[19] in the case of diacetylene and was elucidated by taking the bending-stretching interaction into account. Dimethylmercury also has a low-lying bending mode (~160 cm^{-1}). However, the same treatment applied to the present molecule would require a negative interaction constant, in contradiction to the cases of diacetylene and several linear molecules.[19]

It may be worth considering that the Raman B_0 value might be obscured by overlapping hot bands, as was pointed out by Maki in the case of cyanogen.[20] The effect of the overlapping of bending hot bands is, however, in the direction of increasing the disparity in the present results. Besides the effects of hot bands due to vibrationally-excited states, the effect of the rotation-torsion-vibration coupling seems to be important. At least, with regard to the infrared rotation-vibration bands, it was suggested by Kirtman that such a treatment would be promising in order to study some anomalous features of the spectra.[21]

Judging from the recorded readings of monitoring accelerating voltages there was no indication that the scale factor of the present experiment contained an exceptionally large error.

Numerical computations were carried out on a FACOM 230—60 of the Hokkaido University Computing Center and also on a FACOM 270—20 of the laboratory of Professor Kimio Ohno, whom the authors wish to thank for allowing them to use the facilities.

Electron Diffraction Investigation of Gaseous Mercury(II) Chloride

Kuniaki KASHIWABARA*, Shigehiro KONAKA, and Masao KIMURA**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 26, 1972)

The molecular structure of mercury(II) chloride has been determined by the sector-microphotometer method of gas-phase electron diffraction at accelerating voltages of 29 and 42 kV. The parameter values obtained are: r_g(Hg–Cl), 2.252±0.005 Å; l(Hg–Cl), 0.052±0.005 Å; r_g(Cl–Cl), 4.48±0.04 Å; and l(Cl–Cl), 0.09±0.04 Å. A linear structure has been confirmed within an error of 16°. The experimental mean amplitudes are consistent with the estimated values based on the spectroscopic data. No appreciable differences in the structure parameters have been found between the results of analysis carried out on the basis of the Thomas-Fermi-Dirac and the relativistic Hartree-Fock-Slater scattering factors.

Mercuric chloride has $D_{\infty h}$ symmetry in the normal state. The electronic[1] and vibrational spectra[2–4] measured in the gas phase and the result of mass-spectrometric observation[5] are all consistent with this symmetry. In earlier electron diffraction studies by means of the visual method,[6–8] the bond angle was not observed because of the relatively weak scattering power of the Cl–Cl atom pair. Later, Akishin *et al.* confirmed the linear structure within an error of 40°.[9] The bond lengths reported previously are 2.28,[6] 2.34±0.01,[7] 2.27±0.03,[8] and 2.29±0.02 Å,[9] all involving large uncertainties.

It has been known that the scattering theory based on the first Born approximation is insufficient for the interpretation of the diffraction patterns of about 40 keV electrons by molecules containing both heavy and light atoms. An improvement of the scattering theory has been made by replacing the Born-approximation atomic scattering factors by the complex scattering factors calculated by the partial-waves method.[10] The use of such complex scattering factors is essential for a precise structure analysis of such a molecule as $HgCl_2$, because phase factors have a large effect on the molecular scattering intensity. The complex scattering factors for heavy atoms have been calculated from the Thomas-Fermi-Dirac (TFD) potential[11] and also recently, from the relativistic Hartree-Fock-Slater (RHFS)[12] and the SCF Hartree-Fock (SCF HF)[13] wavefunctions. In a recent work on $Pb(CH_3)_4$, an appreciable discrepancy has been found between the theoretical and observed scattering intensities;[14] in connection with this, further investigations have been desired into the scattering factors for heavy atoms. An improvement of the scattering theory has also been made by adding intramolecular multiple scattering to the simple kinematical framework of the theory.[15] For linear molecules, however, the multiple scattering does not give interference terms dependent on the internuclear distances, at least, not in the first order approximation.[15]

The purposes of the present study are to determine the structure more accurately by the sector-microphotometer method of electron diffraction, to examine the adequacy of the reported scattering factors for mercury, and at the same time, to see whether or not the use of two sets of available scattering factors for mercury produces any difference in the results of analyses. Since the scattering factors are dependent on the accelerating voltage, diffraction photographs were taken at two different voltages, 29 and 42 kV.

