The deuteron and niobium magnetic resonance in the Nb–D system have been measured over a wide range of deuterium concentrations. It has been found that the order-disorder ($\beta \rightarrow \alpha$) phase transition temperature depends on the small amount of interstitial impurities as well as on the concentration of the deuterium. From the concentration dependency of deuterium (Nb) in the α phase, one can determine the amount of deuterium (Nb) in the β phase coexisting with that in the α phase. On the basis of this finding, a tentative Nb–D phase diagram has been proposed. It has been confirmed that the interstitial impurities decrease the deuterium concentration of the β phase which is in equilibrium with the α phase. The niobium signal intensity has been found to be greatly reduced by the interstitial oxygen and other impurities, while the line width is not affected. For the interpretation of these findings, a simple model has been proposed in which only the interstitial atoms, which are present within the spherical sphere of a critical radius, r_c, from a niobium atom, eliminate the niobium resonance by means of the second-order quadrupole interaction.

Numerous studies have been made of the Va metal–Hydrogen system.[1] In these systems, the number of interstitial sites is greater than that of the interstitial hydrogen atoms, and a ninteresting phenomenon related to the order-disorder phase transition[2] has been reported. By the method of neutron diffraction, Somenkov *et al.*[3] have determined the atomic arrangement in niobium deuteride with a composition close to the equiatomic ratio (0.88~0.95 D/Nb) and have found that, at room temperature, the arrangement of deuterium atoms is ordered, filling four tetrahedral sites of the face-centered orthorhombic cell of niobium metal. As the temperature increases, the arrangement of deuteriums becomes disordered. They proposed two possible structures for the high-temperature form (α form). One of the structures, however, seems to be unlikely from the NMR point of view, as will be discussed below.

In the previous paper (hereafter denoted as I),[4] the present author has shown that the deuteron quadrupole splitting spectrum in the ordered β Ta_2D can be accounted for if deuteriums occupy tetrahedral sites with the largest principal component of the electric-field gradient (EFG) parallel to the c axis. In I, it has also been shown that the sharp single resonance line observed for the disordered α Ta is an indicative of the random distribution of deuterium in the tetrahedral interstices of the body-centered cubic metal.

The Nb–D system, like the Ta–D system, shows a spectrum of quadrupole splitting in its ordered state.[5,6] This is consistent with the existence of superlattice diffractions[3] in the same system. In spite of the resemblance of the Nb–D and Ta–D systems in their quadrupole splitting spectra and the superlattice diffraction patterns, there are considerable differences between the two systems. For instance, the deuteride phase (β phase) of the Ta–D system, which is in equilibrium with the metallic phase (α phase), has the composition of Ta_2D, while that for the Nb–D system has a composition close to Nb_4D_3.[7,8] The Ta–D phase diagram, as determined by X-ray measurement,[9] is consistent with the proton[10] and deuteron magnetic resonance[4] results. However, the Nb–H phase diagram, as determined by means of the proton and niobium magnetic resonance[11] is different from the phase diagram as determined by X-rays and by thermal analysis.[8] It is one of the purposes of this paper to reexamine the phase diagram of the Nb–D system.

Together with the tendency to deuteride formation, Va metals have a strong affinity to oxygen. Commercially-available niobium metal powder usually contains about 0.3~0.4 wt% oxygen. In this paper, we will show that discrepancies in the composition of the ordered phase, the phase-transition temperatures, and the solubility of hydrogen in the metallic phase are due to differences in the contents of oxygen and other interstitial impurities.

Experimental

Two types of niobium specimens with different oxygen contents were used for the preparation of deuterides. One specimen was a powdered niobium obtained from Herman Stark; it contained about 3900 ppm oxygen, 560 ppm nitrogen, and 200 ppm carbon (hereafter denoted as the S–II series). This powdered niobium metal was purified by using a electron-beam melting furnance. The purification was carried out

four times. The purified ingot was rolled to make a foil 0.05 mm thick. The final oxygen content, as determined by the inert gas fusion method, was 12 ± 2 ppm. The other interstitial impurities were 30 ppm carbon and 17 ppm nitrogen. This foil was used to prepare deuterides of the S–I series. The deuteration was carried out as follows. The niobium specimen was placed in a quartz tube and subjected to thermal treatment in a vacuum of 1.2×10^{-5} mmHg at about 800 °C. Then, a known amount of deuterium gas as purified by means of Hydrogen Purifier[12] (Pd membrane method), was introduced, after which the sample was cooled to 150 °C and kept about two hours. The deuteride foil was then crushed to powder. In this deuteration process, the oxygen content increased from 12 ppm to 70~80 ppm for the S–I series, and from 3900 ppm to 4100~4500 ppm for the S–II series. The accuracy in the composition determination was within $\pm0.4\%$. The D/Nb atomic ratios of the deuterides examined were as follows:

S–I series: 0.236, 0.347, 0.480, 0.532, 0.587, 0.612, 0.699, 0.715, 0.738, 0.746, 0.796, 0.804, 0.822, 0.855, 0.899, 0.945.

S–II series: 0.232, 0.340, 0.426, 0.562, 0.646, 0.727, 0.807, 0.837, 0.874, 0.890.

The deuteron and niobium-93 resonance measurements were made by using a Varian VF-16 wide-line NMR spectrometer, operating mainly at 6.53 MHz for the deuteron and at 10.47 MHz for the niobium resonance. In some cases, other frequencies were employed to see the effect of the magnetic-field strength. The temperatures of the samples were controlled with a Varian variable-temperature accessory.

Results

Deuteron Resonance at Room Temperature. The room-temperature deuteron resonance spectra of the Nb–D system resemble those of the Ta–D system.[4] In the case of a D/Nb atomic ratio of less than ≈0.65, the powder pattern consists of two parts; one is a sharp, single line located at the center of the spectrum, and the other is a pair of lines which are characteristic of a nuclei with $I=1$ in the presence of an approximately axially-symmetrical EFG. However, for the samples with D/Nb atomic ratios larger than ≈0.65, the central line becomes unobservable. According to the Nb–H phase diagram (Fig. 2), the central line can be attributed to the deuterium of the α phase and the satellites to the β-phase deuterium.

	0.837	31.6	0.04
	0.727	32.2	0.03

a) The mean errors in the e^2qQ/h are less than 0.3 KHz
b) The mean errors in the η are less than 0.02.

A detailed analysis of the powder pattern for the nuclei with $I=1$ in the presence of an asymmetric-field gradient has been shown in the Appendix of I. The quadrupole coupling constants and the asymmetry parameters obtained by using the analytical method of I are shown in Table 1. The observed quadrupole coupling constants and the asymmetry parameters in the same series are almost concentration-independent up to ≈0.822 D/Nb (S-I). However, slight decreases in the quadrupole coupling constants are observed in the highest deuterium-concentration range for both series. The quadrupole coupling constants of the Nb–D system (S-II) containing oxygen are smaller by about 0.6~1.0 KHz than those of the oxygen-free Nb–D system (S-I).

Deuteron Resonance and Phase Transition above Room Temperature. As the temperature of the sample increased from room temperature, the apparent signal intensity of the central line began to increase and that of the satellite line began to decrease, indicating that the $\beta\rightarrow\alpha$ phase transition occurred. Since the line-

width of the central line above room temperature is mainly determined by the bulk magnetization of the deuterides,[11] and since the line-width is constant above room temperature ($\Delta H_{msl} \approx 0.5$ G at 10 KG.), the signal intensity (apparent peak to peak intensity $\times 1/T$) of the central line is taken as proportional to the concentration of the deuterium atoms in the α phase. In Figs. 3 and 4, the signal intensities of the central lines are shown as a function of the temperature. These figures suggest that the phase-transition temperatures of the S-I series are higher than those of the S-II series by about 25 to 10 °C. The following have been noted for the two series.

S-I series: As may be seen in Fig. 3, a sharp phase transition occurs at three different temperatures, about 95, 130, and 170 °C, although some gentle phase-transition curves can be seen at the intermediate temperatures for the samples with intermediate compositions, which will be discussed below. For $NbD_{0.587}$, which is in the $\beta+\alpha$ region at room temperature, the $\beta+\alpha \rightarrow \alpha$ phase transition is initiated at about 90 °C and is finished at a temperature close to the $\beta \rightarrow \alpha$ phase-transition temperature of $NbD_{0.738\sim0.804}$ ($\approx$130 °C). The existence of such a broad two-phase region may be related to the presence of two types of α forms, α and α'. The solubility of deuterium in the α' form is greater than that in the α form. The fact that two types of α forms exist is consistent with the findings in the Nb–H phase diagram.[8]

As has been mentioned above, gentle phase-transition curves are observed with the samples of $NbD_{0.855}$ and $NbD_{0.945}$ in the intermediate region between curves of $NbD_{0.855}$ and $NbD_{0.945}$. This indicates that there is a relatively broad $\beta+\alpha'$ region in the temperature range from 130 to 170 °C. Thus, it may be concluded that, in this two-phase region, the β phase, which is in equilibrium with the α' phase, must have a composition larger than 0.899 D/Nb. For $NbD_{0.899}$, the $\beta \rightarrow \beta+\alpha'$ phase-transition begins at a temperature close to the $\beta \rightarrow \alpha'$ phase-transition temperatures of $NbD_{0.738\sim0.804}$. The $\beta+\alpha' \rightarrow \alpha'$ phase transition for the same sample is finished at a temperature close to the $\beta \rightarrow \alpha'$ phase transition temperature of $NbD_{0.945}$. These facts may be well interpreted by assuming that the β phase consists of two types of β forms. This deuteron magnetic resonance behavior shows a good agreement with the niobium resonance, which will be discussed later.

S–II series: The phase-transition behavior of the S–II series is approximately analogous to that of the S–I series. However, the following points of disagreement are observed. a) The $\beta+\alpha \rightarrow \alpha+\alpha'$ phase-transition temperatures from $NbD_{0.232}$ to $NbD_{0.426}$ are lower by about 20 to 25 °C than those of the corresponding deuterides of the S–I series. The $\beta \rightarrow \alpha'$ phase-transition temperature of $NbD_{0.727}$ is lower by about 10 °C than that of the corresponding deuteride of the S–I series. b) The compositions where the sharp $\beta \rightarrow \alpha'$ ($\approx$130 and $\approx$170 °C) phase transitions occur are lower by about 0.06 D/Nb than those of the S-I series.

Deuteron Resonance below Room Temperature. As the temperature of the sample decreased, the signal intensity of the α form decreased, until finally it vanished in the temperature range from −10 to −70 °C. The quadrupole coupling constants and the asymmetry parameters measured at −50 °C show no significant change as compared with those at room temperature. As the temperature decreased from −70 °C, the satellite lines became broad; this broadening ended at about −120 °C. This is consistent with the temperature dependence of the proton line width in the Nb–H system.[13] In Fig. 1-(C), three calculated line shapes with different asymmetry parameters are shown. The value of the line-width, σ, is taken from the D–Nb dipole-dipole interaction.

Niobium Magnetic Resonance. At room temperature, the observed niobium magnetic resonance intensity is roughly proportional to the concentration of the cubic α phase, which coexists with the unobservable orthorhombic β phase. This is consistent with the findings

on the niobium magnetic resonance in the Nb–H system.[11] Since the variation in the line-width of the α Nb with the temperature is very small as compared with the variation in the apparent signal intensity, the signal intensity may be useful for the investigation of the phase-transition behavior of the Nb–D system. The temperature dependences of niobium-signal intensities shown in Figs. 5 and 6 agree well with the temperature dependence of the deuteron-signal intensities.

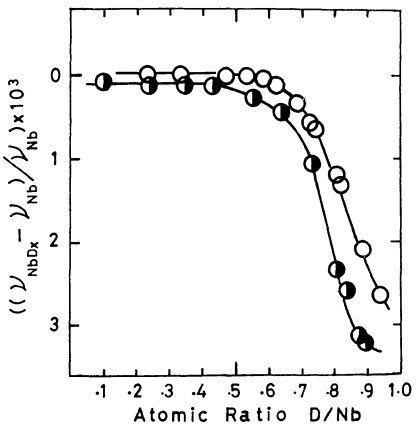

Fig. 7. Concentration dependence of the niobium resonance shift in the NbD_x relative to that in the pure Nb metal.
○: S–I series ◑: S–II series

The concentration dependence of the niobium Knight shift change measured at +180 °C is shown in Fig. 7. The variation in the niobium Knight shift up to 0.7 D/Nb agrees well with the previous results.[11] However, in this case, sharp decreases in the Knight shift are observed in the concentration range from 0.7 D/Nb to the highest concentration studied for both series.

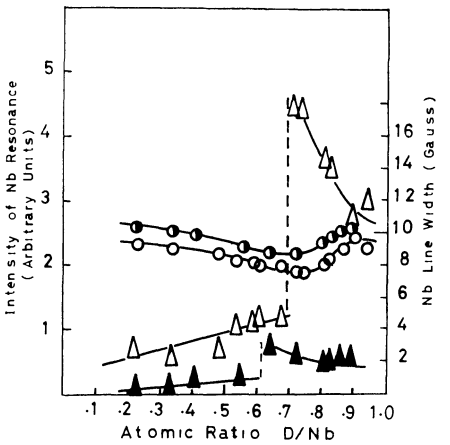

Fig. 8. Concentration dependence of niobium-signal intensity (△ S–I series, ▲ S–II series) and niobium line-width (○ S–I series, ◑S–II series).

The concentration dependence of the niobium-signal intensity shown in Fig. 8 is not so simple as has been indicated in one previous paper.[11] The niobium resonance intensity of Nb metal is affected strongly not only by its heat treatment, but also by the small amount of interstitial impurities. In the Nb–D system, the niobium resonance intensity decrease due to the interstitial impurities is observed for the S–II series, while the line-width increase is unexpectedly small.

A deuterium concentration dependence of the niobium-signal intensity is also observed in this study. A sharp, discontinuous increase in the niobium-signal intensity is observed at about 0.73 D/Nb for the S–I series. However, the line-width change at this concentration is small and gradual. At this temperature, niobium deuteride is in the cubic phase for all the deuterium concentrations. Thus, these sharp and discontinuous intensity changes can not be interpreted in terms of the present phase diagram.

Discussion

Probable Deuterium Arrangement in the β Form. As has previously been shown, the deuteron quadrupole splitting spectra at low temperatures, where the dipolar width of an individual line is assumed to be equal to the rigid lattice one, are essentially the same as that at room temperature. This fact shows that the deuteron quadrupole coupling constant is independent of the translational motion of deuteriums; that is, all the positions occupied by deuterium atoms must be equivalent. For the face-centered orthorhombic cell (a= 4.83, b=4.89, and c=3.44 Å),[7] of the β form, only the following 8 positions are equivalent: 1/4 1/4 1/4, 1/4 1/4 3/4, 1/4 3/4 1/4, 1/4 3/4 3/4, 3/4 1/4 1/4, 3/4

1/4 3/4, 3/4 3/4 1/4, and 3/4 3/4 3/4. This consideration confirms the finding of an recent neutron diffraction study[3] that the deuteriums are in the 2a (1/4 1/4 1/4, 3/4 3/4 3/4) and 2b (3/4 1/4 1/4, 1/4 3/4 3/4) positions of the face-centered orthorhombic cell (space group, Pnnn).

It is of particular interest to see the concentration dependency of the quadrupole coupling constant and the asymmetry parameter of the β form. An X-ray diffraction study[14] of the niobium hydride phase has shown that both the distortion from cubic symmetry and the increase in the lattice parameters occur as the concentration of hydrogen increases from $\approx$0.7 H/Nb. The former effect may increase the asymmetry of the EFG, while the latter decreases the principal component of the EFG. On the other hand, although the electrostatic potential from the positively-charged interstitial deuterium atoms is fairly screened,[16] the increase in the deuterium concentration may increase the quadrupole coupling constant. From a simple electrostatic calculation,[4] this effect can also be seen to increase the asymmetry of the EFG. The experimental results shown in Table 1 exhibit a significant increase in the asymmetry parameters of the S–I series. However, no significant change in the asymmetry parameters is observed for the S–II series. Thus, from the significant change in the quadrupole coupling constants, it may be concluded that the electrostatic potential from the interstitial deuteriums is almost screened and that the effect of lattice expansion is dominant in this case.

Deuteron Resonance Line Shape and Deuterium Arrangement in the Low-temperature Region. Somenkov *et al.*[15] have shown that the partially-ordered deuteride which was found in the solid solution of 3 atomic percent deuterium becomes ordered at -100 °C. The composition of the ordered phase was found to be Nb_4D_3. The crystal has a cell which is double in all directions with respect to the ordered $NbD_{1.0}$ cell. The structure is shown in Fig. 9. An examination of the figure will show that the unit cell consists of four $NbD_{1.0}$-type ordered cells and four Ta_2D-type ordered cells. Since the EFG at the deuterium atom in the Ta_2D-type ordered cell is characterized by a relatively large asymmetry parameter ($\simeq$0.24),[4] the EFG of the ordered Nb_4D_3 is considered to have an asymmetry parameter larger than that for the room-temperature form.

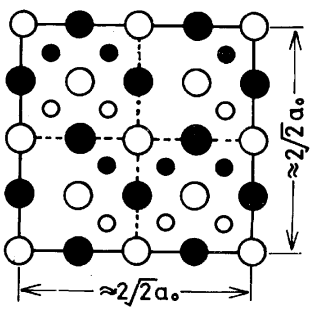

Fig. 9. Projection onto (001) plane of ordered Nb_4D_3 structure.[15] Nb's are at z=0, 1/2 (large open circles) and at z=1/4, 3/4 (large full circles). D's are at z=1/8, 5/8 (small open circles) and at z=3/8, 7/8 (small full circles).

In Fig. 1-(C), the calculated line shapes for three values of asymmetry parameters are shown. Because of the poor signal-to-noise ratio of the observed spectrum, it is difficult to decide which one of the calculated line shapes fits the observed one. Another difficulty in the decision may lie in the approximate-line-shape calculation, for we have disregarded the increase in the EFG due to lattice contraction and the angle dependency of the individual line-width.

Nb–D Phase Diagram as Determined by Deuteron and Niobium Magnetic Resonance. The Nb–H phase diagram proposed by Walter and Chandler[8] is shown in Fig. 2. Apart from the difference in the phase-transition temperature, the essential features of this phase diagram may be used in discussing the Nb–D system. The following features are in accord with our results:

1) At room temperature, the α phase is between 0 and $\simeq$0.1 H/Nb, while $\alpha+\beta$ is between $\simeq$0.1 and $\simeq$0.75 H/Nb.

2) In the concentration range of less than 0.5 H/Nb, the $\alpha+\beta\rightarrow\alpha+\alpha'$ phase transition occurs at about 60 °C, lower by about 20$\sim$30 °C than that for the Nb–D system.

3) In the concentration range between 0.75 and 0.85 H/Nb, the phase transition proceeds according to $\beta\rightarrow\beta+\alpha'\rightarrow\alpha'$.

However, the following aspects of the phase transition behavior can not be interpreted in terms of the Nb–H phase diagram:

4) $\alpha+\beta\rightarrow\alpha'+\beta\rightarrow\alpha'$ two-step phase transition for $NbD_{0.532\sim0.699}$.

5) $\beta\rightarrow\alpha'$ sharp phase transition for $NbD_{0.738\sim0.804}$.

6) $\beta\rightarrow\alpha'$ one-step phase transition for $NbD_{0.945}$.

7) Between 0.7 and 0.8 H/Nb, the Nb–H phase diagram shows that the phase transition proceeds according to $\beta+\alpha\rightarrow\beta\rightarrow\beta+\alpha'\rightarrow\alpha'$. However, if we take into consideration the neutron diffraction[3,15] and the heat capacity findings[9] that the β phase is in an ordered state and that the α phase is in a disordered state, the $\beta+\alpha\rightarrow\beta$ phase transition may be thought to be a disorder-order phase transition. Therefore, the $\alpha+\beta/\beta$ boundary line must be perpendicular to the X axis (composition axis) or, at least, must be a rising gradient.

As has been described previously, the existence of two sharp phase transitions, 5) and 6), can be accounted for if the β phase consists of two types of β forms with similar structures. However, this assumption contradicts the X-ray diffraction finding[14] that the change in the lattice parameters in the β-phase region (0.7 to 0.9 H/Nb) is continuous. A tentative Nb–D phase diagram which is consistent with both our NMR and the X-ray

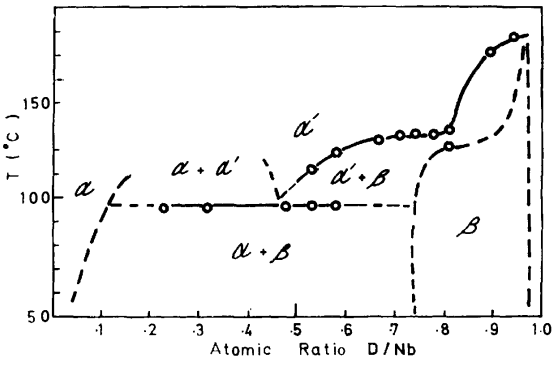

Fig. 10. Proposed phase diagram for Nb–D system.

diffraction results[14] is shown in Fig. 10. This diagram is quite different from any phase diagrams for a binary system ever published. In this phase diagram, the change in the $\alpha'+\beta/\beta$ boundary against the deuterium concentration occurs in one step, as if there are two types of β phases. However, this one-step change in the $\alpha'+\beta/\beta$ boundary may be explained by the schematic free energy-composition diagram shown in Fig. 11.

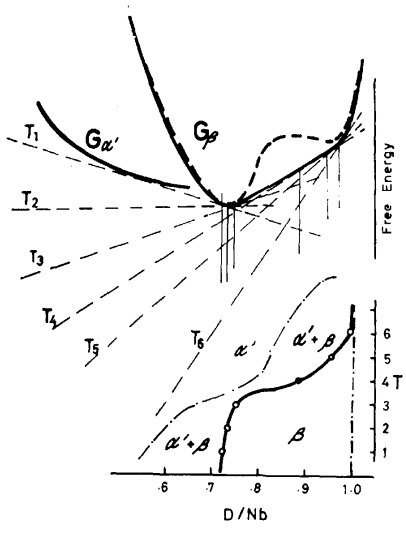

Fig. 11. Common tangents to the schematic free energy-composition curves for the β and α' phases at temperatures from T_1 to T_6 (upper). Only $G_{\alpha'}$ for T_1 is shown. Dotted line shows the free energy curve for the case where two β phase coexists. $\beta+\alpha'/\alpha'$ bundary derived from the upper diagram is shown below.

In Fig. 11, the $\alpha'+\beta/\beta$ boundary may be determined by a common tangent with the free energy-composition curves for the β and α' phases ($G_{\alpha'}$ and G_{β}). For the sake of simplicity, the shape for $G_{\beta'}$ is assumed to be temperature-independent. Since the β phase is an ordered one, while the α phase is a disordered one, the change in the gradient of the common tangent with the increase in the temperature from T_1 to T_6 must be positive. If the G_{β} curve is almost linear between $\simeq$0.7 to $\simeq$1.0 D/Nb, a sharp change in the $\alpha'+\beta/\beta$ boundary may be observed from T_3 to T_5. The resultant phase diagram closely resembles that in which two β phases of different compositions coexist.

Effect of Interstitial Impurities on Niobium Resonance Intensities.[17] In the course of this investigation, we have found large differences between the properties of niobium deuterides prepared from electron beam-melted niobium metal (S–I series) and those prepared from commercially-available powdered niobium metal (S–II series). The major interstitial impurity in the S–II series is oxygen. One of the most outstanding phenomena is the niobium signal intensity reduction in the S–II series. As is shown in Fig. 8, the addition of about 2.3 atomic percent (0.4 wt%) of oxygen reduces the intensity to about 10~40% of that of oxygen-free deuterides. If the dissolved oxygen is used to form a NbO-type oxide, the reduction of the intensity will be of an order of only a few percent. Since the observed reduction is far larger than 2.3%, then, most of the dissolved oxygen atoms must be randomly distributed over the interstices of the metal. This is possible in view of the relatively large solubility of oxygen in the metallic niobium.[18]

In Fig. 8, the maximum resonance intensity is observed for $NbD_{0.738}$ of the S–I series. The intensities of the $NbD_{0.236\sim0.587}$ of the same series are about 13~17% of its maximum intensity. If the satellite lines are eliminated by the first-order quadrupole interaction, and if the observed resonance is due to the $1/2\leftrightarrow-1/2$ transition only, the theoretical intensity should be 15.1% of its maximum intensity. Thus, the intensity loss of the S–I series seems to be due to the first-order quadrupole interaction.

The mechanism of the intensity loss due to the addition of interstitial impurities is somewhat different from that of the S–I series. For samples with D/Nb ratios lower than $\approx$0.5, where the observed resonance is due to the $1/2\leftrightarrow-1/2$ transition only, the reduction of intensity due to the addition of interstitial impurities must be caused by the second-order quadrupole interaction. A comparision of the resonance intensities of the S–I and S–II series shows that the intensity loss of the S–II series is about 87—83%. However, the line-width increase of the same series is less than 10% and the change in the line shape is small. This is contrary to what might be expected from a consideration of the second-order line broadening of the central line.[17]

To account for the above contradiction, we will present a simple model for the intensity loss due to the interstitial oxygen. This model is similar to that proposed by Bloembergen and Rowland[19] for the Cu–Zn substitutional alloy. Since the major impurity is oxygen, it is not unreasonable to confine the discussion to a case where interstitial oxygen is dominant. Consider that there are two niobium atoms and N interstitial sites accessible for oxygen in a unit cell. If the atomic concentration of oxygen is C, the probability

that an interstitial site is occupied by an oxygen atom is $C/(N/2)$. We assume that oxygen atoms within a sphere of a critical radius, r_c, from a given niobium atom casuse a field gradient sufficiently large to make the niobium resonance unobservable. The number of interstitial sites, n_c, within a radius of r_c is $(4\pi/3)\cdot(r_c/a_o)^3\cdot N$. Therefore, $(1-C/(N/2))n_c$ is the fraction of niobium atoms whose resonance is observable.

To calculate n_c, we must take into consideration the intensity loss due to the small line broadening. The fraction of niobium resonance observable has been calculated to be about $0.21\sim0.28$. The number of interstitial sites in a unit cell is 12 for tetrahedral occupation and 6 for octahedral occupation. With an atomic fraction of oxygen of 0.024, and with a fraction of niobium observable of 0.24, n_c and r_c/a_o have been calculated; these values are listed in Table 2. It should be noted that there are small amounts of other interstitial and substitutional impurites, and that the calculated r_c values are the upper limits.

Geometrical Structures of Excited States of Conjugated Molecules. II. The Calculated Vibronic Intensity Distributions in the Absorption Spectra of Naphthalene

Yuichi FUJIMURA, Masamune ONDA, and Takeshi NAKAJIMA

Department of Chemistry, Tohoku University, Sendai 980

(Received November 27, 1972)

The normal coordinates and the vibrational frequencies in the first excited singlet ($^1B_{2u}$), the second excited singlet ($^1B_{1u}$), and the first excited triplet ($^3B_{1u}$) states of naphthalene, whose geometries were calculated by a semi-empirical method, are evaluated by assuming a simplified valence force field. The relation between the normal coordinates of two different electronic states is expressed on the basis of the Franck-Condon principle. The mixing among the excited-state normal coordinates, expressed in terms of the ground-state normal coordinates, is neglected in the present treatment. By using the simple relation between the normal coordinates of two different electronic states, the vibronic intensity distributions in the absorption spectra ($^1B_{2u}\leftarrow{}^1A_g$, ^1L_b, $^1B_{1u}\leftarrow{}^1A_g$, ^1L_a, and $^3B_{1u}\leftarrow{}^1A_g$, ^3L_a) have been calculated. The vibronic intensity distribution of the $^1B_{2u}\leftarrow{}^1A_g$ transition has been calculated, taking into consideration the intensity of the interpenetrating sets of the vibronic band groups on the basis of the Herzberg-Teller perturbation theory.

In the previous paper,[1] we proposed a computational method for determining the molecular symmetries and C–C bond distances in the electronically-excited states of conjugated molecules on the basis of the semiempirical SCF LCAO MO theory, and examined the geometrical structures of the lower excited states of benzene, naphthalene, azulene, and heptalene.

Many phenomena in the excited states of molecules, such as photochemical reactions or intramolecular nonradiative transitions, depend primarily on the geometrical structures of the excited states which are expressed by the multidimensional potential energy surfaces. For example, the large geometrical changes brought about by electronic excitation may lead to predissociation in small molecules,[2] or to photoisomerization[3–9] or to electrocyclic reactions,[10,11] in large

aromatic molecules, all of which may be interpreted by the strong coupling scheme. On the other hand, small geometrical changes in large aromatic molecules lead to nonradiative transitions, such as internal conversions or intersystem crossings, which may be interpreted by the weak coupling scheme.[12-18]

Another interesting manifestation of the geometrical changes on excitation is the appearance of the vibronic intensity distribution in the electronic absorption and emission spectra. As is well known from the Franck-Condon principle, the vibronic intensity distribution depends on the relative displacements of the potential energy surfaces of the two electronic states in the equilibrium positions. The geometrical structures of the excited state of interest can be estimated from the vibronic intensity measurement, provided the ground-state geometrical structure has been established. By analyzing the vibronic intensity distribution in the 2600 Å transition of benzene, Craig[19] has suggested that all the C–C bonds in the $^1B_{2u}$ state are longer by 0.037 Å than those in the ground state. Coon *et al.*[20] have also determined the excited-state molecular geometries of SO_2 and ClO_2 by using the same procedure. Similarly, Anno and Sadô[21] have applied the Franck-Condon principle to the analysis of the 4500 Å absorption system of *p*-benzoquinone. Hunt *et al.*[22] have given a conventional method for calculating the vibronic intensity distribution in aromatic hydrocarbons. Their calculation is based on the assumption that only one vibrational mode or set of degenerate modes contributes to the vibrational progressions. Miller and Murrell[23] have calculated the vibronic intensity distribution in the L_a bands of polyacenes, and have attempted to explain why a vibrational progression of about 1400 cm^{-1} appears in these bands. They have performed the normal coordinate analysis on the assumption that all the rings of polyacenes are hexagonal in the ground state and that the frequencies and the normal modes in the ground and the excited states are identical. Diner and Malrieu[24] have tried to reproduce the vibrational structures in the first UV band of linear polyenes, using the method proposed by Hunt *et al.*[22]

It is our purpose in this paper to examine theoretically the vibronic intensity distribution in the absorption spectrum ($^1B_{2u}\leftarrow{}^1A_g$, ^1L_b) of naphthalene, which is complicated by the occurrence of false origins, and the vibronic intensity distributions in the absorption spectra of the next singlet transition ($^1B_{1u}\leftarrow{}^1A_g$, ^1L_a) and of the lowest triplet transition ($^3B_{1u}\leftarrow{}^1A_g$, ^3L_a).

The following section will describe the relation between the normal coordinates of two different electronic states. In Section 3, a conventional method for determining molecular force fields will be described by using a simplified valence-force-field. The Badger relation[25] is used to obtain the C–C stretching force constant from the corresponding bond distance. The results of the normal coordinate analysis of the ground and excited states are also given in this section. In Section 4, the vibronic intensity distributions in the various absorption spectra of naphthalene are evaluated.

The Relation between the Normal Coordinates of Two Different Electronic States

Let us describe a method for the transformation of the normal coordinates of an electronic state, subjected to interaction with an electromagnetic field, into those of the resultant electronic state. First, let us consider a system in the absorption process. The progression-forming modes of large aromatic molecules are generally totally symmetric in so far as vibronic couplings such as the Jahn-Teller coupling or the pseudo-Jahn-Teller coupling may be neglected. It is recognized that molecular geometries in the lower electronic states of naphthalene belong to the D_{2h} symmetry. In the present calculations, the totally symmetric modes will be restricted to the C–C skeletal stretching modes. These modes are thought to have the strongest effects on the vibronic intensity distribution. Naphthalene has four skeletal stretching normal modes belonging to the A_g irreducible representation of the D_{2h} point group.

The internal symmetry coordinates for the totally-symmetric skeletal stretching modes of naphthalene in the ground state may be specified as follows:

$$S_1 = \frac{1}{2}\sum_{j=1}^{4}\Delta r_j, \qquad S_2 = \frac{1}{2}\sum_{j=5}^{8}\Delta r_j,$$
$$S_3 = \frac{1}{\sqrt{2}}\sum_{j=9}^{10}\Delta r_j, \text{ and } S_4 = \Delta r_{11} \tag{1}$$

where $\Delta r_j = r_j - r_j^0$, and where r_j^0 and r_j are the C–C bond distance at the vibrational equilibrium point and the corresponding instantaneous bond distance respectively. For the excited states also, the same relationships as above hold. (For the r_j^0 values, see Table 1.) By equating the instantaneous bond distances of the ground and excited electronic states, we obtain:

$$S' = S + D, \tag{2}$$

where the primed quantity refers to the excited states. The i-th component of the column matrix, D, is expressed in the form of $a_i\sum_j(r_j^0 - r_j^{0\prime})$, where a_i is a normalization constant for the i-th internal symmetry coordinate. The internal symmetry coordinates are

connected with the normal coordinates, Q, by the transformation matrix, L_s:

$$S = L_s Q \tag{3}$$

and

$$S' = L_s' Q'. \tag{3'}$$

From Eqs. (2), (3), and (3'), the normal coordinates of the excited states are expressed in terms of those of the ground state in the form of:

$$Q' = C_a Q + \Delta Q, \tag{4}$$

$$C_a = (L_s')^{-1} L_s, \tag{5}$$

and

$$\Delta Q = (L_s')^{-1} D, \tag{6}$$

where the subscript, a, refers to the ground state. For the emission process, the following formula can be obtained:

$$Q = C_e Q' - \Delta Q', \tag{7}$$

with:

$$C_e = (L_s)^{-1} L_s', \tag{8}$$

and:

$$\Delta Q' = (L_s)^{-1} D, \tag{9}$$

where the subscript, e, refers to the emitting state.

We have thus obtained the formulas indicating the relation between the normal coordinates of two different electronic states. The off-diagonal matrix elements of the C_a and C_e matrices are related to the magnitudes of the mixing among the normal coordinates of the two relevant electronic states (the Duschinsky effect).[26] In the following section, we will show that the diagonal parts of the C_a matrix in Eq. (4) make the dominant contribution to the transformation of the normal coordinates of the electronic states, and that the Duschinsky effect can be neglected for the totally symmetric skeletal stretching modes in naphthalene. Consequently, Eq. (4) may be safely expressed as follows:

$$Q' = Q + \Delta Q. \tag{10}$$

Determination of the Molecular Force Fields

The molecular force field assumed is of a valence-force type consisting of the C–C stretching force constants, all the interaction constants being neglected. In order to obtain the C–C stretching force constants, k, the following relation is used:

$$k = A(r^0 - B)^{-3} \tag{11}$$

where k is given in millidynes per Å, A and B are the constants to be determined so as to reproduce the observed frequencies. The above relation between the equilibrium bond distances and the corresponding force constants has been proposed by Badger.[25] The relation is applicable not only for the force fields in the ground state, but also for those in excited states, with the proper choice of constants.

The best values of A and B obtained by the variational procedure for the molecular force fields in the ground state of naphthalene are 2.4 millidyne Å^2 and 0.64 Å respectively. The results of the normal coordinate analysis for the ground-state naphthalene obtained by using Eq. (11) are given in Table 2. The fairly good agreement between the calculated and the observed frequencies supports the validity of the molecular force fields determined by the above procedure.

In order to obtain the molecular force fields in the excited states, Eq. (11) with the constants, A and B, determined for the ground-state molecular force fields will be used. The results of the normal coordinate analysis for the $^1B_{2u}$, $^1B_{1u}$, and $^3B_{1u}$ excited states are shown in Tables 3, 4, and 5 respectively.

The Vibronic Intensity Distributions in Electronic Spectra

According to the Franck-Condon principle, the vibronic intensity distribution accompanied by a pure electronic transition is obtained by evaluating the square of the overlap integral between the vibrational wave functions for the relevant electronic states. If the geometrical changes on excitation are relatively small, and if the magnitudes of the off-diagonal matrix elements in the C_a or C_e matrix may be neglected, the vibrational wave function for each electronic state can be expressed in terms of the product of the harmonic-oscillator wave functions. The vibronic intensity distribution of the r-th mode relative to the 0—0 intensity in the electronic spectra is given as follows:

$$I_{I-J}(Q_r) = \frac{S^2_{I-J}(Q_r)}{S^2_{0-0}(Q_r)} \tag{12}$$

where $S_{I-J}(Q_r)$ is the overlap integral between the I and J quantum harmonic oscillators belonging to the normal coordinate, Q_r. The total vibronic intensity distribution relative to the 0—0 intensity is given by the product of the relative vibronic intensity distributions over the possible normal modes.

Because of the small energy separation between the lowest ($^1B_{2u}$) and the second ($^1B_{1u}$) singly-excited states of naphthalene, these two electronic states are strongly subjected to vibronic perturbation from each other, and the shifts of the point of origin, which correspond to the frequencies of b_{3g} vibrations (438 and 911 cm^{-1}), are observed in the absorption spectrum ($^1B_{2u}\leftarrow{}^1A_g$).[27] (see Fig. 1) The vibronic intensity in the absorption spectrum, where the vibronic bands are subjected to vibronic perturbation by a nontotally symmetric mode, Q_p, can be expressed by using the Herzberg-Teller perturbation theory.[28] The perturbed vibronic intensity distribution of the totally symmetric mode, Q_r, relative to the 0—0 vibronic transition of the pure electronic transition is approximately given as follows:

$$I_{I-J}(Q_r) = C(Q_p)\frac{S^2_{I-J}(Q_r)}{S^2_{0-0}(Q_r)} \tag{13}$$

where $C(Q_p)$ is the square of the ratio of the transition moment induced by a unit displacement along the p-th nontotally symmetric normal coordinate to the zeroth-order transition moment. Equation (13) has been derived on the assumption that the two excited states are subjected to vibronic perturbation by the inducing mode, Q_p, the frequency of which is the same in both ground and excited states, and on the assumption that the electronic wavefunction corresponding to the lowest excited state is expanded about the nuclear configuration in the ground state at the vibrational equilibrium to the first order of Q_p in the perturbation theory. $C(Q_p)$ will be evaluated empirically in the present calculation. The analysis of the vibronic intensity distribution in the spectra ($^1B_{2u}\leftarrow{}^1A_g$) of naphthalene vapor shows that the vibronic-band intensity of the false origin at 0+438 cm^{-1} (vs)[29] is five or ten times stronger than that of the 0—0 group (m),[29] and that the intensity of the false origin at 0+911 cm^{-1} (ms)[29] is somewhat stronger than that of the 0—0 group.[28] From the above experimental facts, for the 438 and 911 cm^{-1} inducing modes of b_{3g} the values of $C(Q_p)$ were taken to be 6.0 and 2.0 respectively.

The overlap integrals, $S_{I-J}(Q_r)$, were evaluated by using the formula derived in the previous paper.[30]

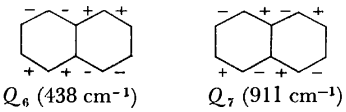

Fig. 1. b_{3g} modes inducing the vibronic perturbation between the $^1B_{2u}$ and $^1B_{1u}$ states. Quantities in parentheses indicate frequencies in the $^1B_{2u}$ state.

Discussion

The mixing among the excited-state normal coordinates expressed in terms of the ground-state ones was neglected in the calculation. This is sufficiently supported by the small off-diagonal matrix elements in the transformation matrixes C_a, *e.g.* for $^1B_{2u}\leftarrow{}^1A_g$ (see Table 6). Consequently, the Duschinsky effect can not be expected for the a_g skeletal stretching modes of naphthalene. On the other hand, for the nontotally

symmetric modes, which induce the vibronic coupling between the first and the second singlet electronic states, the Duschinsky effect must be operative.[31] The neglect of the mixing among the excited-state normal coordinates will be valid in the calculation of the vibronic intensity distribution of the large aromatic molecules, such as polyacenes, with small relative displacements in the points of origin of the normal coordinates. However, in calculating the vibronic intensity distribution of azulene, which retains the C_{2v} molecular symmetry in the first singlet excited state,[1,32] we cannot neglect the mixing among the normal coordinates in the a_g vibrational modes, because there are substantial geometrical changes, especially a shortening of the central bond in the first singlet excited state compared with that in the ground state. In fact, from the analysis of the 7000 Å absorption spectra of azulene vapor, Hunt and Ross[32] concluded that the upper-state vibrational frequencies are difficult to correlate with those of the ground state. The Duschinsky effect for the totally symmetric modes will also have to be explicitly taken into account in calculating the vibronic intensity in the absorption spectra ($S_1 \leftarrow S_0$) of heptalene, which is observed to suffer drastic changes in molecular symmetry on excitation; heptalene has C_{2h} and D_{2h} symmetries in the ground and the first excited states respectively.[1,33,34] The effect of the mixing among normal coordinates will be reflected in the appearance of the combination bands in the vibronic spectra.

The calculated vibronic intensity distributions in the absorption spectra will now be compared with the observed ones.

The analysis of the absorption spectrum ($^1B_{2u} \leftarrow {}^1A_g$)

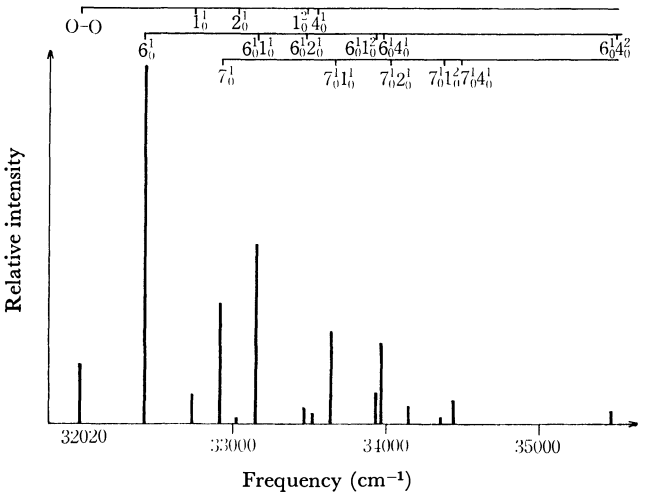

Fig. 2. Calculated vibronic intensity distribution in the absorption spectrum ($^1B_{2u} \leftarrow {}^1A_g$) of naphthalene. The numbers give the normal modes which are involved in the transition. Superscripts and subscripts give the number of vibrational quanta excited in the upper and lower states, respectively.

of naphthalene vapor indicates that the vibrational structures consist of three main interpenetrating sets of band groups which originate at the pure electronic origin and at false origins, 0+438 cm^{-1} and 0+911 cm^{-1}; it indicates further that the progression-forming modes are those with frequencies of 702, 987, and 1435 cm^{-1} with two quantum intervals, while for the 987 and 1435 cm^{-1} modes the one-quantum addition gives a band weaker than the fundamental.[27] On the other hand, for the 702 cm^{-1} mode, the one-quantum addition gives a band much weaker than the fundamental. The vibronic intensity distribution calculated for the absorption spectrum, $^1B_{2u} \leftarrow {}^1A_g$ is shown in Fig. 2. The progression-forming modes calculated are mainly those with frequencies of 757, 993, and 1495 cm^{-1}. For these modes, progressions with two-quantum intervals, in addition to the fundamentals, are thought to appear with significant intensities. It can be recognized that the vibronic intensity distribution calculated is in fairly good agreement with the observed one. However, a slight discrepancy remains between them: for the mode belonging to the lowest vibrational frequency in the calculation, the over-tone band intensity is somewhat stronger than the observed one. This indicates that the relative displacement along its mode on excitation has been slightly overestimated in calculating the geometrical structures in the $^1B_{2u}$ state.

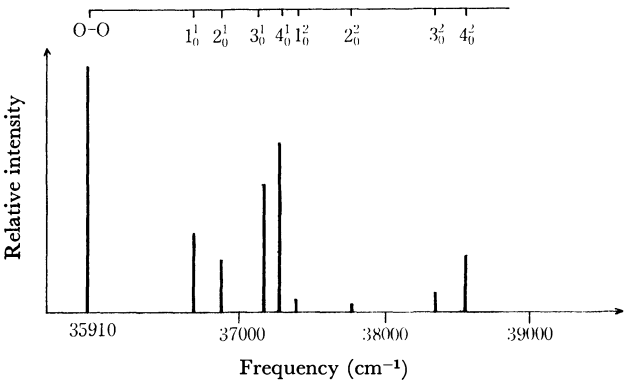

Fig. 3. Calculated vibronic intensity distribution in the absorption spectrum ($^1B_{1u} \leftarrow {}^1A_g$) of naphthalene.

The calculated vibronic intensity distribution in the absorption spectrum of the second singlet transition ($^1B_{1u} \leftarrow {}^1A_g$, ^1L_a) is shown in Fig. 3. The vibronic bands originating from the Herzberg-Teller vibronic coupling are neglected. The vapor absorption spectrum of naphthalene at 2900~2500 Å indicates that the 0—0 band is located at 35910 cm^{-1} and that the strong bands can be explained as resulting from two vibrations, with the 1390 and 485 cm^{-1} bands assigned to the totally symmetric skeletal stretching and bending vibrations respectively.[35] Miller and Murrell[23] have calculated the normal coordinate displacements between the second singlet, $^1B_{1u}$, and the ground states of naphthalene. There is a considerable difference in the vibronic intensity distribution of the absorption spectrum ($^1B_{1u} \leftarrow {}^1A_g$) between their results and ours. Their results indicate that the displacements with higher

frequencies are larger, and that the main intense bands of the spectrum correspond to the frequencies around 1500 and 1400 cm^{-1}. In our treatment, the changes of the C–C skelton on excitation are nearly equally distributed into the totally symmetric normal coordinates considered. These differences can be in part ascribed to the choice of the geometrical structures of the ground state of naphthalene.

Experimental studies of the $^3B_{1u}\leftarrow{}^1A_g$ absorption spectrum on naphthalene have been reported by many authors.[36–38] Castro and Robinson[38] have obtained the high-resolution $^3B_{1u}\leftarrow{}^1A_g$ absorption spectrum of crystalline naphthalene at 4.2 K. The absorption spectrum reported by them consists of the strong a_g modes (498 and 1343 cm^{-1}) primarily polarized normal to the molecular plane and, further, weak antisymmetric fundamentals that behave as false origins for the strong progression-forming modes. The most intense of the antisymmetric modes exhibits an intensity 15 times weaker than the 0—0 band. On the basis of the above experimental evidence, the vibronic spectrum of the lowest triplet transition is calculated, neglecting the bands originating from the false origins (Fig. 4). The calculated largest displacement of the C–C stretching normal coordinates between the lowest triplet and the ground states is that with the frequency of 1393 cm^{-1}. The band of the 1393 cm^{-1} mode with three-quantum intervals appears with a significant intensity. This is in agreement with the observed result. On the other hand, the other normal coordinate diplacements calculated indicate a more uniform distribution in the a_g normal coordinates of the C–C stretching modes than in the observed ones.

The lack of agreement between the calculated and observed $^3B_{1u}\leftarrow{}^1A_g$ spectra mainly originates from the neglect of the contribution of the in-plane C–C–C deformation on excitation.

One of the present authors (Y. F.) wishes especially to thank Professor A. Sadô for his useful discussions of normal coordinate analysis. This research was supported in part by a grant from the Takeda Science Foundation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2039—2044 (1973)

The X-Ray Emission Spectra of the Compounds of Third-period Elements. VI.* The Relationship between the $K\alpha$ and $K\beta$ Spectra

Yoshihito TAKAHASHI

Government Industrial Development Laboratory, Hokkaido, 41-2 Higashi-Tsukisamu, Toyohira, Sapporo 061-01

(Received December 4, 1972)

Data on the $K\beta$ spectra for several compounds of silicon, aluminum, and sulfur are shown. The intensity of the $K\beta'$ line is affected not by the kinds of thrid-period atoms, but by their charges and by the kinds of ligand atoms. The degree of the contribution of each bonding group to the relative intensity of the $K\beta'$ line and to the chemical shift of the $K\alpha_{1,2}$ lines are shown; they have additivity in the molecule. Therefore, the chemical shift of the $K\alpha_{1,2}$ lines can be estimated from the molecular structural formula; the charge of the atom can also be estimated.

Concerning some compounds of sulfur,[3] chlorine,[4] and phosphorus,[5] the fine structures of the $K\beta$ spectra have been investigated with relation to the chemical bonds. On these oxygen-included compounds, a satellite line, $K\beta'$ line, is observed in the spectrum; the relative intensity of the satellite line is related to the energy shift of the $K\alpha_{1,2}$ lines. In addition, it has been

reported that the $K\beta'$ line is also observed in the spectra of compounds of third-period elements in which electronegative elements other than oxygen, such as fluorine, chlorine, and nitrogen, are included as ligands.[6-8] In order to check the character of the $K\beta'$ line and other satellite lines in detail, in this paper the characteristics of the K spectra of several compounds of silicon and aluminum, and also these of a few fluoro-compounds of sulfur and phosphorus, will be discussed.

Many reports have been published on the spectra of the compounds of silicon and aluminum;[6,7,9-11] these reliable reports shall be referred to in this paper as much as necessary. However, in order to compare the band-width and the chemical shift of the line, some easily measurable data were measured anew, consistently with some of the new data, such as those on tetraethylorthosilicate, silicon tetrachloride, aluminium propoxide, sulfur tetrafluoride, by means of our own apparatus.

Experimental

The details of the measurement apparatus and the conditions were presented in previous papers.[1,3] Analyzing crystals were used: EDDT (020) for the measurements of the Si and Al K spectra, germanium (111) for the P K spectra, and sodium chloride (200) for the S K spectra. In the measurements of gaseous samples, the samples were made to flow through a cell at a steady pressure. The gas-sample cell is a stainless-steel vessel with Mylar film window 25 mm × 30 mm, and 25 mm in depth.

The separation of the $K\beta$ spectrum into component peaks was done in a manner similar to that described in previous paper,[3-5] adopting the P $K\beta_1$ line of anhydrous sodium phosphate[5] as the standard shape of the component peak. Previously, we adopted the S $K\beta_1$ line of anhydrous sodium sulfide as the standard shape in peak separation for the S $K\beta$ spectra.[3] However, concerning the peak separation for two sulfur fluoro-compounds, we could find little difference between the results of the two methods.

Results and Discussion

Silicon Compounds. The Si $K\beta$ spectra of the compounds which were measured are shown in Fig. 1. The characteristic values on the $K\alpha_{1,2}$ and the $K\beta$ lines for each compound are listed in Table 1. The chemical shifts of the $K\alpha_{1,2}$ lines were determined with silicon metal as the standard material.

The energy differences between the $K\beta_1$ line (C peak) and the $K\beta'$ line (A peak) are about 14 eV for oxy-compounds, 19 eV for sodium hexafluorosilicate, and 8.6 eV for silicon tetrachloride.

The Si $K\beta$ spectrum of silicon dioxide consists of two main peaks; the $K\beta_1$ (C) and the $K\beta'$ (A). The

A: $K\beta'$ line, C: $K\beta_1$ line.

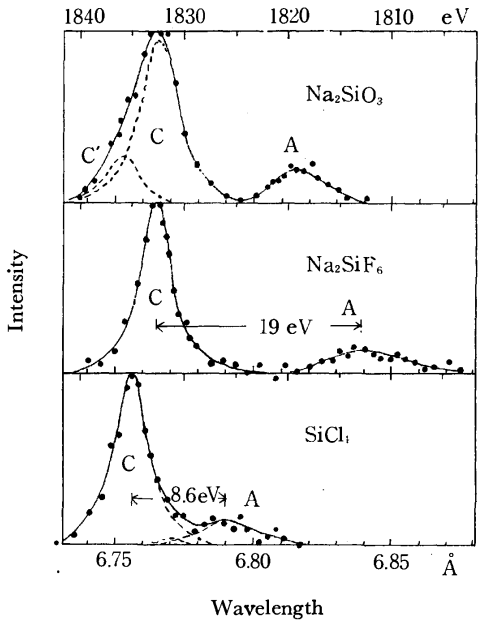

Fig. 1b. Silicon $K\beta$ spectra of some silicon compounds
A: $K\beta'$ line, C: $K\beta_1$ line.

$K\beta_1$ line is about 1.4 times wider than those of the spectra of sodium hexafluorosilicate and silicon tetrachloride. It seems that the spectrum contains a satellite line which is like the C' peak in the P $K\beta$ spectra of molecular phosphorus compounds.[5]

The C peak in the spectrum of silicon monoxide[13] seems to consist of two component peaks. White said that the component peak on the short-wavelength side was the $K\beta_1$ line, which was attributable to the zero valent silicon atom, and that the other was the $K\beta_1$ line of the plus-4 valent silicon atom.[14]

a) Ref. 12.
b) The value was estimated from the spectrum of Ref. 15.

Tetraethylorthosilicate ($Si(OEt)_4$) and sodium metasilicate (Na_2SiO_3) are molecules which have tetrahedral structures,[15] and their silicon atoms do not have any lone pairs. Consequently, it is inferred that, in these spectra, the satellite peak which is so-called D peak does not appear.[17] In their spectra, the energy difference between the shorter-wavelength peak and the $K\beta_1$ line (C) is about 4 eV. This value is close to the energy difference between the $K\beta_1$ line (C) and the C′ peak in the P $K\beta$ spectrum of phosphorus pentoxide, 5 eV. On the other hand, the difference between the $K\beta_1$ line and the D peak is about 7 eV in the spectra of sulfite, chlorite, and sulfur tetrafluoride. Hence, the shortest-wavelength peak may be the C′ peak.

16) R. Kiriyama and H. Kiriyama, "Kozo-Mukikagaku, II," (1966), p. 213.
17) The D peak appears in the $K\beta$ spectrum of a compound in which the central atom has a lone pair, such as sulfite, sulfur tetrafluoride, and phosphorus trichloride.[5]

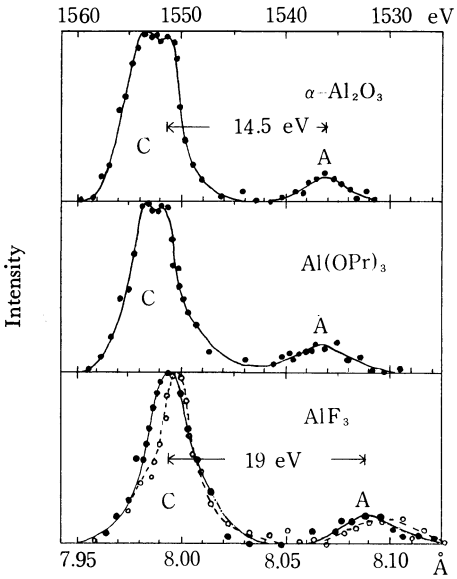

Fig. 2. Aluminum $K\beta$ spectra of some aluminum compounds
A: $K\beta'$ line, C: $K\beta_1$ line.

Aluminum Compounds. The measured Al $K\beta$ spectra are shown in Fig. 2. The data on the $K\alpha_{1,2}$ lines and the $K\beta$ lines of each compound are listed in Table 2. The standard material for the $K\alpha_{1,2}$-line shifts is aluminium metal.

In the spectra of aluminum oxide and aluminum propoxide, the top of the $K\beta_1$ line splits into two peaks, so one may guess that the C′ peak exists in the spectrum. Concerning the spectrum of aluminum oxide, a theory has been advanced attributing the shorter-wavelength peak to the transition of the π-electron, and the longer one, to the σ-electron.[9] The differences between these peaks and the $K\beta'$ line (A) are 16 and 14.5 eV respectively.

The Al $K\beta$ spectrum of aluminum fluoride, the specimen of which was not dried enough (however, it was confirmed to be anhydride by X-ray diffraction), is different from that of the dried specimen and from that which was measured in the vacuum. In the former spectrum, a puff which seems to be the C′ peak is observed, but it is absent in the latter.

Sulfur and Phosphorus Compounds. The measured S $K\beta$ spectra of sulfur hexafluoride, sulfur tetrafluoride, and sulfur dioxide in a gaseous state are shown in Fig. 3. The energy differences between the $K\beta_1$ (C) and the $K\beta'$ (A) lines are 18.5, 17.8, and 15.5 eV for SF_6, SF_4, and SO_2 respectively. The D peak is observed in the spectra of SF_4 and SO_2. The characteristic values of the $K\alpha_{1,2}$ and the $K\beta$ lines for these sulfur compounds and potassium hexafluorophosphate (KPF_6), are listed in Table 3. As the standard materials for the line shift, rhombic sulfur and red phosphorus were chosen.

The $K\beta'$ Line in All the Measured Spectra. The values of the energy difference between the $K\beta_1$ and the $K\beta'$ lines in the oxy-compound are spread from

a) Ref. 7.
b) The value was estimated from the spectrum of Ref. 7.

13.6 to 15.6 eV. Particularly, those of oxy-anions, such as ClO_4^-, ClO_3^-, SO_4^{2-}, and PO_4^{3-}, are less than 14 eV, while in many cases of molecular compounds, such as sulfone, sulfoxide, and SO_2, they are more than 14 eV.[3-5] On the other hand, in the cases of fluoro-compounds and chlorine-compounds (which have chlorine atoms as ligands), the values are 17.9~21 eV[7] and about 8.5 eV[5] respectively. According to Ohno's report,[6] in which several Al $K\beta$ spectra are given, the values are estimated to be about 12 eV for nitride and 8 eV for carbite. In the Si $K\beta$ spectrum, the value of carbite is 9 eV[18] (Table 4). Consequently, the energy difference between the $K\beta_1$ and the $K\beta'$ lines actually differs according to the kind of ligand atom.

The relationship between the relative intensity of the $K\beta'$ line (the ratio of the integral intensity of the A peak to that of the total of the $K\beta$ lines) and the chemical shift of the $K\alpha_{1,2}$ lines for each compound is shown in Fig. 4. In this figure, our results and those of some other researchers are collected. Two points are clear; the measured points make a linear relation for each ligand element, and these linear relations are almost independent of the kind of central atom in the molecule. It has become clearer, therefore, than in the results presented in a previous paper[4] that the intensity of the $K\beta'$ line is affected not by the kinds of central atoms, but by their charges, and by the kinds of ligand atoms. This deduction as to the effects of ligand elements is consistent with Nefedow's theory,[19] in which

c) The value was estimated as a thionyl compound.
d) The value was estimated as a sulfonyl compound.

The degree of the contribution of each bonding group which is linked to the sulfur atom to the relative intensity of the S $K\beta'$ line is shown in Table 5. The effects of these groups have additivity in each molecule. For example, in diethyl sulfate ($(EtO)_2SO_2$), the sulfur atom is linked by two double-bonded oxygen atoms and two single-bonded oxygen atoms, so the relative intensity of the $K\beta'$ line is estimated to be 0.30 ($2\times 0.10+2\times 0.05$); in benzenesulfonamide ($PhSO_2NH_2$), the sulfur atom is linked by two double-bonded oxygen atoms, one nitrogen atom (amino group), and one carbon atom (phenyl group), so the value is estimated to be 0.24 ($2\times 0.10+0.04+0.00$), and in sulfur dioxide, the sulfur atom has two double-bonds and one lone

Vibrational Assignments of Ethylmethylsilane

Michiro HAYASHI, Keiichi OHNO, and Hiromu MURATA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received December 12, 1972)

The infrared spectra of ethylmethylsilane, $CH_3CH_2SiH_2CH_3$, its deuterated species, $CH_3CH_2SiD_2CH_3$, and a mixture of $CH_3CH_2SiHDCH_3$, $CH_3CH_2SiH_2CH_3$, and $CH_3CH_2SiD_2CH_3$ have been measured in the gaseous, liquid, and crystalline states. The Raman spectrum of ethylmethylsilane has also been measured in the liquid state. Vibrational assignments have been made in relation to the rotational isomerism, on the basis of a modified Urey-Bradley force field, in which the force constants have been transferred from those for dimethylsilane and ethylsilane. The conclusion regarding the molecular forms of the rotational isomers, which has been obtained from the experimental evidence of the SiHD deformation vibrations for an asymmetrically-deuterated species, $CH_3CH_2SiHDCH_3$, can be considered to be also supported by the present results of the normal vibration calculations.

In previous notes, we have reported the existence of the rotational isomers in ethylmethylsilane[1] and have determined the molecular forms of the isomers from the SiHD deformation vibrations for the asymmetrically-deuterated species, $CH_3CH_2SiHDCH_3$, experimentally.[2] In the present paper, we will deal with the molecular forms of the isomers and with the vibrational assignments based on the normal vibration calculation using a modified Urey-Bradley force field.

Experimental

The samples of ethylmethylsilane and its deuterated species were prepared by the method of making CH_3CH_2MgBr react with CH_3SiCl_3 in ethylether and by reducing the resultant $CH_3CH_2SiCl_2CH_3$ with $LiAlH_4$, $LiAlD_4$, or an equimolar

mixture of $LiAlH_4$ and $LiAlD_4$ in *n*-butylether.[3] The purities of the samples of $CH_3CH_2SiH_2CH_3$ and $CH_3CH_2SiD_2CH_3$ were found to be better than 95% by a study of the infrared spectra and the gas chromatograph. Though the sample prepared using the mixture of $LiAlH_4$ and $LiAlD_4$ was a mixture of $CH_3CH_2SiHDCH_3$, $CH_3CH_2SiH_2CH_3$, and $CH_3CH_2SiD_2CH_3$, it was used in the measurements without further attempts at isolation.

The infrared spectra in the region from 200 to 4000 cm^{-1} were recorded on a Perkin-Elmer instrument (model 621) using conventional techniques.[1,2] The Raman spectrum in the liquid state was measured with a JEOL Raman spectrometer.

Rotational Isomerism

The observed infrared and Raman spectra of ethylmethylsilane, $CH_3CH_2SiH_2CH_3$, are given in Table 1. The infrared spectra of its deuterated species, $CH_3CH_2SiD_2CH_3$, and the mixture of $CH_3CH_2SiHDCH_3$, $CH_3CH_2SiH_2CH_3$, and $CH_3CH_2SiD_2CH_3$ are also given in Tables 2 and 3. As has been reported in the previous notes,[1,2] from a comparison of the spectra in the gaseous and liquid states with those in the crystalline state in the region from 300 to 950 cm^{-1}, definite evidence of the rotational isomers is obtained, as is shown in Fig. 1; that is, some of the bands existing in both the gaseous and liquid states disappear in the crystalline state. On the other hand, the existence of the isomers cannot be concluded from the spectra in the region from 950 to 1500 cm^{-1} alone, since the infrared spectra in the liquid and crystalline states are not so much different.

Normal Vibration Calculation

A normal vibration calculation based on a modified Urey-Bradley force field was carried out, with the force constants being transferred from those for dimethylsilane and ethylsilane,[4] except the force constant of

b) The spectra were not measured in the region from 900 to 4000 cm^{-1}.

F(C·C·Si), which was adjusted in order to reproduce the observed C–C–Si bending vibration.

The Urey-Bradley force field was modified as follows: 1) the internal rotation force constants for CH_3–C, CH_2–Si, and Si–CH_3 groups were assumed to be the calculated values from the barrier heights of 3.49, 1.24, and 1.24 kcal/mol respectively; 2) the *trans* and *gauche* coupling constants between the CH_3 and SiH_2 groups, between the CH_2 and SiH_2 groups, and between the Si–C–H bendings and the C–Si–C bending were added, and these values were transferred from dimethylsilane and ethylsilane, and 3) the C–H bond interaction constant was added in order to reproduce the observed C–H stretching frequencies.

The bond lengths used in the calculation were the values transferred from those for methylsilane and ethylsilane.[5] All of the valency angles were assumed to be tetrahedral.

The force constants and the observed and calculated frequencies of ethylmethylsilane are given in Tables 4—7. Since the adjustment was made only for F(C·C·Si), while the other transferred force constants were fixed at the original values, relatively larger differences were found between the observed and calculated frequencies of some of the hydrogen deformation modes. However, the results of the calculation were considered still to be valid for the assignments of the observed spectra.

From the calculated potential energy distributions, considerably larger mixings of the modes were found in the following pairs of modes: 1) the CH_2 scissoring and CCH_3 symmetric deformation, 2) the SiH_2 wagging and $SiCH_3$ rocking, 3) the CH_2 rocking and SiH_2 twisting for $CH_3CH_2SiH_2CH_3$, 4) the CH_2 scissoring and CCH_3 symmetric deformation, and 5) the C–Si stretching and SiD_2 scissoring for $CH_3CH_2SiD_2CH_3$. The localization of the CH_2 rocking mode for the

a) See a) of Table 5.

gauche form was worse than that for the *trans* form.

For the SiHD deformation modes of $SiHDCl_2$ and $(CH_3)_2SiHD$, it was found that the SiHD wagging and twisting modes should be more properly called the SiH and SiD deformation modes respectively, while the SiHD scissoring and rocking modes keep their original modes.[4] In $CH_3CH_2SiHDCH_3$, the situation was nearly the same as in $SiHDCl_2$ and $(CH_3)_2SiHD$ for the SiHD rocking and SiD deformation modes, while the SiHD scissoring and SiH deformation modes were different and were considerably mixed with the C–Si stretching, CH_2 rocking, and $SiCH_3$ rocking modes.

Molecular Forms and Vibrational Assignments

The infrared spectra of ethylmethylsilane in the region from 1000 to 1500 cm^{-1} are not much different in the liquid and crystalline states; also, they are close to the superposition of the spectra of ethylsilane and methylsilane. The results of the calculations indicate that, as the coupling between the ethyl and methyl groups seems to be negligible, the calculated frequencies for the *trans* and *gauche* forms are essentially identical with each other. Therefore, the assignments of the observed spectra in this region can easily be obtained from the reported assignments for ethylsilane and methylsilane, without regard to the rotational isomerism.

On the other hand, it can be expected from the calculation that spectra sensitive to the molecular forms of the isomers exist in the region from 650 to 1000 cm^{-1}. Actually, in this region, ten infrared bands are observed in the liquid state for $CH_3CH_2SiH_2CH_3$, while four of them disappear in the crystalline state. For $CH_3CH_2SiD_2CH_3$, six infrared bands are observed in the liquid state; one of them disappears in the

crystalline state.

For $CH_3CH_2SiH_2CH_3$, the strong infrared band at 977 cm^{-1} and the pairs of strong bands around 940 and around 879 cm^{-1} are easily assigned to the CCH_3 rocking, SiH_2 scissoring, and SiH_2 wagging modes respectively, since the band at 940 cm^{-1} and the pair of bands around 879 cm^{-1} are not observed for CH_3-$CH_2SiD_2CH_3$, and since the CCH_3 rocking modes are observed at 979 cm^{-1} for ethylsilane, and the SiH_2 scissoring and wagging modes are observed at 959 and 919 cm^{-1} for dimethylsilane.

There are a weak infrared band at 840 cm^{-1}, a strong band at 770 cm^{-1}, and two pairs of strong bands around 736 cm^{-1} and around 700 cm^{-1}, which correspond to the weak Raman bands at 842, 772, and 741 cm^{-1} and two medium bands around 700 cm^{-1} respectively, while the lower-frequency infrared bands of the two pairs disappear in the crystalline state.

On the basis of a comparison of the spectra with those for methylsilane, ethylsilane, and dimethylsilane, they can be assigned to the CH_2 rocking, $SiCH_3$ rocking of the A' and A'' species, and asymmetric C–Si stretching modes. That is, since the averaged frequency of the observed $SiCH_3$ rocking modes of the A_1 and B_1 species for dimethylsilane is about 780 cm^{-1}, either the band at 770 cm^{-1} or the pair of the bands around 736 cm^{-1} may be the $SiCH_3$ rocking modes of the A' species for both the *trans* and *gauche* isomers, while the weak band at 840 cm^{-1} can be assigned to the $SiCH_3$ rocking modes of the A'' species for both isomers, since the averaged frequency of the $SiCH_3$ rocking modes of the A_2 and B_2 species for dimethylsilane is about 840 cm^{-1}. On the other hand, since the CH_2 rocking mode is found at 764 cm^{-1} for ethylsilane, the CH_2 rocking mode can also be expected in this region for the $SiCH_3$ rocking mode.

As the calculated frequencies of the CH_2 rocking mode are 790 cm^{-1} for the *trans* form and 758 cm^{-1} for the *gauche* form, while those of the $SiCH_3$ rocking mode are 760 and 745 cm^{-1}, the band at 770 cm^{-1} can be assigned to the CH_2 rocking mode for the *trans* isomer, the higher frequency band (743 cm^{-1}) of the pair can be assigned to the $SiCH_3$ rocking mode for the *trans* isomer, and the lower-frequency band (730 cm^{-1}) of the pair can be regarded as the overlapping band of the $SiCH_3$ rocking and CH_2 rocking modes for the *gauche* isomer.

The pair around 700 cm^{-1} can be easily assigned to the asymmetric C–Si stretching mode for the *trans* and *gauche* isomers, since the mode is to be expected in the range of 695—805 cm^{-1}, as has already been pointed out by Janz and Mikawa,[6] and since the corresponding mode can be found at 728 cm^{-1} for dimethylsilane.

For $CH_3CH_2SiD_2CH_3$, three independent infrared bands at 810, 719, and 691 cm^{-1} and a pair of strong bands around 742 cm^{-1} are observed in the liquid state, while the higher-frequency band of the pair disappears in the crystalline state.

Since the $SiCH_3$ rocking modes are found around 800 cm^{-1} for the analogous deuterated molecules such as dimethylsilane, the band at 810 cm^{-1}, which shows a complicated pattern in the crystalline state, may be assigned to the overlapping band of the $SiCH_3$ rocking modes of the A' and A'' species.

Although the above assignments seem questionable at first glance from the fact that the corresponding modes of the A' and A'' species for $CH_3CH_2SiH_2CH_3$ are greatly separated from each other, it may be understood that the $SiCH_3$ rocking modes of the A' species at 743 and 730 cm^{-1} for $CH_3CH_2SiH_2CH_3$ are pushed down by the SiH_2 wagging modes at 868 and 890 cm^{-1}, since the calculation shows that the larger mode mixing

6) G. J. Janz and Y. Mikawa, This Bulletin, **34**, 1495 (1961).

is found between these modes, while the $SiCH_3$ rocking modes of the A'' species at 840 cm^{-1} stay at the original frequency. On the other hand, for $CH_3CH_2SiD_2CH_3$, both of the two $SiCH_3$ rocking modes, belonging to the A' and A'' species, exist in the 800—830 cm^{-1} region, outside the influence of the SiD_2 hydrogen deformation modes which exist in the far lower frequency region, as the calculations indicate.

From the results of the calculations and the comparison of the spectra for $CH_3CH_2SiD_2CH_3$ with those for $CH_3CH_2SiH_2CH_3$, the pair of the bands around 742 cm^{-1} and the two bands at 719 and 691 cm^{-1} can be assigned to the CH_2 rocking, C–Si asymmetric stretching, and SiD_2 scissoring modes respectively.

It is noticeable that the CH_2 rocking mode for the *trans* isomer has a higher frequency than that for the *gauche* isomer for $CH_3CH_2SiH_2CH_3$, while they are the reverse in frequency for $CH_3CH_2SiD_2CH_3$. This is understandable for the following reasons, obtained by an examination of the calculated potential energy distributions.

First of all, for the *trans* form, from the symmetry the coupling is possible between the modes belonging to the same species. Therefore, the CH_2 rocking mode for the *trans* form is pushed up by the SiH_2 twisting mode for $CH_3CH_2SiH_2CH_3$, while the corresponding mode stays at the unaffected frequency for $CH_3CH_2SiD_2CH_3$ since the SiD_2 twisting mode goes to a far lower frequency.

However, for the *gauche* form, as the molecular symmetry is lowered, coupling is possible between all of the modes. For $CH_3CH_2SiH_2CH_3$, the CH_2 rocking mode, which is influenced by the SiH_2 twisting mode, is also affected by the $SiCH_3$ rocking mode corresponding to that of the A' species for the *trans* form, which may be at a slightly higher frequency than the unaffected frequency for the CH_2 rocking mode. Therefore, as the pushing-up effect of the SiH_2 twisting mode may be cancelled by the pushing-down effect of the $SiCH_3$ rocking mode, the CH_2 rocking mode can be found around the unaffected frequency. For $CH_3CH_2SiD_2CH_3$, though the $SiCH_3$ rocking mode in question exists at a higher frequency with a diminishing influence on the CH_2 rocking mode, the SiD_2 scissoring and C–Si stretching modes corresponding to those of the A' species for the *trans* form appear anew at the lower frequencies and push the CH_2 rocking mode up to a higher frequency.

Therefore, the CH_2 rocking mode for the *gauche* form is found at a lower frequency than that for the *trans* form for $CH_3CH_2SiH_2CH_3$, while it is found at a higher frequency than that for the *trans* form for $CH_3CH_2SiD_2CH_3$.

In the region from 350 to 650 cm^{-1}, two pairs of the bands for $CH_3CH_2SiH_2CH_3$ and three pairs of the bands for $CH_3CH_2SiD_2CH_3$ are observed in the liquid state. Since the symmetric C–Si stretching mode is found at 659 cm^{-1} for dimethylsilane, the pairs around 620 and 638 cm^{-1} can be assigned to the symmetric C–Si stretching modes for $CH_3CH_2SiH_2CH_3$ and $CH_3CH_2SiD_2CH_3$ respectively, while the lower-frequency bands in each pair vanish in the crystalline state and belong to the *gauche* isomers.[7]

The SiH_2 and SiD_2 twisting modes can be expected to be very weak bands, since the corresponding band is infrared-inactive because of the symmetry for dimethylsilane. Therefore, another pair of bands, that around 490 cm^{-1} for $CH_3CH_2SiH_2CH_3$ can easily be assigned to the SiH_2 rocking mode; this pair corresponds to the pair around 402 cm^{-1} for $CH_3CH_2SiD_2CH_3$.

The pair around 566 cm^{-1} for $CH_3CH_2SiD_2CH_3$ can be assigned to the SiD_2 wagging mode. As for the SiH_2 and SiD_2 twisting modes, there are no distinct pairs of bands except for the very weak bands in the region expected from the calculations.

For $CH_3CH_2SiH_2CH_3$, a weak band at 577 cm^{-1}, which is found in both the liquid and crystalline states and which corresponds to a medium Raman band at 590 cm^{-1}, may be assigned to the SiH_2 twisting mode for the *trans* isomer, while the mode for the *gauche* isomer cannot be found in the expected region around 620 cm^{-1} where the bands assigned to the C–Si stretching mode are also present.

For $CH_3CH_2SiD_2CH_3$, the weak band at 501 cm^{-1}, existing only in the liquid state, may be assigned to the SiD_2 twisting mode for the *gauche* isomer, while the mode for the *trans* isomer cannot be found in the expected region (around 450 cm^{-1}).

In the region below 350 cm^{-1}, two skeletal bending and three torsional modes are expected. The Raman bands at 298 and 167 cm^{-1} in the liquid state, and the infrared bands at 301 cm^{-1} in the crystalline state and at about 170 cm^{-1} in the gaseous state, are observed for $CH_3CH_2SiH_2CH_3$. These bands may be assigned to the C–C–Si and C–Si–C bending modes for the *trans* isomer.

In Table 3, the observed and calculated frequencies fot the mixture of $CH_3CH_2SiHDCH_3$, $CH_3CH_2SiH_2CH_3$, and $CH_3CH_2SiD_2CH_3$ are shown as a basis for finding the vibrational assignments for $CH_3CH_2SiHDCH_3$, especially in the range from 250 to 900 cm^{-1}, where the bands sensitive to the molecular forms of

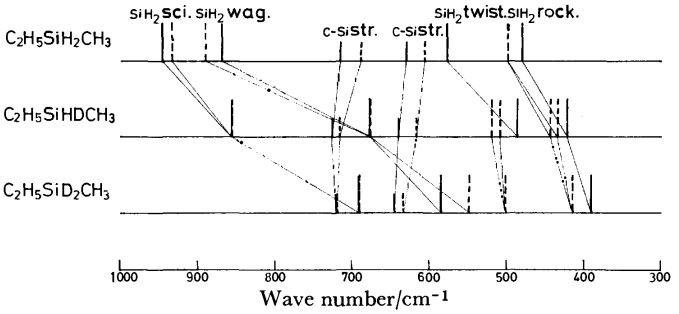

Fig. 2. Observed frequencies for the SiH_2, SiD_2, SiHD deformation modes and the C–Si stretching mode. ——: the spectra which persist in the crystalline state. ·····: the spectra which disappear in the crystalline state.

7) In the previous note (Ref. 1), the pair around 620 cm^{-1} for $CH_3CH_2SiH_2CH_3$ has been erroneously assigned to the SiH_2 wagging mode from the reported assignments for dimethylsilane given by Ball *et al.* (D. F. Ball, P. L. Goggin, D. C. McKean, and L. A. Woodward, *Spectrochim. Acta*, **16**, 1358 (1960).) However, the normal vibration calculation indicates the present assignment is correct for both dimethylsilane and ethylmethylsilane.

the isomers can be expected to exist. A comparison of the spectra of the mixture with the other species easily leads to the vibrational assignments for CH_3CH_2-$SiHDCH_3$ in this region. The correlation of the spectra for the three isotopic species is found to be excellent, as is shown in Fig. 2, where only the SiH_2 hydrogen deformation and C–Si stretching modes are shown. The results of the normal vibration calculations also prove the correctness of the present assignments, as is shown in Table 7.

So far, the vibrational assignments have been made without any impropriety on the assumption of the co-existence of the *trans* and *gauche* isomers in the gaseous and liquid states. In general, the calculated frequencies can be considered to reproduce the observed frequencies well, though most of the force constants are transferred from those for other, similar molecules without any adjustments. Therefore, the co-existence and the molecular forms of the isomers can be regarded as also proved by the present normal vibration calculations.

The authors wish to express their thanks to Professor Tatsuo Miyazawa of Osaka University and to the staff of his research group for allowing us to use their instruments and for their technical assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2052—2056 (1973)

Ionic Equilibria in Mixed Solvents. VIII. Solvent Effects on the Dissociation of Diprotic Acids in Aqueous Methanol Mixtures

Hitoshi OHTAKI and Masunobu MAEDA

Department of Electrochemistry, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received December 11, 1972)

Dissociation constants of protonated 1,6-hexanediamine, 1,8-octanediamine, 1,10-decanediamine, 1,11-undecanediamine, and 1,12-dodecanediamine in aqueous mixtures of 0 to 90% (w/w) methanol were determined potentiometrically at 25 °C, 0.1 M sodium chloride being used as an ionic medium. Values of pK_2-pK_1 of diamines were practically independent of the solvent composition in contrast to those of dicarboxylic acids, which increase monotonously with methanol concentration. Variations of pK_1, pK_2, and pK_2-pK_1 of diamines with solvent composition were discussed in comparison with those of dicarboxylic acids.

It is known that the acid dissociation constant of a monoprotic acid of neutral type (*e.g.* acetic acid or phenol) decreases with an increase in the concentration of an organic solvent in aqueous organic mixtures.[1-11] The solvent effect on dissociation constants of dicarboxylic acids[9,11-18] is similar to that of monocarboxylic acids. This can be explained qualitatively in terms of the electrostatic interaction between a leaving proton on an acid group and the conjugate base radical. On the other hand, the dissociation of a charged acid such as ammonium ion as well as other protonated mono- and diamines is enhanced by the addition of an organic solvent into aqueous solution, decreasing steeply after passing through a maximum.[1,5,9,10,14,19-21]

Kotaka and others[22] studied the association of ammonia in aqueous propanol solution by conductometry and confirmed that the association constant of the reaction

$$NH_4^+ + OH^- = NH_3 + H_2O$$

increases monotonously with solvent composition, and the variation of the dissociation constant of ammonium ion in mixed solvents described in terms of the reaction

$$NH_4^+ + H_2O = NH_3 + H_3O^+; \quad K = \frac{[NH_3][H^+]}{[NH_4^+]}$$

is essentially attributed to the variation of the autoprotolysis constant of the solvent with solvent composition.

In a previous paper[10] we showed that the variation of dissociation constant of a monoprotic acid with solvent composition in aqueous alcoholic solutions, regardless of neutral or charged type, could be explained in terms of free energy changes of transfer of species from water to a mixed solvent taking into account the equilibrium between hydronium and alkoxonium ions:

$$H_3O^+ + ROH = H_2O + ROH_2^+ \quad (1)$$

For protonated diamines we found that dissociation constants vary in the same manner as those of monoamines.[21] A remarkable difference was observed between variations of pK_2-pK_1 for diamine and carboxylic acid. For the latter not only pK_1 and pK_2 but also pK_2-pK_1 increase with solvent composition, as predicted from electrostatic theories.[23-26] On the other hand, values of pK_2-pK_1 for diamines remain practically constant, or in some cases decrease with an increase of the methanol content.

We have attempted to clarify these phenomena of dissociation reactions of diprotic acids in mixed solvents.

Experimental

A. Reagents. Dihydrochlorides of 1,6-hexanediamine, 1,8-octanediamine, 1,10-decanediamine, 1,11-undecanediamine, and 1,12-dodecanediamine (Aldrich Chemical Co., Inc., Milwaukee, Wis., U.S.A.) were prepared by the method described previously.[21] Recrystallization of the salts was repeated three times from water. When a salt was colored, the colored substance was removed with active charcoal before recrystallization. The salts thus prepared were dried *in vacuo* at room temperature and kept in the dark.

Sodium Chloride (ultra pure) from E. Merck Co. was dried at 500 °C.

Sodium Hydroxide was prepared by the method described previously[21] and was stored in a polyethylene bottle under nitrogen. Transfer of the sodium hydroxide solution from the bottle to a buret was carried out under an atmosphere of nitrogen gas.

Methanol. Reagent grade methanol was distilled and stored in a glass bottle.

B. Apparatus. Beckman glass electrodes (No. 40495 and 39301) were used. No difference was observed between two types of electrodes in pH measurements. A silver-silver chloride electrode was prepared according to Brown[27] and was set in the "Wilhelm" type of a reference half-cell.[28] A Radiometer PHM-4d pH-meter (Copenhagen) was used.

Dissociation constants of the diprotonated diamines were determined in aqueous mixtures of 0—90% (w/w) methanol. Experimental conditions were the same as those mentioned previously.[21] The pH values never exceeded 10.4 in the course of measurements in all systems.

Hydrogen ion concentrations in solution at equilibrium were determined from emf measurements by application of the Nernst equation

$$E = E_0 + 59.15 \log [H^+]_s + 59.15 \log f_H + E_j \quad (2)$$

and the liquid junction potential E_j in 90% methanol–water mixture was corrected with the relation $E_j = -450 \pm 50$ mV/M·$[H^+]_s$, where $[H^+]_s$ denotes the concentration of hydrogen ion at equilibrium. In other solutions the liquid junction potential was corrected by the use of E_j values reported previously.[21]

Results and Discussion

Dissociation constants for each diamine were determined from the formation function $\bar{n} = ([H^+]K_2^{-1} + 2[H^+]^2K_1^{-1}K_2^{-1})/(1 + [H^+]K_2^{-1} + [H^+]^2K_1^{-1}K_2^{-1})$ by means of a generalized least-squares method with the aid of an electronic computer FACOM 230-60 in order to make the error square sum ($U = \sum(\bar{n} - \bar{n}_{calcd})^2$) minimum for the set of dissociation constants K_1 and K_2. The results are summarized in Table 1.

In order to assess the solvent effects on the dissociation of diprotic acids, the variation of the dissociation constants of dicarboxylic acids with the methanol concentration is discussed first, the values of pK_1 and pK_2 of the dicarboxylic acids being quoted from literature. Variations of pK_1 and pK_2 of diamines with solvent composition are treated next.

(1) Variation of $pK_2 - pK_1$ for Dicarboxylic Acids with the Solvent Composition. In 1937 Kirkwood and Westheimer[25,26] proposed the following equation for the $pK_2 - pK_1$ value of a diprotic acid in aqueous solution.

$$pK_2 - pK_1 = \frac{Ne^2}{a\varepsilon_e RT \ln 10} + \log \sigma \qquad (3)$$

If we assume that the equation is applicable to a diprotic acid not only in aqueous solution but also in a mixed solvent and that Kirkwood-Westheimer's spherical model can be used, we can calculate from the data of $pK_2 - pK_1$ the radius of the sphere b, the distance between a charge and the center of the sphere r, the angle between lines from the center to the charges θ and the distance between charges a of the model. The values of $pK_2 - pK_1$ found in literature are satisfactorily reproduced with the parameters best chosen by means of the least-squares method over the whole range of methanol concentration (Fig. 1). Parameters thus obtained are given in Table 2. The value of θ decreases as the methylene chain becomes longer. The value of $2r = l$ for an acid is very close to l_{max}. These results lead to a conclusion that a dicarboxylic acid is bent in a nearly V- or U-shape in solution and the bending may be enhanced with chain length. The fact that *p*-phthalic acid has a larger value of θ than that of *o*-phthalic acid supports the model we used. Values of a obtained from $pK_2 - pK_1$ values in aqueous solu-

tions are summarized in Table 3. The values calculated by the present method are slightly smaller than others but seem reasonable.

(2) Variation of pK_2-pK_1 for Diamines with Solvent Composition. The value of pK_2-pK_1 varied with solvent composition in a different manner from that of dicarboxylic acids; the pK_2-pK_1 value was practically independent of methanol concentrations. As ε_e in Eq. (3) is expected to decrease with the increase of the methanol concentration, a should increase in order to keep the pK_2-pK_1 value in solution constant independent of solvent compositions. Increase of a caused by the addition of methanol into aqueous solution may be qualitatively interpreted in terms of the following effects: (1) Electrostatic repulsion between charged sites increases with the decrease of the effective dielectric constant. (2) It is known that hydrophobic groups in molecules tend to gather in hydrophilic solvent. However, the addition of methanol makes the solvent less hydrophilic so that hydrophobic coagulation of methylene groups may be reduced and the molecule turns out to be stretched. (3) The hydrogen bond between amino groups through water molecules may partly be broken by the addition of methanol, although no definite evidence for the hydrogen bond formation between amino groups in a molecule has been found.

(3) Variation of pK_1 and pK_2 for Diamines with Chain Length and with Solvent Composition. In aqueous solution both pK_1 and pK_2 of a diamine are smaller than the pK of the corresponding monoamine when the chain is short, pK_2 increasing with chain length in such a way to cross pK's of monoamines (Fig. 2). At a given solvent composition variations of pK_1 and pK_2 are similar to those of pK's of monoamines. Since the interaction between charges, that is pK_2-pK_1, in a diamine molecule can be assumed to be practically constant, we can assume that free energy changes caused by the interaction between charges is independent of solvent composition and therefore, variations of pK_1 and pK_2 can be treated separately as if there were two independent acids, each having dissociation constants of pK_1 and pK_2. Therefore, equations proposed to monoamines can be used also for diamines. For an acid of BH^+ type, $\Delta pK=pK(s)-pK(w)$ is written as follows:

$$\Delta pK = [(\mu^\circ_{BH}(w)-\mu^\circ_{BH}(s))+(\mu^\circ_{H_2O}(w)-(1-x)\mu^\circ_{H_2O}(s) - x\mu^\circ_{ROH}(s))+(\mu^\circ_{B}(s)-\mu^\circ_{B}(w))+((1-x)\mu^\circ_{H_2O}(s) + x\mu^\circ_{ROH_2}(s)-\mu^\circ_{H_2O}(w))]/RT\ln 10 \quad (4)$$

where $\mu^\circ(w)$ and $\mu^\circ(s)$ stand for standard chemical potentials of a relevant species in water and an aqueous methanol solution, respectively, x a fraction of meth-

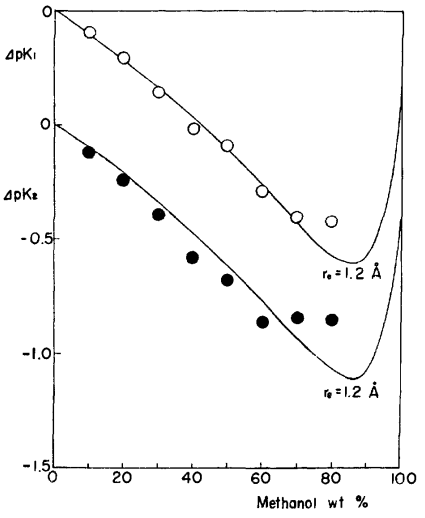

Fig. 3. Variations of ΔpK_1 and ΔpK_2 of 1,6-hexanediamine with the solvent composition.

oxonium ion formed from one mole of proton and is given by the equation

$$x = \frac{\kappa y}{1-y+\kappa y} \quad (5)$$

where y represents the mole fraction of methanol in the solvent. κ is the equilibrium constant of reaction (1).

By application of models proposed by one of the authors (H. O.),[10] we can calculate free energy changes of transfer of species from aqueous solution to a mixed solvent and thus ΔpK, assuming an effective size of a functional group r_e in a diamine molecule. Typical results for ΔpK_1 and ΔpK_2 are shown in Fig. 3 for 1,6-hexanediamine. The effective sizes of each amino group in the diamine were evaluated to be $r_e=1.2$ Å. The value 1.2—1.3 Å of r_e was found for other diamines regardless of the chain length. For ammonium and diethylethanol ammonium ions, the effective sizes of the functional groups were estimated to be 1.4—1.5 Å. The slightly smaller values of r_e for diamines than those for ammonium and diethylethanol ammonium ions may be due to the interaction between charged groups in diamine molecules, the solvent effect on which is neglected in calculation of ΔpK of diamines. The different interactions between an ammonium ion or a tertiary amino group in diethylethanol ammonium ion and a primary amino group of a diamine with solvent molecules might give rise to different values of r_e.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2056—2060 (1973)

The Triplet Excitons in the Anion Radical Salts of $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^+$, $(0 \leq x \leq 1)$

Yukio Suzuki and Yôichi Iida

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 16, 1972)

The electron spin resonance (ESR) absorption and its variation with the temperature were measured with single crystals of the anion radical salts containing the mixed cations, $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$. The paramagnetic excited state of these salts is triplet in character, as was shown from the anisotropic zero-field splitting at low temperatures. The triplet state is not localized, but, rather, corresponds to the triplet exciton state. The exciton exchange frequency and its temperature dependence were determined by analyzing the line shapes of the ESR spectra. The exciton motion in the mixed crystal system was investigated in order to establish the character of the triplet excitons in ion radical salts.

Much attention has been paid to the solid anion radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ) because of their prominent electronic properties.[1-24] In particular, the anion radical salts of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$ have been found to possess non-singlet, excited crystal states lying very close to a singlet ground state.[6] These excited states are triplet in character, as has been demonstrated by electron spin resonance (ESR) studies of the anisotropic zero-field splitting.[1] The excited states of such a system are thought not to be localized, but, rather, to correspond to the exciton states; that is, the excitation may propagate as a quasi-particle (*i.e.*, a triplet exciton).[4]

On the other hand, one can prepare anion radical salts containing the mixed cations represented by $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0 \leq x \leq 1)$.[2] In the present paper, we found that these mixed crystals also show the ESR spectra charac-

teristic of the triplet excitons. At various temperatures, the exchange frequencies due to triplet exciton motion were evaluated by analyzing the line shapes of the observed ESR spectra. In these mixed crystals, if the mixed cations are randomly arranged, the crystal lattice will no longer be periodic. At this time, the triplet exciton exchange and the exciton motion will be much affected in the field of the irregular crystal lattice. In this respect, it is interesting to compare the results of our study with those of the regular crystal lattice for $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ or $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$.[4]

Experimental

Materials. The preparation of TCNQ has been described by Acker and Hertler.[25] It was purified by recrystallization from acetonitrile. The anion radical salts containing the mixed cations, $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0\leq x\leq 1)$, were synthesized according to the method of Melby *et al.*[2] Six salts with the compositions of $x=0.00$, 0.20, 0.40, 0.60, 0.80, and 1.00 were prepared. They were taken from the same batches as those previously used for the differential scanning calorimeter (DSC) measurements and the electrical conductivity measurements.[20,22,23]

Measurements. The ESR spectra of the single crystals (5 mm×5 mm×1 mm) in the temperature range from 112 K to 333 K were measured by means of a JES-ME X-band spectrometer. The steady magnetic field was modulated at 100 KHz, with a modulation amplitude of 0.32 gauss. The temperature of the specimen was controlled to within ±1 K by means of the temperature equipment.

Results

The ESR spectra of the triplet excitons in the anion radical salts of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$, $(x=0.00)$, and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$, $(x=1.00)$, have been described by Jones and Chesnut.[4] Therefore, let us examine the mixed crystals below. As an example, the salt of $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$, $(x=0.80)$, will be investigated in detail.

The ESR absorption of a single crystal of $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$ and its variation with the temperature were measured for three arbitrary orientations. Figure 1 shows the experimental results for one of the orientations. Striking temperature effects were found in the ESR spectra. At low temperatures (approximately at 112 K), doublet components of the triplet-state fine structure and a central paramagnetic impurity signal[26] were observed. The doublet components are sharp (about 0.7_0 gauss in width) and well-resolved. These doublet components, the separation of which is quite anisotropic, arise from the zero-field splitting of the triplet state in the absence of the triplet exciton exchange.[1] As the temperature is raised, the doublet components broaden and move together, eventually collapsing into a single line which becomes progressively sharper, approaching

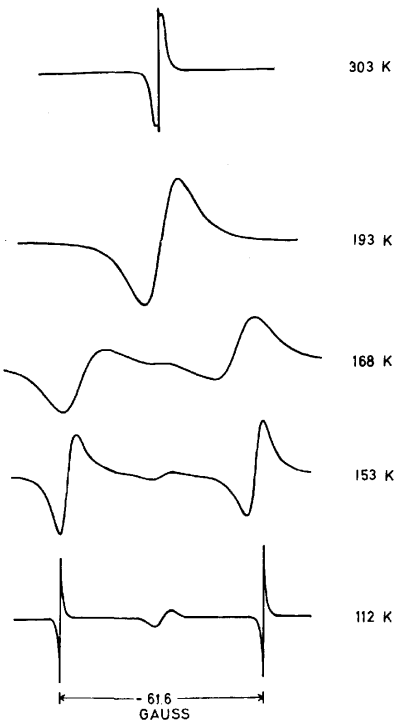

Fig. 1. The temperature dependence of the ESR absorption of a single crystal of the $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$ salt for the $d_0=61.6$ gauss orientation. The spectra were obtained with different spectrometer gain settings at the different temperatures.

a limit of about 1.9_0 gauss in width at room temperature;[27] these changes were found to be thermally reversible. This spectroscopic behavior is characteristic of an exchange interaction, a process which first removes the fine structure (exchange broadening) and then sharpens up the single remaining resonance line (exchange narrowing).

Figure 2 demonstrates the temperature dependence of the ESR spectra of the same salt for another orientation, where the separation of the fine-structure splitting at low temperature is narrower than that in Fig. 1. In this case, the temperature at which the doublet components collapse into a single line was found to be lower than that in Fig. 1. However, the line-widths of the absorptions at the low and high temperature limits were practically the same as those in Fig. 1.

Discussion

There have been various treatments of exchange-narrowing phenomena in magnetic resonance spectra.[28,29] Jones and Chesnut have applied Bloch equa-

25) D. S. Acker and W. R. Hertler, *J. Amer. Chem. Soc.*, **84**, 3370 (1962).

26) The ESR absorption intensity of the central absorption decreased, as the temperature was raised, according to the Curie law.

27) It was noticed that, in addition to the exchange-narrowed absorption, a sharp spike of absorption appeared in the room-temperature ESR spectra. However, no such sharp spike was observed when another smaller crystal was taken as a specimen. The extra absorption may arise from some skin effect, since this material is known to show high electrical conduction.

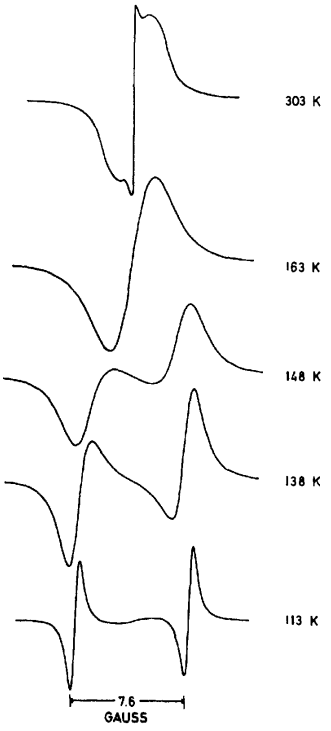

Fig. 2. The temperature dependence of the ESR absorption of a single crystal of the $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$ salt for the $d_0=7.6$ gauss orientation.

tions modified to include the effect of exchange to the systems of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$, $(x=0.00)$, and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$, $(x=1.00)$,[4] which show two-line spectra arising from the zero-field splitting of $S=1$ species. In the following discussion, we shall also examine the exchange effects of the triplet state in the mixed crystals by applying this method to $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$, $(x=0.80)$, and will compare them with those for the regular crystal lattices for $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$.

For the ESR absorption of the simple two-line case, we can express the line separation, d, and the line width, ΔH, in terms of the exchange frequency, ν. For the slow exchange region $(d_0 \gg \sqrt{2}\nu/\gamma)$:

$$\gamma^2(d_0^2-d^2) = 2\nu^2, \tag{1}$$

$$\gamma(\Delta H-\Delta H_0) = \nu/\sqrt{3}, \tag{2}$$

while for the fast exchange region $(d_0 \ll \sqrt{2}\nu/\gamma)$:

$$2\sqrt{3}(\Delta H-\Delta H_0) = \gamma d_0^2/\nu, \tag{3}$$

$$d = 0, \tag{4}$$

where ΔH and ΔH_0 are the linewidths in gauss measured from the points of maximum slope of the first derivative of the absorption in the presence and in the absence of exchange respectively. d and d_0 are the separation of the two lines in gauss with and without exchange respectively, and γ is the gyromagnetic ratio of the electron. These equations demonstrate that, when the exchange frequency is increased, each of the two spectral lines broadens and shifts towards the center of the spectrum, and then the two lines collapse into a single broad line, which becomes progressively sharper. The limiting line width in both extremes is given by ΔH_0.