Experimental

Research-grade mercuric chloride (about 99.5% pure) obtained from Wako Pure Chemical Industries, Inc., was used as the sample. A high-temperature nozzle[16] made of stainless steel was used to obtain a sufficient vapor pressure. Diffraction patterns were taken on Fuji process hard plates by using an r^3-sector with a diffraction unit which has been described elsewhere.[17] Three sets of experimental data were taken under the conditions shown in Table 1. The accelerating voltages were stabilized within 0.01%. Carbon disulfide was used as the reference material for the determination of the scale factors except for a set of plates taken at 29 kV and at a camera length of 25.89 cm. This set of data was scaled so that the molecular scattering intensities became

TABLE 1. EXPERIMENTAL CONDITIONS

Accelerating voltage (kV)	Camera length (cm)	Temperature (°C)	Beam current (μA)	Exposure time (min)	Observed range (q)	Number of plates
42	12.39	160—170	0.27	3—6	17—104	3
29	12.39	160—170	0.29	2—5	12—91	2
29	25.89	160—170	0.19	2—4	6—45	3

consistent with the interatomic distances determined by the other sets of data; it was used only for the examination of background intensities at small angles. The optical densities of the diffraction patterns, D, were measured with a digital microphotometer and were converted to the intensities, E, by assuming the relation, $E=D(1+0.03D)$, and the intensities were corrected for the imperfection of the sector shape.[18]

Analysis of Data

The elastic scattering factors for Hg and Cl used for the data analysis described in this section were those calculated by the partial-waves method based on the Thomas-Fermi-Dirac and the Hartree-Fock (HF) potentials respectively.[11] As for the inelastic scattering factors, the values based on the SCF HF wavefunction[13] and the HF potential[19] were used for Hg and Cl respectively. The 42 kV data were also analyzed using the RHFS elastic scattering factors for Hg, but no significant change was found in the result of analysis. This will be discussed in a later section.

The experimental scattered intensities were leveled by the theoretical background, to which the contribution from the elastic scattering factors for Hg is dominant. The experimental molecular intensities, $qM(q)$, were calculated as $q(I_T-I_B)/I_B$, where I_B is a smooth background drawn through the total intensity curve, I_T. The theoretical expression of $qM(q)$ is given by;

$$qM(q) = k\sum_{i\neq j} A_{ij}\mu_{ij}\cos(\Delta\eta_{ij})\exp\left\{-\frac{1}{2}\left(\frac{\pi}{10}q\right)^2 l_{ij}^2\right\} \times \sin\left\{\frac{\pi}{10}q\left(r_{aij}-\left(\frac{\pi}{10}q\right)^2\kappa_{ij}\right)\right\} \quad (1)$$

with the usual notations.[20]

The background curves were revised by the use of the non-negativity criterion for radial distribution curves. For this purpose, the following g_{ij} functions were chosen so as to fit theoretical $\mu_{ij}\cos(\Delta\eta_{ij})$.[18] For 42 kV:

$$g_{Hg-Cl} = 1.45\cos(0.0283q)$$

$$g_{Cl-Cl} = 2.2$$

and for 29 kV:

$$g_{Hg-Cl} = 1.45\cos(0.0326q)$$

$$g_{Cl-Cl} = 1.64\exp(-3.1\times10^{-4}q^2).$$

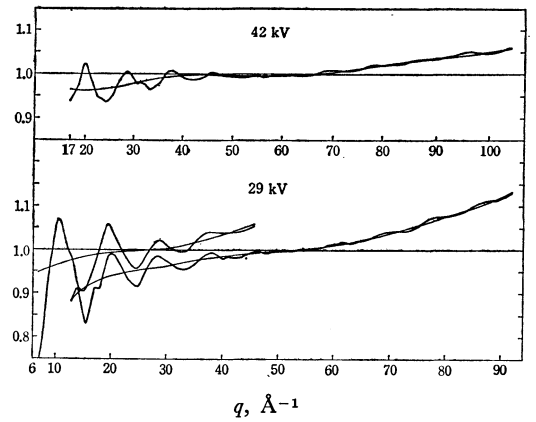

Fig. 1. Leveled total intensities and backgrounds.