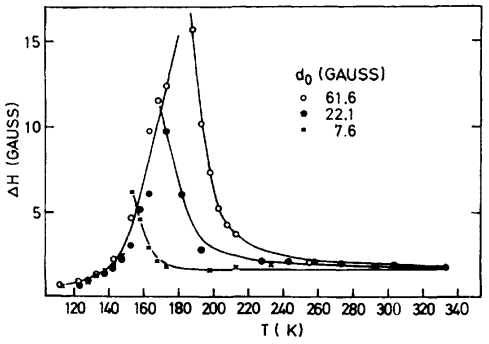

Fig. 3. Plots of line width of the ESR absorption *versus* temperature in K for various orientations of a single crystal of the $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$ salt.

These theoretical features agree well with those of our experimental results in Fig. 3, which shows the line-width measurements of the ESR absorptions of $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$, $(x=0.80)$, as functions of the temperature (and, thus, of the exchange frequency) for several crystal orientations (different values of d_0). The various curves in Fig. 3 intersect at the point where $\nu=\gamma d_0$. In the left region of this point (in the lower temperature region), we observed a two-line spectrum for slow exchange, but in the right region (in the higher temperature region), we observed a single-line spectrum for fast exchange. The application of the above simple two-line analysis to our experimental results is supported by the fact that the intersection at $\nu=\gamma d_0$ takes place at lower temperatures as d_0 is decreased and that, in the slow-exchange region, ΔH is found to depend only on the temperature.

For $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$, $(x=0.80)$, the values of the exchange frequencies, ν, were determined from the observed ESR spectra as a function of the temperature. For three crystal orientations, the calculations were made by the use of the approximations expressed by Eqs. (1), (2), and (3) respectively. The values of d_0 were taken as the limiting values of d at low temperatures. ΔH_0 was taken in a similar way, using the high- or low-temperature limits. For the three d_0 orientations, the estimated values of ν *versus* the temperature are illustrated in Figs. (4)—(6), in which the signs of $\nu(1)$, $\nu(2)$, and $\nu(3)$ indicate the values estimated by using Eqs. (1), (2), and (3) respectively.

In general, it was found that a good linear relation was obtained when the logarithm of the exchange frequency was plotted against the reciprocal of the absolute temperature. Therefore, the exchange frequency, ν, was described by:

$$\nu = \nu_0 \exp(-\Delta E/kT), \tag{5}$$

where ΔE is the activation energy for exchange. The parameters of ν_0 and ΔE were determined from the slow-exchange line collapse of Eq. (1), the slow-exchange line broadening of Eq. (2), and the fast-exchange line narrowing of Eq. (3). They are denoted as $\nu_0(i)$ and $\Delta E(i)$ $(i=1, 2, \text{and } 3)$ respectively. The estimated values are collected in Table 1, together with those for

a) The values of $\nu_0(i)$ and $\Delta E(i)$, ($i=1$, 2, and 3), were derived from Eqs. (1), (2), and (3), respectively.

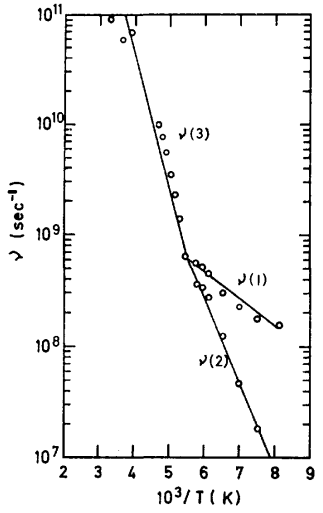

Fig. 4. Semilog plot of ν *versus* $1/T$ K for the $d_0=61.6$ gauss orientation of a single crystal of the $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$ salt. $\nu(1)$, $\nu(2)$, and $\nu(3)$ indicate the values derived from Eqs. (1), (2), and (3), respectively.

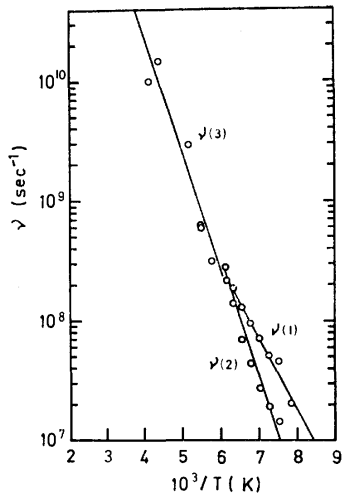

Fig. 5. Semilog plot of ν *versus* $1/T$ K for the $d_0=22.1$ gauss orientation of a single crystal of the $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$ salt.

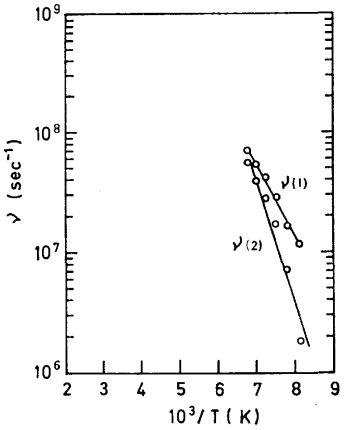

Fig. 6. Semilog plot of ν *versus* $1/T$ K for the $d_0=7.6$ gauss orientation of a single crystal of the $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$ salt.

the salts of $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$, ($x=0.00$), and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$, ($x=1.00$).[4] These parameters were obtained by the method of least-squares. For the $d_0=7.6$ gauss orientation, however, we could scarcely determine the $\nu_0(3)$ and $\Delta E(3)$ values, since the estimation of $\nu(3)$ *versus* the temperature could not be made over the wide temperature range.

For $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$, ($x=0.80$), the data given in Table 1 show that $\Delta E(3) \geqslant \Delta E(2) > \Delta E(1)$ and $\nu_0(3) \geq \nu_0(2) > \nu_0(1)$. As has been pointed out by Jones and Chesnut,[4] for the exchange effect of the triplet exciton system, the simple two-site exchange model may yield different ν_0 and ΔE values, depending on whether one uses Eqs. (1), (2), or (3). This is also shown by the experimental results we give in Table 1. Rigorously speaking, according to the calculations by Lynden-Bell,[30] the simple two-site model is not always applicable to the triplet-exciton system. However, for purposes of comparison with those for $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$, the simple two-site analysis was applied to the present case. Except for the small d_0 crystal orientation, the values of $\nu_0(i)$ and $\Delta E(i)$ ($i=1$, 2, and 3) in $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$ were found to coincide well

30) R. M. Lynden-Bell, *Mol. Phys.*, **8**, 71 (1964).

with those for the regular crystal lattice in $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ or $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$ respectively, within the limits of experimental error.[4] The apparent values of $\Delta E(i)$ ($i=1$, 2, and 3) were found to be somewhat anisotropic; larger values of $\Delta E(i)$ were obtained for the smaller d_0 crystal orientation. As d_0 approaches zero, however, the straight application of Eqs. (1)—(3) may cause apparent ΔE anisotropy, since one can hardly measure the linewidth accurately because of the overlap of the two lines.

The exchange effect of the triplet state can be understood in terms of the movement of pseudo-particles with spin 1 (*i.e.*, triplet excitons). The ESR spectra of the triplet excitons do not show any hyperfine structure, even at low temperatures, since their mobility causes its motional narrowing. At higher temperature, as the concentration of the excitons is increased, the mutual collisions of the triplet excitons lead to an exchange-narrowing effect of the triplet-state fine structure. Thus, we can relate the exchange frequency, ν, to the collision frequency of the triplet excitons:

$$\nu \propto n\sigma v, \tag{6}$$

where n is the concentration of triplet excitons; v, an average propagation velocity, and σ, an effective cross-section for triplet-exciton collisions. For our system below room temperature, we can approximately take:

$$n \propto [\exp(J/kT)+3]^{-1} \approx \exp(-J/kT), \tag{7}$$

where J is the energy difference between the singlet ground state and the triplet excited state. According to Kepler's susceptibility measurements,[6] $J=0.065$ eV below room temperature for the salts of $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0\leq x\leq 1)$. Judging from our experimental expression of $\nu=\nu_0 \exp(-\Delta E/kT)$ for the salt with $x=0.80$, the $\Delta E\approx J$ equality should exist if we assume that σ and v are not strongly temperature-dependent. However, our experimental results given in Table 1 show this correlation not to be generally correct. In general, $\Delta E(1)$, $\Delta E(2)$, $\Delta E(3)>J$, except $\Delta E(1)<J$ for the $d_0=61.6$ gauss crystal orientation. Jones and Chesnut have considered that ΔE might exceed J if the propagation of the triplet exciton could involve an activated process (*i.e.*, a diffusional propagation) with an activation energy of $\Delta E_v=\Delta E-J$, that is:[4]

$$v \propto \exp(-\Delta E_v/kT). \tag{8}$$

In this case, the foregoing anisotropy of the ΔE values, if it exists, seems to be attributable to that of the ΔE_v values.

According to the X-ray diffraction studies by McPhail *et al.*,[31] the crystal structures of both $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$ are triclinic and isomorphous.[32] The planar TCNQ molecules are stacked face-to-face to form a column along the b-axis. Four TCNQ molecules form a repeating unit in the column. The ion radius of the arsonium cation is somewhat longer than that of the phosphonium cation. It is almost certain that the crystal structures of the salts containing the mixed cations are identical with that of the phosphonium or arsonium salt. This kind of molecular stacking should then lead to anisotropic ΔE_v values if the triplet exciton can be described by the diffusional process. At present, a question remains in which crystal direction the activation energy, ΔE_v, has its maximum and minimum values.

Up to now, extensive investigations have been made to distinguish whether or not the triplet excitons in ion radical salts can be characterized by "localized excitons" or "free excitons."[7,8,13–16] The localized exciton carries a distortion with it as it goes through the crystal lattice. The exciton motion is, then, represented by a hopping from one cell to the next through a random walk (*i.e.*, diffusional process). On the other hand, the free exciton goes through the crystal lattice, carries with it essentially no crystal distortion, and has a long mean free path. The free exciton is, then, expressed by extended wave packets distributed over the whole lattice. In the salts containing mixed cations, if the mixed cations are randomly arranged, the crystal lattices will no longer be periodic. In this case, the free excitons are strongly scattered by the irregular crystal lattices, while the localized excitons are not. The present ESR experimental results support the model of localized triplet excitons, since the observed ν_0 and ΔE values for $[(C_6H_5)_3PCH_3]_{0.20}^+$ $[(C_6H_5)_3AsCH_3]_{0.80}^+$ $(TCNQ)_2^-$ coincide well with those in the regular crystal lattices for $[(C_6H_5)_3PCH_3]^+$ $(TCNQ)_2^-$ and $[(C_6H_5)_3AsCH_3]^+$ $(TCNQ)_2^-$ respectively.[4] Soos and McConnell have found that the activation energy for diffusion, ΔE_v, is essentially $\Delta/2$ where Δ is the "self-trapping energy" of the triplet exciton due to exciton-phonon interaction.[14] These results suggest that, at least in the anion radical salts of $[(C_6H_5)_3PCH_3]_{1-x}^+$ $[(C_6H_5)_3AsCH_3]_x^+$ $(TCNQ)_2^-$, $(0\leq x\leq 1)$, the best picture of the triplet-exciton motion is one in which a localized exciton rapidly hops from one site to the next. The motion is, then, "random walk" or diffusional.

32) The electronic state and the crystal properties of the phosphonium salt are very similar to those of the arsonium salt, except for the occurrence of the phase transition of the phosphonium salt at 315.7 K. See Refs. 1,2,4–6,9–11,16,19–24.

The Simultaneous Detection of Gas Phase Atoms and Free Radicals Produced in a Microwave Discharge by ESR Spin Trapping Methods

Edward G. JANZEN,* Toshio KASAI, and Keiji KUWATA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

* *Department of Chemistry, The University of Georgia, Athens, Georgia, 30601 U.S.A.*

(Received December 16, 1972)

The simultaneous detection of gas phase atoms and free radicals produced in a 2450 MHz discharge is demonstrated by use of a previously described technique called spin trapping. The atoms or radicals are allowed to react with phenyl *N*-*t*-butyl nitrone to give relatively stable nitroxide radicals. The ESR spectra of these nitroxides provide the analytical data for identification of the atoms or radicals trapped.

In previous communications we have described a technique for the detection and identification of gas phase free radicals which depends on the rapid radical addition to phenyl *t*-butyl nitrone (PBN) to produce relatively stable nitroxyl radicals:[1,2]

$$R\cdot + C_6H_5CH{=}N(O)C(CH_3)_3 \longrightarrow C_6H_5CH(R)\overset{+}{N}(\overset{-}{O})\cdot C(CH_3)_3$$

The ESR spectra of the nitroxyl radicals recorded at room temperature in liquid solutions (*e.g.* in benzene) provide ideally an unique set of parameters for each radical (R·) trapped. We have called this technique spin trapping and the nitroxyl radicals produced spin adducts.[3,4]

The previously reported gas phase work demonstrated the feasibility of detecting radicals at atmospheric pressures in a carrier gas (N_2) *e.g.* methyl, ethyl, and perfluoroethyl,[1] or at total pressures as low as 0.1 Torr in the presence of the radical precursor *e.g.* methyl from acetone or azomethane, ethyl from 3-pentanone, tetraethyllead or diethylmercury.[2] We now wish to report that hydrogen atoms can be detected simultaneously with radicals in the gas phase by spin trapping methods.

Experimental

A well established source of hydrogen atoms is the microwave discharge of hydrogen molecules. By placing powdered PBN in a 8 mm glass tube about 10—20 cm downstream from the microwave discharge of hydrogen in an apparatus similar to the one shown in Fig. 1, Ref. 2, benzyl *t*-butyl nitroxide, the hydrogen atom adduct of PBN is readily detected in a benzene solution of either the powdered PBN itself or the material collected in the liquid nitrogen trap downstream;

$$H_2 \longrightarrow H\cdot \xrightarrow{PBN} C_6H_5CH_2N(O\cdot)C(CH_3)_3$$

Results and Discussion

Deuterium molecules (D_2) gave the deuterium atom spin adduct in addition to some hydrogen atom addition product (see Table 1 for splitting constants). In some experiments with H_2 or D_2 an additional triplet of doublets was also observed which is tentatively assigned to the hydroxy radical spin adduct presumably produced from the discharge of water vapor inadvertently present in the system. Assignment of this structure is based on the results obtained from water vapor discharge which itself produces a strong hydrogen atom adduct signal and the same triplet of doublets. A previous spectral assignment to this spin adduct does not appear to be correct.[1] Ammonia discharge has only given the hydrogen atom adduct (and the hydroxy radical adduct in some cases). No amino radicals have been detected to date but this result is not considered final.

polymers are obtained from methane discharge but experimental evidence of methyl radical detection has not been reported. In our experiments hydrogen atoms and methyl radicals are readily detected (see Fig. 1) in the microwave discharge of methane. The ratio of these products varies from one experiment to another but the determining factors have not been ascertained.

From these preliminary experiments it can be seen that gas phase spin trapping techniques appear to be potentially useful in studies where simultaneous detection of atoms and radicals is desired. Further application of this technique are in progress.

The microwave discharge was operated at 2450 MHz by a 200 watt power supply. Either a rectangular or a cylindrical (Broida) type cavity was used.

Determination of the Molecular Arrangement in Liquid Crystals. A New Method of Determining the Molecular Arrangement in Liquid Crystals by the Use of the Polarization of the Fluorescence

Sakumitsu SAKAGAMI, Akira TAKASE, Minoru NAKAMIZO, and Hitoo KAKIYAMA

National Industrial Research Institute, Kyushu, Tosu, Saga 841

(Received December 19, 1972)

The molecular order in the liquid crystal states of *p*-*n*-octyloxybenzoic acid (OOBA) has been measured by means of a new method utilizing the polarization of the fluorescence. The polarized components of the fluorescence observed for the isotropic liquid state are independent of the rotation angle; this indicates that no molecular order exists in the liquid state. The polarized components of the fluorescence observed for the nematic state show that the molecular order of the aligned nematic state can be represented by a partially uniaxial orientation. The results observed for the nematic phase are also quantitatively discussed by the use of the uniaxial prolate ellipsoidal orientation pattern. On the other hand, the smectic state of OOBA is not affected by the surface action, and the observed patterns of the polarization of the fluorescence have very little angular dependence, in contrast with those for the nematic state. Furthermore, the molecular orientation for the crystal state of OOBA is briefly described.

It is well established that liquid crystals have properties similar to liquid in mobility, yet are crystal in structure, and that they can be classified into three basic types, *i.e.*, smectic, nematic, and cholesteric. These liquid crystal states are all characterized by a more or less complete orientation of the molecules with their long molecular axes parallel. In particular, the parallel orientation of the nematic state can usually be described by the degree of order: $S=(1/2)\cdot\langle 3\cos^2\theta-1\rangle_{av}$, where θ is the angle between a molecular axis and the preferred axis, which gives the average deviation of orientation of the molecular axes. Saupe and

Maier have shown that this degree of order can be determined by various experimental method[1-5] the principal refractive indices, the principal diamagnetic susceptibilities, the UV or IR dichroism, and the magnetic resonance.

In this paper, we wish to report a new method of determining the molecular order in the liquid crystalline states on the basis of the polarization of the fluorescence from molecules dispersed in liquid crystals. This method has the advantage that it is, in principle, possible to measure not only the extent of orientation, but also the type of orientation, because it utilizes the two-fold optical anisotropy of fluorescent molecules.

Theoretical

The theoretical background of this method has been given by Nishijima *et al.*[6-9] in their studies of molecular orientation in polymer solids; it consists of the application of a simple oscillator model of classical electrodynamics to the polarization phenomena of fluorescence on the assumption that the absorbing and emitting oscillators are linear oscillators whose directions coincide with a single molecular axis. The theory gives the intensities of the parallel and perpendicular components of the polarized fluorescence emitted from a system with a certain degree of optical anisotoropy, $I_{//}$ and $I_{\perp}$, whose electric vectors are, respectively, parallel and perpendicular to the direction of the electric vector of the linearly-polarized exciting light.

$$I_{//} = \frac{K}{2\pi}\int_0^{2\pi}\int_0^{\pi/2} N(\omega, \varphi)M_x^2M_x^2 \sin\omega d\omega d\varphi, \quad (1)$$

$$I_{\perp} = \frac{K}{2\pi}\int_0^{2\pi}\int_0^{\pi/2} N(\omega, \varphi)M_x^2M_z^2 \sin\omega d\omega d\varphi, \quad (2)$$

where K is the proportionality constant, where $N(\omega,\varphi)$ is an angular distribution function in the orientation coordinate system (a, b, c) fixed to the specimen, as is shown in Fig. 1, and where M_x and M_z are the components of the linear axis, **M**, of the fluorescent molecule in the directions of the X and Z axes in the optical coordinate system. The components in the optical coordinate system, M_x, M_y, and M_z, can easily be obtained from its components, M_a, M_b, and M_c, in the orientation coordinate system using a transformation matrix (T):

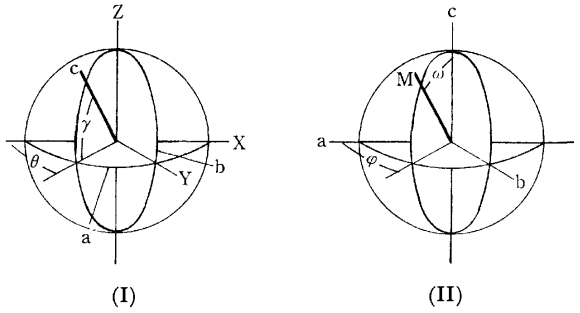

Fig. 1. Coordinate systems. (I): optical coordinate system, (II): orientation coordinate system.

$$\begin{pmatrix} M_x \\ M_y \\ M_z \end{pmatrix} = (T)\begin{pmatrix} M_a \\ M_b \\ M_c \end{pmatrix} \quad (3)$$

$$(T) = \begin{pmatrix} \cos\theta\sin\gamma & -\sin\theta & \cos\theta\cos\gamma \\ \sin\theta\sin\gamma & \cos\theta & \sin\theta\cos\gamma \\ -\cos\gamma & 0 & \sin\gamma \end{pmatrix} \quad (4)$$

The extent as well as the type of molecular orientation in the system can be obtained from measurements of the angular dependency of $I_{//}$ and $I_{\perp}$, and of the degree of polarization of fluorescence, P, which is defined by Eq. (5):

$$P = \frac{I_{//}-I_{\perp}}{I_{//}+I_{\perp}} \quad (5)$$

Experimental

Apparatus. The optical system used in this study is schematically illustrated in Fig. 2. The light of the 365 nm wavelength was separated from a mercury lamp using a monochromator, M, and was used as an exciting light; it illuminated fluorescent molecules dispersed in liquid crystals after passing through a polarizer, P. The wavelength of the exciting light coincides with that of the maximum of the principal absorption peak, which itself corresponds to the electronic transition between the ground and lowest excited states of the fluorescent molecules. The polarized components of the fluorescence intensity are measured by a photomultiplier, PM, through an analyzer, A, and a cut-off filter, CF, and are then recorded as the sample is being rotated through 360° on the rotating stage. The analyzer can also be rotated so that the direction of the electric vector of the fluorescent light lies either parallel ($I_{//}$) or perpendicular ($I_{\perp}$) to that of the exciting light. An ordinary polarizing microscope was modified as the optical system passed from the polarizer to the analyzer. The observed sample area is around 100 μm in diameter.

Materials. The liquid crystal compound used in this study is *p-n*-octyloxybenzoic acid (OOBA), which was purchased from the Tokyo Kasei Co.; it was recrystallized several

times from ethanol and benzene to insure a higher degree of purity. The phase transition of OOBA are:[10-12]

$$C_2 \overset{68^\circ C}{\longleftrightarrow} C_1 \overset{102^\circ C}{\longleftrightarrow} S_m(C) \overset{108^\circ C}{\longleftrightarrow} N \overset{145^\circ C}{\longleftrightarrow} I$$

1,6-Diphenyl-1,3,5-hexatriene was used as the fluorescent compound.[13] This fluorescent molecule can be considered to be an approximately perfect linear oscillator, because the measurement of the degree of the polarization of the fluorescence in various solvents with a wide range of viscosities has given the value of 0.5 at the extrapolation of $T/\eta=0$ theoretically anticipated by the perfect anisotropic molecule.

A mixture of the liquid crystal compound and fluorescent substances of about 10^{-3} wt% was dissolved in chloroform in order to obtain a uniformly-dispersed system, and then the solvent was removed by evaporation at room temperature under reduced pressure. The liquid crystal state was attained by heating this mixture to the isotropic state of the liquid crystal between a glass slide and a cover slip on a microscopic stage with a heating block, and by then slowly cooling it to the mesomorphic state. The sample thickness was approximately 5 μm. The aligned nematic state was obtained by the well-known method of rubbing the glass surface.[14-19]

Results and Discussion

The polarized components of the fluorescence intensity, $I_{//}$ and $I_{\perp}$, observed at each state are shown in Figs. 3 and 4 as a function of the angle of rotation, γ.

As is apparent from Fig. 3, in the isotropic state both $I_{//}$ and $I_{\perp}$ are independent of the angle, γ. This can easily be understood by considering that a molecular ordering in the liquid state is at random because of the

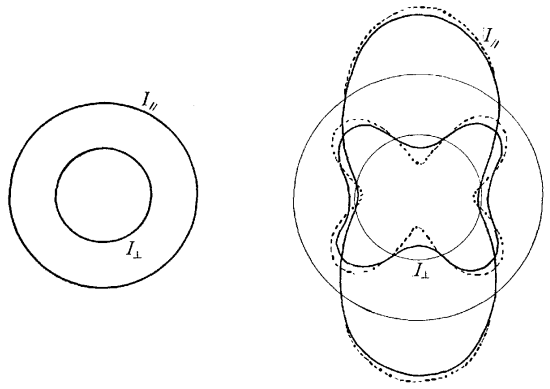

Fig. 3. Angular distributions of the polarized components of fluorescence observed in the aligned nematic state (N) and the isotropic liquid state (I). The dotted lines indicate the calculated intensities of the polarized components of fluorescence corresponding to $\alpha=5$ and $\theta=60°$.

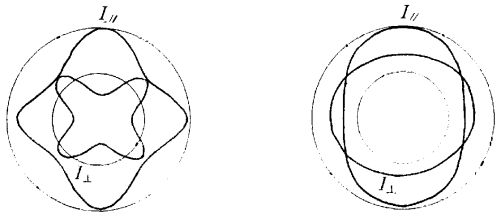

Fig. 4. Angular distributions of the polarized components of fluorescence observed in the smectic C state (S_mC) and the crystalline state (C_1).

vigorous thermal motion of the molecules. In the case of a completely random distribution, the intensity of the polarized component of fluorescence can be expressed by:

$$I_{//} = \frac{3}{15}K\Phi, \tag{6}$$

$$I_{\perp} = \frac{1}{15}K\Phi, \tag{7}$$

where K and Φ are independent of the angle of rotation and are correlated to the maximum probability of excitation and the quantum yield of the fluorescence respectively.[6,9] These equations indicate that the polarized components of the fluorescence for the completely random system are independent of the angle, γ, and that the intensity ratio of the fluorescence, $I_{//}/I_{\perp}$, is equal to 3. The observed polarized components of the fluorescence coincide entirely with those expected from the above equations so far as the angular dependence is concerned. However, the observed intensity ratio of the polarized components of the fluorescence is somewhat smaller than the ratio, $I_{//}/I_{\perp}=3$, theoretically expected from the above equations. This discrepancy is mainly attributable to the facts that the viscosity of the isotropic liquid state is low and that the molecules are very mobile in the liquid state.

At the phase transition from the liquid to the nematic, both $I_{//}$ and $I_{\perp}$ drastically change, as is illustrated in Fig. 3. Although the angular distribution of $I_{//}$ and $I_{\perp}$, in this nematic state, varied little with the measured place of the liquid crystal compound, the substantial features of angular dependence were the same as those shown in Fig. 3. In addition, no significant change in either $I_{//}$ or $I_{\perp}$ with the variation in the temperature was observed throughout the nematic state, except that the fluorescence intensity decreased slightly as the temperature decreased. As is shown in Fig. 3, $I_{//}$ has a maximum intensity at a definite angle of γ, whereas $I_{\perp}$ exhibits a fluorescence pattern with a four-leaf shape. It is evident from the angular dependence of $I_{//}$ and $I_{\perp}$ that the nematic state has a partially uniaxial molecular orientation.

The distribution function, $N(\omega,\varphi)$, is indispensable to explaining quantitatively the observed angular dependence of both $I_{//}$ and $I_{\perp}$. Taking account of the partially parallel molecular orientation in the nematic state, we assume that the molecular orientation for the nematic state can be expressed by the uniaxial prolate ellipsoidal pattern, as is illustrated in Fig. 5. Fig. 5. Schematic representation of the distribution function $N(\omega, \varphi)$.

thermore, it seems quite reasonable to assume that the distribution function, $N(\omega,\varphi)$, is proportional to the cube of the distance from the center of the prolate ellipsoidal of rotation. $N(\omega,\varphi)$ is, then, given by:

$$N(\omega, \varphi) \propto \frac{1}{(\alpha^2 \sin^2 \omega + \cos^2 \omega)^{3/2}}, \quad (8)$$

where α is the axial ratio, C/A. The angular distribution of $I_{//}$ and $I_{\perp}$ can be straightforwardly computed by substituting this distribution function for $N(\omega,\varphi)$ in Eqs. (1) and (2). The final equations representing $I_{//}$ and $I_{\perp}$ include both γ and θ as parameters. The results of the calculations at $\alpha=5$ and $\theta=60°$ are shown by the dotted line in Fig. 3; these results agree well with the observed angular distributions of $I_{//}$ and $I_{\perp}$, aside from a very small difference in the intensity of $I_{\perp}$. This good accordance distinctly indicates that the molecular orientation in the nematic state lies essentially parallel and can be expressed by the uniaxial prolate ellipsoidal pattern, as has been discussed above. The fact that α is equal to 5 indicates that the molecules in the nematic state can be regarded as adopting an almost perfect parallel alignment over regions larger than the molecular dimensions. It is known that the molecular order of the nematic state is not seriously disturbed by the presence of a solute, but is clearly dependent on the molecular shape and size of a solute,[20] although it has thus far been assumed that the molecular order of the fluorescent molecules used as a probe is completely consistent with that of the nematic phase. Therefore, further detailed arguments concerning the molecular order in the nematic state are impossible.

The $I_{//}$ and $I_{\perp}$ observed for the smectic C state of OOBA are strikingly different from those for the nematic state, as is shown in Fig. 4. Both $I_{//}$ and $I_{\perp}$ are very little dependent upon the angle of rotation, γ, in contrast to those of the nematic state, with their sharp angular dependence. Furthermore, microscopic observations also indicate that this smectic C state exhibits the smectic schlieren texture[21,22] characteristic of the smectic C state, while the nematic state gives the pattern of the so-called aligned layers[14] due to the surface action. This suggests that the smectic C liquid crystal, unlike the nematic liquid crystal, is not easily aligned by rubbing glass surfaces.

It is well known that the smectic C state has such a layer structure that the long molecular axis is tilted to a layer and has optically biaxial properties.[23–27] Recently, the present authors have proposed, on the basis of optical observations,[28] twisted smectic layers for the molecular arrangements of the smectic C state. In these twisted smectic layers, the molecules are arranged in layers and have their long molecular axes successively twisted with respect to the normal layer. If this is the case, the observed $I_{//}$ and $I_{\perp}$, which are substantially independent of the rotation angle, are reasonable, since the molecular order in the twisted smectic layers is likely to be essentially distributed at random over the whole region where the polarization measurement of the fluorescence from the system is made.

The polarized fluorescence intensity decreases at the phase transition from the smectic to the crystalline state. The $I_{//}$ and $I_{\perp}$ for the crystalline state (C_1) are also significantly different from those observed for the nematic and smectic states, discussed above, in the angular dependence as well as in the intensity, as is shown in Fig. 4. The angular dependence of $I_{//}$ and $I_{\perp}$ suggests that the crystal state (C_1) of OOBA attained on cooling the smectic state has an approximately perfect biaxial molecular orientation, although a birefringence effect in the crystalline state must be considered for an accurate determination of the molecular orientation.[29]

The authors wish to thank Professor Yasunori Nishijima of Kyoto University for his valuable suggestions.

The *G*-values of Nitrogen Obtained from the Gas-phase γ-Radiolysis of Nitrous Oxide–Hydrocarbon Systems

Kiyoshi Okazaki, Rei Yugeta, and Shin Sato

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 5, 1973)

The gas-phase γ-radiolysis of a N_2O–1-butene system has been reinvestigated. The other hydrocarbons used for the substrate are ethylene, propylene, 1,3-butadiene, cyclopropane, propane, and *n*-butane. The *G*-value of nitrogen from any system increased with an increase in the pressure of N_2O and was saturated at about 4 mol% of N_2O. The saturated value, $G(N_2)_{max}$, was much larger than the *G*-value of electrons estimated from the *W*-value of the hydrocarbon used and was rather strongly dependent upon the irradiation temperature, the dose rate, and the total dose. Some of the results were not consistent with those reported by the previous investigators. The reason for this discrepancy, and also the possible reaction mechanism to explain the large $G(N_2)_{max}$, have been discussed.

Nitrous oxide has been used as an electron scavenger in the gas- and liquid-phase radiolyses of hydrocarbons.[1-3] If the yield of nitrogen is consistent with the amount of scavenged electrons, we can study many features of the radiolysis. Generally, however, the *G*-value of nitrogen from the gas-phase radiolysis of a hydrocarbon in the presence of nitrous oxide is higher than that to be expected from the *W*-value of the hydrocarbon. This excess nitrogen yield has usually been explained in terms of the reactions between nitrous oxide and negative species produced in the electron-scavenging reaction of nitrous oxide.

According to the paper of Warman,[4] there are two groups of alkenes. One consists of isobutene and propylene, which give $G(N_2)_{max}=G_e$. Here, $G(N_2)_{max}$ is the maximum *G*-value of nitrogen which results from the electron scavenging of nitrous oxide and G_e is the *G*-value of electrons, as estimated from the *W*-value of the hydrocarbon. The other group consists of 1-butene and *cis*- and *trans*-2-butene, which give $G(N_2)_{max}=2\,G_e$. On the other hand, in the gas-phase radiolysis of alkanes (C_2, C_3, and C_4), $G(N_2)_{max}=1.55\,G_e$ has been reported. The data so far introduced were obtained at room temperature.

Holtslander and Freeman[5] reported that, in the γ-radiolysis of methylcyclohexane at 110 °C, the *G*-value of nitrogen attains as high as $5\,G_e$; they attributed this high yield to the ionic chain reaction between the oxygen atom ion and the hydrocarbon. In the case of the benzene-nitrous oxide system at room temperature, the $G(N_2)_{max}$ is reported to be $8.2\,G_e$, and the $G(C_6H_5OH)$, to be $6.4\,G_e$.[6] The authors explained this result in terms of the chain reaction including $C_6H_6O^-$ as the chain carrier.

The present authors hoped to find a more systematic explanation of these rather conflicting data, and so reinvestigated the gas-phase γ-radiolysis of 1-butene in the presence of nitrous oxide. For comparison, several experiments were performed with ethylene, propylene, 1,3-butadiene, cyclopropane, propane, and *n*-butane.

Experimental

The nitrous oxide (Showa Denko Co.), ethylene, propylene 1-butene, propane, *n*-butane, cyclopropane, 1,3-butadiene (Takachiho Chemical Co.), and sulfur hexafluoride (Matheson Co.) were used after several bulb-to-bulb distillations. The volume of the irradiation cell was 50 ml. Before preparing the irradiation sample, the cell was heated with a torch under a vacuum. The pressure of the hydrocarbon was around 600 Torr in all the experiments. The irradiation temperatures were 0 °C, room temperature, and 100 ± 1 °C.

For the measurement of the dose rate, use was made of the Fricke dosimeter. In order to check the difference between the gas-phase radiolysis and the liquid one, the radiolysis of ethylene was carried out. The obtained *G*-value of hydrogen from ethylene was 1.30 ± 0.02, which is in agreement with the literature value, 1.31.[7]

The amount of the non-condensable products at 77 K (N_2, H_2, and CH_4) was measured with a Toepler pump equipped with a gas buret. This non-condensable gas was passed through a furnace of cuprous oxide at 300 °C in order to combust the hydrogen into water, which was then trapped at 77 K. After the measurement of the amount, the remaining gas was analyzed by mass spectrometry.

Results

Figure 1 shows the *G*-values of nitrogen as a function of the mol% of nitrous oxide. The hydrocarbons used are propylene, ethylene, 1,3-butadiene, and cyclopropane. The pressure is 600 Torr, and the irradiation temperature is room temperature. The dose rate used here is 2×10^{-13} eV ml^{-1} sec^{-1}. As may be seen in Fig. 1, the $G(N_2)_{max}$'s are 6.5 for propylene, 9.2 for ethylene and 1,3-butadiene, and 10.3 for cyclopropane. The data obtained with 1-butene is not shown because of considerable scattering, although the $G(N_2)_{max}$ was found in the range from 12 to 13. It may be worthwhile to mention here that the $G(N_2)_{max}$ values for propylene and for 1-butene are 1.5 times larger than those reported by Warman.[4]

Since we found considerable scattering data in the

case of 1-butene, we controlled the irradiation temperatures at 0 and 100 °C. Figure 2 shows the results. From this figure, we can understand that the G-value of nitrogen is rather strongly temperature-dependent.

The dose rate-dependence of $G(N_2)$ from the N_2O–1-butene system has also been investigated. The results are shown in Fig. 3. The dose rates are 1.9×10^{13} and 3.6×10^{12} eV ml^{-1} sec^{-1}. The irradiation temperature is 0 °C, and the total dose is 1.9×10^{17} eV ml^{-1}. The $G(N_2)_{max}$ values are 10.7 for the higher dose rate and 12.7 for the lower. When the total dose was changed from 1.9×10^{17} to 9.6×10^{17} eV ml^{-1}, the $G(N_2)_{max}$ decreased from 10.3 to 8.4. With doses lower than 1.9×10^{17} eV ml^{-1}, the $G(N_2)_{max}$ did not change from 10.3.

Table 1 summarizes the $G(N_2)$'s from seven hydrocarbons containing 4.1 mol% nitrous oxide at 0 °C, along with the values at room temperature and the $G(N_2)$'s in the presence of 0.03 mol% SF_6. The dose rate and the total dose used here are 1.9×10^{13} eV ml^{-1} sec^{-1} and 1.9×10^{17} eV ml^{-1}.

Since the dosimetry by the decomposition of nitrous oxide plays an important role in the explanation of the present results, we measured the $G(N_2)$ from pure nitrous oxide at three different temperatures. The results are summarized in Table 2, together with the

Table 2. $G(N_2)$ from pure N_2O

data of previous workers.[8-12] The obtained temperature dependence was very similar to that reported by Jones and Sworski,[11] who used 1 MeV electrons from a Van de Graaff apparatus as the irradiation source. Our data were independent of the dose rate used in the range from 2.8×10^{12} to 1.5×10^{13} eV ml^{-1} sec^{-1}.

Discussion

Accumulating evidence[13-19] seems to establish that a third-body reaction is necessary for thermalized electrons to attach to nitrous oxide. According to Warman and Fessenden,[18] the rate constant of this third-body reaction at 300 K is $5.6\pm0.2\times10^{-33}$ ml^2 molecules^{-2} sec^{-1}, while Johnson and Redpath[13] estimated it to be 2×10^{-31} ml^2 molecules^{-2} sec^{-1}. On the other hand, Holtslander and Freeman[5] estimated the lifetime of the decomposition of N_2O^- into N_2 and O^- in the atmosphere of methylcyclohexane at 110 °C to be in the range from 10^{-4} to 10^{-3} sec.

As is shown in Table 1, the presence of a very small amount of SF_6, a well-known electron scavenger, suppressed the formation of nitrogen from the γ-radiolyses of seven hydrocarbons containing 4.1 mol% N_2O. The precursor of nitrogen, therefore, must be thermalized electrons. A pressure of 600 Torr of hydrocarbons is probably high enough to thermalize electrons before the occurrence of the dissociative electron-capture process of N_2O.

The reactions of electrons in the present system, therefore, may be expressed as follows:

$$e^- + N_2O \xrightarrow{+M} N_2O^- \quad (1)$$

$$e^- + M^+ \longrightarrow \text{products} \quad (2)$$

Here, M and M^+ stand for a hydrocarbon molecule and its positive ion. The G-values of electrons estimated from the W-values of hydrocarbons are to be around 4; accurate values are known for propane (4.27), n-butane (4.37), ethylene (3.86), propylene (4.03), and 1-butene (4.10).[7] Therefore, all of the $G(N_2)_{max}$ values obtained in the present experiment are larger than the G_e's. The excess nitrogen yield ranges from 0.25 G_e for propylene at 0 °C to 2.5 G_e for 1-butene at 100 °C.

As Table 1 shows, there are rather serious discrepancies between the $G(N_2)_{max}$ reported by Warman and his co-workers[3,4,20] and ours. Therefore, we carefully compared their experimental conditions with ours—the dose rate, the total dose, the pressure of the sample, the irradiation temperature, and so on, but we could not find the reason for this discrepancy. The ethylene dosimetry has also been checked; they used $G(H_2)=1.31$, which is in good agreement with our result, $G(H_2)=1.30\pm0.02$. Since most of their experiments were carried out with a cell of about 150 ml, while ours was 50 ml, we also used the same-size cell as theirs; however, the data we thus obtained were the same as those observed with the 50 ml cell. The question of the discrepancy in the $G(N_2)_{max}$ value, therefore, is still open.

In the studies of the γ-radiolysis of propane containing N_2O, Warman reported $G(N_2)_{max}=7.5$,[3] 6.5,[4] and 8.7.[20] The difference between 6.5 and 7.5 is probably due to the dose-rate dependence, although they did not mention it. The large value of 8.7 probably resulted from the nitrous oxide dosimetry; Warman used $G(N_2)=12.0$, but the most reliable G-value at present is 10.0 at room temperature.[11] According to the present measurements, the $G(N_2)$ from the 4.1 mol% N_2O–propane system at 0 °C is 8.2, larger than that reported by Warman. Recently, Johnson and Redpath.[13] reported $G(N_2)=7.5$ from the 2 mol% N_2O–propane system. This result is in accord with ours.

In order to explain the excess nitrogen yield observed in the present experiment, we propose the following reaction scheme:

$$N_2O^- + M \longrightarrow \begin{cases} N_2 + X^- & a \\ N_2 + P^- & 1-a \end{cases} \quad (3)$$

$$X^- + N_2O \longrightarrow N_2O^- + \text{residue} \quad (4)$$

$$N_2O^- + M^+ \longrightarrow N_2 + \text{residue} \quad (5)$$

$$P^- + M^+ \longrightarrow \text{products} \quad (6)$$

Here, a is the branching ratio of the reactions of N_2O^- with a hydrocarbon. X^- and P^- are unspecified ions, which we will discuss below. The essential difference between the X^- and P^- ions in the above scheme is that X^- can react readily with N_2O to produce its ion, while P^- cannot. In this scheme, we have excluded

the neutralization reaction between X^- and M^+ ions. As is shown in Table 1, 0.03 mol% SF_6 was effective enough to suppress the formation of nitrogen. This suggests that the following charge-transfer reaction:

$$N_2O^- + SF_6 \longrightarrow N_2O + SF_6^-$$

takes place very readily and that, in the presence of 0.03 mol% SF_6, this reaction occurs much faster than the neutralization reaction, Reaction (5). If X^- ions are very reactive to N_2O, the neutralization reaction between X^- and M^+ ions may be ignored in the presence of a certain amount of N_2O.

Recently, Bohme and his co-workers[21,22] observed the reactions between O^- ions and several hydrocarbons by using the afterglow method and reported that their specific rates are of the order of 10^{-9} ml molecules^{-1} sec^{-1}:

$$O^- + RH \longrightarrow R^- + OH \quad a'$$
$$\searrow \quad OH^- + R \quad 1-a'$$

They also showed that the branching ratio of these two reactions is strongly dependent on the kind of hydrocarbon. Reaction (3) in the above reaction scheme is analogous with this reaction.

The steady-state treatment based on Reactions (1)~(6) gives the following relationship:

$$\frac{1}{G(N_2)} = \frac{1}{G(N_2)_\infty}\left(1+\frac{k_2}{\sqrt{k_a k_1}}\sqrt{\frac{D}{W}}\frac{1}{[N_2O]}\right) \qquad (I)$$

Here,

$$k_a = \frac{k_2[e^-]+k_6[P^-]}{[e^-]+[P^-]}$$

and D stands for the dose rate, and W, for the W-value of the hydrocarbon used. $G(N_2)_\infty$ is the G-value of nitrogen when all of the ejected electrons are scavenged by N_2O. By using the pulse radiolysis technique, Lias *et al.*[23] measured the rates of the neutralization of the t-butyl ion by an electron and by the SF_6^- ion, and reported $k(t\text{-}C_4D_9^+ + e^-) = 1.92 \times 10^{-6}$ ml molecules^{-1} sec^{-1} and $k(t\text{-}C_4D_9^+ + SF_6^-) = 4.0 \times 10^{-7}$ ml molecules^{-1} sec^{-1}. If we take these values for our k_2 and k_6 respectively, the k_a value may be said to be in between those two values.

Cyclopropane	2.0×10^{13}	11.1	7.2×10^{10}	0.67	

Figure 4 shows the plots of $1/G(N_2)$ against the $[M]/[N_2O]$ ratio, where M's are ethylene, propylene, 1,3-butadiene, and cyclopropane. Figures 5 and 6 show the results obtained with 1-butene. From these linear relationships, we can calculate $G(N_2)_\infty$ and $k_2/(\sqrt{k_a k_1})$, which are summarized in Table 3. All of the $k_2/(\sqrt{k_a k_1})$ values are of the order of 10^{11} (molecules ml^{-1} sec)$^{1/2}$. From this value, the third-body reaction rate of Reaction (1) can be estimated to be 10^{-33} ml^2 molecules^{-2} sec^{-1} by assuming $k_a = 10^{-6}$ ml mole-

21) D. K. Bohme and L. B. Young, *J. Amer. Chem. Soc.*, **92**, 3301 (1970).
22) D. K. Bohme and F. C. Fehsenfeld, *Can. J. Chem.*, **47**, 2717 (1969).
23) S. G. Lias, R. E. Rebbert, and P. Ausloos, *J. Chem. Phys.*, **57**, 2080 (1972).

cules^{-1} sec^{-1} and by taking into account the fact that the pressure of hydrocarbons used in the present experiment is 600 Torr. The estimated value, 10^{-33}, may be compared with that of 5.6×10^{-33} reported by Warman and Fessenden.[18]

From the reaction scheme proposed above, this relationship:

$$\frac{G_e}{G(N_2)_\infty} = 1 - a\left(1+\frac{k_5}{\sqrt{k_a k_3}}\sqrt{\frac{D}{W}}\frac{1}{[M]}\right)^{-1} \quad \text{(II)}$$

can also be derived. In the case of 1-butene at 0 °C, we have a pair of data on the $G(N_2)_\infty$ for two different dose rates. The substitution of these data into Eq. (II) gives:

$$a = 0.71$$

and: $$\frac{k_5}{\sqrt{k_a k_3}} = 1.1\times10^{12} \text{ (molecules ml}^{-1}\text{ sec)}^{1/2}.$$

If we can assume the value of 1.1×10^{12} even for other hydrocarbons and for different temperatures, we can calculate the a values for other hydrocarbons. These values are also listed in Table 3. The accuracy of these numbers is open to further investigation, but we believe that these values can become an index for estimating the $G(N_2)_\infty$.

Speculations for X^- and P^- Ions. When olefins are used as the substrate, Reactions (3) and (4) may be written as follows, by analogy with the O^- reactions:[21]

$$\begin{aligned} N_2O^- + RH &\longrightarrow N_2 + R^- + OH \quad a \\ &\searrow N_2 + R + OH^- \quad 1-a \end{aligned} \quad (3')$$

$$R^- + N_2O \longrightarrow N_2O^- + R \quad (4')$$

As has been shown above, the branching ratio, a, obtained with 1-butene at 0 °C was 0.71, which is not inconsistent with the a' value, 0.6 ± 0.1, reported by Bohme *et al.* However, in the case of propylene, the a value was 0.46, while the a' value was reported to be 0.05 ± 0.05. A more serious difference was observed in the case of ethylene. According to Bohme *et al.*, the reaction between O^- ions and ethylene gives ethylene oxide and electrons. We checked the presence of ethylene oxide in the products of the γ-radiolysis of C_2H_4 containing N_2O, but we could not observe it by gas chromatography. The only product we could observe, except nitrogen, was water, although we did not measure it quantitatively.

In the case of paraffins, the a' values have been reported to be zero.[22] If the a values are also zero, the $G(N_2)_{max}$ cannot be more than the G_e's. The experimental results obviously contradict this. One possible explanation for this contradiction, and also for the discrepancy between the a and a' values for propylene and ethylene, is that the reaction between N_2O^- ions and RH produces the excited OH^{-*} ions, which can then react with other RH's to produce R^- ions.

In order to establish the reaction mechanism of the formation of nitrogen, it is necessary to continue further investigations, probably using a different approach.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2070—2074 (1973)

Crystal Structure of μ-Peroxo-bis[nitrobis(ethylenediamine)-cobalt(III)] Dinitrate Tetrahydrate[1)]

Takashi SHIBAHARA, Shigetaka KODA,* and Masayasu MORI

Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received January 5, 1973)

The crystal and molecular structure of μ-peroxo-bis[nitrobis(ethylenediamine)cobalt(III)] dinitrate tetrahydrate, $[NO_2(en)_2CoO_2Co(en)_2NO_2](NO_3)_2 \cdot 4H_2O$ has been determined using visual intensity data of three dimensional Weissenberg photographs taken with Ni-$K\alpha$ radiation. The brown-black salt is monoclinic with space group $P2_1/n$ and cell dimensions $a=10.755\pm0.011$, $b=12.941\pm0.008$, $c=9.709\pm0.006$ Å, and $\beta=100.4\pm0.1°$. The least-squares refinement with anisotropic temperature factors gave an R index of 0.106. The coordinating ligands form nearly regular octahedra about the cobalt atoms, with Co–N(en), Co–N(NO_2), and Co–O distances of about 1.95, 1.94, and 1.89 Å, respectively. Both NO_2^-'s are *trans* to the O–O bridge, and the geometry of Co–O–O–Co is *trans* planar with O–O distance of 1.53 Å and Co–O–O angle of 110°. The two Co–$(en)_2$ moieties have $\delta\delta$ and $\lambda\lambda$ conformations.

It is well-known that a cobalt-ammonia solution takes up molecular oxygen in aqueous solution to give a brown diamagnetic decaammine μ-peroxo dicobalt complex, which can be oxidized further by Cl_2, $KMnO_4$, *etc.* to yield a green paramagnetic decaammine μ-superoxo dicobalt complex. Several instances of X-ray analyses of decaammine μ-O_2 (both peroxo and superoxo) dicobalt complexes $[(NH_3)_5CoO_2Co(NH_3)_5]^{n+}$

* Present address: Research Laboratories, Fujisawa Pharmaceutical Co. Ltd., Higashiyodogawa-ku, Osaka, Japan.

1) Presented at the 22nd Conference on Coordination Chemistry of the Chemical Society of Japan, Osaka, November (1972), Proceedings, p. 1.

(n=4, 5) have been reported.[2-5] The O–O distances were reported to be 1.31—1.32 Å for superoxo complexes; the O–O distance in KO_2 is 1.28 Å. For peroxo complexes, Schaefer reported 1.47 Å,[5] although Vannerberg had given a considerably longer O–O distance (1.65 Å).[4] Recently we found that $[NH_3(en)_2CoO_2Co(en)_2NH_3]^{4+}$ reacts with NO_2^- in a neutral solution to give $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$ without causing any cleavage of the O_2-bridge.[6] The present report deals with the crystal and molecular structure of this new complex. This seems to be the first example of an O_2-single-bridged dicobalt complex with coordinated nitro groups as studied by X-ray analysis.

Studies have been carried out on the *cis-trans* problem of a mononuclear complex, but very little is known about *cis-trans* configuration in binuclear complexes, partly because most of the binuclear dicobalt complexes so far determined by X-ray analyses were of the unsubstituted ammine type. It seemed worthwhile to investigate the geometrical isomerism of binuclear complexes.

Experimental

Crystals of μ-peroxo-bis[nitrobis(ethylenediamine)cobalt(III)] dinitrate tetrahydrate recrystallized from an aqueous solution are monoclinic brown-black prisms. The compound is stable against air oxidation. Cell dimensions were obtained from zero-level Weissenberg films, taken about the a and b axes, on which the diffraction pattern of silicon powder (a= 5.43066 Å) was superimposed for calibration. The space group $P2_1/n$ was indicated on Weissenberg photographs by a systematic absence of reflections $h0l$ with $h+l$ odd and $0k0$ with k odd. The density of the compound was determined by flotation in a chloroform–bromoform mixture. The crystal data are listed in Table 1. The intensities were measured visually on integrated multi-film equiinclination Weissenberg photographs taken with Ni-$K\alpha$ radiation, for layers from $0kl$ through $7kl$ and from $h0l$ through $h8l$. The intensities were corrected for Lorentz, polarization and absorption factors. In all, 2331 independent (1994 non-zero) reflections were obtained.

Linear absorption coefficient for Ni-$K\alpha$ radiation,
$\mu=28.39$ cm^{-1}

Structure Determination

Approximate coordinates of the cobalt atom were found from three-dimensional Patterson synthesis. The center of the μ-peroxo group lies on the crystallographic center of symmetry. A three dimensional electron density map was then calculated on the basis of cobalt contribution. R index ($\Sigma||F_o|-|F_c||/\Sigma|F_o|$) was 0.435. Several cycles of Fourier and differential Fourier syntheses revealed all the non-hydrogen atoms. The atomic parameters and individual isotropic temperature factors were refined by three cycles of the block diagonal least-squares method. At this stage the R index was 0.154. Three more cycles of refinement were carried out on introduction of anisotropic temperature factors. The following weighting scheme was employed:

$$w = 0.15, \text{ if } F_o \leqq F_{min} (=4.04);$$

	H(16)	−227	3158	2169

a) All hydrogen atoms were assigned isotropic temperature factors, B=3.5 Å^2.

$w = 1.0$, if $F_{min} < F_o < F_{max}$ (=30.7);

$w = F_{max}/F_o$, if $F_o > F_{max}$

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[7] The R index was 0.113 for all the observed reflections. The positions of fourteen hydrogen atoms attached to ethylenediamine molecules were apparent from difference maps, but residual two hydrogen-atom positions were obscure. Although least-squares refinement including hydrogens gave R of 0.103, it indicated some unreasonable short C–H and N–H distances. Thus, neither their coordinates nor their temperature factors were refined. Instead, the hydrogen-atom positions were calculated assuming a tetrahedral configuration about the carbon and nitrogen atoms in ethylenediamine molecules, and C–H and N–H distances of 1.00 and 0.90 Å.[5,8] Inclusion of these assumed hydrogen positions gave R index of 0.106.

The final atomic coordinates and anisotropic temperature factors of the form: $\exp(-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl))$ together with their estimated standard deviations are given in Table 2, and the calculated hydrogen-atom parameters in Table 3. A complete list of the observed and calculated structure factors is preserved by the Chemical Society of Japan.[9]

Description and Discussion of Structure

A perspective drawing of the complex cation is given in Fig. 1, and the atomic arrangement in the crystal in projection along the b axis in Fig. 2. Interatomic distances and bond angles within the ions are listed, along with their estimated standard deviations, in Tables 4 and 5. Each cobalt atom is surrounded octahedrally by four nitrogen atoms of ethylenediamine molecules, a nitrogen atom of the nitro group, and an oxygen atom of the bridging group. As the center of the μ-peroxo group lies on the crystallographic center of symmetry, the geometry of Co–O–O–Co is *trans* coplanar. The torsion angle (180°) about the O–O bond is thus much larger than 146° found for the decaammine μ-peroxo dicobalt (4+) cation reported by Schaefer.[5] This is probably due to the greater steric hindrance between coordinated ethylenediamine groups across the bridge than that between coordinated ammine groups. The short distances across the bridge are those of C(1)···C(3′) and C(3)···C(1′), and are both 3.83 Å, *i.e.* less than twice the van der Waals radius (2.0 Å) of C–H. The nitro ligand has *trans* configuration to the μ-peroxo bridge. The O–O distance in the bridge is 1.53 Å, somewhat longer than that found in H_2O_2 (1.47—1.49 Å)[10,11] and BaO_2

(1.49 Å).[12] The Co–O distance is 1.89 Å about the same as that found in the μ-O_2 decaammine (both superoxo and peroxo) complexes. The Co–N(NO_2) distance is 1.940(8) Å, essentially the same as the value 1.92(2) Å in $[CoNO_2(NH_3)_5]Br_2$.[13] Thus, there appeares no significant structural *trans* effect of the O_2 and NO_2 groups. This is in agreement with the fact that $[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$ is stable in an aqueous solution. The Co–O–O angle is 110°, somewhat smaller than that reported for the μ-O_2 compound. An average of 1.947(8) Å was obtained for the four Co–N(en) distances, comparable with Co(III)–N(sp^3) distances given in literature such as $[(NH_3)_5CoO_2Co(NH_3)_5](SO_4)_2 \cdot 4H_2O$, 1.962(9) Å; *trans* $[CoCl(NO)(en)_2]ClO_4$,[14] 1.964(5) Å; and $[Co(NH_3)_6]I_3$,[15] 1.936 (15) Å.

The Co–$(en)_2$ moieties have unusual $\delta\delta$ and $\lambda\lambda$ con-

Table 6. Puckering of the ethylenediamine rings

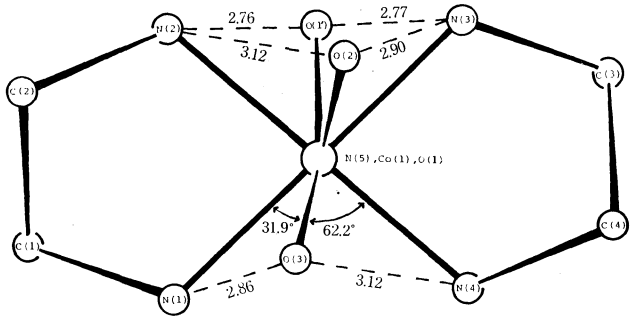

Fig. 3. The view of half of the cation along the N(5), Co(1), O(1) bonds.

figurations. The out-of-plane distances in relation to the puckering of the ethylenediamine rings are listed in Table 6. All *trans* bis(ethylenediamine) complexes so far determined by X-ray analyses have $\delta\lambda$ conformation[16,17] except for $[CoCl(NO)(en)_2]ClO_4$. As is shown in Fig. 3, the NO_2 plane does not bisect the N(1)–Co(1)–N(4) angle, in contrast to $[CoNO_2(NH_3)_5]Br_2$, and O(3)–N(1) and O(2)–N(3) have rather short distances 2.86 and 2.90 Å, respectively, implying hydrogen bonding. Existence of hydrogen bonding can also be inferred between O(1′) and N(2) (2.76 Å) as well as between O(1′) and N(3) (2.77 Å). The two sp^3-type unshared electron orbitals of bridging oxygen O(1′) should point toward the vicinity of hydrogen atoms attached to N(2) and N(3) atoms. These may be partly respondible to the $\delta\delta$ and $\lambda\lambda$ configurations of the complex ion. The possible hydrogen bondings

O(7)	O(8), c	2.68

a) The translations are as follows:
(a) x, y, z; (b) $-x, -y, -z$;
(c) $-x, +y, -z$; (d) $+x, -y, +z$.

with N–H···O distances less than 3.3 Å and O–H···O distances less than 3.0 Å are listed in Table 7. It is interesting that both the first example of $\delta\delta$ and $\lambda\lambda$ configuration ($[CoCl(NO)(en)_2]^+$) and the present one ($[NO_2(en)_2CoO_2Co(en)_2NO_2]^{2+}$) have rather abnormal ligands such as –NO or –O–O– considered to give some specific π-bonding character. The nitro group is planar within experimental error, with N–O distances of 1.21—1.26 Å and O–N–O angles of 118.1—121.6°. The short distances between N(4)–O(8), O(8)–O(7), O(7)–O(4), and O(7)–O(6) appear to be due to intermolecular hydrogen bonds. Cations and anions alternately form layers parallel to the plane ($\bar{1}01$).

The authors wish to express their thanks to Dr. S. Ooi for his kind suggestions. They are also indebted to Mr. K. Hirotsu, for adaptation of the HBLS-4 and RSSFR-3 computer programs to the FACOM 270-30 computer at Osaka City University.

Photovoltaic Effect of Aromatic Diamine in Solution

Takeshi IMURA, Seishi TAKAGI, and Kazuo KAWABE

Electrophysics Laboratory, Department of Electrical Engineering, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received January 12, 1973)

Photovoltaic behaviors are described of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine dissolved in various polar solvents. Positive photovoltage is observed on the illuminated electrode in highly polar solvents such as methanol and acetonitrile, and none in moderately polar ones such as ethanol and acetone. The influence of a few electrode metals on photovoltage has been examined. The electromotive force increases with the work function of metals from tantalum to platinum. Conditions for the appearance of photovoltage are discussed and the photo-ionization process of the aromatic diamine is considered.

Photovoltaic effects are sometimes observed when an electrode immersed in some organic solution is irradiated with light. This phenomenon has been utilized by a few researchers for studying photochemical or photobiological reactions where ionic species play an important role. Methanol solutions of chlorophyll containing benzoquinone were shown to produce photovoltages which depend upon the pH of the solutions.[1,2] Photovoltage measurements were also carried out in tetracyanoethylene dissolved in tetrahydrofuran by exciting the charge-transfer band.[3] The first problem was to identify the active species inducing electromotive force, identification being carried out by means of ESR, flash photolysis and other spectroscopic techniques. The active species are generally the anions or cations which are generated in solutions by photo-ionization, and held on the electrode by adsorption.

The present work deals with the photovoltaic behaviors of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD) in polar solvents. This system seems to be the best for general and exhaustive investigation of photoelectric phenomena in organic fluid solutions, since a number of detailed studies have clarified the primary products and processes which take place on the photo-ionization of TMPD.[4-14]

When TMPD is photo-ionized in solution, a fairly large photocurrent is observed,[4,8,10-13] suggesting the generation of voltaic effect. Although the photovoltaic effect is a phenomenon taking place on the interface between liquid solvent and solid metal, detailed information is scarce as regards the properties and reactions of the active species which produces photo-emf on the interface. It was thought desirable to carry out experiments from the viewpoint of surface phenomenon. In this paper discussions are given on the influence of electrode metals and solvents upon the photovoltaic effect of TMPD solutions.

Experimental

Materials. TMPD was obtained as described.[4] Ethanol for spectroscopy (Nakarai Chemicals), spectrosol-grade acetone and methanol (Dotite), and luminasol-grade dimethylformamide (Dotite) were used without purification for the preparation of solutions. Acetonitrile was refluxed, fractionally distilled twice over phosphorus pentoxide, and finally distilled over potassium carbonate.

Apparatus and procedure. The cell for photovoltaic measurement is shown in Fig. 1. It is made from a quartz tube, the top of the cell being a ground joint fitted to the upper cover, from which 5 mm × 50 mm electrodes are suspended with two tungsten rods.

The electrode metals were cleaned as follows. Platinum and tantalum were washed successively with a solution of a surfactant (R.B.S. 25, Chemical-Products R. Borghgraef), deionized water and distilled methanol, and were then dried. Copper was treated with dilute hydrochloric acid, washed with deionized water and distilled methanol, and then dried.

Table 1. Effect of polarity and viscosity of solvent[15] on the photo-emf of TMPD solution (5×10^{-3} M)

	Dielectric constant (25 °C)	Dipole moment (D)	Viscosity (cp, 25 °C)	Photo-emf (mV)	$TMPD^+$ spectrum	Appearance[4] of phto-current
Acetone	20.7	2.90	0.304	—	—	···
Ethanol	24.3	1.69	1.078	—	+	—
Methanol	32.6	1.69	0.545	10.2(±15%)	+	···
Dimethylformamide	36.7	3.86	0.802	8.6(±10%)	+	+
Acetonitrile	37.5	3.92	0.325 (30 °C)	40.5(±15%)	+	+

The sample solution was introduced into the cell, the electrodes inserted, and high-purity nitrogen (more than 99.999%) was bubbled into the solution for a few minutes through a fine Teflon tube to remove dissolved oxygen. The tube was then pulled out, the upper ground stopper being closed before each experiment.

Only the front electrode was illuminated by light from a high-pressure mercury lamp (250 W, Ushio) with quartz lenses and a glass filter (UV-D1C, Toshiba) which passes only light having energy 3.1—4.1 eV. The distance between the lamp and the cell was fixed at about 400 mm. The lower part of the front electrode was illuminated over a 20 mm× 2—3 mm area.

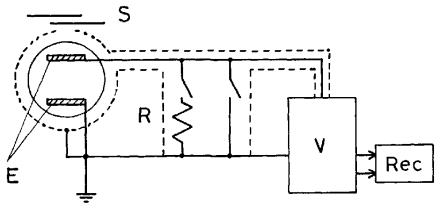

Fig. 2. Schematic diagram of measureing circuit.
S: Shutter, E: Electrodes, R: 100 kΩ resistor, V: Vibrating-reed electrometer, Rec: Recorder.

The apparatus for measurement of photovoltage is shown in Fig. 2. The entire cell was put in a brass pipe to be protected from electrical noise. A vibrating-reed electrometer (TR-84 M Takeda Riken) was used to read photo-induced voltage. Photovoltage was recorded with values across a shunt resistor of 100 kΩ. This helped improve the reproducibility of measurement and produce the stable value of voltage, though the magnitude of the observed voltage became smaller. The resistance of the sample solutions were in the range 4×10^5—5×10^6 Ω, differing with solvent. The lower limit of the detection of photovoltage was down to 0.05 mV.

Results

The photovoltage responses are shown in Table 1 for 5×10^{-3} M solutions of TMPD in various polar solvents. Positive photovoltages were observed on the illuminated electrode in methanol, dimethylformamide, and acetonitrile. Experiments in dimethylformamide were repeated several times for each sample, the deviation from the mean value being within ±10%. In the other solvents the error, partly due to the optical system, was estimated to be within ±15%.

No photo-emf was detected in moderately polar solvents, acetone or ethanol. The positive sign in the column of $TMPD^+$ spectrum in Table 1 indicates that the sample solution turns bluish after the irradiation for measurement of the photo-voltage, *viz.*, $TMPD^+$ is photo-generated and exists either in the form of the free or paired ion in the solution. Appearance of the photocurrent indicates the existence of photo-generated free ions, not paired, in the solution.[4]

The effect of electrode metal on the photovoltage response is shown in Table 2 for 5×10^{-4} M solutions of TMPD in dimethylformamide. The electromotive force shows a tendency to increase with the work function of the metal.

Table 2. Effect of work functions of electrode metals on the photo-emf of TMPD solutions (5×10 M) in dimethylformamide

	Work function[16] (eV)	Photo-emf (mV) (±15%)
Pt	5.4	10.2
Cu	4.5	4.7
Ta	4.1	0.5

The maximum quantity of the photo-emf was obtained over the concentration range 10^{-3}—10^{-4} M. The phtovoltage decreased remarkably when the solution was diluted to 10^{-5} M or less. In concentrated solution ($\geqq10^{-2}$ M) photovoltage response became small due to the diminution in intensity of the exciting light on the surface of the electrode caused by the inner filter effect in the front portion of the sample solution. The molar extinction coefficient was determined to be $(2.6\pm0.1)\times10^3$ M^{-1} cm^{-1} for the first absorption maximum of TMPD at 3.8 eV in dimethylformamide.

No photovoltage (more than 0.05 mV) was generated by irradiating the system containing no TMPD and composed of only solvent and electrodes.

Discussion

Cationic and anionic species should be photo-generated in equal concentration. However, the photovoltage appeared positively on the illuminated electrode. The concentration gradient of charged species in the vicinity of the electrode can be induced from the difference in the diffusion velocity between $TMPD^+$ and anionic species. The latter might have a larger

16) A. J. Dekker, "Solid State Physics," Asian ed., Maruzen Co., Ltd., Tokyo (1960), p. 223.

diffusion velocity since the electron is to react easily with the solvent molecules and to be transferred successively. On the contrary, stable $TMPD^+$ has ordinary diffusion velocity of the solvated ion. It is well-known that either cation or anion is adsorbed preferentially from electrolyte solution onto the metal surface. $TMPD^+$ might be adsorbed preferably onto the surface of the illuminated electrode.

No response of photo-emf was detected in acetone (Table 1). Ultraviolet excitation of TMPD in acetone produced no absorption of $TMPD^+$. Thus the cation, active species, does not seem to be generated in the solution. In ethanol the photo-generation of $TMPD^+$ surely occurs (Table 1), but neither photocurrent nor photovoltage was detected. This implies that $TMPD^+$ observed spectroscopically in ethanol is to be present in the form of ion-pair which gives rise to absorption but cannot contribute to photoelectric effect. The particular situation in ethanolic solution was discussed in other papers.[4,7] The polarization energy seems to be somewhat short in acetone or ethanol for the photo-generation of ion-pair or dissociation into free ions.

Methanol, dimethylformamide, and acetonitrile, in which the photoelectric effects could be observed are highly polar. The fall in the ionization level by polarization energy or the ease for photo-ionization should be in the order of polarity of the solvents. The magnitude of the photovoltage, however, was not in the order of polarity, and seems to depend on the viscosity of solvents as well (Table 1). Actually, the photo-emf was hardly observed in *N*-methylpropionamide which has a high dielectric constant ($\varepsilon = 172$[14] at 25 °C) and high viscosity (5.2 cp[14] at 25 °C) due to the hydrogen-bonded aggregation. A lower viscosity may accelerate the formation of the concentration gradient of the active ionic species. Higher viscosity of dimethylformamide in spite of its large polarity, would prevent the generation of a larger photo-emf than in methanol. Photoelectric responses were especially large in acetonitrile. A possible explanation might be that the anionic species in acetonitrile is very mobile and diffuses away rapidly.

The cation present in the adjacent neighborhood of the electrode was supposed to be the active species to produce electromotive force. The cation will pull out the electron from electrode metal if the metal had a small work function, and will be changed to neutral TMPD which cannot produce electromotive force. The electron-transfer process between $TMPD^+$ and metal or the oxidation-reduction reaction on the metal surface can take place more easily as the work function of the metal decreases. Thus the photovoltage obtained gets smaller, as the work function of electrode metal becomes smaller (Table 2). If the work function is smaller than the energy of the state of $TMPD^+$, no photovoltage response would be detectable, because of the instant reduction of cation to neutral molecule.

It is concluded that photo-generation of dissociated $TMPD^+$ is necessary for the appearance of photovoltage in the solution. The magnitude of photo-emf seems to be determined by the quantity of $TMPD^+$ in the vicinity of the electrode.

The Emission Spectra of Hexamminechromium(III) Hexacyanocobaltate(III), $[Cr(NH_3)_6][Co(CN)_6]$

Hiroshi KATAOKA

Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-ikebukuro, Toshima-ku, Tokyo 171

(Received August 15, 1972)

Spin-forbidden absorption bands of $K_3[Co(CN)_6]$ were reexamined employing conventional transmission spectroscopy, diffuse reflectance spectroscopy, and microspectrophotometry. A small but very distinct shoulder ($\varepsilon \approx 0.3$—0.4) obtained at a low temperature at 26000 cm^{-1} was assigned to the $^3T_{1g} \leftarrow {}^1A_{1g}$ transition. Another very small band ($\varepsilon \approx 0.001$) at 16300 cm^{-1} was probably due to an impurity. The emission spectra of $K_3[Co(CN)_6]$ powder in the temperature range from room temperature to that of liquid hydrogen were observed by means of a modified Hitachi 203 fluorescence spectrophotometer. The broad emission band at room temperature showed some vibrational structures at low temperatures. The emission spectra of powders of $[Cr(NH_3)_6](NO_3)_3$ and $[Cr(NH_3)_6][Co(CN)_6]$ were also measured. The following results were obtained: i) Similar emission spectra, which seemed to originate from $[Cr(NH_3)_6]^{3+}$, were observed with both complexes $[Cr(NH_3)_6](NO_3)_3$ and $[Cr(NH_3)_6][Co(CN)_6]$ using mercury lines at 313, 365, and 435 nm for excitation. ii) With 254 nm excitation, such emission spectra as i) were not observed with $[Cr(NH_3)_6](NO_3)_3$, but the same emission spectra as in i) were observed with $[Cr(NH_3)_6][Co(CN)_6]$. iii) The ratio of the emission intensities at 15000 cm^{-1} with 435 and 313 nm excitations was 1 : 0.25—0.30 for $[Cr(NH_3)_6](NO_3)_3$, but it was 1 : 1.5—1.7 for $[Cr(NH_3)_6][Co(CN)_6]$. From these results, it was presumed that, in $[Cr(NH_3)_6][Co(CN)_6]$, there occurred an energy transfer from the complex anion to the complex cation. Furthermore, emission spectra were observed with $[Cr(NH_3)_6](ClO_4)_3$ and the equimolar mixture of complex salts $[Cr(NH_3)_6](ClO_4)_3$–$K_3[Co(CN)_6]$ and $[Cr(NH_3)_6](NO_3)_3$–$K_3[Co(CN)_6]$ for the purpose of confirming the energy transfer in $[Cr(NH_3)_6][Co(CN)_6]$. The temperature dependence of the emission intensity was also discussed.

Recently it has been found by many authors that chromium(III) complexes show emission spectra,[1] and several papers have been published presenting evidence for energy transfer in chromium complexes in solutions[2] and in solids.[3,4]

On the other hand, although there have been extensive studies of the absorption spectra of cobalt(III) complexes, there have been few papers on their emission spectra. Those reported up to this time are $Na_5[Co(SO_3)_2(CN)_4]$,[5] $Ag_3[Co(CN)_6]$,[6], and $K_3[Co(CN)_6]$.[7-10] Several papers on energy transfer with cobalt(III) complexes in solutions have also been presented,[11-13] but there have been few papers on that in solids. One of the reasons why the relationship between the absorption and the emission spectrum has not been discussed fully in those reports seem to have been the difficulty of observing the very weak spin-forbidden absorption band. Some authors have observed the spin-forbidden band of $K_3[Co(CN)_6]$,[7,10,14] but differing results have been reported.

In the present work, $K_3[Co(CN)_6]$ was studied in order to establish the relationship between the emission band and the spin-forbidden absorption band. Furthermore, the double complex salt $[Cr(NH_3)_6][Co(CN)_6]$ was studied to get information on the emission spectrum and energy transfer. The reasons why the double complex salt $[Cr(NH_3)_6][Co(CN)_6]$ was selected were as follows: i) The relation between the emission spectrum and the spin-forbidden band of $[Cr(NH_3)_6]^{3+}$ has been elucidated by extensive studies.[15] ii) The absorption spectra of the double complex salt nearly form a superposition of the spectra of the complex cation $[Cr(NH_3)_6]^{3+}$ and the complex anion $[Co(CN)_6]^{3-}$. Therefore, the selective excitation of the complex anion or cation is possible if a suitable wavelength is selected for the excitation. Furtheremore, $[Cr(NH_3)_6](NO_3)_3$, $[Cr(NH_3)_6](ClO_4)_3$, and an equimolar mixture of the complex salts $[Cr(NH_3)_6](ClO_4)_3$–$K_3[Co(CN)_6]$ and

$[Cr(NH_3)_6](NO_3)_3$–$K_3[Co(CN)_6]$ were studied for the purpose of confirming the energy transfer.

Recently, energy transfer in the double complex salt composed of $[Ru(bipy)_3]^{2+}$ and $[Cr(ox)_3]^{3-}$ (bipy: bipyridine, ox: oxalate ion) was studied by Fujita and Kobayashi.[16] Their observations provided interesting evidence for an electronic excitation energy transfer between complexes with different central metals.

Experimental

Preparation of Materials. $K_3[Co(CN)_6]$, $[Cr(NH_3)_6](ClO_4)_3$, and $[Cr(NH_3)_6](NO_3)_3$ were prepared according to the published methods.[17,18] These compounds were recrystallized three times from an aqueous solution.

The double complex salt $[Cr(NH_3)_6][Co(CN)_6]$ was prepared by adding an aqueous solution of $K_3[Co(CN)_6]$ (0.02 mol/l, 500 ml), with rigorous stirring, drop by drop into an aqueous solution of $[Cr(NH_3)_6](NO_3)_3$ (0.02 mol/l, 500 ml).[19] The fine precipitate thus obtained was filtered using a 4G-glass filter, washed with a large amount of water, and dried in a vacuum desiccator.

An equimolar mixture of the complexes was obtained by grinding powder of $[Cr(NH_3)_6](NO_3)_3$ and $K_3[Co(CN)_6]$ or $[Cr(NH_3)_6](ClO_4)_3$ and $K_3[Co(CN)_6]$ in an equimolar ratio.

The Growing of a Single Crystal of $K_3[Co(CN)_6]$. Because of the small molar extinction coefficient of the spin-forbidden bands of $K_3[Co(CN)_6]$,[7,14] a large single crystal was necessary for measuring its absorption spectrum. This single crystal was grown using equipment similar to that of Galsbøl.[20] The solution was prepared by dissolving about 150 g of $K_3[Co(CN)_6]$ in 300 ml of water containing a small amount of KCN at 50—55 °C. The vessel was then covered with a wrap sheet and placed in a thermostated bath at 50 °C. After one day, the solution was decanted into a 300 ml beaker, and then again placed in the thermostated bath as quickly as possible. A small seed[21] (*ca.* $1.5\times1\times1$ mm or larger) was put on the bottom of the beaker, and the surface was covered with a small amount of liquid paraffine in order to avoid evaporation. The solution at 50 °C was slowly cooled to room temperature at a velocity of 2.50 ± 0.01 °C/day. The temperature controller was a Jumo (Western Germany) model MS.D.B.P.8.66. After 10—15 days, a large single crystal weighing 23 g (approximately $25\times30\times20$ mm) was obtained.[22] It was greenish yellow and had some fine cracks, only a small portion being available for measuring the spectra.

Measurements of Absorption and Diffuse Reflectance Spectra. The absorption spectra of aqueous solutions were measured with a Hitachi EPS-3T recording spectrophotometer. The inside of the monochromator was filled with nitrogen gas during the measurement in the 190—220 nm region. The visible and ultraviolet spectra of a single crystal (thickness: 1.5 mm) of $K_3[Co(CN)_6]$ were measured with this spectrophotometer using a microspectrophotometric attachment constructed in this laboratory at room temperature (*ca.* 295 K) and at the temperature of liquid nitrogen (77 K).

The visible and near-infrared spectra of a large single crystal (*ca.* $25\times30\times20$ mm) were also measured by the conventional method at room temperature using a Cary-14 recording spectrophotometer.

The diffuse reflectance spectra were measured with a Hitachi EPS-3T spectrophotometer, using a reflectance accessory at room temperature.

The infrared spectra in the 700—4000 cm^{-1} region and in the 200—700 cm^{-1} region were obtained with, respectively a JASCO DS-301 infrared spectrophotometer and a JASCO Model IR-F far-infrared spectrophotometer, using the Nujol-mull method.

Measurement of Emission Spectra. For the present purpose, a Hitachi 203 fluorescence spectrophotometer (with two grating monochromators for the excitation and the detection) was modified as follows: i) the sample chamber of the Hitachi 203 spectrophotometer was modified to accommodate a cryostat-type AC-2 apparatus made by Air Products and Chemicals;[23,24] ii) the usual Hamamatsu R-212 (maximum sensitive wavelength 340 nm) photomultiplier was replaced with two photomultipliers, a Hamamatsu R-406 (S-1 characteristic, maximum sensitive wavelength 800 nm) and an R-136 (maximum sensitive wavelength 430 nm), for the purpose of detecting weak emission spectra in the near-infrared and red regions; iii) in most cases, the sample was excited with a mercury lamp (120 W, Ushio, UM-102) but in a few cases it was excited with a xenon lamp (150 W, Ushio, UXI-151D), and iv) in order to record the emission spectra automatically a Hitachi wavelength driving apparatus and a Hitachi QPD-53 recorder were used.

The emission spectra were passed through a yellow cut-off filter in order to remove the exciting light, and were detected at the right angle to the exciting light. Furthermore, the correction for the small amount of stray light from the exciting light source was made by means of powdered magnesium oxide, as has been described by Kirk and his co-workers.[9] The sample temperature was measured using a calibrated chromel-constantan thermocouple and a reference junction. The entrance and exit slit widths were 0.8 mm in all the measurements. The emission spectra thus obtained were not corrected for the spectrophotometer, incident light intensity, detector, and particle size. The measurement region was 500—780 nm, while the temperatures ranged from room temperature to the temperature of liquid hydrogen (20 K). The measurement error of the temperature was $\pm0.5\%$ near 250 K, $\pm1.0\%$ near 150 K, and $\pm5\%$ near 50 K. The errors of the emission intensity measurement were $\pm5\%$.

Wavelength calibrations of the Hitachi EPS-3T spectrophotometer and Hitachi 203 fluorescence spectrophotometer were made by the use of mercury lines.

Results and Discussion

Diffuse Reflectance Spectra. Figure, 1 shows the diffuse reflectance spectra of the complex salts $[Cr(NH_3)_6](NO_3)_3$, $[Cr(NH_3)_6](ClO_4)_3$, $K_3[Co(CN)_6]$, and the double complex salt $[Cr(NH_3)_6][Co(CN)_6]$. The diffuse reflectance spectra of an equimolar mixture of complex salts $[Cr(NH_3)_6](NO_3)_3$–$K_3[Co(CN)_6]$ and $[Cr(NH_3)_6](ClO_4)_3$–$K_3[Co(CN)_6]$ are shown in Fig. 2.

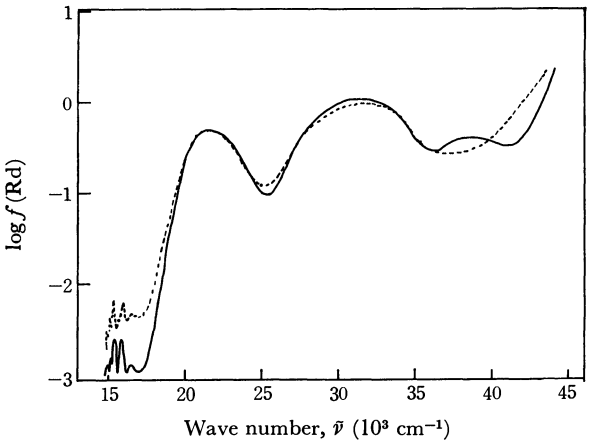

Fig. 2. Diffuse reflectance spectra of equimolar mixture of complex salts.
------$[Cr(NH_3)_6](ClO_4)_3$–$K_3[Co(CN)_6]$
———$[Cr(NH_3)_6](NO_3)_3$–$K_3[Co(CN)_6]$

From these figures it is evident that the spectrum of the double complex salt compares well with the spectra of equimolar mixtures, which are considered to be the sum spectra of the individual spectra of the component complexes.

The Absorption Spectrum of $K_3[Co(CN)_6]$. Spin-allowed ligand-field bands and the charge-transfer band of $K_3[Co(CN)_6]$ were measured in an aqueous solution. The position (cm^{-1}) and the logarithms of the molar extinction coefficients of the bands are shown in Table 1, together with other workers' data. The oscillator strength, f, was calculated by the use of:

$$f = 4.32 \times 10^{-9} \int \varepsilon d\bar{\nu} = 5.6 \times 10^{-9} \varepsilon_{max} \Delta\bar{\nu} \quad (1)$$

where ε is the molar extinction coefficient; $\bar{\nu}$, the wave number, and $\Delta\bar{\nu}$, the half-band width.[25a] There is a rather good agreement between the present data and those of others.

Spin-forbidden bands for a number of cobalt(III) complexes have been reported by many workers.[26] Those of $K_3[Co(CN)_6]$ were also reported by Kida *et al.*[14] and Porter *et al.*[7] The former found a shoulder at 24000 cm^{-1} and suggested that it represented a spin-forbidden band. The latter workers obtained a weak band ($\varepsilon \approx 0.01$) at 18500 cm^{-1} and assigned it to the $^3T_{1g} \leftarrow {}^1A_{1g}$ transition. The Tanabe-Sugano diagram[27] suggests that two spin-forbidden bands ($^3T_{1g}$, $^3T_{2g} \leftarrow {}^1A_{1g}$) exist in the near-ultraviolet and visible regions. It is thus necessary to elucidate whether the weak bands obtained by the above authors originate from similar transitions or from different transitions. In this paper, the spin-forbidden absorption bands of $K_3[Co(CN)_6]$ were reexamined employing conventional transmission spectroscopy, diffuse reflectance spectroscopy, and microspectrophotometry.

With the conventional transmission method, using various concentrations, it was impossible to obtain an absorption spectrum that showed a clear shoulder at 24000 cm^{-1}. Thus, the weak band might have been covered by the tail of the first spin-allowed band. A curve analysis of the first spin-allowed band was made using the equation presented by Shimura and Tsuchida.[28] Their equation is a modification of Kuhn

and Braun's[29] containing as a correction term δ, the inclination parameter.

On account of the superposition of the first and second spin-allowed ligand field bands of $K_3[Co(CN)_6]$, the true half-width of the first band was expected to be smaller than that obtained from the experimental curve. Thus, curve analyses were done in which the parameters, l (half-width of the band) and δ, were changed in the regions of 3300—5000 cm^{-1} and 0—300 cm^{-1} respectively. The best agreement between the experimental curve and the calculated one in the region 28000—35000 cm^{-1} was found when l and δ were 4900 and 170 cm^{-1} respectively. These two curves are shown in Fig. 3. However, much larger inconsistencies than those found in most cobalt(III) complexes were found in the wave number region below 28000 cm^{-1}. This must have been due to the presence of a small band ($\log \varepsilon \approx 0.4$) at about 27000 cm^{-1}.

An indistinct shoulder appeared at about 25000 cm^{-1} in the diffuse reflectance spectrum of $K_3[Co(CN)_6]$ (Fig. 1). The absorption spectra obtained by microspectrophotometry are shown in Fig. 4. Although no maximum or shoulder in the region in question was found at room temperature, a small but very distinct shoulder was obtained at 26000 cm^{-1} at the temperature of liquid nitrogen. The subtraction of the tail of the first spin-allowed band from this spectrum gave a small band whose maximum was at about 26000 cm^{-1}, its molar extinction coefficient was about 0.3—0.4. This small band may be the spin-forbidden band of $K_3[Co(CN)_6]$.[30]

Furthermore, a very weak band ($\varepsilon \approx 0.001$) was observed at 16300 cm^{-1} using a 10 cm cell and a concentrated solution (1.24 mol/l). This band was also observed at about the same position using a single crystal (thickness, 20 mm). The half-width of this band was about 1000 cm^{-1}.

The single crystal showed two very strong bands, at 4246 and 4279 cm^{-1}, and some other bands at 4155, 4160, 4290, 6333, and 6341 cm^{-1} in the near-infrared region. The two strong bands at 4246 and 4279 cm^{-1} were assigned by Jones to the combination bands for $(\nu_3+\nu_6)$ and $(\nu_1+\nu_6)$.[34] The two very weak bands in the 6000 cm^{-1} region may be due to the combination band for 2 (ν_1, ν_3, or ν_6)+(ν_1, ν_3, or ν_6). The next combination band, related to ν_1, ν_3, and ν_6, could be expected to appear in about the 8500 cm^{-1} region; however, no band was observed until the weak and broad band at 16300 cm^{-1} was reached. Therefore, this band might also be due to the spin-forbidden band of K_3-$[Co(CN)_6]$ (Fig. 5).

29) W. Kuhn and E. Braun, *Z. Phys. Chem.*, **B8**, 281 (1930).

30) If a small amount of $K_2[Co(CN)_5H_2O]$ exists in a $K_3[Co(CN)_6]$ crystal, a shoulder might appear at about 26000 cm^{-1}, because $K_2[Co(CN)_5H_2O]$ has the first spin-allowed band at 26300 cm^{-1} ($\varepsilon \approx 260$).[31] It is well-known in the preparation of $K_3[Co(CN)_6]$ that the uptake of the sixth cyanide by $[Co(CN)_5H_2O]^{2-}$ is a slow process at room temperature,[32] but very rapid at 95°C.[33] Thus, the reaction solution was boiled long enough to avoid contamination with $[Co(CN)_5H_2O]^{2-}$. Recrystallization was repeated several times. It is, therefore, more reasonable to attribute the small shoulder at 26000 cm^{-1} to the spin-forbidden band of $K_3[Co(CN)_6]$.

However, it is more probable that this band is due to an impurity[35] contained in $K_3[Co(CN)_6]$. This is for the following reasons. i) There is a linear relation, as found by Fujita and Shimura, between the positions of the first spin-forbidden band and the first spin-allowed band of cobalt(III) complexes.[26a] The position of the band in question shifted very much from that expected from this relationship. The band found at 26000 cm^{-1}, however, is in agreement with the relationship, thus, it should be assigned to the $^3T_{1g}\leftarrow{}^1A_{1g}$ transition. The $^3T_{2g}\leftarrow{}^1A_{1g}$ band will exist at higher wave numbers, thus being covered completely by the first spin-allowed band. ii) Based on a theoretical calculation, Alexander and Gray concluded that the spin-forbidden $^3T_{1g}\leftarrow{}^1A_{1g}$ band will appear at about 27000 cm^{-1}.[36] iii) The intensity of this band ($\varepsilon\approx 0.001$) is abnormally small compared with those of the spin-forbidden bands of other cobalt(III) complexes ($\varepsilon=0.1$—1). iv) The separation between the positions of this band and the phosphorescence band seems to be too small if it is assumed that this band is due to the $^3T_{1g}\leftarrow{}^1A_{1g}$ transition.[37] v) The position (16300 cm^{-1}) and the intensity ($\varepsilon\approx 0.001$) of the band found in this work differ very much from the position (18500 cm^{-1}) and the intensity ($\varepsilon\approx 0.01$) reported by Porter *et al.*

Energy Level Diagram. The evergy level diagram based on the results of the conventional transmission and diffuse reflectance measurements on $[Cr(NH_3)_6](ClO_4)_3$, $K_3[Co(CN)_6]$ and $[Cr(NH_3)_6][Co(CN)_6]$ is shown in Fig. 6. The positions of the maxima of the absorption bands are shown by solid lines and dashed lines, and the half-widths of the bands, by hatched areas. The solid lines and dashed lines represent the electronic states possessing the same multiplicity and different multiplicities with respect to that of each ground state respectively. The electronic configurations of each level are given in parentheses. The wavelengths of the light used for excitation are also shown by the arrows on the left of the diagram.

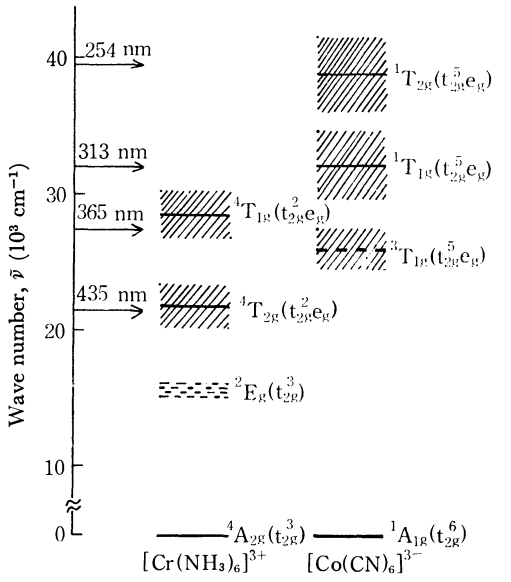

Fig. 6. Energy level diagram of $[Cr(NH_3)_6]^{3+}$ and $[Co(CN)_6]^{3-}$

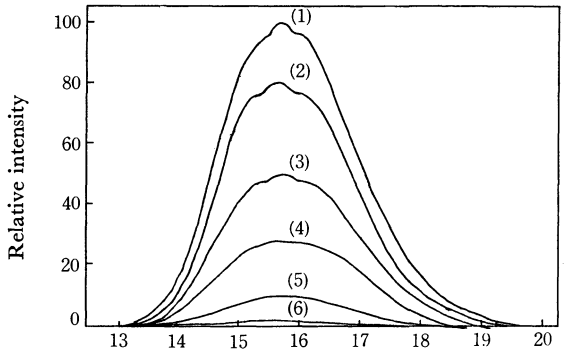

Fig. 7. Emission spectra of $K_3[Co(CN)_6]$ excited with 313 nm light.
Temperature (K): (1): 20, (2) : 100, (3): 151, (4): 190, (5): 235, (6): 295.

Emission Spectrum of $K_3[Co(CN)_6]$. The emission spectra at various temperatures excited with 313 nm light, which has almost the same energy as that of the maximum of the first spin-allowed band, are shown in Fig. 7.[38] It was found that the extremely weak and broad structureless emission band at room temperature gradually increased in intensity with a decrease in the temperature and that it showed some vibrational structures below *ca.* 150 K. Excitations with 365 nm light, and with 254 nm light, which has almost the same energy as that of the maximum of the second spin-allowed band, gave the same spectral pattern as that obtained by excitation with 313 nm light. The temperature dependence of the emission spectra excited with 313 and 254 nm light showed practically the same behavior.

The emission band of $K_3[Co(CN)_6]$ had been observed previously by Porter and Mingardi[7,25a] with a crystal at 4.2 and 77 K at 14000 cm^{-1} and assigned to the $^3T_{1g}\rightarrow{}^1A_{1g}$ phosphorescence of $[Co(CN)_6]^{3-}$, mainly on the basis of the mirror-image relationship between the emission band and the absorption band (18500 cm^{-1}), and on the basis of the lifetime measurement of the emission band (6.8×10^{-4} sec). A broad structureless band with a maximum at 14000 cm^{-1} was also obtained by Kirk *et al.*[9] The discrepancy in the

35) One possible impurity may be a binuclear cyanoaquo Co(II)-Co(III) complex with, in the low wave number visible region, a spin-allowed band, a charge transfer band, or an interaction absorption band. According to the conditions of synthesis, the complex with a band at 16300 or 18500 cm^{-1} will be produced.

36) J. J. Alexander and H. B. Gray, *Coord. Chem. Rev.*, **2**, 29 (1967).

37) Since the maximum of the absorption band lies at 16300 cm^{-1}, and since the half-width of the band is about 1000 cm^{-1}, the 0-0 position of the band must lie at about 15300 cm^{-1}, which limits the position of the phosphorescence band to wave numbers smaller than this. If a phosphorescence band larger than 15300 cm^{-1} is found, it should be an anti-Stokes band and thus should show a decrease of intensity with a decrease in the temperature. This was not the case in our experiment, as may be seen in Fig. 7.

38) The maximum of the phosphorescence band of $K_3[Co(CN)_6]$ shifted to a low wave number of about 1000 cm^{-1} when an R-406 tube was used instead of an R-136 tube. However, only the results obtained by the latter tube are shown throughout this work because the sensitivity of the former tube is much lower than that of the latter.

phosphorescence band position between this work (14700 cm^{-1} using an R-406 tube) and other authors' works may be due to the use of different experimental setups.

As has been stated above, the weak absorption band at 26000 cm^{-1} was assigned to the $^3T_{1g} \leftarrow {}^1A_{1g}$ transition. Thus, the emission band at 14700 cm^{-1} should be assigned to the $^3T_{1g} \rightarrow {}^1A_{1g}$ transition. The position of the emission band might seem to be too far apart from the position of the absorption band, the difference being about 10000 cm^{-1}. However, a similar large difference has been observed by Mingardi *et al.*[25a] in a d^6 cyano-complex, $K_4[Ru(CN)_6]$. They found the corresponding absorption and emission bands at 31000 and 22650 cm^{-1} respectively. The large Stokes shifts 11600 and 17200 cm^{-1} in other d^6 complexes have also been found by DeArmond *et al.* in $[Rh(en)_3]Cl_3$ and $[Ir(en)_3]Cl_3$ (en=ethylenediamine) respectively.[25b]

Schläfer *et al.* observed the phosphorescence of $K_3[Cr(CN)_6]$ in a glycerol/H_2O (1 : 1) rigid solution and in a fine crystal state at −190 °C and assigned the interval (*ca.* 350 cm^{-1}) between the vibrational structures of the phosphorescence band to the Cr–C stretching vibration.[39] The mean interval, 400 cm^{-1}, in the phosphorescence spectrum of $K_3[Co(CN)_6]$ in this work may be due to the Co–C stretching or Co–CN bending vibration.

Emission Spectra of $[Cr(NH_3)_6](NO_3)_3$ *and* $[Cr(NH_3)_6](ClO_4)_3$. The emission spectra of $[Cr(NH_3)_6](NO_3)_3$ and $[Cr(NH_3)_6](ClO_4)_3$ are shown in Figs. 8 and 9. The following results were obtained:

i) The emission spectra excited with 313, 365, and 435 nm light showed the same pattern in both complexes.[40,41] On the other hand, with 254 nm light it was very difficult to distinguish between the emission spectrum and the noise signal at any temperature used in this work.

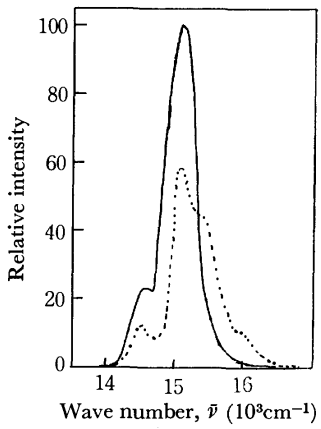

Fig. 8. Emission spectra of $[Cr(NH_3)_6](NO_3)_3$ excited with 313 nm light.
——: 20 K --------: 295 K

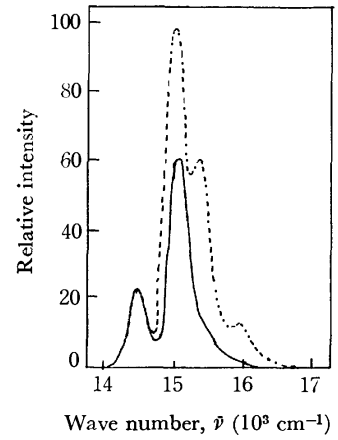

Fig. 9. Emission spectra of $[Cr(NH_3)_6](ClO_4)_3$ excited with 435 nm light.
——: 20 K -----: 295 K

ii) In $[Cr(NH_3)_6](NO_3)_3$, the two emission bands at 15390 and 15970 cm^{-1} decreased in intensity with a decrease in the temperature and almost disappeared at 20 K. However, the other two bands at 14470 and 15040 cm^{-1}, increased in intensity with a decrease in the temperature.

iii) In $[Cr(NH_3)_6](ClO_4)_3$, the emission band at 14550 cm^{-1} did not change in intensity with a decrease in the temperature. The other three bands, at 15020, 15390, and 15900 cm^{-1}, decreased in intensities with a decrease in the temperature.

As may be seen from the results shown in ii), the two bands at 15390 and 15970 cm^{-1} can be assigned to the transitions from the higher vibrational levels of the ^2E_g state to the ground state. The band at 15390 cm^{-1} may correspond to the 15120 cm^{-1} band reported by Porter *et al.*,[15c] which was assigned to the 0–0 band. However, it is more reasonable to assign the band at 15040 cm^{-1} to the 0–0 band, judging from the findings on the temperature dependence of the emission spectra (see Fig. 8).

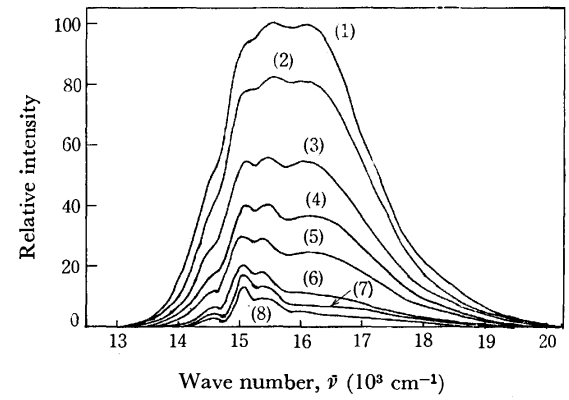

Fig. 10. Emission spectra of equimolar mixture of complex salts $[Cr(NH_3)_6](ClO_4)_3$–$K_3[Co(CN)_6]$ excited with 313 nm light.
Temperature (K)
(1): 20, (2): 57, (3): 115, (4): 150, (5): 170, (6): 222, (7): 235, (8): 295.

39) H. L. Schläfer, H. Gausman, H. F. Wasgestian, and H. U. Zander, *Z. Phys. Chem.*, (*N.F.*) **51**, 274 (1966).

40) The position of the maxima of the phosphorescence band of $[Cr(NH_3)_6]^{3+}$ shifted to a low wave number of about 200 cm^{-1} when an R-406 tube was used instead of an R-136 tube.

41) The emission spectra excited with 435 nm light are shown in $[Cr(NH_3)_6](ClO_4)_3$. This is because the emission intensity was very weak with 313 nm light, which has the same energy as that of the valley between the second spin-allowed band and the charge-transfer band (see Fig. 1).

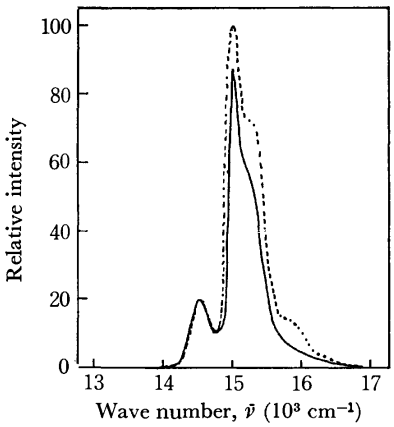

Fig. 11. Emission spectra of equimolar mixture of complex salts $[Cr(NH_3)_6](ClO_4)_3$–$K_3[Co(CN)_6]$ excited with 435 nm light. ——: 20K ------: 295 K

Emission Spectra of Equimolar Mixtures of Complex Salts $[Cr(NH_3)_6](NO_3)_3$–$K_3[Co(CN)_6]$ *and* $[Cr(NH_3)_6](ClO_4)_3$–$K_3[Co(CN)_6]$. The emission spectra for these two equimolar mixtures of complex salts were observed. All the results obtained could be explained by considering the superposition of the spectra of the component complexes. Some of the results are shown in Figs. 10 and 11. Figure 10 gives the emission spectra of an equimolar mixture of $[Cr(NH_3)_6](ClO_4)_3$–$K_3[Co(CN)_6]$ excited with 313 nm light at various temperatures. It is evident from the figure that the spectra consist of the emission bands of $[Cr(NH_3)_6]^{3+}$ and $[Co(CN)_6]^{3-}$. Figure 11 shows the emission spectra of an equimolar mixture of $[Cr(NH_3)_6](ClO_4)_3$–$K_3[Co(CN)_6]$ at 20 and 295 K excited with 435 nm light. As may be seen from Fig. 1, $[Co(CN)_6]^{3-}$ absorbs little in this region; thus, only the emission spectrum due to $[Cr(NH_3)_6]^{3+}$ is observed.

Emission Spectra of $[Cr(NH_3)_6][Co(CN)_6]$. The emission spectra of the double complex salt $[Cr(NH_3)_6][Co(CN)_6]$ are shown in Fig. 12.[42] The following results were obtained:

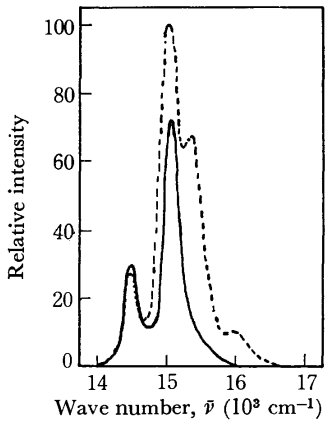

Fig. 12. Emission spectra of $[Cr(NH_3)_6][Co(CN)_6]$ excited with 313 nm light. ——: 20 K ------: 295 K

i) The emission spectra excited with 254, 313, 365, and 435 nm light were different from the emission spectra of the equimolar mixtures of the complex salts excited with 313 nm light, but had nearly the same pattern and position as those of the emission spectra of $[Cr(NH_3)_6](NO_3)_3$ or $[Cr(NH_3)_6](ClO_4)_3$. The only difference was that the two emission bands in the higher wave number region observed as shoulders in $[Cr(NH_3)_6](NO_3)_3$ and $[Cr(NH_3)_6](ClO_4)_3$ showed distinct maxima in this double complex salt. The emission intensity of $[Cr(NH_3)_6]^{3+}$ in the double complex was several times stronger than that of $[Cr(NH_3)_6]^{3+}$ in equimolar mixtures.

ii) The ratio of the emission intensities at 15000 cm^{-1} excited with 435 and 313 nm light was 1 : 1.5—1.7 at room temperature, and the ratio hardly changed at 20 K. The ratio was 1 : 0.25—0.30 in the case of $[Cr(NH_3)_6](NO_3)_3$.[43]

iii) The two bands at 15400 and 15970 cm^{-1} decreased in their intensities with a decrease in the temperature and almost disappeared at 20 K; the intensity of the emission band at 15000 cm^{-1} also decreased with a decrease in the temperature. However, no temperature dependence of the intensity was observed with the emission band at 14470 cm^{-1}.

Energy Transfer. The fact that the emission spectra of the double complex salt had nearly the same pattern as that of $[Cr(NH_3)_6](NO_3)_3$ or $[Cr(NH_3)_6](ClO_4)_3$ and did not resemble that of $K_3[Co(CN)_6]$, even if 254 nm light, which was mostly absorbed by the complex anion, was used, strongly suggests that some energy transfer occurs from the complex anion to the complex cation in the double complex salt. This becomes clearer when we compare the phosphorescence band of the double complex salt (Fig. 12) with that of the equimolar mixture of the complexes (Figs. 10 and 11) in which the energy transfer cannot be considered and in which the spectrum thus consists of those of the component complexes. Additional evidence is given by the ratio of the intensities of the emission bands at 15000 cm^{-1} excited with 435 and 313 nm light. If the two ratios mentioned above are compared, it is more reasonable to consider that the increase in the ratio from 1 : 0.25—0.30 in $[Cr(NH_3)_6](NO_3)_3$ to 1 : 1.5—1.7 in $[Cr(NH_3)_6][Co(CN)_6]$ corresponds to the increase in the absorption due to [Co-

42) The intensity of the emission band excited with 254 nm light was weak because of the low intensity of the light source in this region. However, it was confirmed that the pattern and position of this band were similar to those of the emission band excited with 313 nm light. Thus, the emission spectrum excited with 254 nm light was not shown; that excited with 313 nm light was shown instead.

43) The intensities of the 313 and 435 nm emission lines of the Ushio UM-102 mercury lamp were almost the same (private communication from Ushio, Incorporated). The sensitivities of the photomultiplier R-136 at 313 and 435 nm were 1 : 2 (Hamamatsu Corporation Information Bulletin, **1972**, 8). When powdered magnesium oxide was irradiated with these mercury light, the Hitachi 203 fluorescence spectrophotometer out-put indicated the 1 : 2 ratio at these wavelengths. Therefore, the transmittance of the fluorescence spectrophotometer was considered to be nearly the same at these wavelengths. From these results, it was concluded that the ratios of the emission band at 15000 cm^{-1} excited with 313 and 435 nm were not much different from the true value if we neglect the problems concerning the samples, that is, the inner-filter effect, the particle size effect, etc. A more detailed experiment concerning the quantitative aspects of this work using ferrioxalate solutions in a chemical actinometer is now under way in this laboratory.

$(CN)_6]^{3-}$.[44]

As possible energy transfer paths, the following two are suggested. They satisfy the spin conservation rule in consideration of the energy level diagram shown in Fig. 6:

$$^1T_{2g} \dashrightarrow {}^1T_{1g} \begin{cases} \nearrow {}^4T_{1g} \dashrightarrow {}^4T_{2g} \rightsquigarrow {}^2E_g \\ \searrow {}^4T_{2g} \rightsquigarrow {}^2E_g \end{cases}$$

where→means energy transfer; ⇢, internal conversion, and ⇝, intersystem crossing. However, if the formation of the molecular orbitals between the complex cation and the complex anion are considered, the following two paths are also possible, as in the case of $[Ru(bipy)_3]_3[Cr(ox)_3]_2$ (bipy: 2,2'-bipyridyl, ox: oxalate ion) studied by Fujita and Kobayashi:[16]

$$^1T_{2g} \dashrightarrow {}^1T_{1g} \rightsquigarrow {}^3T_{1g} \begin{cases} \nearrow {}^4T_{2g} \rightsquigarrow {}^2E_g \\ \searrow {}^2E_g \end{cases}$$

It is interesting to note that the latter paths are prohibited if importance is attached to the simple consideration of the spin conservation rule, although they are usually considered to be more favorable from the point of view of the longer lifetime of $^3T_{1g}$.

Temperature Dependence of the Emission Intensity. The temperature dependence of the emission intensity of $K_3[Co(CN)_6]$, $[Cr(NH_3)_6](NO_3)_3$, $[Cr(NH_3)_6](ClO_4)_3$, and $[Cr(NH_3)_6][Co(CN)_6]$ is shown in Figs. 13—16.

These data may be classified into two groups according to whether the emission intensity increases or decrease with a decrease in the temperature. The emission intensity in $K_3[Co(CN)_6]$ and $[Cr(NH_3)_6](NO_3)_3$ increases with a decrease in the temperature. These phenomena can be explained in terms of the usual emission process competing with the nonradiative relaxation process.

44) Kirk and Schläfer proposed a crystal perturbation theory against an energy transfer in order to explain an abnormal emission spectrum of $[Cr(atp)_6][Cr(CN)_6]$ (atp: antipyrin). Their case must be the result of a special ligand which prohibits the energy transfer, as they pointed out.[45]

45) A.D. Kirk and H.L. Schläfer, *Z. Phys. Chem.*, **52**, 2411 (1970).

However, the temperature dependence of the emission intensity of $[Cr(NH_3)_6](ClO_4)_3$ and $[Cr(NH_3)_6][Co(CN)_6]$ is anomalous; that is, the intensity decreases with a decrease in the temperature except in the cases of the bands at 14550 and 14470 cm^{-1} respectively. The explanation of this anomalous temperature effect is very difficult. Flint studied the emission spectra of crystalline $2[Cr(en)_3]Cl_3 \cdot KCl \cdot 6H_2O$ and $[Cr(en)_3]Cl_3 \cdot 3H_2O$ (en=ethylenediamine) at temperatures down to 5 K.[46] He found that the emission band at 14880 cm^{-1} (N-band) having vibronic structure to lower energy due to $^2E \rightarrow {}^4A_2$ was quenched at temperatures below 200 K, and that a new broader emission band appeared at *ca.* 14500 cm^{-1} (B-band) and increased in intensity with a decrease in the temperature. He explained this new emission band as being due to a transition within a new Cr(III) center associated with lattice defects. Probably a similar explanation would hold for $[Cr(NH_3)_6](ClO_4)_3$ and $[Cr(NH_3)_6][Co(CN)_6]$. That is, if we assume that, in our case, the bands 15020 and 15000 cm^{-1} correspond to the N-bands, the anomalous decrease in the intensity with the decrease in the temperature can be explained. Therefore, the bands at 14550 and 14470 cm^{-1} should be assigned to the B-bands. The fact that the B-bands in our case do not show any increase in intensity with a decrease in the temperature may be explained by the overlap of the decreasing lower-energy part of the N-band.

The temperature dependence of the emission intensity of equimolar mixtures of complex salts, $K_3[Co(CN)_6]$-$[Cr(NH_3)_6](ClO_4)_3$, are shown in Fig. 17. In these cases, the temperature dependence can be explained by a superposition of those of the component complexes.

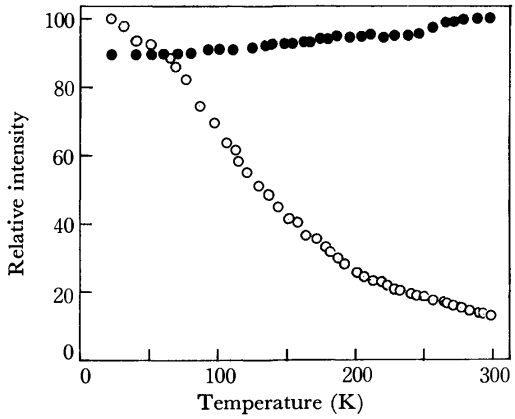

Fig. 17. Temperature dependence of the emission intensity of equimolar mixture of complex salts $[Cr(NH_3)_6](ClO_4)_3$-$K_3[Co(CN)_6]$ at 15040 cm^{-1}
●: excited with 435 nm light
○: excited with 313 nm light
Relative intensity of the emission spectra excited with 435 nm light was obtained by mornalizing its value at room temperature to 100, and relative intensity of the emission spectra excited with 313 nm light was obtained by normalizing its value at 20 K to 100.

The author wishes to express his gratitude to Professor Y. Kondo and Professor M. Nakahara for their stimulating suggestions and discussion during this work. He is also indebted to Dr. A. Kuboyama (The Government Chemical Industrial Research Institute) for the use of a Cary-14 spectrophotometer, and to Mr. A. Urushiyama for his help with the microscopic measurements. Special thanks are also due to Professor H. Kobayashi and Dr. I. Fujita (Tokyo Institute of Technology) for pre-prints of their reports. He also wishes to thank Professor Gene S. Lehman for his kindness in reading the original manuscript.

Phase Equilibria in the V_2O_3-VO_2 System at High Temperatures

Hozumi ENDO, Masataka WAKIHARA, Masao TANIGUCHI, and Takashi KATSURA*

Department of Synthetic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152
**Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received August 19, 1972)

The phase equilibria in the V_2O_3–VO_2 system were established at 1307 K by varying the oxygen partial pressures from 10^{-4} to 10^{-12} atm. Eight phases, V_2O_3, V_3O_5, V_4O_7, V_5O_9, V_6O_{11}, V_7O_{13}, V_8O_{15}, and VO_2, were observed under these experimental conditions. Vanadium sesquioxide has an extensive range of solid solutions at 1307 K. Also, the phase diagram and isobaric lines of oxygen partial pressure in the V_2O_3 phase were determined from 1307 to 1700 K on the basis of our present and previous studies. Quenching and thermogravimetric methods were applied under a controlled oxygen atmosphere. The oxygen partial pressures were determined by means of a solid electrolyte cell composed of $(ZrO_2)_{0.85}(CaO)_{0.15}$. The standard free energies of the oxidation of V_2O_3 to V_3O_5, of V_3O_5 to V_4O_7, of V_4O_7 to V_5O_9, of V_5O_9 to V_6O_{11}, of V_6O_{11} to V_7O_{13}, of V_7O_{13} to V_8O_{15}, and of V_8O_{15} to VO_2 were determined on the basis of the equilibrium oxygen partial pressure at 1307 K. The enthalpy and entropy data of the oxidations of V_2O_3 to V_3O_5 and of V_3O_5 to V_4O_7 were evaluated from the oxygen partial pressures on the basis of the present results and previous data.

Among early studies,[1-5] Andersson[4,5] investigated a series of compounds formulated by V_nO_{2n-1} (n: integer) at temperatures from 800 to 900 °C, and distinguished such compounds as varied in n value from 2 to 8. Kosuge *et al.*[6] found V_nO_{2n-1} phases in which the n value varied from 2 to 7 at 800 °C. Later, Okinaka *et al.*[7] presented a general-phase diagram of the V_2O_3–VO_2 system up to 1600 K based on their previous data.

In spite of a number of studies of the V_2O_3–VO_2 system at lower temperatures, only a few works have been reported about the thermochemical properties of the V_2O_3–VO_2 system at higher temperatures except for the V_2O_3 and VO_2 phases. Katsura and Hasegawa[8] reconfirmed the phase equilibria studied by Andersson,[4,5] and presented the standard free energies of the compounds which exist in the V_2O_3–VO_2 system at 1600 K. Wakihara and Katsura[9] reported thermodynamic data on the V_2O_3, V_3O_5, and V_4O_7 phases from 1400 to 1700 K. Recently, Anderson and Khan[10] and Okinaka *et al.*[7] studied the V_2O_3–VO_2 system up to 1423 K, and from 600 to 1200 °C, respectively, and reported some thermodynamic data of this system.

The present objectives are: (1) to obtain a detailed phase equilibria of the V_2O_3–VO_2 system at 1307 K in order to establish the phase diagrams at higher temperatures on the basis of both the present and previous studies,[8,9] and also to compare our results with the estimated phase diagrams proposed by several previous investigators; (2) to obtain linear free-energy equations at higher temperatures by determining three thermodynamic functions $\Delta G°$, $\Delta H°$, and $\Delta S°$, and (3) to ascertain the phase transition of V_6O_{11}, which had a different structure at 1600 K from that obtained by Andersson at around 1000 °C.

Experimental

The quenching and thermogravimetric methods were adopted in the present study. Since the details of the procedure have been previously described by Katsura and Muan[11] and by Katsura and Hasegawa,[8] only a brief description of the general procedure will be given here.

In the thermogravimetric method, a pre-reduced vanadium oxide sample was heated at 1307 K in an atmosphere of a CO_2 and H_2 mixture (ratio of 1: 1). The pellet thus obtained was suspended in a furnace by means of a Pt-40%Rh wire connected to a quick-weighing balance. The oxide had a chemical formula of $VO_{1.500}$ as this oxygen partial pressure and temperature. It was also found that the substantially stoichiometric V_2O_3 phase was stable at lower oxygen partial pressures than 10^{-12} atm. Thus, the weight of $VO_{1.500}$ prepared at an oxygen partial pressure of 10^{-12} atm was chosen as the reference weight standard.

In the quenching method, an oxide sample was heated at 1307 K and at a particular oxygen pressure until an equilibrium was attained between the gas and condensed phases. The sample was then quenched rapidly to the temperature of ice by burning away the thin platium wire with an electric current and by allowing the sample to drop into an ice-cooled tube. The sample thus obtained was used for identifying the phases present by means of the powder X-ray diffraction method and for determining the compositions by means of gravimetric analysis.

The atmospheres of the desired oxygen partial pressures were obtained by using mixtures of CO_2 and H_2. In the present study, the ratios of CO_2/H_2 were changed from 1.0 to 4000, and the flow rate in the furnace was set at 0.8 cm/sec. The actual partial pressures of oxygen in the gas mixture were stably and accurately measured by inserting a solid electrolyte cell, $(ZrO_2)_{0.85}$ $(CaO)_{0.15}$, into the furnace tube before a sample was suspended in it. The error of $\log P_{O_2}$ was estimated to be within ± 0.01. The details of the procedure have been described in the authors' previous papers.[8,9]

Results and Discussion

Phase Equilibria. The data obtained at 1307 K are summarized in Table 1 and are graphically illustrated in Fig. 1.

TABLE 1. EQUILIBRIA OF THE V_nO_{2n-1} PHASES AT 1307K

$-\log P_{O_2}$	CO_2/H_2	Value of x in VO_x	Phase
11.99 (±0.02)	10.0	1.500 (±0.001)	V_2O_3
10.50	40.6	1.503	V_2O_3
10.45	42.9	1.505	V_2O_3
10.38	45.4	1.506	V_2O_3
10.33	47.5	1.506	V_2O_3
10.32	48.3	1.509	V_2O_3
10.24	51.9	1.507	V_2O_3
10.18	54.9	1.510	V_2O_3
10.13	56.4	1.512	V_2O_3
10.04	61.8	1.512	V_2O_3
9.90	68.9	1.520	V_2O_3
9.85 (±0.02)	72	1.667 (±0.008)	V_3O_5
9.73	79	1.667	V_3O_5
8.00	430	1.667	V_3O_5
7.96	450	1.674	V_3O_5
7.93 (±0.02)	470	1.753 (±0.008)	V_4O_7
7.80	540	1.748	V_4O_7
7.42	870	1.747	V_4O_7
7.40	880	1.750	V_4O_7
7.39	910	1.757	V_4O_7
7.31	960	1.756	V_4O_7
7.19	1070	1.760	V_4O_7
7.11 (±0.02)	1130	1.798 (±0.008)	V_5O_9
7.00	1200	1.808	V_5O_9
6.66	1460	1.803	V_5O_9
6.55	1550	1.803	V_5O_9
6.49 (±0.05)	1610	1.830 (±0.008)	V_6O_{11}
6.26	1830	1.830	V_6O_{11}
5.91	2230	1.836	V_6O_{11}
5.80 (±0.06)	2370	1.859 (±0.008)	V_7O_{13}
5.63	2590	1.861	V_7O_{13}
5.57 (±0.06)	2680	1.918 (±0.008)	$V_8O_{15}+VO_2$
5.50	2770	1.901	$V_8O_{15}+VO_2$
5.32 (±0.06)	3100	1.997 (±0.008)	VO_2
4.86	4000	1.997	VO_2

The following eight phases were found to be stable under the present experimental conditions: V_2O_3, with a corundum-type structure and various V/O ratios; V_3O_5, with a monoclinic structure showing no significant variation in the V/O ratio; V_4O_7, V_5O_9, V_6O_{11}, V_7O_{13}, and V_8O_{15}, showing no significant variations in the V/O ratio, and VO_2, with a monoclinic rutil-type structure.

According to the previous paper,[8] the V_6O_{11} phase had a wide range of composition, from $VO_{1.833}$ to $VO_{1.905}$, and $VO_{1.905}$ was in equilibrium with the stoichimoetric VO_2. In addition, it is significant that the structural powder X-ray patterns of $VO_{1.834}$, $VO_{1.853}$, and $VO_{1.898}$ obtained at 1600 K, all of which compositions belong to the V_6O_{11} phase, were identical with each other, but definitely different from that of

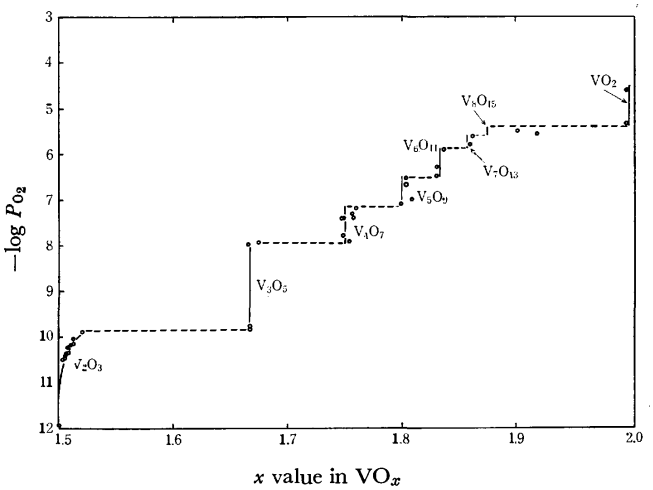

Fig. 1. Relationship between composition of oxide and oxygen partial pressure represented by logarithmic scale on the V_nO_{2n-1} phases at 1307 K.

the V_6O_{11} phase obtained by Andersson[4] at around 1000 °C. Under the present experimental conditions, the stoichiometric V_6O_{11} phase was in equilibrium with the stoichiometric V_7O_{13} phase at the oxygen partial pressure of $10^{-5.91}$ atm. Also, the structural powder X-ray pattern of the present V_6O_{11} phase was identical with that obtained by Andersson.[4] This leads to the conclusion that the transition point must be located at a temperature between 1307 and 1600 K.

The compositions of $VO_{1.901}$ and $VO_{1.918}$ in Table 1 correspond to a mixture of the V_8O_{15} and VO_2 phases. The single phase of V_8O_{15} could not be obtained under the present conditions, because the stable range of oxygen partial pressure to the V_8O_{15} phase was too narrow for us to obtain an equilibrated single phase of V_8O_{15} at the present temperature; therefore, no exact composition range of the V_8O_{15} phase was determined.

As is shown in Fig. 2, the homogeneous region and

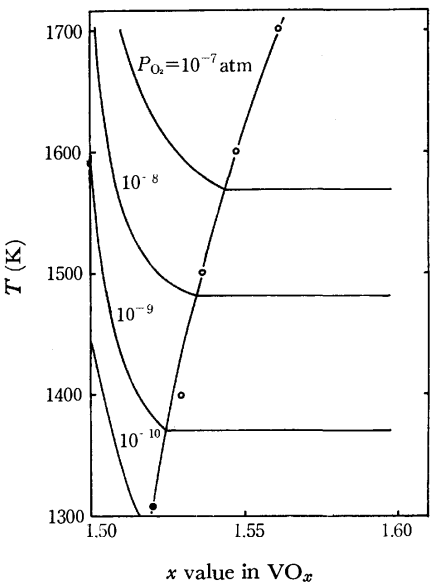

Fig. 2. Isobaric lines of oxygen partial pressure and the homogeneous range in the V_2O_3 solid solution at temperatures from 1300 to 1700 K.

the isobaric lines of the oxygen pressure relating to the change in composition and temperature in the V_2O_3 phase were determined from 1300 to 1700 K on the basis of the present study and previous results.[8,9] The compositions of the V_2O_3 phase were determined by applying the thermogravimetric method, while the compositions from V_3O_5 to VO_2 phase were obtained using the quenching method, because of the appreciable amounts of sublimation in these samples.

Andersson[4] pointed out a narrow homogeneity range in the V_3O_5 phase at 900 °C. On the other hand, Kosuge *et al.*[6,7] suggested a fairly wide range of variations in the V/O ratio in the phases of V_3O_5, V_4O_7, and V_6O_{11}, as well as that in the phase of V_2O_3 over a wide range of temperature. However, a wide homogeneous range was seen only in the phase of V_2O_3 at 1307 K. The results in the present study may be reliable because the samples were quenched in an equilibrium state. Also, in a preliminary experiment, no change in the composition was found in any phase between before and after quenching. By way of summarizing both the present and previous results,[8,9] the phase diagram of the V_2O_3–VO_2 system at higher temperatures is briefly given in Fig. 3; this diagram is somewhat different from that of Okinaka *et al.*[7]

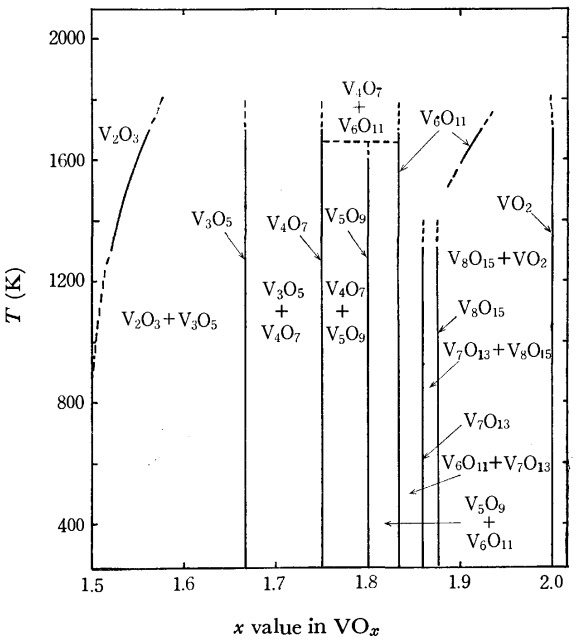

Fig. 3. Phase diagram of the V_2O_3–VO_2 system based on the present and previous data.[8,9]

Thermodynamic Properties of Oxidation. Since the oxygen partial pressure at which two oxide phases coexist had been determined, the standard free energy of the oxidation of each oxide could readily be estimated by means of the van't Hoff equation except for Reaction (1), as is shown in Table 2. It may be necessary for Reaction (1) to use a correction term because of the existence of homogeneity in the V_2O_3 phase. The method of calculating the standard free energy of the formation of a solid solution has been derived from the expansion of the Gibbs-Duhem equation described in previous papers.[8,9] In the present study, the correction term for the standard free energy was estimated to be about 21 cal. Since the establishment of a discrete oxygen partial pressure for the V_8O_{15} phase was impossible, the proper oxygen partial pressure for the stoichiometric V_8O_{15} phase was estimated (Table 2) on the basis of the powder X-ray pattern. The standard free energies of the oxidation of Reactions (1) to (7) are summarized in Table 2.

Table 2. Oxidation reactions and corresponding free energies at 1307K

Reaction	$-\log P_{O_2}$	Free energy $\Delta G°$ (cal)
$VO_{3/2}+1/12\ O_2=VO_{5/3}$(1)	9.88±0.05	−4955± 50
$VO_{5/3}+1/24\ O_2=VO_{7/4}$(2)	7.95±0.05	−1981± 30
$VO_{7/4}+1/40\ O_2=VO_{9/5}$(3)	7.15±0.07	−1069± 10
$VO_{9/5}+1/60\ O_2=VO_{11/6}$(4)	6.52±0.05	− 650± 5
$VO_{11/6}+1/84\ O_2=VO_{13/7}$(5)	5.86±0.12	− 417± 10
$VO_{13/7}+1/112\ O_2=VO_{15/8}$(6)	5.60±0.09	− 299± 5
$VO_{15/8}+1/16\ O_2=VO_2$(7)	5.41±0.17	−2022± 60
$VO_{3/2}+1/4\ O_2=VO_2$(8)		−11393± 170
[Mah *et al.*[12]]		−12604± 200]
[Coughlin[13]]		−10879±1000]
[Okinaka *et al.*[7]]		−11922± 100]

The summation of these reactions gives Reaction (8) and the corresponding free energy, shown in Table 2. The value thus obtained is compared with those obtained by Mah *et al.*,[12] by Coughlin[13] and by Okinaka *et al.*[7] in the same table.

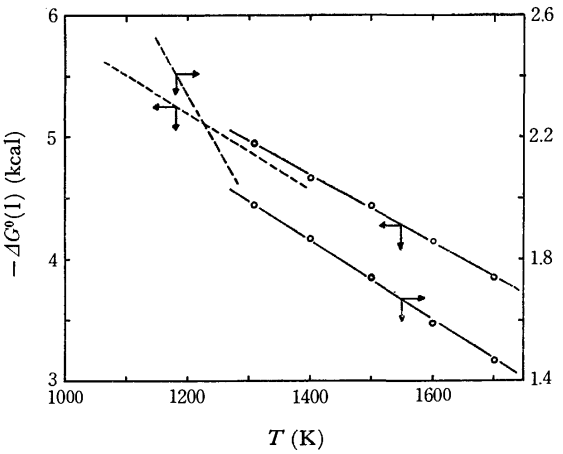

Fig. 4. Free energy change *vs.* temperature of reactions (1) and (2). Solid lines indicate our data, while dashed lines are derived from the data of Okinaka *et al.*[7]

The values of $\Delta G°(1)$ and $\Delta G°(2)$ are plotted against the temperatures from 1307 to 1700 K in Fig. 4, on the basis of the present and our previous data,[9] together with the relationships of Okinaka *et al.*[7] It may be expected from Fig. 4 that the linear free-energy equations for Reaction (1) are in pretty good agreement with each other, but for Reaction (2) there is a slight difference in slope. The standard entropy changes in Reactions (1) and (2) were evaluated from the slope

12) A. D. Mah and K. K. Kelley, *U. S. Bur. Mines Rept. Invest.*, (1961), p. 5858.
13) J. P. Coughlin, *U. S. Bur. Mines, Bulletin*, **542**, (1954).

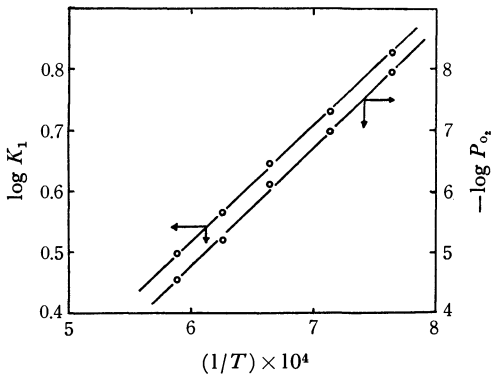

Fig. 5. log K_1 corresponding to Eq. (1) and equilibrium oxygen partial pressure in Eq. (2) *vs.* reciprocal absolute temperature, $1/T$.

in Fig. 4. The least-squares method was used to estimate the standard entropy changes of the two reactions. Also, the entropy changes of Reactions (1) and (2) were evaluated by means of the van't Hoff equation. The logarithmical equilibrium constant of Reaction (1) was calculated from the following equation:

$$\log K_1 = \log \frac{P_{O_2}(1)}{a_{V_2O_3}} = -\frac{\Delta G^\circ(1)}{RT}$$

The relationship between $\log K_1$ and $1/T$ was substantially linear, as is illustrated in Fig. 5. Hence, the following equation may be deduced from the above equation:

$$\frac{\mathrm{d}\log K_1}{\mathrm{d}(1/T)} = -\frac{\Delta H^\circ(1)}{2.303R}$$

where $\Delta H^\circ(1)$ and R are the heat of Reaction (1) and the gas constant respectively. The heat of Reaction (2), $\Delta H^\circ(2)$, may be estimated from this reaction:

$$\frac{\mathrm{d}(-\log P_{O_2}(2))}{\mathrm{d}(1/T)} = -\frac{\Delta H^\circ(2)}{2.303R}$$

The equilibrium constant of Reaction (2), K_2, is equal to the equilibrium oxygen partial pressure ($P_{O_2}(2)$).

TABLE 3. ESTIMATED RESPECTIVE THERMODYNAMIC FUNCTIONS AT TEMPERATURES FROM 1300 TO 1700 K

$\Delta H^\circ(1) = -8310$	(± 230)	(cal)
$\Delta H^\circ(2) = -3716$	(± 250)	(cal)
$\Delta S^\circ(1) = -2.73$	(± 0.30)	(e.u.)
$\Delta S^\circ(2) = -1.32$	(± 0.13)	(e.u.)
$\Delta G^\circ(1) = -8310+2.73T$	(± 630)	(cal)
$\Delta G^\circ(2) = -3716+1.32T$	(± 430)	(cal)

The respective entropy and enthalpy data are shown in Table 3. The linear equations of the standard free energies of Reactions (1) and (2) were estimated by using the entropy and enthalpy data obtained above over the temperature range from 1307 to 1700 K. The equations are also listed in the last two lines of Table 3.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2090—2092 (1973)

Analysis of Metals by Solid-Liquid Separation. Spectrophotometric Determination of Cadmium by Extraction of Cadmium Salt of Oxine with Melted Naphthalene

Taitiro FUJINAGA,* Masatada SATAKE, and Tatsuo YONEKUBO

*Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
Faculty of Engineering, Fukui Universtiy, Fukui 910

(Received September 22, 1972)

A method is described for the spectrophotometric determination of a minute quantity of cadmium. A cadmium complex stable at 90 °C is easily extracted with melted naphthalene. The resulting mixture of cadmium complex and naphthalene is dissolved in dimethylformamide and absorbance of the solution is measured at 400 nm. Effects of pH, amounts of oxine, naphthalene and diverse salts are given.

Oxine (8-hydroxyquinoline) reacts with various metal ions to form stable complexes which have been widely used for spectrophotometric determination of metal ions by extraction from aqueous solution into organic solvents such as chloroform or benzene. However, this method cannot be applied to metals such as zinc, magnesium and cadmium, since their salts of oxine are insoluble in organic solvents; zinc and magnesium salts extracted are not very soluble, those of cadmium and beryllium are hardly soluble.

We found that most metal salts of oxine in aqueous solution can be easily extracted with melted organic compounds such as naphthalene and diphenyl as in the case of liquid-liquid extraction. The method was named "analysis by solid-liquid separation", and applied to the spectrophotometric determination of copper,[1] zinc,[2] and magnesium.[3] It is particularly convenient for the determination of metals whose salts of oxine are strongly hydrated. The method is also applicable to the determination of nickel[4] and palla-

dium[5] using dimethylglyoxime as the chelating reagent.

Cadmium was chosen in the present work, and its salt of oxine was extracted completely with melted naphthalene from aqueous solution at pH above 5.5. The solidified naphthalene crystals containing the metal salt of oxine were separated and dissolved in dimethylformamide, the absorbance of the solution being measured at 400 nm against the reagent blank. Effects of diverse ions were studied. The method seems to be promising since the extract with naphthalene has adequate solubility, colour intensity and stability in dimethylformamide. Cadmium salt of oxine is insoluble in organic solvents except dimethylformamide.

Experimental

Reagents. Reagents of analytical grade were used without purification. Water used was redistilled after deionization.

Standard cadmium solution, 1.997×10^{-3} g per ml: Prepared by dissolving 0.99855 g of cadmium metal (purity 99.999%) in 3 ml of concentrated nitric acid, diluted to 500 ml with water. More dilute cadmium solution (19.97 μg per ml) was prepared as required.

Oxine solution, 1%: Prepared by dissolving 1.0 g of oxine in glacial acetic acid (2 ml) on a water bath, diluted to 100 ml with water.

Alkali metal salt solutions, 10 mg of the corresponding salt per ml: Prepared by dissolving 1.000 g of the salt in water, diluted to 100 ml.

Other metal salt solutions, 1 mg of the individual salt per ml: Prepared by dissolving 0.100 g of each salt in water. In some cases, a small amount of acid was added to prevent hydrolysis.

Apparatus. A Hitachi Model 124 spectrophotometer was employed for the absorbance measurements with matched 10 mm glass cells. A Toa-Denpa HM-6A pH meter equipped with combined glass and calomel electrodes was used for all pH measurements.

Procedure. Pipet a sample solution containing 10—160 μg of cadmium into an 80 ml tightly stoppered Erlenmeyer flask, and dilute with water to *ca.* 30 ml. Add 1.5 ml of 1% oxine and adjust the pH of the solution to 6—10 with 0.5—1.0 N ammonia. Heat the flask on a water bath to precipitate cadmium salt of oxine completely. Add 2.0 g of naphthalene and warm the flask at 90 °C until naphthalene melts completely. Remove the flask from the bath and shake vigorously. Naphthalene will be solidified forming fine crystals suspended in the solution. Warm the flask again and melt slowly the fine crystals. Cool the mixture to room temperature. Larger crystalline deposits will grow up in the solution. Filter the mixture and wash the solidified deposits on the filter paper with water. Remove the water from the filter paper with a separate piece of paper. Spread the yellow deposits on a dry filter paper for air-drying. Transfer them to a volumetric flask and add dimethylformamide so that the final volume becomes 10 ml. Shake well and measure the absorbance of the solution in a 10 mm cell against the reagent blank. The amount of cadmium can be determined using a calibration curve.

Results and Discussion

Absorption Spectra. Cadmium in the test solution containing 99.86 μg of cadmium was extracted with melted naphthalene as complex salt of oxine at pH *ca.* 7.5. The mixture of cadmium-oxine complex and naphthalene was dissolved in dimethylformamide, and the absorbance of the solution was measured at various wavelengths between 360 and 470 nm. The result is shown in Fig. 1. Curves 1 and 2 show the absorption spectra of the reagent blank and the complex, respectively. Curve 3 shows the absorption spectra of the complex against the reagent blank. The curve has a maximum at 400 nm, beyond which the absorbance decreases gradually and becomes insignificant beyond 470 nm. Wavelength 400 nm was chosen for the measurement.

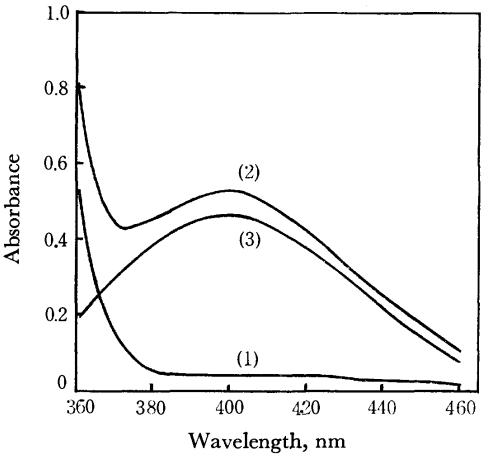

Fig. 1. Absorption spectra of oxine and cadmium oxinate in naphthalene-dimethylformamide.
Cadmium: 99.86 μg, 1% oxine: 1.5 ml, pH: 7.5, naphthalene: 2.0 g, (1) Reagent blank *vs.* water, (2) Cadmium oxinate *vs.* water, (3) Cadmium oxinate *vs.* reagent blank.

Effect of pH. The pH of a solution containing 99.86 μg of cadmium and 1.5 ml of 1% oxine solution was carefully controlled to 4—10 with dilute ammonia. The solution was heated on a water bath till the precipitate of complex salt between cadmium and oxine appeared, and the complex salt was extracted with melted naphthalene. The absorbance of the mixture of the salt and naphthalene in dimethylformamide was

5) T. Fujinaga, M. Satake, and T. Yonekubo, *Talanta*, **19**, 689 (1972).

measured. Curves 1 and 2 show respectively the effect of pH on the absorbance of the reagent blank and on that of the salt in the solution against water. Curve 3 shows the difference in the absorbances between the reagent blank and the salt at each pH value. We see that extraction starts from pH 4.0, increases sharply with increasing pH and reaches the maximum, then becomes constant beyond pH 6.0. Thus the pH range 6—10 is suitable.

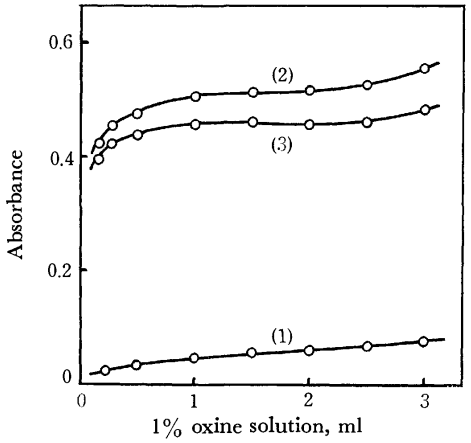

Fig. 3. Effect of oxine concentration on absorbance
Cadmium: 99.86 μg, pH: 7.5, naphthalene: 2.0 g, wavelength: 400 nm, (1) Reagent blank *vs.* water, (2) Cadmium oxinate *vs.* water, (3) Cadmium oxinate *vs.* reagent blank.

Effect of Oxine Concentration and Amount of Naphthalene. Various amounts of oxine were added to the solution containing 99.86 μg of cadmium at pH about 7.5, and the effect of variation in the oxine concentration on the absorbance of the complex salt has been studied. The absorbance increased with increasing amounts of oxine up to 1 ml of 1% oxine solution, whereas addition of 1—2 ml of it gave difinite absorbance, and the absorbance increased again when more than 2 ml was added. Thus, 1.5 ml of oxine solution was found to be the proper amount. On the other hand, addition of 0.5—3.0 g of naphthalene gave almost no difference.

Effect of Shaking Time and Stability. A mixture containing 99.86 μg of cadmium and 1.5 ml of 1% oxine solution was heated till larger particles of the precipitate of the complex salt were formed. Extraction of the salt was then carried out with melted naphthalene by vigorous shaking, and the absorbance of the extract in the dimethylformamide solution was measured. It was observed that the speed of extraction was very rapid and the salt was easily extracted from aqueous solution merely by contact with melted naphthalene. For the sake of good reproducibility, the precipitate of the salt should be digested sufficiently before extraction with naphthalene. The extracted salt was very stable in naphthalene-dimethylformamide solution as well as in naphthalene, and the absorbance remained unchanged for a long time.

Calibration Curve, Sensitivity and Reproducibility. A linear relationship was obtained between the concentration of cadmium and the absrobance in the range of 10—160 μg of cadmium per 10 ml of dimethylformamide. The molar absorptivity of the extracted complex salt was found to be 5.45×10^4 l·mol^{-1}·mm^{-1} at 400 nm and the sensitivity for the absorbance of 0.001 was 0.00263 μg cadmium per cm^2.

An average of ten determinations on 99.86 μg of cadmium gave a mean absorbance of 0.484 with a standard deviation of 0.0041 (relative standard deviation, 0.85%).

Table 1. Effect of diverse salts

Salts	Added (mg)	Absorbance
—	—	0.484
NaF	50	0.488
	100	0.547
KH_2PO_4	50	0.479
	100	0.484
$Na_2HPO_4\cdot12H_2O$	50	0.477
	100	0.484
NaCl	50	0.471
	100	0.475

Mohr's salt	0.25	0.713
Potassium alum	0.26	0.715
Iron alum	0.10	1.159

Effect of Diverse Ions. Solutions containing 99.86 μg of cadmium were prepared with varying amounts of salt and the determination of cadmium was performed. Some results are given in Table 1. One hundred milligrams of the following salts gave no interference: NaCl, KCl, Na_2SO_4, KH_2PO_4, $Na_2HPO_4\cdot12H_2O$, CH_3COONH_4, $Na_2C_2O_4$, sodium tartrate and sodium citrate. Fifty milligrams of sodium fluoride gave no interference, but 100 mg of it did. Sodium acetate and ammonium chloride gave considerable interference, while even a small amount of EDTA gave serious interference. Many metal ions reacting with oxine to form complex salt at pH 4—10 interfered with the determination. Of the metal salts tested, the following gave interference: $CuSO_4\cdot5H_2O$, $Co(NO_3)_2\cdot6H_2O$, $MnCl_2\cdot4H_2O$, $ZnCl_2$, $Ni(NO_3)_2\cdot6H_2O$, Mohr's salt, potassium alum, iron alum. Magnesium and calcium gave no interference when pH was adjusted to *ca.* 6.5 with ammonium acetate and dilute ammonia or with phosphate buffer. Copper and iron can be removed by oxine-chloroform extraction at pH 3.5—4.0. The interference should be completely suppressed before extraction by some methods such as ion-exchange separation,[6] addition of masking reagent or pH adjustment.[7]

Reductions of Cobalt(III) Complexes by Iron(II) Chelates. I. The Kinetics and Mechanisms of the Reductions of Acidopentaamminecobalt(III) Complex Ions by Iron(II) Chelates of Nitrilopolycarboxylic Acids

Yoshimi KURIMURA

Chemical Laboratory, College of General Education, Ibaraki University, Mito 310

(Received October 24, 1972)

Kinetic studies have been made of the reactions of $FeEDTA^{2-}$ with complex ions of the $Co(NH_3)_5X^{2+}$ ($X=F^-$, Cl^-, Br^-, I^-, NO_3^-, NCS^-, and N_3^-) type. The pattern of reactivity suggests that $FeEDTA^{2-}$ reacts with $Co(NH_3)_5X^{2+}$ mainly through an innersphere mechanism. The variation in the rate of the reactions of $Fe^{II}Z_m^-$ ($Z=$EDTA, CyDTA, EDTA-OH, and DTPA), in which the Z ligand is varied, with $Co(NH_3)_5Cl^{2+}$ can be explained in terms of the steric effect, the charge effect, and the stabilization effect.

The ferrous-ion reductions of cobalt(III) complexes of several types have been investigated. However, rate studies of only a relatively small number of redox reactions between iron(II)–nitrilopolycarboxylate complex ions and metal complex ions have been reported. The reactions of $FeEDTA^{2-}$–$MnCyDTA^-$,[1,2] $FeEDTA^{2-}$–$FeCyDTA^-$,[1] and $CrEDTA^{2-}$–$FeEDTA^-$ [3] are known to be rapid reactions, and the reductions of Co(III)-chelate by Fe(II)-chelates such as $FePDTA^{2-}$–$CoEDTA^-$ [3] and $FePDTA^{2-}$–$CoCyDTA^-$,[3] to be relatively slow reaction. All of the above reactions seem to proceed *via* the outer-sphere activated states.[1,3] On the other hand, the inner-sphere nature of the reactions was suggested in the $FePDTA^{2-}$ reductions of RX^{2+} ($R=Co(NH_3)_5$, $X=Cl^-$, Br^-, N_3^-, and NCS^-).[3]

The pattern of reactivity for the reduction of RX^{2+} by several reducing agents has been studied: the dependence of the rate for the reductions of RX^{2+} by a given reductant would give information about whether the mechanism of the electron-transfer reaction is of outer- or inner-sphere type, though it is a less direct manner.

This article will describe our investigations of the kinetics of the $Fe^{II}EDTA$ reductions of RX^{2+} and the $Fe^{II}Z$ ($Z=$EDTA, CyDTA, EDTA-OH, and DTPA) reductions of RCl^{2+}. The observed rate data will be explained in terms of the effects of the charge, the steric hindrance of $Fe^{II}Z$, and the free energy change from the ferrous to the ferric chelate.

Experimental

Materials. The cobalt(III) complexes of the perchlorate form, $[RF](ClO_4)_2$,[5] $[RCl](ClO_4)_2$,[6] $[RBr](ClO_4)_2$,[7] $[RI](ClO_4)_2$,[8] $[RNO_3](ClO_4)_2$,[6] $[RNCS](ClO_4)_2$,[9] and $[RN_3](ClO_4)_2$[10] were prepared according to the published procedures. The identity and purity of the cobalt(III) products were confirmed analytically and spectrophotometrically. The wavelengths and molar absorption coefficients of the first absorption maximum of the cobalt(III) complexes prepared are summarized in Table 1.

Table 1. Spectral data ($R=Co(NH_3)_5$)

Complex	λ_{max}[a,b] nm	ε_{max}[b]
$[RF](ClO_4)_2$	509 (510)	44 (44)

$[RNO_3](ClO_4)_2$	501 (500)	58 (57)
$[RNCS](ClO_4)_2$	496 (497)	191 (192)
$[RN_3](ClO_4)_2$	518 (520)	260 (265)

a) Wavelength for first absorption maximum.
b) Values in parentheses are from the literature.[4]

The preparation of the ferrous perchlorate solution and the determinations of the concentrations of hydrogen and perchlorate ions in the solution were carried out by methods similar to those described previously.[11] The disodium salts of the ethylenediaminetetraacetic acid, cyclohexanediaminetetraacetic acid, hydroxyethylethylenediaminetriacetic acid, and diethylenetriaminepentaacetic acid used were Dotite reagents and were used without further purification. The ferrous chelate solutions were prepared by mixing a deaerated solution of ferrous perchlorate and a slight excess of a deaerated solution of a chelating agent which had been prepared by neutralizing a solution of the chelating agent with a dilute sodium hydroxide solution. The solutions of the cobalt(III) complexes were prepared by dissolving weighed amounts of a cobalt(III) complex into an acetate buffered solution. The ionic strength of the reaction mixture was maintained at 0.50 by the addition of sodium perchlorate. All the reactant solutions were prepared under a nitrogen atmosphere. For all the reactions except for $RNCS^{2+}$ it was necessary to use a stopped-flow technique. The spectrophotometers used

were a Yanagimoto Model SPS-1 stopped-flow apparatus and a Hitachi Model 124 recording spectrophotometer. The reactions were followed under pseudo-first-order conditions in which the concentration of the ferrous chelate was at least 10 times greater than that of the Co(III) complex. The reactions were monitored by following the variation in the absorbance of the reaction mixture in the vicinity of the first absorption maximum of the Co(III) complex. The pH value of the solution was measured by means of a Hitachi-Horiba F-5 type pH meter. The hydrogen-ion concentration of the reaction mixture was calculated using the relationship: $-\log[H^+]=pH-0.10$. In this calculation, the activity coefficient of the hydrogen ions was estimated to 0.8 at $\mu=0.5$ from the data obtained by Kielland ($f_{H^+}=0.83$ at $\mu=0.2$).[12]

Results

The observed rate constant, k_{obsd}, defined by:

$$-d[Co(III)]/dt = k_{obsd}[Co(III)][Fe(II)] \quad (1)$$

was obtained from the slope of log (A_t-A_∞) *vs.* the time plot (A_t is the absorbance at time t, and A_∞, that at the time the reaction was completed). The plots were linear for at least for 2 half-lives in all cases The initial reactant concentrations were generally varied over at least a two-fold range, and a first-order dependence on the reactants was confirmed for the Co(III) and Fe(II).

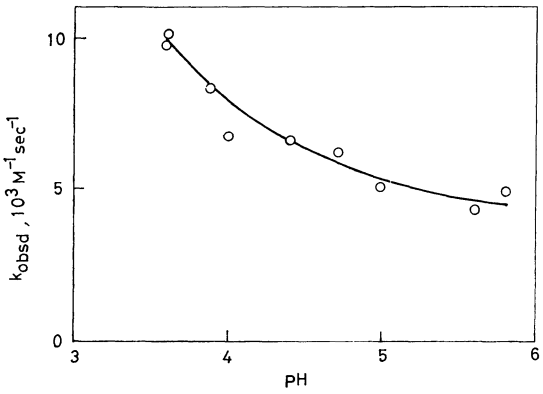

Fig. 1. Rate profile for the reduction of $Co(NH_3)_5Cl^{2+}$ by $Fe^{II}EDTA$.
$[Co(NH_3)_5Cl^{2+}]=8-10\times10^{-4}$M, $[Fe^{II}EDTA]=1.0\times10^{-2}$M, $\mu=0.50$, 25 °C.

Reduction of $Co(NH_3)_5Cl^{2+}$ by $Fe^{II}EDTA$. The values of k_{obsd} for the $Fe^{II}EDTA$ reduction of RCl^{2+} depend on the hydrogen-ion concentration. The rate profile for the reaction is shown in Fig. 1. The variation in the k_{obsd} with the pH indicates the following competition reactions:

$$Co(NH_3)_5Cl^{2+} + FeEDTA^{2-} \xrightarrow{k_n} Co(II) + Fe(III) \quad (2)$$

$$Co(NH_3)_5Cl^{2+} + FeHEDTA^{-} \xrightarrow{k_p} Co(II) + Fe(III) \quad (3)$$

The $FeHEDTA^-$ is the protonated species of Fe^{II}-EDTA, and k_n and k_p are the rate constants for the (2) and (3) reactions respectively. The amounts of free ferrous ion can be neglected under the present experimental conditions. The concentration of Fe(II) can be expressed by:

$$[Fe(II)] = [FeEDTA^{2-}] + [FeHEDTA^{-}] \quad (4)$$

The rate equation derived from Eqs. (2) and (3) is:

$$\text{Rate} = \frac{k_n+k_pK_{FeHY}[H^+]}{1+K_{FeHY}[H^+]}[Co(III)][Fe(II)] \quad (5)$$

where K_{FeHY} is the formation constant for the protonated ferrous chelate. From a comparison of Eqs. (1) and (5), we obtain:

$$k_{obsd}(1+K_{FeHY}[H^+]) = k_n + k_pK_{FeHY}[H^+] \quad (6)$$

The plots of $k_{obsd}(1+K_{FeHY}[H^+])$ *vs.* $[H^+]$ form straight lines, and the slope and intercept of the line give the values of k_p and k_n respectively if the redox reaction can be expressed by the (2) and (3) reactions. The relationship between $k_{obsd}(1+K_{FeHY}[H^+])$ *vs.* $[H^+]$ for the $Fe^{II}EDTA$ reduction is shown in Fig. 2. The value of K_{FeHY} used was $10^{2.8}$ [13]; this value was obtained under conditions of $\mu=0.1$ and 25 °C, and was used without any correction. The values of k_n and k_p, as calculated from the intercept and slopes of the straight line in Fig. 2, are 4.7×10^3 $M^{-1}sec^{-1}$ and 3.5×10^4 $M^{-1}sec^{-1}$ respectively at 25 °C and $\mu=0.50$.

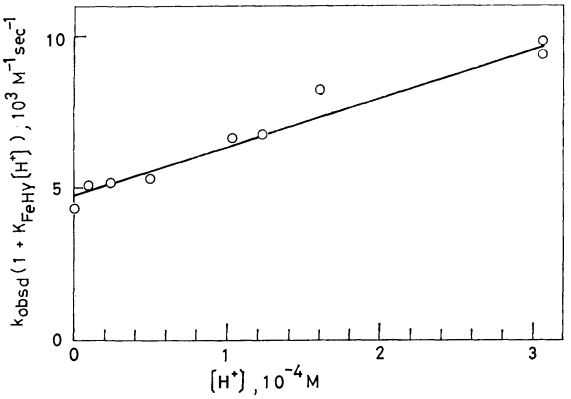

Fig. 2. Plots of $k_{obsd}(1+K_{Fe^{II}HY}[H^+])$ *vs.* $[H^+]$ for the reduction of $Co(NH_3)_5Cl^{2+}$ by $Fe^{II}EDTA$.

Reductions of RX^{2+} ($X=F^-$, Cl^-, Br^-, I^-, NO_3^-, NCS^-, and N_3^-) by $FeEDTA^{2-}$. The rate constants for the $FeEDTA^{2-}$ reduction of RX^{2+} were obtained in the higher pH region (pH=4—5). In this pH region, the protonated species of the ferrous chelate is less important; the only species to be considered is the $FeEDTA^{2-}$. The second-order rate constants obtained are shown in Table 2.

TABLE 2. RATE CONSTANTS FOR THE $FeEDTA^{2-}$ REDUCTION OF PENTAAMMINECOBALT(III) COMPLEXES AT 25 °C AND $\mu=0.50$

Complex ($R=Co(NH_3)_5$)	k, $M^{-1}sec^{-1}$
RF^{2+}	6.0×10^3

12) J. Kielland, *J. Amer. Chem. Soc.*, **59**, 1675 (1937).

13) A. Ringbom, "Complexation in Analytical Chemistry," John Wiley and Sons, New York, 1963.

Reduction of $Co(NH_3)_5Cl^{2+}$ by $Fe^{II}Z^{m-}$ (Z=CyDTA, EDTA-OH, and DTPA). In the Fe^{II}CyDTA–RCl^{2+} and Fe^{II}EDTA-OH–RCl^{2+} reactions, the only predominant species of the ferrous chelate are the normal ones, $FeCyDTA^{2-}$ and $FeEDTA\text{-}OH^{-}$ respectively, under the experimental conditions employed. Therefore the second-order rate constants for these two reactions can simply be obtained from the rates evaluated in the pH region between 4 and 5. The rate constants thus obtained are shown in Table 3.

Table 3. Rate constants for the $FeCyDTA^{2-}$ and $FeEDTAOH^{-}$ reductions of $Co(NH_3)_5Cl^{2+}$ at 25 °C and μ=0.50

Reductant	pH	k, $10^3 M^{-1} sec^{-1}$	Average value ($M^{-1} sec^{-1}$)
$FeCyDTA^{2-}$	4.0	2.6	
	4.4	2.9	
	5.0	2.9	2.9×10^3
$FeEDTAOH^{-}$	4.0	4.4	
	4.5	4.5	
	5.0	4.4	4.4×10^3

The rate constants for the $FeHDTPA^{2-}$–RCl^{2+} and $FeDTPA^{2-}$–RCl^{2+} reactions were obtained in the manner employed in the case of the Fe^{II}EDTA–RCl^{2+} reaction. The value of $K_{Fe^{II}HL}$ used for the calculation was $10^{5.4}$ (μ=0.1 and 25 °C).[13] The second-order rate constants were 4.8×10^3 $M^{-1} sec^{-1}$ for $FeHDTPA^{2-}$ and $\sim10^2$ $M^{-1} sec^{-1}$ for $FeDTPA^{3-}$. The rate constant for the $FeDTPA^{3-}$ may be less accurate, since the intercept of the straight line of the $k_{obsd}(1+K_{MHL}[H^+])$ *vs.* $[H^+]$ plot is relatively small.

Discussion

The relative rates for the reductions of Co(III)-pentaammine complexes by several reductants are shown in Table 4. It may be possible to assume that the reductions of RX^{2+} by Cr^{2+} [18] and, perhaps, by Fe^{2+} proceed *via* the inner-sphere mechanism, and those by $Cr(bipy)_3^{2+}$ [4] and $Ru(NH_3)_6^{2+}$,[19] *via* the outer-sphere mechanism. If we accept the suggestion that Cr^{2+} reacts by means of a bridging mechanism,[19] is possible to suggest that the ligand, X, acts as the bridge in the Fe^{II}EDTA reductions of RX^{2+}. Furthermore, the large value of $k_{N_3^-}/k_{NCS^-}$ ($=5.5\times10^5$), which can often be used to distinguish between an inner-sphere and an outer-sphere mechanism,[20] also indicates the inner-sphere nature of the reactions in the present system. Since the $Fe^{II}Z^{m-}$ complex ion is labile for the ligand exchange, one of the coordinated positions of the chelate could easily be open, so a bridged intermediate of the $[R\cdot X\cdot FeZ]^{(n-m)+}$ form might be formed prior to electron-transfer.

In the cases of $X=F^-$, Cl^-, Br^-, and I^-, the variation in the rate constants for FeY^{2-} ($Y=EDTA^{4-}$) shows the same tendency as Fe^{2+}; that is, the reactivity of the FeY^{2-} toward the RX^{2+} shows an "inverted order" of bridging efficiency:[18] $RF^{2+}>RCl^{2+}>RBr^{2+}>RI^{2+}$.

The relative rates for the reduction of RCl^{2+} by several ferrous chelate species are presented in Table 5. The results show that the decreasing order of the reactivities of the ferrous chelates is: $FeHEDTA^{-}>FeHDTPA^{2-}=FeEDTA^{2-}>FeEDTA\text{-}OH^{-}>FeCyDTA^{2-}>FeDTPA^{3-}$. This order shows that the rate does not depend so much on the charge of the chelate. The decreasing order of the values of "relative stabiliza-

TABLE 5. COMPARISON OF REACTIVITY FOR FeZ^{m-} REDUCTIONS OF $Co(NH_3)_5Cl^{2+}$ AT 25 °C AND $\mu=0.50$

Complex	Relative rate
$FeEDTA^{2-}$	1.0
$FeCyDTA^{2-}$	0.62
FeEDTA-OH$^-$	0.94
$FeDTPA^{3-}$	0.02
FeHEDTA$^-$	6.0
$FeHDTPA^{2-}$	1.0

TABLE 6. VALUES OF log $K_{Fe^{III}Z}/K_{Fe^{II}Z}$ OF Fe(III)–Fe(II) REDOX COUPLES

Redox couple	log $K_{Fe^{III}Z}/K_{Fe^{II}Z}$ (R_s)[a]
$FeEDTA^-/FeEDTA^{2-}$	0.25
FeEDTA-OH/FeEDTA-OH$^-$	0.21
$FeCyDTA^-/FeCyDTA^{2-}$	0.21
$FeDTPA^{2-}/FeDTPA^{3-}$	0.24
$FeEDT^-/FeHEDTA^-$ [b]	0.95
$FeDTPA^{2-}/FeHDTPA^{2-}$ [b]	0.71

a) The values are calculated using formation constants estimated at 25 °C and $\mu=0.1$.[13]

tion," which is expressed by R_s, in Table 6 is: $FeHEDTA^- > FeHDTPA^{2-} > FeEDTA^{2-}$ $FeDTPA^{3-} > FeEDTA\text{-}OH^- = FeCyDTA^{2-}$. For the $FeHEDTA^-$ and $FeHDTPA^{2-}$ reductions, the predominant species of the oxidized forms which are formed in the solutions are normal ferric chelates, $Fe^{III}EDTA^-$, and $Fe^{III}DTPA^{2-}$ respectively under the experimental conditions employed. Therefore, the values of R_s for $FeHEDTA^-$ and $FeHDTPA^{2-}$ are evaluated on the basis of the change from a protonated ferrous chealte to a normal ferric chelate. The decreasing order of reactivity agrees with that of R_s except for $FeDTPA^{3-}$. Such a correspondence between the order of reactivity and that of R_s suggests that one of the most important factors controlling the rates of the ferrous chelate reductions of RX^{2+} is the effect of the relative stabilization (stabilization effect). This indicates that there is some correlation between ΔF and ΔF^* for the reaction. The smaller reactivity for $FeDTPA^{3-}$ may be due to the steric hindrance of the bulky ligand.

The author wishes to express his thanks to Mr. Kosaburo Ohashi, Miss Ikuko Sekine, and Miss Chiyoko Endo for their help in part of the measurements and in the syntheses of the complexes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2096—2101 (1973)

Some β-Diketone Chelate Complexes with Uranium(IV), Thorium(IV), and Cerium(IV). Preparation and IR Spectra

Tetsuhiko YOSHIMURA,* Chie MIYAKE, and Shosuke IMOTO

Department of Nuclear Engineering, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received August 9, 1972)

The tetrakis β-diketonates of U(IV), Th(IV), and Ce(IV) with acetylacetone, trifluoroacetylacetone, hexafluoroacetylacetone, benzoylacetone, dibenzoylmethane, benzoyltrifluoroacetone, and thenoyltrifluoroacetone have been prepared and their infrared spectra measured in the range 4000—200 cm^{-1}. In every chelate, a strong, broad and metal sensitive band related to the M–O stretching mode was found in the 200—250 cm^{-1} region.

Many β-diketones coordinate to various metal ions as a bidentate ligand, generally forming stable chelates. Acetylacetone and thenoyltrifluoroacetone are well-known as extraction reagent for various metal ions and as metal indicator in chelatometry. The β-diketonato chelates of actinoid and lanthanoid elements are of particular interest, since they are used as solvent extraction reagent for the actinoid elements in the reprocessing of spent fuel and the separation of actinoid elements from fission products.[1] The possibility of their use as nuclear fuel with organic moderator has been suggested. Most β-diketonato chelates are so volatile that they are often purified by means of sublimation, and the volatility of the β-diketonates of uranium has been investigated from the view point of isotope separation.[2]

The measurements of the infrared spectra for tetrakis β-diketonates of uranium(IV), thorium(IV), and cerium(IV) have been carried out for acetylacetonates and thenoyltrifluoroacetonates.[3,4] Fay and Pinnavaia[3] measured the IR and Raman spectra of $M(acac)_4$ (M=Zr(IV), Hf(IV), Ce(IV), and Th(IV)) and assigned the IR absorption bands in the 1600—500 cm^{-1} region according to the assignments for the

β-diketonato chelates with transition metal ions reported by Behnke and Nakamoto.[5] They also assigned some metal sensitive bands in the 500—70 cm^{-1} region to the M–O band. The IR study for the effect of replacement of the methyl groups of the acetylacetonates in the β-diketonato chelates with Cu(II) and Ni(II) has been made by Nakamoto *et al.*[6]

This paper deals with the preparation of several tetrakis-β-diketonates of U(IV), Th(IV), and Ce(IV) with acetylacetone, trifluoroacetylacetone, hexafluoroacetylacetone, benzoylacetone, dibenzoylmethane, benzoyltrifluoroacetone and thenoyltrifluoroacetone and their IR spectra in the range 4000—200 cm^{-1} together with the substituent effects on the M–O bond.

Experimental

Preparation. Hydrochloric acid (6N) solution of U(IV) (supplied by Power Reactor and Nuclear Fuel Corporation, Tokai works) was used for preparation of uranium(IV) chelates. The solution contained 302.8 g U(IV) per liter. Thorium tetrachloride hydrate and cerium(IV) ammonium sulfate tetrahydrate, both of GR grade, were used for the preparation of thorium(IV) and cerium(IV) chelates, respectively. All the ligands and other reagents were of GR grade and used without further purification. As the U(IV) ion in solution is particularly sensitive towards oxidation, the syntheses and purification of U(IV) chelates were carried out in a dry box filled with argon or nitrogen gas. The seven β-diketonato ligands used are denoted by: acetylacetonato, acac; trifluoroacetylacetonato, tfac; hexafluoroacetylacetonato, hfac; benzoylacetonato, bzac; dibenzoylmethanato, dbm; benzoyltrifluoroacetonato, bfac; thenoyltrifluoroacetonato, TTA. The chelates of uranium(IV), thorium(IV) and cerium(IV) were prepared as follows.

(1) $U(acac)_4$, $Th(acac)_4$, and $Ce(acac)_4$. Acetylacetone was added to a dilute U(IV) hydrochloric acid solution, aqueous thorium tetrachloride solution and the aqueous cerium(IV) ammonium sulfate solution each with the metal ion to acetylacetone ratio 1:4. These solutions were then gradually neutralized with concd. aqueous ammonia. The precipitates were filtered off, washed with water and dried *in vacuo*. The products were recrystallized twice from benzene-petroleum ether or toluene–petroleum ether and dried *in vacuo*. Found: C, 37.81; H, 4.40; U, 37.60%. Calcd. for $U(acac)_4$ (slightly greenish brown): C, 37.86; H, 4.45; U, 37.52%. Found: C, 38.08; H, 4.58; Th, 36.2%. Calcd for $Th(acac)_4$ (white): C, 38.22; H, 4.49; Th, 36.92%. Found: C, 44.51; H, 5.14; Ce, 25.82%. Calcd for $Ce(acac)_4$ (brown): C, 44.77; H, 5.26; Ce, 26.11%.

(2) $U(hfac)_4$, $Th(hfac)_4$, and $Ce(hfac)_4$. The U(IV) ion, Th(IV) ion and Ce(IV) ion were extracted from dilute U(IV) hydrochloric acid solution, aqueous Th(IV) solution and aqueous Ce(IV) solution respectively with a hexafluoroacetylacetone benzene solution. The products crystallized from these benzene solutions were recrystallized twice from benzene and dried *in vacuo*. Found: C, 23.77; H, 0.88%. Calcd for $U(hfac)_4$ (brown): C, 22.53; H, 0.38%. Found: C, 21.13; H, 0.52%. Calcd for $Th(hfac)_4$ (white): C, 22.66; H, 0.38%. Found: C, 23.12; H, 0.63%. Calcd for $Ce(hfac)_4$ (brown): C, 24.81; H, 0.42%.

(3) $U(tfac)_4$, $Th(tfac)_4$, $U(bfac)_4$, $Th(bfac)_4$, $U(bzac)_4$, $Th(bzac)_4$, $U(bdm)_4$, $Th(dbm)_4$, and $U(TTA)_4$. The ethanol solution of ligand was added to aqueous Th(IV) solution or U(IV) hydrochloric acid solution diluted with water or ethanol (metal ion: ligand≒1:4). The precipitates thus obtained were filtered, washed with water, dried *in vacuo* and purified as in the case of acetylacetonates. Found: C, 28.17; H, 2.10%. Calcd for $U(tfac)_4$ (yellowish brown): C, 28.25; H, 1.90%. Found: C, 28.62; H, 2.18%. Calcd for $Th(tfac)_4$ (white): C, 28.45; H, 1.91%. Found: C, C, 44.24; H, 1.98%. Calcd for $Th(bfac)_4$ (pale orange): C, 43.97; H, 2.21%. Found: C, 43.66; H, 2.13%. Calcd for $U(bfac)_4$ (reddish brown): C, 43.73; H, 2.20%. Found: C, 54.58; H, 4.39; U, 27.15%. Calcd for $U(bzac)_4$ (reddish brown): C, 54.42; H, 4.11; U, 26.97%. Found: C, 55.02; H, 4.42; Th, 26.88%. Calcd for $Th(bzac)_4$ (white): C, 54.79; H, 4.14; Th, 26.47%. Found: C, 63.89; H, 3.88; U, 21.17%. Calcd for $U(dbm)_4$ (reddish brown): C, 63.71; H, 3.92; U, 21.05%. Found: C, 63.84; H, 3.85; Th, 20.6%. Calcd for $Th(dbm)_4$ (yellow): C, 64.05; H, 3.94; Th, 20.63%. Found: C, 34.34; H, 1.74%. Calcd for $U(TTA)_4$ (reddish brown): C, 34.23; H, 1.44%. Found: C, 34.79; H, 1.50%. Calcd for $Th(TTA)_4$ (pale yellow) :C, 34.42; H, 1.44%.

(4) $Ce(tfac)_4$, $Ce(bfac)_4$, $Ce(bzac)_4$, $Ce(dbm)_4$, and $Ce(TTA)_4$. The ethanol solution of ligand was added to aqueous Ce(IV) solution. The chelates thus formed were extracted from the crude precipitates with benzene or toluene. The products crystallized from these benzene or toluene solutions were purified as in the case of hexafluoroacetylacetonates. Found: C, 31.99; H, 2.40%. Calcd for $Ce(tfac)_4$ (buff brown): C, 31.92; H, 2.15%. Found: C, 47.51; H, 2.35%. Calcd for $Ce(bfac)_4$ (brownish purple): C, 48.01; H, 2.42%. Found: C, 60.48; H, 4.63; Ce, 18.3%. Calcd for $Ce(bzac)_4$ (brown): C, 61.21; H, 4.62; Ce, 17.86%. Found: C, 69.53; H, 4.49; Ce, 13.54%. Calcd for $Ce(dbm)_4$ (reddish brown): C, 69.75; H, 4.30; Ce, 13.56%. Found: C, 37.58; H, 1.51%. Calcd for $Ce(TTA)_4$ (reddish brown): C, 37.50; H, 1.57%.

Measurements. IR absorption spectra were recorded on Hitachi-Perkin-Elmer 225 (4000—250 cm^{-1}) and Hitachi EPI-L (700—200 cm^{-1}) IR grating spectrophotometers, using the technique of Nujol mull and HCB mull supported between caesium iodide plates.

Results and Discussion

The yield of U(IV) β-diketonates was quantitative by the present method. However, yields of Th(IV)- and Ce(IV)-β-diketonates were not quantitative because of the fact that Th(IV)- and Ce(IV)-ion are easily hydrolyzed and their hydrolyzed products are less soluble in water. Generally, the yields of metal chelates with acetylacetone, trifluoroacetylacetone and hexafluoroacetylacetone were lower than those with the other four ligands, benzoylacetone, dibenzoylmethane, benzoyltrifluoroacetone and thenoyltrifluoroacetone. The U(IV) β-diketonates were gradually oxidized and discolored in air at room temperature, except for the chelates with the ligand containing phenyl and thienyl groups which were relatively stable in air. It was found from the absorption spectra in visible region that $U(acac)_4$, $U(tfac)_4$, and $U(hfac)_4$ were not stable even in organic solution. All the U(IV) β-diketonates were kept in a vacuum container, and all operations involved in preparations and measurements were carried out as rapidly as possible.

Tetrakis-bidentate chelate, to which all tetrakis β-

6) K. Nakamoto, Y. Morimoto, and A. E. Martell, *J. Phys. Chem.*, **66**, 346 (1962).

diketonato chelates belong, has the coordination number of eight around the central metal ion. The configuration of tetrakis β-diketonato chelates has been determined for two chelates $M(acac)_4$ (M=Zr, Ce, Th, and U)[7] and $M(dbm)_4$ (M=Ce, Th, and U)[8] to be square antiprism with D_2 symmetry and dodecahedron with D_{2d} symmetry, respectively. It seems that the tetrakis β-diketonato chelates with the other kind of ligand dealt with are also isomorphous for Ce(IV), Th(IV), and U(IV).

IR Spectra. In Fig. 1 are shown the IR spectra in the 1800—600 cm^{-1} region of $U(acac)_4$, $U(tfac)_4$, $U(hfac)_4$, $U(bzac)_4$, $U(dbm)_4$, $U(bfac)_4$, and $U(TTA)_4$ chelates. Above 1800 cm^{-1}, no absorption band is found except the C–H stretching bands (not given in the figure) of the methyl group, the γC–H bond, the phenyl group and the thienyl group near 3000 cm^{-1}.

The IR spectra of acetylacetonates of uranium reported by Lecomte[9] do not show the valence state of uranium. The present result differs from that given by Lecomte, but is in line with $Th(acac)_4$ given by Fay and Pinnavaia.[3] The spectra of $M(acac)_4$ (M= U(IV), Th(IV), and Ce(IV)) in the 1600—500 cm^{-1} region are very similar to each other and to those of $Pt(acac)_2$ and $Cu(acac)_2$.[5,10] They are independent of both mass and coordination number of the central metal ion. The absorption bands of each chelate in the 1700—500 cm^{-1} region can be assigned on the basis of β-diketonato chelates with bivalent- or trivalent-transition metal ion reported by Nakamoto *et al.*,[5,6] Mikami *et al.*,[10] and also based on the result reported by Fay and Pinnavaia.[3] The infrared frequencies and tentative assignments for $U(acac)_4$ are given in Table 1.

In the spectra of tetrakis β-diketonates other than tetrakis acetylacetonates, intense bands are found in the region 1500—1700 cm^{-1}, corresponding to the C=O+C=C stretching bands in the spectra of $M(acac)_4$. Other bands are possibly a combination band of bands appearing in the 700—800 cm^{-1} region such as CH

ligands such as tfac, bzac, bfac, and TTA in the chelate. The frequencies of the intense bands in the 1500—1700 cm^{-1} are summarized in Table 2.

In Fig. 2 are shown the IR spectra of the seven β-diketonates of Ce(IV) in the region 200—700 cm^{-1}. Vibrational bands contributed by appreciable amounts of M–O stretching mode are expected in the 500—200 cm^{-1} region. The spectra of $M(acac)_4$ show a strong band in the 220—250 cm^{-1} region and one in the 397—400 cm^{-1} region. The former band is relatively broad and metal sensitive, having a tendency to shift towards lower frequency side with an increase in the mass of the central metal, and can be assigned to the nearly pure M–O stretching mode, after the assignments for $M(acac)_4$ (M=Zr(IV), Hf(IV), Ce(IV), and Th(IV)) reported by Fay and Pinnavaia. The latter was assigned to a predominant M–O stretching mode.[3]

In tetrakis β-diketonates other than $M(acac)_4$, a strong, broad and metal sensitive band is found in the region 200—240 cm^{-1}. This band is also considered to be the nearly pure M–O stretching band corresponding to the 220—250 cm^{-1} band of $M(acac)_4$. The frequencies of the M–O stretching band in the lower frequency side are given in Table 3. They decrease for each metal ion in the order: $M(acac)_4 > M(bzac)_4 > M(tfac)_4 > M(TTA)_4 > M(dbm)_4 > M(hfac)_4$. In $U(hfac)_4$ and $Th(hfac)_4$ no such band was observed since it shifts out of the frequency region due to the mass effect of central metal ion.

Table 3. Frequencies of M–O stretching band (cm^{-1})

Metal	Ligand						
	acac	bzac	tfac	TTA	bfac	dbm	hfac
U(IV)	221	213	219	215	210	207	—
Th(IV)	225	215	212	212	210	210	—
Ce(IV)	250	242	240	233	230	225	218

In the β-diketonates containing the trifluoromethyl group, the M–O stretching band is found in the lower frequency side than that for $M(acac)_4$. This shows that the M–O bond is weakened because electron density on the carbonyl oxygens decreases by the strong electron-withdrawing property of the trifluoromethyl group. In the $M(bzac)_4$ and $M(dbm)_4$ which contain the phenyl group, the M–O stretching band is also found in the lower frequency side than that of $M(acac)_4$, showing that the M–O bond is weakened by the substitution of phenyl group for methyl group. This is in contradiction to the result reported by Nakamoto *et al.* in the study of the bis β-diketonates with Cu(II) and Ni(II), that the M–O bond is strengthened as a result of the mesomeric interactions of the phenyl group with the chelate ring.[6] The mesomeric interactions of the phenyl group with the chelate ring are assumed to occur only when the phenyl group is coplanar with the chelate ring. It has been suggested, however, by X-ray structure analysis for $M(dbm)_4$ (M=U(IV), Th(IV), and Ce(IV)) that the phenyl group is not coplanar with the chelate ring because of a steric hindrance.[8] The phenyl group seems hardly to release the electron by the mesomeric effect, but like

the trifluoromethyl group, to act as an electron-withdrawing group by its inductive effect. Thus, in the β-diketonates with the phenyl group and probably with the 2-thienyl group, the M–O bond is weakened and the frequencies of the M–O stretching band are lowered as in the case of the trifluoromethyl group.

As the strength of the M–O bond changes with substituent, so is that of the C=O and C=C bonds expected to change. In fact, the C=O+C=C stretching bands move to the higher frequency side as the M–O stretching band moves to the lower. Thus, as the M–O bond weakens, the C=O and the C=C bonds are generally strengthened and their bands move to the higher frequency side. These tendencies are particularly remarkable in the β-diketonates with the trifluoromethyl group.

Electron-transfer Kinetics of Transition-metal Complexes in Lower Oxidation States. Part I. Electron Spin Resonance Measurements of the Electron-exchange Rate between $Cr(bipy)_3^{1+}$ and $Cr(bipy)_3$

Tetsuo SAJI and Shigeru AOYAGUI

Faculty of Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received November 2, 1972)

The rate of the electron-exchange reaction between $Cr(bipy)_3^{1+}$ and $Cr(bipy)_3$ was measured in *N*,*N*-dimethylformamide by the ESR method, with the line-broadening procedure. The width of the partly-overlapped hyperfine lines was determined by comparing the observed spectrum with the computer-simulated one. The observed second-order rate constant was $(1.5\pm0.4)\times10^9\ M^{-1}\ sec^{-1}$ at 25 °C. When corrected for diffusion, this yielded the activation-controlled rate constant of $2.0\times10^9\ M^{-1}\ sec^{-1}$. It was pointed out that the rate constant obtained here was the largest of all those ever reported for the electron-exchange reactions in which the transition-metal complexes participated. The observed rate constant was in good agreement with the one calculated non-empirically according to the theory of R. A. Marcus. Although the value for the molecular radius must be chosen somewhat arbitrarily in applying this theory, the "good" radius was a reasonable one in view of the molecular geometry and dimensions of the reactants. The rate constant of the Heisenberg spin-exchange process was also determined to be $1.8\times10^9\ M^{-1}\ sec^{-1}$ at 25 °C in the same solvent.

From the mechanistic point of view, the electron-transfer reactions of transition-metal complexes may be divided into two groups: one is the group of reactions proceeding *via* an outer-sphere activated complex, and the other, an inner-sphere activated complex.[1,2] In the reactions of the former group, the inner coordination shells of the reactant complex ions are left intact in the transition state; in the latter, two reactants share the ligands of their first coordination spheres in the transition state. In general, it may be difficult to show which mechanism is realized in an electron-transfer reaction. However, it is known that reactions of some kind proceed with the outer-sphere mechanism: they are the fast electron-transfer reactions between substitution-inert complexes. Particularly, the electron-exchange rate constant is very large for a pair of complexes differing by one in the number of electrons in the lower t_{2g} orbitals, which are not used in ligand bondings.[1] For example, the electron-exchange reaction between $Fe(phen)_3^{3+}(t_{2g}^5)$ and $Fe(phen)_3^{2+}(t_{2g}^6)$ is too fast to be measured by the NMR method; the largest second-order rate constant observable by this method is of the order of $10^7\ M^{-1}\ sec^{-1}$. The lower limit of the rate constant of this reaction has been reported by Larsen and Wahl to be $3\times10^7\ M^{-1}\ sec^{-1}$ at 25 °C in aqueous solutions.[3]

Among the methods for measuring the rates of isotopic exchange-reactions, the ESR method is probably the only one which is applicable to such fast reactions as were mentioned above. This method has been applied extensively to electron-transfer reactions between aromatic hydrocarbons and their anion radicals. On the other hand, there has been only one report on the application of this procedure to the transition-metal complexes.[4] This may be because of the following difficulties: most of the ESR spectra of these complexes thus far reported are very broad at ordinary temperatures, and they scarcely ever exhibit a hyperfine structure. Moreover, the rate constants measurable by this method must be larger than $10^6\ M^{-1}\ sec^{-1}$.

The present investigation deals with the ESR measurement of the rate of electron-exchange between

$Cr(bipy)_3^{1+}$ and $Cr(bipy)_3$ in *N,N*-dimethylformamide (DMF). The latter complex is diamagnetic,[5] while the former complex yields the ESR spectra with the most resolved nitrogen hyperfine splittings of all the tris-bipyridyl complexes of transition metals ever reported.[6,7] Furthermore, the electronic configurations of $Cr(bipy)_3^{1+}$ and $Cr(bipy)_3$ are t_{2g}^5 and t_{2g}^6 respectively, as in $Fe(phen)_3^{3+}$ and $Fe(phen)_3^{2+}$; it may thus be expected that the reaction rate for this pair of complexes is sufficiently fast for it to be measured by the ESR method. The determination of the hyperfine linewidth is made by comparing the observed ESR spectrum with the computer-simulated one. The observed rate constants are discussed in comparison with those predicted by the theory of R. A. Marcus on the electron-transfer reactions with the adiabatic outer-sphere mechanism.[8]

The present discussion is based on the following premises: (1) both complexes, $Cr(bipy)_3^{1+}$ and $Cr(bipy)_3$, are substitution-inert, and (2) the electron-transfer reaction between them proceeds *via* an outer-sphere activated complex. Experimental evidence for the validity of the former premise will be described elsewhere. In regard to the latter one, there is no data which assures us of its validity. However, it may reasonably be considered that this reaction has a fair chance of being an outer-sphere reaction because of its very large rate constant, which will be seen in the later part of this article.

Experimental

Reagents. All the reagents and solvents were commercially obtained. The 2,2′-bipyridine was supplied by the Tokyo Chemical Industry Co., Ltd. The DMF used as the solvent was refluxed over calcium hydride, distilled *in vacuo*, and then stored in an evacuated ampoule already containing solid $Cr(bipy)_3(ClO_4)_2$ and magnesium powder in order to remove the trace of oxygen.

Complexes. Tris(2,2′-bipyridyl)chromium(1+) perchlorate[9] and tris(2,2′-bipyridyl)chromium(0)[10] were prepared in a nitrogen atmosphere or in a vacuum, according to the procedures described in the literature cited. They were identified by means of their electronic spectra[11] and by elemental analyses.

Found: C, 57.8; H, 3.79; N, 13.9. Calcd for $Cr(bipy)_3ClO_4$: C, 58.1; H, 3.90; N, 13.6.

Found: C, 67.0; H, 4.60; N, 16.0. Calcd for $Cr(bipy)_3$: C, 69.2; H, 4.65; N, 16.2.

Solutions. Solutions of $Cr(bipy)_3ClO_4$ with various concentrations were required in order for us to evaluate the contribution to the linewidth of the $Cr(bipy)_3^{1+}$ spectrum from the Heisenberg spin-exchange process. They were prepared separately in the ESR sample tubes by diluting each aliquot from the stock solution of $Cr(bipy)_3ClO_4$ to a desired concentration with the solvent distilled from the stock solution *in vacuo*. Their concentrations were determined ESR-spectroscopically.

The sample solutions used in the measurement of the electron-exchange rates contained both $Cr(bipy)_3ClO_4$ and $Cr(bipy)_3$; they were prepared by dissolving a known amount of solid $Cr(bipy)_3$ into a $Cr(bipy)_3ClO_4$ solution of a known concentration in such an ampoule as is shown in Fig. 1.

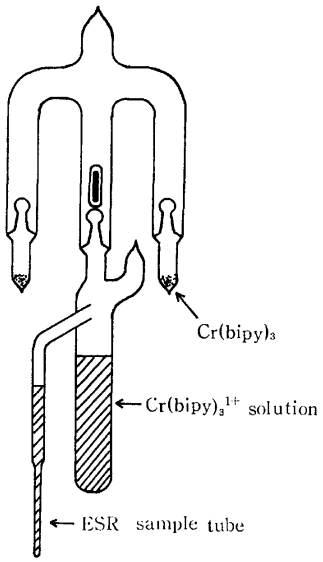

Fig. 1. Apparatus for preparation of ESR sample solutions.

In handling the sample solutions, all the operations were performed on a vacuum line by the use of glassware fitted with a breakable seal.

ESR Measurements. The ESR spectra of $Cr(bipy)_3^{1+}$ were measured in solutions with and without $Cr(bipy)_3$ added under experimental conditions otherwise identical. A JEOL-3SB spectrometer was operated at a frequency near 9.7 kMHz, with a 100 kHz field modulation and with a modulation amplitude of 0.5 gauss. The measurements were carried out at room temperature maintained at 25±1 °C. Calculations of the linewidth were performed on a FACOM 270-20/30 computer using a FORTRAN program.

Results and Discussion

Let the rate of the electron-transfer reaction between a diamagnetic and a paramagnetic molecule be described by the following equation:

$$\text{rate} = k[P][D] = [P]/\tau_p$$

where k is the second-order rate constant and τ_p, the mean life of the paramagnetic species; [D] and [P] are the concentrations of $Cr(bipy)_3$ and $Cr(bipy)_3^{1+}$ respectively, in this case. The hyperfine linewidth as a function of τ_p can be linearlized with regard to τ_p and $1/\tau_p$ respectively, under the following fast-limit and slow-limit conditions:[12]

$$\text{fast-limit: } |\omega_i-\omega_j|\tau_p \ll 1 \quad \text{for all i's}$$

$$\text{slow-limit: } |\omega_i-\omega_j|\tau_p \gg 1 \quad \text{for all i's}$$

where ω's are the resonance frequencies of the designated hyperfine lines. As will be seen below, it is necessary that [D] be larger than 1 M to fulfill the fast-limit condition. This is not possible in the present investigation, however, because of the poor solubility of the D species; thus, in the present experiment the rate constant is determined by the line-broadening procedure, with the slow-limit approximation. The rate constant is, then, given by Eq. (1), when the broadened hyperfine lines are assumed to maintain the Lorentzian lineshape:[13]

$$k = (1.5\times10^7)\Delta(\Delta H_{pp})/[D] \quad (1)$$

where $\Delta(\Delta H_{pp})$ is the increase in the peak-to-peak linewidth of the first derivative spectra caused by electron exchange.

Although evidence has been reported for the disproportionation of $Cr(bipy)_3^{1+}$ ions,[14] their absorption spectrum obtained in DMF exhibited no sign of absorption due to either $Cr(bipy)_3^{2+}$ or $Cr(bipy)_3$; it was identical with the spectrum reported by König and Herzog in methanol.[11] Hence, the disproportionation was not taken into consideration.

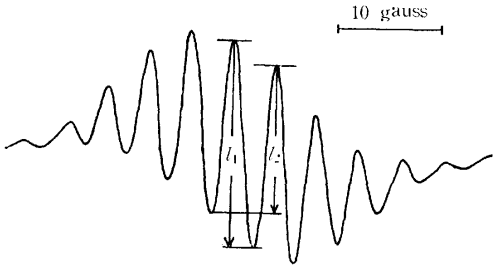

Fig. 2. ESR spectrum of 0.7 mM $Cr(bipy)_3^{1+}$ in DMF.

The ESR spectrum of $Cr(bipy)_3^{1+}$, shown in Fig. 2, exhibits eleven poorly-resolved lines with a spacing of about 3.05 gauss. They may be attributed to the hyperfine interaction due to six equivalent nitrogen nuclei of three bipyridyls. Such an interaction would give rise to thirteen lines. Because of the broadening in linewidth and poor signal-to-noise ratio, not all the thirteen lines were observed. The following procedure was used in order to determine the hyperfine linewidth of such a poorly-resolved spectrum as this. A linewidth parameter is defined here as l_2/l_1, where l_1 and l_2 are taken in the way shown in Fig. 2. The parameter was calculated for each given width of the hypothetical unoverlapping hyperfine lines and is shown plotted *vs.* the latter quantity in Fig. 3. From the observed values for the linewidth parameter, the true or unoverlapped hyperfine linewidths are obtained by the use of this figure.

Figure 4 illustrates a plot of the linewidth *vs.* the concentration of $Cr(bipy)_3ClO_4$. The experimental points lie on a straight line; this may serve to support this procedure for the linewidth determination. From the slope of this line, the second-order rate constant

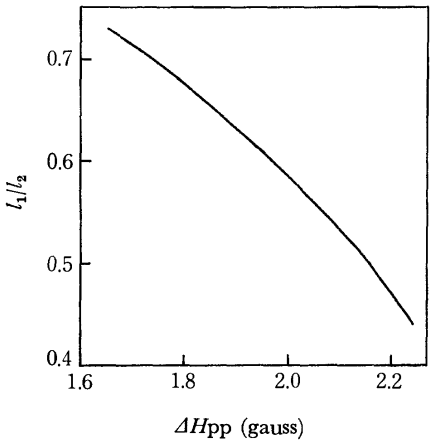

Fig. 3. Linewidth parameter *vs.* unoverlapped hyperfine linewidth.

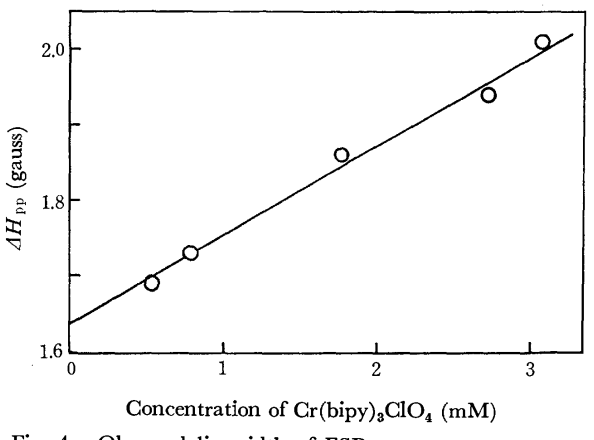

Fig. 4. Observed linewidth of ESR spectrum *vs.* concentration of $Cr(bipy)_3ClO_4$.

of the Heisenberg spin-exchange process[15] was estimated to be $1.8\times10^9\ M^{-1}\,sec^{-1}$. An inevitable increase in the concentration of $Cr(bipy)_3ClO_4$ is caused by the addition of $Cr(bipy)_3$;[16] this can be corrected by a procedure described elsewhere.[17] The increase, however, was less than 0.02 mM; its effect on the linewidth is negligible.

Figure 5 shows with circles the observed increase in the linewidth plotted *vs.* the concentration of added $Cr(bipy)_3$. The second-order rate constant of the electron-exchange reaction was determined from the slope of the straight line drawn through the point of origin and the circles as $k_{obs}=(1.5\pm0.4)\times10^9\ M^{-1}\,sec^{-1}$. No such a large rate constant exceeding $10^9\ M^{-1}\,sec^{-1}$ has, to our knowledge, ever been reported for the electron-exchange reactions of transition-metal complexes. The observed rate constant must be corrected for diffusion because of its large value, approaching the value for the diffusion-controlled rate constant. The correction was performed using the following relation:

13) R. L. Ward and S. I. Weissman, *J. Amer. Chem. Soc.*, **79**, 2086 (1957).

14) U. P. Geiger and E. Class, *Experientia*, **17**, 444 (1961).

16) When a known amount of $Cr(bipy)_3$ is added to the solution of $Cr(bipy)_3^{1+}$, a part of $Cr(bipy)_3$ may inevitably be oxidized by oxygen to yield $Cr(bipy)_3^{1+}$.

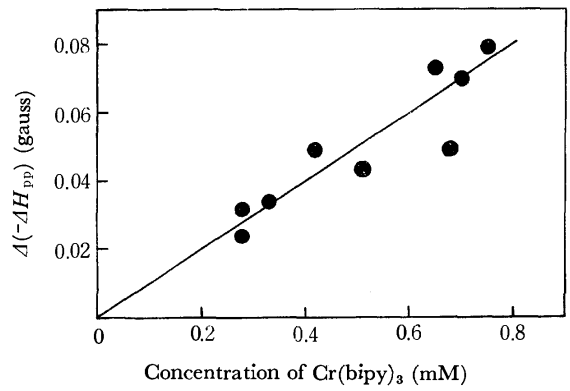

Fig. 5. Increase in linewidth of ESR spectrum *vs.* concentration of added Cr(bipy)$_3$.

$$k_{act}^{-1} = k_{obs}^{-1} - k_{dif}^{-1}$$

where k_{act} is the corrected or activation-controlled rate constant, and k_{obs} and k_{dif} are the observed and the diffusion-controlled rate constant respectively. The last one was estimated in the following way. When one of the reactants is neutral and when, accordingly, the electrostatic interaction between the reactants is negligibly small or zero, the diffusion-controlled second-order rate constant in $M^{-1}\,sec^{-1}$ may be given by:[18]

$$k_{dif} = 4\pi\sigma DN/1000 \qquad (2)$$

where σ is the collision diameter; D, the sum of the diffusion coefficients of the two reactants, and N, Avogadro's number. The value for σ was assumed to be equal to the sum of the molecular radii of the reactants; the latter quantities were estimated from the molecular geometry of Cr(bipy)$_3$, drawn in Fig. 6 on the basis of the X-ray diffraction data[19] as well as the van der Waals radius of the hydrogen atom (1.2 Å). It may reasonably be assumed that a common value can be attributed to the radii of Cr(bipy)$_3^{1+}$ and Cr(bipy)$_3$. In the subsequent calculations, this common molecular radius is designated by a and taken in the two ways shown in Fig. 6: 7.1 and 6.1 Å. The diffusion coefficients of Cr(bipy)$_3$ and Cr(bipy)$_3^{1+}$ are both 3.2×10^{-6} cm^2 sec^{-1} at 25 °C in DMF.[20] The diffusion-controlled rate constants calculated from Eq. (2) with the a values of 7.1 and 6.1 Å were 7×10^9 and 6×10^9 $M^{-1}\,sec^{-1}$ respectively. Both k_{dif} values, however, actually yielded the same k_{act} value, 2.0×10^9 $M^{-1}\,sec^{-1}$. The limiting condition for slow-exchange

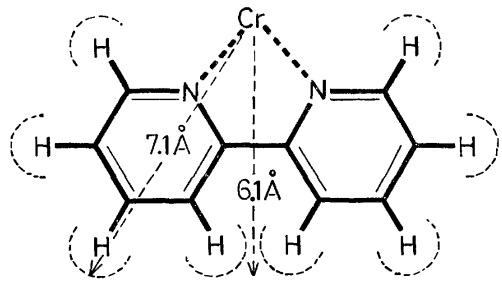

Fig. 6. Molecular geometry of Cr(bipy)$_3$.

is obviously fulfilled with the observed k value of 1.5×10^9 $M^{-1}\,sec^{-1}$ and the minimum value for $|\omega_i-\omega_j|$, 3.05 gauss, as well as the maximum value for $[D]$, 0.7 mM. On the other hand, the limiting condition for fast-exchange requires that $[D]$ be significantly larger than 0.4 M when the maximum value for $|\omega_i-\omega_j|$, *ca.* 30 gauss, is applied.