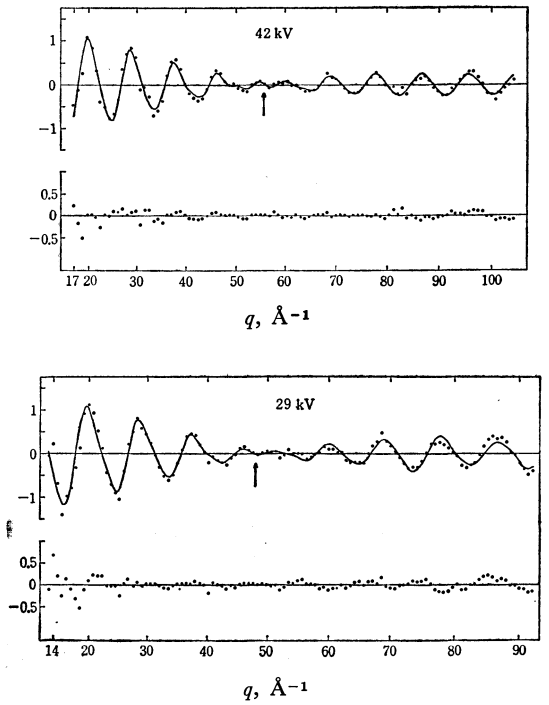

Fig. 2. Molecular intensities and the residuals.
Dots and solid curves show the observed values and the best-fit theoretical curves respectively. The arrows indicate the theoretical cut-off points based on the TFD scattering factors.

One of the leveled total intensities and its background thus obtained[21] are shown in Fig. 1 for each of the three combinations of accelerating voltage and camera length listed in Table 1.

The interatomic distances, r_a(Hg–Cl) and r_a(Cl–Cl), the mean amplitudes, l(Hg–Cl) and l(Cl–Cl), and the index of resolution, k, were determined by least-squares fittings of the experimental molecular intensities to

r_a(Hg-Cl)	24	3	−3	−1	16
l(Hg-Cl)		26	10	18	69
r_a(Cl-Cl)			182	−17	37
l(Cl-Cl)				156	80
k					312

a) Elements of the matrix are given by $\sigma_{ij}=\mathrm{sgn}(B^{-1})_{ij}\{|(B^{-1})_{ij}|V'PV|/(N-m)\}^{1/2}$, where the notations follow Ref. 23. Units ($\times 10^{-4}$) for r_a and l are Å and the index of resolution, k, is dimensionless.

the theoretical expression with our conventional weighting scheme.[18] The asymmetry parameter, $\kappa_{\mathrm{Hg-Cl}}$, was fixed at an estimated value of 5.3×10^{-6} Å^3 in a diatomic approximation,[22] and the $\kappa_{\mathrm{Cl-Cl}}$ was assumed to be zero. The data analysis was made by using the computer program used for AsF_3.[18] The experimental molecular intensities, the theoretical curve calculated from the best-fit parameters, and the difference curves are shown in Fig. 2.

The results of the analyses are given in Table 2. An error matrix for a plate taken at 42 kV is given in Table 3. As may be seen in Table 2, the data at different accelerating voltages led to results consistent with each other. For the determination of the molecular parameters, the two results were averaged with weights inversely proportional to the squares of the limits of error, which were estimated from both random and systematic errors as follows. Since the standard deviations, σ_2, estimated from the fluctuations in the results are slightly larger than the standard errors, σ_1, as estimated by the least-squares treatment, $2.6\sigma_2$ was chosen as the random error corresponding to the 99% confidence interval.[18] The systematic error estimated for the interatomic distance includes the uncertainty in the scale factor and the errors associated with ambiguities in the κ values. For the means amplitudes, an error due to the uncertainty in the nozzle temperature was taken into account.