According to the theory of Marcus,[8] the rate constant of the electron-exchange reaction between a neutral and a charged species is, the inner-sphere reorganization being neglected:

$$k_{act} = Z\exp(-\Delta G^*/RT)$$
$$= Z\exp[-(e^2/8a)(1/D_{op}-1/D_s)] \qquad (3)$$

where Z, the collision number between two uncharged species in solution, is assumed to be 10^{11} $M^{-1}\,sec^{-1}$; ΔG^* is the reorganization free energy of solvent molecules in forming the activated complex; e is the electronic charge, and D_{op} and D_s are the optical and the static dielectric constants respectively. The activation-controlled rate constant was calculated from Eq. (3) for each radius mentioned above. They are listed in

Table 1. Comparison of the corrected observed rate constant with the calculated one in the electron exchange reaction between Cr(bipy)$_3^{+1}$ and Cr(bipy)$_3$

k_{act} (M^{-1} sec^{-1})	Radius (Å)	k_{calc} (M^{-1} sec^{-1})	ΔG^* (kcal/mol)
	6.1	3.7×10^8	3.3
	7.1	1.2×10^9	2.6
2.0×10^9	8.2	2.0×10^9	2.2

Table 1, together with the corrected observed rate constant. The agreement between k_{act} and k_{calc} was satisfactory. In order for k_{calc} to be in exact agreement with k_{act}, a should be taken as 8.2 Å, a reasonable value in view of the molecular dimensions of Cr(bipy)$_3$. This suggests that the inner-sphere reorganization energy contributes to the activation free energy to only a small extent in this reaction. However, the value of k_{calc} is quite sensitive to that of a, and unfortunately a is not a sufficiently definite quantity for the Marcus theory to be applied to the existing molecules. Thus, the theory must be tested experimentally with regard to a variety of aspects of its theoretical expression for the rate constant before we can consider that the theory is successful in the nonemiprical prediction of the electron-exchange rate constant. Such an extensive examination of this theory has recently been attempted for the electron-transfer reactions between aromatic hydrocarbons and their anion radicals.[21] The theoretical calculation of the rate constant can be done more reasonably for the reactions participated by the octahedral complex ions than for those participated by the planar aromatic hydrocarbons, because of the premise of a spherical molecular shape in this theory. However, there may be more difficulties in finding a suitable reactant among the former complexes than among the latter.

21) K. Suga and S. Aoyagui, This Bulletin, **46**, 755, 808 (1973).

One of the most outstanding features of the Marcus theory is that it can treat the homogeneous and the electrochemical electron-transfer reactions in a unified way.[22] An attempt to test this theory in the electrochemical electron-transfer reaction of the $Cr(bipy)_3^{1+}$/$Cr(bipy)_3$ redox couple, the corresponding homogeneous reaction having been revealed to be the fastest of all the electron-transfer reactions participated by the transition-metal complexes, is now in progress in our laboratory. It will be reported in the near future.[20]

Studies on Mass Spectrometry of Metal Chelates. I. Mass Spectrometry of Oxine Metal Chelates[1]

Yoshinori KIDANI, Shinobu NAGA, and Hisashi KOIKE

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

(Received November 8, 1972)

With a view to applying mass spectrometry to the studies of metal chelates, we investigated the mass spectrometry of divalent metal oxinates (Mn, Co, Ni, Cu, Zn, Pb, and Pd). The molecular ion I, whose peaks correspond to the metal chelates in a 2: 1 ratio, were observed in every spectrum. A loss of 144 mass units from I, corresponding to one molecule of coordinated oxine, occurred to afford the fragment ions II of metal chelates in a 1: 1 ratio. The peaks of the fragment ions III which lost 28 mass units (CO) from II were observed for Mn, Co, Ni, Cu, and Pd chelates. In order to study the stability of metal chelates against electron impact, special attention was paid to the peaks of I and II, which are supposed to be affected strongly by the *d*-electron number, electronegativity, ionization potential, and the ionic radius of central metal atoms. The intensity ratios of peaks I to II were obtained in the order Zn>Ni>Pd≈Co>Mn>Cu>Pb. It has been shown that the intensity ratios are related to the charge-radius ratio (e/r) of central metal atoms and the stability constants ($\log k_2$) of oxine metal chelates.

Studies have been carried out on metal chelates of acetylacetone and its derivatives by mass spectrometry.[2] With respect to the metal chelates of 8-quinolinol (oxine) and its derivatives, Jenkins *et al.* reported on the determination of metal purity in the order of 10^{-12} g as a form of oxine metal chelate by mass spectrometry.[3] Charalambous *et al.* recently reported on the fragmentation of oxine chelates with trivalent metals.[4] Budzikiewicz *et al.* found that fragmentation of the side chain in 2-*n*-butyloxine chelates was affected by their central metal atoms.[5] Although studies on mass spectrometry have been carried out to confirm the molecular weight of the metal complexes isolated,[6] no investigation has been made from the viewpoint of coordination chemistry. We have thus investigated mass spectrometry of oxine metal chelates in order to examine the stability of metal chelates against electron impact.

Results and Discussion

Mass spectra of divalent metal oxinates are shown in Fig. 1.

The fragmentation sequences are summarized in Chart 1. A peak of the molecular ion (M^+, I) appeared in the highest portion of the mass number of each metal chelate, attributable to the chelates in a 2: 1 ratio. A loss of 144 mass units was observed in each spectrum in common. This may be explained by the loss of one molecule of the coordinated oxine from I, affording fragment ion II of a 1: 1 complex. The peaks of III produced by the loss of 28 mass units from II are observed for Mn, Co, Ni, Cu, and Pd chelates. This can be explained by the loss of CO since the metastable ion peaks are observed distinctly in these spectra (ex. $Ni(oxine)_2$; *m/e* 202→174, calcd 149.8812, found 150.0). However, the peak of fragment ion III has not been detected for both Zn and Pb chelates. A plausible explanation for the lack of ion III in the mass spectra of both Zn and Pb chelates is that ion IV is directly produced from ion II, ion III being skipped, but the reason why the fragmentation schemes of these two chelate compounds are different from other chelates has not yet been clarified.

No peak at *m/e* 144 due to the oxinate ion was observed in almost all the chelates, that at *m/e* 145 (oxine ion) being found instead. (A similar phenomenon was

also observed in the mass spectra of acetylacetone metal chelates; no peak at *m/e* 99, acetylacetonate ion, but one at *m/e* 100, acetylacetone ion, being found.[2] This can be explained as follows: (a) the peak at *m/e* 144 is afforded by the production of the oxinate ion, but it is very unstable and does not reach the ion collector in the mass spectrometer, (b) the peak at *m/e* 145 can be attributed to the oxine, whose oxinate ion produced from I may pick up one hydrogen atom affording the peak at *m/e* 145. However, in this experiment, the sample was introduced by a direct inlet system, being the little possibility for a hydrogen atom to be picked up in the mass spectrometer. The peak at *m/e* 145 is regarded to arise from the oxine molecule produced by thermal decomposition prior to the vaporization of sample. Charles studied the differential thermal analyses of oxine metal chelates and reported that the heat stability at melting point was in the order Cu>Pb>Zn>Ni>Co>Mn>Mg.[7] The intensity ratio of the peak at *m/e* 145 to I were therefore obtained, since the peak of I was supposed to be unaffected by thermal decomposition. The order of the ratios is Mg>Zn>Mn>Co>Ni>Pb>Cu, coinciding well with the heat instability order by Charles, since the peak at *m/e* 145 was considered to be due to the oxine molecule produced by thermal decomposition.

In order to compare the stability of metal chelates against electron impact, special attention was paid to the relationship between ions I and II, both of which might be affected strongly by the *d*-electron number, electronegativity, ionization potential and ionic radius of central metal atoms. In order to find the stability of ion I of the chelates with various metals, the intensity ratios of the peaks were substituted into formula I/(I+II), the stability of the molecular ions against electron impact being found to be in the order Zn> Ni>Pd≈Co>Mn>Cu>Pb (Table 1).

Table 1. Intensity ratios of the molecular ion, I, to the fragment ion, II

	Zn	Ni	Pd	Co	Mn	Cu	Pb
I/(I+II)%	67	63	61	61	55	48	22

By plotting the values of the intensity ratio against the charge-radius ratio (*e/r*),[8] a linear relationship was obtained (Fig. 2). It was found that the greater the charge-radius ratio of metal atoms, the higher the stability of ion I.

The correlation between the stability constants of oxine metal chelates in solution[9] and the stabilities to electron impact is given in Fig. 3. The process which produced ion II from I may be understood in relation

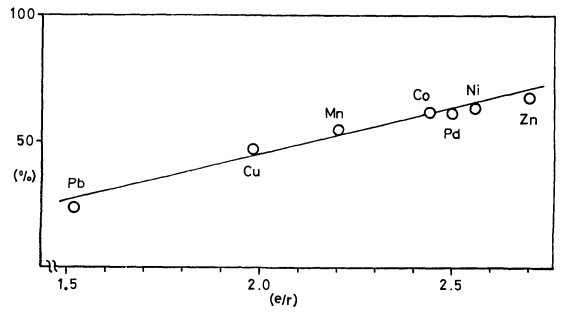

Fig. 2. Correlation between the stability upon electron impact and the charge-radius ratio.

to the step of the second stability constant ($\log k_2$). From the plot intensity ratio *vs.* $\log k_2$, (broken line) we see that there is a correlation between the stability constant and the charge-radius ratio, showing a linear relationship for the stability of ion I, against electron impact. A similar, plot e/r *vs.* $\log k_2$ (solid line) is given. The plots are similar in form, indicating that intensity ratio is correlated to stability constant.

In conclusion, the binding ratios of the ligands to metals can be easily determined by measurements of the mass spectra of metal chelates with a trace amount of the sample. Helpful information can be obtained for the stability of metal chelates against electron impact.

Experimental

Mass spectra were measured by a Hitachi RMU-7 mass spectrometer according to a direct inlet system under the following conditions: ionizing voltage 70 eV, ion accelerating voltage 1800 V, total emission current 80 μA, ion source temperature 250 °C. Metal oxinates were prepared by the usual method,[10] their purity being confirmed by elemental analyses.

The authors' thanks are due to Professor Akira Tatematsu, Faculty of Pharmacy, Meijo University, for the use of apparatus, and to Professor Hisao Nakata, Department of Chemistry, Aichi Kyoiku University, for valuable discussions.

Polarographic Study of Monosaccharides in Unbuffered Solution and Its Application to the Determination of the Mutarotation Rate Constants

Tokuji IKEDA and Mitsugi SENDA

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Sakyo-ku, Kyoto 606

(Received November 8, 1972)

The polarographic behavior of monosaccharides in unbuffered neutral solution was investigated. The limiting current was ascertained to be an autocatalytic current which could be caused by the production of hydroxyl ion at the electrode surface. Equations for the characteristic limiting current and for the shape of current-potential curve were derived by use of the reaction layer concept. Experimental results for D-glucose, D-galactose, and D-xylose were fairly well expressed by these equations. The wave can also be applied to the determination of the mutarotation rate constants of monosaccharides, the values obtained (D-glucose: 0.53×10^{-3} s^{-1}, D-galactose: 0.54×10^{-3} s^{-1}, and D-xylose: 1.31×10^{-3} s^{-1}) being in fairly good agreement with those obtained by the polarimetric method (D-glucose: 0.4×10^{-3} s^{-1}, D-galactose: 0.5×10^{-3} s^{-1}, and D-xylose: 1.3×10^{-3} s^{-1}).

The polarographic behavior of monosaccharides in buffered solutions has been investigated by a number of workers.[1-4] The limiting current of the wave in buffered solutions has a kinetic character; it depends on the pH as well as the concentration of buffer salts. The mutarotation rate constants of monosaccharides have been determined by detailed analysis of the polarographic limiting currents.[5]

Little attention has been paid to their polarographic behavior in unbuffered solutions. We have observed that in unbuffered solutions the polarographic wave of monosaccharide gives a limiting current, which seems to be an autocatalytic current. The present investigation was undertaken to elucidate the characteristic behavior of the polarographic wave of monosaccharide in unbuffered media. Application of the wave to the determination of the mutarotation rate constants of monosaccharide has also been studied.

Experimental

Materials. Commercial D-glucose, D-galactose and D-xylose of reagent grade were used. Pure α-D-glucose: $[\alpha]_D^{25}=+112$ (*c* 4 in water), mp 146 °C, was supplied by Tokai Togyo Co., Ltd. Pure α-D-galactose[6] and α-D-xylose[7] were prepared by recrystallization from ethanol and water, respectively; α-D-galactose: $[\alpha]_D^{25}=+150$ (*c* 4 in water), mp 167 °C, α-D-xylose: $[\alpha]_D^{25}=+94$ (*c* 1 in water), mp 145 °C. Commercial potassium chloride and tetraethyl ammonium iodide (TEAI) of reagent grade were used as supporting electrolytes. The latter was used after recrystallization from methanol.

Apparatus. Polarograms were recorded with a Yanagimoto PE 21-TB2S polarograph connected to a Yokogawa 3077 X-Y recorder. Polarimetry was carried out with a Yanagimoto polarimeter OR-20.

Measurements were carried out with an H-type cell. A saturated calomel electrode (SCE) was used as reference electrode. In order to minimize accumulation of hydroxyl ions in the close neighbourhood of the electrode, which could be caused by unsufficient stirring of the neighbouring solutions after the detachment of the individual mercury drops, a pencil-sharpened capillary (tip outside-diameter 1 mm) was used. The capillary characteristics of the dropping mercury electrode measured in 0.1 M potassium chloride (open circuit) at a mercury reservoir height of 52.5 cm were $m=1.306$ mg s^{-1} and $t=5.65$ s. All experiments were carried out at 25± 0.05 °C. The procedure for measuring the polarographic current has been described previously.[8]

Theory

Limiting Current. According to Los, Simpson and Wiesner,[5] the strictly rate-controlled limiting current $\bar{i}_l$ of reaction scheme (1)

$$\alpha\text{-pyranose} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \gamma(\text{reducible form}) \underset{k_2}{\overset{k_{-2}}{\rightleftharpoons}} \beta\text{-pyranose} \quad (1)$$

is given by

$$\bar{i}_l = nF\bar{q}\bar{\mu}(k_1C_\alpha + k_2C_\beta) \quad (2)$$

$$\bar{\mu} = (D_s/(k_{-1}+k_{-2}))^{1/2}, \quad (3)$$

where n denotes the number of electrons consumed in the electrolysis per one molecule of monosaccharide, F Faraday constant, $\bar{q}$ the mean electrode surface area, D_s the diffusion coefficient of monosaccharide, C_α and C_β the bulk concentration of α- and β-pyranose, respectively, and $\bar{\mu}$ the mean thickness of the reaction layer. Equation (2) was later derived by one of us (M.S.)[9] and Paldus and Koutecký[10] on the basis of a rigorous mathematical procedure.

The rate constants k_i (i=1, 2, −1, and −2) of Eq. (1) depend on the concentrations (activities) of acid and base catalysts. In unbuffered aqueous solutions, they are generally given by[11,12]

$$k_i = k_{i,w} + k_{i,H}(H^+) + k_{i,OH}(OH^-), \quad (4)$$

where $k_{i,w}$ represents the catalytic constant of water, $k_{i,H}$ and $k_{i,OH}$ the catalytic coefficients of the catalysts indicated by subscripts, and the symbols in brackets the concentrations (activities) of the catalysts, H^+ and OH^- being hydrogen ion and hydroxyl ion, respectively.

In the reaction layer the solution is basic because of the production of hydroxyl ions by the electro-reduction of monosaccharide at the electrode surface. For example, a rough estimation (see below) shows pH is 9.8 at the electrode when 0.006 M D-xylose solution is reduced at d.m.e. in unbuffered solution. The catalytic effect of hydrogen ion can be neglected in such a basic solution. The first term on the right hand side of Eq. (4), $k_{i,w}$, can also be neglected in comparison with the third term. Accordingly, the rate constants k_i ($i=1$, 2, −1, and −2), in the reaction layer are eventually expressed, in the first approximation, by

$$k_i = k_{i,OH}(OH^-)^\circ, \quad (5)$$

where $(OH^-)^\circ$ represents the mean concentration of hydroxyl ions at the electrode surface, which may be assumed to be approximately constant throughout the reaction layer due to the thinness of the layer.

Since hydroxyl ions diffuse into the solution and the concentration of hydroxyl ion is practically zero in the bulk solution, the limiting current of monosaccharide is related to the concentration of hydroxyl ions at the electrode surface, with the aid of the Ilković equation[13]

$$\bar{i}_l = \bar{\kappa}_{OH}(OH^-)^\circ, \quad (6)$$

where $\bar{\kappa}_{OH}$ denotes the Ilković constant for hydroxyl ion.

Substitution of Eqs. (5) and (6) into Eq. (2) gives

$$\bar{i}_l = 1.322\bar{\kappa}_s(D_s/D_{OH})^{1/2}\tau(k_{-1,OH}+k_{-2,OH})^{-1} \times (k_{1,OH}C_\alpha + k_{2,OH}C_\beta)^2, \quad (7)$$

where $\bar{\kappa}_s$ denotes Ilković constant for the hypothetical diffusion current for monosaccharide with $n=2(\bar{\kappa}_s = 2(D_s/D_{OH})^{1/2}\bar{\kappa}_{OH})$, D_{OH} the diffusion coefficient of hydroxyl ion and τ the drop time. For the solution of equilibrated mixture of monosaccharide, Eq. (7) is reduced to

$$\bar{i}_l = 1.322\bar{\kappa}_s(D_s/D_{OH})^{1/2}\tau(k_{1,OH}+k_{2,OH}K)^2(C_{\alpha,eq}+C_{\beta,eq})^2 \times (k_{-1,OH}+k_{-2,OH})^{-1}(1+K)^{-2} \quad (7')$$

where $C_{\alpha,eq}$ and $C_{\beta,eq}$ represent the equilibrated concentrations of α- and β-pyranose, respectively, and K the equilibrium constant defined by $K=C_{\beta,eq}/C_{\alpha,eq}$. The sum $C_{\alpha,eq}+C_{\beta,eq}$ is equal to the total concentration of monosaccharide because the concentration of the intermediate γ-form is negligibly small.

Electrode reaction of the same mechanism as that described above was proposed for the electro-reduction of formaldehyde in unbuffered solution by Brdička[13] and a mathematically rigorous solution of the process was given by Koutecký.[14] The result requires that the numerical coefficient of Eq. (7'), 1.322, should be replaced by 0.966. The value was adopted in the following.

Current Potential Curve. Since the electroactive intermediate γ-form is formed from α- and β-pyranose, the current at a point of the kinetic wave of monosaccharide can be given by

$$\bar{i} = nF\bar{q}\bar{\mu}(k_1C_\alpha^\circ + k_2C_\beta^\circ - (k_{-1}+k_{-2})C_\gamma^\circ), \quad (8)$$

where C_α°, C_β°, and C_γ° represent the mean concentration of α-, β-, and γ-form, respectively, in the reaction layer. Provided that the limiting current has a strictly kinetic character as given by Eq. (2), there is no significant depletion of α- and β-pyranose in the reaction layer. Thus substitution of Eq. (2) in Eq. (8) gives

$$\bar{i} = \bar{i}_l - nF\bar{q}\bar{\mu}(k_{-1}+k_{-2})C_\gamma^\circ \quad (8')$$

Based on the theory of slow discharge, the current intensity can be given by

$$\bar{i} = nF\bar{q}k_{el}\exp\left((-\alpha_a n_a F/RT)(E-E_0)\right)C_\gamma^\circ, \quad (9)$$

where k_{el} represents the standard rate constant at the standard potential E_0, $\alpha_a n_a$ the product of the transfer coefficient and the number of electrons in discharge process, R the gas constant and T the absolute temperature. Other symbols were defined above.

In unbuffered solutions the current intensity can also be related to the concentration of hydroxyl ion at the electrode surface by

$$\bar{i} = \bar{k}_{OH}(OH^-)^\circ \quad (6')$$

Substituting the appropriate values from Eqs. (5), (6'), and (9) into Eq. (8'), we obtain after rearrangement

$$E = E_0 + \frac{RT}{\alpha_a n_a F}\ln\left[\frac{k_{el}(\bar{k}_{OH})^{1/2}}{(D_s(k_{-1,OH}+k_{-2,OH}))^{1/2}}\right] + \frac{RT}{\alpha_a n_a F}\ln\left[\frac{\bar{i}_l-\bar{i}}{\bar{i}^{3/2}}\right], \quad (10)$$

here it is assumed that Eq. (5) holds.

Results and Discussion

Experiments were carried out for several monosaccharides (D-glucose, D-galactose, and D-xylose) in unbuffered solutions of 0.1 M potassium chloride.

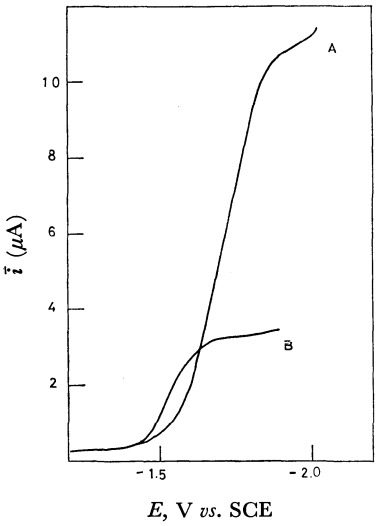

Fig. 1. Polarogram of 0.06M D-xylose in 0.1M potassium chloride A, 0.2M ammonia buffer pH 8.59 B.

Curve A in Fig. 1 shows an example of the polarographic wave of D-xylose in unbuffered neutral solution. The wave is very large in comparison with that of D-xylose of the same concentration (curve B in Fig. 1) in buffered solution of 0.2 M ammonia at pH 8.59. Similar large waves were observed for all other monosaccharides studied. The value of $\bar{i}_l/\bar{i}_d$ is shown in Table 1, $\bar{i}_d$ being the hypothetical diffusion current of monosaccharide. The limiting current $\bar{i}_l$ is still small enough to be considered as strictly kinetic-controlled in the concentration ranges studied. Thus the use of Eq. (2) in deriving the theoretical equations is justified.

Table 1. Dependence of the limiting current $\bar{i}_l$ on the height of mercury reservoir h
(Current sens 0.2 μA/cm Temp. 25 °C)

	D-Xyl.(10mM)[a]		D-Glu.(60mM)[b]		D-Gal.(14mM)[c]	
h (cm)	$\bar{i}_l$ (cm)	$\bar{i}_l(h^{1/2})$	$\bar{i}_l$ (cm)	$\bar{i}_l(h^{1/2})$	$\bar{i}_l$ (cm)	$\bar{i}_l(h^{1/2})$
42.5	5.16	34	4.26	28	4.51	29
52.5	4.80	35	4.16	30	4.25	31
62.5	4.45	35	3.87	31	4.10	32

at h=52.5 cm a) $\bar{i}_l/\bar{i}_d=2.1\times10^{-2}$ b) $\bar{i}_l/\bar{i}_d=3.0\times10^{-3}$ c) $\bar{i}_l/\bar{i}_d=1.3\times10^{-2}$

It is expected from Eq. (7') that $\bar{i}_l$ is approximately proportional to $m^{2/3}\tau^{7/6}$. Since m is proportional to the height of mercury reservoir h, and τ is inversely proportional to h, $\bar{i}_l$ is eventually proportional to $h^{-1/2}$. Experimental results (Table 1) show that $\bar{i}_l$ decreases with increasing height of mercury reservoir and is approximately proportional to $h^{-1/2}$.

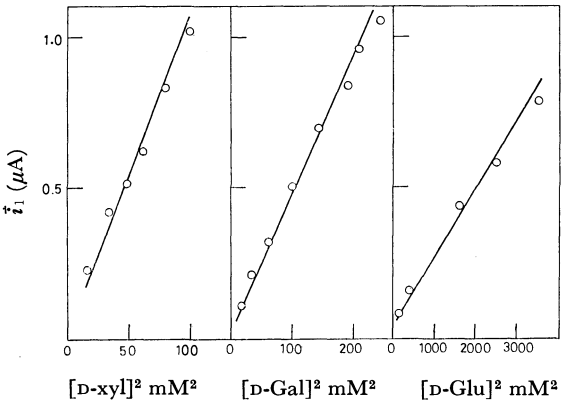

Fig. 2. Relationship between the limiting current $\bar{i}_l$ and the square of the concentration of monosaccharides.

Figure 2 shows the plot of $\bar{i}_l$ against the square of the monosaccharide concentration $(C_\alpha+C_\beta)^2$. In accordance with theoretical consideration, all the data in Fig. 2 are distributed along a straight line, deviating downward from the line at higher concentrations of monosaccharides. A similar deviation from linearity was also observed for the limiting current of formaldehyde in unbuffered solutions by Brdička,[13] who attributed the deviation to the streaming of the solution in the neighbourhood of the electrode.

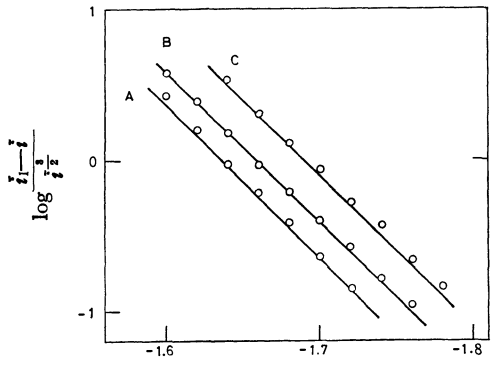
The concentration of hydroxyl ions in the reaction layer $(OH^-)^\circ$ can be calculated with the aid of the Ilković equation (6). Even at the lowest concentration studied (0.04 M D-xylose) $\bar{i}_l$ reached 0.23 μA. Thus $(OH^-)^\circ$ may be estimated as 3.6×10^{-5} M or more, where $D_{OH}=5.23\times10^{-5}$ cm² s^{-1} was used.[15] In view of the numerical values of the rate constants,[8] *i.e.* $k_{1,w}=2.4\times10^{-3}$ s^{-1} and $k_{1,OH}=1.2\times10^3$, the catalytic effect of water may be considered to be of secondary significance under the present experimental conditions. Thus the use of Eq. (5) in place of Eq. (4) is justified.

The mean thickness of the reaction layer $\bar{\mu}$, which

15) J. Heyrovský and J. Kůta, "Principle of Polarography," Academic Press, New York and London (1966), p. 105.

is now given by $\bar{\mu}=(D_{xy}/(k_{-1,OH}(OH^-)^o+k_{-2,OH}(OH^-)^o))^{1/2}$, is calculated to be 9.3×10^{-4} cm when $(OH^-)^o=3.6\times10^{-5}$ M, D_{xy}[16] $=6.7\times10^{-6}$ cm^2 s^{-1}, $k_{-1,OH}=8.4\times10^4$ s^{-1} l mol^{-1}, and $k_{-2,OH}=11.5\times10^4$ s^{-1} l mol^{-1}. The numerical value of the rate constants used were obtained in the present study (Table 3). The magnitude of $\bar{\mu}$ is less than one twentieth of the thickness of the mean diffusion layer for hydroxyl ion, ($\delta\simeq2.3\times10^{-2}$ cm). This is acceptable.

Similar arguments can also be applied to D-glucose and D-galactose.



E, V *vs.* SCE

Fig. 3. Log$((\bar{i}_l-\bar{i})/\bar{i}^{3/2})$ *vs.* E plot for the polarographic current of D-xylose(8 mM) A, D-glucose(40 mM) B, D-galactose (12 mM) C, in 0.1M potassium chloride. Reciplocal slope of the solid lines: 100 mV.

Figure 3 shows the plot of $\log[(_{l}\bar{i}-\bar{i})/\bar{i}^{3/2}]$ against E. The experimental points lie on a straight line, as expected from Eq. (10) with a reciprocal slope 2.303 $RT/\alpha_a n_a F\sim100$ mV per log unit.

The general solution of the current-potential curve of the kinetic wave in buffered solutions has been given by Koutecký.[17] Rewriting his result for the current-potential curve of monosaccharide in buffered solutions, we obtain

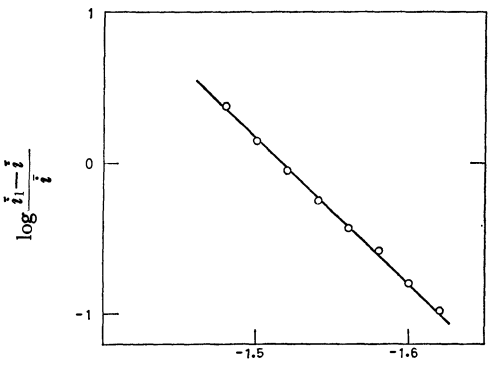
$$E=E_0+\frac{RT}{\alpha_a n_a F}\ln[k_{el}(D_s(k_{-1}+k_{-2}))^{-1/2}]+\frac{RT}{\alpha_a n_a F}\ln\left[\frac{\bar{i}_l-\bar{i}}{\bar{i}}\right] \quad (11)$$

Figure 4 shows the plot of $\log[(\bar{i}_l-\bar{i})/\bar{i}]$ *vs.* E for the polarographic current of monosaccharides in buffered solution of pH 8.56. As expected from Eq. (11), a straight line was obtained. The value of the slope 2.303 $RT/\alpha_a n_a F$ was again *ca.* 100 mV; this is reasonable provided that the discharge process of monosaccharides is identical both in buffered and in unbuffered solutions.

From Eq. (10) we obtain

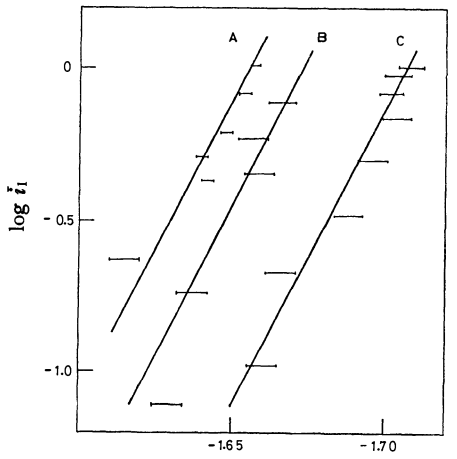
$$E_{1/2}=E_0+\frac{RT}{\alpha_a n_a F}\ln\left[\frac{k_{el}(\bar{k}_{OH})^{1/2}}{(D_s(k_{-1,OH}+k_{-2,OH}))^{1/2}}\right]-\frac{RT}{\alpha_a n_a F}\ln\left[\frac{\bar{i}_l}{2}\right]^{1/2} \quad (12)$$

for the half-wave potential of the polaragraphic wave in unbuffered solutions. Figure 5 shows the plot of



E, V *vs.* SCE

Fig. 4. Log$((\bar{i}_l-\bar{i})/\bar{i})$ *vs.* E plot for the polarographic current of D-xylose (0.06 M) in ammonia buffer pH 8.56. Reciprocal slope of the solid line: 100 mV.



$E_{1/2}$ V *vs.* SCE

Fig. 5. Log$(\bar{i}_l)$ *vs.* $E_{1/2}$ plot for the polarographic current of D-xylose A, D-glucose B, and D-galactose C, in 0.1M potassium chloride. Reciprocal slope of the solid lines: −50 mV.

log $\bar{i}_l$ against $E_{1/2}$. As expected from Eq. (12), the data are distributed along a straight line with a reciprocal slope $RT/2\alpha_a n_a F\sim-50$ mV. The fact that the values of $\alpha_a n_a$ are nearly identical for all monosaccharides investigated (Figs. 3 and 4) suggests the similarity of the discharge process for these monosaccharides.

In conclusion, the current-potential relationship of the monosaccharide is fairly well reproduced by Eq. (10). It is to be noted that in deriving Eq. (10), k_{el} is assumed to be independent of the concentrations of acid and/or base at the electrode surface. However, there is a reason to believe that the discharge process should depend on acid and/or base.

When TEAI was used as a supporting electrolyte, the half-wave potential of the monosaccharide appeared in more negative potential than in KCl solution. The reciprocal slope of the plot of $\log[(\bar{i}_l-\bar{i})/\bar{i}^{3/2}]$ against E became 200 mV or even greater. A similar effect was observed[3,4] when tetramethylammonium phosphate was used as the supporting electrolyte. This effect may be attributed to the adsorption of the quarternary

ammonium cation on the electrode surface,[18] which results in the retardation of the electro-reduction of monosaccharide.

Determination of the Mutarotation Rate Constant

When a weighed amount of a monosaccharide in pure α-pyranose form was dissolved in 0.1 M potassium chloride, the limiting current decreased with time and reached a constant value corresponding to the value for the equilibrated mixture of the monosaccharide. This behavior is very much similar to that in buffered solutions and the mutarotation rate constants may be obtained by analyzing the limiting current with the aid of Eq. (7) as a function of time.

When we start from α-pyranose, the change of concentrations of α- and β-pyranose with time is given as follows,[5]

$$C_\alpha = C_{\alpha,eq}(1+Ke^{-k_{o,w}t})$$
$$C_\beta = C_{\beta,eq}(1-e^{-k_{o,w}t}), \quad (13)$$

where $k_{o,w}$ is the overall mutarotation constant of water and is defined by four individual rate constants as follows.

$$k_{o,w} = (k_{1,w}k_{-2,w}+k_{-1,w}k_{2,w})/(k_{-1,w}+k_{-2,w}) \quad (14)$$

Substitution of Eq. (13) into Eq. (7) gives

$$\bar{i}_1(t)^{1/2} = (0.966\bar{\kappa}_s(D_s/D_{OH})^{1/2}\tau)^{1/2}(k_{-1,OH}+k_{-2,OH})^{-1/2} \times (1+K)^{-1}(C_{\alpha,eq}+C_{\beta,eq})((k_{1,OH}+Kk_{2,OH}) +K(k_{1,OH}-k_{2,OH})e^{-k_{o,w}t}) \quad (15)$$

Subtraction of the expression corresponding with Eq. (15) at time $t+\Delta t$ and taking logarithms leads to the result

$$\ln[\bar{i}_1(t)^{1/2}-\bar{i}_1(t+\Delta t)^{1/2}] = \ln[(0.966\bar{\kappa}_s(D_s/D_{OH})^{1/2}\tau)^{1/2} \times (k_{-1,OH}+k_{-2,OH})^{-1/2}(1+K)^{-1}K(k_{1,OH}-k_{2,OH}) \times (C_{\alpha,eq}+C_{\beta,eq})(1-e^{-k_{o,w}\Delta t})] - k_{o,w}t \quad (16)$$

Plotting $\log[\bar{i}_1(t)^{1/2}-\bar{i}_1(t+\Delta t)^{1/2}]$ with constant Δt *vs.* t, according to the method of Guggenheim,[19] should give a straight line with slope $-k_{o,w}$, and

$$\text{intercept} = \ln[(0.966\bar{\kappa}_s(D_s/D_{OH})^{1/2}\tau)^{1/2} \times (k_{-1,OH}+k_{-2,OH})^{-1/2}(1+K)^{-1}K(k_{1,OH}-k_{2,OH}) \times (C_{\alpha,eq}+C_{\beta,eq})(1-e^{-k_{o,w}\Delta t})] \quad (17)$$

At $t\to\infty$, Eq. (15) is reduced to

$$\bar{i}_1(t\to\infty)^{1/2} = (0.966\bar{\kappa}_s(D_s/D_{OH})^{1/2}\tau)^{1/2} \times (k_{-1,OH}+k_{-2,OH})^{-1/2}(1+K)^{-1}(C_{\alpha,eq}+C_{\beta,eq}) \times (k_{1,OH}+Kk_{2,OH}) \quad (18)$$

Namely, the overall catalytic rate constant $k_{o,w}$ is determined from the slope of the Guggenheim plot. Furthermore, if the overall catalytic rate coefficient of hydroxyl ion $k_{o,OH}$ and the equilibrium constant K are known, Eqs. (17) and (18) in combination with the following two equations

$$k_{o,OH} = (k_{1,OH}k_{-2,OH}+k_{-1,OH}k_{2,OH})/(k_{-1,OH}+k_{-2,OH}) \quad (19)$$
$$K = C_{\beta,eq}/C_{\alpha,eq} = k_{1,OH}k_{-2,OH}/k_{-1,OH}k_{2,OH} \quad (20)$$

can be solved with respect to four individual rate coefficients $k_{1,OH}$, $k_{2,OH}$, $k_{-1,OH}$, and $k_{-2,OH}$.

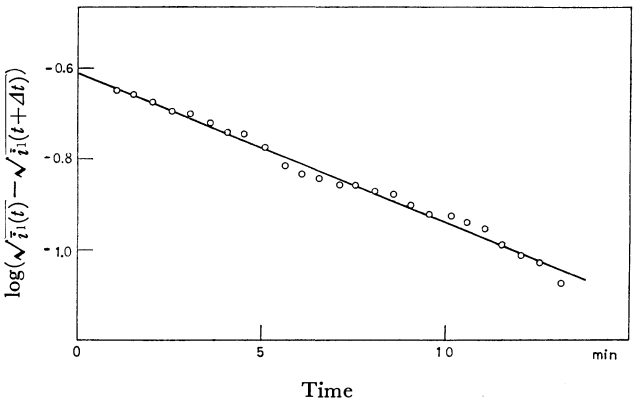

Fig. 6. Analysis of $\bar{i}_1$ *vs.* time curve of (α—β) D-xylose in 0.1M potassium chloride solution. Δt=15 min.

An example of the Guggenheim plot according to Eq. (16) is shown in Fig. 6. The values of $k_{o,w}$ determined by the present method and by the polarimetric method are given in Table 2. The results are in good accordance with each other.

Table 2. The overall mutarotation rate constant $k_{o,w}$ in 0.1M KCl solution (Temp. 25 °C)

	$k_{o,w}$ (s^{-1})	
	Polarography	Polarimetry
D-Xylose	1.31×10^{-3}	1.3×10^{-3}
D-Glucose	0.53×10^{-3}	0.4×10^{-3}
D-Galactose	0.54×10^{-3}	0.5×10^{-3}

Table 3. The forward and backward rate coefficients $k_{i,OH}$ (i=1,2, −1, and −2) (Temp. 25 °C)

	$k_{1,OH}$	$k_{2,OH}$	$k_{-1,OH}$	$k_{-2,OH}$
	($l\ mol^{-1}\ s^{-1}$)			
D-Xylose	8.2×10^2	6.0×10^2	8.4×10^4	11.5×10^4
D-Glucose	11.6×10	6.5×10	9.1×10^4	8.9×10^4

Table 3 shows the individual rate coefficients of hydroxyl ion for D-xylose and D-glucose, $k_{o,OH}$= $8\times10^2\ s^{-1}\ l\ mol^{-1}$ (D-xylose),[8] $9\times10\ s^{-1}\ l\ mol^{-1}$ (D-glucose),[11] D_{xy}[16]$=6.71\times10^{-6}\ cm^2\ s^{-1}$, D_{glu}[16]$=6.65\times10^{-6}\ cm^2\ s^{-1}$, K_{xy}[20]$=1.87$ and K_{glu}[20]$=1.74$ being used. The forward rate coefficients $k_{1,OH}$ and $k_{2,OH}$ for D-xylose are in fair agreement with those obtained from the analysis of the polarographic currents in buffered media.[8] The ratio of the concentration of the intermediate γ-form $C_{\gamma,eq}$ to that of α- and β-pyranose form, $C_{\alpha,eq}+C_{\beta,eq}$, was 3×10^{-1}% for D-xylose and 4×10^{-2}% for D-glucose. The results are also in the same order as those obtained from the experiments in buffered media.[8]

The authors thank Tokai Togyo Co., Ltd. for supplying α-D-glucose.

Thermal and Spectrophotometric Studies of 8-Mercaptoquinoline-5-sulfonic Acid and Its Sodium Salt

Eiichi SEKIDO, Junichi TANAKA, and Yoshitaka MASUDA

Department of Chemistry, Faculty of Science, Kobe University, Nada-ku, Kobe 657

(Received November 9, 1972)

Thermal and spectrophotometric studies of 8-mercaptoquinoline-5-sulfonic acid and its sodium salt synthesized by an improved method are reported. In order to determine the best formula for the weighing of organic reagent, the thermal stabilities of 8-mercaptoquinoline-5-sulfonic acid and its sodium salt and the amount of water of crystallization were examined with a thermal balance. It was found that the disodium dihydrate was of the best form. The ultraviolet and visible absorption spectra in aqueous-ethanol solution were measured, the tautomeric constant K_t between neutral and zwitterion forms being estimated and acid dissociation constants obtained spectrophotometrically. The absorption spectra and the equilibrium constants of the reagents were compared with those of 8-mercaptoquinoline, 8-hydroxyquinoline and 8-hydroxyquinoline-5-sulfonic acid.

Analytical application of 8-mercaptoquinoline, a typical organic reagent containing nitrogen and sulfur ligand atoms, has recently been studied by many analytical chemists. Stoichiometric studies of 8-mercaptoquinoline have been reported by a few investigators,[1-3] but they are not as extensive and systematic as those of 8-hydroxyquinoline and its metal chelates. This may be attributed to the difficulty of finding a favorable organic solvent capable of dissolution of many kinds of metal 8-mercaptoquinoline chelates.

Introduction of a sulfonic acid group at 5-position of the quinoline nucleus makes its metal chelates soluble in water. Thus it is possible to study stoichiometrically the various metal 8-mercaptoquinoline-5-sulfonic acid chelates as water soluble metal 8-mercaptoquinoline chelates.

The present paper deals with the thermal and spectrophotometric studies of 8-mercaptoquinoline-5-sulfonic acid and its sodium salt synthesized by an improved method. Their thermal stabilities, air oxidation, acid dissociation constants and ultraviolet and visible absorption spectra are compared with those of 8-mercaptoquinoline, 8-hydroxyquinoline, and 8-hydroxyquinoline-5-sulfonic acid.

Experimental

Materials. 8-Mercaptoquinoline-5-sulfonic acid and its derivatives have been synthesized by Vogt and Hein[4] and Bankovskis *et al.*[5] In order to raise the yield of the reagents, an improved synthesis from 8-hydroxyquinoline was attempted.

8-Hydroxyquinoline-5-sulfonic Acid: The methods by Coll and Coll[6] and Matsumura[7] were adopted for the synthesis from 8-hydroxyquinoline. Yield: 90%.

8-Aminoquinoline-5-sulfonic Acid: The synthesis of 8-aminoquinoline from 8-hydroxyquinoline by Vorozhtzov and Kogan[8] was utilized. 8-Hydroxyquinoline-5-sulfonic acid (45 g, 0.20 mol), ammonium sulfite (70 g, 0.52 mol), 28% ammonia (50 ml, 0.36 mol) and 100 ml of water are charged in an autoclave and heated at 150—160 °C, for 6—7 hr. under 10—15 atm. The gray green precipitate formed was dissolved with water, insoluble residues being filtered off. When the filtrate was concentrated to 300 ml followed by addition of 36% hydrochloric acid (50 ml, 0.58 mol), yellow to orange precipitate was formed. This was filtered and washed with water. One litre of water was added to the crude 8-aminoquinoline-5-sulfonic acid (10 g). A small amount of active carbon was added to the solution and heated for 30 min. After filtration, the filtrate was concentrated to 500 ml. On cooling, pure 8-aminoquinoline-5-sulfonic acid (*ca.* 6 g) was obtained.

Found: C, 44.55; H, 3.99; N, 11.32%. Calcd for $C_9H_{10}N_2O_4$: C, 44.62; H, 4.16; N, 11.56%. 8-Aminoquinoline-5-sulfonic acid was obtained by recrystallization from water as a mixture of yellow needle crystal and orange cube crystal. Both exist as monohydrate at room temperature, their anhydride being obtained by drying at 100—110 °C. Decomposition temperature is 220 °C.

8-Mercaptoquinoline-5-sulfonic Acid Disodium Salt Trihydrate: The synthesis of 8-mercaptoquinoline from 8-aminoquinoline by Kealey and Freiser[9] was utilized. 8-Aminoquinoline-5-sulfonic acid monohydrate (4.84 g, 0.02 mol) once at least recrystallized, was added to 150 ml of 24% hydrobromic acid solution (0.65 mol) and heated for dissolution. After complete dissolution, the solution was rapidly cooled in an ice-bath to deposit the fine crystal. To the resulting suspension, was added 10% sodium nitrous acid solution dropwise in an ice-bath until potassium iodide-starch paper turned blue. Excess sodium nitrous acid was decomposed by addition of 2 M sulfamic acid solution. The diazotized solution was gradually added to a solution of thiourea (1.7 g, 0.022 mol) dissolved in 50 ml of water at 30—40 °C, the solution then being heated at 90 °C for a short time. The reacting solution changed to red and a white precipitate was formed. To the resulting solution containing the precipitate was added hypophosphorous acid (2—5 equivalent amounts of 8-aminoquinoline-5-sulfonic acid) and heated to dissolve the precipitate. After the solution was filtered, the filtrate was cooled in an ice-bath and 100 g of solid sodium hydroxide

was gradually added with sufficient stirring under nitrogen gas. 8-Mercaptoquinoline-5-sulfonic acid disodium salt trihydrate formed as a yellow precipitate. After being filtered, the precipitate was washed twice with 90% ethanol. It was then dried for 1—2 hr under reduced pressure by means of a water-jet pump.

Yield: 80—90%. The crude product of 5—6 g was throughly dissolved in 50 ml of water and then 150 ml of ethanol was added. A yellow cube crystal was formed. After filtration, the precipitate was washed twice with 10 ml of ethanol and dried for 1—2 hr under reduced pressure by means of water-jet pump and then kept in a desiccator with silica gel under nitrogen.

Yield: 60—65%. Yellow cube crystals.

Found: C, 31.68; H, 3.19; N, 3.97%. Calcd for $C_9H_5NO_3S_2Na_2$: C, 31.86; H, 3.27; N, 4.13%.

8-Mercaptoquinoline-5-sulfonic Acid: To 8-mercaptoquinoline-5-sulfonic acid disodium salt trihydrate (3.3 g, 0.01 mol) dissolved in 45 ml of water was added 2.5 ml of 35% hydrochloric acid solution and 2.5 ml of 50% hypophosphorous acid, and the resulting red solution was heated for 1—2 hr on a water-bath and allowed to stand overnight. Faint yellow to faint brown silk thread-like 8-mercaptoquinoline-5-sulfonic acid was formed from the deep red solution. After the precipitate was filtered, it was washed twice with 3—4 ml ethanol and dried for 1—2 hr under reduced pressure, and kept in a desiccator with silica gel under nitrogen. The crude product was recrystallized from water containing hypophosphorous acid.

Yield: 63%.

8,8'-Diquinolyldisulfide-5,5'-disulfonic Acid Trihydrate: To 8-mercaptoquinoline-5-sulfonic acid disodium salt trihydrate (3.43 g, 0.01 mol) dissolved in 50 ml of water was added 2 ml of 35% hydrochloric acid and then 3% hydrogen peroxide solution until the red color disappeared completely. The resulting solution was allowed to stand overnight. Faint yellow cube crystal was formed.

Yield: 70%.

Found: C, 40.15; H, 3.42; N, 5.49%. Calcd for $C_{18}H_{18}N_2O_9S_4$: C, 40.44; H, 3.39; N, 5.24%.

Apparatus. Ultraviolet and visible absorption spectra were measured with a Hitachi 124 type spectrophotometer with 1 cm quartz cells. A Horiba Model P pH meter with glass and calomel electrodes was standardized against aqueous buffer (pH 4.01 and 6.86). Thermogravimetric curves were obtained with a Cho Thermobalance apparatus.

Thermogravimetric Measurement. About 100 mg of sample powder was weighed out into a holder for thermobalance and the temperature was elevated at a rate of 5 °C/min. The weight and temperature were read at regular time intervals.

Spectrophotometric Measurement. All the solutions were deaerated by bubbling with nitrogen. The absorption spectra were measured at 20±1 °C under nitrogen atmosphere. The solutions were buffered with perchloric acid, sodium hydroxide, acetic acid and disodium hydrogen phosphate and were adjusted with sodium perchlorate to maintain the ionic strength at 0.1 except for the solution with pH below 1.0.

Determination of Acid Dissociation Constants. All the acid dissociation constants for 8-mercaptoquinoline-5-sulfonic acid were determined spectrophotometrically. The macroscopic acid dissociation constants K_a at the ionic strength 0.1 and at 20±1 °C were determined by the equation

$$pK_{a_i} = \log (d_b - d)/(d - d_a) + pH \quad (1)$$

where d is the absorbance at 454 or 278 nm at the particular pH, d_b the absorbance in 1.00×10^{-3} M perchloric acid and d_a the absorbance in 5 M perchloric acid. The values of pK_{a_1} obtained for each pH were averaged. pK_{a_2} was determined in a similar way. pK_a' was estimated roughly by a graphical method. The values of the microscopic acid dissociation constants K_{a_A}, K_{a_B}, K_{a_C}, and K_{a_D} were obtained by the following equation and the values of K_{a_1}, K_{a_2} and the tautomeric constant K_t.

$$K_t = [\text{zwitterion}]/[\text{neutral}] = K_{a_D}/K_{a_C} \quad (2)$$

$$K_{a_1} = K_{a_A} + K_{a_B} \quad (3)$$

$$1/K_{a_2} = 1/K_{a_C} + 1/K_{a_D} \quad (4)$$

Determination of Tautomeric Constant. The tautomeric constant K_t was roughly estimated by two methods. 1) On the assumption that both extinction coefficients for 8-methylmercaptoquinoline-5-sulfonic acid and the neutral form of 8-mercaptoquinoline-5-sulfonic acid are the same at a corresponding wavelength, the ratio of the extinction coefficient at 339 nm of 8-methylmercaptoquinoline-5-sulfonic acid to the apparent extinction coefficient of 8-mercaptoquinoline-5-sulfonic acid in aqueous solution at 322 nm gives the fraction of the neutral form of 8-mercaptoquinoline. 7980 was taken[4] as the molar extinction coefficient at 339 nm for 8-methylmercaptoquinoline-5-sulfonic acid. 2) It is possible to estimate the expected absorbance at 322 nm for 100% neutral form of 8-mercaptoquinoline-5-sulfonic acid by using the data that the ratios of the increment of the absorbance at 322 nm to the decrement of the absorbance of the absorption maxima around 450 nm in various v/v% ethanol solution are approximately 1.6. The ratio of the absorbance in aqueous solution at 322 nm to the expected absorbance as 100% neutral form at the same wavelength gives the fraction of the neutral form of 8-mercaptoquinoline-5-sulfonic acid.

Results and Discussion

Thermal Stability. In order to find the best formula for gravimetry of the reagent, the thermal stability of 8-mercaptoquinoline-5-sulfonic acid and its sodium salt and the amount of water of crystallization were examined with a thermal balance. The thermogravimetric curves are given in Fig. 1 and the results in Table 1. We see that 8-mercapto and 8-hydroxyquinoline-5-sulfonic acids are less stable than the corresponding sodium salts and that 8-mercaptoquinoline-

8-Hydroxyquinoline-5-sulfonic acid dihydrate	70—105°C	Found: 7.23% Calcd for $C_9H_7NO_4S \cdot 2H_2O$: H_2O, 6.90%	270°C
	105—147°C	Found: 6.42% Calcd for $C_9H_7NO_4S \cdot 2H_2O$: H_2O, 6.90%	

5-sulfonic acid and its sodium salt are more stable than the corresponding 8-hydroxy compounds. 8-Mercaptoquinoline-5-sulfonic acid sodium salt anhydride is so hygroscopic that it rapidly increases about 11.8% in wt. when exposed to air for 1 hr. It may be concluded that the form of 8-mercaptoquinoline-5-sulfonic acid disodium dihydrate is the best for weighing. In the thermogravimetric curves in air for 8-mercaptoquinoline-5-sulfonic acid and its disodium salt (dashed lines of curves A and B, respectively), the former increases in weight by 1.0—1.2% in the temperature range 120—240 °C, the latter by 1.8—2.1% in the range 240—408 °C. A similar phenomenon was found with the sodium salts of 8-mercaptoquinoline[10] and 8-selenoquinoline.[11] It is assumed that the sodium salt of 8-mercaptoquinoline-5-sulfonic acid is oxidized by air.

Ultraviolet and Visible Absorption Spectra of the Reagent. Ultraviolet and visible spectra of 8-mercaptoquinoline-5-sulfonic acid were measured in order to know the stability of the reagent in aqueous solution against oxidation, species existing in various pH, acid dissociation constant, and tautomeric constant.

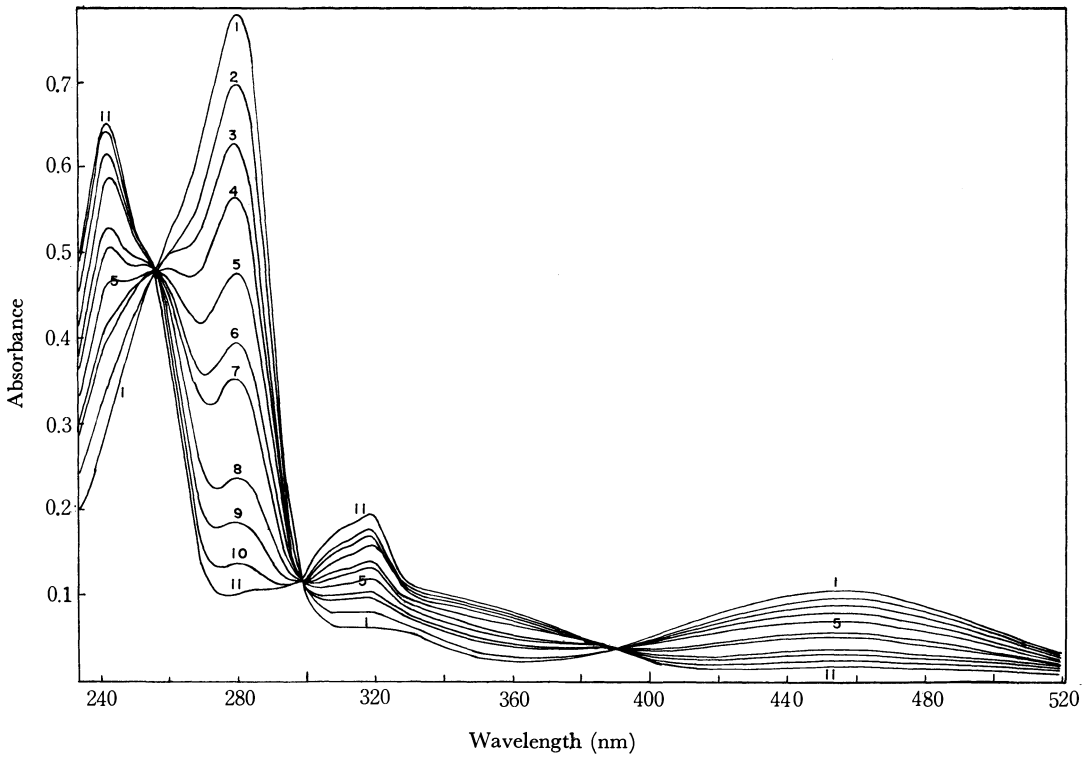

Fig. 5. Absorption spectra of 8-mercaptoquinoline-5-sulfonic acid in various pH solution at $\mu=0.10$.
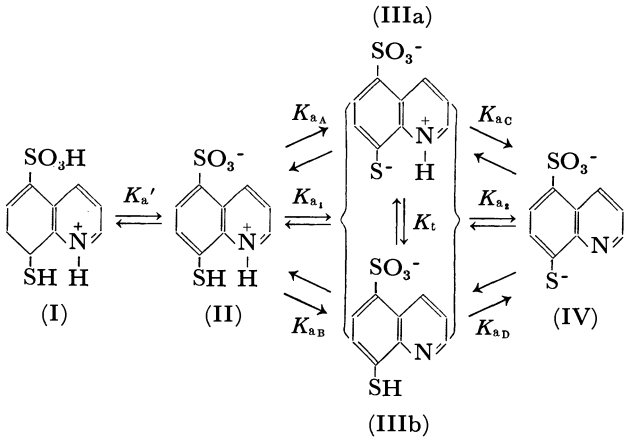
Concentration of the reagent: 3.00×10^{-5}M. pH: 1: 2.73, 2: 4.82, 3: 6.18, 4: 6.75, 5: 7.10, 6: 7.26, 7: 7.46, 8: 7.56, 9: 7.74, 10: 8.02, 11: 8.42, 12: 9.00, 13: 11.03.

to stand in air, it is gradually oxidized giving rise to the formation of 8,8′-diquinolyldisulfide-5,5′-disulfonic acid. Changes in the ultraviolet and visible absorption spectra by air oxidation at pH 3.0 and 10.0 were examined at 35 °C at which temperature oxidation is more accelerated than that at room temperature. The results are shown in Figs. 2 and 3, respectively. The intensities of the absorption maxima at 454 and 279 nm for pH 3.0 and at 378 nm for pH 10.0 decrease with time, while those at 322 and 243 nm for pH 3.0 and at 378 nm for pH 10.0 increase with time. The time required to oxidize half the amount of reagent at 35 °C is about 12 hr for pH 3.0 and about 5 hr for pH 10. The reagent is more rapidly oxidized with increase in pH. It is assumed that electron donation, or the oxidation of the $-S^-$ group of the anion (IV) existing in a high pH solution, accelerated to a greater extent than in the other species (I), (II), (III_a), and (III_b) of the reagent.

Ultraviolet and Visible Absorption Spectra of 8-Mercaptoquinoline-5-sulfonic Acid in Aqueous Solution: The ultraviolet and visible absorption spectra of 1.00×10^{-4} M 8-mercaptoquinoline-5-sulfonic acid at various concentrations of perchloric acid from 1.00×10^{-3} to 10.0 M and those in the pH range 3.0—12.0 are shown in Figs. 4 and 5, respectively. The relationship between the absorption maxima of 8-mercaptoquinoline-5-sulfonic acid and pH is shown in Fig. 6. The intensities of absorption at 454 and 279 nm decrease with the concentration of perchloric acid and disappear above 3.0 M. The absorption maximum at 322 nm in the solution of pH 3.0 shifts slightly toward 318 nm with acid concentration. The intensity increases and a weak absorption appears around 360 nm as a shoulder of the absorption at 318 nm. The weak absorption of 311 nm hardly recognized as an absorption at pH 3.0 appears as a shoulder of the absorption of 318 nm. The isosbestic points appear at 389 and 298 nm in the pH range 5.0—0, but the absorption bands in perchloric acid with concentration above 3 M deviate from these points. The absorption bands at 454 and 279 nm which exhibit the constant maximum absorbance in the pH range 3.0—5.0 decrease with alkaline concentration. Those at 378 and 265 nm increase. Isosbestic points exist at 419, 323, and 270 nm. (Fig. 5).

The ultraviolet and visible absorption spectra for 8-mercaptoquinoline-5-sulfonic acid in various pH solutions are similar to those for 8-mercaptoquinoline[2,3] except for the change in absorption at 318 nm below pH 0. Thus the changes in absorption spectra correspond to those of the structures I↔II↔III↔IV as follows:



From the changes of absorbance at 454 nm in the acidic and alkaline sides we obtained the values $pK_{a_1}=0.90\pm0.03$ and $pK_{a_2}=7.50\pm0.04$, respectively. Similarly from the changes of absorbance at 278 nm, $pK_{a_1}=0.90\pm0.01$ and $pK_{a_2}=7.48\pm0.09$ were obtained in good accordance with above.

The following results are found for the absorption band at 318 nm. 1) The absorption curves of the reagent in perchloric acid with concentration above 1.00 M deviate from the isosbestic points at 389 and 298 nm. 2) The plot of the absorbance *vs.* pH at

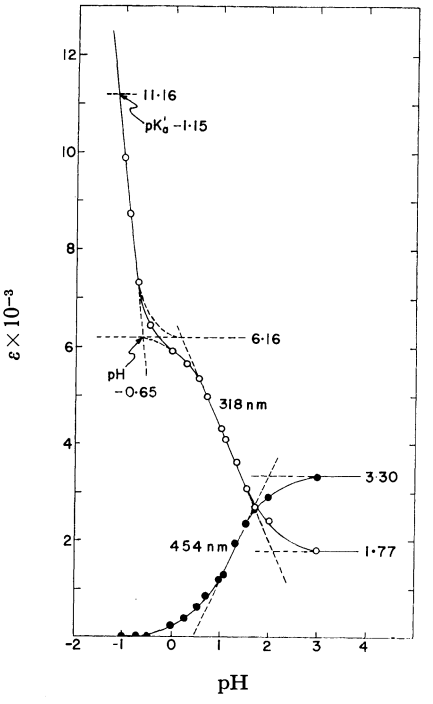

Fig. 7. Graphical determination of p*Ka*′.

Table 2. Relationship between absorbance of 8-mercaptoquinoline-5-sulfonic acid and concentration of perchloric acid

Concentration of perchloric acid (M)	Absorbance at 454 nm	Absorbance at 318 nm	$\frac{A_{318}-0.177}{0.330-A_{454}}$
1.00×10^{-3}	0.330	0.177	
1.00×10^{-2}	0.292	0.237	
2.00×10^{-2}	0.261	0.267	
3.00×10^{-2}	0.232	0.305	
5.00×10^{-2}	0.195	0.359	1.35
8.00×10^{-2}	0.155	0.403	1.29
1.00×10^{-1}	0.140	0.429	1.33
2.00×10^{-1}	0.087	0.495	1.31
3.00×10^{-1}	0.065	0.532	1.34
5.00×10^{-1}	0.041	0.562	1.33
1.00	0.023	0.590	1.35
		Mean	1.33 ± 0.04
3.00	0.002	0.640	1.41
5.00	0	0.731	1.61
8.00	0	0.870	2.10
10.00	0	0.987	2.45

318 nm has a point of inflexion around pH 0 (Fig. 7). 3) The ratio of the increase in absorbance at 318 nm to its decrease at 454 nm becomes greater in perchloric acid with concentration above 1 M (Table 2). These results are obtained also in the case of hydrochloric acid. This indicates that species (I) may be formed in a strong acid solution. The value of pK_a' for the equilibrium $I \rightleftarrows II + H^+$ is estimated as follows. The absorbances at 454 and 318 nm of the 1.0×10^{-4} M reagent in various concentrations of perchloric acid solution in the range 1.00×10^{-3}—10.0 M were measured. The ionic strength at 1.0 was maintained in the range 1.00×10^{-3}—1 M perchloric acid. The results are given in Table 2, and the plots of absorbances at 454 and 318 nm *vs.* pH in Fig. 7. $pK_{a_1}=1.14\pm0.02$ ($\mu=1.0$) was obtained from the values of absorbance at 454 nm and Eq. (1). If species (I) is not formed in a strong acid solution, the upper limit of the absorbance at 318 nm will be estimated as $d_a=0.330\times1.33\pm0.177=0.616$. Using $d_a=0.616$ and $d_b=0.177$, $pK_{a_1}=1.13\pm0.02$ ($\mu=1.0$) could be obtained. This is in good accordance with 1.14 ± 0.02 mentioned above. The plot of the absorbance at 318 nm *vs.* pH below -0.5 is found to be linear with a slope -1 (Fig. 7). Thus the value of pK_a' was roughly estimated to be -1 (dotted line, Fig. 7).

Ultraviolet and Visible Absorption Spectra of 8-Mercaptoquinoline-5-sulfonic Acid in Ethanol-Water Media: The absorption spectra of 8-mercaptoquinoline-5-sulfonic acid in aqueous-ethanol mixtures containing 1.00×10^{-3} M of perchloric acid are sohwn in Fig. 8. The wavelength of the absorption maxima and the molar extinction coefficients of the species in several kind of aqueous-ethanol mixtures are given in Table 3. The

absorption maximum in aqueous solution shifts to longer wavelength with the increase of ethanol content, its intensity decreasing significantly. Thus in 95% ethanol solution the absorption maximum shifts from 454 nm in aqueous solution to 498 nm in 95% ethanol and the apparent extinction coefficient decreases from 3.26×10^3 to 1.8×10^2. On the other hand, the absorption maximum at 322 nm in aqueous solution shifts slightly to longer wavelength 325 nm in 95% ethanol, but the apparent extinction coefficient increases from 1.42×10^3 to 6.58×10^3. In the range 300—200 nm, the absorption maximum at 279 nm decreases with the increase of ethanol content and that at 255 nm increases. It is assumed that zwitterion form IIIa is transferred into neutral form IIIb with the increase of ethanol content which causes the lowering of the dielectric constant of the solution. The absorption bands having peaks at 454 and 279 nm correspond to the zwitterion form and those at 323 and 255 nm to the neutral form. The absorption maxima of both the cation and the neutarl having –SH group are slightly shifted, but those at the longer wavelengths of both the zwitterion and anion having $-S^-$ group are significantly shifted to longer wavelength with the increase of the ethanol content (Table 3). This is remarkable for the zwitterion. Increase of the water content may stabilize the ground state to a greater extent for zwitterion (IIIa) or anion (IV) and the absorption maximum will shift to the blue side. Thus these absorption bands might be assigned to the charge transfer absorption in which $-S^-$ group takes part.

Equilibrium Constants of 8-Mercaptoquinoline-5-sulfonic Acid in Aqueous Solution. The tautomeric constant K_t=[zwitterion]/[neutral] was calculated to be 5.6 by method (1), and 3.9 by method (2). It was found that 80—85% of the reagent exists as the zwitterion and 20—15% as the neutral form in aqueous solution. Table 4 shows the equilibrium constants of 8-mercaptoquinoline-5-sulfonic acid and 8-mercaptoquinoline. The values of pK_{a_1} and pK_{a_2} for 8-mercaptoquinoline-5-sulfonic acid are lower than the corresponding ones for 8-mercaptoquinoline. This can be attributed to the electron with drawing power of the sulfonic acid group substituted at 5-position of the quinoline nucleus. The difference for pK_{a_1} (1.09) is larger than that for pK_{a_2} (0.86). The somewhat larger decrease of pK_{a_1} seems to be due to the fact that the value of K_t 3.9—5.6 for 8-mercaptoquinoline-5-sulfonic acid is somewhat larger than that for 8-mercaptoquinoline, 3.8.

Stability of Fused Rings in Metal Chelates. X. Structures and Stability Constants of the Copper(II) Complexes of Tripeptides Composed of Glycine and/or β-Alanine

Osamu YAMAUCHI, Yasuo NAKAO, and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

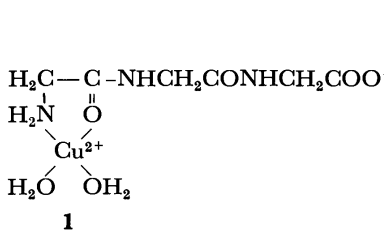
(Received November 15, 1972)

On the basis of comparative studies of the equilibria involving copper(II) and triglycine (G·G·G), glycylglycyl-β-alanine (G·G·β-A), glycyl-β-alanylglycine (G·β-A·G), or β-alanylglycylglycine (β-A·G·G), the structures of the complexes formed at various pH values and the structure-stability relationship between the fused-ring chelates have been discussed in reference to the equilibrium constants determined by potentiometric titration at 25° (μ=0.1 (KNO_3)) and the properties of the copper(II) chelates isolated. For each tripeptide, the stability constant K_1 for the 1 : 1 complex and the constants for the deprotonation reactions K_{c_1} and K_{c_2} were calculated by the method of non-linear least-squares. For G·G·G, G·G·β-A, and G·β-A·G, the equilibrium indicating the formation of a protonated complex was detected at pH 3.5—4.5. The relatively small difference in the log K_1 values (5.25—5.60) and the $-\log K_{c_1}$ values (5.23—5.36) and the larger difference in the $-\log K_{c_2}$ values (5.54—6.73) have been interpreted in terms of the steric requirements around copper(II) in the fused-ring chelates. Relative stabilities of the fused-ring systems in the deprotonated chelates have been inferred from the $K_1K_{c_1}K_{c_2}$ values to be in the order 5-6-5(G·β-A·G–Cu(II))≃6-5-5(β-A·G·G–Cu(II))>5-5-6(G·G·β-A–Cu(II))>5-5-5(G·G·G–Cu(II)).[1]

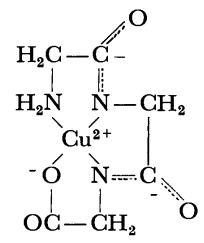
In view of the importance of the metal-protein interactions in biological systems, attention has been paid to various fundamental aspects of the protein-metal bonding, such as the bonding modes and the extents or strengths of the interactions in simplified systems. The complex formation between peptides and metal ions has been extensively investigated.

However, there still exist some ambiguities about the nature of the metal–peptide binding in aqueous solution, which is a prerequisite for understanding the interactions in the biological fluid. In this connection we have extended our studies on the copper(II) complexes of the dipeptides[2] and the amino acid amides[3] to the tripeptides composed of glycine and β-alanine, in order to reveal their behavior toward copper(II) ion.

Valuable findings characterizing the triglycine-copper(II) complexes in solution have accumulated by detailed potentiometric,[4-8] thermodynamic,[9,10] kinetic,[11,12] and spectral studies.[6,7,13] The coordination sites in the complexes in aqueous solution have been inferred from these findings and the results of X-ray crystal structure analyses[14,15] to be the amino nitrogen and the peptide oxygen in the acid region (structure **1**), and the amino nitrogen, the peptide nitrogens and the carboxyl oxygen in the neutral and alkaline regions (structure **2**). Probably because of the steric requirements around copper(II), the triglycine complex isolated from the alkaline solution has a dimeric structure,[15] where the carboxyl group coordinates to the copper(II) above (or below) the plane of the chelate ring considered and one of the peptide nitrogens axially interacts with that copper(II).



1



2

We considered it to be of basic importance to investigate how and to what extent the steric requirements in the consecutive chelate rings affect the stability in solution of the copper(II)–tripeptide complexes and, if possible, to infer the bonding modes in the fused-ring chelates. Since replacement of a glycyl group of triglycine with a β-alanyl group is expected to introduce a six-membered ring which would affect the stability of the fused-ring system, we have investigated the solution equilibria of the copper(II) complexes of several tripeptides containing glycine and/or β-alanine, and attempted to elucidate the structure-stability relationship between them.

1) Such notations are used throughout the text to express arrangement and size of the individual rings involved in the fused-ring system.

a) The corresponding chelate used by Freeman *et al*[15] for X-ray study was a monohydrate.
b) Determined on a micro melting point apparatus.
c) Values of 5.0×10^{-3}M aqueous solutions of the chelates.

For the present purpose, we chose triglycine (G·G·G), glycylglycyl-β-alanine (G·G·β-A), glycyl-β-alanylglycine (G·β-A·G), and β-alanylglycylglycine (β-A·G·G) as typical ligands, and carried out potentiometric titration and preparation of the copper(II) chelates. Determination of the equilibrium constants and the discussion of the structures and relative stabilities of the complexes in solution constitute the main subjects.

Experimental

Ligands. *G·G·G*: This was purchased from Nakarai Chemicals Co., Ltd. and checked by elemental analysis and amino acid analysis with a Yanagimoto amino acid analyzer LC-5.

G·G·β-A: To a cooled and stirred solution of glycyl-β-alanine[16] (7.8 g) in 4 M sodium hydroxide (13.4 ml) was added, alternately, chloroacetyl chloride (9.1 g) and 4 M sodium hydroxide (20.4 ml) at such a rate that the reaction mixture could be maintained alkaline at a temperature below 5 °C. After addition was over, stirring was continued for 10 min, and the pH of the solution was adjusted to *ca.* 2 with concd. hydrochloric acid. The colorless precipitate formed was collected by filtration and recrystallized from acetone to give chloroacetylglycyl-β-alanine, mp 158—159 °C (uncor.). Found: C, 37.75; H, 4.83; N, 12.20%. Calcd for $C_7H_{11}N_2O_4Cl$: C, 37.76; H, 4.99; N, 12.58%.

Chloroacetylglycyl-β-alanine was treated with aqueous ammonia as for chloroacetyl-β-alanine,[16] and the product was recrystallized from water–ethanol to give G·G·β-A, which was checked by melting point[16] and elemental analysis.

G·β-A·G: This was prepared by catalytic reduction[16] of carbobenzoxyglycyl-β-alanylglycine prepared from β-alanylglycine[17] and carbobenzoxyglycyl chloride,[18] and checked by melting point and elemental analysis.

β-A·G·G: This was prepared and checked analogously.[16]

(1) Copper(II) Chelates: All the chelates were prepared by the method described for sodium glycylglycylglycinatocuprate(II) monohydrate[15] and dried over silica gel. The analytical data and the spectral properties of the four chelates isolated are summarized in Table 1.

(2) Measurements of Spectra: Visible spectra were measured for 5.0×10^{-3} M aqueous solutions with a Shimadzu QR-50 spectrophotometer.

(3) pH Titrations: *(a) Reagents*: 0.1 M Potassium hydroxide, 0.1 M nitric acid, and 0.01 M copper(II) nitrate were prepared in the same manner as described.[3] All the reagents used were of analytical grade, distilled and deionized water being used.

(b) Apparatus: A Radiometer PHM 4d pH meter equipped with a G202B glass electrode and a K401 calomel electrode was used after standardization with a Horiba and a Radiometer standard buffer solution (pH 4.01 and 6.48 at 25 °C).

(c) Procedure: The procedure was essentially the same as that reported.[3] An aqueous solution containing nitric acid and equimolar amounts of a ligand and copper(II) nitrate (*ca.* 0.004 M) was titrated with 0.1 M potassium hydroxide, the pH being measured at 25±0.05 °C under a nitrogen atmosphere. The ionic strength was adjusted to 0.1 with potassium nitrate. The ligands were titrated in the absence of copper(II) nitrate under the same conditions. Conversion of pH to $-\log[H^+]$ and determination of the apparent ion product of water were made as reported.

Results

Titration Curves and Equilibria. The titration curves obtained for the tripeptides in the absence and the presence of copper(II) are given in Figs. 1 and 2, respectively. All the peptides give similar titration curves with four protons dissociating from the protonated peptide molecule in the presence of copper(II). The same reaction sequence can thus be reasonably assumed for all the systems. The G·G·G–Cu(II) system has been expressed by the following equilibria in acid and neutral solutions corresponding to *a* values (moles of KOH added per mole of ligand) of 1—4:[4-8]

$$Cu^{2+} + H_2L^- \overset{K_1}{\rightleftharpoons} Cu(H_2L)^+ \quad (1)$$

$$Cu(H_2L)^+ \overset{K_{c_1}}{\rightleftharpoons} Cu(HL) + H^+ \quad (2)$$

$$Cu(HL) \overset{K_{c_2}}{\rightleftharpoons} CuL^- + H^+ \quad (3)$$

where Cu^{2+} and H_2L^- refer to free copper(II) ion and free ligand, respectively, and equilibria (2) and (3) express the dissociation of protons from the peptide groups in the complex. The equilibrium constants are

a: moles of KOH added per mole of ligand.

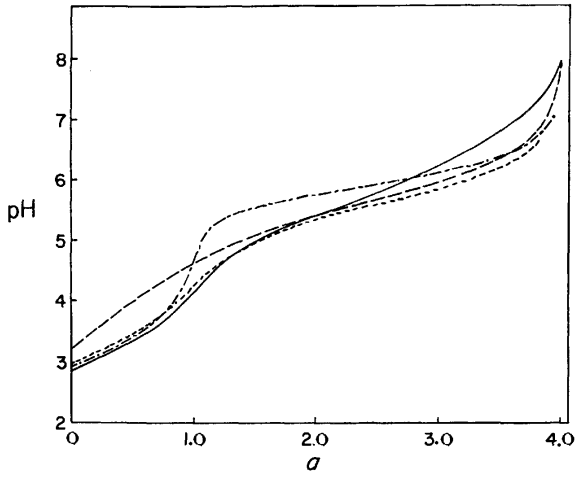

Fig. 2. Titration curves for the 1:1 tripeptide–copper(II) systems.
———: G·G·G–Gu(II), – – – –: G·G·β-A–Cu(II), --------: G·β-A·G–Cu(II), —·—·—: β-A·G·G–Cu(II).

defined by the following equations.

$$K_1 = \frac{[Cu(H_2L)^+]}{[Cu^{2+}][H_2L^-]} \quad (4)$$

$$K_{c_1} = \frac{[H^+][Cu(HL)]}{[Cu(H_2L)^+]} \quad (5)$$

$$K_{c_2} = \frac{[H^+][CuL^-]}{[Cu(HL)]} \quad (6)$$

In the pH range 3.5—4.5, pH depressions due to complex formation with copper(II) are small but not negligible for the G·G·G–, G·G·β-A–, and G·β-A·G–Cu(II) systems, whereas hardly any depression is observed for the β-A·G·G–Cu(II) system. In order to achieve better fit to the titration curves in this region, it was found necessary to add the following equilibria when the tripeptides have glycine residue as the NH_2-terminus:

$$Cu^{2+} + H_3L \overset{K^H}{\rightleftharpoons} Cu(H_3L)^{2+} \quad (7)$$

$$Cu(H_3L)^{2+} \overset{K_a^H}{\rightleftharpoons} Cu(H_2L)^+ + H^+ \quad (8)$$

where H_3L is the zwitterionic species of the tripeptides and $Cu(H_3L)^{2+}$ the protonated complex. The equilibria involving such a protonated complex have been reported for G·G·G at $\mu=3.0$ ($NaClO_4$) by Österberg and Sjöberg,[8] and they seem to exist also in the other tripeptide–Cu(II) systems in 0.1 M KNO_3.

Method of Calculation. On the basis of equations for the mole balance for total ligand and total metal ion concentrations C_L and C_M and for the electroneutrality of solution, the equilibrium constants K^H, K_1, K_{c_1}, and K_{c_2} were calculated by the method of non-linear least-squares with the aid of a NEAC 2200/500 computer. Constant K_a^H for the equilibrium (8) was calculated by

$$K_a^H = \frac{K_{a_2}K_1}{K^H} \quad (9)$$

where K_{a_2} refers to the acid dissociation constant of the amino group.

Details of the computer calculations are the same as those reported previously.[3] The Newton-Raphson iterations for calculating the free ligand and free metal ion concentrations at each data point were continued until satisfactory convergence had been attained. When the residuals $|C_L(\text{observed}) - C_L(\text{calcd})|$ and $|C_M(\text{observed}) - C_M(\text{calcd})|$ failed to converge to within $10^{-5}\times C_L(\text{observed})$ and $10^{-5}\times C_M(\text{observed})$, respectively, after 150 iterations, the calculation was abandoned, and the computer proceeded to the next data point. When the total number of such non-convergent data points amounted up to 10, the initial constants were replaced by another set of estimates. Least-squares refinements were complete after 5—10 cycles when the initial estimates were nearly satisfactory, but 30 or more cycles were necessary when they were poor. Usually, 70—100 data were subjected to the least-squares treatment, which afforded the constants that could satisfactorily reproduce the titration curves. The difference between the observed and calculated titers of 0.1 M potassium hydroxide was less than 0.03 ml for all the data points with the titers ranging from 2.0 to 6.5 ml. The acid dissociation constants for each ligand were calculated from 40—50 data points.

Equilibrium Constants. Table 2 shows the equilibrium constants for the tripeptides and the two dipeptides included for comparison. The excellent fit of the theoretical titration curves to the observed ones over all the data points used substantiates the equilibria considered and the relevant constants in the 1:1 tripeptide–Cu(II) systems. When the theoretical curves were described by the three constants K_1, K_{c_1}, and K_{c_2} calculated from the data corresponding to $a=1$—4, serious deviations (*ca.* 8% when expressed in the titer) from the experimental curves were observed at $a<1$ for G·G·G–, G·G·β-A–, and G·β-A·G–Cu(II) systems. In the case of the β-A·G·G–Cu(II) system, calculation of the reliable values of K^H was not successful probably because of the very low stability of

Table 2. Equilibrium constants (25 ± 0.05 °C; $\mu=0.1$ (KNO_3))[a]

Ligand	pK_{a_1}	pK_{a_2}	log K^H	$pK_a^{Hb)}$	log K_1	pK_{c_1}	pK_{c_2}	log $K_1K_{c_1}K_{c_2}$

a) Variances are expressed in standard deviations estimated from the elements of the inverted matrix and the assumed error (0.01 ml) for the titers of 0.1 M potassium hydroxide. b) Calculated by eq. (9). c) The value reported by Österberg and Sjöberg[8] is 1.58 at 25° (μ=3.0($NaClO_4$)). d) Previously reported.[3] e) Not measured.

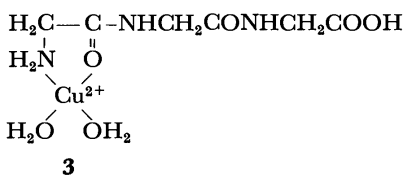
the protonated complex. Log K^H and hence the pK_a^H ($=-\log K_a^H$) values may not be sufficiently accurate, and we may safely use two significant figures for each. Some characteristic features of chelate stability can be seen from Table 2. The log K_1 values for G·G·G, G·G·β-A, and β-A·G·G are nearly the same, the value for G·β-A·G being slightly higher. A somewhat different trend is observed for the log K^H values which indicate the importance of the size of the NH_2-terminal chelate ring and the pK_a of the amino group. It is also evident from the values for G·G·G and G·G·β-A that the nature of the COOH-terminus has practically no influence on the stability constants.

Replacement of a glycine residue of G·G·G with a β-alanine residue does not seem to affect the log K_1 and pK_{c_1} ($=-\log K_{c_1}$) values greatly, but the steric effects associated with it are most clearly reflected in the pK_{c_2} ($=-\log K_{c_2}$) values, which vary from 5.54 of β-A·G·G to 6.73 of G·G·G.

The relative abundances of the species present at various pH in the tripeptide–copper(II) systems were calculated from the equilibrium constants and plotted against pH (Figs. 3(a)—(d)).

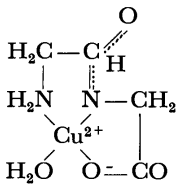
Discussion

The sequence and mode of coordination to copper(II) of the amino, peptide, and carboxyl groups of peptides have been discussed by many investigators. As regards the structures of the protonated copper(II) complexes $Cu(H_3L)^{2+}$ in acid solution, the log K^H values suggest the structure like **3** where the amino group in the coordination sphere of copper(II) is

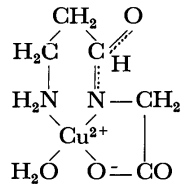


3

assumed with the carboxyl group left un-ionized. Such a structure seems to explain the higher stability of the protonated G·G·G–, G·G·β-A–, and G·β-A·G–Cu(II) complexes, which have a stable five-membered ring as compared with the less stable six-membered ring in the β-A·G·G–Cu(II) complex. The structure is not inconsistent with the crystal structure for $Cu(H_2L)^+$ [14] formed upon dissociation of a proton from $Cu(H_3L)^{2+}$ and is also in line with the NMR studies by Li *et al.*[19] and Kim and Martell[13] on the pH-dependent disappearance of the signals of the three CH_2-groups in the G·G·G–Cu(II) complex. On the other hand, no appreciable formation of the protonated complexes was detected for glycylglycine(G·G) and β-alanylglycine(β-A·G). Their titration curves could be reproduced without serious deviations by K_1 and K_{c_1} over the range covering $a=0$—3. Since the pK_a values of G·G do not differ much from those of G·G·G, the lack of the intermediate step similar to reaction 7 in the G·G–Cu(II) system suggests that the complex formation therein must be achieved, even before dissociation of the peptide proton, by the coordination of the amino, peptide, and carboxyl groups (structures **4a** and **4b**). This mode of coordination may be due to the quite favorable locations of these groups in the ligand molecule for constructing a fused-ring chelate. The reason for the behavior of β-A·G may in part be the same as that for β-A·G·G.



4a



4b

We have disclosed by X-ray crystal structure analysis[20] that chloroglycylglycinatocopper(II) monohydrate, which corresponds to the tripeptide complexes of the type $Cu(H_2L)^+$, has a dimeric structure very similar to that of the G·G·G–Cu(II) complex. Although the crystal structure generally gives evidence to the structures in solution, it seems unlikely that the carboxyl groups maintain the dimeric structure even in dilute aqueous solution.[2,3] In this connection, Bair and Larsen[21] inferred from spectral studies on the isolated chelates that the binding sites in the G·G–Cu(II) chelate of the type $Cu(HL)^+$ (HL^- refers to the free G·G ion) were the amino and peptide nitrogens, although contribution of the carboxyl group remained

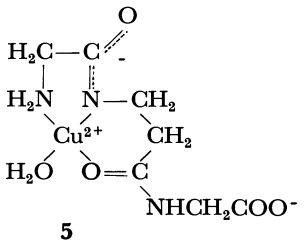
unknown.

The complexes of the type Cu(HL), where one of the peptide hydrogens is removed, have been expressed by a fused-ring structure like **5** which is also consistent with our finding about the pK_{c_1} values. We see from Table 2 that the pK_{c_1} values for the four tripeptides are very close to each other. If we assume the coordination by the tripeptides to be bidentate, we should expect a



5

higher pK_{c_1} value for β-A·G·G from the usual rule for the steric effects of the ring size on stability, because pK_{c_1} can be taken as a measure of the steric accessibility of the peptide group to copper(II). The degrees of formation of Cu(HL) can be compared at a constant pH by the $K_1K_{c_1}$ values according to the following equation[2]

$$\frac{[Cu(HL)]}{[Cu^{2+}][H_2L^-]} = \frac{K_1K_{c_1}}{[H^+]} \qquad (10)$$

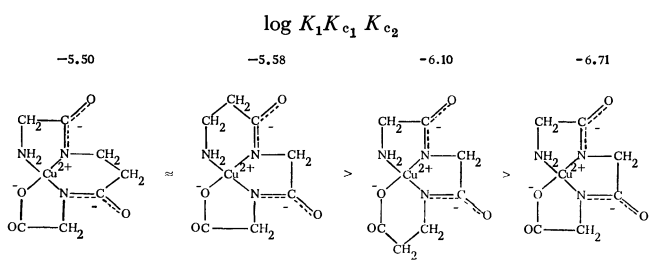
The small difference between the ligands (less than 0.28 log unit) is similar to that in the results obtained for the dipeptide–copper(II) systems and may be considered as indicative of approximately equal stability of 5-5-membered systems (G·G·G– and G·G·β-A–Cu(II)) and 6-5-(or 5-6-)membered systems (β-A·G·G– and G·β-A·G–Cu(II)).

In contrast to the log K_1 and pK_{c_1} values, a striking difference is observed between the pK_{c_2} values. The value for G·G·G is the highest, which may reasonably be interpreted as resulting from the steric strain due to the fused 5-5-5-membered ring (structure **2**), where the accumulated ring strains can not be relieved by a six-membered ring existing in the complexes of the other three β-alanine-containing tripeptides, whose pK_{c_2} values are more than 0.6 log unit lower.

The relative stability of the complexes of the type CuL^- at a constant pH inferred from the $K_1K_{c_1}K_{c_2}$ values in the following equation clearly indicates the effects of the overall steric requirements around copper(II) on the stability of the chelates:

$$\frac{[CuL^-]}{[Cu^{2+}][H_2L^-]} = \frac{K_1K_{c_1}K_{c_2}}{[H^+]^2} \qquad (11)$$

We see that the values decrease in the order G·β-A·G≈ β-A·G·G>G·G·β-A>G·G·G (Scheme 1), being the manifestation of accumulation of, or release from, the strains in the rigid fused-ring systems composed of three individual rings. The low stability of the probably monomeric G·G·G–Cu(II) formed in neutral and alkaline solutions might give rise to the formation of a dimer with a less hindered structure in the crystalline state.[15] Hence, it may be expected that the



Scheme 1. Relative stabilities of the tripeptide–Cu(II) chelates of the type CuL^-

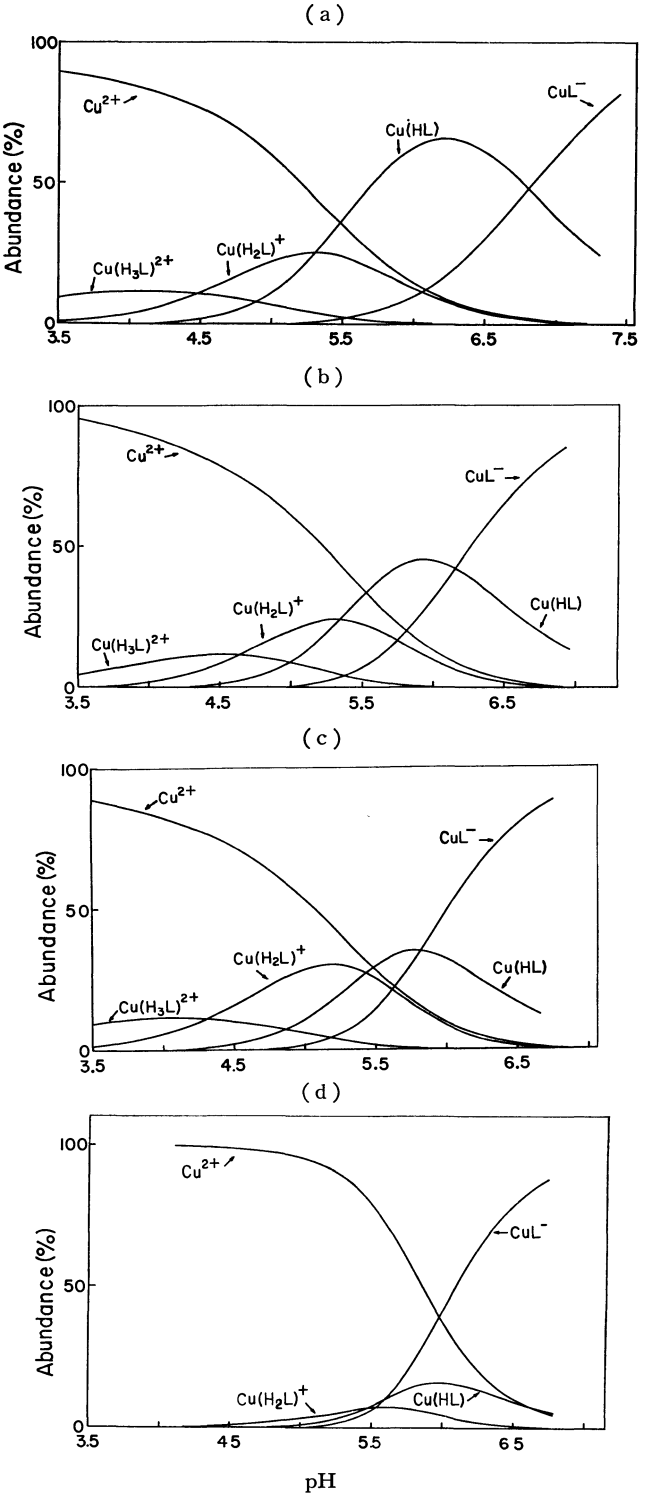


Fig. 3. Calculated abundances of the coordinated species in the 1:1 tripeptide–copper(II) systems.
(a): G·G·G–Cu(II) system, (b): G·G·β-A–Cu(II) system, (c): G·β-A·G–Cu(II) system, (d): β-A·G·G–Cu(II) system.

chelates are monomeric also in the crystalline state when the steric strains are cancelled by a β-alanine residue. It is of particular interest to note in this connection that the recent studies[22] on temperature dependence of magnetic susceptibilities of the chelates isolated as crystals indicated no copper(II)-copper(II) interactions. This supports the view that in the crystalline state the chelates of the β-alanine-containing tripeptides may have monomeric structures. On the other hand, the dimeric G·G·G–Cu(II) chelate exhibits such interactions owing to the short distance (3.077 Å)[15] between the copper(II) ions constituting the dimeric structure.

Figures 3(a)—(d) show the pH dependence of the relative amounts of the species present in the 1:1 tripeptide–copper(II) systems. In acid solution, the protonated complexes are present over considerably wide pH ranges. The four coordinated species $Cu(H_3L)^{2+}$, $Cu(H_2L)^{+}$, Cu(HL), and CuL^{-} are present at pH 5—6 in the systems of the tripeptides with glycine at the NH_2-terminus. In the G·G·G–Cu(II) system, there is a distinct peak for Cu(HL) at pH 6.2 ascribable as being due to the difficulty of deprotonation from the peptide group nearest the carboxyl terminus. Thus, formation of the species CuL^{-} in this system occurs at higher pH values as compared with other systems. However, the predominant species at pH above 7 is CuL^{-} in all the systems investigated, which may be taken as evidence for the bonding modes in the biological fluid.

The authors wish to thank members of the Osaka University Computation Center for computations. The investigation was supported in part by a grant from the Japanese Ministry of Education.

The Metal Ammine Cyanide Aromatics Clathrates. XVI. Wide-Line NMR Studies of the Three-Spin Systems of Ligand Ammonia in Paramagnetic Hofmann-type Clathrates

Taku NAKANO*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received November 7, 1972)

Wide-line NMR studies of ammonia molecules in Hofmann-type clathrates with the general formula jo $M(NH_3)_2M'(CN)_4 \cdot 2C_6D_6$ are reported. In the Hofmann-type clathrates, two ammonia molecules coordinate to the paramagnetic metal ions in *trans* positions and have only a slight interaction with each other. In powder samples, the proton NMR spectra of ammonia give fine structures with three components, which are caused by dipolar interaction between protons of the rotating triangular three-spin system. The signals shift to the higher-field side under the influence of the paramagnetic moments of the metal ions. The temperature dependence of the shifts and line shapes, where M is iron(II), cobalt(II), nickel(II), and copper(II), will be reported on. No rigid ammonia was found, even at the temperature of liquid nitrogen.

Previously, in this laboratory, the Hofmann-type clathrates with general formula of $M(NH_3)_2M'(CN)_4 \cdot 2G$ have been prepared.[1-4] Their structure, determined on the basis of the single-crystal X-ray diffraction data, are illustrated in Fig. 1.[5-8] The clathrates consist of an inorganic host lattice formed infinite net planes, $[M(NH_3)_2M'(CN)_4]_\infty$, and aromatic guest molecules, G, such as benzene or aniline, trapped

in the lattice. Here, M means the divalent transition metal ions, Mn, Fe, Co, Ni, Cu, Zn, and Cd, which occupy the octahedral site, $M(NH_3)_2(NC)_4$, and M′ is divalent Ni, Pd, or Pt, in the square-palnar site, $M'(CN)_4$. To the metal ion, M, four bridging cyanide ions coordinate with nitrogen atoms in the square-planar configuration and two ammonia molecules in *trans* positions (Fig. 1b).

As has been reported in previous papers, the clathrates whose octahedral sites are occupied by Zn or Cd are diamagnetic, and those containing paramagnetic divalent transition metals are high-spin complexes. The temperature dependence of the paramagnetic susceptibility obeys Curie's law throughout the range from 76 to 300 K.[4]

Beside the structure determination, wide-line NMR studies were undertaken, and the motion of the guest molecules was successfully studied.[9] Two ammonia ligands attached to an octahedral metal ion appear to be magnetically well shielded from each other, and the NMR signals split into fine structures which could not be observed in other, ordinary metal ammine complexes.[10]

A diamagnetic clathrate, $Cd(NH_3)_2Ni(CN)_4\cdot 2C_6D_6$, has already been studied by Miyamoto.[11] He used single crystals containing deuterated benzene and analyzed the ammonia spectra by the use of the three-spin-system model of Andrew and Bersohn;[12] he thus obtained the proton-proton distance from the line splitting in the fine structures, and also from the second-moment data. No rigid ammonia was found at the temperature of liquid nitrogen.

In paramagnetic substances, a wide-line NMR is influenced by electron spins and so is the source of much information about structures. The subjects of the present report are paramagnetic Hofmann-type clathrates containing divalent transition metals, Mn, Fe, Co, Ni, and Cu, in the high-spin state.

Apart from their interest in the connection with the phenomena of clathration, these compounds were used to study the general problem of the magnetic behavior of ammonia molecules coordinated to paramagnetic cations. The situations are favorable; the NMR spectra show fine structures, the metals take a series of electron configurations from d^5 to d^9, and moreover, all the complexes are isostructural.

The only data previously available were those of Umemoto and Danyluk[13] for $Ni(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$ and $2C_6D_6$; our interpretations are different from theirs.

Experimental

Materials. The clathrates investigated were prepared by the methods described in the previous papers.[2,4] When M was Mn, Fe, or Co, the preparations and measurements were carried out in a nitrogen atmosphere to protect the metal ions from oxidation. The powder samples of about one gram for each species were sealed in a glass tube 10 mm in diameter, avoiding the oxidation of the sample and the escape of benzene from the clathrates.

Apparatus. The NMR spectra were recorded with a JEOL-JNM-W30 spectrometer (30 MHz) of the Anderson-bridge type. The spectra of the clathrates were recorded as derivative curves at temperatures from 100 to 296 K, the measurements being made with a copper-constantan thermocouple. The samples were cooled with a cold nitrogen stream from a liquid nitrogen bottle. To ascertain the values of the shifts of the signals from the Larmor frequency, isopentane (mp 113 K) in a capillary on the wall of the sample tube was used as the reference compound.

Results and Discussion

The Wide-line NMR Spectra of $M(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$. The superimposed spectra of the protons of benzene and ammonia molecules in Hofmann-type clathrates at room temperature are shown in Fig. 2.

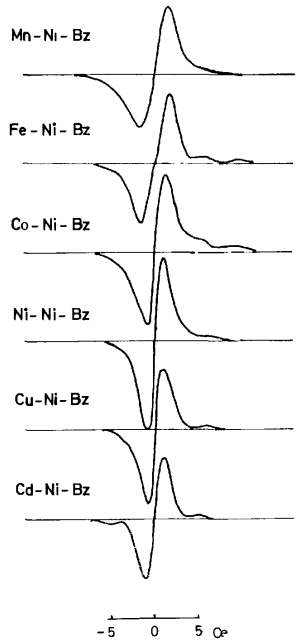

Fig. 2. Wide-line NMR spectra of ammonia protons and benzene protons in Hofmann-type clathrates, $M(NH_3)_2Ni(CN)_4\cdot 2C_6H_6$ at 296 K.

The signal of diamagnetic clathrate is symmetric with respect to the Larmor frequency, whereas the signals of the paramagnetic ones are asymmetric; the degree of asymmetry grows with the paramagnetic moments of the compounds. Apparently, the asymmetry is mainly due to the large shift of the ammonia protons. The signals of benzene protons do not vary for different clathrates at room temperature.

The Spectra of $M(NH_3)_2Ni(CN)_4\cdot 2C_6D_6$. As is shown in Fig. 3, ammonia in the Hofmann-type clathrates which contain deuterated benzene gives NMR spectra at 296 K with fine structures, typical of a trianglar three-spin system, except in the case of the manganese compound.

In Figs. 4—7, the signals of ammonia in four complexes in the derivative form at various temperatures are

shown. All the spectra show a higher-field shift at lower temperatures, though they have delicate variations in shape. If they are compared as integral forms, the distances between the three peaks are constant. The shift increases to the higher-field side, and the tails of the signals are more elongated to the lower-field side, so that the accurate computation of the second moments was not possible, in practice. As will be shown later, the long tailing in the spectra demonstrates that the shift depends upon the angle of the *c*-axis of the crystallines in the magnetic field.

Analyses of Ammonia Spectra. The above features of the spectra were explained theoretically and provide knowledge of the molecular structure.

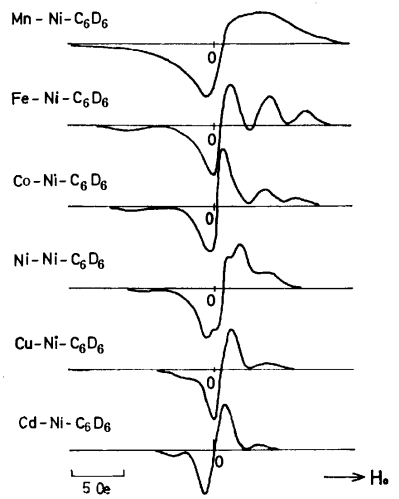

Fig. 3. Wide-line NMR spectra of ammonia protons in Hofmann-type clathrates, $M(NH_3)_2Ni(CN)_4\cdot 2C_6D_6$ at 296 K.

In order to consider the system,[10,11] we take the effective spin Hamiltonian of the system as:

$$H_{\text{eff}} = H^\circ + H_1' + H_2' + H_3'$$

$$H^\circ = -\sum_{j=1}^{3}\gamma_N\hbar I_{zj}H_0$$

$$H_1' = \sum_{i>j}\frac{\gamma_N^2\hbar^2(3\cos^2\theta_{ij}-1)}{2r_{ij}}(\mathbf{I}_i\cdot\mathbf{I}_j - 3I_{zj}I_{zi})$$

$$H_2' = -\sum_{j=1}^{3}\frac{\gamma_N\hbar(3\cos^2\theta_j-1)}{r_j^3}(\gamma_e\hbar\langle S_z\rangle)I_{zj}$$

$$H_3' = \sum_{j=1}^{3}a_j\langle S_z\rangle I_{zj}$$

$$a_j = \frac{8\pi}{3}\gamma_N\gamma_e\hbar^2\delta_j$$

$$\delta_j \equiv \langle\Psi_1|\sum_k\delta(r_{kj})S_{kz}|\Psi_1\rangle/S_z \qquad (1)$$

where the four terms, H°, H_1', H_2', and H_3', are the Zeeman term, the dipolar interaction between three protons, the dipolar interaction between paramagnetic moment and protons, and the Fermi-type contact interaction respectively. In Eq. (1), r_{ij} is the distance between the i and j nuclei, r_j is the distance between the metal ion and the j nucleus, θ_j is the angle between the applied field, $\boldsymbol{H}_0$, and $\boldsymbol{r}_j$, a_j is the coefficient of the contact interaction, Ψ_1 is a wave function of the electrons, and $\boldsymbol{r}_{kj}$ is the vector between the electron and j nucleus. The other symbols have their usual meanings.

In the present compounds, the paramagnetism obeys Curie's law, so we assumed the time-average value of the z component of the electron spin, $\langle S_z\rangle$, to be:

$$\langle S_z\rangle = \frac{\gamma_N\hbar S(S+1)}{3kT}\boldsymbol{H}_0 \qquad (2)$$

When the applied magnetic field is large enough, *i.e.*, $H^\circ \gg H'$, H' is treated as a first-order perturbation.

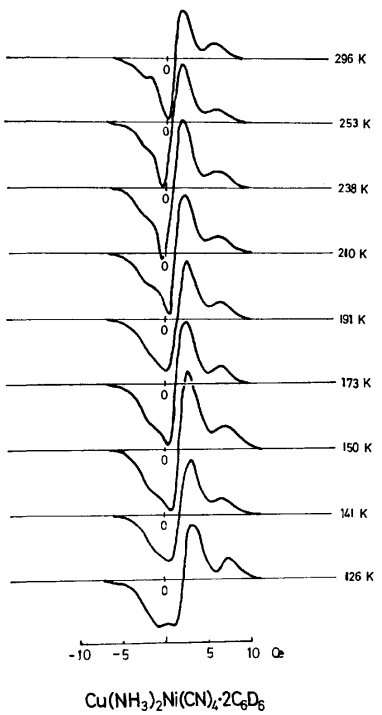

Fig. 4. Wide-line NMR spectra of ammonia of $Cu(NH_3)_2Ni(CN)_4\cdot 2C_6D_6$ at various temperatures,

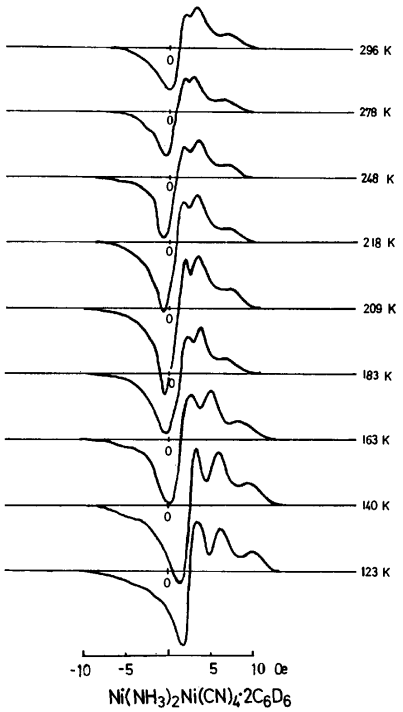

Fig. 5. Wide-line NMR spectra of ammonia of $Ni(NH_3)_2Ni(CN)_4\cdot 2C_6D_6$ at various temperatures.

Taking the spin eigenfunctions of the three-spin system ($\mathbf{I}_i=1/2$), and assuming that the ammonia molecules rotate about the three-fold axes, parallel to the c-axis of the crystals, we may obtain the diagonal matrix and then the energy diagram for this system shown in Fig. 9. The possible transitions are shown in Fig. 9; the selection rules are $\Delta M_I=\pm 1$, $\Delta\mathbf{J}=0$, and $\Delta\mathbf{I}=0$, where $\mathbf{J}=\mathbf{I}_1+\mathbf{I}_2$ and $\mathbf{I}=\mathbf{J}+\mathbf{I}_3$.

Since $\gamma_N\hbar\boldsymbol{H}^*=h\nu$, the absorptions occur at:

$$\begin{aligned}
&\mathbf{1} \quad \boldsymbol{H}_0=\boldsymbol{H}^*+\frac{1}{\gamma_N\hbar}(\mathrm{B}+4\mathrm{X}) \quad |-\tfrac{1}{2}\rangle\rightarrow|-\tfrac{3}{2}\rangle\\
&\mathbf{2,3} \quad \boldsymbol{H}_0=\boldsymbol{H}^*+\frac{1}{\gamma_N\hbar}\mathrm{B} \quad |\tfrac{1}{2}\rangle\rightarrow|-\tfrac{1}{2}\rangle\\
&\mathbf{4} \quad \boldsymbol{H}_0=\boldsymbol{H}^*+\frac{1}{\gamma_N\hbar}(\mathrm{B}-4\mathrm{X}) \quad |\tfrac{3}{2}\rangle\rightarrow|\tfrac{1}{2}\rangle \qquad (3)
\end{aligned}$$

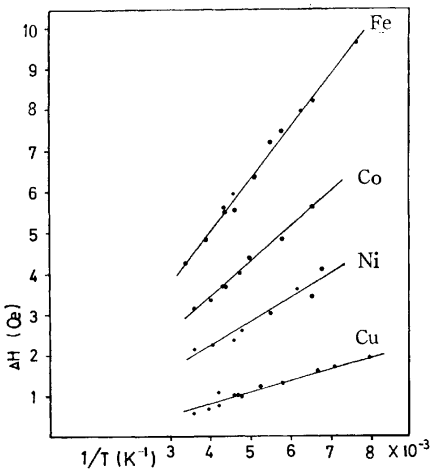

Fig. 8. Temperature dependency of paramagnetic shifts of Hofmann-type clathrates.

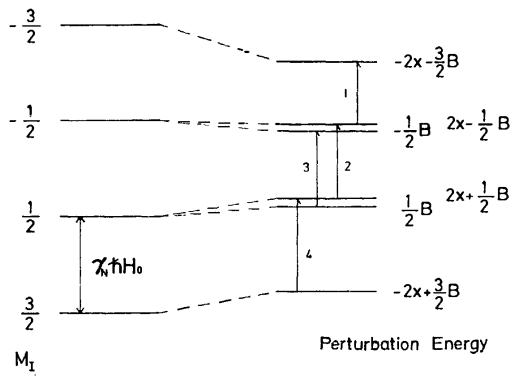

Fig. 9. Energy diagram for the three-spin system perturbed by a paramagnetic moment.

where

$$\mathrm{X}=\frac{3}{16}\gamma_N^2\hbar^2(1-3\cos^2\theta)r_{p\text{-}p}^{-3}$$

$$\mathrm{B}=\frac{1}{2}\gamma_N\hbar(3\cos^2\gamma-1)(1-3\cos^2\theta)r_{p\text{-}p}^{-3}$$

$$\times\ \gamma_e\hbar\langle S_z\rangle+a\langle S_z\rangle$$

and where θ and γ are angles between c-axis and the applied magnetic field and between c-axis and the vector $\boldsymbol{r}_j$ respectively.

The probabilities of the transitions are 1/4, 1/2, and 1/4 respectively. The theoretical spectra are illustrated in Fig. 10. In terms of the dipole-dipole interactions among protons, the signal consists of three components and the distance is $4X/\gamma_N\hbar$, while the paramagnetic shift, $B/\gamma_N\hbar$, equally contributes to each component and depends upon the reciprocal absolute temperature.

In powder samples, fine crystallites are distributed over the angle, θ, on which the positions of the signals for the segments depend. The theoretical line shape for polycrystalline samples is obtained in calculating $g(h)=P\cdot d(\cos\theta)/dh$, where P is a transition probability and where $h=\boldsymbol{H}_0-(\boldsymbol{H}^*+C)$; it is shown in Fig. 10; $g(h)=(-h/\alpha_i+1)^{-1/2}$; α_i and C are given in the caption of Fig. 10.

The Shift Caused by the Paramagnetic Moment. The observed spectra can be satisfactorily explained by

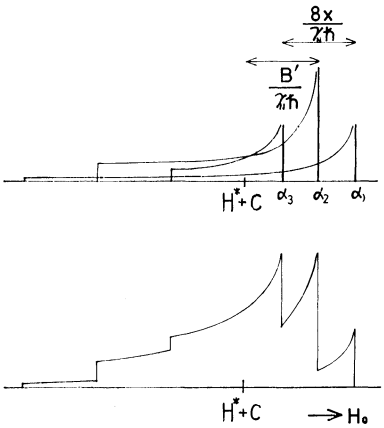

Fig. 10. Paramagnetic shifts and theoretical line shapes for components, where
$\alpha_1=1/2\,\gamma_e\hbar\langle S_z\rangle(3\cos^2\gamma-1)r_{p\text{-}e}^{-3}+3/4\,\gamma_N\hbar r_{p\text{-}p}^{-3}$
$\alpha_2=1/2\,\gamma_e\hbar\langle S_z\rangle(3\cos^2\gamma-1)r_{p\text{-}e}^{-3}$
$\alpha_3=1/2\,\gamma_e\hbar\langle S_z\rangle(3\cos^2\gamma-1)r_{p\text{-}e}^{-3}-3/4\,\gamma_N\hbar r_{p\text{-}p}^{-3}$
$C=a/\gamma_N\hbar\langle S_z\rangle$, $B'=B-a\langle S_z\rangle$
$r_{p\text{-}p}$ is the distance between adjacent protons, $r_{p\text{-}e}$ is the distance between metal ion and protons, and γ is the angle between $r_{p\text{-}e}$ and c-axis.

the above theoretical treatment of the shifts and line shapes. Both the isotropic and anisotropic paramagnetic interactions cause the signals to shift to the higher-field side; this makes the signal very asymmetric.

As the central peak in the three components does not always have the highest intensity in the powder samples shown in Fig. 10, we should read the value of the paramagnetic shift not at the highest peak, as has been done,[13] but at the central peak, *i.e.*, the second one from the higher-field side.

When the fine structure does not appear, as in the case of the previously-reported metal ammine complexes, the value of the shift cannot be read with certainty.

The linearity of the paramagnetic shift expressed by Eq. (2) is seemingly well demonstrated in Fig. 8. The paramagnetic shift thus measured contains the dipolar and the contact interaction, both of them proportional to $1/T$. The former is angular-dependent, but the latter is not. By the use of single-crystal samples, these two kinds of shifts could be measured separately.

The sole data[14] of the contact shift for metal ammine complexes have been obtained by the use of liquid ammonia solutions, in which the angular-dependent shift vanishes because of the thermal motion. The reported values for the hexammine complex ions, $[Mn(NH_3)_6]^{2+}$, $[Co(NH_3)_6]^{2+}$, $[Ni(NH_3)_6]^{2+}$, and $[Cu(NH_3)_6]^{2+}$, at 311 K are −0.68, 0.17, 0.50, and 0.34 Oe (recalculated for 30 MHz) respectively. In the present systems, the contact shifts may be of the same order and may be rather small compared to the total shift values.

The fine structure of the spectra indicates that the ammonia molecule in the compounds does not interact with the neighboring one at the *trans* position and the other nuclei; then, width become narrower than that of other ammine complexes. Furthermore, the fact that the values of the paramagnetic moments scarcely affect the dipolar broadening of the components, except for manganese clathrate, means that the electron spins on the metal ions next to the one to which ammonia coordinates do not interact with protons.

Structure and Motion of Ammonia. Using the above model, it is possible to obtain the proton-proton distance if the value of the line splitting X, in Eq. (3), is known with enough accuracy.

The spectra were transformed into the integral form and then analyzed to obtain the proton-proton distances by means of Eq. (3). The values of $r_{p\text{-}p}=1.7_0-1.7_9$ Å were obtained for all the clathrates, though the accuracy is not very high. The assumption of rigid ammonia would also explain the fine structure with three peaks, but numerical calculations lead to an abnormally long proton-proton distance.

The constancy of the X value on the change in the temperature suggests that ammonia molecules are not rigid even at the temperature of liquid nitrogen, and that the proton-proton interaction is not decoupled by the paramagnetism of the metal cation to which the ammonia molecules are coordinated.

The values of the shifts and the shape of the spectra of the ammonia protons were thus explained by the model of the triangular rotating three-spin system perturbed by the paramagnetism of the transition metal cation to which the ammonia ligands are coordinated.

Although the lattice is composed of infinite net planes with bridges of cyanide ions, the d-electrons of the metal ion appear to be around the divalent cations and are not delocalized.

The manganese clathrate is different from the other compounds; independent study of it necessary.

The author wishes to thank Professor Yukiyoshi Sasaki for encouraging him throughout this work.

Cathodic Waves of *o*-Hydroxyphenylmercury Chloride in Aqueous Nitric Acid Medium. Inhibition by Reaction Product and Reduction of Precipitate

Teisuke MURAYAMA and Motonobu MORIOKA

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received December 1, 1972)

Polarographic behavior of *o*-hydroxyphenylmercury chloride was examined in aqueous nitric acid medium. An abnormal first wave and a peculiar angular-shaped second wave were observed. Equations of the current-potential curves of the first and second waves are derived on the following assumptions: the first wave is inhibited by a reduction product adsorbed on the surface of the dropping mercury electrode as solid particles, the adsorbed precipitate being reduced at the second wave. The equations agree well with the observed results.

In a previous paper, inhibition of an electrode process by a reduction product of another electroactive species was discussed in relation to its current-time behavior.[1] This paper reports inhibition of an electrode process by its own reduction product.

Polarographic behavior of *o*-hydroxyphenylmercury chloride (*o*-HPMC) in 80% ethanol solution was studied by Sato.[2] He observed double one-electron waves of normal shape. This compound is soluble in water. We examined its polarographic behavior in aqueous solutions and observed an abnormal first wave and a peculiar angular-shaped second wave in aqueous nitric acid medium. It was revealed that the first wave is inhibited by a reduction product which is adsorbed on the surface of the dropping mercury electrode (DME) as solid particles, and that the adsorbed precipitate is reduced at the second wave.

Experimental

o-HPMC was prepared according to the method of Whitmore and Middleton,[3] and recrystallized from water several times: mp 152 °C (lit.[4] 152.5 °C). A stock solution was made by dissolving a weighed amount.

The nitric acid medium, used as a supporting electrolyte solution, was a mixture of 0.05 M nitric acid and 0.45 M sodium nitrate. Acetate buffer solutions, whose ionic strength was controlled to 0.50 with sodium nitrate, were also used as supporting electrolyte solution. All the supporting electrolyte solutions contained also 0.005% gelatin.

All solutions were prepared with redistilled water. Test solutions were degassed with nitrogen and thermostated at 25.0±0.1 °C.

The capillary constant ($m^{2/3}t^{1/6}$) of a DME was 1.810 $mg^{2/3}\,sec^{-1/2}$ at zero applied potential *vs.* SCE and at mercury pressure of 1000 mm. The cell and salt bridge are described elsewhere.[5] A manual instrument was used for the measurement of polarograms. Polarograms were corrected for the internal resistance (*iR* drop) across the cell and the residual current.

Results and Discussion

Figure 1 shows typical polarograms of *o*-HPMC in aqueous solutions. Polarograms in acetate buffer solutions have a normal shape and their diffusion currents increase linearly with increasing concentration of *o*-HPMC. The polarogram in the nitric acid medium, however, has a peculiar angular-shaped second wave. The first wave shifts to negative potentials with increasing concentration of *o*-HPMC in spite of its irreversibility. In the following discussion is confined to the behavior in the nitric acid medium.

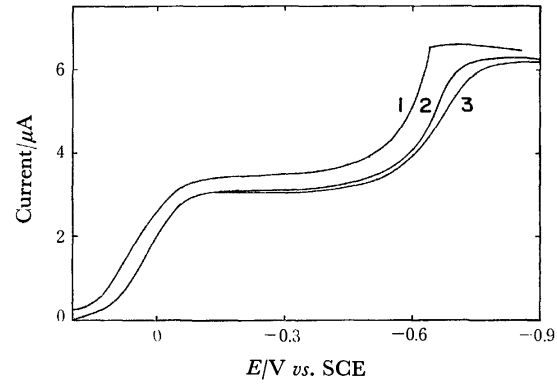

Fig. 1. Polarograms of *o*-HPMC.
Concentration of *o*-HPMC, 1.000 mM. Supporting electrolyte solution: 1, nitric acid medium; 2, acetate buffer (pH 4.38); 3, acetate buffer (pH 5.21).

The first wave in the nitric acid medium is preceded by a small wave, which does not exist in polarograms in acetate buffer solutions (Fig. 1). The height of this small wave increases slowly with degassing time. Dimroth decomposed *o*-HPMC by boiling with hydrochloric acid, and obtained phenol and mercuric chloride.[6] Thus it seems that the small wave is due to mercuric ions produced by the protolysis of *o*-HPMC. The current measured at 0.20 V *vs.* SCE was identified as diffusion current of mercuric ions produced by the protolysis reaction, and subtracted from the current due to *o*-HPMC. The current corrected in this way is denoted by i^{I}.

Logarithmic plots of the first wave are given in Fig. 2, where i_d^{I} is the diffusion current of the first wave.

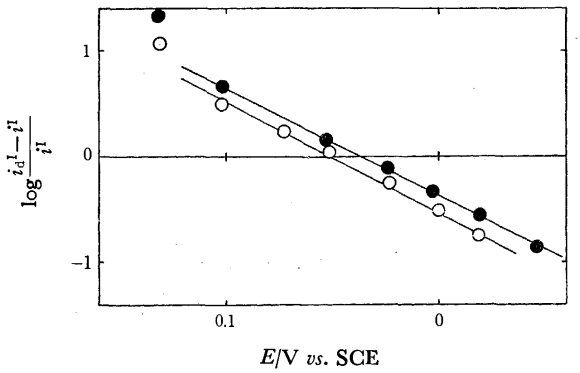

Fig. 2. Relation of log $(i_d^I-i^I)/i^I$ *vs.* E.
Mercury pressure, 1000 mm. Concentration of *o*-HPMC: ○, 0.400 mM; ●, 1.000 mM.

The slope of these plots indicates that the electrode process is totally irreversible. Thus the half-wave potential of the wave is expected to be constant and independent of the concentration of the electroactive species.[7] However, the half-wave potential shifts actually to negative with increasing concentration of *o*-HPMC. The first wave is abnormal in this respect.

The result of measurement of the electrocapillary curve indicates that a considerable adsorption takes place on the surface of DME in the range of potentials between the first and second waves (Fig. 3). This suggests that a reduction product of the first wave is adsorbed on the electrode surface and reduced further to non-adsorbable species at the potential of the second wave.

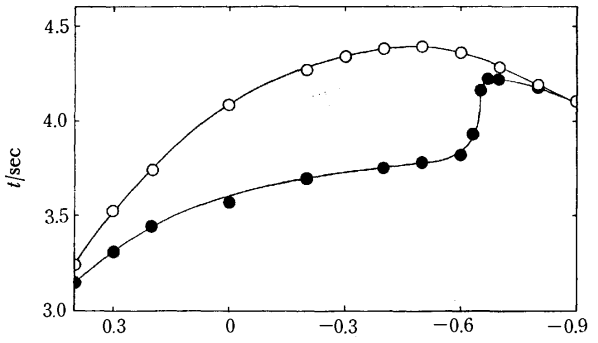

Fig. 3. Effect of *o*-HPMC on the electrocapillary curve.
○, nitric acid medium; ●, nitric acid medium + 1.000 mM *o*-HPMC.

If this is the case, the electrode reaction at the second wave may be written as

$$A + e \xrightarrow{k_2} B \qquad (1)$$

where A is the reduction product of the first wave and adsorbable on the surface of DME, B the reduction product of the second wave and non-adsorbable, and k_2 the rate constant of the electrode process. The rate constant k_2 varies with the electrode potential E according to the equation

$$k_2 = k_2^\circ \exp\left[-\frac{\alpha_2 F}{RT}(E-E_2^\circ)\right] \qquad (2)$$

where E_2° is the standard potential of reaction (1), k_2° the rate constant at E_2°, α_2 the transfer coefficient, F the Faraday constant, R the gas constant, and T the absolute temperature. The current of the second wave is given by

$$i^{II} = Fqk_2C_A^* \qquad (3)$$

where i^{II} is $i^I-i_d^I$, q the mean surface area of DME, and C_A^* the concentration of A at the electrode surface.

In order to account for the peculiar shape of the second wave we assume that A is a precipitate with very low solubility. Thus C_A^* is given by

$$C_A^* = S_A \qquad (4)$$

where S_A is the solubility of A. Introduction of Eqs. (2) and (4) into Eq. (3) results

$$i^{II} = FqS_Ak_2^\circ \exp\left[-\frac{\alpha_2 F}{RT}(E-E_2^\circ)\right]$$

This equation can be written in the form

$$E = E_2^\circ + \frac{2.303RT}{\alpha_2 F}\log FqS_Ak_2^\circ - \frac{2.303RT}{\alpha_2 F}\log i^{II} \qquad (5)$$

It is evident from Eq. (5) that a plot of log i^{II} *vs.* E should produce a straight line with a reciprocal slope equal to $2.303\,RT/(\alpha_2 F)$. The plot constructed from observed polarograms is shown in Fig. 4. The reciprocal slope of the straight line is 0.167 V, consistent with the total irreversibility of reaction (1).

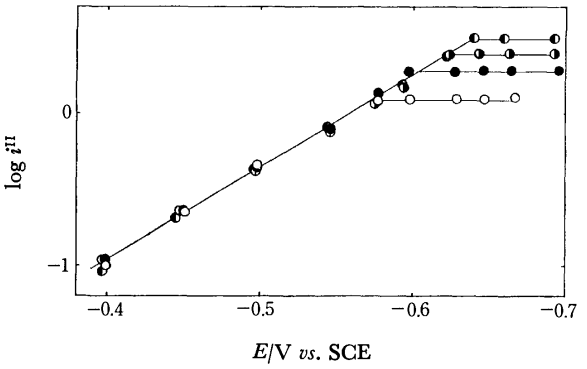

Fig. 4. Relation of log i^{II} *vs.* E.
Concentration of *o*-HPMC: ○, 0.400 mM; ●, 0.600 mM; ◑, 0.800 mM; ◐, 1.000 mM.

If A is a precipitate and is adsorbed on the electrode surface, it is expected that A inhibits the electrode process of the first wave. In the absence of inhibition the electrode reaction of the first wave may be written as

$$Z + e \xrightarrow{k_1} A \qquad (6)$$

where Z is *o*-HPMC, and k_1 is the rate constant of the electrode reaction in the absence of inhibition. The rate constant k_1 varies with E as given by

$$k_1 = k_1^\circ \exp\left[-\frac{\alpha_1 F}{RT}(E-E_1^\circ)\right] \qquad (7)$$

where E_1° is the standard potential of reaction (6), k_1° the rate constant at E_1°, and α_1 the transfer coefficient. If k_1 varies according to Eq. (7), the electrode potential

7) J. Heyrovský and J. Kůta, "Principles of Polarography," Academic Press, New York, N. Y. (1966), p. 213.

is given by

$$E = E_1^\circ + \frac{RT}{\alpha_1 F} \ln 0.886 k_1^\circ D_Z^{-1/2} t^{1/2} + \frac{RT}{\alpha_1 F} \ln \frac{i_d^I - i^I}{i^I} \quad (8)$$

where t is the drop time of DME, and D_Z the diffusion coefficient of Z.[7]

In the presence of inhibition the electrode reaction at the surface covered with A proceeds with the rate constant k_{1c}, differing from that at free surface. As a first approximation, the effective rate constant k_{ef} can be written as

$$k_{ef} = k_1(1-\Theta) + k_{1c}\Theta \quad (9)$$

where Θ is the mean surface fraction of the electrode covered with A.[8] The rate constant k_{1c} is given by

$$k_{1c} = k_{1c}^\circ \exp\left[-\frac{\alpha_{1c} F}{RT}(E - E_1^\circ)\right] \quad (10)$$

where k_{1c}° is the rate constant at E_1°, and α_{1c} the transfer coefficient at the covered surface. Substituting k_{ef} for k_1 in the derivation of Eq. (8) one obtains

$$E = E_1^\circ + \frac{RT}{\alpha_1 F} \ln 0.886 k_1^\circ D_Z^{-1/2} t^{1/2} + \frac{RT}{\alpha_1 F} \ln\left[1 - \left(1 - \frac{k_{1c}}{k_1}\right)\Theta\right] + \frac{RT}{\alpha_1 F} \ln \frac{i_d^I - i^I}{i^I} \quad (11)$$

The half-wave potential is given by

$$E_{1/2} = E_1^\circ + \frac{RT}{\alpha_1 F} \ln 0.886 k_1^\circ D_Z^{-1/2} t^{1/2} + \frac{RT}{\alpha_1 F} \ln\left[1 - \left(1 - \frac{k_{1c}}{k_1}\right)\Theta\right]_{1/2} \quad (12)$$

where the subscript 1/2 indicates the value at the half-wave potential. The first and second terms in the right-hand side are independent of the concentration of *o*-HPMC, whereas the third term becomes zero by decreasing the concentration to zero.

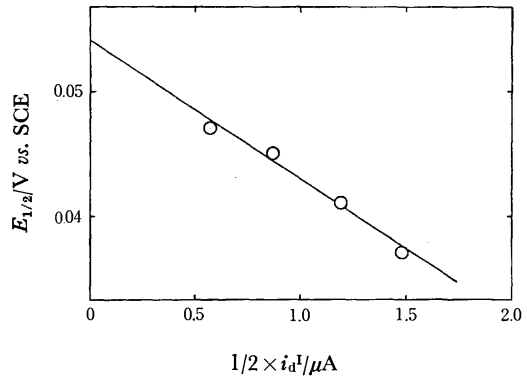

Fig. 5. Relation of $E_{1/2}$ *vs.* $i_d^I/2$.
Mercury pressure, 1000 mm.

The observed $E_{1/2}$ shifts linearly to negative by increasing the current at $E_{1/2}$, *i.e.* $i_d^I/2$, as shown in Fig. 5. One may write as

$$E_{1/2} = a + b(i_d^I/2) \quad (13)$$

where a and b are constants. Comparison of Eqs. (12) and (13) results

$$b\left(\frac{i_d^I}{2}\right) = \frac{RT}{\alpha_1 F} \ln\left[1 - \left(1 - \frac{k_{1c}}{k_1}\right)\Theta\right]_{1/2} \quad (14)$$

The fraction of covered surface increases proportionately with the amount of A on the surface of DME, which is proportional to $i^I t$. Hence Θ is given by

$$\Theta = \frac{si^I t}{q} \quad (15)$$

where s is a proportionality constant.

By introducing Eq. (15) into Eq. (14), expanding the logarithm, and retaining only the first term, one get

$$b\left(\frac{i_d^I}{2}\right) = -\frac{RTst}{\alpha_1 Fq}\left[1 - \left(\frac{k_{1c}}{k_1}\right)_{1/2}\right]\frac{i_d^I}{2} \quad (16)$$

where

$$\left(\frac{k_{1c}}{k_1}\right)_{1/2} = \frac{k_{1c}^\circ}{k_1^\circ} \exp\left[\frac{(\alpha_1 - \alpha_{1c})F}{RT}(E_{1/2} - E_1^\circ)\right] \quad (17)$$

Division of Eq. (16) by $i_d^I/2$ results

$$b = -\frac{RTst}{\alpha_1 Fq}\left[1 - \left(\frac{k_{1c}}{k_1}\right)_{1/2}\right] \quad (18)$$

Since the half-wave potential of a totally irreversible wave is more negative than the standard potential of the reaction, $E_{1/2} - E_1^\circ$ is not equal to zero. Hence the right-hand side of Eq. (18) does not generally remain constant. To keep this remaining constant one must conclude that

$$\alpha_1 - \alpha_{1c} = 0 \quad (19)$$

By expansion of the logarithm and introduction of Eqs. (15) and (19), the third term in the right-hand side of Eq. (11) can be approximately written as

$$\frac{RT}{\alpha_1 F} \ln\left[1 - \left(1 - \frac{k_{1c}}{k_1}\right)\Theta\right] = -\frac{RTst}{\alpha_1 Fq}\left(1 - \frac{k_{1c}^\circ}{k_1^\circ}\right) i^I \quad (20)$$

Combination of this with Eq. (11) yields

$$E = E_1^\circ + \frac{2.303RT}{\alpha_1 F} \log 0.886 k_1^\circ D_Z^{-1/2} t^{1/2} - \frac{RTst}{\alpha_1 Fq}\left(1 - \frac{k_{1c}^\circ}{k_1^\circ}\right) i^I + \frac{2.303RT}{\alpha_1 F} \log \frac{i_d^I - i^I}{i^I} \quad (21)$$

The half-wave potential is now given by

$$E_{1/2} = E_1^\circ + \frac{2.303RT}{\alpha_1 F} \log 0.886 k_1^\circ D_Z^{-1/2} t^{1/2} - \frac{RTst}{\alpha_1 Fq}\left(1 - \frac{k_{1c}^\circ}{k_1^\circ}\right)\frac{i_d^I}{2} \quad (22)$$

Rearranging Eq. (21) one has

$$E + \frac{RTst}{\alpha_1 Fq}\left(1 - \frac{k_{1c}^\circ}{k_1^\circ}\right) i^I = E_1^\circ + \frac{2.303RT}{\alpha_1 F} \log 0.886 k_1^\circ D_Z^{-1/2} t^{1/2} + \frac{2.303RT}{\alpha_1 F} \log \frac{i_d^I - i^I}{i^I} \quad (23)$$

It is evident from Eq. (23) that a plot of $\log (i_d^I - i^I)/i^I$ *vs.* $E + RTst(1 - k_{1c}^\circ/k_1^\circ) i^I/(\alpha_1 Fq)$ should produce a straight line as far as q and t are kept constant. This is in agreement with results shown in Fig. 6, where a value of 0.011_1 V μA^{-1}, calculated from the slope of the straight line in Fig. 5, is used for $RTst(1 - k_{1c}^\circ/k_1^\circ)/(\alpha_1 Fq)$. A value of 0.081 V is obtained for the reciprocal slope of the plot, which is given as $2.303RT/(\alpha_1 F)$ in Eq. (23). This is in accord with the assumption of total irreversibility of reaction (6).

500	2.000	1.07	0.005	0.041	0.039

a) Concentration of *o*-HPMC, 1.000 mM.
b) The ratio of drop time to the one at mercury pressure of 1000 mm, calculated from the ratio of mercury pressure.
c) The difference between $E_{1/2}$ and the one at mercury pressure of 1000 mm, calculated according to Eq. (22).

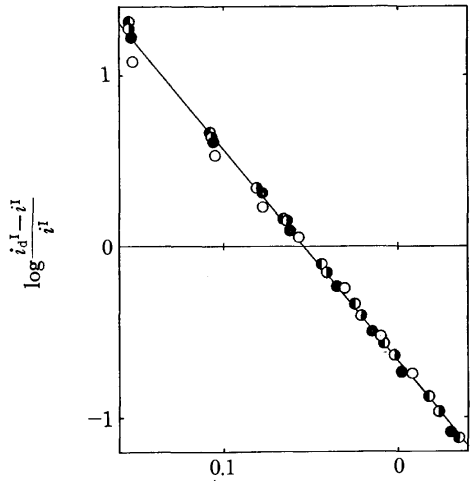

Fig. 6. Relation of log $(i_d^I-i^I)/i^I$ *vs.* $E+0.011_1\, i^I$.
Mercury pressure, 1000 mm. Concentrations are same as in Fig. 4.

The half-wave potential shifts to positive when t increases. As shown in Table 1, the observed results are in good agreement with theoretical prediction given by Eq. (22).

The results support the assumptions that the first wave is inhibited by a reduction product adsorbed on the surface of DME as solid particles, and that the adsorbed precipitate is reduced at the second wave. Benesch and Benesch reported that an organomercury free radical RHg· is formed by one-electron reduction of organomercury compound RHgX.[9] At present we are not certain whether $HOC_6H_4Hg\cdot$ corresponds to the sparingly soluble precipitate A or its dimer $(HOC_6H_4Hg)_2$ does. Because of its irreducibility $(HOC_6H_4)_2Hg$ should be excluded from possible reaction intermediates. However, a slow chemical reaction will produce $(HOC_6H_4)_2Hg$ from $HOC_6H_4Hg\cdot$ or $(HOC_6H_4Hg)_2$ as a final product at the first wave. These considerations lead to the following mechanism:

First wave

$$HOC_6H_4HgCl + e \longrightarrow HOC_6H_4Hg\cdot\text{(or 1/2 mol of its dimer)} + Cl^-$$

$$2HOC_6H_4Hg\cdot\text{(or 1 mol of its dimer)} \longrightarrow (HOC_6H_4)_2Hg + Hg$$

Second wave

$$HOC_6H_4HgCl + e \longrightarrow HOC_6H_4Hg\cdot\text{(or 1/2 mol of its dimer)} + Cl^-$$

$$HOC_6H_4Hg\cdot\text{(or 1/2 mol of its dimer)} + H^+ + e \longrightarrow C_6H_5OH + Hg$$

Studies of Ruthenium Complexes. IV. The Solvent Effect on the Isotopic Ligand-exchange Reaction of the *cis*-Dibromotetraammineruthenium(III) Complex

Akira OHYOSHI, Tetsuo SHINOHARA, Yoshihiro HOSOYAMADA, Takato YAMADA, and Yutaka HIROSHIMA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto-shi, Kumamoto 860

(Received December 4, 1972)

The isotopic ligand-exchange reactions of *cis*-dibromotetraammineruthenium(III) were studied in aqueous and methanol–water solutions in order to distinguish them from those in the case of the monobromocomplex and in order to ascertain the role of the water molecule with respect to the reaction mechanism. In an aqueous solution, the reaction proceeds through the rate-determining aquation step with the S_N2 mechanism: $Ru(NH_3)_4Br_2^+ + H_2O \rightarrow Ru(NH_3)_4(H_2O)Br^{2+} + Br^-$, $Ru(NH_3)_4(H_2O)Br^{2+} + {}^*Br^- \rightarrow Ru(NH_3)_4Br{}^*Br^+ + H_2O$. This result is similar to that for the monobromocomplex. In the methanol solution ($H_2O \sim 1.5\%$), the exchange reaction proceeds through the S_N1 mechanism: $Ru(NH_3)_4Br_2^+ \rightarrow Ru(NH_3)_4Br^{2+} + Br^-$, $Ru(NH_3)_4Br^{2+} + {}^*Br^- \rightarrow Ru(NH_3)_4Br{}^*Br^+$. When the concentration of water becomes very low, the number of solvated water molecules decreases; therefore, the coordinated bromide ion may easily be liberated. When the concentration of water is higher than 10%, the rate constant increases with the increase in the water concentration. Since the electronic spectra did not change during the exchange reaction, it would seem that the water molecule attacks a *cis*-position as a nucleophile. These results can be interpreted by postulating a hydrogen-bond between the proton of the water molecule and the coordinated bromide ion.

In our previous work,[1] it was found that the rate-determining step in the isotopic ligand-exchange reaction of halogenopentaammineruthenium(III) is the aquation process, which proceeds through the S_N2 mechanism, however, the role of the water molecule in connection with this reaction was not yet clear. For this purpose, it was necessary to use a considerably soluble complex in a mixed solution of methanol and water, because the monohalogenopentaamminecomplexes are less soluble in this solution. Thus, the *cis*-dibromotetraammine complex was chosen as a basis for a study of the ligand-exchange reaction.

In the present paper, the comparison of the reaction rate in the cases of mono- and dibromocomplexes in aqueous solutions, and the reaction mechanisms for the latter complex in a methanol–water solution, will be discussed in connection with those in the aqueous solution.

Experimental

Reagents. All the chemicals used were of a reagent grade. The radio-isotope, $^{82}Br(NH_4Br)$, was obtained from the Japan Radioisotope Association, Tokyo, and was used as a radioactive tracer. Doubly-distilled water was used in all the kinetic runs. The ionic strength and the acidity of the reaction mixture were adjusted with *p*-toluenesulfonic acid and its sodium salt. The sodium salt was prepared by the neutralization of the acid with sodium hydroxide.

Preparation of Complexes and Kinetic Measurements. Chloropentaammineruthenium(III) was dissolved in an ammonia solution, and then transformed into a hydroxo-complex. Oxalic acid was subsequently added to make the solution acidic. This solution was heated for about ten minutes, after it has then been cooled, sodium dithionate was added and the solution was left alone. The yellow precipitates thus obtained consisted of *cis*-$[Ru(NH_3)_4C_2O_4]_2S_2O_6$, and the molar extinction coefficient was $4.87 \times 10^3\ M^{-1}\ cm^{-1}$ (at 283 mμ).

Concentrated hydrobromic acid was added to this oxalato-complex, and the solution was heated for a few minutes. When the electronic spectrum showed *cis*-$Ru(NH_3)_4Br_2^+$, ethanol was added to isolate *cis*-$[Ru(NH_3)_4Br_2]Br$ as a precipitate. The final product was obtained by three recrystallizations from distilled water. The molar extinction coefficient of this compound was $1.67 \times 10^3\ M^{-1}\ cm^{-1}$ (at 442 mμ) and $1.22 \times 10^3\ M^{-1}\ cm^{-1}$ (at 370 mμ).

Found: H, 2.91; N, 13.82%. Calcd for $[Ru(NH_3)_4Br_2]Br$: H, 2.94; N, 13.70%.

The procedures of kinetic measurement and the apparatus and technique for radiometry used in this work were similar to those already described.[1] A reaction vessel with a refluxing apparatus was used to avoid the loss of any volatile material. A Hitachi Model 124 spectrophotometer was used to determine the absorption spectra of the complexes.

Results and Discussion

Estimation of the Exchange Rate, R, and the Rate Constant, k_{ex}. The reactions have been carried out for a period of 8—10 times half-time, and the exchange rates were calculated by means of McKay's equations.[2]

$$\ln(1 - X/X_\infty) = -[(a+b)/ab]Rt \quad (1)$$

$$R = 0.693ab/[(a+b)\cdot T_{1/2}] \quad (2)$$

where R is exchange rate; t, time; a and b, the initial concentrations of the complex and the halide ion, and X and X_∞, the radioactivity of the *cis*-dibromotetraammine complex at time t and at an infinite time. From the plots in Fig. 1, the half-time of the exchange reaction was determined.

From the measurements of the reaction rates varying

2) H. A. C. McKay, *J. Amer. Chem. Soc.*, **65**, 702 (1943).

Table 1. Rate constants (at 70 °C) and activation parameters for ligand-exchange reactions

Complex ion	k_{ex}(sec^{-1})	E_a(kcal/mol)	ΔS(e.u.)
$Ru(NH_3)_5Br^{2+}$	1.5×10^{-4} a)	23.2±0.9	−9±2
cis-$Ru(NH_3)_4Br_2^+$ in aqueous solution	4.8×10^{-4}	23 ±3	−7±8
in 98.5% Metanol solution	4.2×10^{-4} b)	24.8±0.6	−0.1±0.1

a) This value was obtained by extrapolating the value obtained at 80 °C.
b) This value was obtained by extrapolating the value obtained at 55 °C.

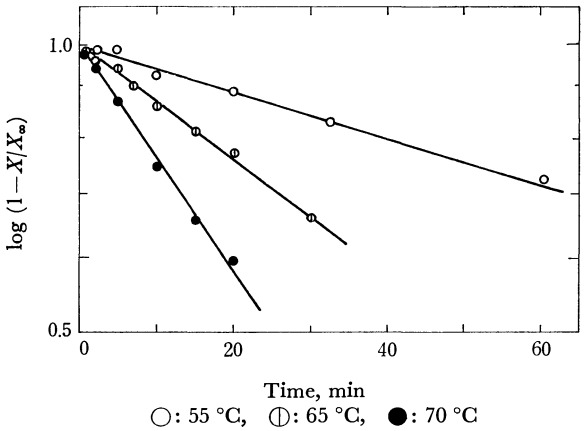

Fig. 1. Plots of $\log(1-X/X_\infty)$ *vs.* reaction time.

with the concentration of the complex in aqueous and methanolic solutions, it is found that both the exchange reactions are first-order with respect to the concentration of the complex. No influence of the concentrations of the bromide ion and the hydrogen ion on the reaction rate has been observed, and no practical salt effect on the rate is found in either solution. Thus, the reaction rate, R, and the rate constant, k_{ex}, can be expressed by the following equations, just as in the case of the monobromopentaammine complex.[1]

$$R = k_{ex}[\text{complex}] \quad (3)$$

$$k_{ex} = 0.693b/[(a+b)\cdot T_{1/2}] \quad (4)$$

The values of the rate constants of the exchange reactions are listed, along with that of the reference reaction, in Table 1.

Ligand-exchange Reaction of the cis-*Dibromotetraammine Complex in an Aqueous Solution.* To ascertain the dependence of the rate on the ionic strength, experiments were carried out while varying the ionic strength of the aqueous solution from 4.0 to 5.0 using sodium *p*-toluenesulfonate. From the plot of k_{ex} *vs.* ionic strength (Fig. 2), it was found that the rate constant decreases slightly with the increase in the ionic strength. By succesive measurements of the absorption spectrum of the reaction solution, it was confirmed that the exchange reaction was accompanied by aquation as a side reaction. The extent of this decomposition was about 9% when 8 times the half-time had elapsed at the ionic strength of 5.0.

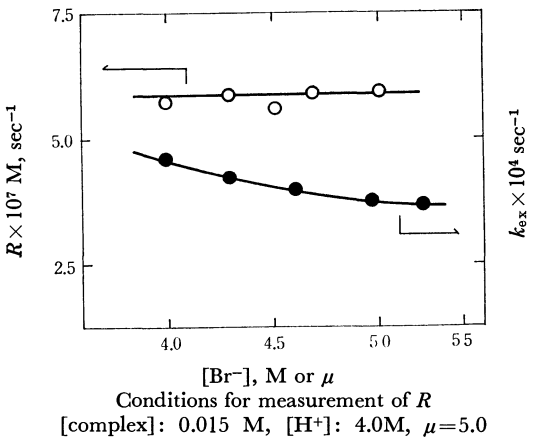

Fig. 2. Effects of bromide-ion concentration and ionic strength on the exchange rate in aqueous solution at 70 °C.

It is plausible that the exchange rate is essentially independent of the ionic strength; therefore, the charged species is not involved in the rate-determining step. Thus, it may be concluded that the exchange reaction proceeds through the aquation process (5) and that the anation reaction (6) follows:

$$cis\text{-}Ru(NH_3)_4Br_2^+ + H_2O \longrightarrow cis\text{-}Ru(NH_3)_4BrOH_2^{2+} + Br^- \quad (5)$$

$$cis\text{-}Ru(NH_3)_4BrOH_2^{2+} + {}^*Br^- \longrightarrow cis\text{-}Ru(NH_3)_4Br{}^*Br^+ + H_2O \quad (6)$$

The former step is presumably the rate-determining one. These reaction schemes are similar to those of the monobromocomplex.[1]

The rate constant of the dibromocomplex is nearly three times greater than that of the monobromocomplex (Table 1). The difference between these rate constants may be statistically understood, as will be described below.

In the aquation reaction of halogenoamminecobalt(III), the rate constant for the *cis*-dichlorotetraammine complex is 100 times that for monochloropentaammine.[3] On the basis of this evidence, it was concluded that the aquation reaction proceeded by means of the S_N1 mechanism.

In the present study, such a discrepancy between the two rate constants is seen to be small in comparison with that in the above case. It would seem that the dissociative mechanism could not be involved in the rate-determining step expressed by Eq. (5). From the measurements of the absorption spectra in the present study, it was found that the steric configuration of the *cis*-dibromocomplex was retained during the exchange reaction. This fact suggests that the water molecule enters from the front side of coordinated bromide ions. The process of Eq. (5) involves an intermediate which is formed by hydrogen bondings between coordinated bromide-ions and the protons of the water molecule, that is, the S_N2 Front-side mech-

3) R. G. Pearson, C. R. Boston, and F. Basolo, *J. Phys. Chem.*, **59**, 304 (1955).

anism. This mechanism has also been reported in the acid-hydrolysis reaction of *cis*-dihalogenodiethylendiammineruthenium(III) by Broomhead and Maguire.[4]

The fact that the exchange rate for the dibromocomplex is three times as fast as that for the monobromocomplex can be interpreted by indicating that the probability of the hydrogen-bond formation in the former case is twice as much as that in the latter case.

Exchange Reaction in Water-Methanol Mixed Solutions. In the aqueous solution, the ligand exchange reaction was found to proceed through the S_N2, F.S. mechanism. To ascertain the role of water molecule for the reaction mechanism, therefore, experiments were carried out varying the water concentration with a methanol solvent. The plot of the observed rate constant *vs.* the water content (mol %) in a methanol solution is shown in Fig. 3. In the region where the concentration of

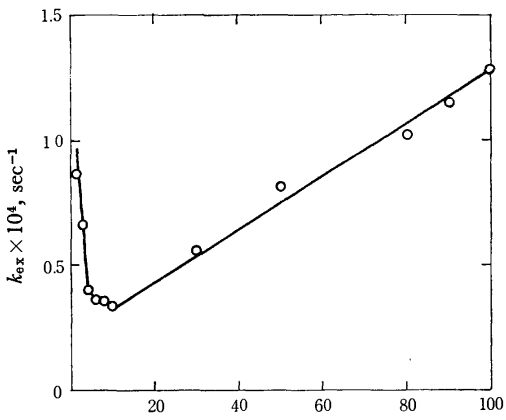

Fig. 3. Effect of water concentration on the exchange rate constant.

water is lower than 10%, the sign of the slope is negative, while it is positive in the concentration region higher than 10%. It appears that the water molecule behaves as a nucleophile in the rate-determining process (5). This action of the water molecule gives an evidence for the S_N2, F.S. mechanism discussed in a previous paragraph. When the water concentration is less than 10%, the exchange reaction mechanism may be different from the above one; that is, the following mechanisms may be presumed: (1) the S_N1 dissociative mechanism, (2) a S_N2 mechanism involving the bromide-ion as a nucleophile, or (3) a mechanism which involves methoxide ion or methanol molecule in the intermediate. The last mechanism is the most improbable, because it is difficult for the methoxide to exist in a hydrogen-ion solution of 0.05 M and a methanol molecule has even less coordination ability. To distinguish the S_N1 mechanism (1) from the S_N2 mechanism (2), both the concentration of the bromide ion and the ionic strength were varied. As is shown in Fig. 4, on neither the bromideion concentration nor the ionic strength depends the exchange rate constant; that is, both the bromide ion and charged species are not involved in the rate-

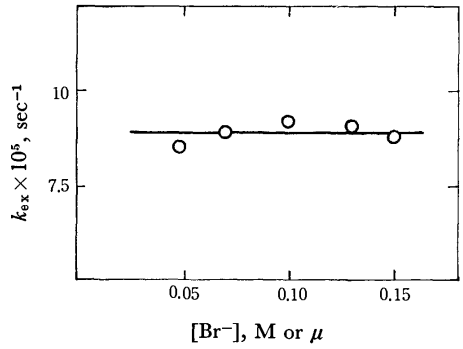

Fig. 4. Effects of bromide-ion concentration and relative ionic strength on the rate constant in 98.5% methanol solutions at 55 °C.

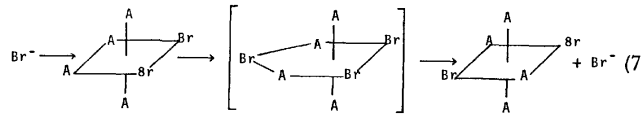
determining step, and the S_N2 mechanism may be concluded to be impossible. Moreover, when the S_N2 mechanism proceeds, the bromide-ion should attack the bromide ligands from the opposite side because a front-side attack is difficult because of the electrostatic repulsion between the nucleophile-bromide and the ligand-bromide ions. This is schematically expressed by Eq. (7):



For this reason, the reaction product should be a *trans*-isomer. Since there is no change in the absorption spectrum during the exchange reaction, no isomerization of the *cis*-dibromocomplex occurs; therefore, the S_N2 mechanism (2) is also improbable. As for the remaining mechanism, that is, the dissociative

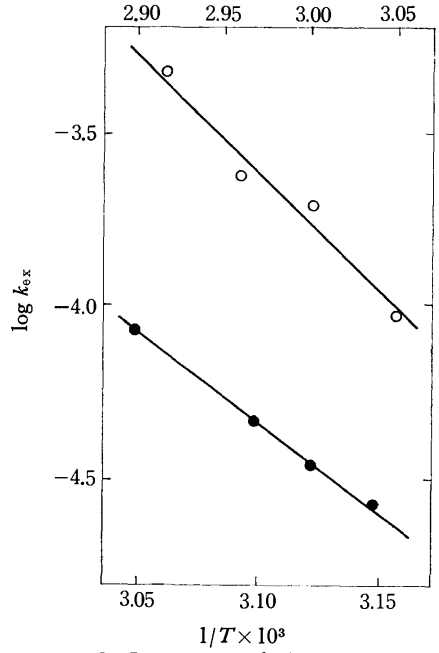


Fig. 5. Arrhenius plots for isotopic ligand-exchange reactions.

4) J. A. Broomhead and L. Kane-Maguire, *Inorg. Chem.*, **7**, 2519 (1968).

S_N1 mechanism may be considered acceptable on the basis of the following explanation. The rate constant increases with the decrease in the water concentration in the region less than 10% (Fig. 3). When the water concentration is comparatively high, the solvated water molecule in the second coordination sphere can be repressed until the bromide ion dissociates. When the water concentration is extremely low, the decrease in the solvated molecule facilitates the dissociation of the bromide ion. Thus, it may be concluded that the exchange reaction proceeds through two reaction processes, (8) and (9), and that the former using the S_N1 mechanism is the rate-determining step.

$$cis\text{-}Ru(NH_3)_4Br_2^+ \longrightarrow Ru(NH_3)_4Br^{2+} + Br^- \quad (8)$$

$$Ru(NH_3)_4Br^{2+} + {}^*Br^- \longrightarrow cis\text{-}Ru(NH_3)_4Br{}^*Br^+ \quad (9)$$

Figure 5 shows the Arrhenius plots, while the activation parameters are listed, along with those of the reference reactions, in Table 1. The values of the activation energies are nearly the same for all the reactions, though the value of the activation entropy for the reaction in the 98.5% methanol solution is extremely small. The degree of entropy change in the transition state of the S_N1 mechanism was estimated to be $-2 \sim -20$ e.u. for the aquations of carboxylatopentaammineruthenium(III) in aqueous solutions.[5] The small value of entropy change for the same mechanism in the methanolic solution may be ascribed to the poor solvation ability of the methanol molecule compared with that of the water molecule.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2136—2139 (1973)

The Synthesis of Some *N,N*-Dialkylselenocarbamate Complexes of Tin(IV), and Their Infrared and PMR Spectra

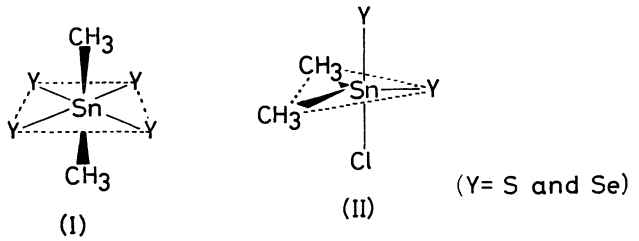
Koji TANAKA, Shigeo ARAKI, and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received December 21, 1972)

Several *N,N*-dialkylselenocarbamate complexes of tin(IV), $(CH_3)_2Sn[OSeCNR_2]_2$ (**1**), $(CH_3)_2ClSn[OSeCNR_2]$ (**2**) ($R=CH_3$ and C_2H_5) and $(CH_3)_3Sn[OSeCN(CH_3)_2]$ (**3**), have been prepared, and their infrared and proton magnetic resonance spectra have been examined. The results indicate that in **1** and **2** the selenocarbamate ligands are coordinated to the tin atom in a bidentate manner, although the coordination of the oxygen atom is weak. On the other hand, **3** has a tetra-coordinate tin with a free carbonyl bond. The configurations of these complexes are discussed and compared with those of the corresponding thio-, dithio-, diseleno-, and thioselenocarbamate complexes of tin(IV).

In previous papers, one of the present authors has demonstrated that dimethyltin(IV) bis(*N,N*-dimethyldithio-[1] and -diselenocarbamates,[2] $(CH_3)_2Sn[Y_2CN(CH_3)_2]_2$ (Y=S and Se), have a distorted octahedral *trans*-configuration (I), and that dimethylchlorotin(IV) *N,N*-dimethyldithio-[1] and -diselenocarbamates,[2] $(CH_3)_2ClSn[Y_2CN(CH_3)_2]$, form a trigonal bipyramid, with the (Sn–)CH_3 groups being located in equatorial positions (II); we reached these conclusions on the basis of the infrared and proton magnetic resonance spectra.



These structures have been confirmed by the X-ray crystallographic analysis of $(CH_3)_2Sn[S_2CN(CH_3)_2]_2$[3] and $(CH_3)_2ClSn[S_2CN(CH_3)_2]$.[4] Similar configurations have been suggested for the *N,N*-dimethylthioselenocarbamate complexes of tin(IV), $(CH_3)_2Sn[SSeCN(CH_3)_2]_2$ and $(CH_3)_2ClSn[SSeCN(CH_3)_2]$, in which the Sn–Se bond is more ionic than the Sn–S bond, judging from the benzene-induced solvent shifts of the N–CH_3 proton signals in the PMR spectra.[5]

It seems to be of interest at this stage to prepare other types of tin(IV)-carbamates, such as thio- and selenocarbamates, and to compare their spectroscopic properties with those of the complexes described above. Concerning the thiocarbamates, only the trimethyltin(IV) derivative has been reported on thus far,[6,7]

although a few transition metal complexes have been characterized.[8]

The present paper was undertaken to prepare some *N,N*-dialkylselenocarbamate complexes of tin(IV), $(CH_3)_2Sn[OSeCNR_2]_2$, $(CH_3)_2ClSn[OSeCNR_2]$ (R= CH_3 and C_2H_5), and $(CH_3)_3Sn[OSeCN(CH_3)_2]$, which are the first metal-selenocarbamates, and to elucidate their configurations and the bonding between the ligand anions and the tin(IV) on the basis of the infrared and PMR spectra.

Experimental

Dimethylammonium N,N-*Dimethylselenocarbamate, $[(CH_3)_2NH_2](dmsc)$ (dmsc: $OSeCN(CH_3)_2$), and Diethylammonium* N,N-*Diethylselenocarbamate, $[(C_2H_5)_2NH_2](desc)$ (desc: $OSeCN(C_2H_5)_2$).* These starting substances were synthesized by the reaction of dimethyl- or diethylamine, selenium powder, and carbon monoxide in tetrahydrofuran according to a procedure described elsewhere.[9]

*Dimethyltin Bis(*N,N-*dimethylselenocarbamate), $(CH_3)_2Sn(dmsc)_2$.* A solution of $(CH_3)_2SnCl_2$ (2.54 g, 11.5 mmol) in dry benzene (25 ml) was stirred, drop by drop, into a solution of $[(CH_3)_2NH_2]$(dmsc) (4.53 g, 23.0 mmol) in tetrahydrofuran (25 ml) at room temperature; the mixture was then stirred further for 2 hr. Then the precipitate which appeared, $(CH_3)_2NH_2Cl$, was filtered off, and the filtrate was evaporated under reduced pressure. The resulting product was recrystallized from carbon tetrachloride to give pale yellow crystals (4.93 g, 10.9 mmol); mp 166 °C.

Found: C, 21.06; H, 3.96; N, 6.07%; mol wt, 458. Calcd for $C_8H_{18}N_2O_2Se_2Sn$: C, 21.31; H, 4.02; N, 6.21%; mol wt, 458.

*Dimethyltin Bis(*N,N-*diethylselenocarbamate), $(CH_3)_2Sn(desc)_2$.* This compound was similarly prepared by the reaction of $(CH_3)_2SnCl_2$ (1.87 g, 8.50 mmol) with $[(C_2H_5)_2NH_2]$(desc) (4.31 g, 17.0 mmol) in benzene. Recrystallization from petroleum ether gave yellow crystals (4.08 g, 8.05 mmol); mp 81—83 °C.

Found: C, 28.62; H, 5.47; N, 5.31%; mol wt, 528. Calcd for $C_{12}H_{26}N_2O_2Se_2Sn$: C, 28.43; H, 5.17; N, 5.53%; mol wt, 507.

Dimethylchlorotin N,N-*Dimethylselenocarbamate, $(CH_3)_2ClSn(dmsc)$.* A mixture of $(CH_3)_2Sn(dmsc)_2$ (4.73 g, 10.5 mmol) and $(CH_3)_2SnCl_2$ (2.32 g, 10.5 mmol) in dry benzene was stirred for 2 hr at room temperature. Then the solution was evaporated under reduced pressure, and the resulting product was recrystallized from carbon tetrachloride to give pale yellow crystals (6.34 g, 18.9 mmol); mp 75 °C.

Found: C, 17.96; H, 3.86; N, 4.06%; mol wt, 352. Calcd for $C_5H_{12}NClOSeSn$: C, 17.91; H, 3.61; N, 4.18%; mol wt, 355.

Dimethylchlorotin N,N-*Diethylselenocarbamate, $(CH_3)_2ClSn(desc)$.* A mixture of $(CH_3)_2Sn(desc)_2$ (3.25 g, 6.41 mmol) and $(CH_3)_2SnCl_2$ (1.41 g, 6.41 mmol) in carbon tetrachloride was treated as in the case of $(CH_3)_2ClSn$(dmsc). The resulting oily product was dissolved in an ether–petroleum ether mixture, and then the solution was cooled to −78 °C to give pale yellow crystals (4.07 g, 11.2 mmol); mp 31 °C.

Found: C, 22.85; H, 4.74; N, 3.99%; mol wt, 373. Calcd for $C_7H_{16}NClOSeSn$: C, 23.12; H, 4.44; N, 3.86%; mol wt, 363.

Trimethyltin N,N-*Dimethylselenocarbamate, $(CH_3)_3Sn(dmsc)$.* A solution of $(CH_3)_3SnCl$ (1.34 g, 6.72 mmol) in benzene was added to a solution of $[(CH_3)_2NH_2]$(dmsc) (1.32 g, 6.72 mmol) in tetrahydrofuran, after which the mixture was stirred for 3 hr at room temperature. After the precipitate of $(CH_3)_2NH_2Cl$ had been filtered off, the filtrate was evaporated under reduced pressure; the resulting product was recrystallized from tetrahydrofuran to give brownish yellow crystals (1.27 g, 4.03 mmol); mp 32 °C.

Found: C, 22.76; H, 5.05; N, 4.54%; mol wt, 325. Calcd for $C_6H_{15}NOSeSn$: C, 22.89; H, 4.80; N, 4.45%; mol wt, 325.

Physical Measurements. The molecular-weight determinations were carried out by the use of Mechrolab vapor pressure osmometer in the 0.018—0.034 M range in chloroform. The infrared spectra were recorded in Nujol and in hexachlorobutadiene mulls on a Hitachi-Perkin 225 Spectrophotometer, while the proton magnetic resonance spectra were measured at 100 MHz on a Japan Electron Optics PS-100 Spectrometer, equipped with a variable-temperature probe and controller. The chemical shifts were measured against tetramethylsilane as the internal standard.

Results and Discussion

Properties. All the complexes are soluble in common organic solvents, except for $(CH_3)_2Sn(dmsc)_2$ and $(CH_3)_2ClSn$(dmsc), which are less soluble in petroleum ether. They are stable to air and moisture, in contrast with the very hygroscopic property of $[(CH_3)_2NH_2]$(dmsc) and $[(C_2H_5)_2NH_2]$(desc), but somewhat sensitive to the light in the solid state and in solution. The molecular-weight determination indicates that the selenocarbamate complexes are all monomeric in chloroform.

Configurations. The relevant infrared frequencies of the present complexes are listed in Table 1. All the complexes exhibit an intense band about 1600 cm^{-1};

Table 1. Relevant infrared frequencies (cm^{-1} in Nujol) of selenocarbamate-tin(IV) complexes[a]

Compound	ν(C=O)	ν_{as}(Sn–C)	ν_s(Sn–C)	ν(Sn–Se)	ν(Sn–Cl)

b) The values in CCl_4.

this band can tentatively be assigned to the ν(C=O).[11] In the $(CH_3)_3Sn(dmsc)$ complex, the ν(C=O) frequency is in agreement with those of the desc anion (1620 cm^{-1})[12] and of $(CH_3)_3Sn[OSCN(CH_3)_2]$ (1621 cm^{-1}), the latter of which has a tetracoordinate tin with the tin-sulfur bond.[6] It may, therefore, be assumed that in $(CH_3)_3Sn(dmsc)$ only the selenium atom, not the oxygen, attaches to the tin. The similar tetra-coordinate tin was also reported on in recent X-ray structure determinations for the two modifications (orthorhombic and monoclinic) of trimethyltin *N,N*-dimethyldithiocarbamate, $(CH_3)_3Sn[S_2CN(CH_3)_2]$.[13]

On the other hand, the dimethyltin(IV) complexes exhibit the ν(C=O) band at a frequency lower by about 30 cm^{-1} than $(CH_3)_3Sn(dmsc)$. In addition, all the complexes, including $(CH_3)_3Sn(dmsc)$, commonly show an medium intense band due to the ν(Sn-Se) in the 322—343 cm^{-1} range. There seems to be no band ascribable to the ν(Sn-O) vibration down to 200 cm^{-1}. In view of these results, the selenocarbamate anions can be said to act as bidentate ligands in the dimethyltin(IV) complexes, but the coordination of the oxygen to the tin atom is weak.

The weak coordination of the oxygen atom brings about a stereochemical characteristic of the selenocarbamate complexes of tin(IV), which may be examined by comparing the intensities of the ν_{asym}(Sn-C) and ν_{sym}(Sn-C) bands in the infrared spectra. The intensity ratio of $I\nu_{sym}$(Sn-C)/$I\nu_{asym}$(Sn-C) (abbreviated as I_s/I_a) of $(CH_3)_2Sn(dmsc)_2$ (0.61) is appreciably larger than those of the corresponding dithio-,[1] diseleno-,[2] and thioselenocarbamate[5] complexes (0.21, 0.23, and 0.19 respectively). In the PMR spectra of both $(CH_3)_2Sn(dmsc)_2$ and $(CH_3)_2Sn(desc)_2$, the $J(^{119}Sn-CH_3)$ values (Table 2) are considerably smaller than those (83—84 Hz) of the analogous dithio-,[1] diseleno-,[2] and thioselenocarbamates.[5] These infrared and PMR results may be interpreted as much more a distortion of the $(CH_3)_2Sn$ moiety in $(CH_3)_2Sn(dmsc)_2$ and $(CH_3)_2Sn(desc)_2$ from the *trans*-octahedron(I) configuration, which may result in a configuration like a *cis*-one, although a detailed structure has to await the X-ray structure determination.

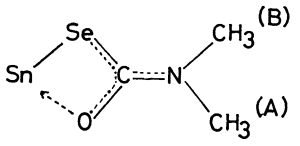
The I_s/I_a value of $(CH_3)_2ClSn(dmsc)$ (0.95) is close to those of the corresponding dithio-,[1] diseleno-,[2] and thioselenocarbamates[5] (0.97, 0.93, and 0.91 respectively). Furthermore, the $J(^{119}Sn-CH_3)$ values are virtually invariant (73—75 Hz; Table 2 and Refs. 1, 2, and 5) among all of these complexes, including $(CH_3)_2ClSn(desc)$. Thus, the present dimethylchlorotin(IV) complexes may be concluded to have the configuration shown by II.

Description of the PMR Spectra. The dmsc complexes in solution exhibit a doublet for the N-CH_3 proton signals at room temperature (Table 2), as expected from the restricted rotation around the carbamate C=N bond. The down-field signal is smaller in height and broader than the up-field one both in carbon tetrachloride and in benzene. These appearances are quite similar to the case of $(CH_3)_2ClSn[SSeCN(CH_3)_2]$ in carbon tetrachloride;[5] therefore, the former signal may be assigned to the $CH_3^{(A)}$ protons *trans* to the selenium atom with respect to the

11) The dithio-,[1] diseleno-,[2] and thioselenocarbamate[5] complexes of tin(IV) exhibit an intense band due to ν(C=N) in the 1490—1550 cm^{-1} range. It may, therefore, be more reasonable to identify the band at about 1600 cm^{-1} as the ν(N=C=O). However, the ν(C=N) dose not very largely contribute to this frequency, since the partial double-bond character is not large, as will be described below.

12) The wave number of $[(C_2H_5)_2NH_2]$ (desc); the spectrum of $[(CH_3)_2NH_2]$ (dmsc) has not been recorded because of its extremely hygroscopic property.

13) G. M. Sheldrick and W. S. Sheldrick, *J. Chem. Soc.*, **A**, **1970**, 490.



C=N bond in the planar selenocarbamate. The desc complexes in benzene[14] show doublets of a quartet and of a triplet for the N–CH_2 and C–CH_3 proton signals respectively at room temperature. By the analogy with the dmsc complexes, the down-field signals of each pair may be ascribed to the N–CH_2 or C–CH_3 protons *trans* to the selenium atom with respect to the C=N bond.

The N–CH_3 proton chemical shifts of $(CH_3)_2Sn(dmsc)_2$ in varying volume ratios of carbon tetrachloride to benzene are depicted in Fig. 1, which indicates that the solvent effect in benzene is a little larger with the $CH_3^{(A)}$ than with the $CH_3^{(B)}$. This is also the case with the remaining dmsc and desc complexes (Table 2). It may further be noticed in Table 2 that the *N*-alkyl protons of $(CH_3)_2ClSn(dmsc)$ and $(CH_3)_2ClSn(desc)$ undergo profound benzene shifts compared with those of $(CH_3)_2Sn(dmsc)_2$ and $(CH_3)_2Sn(desc)_2$ respectively. This may be responsible for decreasing the electron density of the nitrogen atom of the former complexes relative to the latter; this idea is supported by the fact that the coalescence temperatures of the N–CH_3 proton signals of $(CH_3)_2ClSn(dmsc)$ are a little higher than those of $(CH_3)_2Sn(dmsc)_2$, 55 and 50 °C in nitrobenzene respectively. These temperatures are considerably lower than that of $(CH_3)_2ClSn[SSeCN(CH_3)_2]$ (110 °C in 1,1,2,2-tetrachloroethane),[15] indicating, although only qualitatively, that the C=N double bond character of the selenocarbamate complexes of tin(IV) is not very large. This conclusion is in accordance with the weak coordination of the carbonyl oxygen of the selenocarbamates to the tin atom.

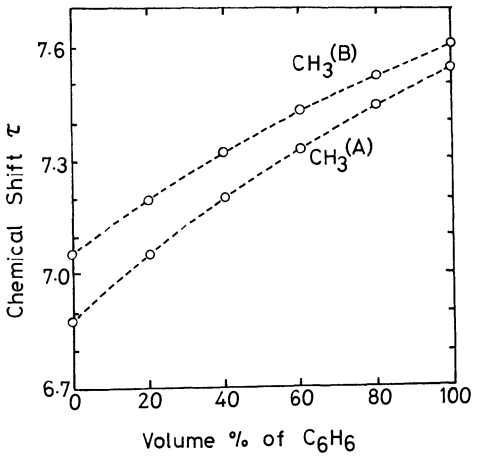


Fig. 1. Chemical shifts of the N–CH_3 protons of $(CH_3)_2Sn(dmsc)_2$ in CCl_4–C_6H_6 mixtures.

The authors wish to express their hearty thanks to Professor Noboru Sonoda and Mr. Kiyoshi Kondo of this University for giving them guidance in preparing the starting materials, $[(CH_3)_2NH_2](dmsc)$ and $[(C_2H_5)_2NH_2](desc)$; they are also grateful to the Shinko Chemical Co., Ltd., Osaka, for supplying the elemental selenium.

14) In carbon tetrachloride, the N–CH_2 proton signals occur as a quintet (1:4:6:4:1), a superposition of two quartets.

Adducts of Neodymium(III) and Lanthanum(III) Acetylacetonate with some Bidentate Organic Bases[1]

Isao YOSHIDA, Hiroshi KOBAYASHI, and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received January 16, 1973)

Several bidentate uncharged organic base adducts of neodymium(III) and lanthanum(III) acetylacetonate were prepared by the reaction of the free bases with tris(acetylacetonato)neodymium(III) monohydrate and tris-(acetylacetonato)lanthanum(III) dihydrate in ethyl acetate, respectively. Elemental analyses, molecular weight determinations, NMR, IR, and visible absorption spectra indicate that the adducts are of the general formula $Ln(AA)_3(BB)$, where AA, BB, and Ln denote acetylacetonate ion, bidentate uncharged base and lanthanide ion, respectively. Thermal stability of the base adducts as well as the hydrates was studied by differential thermal analysis (DTA) and thermogravimetric analysis (TGA). Coordination of the additional ligand having reactive hydrogen atoms resulted in poor thermal stability of the addition complexes. This might be explained by assuming that the coordinated acetylacetonate ion reacts readily with the reactive hydrogen atom of the neighboring ligand to liberate acetylacetone molecule, though the nature of the resulting pyrolyzed products is unknown.

It is well-known that the reaction of a lanthanide ion with acetylacetone in an aqueous solution affords always hydrated chelates[2,3] of hepta-[4,5] or octa-coordinate[6,7] structure. Dehydration from the hydrated chelates gave no anhydrous lanthanide acetylacetonate but a polymerized hydroxo chelate by liberating an acetylacetone molecule.[3,8] Przystal and his co-workers[9] obtained anhydrous chelates by the reaction of lanthanide hydrides with acetylacetone. However, the anhydrous chelates hydrolyzed easily to the hydroxo complex accompanied by weight loss when they were exposed to the moist air.

With the hope of obtaining thermally stable lanthanide complexes,[10] bidentate organic base adducts of tris(acetylacetonato)neodymium(III) and -lanthanum-(III) were prepared.

The organic bases used were ethylenediamine(en), 1,2-propanediamine(pn), 2,2′-dipyridyl(2-dipy), 4,4′-dipyridyl(4-dipy), 1,10-phenanthroline(phen), and isopropanolamine(ipa). These uncharged bidentate bases are expected to occupy the coordination sites of hydrated water to afford the mixed ligand uncharged complexes of the general formula of $Ln(AA)_3(BB)$, where AA, BB and Ln denote acetylacetonate ion, bidentate base and lanthanide ion, respectively. The structures and thermal properties of these addition complexes were studied.

Experimental

Materials. Lanthanide nitrates, organic bases and acetylacetone were of reagent grade and used without further purification. Chloroform and pyridine used for spectral measurements were dried and distilled according to standard procedures.

Preparation of Addition Complexes. Neodymium and lanthanum acetylacetonate of unknown degree of hydration, prepared by a slight modification of the standard procedure,[2] were recrystallized from ethyl acetate and the products were dried at room temperature to obtain $Nd(AA)_3 \cdot H_2O$ and $La(AA)_3 \cdot 2H_2O$[11] respectively, their compositions being confirmed by elemental analyses.

The base adduct was prepared by dissolving 0.8 g of a hydrated complex in 25 ml of warm (60—70 °C) ethyl acetate containing an appropriate amount of an organic base. The insoluble residue was filtered off after about ten minutes and the filtrate was cooled to about 0 °C. The neodymium-(III) and lanthanum(III) adducts precipitated as red-purple and white crystalline products, respectively. They were collected by filtration, and dried at room temperature under reduced pressure. Yield: 40—80%. Results of elemental analyses are shown in Table 1.

Diaquo complex, $Nd(AA)_3 \cdot 2H_2O$[11] was also prepared by recrystallizing 0.8 g of monohydrate from about 25 ml of ethyl acetate–water–acetone mixture (90: 5: 5 in volume). Similarly mono pyridine adduct of the formula $Ln(AA)_3(Py)-(H_2O)_2$ was obtained by recrystallizing 0.8 g of the corresponding dihydrate from 20 ml of warm pyridine–cyclohexane mixture (95: 5). Compositions of these complexes were confirmed by elemental analyses.

Measurements. IR measurements were carried out with a JASCO-DS-403G spectrophotometer. A Hitachi-124 spectrophotometer was used to observe visible absorption spectra. DTA was measured with Rigaku Denki-thermoflex-8001 in nitrogen atmosphere using α-alumina as a reference. TGA was measured with a Shimadzu-thermobalance TB-10B in a nitrogen stream. The thermal analyses were carried out mostly at a heating rate of 10 °C min^{-1}. NMR spectra were obtained by use of a Varian A-60 NMR spectrometer in deuterated chloroform using TMS as an internal reference. Molecular weight was determined with a Mechrolab 301A vapor pressure osmometer.

a) The product as isolated from an ethyl acetate solution contained one mole of ethyl acetate as a lattice solvent. Found: C, 52.42; H, 4.86; N, 4.16%. Calcd for $La(AA)_3(phen)$ (ethylacetate): C, 52.94; H,5.12; N, 3.98%. IR(Nujol): $\nu_{C=O}$= 1732 cm^{-1}. NMR in $CDCl_3$ (TMS reference): 1.27$_t$ ($-CH_2\underline{CH_3}$); 2.05$_s$ ($\underline{CH_3}CO$); 4.16 ppm$_q$ ($-\underline{CH_2}CH_3$). Ethylacetate can be removed by drying at about 80°C under reduced pressure to give a complex having the formula shown in the table.

Results and Discussion

Structures of Complexes. The structures of the addition complexes were elucidated by IR, visible and NMR spectral data.

Elemental Analysis and Molecular Weight. Results of elemental analyses (Table 1), indicate the formation of a 1: 1 addition complex with each bidentate base, suggesting that the bidentate base occupies the coordination sites of hydrated water through ligand exchange reaction.

Table 2. Molecular weights(37 °C)

Compound	Molecular weight		Solvent
	Found	Calcd	
$Nd(AA)_3(pn)$	532	515.44	Pyridine
$La(AA)_3(pn)$	548	510.11	Pyridine
$Nd(AA)_3(phen)$	564	621.53	Pyridine
$La(AA)_3(phen)$	601	616.20	Chloroform
$Nd(AA)_3(2\text{-dipy})$	620	597.51	Pyridine
	810		Chloroform
$Nd(AA)_3(4\text{-dipy})$		597.51	
	327		Pyridine

Molecular weights of the bidentate base adducts were measured with a vapor pressure osmometer. Results are summarized in Table 2 together with solvents used. Observed values agreed fairly well with those calculated from the formula of mononuclear 1: 1 adducts, except for the 4,4′-dipyridyl adduct. Thus, the addition complexes, with exception of the 4,4′-dipyridyl adduct, can be considered to be of octa-coordinated mononuclear structure.

As regards the 4,4′-dipyridyl adduct, both terminal nitrogen atoms can not coordinate to the central metal ion simultaneously, and the resulting adduct may be of polymeric form bridged by 4,4′-dipyridyl. The 4,4′-dipyridyl adduct in chloroform showed a molecular weight slightly larger than that corresponding to the monomeric structure, suggesting that the depolymerization occurred upon dissolution of the polymeric complex in chloroform. On the other hand, the molecular weight of the adduct in pyridine was half the value of monomeric form, showing the complete dissociation of 4,4′-dipyridyl from the addition complex by coordination of pyridine molecule.

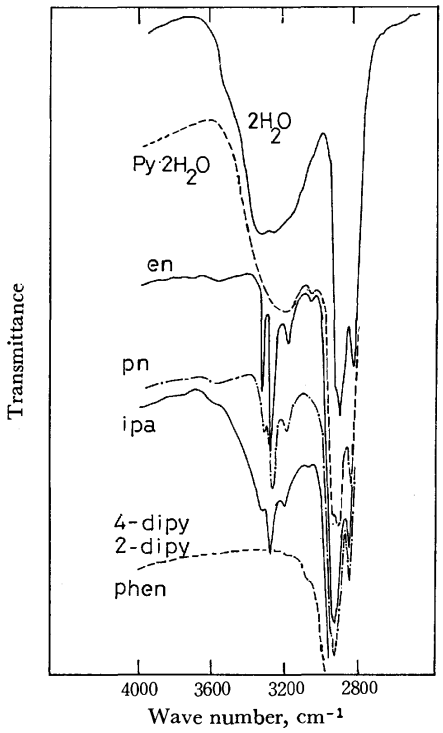

Fig. 1. IR spectra of $Ln(AA)_3(BB)$ in which BB represents the respective base (or bases) indicated in the figure.

Infrared Spectra. IR spectra of the base adducts as well as the hydrated complexes are given in Fig. 1 in the region 2800—4000 cm^{-1}. The dihydrate and the pyridine adducts show a relatively intense and broad absorption at about 3200—3300 cm^{-1} region due to ν_{OH}, and at about 1670—1690 cm^{-1} region due to δ_{OH} of water.[11]

Table 3. Absorption bands (500—600 nm) of neodymium complexes

On the other hand, 2,2′-dipyridyl, 4,4′-dipyridyl and 1,10-phenanthroline adduct show no absorption band due to water molecule. Ethylenediamine and 1,2-propanediamine adducts show sharp triplet absorptions in the 3300 cm^{-1} region due to ν_{NH}. Isopropanolamine adducts show a rather complicated spectra in the 3300 cm^{-1} region due to the superimposition of ν_{NH} and ν_{OH}.

IR absorptions of the β-diketone moiety of these addition complexes appear at 1590—1600 and 1510—1520 cm^{-1} for $\nu_{C=O}$ and $\nu_{C=C}$, respectively.[11,12]

Visible Absorption Spectra of Neodymium Complexes. Visible absorption spectra of the 2,2′-dipyridyl adducts are shown in Fig. 2 and the numerical data for a series of neodymium complexes in Table 3 in the range 500—600 nm. The spectral characteristics of the base adducts are very similar to each other regardless of the kind of base. The absorption intensity was found to be higher in pyridine than in chloroform. A similar increase in absorption intensity was observed when excess bidentate base was added to the chloroform solution of the corresponding addition complex.

Although the shape of absorption band of the base adduct in chloroform is similar to that for neodymium β-diketonates[13] believed to be heptacoordinate, the present addition complexes are definitely octacoordinate even in chloroform solution as evidenced by NMR spectra. Thus, the diagnosis on the coordination structure of lanthanide chelates from the hypersensitive absorption bands may be useful only within a limited

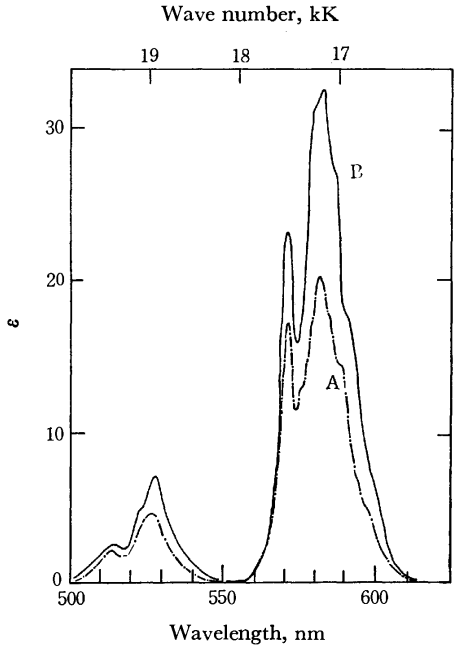

Fig. 2. Visible absorption spectra of $Nd(AA)_3$ (2-dipy) in chloroform(A) and pyridine(B).

combination of ligands.[13,14]

NMR Spectra of Lanthanum Complexes. NMR spectral data for several addition complexes of lanthanum(III) are summarized in Table 4. NMR signals of acetylacetone moiety of the complexes appear at 1.73—1.87 ppm for methyl protons and at 5.19—5.30 ppm for methine proton as a relatively broad singlet

s) Singlet peak. d) Doublet peak. q) Quartet peak. hd) Sixteen multiplet peak. u) proton signals of the uncharged base. e) A part of proton signals could be assigned as shown in table, multiplet peaks of others appearing at 2.3—2.9 ppm region.

Superscripts, a, b, c, ·····, denote the signals from the corresponding protons indicated on the structural formula.

peak. Other signals can be assigned to those of the base coordinated to the complexes.

Amine protons of the free ethylenediamine and 1,2-propanediamine are known to give a singlet peak, while those of the coordinated ligands were found to shift remarkably to the lower field (0.71 ppm for ethylenediamine and 0.66 ppm for propanediamine). This deshielding effect of the amine protons obviously suggests the coordination of amino groups to the lanthanide ion.

Deshielding shifts of proton signals due to ethylene- or propylene moiety of the corresponding coordinated diamines were apparent but very slight. A remarkable change in the adduct formation arose on the spin-spin coupling constants, presumably due to fixation of the most favorable conformation for chelation of the metal ion. The coupling constants of the ring protons on a rigid 1,10-phenanthroline nucleus in $La(AA)_3(phen)$ remained equal to those in the free base, although the signals appeared at 0.27—0.07 ppm field lower than those of the free base.

Base adducts of paramagnetic neodymium chelate showed very broad proton signals, giving no high resolution signals due to base. This suggests that the coordinated base did not dissociate from the neodymium(III) adduct in deuteriochloroform.

The structure of base adducts of the general formula $Ln(AA)_3(BB)$ is very likely to be of a mononuclear octa-coordination, in which each of three acetylacetonate ion and an uncharged bidentate base occupy *cis*-coordination sites.[15] In the case of 4,4'-dipyridyl adducts, the structure is still octa-coordinate but may be polymeric. The coordination site of the base is not certain.

Thus it is interesting to note that most unidentate uncharged bases gave no bis-adduct with acetylacetonate chelate under similar conditions. For example, pyridine afforded a mono pyridine adduct of the general formula $Ln(AA)_3(Py)(H_2O)_2$ when the hydrated chelate was recrystallized from pyridine. The only known example for bis-base adduct is of dipivaloylmethane chelates such as $Eu(DPM)_3(Py)_2$[16] and $Ho(DPM)_3(4\text{-pic})_2$,[17] where DPM and 4-pic denote dipivaloylmethanate ion and 4-picoline, respectively.

The relative lower preference of forming bis-adduct with unidentate base in comparison with bidentate base can be understood to be due to the chelate effect of the latter. The formation of bis base adduct of dipivaloylmethane chelates can then be ascribed to the increased hydrophobic interaction between the hydrocarbon moieties of the diketone ligand and water molecules.

Thermal Properties. Thermal properties of the addition complexes were examined by DTA and TGA methods. Those of the hydrate complexes were also studied for comparison. Numerical data are summarized in Table 5.

$Nd(AA)_3(H_2O)_2$ released one mole of water at 68 °C giving a monohydrate, which subsequently liberated one-half mole of acetylacetone at 110—116 °C. Residual polymeric complex[3,9] decomposed at about 200 °C. DTA curve also showed three endotherms at temperatures corresponding to the above reactions. $La(AA)_3(H_2O)_2$ also showed similar DTA and TGA curves.

Pyridine adducts $Ln(AA)_3(Py)(H_2O)_2$ showed three DTA endotherms. One mole each of water and pyridine was released at about 80 °C forming monohydrates, then at about 120 °C one-half mole of acetylacetone was liberated from the monohydrates. Liberated water, pyridine and acetylacetone upon pyrolysis were identified by gas-chromatographic analysis.

$Ln(AA)_3(en)$ and $Ln(AA)_3(pn)$ showed irreversible pyrolytic DTA endotherms and subsequent exotherms in the range 130—160 °C. $Ln(AA)_3(ipa)$ also decomposed at 123—124 °C, accompanied by weight loss corresponding to the elimination of isopropanolamine.

On the other hand, $Ln(AA)_3$(phen), $Nd(AA)_3$(2-dipy) and $Nd(AA)_3$(4-dipy) showed pyrolysis in the range 190—200 °C.

Thermal stability increased in the following order, hydrate and unidentate base adducts<bidentate primary amine and isopropanolamine adducts<bidentate heterocyclic nitrogen base adducts.

Ease with which acetylacetone evolves from the hydrates, could be ascribed to the structure of complexes in which acetylacetone moieties were so arranged that they react readily with hydrogen atom in a coordinated water, forming hydrogen bonding between the carbonyl oxygen and the water hydrogen atoms.[11,18] Such a hydrogen bonding should also exist in the primary amine adducts. The relatively high thermal stability of the addition complexes with the bases such as dipyridyl or 1,10-phenanthroline may be thus understood to be due to the absence of reactive hydrogen atoms.

Hexaammine, Tris(ethylenediamine), Glycinato, and L-Alaninato Complexes of a Triperiodatotetracobaltate(III) Condensed Anion

Tomoharu AMA,* Jinsai HIDAKA, and Yoichi SHIMURA

**Faculty of Literature and Science, Kochi University, Asakura, Kochi 780*

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received January 29, 1973)

Malaprade's triperiodatotetracobaltate(III) heteropoly condensed acid, $H_3[Co_4I_3O_{18}(OH_2)_6]\cdot nH_2O$, was characterized by examination of its coordination derivatives with ammonia, ethylenediamine, glycinato, or L-alaninato ligands. It was concluded that the ion of parent acid and its derivatives, $[Co_4I_3O_{18}X_6]^{n-}$ ($X_6=(OH_2)_6$, $(NH_3)_6$, en_3, $(OH_2)_4$(gly), or $(OH_2)_4$(L-ala)), commonly have a hexol-like arrangement of four cobalt(III) octahedra so that the whole skeletons are based on the Anderson structure. The hexol-like configuration is chiral, this being demonstrated by the separation of two diastereomers of $[Co_4I_3O_{18}(OH_2)_4(L\text{-ala})]^{4-}$ ion.

A dark green heteropoly condensed acid $H_3[Co_4I_3O_{24}H_{12}]\cdot nH_2O$ was first separated by Malaprade.[1] Nyman and Plane[2] proposed two possible structures, one being based on the so-called Anderson structure.[3] The Anderson structure consists of seven octahedra condensed by edge sharing into a flat aggregate of trigonal symmetry and includes some important examples such as $[TeMo_6O_{24}]^{6-}$,[4] and $[CrMo_6O_{18}(OH)_6]^{3-}$.[5] If this is the case for $H_3[Co_4I_3O_{24}H_{12}]$, the arrangement of four cobalt(III) octahedra in the green acid have a chiral configuration same as that in a hexol-cobalt(III) ion $[Co\{(\mu\text{-}OH)_2Co(NH_3)_4\}_3]^{6+}$, and accordingly the green acid should be optically resolved into enantiomers. Our attempts at optical resolution of this acid were unsuccessful but we obtained several coordination derivatives of the acid, and finally two diastereomers of $[Co_4I_3O_{18}(OH_2)_4(L\text{-ala})]^{4-}$ ion, which proves the chiral configuration of the skeleton of the starting acid. Details of preparation and electronic absorption and circular dichroism (CD) spectral studies are presented. These compounds may be new examples of a hybrid between ordinary metal complex and heteropoly condensed compound. So far only a few examples of this compound have been reported, such as $Na_5[CoNb_6O_{19}(OH_2)(en)]\cdot 17H_2O$[6] and $K_5[SiCoW_{11}O_{39}(NH_3)]\cdot 14H_2O$.[7]

Experimental

Preparation. *1)* $H_3[Co_4I_3O_{24}H_{12}]\cdot nH_2O$: This was prepared by the method described in literature.[8] Previous authors reported $n=3$[8] or $n=6$,[2,9] but the following elemental analysis showed our samples to be an octahydrate with $n=8$. Found: H, 2.62; I, 32.56%. Calcd for $H_3[Co_4I_3O_{24}H_{12}]\cdot 8H_2O$: H, 2.69; I, 32.83%.

Sodium salt of this acid was also prepared. Found: H, 2.81; I, 29.28%. Calcd for $Na_3[Co_4I_3O_{24}H_{12}]\cdot 12H_2O$: H, 2.80; I, 29.33%.

2) $H_3[Co_4I_3O_{18}(en)_3]\cdot 5H_2O$: The starting acid $H_3[Co_4I_3O_{24}H_{12}]\cdot 8H_2O$ was reacted with 98% ethylenediamine at 55 °C for 3 hr. The reaction mixture was filtered and the resulting solid was washed with methanol. The crude product was dissolved in a minimum amount of water and the insoluble material was filtered off. To the filtrate was gradually added 15% perchloric acid and the complex deposited was purified by adding 15% perchloric acid to an alkaline solution (pH=about 12) of the complex. The reddish brown precipitate was filtered and washed with water, methanol and finally with acetone. Found: N, 7.20; C, 6.14; H, 3.18; I, 32.28%. Calcd for $H_3[Co_4I_3O_{18}(en)_3]\cdot 5H_2O$: N, 7.14; C, 6.12; H, 3.17; I, 32.32%.

3) $H_3[Co_4I_3O_{18}(NH_3)_6]\cdot 9.5H_2O$: This was derived from $H_3[Co_4I_3O_{24}H_{12}]\cdot 8H_2O$. Five grams of the starting acid was dried *in vacuo* overnight and was added in an excess of liquid ammonia at room temperature. The suspension was allowed to stand for 30 hr to complete the reaction. The solid phase gradually turned brown from green. Both the green starting compound and the reddish brown reaction product were sparingly soluble in liquid ammonia. The resulting solid was filtered and washed with a large amount of methanol. The crude product was dissolved in a minimum amount of water and the insoluble material was filtered off. An appropriate amount of methanol was added to the filtrate, a reddish brown precipitate being formed. This was recrystallized from a minimum amount of water by addition of methanol. When an aqueous solution of the complex was acidified, it precipitated immediately. Found: N, 7.10; H, 3.40%. Calcd for $H_3[Co_4I_3O_{18}(NH_3)_6]\cdot 9.5H_2O$: N, 7.12; H, 3.41%.

4) $(NH_4)_7H[Co_4I_3O_{18}(OH_2)_4(gly)]_2\cdot 14H_2O$: Two and a half grams of glycine was dissolved in a solution containing 5 g of $H_3[Co_4I_3O_{24}H_{12}]\cdot 8H_2O$ in 1.5 l of water. This solution was kept at 65 °C for 10 hr, during which the pH of the solution was about 2.8. After the solution had been cooled to room temperature and filtered, the filtrate was poured into a column (length *ca.* 0.5 m, diameter 3 cm) containing an anion exchanger, QAE-Sephadex A-25 chloride form. The dark green layer adsorbed at the top of the column was eluted with a solution of NaCl (5 g in 1 l of 1M acetic acid). It was confirmed from measurements of absorption spectra that the first eluted green band is the original aquo complex (sodium salt). The second eluted dark green species was adsorbed again on a column of QAE-Sephadex and eluted with NH_4Cl (100 g in 1 l of 1M acetic acid). When an appropriate amount of methanol was added to the eluate,

the dark green complex was precipitated. This was recrystallized from a minimum amount of water by addition of NH_4Br and methanol. Found: N, 5.03; C, 1.92; H, 3.28; I, 30.07%. Calcd for $(NH_4)_7H[Co_4I_3O_{18}(OH_2)_4(gly)]_2 \cdot 14H_2O$: N, 5.08; C, 1.94; H, 3.29; I, 30.69%.

5) $(NH_4)_2H_2[Co_4I_3O_{18}(OH_2)_4$(L-ala)$]\cdot 9H_2O$: This was obtained by the same procedure as for 4), using 2.5 g of L-alanine instead of glycine. The L-alaninato complex was recrystallized from water by addition of methanol. The ammonium salt of the complex was less soluble than that of the glycinato complex. Found: N, 3.30; C, 2.65; H, 3.33; I, 29.79%. Calcd for $(NH_4)_2H_2[Co_4I_3O_{18}(OH_2)_4$ (L-ala)$]\cdot 9H_2O$: N, 3.32; C, 2.85; H, 3.35; I, 30.10%.

6) $(+)_{589}$-$Na_4[Co_4I_3O_{18}(OH_2)_4$(L-ala)$]\cdot 8H_2O$ *and* $(-)_{589}$-$Na_4[Co_4I_3O_{18}(OH_2)_4$(L-ala)$]\cdot 9H_2O$: For the separation of isomers of L-alaninato complex, the reaction mixture prepared in 5) was chromatographed by use of an eluent containing 3 g of NaCl in 1 l of 1M acetic acid and a column of 1.5 m length and 3 cm diameter. The first eluted band was the starting aquo complex (sodium salt) as in the case of the glycinato complex, and the second eluted band was broader than that of the glycinato complex. In this band, the species eluted faster showed a positive rotation at 589 nm and that eluted more slowly a negative one. These were sorbed separately on QAE-Sephadex columns, each adsorbed band being eluted again with a solution of NaCl (100 g in 1 l of 1M acetic acid). The sodium salts of L-alaninato isomers were obtained by adding methanol to each purified eluate and recrystallized from water by addition of methanol. Found: N, 0.79; C, 2.50; H, 2.36; I, 29.76%. Calcd for $(+)_{589}$-$Na_4[Co_4I_3O_{18}(OH_2)_4$(L-ala)$]\cdot 8H_2O$: N, 1.08; C, 2.77; H, 2.32; I, 29.27%. Found: N, 0.92; C, 2.78; H, 2.48; I, 28.84%. Calcd for $(-)_{589}$-$Na_4[Co_4I_3O_{18}(OH_2)_4$(L-ala)$]\cdot 9H_2O$: N, 1.06; C, 2.73; H, 2.45; I, 28.87%.