TABLE 4. DISTANCES, MEAN AMPLITUDES AND SHRINKAGE (IN Å UNITS)

	r_g	l	δ_g
Hg-Cl	2.252±0.005	0.052±0.005	
			0.024±0.045
Cl-Cl	4.480±0.044	0.09±0.04	

Other systematic errors were ignored since they were estimated to be much smaller than the random error. The final results thus determined are listed in Table 4. The shrinkage, δ_g, given in this table was calculated as $2r_g$(Hg-Cl)$-r_g$(Cl-Cl).[24]

Discussion of the results

The mean amplitudes and shrinkage can be calculated from the vibrational frequencies according to an ordinary harmonic approximation.[24] The fundamental frequencies of $HgCl_2$ observed in the gas phase have been summarized by Klemperer *et al.* as follows[4,5]: ν_1, 360 cm^{-1} (the average of the frequencies from the Raman[2] and electronic spectra[1]); ν_2, 70 cm^{-1} (a value from the electronic spectra[1] which is close to the value of 71 cm^{-1} deduced by statistical thermodynamics[6]); and ν_3, 413 cm^{-1} (a value from the infrared spectra[3]). The values calculated from these frequencies at 165°C are as follows: l(Hg-Cl), 0.0506 Å; l(Cl-Cl), 0.0706 Å; and δ_g, 0.036 Å. They are consistent with the present experimental values. Since the bending frequency is very low, the above calculation might be insufficient for the l(Cl-Cl).[25] However, no further treatment was made because of the large experimental uncertainties in the mean amplitude and vibrational frequencies.

If we assume the shrinkage in this molecule to be 0.036 Å, then the bond angle in the r_a-structure[26] is found to equal 180°, within an uncertainty of 16°. The bond lengths obtained by the previous studies were too long, by from 0.02 to 0.09 Å.[6-9]

Figure 1 shows that the theoretical backgrounds based on the TFD scattering factor are in agreement with the experimental values within their uncertainties. Although the experimental backgrounds deviate by 10% or less from unity, the possibility of this amount of deviation being caused by extraneous scattering cannot ruled out judging from the shape of the leveled intensity and the observed indices of resolution. The agreement of the observed mean amplitude, l(Hg-Cl), with the theoretical one is another support for the adequacy of the scattering factors used. No significant deviations are seen between the observed and calculated molecular intensities as shown by the difference curves in Fig. 2; the agreement near the cut-off points, 55.8 Å^{-1} for 42 kV and 48.1 Å^{-1} for

29 kV in the q scale, is satisfactory for both accelerating voltages.

The data at 42 kV were also analyzed using the RHFS elastic scattering factor for Hg.[12] Since the calculated values are available only at 10, 40, 70 and 100 kV, the values for 42 kV were estimated by referring to the TFD values calculated at 40 and 42 kV. The theoretical cut-off point derived from the RHFS scattering factor is about 3 $Å^{-1}$ larger than that obtained from the TFD scattering factor.

The use of the RHFS scattering factor made the background curves in Fig. 1 closer to unity, and caused the index of resolution and mean amplitude, l(Hg–Cl), to decrease by 0.05 and 0.002 Å respectively. However, the magnitudes of the variations are within the experimental uncertainties or the limits of error. The other parameter values and their standard deviations were practically unchanged. In conclusion, both the TFD and the RHFS scattering factors are consistent with the results of the present experiment; they caused no significant difference in the results of the structure determination.

The authors wish to thank Professor Takao Iijima for his helpful discussions. The numerial computations were carried out on a FACOM 230—60 of the Hokkaido University Computing Center.