Measurements. The electronic absorption spectra were measured with Shimadzu QR-50 and Hitachi EPS-3T recording spectrophotometers. The CD spectra were recorded with a Roussel-Jouan dichrographe. All the measurements except for $[Co_4I_3O_{18}(en)_3]^{3-}$ were made in aqueous solutions at room temperature. The spectra of $[Co_4I_3O_{18}(en)_3]^{3-}$ were measured in 1/10M NaOH aqueous solution.

Results and Discussion

Nyman and Plane[2] proposed two possible structures for the dark green triperiodatotetracobaltate(III) heteropoly acid $H_3[Co_4I_3O_{30}H_{24}]\cdot nH_2O$ (Fig. 1), one chain and the other hexol-like, which have a notable difference in the number of water molecules coordinating to the cobalt(III) ions; *viz.*, 12 for the former and 6 for the latter. $[Co_4I_3O_{18}(NH_3)_6]^{3-}$ and $[Co_4I_3O_{18}(en)_3]^{3-}$ were derived from the reactions of the dark green acid with liquid ammonia and 98% ethylenediamine, respectively. This supports the view that the original dark green acid has structure (a) in Fig. 1. The formation of ethylenediamine complex indicates out that every two of the six water molecules take a *cis* position to each other. The dark green acid and its derivatives are thus assigned to have a hexol-like structure. One monoglycinato and two mono(L-alaninato) complexes resulted from the reactions of the dark green starting acid and glycine or L-alanine. The two L-alaninato isomers separated by column chromatographic method are assigned to a pair of diastereomers (Fig. 2) from their CD behaviors.

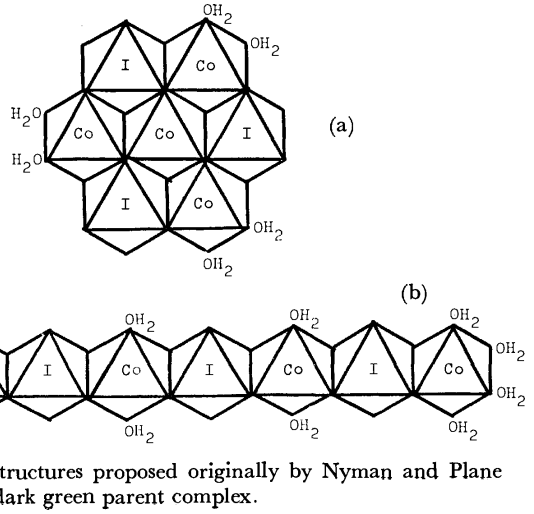

Fig. 1. Structures proposed originally by Nyman and Plane for the dark green parent complex.

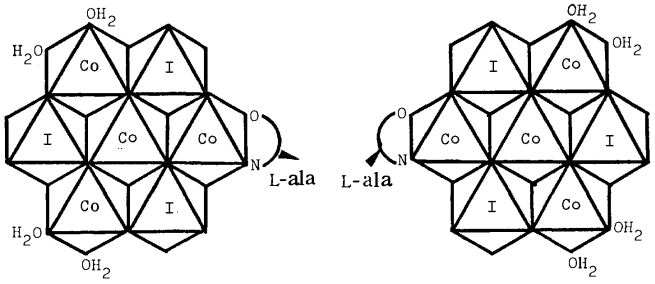

Fig. 2. Two diastereomers of the L-alaninato complex.

The absorption curves of the complexes are on the whole similar to each other (Figs. 3 and 4). Each complex shows three absorption bands in the region from visible to near-ultraviolet. Of these bands a shoulder at about $25—30\times10^3$ cm^{-1} is assigned to the "poly-nuclear band"[10-12] due to a charge-transfer transition in the group $Co\langle_O^O\rangle Co$, from a comparison of the spectra of present complexes to those of $[(ox)_2Co(\mu\text{-}OH)_2Co(ox)_2]^{4-}$,[13] and $[Co_2Mo_{10}O_{34}(OH)_4]^{6-}$,[12,14]. This assignment is emphasized by the fact that the mono-nuclear complexes $[CoMo_6O_{24}H_6]^{3-}$,[12] and $[CoW_6O_{22}]^{5-}$,[15] did not have this kind of absorption band.

The first absorption band for the dark green parent complex $[Co_4I_3O_{18}(OH_2)_6]^{3-}$ appears at 16.8×10^3 cm^{-1} which agrees well with the behavior of several $[Co(O)_6]$ type complexes[12,16] (Table 1). The first bands of the

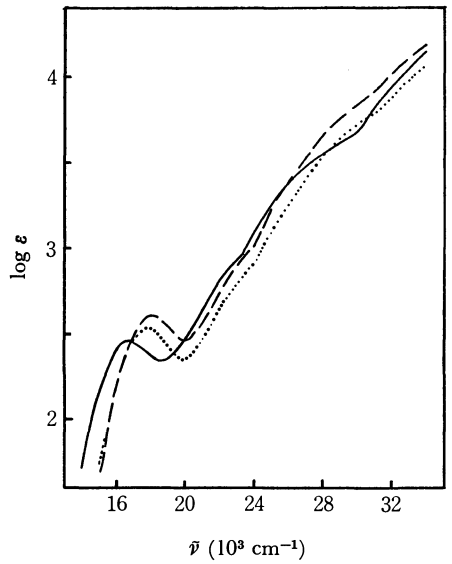

Fig. 3. Absorption curves of $[Co_4I_3O_{18}(OH_2)_6]^{3-}$ (———), $[Co_4I_3O_{18}(NH_3)_6]^{3-}$ (····) and $[Co_4I_3O_{18}(en)_3]^{3-}$ (– – – –).

ammine and ethylenediamine complexes shift to somewhat higher energy, *i.e.*, 17.7 and 18.0×10^3 cm^{-1}, respectively (Fig. 3). These positions may be reasonable, since the hexol-like complexes containing six ammonia or three ethylenediamine ligands have one $[Co(O)_6]$ and three *cis*-$[Co(O)_4(N)_2]$ type chromophores. A similar consideration is applicable to the first absorption bands of glycinato and L-alaninato complexes, which are contributed from three $[Co(O)_6]$ and one $[Co(O)_5(N)]$ type chromophores (Fig. 4 and Table 1). The second absorption bands appear at about $20—25\times10^3$ cm^{-1} as a vague shoulder on the strong poly-nuclear band in all of the present complexes.

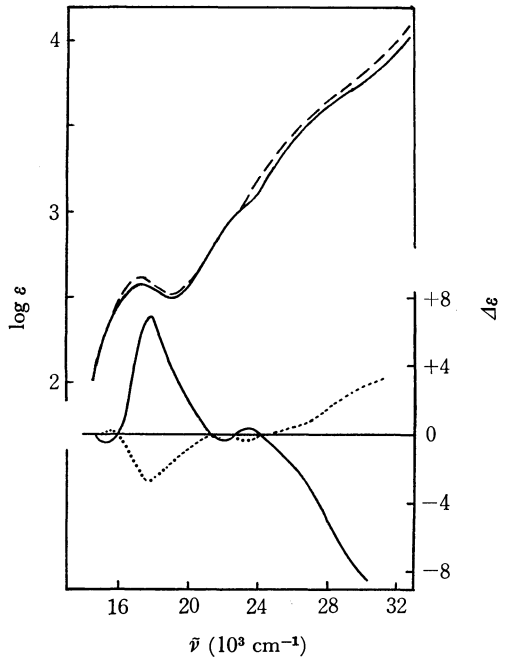

Fig. 4. Absorption and CD curves of $(+)_{589}$-$[Co_4I_3O_{18}(OH_2)_4$(L-ala)$]^{4-}$ (——), absorption curve of $[Co_4I_3O_{18}(OH_2)_4$(gly)$]^{4-}$ (– – –) and CD curve of $(-)_{589}$-$[Co_4I_3O_{18}(OH_2)_4$(L-ala)$]^{4-}$ (····).

The CD curves of the two L-alaninato complexes are shown in Fig. 4. Roughly speaking two CD curves are antipodal to each other, indicating that the two complexes are a diastereomeric pair, *Δ*L and *Λ*L. Two CD bands with opposite signs to each other appear in the first absorption band region ($14—21\times10^3$ cm^{-1}); that at lower energy is weak and the other at higher energy comparatively intense and broad. Broadening

b) Estimated from figure.

in the latter suggests a contiguity of two CD bands of the same sign. The CD bands in the second absorption band region ($21—25\times10^3$ cm^{-1}) are weak as compared with those in the first band region. The CD in the poly-nuclear band region is considerably strong.

As seen in Table 2, the CD behavior in the region of d-d absorption band due to the $[Co(O)_6]$ chromophore ($14—18\times10^3$ cm^{-1}) is quite similar to that observed for some hexol-cobalt(III) ions with ammonia,[17] ethylenediamine,[17,18] and L-propylenediamine[19] in the corresponding region. Thus, it is concluded that the complexes have the hexol-like Anderson structure. For the absolute configurations of hexol-cobalt(III) ions with ammonia, ethylenediamine or L-propylenediamine, Mason *et al.*[17] and Douglas *et al.*[19] gave reversed assignments, but Wentworth *et al.*[18] none. Since the one X-ray study of this type of compound is confined to the racemic ammine hexol,[20] we have not attempted to assign the absolute configurations of the L-alaninato diastereomers. Nevertheless, it is evident from Table 2 that the $(+)_{589}$-L-alaninato diastereomer has the same configuration as the $(-)_{589}$-isomers of the ammine-, ethylenediamine-, and L-propylenediamine-hexols.

Polarographic Reductions of Some Alkali and Alkaline Earth Metal Ions in Dimethylacetamide. Effect of Cation of the Supporting Electrolyte

Kosuke IZUTSU,* Sachiko SAKURA, and Taitiro FUJINAGA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 19, 1973)

Polarographic reductions of lithium, barium, strontium, and calcium ions in dimethylacetamide (DMA) have been examined in the supporting electrolytes of various kinds of tetraalkylammonium perchlorates. As having been observed in hexamethylphosphoramide, the reductions of these metal ions in DMA are influenced significantly by the cation of the supporting electrolyte. When the cation of the supporting electrolyte is small in size and easily adsorbed onto the negatively charged electrode surface, as in the case in Et_4NClO_4, the reductions of these metal ions are difficult and they either do not occur at all until the reduction of the supporting electrolyte itself or, if they occur, the limiting currents are small and controlled by some preceding processes. With the increase of the cationic size of the supporting electrolyte, the reductions become much easier. Thus, in Bu_4NClO_4 and in Hex_4NClO_4, these metal ions are reduced almost reversibly. The effect of cation of the supporting electrolyte on the reduction of lithium ion has also been examined briefly in dimethylsulfoxide, dimethylformamide and propylenecarbonate.

In our recent papers,[1-3] we reported that the polarographic reductions of alkali and alkaline earth metal ions in hexamethylphosphoramide (HMPA) are strongly influenced by the cation of the supporting electrolyte. As an example, the behavior of sodium ion in various kinds of perchlorate solutions is shown in Fig. 1: In 0.05 M Et_4NClO_4, sodium ion is not reduced until the reduction of the supporting electrolyte. In 0.05 M Pr_4NClO_4 or in Bu_4NClO_4, however, a small sodium wave is observed and its limiting current is controlled kinetically. In 0.05 M Hex_4NClO_4, the sodium wave becomes much higher, but still partly controlled by the kinetic process. If 0.05 M $LiClO_4$ is used instead of tetraalkylammonium salts, the reduction of sodium ion becomes reversible and diffusion controlled. We showed that these effects are mainly due to the pheno-

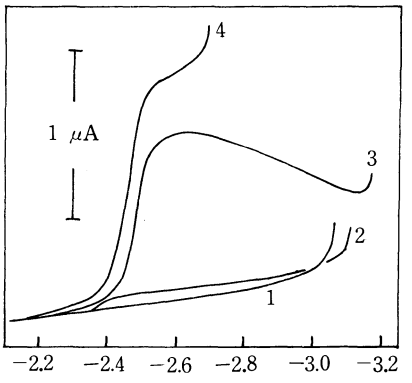

Fig. 1. Polarograms of 1 mM $NaClO_4$ in HMPA. Supporting electrolyte: curve 1, Et_4NClO_4; 2, Bu_4NClO_4; 3, Hex_4NClO_4; and 4, $LiClO_4$. Each in 0.05 M.

* Present Address: Department of Chemistry, Faculty of Science, Shinshu University, Matsumoto 390.

mena occurring near the electrode double layer. At extremely negative potentials, smaller cations are preferentially attracted onto the electrode surface. Thus, Et_4N^+ ion, which is smallest of the cations used in Fig. 1, is most easily adsorbed and inhibits the reduction of heavily solvated sodium ion completely. The inhibition seems to be due mainly to electrostatic effect but steric effect may also be involved. In Pr_4NClO_4 or in Bu_4NClO_4, Bu_4N^+, or Pr_4N^+ ion is still adsorbed rather easily and the reduction of sodium ion must be preceded by a process, which may be considered to be either a (partial) desolvation of the sodium ion or its penetration through the layer of the adsorbed tetraalkylammonium ion, and the rate of the preceding process controls the limiting current of the sodium wave. In $LiClO_4$, on the contrary, sodium ion is more easily attracted onto the electrode surface than lithium ion and its reduction is not inhibited at all.

Polarographic reductions of alkali and alkaline earth metal ions in dimethylacetamide (DMA) have already been studied by Gutmann *et al.*[4,5] and by Broadhead and Elving,[6] but they used only tetraethylammonium salt as the supporting electrolyte. In the present paper, the reductions of these metal ions in DMA and in several other dipolar aprotic solvents have been examined by using various kinds of tetraalkylammonium perchlorates as the supporting electrolytes.

Apparatus and Reagents

Most of the apparatus are the same as those used in the previous reports.[1,3] Except the measurement of Fig. 8, the dropping mercury electrode had the following characteristics in 0.05 M Et_4NClO_4–DMA and at $h=62$ cm; $m=1.88$ mg/sec with the circuit open and $t=1.31$ sec at -3.1 V *vs.* Ag/0.1 M $AgClO_4$ (DMA) reference electrode. The DME for Fig. 8 had $m=1.62$ mg/sec at $h=62$ cm and with the circuit open.

DMA was distilled following the method of Gutmann *et al.*[4] All perchlorates used in this experiment are the same as those in the previous reports[1,3] and were dried before use. Measurements were carried out at 25 ± 0.1 °C.

Results and Discussion

Alkali Metal Ions in DMA: Gutmann *et al.*[4] have shown that lithium ion is irreducible in truly anhydrous DMA by using 0.1 M Et_4NClO_4 as the supporting electrolyte.

Figure 2 shows the effect of the cation of the supporting electrolyte on the lithium wave. In accordance with the Gutmann's results, lithium ion is irreducible in 0.1 and 0.05 M Et_4NClO_4 untill the reduction of the supporting electrolyte, though a very small wave becomes to be observed in 0.02 M Et_4NClO_4. In 0.05 M Bu_4NClO_4 and Hex_4NClO_4, the lithium wave is AC polarographically reversible and the DC limiting current is diffusion controlled, though a big polarographic

Concn. of Et_4NClO_4: curve 1, 0 mM; 2, 2 mM; 3, 4 mM; and 4, 10 mM.

maximum of the first kind appears. In 0.05 M Pr_4NClO_4, the limiting current is still somewhat smaller than that expected for diffusion controlled process. In 0.05 M Bu_4NClO_4–DMA, $E_{1/2}$ is -2.8_5 V.

Figure 3 shows how the addition of Et_4NClO_4 affects the lithium wave in 0.05 M Bu_4NClO_4. The addition of as small as 2 mM Et_4N^+ ion decreases the limiting current to about a half of its original value.

Though the reduction wave of lithium ion in DMA is influenced by the cation of the supporting electrolyte, the reversible reduction wave of cesium, rubidium, potassium, and sodium ion is not influenced. For an example, the wave of cesium ion has $E_{1/2}$, -2.4_6 V in all the supporting electrolytes used.

trolled barium wave with $E_{1/2}$ of *ca.* -2.4_5 V is observed. AC polarographic measurement shows that the wave is reversible. The barium wave in 0.1 M and 0.05 M Et_4NClO_4, on the other hand, is partly controlled kinetically (Fig. 7) and its limiting current is smaller than that expected for the diffusion process.

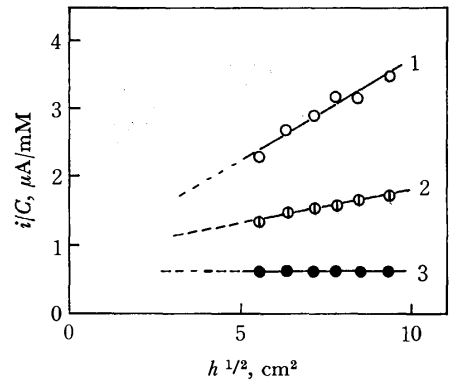

Fig. 7. Change of the limiting currents with the height of the mercury column.
Curve 1, 1.0 mM Ba^{2+} in 0.05 M Et_4NClO_4–DMA; 2, 1.0 mM Ba^{2+} in 0.1 M Et_4NClO_4–DMA; and 3, 0.9 mM Sr^{2+} in 0.05 M Et_4NClO_4–DMA.

Strontium ion is irreducible in 0.1 M Et_4NClO_4 but gives a small, kinetically controlled wave in 0.05 M Et_4NClO_4 (Fig. 7). In 0.05 M Pr_4NClO_4, Bu_4NClO_4, and Hex_4NClO_4, strontium wave is diffusion controlled with $E_{1/2}$ of *ca.* -2.6_8 V.

Calcium ion is irreducible in 0.05 M Et_4NClO_4, but in other supporting electrolytes, the wave is reversible and diffusion controlled with $E_{1/2}$ of *ca.* -2.8_5 V.

These effects of cation of the supporting electrolyte can be explained almost in the same way as in the case in HMPA. Figure 8 shows the drop-time potential curves. The drop-time at extremely negative potentials differs considerably by the cation of the supporting

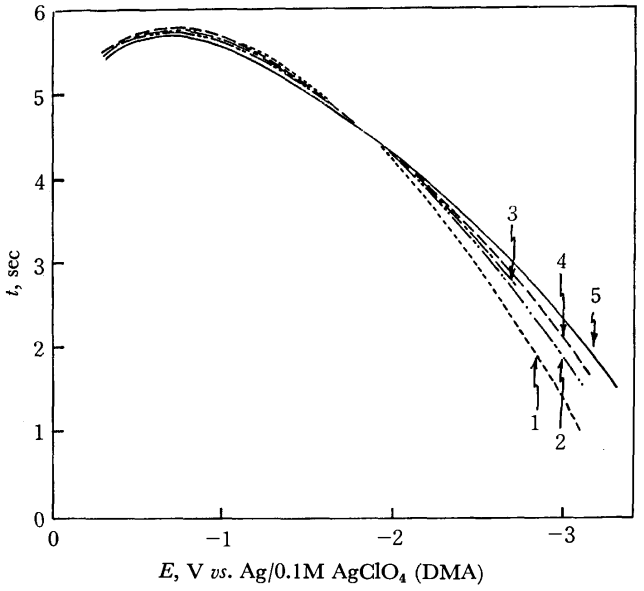

Fig. 8. Drop time—potential curves in 0.05 M perchlorates in DMA.
Curve 1, Et_4NClO_4; 2, Pr_4NClO_4; 3, $LiClO_4$; 4, Bu_4NClO_4; and 5, Hex_4NClO_4.

electrolyte. For tetraalkylammonium ions, it increases in the order $Et_4N^+ < Pr_4N^+ < Bu_4N^+ < Hex_4N^+$ and the drop time in 0.05 M $LiClO_4$ is approximately the same as that in 0.05 M Bu_4NClO_4. From these results, it is apparent that Et_4N^+ ion is preferentially adsorbed onto the electrode surface in the presence of other cations. Thus, for the metal ions to be reduced in Et_4NClO_4 solutions, they must approach to the electrode surface through the layer of adsorbed Et_4N^+ ions. If metal ions are lightly solvated and with moderate sizes, this process will be relatively easy. But, for heavily solvated, bulky metal ions, the process must be difficult, from both electrostatical and sterical points of view. The reduction either does not occur at all or, even if it occurs, it may take place at the rate controlled by the preceding process of the approach of solvated forms or somewhat desolvated forms of metal ions to the electrode surface.

Lithium Ions in DMF, DMSO, and PC: The reductions of lithium ion in Et_4NClO_4–DMSO and Et_4NClO_4–DMF have been reported to be irreversible.[6] Figure 9 shows the effect of supporting electrolytes on the lithium wave in DMF. In 0.05 M Me_4NClO_4 and Et_4NClO_4, lithium wave is irreversible as having been reported in literatures. But in solutions with larger tetraalkylammonium ions, the reduction of lithium ion becomes much more reversible. Similar increase of reversibility of lithium wave by the increase of the size of the cation of the supporting electrolyte is observed also in DMSO.

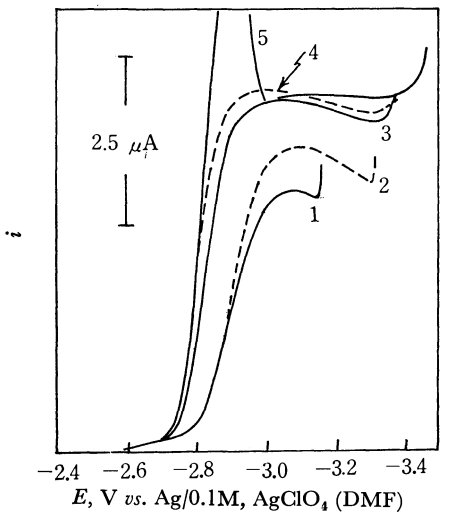

Fig. 9. Polarograms of 2.0 mM Li^+ in DMF.
Supporting electrolyte: curve 1, Me_4NClO_4; 2, Et_4NClO_4; 3, Pr_4NClO_4; 4, Bu_4NClO_4; and 5, Hex_4NClO_4. Each in 0.05 M.

In propylenecarbonate, in which the solvation of lithium ion is considered to be moderate, the lithium wave keeps almost reversible in all the tetraalkylammonium perchlorates solutions used.

Polarography of Ammonium 1-Pyrrolidinecarbodithioate and Ammonium 2-Carboxy-1-pyrrolidinecarbodithioate at the Dropping Mercury Electrode

Toyokichi KITAGAWA and Koji TAKU

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received February 22, 1973)

Direct current and alternating current polarographic behaviors of ammonium 1-pyrrolidinecarbodithioate (APCD) and ammonium 2-carboxy-1-pyrrolidinecarbodithioate (ACPCD) were investigated at the dropping mercury electrode. APCD showed an adsorption pre-wave (−0.70 V *vs.* SCE) and one-electron oxidation wave (−0.42 V). ACPCD showed only an adsorption wave (−0.65 V). These results were also confirmed by the investigation of the electrocapillary curves and the current-time curves. The surface excess of APCD or ACPCD on the surface of mercury drop electrode at the potential which the adsorption process was observed were 5.76×10^{-10} mol/cm^2 and 2.62×10^{-10} mol/cm^2, respectively.

APCD forms insoluble complexes with various metal ions and these complexes are much more stable than 1,1-diethylcarbodithioate complexes for heat and acidity. This reagent has been used for colorimetric determinations[1] and atomic absorption spectrophotometric determinations[2] since it was found that these precipitates were extracted with organic solvents.[3] On the other hand, ACPCD forms soluble complexes with various metal ions in aqueous solution.

This paper concerns the polarographic behaviors of APCD and ACPCD at the dropping mercury electrode. The mechanism of electrode reactions and the number of moles adsorbed per unit area of the electrode surface of these substances are also discussed.

Experimental

APCD was prepared according to Mallisa and Schöff-

1) R. W. Looyenga and D. F. Boltz, *Talanta*, **19**, 82 (1972).
2) R. R. Brooks, B. J. Presley, and I. R. Kaplan, *ibid.*, **14**, 809 (1967).
3) W. Doll und H. Specker, *Z. Anal. Chem.*, **161**, 354 (1958).

mann.[4]

ACPCD was prepared by the following procedure. Dissolve 0.1 mol of 2-carboxypyrrolidine(L-proline) in the minimum amount of methanol and add 6 ml of carbon disulfide. Saturate the solution with ammonia gas at 0 °C. Filter off the product and recrystallize twice by dissolving in methanol and precipitating with ethyl ether. Found: C, 32.05; H, 6.80; N, 18.37%. Calcd for $C_6H_{15}O_2N_3S_2$: C, 31.98; H, 6.71; N, 18.65%. All other reagents were A.R. grade.

Polarographic curves were recorded using Yanagimoto P-8 type Polarograph in conjunction with a H-type cell with a saturated calomel electrode and a spiral platinum wire as an auxiliary electrode. The dropping mercury electrode used had the following characteristics; mercury flow rate $m=1.32$ mg/s, drop time $t=5.57$ s at open circuit and at a height of mercury reservoir 65 cm in 0.1 M sodium hydroxide. The current-time curves were recorded using National Oscilloscope VP-546A in conjunction with the polarograph.

A freshly prepared sample solution which contained 0.1 M sodium hydroxide as a supporting electrolyte, was taken into the H-type cell. The dissolved oxygen was removed by bubbling with highly purified nitrogen and then the polarogram was recorded. Experiments were carried out in alkaline solution at 25.0±0.1 °C in order to prevent the decomposition of the sample.[5,6]

Results

Ammonium 1-Pyrrolidinecarbodithioate (APCD).

Direct Current (DC) Polarography: Figure 1 shows the DC and AC polarograms of 5×10^{-4} M APCD in 0.1 M sodium hydroxide solution. Only one DC wave A is observed at −0.70 V in APCD solution less than 1.5×10^{-4} M. When the concentration of APCD exceeds 1.5×10^{-4} M, however, another DC wave B appears at −0.42 V. The limiting current of wave A does not change with increasing concentration of APCD above 1.5×10^{-4} M. The limiting current of total wave (A+B), however, increases linearly with the concentration of APCD less than 2×10^{-3} M as shown in Fig. 2. The effect of the height of the mercury reservoir is shown in Table 1. The height of wave A is approximately proportional to $h_{corr.}$ linearly, while the total wave height is approximately proportional to $h_{corr.}^{1/2}$ The temperature coefficient of the limiting current of the total wave is +1.3% per degree in the temperature range of 5 to 40 °C (Fig. 3). These results show that

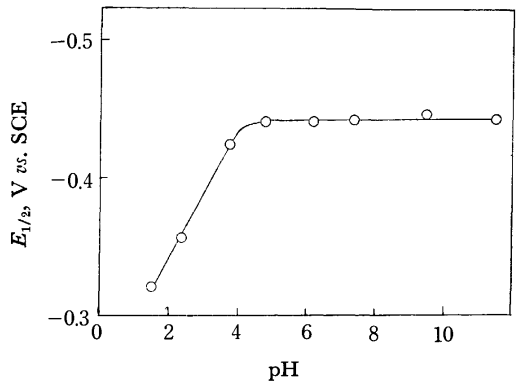

Fig. 4. The effect of pH on the half-wave potential of the wave B of APCD (Britton-Robinson buffers).

wave A is an adsorption wave and that the total anodic wave of APCD is diffusion controlled. The effect of pH on the half-wave potential was also studied. The results are shown in Fig. 4. The half-wave potential of wave B shifts to more negative potential with increasing pH in the pH range less than 4.2 and at higher pH value the half-wave potential of wave B is almost pH independent. This result shows that hydrogen ion participates in the anodic oxidation process of APCD in the pH range less than 4.2.

Alternating Current (AC) Polarography. Two AC waves are observed (Fig. 1, curve 2', A' and B'). AC peak A' is observed in the potential region in which DC wave A is observed, and AC peak B' in the region of DC wave B. The peak height of A' is considerable high in comparison with the corresponding small DC wave A.

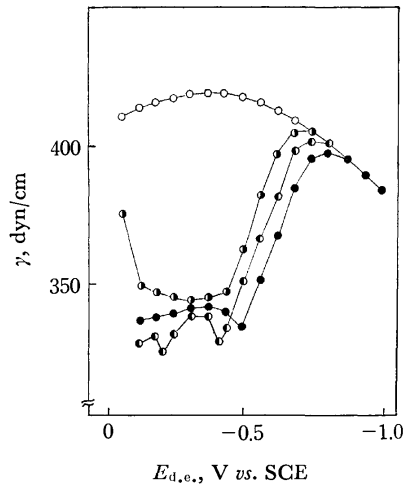

Fig. 5. Electrocapillary curves of APCD in 0.1M NaOH at 25 °C.
(○—○): 0 M, (◑—◑): 10^{-4}M, (◐—◐): 2×10^{-4}M, (●—●): 10^{-3}M.

Electrocapillary Curves. The electrocapillary curves of APCD are shown in Fig. 5. In the presence of APCD, marked decrease of the surface tension of mercury is observed in the potential range between 0 and −0.7 V. At more negative potential than −0.7 V, the surface tension of mercury in the presence of APCD is almost equal to that in its absence. This indicates that APCD adsorbs on the mercury surface strongly in the potential region between 0 and −0.7 V.

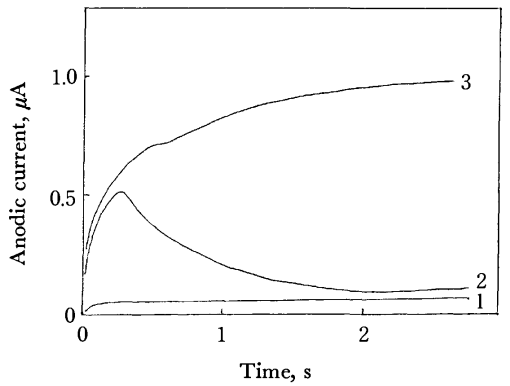

Fig. 6. The effect of the potential on *i-t* curves of 3×10^{-4}M APCD in 0.1M NaOH at 25 °C.
1: −0.80 V, 2: −0.47 V, 3: −0.20 V.

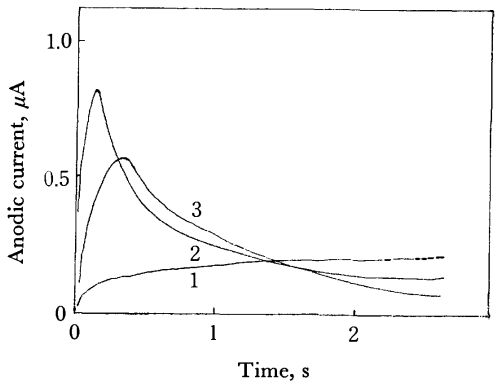

Fig. 7. The effect of the concentration on *i-t* curves of APCD at −0.47 V.
1: 10^{-4}M, 2: 3×10^{-4}M, 3: 5×10^{-4}M.

Current-Time Curves. A series of the current-time (*i-t*) curves of APCD during single mercury drop life was measured. The results are shown in Figs. 6 and 7. At the potential more positive than −0.4 V, the *i-t* curves of 5×10^{-4} M APCD show the diffusion current, which are approximately proportional to $t^{1/6}$. At the potential −0.47 V, however, the *i-t* curves are deformed anomalously. The current increases rapidly for a short time, and then decreases slowly. The time t_m, at which the *i-t* curves reaches maximum, decreases with increasing concentration of APCD, and the height of the maximum current i_m increases with increasing concentration of APCD. These facts are discussed later. This shape of *i-t* curve is the same as that for 1,1-diethylcarbodithioate.[7]

From DC and AC polarograms, electrocapillary curves and *i-t* curves, it seems to be considered that the wave A is adsorption controlled and the total wave is diffusion controlled.

According to Ilkovič equation, the diffusion current constant I of APCD can be calculated; $I=1.77$ μA·mg$^{-2/3}$·s$^{1/2}$·mM^{-1}. This value indicates that the number of electron in the oxidation process of APCD is one and the diffusion coefficient of APCD is 8.52×10^{-6} cm^2·s^{-1}.

7) Unpublished data.

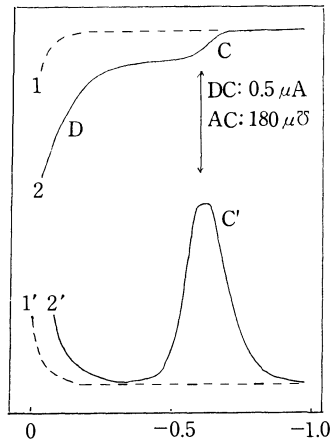

Fig. 8. Polarograms of ACPCD in 0.1M NaOH at 25 °C.
1, 1′: 0 M ACPCD, 2, 2′: 5×10^{-4}M ACPCD, 1, 2: DC porlarograms, 1′, 2′: AC polarograms.

Ammonium 2-Carboxy-1-pyrrolidinecarbodithioate (ACPCD). DC and AC Polarography: Figure 8 shows the DC and AC polarograms of 5×10^{-4} M ACPCD in 0.1 M sodium hydroxide. ACPCD shows DC wave C at −0.65 V, and the limiting current becomes constant above 10^{-4} M. Another DC wave D which appears at more positive potential is overlapped with the anodic dissolution of mercury and can not be analyzed. An AC peak C′ is observed at the potential corresponding to the DC wave. The height of the AC peak is considerably high in comparison with the corresponding DC wave.

From these results, it is found that the DC wave C of ACPCD corresponds to the DC wave A of APCD and that the wave C is also adsorption controlled. The fact that the DC wave D of ACPCD shifts to more positive potential than the DC wave B of APCD may be attributed to the difference of the formation constant of their mercuric complexes, that is, mercury(II) PCD complex is more stable than mercury(II) CPCD complex.

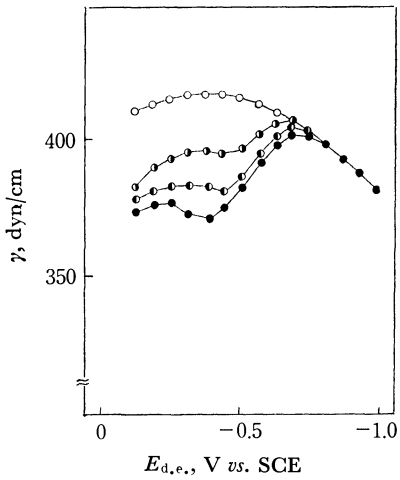

Fig. 9. Electrocapillary curves of ACPCD in 0.1 M NaOH at 25 °C.
(○—○): 0 M, (◑—◑): 10^{-4}M, (◐—◐): 5×10^{-4}M, (●—●): 10^{-3}M.

Electrocapillary Curves. The electrocapillary curves of ACPCD are shown in Fig. 9. ACPCD also causes a decrease of the surface tension of mercury in the potential range between 0 and −0.65 V. However, the degree of decrease of the surface tension is not so remarkable as that of APCD.

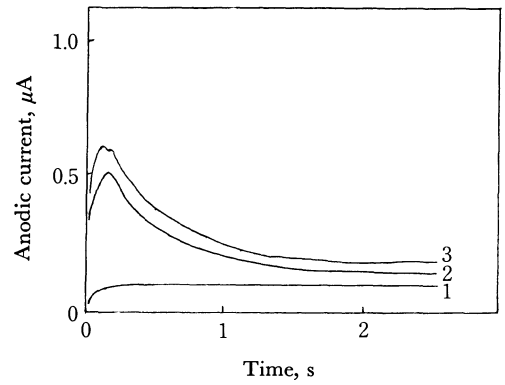

Fig. 10. The effect of the potential on *i-t* curves of 4×10^{-4}M ACPCD in 0.1 M NaOH at 25 °C.
1: −0.75 V, 2: −0.49 V, 3: −0.38 V.

Current-Time Curves. The results of the *i-t* curves of ACPCD are shown in Fig. 10. The *i-t* curves of ACPCD are similar to those of APCD, and it is found that ACPCD also adsorbs on the surface of mercury electrode in the potential range below −0.5 V.

Discussion

The Electrode Reaction Mechanism. The following electrode reactions are considered at the potential which the adsorption process occurs

$$Hg \overset{\text{reversible}}{\rightleftharpoons} Hg^{2+} + 2e^- \quad (1)$$

$$Hg^{2+} + 2L \rightleftharpoons HgL_2 \quad (2)$$

where L stands for a ligand (*e.g.*, PCD^- or $CPCD^{2-}$). It is assumed that Hg^{2+} and HgL_2 are absent in the bulk of the solution and that the mass transfer of L and HgL_2 is controlled by diffusion.

The current is expressed in a following equation.[8]

$$i = i_d/(1+\xi\theta) \quad (3)$$

$$i_d = 7.08\times10^4 nm^{2/3}t^{1/6}D^{1/2}C \quad (4)$$

$$\xi = \exp\frac{nF}{RT}(E^0 - E_{1/2}) \quad (5)$$

$$\theta = \exp\frac{nF}{RT}(E - E^0) \quad (6)$$

The net current until the surface of the mercury electrode is completely covered with HgL_2 is;

$$i = \int_0^{t_m} i\,dt = nF\Gamma_m A \quad (7)$$

$$A = 0.85m^{2/3}t^{2/3} \quad (8)$$

where Γ_m is a surface excess of L and A is a surface area of electrode.

From Eqs. (3)—(8), the time t_m till which the current reaches maximum is;

8) E. Laviron and C. Dogrand, *Bull. Soc. Chim. Fr.*, **1964**, 864.

$$t_m = 1.82\Gamma_m^2(1+\xi\theta)^2/C^2D \quad (9)$$

and at $t=t_m$, the maximum current i_m is;

$$i_m = 7.08\times10^4 nm^{2/3}D^{1/3}\Gamma_m^{1/3}C^{2/3}/(1+\xi\theta)^{2/3} \quad (10)$$

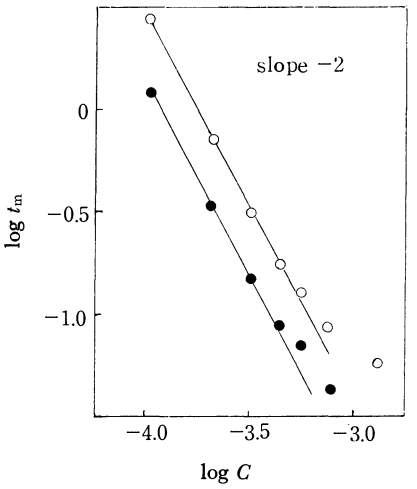

Fig. 11. The effect of concentration on the time till which the current reaches maximum.
(○—○): APCD, (●—●): ACPCD.

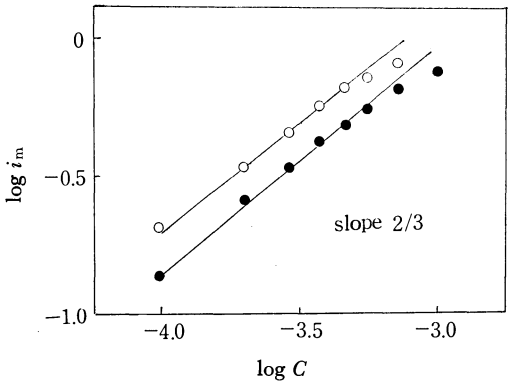

Fig. 12. The effect of concentration on the maximum currents.
(○—○): APCD, (●—●): ACPCD.

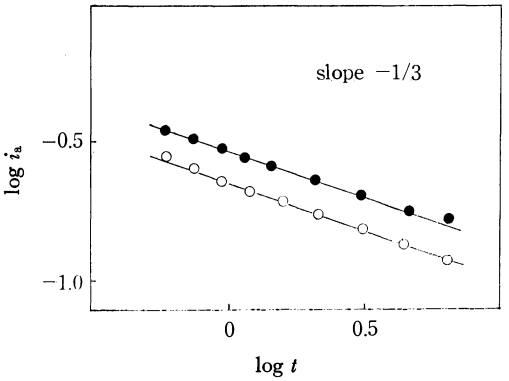

Fig. 13. Log plots of i-t curves of 10^{-3}M of APCD (○—○) and ACPCD (●—●) in 0.1M NaOH at 25 °C.

and in case of $t>t_m$, the adsorption controlled current i_a is;

$$i_a = 5.47\times10^4 nm^{2/3}\Gamma_m/t^{1/3} \quad (11)$$

then the values of

$$\partial \log t_m/\partial \log C = -2,$$

$$\partial \log i_m/\partial \log C = 2/3,$$

and

$$\partial \log i_a/\partial \log t = -1/3$$

can be obtained. In Figs. 11—13, the log plots of these experimental values are shown and the results are in accordance with the theoretical values.

Surface Excess. The values of surface excess of APCD and ACPCD can be calculated from the following three methods.

The first method is based upon a mean adsorption current of DC polarogram using the following equation.[9]

$$\Gamma_s = i_a\tau^{1/3}/8.17\times10^4 nm^{2/3} \quad (12)$$

where τ is a drop time.

The second method is a calculation from the surface tensions at the constant potential E using the following equation.[10]

$$\Gamma_i = -(1/RT)(\partial\gamma/\partial \ln C)_E \quad (13)$$

where γ is the surface tension.

Third method is a calculation from the maximum currents of the i-t curves using Eq. (9).

Table 2. Surface excess of carbodithioates

Substance	Γ, 10^{-10} mol/cm^2
APCD	6.9[a]
	5.8[b]
	3.7[c]
ACPCD	4.8[a]
	2.6[b]
	2.5[c]

a) Calculated from adsorption wave (i_a).
b) Calculated from surface tention (γ).
c) Calculated from current-time curve (t_m).

The results are shown in Table 2. The second method seems to be the most accurate experimentally. In all cases, the values of the surface excess of APCD are larger than that of ACPCD. This will be due to the steric hindrance of mercuric CPCD complex owing to the presence of carboxy group at 2 position.

Reactions of *N*-Sulfinylamines with Carbodiimides[1a]

Toru MINAMI, Michihiko FUKUDA, Masahiro ABE, and Toshio AGAWA
Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received August 29, 1972)

N-Sulfinylsulfonamides **1a, b** reacted with carbodiimides **2** to give the 1,2-cycloadducts, 3-imino-1,2,4-thiadiazetidin-1-oxides **3**, which were readily thermolyzed to sulfonylcarbodiimides **4** and *N*-sulfinylamines **5**. The alkaline or acidic hydrolysis of the cycloadducts **3a, b, d** in ethanol gave the corresponding 1,3-disubstituted-2-*p*-toluenesulfonylguanidines **6a, b, d** in good yields. Reduction of **3a** by the Raney Ni produced similarly **6a** in 87% yield. Reactions of *N*-sulfinylacylamides **1c, d** with **2** led to the formation of an oily mixture of the 1,2-cycloadducts, 3-imino-4-acyl-1,2,4-thiadiazetidin-1-oxides **7** and the 1,4-cycloadducts, 5-imino-1,2,4,6-thiaoxadiazines **8**. Thermal decomposition of the mixture gave **5**, isocyanates **9**, nitriles **10**, and amides **13** as major products.

We reported on the exchange reactions[1b,2a] between *N*-sulfinylamine and heterocumulenes such as isocyanate and isothiocyanate *via* the intermediate 1,2-cycloadducts, which are not isolated.

$$R\text{-}N{=}S{=}O + R'\text{-}N{=}C{=}O \rightleftarrows \begin{bmatrix} R\text{-}N\text{—}S{=}O \\ | \quad | \\ O{=}C\text{—}N\text{-}R' \end{bmatrix} \rightleftarrows R'\text{-}N{=}S{=}O + R\text{-}N{=}C{=}O$$

$$R\text{-}N{=}S{=}O + R'\text{-}N{=}C{=}S \rightleftarrows \begin{bmatrix} R\text{-}N\text{—}S{=}O \\ | \quad | \\ S{=}C\text{—}N\text{-}R' \end{bmatrix} \rightleftarrows R'\text{-}N{=}S{=}O + R\text{-}N{=}C{=}S$$

However use of carbodiimide instead of the above heterocumulenes gave rise to the formation of unstable 1:1-cycloadducts.[2b] This paper deals with the structures of the unstable cycloadducts and their reactivities.

Results and Discussion

N-Sulfinylsulfonamide. The reaction of *N*-sulfinyl-*p*-toluenesulfonamide (**1a**) with dicyclohexylcarbodiimide (**2a**) in ether afforded immediately a 1:1-cycloadduct **3a**, which was precipitated on standing, in 95% yield. The infrared spectrum (Nujol) of the adduct **3a** showed the characteristic absorption bands for the C=N group and the S=O group at 1635 and 1145 and 1100 cm^{-1}, respectively. The mass spectrum exhibited the molecular ion at *m/e* 423 and the fragment ions at 278 and 145 due to $(Ts\text{–}NCN\text{–}C_6H_{11})^+$ and $(C_6H_{11}\text{–}NSO)^+$. Thus, the structure of **3a** was assigned as 2-cyclohexyl-3-cyclohexylimino-4-*p*-toluenesulfonyl-1,2,4-thiadiazetidin-1-oxide. The structure was confirmed by chemical degradation as follows. The cycloadduct **3a** readily decomposed into *p*-toluenesulfonylcyclohexylcarbodiimide (**4a**) and *N*-sulfinylcyclohexylamine (**5a**) under refluxing benzene. Both basic and acidic hydrolysis of **3a** in ethanol gave 1,3-dicyclohexyl-2-*p*-toluenesulfonylguanidine (**6a**) in good yield. Reduction of **3a** by the Raney Ni afforded **6a** in 87% yield.

The reactions of **1a** with other carbodiimides **2b—d** also gave the 1,2-cycloadducts **3b—d**.

In the reaction between *N*-sulfinylmethanesulfon-

2b) Note added in proof. These results in part now appear in: H. Ulrich, B. Tucker and A. A. R. Sayigh, *J. Amer. Chem. Soc.*, **94**, 3484 (1972).

amide (**1b**) and **2a**, the 1,2-cycloadduct **3e** was obtained. However, the expected adducts **3f—g** from **2b—c** and **1b** could not be isolated in pure form since they are unstable and readily thermolyzed to generate the corresponding methanesulfonylcarbodiimides **4f—g** and *N*-sulfinylamines **5b—c**. The physical and analytical data and yields of the cycloadducts obtained above are shown in Table 1.

N-*Sulfinylacylamide.* *N*-Sulfinylbenzamide (**1c**) reacted easily with **2a** to afford an oily product which could not be crystallized even after prolonged standing at −20 °C, and which exhibited carbonyl and C=N absorption bands at 1655 and 1620 cm^{-1}, respectively, in the IR spectrum. For confirmation of structure, the product was pyrolyzed at 110 °C under reduced pressure to give a volatile liquid consisting of *N*-sulfinylcyclohexylamine (**5a**, 42%), cyclohexylisocyanate (**9a**, 17%) and benzonitrile (**10c**, 6%) and the residual solid, which was chromatographed on alumina to afford 1,3-dicyclohexyl-2-benzoylguanidine (**11a**, 14%), 2,4-diphenyl-6-cyclohexylamino-*s*-triazine (**12a**, 6%), and *N*-cyclohexylbenzamide (**13a**, 6%). The product seems to be a mixture of the 1,2-cycloadduct, 2-cyclohexyl-3-cyclohexylimino-4-benzoyl-1,2,4-thiadiazetidin-1-oxide (**7a**) and the 1,4-cycloadduct, 5,6-dihydro-3-phenyl-5-cyclohexylimino-6-cyclohexyl-1,2,4,6-thiaoxadiazine (**8a**), since the guanidine derivative **11a** would be formed *via* hydrolysis of the 1,2-cycloadduct **7a** containing the carbonyl absorption band in the IR spectrum and cyclohexylisocyanate (**9a**) and benzonitrile (**10c**) *via* thermolysis of the 1,4-cycloadduct **8a**. The difference in yield between **5a** and **9a** suggests that **5a** would arise from the thermal decomposition of both cycloadducts **7a** and **8a**, since an equimolar amount of **5a** and **9a** from **8a** should be obtained. However, the benzoylcyclohexylcarbodiimide moiety, which would be formed by elimination of **5a** from **7a**, could not be isolated because of instability. The triazine derivative **12a** might be yielded from **10c** and **11a** in the presence of sulfur dioxide, which would be generated by thermolysis of **1c** or hydrolysis of **7a** in the reaction system, as known in the synthesis of 2,4-diaryl-6-amino-*s*-triazine[3] from arylnitrile, sulfur trioxide and guanidine. Accordingly, the formation of **13a** is explicable by the elimination of cyclohexylcyanamide moiety, which would be used for the formation of **12a** from **11a**.

Scheme 2.

In thermal decomposition of the reaction product between **1c** and diphenylcarbodiimide (**2c**), *N*-sulfinylaniline (**5c**), phenylisocyanate (**9c**), **10c**, and benzanilide (**13b**) were obtained in 47, 19, 10, and 12% yields, respectively, but no guanidine **11b** and triazine **12b** corresponding to **11a** and **12a**.

Thermolysis of the reaction product between *N*-sulfinylacetamide (**1d**) and **2a** gave a similar result (Table 3).

In contrast to reactive *N*-sulfinylamine attached to the polar group such as the sulfonyl and carbonyl groups, *N*-sulfinylarylamine and *N*-sulfinylalkylamine gave no cycloadduct in the reaction with carbodiimide.

methylsilane as an internal standard. The IR spectra were recorded with a JASCO IR-E spectrometer. The mass spectra were taken with a HITACHI RMU-6E spectrometer.

Materials. *N*-Sulfinyl-*p*-toluenesulfonamide,[4] *N*-sulfinylmethanesulfonamide,[4] *N*-sulfinylbenzamide,[5,6] *N*-sulfinylacetamide,[5] di-*n*-butylcarbodiimide,[7] and diphenylcarbodiimide[8] were prepared according to the established procedures. Commercial dicyclohexylcarbodiimide and diisopropylcarbodiimide were purified by distillation before use.

*2-Cyclohexyl-3-cyclohexylimino-4-*p*-toluenesulfonyl-1,2,4-thiadiazetidin-1-oxide (3a).* Dicyclohexylcarbodiimide (**2a**, 5.15 g, 25 mmol) in 20 ml of dry ether was added dropwise to a stirred solution of 5.43 g (25 mmol) of *N*-sulfinyl-*p*-toluenesulfonamide (**1a**) in 40 ml of dry ether. After being stirred at ambient temperature for 1 hr, the solution was allowed to stand overnight to give 10.2 g (95%) of a white solid **3a**. Recrystallization from hexane–benzene afforded the analytical sample, mp 149—149.5 °C; IR (Nujol) ν 1635 (C=N), 1290 (SO_2), 1185 (SO_2), 1145 (SO), and 1100 cm^{-1} (SO); NMR ($CDCl_3$) δ 1.05—2.25 (m, 20H, cyclohexyl protons), 2.43 (s, 3H, $-CH_3$), 7.28 (d, J=8 Hz, 2H, phenyl protons), and 7.84 (d, J=8 Hz, 2H, phenyl protons); mass spectrum (70 eV) *m/e* 423 (M^+), 278 $(TsNCNC_6H_{11})^+$, 206 $(C_6H_{11}NCNC_6H_{11})^+$, and 145 $(C_6H_{11}NSO)^+$.

*2-n-Butyl-3-n-butylimino-4-*p*-toluenesulfonyl-1,2,4-thiadiazetidin-1-oxide (3b).* This was prepared in the same way as for **3a**, from the reaction of di-*n*-butylcarbodiimide (**2b**, 3.85 g, 25 mmol) with **1a** (5.43 g, 25 mmol). After removal of solvent *in vacuo*, the resulting residue was recrystallized from petroleum ether–ether to give 4.16 g (45%) of pure **3b**, mp 58.5—59 °C as a white crystal; IR (Nujol) ν 1635 (C=N), 1290 (SO_2), 1150 (SO), and 1095 cm^{-1} (SO); NMR ($CDCl_3$) δ 0.96 (t, J=5 Hz, 6H, methyl protons), 1.13—1.95 (m, 8H, methylene protons), 2.40 (s, 3H, $\underline{H}_3CAr$), 3.60 (t, J=6 Hz, 4H, N–$C\underline{H}_2$–), 7.16 (d, J=8 Hz, 2H, phenyl protons), and 7.70 (d, J=8 Hz, 2H, phenyl protons); mass spectrum (70 eV) *m/e* 371 (M^+), 252 (TsNCN-*n*-Bu)$^+$, and 119 (*n*-BuNSO)$^+$.

*2-Phenyl-3-phenylimino-4-*p*-toluenesulfonyl-1,2,4-thiadiazetidin-1-oxide (3c).* This was prepared in the same way as for **3a** from the reaction of diphenylcarbodiimide (**2c**, 4.70 g, 25 mmol) with **1a** (5.43 g, 25 mmol) at ether refluxing temperature for 2 hr. The crude product was recrystallized from acetone to give 8.50 g (85%) of pure **3c**, mp 125—126 °C; IR (Nujol) ν 1650 (C=N), 1320 (SO_2), 1200 (SO_2), 1160 (SO), and 1095 cm^{-1} (SO); NMR ($CDCl_3$) δ 2.35 (s, 3H, $-CH_3$) and 7.00—7.90 (m, 14H, phenyl protons); mass spectrum (70 eV) *m/e* 272 $(TsNCNPh)^+$, 194 $(PhNCNPh)^+$, and 139 $(PhNSO)^+$.

*2-Isopropyl-3-isopropylimino-4-*p*-toluenesulfonyl-1,2,4-thiadiazetidin-1-oxide (3d).* This was prepared in the same way as for **3a**, from the reaction of **1a** (4.10 g, 20 mmol) with diisopropylcarbodiimide (**2d**, 2.52 g, 20 mmol). The crude product was recrystallized from ether–petroleum ether to give 5.10 g (77%) of pure **3d**, mp 90 °C as a white granular crystal; IR (Nujol) ν 1625 (C=N), 1280 (SO_2), 1180 (SO_2), 1150 (SO), and 1090 cm^{-1} (SO); NMR ($CDCl_3$) δ 1.37 (d, J=7 Hz, 12H, methyl protons), 2.37 (s, 3H, $\underline{H}_3CAr$), 4.35 (qq, J=7 Hz, 2H, methine protons), 7.25 (d, J=9 Hz, 2H, phenyl protons), and 7.80 (d, J=9 Hz, 2H, phenyl protons); mass spectrum (70 eV) *m/e* 343 (M^+), 238 (TsNCN-*iso*-Pro)$^+$ and 105 (*iso*-Pro–NSO)$^+$.

2-Cyclohexyl-3-cyclohexylimino-4-methanesulfonyl-1,2,4-thiadiazetidin-1-oxide (3e). This was prepared in the same way as for **3a** except that the reaction temperature was kept below 10 °C. The crude product was recrystallized from hexane–benzene to give pure **3e** (45%), mp 119—119.5 °C; IR (Nujol) ν 1620 (C=N), 1290 (SO_2), 1185 (SO_2), and 1135 cm^{-1} (SO); mass spectrum (70 eV) *m/e* 374 (M^+), 202 $(CH_3SO_2NCNC_6H_{11})^+$, and 147 $(C_6H_{11}NSO)^+$.

Thermolysis of 3a. The compound (4.23 g, 0.01 mol) was pyrolyzed at 180 °C under reduced pressure (15 mmHg) for 1 hr. The distillate (1.11 g, 75%) was identified as *N*-sulfinylcyclohexylamine (**5a**) by comparison of its IR spectrum and glpc behavior with those of an authentic sample.[9,10] Vacuum distillation of the residue gave 1.57 g (76%) of *p*-toluenesulfonylcyclohexylcarbodiimide (**4a**), bp 165 °C/0.05 mmHg (lit,[11] bp 203—206 °C/0.3 mmHg).

Thermolysis of 3d. The compound (3.40 g, 10 mmol) was thermolyzed at 80—100 °C under reduced pressure (10 mmHg) for 1 hr. The yellow liquid **5d** (0.50 g, 48%) identified as *N*-sulfinylisopropylamine by comparison of its IR spectrum with that of an authentic sample, bp 95—100 °C prepared from isopropylamine and thionyl chloride according to the established procedure[12] was trapped in an ice cooled flask. Vacuum distillation of the residue afforded 1.0 g (42%) of *p*-toluenesulfonylisopropylcarbodiimide (**4d**), bp 90—100 °C/0.01 mmHg (lit,[11] 168 °C/0.1 mmHg); IR (neat) ν 2180 (SO_2N=C=N), 1340 (SO_2), and 1160 cm^{-1} (SO_2).

Found: C, 55.25; H, 5.90; N, 11.26%. Calcd for $C_{11}H_{14}N_2O_2S$: C, 55.45; H, 5.92; N, 11.76%.

Exchange Reaction between 1a and 2b. To 5.43 g (25 mmol) of **1a** in 20 ml of benzene was added dropwise 3.85 g (25 mmol) of **2b** in 10 ml of benzene. The mixture was stirred for 2 hr at ambient temperature. After evaporation of solvent under reduced pressure, vacuum distillation of the residue yielded 1.04 g (57%) of *N*-sulfinyl-*n*-butylamine (**5b**), bp 30 °C/20 mmHg (lit,[9] bp 30 °C/20 mmHg) and 4.66 g (74%) of *p*-toluenesulfonyl-*n*-butylcarbodiimide (**4b**), bp 150—155 °C/0.1 mmHg (lit,[11] bp 155—158 °C/0.2 mmHg); IR (neat) ν 2180 (SO_2N=C=N).

Exchange Reaction between 1a and 2c. In a similar way, the reaction of **1a** (5.43 g, 25 mmol) with **2c** (4.85 g, 25 mmol) was carried out. Vacuum distillation of the reaction mixture yielded 1.67 g (48%) of *N*-sulfinylaniline (**5c**), bp 80 °C/12 mmHg (lit,[9] bp 84 °C/12 mmHg) and 7.50 g of the sticky residue whose IR spectrum displayed a characteristic band of the SO_2N=C=N group at 2180 cm^{-1}. Upon addition of the residue to wet acetone, *N-p*-toluenesulfonyl-*N'*-phenylurea (5.10 g, 70%), mp 171 °C (lit,[13] mp 169—170 °C) was obtained.

Exchange Reaction between 1b and 2a. In a similar way, the reaction of **1b** (2.82 g, 0.02 mol) with **2a** (4.10 g, 0.02 mol) was carried out, vacuum distillation of the reaction mixture yielding 1.95 g (68%) of **5a** and 3.14 g (78%) of methanesulfonylcyclohexylcarbodiimide (**4e**), bp 165 °C/0.1 mmHg; IR (neat) ν 2180 cm^{-1} (SO_2N=C=N).

*Exchange Reaction between **1b** and **2b**.* In a similar way, the reaction of **1b** (2.82 g, 0.02 mol) with **2b** (3.80 g, 0.02 mol) was carried out, vacuum distillation yielding 1.12 g (47%) of **5b** and 2.0 g (52%) of methanesulfonyl-*n*-butylcarbodiimide (**4f**), bp 100 °C/0.2 mmHg (lit,[14] bp 103—105 °C/0.3 mmHg); IR (neat) ν 2180 cm^{-1} ($SO_2N{=}C{=}N$).

*Exchange Reaction between **1b** and **2c**.* In a similar way, the reaction of **1b** (2.82 g, 0.02 mol) with **2c** (3.88 g, 0.02 mol) was carried out, vacuum distillation yielding 1.72 g (62%) of **5c** and 2.86 g (72%) of methanesulfonylphenylcarbodiimide (**4g**), bp 145 °C/0.1 mmHg; IR (neat) ν 2180 cm^{-1} ($SO_2N{=}C{=}N$).

*Base Catalyzed Hydrolysis of **3a**.* A solution of **3a** (0.85 g, 2 mmol) in 95% ethanol (15 ml) containing sodium hydroxide (0.08 g, 2 mmol) was refluxed for 8 hr. After removal of the solvent, the residue was washed with water, followed by drying. The white solid obtained was recrystallized from benzene–hexane to give pure 1,3-dicyclohexyl-2-*p*-toluenesulfonylguanidine (**6a**, 0.69 g, 91%), mp 158 °C (lit,[15] mp 161 °C).

*Acid Catalyzed Hydrolysis of **3a**.* A solution of **3a** (0.85 g, 2 mmol) in 95% ethanol (15 ml) containing 48% aqueous HBr (2 ml) was refluxed for 5 hr. After removal of the solvent, the residue was recrystallized from benzene–hexane to afford 0.70 g (93%) of **6a**.

*Base Catalyzed Hydrolysis of **3b**.* A solution of **3b** (1.48 g, 4 mmol) in ethanol was treated under the same condition as for **3a**. After a similar work-up, the white solid obtained was recrystallized from ether–petroleum ether to give pure 1,3-dibutyl-2-*p*-toluenesulfonylguanidine (**6b**, 1.24 g, 95%), mp 82 °C; IR (Nujol) ν 3350 (NH) and 1580 cm^{-1} (C=N).

Found: C, 58.86; H, 8.37; N, 12.91%. Calcd for $C_{16}H_{27}N_3O_2S$: C, 59.05; H, 8.36; N, 12.91%.

*Base Catalyzed Hydrolysis of **3d**.* The reaction was carried out as described above using **3d** (2.60 g, 7.6 mmol). After removal of the solvent, the residue was recrystallized from hexane–benzene to give pure1,3-diisopropyl-2-*p*-toluenesulfonylguanidine (**6d**, 1.85 g, 82%), mp 120 °C; IR (Nujol) ν 3350 (NH) and 1590 cm^{-1} (C=N).

Found: C, 56.77; H, 7.91; N, 13.91%. Calcd for $C_{14}H_{23}N_3O_2S$: C, 56.55; H, 7.80; N, 14.13%.

*Reduction of **3a**.* A solution containing **3a** (0.85 g, 2 mmol) and the Raney Ni (1 g) in 30 ml of ethanol was refluxed for 5 hr. The organic layer was separated and concentrated under reduced pressure. The residue was recrystallized from benzene–hexane to give pure **6a** (0.65 g, 86%).

*Reaction between **1c** and **2a**.* The reaction between **1c** (2.70 g, 16 mmol) and **2a** (3.33 g, 16 mmol) was carried out in a similar way to that described for the exchange reaction between **1a** and **2a**. After removal of the solvent under reduced pressure, the oily residue was dissolved in ether–petroleum ether and allowed to stand at −20 °C for a week, but no crystallization took place. Vacuum distillation of the oily product yielded 1.40 g of a mixture, bp 53—56 °C/7—8 mmHg, of **5a** (0.95 g, 42%), cyclohexylisocyanate (**9a**, 0.35 g, 17%) and benzonitrile (**10c**, 0.10 g, 6%), whose ratio was determined by gas chromatography by use of a 1 m Silicon Gum column at 176 °C. The residue was chromatographed on alumina using hexane, hexane–benzene and benzene as eluent to give 0.30 g (6%) of 2,4-diphenyl-6-cyclohexylamino-*s*-triazine (**12a**), 0.76 g (14%) of 1,3-dicyclohexyl-2-benzoylguanidine (**11a**) and 0.20 g (6%) of *N*-cyclohexylbenzamide (**13a**). The structure of **12a** was confirmed by comparison of mp and IR with those of an authentic sample prepared from 2,4-diphenyl-6-chloro-*s*-triazine[16] and cyclohexylamine. The analytical and physical data of the products are as follows.

12a: mp 148 °C; IR (Nujol) ν 3330 (NH), 1590, 1560, and 1530 cm^{-1} (C=N and N–H); mass spectrum (70 eV) *m/e* 330 (M^+) and 248 ($M^+-C_6H_{10}$).

Found: C, 76.27; H, 6.67; N, 16.86%. Calcd for $C_{21}H_{22}N_4$: C, 76.33; H, 6.71; N, 16.96%.

11a: mp 158 °C; IR (Nujol) ν 3310 (N–H), 1605 (C=O), 1590 and 1570 cm^{-1} (C=N); mass spectrum (70 eV) *m/e* 327 (M^+) and 245 ($M^+-C_6H_{10}$).

Found: C, 73.55; H, 9.02; N, 12.91%. Calcd for $C_{20}H_{29}N_3O$: C, 73.35; H, 8.93; N, 12.83%.

13a: mp 151 °C (lit,[17] mp 153 °C); IR (Nujol) ν 3320 (NH), 1625 (C=O), and 1530 cm^{-1} (NH).

*Reaction between **1c** and **2c**.* In a similar way, the reaction of **1c** (2.40 g, 14.4 mmol) with **2c** (2.79 g, 14.4 mmol) was carried out, vacuum distillation of the oily product yielding 1.42 g of a mixture, bp 70—73 °C/9 mmHg, of **5c** (0.95 g, 47%), phenylisocyanate (**9c**, 0.32 g, 19%) and **10c** (0.15 g, 10%), whose ratio was determined as described above. The residue was chromatographed on alumina to give 0.34 g (12%) of benzanilide (**13b**) and a small amount of *N*-phenyl-*N'*-benzoylurea, which were identified by comparison of their IR spectrum and mp with those of authentic samples.[18,19]

*Reaction between **1d** and **2a**.* In a similar way, the reaction of **1d** (2.0 g, 19 mmol) with **2a** (3.68 g, 18 mmol) was carried out, distillation of the oily product yielding 0.20 g (22%) of acetonitrile (**10d**), bp 68—73 °C/760 mmHg (lit, 77 °C/760 mmHg), and a mixture, bp 55—57 °C/5—6 mmHg, of **5a** (0.40 g, 15%) and **9a** (0.15 g, 7%), whose ratio was determined as described above. No identification of the residue was attempted.

Ferricyanide Oxidation of 4-Arylazo-2,6-di-*t*-butylphenols

Eiichiro MANDA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

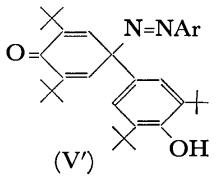
(Received June 10, 1972)

Alkaline ferricyanide oxidation of 4-arylazo-2,6-di-*t*-butylphenols (I) gave molecular nitrogen, diphenyl derivatives (VI), 2,6-di-*t*-butyl-*p*-benzoquinone-*N*-(3′,5′-di-*t*-butyl-4′-hydroxyphenyl)arylhydrazone (V) and red tarry compounds. Picryl derivative of phenol (I) gave 2,6-di-*t*-butyl-*p*-benzoquinone-picrylanil (X) instead of hydrazone (V). The reaction path was studied on the basis of isolated compounds.

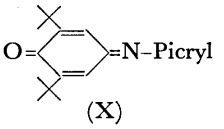
4-Arylazo-2,6-di-*t*-butylphenols (I) have been found to give some mixtures of stable free radicals by alkaline ferricyanide oxidation.[1] The oxidation products of phenols (I: Ar=*p*-nitrophenyl, *p*-chlorophenyl, phenyl, *p*-methoxyphenyl, and picryl) and the reaction path were studied, and the results are reported in this paper. A few papers have appeared on the oxidation of hydroxyazo dyes as studied by the synthesis of azoxy compounds, photochemical or oxidative color fading,[2,3] and the effect of chemical structure on reactivity.[4–7] Azoxy compounds, phthalic acid and some phenolic compounds were obtained by hydrogen peroxide oxidation,[2] and quinone derivatives and other compounds were obtained by oxidation with ceric sulphate,[3] lead peroxide,[4] ferric chloride,[5] sodium hypochlorite,[7] and molecular oxygen.[6] These oxidation reactions were carried out under acidic conditions and little is known about the reaction path.

Results and Discussion

Benzene solution of phenols (I: Ar=*p*-nitrophenyl, *p*-chlorophenyl, phenyl, *p*-methoxyphenyl, and picryl), prepared from 2,6-di-*t*-butyl-*p*-benzoquinone and aryl hydrazine hydrochlorides, were oxidized with an aqueous solution of potassium ferricyanide and potassium hydroxide accompanied by vigorous evolution of molecular nitrogen. The reaction was stopped in a few minutes at the end of vigorous gas evolution, though slight gas evolution was observed to continue for a few hours. Picryl derivative of phenol (I: Ar=picryl), which has strong electron-attracting groups and exists completely as a hydrazone tautomer,[8] showed quite slow gas evolution and required a longer period of oxidation than the other four phenols (I). After the organic layer of the reaction mixture was left standing until stable free radicals in it had almost faded away, tarry residual compounds were obtained by distilling off the solvent. Appropriate purification of the residual compounds gave 2,6-di-*t*-butyl-*p*-benzoquinone-*N*-(3′,5′-di-*t*-butyl-4′-hydroxyphenyl)arylhydrazones (V: Ar=*p*-nitrophenyl, *p*-chlorophenyl, phenyl, and *p*-methoxyphenyl), diphenyl derivatives (VI: Ar=*p*-nitrophenyl, *p*-chlorophenyl, phenyl, *p*-methoxyphenyl, and picryl), 2,6-di-*t*-butyl-*p*-benzoquinone (VIII), 3,3′,5,5′-tetra-*t*-butyldiphenoquinone (IX), 2,6-di-*t*-butyl-*p*-benzoquinonepicrylanil (X) and a large amount of red brown tarry compounds. The chemical structures of these oxidation products were determined by means of their melting points, elemental analyses, infrared spectra, and mass spectra. The presence of ν_{OH} band at 3630 cm^{-1}, the value of the molecular ion peak (M^+) and elemental analyses offered two isomeric forms (V) and (V′) for hydrazones (V). However, (V′) was excluded since the peak of a fragment ion  was observed in the mass spectra, but the characteristic strong absorption bands (1670 and 1630 cm^{-1}) of 4-substituted-2,5-cyclohexadienone[9,10] were not observed in the infrared spectra.



(V′)



(X)

One of the oxidation products of picryl derivative of phenol (I: Ar=picryl) was found to be an anil derivative (X) from its mass spectrum (M^+), infrared spectrum (absence of ν_{OH} band) and elemental analysis. Diphenyl derivatives (VI) were isolated from the oxidation products of each phenol (I). A very small amount of 3,3′,5,5′-tetra-*t*-butyldiphenoquinone (IX) was isolated from the oxidation products of nitro derivative of phenol (I: Ar=*p*-nitrophenyl), and a trace amount of 2,6-di-*t*-butyl-*p*-benzoquinone (VIII) was detected in the oxidation products of unsubstituted derivative of phenol (I: Ar=phenyl). Their melting points were the same as those in literature and their infrared spectra were consistent with the structures. The rest of the oxidation products were tarry materials which could not be crystallized, and were found to be of phenolic character from the infrared spectra. The yields of oxidation products are given in Table 1. The yields of hydrazones (V) and diphenyl derivatives (VI) are not high. Substituent effect on the yield seems apparent. This might be caused by the difficulty of isolating these compounds. High yields of diphenyl derivative (VI) and molecular nitrogen, and low yields of hydrazone (V) were ob-

tained when large amounts of oxidizing agent were used for long period of oxidation. When nitro derivative of phenol (I: Ar=*p*-nitrophenyl) was treated with 7.5 mol of oxidizing agent, the resulting products were 4-nitrodiphenyl, molecular nitrogen and a red tarry compound. Disappearance of hydrazone (V) is due to its oxidative degradation since it has also an oxidizable phenol group. Thus, the oxidation of hydrazone (V) was carried out at 10 °C with an excess aqueous alkaline solution of potassium ferricyanide. The reaction proceeded slowly and evolution of nitrogen gas continued for several hours. The ESR spectra (Fig. 1) indicate that more than two species of stable free

radicals exist in the organic layer of the reaction mixture of hydrazone (V), and the location of the peaks in the ESR spectrum of each derivative of hydrazone (V) is the same as that observed in the oxidation of the corresponding derivative of phenol (I) (Fig. 2). Thus, it is very likely that the stable radicals observed in the oxidation of phenol (I) are not radical (II) but other radicals originating from hydrazone (V). One might be radical (VII), and the others might be some radicals possibly formed during the process of degradation of

radical (VII). Diphenyl derivatives (VI), 2,6-di-*t*-butyl-*p*-benzoquinone (VIII), 3,3′,5,5′-tetra-*t*-butyldiphenoquinone (IX) and red tarry compound were obtained from the organic layer which had been kept standing for about four weeks to allow stable radicals to disappear (Table 2). The result shows that some

Table 2. Oxidation products of hydrazones (V)

Ar of (V)	Reaction time (hr)	Yields of oxidation products (%) (VI)	(VIII)	(IX)	N_2
p-Nitrophenyl	6.5	40.2	34.1	1.2	54.0
p-Chlorophenyl	5	21.1	20.5	1.7	71.0
Phenyl	4	16.2	25.0	0.7	65.0

parts of diphenyl derivative (VI) and 3,3′,5,5′-tetra-*t*-butyldiphenoquinone (IX) in the oxidation products of phenol (I) originated from hydrazone (V). The path of oxidation presumed from the isolated compounds is given in Fig. 3. Oxidizing agent will generate free radical (II) by the abstraction of a hydrogen atom from phenol (I). Radical (II) might disappear thorugh a few routes. One possible reaction is homolytic sub-

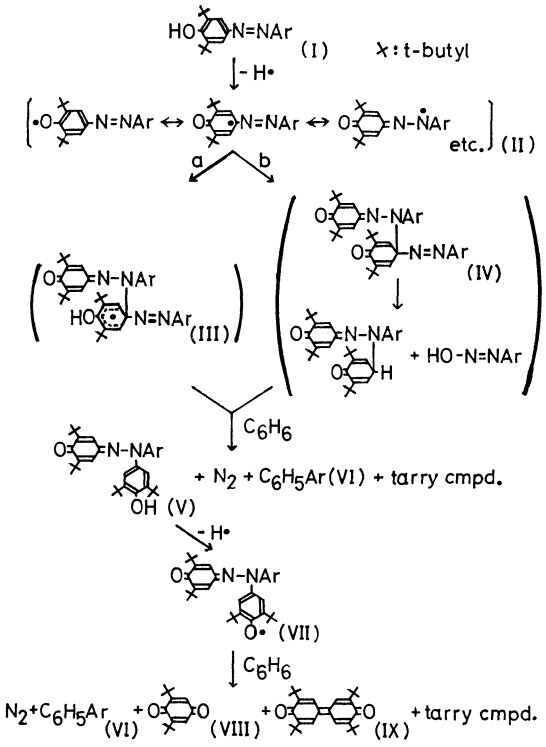

Fig. 3. Presumed reaction path.

stitution (route a). Radical (II) attacks phenol (I), and hydrazone (V) is formed from the intermediate (III) through elimination of arylazo radical, which gives out molecular nitrogen and diphenyl derivative (VI) through the reaction with benzene used as solvent. Another possible reaction is the recombination of radical (II) (route b). The self-coupling of radical (II) at carbon and nitrogen atom forms a dimer (IV), which is hydrolyzed to aryldiazonium hydroxide and hydrazone (V) *via* its dienone form. Aryldiazonium hydroxide undergoes decomposition to yield molecular nitrogen and diphenyl derivative (VI).[11] As for recombination reaction of radical (II), modes of coupling other than oxygen-oxygen coupling[12] and polymerization are possible since the maximum yield of molecular nitrogen based on the used phenol (I) is 75% and a large amount of tarry materials which may consist of the compounds through such a reaction path are obtained. Oxidizing agent will give a phenoxy radical (VII) by abstraction of a hydrogen atom from hydrazone (V), and radical (VII) will decompose to yield the final oxidation products (Table 2).

Picryl derivative of phenol (I; Ar=picryl) gave picrylbenzene (VI: Ar=picryl) and an anil derivative (X) instead of hydrazone (V). The strong electron-attracting power of picryl group might weaken and cleave the nitrogen-nitrogen bonding (=N–N<) of the dimer (IV), and an anil derivative might be formed as a result of the elimination of quinone-imino nucleus and picrylazo group.

Experimental

4-Arylazo-2,6-di-t-butylphenols (I). Phenols (I) were prepared by the same method as reported previously.[1]

Oxidation of 4-Arylazo-2,6-di-t-butylphenols (I). An aqueous solution (0.2 mol/l) of potassium ferricyanide and potassium hydroxide was placed in a Schlenk tube equipped with a gas buret. A solution of phenol (I) in benzene was placed in another Schlenk tube. Both solutions were degassed three times by freezing with dry ice–acetone, then argon gas was led into both Schlenk tubes. While the temperature of each solution was kept at 10 °C, a benzene solution of phenol (I) was carefully added to the aqueous solution of the oxidizing agents. The mixture was then stirred for several minutes (Table 1), and the volume of evolved gas was determined with the gas buret in the course of stirring. The reaction was stopped by pouring the reaction mixture to degassed water in a separatory funnel of Schlenk type. The organic layer was washed with degassed water and dried over anhydrous sodium sulphate under the atmosphere of argon until the ESR spectrum showed almost complete absence of radical species in the organic layer. A tarry residual compound was obtained after distilling off benzene from the organic layer and the oxidation products of each phenol (I) were separated from the residual tarry compound according to the following.

Oxidation Products of 4-p-Nitrophenylazo-2,6-di-t-butylphenol (I: Ar=p-nitrophenyl) (1.75 g, 5.0 mmol) in benzene (200 ml): Yellow brown powder was obtained by washing the tarry compounds with cyclohexane, and yellow brown needles of nitro derivative of hydrazone (V: Ar=*p*-nitrophenyl) (0.76 g, 27.2%) were recrystallized from methanol solution of this powder. Mp 197.0—199.0 °C *m/e* 559.344 (M^+). Found: C, 72.22; H, 8.18; N, 7.51%. Calcd for $C_{34}H_{45}O_4N_3$: C, 72.96; H, 8.10; N, 7.32%. IR (KBr) cm^{-1}: 3630 (ν_{OH}), 3030, 2950 (ν_{CH}), 1640 ($\nu_{C=N}$), 1625 ($\nu_{C=O}$), 1610 ($\nu_{C=C}$), 1510, 1355 (ν_{NO_2}), 1260 (*t*-butyl), 845, 820 (δ_{CH}). 4-Nitrodiphenyl (VI: Ar=*p*-nitrophenyl) (0.15 g, 15.0%) was isolated from the filtrate. Mp 113.0—114.0 °C. (lit,[13] 114 °C). All the resulting filtrate and washing were collected and the solvent was completely distilled. Chromatographic separation of *n*-hexane solution of residual compound on a column of silica gel yielded some phenolic red brown tarry compound, a small amount of hydrazone, 4-nitrodiphenyl and 3,3′,5,5′-tetra-*t*-butyldiphenoquinone (IX) (1 mg) mp 247.0—248.0 °C (lit,[14] 247.0 °C) *m/e* 408.311 (M^+).

Oxidation Products of 4-p-Chlorophenylazo-2,6-di-t-butylphenol (I: Ar=p-chlorophenyl) (3.44 g, 10.0 mmol) in Benzene (50 ml): Yellow powder was obtained by washing the red brown tarry compound with *n*-hexane. By recrystallization of the powder from *n*-hexane solution, yellow needles of chloro derivative of hydrazone (V: Ar=*p*-chlorophenyl) (1.1 g, 20.0%) were obtained. Mp 203.0—205.0 °C. *m/e* 548.319 (M^+). Found: C, 74.05; H, 8.28; N, 5.15; Cl, 6.37%. Calcd for $C_{34}H_{45}O_2N_2Cl$: C, 74.36; H, 8.26; N, 5.10; Cl, 6.46%. IR (KBr) cm^{-1}: 3630 (ν_{OH}), 3030, 2950 (ν_{CH}), 1625 ($\nu_{C=N}$), 1615 ($\nu_{C=O}$), 1605 ($\nu_{C=C}$), 1260 (*t*-butyl), 880, 820 (δ_{CH}). Chromatographic separation of the washing on a column of alumina gave pale yellow plates of 4-chlorodiphenyl (VI: Ar=*p*-chlorophenyl) (0.1 g, 5.3%), mp 74.5—76.0 °C (lit,[13] 77.5 °C), a small amount of hydrazone and a red tarry compound.

Oxidation Products of 4-Phenylazo-2,6-di-t-butylphenol (I: Ar=phenyl) (3.10 g, 10.0 mmol) in Benzene (60 ml): Chromato-

graphic separation of *n*-hexane solution of the red tarry compound gave colorless plates of diphenyl (VI: Ar=phenyl) (0.03 g, 2.2%), mp 69.0—69.5 °C (lit,[13] 70.5 °C), a red brown tarry compound and yellow brown plates of unsubstituted derivative of hydrazone (V: Ar=phenyl) (0.5 g, 12.1%), mp 151.0—153.0 °C. Found: C, 78.45; H, 8.86; N, 5.29%. Calcd for $C_{34}H_{46}O_2N_2$: C, 79.33; H, 9.01; N, 5.44%. IR (KBr) cm^{-1}: 3630 (ν_{OH}), 3030, 2950 (ν_{CH}), 1640 ($\nu_{C=N}$), 1620 ($\nu_{C=O}$), 1605 ($\nu_{C=C}$), 1255 (*t*-butyl), 880, 750 (δ_{CH}). A very small amount of 2,6-di-*t*-butyl-*p*-benzoquinone (VIII) was detected inside the flask containing the red brown tarry compound after it had been left standing for a long time. Mp 65.5—67.0 °C (lit,[15] 68.0 °C).

Oxidation Products of 4-p-Methoxyphenylazo-2,6-di-t-butylphenol (I: Ar=p-methoxyphenyl) (3.41 g, 10.0 mmol) in Benzene (50 ml): Yellow powder was obtained by washing the red brown tarry compound with *n*-hexane. By recrystallization of this powder from methanol solution, yellow plates of hydrazone (V: Ar=*p*-methoxyphenyl) (0.73 g, 14.7%) were obtained. Mp 181.0—182.0 °C, *m/e* 544.355 (M^+). Found: C, 76.65; H, 8.86; N, 4.89%. Calcd for $C_{35}H_{48}N_2O_3$: C, 77.16; H, 8.88; N, 5.14%. IR (KBr) cm^{-1}: 3630 (ν_{OH}), 3030, 2950 (ν_{CH}), 1625 ($\nu_{C=N}$), 1615 ($\nu_{C=O}$), 1610 ($\nu_{C=C}$), 1245 (*t*-butyl), 1020 (ν_{OMe}) 880, 825 (δ_{CH}). Chromatographic separation of the washing on a column of alumina gave yellow plates of 4-methoxydiphenyl (VI: Ar=*p*-methoxyphenyl) (0.2 g, 10.9 %), mp 87.0—88.0 °C (lit,[13] 90 °C), and a red brown tarry compound.

Oxidation Products of 4-Picrylazo-2,6-di-t-butylphenol (I: Ar=picryl) (0.41 g, 0.9 mmol) in Benzene (35 ml): Yellow brown powder was obtained by washing the red brown tarry compound with cyclohexane. Chromatographic separation of benzene solution of this powder on a column of silica gel gave a yellow compound, pale yellow plates of picrylbenzene (0.03 g, 11.9%) mp 130.0—131.5 °C (lit,[16] 130.0 °C), a small amount of starting material and a dark red tarry compound. Yellow plates of anil (X) (0.08 g, 19.1%) were recrystallized from methanol solution of the yellow compound. Mp 176.0—177.0 °C, *m/e* 430.152 (M^+). Found: C, 56.03; H, 4.91; N, 12.97%. Calcd for $C_{20}H_{22}O_7N_4$: C, 55.81; H, 5.15; N, 13.02%. IR (KBr) cm^{-1}: 3030, 2950 (ν_{CH}), 1660 ($\nu_{C=N}$), 1640 ($\nu_{C=O}$), 1620 ($\nu_{C=C}$), 1540, 1345 (ν_{NO_2}), 1250 (*t*-butyl), 880, 820 (δ_{CH}).

Oxidation of Hydrazone (V). A solution of hydrazone (V) (1.0 mmol) in benzene (60 ml) was oxidized with an aqueous alkaline solution of potassium ferricyanide (5.0 ml) at 10 °C until cessation of nitrogen gas evolution, and the reaction mixture was treated in the same way as in the oxidation of phenols (I). The solvent was distilled off after the stable radicals in the organic layer had disappeared, and isolation of oxidation products from the residual compounds was carried out as described below.

Oxidation Products of Nitro Derivative of Hydrazone (V: Ar=p-nitrophenyl): The yellow brown residual compound was dissolved in *n*-hexane and a small amount of insoluble material remained. The starting material (9 mg, 1.6%) was obtained by recrystallization of this insoluble material from methanol solution. The *n*-hexane solution was passed through a column of alumina, and 3,3′,5,5′-tetra-*t*-butyldiphenoquinone (X) (5 mg, 1.2%), 2,6-di-*t*-butyl-*p*-benzoquinone (VIII) (75 mg, 34.1%), 4-nitrodiphenyl (VI: Ar=*p*-nitrophenyl) (80 mg, 40.2%) and a red brown tarry compound were obtained.

Oxidation Products of Chloro Derivative of Hydrazone (V: Ar=p-chlorophenyl): The red brown residual compound was dissolved in *n*-hexane and passed through a column of alumina. 4-Chlorodiphenyl (VI: Ar=*p*-chlorophenyl) 40 mg, 21.1%), 3,3′,5,5′-tetra-*t*-butyldiphenoquinone (IX) (7 mg, 1.7%), 2,6-di-*t*-butyl-*p*-benzoquinone (VIII) 45 mg, 20.5%) and a red brown tarry compound were obtained.

Oxidation Products of Unsubstituted Derivative of Hydrazone (V: Ar=phenyl): The red brown residual compound was dissolved in *n*-hexane and passed through a column of alumina. Diphenyl (VI: Ar=phenyl) (25 mg, 16.2%), 3,3′,5,5′-tetra-*t*-butyldiphenoquinone (VIII) (3 mg, 0.7%), 2,6-di-*t*-butyl-*p*-benzoquinone (VIII) (55 mg, 25.0%) and a red brown tarry compound were obtained.

Oxidation Products of Methoxy Derivative of Hydrazone (V: Ar=p-methoxyphenyl): Red brown residual compound was dissolved in *n*-hexane and passed through a column of alumina. 3,3′,5,5′-Tetra-*t*-butyldiphenoquinone (IX) (2 mg, 0.5%) was obtained from the first yellow band. The eluent from the second yellow brown band was passed through a column of silica gel, and 4-methoxydiphenyl (VI: Ar=*p*-methoxydiphenyl) (30 mg, 16.3%), 2,6-di-*t*-butyl-*p*-benzoquinone (VIII) (50 mg, 22.7%) and a red brown tarry compound were obtained.

All the melting points were uncorrected. The infrared spectra were taken with a Shimadzu IR-27G grating spectrophotometer. The ESR spectra for the benzene-diluted organic layer of the reaction mixture, which had been dried over anhydrous sodium sulphate for a few minutes directly following cessation of oxidation, were taken with a Hitachi 771 electron spin resonance spectrometer.

The author is indebted to Mr. Wasada for the mass spectra.

Selective Formations of Several Carboxylic Acids by Carbonylation in the $SbCl_5$–Liquid Sulfur Dioxide System*

Masakatsu YOSHIMURA, Masatomo NOJIMA, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received September 4, 1972)

The carbonylations of *cis*- and *trans*-4-*t*-butyl-1-methylcyclohexanols, *exo*- and *endo*-2-methyl-2-norbornanols and *exo*- and *endo*-2-norbornanols were carried out in $SbCl_5$–liq.SO_2 at −70°. From both the *cis*- and *trans*-4-*t*-butyl-1-methyl-cyclohexanols, *cis*-4-*t*-butyl-1-methylcyclohexanecarboxylic acid was formed exclusively in an excellent yield (over 90%). Both *exo*- and *endo*-2-methyl-2-norbornanols gave only *endo*-2-methyl-*exo*-2-norbornylcarboxylic acid in a high yield. The reason for the stereoselectivity of the reactions was discussed.

A convenient carbonylation of alkyl halides with carbon monoxide at −70 °C in the $SbCl_5$–SO_2 system to give carboxylic acids or esters in good yields and with a high selectivity has been reported in a preceding paper.[1] In the present paper we wish to describe the results of the carbonylation of alicyclic alcohols, whose stereochemistries had previously been confirmed, in order to investigate the steric course of the carbonylation in this system along with the mechanism of the reaction. The reactions of *cis*- and *trans*-4-*t*-butyl-1-methylcyclohexanols, *exo*- and *endo*-2-methyl-2-norbornanols and *exo*- and *endo*-2-norbornanols have been carried out. The results thus obtained are gathered in Table 1.

From both *cis*- and *trans*-4-*t*-butyl-1-methylcyclohexanols (I and II), *cis*-4-*t*-butyl-1-methylcyclohexanecarboxylic acid (III) was obtained exclusively in a yield of over 90%. *exo*- and *endo*-2-Methyl-2-norbornanols (IV and V) also gave 2-*endo*-methyl-2-*exo*-norbornanecarboxylic acid (VI) exclusively in a high yield. Furthermore, *exo*- and *endo*-2-norbornanols (VII and VIII) were carbonylated to give only *exo*-norbornane-2-carboxylic acid (IX). The yield of IX from VII is very good (92%), but that of IX from VIII is low (16%). These results seem to be important from the preparative point of view, and also to be suggestive of the reaction mechanism. Whereas the carbonylation reaction of the mixture of I and II with formic acid and sulfuric acid (Koch's method) has been reported to give III (*cis*-carboxylic acid) in a 35% yield along with six other isomeric carboxylic acids,[2] III was obtained stereospecifically in the present reaction.

The stereochemistry of the reactions of a number of nucleophiles with 4-*t*-butyl-1-methylcyclohexanol in the presence of acetic acid and sulfuric acid has previously been studied. According to Beeby and Sternhell, the stereoselectivity of the reaction was found to depend upon the size of the attacking nucleophile.[2] The stereochemistry of the product is determined by the stability of the oxocarbonium ion (B) and not by the attacking facility of carbon monoxide on the carbonium ion (A), although the attack of carbon monoxide seems to be possible from the equatorial direction because of the lack of 1,3-diaxial interaction. Carbon monoxide, whose steric bulkiness is comparable to that of acetylene,[3] is much smaller than the methyl group. The formation of III in the $SbCl_5$–SO_2 system with a high selectivity and a high yield seems to be due to the irreversible formation of 1:1 donor acceptor complex (C) between acyl halide and $SbCl_5$ from B, which is predominantly formed under those reaction conditions. The reaction course is depicted in Chart 1.

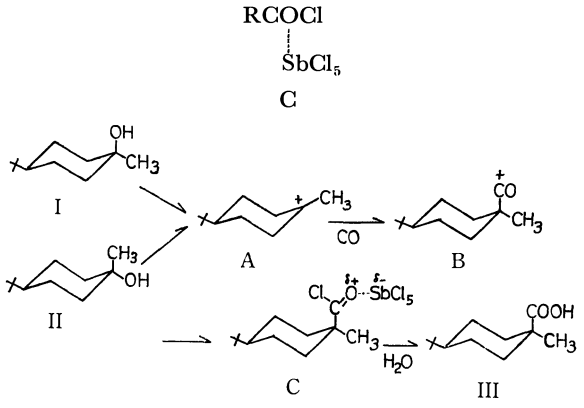

Chart 1.

In the Koch reaction, the formation of olefin is frequently encountered, this gives other side products

Table 1. Carbonylation of alicyclic alcohols in $SbCl_5$–liq. SO_2 at −70 °C

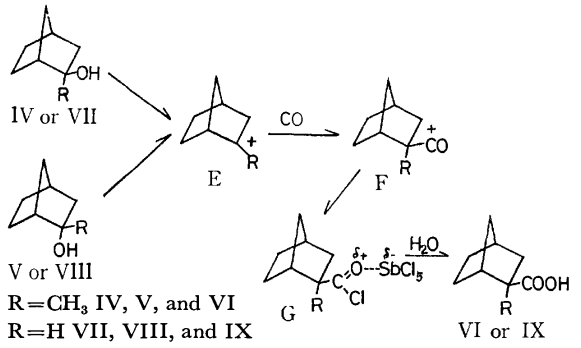

Chart 2.

in the reaction.[4] In the present reaction, the formation of olefin, polymerization, and oxidation were depressed for the reason described before.

The selective formations of *endo*-2-methyl-*exo*-2-norbornanecarboxylic acid from *exo*- and *endo*-2-methyl-2-norbornanols and *exo*-2-norbornanecarboxylic acid from *exo*- and *endo*-2-norbornanols are interesting. It was clarified by Hogeveen and Roobeek[5] that the formation of F in Koch's reaction is kinetically controlled, while, under thermodynamically-controlled conditions, both *exo*- and *endo*-norbornyl oxocarbonium ions were formed to the same extent, the ratio of the *exo*- and *endo*-norbornanecarboxylic acids produced being 51 to 49.

These results suggest that, in our reaction, the same carbonium ion was formed from epimers and was subsequently carbonylated by the stereospecifical *exo* attack of CO on an oxocarbonium ion, followed by the formation of a 1:1 donor-acceptor complex[6] of acyl halide and $SbCl_5$.

The *exo* attack of the nucleophilic reagent on norbornyl and 2-methylnorbornyl cations in kinetically-controlled reactions, has been well confirmed.[7] The present results seem to be consistent with these facts and with the formation of the norbornyl cation and the 2-methylnorbornyl cation, followed by the attack of carbon monoxide from the *exo* direction.

In the carbonylation of *endo*-2-norbornanol (VIII), the conversion to the product, IX, was very low, the starting norbornanol was almost all recovered, and no olefinic or polymeric material was found in the reaction mixture. These results suggest that the formation of the carbonium ion is the rate-determining step in this reaction and that the attack of carbon monoxide on this carbonium ion is a very fast step, as has already been indicated by Hogeveen.[5]

The authors wish to express their deep gratitude to the Seitetsu Kagaku K.K. for its donation of liquid sulfur dioxide. They are also grateful for the grant from the Ministry of Education, Japan, which supported this project.

Experimental

Materials. *cis*-4-*t*-Butyl-1-methylcyclohexanol (I) was obtained by the oxymercuration of 4-*t*-butyl-1-methylcyclohexene.[8] *trans*-4-*t*-Butyl-1-methylcyclohexanol (II) was prepared by the method of Corey.[9] *exo*-2-Methyl-2-norbornanol (IV) was obtained by the oxymercuration and reduction of 2-methylnorbornene-2.[10] *endo*-2-Methyl-2-norbornanol (V) was obtained by the reaction of 2-norbornanone with methylmagnesium iodide.[11] By the hydrolysis of *exo*-2-norbornyl formate, *exo*-2-norbornanol (VII) was obtained.[10] *endo*-2-Norbornanol (VIII) was prepared by the reduction of 2-norbornanone with lithium aluminum hydride.[12]

General Procedure of Carbonylation. Into a mixture of 20 g (0.07 mol) of $SbCl_5$ and 50 ml of liq. SO_2, an alcohol in 20 ml of dichloromethane was dropped at −70 °C over a thirty-minute period while a current of carbon monoxide gas was being bubbled into the flask at a velocity of 70 ml per minute, after which the reaction was continued for an additional thirty minutes. Then the reaction mixture was poured into ice-cold aqueous sodium hydroxide, and the neutral products were extracted by ether. Then the acidic products were extracted with ether after the water layer had been acidified with aqueous hydrogen chloride. After the evaporation of the ether, the product was characterized by NMR, infrared, and mass spectroscopies.

The Reaction of I and II. *cis*-4-*t*-Butyl-1-methylcyclohexanol, (I) (1.70 g, 0.01 mol), was allowed to react with carbon monoxide following the general procedure. After the evaporation of the ether, 1.86 g of a solid (III) was obtained. III was identified as 4-*t*-butyl-1-methylcyclohexanecarboxylic acid by comparing it with the physical data of an authentic sample;[2] mp 132—133 °C (lit,[2] 132—133 °C). The crude product was reduced by lithium aluminum hydride and was analyzed by glc; the glc showed the formation of only *cis*-4-*t*-butyl-1-methylcyclohexylcarbinol.[2]

By the reaction of II (1.70 g, 0.01 mol), III was obtained in a 90% yield.

The Reaction of IV and V. From *exo*-2-methyl-2-norbornanol (IV) (1.26 g, 0.01 mol), 1.48 g (96% yield) of 2-*endo*-methyl-2-*exo*-norbornanecarboxylic acid were obtained; mp 50—51 °C (lit,[13] 50—52 °C). The physical data were identical with those of an authentic sample.[13]

The selective formation of VI was clarified by the glc analysis of the reduction products with lithium aluminum hydride. From V, VI was obtained exclusively in an 85% yield.

The Reaction of VII and VIII. By the reaction of VII (1.12 g, 0.01 mol) under these reaction conditions, 1.29 g (92% yield) of 2-*exo*-norbornanecarboxylic acid (IX) was obtained; mp 52—53 °C (lit,[14] 52—53 °C).

In the reaction of *endo*-2-norbornanol (VIII), IX was obtained as the acidic product in a 16% yield, and from the neutral part 80% of the starting material, VIII, was recovered.

The Mass Spectra of 3-Aryl-5-chloromethyl-1,2,3-oxathiazolidine-2-oxides

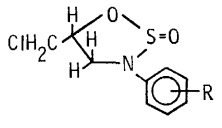
Tomihiro NISHIYAMA and Fukiko YAMADA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received September 19, 1972)

The mass spectra of 3-phenyl- (I), 3-tolyl- (II), 3-chlorophenyl- (III), and 3-trichlorophenyl- (IV), -5-chloromethyl-1,2,3-oxathiazolidine-2-oxides have been obtained. The major path in the electron impact-induced cleavage of all the compounds involves the loss of SO_2 and Cl from each molecular ion (M). The $M-SO_2-Cl$ ions show the loss of $CH{=}CH_2$, followed by the loss of the hydrogen radical and HCN. On the other hand, in compounds II, III, and IV, the $M-SO_2-Cl$ ions show the loss of the ring-substituted methyl or chloro radical. The above fragmentation pathways associated with metastable transitions or the chlorine isotopic clusters for each ion of III or IV have been outlined and discussed for each group of compounds.

Recently, we have reported the mass spectra of 3-aryl-1,2,3-oxathiazolidine-2-oxides[1] and 3-aryl-5-methyl-1,2,3-oxathiazolidine-2-oxides.[2] This time we wish to report the mass spectral data of new compounds of oxathiazolidines as an extension of our previous work. That is, the 3-aryl-5-chloromethyl-1,2,3-oxathiazolidine-2-oxides have been easily prepared by a previously-reported method,[3] and the mass spectra of the following eight compounds have been determined.



I, R=H (*cis*)
IIa, R=*o*-CH_3 (*cis*)
IIb, R=*m*-CH_3 (*trans*)
IIc, R=*p*-CH_3 (*cis*)
IIIa, R=*o*-Cl (*cis*)
IIIb, R=m-Cl (*trans*)
IIIc, R=*p*-Cl (*cis*)
IV, R=2,4,6-Cl (*trans*)

The present work is concerned with the fragmentation schemes of the above oxathiazolidines.

Experimental

Materials. All the eight oxathiazolidines examined were prepared by the reported method, and the general structures of these compounds were confirmed by means of the NMR spectral data.[3]

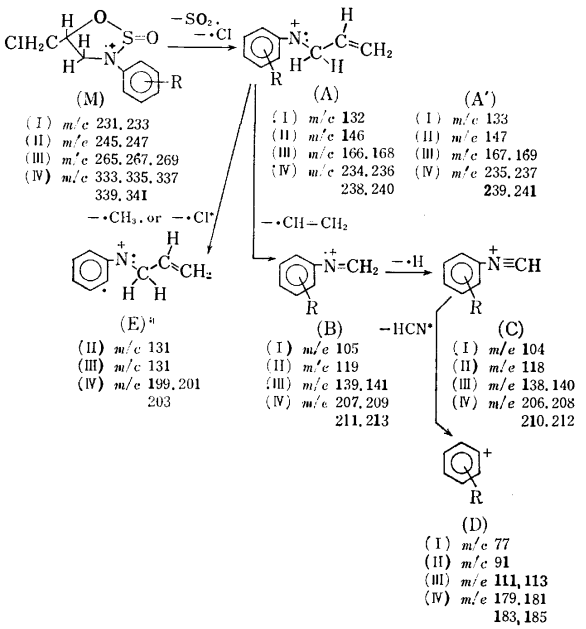
Compound IV: mp 77.5—78.7 °C (uncorrected), elemental analysis, Found: C, 32.31; H, 2.10; N, 4.25; S, 9.51; Cl, 42.10%. Calcd for $C_9H_7NSO_2Cl_4$: C, 32.24; H, 2.09; N, 4.18; S, 9.55; Cl, 42.38%.

Measurement. The high-resolution mass spectra were obtained by means of a Japan Electron Optics Co. Ltd., JMS-O1SG Mattauch-Herzog double-focusing mass spectrometer, at an ionizing voltage of 75 eV, an emission current of 200 μA, an accelerating voltage of 6.4 kV, and a vapor pressure of 1.0×10^{-6} mmHg. The ion-source temperature varied between 100 and 150 °C. The accurate masses and elemental compositions were determined by a previously-reported method.[1]

Results and Discussion

The mass spectral data of compounds I, II, and III, are summarized in Table 1, while their fragmentation pathways are shown in Scheme 1. It has previously been established that the oxathiazolidines exist in the *cis* and *trans* configurations between the S=O group and the chloromethyl group in the 5-position.[3] On the other hand, we have found that the fragmentation patterns of the oxathiazolidines are the same in the *cis* and *trans* configurations.[2] Thus, the fragmentation pattern for each compound will be discussed on the basis of the data obtained in the case of either the *cis* or *trans* isomer.

The molecular ions of these compounds are of low abundance. The base peaks of compounds I, IIb and c, and IIIc appeared at the mass numbers of 132, 146, and 166 respectively, corresponding to that of the



* Asterisks denote the processes for which metastable transitions were observed.

a) The radical on the benzene ring exists at *ortho*, *meta*, and *para* position in the corresponding compounds, II and III.

Scheme 1. The major fragmentation pathways of oxathiazolidines, I, II, III, and IV.

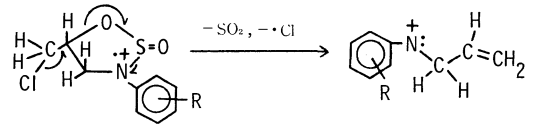
111	C_6H_4Cl	40	74	46

a) The high-resolution mass spectra of these compounds gave the correct composition of all the ions mentioned in the table within an error of ±5millimass units.

$R-C_6H_4NC_3H_5$ ion (A). In the case of compounds IIa, IIIa, and IIIb, the $R-C_6H_4NCH$ cation (C) was the base peak. The ion A was formed from the molecular ion by the loss of the SO_2 group and a chloro radical. In the fragment ion A, the isotope peaks (A') appeared.

Our reports which have appeared in recent years have indicated that in the electron impact-induced cleavage of the 3-aryl-1,2,3-oxathiazolidine-2-oxides[1] and the 3-aryl-5-methyl-1,2,3-oxathiazolidine-2-oxides[2] the major path involves the loss of sulfur dioxide from the molecular ions. In view of these findings, it was interesting to find that the mass spectra of the 3-aryl-5-chloromethyl-1,2,3-oxathiazolidine-2-oxides showed no such $(M-SO_2)^{+\cdot}$ peak at all. Each showed peaks representing the loss of SO_2 and Cl. In none of these spectra were Cl-, SO_2-, or SO_2–Cl-positive ions present. The probable mechanism is indicated by the following diagram.



This decomposition implied that the loss of SO_2 and Cl is either concerted or so nearly so that no substantial amount of the $(M-SO_2)^{+\cdot}$ ion or $(M-Cl)^{+\cdot}$ ion is formed.

The ion B is formed from the ion A by the loss of the $CH=CH_2$ radical, and the resulting ion loses a hydrogen radical to give the ion C. In compound I, the peak at mass 77 due to the hydrocarbon ion (D), $C_6H_5^+$, is about 70% of the base peak intensity and was produced by the loss of the HCN group from the ion C. Similar methyl- or chloro-substituted hydrocarbon ions, $R-C_6H_4^+$, can also be observed in the spectra of compounds II, III, and IV and are abundant. This fragmentation pathway, (C)→(D), is verified by the metastable peaks at *m/e* 57.0, 70.2, and 89.3 respectively. On the other hand, no metastable peak was observed in Compound IV. Moreover, there have been many reports concerning the fragmentation pathway of $R-C_6H_4N^+\equiv CH \longrightarrow R-C_6H_4^+ + HCN$.[1,2,4,5]

In the spectra of II, the ion at *m/e* 131, which is of a 7% abundance for the *ortho* isomer, 9% for the *meta*, and 9% for the *para*, is present. This ion, corresponding to the C_9H_9N cation (E), is formed from the ion A. On the other hand, in the oxathiazolidines having the ring-substituted chloro atom, such as IIIa, IIIb, and IIIc, the ion at *m/e* 131, which is of a 9% abundance for the *ortho*, 13% for the *meta*, and 13% for the *para* isomer, is observed. In this case, the metastable peaks at *m/e* 103.3 are also observed. In the case of IV, the $C_9H_7NCl_2$ ion (*m/e* 199, 201, and

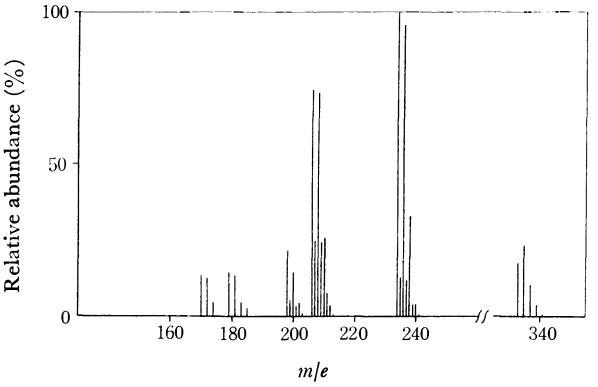


Fig. 1. Relative abundance of the fragment ions of the compound IV (75 eV).
The peaks below *m/e* 160 are omitted here.

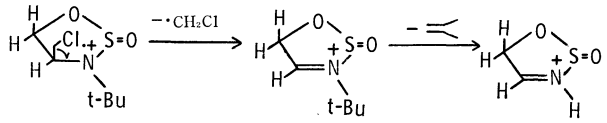
5) D. J. Elias and R. G. Gillis, *Aust. J. Chem.*, **19**, 251 (1966).

203), with two ring-substituted chloro atoms, is present (E in Scheme 1). The above results suggest that these ions are produced by the loss of the methyl- or chloro-radical from the ion A.

It is interesting to compare these spectra with the spectra of the other oxathiazolidines reported by Deyrup and Moyer.[6,7] They reported that the mass spectrum of 2-oxo-3-*t*-butyl-4-chloromethyl-1,2,3-oxathiazolidines showed the $M-CH_3$ and $M-CH_3-SO_2$ peaks. The molecular ion is obviously of low abundance, and there are intense peaks at *m/e* 162 and *m/e* 106 as a result of the loss of the chloromethyl radical, followed by the loss of the isobutylene.



m/e 162 *m/e* 106 (Base peak)

On the contrary, in the cases of compounds I, II, III, and IV, the $M-CH_2Cl$ peaks are extremely small (4—5% of the base peak). These differences can be explained by the substituted groups on the oxathiazolidine ring. The fragmentations are influenced by the presence of the *N*-substituted aromatic nucleus and the position of the chloromethyl group (4- or 5-position).

The present fragmentation pathways are further illustrated by those of the 2,4,6-trichlorophenyl-5-chloromethyl-1,2,3-oxathiazolidine-2-oxide (IV). The mass-spectral data of IV are shown in Fig. 1, and the major fragmentation pathways are shown in Scheme 1.

Synthesis and Biological Activity of Peptides Related to Eledoisin. III.[1] *C*-Terminal Hexapeptide Amides Modified in Methionine and Isoleucine Residues[2,3]

Hiroshi SUGANO

Department of Synthetic Chemistry, Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., Kashima-cho, Higashiyodogawa-ku, Osaka 532

(Received September 16, 1972)

New analogs of hexapeptide related to eledoisin containing *N*-methylmethionine and α-hydroxy-γ-methylthiobutyric acid in place of the methionine, and α-hydroxyisovaleric acid in place of the isoleucine, were synthesized in order to obtain some information about the role of the amide bond in the peptide backbone. The former two were practically inactive in the rabbit pressure assay. These results indicated that the amide bond between the leucine and the methionine residues was important for the depressor activity of eledoisin. The last one showed very little activity. The results supported the suggestion made previously that the amide bond between the phenylalanine and the isoleucine residues is important in eliciting the biological response. The role of the amide bonds in the peptide backbone of eledoisin was also discussed.

Eledoisin, Pyroglu–Pro–Ser–Lys–Asp–Ala–Phe–Ile–Gly–Leu–Met–NH_2, is a potent, naturally occurring depressor substance. A number of data have accumulated on the relation between the structure of eledoisin and the biological activity. The *C*-terminal pentapeptide sequence, H–Phe–Ile–Gly–Leu–Met–NH_2, is of particular importance for the depressor activity.[4] The low depressor activity (1%) of this sequence is enhanced to almost full hormonal activity by introducing lysine to the *N*-terminus.[5] It has also been reported that the amino acid residues, phenylalanine, isoleucine, leucine, and methionine are the essential elements for the depressor activity.[4] The hydrophobic side chains in these residues may play a role in interaction with the biological receptor site.

However, there is practically no knowledge as to the part played by the amide bond which is a structural element of the polypeptide chain of eledoisin.

In previous papers,[1,6] the present author chose the [Lys^6]-eledoisin-(6-11)-hexapeptide (I) as a model compound of eledoisin and described the synthesis and the biological activity of several analogs. In these peptides, some amide bonds in I were replaced by ester bonds or *N*-methylamide bonds by the replacement of the parent amino acids with α-hydroxy acids or *N*-methylamino acids. These studies gave us some information about the relationship between the structure of the peptide backbone of eledoisin and the activity. It was found that, in the case of the substitution of the amide group in the peptide I by an ester group or an *N*-methylamide group without any change in the amino acid side chain, the potency of the activity was dependent upon the position substituted. The replacement of the amide bond between the phenylalanine and the isoleucine residues by an ester bond or an *N*-methylamide bond led to a much less active compound. These facts suggest that the amide bond between the phenylalanine and the isoleucine residues is essential for the activity.

In order to provide further information concerning the role of the amide bond in the peptide backbone, the author will report, in the present paper, on the synthesis of [Lys^6, MeMet^{11}]-eledoisin-(6-11)-hexapeptide (XIV) and [Lys^6, HyMtb^{11}]-eledoisin-(6-11)-hexapeptide (VIII) and on their depressor activities. In these peptides the amide bond between the leucine and the methionine residues was replaced by an *N*-methylamide bond or an ester bond. In addition, to confirm the necessity of the amide bond between the phenylalanine and the isoleucine residues for the activity, [Lys^6, HyIv^8]-eledoisin-(6-11)-hexapeptide (IV) was synthesized and its activity was estimated.

A synthetic route to the [Lys^6, MeMet^{11}]-analog (XIV) is shown in Scheme 1.

Scheme 1.

Optically active *N*-methylmethionine was prepared by the method reported by Izumiya *et al.*[7] Boc-leucine was condensed with *N*-methylmethionine ethyl ester with dicyclohexylcarbodiimide (DCC) to yield the Boc-dipeptide ester, **2**, which was then converted to the amide, **3**. After the removal of the protecting group, the resulting dipeptide amide was coupled with Boc-glycine *p*-nitrophenyl ester to form the Boc-tripeptide amide, **4**. The condensation of the azide derived from *t*-amyloxycarbonylphenylalanylisoleucine hydrazide, Aoc-Phe-Ile-N_2H_3, with the tripeptide amide gave an acylpentapeptide amide, **5**. The di-Boc-hexapeptide amide, **6**, was obtained *via* the *p*-nitrophenyl ester method. Since all attempts to crystallize the intermediates **2**—**6** were unsuccessful, the products were purified by column chromatography on silica gel after each coupling step.

The [Lys^6, HyMtb^{11}]-analog (VIII) was synthesized by the method shown in Scheme 2.

Scheme 2.

L-α-Hydroxy-γ-methylthiobutyric acid (**7**) was prepared from L-methionine by the procedure of Winitz *et al.*[8] The α-hydroxy acid, **7**, was converted to the methyl ester, **8**; subsequent amidation yielded the corresponding amide, **9**. Boc-leucine was coupled with the free hydroxyl by the use of *N*,*N*′-carbonyldiimidazole (CDI)[9] to yield the Boc-didepsipeptide amide, **10**, in a good yield. After the removal of the Boc-group of **10**, the resulting didepsiptide amide was condensed with Boc-isoleucylglycine *p*-nitrophenyl ester to yield the Boc-tetradepsipeptide amide, **11**. The di-Boc-hexapeptide amide, **13**, was prepared by two successive stepwise elongations *via* the *p*-nitrophenyl ester method.

In the synthesis of [Lys^6, HyIv^8]-analog (IV), benzenesulfonyl chloride and pyridine were used for the formation of the depsipeptide bond, as had been reported previously for the synthesis of [Lys^6, HyMeV^8]-analog (III)[6] (Scheme 3).

The peptides, XIV, VIII, and IV, were obtained by the removal of the Boc group of the di-Boc-hexapeptide amides with hydrogen chloride in acetic acid.

a) The activity of the reference standard (I) is taken as 100. The potency of the other peptides is compared on a weight basis which causes fall of 20 mmHg of the blood pressure and expressed in per cent.
b) Taken from the previous papers.[1,6]

Results and Discussion

Table 1 shows the biological activities of the analogs synthesized here, together with those reported previously. In the rabbit blood pressure assay, the peptides VIII and XIV possessed 0.1% and the peptide IV possessed 6% of the depressor activity of the reference standard (I). The inactivity of the former two analogs strongly suggests the necessity of the amide bond between the leucine and the methionine residues for the biological activity. Although IV still had an appreciable activity, its potency was more decreased than those of II, V, VI, and VII, in which the phenylalanine, the glycine, or the leucine was replaced by the α-hydroxy acid. This low activity may be due not to the change in the side chain, but to the change in the backbone, because α-hydroxyisovaleric acid has a β-branched side chain like isoleucine, and because a [Val[8]]-eledoisin-(6-11)-hexapeptide, in which the isoleucine is replaced by valine, retains the same activity as the parent *C*-terminal hexapeptide of eledoisin.[10] These results support the suggestion made previously that the amide bond between the phenylalanine and the isoleucine residues is probably important for the depressor activity.[6]

Summarizing the results obtained in this series of studies, both the amide bond between the phenylalanine and the isoleucine residues and that between the leucine and the methionine residues are indispensable in manifesting the depressor activity of eledoisin. The analogs which are lacking in either of the essential amide bonds show much less activity.

Apart from minor differences in geometry, such as the steric effect of the *N*-methyl group, the amide bond differs fundamentally from the ester bond or the *N*-methylamide bond in its ability of hydrogen-bond formation. This loss of activity may indicate that the hydrogen bonding is required to maintain a favorable conformation of the peptide for the activity or to bind the molecule with the biological receptor site.

To gain some insight into conformational changes in solution following chemical alteration, circular dichroism (CD) spectroscopy was applied. Figures 1 and 2 show representative CD spectra in water between 250 and 210 nm. The biologically active hexapeptide analog of eledoisin (I) shows a trough at 233 nm ($[\theta]=-2800$). The CD curves of the biologically active analogs, such as [Lys[6], Phlac[7]]-analog (II), [Lys[6], Glyc[9]]-analog (V), [Lys[6], HyIc[10]]-analog (VI),

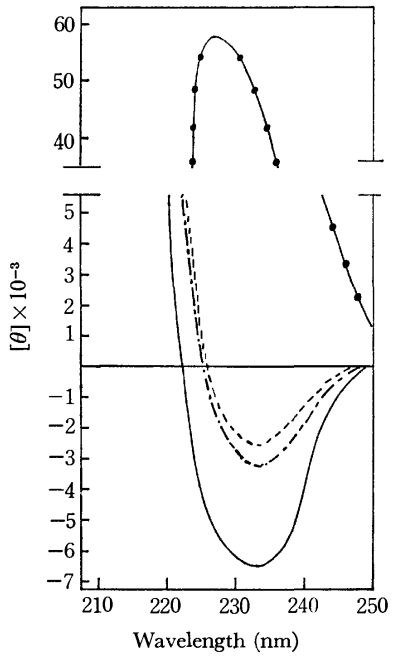

Fig. 2. Circular dichroism of *N*-methylpeptide analogs in the region 210—250 nm in water; concentration 1 mg/ml.
———: [Lys^6, MePhe^7]-analog (IX)
●—●: [Lys^6, MeIle^8]-analog (X)
— — —: [Lys^6, Sar^9]-analog (XI)
------: [Lys^6, MeMet^{11}]-analog (XIV)

[Lys^6, Phlac^7, HyIc^{10}]-analog (VII), [Lys^6, Sar^9]-analog (XI), and [Lys^6, MeLeu^{10}]-analog (XII), are very similar to that of the standard peptide (I). On the other hand, in the spectra of the less active peptides, such as [Lys^6, HyMeV^8]-analog (III) and [Lys^6, HyIv^8]-analog (IV), the positions of the troughs are shifted to longer wavelengths and the troughs are shallower. In the inactive compound, [Lys^6, MeIle^8]-analog (X), an anomalous spectrum is observed. However, [Lys^6, MeMet^{11}]-analog (XIV) and [Lys^6, HyMtb^{11}]-analog (VIII), which are devoid of biological activity, give spectra like that of I. These findings suggest that all the active peptides have very similar molecular conformations, and that the less active ones, such as III, IV, and X, are different from the active ones in backbone conformation. Furthermore, in the spectra of the less active compounds, such as [Lys^6, MePhe^7]-analog (IX) and [Lys^6, MePhe^7, MeLeu^{10}]-analog (XIII), the shapes and the positions of the troughs are almost identical with that of I, but the depths of the troughs are much enhanced ($[\theta]=-6500$ and -5900 respectively). Although the origin of the Cotton effect at about 233 nm is considered to be the n-π^* peptide transition, the contribution from the absorption of the aromatic group cannot be disregarded. From this point of view, the author assumes that these two peptides (IX and XIII) are different from I in the aromatic side chain conformation due to the steric effect of the *N*-methyl group in the *N*-methylphenylalanine residue.

Judging from these observations, the amide bond between the phenylalanine and the isoleucine residues probably restricts the favorable conformation of eledoisin. Such a conformation would facilitate an orientation of the side chains of the phenylalanine, the isoleucine, the leucine, and the methionine to a position in space in which a productive interaction with the biological receptor could occur. When *N*-methylisoleucine was introduced in place of the isoleucine, the conformation would be destroyed because of the lack of hydrogen bonding and also because of the steric effect of the *N*-methyl group. This is a factor which accounts for the much lower activity of the peptide, X, and for the anomalous spectrum. The exchange of the amide bond between the phenylalanine and the isoleucine residues by the ester bond appears to change the conformation to a considerable degree, but it does not completely destroy the molecular shape in spite of the lack of hydrogen bonding. In addition, the replacement of the amide bond between the lysine and the phenylalanine residues by the *N*-methylamide bond would cause a change in the orientation of the aromatic side chain and thereby affect the interaction with the receptor site.

From the fact that the peptides, VIII and XIV, were inactive even though they had favorable conformations, one can also guess that the amide bond between the leucine and the methionine residues plays an important role in exhibiting the biological activity. The possibility of binding *via* hydrogen bonding between the amide bond and the receptor site may be considered.

Experimental

The melting points are uncorrected. All the intermediates containing *N*-methylmethionine were purified by column chromatography on silica gel (Merck, 70-325 mesh). Each fraction was checked by thin-layer chromatography (tlc) on silica gel G(Merck); the products were determined by NMR in $CDCl_3$, which showed *N*-methyl protons (2.8—3.1 ppm) and *S*-methyl protons (2.0—2.1 ppm). The CD spectra were recorded on a JASCO Model ORD/UV-5 spectrophotometer. The amino acid analysis was performed as had been described previously.[1]

Pharmacological Assay. White male rabbits (2—3 kg) were anesthetized subcutaneously with 1.2 g/kg of urethane. Anesthesia was maintained with additional doses as needed. Arterial blood pressure was measured from a canulated carotid artery and recorded on a Kymograph by mercury manometer. All the peptides were dissolved in physiological saline and were injected into the femoral vein. Each dose was tested on five animals and was always checked against the reference standard material, I. The activity of the peptides was compared on a weight basis. The data were obtained with five animals per group.

H-MeMet-OEt·HCl (1). Thionyl chloride (22 g, 180 mmol) was added to absolute ethanol (200 ml) at 0—2 °C. To this solution, *N*-methylmethionine[7] (9.8 g, 60 mmol) was added, after which the solution was stirred at room temperature for 5 hr. After the removal of the solvent, this procedure was repeated two times. The oily residue thus obtained was dissolved in water, and the solution was filtered with activated charcoal and made alkaline by the addition of sodium bicarbonate. The oil thus separated was extracted repeatedly with ether, and the extracts were washed with saturated sodium chloride solution and dried over magnesium sulfate. To the filtered solution, dry hydrogen chloride was introduced, and the precipitated white crystals were collected

and recrystallized from ethanol–ether; yield, 6.7 g (29%); mp 95—97 °C; $[\alpha]_D^{25}$ +35.7° (*c* 1, EtOH). Found: C, 42.40; H, 7.78; N, 5.80; S, 13.98; Cl, 15.78%. Calcd for $C_8H_{18}NO_2SCl$: C, 42.19; H, 7.91; N, 6.15; S, 14.06; Cl, 15.60%.

Boc–Leu–MeMet–OEt (2). To a solution of Boc–Leu–OH·H_2O (8.3 g, 33 mmol) in chloroform (100 ml), DCC (7.2 g, 35 mmol) was added with stirring at −5—0 °C. After 1 hr, there was added a solution of **1** (6.7 g, 30 mmol) and triethylamine (4.2 ml, 30 mmol) in chloroform (50 ml). After the mixture had been stirred overnight at room temperature, the dicyclohexylurea was filtered off. The filtrate was washed successively with 4% sodium bicarbonate, 1 M hydrochloric acid, and water, and dried over magnesium sulfate. The filtrate was evaporated *in vacuo* to yield an oil (11 g), which was then chromatographed on silica gel, with elution by a mixture of benzene and ethyl acetate (9: 1). In this solvent system, the by-products (R_f 0.8 and 0.9) were eluted. The desired product (R_f 0.4) was then removed by a mixture of ethyl acetate and methanol (8: 2). The fractions containing the product, as detected by tlc, were combined and evaporated *in vacuo* to yield a colorless oil; yield, 6.5 g (51%); $[\alpha]_D^{25}$ −64.8° (*c* 2.6, MeOH). NMR δ ($CDCl_3$): 3.03 (s, 3H, $-NCH_3$), 2.08 (s, 3H, $-SCH_3$), 1.43 (s, 9H, $-C(CH_3)_3$), 4.16 (q, 2H, $-OCH_2-$), 0.95 (dd, 6H, $-CH(CH_3)_2$).

Boc–Leu–MeMet–NH_2 (3). A solution of compound **2** (6.5 g) in methanol (100 ml) was saturated with dry ammonia gas at 0 °C, and the solution was allowed to stand for 40 hr at room temperature. The reaction mixture was then concentrated to dryness under reduced pressure, and the residual oil (6 g) was chromatographed on silica gel, with elution by a mixture of benzene and ethyl acetate (6: 4). After removal of the unreacted ester **2** (R_f 0.9), the product was eluted by a mixture of benzene and ethyl acetate (4: 6). The fractions containing the product (R_f 0.7, benzene–AcOEt (3: 7)) were pooled and evaporated, yield of oil, 5.45 g (86%); $[\alpha]_D^{25}$ −26.4° (*c* 0.7, MeOH). NMR δ ($CDCl_3$): 3.08 (s, 3H, $-NCH_3$), 2.10 (s, 3H, $-SCH_3$), 1.43 (s, 9H, $-C(CH_3)_3$), 6.45 (s, 2H, $-NH_2$).

Boc–Gly–Leu–MeMet–NH_2 (4). Compound **3** (5.6 g, 15 mmol) was dissolved in 3M hydrogen chloride in dioxane (450 ml), and the solution was allowed to stand at room temperature for 30 min. The solvent was distilled off *in vacuo*, and the residue was triturated with ether. The H–Leu–MeMet–NH_2·HCl thus obtained was dissolved in chloroform (30 ml), neutralized with triethylamine (2.1 ml), and then subjected to a reaction with Boc–Gly–ONp[11] (6 g, 20 mmol). After standing overnight at room temperature, the solution was diluted with ethyl acetate (350 ml), washed successively with 1 M hydrochloric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The solvent was distilled off *in vacuo*, and the remaining oil was chromatographed on silica gel, with elution by a mixture of benzene and ethyl acetate (9: 1). In this solvent system, the unreacted Boc–Gly–ONp (R_f 0.8) was eluted, while the product was not eluted ($R_f < 0.1$). The product was removed from the column by a mixture of ethyl acetate and benzene (9: 1). The fractions containing the product, as determined by tlc (R_f 0.35, $CHCl_3$–MeOH–AcOH (95: 5: 3)) was pooled and evaporated *in vacuo*; yield of oil, 4.3 g (66%); $[\alpha]_D^{25}$ −25.0° (*c* 1, MeOH). Found: C, 52.41; H, 8.27; N, 12.00; S, 7.01%. Calcd for $C_{19}H_{36}N_4O_5S$: C, 52.77; H, 8.33; N, 12.96; S, 7.40%.

Aoc–Phe–Ile–Gly–Leu–MeMet–NH_2 (5). Compound **4** (2.2 g, 5 mmol) was treated with 2M hydrogen chloride in dioxane (30 ml) for 30 min at room temperature. After evaporation, the residue was triturated with ether; the remaining oil, corresponding to H–Gly–Leu–MeMet–NH_2·HCl, was used without further purification. To a solution of Aoc–Phe–Ile–$NHNH_2$[6] (2 g, 5 mmol) in a mixture of 2 M hydrochloric acid (10 ml) and dimethylformamide (100 ml), was added with stirring a chilled solution of sodium nitrite (350 mg, 5 mmol) in water (1 ml) over a period of 15 min at −15—−13 °C. After 20 min, a solution of previously prepared tripeptide amide hydrochloride, dissolved in dimethylformamide (20 ml), was added to the reaction mixture, and then the pH was adjusted to 7 with triethylamine. Stirring was continued for 3 hr at 0 °C and the mixture was then poured into cold water (500 ml). The oil thus separated was extracted with ethyl acetate, and the extract was washed successively with 0.5M sulfuric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The dried solution was concentrated to an oil, which was subsequently chromatographed with elution by a mixture of ethyl acetate and methanol (95: 5). After the undesired products had been eluted (R_f 0.9, 0.8, and 0.6, AcOEt), the desired product (R_f 0.1, AcOEt; 0.35, $CHCl_3$–MeOH–AcOH (95: 5: 3)) was eluted with methanol; yield of oil, 700 mg (20%); $[\alpha]_D^{25}$ −24.8° (*c* 1, MeOH). Found: C, 58.34; H, 8.41; N, 11.29; S, 4.28%. Calcd for $C_{35}H_{58}N_6O_7S \cdot H_2O$: C, 58.01; H, 8.28; N, 11.60; S, 4.42%.

Di-Boc–Lys–Phe–Ile–Gly–Leu–MeMet–NH_2 (6). Compound **5** (700 mg, 1 mmol) was treated with 3M hydrogen chloride in dioxane (7 ml) for 40 min at room temperature. After evaporation, the residue was dissolved in dimethylformamide (5 ml), neutralized with triethylamine (0.13 ml), and subjected to a reaction with di-Boc–Lys–ONp[12] (700 mg) for 24 hr at room temperature. Ethyl acetate (100 ml) was then added to the reaction mixture, and the solution was washed with 1% hydrochloric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The solution was concentrated to dryness, and remaining oil was purified by silica gel column chromatography, by elution with a mixture of ethyl acetate and methanol (9: 1). After the unreacted di-Boc–Lys–ONp ($R_f \fallingdotseq 1.0$, AcOEt–MeOH (9: 1)) had been eluted, the product ($R_f < 0.1$, AcOEt–MeOH (9: 1); 0.3, $CHCl_3$–MeOH–AcOH (95: 5: 3)) was eluted with methanol; yield of oil, 660 mg (70%); $[\alpha]_D^{25}$ −34.0° (*c* 1, MeOH). Found: C, 57.39; H, 8.28; N, 11.20; S, 3.14%. Calcd for $C_{45}H_{76}N_8O_{10}S \cdot H_2O$: C, 57.50; H, 8.30; N, 11.92; S, 3.40%.

H–Lys–Phe–Ile–Gly–Leu–MeMet–NH_2·2HCl (XIV). Compound **6** (200 mg) was dissolved in 2M hydrogen chloride in acetic acid (5 ml), and the solution was allowed to react at room temperature for 20 min. The product was precipitated by adding ice-cold dry ether (20 ml), and the precipitate was collected by filtration, washed well with ether, and dried over sodium hydroxide *in vacuo*. The product was dissolved in 60% methanol (4 ml), and an insoluble material was filtered off. The filtrate was concentrated to dryness over phosphorus pentoxide *in vacuo* to afford the final product; yield, 170 mg; mp 80—120 °C; $[\alpha]_D^{25}$ −34.0° (*c* 0.5, H_2O); R_f, 0.74;[13] amino acid ratios in the acid hydrolysate: Lys, 1.14; Phe, 1.03; Ile, 1.02; Gly, 0.95; Leu, 1.00; MeMet, 1.09. Found: C, 51.26; H, 7.88; N, 12.92; S, 3.68%. Calcd for $C_{35}H_{60}N_8O_6S \cdot 2HCl \cdot 2H_2O$: C, 50.66; H, 7.96; N, 13.51; S, 3.86%.

H–HyMtb–OH (7). This was prepared by the nitrous acid deamination of L-methionine (150 g) by the procedure reported by Winitz *et al.* for L-α-hydroxy-β-methylvaleric acid;[8] yield of oil, 27 g (16.7%). A sample for analysis was dissolved in ether; the subsequent addition of dicyclohexylamine to the solution gave crystalline dicyclohexylammonium salt, which was then recrystallized from ethyl acetate–petroleum ether; mp 130—131 °C; $[\alpha]_D^{25}$ −20.3° (*c* 1, EtOH). Found: C, 61.49; H, 10.15; N, 4.28; S, 9.92%. Calcd for $C_5H_{10}O_3S \cdot C_{12}H_{23}N$: C, 61.63; H, 9.96; N, 4.22; S, 9.66%.

H–HyMtb–OMe (8). Thionyl chloride (28 g, 230 mmol) was added with stirring to methanol (150 ml) at −2—2 °C. To the solution, compound **7** (33 g, 220 mmol) was added and the mixture was stirred for 1 hr at 0 °C and 3 hr at room temperature. After the solution had then been concentrated *in vacuo*, the remaining oil was distilled to give the ester (**8**); yield, 22 g (62%); bp 91—93 °C/3 mmHg; $[\alpha]_D^{25}$ −16.4° (*c* 1, MeOH). IR cm^{-1} (liq. film): 3450 (OH), 1740 (C=O). NMR δ ($CDCl_3$): 4.30—4.50 (dd, 1H, –CH–), 3.82 (s, 3H, $-OCH_3$), 3.15 (s, 1H, –OH), 2.54—2.82 (m, 2H, $-CH_2S$–), 2.15 (s, 3H, $-SCH_3$), 1.82—2.20 (m, 2H, $-CH_2$–).

H–HyMtb–NH₂ (9). A solution of compound **8** (18 g, 110 mmol) in methanol (300 ml) was saturated with dry ammonia gas at 0 °C. After standing for 48 hr at room temperature, the solution was concentrated to dryness; yield of oil, 16 g (100%); $[\alpha]_D^{25}$ −55.0° (*c* 0.65, H_2O). NMR δ ($CDCl_3$): 6.88 (d, 2H, $-NH_2$), 5.34 (s, 1H, –OH), 4.13—4.34 (dd, 1H, –CH–), 2.45—2.75 (m, 2H, $-CH_2S$–), 2.10 (s, 3H, $-SCH_3$), 1.60—2.18 (m, 2H, $-CH_2$–).

Boc–Leu–HyMtb–NH₂ (10). To a solution of carbonyldiimidazole[9] (13 g, 80 mmol) in tetrahydrofuran (80 ml) was added a solution of Boc–Leu–OH·H_2O (20 g, 80 mmol) in tetrahydrofuran (50 ml) at 0 °C over a period of 30 min. Then there was added a solution of compound **9** (11.5 g, 80 mmol) in tetrahydrofuran (20 ml); the reaction mixture was stirred at 0 °C for 1 hr and then at room temperature for 2 days. Water (20 ml) was added to the solution, and the solvent was removed under reduced pressure. The residue was dissolved in ethyl acetate, and the ethyl acetate solution was washed with 1% hydrochloric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The evaporation of the solvent gave white crystals, which were then recrystallized from ethyl acetate–petroleum ether; yield, 20 g (69%); mp 97—99 °C; $[\alpha]_D^{25}$ −56.5° (*c* 1, EtOH). Found: C, 52.98; H, 8.32; N, 7.61; S, 8.77%. Calcd for $C_{16}H_{30}N_2O_5S$: C, 53.02; H, 8.34; N, 7.73; S, 8.82%.

Boc–Ile–Gly–Leu–HyMtb–NH₂ (11). Compound **10** (4 g, 11 mmol) was treated with 3M hydrogen chloride in dioxane for 30 min. After evaporation, the residue, corresponding to didepsipeptide amide hydrochloride, was dissolved in dimethylformamide (50 ml), neutralized with triethylamine (1.5 ml), and subjected to a reaction with Boc–Ile–Gly–ONp[14] (3.6 g, 9 mmol) for 24 hr at room temperature. Ethyl acetate (500 ml) was then added to the reaction mixture, and the solution was washed thoroughly with 1M ammonia, 1% hydrochloric acid, and water, and dried over magnesium sulfate. On removal of the solvent a crystalline residue was obtained; this was recrystallized from ethyl acetate–petroleum ether; yield, 2.8 g (60%); mp 114—115 °C; $[\alpha]_D^{25}$ −39.1° (*c* 1, MeOH). Found: C, 54.47; H, 8.41; N, 10.43; S, 5.88%. Calcd for $C_{24}H_{44}N_4O_2S$: C, 54.12; H, 8.33; N, 10.52; S, 6.00%.

Boc–Phe–Ile–Gly–Leu–HyMtb–NH₂ (12). Compound **11** (2.7 g, 5 mmol) was treated with 3M hydrogen chloride in dioxane for 40 min. The solvent was evaporated under reduced pressure, and the residue was dissolved in dimethylformamide (25 ml), neutralized with triethylamine, and subjected to a reaction with Boc–Phe–ONp[11] (2 g, 5 mmol) for 24 hr at room temperature. Ethyl acetate (200 ml) was then added to the reaction mixture, and the solution was treated as described for the preparation of **11**. The crude product was recrystallized from ethyl acetate–methanol–petroleum ether; yield, 3.1 g (92%); mp 179—183 °C; $[\alpha]_D^{25}$ −35.5° (*c* 1, MeOH). Found: C, 58.81; H, 7.84; N, 10.13; S, 4.50%. Calcd for $C_{33}H_{53}N_5O_8S$: C, 58.32; H, 7.80; N, 10.30; S, 4.71%.

Di-Boc–Lys–Phe–Ile–Gly–Leu–HyMtb–NH₂ (13). Compound **12** (700 mg, 1 mmol) was treated with 3M hydrogen chloride in dioxane for 30 min. After evaporation, the residue was dissolved in dimethylformamide (5 ml), neutralized with triethylamine, and subjected to a reaction with di-Boc–Lys–ONp (450 mg, 0.97 mmol) for 48 hr. Ethyl acetate (100 ml) was then added to the reaction mixture, and the solution was treated as described for the preparation of **11**. The crude product was recrystallized from ethyl acetate–methanol–petroleum ether; yield, 700 mg (75%); mp 172—175 °C; $[\alpha]_D^{25}$ −47.4° (*c* 1, MeOH). Found: C, 58.30; H, 8.21; N, 10.69; S, 3.23%. Calcd for $C_{44}H_{93}N_7O_{11}S$: C, 58.19; H, 8.10; N, 10.79; S, 3.53%.

H–Lys–Phe–Ile–Gly–Leu–HyMtb–NH₂·2HCl (VIII). This was obtained from compound **13** (200 mg) as described for the preparation of XIV; yield, 165 mg; mp 225—227 °C; $[\alpha]_D^{25}$ −36.6° (*c* 0.21, H_2O); R_f, 0.76;[13] amino acid ratios in the acid hydrolysate: Lys, 1.01; Phe, 0.98; Ile, 1.10; Gly, 0.95; Leu, 1.00. Found: C, 50.81; H, 7.48; N, 12.08; S, 3.80%. Calcd for $C_{34}H_{57}N_7O_7S \cdot 2HCl \cdot 2H_2O$: C, 51.12; H, 7.64; N, 12.28; S, 4.01%.

Boc–Phe–HyIv–OH (14). To a solution of Boc–Phe–OH (15 g, 57 mmol) in a mixture of pyridine (100 ml) and tetrahydrofuran (100 ml), was added with stirring benzenesulfonyl chloride (8.8 g, 50 mmol) at −10 °C over a period of 10 min. After 10 min, a solution of benzyl L-α-hydroxyisovalerate[15] (10 g, 48 mmol) in pyridine (30 ml) was added to the solution. The mixture was then allowed to stand at 0 °C for 1 hr and at room temperature for 8 hr, and subsequently poured into water (1000 ml). The oil thus separated was extracted with ether. The extract was washed repeatedly with 2% hydrochloric acid, 4% sodium bicarbonate, and water, and dried over magnesium sulfate. The solvent was distilled off *in vacuo* to leave an oil (19.6 g); this oil was then dissolved in methanol (100 ml) and hydrogenated in the presence of 10% palladium on charcoal. The filtrate from the catalyst was evaporated to dryness, and the crude acid was dissolved in 4% sodium bicarbonate, washed with ether, and acidified with 1% hydrochloric acid. The oil thus separated was extracted with ether. The ethereal solution was washed with water and dried over magnesium sulfate. The ether was removed under reduced pressure; yield of oil, 15 g (88%). IR cm^{-1} (liq. film): 1740, 1720, 1705 (C=O).

Boc–Phe–HyIv–Gly–Leu–Met–NH₂ (15). To a solution of **14** (7.3 g, 20 mmol) and triethylamine (2.8 ml) in chloroform (200 ml), was added ethyl chloroformate (2.2 g, 20 mmol) at −15—−10 °C. After 15 min, there was added a solution of H–Gly–Leu–Met–NH_2·HCl[16] (7.3 g, 20 mmol)

and triethylamine (2.8 ml) in dimethylformamide (50 ml) at −15—−10 °C, and this mixture was allowed to stand at room temperature overnight. The mixture was poured into cold water (1000 ml), and the resulting solid material was extracted with chloroform. The extract was washed successively with 2% hydrochloric acid, 4% sodium bicarbonate, and water. The solvent was then evaporated *in vacuo*, and the crude product thus obtained was recrystallized from ethyl acetate–methanol–petroleum ether; yield, 9.4 g (71%); mp 160—164 °C; $[\alpha]_D^{25}$ −43.3° (*c* 1, MeOH). Found: C, 57.32; H, 7.80; N, 10.26; S, 4.75%. Calcd for $C_{32}H_{51}N_5O_8S$: C, 57.73; H, 7.72; N, 10.52; S, 4.80%.

*Di-Boc–Lys–Phe–HyIv–Gly–Leu–Met–NH$_2$ (**16**).* Compound **15** (5.32 g, 8 mmol) was dissolved in 3M hydrogen chloride in dioxane (70 ml) at room temperature. After 20 min, the solution was evaporated to dryness *in vacuo*. The pentadepsipeptide amide hydrochloride thus obtained was dissolved in dimethylformamide (40 ml) and then neutralized with triethylamine (1.2 ml). Di-Boc–Lys–ONp (4.2 g, 9 mmol) was added to the solution, and the mixture was allowed to stand at room temperature for 20 hr. Water was added to the reaction mixture to precipitate the product, which was then collected by filtration, washed well with 2% hydrochloric acid, 1M ammonia, and water, and dried. Recrystallization from ethyl acetate–petroleum ether gave 4.2 g (58%) of a product; mp 198—201 °C; $[\alpha]_D^{25}$ −40.2° (*c* 1, MeOH). Found: C, 57.53; H, 8.08; N, 11.05; S, 3.85%. Calcd for $C_{43}H_{71}N_7O_{11}S$: C, 57.76; H, 8.00; N, 10.96; S, 3.58%.

H–Lys–Phe–HyIv–Gly–Leu–Met–NH$_2$·2HCl (IV). The Synthesis of γ-3,4,5,6-Tetrachlorocyclohexene (γ-BTC) by Means of a Diels-Alder Reaction

Kiichi SHINODA

Nishiki Research Laboratory of Kureha Chemical Industry Co., Ltd., Nishiki-machi, Iwaki-shi, Fukushima 974

(Received October 2, 1972)

γ-3,4,5,6-Tetrachlorocyclohexene (γ-BTC) was synthesized in a yield of 14—30% by a Diels-Alder reaction between *trans,trans*-1,4-dichloro-1,3-butadiene and *trans*-dichloroethylene. The *s-cis* requirement and stereochemical relationships consistent with Alder's rule are shown. Antioxidants are effective in this reaction.

Orloff *et al.*[1,2] isolated 3,4,5,6-tetrachlorocyclohexene (benzene tetrachloride, BTC) isomers and clarified their conformations and their relationships with 1,2,3,4,5,6-hexachlorocyclohexane (BHC) isomers. By Orloff's method, however, the yield of γ-BTC is very low and the isolation procedure is very laborious. Kurihara *et al.*[3] obtained γ-BTC from α-BTC, which is the main product in Orloff's method, through several routes.

In this report, the synthesis of γ-BTC by a Diels-Alder reaction between 1,4-dichloro-1,3-butadiene (I) and 1,2-dichloroethylene (II) will be described.

Results and Discussion

Each isomer of 1,4-dichloro-1,3-butadiene, which had been prepared[4-6] by the dechlorination of 1,3,4,4-tetrachlorobutene, was reacted in a small bomb with *trans*-dichloroethylene (IIa), under the conditions below: temperature, 150 °C; time, 30 hr; molar ratio, I/IIa= 1/20.

The results are shown in Table 1. γ-BTC was obtained in the reactions of *trans,trans*-I (Ia), *trans,cis*-I (Ib) and an isomer mixture of I with IIa. None of the BTC could be obtained by the reaction of *cis,cis*-I (Ic) with IIa. γ-BTC was identified by IR, its mp (87—88 °C, Orloff *et al.*,[2] mp 88.2—88.8 °C), and by photochlorination to BHC. As has already been clarified by Orloff *et al.*,[2] γ-BTC formed α, γ, and δ-BHC upon photochlorination.

Stereochemical Relationships. It has been illustrated in many cases that, in Diels-Alder reactions, dienes

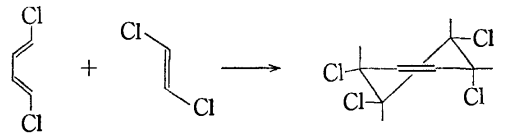
must take the cisoid conformation.[7] It is probable that, in our case, only Ia can exist in the *s-cis* conformation and react with IIa. In the case of Ib, it is clear that Ib is isomerized to Ia, and then enters into the reaction, because the recovered I was a mixture of I isomers.



Ia IIa γ-BTC

According to Alder's rule,[7,8] the chlorine atoms at the 4,5-position of BTC produced from Ia and IIa must be *trans* (aa or ee) to each other, while those of 3,6 must be *cis* (ae). Therefore, the BTC have to be γ ($\overline{\text{HH}}$ aeee⇄$\overline{\text{HH}}$ eaaa). Our results shown in Table 1 are consistent with Alder's rule.

Table 1. Diels-Alder reaction of 1,4-dichloro-1,3-butadiene isomers (I) with *trans*-dichloroethylene (IIa)
Temp. 150 °C, 30 hr, Molar ratio I/IIa=1/20

I isomer	Product	Yield %	Recovered I %	Ia	Ib	Ic
trans, trans(Ia)[a]	γ-BTC	14.3	36.3	24.9	48.8	26.3
trans,cis (Ib)[a]	γ-BTC	0.03	41.6	4.9	90.0	5.1
cis,cis (Ic)[a]	no BTC	0			4.2	95.8
Isomer mixture[b] Ia:Ib:Ic= 18.1:46.4:25.5	γ-BTC	16.8[c]	58.5	13.3	48.2	38.3

a) The amounts used were Ia 1.12 g, Ib 1.23 g, and Ic 1.23 g, respectively.
b) The amount used was 4.1 g. Molar ratio I/IIa was 1/5.
c) The yield is based on Ia charged initially.

Effects of Antioxidants and Temperature. The reaction mixture, after the excess II and the unreacted I had been removed, was generally reddish-brown in color. This colored material seemed to be the decomposition product of I. In order to suppress the decomposition of I, the effect of the antioxidants was examined. The results are shown in Table 2. The effect of the antioxidants was obvious; the effective ones were *p*-phenylenediamine and *p*-aminophenol.

Table 2. Diels-Alder reaction of *trans,trans*-1,4-dichloro-1,3-butadiene (Ia) with *trans*-dichloroethylene (IIa). Effect of antioxidants and temperature

a) The amounts used were 1.0 mol % *vs.* Ia.

Effect of Friedel-Crafts Catalysts. There have been reports[9,10] that, in some cases, Friedel-Crafts-type metal halides function as catalysts in Diels-Alder reactions. We tried several metal halides—anhydrous $AlCl_3$, $FeCl_3$, $TiCl_4$, and $SnCl_4$, but no BTC was obtained because of the decomposition-promoting property of metal halides.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Nihonbunko DS-301 or a Shimadzu IR-27 spectrophotometer.

1,3,4,4-Tetrachlorobutene (IV).[11,12] *cis*-Dichloroethylene (IIb) (700 g) was refluxed for 80 hr, with 1.0 g of benzoyl peroxide being added every 5 hr. The reaction mixture was then subjected to distillation at reduced pressure, and a fraction boiling at 79—85 °C/15 mmHg was collected. The yield was 28.9%, based on the IIb used.

Similarly, IV was prepared from IIa. The yield was 5.3%. The IV obtained consisted of 39% *trans*- and 61% *cis*-isomer.

Dechlorination of IV. Criegee's procedure[4] was followed, and a fraction boiling at 50—55 °C/50 mmHg was collected. The yield was 60—80%. The isomer ratio (Ia: Ib: Ic) was measured by glc (Shimadzu polyethylene glycol 6000). In general, the Ia: Ib: Ic ratio was 15: 50: 35.

Separation of 1,4-Dichloro-1,3-butadiene Isomers (Ia, Ib, and Ic). The separation of isomers was carried out by preparative glc; apparatus, Shimadzu GC-10A, using polyethylene glycol.

Ia, purified by sublimation at reduced pressure, has a mp of 36—37 °C (37—38 °C,[4] 38—39.6 °C[6]). Ib is a liquid (bp 53.0—55.0 °C/50 mmHg). Ic is also a liquid (bp 48.0—48.5 °C/50 mmHg). From 54.9 g of a mixture of I, pure Ia (1.5 g (after sublimation)), Ib (10.9 g), and Ic (8.4 g (after distillation)) were obtained.

In order to obtain only pure Ia from the isomer mixture, the mixture was cooled with dry ice–methanol, partially frozen, and then filtered under cooling with dry ice. The solid collected was purified by sublimation under reduced pressure. This Ia was pure enough for the reaction.

Diels-Alder Reaction between I and IIa. Usually IIa (19.4 g, 0.20 mol) was weighed in a 50 ml autoclave, and then the I isomer (1.23 g, 0.01 mol) was added, the solution was mixed well, and the autoclave was sealed. Then, the autoclave was placed in an oil bath kept at 150 or 200 °C. After the reaction, the excess IIa and unreacted I were removed by distillation under reduced pressure, first at about 100 mmHg and then 15 mmHg. The residue, usually a reddish brown solid with a little oily matter, was subjected to column chromatography. The column chromatography was carried out as follows: absorbent, activated alumina (Kanto Chemical, for chromatography); solvent, methanol or *n*-hexane; column dia., 15 mm; height of alumina layer, 50 mm. About 100 ml of the elute had been taken up, the solvent was removed under reduced pressure. The white solid thus obtained, a little yellowish in color, was found by

IR to be almost pure γ-BTC. The yields were calculated on the basis of the weights at this stage. After recrystallization from ethanol, mp was 87—88 °C.

Photochlorination of γ-BTC to BHC. Pure γ-BTC (0.44 g, 0.002 mol), chlorine (0.17 g, 0.0024 mol), and 10 ml of dry distilled carbon tetrachloride were charged in an ampoule (1.2×15 cm). The air in the ampoule and the carbon tetrachloride were then replaced by dry nitrogen. The ampoule was immersed in a methanol–dry ice bath kept at -10 ± 2 °C, and a 10 W blue fluorescent lamp (Mazda) was placed at a distance of 14 cm as the light source. The photochlorination was over within one hour.

After the reaction, the reaction mixture was subjected to steam distillation and a white solid (0.515 g, 88.9% as BHC) was obtained.

By IR the reaction product was found to consist of γ, α, and δ-BHC. The amount of each BHC isomer was determined by IR according to Milone.[13] The key bands for the isomers were α, 15.93; γ, 20.70; and δ, 17.65 μ. By our experiment, at -10 °C in carbon tetrachloride the produced BHC contained α, 37.6; γ, 56.0; and δ, 6.4%.

The author wishes to thank Mr. Shigeto Ohtsuka and Dr. Hiromichi Watanabe for their encouragement, and Mr. Tadashi Uzuki and Mr. Eiji Yokoyama for their experimental help.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2176—2180 (1973)

The Formation of Tin-Nitrogen Bonds. V. The Selective 1-Substitution Reaction of Tetrazoles by the Reaction of 5-Substituted 2-(Tri-*n*-butylstannyl)tetrazoles with Methyl Iodide, Methyl *p*-Toluenesulfonate, Dimethyl Sulfate, and Ethyl Bromoacetate

**Department of Chemistry, College of Liberal Arts and Sciences, Kyôto University, Sakyô-ku, Kyôto 606*

(Received October 11, 1972)

The selective 1-substitution reaction of tetrazole was developed by the treatment of 5-substituted 2-(tri-*n*-butylstannyl)tetrazoles with methyl iodide, methyl *p*-toluenesulfonate, dimethyl sulfate, or ethyl bromoacetate at room temperature. This selectivity was introduced by blocking the 2-nitrogen with the tri-*n*-butyltin group against the 2-substitution. In the case of 5-substituted 2-(trimethylstannyl)tetrazoles, a low selectivity was observed. The possible reaction pathways have been discussed.

In continuation of our research into the preparation and reaction of tetrazoles and their derivatives,[1] this paper will describe a highly selective 1-methylation method of tetrazoles.

The *N*-alkylation of 5-substituted tetrazoles has, until now, always been carried out by the reaction of tetrazole with either alkyl halide[2-10] or dialkyl sulfate[4,7,11,12] in the presence of a base, and also with diazomethane.[12-14] These reactions, in general, have provided the 2-alkyl isomers in a greater proportion than the 1-alkyl isomers.

It has now been found that the treatment of 5-substituted 2-(tri-*n*-butylstannyl)tetrazoles (I) with methyl iodide at room temperature for several hours afforded the 1-methyl isomer with a high selectivity (1-methyl-: 2-methyl isomer=90: 10). For the preparation of 5-substituted 1-methyltetrazole (III), this method is facile and comparable to the steady route of Harville, Herbst, Schreiner, and Roberts,[15] who prepared 1,5-disubstituted tetrazole from *N*-monosubstituted amide. Since the 2-(tri-*n*-butylstannyl)tetrazoles (I) can be prepared very easily by mixing free tetrazoles with bis(tri-*n*-butyltin) oxide,[1a] the 1-methylation can be carried out

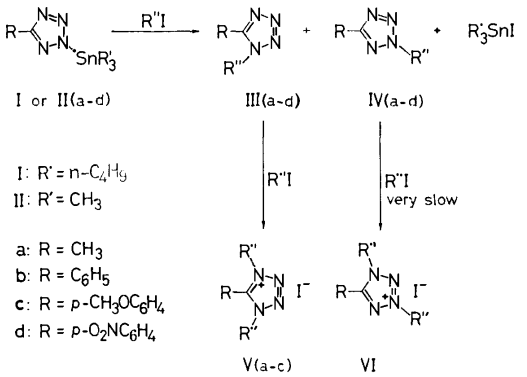
by the simple procedure of dissolving a mixture of tetrazole and bis(tri-*n*-butyltin) oxide in methyl iodide. Additionally, the tri-*n*-butyltin iodide formed by the methylation process can be easily removed from the reaction mixture by extraction with light petroleum ether.



When 2-(tri-*n*-butylstannyl)-5-methyltetrazole (Ia) was dissolved in excess methyl iodide at room temperature and the solution was kept standing overnight, the *N*-methylation was completed. The ratio of 1,5-dimethyltetrazole (IIIa) and 2,5-dimethyltetrazole (IVa) was found to be 92: 8 by NMR analysis. Since 2,5-dimethyltetrazole (IVa) is much more volatile[1a,14] and far less reactive toward methyl iodide[1a] than IIIa, the evaporation of IVa and the surplus methyl iodide from the reaction products gave a mixture of IIIa and tri-*n*-butyltin iodide. Tri-*n*-butyltin iodide was also removed by simple extraction with light petroleum ether. Analytically pure 1,5-dimethyltetrazole (IIIa) was isolated in a good yield. 1,5-Dimethyltetrazole (IIIa) reacted gradually with excess methyl iodide at room temperature to give crystalline 1,4,5-trimethyltetrazolium iodide (Va), which began to precipitate after about 30 hr. When the reaction of Ia with excess methyl iodide was carried out at a higher temperature, a greater part of the IIIa was converted into the thermally stable tetrazolium iodide (Va).[1d]

A similar selective 1-methylation was also observed in the reactions of 5-phenyl and 5-(*p*-methoxyphenyl) analogues (Ib and Ic) with methyl iodide (Table 1). In the reaction of Ib with methyl iodide, the reaction temperature should be maintained at room temperature for the preparation of the 1-methyl isomer (IIIb), because on heating IIIb is easily converted into the 2-methyl isomer (IVb) in the presence of methyl iodide.[1b]

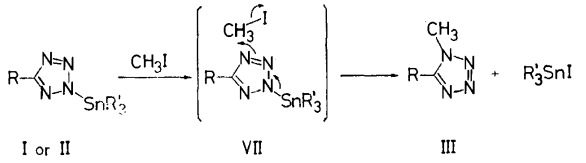
A less selective and much slower *N*-methylation was found in the reaction of 2-(tri-*n*-butylstannyl)-5-(*p*-nitrophenyl)tetrazole (Id) (Table 1). There occurred no further methylation of IIId to form the 1,4-dimethyltetrazolium salt (Vd). These results can be interpreted in terms of the electron-withdrawing character of the *p*-nitrophenyl group, which preferentially decreased the electron density of the 1- and 4-nitrogen atoms of the tetrazole ring, analogously to the reaction of potassium or sodium 5-substituted tetrazolate with methyl iodide.[4,6-8]

When the reaction of Ia—d with methyl iodide was carried out in the presence of methanol,[16] little change was found either in the isomer ratios of the products or in the reaction rate in comparison with the case of a reaction without methanol. This shows that the associative polymeric structure[1b] can not be involved in the selective 1-substitution reaction pathway.

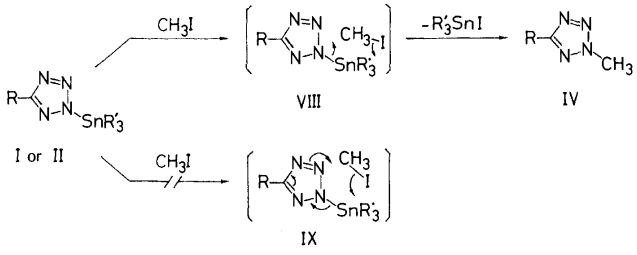
Table 1. Distribution of III and IV formed by the reaction of I with methyl iodide

Compound	5-Substituent	Distribution (%) III	IV
Ia	CH_3	92	8
Ib	C_6H_5	90	10
Ic	p-$CH_3OC_6H_4$	91	9
Id	p-$O_2NC_6H_4$	68	32

It might be reasonable to consider that both the electron densities and steric requirements of the nitrogen atoms of tetrazole ring govern the site of the *N*-substitution. Since 2-substituted (or 2,5-disubstituted) tetrazoles react with methyl iodide[1b] or methyl *p*-toluenesulfonate[19] to yield exclusively 1,3-disubstituted (or 1,3,5-trisubstituted) tetrazolium salts, the 4-nitrogen of the 2-substituted tetrazole must be the most favorable site among the nitrogens to be attacked.[20] Analogously, it is probable that the *N*-methylation of 2-(trialkylstannyl)-5-substituted tetrazole (I or II) occurs preferentially on the 4-nitrogen.



The minor product, the 2-methyl isomer (IV), could be formed by the methylation of the 2- or 3-nitrogen of I (or II). Since the formation of 2,3,5-trisubstituted tetrazolium salt from 2,5-disubstituted tetrazole has never been observed by spectroscopic investigations,[1d] the *N*-methylation of the 3-nitrogen of I (or II) might



16) Addition of ligands such as alcohol to the toluene solution of tri-*n*-butylstannylimidazole has been reported to lower the viscosity, and hence the associative polymeric structure was fractured by the ligand to be the monomeric one.[17] Analogous fact has also been observed in the case of Ia—d.[18]

17) M. J. Janssen, J. G. A. Luijten, and G. J. M. van der Kerk, *J. Organometal. Chem.*, **1**, 286 (1963).

18) T. Isida, S. Kozima, and K. Sisido, unpublished results.

19) W. P. Norris and R. A. Henry, *Tetrahedron Lett.*, **1965**, 1213.

20) Formation of the 1,2,5-trisubstituted tetrazolium salts has never been reported and hence the 1-substitution of 2-substituted tetrazole can be excluded since the 1-nitrogen is sterically much more hindered than the 4-nitrogen.

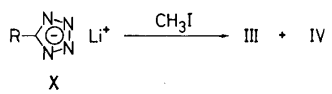
be much less probable; a possible process can be the direct methylation of the 2-nitrogen bonded to the tin atom *via* VIII.

In this selective methylation, consequently, the tri-*n*-butyltin group blocked the 2-nitrogen against the 2-methylation and led the methyl group into the 4-nitrogen. A comparable protection of the 1-nitrogen of 4-substituted imidazole by the benzoyl group has been reported for the specific preparation of 5-substituted 1-methylimidazole.[21,22]

Table 2. Distribution of III and IV formed by the reaction of II with methyl iodide

Compound	5-Substituent	Distribution (%)	
		III	IV
IIa	CH_3	40	60
IIb	C_6H_5	38	62
IIc	p-$CH_3OC_6H_4$	49	51
IId	p-$O_2NC_6H_4$	21	79

In the reaction of 5-substituted 2-(trimethylstannyl)-tetrazoles (II) with methyl iodide in methanol, the 2-methyl isomers (IV) have been produced in greater yields than the 1-methyl isomers (III) (Table 2). In the case of 2-(trimethylstannyl)-5-(*p*-nitrophenyl)tetrazole (IId), the distribution ratio of the 1-methyl *vs.* 2-methyl isomer was smaller than those in the case of the other homologs (IIa, IIb, and IIc). The electron-withdrawing *p*-nitrophenyl group apparently decreased the ratio of the 1-methylation, much as in the case of 2-(tri-*n*-butylstannyl) derivatives of tetrazoles with methyl iodide. In the presence of the electron-donating *p*-methoxyphenyl group in the 5-position, the 1-methyl isomer was obtained in a greater proportion than the cases of the phenyl and *p*-nitrophenyl groups. This is an additional case of how the electronic effect of the 5-substituent greatly influences the ratio of the 1-methylation *vs.* 2-methylation. The low selectivity in the *N*-methylation of 5-substituted 2-(trimethylstannyl)-tetrazoles (II) (Table 2), compared with the case of the 2-(tri-*n*-butylstannyl) analogues (I) (Table 1), is apparently correlated to the higher polarity of the tin-nitrogen bond in II. Because IIa is insoluble in non-polar solvents and is undistillable, while Ia is soluble and distillable,[1a] the trimethyltin-nitrogen bond in II is considered to be more polar than the tri-*n*-butyltin-nitrogen bond in I. As the polarity of the tin-nitrogen bond in II increases, the direct methylation of the 2-nitrogen atom *via* VIII could possibly increase. This trend has been supported by the predominant 2-methylation in the case of lithium salt of tetrazole (X), in which the lithium-nitrogen bond has a strongly ionic character (Table 3).



X

Table 3. Distribution of III and IV formed by the reaction of X with methyl iodide

Compound	5-Substituent	Distribution (%)	
		III	IV
Xb	C_6H_5	21	79
Xc	p-$CH_3OC_6H_4$	29	71
Xd	p-$O_2NC_6H_4$	19	81

Highly selective 1-methylation was also found in the reaction of 5-substituted 2-(tri-*n*-butylstannyl)tetrazole (I) with methyl *p*-toluenesulfonate or dimethyl sulfate (Table 4). In contrast to the easy removal of surplus methyl iodide from the products by evaporation, the use of these methyl esters as a methylating reagent is not preferred for the synthesis of III, since it is troublesome to remove the residual reagents and tri-*n*-butyltin salts from the product (III) by simple evaporation or extraction.

a) Methyl *p*-toluenesulfonate.

A similar specific 1-substitution of tetrazole has also been achieved in the reaction of I with ethyl bromoacetate (Table 4). The synthesis of 5-substituted tetrazolylacetic acids and esters has been investigated for pharmaceutical purposes.[8,9,23,24] This method will provide a convenient route for the preparation of 5-substituted 1-tetrazolylacetic or -propionic acids and their esters.

Experimental

5-Substituted 2-(tri-*n*-butylstannyl)- and 2-(trimethylstannyl)tetrazoles (Ia—e and IIa—d) were prepared as has previously been described.[1a] The distribution of the 1-methyl and 2-methyl isomers was determined by studying the NMR spectrum, which was taken on a JEOL C-60HL spectrometer. All the melting points are uncorrected.

*Reaction of 2-(Tri-*n*-butylstannyl)-5-methyltetrazole (Ia) with Methyl Iodide.* A solution of 0.200 g of Ia in 0.25 ml of methyl iodide and 0.25 ml of $CDCl_3$ was kept in an NMR tube at room temperature for one day. The NMR spectrum of the reaction mixture was then measured. The distribution of the IIIa and IVa was determined to be 92:8 by

means of the integral ratio of the peak areas at δ 4.14 and 4.34 ppm respectively.[1c,d,14]

A mixture of 3.362 g (9.00 mmol) of Ia and 7 ml of methyl iodide was kept at room temperature for two days. The subsequent evaporation of the surplus methyl iodide and IVa from the reaction mixture gave a pasty liquid containing colorless crystals. To the residue was added 50 ml of light petroleum ether (bp 40—48 °C); fine crystals were then separated by filtration and rinsed twice with petroleum ether. The crystals were identified as IIIa; mp 70—71 °C (lit,[14] mp 71.8—72.6 °C), 0.515 g (58%).

*Reaction of 2-(Tri-*n*-butylstannyl)-5-phenyltetrazole (Ib) with Methyl Iodide.* A solution of Ib (4.009 g, 9.22 mmol) in 5.0 ml of methyl iodide was kept at room temperature for 3 days. The subsequent evaporation of the residual methyl iodide *in vacuo* gave 5.230 g of a liquid containing crystals. To the residue was then added three 20 ml portions of light petroleum ether to extract tri-*n*-butyltin iodide. The petroleum ether was then evaporated off to give 3.723 g (97%) of tri-*n*-butyltin iodide. The crystals (1.491 g), insoluble in petroleum ether, consisted of IIIb and IVb in a ratio of 90:10. The NMR peaks at δ 4.15 and 4.35 ppm were assigned to the *N*-methyl protons of IIIb and IVb respectively.[25] The recrystallization of the crystals from *n*-hexane gave 1.252 g (78%) of pure IIIb;[1b,15] mp 103—104 °C (lit,[15] mp 101—102 °C).

*Reaction of 2-(Tri-*n*-butylstannyl)-5-(*p*-methoxyphenyl)tetrazole (Ic) with Methyl Iodide.* A solution of 1.447 g (3.12 mmol) of Ic in 3 ml of methyl iodide was kept at room temperature for two days. The subsequent evaporation of the surplus methyl iodide gave 1.871 g of a liquid containing crystals. The proportional ratio of IIIc and IVc in the reaction mixture was determined to be 91:9; the peaks at δ 4.11 and 4.34 ppm were assigned to IIIc and IVc respectively. The reaction mixture was treated with two 20 ml portions of petroleum ether to remove the tri-*n*-butyltin iodide. The resulting crystals, 0.492 g (84.7%), were recrystallized from a mixture of diisopropyl ether and tetrahydrofuran (4:1) to give 1-methyl-5-(*p*-methoxyphenyl)tetrazole (IIIc); mp 121—122 °C.[26] NMR ($CDCl_3$): δ 3.84 (s, 3H, methoxy protons), 4.11 (s, 3H, 1-methyl protons), 7.24 (d, 2H, *meta*-protons with respect to the tetrazole ring, $J_{o,m}$ 8.7 Hz), 7.67 ppm (d, 2H, *ortho*-protons).

*Reaction of 2-(Tri-*n*-butylstannyl)-5-(*p*-nitrophenyl)tetrazole (Id) with Methyl Iodide.* A solution of 0.460 g (0.955 mmol) of Id in 5 ml of methyl iodide was kept at room temperature for 40 days. The subsequent evaporation of the surplus methyl iodide gave 0.587 g of solids. The NMR spectrum of the solids had two peaks, at δ 4.25 and 4.42 ppm, assignable to the *N*-methyl protons of IIId and IVd respectively.[25] The integral ratio of the two peaks showed the distribution of IIId and IVd to be 68:32. The reaction mixture was subsequently treated with 100 ml of diethyl ether to extract the tri-*n*-butyltin iodide, IVd, and the recovered Id. The resultant crystals, insoluble in ether, were treated with hot diisopropyl ether to isolate 0.107 g (55%) of IIId; mp 122—123 °C (lit,[25] mp 121—123 °C). The ether solution was then concentrated and treated with hot diisopropyl ether. From the insoluble part 0.048 g (25%) of IVd was isolated by column chromatography (Silica Gel, benzene–tetrahydrofuran 10:2); mp 173—174 °C (lit,[25] mp 171—172 °C).

Reaction of 2-(Trimethylstannyl)-5-methyltetrazole (IIa) with Methyl Iodide. A solution of 0.062 g (0.23 mmol) of IIa in 0.25 ml of methyl iodide and 0.1 ml of methanol was kept in an NMR tube at room temperature for 4 days. Long needles of Va were found in the reaction mixture. In the NMR spectrum of the mixture there were not the peaks at δ 4.14 and 0.74 ppm characteristic of IIIa and the starting ingredient, IIa respectively, but there were peaks at δ 4.34 and 0.87 ppm assignable to the 2-methyl protons of IVa and the methyl protons of trimethyltin iodide respectively. Methanol, IVa, and surplus methyl iodide were evaporated off from the reaction mixture *in vacuo* to leave crystalline Va and trimethyltin iodide. The iodide was then removed by extraction with ether. The resultant crystals were identified as Va, 0.0242 g (40%); mp 266 °C (dec).[1d] The distribution of IIIa and IVa was determined to be 40:60 on the basis of the following facts: the starting IIa was completely converted into IIIa and IVa, and the resultant IIIa reacted with methyl iodide quantitatively to give Va, while little reaction occurred between IVa and methyl iodide.[1d]

Reaction of 2-(Trimethylstannyl)-5-phenyltetrazole (IIb) with Methyl Iodide. A solution of 0.378 g (1.22 mmol) of IIb in 2 ml of methyl iodide and 5 ml of methanol was kept at room temperature for two days. Evaporation of methanol and surplus methyl iodide *in vacuo* gave 0.383 g of crystals, which were then treated with benzene to separate the insoluble IIb, which was recovered unchanged; 0.158 g (42%). From the benzene extract the trimethyltin iodide was removed by extraction with water. The resultant benzene solution was concentrated to give a mixture of IIIb and IVb; 0.085 g (44%); IIIb:IVb=38:62.

Reaction of 2-(Trimethylstannyl)-5-(p-methoxyphenyl)tetrazole (IIc) with Methyl Iodide. A solution of IIc (0.351 g) in 1 ml of methyl iodide and 2 ml of methanol was kept at room temperature for 5 days. Methanol and surplus methyl iodide were then evaporated off *in vacuo* to give 0.362 g of crystals, whose components were determined by NMR analysis to be IIc (49%) and IVc (51%).

Reaction of 2-(Trimethylstannyl)-5-(p-nitrophenyl)tetrazole (IId) with Methyl Iodide. A solution of 0.088 g (0.25 mmol) of IId in 0.25 ml of methyl iodide and 0.25 ml of methanol was kept at room temperature for 5 days. The subsequent evaporation of methanol and surplus methyl iodide gave yellowish crystals (0.076 g) which were then treated with chloroform to extract *N*-methyl isomers and leave the recovered IId (0.012 g, 14%). The chloroform solution was evaporated off to give 0.057 g of the yellowish crystals. The ratio of IIId and IVd in the crystals was determined by NMR analysis to be 21:79.

Reaction of Lithium 5-Phenyltetrazolate (Xb) with Methyl Iodide. The monohydrate of Xb (0.1062 g, 0.625 mmol), prepared from an equimolar mixture of lithium hydride and 5-phenyltetrazole, was dissolved in 1.0 ml of methyl iodide and 2.0 ml of methanol. The solution was kept at room temperature for 3 days. The subsequent evaporation of methyl iodide and methanol gave 0.226 g of a pasty liquid, which was then extracted with dry ether. The ether solution was evaporated off to give 0.106 g of a liquid. The distribution of IIIb and IVb was determined by NMR analysis to be 21:79.

Reaction of Lithium 5-(p-Methoxyphenyl)tetrazolate (Xc) with Methyl Iodide. A solution of 0.094 g (0.47 mmol) of Xc in 0.25 ml of methanol and 0.25 ml of methyl iodide was kept at room temperature for two days. The subsequent evaporation of methanol and methyl iodide *in vacuo* gave 0.216 g of brownish crystals which were dissolved in chloroform. The chloroform solution was evaporated off to give 0.081 g (91%) of crystals. The ratio of IIIc and IVc in the crystals was determined by NMR analysis to be 21:79. The separation of IVc from IIIc was carried out by column

25) R. R. Fraser and K. E. Haque, *Can. J. Chem.*, **46**, 2855 (1968).

26) Although the melting point was different from the reported one (mp 93—94 °C),[15] not only the elemental analysis but also the NMR and mass spectra were consistent with the structure of IIIc.

chromatography (silica gel, benzene–chloroform 2:1) to isolate 0.055 g of IVc; mp 86.5—87.5 °C, NMR: δ 3.86 (s, 3H, methoxy protons), 4.37 (s, 3H, 2-methyl protons), 7.02 (d, 2H, *meta*-protons with respect to the tetrazole ring, $J_{o,m}$ 9.0 Hz), 8.12 ppm (d, 2H, *ortho*-protons).

Found: C, 57.17; H, 5.19; N, 30.05%. Calcd for $C_9H_{10}N_4O$: C, 56.83; H, 5.30; N, 29.46%.

From the later fraction 0.015 g of IIIc was collected.

Reaction of Lithium 5-(p-Nitrophenyl)tetrazolate (Xd) with Methyl Iodide. A solution of 0.076 g (0.35 mmol) of the monohydrate of Xd in 0.25 ml of methanol and 0.25 ml of methyl iodide was kept at room temperature for two days. The subsequent evaporation of the methanol and surplus methyl iodide gave 0.176 g of brownish crystals, which were then dissolved in chloroform. The solution was treated with water to remove the lithium iodide and Xd. From the chloroform layer was obtained 0.060 g (83%) of brownish-yellow crystals in which IIId and IVd were present in a ratio of 19:81.

Reaction of Ia with Methyl p-Toluenesulfonate. An equimolar solution of Ia and methyl *p*-toluenesulfonate in $CDCl_3$ was kept in an NMR tube at room temperature. After 21 days, the conversion of Ia into IIIa and IVa reached 42%. The distribution of IIIa and IVa was 79:21.

Reaction of Ib with Methyl p-Toluenesulfonate. A solution of 0.870 g (2 mmol) of Ib and 0.372 g (2 mmol) of methyl *p*-toluenesulfonate in 5 ml of ether was kept at room temperature for one day. The subsequent purification of the reaction mixture by column chromatography (silica gel, benzene: ether=1:1) yielded 0.280 g (89%) of crystals, which contained IIIb and IVb (92:8).

Reaction of Ib with Dimethyl Sulfate. A solution of 0.383 g of Ib and 0.200 g of dimethyl sulfate in 10 ml of ether was kept at room temperature for 8 days. After the evaporation of the ether, the reaction mixture was extracted with petroleum ether. The remaining crystals (0.087 g) were pure IIIb. From the extract, 0.015 g of a mixture of IIIb and IVb (1:1) was obtained by column chromatography. Consequently, the ratio of IIIb and IVb was found to be 93:7.

Reaction of Ib with Ethyl Bromoacetate. A solution of 0.671 g (1.5 mmol) of Ib and 0.259 g (1.5 mmol) of ethyl bromoacetate in 10 ml of benzene was refluxed for 10 days. The subsequent separation of the products by column chromatography (silica gel, benzene: ether=1:1) gave 0.327 g (91%) of crystalline ethyl 5-phenyl-1-tetrazolylacetate[8] and 0.033 g (9%) of ethyl 5-phenyl-2-tetrazolylacetate.[8] These esters were converted into the corresponding acids by alkali hydrolysis. 5-Phenyl-1-tetrazolylacetic acid, mp 169—170 °C (*n*-hexane) (lit,[8] mp 148—150 °C). Although the melting point is different from the reported one, the NMR and elemental analyses are consistent with the structure. NMR ($CDCl_3$: CF_3COOH=1:2): δ 7.70 (s, 5H, phenyl protons), 5.37 ppm (s, 2H, methylene protons). 5-Phenyl-2-tetrazolylacetic acid, mp 183—184 °C (*n*-hexane), (lit,[8] mp 182—184 °C). NMR ($CDCl_3$: CF_3COOH=1:2): δ 8.0 (m, 2H, *ortho*-protons), 7.55 (m, 3H, *meta*- and *para*-protons), 5.64 ppm (s, 2H, methylene protons).

Reaction of Ia with Ethyl Bromoacetate. An analogous treatment of Ia with ethyl bromoacetate for four days gave a mixture of the 1- and 2-substituted isomers. The NMR spectrum of the mixture showed that the ratio of the 1- and 2-substituted isomers was 90:10. The peaks at δ 5.23 and 5.40 ppm were assigned to the methylene protons of the 1- and 2-substituents respectively.[8] 5-Methyl-1-tetrazolylacetic acid was isolated by the hydrolysis of the ester; mp 183—184 °C (dec) (*n*-hexane and ethyl acetate) (lit,[8] mp 184—186 °C (dec)).

Reaction of 2-(Tri-n-butylstannyl)-5-benzyltetrazole (Ie) with Ethyl Bromoacetate. An analogous treatment of Ie with ethyl bromoacetate gave a mixture of the 1- and 2-substituted isomers in a ratio of 94:6. 5-Benzyl-1-tetrazolylacetic acid was isolated by the hydrolysis of the ester; mp 181—182°C (ethanol). NMR ($CDCl_3$: CF_3COOH=1:2): δ 7.6—7.0 (m, 5H, phenyl), 5.10 (s, 2H, $C\underline{H}_2COOH$), 4.43 ppm (broad s, 2H, $C_6H_5C\underline{H}_2$–).

Found: C, 54.95; H, 4.63; N, 25.43%. Calcd for $C_{10}H_{10}N_4O_2$: C, 55.04; H, 4.62; N, 25.68%.

A Study on the Photochemistry of α,β-Unsaturated γ-Lactones. II. Photoisomerization of 3-Ethylidene-4,5-dihydro-2(3*H*)-furanone[1]

Kazuya Ohga and Taku Matsuo

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka 812

(Received December 8, 1972)

On irradiation of *cis*-3-ethylidene-4,5-dihydro-2(3*H*)-furanone with 2537 Å light, both the *cis-trans* isomerization of the exocyclic double bond and transformation into the β,γ-unsaturated isomer, 3-vinyl-4,5-dihydro-2(3*H*)-furanone, were observed. By the use of sensitizers such as acetone, acetophenone, *p*-methoxyacetophenone and benzophenone, it was possible to induce *cis-trans* isomerization exclusively. On the basis of the solvent effect and the wavelength dependence of the reactions, transformation into the β,γ-unsaturated isomer and *cis-trans* isomerization were suggested to proceed *via* $T_2(n,\pi^*)$ and $T_1(\pi,\pi^*)$ states, respectively.

In contrast to the case of α,β-unsaturated ketones, information on the excited states of α,β-unsaturated esters and their analogues is scarce on account of the fact that systematic studies have not been made on the photochemistry of the latter.[2] The n,π* absorption bands of esters and their analogues are extremely blue-shifted from those of the corresponding α,β-unsaturated ketones as a result of conjugation between the carbonyl group and the adjacent hetero atom.[3] Hence, one may expect the photochemical behaviors ascribable to the n,π* excited state to differ considerably. We reported on the photodimerization of 2(5*H*)-furanone where no significant difference in stereo-selectivity and solvent effects on the yield were observed as compared with those of 2-cyclopentenone.[4] On irradiation of 2(5*H*)-furanone in 2-propanol, we obtained the same type of compound as in the case of the photoaddition of 2-cyclopentenone to 2-propanol;[5] the yield of the adduct in the former system, however, was very large in contrast to that of the latter system.[6] In order to investigate the photochemical behaviors of α,β-unsaturated lactones, we synthesized 3-ethylidene-4,5-dihydro-2(3*H*)-furanone, which is a new α,β-unsaturated lactone having a carbon-carbon double bond exocyclic to the lactone ring. The photochemical reactions of this compound are dealt with in this paper.

Results and Discussion

Synthesis and Identification of Starting Materials and Reaction Products. In order to synthesize the starting material, *trans*-3-ethylidene-4,5-dihydro-2(3*H*)-furanone (I), some modifications were made in the method by Zimmer and Rothe who mainly prepared 3-benzylidene derivatives of 4,5-dihydro-2(3*H*)-furanone.[7] The product contained at least two impurities which could not be removed by either repeated distillation or preparative vapor phase chromatography (vpc). The benzene solution was then irradiated in the presence of acetone as a sensitizer to yield *cis*-3-ethylidene-4,5-dihydro-2(3*H*)-furanone (II), which was readily isolated by preparative vpc. By the use of either acetone or benzophenone as a sensitizer, II was further photoisomerized back to I. Isolation of I from a small amount of the by-product III was achieved by the use of preparative vpc. The IR and NMR spectroscopic data of I and II given in Table 1 are in line with those of the isomeric 3-ethylidene-4,5-dihydro-2(3*H*)-furanones. The mass spectra and results of elementary analyses are in agreement with the assigned structure. A large difference in the chemical shift of methyl and methine protons on the exocyclic double bond can be seen in the NMR spectra. In the case of five- or six-membered ketones or lactones with structures analogous to compounds I and II, the methine proton signals for the *trans*-isomer are observed at lower field than those for *cis*-isomer, while a reverse tendency is observed for methyl proton signals.[8] Hence, compounds I and II were assigned to *trans*- and *cis*-3-ethylidene-4,5-dihydro-

a) Obtained in $CDCl_3$ with TMS as an internal standard.
b) Liquid sample.
c) Obtained by the simulation of the vinyl proton signals (ABC type) of III, deuterated at the α-position.

2(3*H*)-furanones, respectively. In the following experiments, the *cis*-isomer II (prepared as described above) was used as the starting material for photochemical investigations.

In addition to the *trans*-isomer I, another compound III was also produced when the acetonitrile solutions of isomer II in a sealed quartz tube was irradiated with a high-pressure mercury lamp. Compound III was isolated by preparative vpc, and the mass spectra as well as the result of elementary analysis indicate that III is another isomer. The spectral data are also summarized in Table 1. The wave number of the carbonyl absorption band (1771 cm^{-1}) indicates that the structure of γ-lactone is still retained in III but the carbonyl group is not conjugated with the carbon-carbon double bond. The IR spectra suggest the presence of a terminal vinyl group (δ_{CH}, 1005, 927 cm^{-1}). This was confirmed by the observation of ABC-type proton signals ascribable to the vinyl group in the NMR spectra of the sample, which was deuterated at the α-position with respect to the carbonyl group. Compound III was thus assigned to β,γ-unsaturated 3-vinyl-4,5-dihydro-2(3*H*)-furanone(β,γ-isomer).

Direct Irradiation of cis-*Isomer II.* Acetonitrile solutions of II were irradiated with a low-pressure mercury lamp in nitrogen atmosphere. The variation of each component with time was monitored by the use of vpc (Fig. 1). A very small amount of an unidentified compound (X) is produced together with the main products (I and III). The NMR spectra of the irradiated solution also indicates that isomers I and III are absolutely predominant reaction products and that the formation of X is negligible compared with those of I and III. The absorption maximum in the UV spectra shifted to shorter wavelength and the absorbance decreased with time. These changes can be accounted for by the formation of β,γ-unsaturated isomer III. Thus we see that the direct excitation of II induces both *cis-trans* isomerization between I and II and transformation from II to III.

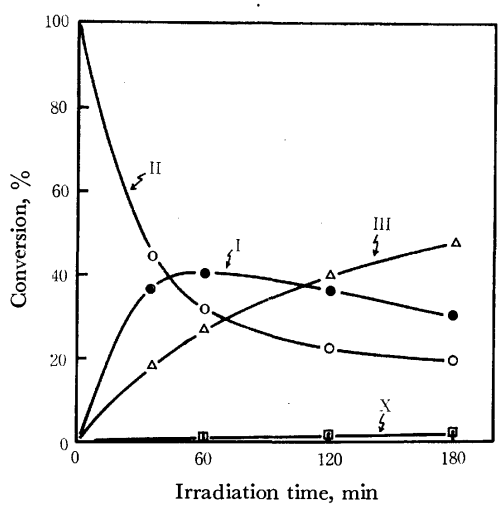

Fig. 1. Variation in the population of each component during the direct irradiation of II in acetonitrile (3×10^{-3}M).

When irradiation was carried out in D_2O–acetonitrile mixed solvent (4: 1), the methine group α to the carbonyl group of III was deuterated up to 89% as determined by NMR spectra. The formation of III is considered to proceed through an enol intermediate produced by the intramolecular hydrogen abstraction in analogy with the isomerization of α,β-unsaturated esters[9] or 5-methyl-3-hexen-2-one.[10]

Photosensitized cis-trans *Isomerization.* In Fig. 2 is shown the variation of isomer ratio with irradiation time, when either the *cis*- or *trans*-isomer was irradiated with a high-pressure mercury lamp in the presence of

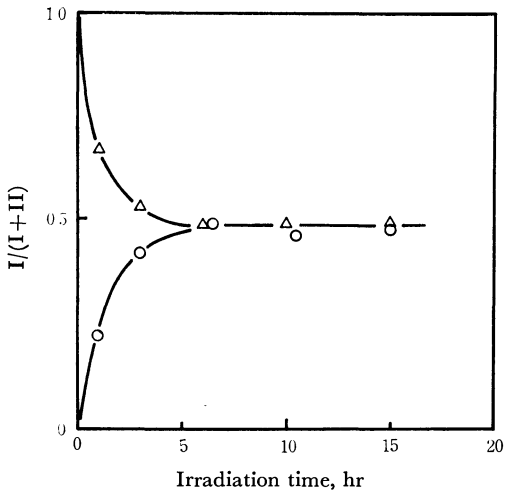

Fig. 2. Variation of the isomer ratio along the elapsed time in the acetophenone photosensitized isomerization of I and II.

Table 2. The isomer ratio at the photostationary state in the photosensitized isomerization between I and II[a)]

Sensitizer	[Sensitizer] M	E_T of the sensitizer kcal/mol	Isomer ratio[b)] I/II
Acetone	0.11	80	1.0
Acetophenone	0.01	74	0.96
p-Methoxy-acetophenone	0.01	72	1.0
Benzophenone	0.01	69	1.7

a) The concentrations of both I and II were 2.0×10^{-2}M. The reactions were carried out in an ordinary glass sample tube except for the case of acetone sensitization where a Pyrex tube was utilized.
b) Average values for the two reactions started from the pure sample of either of the two isomers. The errors are within 5%.

acetophenone as a sensitizer. The isomer ratio was determined by vpc analysis, assuming that both isomers can be detected with equal sensitivity. The isomer ratios at the photostationary states in the presence of a series of sensitizers were investigated in a similar way and the results are summarized in Table 2. The relationship between the triplet energy of the sensitizer and the isomer ratio at the photostationary state indicates that the triplet energy of the *cis*-isomer is lower than that of the *trans*-isomer estimated to be approximately 70 kcal/mol.

On direct excitation of the *cis*-isomer with 2537 Å light, the β,γ-isomer was obtained in 45% yield of the *trans*-isomer. In the case of the photosensitized reaction, the formation of the β,γ-isomer was completely suppressed. Thus, the excited precursor of the β,γ-isomer seems to differ from that of the *trans*-isomer. Since it is clear that *cis-trans* isomerization proceeds *via* the lowest triplet state (T_1) in the photosensitized reaction, the excited precursor leading to the β,γ-isomer seems to be either an excited singlet state (S_1) or the second-lowest triplet state (T_2) located above the triplet energy of acetone.

Solvent Effects of the Relative Yields of the β,γ-Isomer on the Direct Excitation of the cis-Isomer. When the

Table 3. Solvent effects on the relative quantum yields of the *trans*-isomer and the β,γ-isomer in the direct excitation of the *cis*-isomer

a) The relative quantum yield for the formation of I in the given solvent with respect to that in cyclohexane.
b) The relative quantum yield for the formation of III with respect to that of I.

cis-isomer in various solvents was irradiated with 2537 Å light, the relative quantum yield of the β,γ-isomer varied considerably with solvent polarity (Table 3), while that of the *trans*-isomer was unaffected by the change of solvent. The quantum yield of the β,γ-isomer in cyclohexane is reduced to a value less than 50% of that in either methanol or acetonitrile (Table 3).

A similar solvent effect has been reported also on the photoisomerization of α,β-unsaturated esters: conversion of ethyl *trans*-crotonate into the β,γ-unsaturated isomer proceeds much more easily in ethanol than in *n*-hexane.[9d)] This is explained by the effect of crossing between the π,π* triplet and the n,π* triplet levels on the change of solvents. The n,π* triplet seems to be the reactive species responsible for the formation of the β,γ-isomer.

It is quite likely that the solvent dependence of the quantum yield can also be explained by assuming the crossing of two closely separated energy levels with different reactivities. The plausibility of this speculation was further examined by studying the electronic absorption spectra. The UV-spectra of the *cis*-isomer II are shown in Fig. 3. The strong absorption band at the shorter wavelength is assigned to π,π* absorption in analogy with the case of α,β-unsaturated esters.[3)] We see that a week absorption band is superimposed on the tail of the π,π* absorption band in the cyclo-

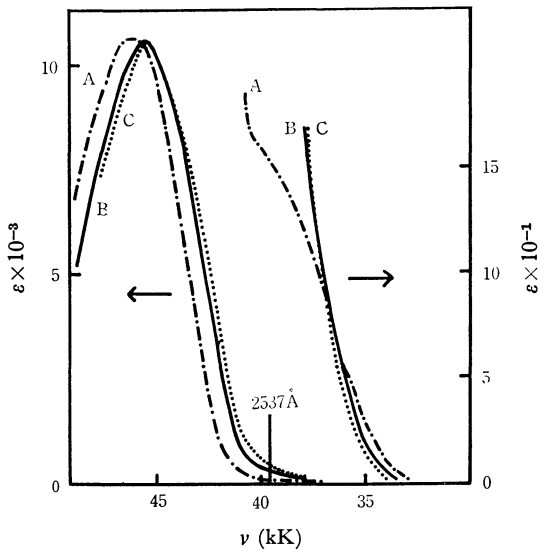

Fig. 3. UV absorption spectra of the *cis*-isomer II. A, in cyclohexane,; B in acetonitrile; C, in methanol.

hexane solution. On closer examination it can be seen to be associated with a series of broad vibrational structures frequently observed with n,π^* absorptions. The weak absorption band observed in cyclohexane is concealed under the red-shifted π,π^* absorption in acetonitrile and methanol. Hence, the weak absorption band is suggested to be either unaffected or slightly blue-shifted in polar solvents. We thus assigned the weak absorption band to the n,π^* transition of the *cis*-isomer II. As far as the singlet states of the *cis*-isomer II are concerned, the energy level of the lowest n,π^* excited state is concluded to be very close to that of the lowest π,π^* excited state in both acetonitrile and methanol. The 2537 Å exciting light is situated in the middle of the region where the n,π^* transition is superposed on the tail of the π,π^* transition (Fig. 3). Hence, the ratio in population between the n,π^* singlet and the π,π^* singlet species obtained in the excitation should vary with solvent. This might be why the relative yield of the β,γ-isomer considerably varies with the solvent while that of the *trans*-isomer remains the same (Table 3).

It should be noted, however, that the solvent effect on the yield of Norrish type II photolysis of valerophenone has been explained as being due to stabilization of the hydroxyl biradical intermediate which is capable of making a hydrogen bonding with the polar solvent molecules.[11] An *enol* type intermediate is suggested to be involved in the isomerization from II to III. The solvent effect on the secondary processes after the photoexcitation might be partly responsible for the variation in the relative yield of the β,γ-isomer with the change of solvent.

Dependence of the Relative Quantum Yields on the Wavelength of the Exciting Light. If the solvent effect on the relative yield of the β,γ-isomer is due to the change in population ratio between the n,π^* singlet and the π,π^* singlet just after excitation, the yield should show an appreciable variation with the wavelength of the exciting light, when examined in the absorption edge of the sample in a given solvent. The experiment was carried out under two different irradiation conditions: (a) with 2537 Å light from a low-pressure mercury lamp and (b) with a xenon short arc lamp filtered through carbon tetrachloride layer of 15 mm thickness, the incident lights being limited to be those with wavelength longer than 260 mμ. The results are summarized in Table 4. In cyclohexane, the ratio of the relative yield of the β,γ-isomer to that of the *trans*-isomer under conditions (b) is reduced to 35% of that under conditions (a). The isomer ratio (β,γ-isomer/*trans*-isomer) in acetonitrile under the same conditions varies only by 20%. The n,π^* absorption band of the *cis*-isomer in cyclohexane appears as a clear shoulder superimposed on the tail of the π,π^* absorption band (Fig. 3). Hence the longer the wavelength of the excitation light, the larger the population ratio between the $S_1(n,\pi^*)$ and $S_2(\pi,\pi^*)$. Thus, the rapid decrease in the isomer ratio in cyclohexane is nicely correlated to the increase in the relative population of the first n,π^* singlet state. Analogously, the small wavelength dependence of the isomer ratio in the acetonitrile solution is suggested to correspond to the fact that the n,π^* absorption band is located in almost the same wavelength region where the π,π^* absorption is observed. It is thus difficult to enhance selectively the relative population of the n,π^* excited species only by selection of the wavelength of exciting light.

Table 4. Dependence of the ratio of the relative quantum yields (III/I) on the wavelength of the exciting light (λ)[a]

Solvent	$\lambda>260$ mμ[b]	$\lambda=254$ mμ
C_6H_{12}	0.059	0.17
CH_3CN	0.33	0.41

a) The relative yield was estimated from the vpc chart by assuming that the molar sensitivities of the two isomers are the same.
b) Obtained by the use of Xe lamp in combination with CCl_4.

Proposal of a Reaction Scheme. As regards solvent effects and wavelength effects on the relative quantum yields of the β,γ- and the *trans*-isomer, we might suggest that the former mainly comes from the π,π^* singlet state and the latter from the n,π^* singlet state. The relative heights of the n,π^* and π,π^* singlet energy levels can be determined from the UV absorption spectra of the *cis*-isomer (Fig. 3). We have no data for the location of the triplet energy levels. However, the following theoretical consideration can be given.

On spectroscopic evidences, Marsh *et al.* have shown that the energy of n,π^* triplet state of steroidal enones is very close to that of the π,π^* triplet state.[12] This may be also true for other α,β-unsaturated ketones in general. In the case of esters and lactones, the conjugation between the carbonyl group and the adjacent oxygen atom raises the n,π^* state considerably and leaves the π,π^* state almost unchanged in comparison with those of the corresponding ketones or aldehydes.[13] The lowest n,π^* triplet state of an ester or a lactone is thus expected to be located much above the lowest π,π^* triplet state so that the change of solvents can not reverse the relative heights of these energy levels. A schematic energy-level diagram for the relevant states of the *cis*-isomer is shown in Fig. 4.

Intramolecular hydrogen abstraction is generally considered to take place at the n,π^* excited state. In the present experiment, however, $S_1(n,\pi^*)$ species is considered to hardly contribute to the hydrogen abstraction reaction since the relative yield of the β,γ-isomer decreases on irradiation of the *cis*-isomer in cyclohexane with the longer wavelength light which predominantly induces n,π^* transition. Formation of the β,γ-isomer should be correlated to the population of $S_2(\pi,\pi^*)$ species, since the relative quantum yield on the irradiation with 2537 Å light decreases in cyclohexane, where an appreciable blue shift of the π,π^* absorption band

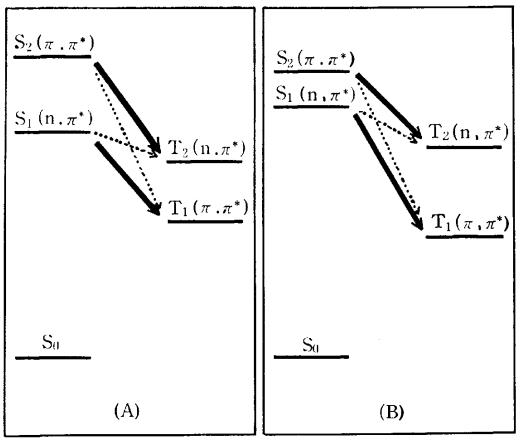

Fig. 4. Schematic energy level diagram for the relevant states of the *cis*-isomer: A (in cyclohexane) and B (in acetonitrile). The solid and dotted arrows represent the intersystem crossing manifolds with the higher- and the lower-efficiency, respectively.

is observed. The quantum yield of the *cis-trans* isomerization, in turn, should be related to the population of $S_1(n,\pi^*)$ species. However, it is rather unusual that the *cis-trans* isomerization takes place directly at the $S_1(n,\pi^*)$ state, since this type of reaction is known to proceed *via* π,π^* state. Taking into account the fact that *cis-trans* isomerization is sensitized by the triplet sensitizers, and that the lowest triplet state is estimated to be a π,π^* state, it is more likely that *cis-trans* isomerization takes place at $T_1(\pi,\pi^*)$ state which mainly comes from $S_1(n,\pi^*)$ state even in direct excitation. The results on the formation of the β,γ-isomer, are well accounted for if we consider that the hydrogen abstraction reaction takes place at $T_2(n,\pi^*)$ state which mainly comes from $S_2(\pi,\pi^*)$ state. This is in accordance with the general principle on the reactive species in the photochemical hydrogen abstraction reactions.