The Molecular Structure and Force Constants of Antimony Tribromide as Determined by Gas-phase Electron Diffraction

Shigehiro KONAKA and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 28, 1972)

The molecular structure and mean amplitudes of $SbBr_3$ at 102°C have been determined by the sector-microphotometer method of gas-phase electron diffraction to be as follows: r_g(Sb–Br)=2.490±0.003 Å, r_g(Br–Br)=3.76±0.01 Å, θ_α=98.2°±0.6°, l(Sb–Br)=0.060±0.003 Å and l(Br–Br)=0.15±0.01 Å. General quadratic force constants have been determined from the observed mean amplitudes and vibrational frequencies. The molecular structure supports the validity of the empirical rules between a bond length and the covalent radii and electronegativities of its constituent atoms. An empirical equation, $\theta(YXY)=92+8x_X-3x_Y(+x_Z)$, has been proposed for the bond angles of Vb-group halides, $(Z)XY_3$, and the electronegativities, x.

Precise measurements of the molecular structures of simple inorganic compounds are essential to our understanding of chemical bonds. Recently, many of the molecular structure of trihalides of Vb-group atoms have been reinvestigated, and the regularity of the structures has been discussed in connection with the covalent radii and electronegativities.[1-4] However, we do have no up-to-date data on the molecular structures of several Vb-group trihalides.[3,4] The main purpose of the present study is to improve the structural data of antimony tribromide by the sector-microphotometer method of gas-phase electron diffraction. The structural parameters obtained by previous electron diffraction studies based on the visual method were: r(Sb–Br)=2.52±0.02 Å, θ(Br-SbBr)=96°±2°;[5] r(Sb–Br)=2.51±0.02 Å, and θ(Br-SbBr)=97°±2°.[6]

The general quadratic force field of antimony tribromide has not yet been reported. For its determination, some supplementary information in addition to the vibrational frequencies is required. Spectroscopic data, such as the Coriolis coupling or centrifugal distortion constants, are not available, but the vibrational mean amplitudes, as measured by electron diffraction, can be used for the force-field determination.[7-9] It is another purpose of the present study to determine the general force field of $SbBr_3$ by a combined use of the vibrational frequencies and the mean amplitudes.

Experimental

The sample of antimony tribromide was an extra-pure reagent obtained from Nakarai Chemicals, Inc. The sample was vaporized by using a high-temperature nozzle.[10] Diffraction photographs were taken on Fuji process hard plates with a diffraction unit equipped with an r^3-sector.[11] The experimental conditions were as follows: camera length, 12.39 cm; accelerating voltage, about 42 kV; exposure time,

3—5 min; electron-beam current, about 0.28 μA; nozzle temperature, about 102°C. The pressure in the diffraction chamber during exposures was about 7×10^{-5} Torr. The diffraction patterns of CS_2 molecules were taken at the same nozzle temperature just after those of the sample in order to determine the scale factor accurately. The developing and photometric process were described in previous papers.[3,12] Eight plates, five for $SbBr_3$ and three for CS_2, taken in the same sequence of exposure, were selected for structure analysis.

Data Analysis

The intensities converted from the densities according to the $E=D(1+0.03\,D)$ relation were corrected for the imperfection of the sector shape and then leveled by means of the theoretical backgrounds.[13] The elastic and inelastic scattering factors were taken from the literature.[14-16] The experimental background and molecular intensities were determined according to our routine procedure.[3,12] The interatomic distances, r_a, the mean amplitudes, l, and the index of resolution, k, were determined by the least-squares fittings of experimental molecular intensities to the corresponding theoretical expression. The asymmetry parameter, κ_{Sb-Br}, was fixed at 1.1×10^{-5} Å^3, which was estimated by diatomic approximation,[17] and the κ_{Br-Br} was assumed to be zero.

The observed molecular intensity, $qM(q)$, and the theoretical one calculated by the use of best-fit parameters are shown in Fig. 1. The least-squares results are summarized in Table 1. An error matrix is given in Table 2. The thermal average distances, r_g, which were obtained as the sum of r_a and l^2/r_a, and the mean amplitudes are listed in Table 3, along with the estimated limits of error.

Results and Discussion

Force Constants. In order to determine the quadratic force constants of antimony tribromide, the observed mean amplitudes were used together with the four fundamental frequencies measured in the liquid state.[18] The general quadratic force field can be expressed in terms of the symmetry coordinates as follows:[9]

$$2V = F_{11}S_1^2 + 2F_{12}S_1S_2 + F_{22}S_2^2 + F_{33}(S_{3a}^2+S_{3b}^2) + 2F_{34}(S_{3a}S_{4a}+S_{3b}S_{4b}) + F_{44}(S_{4a}^2+S_{4b}^2). \quad (1)$$

Here the symmetry coordinates are taken as:

$$S_1 = \frac{1}{\sqrt{3}}(\Delta r_1+\Delta r_2+\Delta r_3),$$

$$S_2 = \frac{1}{\sqrt{3}}r_e(\Delta\theta_{12}+\Delta\theta_{23}+\Delta\theta_{31}),$$

$$S_{3a} = \frac{1}{\sqrt{2}}(\Delta r_1-\Delta r_2),$$

$$S_{4a} = \frac{1}{\sqrt{2}}r_e(\Delta\theta_{23}-\Delta\theta_{31})$$

$$S_{3b} = \frac{1}{\sqrt{6}}(\Delta r_1+\Delta r_2-2\Delta r_3),$$

$$S_{4b} = \frac{1}{\sqrt{6}}r_e(\Delta\theta_{23}+\Delta\theta_{31}-2\Delta\theta_{12}),$$

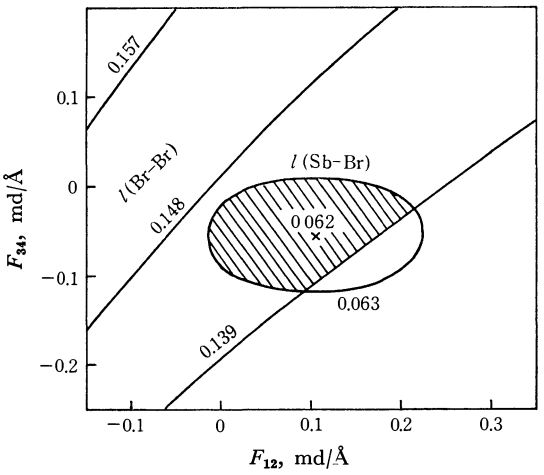

Fig. 2. Force constants of $SbBr_3$ allowed by the observed mean amplitudes at 375 K. An elliptical curve indicates the force constants giving the boundary of the observed value, 0.063 Å, for l(Sb-Br) and three parallel curves indicate those giving the observed value, 0.148 Å, and its boundary values, 0.157 Å and 0.139 Å, for l(Br-Br).

where Δr_i denotes the stretching of the i-th bond length; $\Delta\theta_{jk}$, the increase in the valence angle opposite to r_i, and r_e, the equilibrium bond length.

For given values of the off-diagonal force constants, F_{12} and F_{34}, the diagonal constants can be determined uniquely so as to reproduce the observed frequencies, under the condition that the stretching force constants, F_{11} and F_{33}, are larger than the bending ones, F_{22} and F_{44} respectively.[9] From the set of force constants, the corresponding mean amplitudes can be calculated. Figure 2 illustrates the force constants, F_{12} and F_{34}, allowed by the observed mean amplitudes. The shaded area denotes the force field compatible with all the experimental frequencies and mean amplitudes. The force constants thus determined are listed in Table 4.

Table 4. Force constants of $SbBr_3$ determined from the observed mean amplitudes and vibrational frequencies (in md/Å units)

	A_1 species		E species
F_{11}	1.72±0.17	F_{33}	1.33±0.07
F_{12}	0.10±0.11	F_{34}	−0.05±0.07
F_{22}	0.14±0.01	F_{44}	0.12±0.01

Structure. By using the above force constants, the r_g distances were converted to the r_α distances. The stretchings due to the perpendicular thermal vibrations were computed to be 0.0047 and 0.0021 Å for Sb–Br and Br–Br respectively. The calculated values for the centrifugal stretching were 0.0011 and 0.0034 Å for the bonded and non-bonded pairs respectively. The r_α distances and the corresponding bond angle are given in Table 3. Both the bond length (r_g) and the bond angle agree with the previous electron-diffraction values, obtained by the visual method, within their estimated limits of error.

The bond length of the trihalides of group-Vb elements, XY_3, can be given approximately by a modified Schomaker-Stevenson rule as:[4]

$$r_{X-Y} = r_X + r_Y - c|x_X - x_Y|.$$

Here, r_X and x_X are the covalent radius and the electronegativity of the X atom respectively, and c is an empirical constant which takes different values for the fluorides and the other halides.[4,19] In a previous paper,[3] the present authors proposed a slightly different empirical equation for the trihalides of group-Vb elements:

$$r_{X-Y} = r_X + r_Y - 0.06(x_X - x_Y)^2. \quad (4)$$

The Sb-Br distance estimated by Kuchitsu using Eq. (3) with c=0.04 Å is 2.51 Å,[4] while Eq. (4) gives a value of 2.49 Å for the covalent radii[20] and electronegativities[21] taken from the literature. Both are in agreement with the present observed value, 2.490 Å.

It has been found by recent experimental work[4] that the bond angles in the group-Vb-element trihalides generally decrease with an increase in the electronegativities of halogens relative to the central atoms, in accordance with the valence-shell electron-pair repulsion (VSEPR) theory proposed by Gillespie.[22] The observed bond angle in $SbBr_3$ confirms this finding, for it has a value between the angles in $SbCl_3$ and SbI_3, and smaller than those in PBr_3 and $AsBr_3$ (Table 5). The relationship between the bond angles and the electronegativities has been stated only qualitatively in previous studies. By examining the experimental data of the bond angles accumulated so

19) Equation (3) was originally proposed by Schomaker and Stevenson with c=0.09 Å as applicable to more general cases: V. Schomaker and D. P. Stevenson, *J. Amer. Chem. Soc.*, **63**, 37 (1941).

far, it has been found that there exists the following simple empirical relation:

$$\theta(^\circ) = 92 + 8x_X - 3x_Y. \quad (5a)$$

The bond angles calculated by means of Eq. (5a) using the electronegativities[21] are all close to the experimental values, as is shown in Table 5.

According to the VSEPR theory,[22] the YXY angle increases by the coordination of an atom to the lone-pair electrons of the central group-Vb atom. This has been confirmed by recent electron-diffraction work of phosphine compounds.[34,35] The YXY angles in ZXY_3 molecules may be approximated by the following equation, with an additional term, x_Z, to Eq. (5a):

$$\theta(^\circ) = 92 + 8x_X - 3x_Y + x_Z, \quad (5b)$$

where x_Z is the electronegativity of the coordinated Z atom. The calculated bond angles for the phosphine compounds are compared with the observed values in Table 5. Satisfactory agreements are seen except for the bromides. The elucidation of the origin of the discrepancy in $SPBr_3$ and $OPBr_3$ will be left for future investigations, as the data cited in Table 5 are those determined by the visual method.

The authors wish to thank Professor Takao Iijima for his helpful discussions. The numerical computations were performed on a FACOM 230—60 of the Hokkaido University Computing Center, to which the authors' thanks are also due.

The Electronic Absorption Spectra and Electronic Structures of Aromatic Azides, Nitrenes, and Diazonium Ions

Hiroshi KASHIWAGI, Suehiro IWATA,* Tsuguo YAMAOKA,** and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received July 26, 1972)

Electronic spectra were measured for azidobenzene, 1-azidopyrene, benzenediazonium ion, and 1-pyrenediazonium ion at room temperature, and also for nitrenobenzene and 1-nitrenopyrene at liquid nitrogen temperature. The π-electron structures of these compounds were calculated by the Pariser-Parr-Pople LCAO SCF MO CI method for the closed-shell systems and by the restricted open-shell SCF MO CI method for the open-shell systems. The calculated transition energies and oscillator strengths could satisfactorily explain the observed spectra. It was shown that the π-electron structures of azidobenzene and nitrenobenzene are similar to those of dimethylaniline and the benzyl or anilino radical, respectively.

Aromatic azides, nitrenes, and diazonium ions are interesting research subjects from both physicochemical and photochemical points of view. Reiser *et al.*[1] and also Tsunoda *et al.*[2] observed the electronic absorption spectra of azidobenzene and its derivatives. Theoretical studies of the electronic structure of azidobenzene have been made by several authors with the aid of the Hückel type MO method.[1-4] The more improved LCAO MO SCF CI calculation, however, has not yet been reported on azidobenzene.

The electronic absorption spectra of aromatic diazonium ions were measured by several authors.[5-11] The Hückel type MO studies of their electronic structures have been carried out by Evleth and Cox,[6] Schuster and Polansky,[9] Kikuchi *et al.*,[10] and Bochvar *et al.*[11] The more improved theoretical treatment based on the Pariser-Parr-Pople SCF MO method[12,13] has been made by Sukigara and Kikuchi[7] and also by Yoshida and Kobayashi.[14]

Reiser *et al.*[1,15,16] measured the electronic absorption spectra of several aromatic nitrenes at 77°K and interpreted the observed bands of nitrenobenzene from its similarity to that of the benzyl radical.[1] However, no detailed theoretical study with the aid of the MO method, was made on their electronic spectra.

We have measured the electronic absorption spectra of azidobenzene, nitrenobenzene, and benzenediazonium ion over a wider wavelength region than before and also measured the spectra of some new compounds; 1-azidopyrene, 1-nitrenopyrene, and 1-pyrenediazonium ion. In order to assign the observed spectra, we have theoretically studied the electronic structures of the compounds under consideration by the Pariser-Parr-Pople SCF MO CI method[12,13] and also by the restricted open-shell SCF MO CI method.[17]

Experimental

Materials. Azidobenzene and 1-azidopyrene were prepared by treating 10% hydrochloric acid solution of the corresponding amino-compounds with aqueous sodium nitrite solution and thereafter with aqueous sodium azide solution below 5°C. The precipitate of 1-azidopyrene separated by filtration of the solution was purified by means of column chromatography with active alumina. Azidobenzene was separated from the solution by centrifuging, washed with water, and finally distilled under reduced pressure.

Nitrenes were prepared by illuminating the rigid benzene and ethanol solutions of parent azides with a 500 W mercury lamp at 77 K.

Benzenediazonium fluoroborate and 1-pyrenediazonium fluoroborate were prepared by treating the corresponding amino-compounds with sodium nitrite in 10% hydrochloric acid below 5°C. The precipitates of benzenediazonium fluoroborate and 1-pyrenediazonium fluoroborate were obtained by adding excess 40% fluoroboric acid to the solutions and purified by repeated recrystallizations from methanol.

Ethanol and benzene used as solvents were purified by the methods described previously.[18,19]

Measurements. The electronic spectra of the ethanol solutions of azides and diazonium ions were measured at room temperature with a Cary spectrophotometer Model 14 R. Concerning the benzene and ethanol solutions of nitrenes, spectrophotometric measurements were made at

77 K with a Shimadzu MPS type spectrophotometer at the Institute of Physical and Chemical Research.

The concentrations of the solutions used for the spectrophotometric measurements were in the range 10^{-4}—10^{-5} M.

Theoretical

For the calculation of the closed-shell systems, we adopted the Pariser-Parr-Pople SCF MO method.[12,13,20] The configuration interactions were considered by taking all the singly excited configurations for the benzene derivatives and by taking the lowest 40 singly excited configurations for each symmetry in the case of the pyrene derivatives. For the open-shell molecules, the restricted SCF MO CI procedure presented by Longuet-Higgins and Pople[17] was adopted. In this case the lowest 40 singly and doubly excited configurations were taken for each symmetry. The penetration integrals were neglected for both closed- and open-shell systems. The core reasonance integrals (β) were taken to be proportional to the corresponding overlap integrals, the value of β, −2.39 eV, for the C–C bond of the benzene ring being taken as the standard. Two-center Coulomb repulsion integrals were estimated by means of the Nishimoto-Mataga approximation.[21] One-center integrals were determined by taking the effect of charge densities according to the method presented by Iwata and Shida.[22]