On the basis of theoretical arguments and experimental observations on the radiation yields of ketones, El-Sayed proposed a selection rule for the intersystem crossing at the excited states: the intersystem crossing between the levels of different nature [$S(n,\pi^*)\rightarrow T(\pi,\pi^*)$ and $S(\pi,\pi^*)\rightarrow T(n,\pi^*)$] should be faster than those between the levels of the same nature [$S(\pi,\pi^*)\rightarrow T(\pi,\pi^*)$ and $S(n,\pi^*)\rightarrow T(n,\pi^*)$] by a factor of 10^3.[14] If this selection rule holds also in the case of the photoexcited states of II, the routes for photoisomerization can be reasonably accounted for as shown in Fig. 4, where the intersystem crossing with higher efficiency is denoted by a broad solid arrow, and that with lower efficiency by a dotted arrow.

In order to confirm the reaction scheme, we made several attempts to quench the excited states in the photoisomerization of II on direct excitation. However, no positive results were obtained. This is understandable from the fact that the lifetimes of the concerned states are expected to be extremely short in the present case. We can not completely disregard the contribution of singlet species to isomerization on direct excitation at this stage. The present model might be adopted as reasonable means for explaining the characteristics of the photoisomerization of α,β-unsaturated γ-lactones.

Experimental

Instrumental Analysis. The NMR spectra were measured with a Varian Model A-60 analytical spectrometer. The IR, UV, and mass spectra were recorded on a JASCO Model DS-301 IR spectrometer, a Shimadzu Model UV-200 spectrophotometer, and JEOL Model JMS-01SG mass spectrometer, respectively. Vapor phase gas-chromatography for qualitative analysis was carried out by the use of a Shimadzu Model GC-2C chromatograph equipped with a thermal conductivity detector. Analysis was carried out by the use of a column (2.25 m × 3 mm) with packings made by coating polyphenyl ether 5-rings (10%) on Chamelite CS (DMCS-treated Celite 545) support. The column temperature was kept to 175 °C. The preparative vpc was also carried out under the same conditions. The quantitative analyses were carried out at either 120 or 130 °C by the use of a Shimadzu Model GC-3BF gas chromatograph equipped with a flame ionization detector.

Preparation of trans-*3-Ethylidene-4,5-dihydro-2(3H)-furanone (I).* Preparation of I was carried out by a modification of the method reported by Zimmer and Rothe.[7] Acetaldehyde (18 g) and γ-butyrolactone (70 g) in benzene (500 ml) were maintained at 5 °C in the presence of powdered sodium ethoxide for 1.5 hr, and the reaction was completed by heating the solution up to 45 °C for 15 min. Dilute sulfuric acid (10%, 360 ml) was added to the solution, and the organic layer was separated from the aqueous phase. The aqueous phase was extracted with 350 ml of benzene, and the extract was combined with the previously separated organic layer. The benzene solution was successively washed with water, aqueous sodium hydroxide and finally with water. Benzene was removed by distillation and the succeeding distillate was collected (up to 114 °C/6 mmHg). The same procedure was repeated and crude products were combined (21.7 g), which yielded 6.2 g of the final product (72.5—76.0 °C/5 mmHg) after fractional distillation. In addition to the main product I, several other byproducts were involved in the collected distillate. Preparative vpc was then applied to obtain I, which was still accompanied by small amounts of two other impurities difficult to separate. An attempt was also made to prepare I according to Pinder's method[15] for the preparation of the benzylidene analogue of I, but the yield was too small for the method to be adopted.

Preparation of cis-*3-Ethylidene-4,5-dihydro-2(3H)-furanone (II).* The *trans*-isomer I (1.8 g), together with small amounts of accompanying impurities were dissolved in 100 ml of benzene. Acetone (10 g) was added as a sensitizer, and the solution was internally irradiated with a high-pressure mercury lamp (Riko-Sha UVL-700P) equipped with a pyrex water-jacket in nitrogen atmosphere for 21 hr. According to the vpc analysis, the *cis*-isomer II was the sole product. The *cis*-isomer was isolated by fractional distillation followed by preparative vpc. Yield, 325 mg; m/e=112 (M^+). Found: C, 64.18; H, 7.28%. Calcd for $C_6H_8O_2$: C, 64.27; H, 7.19%.

Photosensitized Reaction of cis-*3-Ethylidenedihydro-2(3H)-furanone (II).* *(A) Preparation of the Authentic Sample of* trans-*Isomer (I):* The *cis*-isomer II (179 mg) and benzophenone (5 mg) were dissolved in 1 ml of benzene. The

15) A. R. Pinder, *J. Chem. Soc.*, **1952**, 2236.

solution was placed in a pyrex tube which was sealed after evacuation under nitrogen atmosphere. The sample was externally irradiated with a high-pressure mercury lamp (Toshiba H-400P) for 22 hr at room temperature. The NMR and vpc of the irradiated sample indicated that the *trans*-isomer I was formed together with a small amount of III. Preparative vpc was applied to isolate I. Yield, 39 mg; $m/e=112$ (M^+); Found: C, 64.05; H, 7.37%. Calcd for $C_6H_8O_2$: C, 64.27; H, 7.19%.

(B) Determination of the Isomer Ratio between I and II at the Photostationary State: Acetone was purified by treating with potassium permanganate followed by fractional distillation. Acetophenone (reagent grade) was also purified by fractional distillation under reduced pressure just before use. *p*-Methoxyacetophenone was recrystallized from *n*-hexane–benzene mixed solvent (mp 39.1—40.1 °C). Benzophenone was recrystallized from methanol (mp 51.2—51.5 °C). Each sample tube was sealed after flushing with nitrogen and irradiated with a high-pressure mercury lamp (Riko-Sha UVL-700P) equipped with a pyrex glass filter. The reaction was carried out at 20.2 °C, and the products were analyzed by vpc at 130 °C.

Direct Irradiation of cis-*Ethylidene-4,5-dihydro-2(3H)-furanone II.* *(A) Preparation of β,γ-Unsaturated 3-Vinyl-4,5-dihydro-2(3H)-furanone III*: The *cis*-isomer II (73 mg) was dissolved in 0.5 ml of acetonitrile, and the solution was irradiated in a quartz tube under exactly the same conditions, as for the preparation of I, except for the absence of the sensitizer. The main products were isomers I and III, the latter being isolated by distillation under reduced pressure followed by vpc in a preparative scale. Yield, 20 mg; $m/e=112$ (M^+); Found: C, 63.89; H, 7.28%. Calcd for $C_6H_8O_2$: C, 64.27; H, 7.19%.

(B) Variation of UV Spectra during Irradiation: Acetonitrile solution of II (3×10^{-3}M, 150 ml) was internally irradiated with a low-pressure mercury lamp (Riko-Sha UVL-303Q) under nitrogen atmosphere at room temperature. Four ml of the sample was periodically extracted from the irradiated solution, and a quarter of the sample was used for measurement of the UV spectra after being diluted with acetonitrile to one hundredth of the initial concentration. The remaining 3 ml of the sample was concentrated to approximately one twentieth in volume, and was analyzed by vpc. After irradiation for 3 hr most of the acetonitrile was removed by distillation under reduced pressure and the residue was analyzed by NMR spectroscopy. No absorption was observed due to the compound other than the three isomers.

(C) Irradiation in D_2O-Acetonitrile System: Approximately 60 mg of the *cis*-isomer was dissolved in a mixed solvent consisting of D_2O (0.8 ml) and acetonitrile (0.2 ml). A quartz tube containing the solution was sealed under reduced pressure, after the remaining oxygen had been replaced with purified nitrogen. The sample was externally irradiated for 12 hr with a high-pressure mercury lamp. After irradiation was completed, the products were extracted into benzene (20 ml), and successively distilled under reduced pressure. The NMR spectra in deuterochloroform indicated the isomers I, II, and III to be 24, 9, and 67%, respectively.

Solvent Effect on the Quantum Yield of the Isomers on the Irradiation of II with 2537 Å Light. The *cis*-isomer was purified by vpc on a preparative scale and successive distillation under reduced pressure (2 mmHg) so that it gave a single peak in the vpc. The purified *cis*-isomer was dissolved in solvents of spectrograde purity. Eight ml of each solution was pippetted into a quartz tube (15 mm inner diameter), fused to a pyrex tubing of the same diameter with a graded seal. The air inside the sample tube was purged by a stream of purified nitrogen, and the tube was sealed under reduced pressure (2 mmHg) after it was cooled by being dipped into dry ice–methanol mixture. In the case of the acetonitrile and methanol solutions, the samples were also prepared by the use of a vacuum line (less than 10^{-4} mmHg) for degassing. Good agreement was observed with the pair of samples prepared by the above two methods. Each sample tube was set in a cylindrical glass holder, mounted on a turn table with a radius of 12 cm. A square window (10×30 mm) on the wall of the holder allowed more than 99% of the incident 2537 Å light to be absorbed in the sample at the concentration of the experiment. At the center of the turn table was placed a low-pressure mercury lamp (Riko-Sha UVL-303Q), surrounded by a layer of aqueous 2,7-dimethyl-3,6-diazocyclohepta-1,6-diene perchlorate filter solution (175 mg/l)[16] of approximately 2 cm thickness. Under such conditions, the sample absorbs only 2537 Å light from the low-pressure mercury lamp since no absorption band is observed for the *cis*-isomer at the wavelength longer than 300 mμ. The characteristic of each sample tube was calibrated in advance by monitoring the change in the potassium ferrioxalate actinometer solution in each tube when it was irradiated by the light filtered through an aqueous solution containing $NiSO_4\cdot xH_2O$ (450 g), $CoSO_4\cdot 6H_2O$ (150 g), and 2,7-dimethyl-3,6-diazocyclohepta-1,6-diene perchlorate (175 mg).[17] The relative quantum yield of each isomer was determined after irradiation of the sample for 1,5 hr. The reaction was carried out at 20.0 °C by immersing the whole irradiation unit in a thermostat bath. The content of the sample tube was concentrated, under nitrogen stream, down to approximately one tenth of the initial volume and the residue was analyzed by vpc in the presence of β-methylnaphthalene as an internal standard. On irradiation of the cyclohexane solution, small amounts of a by-product other than the three isomers were also detected. No further attempt was made to identify the by-product since the yield was extremely small.

Determination of the Relative Quantum Yield on Irradiation of Light with Wavelength longer than 260 mμ. Either acetonitrile solution (2.2×10^{-2}M) or cyclohexane solution (2.18×10^{-2}M) was placed in a cylindrical cell, ($25\phi\times10$ mm) which was sealed under reduced pressure (2 mmHg) after being flushed with nitrogen. The light beam from a xenon lamp (Ushio UXL-500D) was filtered through a layer of carbon tetrachloride (15 mm), and was irradiated on the optically flat surface of the cylindrical cell. Irradiation was continued for 4.5 hr at a constant temperature (19—20 °C), and the product was analyzed by vpc.

Syntheses of Organic Phosphates. III. Syntheses and Properties of 2-Amino-3-pyridylmethyl and 2-Chloro-3-pyridylmethyl Phosphates[1]

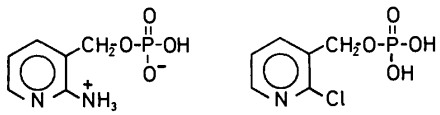
Yukito MURAKAMI, Junzo SUNAMOTO, Seiichiro KINUWAKI, and Haruomi HONDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received December 25, 1972)

Two substituted pyridylmethyl phosphates, 2-amino-3-pyridylmethyl (I) and 2-chloro-3-pyridylmethyl phosphates (II), were prepared and their properties were discussed. Acid dissociation constants and NMR data suggested that the neutral species of I exists in the zwitterion form consisting of the protonated amino group and the monoanionic phosphate moiety, while that of II in the dihydrogen phosphate form analogous to the simple alkyl phosphates. In addition, physical properties of 2-amino-3-pyridylmethanol and 2-chloro-3-pyridylmethanol, which are respectively precursors of phosphates I and II, as well as 1,2-dihydro-2-oxo-3-hydroxymethylpyridine, were examined by IR and NMR measurements.

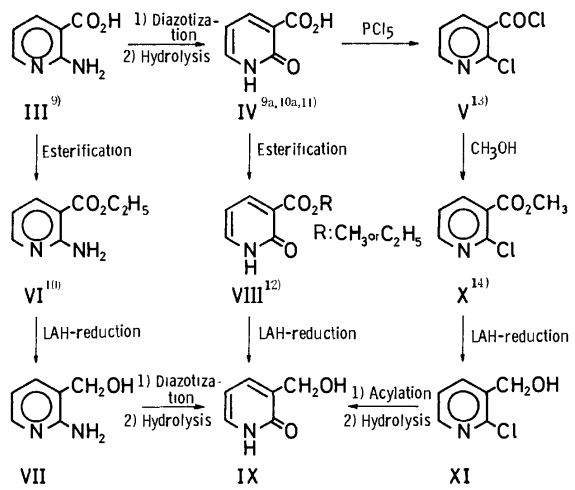
In a series of our studies on the chemistry of organic phosphates, some phosphates, which carry a heteroaromatic moiety, have been prepared.[2-5] Their hydrolytic behaviors have been investigated with particular attention to the intramolecular catalysis brought about by the proximity participation of a functional group.[4-7] In order to search for further evidence of the proximity catalysis in hydrolysis, two phosphates, 2-amino-3-pyridylmethyl (I) and 2-chloro-3-pyridylmethyl phosphates (II), were synthesized in this work.



I II

2-Chloro-3-pyridylmethanol (XI) which is the precursor of II was also found to be a new material. On the other hand, Cislak has already prepared 2-amino-3-pyridylmethanol (VII), the precursor of I, by a method different from the present one.[8] Their physical properties were examined in this work.

Pyridylmethanols. Both pyridylmethanols, VII and XI, were prepared from the same starting material, 2-aminonicotinic acid (III),[9] according to the processes shown in Scheme 1. The synthesis of 1,2-dihydro-2-oxo-3-hydroxymethylpyridine (IX) was also carried out.



Scheme 1.

The following tautomerism would be considered for 2-aminopyridines.[15] In the case of 2-amino-3-pyridylmethanol, however, we confirmed the absence of such a tautomerism on the basis that the correlation between the symmetric and asymmetric N–H stretching vibrational modes for this alcohol is in good agreement with the Bellamy-Williams relationship for the aromatic primary amines.[16] The alcoholic hydroxyl proton only

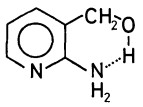
d) 10 wt% in acetone.

gave a broad singlet NMR signal even in dimethyl sulfoxide. Apparently, the hydrogen bonding of the hydroxyl proton with the solvent must be disturbed by a strong intramolecular hydrogen bonding involving both hydroxyl and amino groups. This interaction may give rise to a slow hydrogen exchange, causing NMR line-broadening. The result is consistent with configuration XII. The appropriate data for NMR chemical shifts are summarized in Table 1.

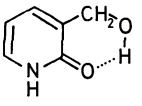


XII

Albert *et al.* reported the pK_a-value of the protonated 2-aminopyridine as 6.86 at 20 °C.[15] The pK_a value of the protonated 2-amino-3-pyridylmethanol was determined in this work to be 6.35 at 25 °C (μ= 0.10 with potassium chloride). Although the hydroxymethyl group is an electron-withdrawing substituent ($\sigma^*=+0.555$),[17] the decrease in pK_a upon substitution with the group ($\Delta pK_a=0.51$) seems to be too large to be attributed wholly to its electronic nature: pK_a, 9.94 for phenol, 9.92 for 2-hydroxymethylphenol, 9.83 for 3-hydroxymethylphenol, and 9.82 for 4-hydroxymethylphenol at 25 °C;[18] 3.99 for benzoic acid and 3.84 for 2-hydroxymethylbenzoic acid at 20 °C.[19] Consequently, the intramolecular hydrogen bonding, XII, may take place and result in the enhanced dissociation of proton from the protonated 2-amino group.

For 2-chloro-3-pyridylmethanol, the NMR hydroxyl proton resonance in dimethyl sulfoxide was well resolved into a triplet through coupling with the α-methylene. The strong hydrogen bonding of the hydroxyl group with dimethyl sulfoxide seems to be responsible for the inhibition of the hydroxyl proton exchange. As a result, pyridylmethanol does not involve an intramolecular hydrogen bonding strong enough to reject the interaction with dimethyl sulfoxide.

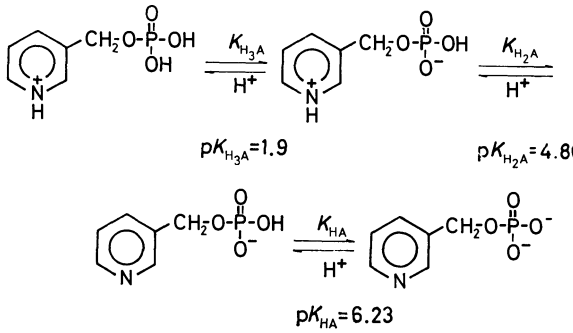
1,2-Dihydro-2-oxo-3-hydroxymethylpyridine (IX) showed a broad hydroxyl proton resonance signal in its NMR spectrum, indicating the existence of an intramolecular hydrogen bonding (XIII).



XIII

Pyridylmethyl Phosphates. Both phosphates, I and II, were prepared from the corresponding pyridylmethanols according to the established procedures.[2-5]

For simple alkyl phosphate monoesters, three species have to be considered, in general, where $pK_{H_2A}=1$—2 and $pK_{HA}=5$—7. Meanwhile, an additional ionic species must be considered for pyridylalkyl phosphates as shown typically for 3-pyridylmethyl phosphate in Scheme 2.[2] The second acid dissociation constant



Scheme 2.

found for 2-chloro-3-pyridylmethyl phosphate (pK_{H_2A}= 2, Table 2) is considerably smaller than those for the other pyridylalkyl phosphates ($pK_{H_2A}=4$—5).[2-5] Brown and McDaniel obtained the pK_a value of 0.72 for 2-chloropyridine in an aqueous media at 25 °C.[20] The phosphorylated hydroxymethyl group acts as an electron-withdrawing group to some extent.[2] Consequently, the pK_a-value for dissociation of a pyridinium proton in 2-chloro-3-pyridylmethyl phosphate should

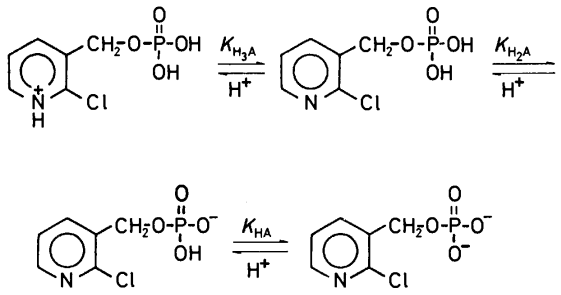
Table 2. Acid dissociation constants for the phosphates at μ=0.10 (KCl or KNO_3)

Phosphate	pK_{H_2A}		pK_{HA}	
	25 °C	80 °C	25 °C	80 °C
2-Chloro-3-pyridylmethyl	2.17	1.8[a]	5.97	6.3[a]
2-Amino-3-pyridylmethyl	5.42	5.11[b]	7.03	7.40[b]
3-Pyridylmethyl	4.86[c]	4.43[d]	6.23[c]	6.48[d]

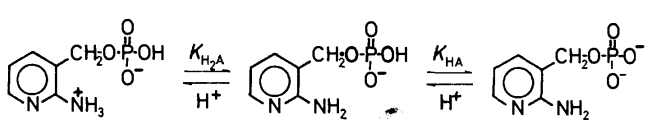
a) Quoted from Ref. 21.
b) At 70.0 °C.
c) Quoted from Ref. 2.
d) Quoted from Ref. 6.

be less than that for 2-chloropyridine. If the pK_{H_2A} refers to the dissociation of the first phosphate proton, a little larger value (2.2), relative to that of 3-pyridylmethyl phosphate (1.9), can be attributed to trapping of the phosphate proton by the chlorine atom through an intramolecular hydrogen bonding.[21] Therefore, the plausible acid dissociation processes for the phosphate are reasonably presented in Scheme 3. The neutral species of 2-chloro-3-pyridylmethyl phosphate does not exist in the zwitterion form but in the dihydrogen phosphate. This characteristic structural feature was closely reflected on its hydrolytic behavior.[21]



Scheme 3.

Since 2-amino-3-pyridylmethyl phosphate is tetrabasic, the acid dissociation processes become somewhat complex. The pK_a value of the protonated 2-amino group can be reduced by the phosphorylated 3-hydroxymethyl group playing as an electron-withdrawing substituent, while the acid dissociation of the last-dissociating proton on the phosphate moiety is somewhat depressed by the substitution of an electron-donating 2-amino group. The most plausible acid dissociation processes for the phosphate are reasonably given in Scheme 4.



Scheme 4.

For both phosphates of the present study, the dissociation of the pyridinium proton seems to be much enhanced by the presence of an electron-withdrawing group, protonated amino group or chlorine, and the reliable pK_a value for such dissociation was not evaluated under present experimental conditions.

Experimental

2-Amino-3-pyridylmethanol (VII). A mixture of 16.3 g of lithium aluminum hydride (LAH) and 1 l of dry ether was stirred for 20 min at room temperature. The reaction flask was assembled with a Soxhlet extraction apparatus equipped with an extraction thimble in which 30.0 g of ethyl 2-aminonicotinate was placed. With care for vigorous reaction, the ether–LAH mixture was gently refluxed. After most of the ester was dissolved in ether, an additional 29.3 g sample of the ester was placed in the thimble. Upon refluxing for about 60 hr, the reaction mixture was cooled down to room temperature. After decomposing the excess hydride with water, the ether layer was separated and concentrated to crystallize the crude alcohol (22.9 g). From the residue containing metal hydroxide, 10.5 g of the alcohol was recovered. Both crops of the crude alcohol were combined and recrystallized from ether: colorless leaflet, mp 70 °C. Found: C, 58.11; H, 6.44; N, 22.54%. Calcd for $C_6H_8N_2O$: C, 58.04; H, 6.50; N, 22.57%. UV (methanol): 235.5 (log ε 3.97) and 295.5 nm (log ε 3.66). IR (KBr disk): ν_{NH}, 3410, 3335; δ_{NH}, 1650; ν_{ring}, 1605, 1575; ν_{C-O}, 1036, 1006; δ_{CH}, 791 and 756 cm^{-1}. NMR data are given in Table 1.

2-Chloro-3-pyridylmethanol (XI). A 27.1 g sample of methyl 2-chloronicotinate was treated with LAH in an established manner; yield 11 g (48%), bp 105—112 °C/0.20 mmHg. After being left overnight at room temperature, the distillate was solidified and recrystallized from chloroform: white needles, mp 63—64 °C. Found: C, 50.46; H, 4.24; N, 9.86%. Calcd for C_6H_6NOCl: C, 50.20; H, 4.21; N, 9.76%. UV (methanol): 265.5 nm (log ε 3.62). IR (KBr disk): ν_{OH}, 3280; ν_{ring}, 1588, 1571; ν_{C-O}, 1054, 1044; δ_{CH}, 817, 796, 734, and 718 cm^{-1}. NMR data are given in Table 1.

1,2-Dihydro-2-oxo-3-hydroxymethylpyridine (IX). (i) By the LAH reduction of ethyl 1,2-dihydro-2-oxonicotinate (1.0 g) according to the general procedure, the corresponding alcohol was obtained in poor yield (63 mg); mp 134 °C.

(ii) A solution containing 28.4 g of 2-amino-3-pyridylmethanol in 253 ml of 10% sulfuric acid was poured onto 950 ml of water warmed at 60—70 °C. At the same temperature, 230 ml aqueous solution of sodium nitrite (22.15 g) was added dropwise in 1 hr. After addition of aqueous nitrite was completed, the mixture was continuously stirred at the same temperature for additional 1 hr. The acidic solution was neutralized with anhydrous sodium carbonate and concentrated to 200 ml, to which double volume of ethyl acetate was added. The precipitated inorganic salt was removed. This procedure was repeated until inorganic salt was not detected any longer. Needle-like crystals were recovered from the cooled ethyl acetate solution, and recrystallized from ethanol: yield 19.9 g (70%), mp 137.5—138.4 °C. Found: C, 57.63; H, 5.78; N, 11.11%. Calcd for $C_6H_7O_2N$: C, 57.59; H, 5.64; N, 11.19%. UV (methanol): 230 (log ε 3.79) and 299 nm (log ε 3.77). IR (KBr disk): ν_{NH}, 3400; $\nu_{C=O}$, 1647; ν_{ring}, 1620, 1567; ν_{C-O}, 1040; δ_{CH}, 765 cm^{-1}. NMR data are listed in Table 1.

(iii) The pyridone IX was also obtained through acylation of the alcohol XI, followed by hydrolysis with diluted hydrochloric acid in the presence of sodium acetate; very poor yield.

2-Amino-3-pyridylmethyl Phosphate (I) 2-Amino-3-pyridylmethanol (VII) (1.0 g) was mixed with pyrophosphoric

acid, which was freshly prepared by brief heating of 85% orthophosphoric acid (6.5 g) and phosphorus pentoxide (5.0 g), at 50 °C under protection from moisture. The reaction mixture was heated at 70—80 °C for 20 hr, diluted with 20 ml of water, and heated again in order to hydrolyze any coexisting polyphosphate. The resulting hydrolyzate was poured onto 250 ml of acetone and allowed to stand overnight in a refrigerator. White precipitates were separated and washed sufficiently with acetone; yield 1.18 g. Further recrystallization from water gave white crystals; neutralization equivalence, 102.62 (calcd. 102.06). Found: C, 34.92; H, 4.84; N, 13.42%. Calcd for $C_6H_9O_4N_2P$: C, 35.31; H, 4.44; N, 13.72%. IR (KBr disk): $\nu^{+}_{NH_3}$, 3300, 3130, 2600, 2400, 2020, 1980; $\delta^{+}_{NH_3}$, 1685, 1646; $\nu_{P=O}$, 1247, 1150, 1130; $\nu_{P-O-C(alk)}$, 1020 and 946 cm^{-1}. UV (10^{-4}M, water): 232.5 (ε 8080) and 303.0 nm (ε 6840).

2-Chloro-3-pyridylmethyl Phosphate (II). A 1.44 g sample of 2-chloro-3-pyridylmethanol (XI) was phosphorylated with 12.7 g of pyrophosphoric acid at 80—100 °C for 4 hr according to the method similar to that used for 2-amino-3-pyridylmethanol. The resulting mixture was neutralized with concentrated aqueous ammonia and evaporated to dryness. The residue was extracted twice with a 100 ml portion of hot ethanol. The extracts were evaporated to 10 ml and white crystals (the diammonium salt) were recovered; yield 440 mg. Found: P, 12.1%. Calcd for $C_6H_{13}O_4N_3PCl$: P, 12.02%. The ammonium salt of the phosphate was converted to the free acid form with the use of cation exchange resin, Dowex-50W×8; neutralization equivalence, 108.90 (calcd. 111.77). Found: C, 32.22; H, 3.31; N, 6.12%. Calcd for $C_6H_7NO_4PCl$: C, 32.24; H, 3.16; N, 6.27%. UV (10^{-4}M, water): 266 (ε 3140) and 272 nm (ε 2840). IR (KBr disk): ν_{OH}, ~3400; $\nu_{P=O}$, 1287, 1230—1195 (broad), 1110; $\nu_{P-O-C(alk)}$, 1054 and 1010—970 cm^{-1} (broad). NMR (0.71M, dimethyl sulfoxide-d_6, TMS as an internal reference): δ 5.03 (2H, d, $J_{CH_2-^{31}P}$=8.0 Hz, $-C\underline{H}_2-$), 6.61 (2H, s, $-O\underline{H}$), 7.54 (1H, q, J_{4-5}=7.5 Hz and J_{5-6}=5.0 Hz, H-5), 8.02 (1H, q, J_{4-6}=2.0 Hz, H-4), and 8.46 (1H, q, H-6).

Acid Dissociation Constants. Acid dissociation constants of the pyridylmethyl phosphates and the pyridylmethanols were measured by potentiometric titrations of the corresponding aqueous solutions (2.0×10^{-3}M) with standard base or acid at an ionic strength of 0.10 (KCl or KNO_3). All the measurements were checked by duplicate runs. The procedures for measurements were essentially the same as those adopted in the previous studies.[2-5] A set of electrodes used for pH measurements were glass electrode TOA HG-6005 and reference electrode TOA HC-605, which were connected to the TOA HM-9A expandomatic pH meter. The evaluated acid dissociation constants are listed in Table 2 along with the previous data for comparison.

Thanks are due to Miss Chieko Gondo for her assistance in part of the potentiometric measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2190—2193 (1973)

Chemical Studies on the Mistletoe. II.[1] The Structure of Viscumamide, a New Cyclic Peptide Isolated from *Viscum album* Linn. *var. coloratum* Ohwi

Yasuaki OKUMURA and Atsushi SAKURAI

Chemical Institute, Faculty of Science, Shizuoka University, Ohya, Shizuoka 420

(Received December 25, 1972)

A new cyclic peptide, viscumamide ($C_{30}H_{55}N_5O_5$) was isolated from *Viscum album* Linn. *var. coloratum* Ohwi, and the structure Ia ($\overline{\text{→L-Leu→L-Ileu→L-Leu→L-Ileu→L-Leu—}}$) was assigned to this substance from gas-chromatographic studies on the products of partial hydrolysis.

During our studies on the constituents of a mistletoe, *Viscum album* Linn. *var. coloratum* Ohwi, we isolated a new cyclic peptide and named it viscumamide.

The mistletoe which occurred on a hackberry (*Celtis sinensis* Pers. *var. japonica* Nakai) was collected and extracted with methanol in the usual way. The extract was fractionated into the neutral, basic, and acidic fractions. The neutral fraction was chromatographed on a column of activated alumina and gave a crystalline substance of mp 349.5—351 °C. This substance, viscumamide is optically active, $[\alpha]_D^{25}$ −49.1°. Elemental analyses and the mass spectrum (Fig. 1) show that viscumamide has a composition of $C_{30}H_{55}N_5O_5$ and a molecular weight of 565.8. The infrared spectrum of this substance (Fig. 2) shows absorption bands at

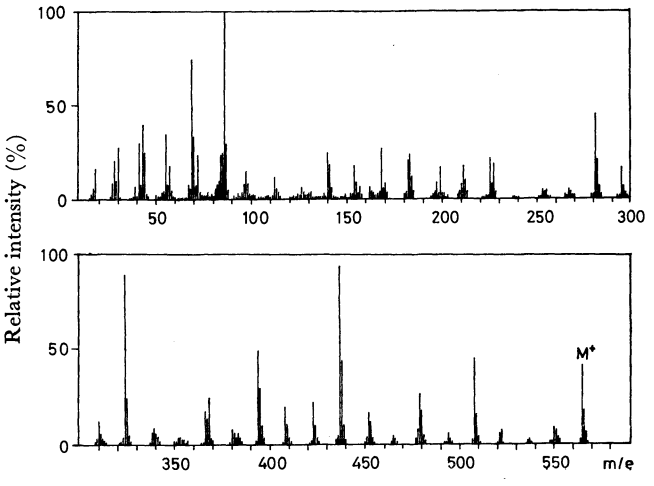

Fig. 1. Mass spectrum of viscumamide.

1) Part I: A. Sakurai and Y. Okumura, Reports of Faculty of Science, Shizuoka University, **6**, 63 (1971).

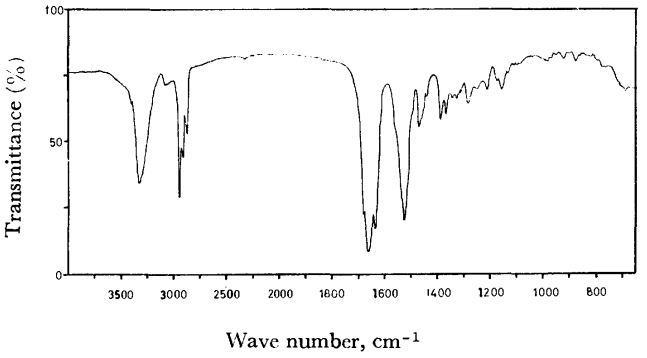

Fig. 2. Infrared spectrum of viscumamide.

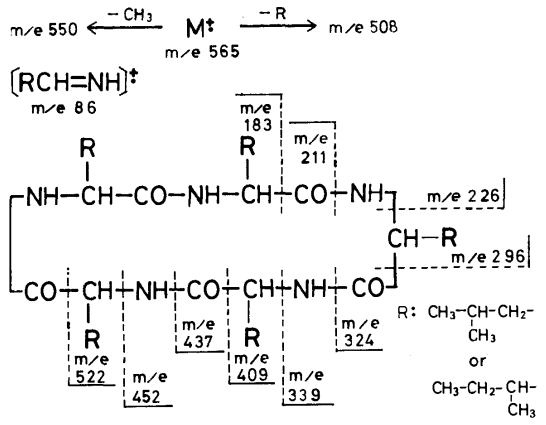
3315, 3050, 1658, and 1530 cm^{-1} ascribed to secondary amide groups, and shows no absorption band indicative of the existence of a free amino group or a carboxyl group. The potentiometric titration of viscumamide in a dilute hydrochloric acid solution with potassium hydroxide shows that the substance has no dissociating group. And this substance shows a negative reaction with ninhydrin and is sparingly soluble in numerous solvents. These results suggest a cyclic structure linked by five peptide bonds for viscumamide.

Hydrolysis of viscumamide with 6M hydrochloric acid according to the method described by Harfenist[2] gave a mixture of leucine (60.6%) and isoleucine (39.4%). Gas-chromatographic analysis of the hydrolysate after esterification and treatment with trifluoroacetic anhydride[3] also showed to be a mixture of leucine and isoleucine, and showed the absence of alloisoleucine.



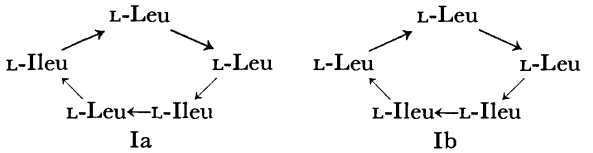
Scheme.

The mass spectrum of the homocyclic hexapeptide[4] has been investigated and shows that its fragmentation obeys the simple rules established with cyclodipeptides[5] as follows: the lower mass range is governed by the amine fragments ($RCH{=}\overset{+}{N}H_2$), while in the higher mass range expulsion of HNCO followed by several alternating losses of RCH=NH and carbon monoxide can be discerned. The mass spectrum of viscumamide shows fragmentations according to the fragmentation rules of these cyclopeptides. A primary process in the fragmentation of viscumamide is the loss of a HNCO fragment from $M^{\ddagger}$ (*m/e* 565) which gives a fragment ion peak at *m/e* 522. Then, the successive eliminations of RCH=NH (R=*i*-butyl or *s*-butyl) followed by loss of carbon monoxide occur, and intensive fragment ion peaks are formed at *m/e* 437, 409, 324, 296, 211, and 183, respectively. The amine fragments ($RCH{=}\overset{+}{N}H_2$) in the lower mass range appear at the same mass number, *m/e* 86, as the base peak. These results lead to a fragmentation sequence and a possible partial structure for viscumamide, which is shown in the scheme.

Table. Specific optical rotation of amino acids

Amino acid		$[\alpha]_D^{27}$	*c* in 20% HCl
Amino acids isolated from the hydrolysate of viscumamide	Leucine	+12.1°	0.40
	Isoleucine	+34.8°	0.39
Amino acids treated under the same conditions as the hydrolysis of viscuammide	L-Leucine	+13.2°	0.40
	L-Isoleucine	+33.8°	0.41

Specific optical rotation of leucine and isoleucine, which were isolated from the hydrolysate of viscumamide by chromatography on a column of Dowex 50×4, are summarized in the table and are in good agreement with the data of L-leucine and L-isoleucine, respectively, which were treated under the same conditions as the hydrolysis of viscumamide. These results indicate that this substance is constructed of three molecules of L-leucine and two molecules of L-isoleucine. And this leads to two possible structures, Ia and Ib for viscumamide.



Partial hydrolysis of viscumamide with alcoholic hydrochloric acid gave a mixture of five substances, which were analyzed by gas-chromatography after esterification and treatment with trifluoroacetic anhydride. The gas-chromatogram of this mixture showed five peaks.

The substances of the first and the second peaks in order of the retention time in the gas-chromatogram were identified as *n*-butyl *N*-trifluoroacetylisoleucinate and *n*-butyl *N*-trifluoroacetylleucinate, respectively. After being fractionated by gas-chromatography, the substances of the third, the fourth and the fifth peaks were hydrolyzed respectively with 6M hydrochloric acid. And each hydrolysate was analyzed by gas-chromatography in the form of *N*-trifluoroacetylated *n*-butyl ester. The gas-chromatograms of the hydrolysates showed that upon hydrolysis, both the substances of the third and the fourth peaks gave isoleucine and leucine in equal amounts, and that the substance of the fifth peak gave only leucine. By comparison with

2) E. J. Harfenist, *J. Amer. Chem. Soc.*, **75**, 5528 (1953).
3) G. W. Gehrke and W. M. Lamkin, *Chem. Eng. News*, **42**, 62 (1964).
4) K. Heyns and H.F. Grützmacher, *Ann. Chem.*, **669**, 189 (1963).
5) H. J. Svec and G. A. Junk, *J. Amer. Chem. Soc.*, **86**, 2278 (1964).

synthetic samples of dipeptide, the substances of the third, the fourth and the fifth peaks were identified as *n*-butyl *N*-trifluoroacetylisoleucylleucinate, *n*-butyl *N*-trifluoroacetylleucylisoleucinate and *n*-butyl *N*-trifluoroacetylleucylleucinate, respectively.

Thus, partial hydrolysis of viscumamide gave leucine, isoleucine, isoleucylleucine (II), leucylisoleucine (III), and leucylleucine (IV). The absence of isoleucylisoleucine (V) in the partial hydrolysate eliminates the validity of the structure Ib for viscumamide, and all experimental results described above support the structure of Ia for viscumamide.

Experimental

All melting points are uncorrected. Infrared spectrum was measured in KBr disk with a model EPI-G3 Hitachi spectrophotometer and gas-chromatogram was measured with a model K-53 Hitachi gas-chromatograph.

Extraction and Isolation of Viscumamide. The mistletoe (10 kg)[6] was extracted with methanol in the usual way, and the extract was concentrated under reduced pressure. The concentrate was dissolved in ethyl acetate and fractionated into the basic, acidic, and neutral fractions by shaking with dilute hydrochloric acid and then with sodium carbonate solution. The neutral fraction was concentrated to a syrup *in vacuo*. This syrup was digested with boiling *n*-hexane and the insoluble residue was collected by filtration. The faintly brown residue (18.2 g) was dissolved in hot methanol (100 ml), and activated alumina (50 g) was added to this solution and stirred. The suspension was evaporated to dryness *in vacuo*. The alumina which adsorbed the residue was placed on the top of a column of activated alumina (450 g), and the column was eluted with solvents. Elution with a mixture of ethyl acetate and ethanol and recrystallization from ethanol gave colorless needles, mp 349.5—351 °C (158 mg, 0.0158% from wet plant). $[\alpha]_D^{25}$ −49.1° (*c* 0.199, ethanol).

Found: C, 63.52; H, 10.07; N, 12.55%. Calcd for $C_{30}H_{55}N_5O_5$: C, 63.68; H, 9.80; N, 12.38%.

Potentiometric Titration of Viscumamide. Viscumamide (5.6 mg) in 0.01*M* hydrochloric acid (20 ml) was titrated with 0.1M sodium hydroxide using a Hiranuma Rat-1(P) autotitrator. The titration curve was identical with that of blank titration. This results showed that the substance has no dissociating group.

Hydrolysis of Viscumamide. Viscumamide (1.51 mg) in 6M hydrochloric acid (2 ml) was heated in a sealed tube at 110 °C for 120 hr according to the method described by Harfenist.[2] The reaction mixture was evaporated to dryness *in vacuo* and was dissolved in water. This solution was analyzed with a model KLA-3B Hitachi amino acid analyzer and showed to be a mixture of 0.91 mg of leucine (60.6%) and 0.59 mg of isoleucine (39.4%) at the recovery rate of 86.3%.

Separation of Leucine and Isoleucine from the Hydrolysate of Viscumamide. Viscumamide (100 mg) in 6M hydrochloric acid (20 ml) was hydrolyzed in the same manner as described above. The reaction mixture evaporated to dryness *in vacuo*, was dissolved in water (5 ml) and was submitted to chromatography on a column of Dowex 50 X 4 (150×2 cm, H^+ form, 200—400 mesh; developer: hydrochloric acid, pH value being changed continuously from 1M hydrochloric acid (1 l) to 12M hydrochloric acid (1 l). The fractions containing a mixture of leucine and isoleucine were evaporated to dryness *in vacuo*, and the residue of the mixture was chromatographed again in the same manner. The respective fractions containing pure leucine and isoleucine were evaporated to dryness *in vacuo*, and dissolved in ethanol (2 ml) and treated with ethyl acetate. The solutions were allowed to stand at 0 °C. Leucine hydrochloride (15 mg) and isoleucine hydrochloride (13 mg) were obtained as colorless powder.

Specific rotations of these amino acid hydrochlorides were measured in 20% hydrochloric acid, and the data were summarized in the table.

Preparation of Amino Acids for the Measurement of Specific Rotation. L-Leucine and L-isoleucine were respectively treated with 6M hydrochloric acid in the same manner as described above. The solutions were evaporated to dryness *in vacuo*. The residue was dissolved in ethanol and treated with ethyl acetate. The specific rotations of the resulted L-leucine hydrochloride and L-isoleucine hydrochloride were measured and the data were summarized in the table.

Preparation of L-Isoleucyl-L-Leucine (II). To a solution containing carbobenzoxy-L-isoleucine[7] (1.6 g) in dry chloroform (20 ml), dry triethylamine (0.6 g) was added at 0 °C and ethyl chloroformate (0.65 g) was added to this solution. After 30 min methyl L-leucinate dissolved in chloroform (10 ml) was added in about 20% excess of the calculated amount. The solution was allowed to stand at room temperature for 1 hr and then washed successively with 1M hydrochloric acid, sodium bicarbonate, and water. The solution was dried over sodium sulfate and evaporated to dryness *in vacuo*. The residue was dissolved in ether (10 ml) and treated with petroleum ether (15 ml, bp 50—80 °C). After being chilled, methyl carbobenzoxy-L-isoleucyl-L-leucinate (1.9 g) was obtained as colorless needles; 83% of the theoretical yield and mp 121.5—122 °C.

The above-described ester (1.5 g) in acetone (15 ml) was saponified by treating with 1M sodium hydroxide (4.2 ml) at room temperature for 45 min. The solution was acidified until acid to Congo red with concentrated hydrochloric acid and was concentrated *in vacuo*. Then the product was extracted with ethyl acetate and the extract was dried over sodium sulfate. By adding petroleum ether, carbobenzoxy-L-isoleucyl-L-leucine (1.2 g) was obtained as colorless crystals; 85% of the theoretical yield and mp 130—131 °C (lit,[8] mp 130—131 °C).

The carbobenzoxydipeptide (500 mg) was hydrogenated in methanol (6 ml) containing water (0.30 ml) and glacial acetic acid (0.30 ml) in the presence of palladium black. The catalyst was removed by filtration and the filtrate was concentrated *in vacuo* with repeated additional methanol. Ether was added to complete the crystallization. After recrystallization from methanol–water, L-isoleucyl-L-leucine (243 mg)was obtained as colorless needles; 71% of the theoretical yield and $[\alpha]_D^{18}$ −11° (*c* 1, 1M sodium hydroxide).

Found: C, 58.71; H, 10.02; N, 11.36%. Calcd for $C_{12}H_{24}N_2O_3$: C, 58.99; H, 9.90; N, 11.47%.

Preparation of L-Leucyl-L-isoleucine (III). L-Leucyl-L-isoleucine was prepared in 58% yield in the same manner as described above *via* methyl carbobenzoxy-L-leucyl-L-isoleucinate, colorless needles, mp 64.5—65.5 °C (lit,[9] mp 64—65 °C) and carbobenzoxyl-L-leucyl-L-isoleucine, colorless crystals, mp 99—101 °C (lit,[10] mp 101—101.5 °C) from carbo-

Preparation of L-*Isoleucyl*-L-*isoleucine (V).* L-Isoleucyl-L-isoleucine was prepared in 63% yield in the same manner as described above *via* methyl carbobenzoxy-L-isoleucyl-L-isoleucinate, colorless needles, mp 132—132.5 °C and carbobenzoxy-L-isoleucyl-L-isoleucine, colorless crystals, mp 120.5—122°C from carbobenzoxy-L-isoleucine[7] (1.6 g) and methyl L-isoleucinate (1.0 g); colorless needles, $[\alpha]_D^{20}$ +7° (*c* 0.1, water).

Found: C, 55.05; H, 9.79; N, 10.79%. Calcd for $C_{12}H_{24}N_2O_3 \cdot H_2O$: C, 54.94; H, 9.99; N, 10.68%.

Preparation of N-*Trifluoroacetylated Amino Acid* n-*Butyl Esters and* N-*Trifluoroacetylated Dipeptide* n-*Butyl Esters.* These substances were prepared by a modification of the procedure described by Gehrke and Lamkin.[3] One mg of amino acid or dipeptide was treated with methanol (1 ml) saturated with hydrogen chloride at room temperature for 4 hr. The reaction mixture was evaporated to dryness *in vacuo*, and the residue was dissolved in *n*-butanol (1 ml) saturated with hydrogen chloride. And then the mixture was heated in a sealed tube at 120 °C for 2 hr. After the solvent was removed *in vacuo*, the resulted *n*-butyl ester was treated with trifluoroacetic anhydride (1 ml) in dichloromethane (1 ml) at room temperature for 15 min. After the solvent was removed *in vacuo*, the residue was dissolved in dichloromethane and was submitted to gas-chromatography.

Gas-Chromatogram of the Hydrolysate of Viscumamide. The hydrolysate of viscumamide was esterified and was treated with trifluoroacetic anhydride in the same manner as described above. The resulted *N*-trifluoroacetylated amino acid *n*-butyl esters showed the identity with authentic *n*-butyl *N*-trifluoroacetylleucinate and *n*-butyl *N*-trifluoroacetylisoleucinate, but not with authentic *n*-butyl *N*-trifluoroacetylalloisoleucinate in gas-chromatography (column: 3 mm×4 m stainless steel column, stationary phase; 20% diethylene glycol adipate on Celite 545, column bath temperature; 175 °C, carrier gas; He, 20 ml/min). The retention times of *n*-butyl *N*-trifluoroacetylleucinate, *n*-butyl *N*-trifluoroacetylisoleucinate and *n*-butyl *N*-trifluoroacetyl-alloisoleucinate were 31.6, 25.6, and 24.2 min, respectively.

Partial Hydrolysis of Viscumamide. Viscumamide (10 mg) in a mixture of 6M hydrochloric acid (10 ml) and ethanol (10 ml) was refluxed for 4 hr. After being evaporated to dryness *in vacuo*, the hydrolysate was esterified and treated with trifluoroacetic anhydride in the same manner as described above. The resulted *N*-trifluoroacetylated amino acid *n*-butyl esters and *N*-trifluoroacetylated dipeptide *n*-butyl esters were submitted to gas-chromatography (column; 3 mm×2 m stainless steel column, stationary phase; 20% diethylene glycol adipate on Celite 545, column bath temperature; 200 °C, carrier gas; He, 40 ml/min) and fractionated. The chromatogram of this mixture showed five peaks and the retention times of these peaks were 1.0, 1.2, 20.4, 22.1, 23.5 min. The fractions of the first and the second peaks in order of the retention time showed the identity with authentic *n*-butyl *N*-trifluoroacetylisoleucinate and *n*-butyl *N*-trifluoroacetylleucinate, respectively. The fraction of the third peak was hydrolyzed with 6M hydrochloric acid, and then was esterified and treated with trifluoroacetic anhydride in the same manner as described above. The reaction mixture showed the identity with a mixture (1 : 0.99) of authentic *n*-butyl *N*-trifluoroacetylisoleucinate and *n*-butyl *N*-trifluoroacetylleucinate in gas-chromatography. The fraction of the fourth peak was treated in the same manner as the fraction of the third peak and showed the identity with a mixture (0.96: 1) of authentic *n*-butyl *N*-trifluoroacetylisoleucinate and *n*-butyl *N*-trifluoroacetylleucinate. The fraction of the fifth peak was treated in the same manner and showed the identity with only authentic *n*-butyl *N*-trifluoroacetylleucinate. And the fractions of the third, the fourth and the fifth peaks showed to be *n*-butyl *N*-trifluoroacetylisoleucylleucinate, *n*-butyl *N*-trifluoroacetylleucylisoleucinate and *n*-butyl *N*-trifluoroacetylleucylleucinate, respectively, by gas-chromatographic comparison with the synthetic samples.

The authors wish to express their thanks to Professor Yoshimasa Hirata of Nagoya University for the measurement of mass spectrum, Dr. Takayuki Naito of Bristol-Banyu Research Institute for microanalyses and Mr. Koichi Mochizuki of Japan Spectroscopy Co. Ltd. for the measurement of specific rotation.

Crystal and Molecular Structure of ω-Amino Acids, ω-Aminosulfonic Acids and Their Derivatives. III. The Crystal and Molecular Structure of γ-Guanidino-β-hydroxypropane Sulfonic Acid

Yang Bae KIM, Akio WAKAHARA, Takaji FUJIWARA, and Ken-ichi TOMITA
Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka 560
(Received December 28, 1972)

γ-Guanidino-β-hydroxypropane sulfonic acid $C_4H_{11}O_4N_3S$ crystallizes in the monoclinic space group $P2_1/c$, with four formula units in a unit cell of dimensions, $a=7.44$, $b=9.89$, $c=11.11$ Å and $\beta=97.75°$. The crystal structure was determined by the heavy atom method and refined by block-diagonal least-squares to an R-value of 0.12 using intensity data collected photographically. The molecule takes the zwitterionic form, $(NH_2)_2{}^+CNHCH_2CH(OH)CH_2SO_3{}^-$. The skeletal conformation of the molecule is planar *trans* zigzag. The molecules are held together in the crystal by a three-dimensional network of NH···O and OH···O hydrogen bonds.

γ-Guanidino-β-hydroxypropane sulfonic acid (GGBOPSA) is one of the derivatives of chemical transmitter in the central nervous system[1-3] such as γ-aminobutyric acid (GABA), γ-amino-β-hydroxybutyric acid (GABOB), homotaurine and taurine. This work is a part of a series of structural studies on the derivatives of the above compounds. Details of action mechanisms are not clear. However, it was reported that guanidino derivatives of ω-aminosulfonic acid such as GGBOPSA and γ-guanidinopropane sulfonic acid (GGPSA) act as a depressant for the lowering of blood pressure, whereas homotaurine and γ-amino-β-hydroxypropane sulfonic acid (GABOPSA) show an excitatory action for it.[4] It would be of great interest to elucidate the correlation between structural specificities and biological implications of these compounds.

Some structural features of GGBOPSA and its related compounds have been reported.[5] This paper deals with the precise structure analysis of GGBOPSA and comparison of the molecular structure with that of the related compounds.

Experimental

A racemic sample of GGBOPSA (supplied by Prof. S. Tsunoo, Medical School of Showa University) was recrystallized from water at room temperature as colorless, transparent prisms elongated along the a-axis. The space group and cell constants were determined from Weissenberg and precession photographs. The crystal data are presented in Table 1. Intensity data of 1452 independent reflections around a and b-axes were collected from equi-inclination Weissenberg photographs by the multiple film method with Cu$K\alpha$ radiation and estimated by visual comparison with a calibrated scale. Lorentz, polarization and spot-shape corrections were applied, but no absorption correction was made. The approximate scale factor and over-all temperature factor were calculated by Wilson's method.

TABLE 1. CRYSTAL DATA OF GGBOPSA

Molecular Formula: $C_4H_{11}O_4N_3S$	M.W.=197.21
Colorless transparent prism, Monoclinic system	
$a=7.44\pm0.02$ Å	$b=9.89\pm0.02$ Å
$c=11.11\pm0.03$ Å	$\beta=97.75\pm0.5°$
Volume of the unit cell, 810.02 Å^3	
Density (by flotation) 1.621 g cm^{-3}	
Density(calculated) 1.617 g cm^{-3}	
$Z=4$	$F(000)=416$
Absent spectra: $h0l$ when $l=2n+1$	
$0k0$ when $k=2n+1$	
Space group, $P2_1/c$	

Structure Determination and Refinement

The structure was solved by the usual heavy-atom procedure. By interpretation of high peaks on sharpened Patterson function, the coordinates of sulfur atom were easily determined. From the Fourier synthesis with only the heavy atom phase, all the non-hydrogen atoms could be found. R-index, $R=\sum||F_o|-|F_c||/\sum|F_o|$, was reduced from 0.32 to 0.18 by block-diagonal least-squares refinement with isotropic temperature factors, the unit weight being applied for the non-zero reflections. Refinement was continued with anisotropic temperature factors and R-index was reduced to 0.14. The used anisotropic temperature factors are of the form: $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$.

A difference Fourier synthesis calculated in this stage revealed all the hydrogen atoms which were included in the further refinement. The final R-value was 0.12. The used atomic scattering factors were taken from *International Tables for X-ray Crystallography*.[6]

All the computations were carried out on NEAC 2200-500 and 2200-700 machines at this University and on FACOM 230-60 at the University of Kyoto, using the programs of UNICS system.

Results and Discussion

The final positional and thermal parameters are listed in Tables 2-a and b, together with their estimated

standard deviations. The observed and calculated structure factors are listed in Table 3. Figure 1 shows bond distances and angles with the numbering of atoms. The bond lengths and angles are compared in Table 4 with those of other compounds such as L-arginine dihydrate,[7] taurine,[8,9] homotaurine,[10] GABA,[11] GABOB,[12] and γ-guanidinobutyric acid hydrochloride (GGBA·HCl).[13] Similarly, in the cases of taurine and homotaurine, the guanidyl group is protonated by one hydrogen atom of the sulfonate group, the three S–O bonds of the resultant $-SO_3^-$ group being equivalent in the state of resonance. The average O–S–O and C–S–O angles in the sulfonate group are 112.1 and 106.7°, respectively. Deviations from the tetrahedral angles are probably due to the repulsion between the adjacent oxygen atoms which lie at the short contact distances of 2.42 Å as discussed in taurine by Sutherland and Young.[8]

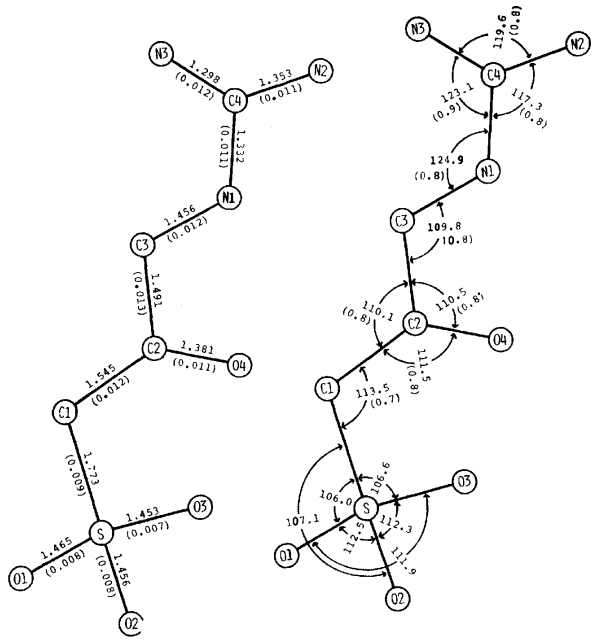

Fig. 1. Bond lengths (Å) and angles (°) of GGBOPSA. Estimated standard deviations are listed in the parentheses and those of angles around sulfur atom are 0.5°.

The guanidyl group is planar and the equation of the least-squares plane through the four atoms, N(1), C(4), N(2), and N(3), is

$$-0.51539X + 0.47909Y - 0.71053Z = -4.76419.$$

Deviations of the individual atoms from this plane are N(1): −0.0027, C(4): 0.0081, N(2): −0.0026 and N(3): −0.0028 Å. The dihedral angle between this plane and that passing through C(1)–C(2)–C(3) is 27.4°. In L-arginine dihydrate,[7] the deviations of the individual atoms from the least-squares plane of guanidyl group are N(1): −0.0005, C(4): 0.0015, N(2): −0.0005, and N(3): −0.0005 Å. Thus, the planarity of the guanidyl group in GGBOPSA is in good agreement with that of L-arginine dihydrate. All the C–N bond distances of the guanidyl group are halfway between the value of single bond (1.47 Å) and that of double bond (1.24 Å) proposed by Shomaker and

Stevensen,[14] the average being 1.328 Å. We see from Table 4 that C–N distances of the guanidyl group differ (greater than 2σ) from those of GGBA·HCl. This difference is probably due to the difference of molecular environments, *i.e.*, GGBOPSA molecule is in free state while GGBA molecule is in hydrochloride salt state. Three C–N bonds of GGBOPSA have somewhat double bond character and calculation by Pauling's method[15] indicates that the double bond characters of C(4)–N(1), C(4)–N(2), and C(4)–N(3) bonds are 32, 25, and 43%, respectively, whereas the corresponding values for GGBA·HCl are 35, 29, and 36%.[13]

It is of interest to note that C(2)–O(4) distance of the hydroxyl group is 1.381 Å, significantly shorter than that of found in GABOB (1.425 Å) which is normal C–O single bond. Other bond distances and angles in the molecule are quite normal.

The skeletal conformation of GGBOPSA molecule (Fig. 2) is of *trans* zigzag form as found in GGBA·HCl, GABA·HCl, GABOB, and homotaurine. The torsion angles around C(1)–C(2) and C(2)–C(3), which are in the skeletal conformation of the molecules, are both almost 180° in homotaurine, GABA·HCl, and GGBA·HCl. On the other hand, the corresponding values of GGBOPSA are 161.9 and 177.8°, and those of GABOB, 173.7 and 168.8°, respectively. The effect of β-hydroxyl group in the molecule might be one of the factors influencing the restricted conformation and

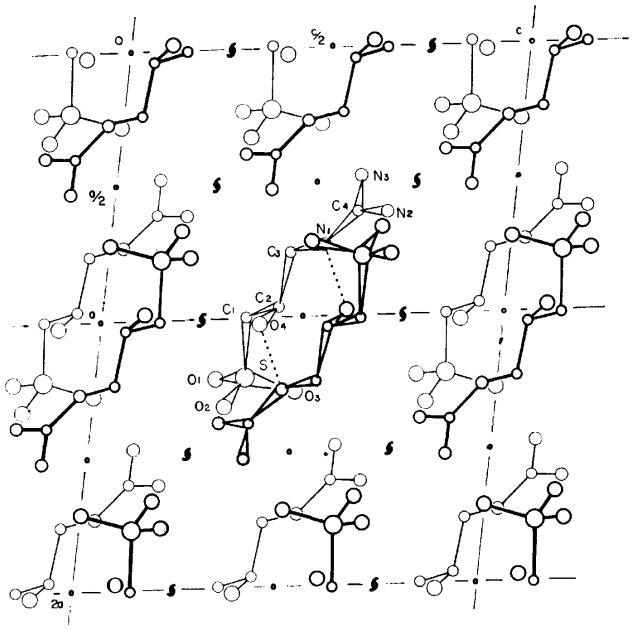

Fig. 3. The crystal structure projected along *b*-axis.

also the physiological action. Torsion angles of sulfonate group have similar values to those of homotaurine. The torsion angle around C(3)–N(1) is 150.5°, which is similar to 162.0° of L-arginine dihydrate[7] calculated.

Similarly in the case of L-arginine dihydrate, GGBOPSA molecule occurs in zwitterionic form, $(NH_2)_2^+$-$CNHCH_2CH(OH)CH_2SO_3^-$.

Distances and angles of hydrogen bonds are listed in Table 5. As shown in Fig. 3, *d*- and *l*-forms of GGBOPSA molecules were dimerized through the N(1)–H···O(4) hydrogen bonds (2.907 Å) related by a center of symmetry. This cyclic *d*–*l*, dimerization can be also seen in GABOB,[12] which were dimerized through OH···O hydrogen bond between β-OH group and oxygen atom of carboxyl group related by a center of symmetry. In these cases, however, the oxygen atom, O(4), of β-hydroxyl group of GGBOPSA molecule takes part in the intermolecular hydrogen bond system as an acceptor, while β-OH of GABOB is used to form intra- and intermolecular bifurcated hydrogen

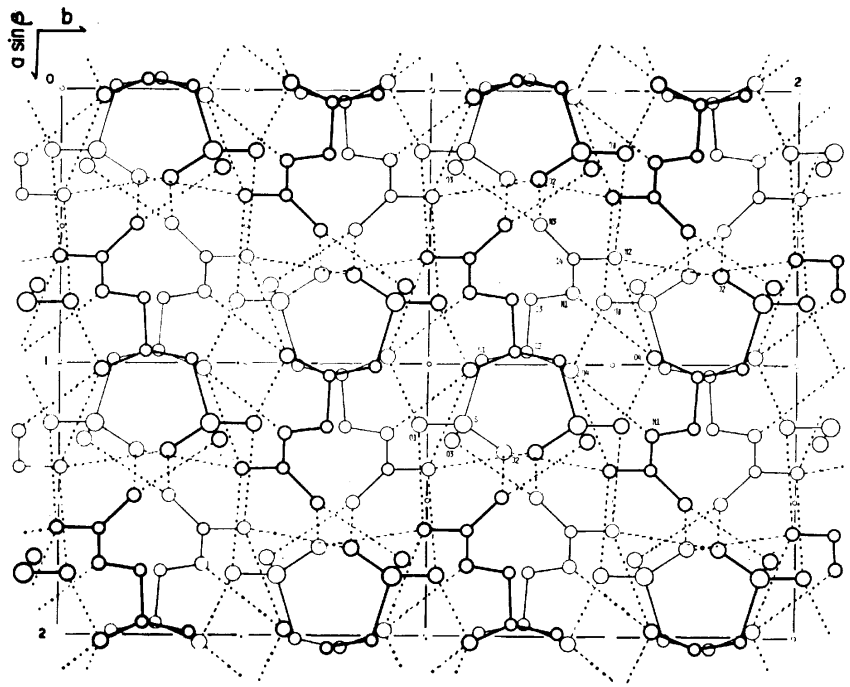

Fig. 4. The crystal structure projected along *c*-axis. The broken lines indicate the hydrogen bonds.

bond as a donor.

The crystal structure projected downward to *c*-axis is shown in Fig. 4. Among the hydrogen atoms in the molecule, all the feasible ones are utilized to form hydrogen bonds and the molecules are held together by three-dimensional network of NH···O and OH···O hydrogen bonds. The guanidyl group is connected with three neighboring molecules by six hydrogen bonds, the sulfonate group acting as an acceptor of five hydrogen bonds, and oxygen atom of hydroxyl group as both acceptor and donor. The distances of N(2) to O(2) and to O(4) by a translational operation (2.0-*x*, 1.0-*y*, 1.0-*z*) are 2.994 and 3.231 Å, respectively, H(8) atom being located on a line bisecting these two directions. Thus, the H(8) atom seems to contribute to form a bifurcated hydrogen bond. On the other hand, homotaurine molecules are jointed with each other with three NH···O hydrogen bonds to form a three-dimensional network, while in taurine, there are three NH···O intermolecular hydrogen bonds and one intramolecular hydrogen bonding. The intermolecular contacts between adjacent molecules are kept by normal van der Waals distances.

This work was partly supported by a research grant from the Ministry of Education.

Crystal and Molecular Structure of ω-Amino Acids, ω-Amino Sulfonic Acids and Their Derivatives. IV. The Crystal and Molecular Structure of γ-Aminobutyric Acid (GABA), a Nervous Inhibitory Transmitter

Ken-ichi TOMITA, Hideko HIGASHI, and Takaji FUJIWARA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka 560

(Received December 28, 1972)

The structure of γ-aminobutyric acid (GABA), $C_4H_9NO_2$, was determined by single-crystal X-ray diffraction analysis using the data collected on a four-circle diffractometer. The compound was crystallized from an aqueous ethanol solution as needles of the monoclinic space group $P2_1/c$ with four molecules in the following unit cell; $a=7.193$, $b=10.120$, $c=8.260$ Å and $\beta=111.05°$. The structure was solved directly by a symbolic addition method and refined by a least-squares procedure. The final R is 9.3%. The molecular geometry is not a planar *trans*-zigzag configuration as found in γ-guanidinobutyric acid hydrochloride or homotaurine, but a *gauche* configuration with respect to $C_\alpha-C_\beta$ bond. The expected zwitterionic structure is evident from the locations of the hydrogen atoms in a difference Fourier map, each molecule being connected with three N–H···O hydrogen bonds to form a three-dimensional network.

Unusual amino acids, in particular ω-amino acids, are of interest with respect to their characteristic biological actions. γ-Aminobutyric acid (GABA) occurs especially in the mammalian brain[1] where it is enzymatically produced.[2] By virtue of its potent synaptic effect and other extensive evidence, GABA may play the physiological role of "inhibitory transmitter" in the mammalian central nervous system.[3-7]

It seems important to determine the molecular structure of such biologically active compounds and to compare it with that of other related derivatives in order to elucidate the close relation between molecular conformation and its specific physiological action.

The crystal data and some structural features of GABA and its derivatives were reported briefly.[8] As a part of this project, the details of structure analysis of homotaurine and γ-guanidinobutyric acid hydrochloride and hydrobromide were recently given.[9-10] This paper deals with precise analyses of crystal and molecular structure of γ-aminobutyric acid.

Experimental

Commercial γ-aminobutyric acid (GABA) was used, colorless needle-like crystals elongated along *a* axis being obtained by slow evaporation of an aqueous ethanol solution. They were somewhat hygroscopic and were used for X-ray investigation on being sealed in a quartz capillary together with a few piece of ssilica gel. Oscillation and Weissenberg photographs showed the crystals to be monoclinic. Systematic extinctions, $0k0$ absent with k odd and $h0l$ absent with l odd, indicated the space group to be $P2_1/c$. Unit-cell dimensions, $a=7.193(4)$, $b=10.120(5)$, $c=8.260(5)$ Å and $\beta=$

111.05(7)° were determined on a diffractometer. The calculated density corresponding to four molecules in the unit cell is 1.226 g·cm^{-3} and in good agreement with the observed density of 1.225 g·cm^{-3}, determined by flotation in a mixture of benzene and carbon tetrachloride. Using a cuboid crystal with an edge of 0.3 mm, all the intensities of 1243 independent reflections within $2\theta<55°$ were measured on a Rigaku-Denki computer-controlled four-circle diffractometer with Zr-filtered MoK_α radiation. The ω-2θ scanning was employed at a rate of 2° per min, and backgrounds were measured for 10 sec at each start and end point of the scan interval. Lorentz and polarization corrections were applied, but neither extinction nor absorption corrections were considered. The observed structure factors were adjusted to their absolute values by Wilson's method and then normalized structure factors $|E|$ were obtained.

Structure Determination and Refinement

The crystal structure of GABA was determined by direct phase determination using the symbolic addition procedure.[11] From a $\sum_2$ list for 169 reflections with $|E|\geqq1.5$ and with probability greater than 97%, the signs of three reflections were chosen for specifying the origin and four symbols for initiating the sign determinations (Table 1). The signs were determined as follows by many different combinations in $\sum_2$ interactions; A=B=C=− and D=+. An E map calculated with the signs of 161 reflections revealed the locations of all atoms except hydrogen atoms in the unit cell. Refinement of the structure was carried out using a block-diagonal least-squares program (BLLS) with unit weight for non-zero reflections. Atomic scattering factors were taken from "International Tables for X-ray Crystallography" (1962). Application of isotropic temperature factor to non-hydrogen atoms decreased the R index ($R=\sum||F_o|-|F_c||/\sum|F_o|$) to 0.21 after five cycles. The following five cycles of anisotropic refinement lowered R to 0.13. A difference Fourier synthesis at this stage was calculated and all hydrogen atoms were shown in this map. The final cycles of refinement including the hydrogen atoms with isotropic temperature factors reduced the R index to 0.093 (0.127 including $|F_o|=0$). The final positional and thermal parameters are given in Table 2, and the observed and calculated structure factors in Table 3.

All the numerical computations were carried out on NEAC 2200-500, NEAC 2200-700 computers in the computing center of this University, and FACOM 230-60 in the data processing center of Kyoto University, using the programs written by Dr. Tamaichi Ashida and by the authors.

Table 1. Starting set for the symbolic addition procedure

8	3	−7	D	3.963

Results and Discussion

The bond lengths and angles of GABA are shown in Figs. 1(a) and 1(b), respectively. The C4–N bond length of 1.469 Å is very close to the sum of each covalent bond radius for the carbon and nitrogen atom (1.47 Å), being a little less than the average value of 1.487 Å found in α-amino acids.[12] The

GABA molecule has the zwitterionic structure as well as γ-amino-β-hydroxybutyric acid[13] or α-amino acids so far investigated. The molecular projections of GABA around the C2–C3 (C_α–C_β) and C1–C2 bonds are shown in Fig. 2. Three hydrogen atoms attached to the amino nitrogen atom are shown clearly in the difference Fourier map. This indicates that the rotation around the N–C4 bond is so restricted as having the most stable *trans* configuration (Fig. 2). The GABA molecule has no planar zigzag configuration but a somewhat twisted structure, *i.e.*, the C3–C4 bond has the *gauche* configuration to the C1–C2 bond with respect to the C2–C3 bond, the torsion angle around the C2–C3 bond being 73.6°. On the other hand, the carboxyl C1–O1 and C1–O2 bonds have nearly the *trans* and *cis* configuration to the C2–C3 bond with respect to the C1–C2 bond, and the torsion angles are 167.3 and 11.9°, respectively. It is of particular interest that the twisted molecular structure of GABA in the present work and the extended *trans*-zigzag one

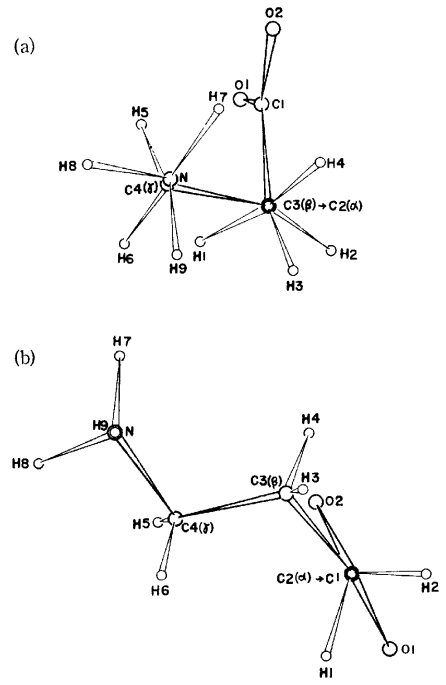

Fig. 2. Projections of the molecule. (a) around the C3–C2 (C_β–C_α) bond, (b) around the C2–Cl bond.

in GABA hydrochloride[14] are also found in bis(γ-aminobutyrato)copper(II)[15] and its dihydrate,[15] respectively. Three atoms, Cl, O1, and O2, of the carboxyl group and the C2 atom are exactly in one plane (mean deviation from the least-squares plane is 0.001 Å), another plane being formed by the C2, C3, C4, and N atoms with the mean deviation of 0.03 Å. The dihedral angle between these two planes is 79.1°, which coincides well with 68.4° in bis(γ-aminobutyrato)-copper(II). Similar dihedral angles between the plane of carboxyl group and that containing C_α, C_β, and N atoms have been observed in β-alanine (83.8°),[16] bis-β-alaninatocopper(II) hexahydrate (about 70°)[17] and bis(β-amino-*n*-butyrato)copper(II) dihydrate (about 67°).[18]

The GABA molecule is thought to be like a chemical condenser which is composed of the amino terminal with a positive charge, the carboxyl end with a negative charge and three non-conductive methylene linkages connecting both ends. It is also of interest to assume that the GABA molecule is a biological on-off switch which works with the change of surrounding environments such as pH, the concentration of Na^+ and Cl^- ions and so on. GABA is well-known as a chemical transmitter in the central nervous system. Which of the two observed configurations around the C2–C3 bond is the active form is not yet certain but correlation between configuration and charge of the GABA molecule, such as monovalent cationic, monovalent anionic and zwitterionic, is probably substantial for the interaction to its receptor. The intramolecular distances between the nitrogen and oxygen atoms are listed in Table 4 together with those of the related compounds.

The crystal structure of GABA is shown in projection along the crystallographic *b* and *c* axes in Figs. 3 and 4, respectively. Distances and angles about the hydrogen

Table 4. Intramolecular distances in GABA and related compounds

From atom	To atom	Distance (in Å)	Compound
O1	N	5.612 (0.006)[a]	GABA (this work)
O2	N	4.238 (0.007)	
O1	N	6.052 (0.007)	γ-Amino-β-hydroxybutyric acid[13]

O2	O2 (III)	3.867 (0.010)

a) See symmetry codes in Table 5.
b) Estimated standard deviations are in parentheses.

bonds are listed in Table 5 and intermolecular distances less than 4.0 Å in Table 6. GABA molecules in the crystal are connected by three-dimensional networks of NH···O hydrogen bonds. Each hydrogen bond has nearly equal distance, three C4–N···O angles being also almost tetrahedral. The O2 atom is the acceptor of two hydrogen bonds whereas the O1 atom accepts only one hydrogen bonding. There are no unusual short contacts in this crystal, the shortest one of 3.346 Å being found between the N and O2 atoms.

The authors wish to thank the late Professor Masaji Tomita, Kobe Women's College of Pharmacy, for his valuable advice and continuous encouragement during the course of this work. The investigation was partly supported by a research grant from Ministry of Education.

The Electrochemical Fluorination of Benzenes and Pyridines[1)]

Yoshio INOUE,* Shunji NAGASE, Kazuo KODAIRA, Hajime BABA, and Takashi ABE
Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya 462

(Received January 25, 1973)

The electrochemical fluorination of several aromatic compounds (benzene, fluorobenzene, chlorobenzene, *m*-dichlorobenzene, anisole, *o*-chloroanisole, thiophenol, *p*-chlorothiophenol, *m*-thiocresol, 2-chloropyridine, and 3-chloropyridine) has been carried out. Perfluorocyclohexane was the principal product from benzene and fluorobenzene. In addition, chloro-derivatives of perfluorocyclohexane were produced from chlorobenzenes. Anisoles gave fully-saturated perfluoroethers, together with cleaved products. Extensive cleavage was observed in the fluorination of thiophenols and chloropyridines, and fluorocarbons and sulfur hexafluoride or nitrogen trifluoride were characteristic products. New compounds were also formed, trifluoromethyl 2-chlorodecafluorocyclohexyl ether from *o*-chloroanisole, and 3-chlorodecafluoropiperidine and 2-chloroundecafluoropentane from 3-chloropyridine.

Although a number of papers dealing with the fluorination of aromatic compounds with elemental fluorine[2)] and with higher valency metallic fluoride[3)] have appeared, works on the electrochemical fluorination of these compounds are rare. A patent[4)] mentioned the electrochemical fluorination of several aromatic compounds, but no details were given. Shepard

and Dannels,[5] and Kokhanov and Per'kova[6] have discussed a fluorine-containing polymer formed by the electrochemical fluorination of benzene. The difficulty of the fluorination of benzene itself by the electrochemical process has been described.[7] Soviet chemists have reported on the electrochemical fluorination of fluorinated anisole[8] and *N*,*N*-dimethylaniline,[9] but they have also described their failure in the fluorination of unfluorinated anisole.[8]

The present paper will deal with the electrochemical fluorination of benzene and its derivatives in order to clarify their behavior in the fluorination. For the sake of comparison with the fluorination of chlorobenzenes, the fluorination of chloropyridines was also included in the present work. Pyridine has often been subjected to electrochemical fluorination,[10] but no works on chlorinated pyridines have been reported.

The reaction conditions for the electrochemical fluorination of benzene and its derivatives, and pyridines, and the results obtained, are shown in Tables 1 and 2 respectively. Benzene was only slightly soluble in anhydrous hydrogen fluoride,[11] and the resulting solution did not have enough electric conductivity; therefore, its electrochemical fluorination required the use of a conductivity additive, sodium fluoride.

From benzene, perfluorocyclohexane, which consitituted a high percentage of the product composition, and perfluoro(methylcyclopentane) were produced, together with fragmented products. A considerable amount of tarry material in the cell and on the electrodes was also found. No simple fluorinated aromatic compound could be isolated. The formation of perfluorocyclohexane and perfluoro(methylcyclopentane) has also been reported in the electrochemical fluorination of 1,1-difluorocyclohexane.[7]

The mechanism for the fluorination of benzene to form perfluorocyclohexane may be of the free-radical type. The initial attack of the fluorine radical is presumably by direct addition to benzene nucleus to form the fluorocyclohexadienyl radical. This combines with the fluorine radical; the resulting intermediate is fluorinated further to yield hexafluorocyclohexane or a similar compound. The replacement of the hydrogens of the cyclohexane by fluorines follows to produce perfluorocyclohexane. The cleavage of the carbon-carbon bond probably occurs in this replacement stage by the energy which is liberated from the formation of the hydrogen-fluorine and carbon-fluorine bonds. Perfluoro(methylcyclopentane) may be yielded by the rearrangement of the carbon skeleton of partially-fluorinated cyclohexanes. The ease of the isomerization of the cyclohexane ring to methylcyclopentane has been established.[12]

No partially fluorinated products except trifluoromethane were obtained. Even if such compounds were formed, their amounts would be small and they would be dissolved in anhydrous hydrogen fluoride. The tarry material would be formed by radical mech-

Table 1. Conditions for fluorination

Run No.	Sample[a]	Voltage (V)	Electricity[b,c] passed (A. hr)	Procedure[d,e]
1	Benzene	5.2—9.0	64 (65)	A
2	Fluorobenzene	4.0—7.4	87	A
3	Chlorobenzene	4.8—6.1	94	A
4	*m*-Dichlorobenzene	4.9—5.8	106	A
5	Anisole	5.4—9.0	86 (74)	A
6	*o*-Chloroanisole	6.0—9.0	97 (85)	A
7	Thiophenol	5.0—6.3	131	B
8	*p*-Chlorothiophenol	6.2—6.8	131	B
9	*m*-Thiocresol	5.0—5.5	164	B
10	2-Chloropyridine	5.0—5.2	87	B
11	3-Chloropyridine	5.3—6.0	87	B

a) The amount of the starting material used was 0.20 mol except *o*-chloroanisole, 0.175 mol.
b) The amount of electricity supplied was 1.1 times of the theoretical one that was, as indicated below, assumed to be required to form perfluorocyclohexane from benzene and its derivatives, and undecafluoropiperidine from pyridines, respectively. For example,
$C_6ClH_5 + 18\,F \longrightarrow c\text{-}C_6F_{12} + 5\,HF + ClF$
$ClC_5H_4N + 16\,F \longrightarrow C_5F_{11}N + 4\,HF + ClF$
c) The anodic current density was adjusted as 1.2—1.5 A/dm^2; however, in runs 1, 5, and 6, the current block occurred. The numerical values in the parentheses shows the percentage of electricity used to the theoretical amount.
d) Cell temperature was kept at 5—8 °C.
e) A: sodium fluoride (10 g) was used; B: Carried out without using the additive.

a) In the calculation, the total number of mole of the products including fragmented ones was divided by the mole of starting material fed.
b) Expressed in mole percent.

anism: the addition of the fluorine radical to the benzene nucleus occurs, and the fluorohexadienyl radical thus formed would attack benzene to produce another radical; this process could be repeated and would ultimately result in the formation of a highly polymerized material.

Halobenzenes and anisoles also produced considerable amounts of a resinous material. These aromatic compounds, similar to benzene, seemed to have only a limited solubility in anhydrous hydrogen fluoride. Their fluorinations were carried out by the use of the conductivity additive. Fluorobenzene was converted into perfluorocyclohexane in a better yield than benzene was. Chlorobenzene gave chloroundecafluorocyclohexane,[13] in addition to perfluorocyclohexane, together with cleaved products. 1,3-Dichlorodecafluorocyclohexane[13] was produced from *m*-dichlorobenzene in a small yield. The fluorination of *m*-dichlorobenzene was carried out with some difficulty. Explosions often occurred in the reaction system. Among the compounds subjected to the present fluorination, *m*-dichlorobenzene appeared to have the least solubility in anhydrous hydrogen fluoride. The generation of free fluorine was presumably the cause of the explosion.

The ether linkage was relatively stable in the electrochemical fluorination, and anisole and *o*-chloroanisole gave fully-fluorinated derivatives which retained the original ether linkage. *o*-Chloroanisole yielded a new compound, trifluoromethyl 2-chlorodecafluorocyclohexyl ether, but the yield was low. From these results, it may be stated that the chlorine in the aromatic nucleus is retained in the electrochemical fluorination, and chlorinated polyfluorocyclohexyl derivatives are given.

In contrast to the behavior of the compounds described above, thiophenol, *p*-chlorothiophenol, *m*-thiocresol, 2-chloropyridine, and 3-chloropyridine gave an electro-conducting solution as would be expected by their basic character. Therefore, their fluorinations were accomplished without using the conductivity additive. These thiophenols and pyridines afforded the perfluorinated products and did not yield any tarry material.

However, extensive cleavage occurred at the site of the hetero-atoms, such as nitrogen or sulfur, resulting in the formation of nitrogen trifluoride or sulfur hexafluoride, along with fluorocarbons. These phenomena may be caused mainly by the weakness of the carbon-nitrogen and carbon-sulfur bonds, whose single-bond energies are 69.7 and 62.0 kcal/mol respectively (carbon-carbon bond energy, 83.1 kcal/mol).[14] As has been shown in connection with the electrochemical fluorination of amines,[15] the adsorption of the hetero-compounds at the active sites on the nickel anode may give the conditions for the preferential attack of fluorine on the hetero-atoms.

As the principal products, thiophenol and *m*-thiocresol afforded perfluorocyclohexane and perfluoro(methyl-

cyclohexane) respectively, in reasonable yields while *p*-chlorothiophenol yielded perfluorocyclohexane and chloroundecafluorocyclohexane. The formation of the perfluorocyclohexyl-[16] or chloropolyfluorocyclohexyl-derivative of sulfur hexafluoride could not be confirmed under the reaction conditions used. Chloropyridines yielded nitrogen trifluoride, perfluoropentane, and 1-chloro- or 2-chloroundecafluoropentane as the main products. 3-Chloropyridine gave a small amount of a new compound, 3-chlorodecafluoropiperidine.

Experimental

Materials and Apparatus. The starting materials subjected to the fluorination were all of a reagent grade. Their purities were confirmed by gas chromatography. Anhydrous hydrogen fluoride was more than 99.5% pure. The electrolytic cell used was the same as that described in a previous paper.[17] The product identifications and analyses were performed by means of gas chromatography (Shimadzu GC-2C model chromatograph) and IR spectroscopy (Hitachi EPI-S2 spectrometer), as before.[18] Mass spectrometry-(Hitachi RMU-7 spectrometer) was frequently used.

Procedure A (for a poor electro-conducting solution). As a typical example, the procedure for the fluorination of chlorobenzene (Run 3) will be described. In electrically-purified anhydrous hydrogen fluoride (1.28 l) in the cell, sodium fluoride (10 g) was dissolved. Then, while the current was being passed through the hydrogen fluoride solution, chlorobenzene (22.5 g, 0.20 mol) was charged in over a period of 2.5 hr by the use of a mechanical micro-pump.

The reflux condenser of the cell was kept at −15 °C. Helium (200 ml/min) was introduced through the bubbler placed at the bottom of the cell in order to agitate the solution and also to carry away the fluorinated products from the cell. In the begining of the electrolysis, the cell voltage was 4.8 V, with an anodic current density of 1.2 A/dm² (effective surface areas of the anodes and cathodes, 20 dm²), and the cell temperature was 6—8 °C; however, the voltage rose gradually until it reached 6.1 V at the end of the operation. The total amount of electricity supplied over the 4-hr period was 94 A·hr. The passing of the cold brine through the reflux condenser was stopped for the last 30 min of the electrolysis. The blowing of helium was continued for 2 hr after the electrolysis was over.

The fluorinated products evolving from the cell were passed through the sodium fluoride tubes[17] (for the removal of the hydrogen fluoride) and gas-washing bottles (for the removal of a small amount of oxygen difluoride); these bottles were filled with an aqueous solution of sodium sulfite containing a small amount of potassium iodide. The products were further guided to a series of cold traps kept in ice and in liquid nitrogen.

The products thus obtained were separated into a lower-boiling (0.7 g) and a higher-boiling (14.9 g) fraction in the usual manner. The former was analyzed by gas chromatography, using a silica gel column at 80 and 120 °C, with helium as the carrier gas. It consisted of carbon tetrafluoride, trifluoromethane, chlorotrifluoromethane, perfluoroethane, perfluoropropane, and traces of other compounds. These and the compounds described below were identified by a comparison of their IR spectra (and of their mass spectra if necessary) with those of authentic specimens.

The higher-boiling portion was analyzed with a column packed with 30% of Daifl oil #50 (Daikin Industries Co.) on Chromosorb P-AW, 60—80 mesh (Johns-Manville Co.), at room temperature. It consisted of perfluorobutane, perfluoropentane, perfluoro(methylcyclopentane), perfluorohexane, perfluorocyclohexane, chloroundecafluorocyclohexane, and small amounts of unidentified compounds. The product distribution (mol%) and total yield are shown in Table 2, Run 3.

Most of the hydrogen fluoride used was distilled off from the cell, and the residual solution, containing much tarry material, was extracted with 1,1,2-trichloro-1,2,2-trifluoroethane and with ethyl ether; however, from the extract no pure individual compound was isolated.

By means of Procedure A, trifluoromethyl 2-chlorodecafluorocyclohexyl ether was obtained from *o*-chloroanisole (Run 6), although in a low yield (2.3%), together with cleaved products. The ether was a colorless liquid with a bp of 104 °C, n_D^{20} 1.3052. Found: Cl, 9.4; F, 64.0%; mol wt (mass), 382. Calcd for $C_7ClF_{13}O$: Cl, 9.3; F, 64.6%; mol wt, 382.5. The mass spectrum had peaks at 382 [M], 347 [M−Cl], 313 [M−CF_3], 247 [C_5F_9O], and 247 [C_5F_8Cl].

Procedure B (for an electro-conducting solution). As a representative example, the procedure for the fluorination of 3-chloropyridine (Run 11) will be described below. Several minor points were different from Procedure A. 3-Chloropyridine (22.7 g, 0.20 mol) was fed into the cell by the use of the micro-pump. The electrolysis was carried out with the anodic current density of 1.3 A/dm², the cell voltage of 5.3—6.0 V, and the cell temperature of 6 °C. Helium (200 ml/min) was blown into the cell.

The gases evolving from the cell were led to the sodium fluoride tubes, to gas-washing bottles filled with an aqueous solution of potassium hydroxide, to traps (Trap A) immersed in ice and in CO_2–acetone, to gas-washing bottles filled with an aqueous solution of sodium sulfite containing potassium iodide, and finally to traps (Trap B) immersed in ice and in liquid nitrogen. These were connected in a series. A total of 87 A·hr was consumed over a 3.5-hr period. Passing the cold brine through the reflux condenser was stopped for the last 30 min of the electrolysis, and the blowing of helium was continued for 1.5 hr after the electrolysis was over.

The product (11.0 g) obtained in Trap A was analyzed by means of a column packed with 30% of Daifl oil #50 on Chromosorb P-AW and one packed with 30% of dinonyl phthalate on Chromosorb P-AW at room temperature. It contained perfluoropentane, undecafluoropiperidine, and 2-chloroundecafluoropentane, together with small amounts of unidentified compounds. 3-Chlorodecafluoropiperidine was also detected, but its amount was very small and it was identified only by mass specrtometry. 2-Chloroundecafluoropentane, obtained in a 9.7% yield, was a colorless liquid with a bp of 61 °C, $n_D^{20}<1.28$. Found: Cl, 11.6; F, 68.1%; mol wt (mass), 304. Calcd for C_5ClF_{11}: Cl, 11.6; F, 68.6%; mol wt, 304.5. The mass spectrum had peaks at 304 [M], 285 [M−F], 269 [M−Cl], and 235 [M−CF_3].

The mass spectrum of 3-chlorodecafluoropiperidine had peaks at 299 [M], 280 [M−F], 264 [M−Cl], 261 [M−F_2], 245 [M−ClF], 183 [M−C_2F_3Cl], and 116 [C_2F_3Cl].

The product (5.0 g) in Trap B was analyzed by means of a silica gel column at 0 and 80 °C; it was found to consist of carbon tetrafluoride, trifluoromethane, perfluorobutane, and nitrogen trifluoride. The over-all results are shown in Table 2, Run 11.

Autoxidation of Trimethyl Phosphite Initiated by One-Electron Transfer from Phosphite to Quinones*

Yoshiro OGATA and Mitsuji YAMASHITA

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 29, 1973)

The reaction of trimethyl phosphite (I) with acenaphthenequinone (II) under air affords quantitatively trimethyl phosphate (III) and 1:2 adduct (IV), which was converted into δ-lactone (V) and III by addition of water, while only IV was obtained quantitatively under N_2 atmosphere. ESR and UV spectra, decolorization of 1,1-diphenyl-2-picrylhydrazyl (DPPH), and initiation of styrene polymerization suggest the transient formation of radical ions VI and VII. The rate law for the autoxidation of I is expressed as: $v=k[I][II]^{0.7-1.0}$. The reaction in chloroform proceeds faster than that in dioxane. The reaction of I with chloranil is much slower, and no reaction occurs with phenanthrenequinone and anthraquinone which have low reduction potentials. A mechanism which involves one-electron transfer from phosphite to acenaphthenequinone followed by autoxidation was proposed for the reaction under air.

The reaction of trimethyl phosphite with acenaphthenequinone was reported to give a 1:2 adduct under nitrogen atmosphere.[1] Trimethyl phosphite is stable toward molecular oxygen in the absence of a radical source or light.[2] The peculiar behavior in the reaction of phosphite with acenaphthenequinone, *i.e.*, the rapid red-shift of color of the reaction mixture followed by a slow blue-shift,[3] prompted us to study the reaction in detail.

Some reactions of trivalent phosphorus compounds with carbonyl compounds are of radical character, but little evidence is available.[4] The present paper is a summary of our study on the products and mechanism of the autoxidation of trimethyl phosphite initiated by one-electron transfer reaction from phosphite to acenaphthenequinone.

Results and Discussion

The reaction of trimethyl phosphite (I) with acenaphthenequinone (II) proceeds exothermally at room temperature. The color of II fades rapidly,[3] producing trimethyl phosphate (III) in the air as the only liquid product together with a white solid. The former was confirmed by glc, tlc, IR and NMR spectra, and latter was identified by means of NMR to be an adduct of I to II in a molar ratio of 1:2. The adduct after treatment with water and recrystallization gave 8-[hydroxy(2-oxo-acenaphthenylidene)methyl]-1-naphthoic acid δ-lactone (V) [see Experimental].

The reaction of acenaphthenequinone with a large excess of trimethyl phosphite under oxygen atmosphere gives an excess equivalent of trimethyl phosphate, while under nitrogen atmosphere the yield is lower, most of trimethyl phosphite being recovered as shown in Table 1. This shows that the autoxidation of I occurs under O_2 atmosphere. The 1:2 adduct (IV) does not initiate the autoxidation. An increase of ratio of trimethyl phosphite to acenaphthenequinone under O_2 atmosphere results in a higher yield of phosphate (based on the used quinone), indicating a long length of radical chain (Table 2).

Stoichiometry. Stoichiometry of the autoxidation of trimethyl phosphite in the presence of acenaphthenequinone was determined in dioxane at 25.0 °C by use of an apparatus for kinetic study.[3] The reaction produced a quantitative amount of trimethyl phosphite with consumption of a half equivalent of molecular oxygen (Table 3). As reported by Ramirez and Ramanathan,[1] acenaphthenequinone is converted into a 1:2 adduct (IV) with trimethyl phosphite [(1a), (1b)]. We found that the adduct gives δ-lactone (V) and trimethyl phosphate (III) by treatment with water. Both reaction (1a) and (1b) take place in the air, but only (1b) under N_2.

Detection of Radicals. When trimethyl phosphite was added to a dioxane solution of acenaphthenequinone, the yellow color of the solution deepened (red-shift) and then faded away gradually. Immeasurably fast change of color was observed in chloroform. ESR spectra in dioxane showed a broad signal.[5] On addition of DPPH to the reaction mixture, the color

Table 1. Effect of oxygen on the yield of trimethyl phosphate at room temperature[a]

(1b)

of DPPH vanished rapidly, but it did not vanish by the action of IV, I, or II. The decolorization rate of DPPH was much faster in chloroform than in dioxane. A similar decolorization was observed for the reaction with chloranil (though slow in the initial period), but not with phenanthrenequinone.[3] These facts suggest that the reaction of trimethyl phosphite with acenaphthenequinone produces radical species by one-electron transfer as in the case of chloranil and that the autoxidation is initiated by these radicals. The formation of a charge-transfer complex of I with II is less probable, since no autoxidation of I would occur in the stage of charge-transfer complex.

Triphenylphosphonium radical cation ($Ph_3P^{\cdot+}$) may be an intermediate in the reaction of triphenylphosphine with some quinones.[6] The ESR spectra of some semiquinone radicals are well-known,[7] while those of phosphoranyl radicals[8] and phosphoranylperoxy radicals,[9] prepared by the photolysis of di-*t*-butyl peroxide in the presence of trivalent phosphorus compounds, have been reported recently. The observed broad signal may be either an anion radical of ketyl or a cation radical of phosphorus, or both.

Kinetics. The kinetics of the autoxidation was studied by the manometric method.[3] As shown in

Table 4. Rate constants for the autoxidation of trimethyl phosphite (I) with acenaphthenequinone (II) in dioxane at total pressure of 760 mmHg

Concentration		Partial pressure of O_2 (mmHg)	Temp. (°C)	Rate and rate constant	
$[I]_0$ (10^{-1} M)	$[II]_0$ (10^{-3} M)			$10^5\ v$[a] (M sec^{-1})	$10^2\ k_2$[b] (M^{-1} sec^{-1})

H. Godden, *J. Chem. Soc., B*, **1969**, 546. d) G. A. Russell, "Radical Ions," ed. by K. T. Kaiser and L. Kevan, Interscience Publishers, New York (1968), Chapter 3.

8) a) J. K. Kochi and P. J. Krusic, *J. Amer. Chem. Soc.*, **91**, 3944 (1969). b) A. G. Davies, D. Griller, and B. P. Roberts, *J. Chem. Soc. Perkin II*, **1972**, 993. c) P. J. Krusic, W. Mahler, and J. K. Kochi, *J. Amer. Chem. Soc.*, **94**, 6033 (1972).

9) G. B. Watts and K. U. Ingold, *ibid.*, **94**, 2528 (1972).

Table 4, the rate is independent of partial pressure of oxygen as expressed by

$$v = k[\mathrm{I}][\mathrm{II}]^{0.7\text{-}1.0} \quad (2)$$

It is also shown that the temperature effect is small, which reflects a small activation energy for the initiation. Chloranil initiates the autoxidation very slowly,[10] while rapid autoxidation is observed with AIBN (Table 5).

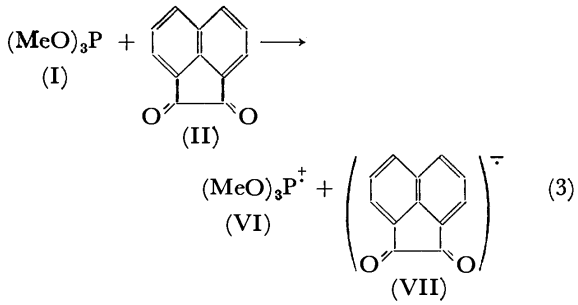
TABLE 5. SECOND-ORDER RATE CONSTANTS FOR AUTOXIDATION OF TRIMETHYL PHOSPHITE IN DIOXANE AT 60.0 °C

$[(MeO)_3P]_0$ (10^{-1} M)	Added compound (concentration) (10^{-3} M)	k_2 [a] ($M^{-1}sec^{-1}$)
1.99	Acenaphthenequinone (8.45)	2.43×10^{-2}
1.99	AIBN (9.40)	4.84×10^{-2}
1.99	Chloranil (7.95)	1.61×10^{-7}

a) $v=k_2[(MeO)_3P][\text{Added compound}]$.

Mechanism. The above fact suggest that the one-electron transfer occurs at the initiation step, and the radicals formed initiate the autoxidation of trimethyl phosphite. Thus a probable initiation reaction is expressed as follows.

Initiation:



(I) (II) (VI) (VII) (3)

Radicals VI and/or VII, represented by R·, may initiate the autoxidation.

The propagation reaction can be expressed by the mechanism involving alkyl, alkoxy, and alkylperoxy radicals as chain carriers,[3] *e.g.*,

$$(MeO)_3P + RO_2\cdot \longrightarrow (MeO)_3PO + RO\cdot$$

$$\text{or } (MeO)_3P + RO\cdot \longrightarrow (MeO)_3PO + R\cdot.$$

The termination reaction can be expressed as follows.

$$2RO_2\cdot \longrightarrow RO_4R \text{ or other inactive products} \quad (4)$$

$$RO_2\cdot \longrightarrow \text{inactive products} \quad (5)$$

$$RO_2\cdot + R'\cdot \longrightarrow \text{inactive products} \quad (6)$$

where R'· represents radicals other than $RO_2\cdot$.

If step (4) is favorable for termination, the order with respect to II in the rate law should be 0.5, while if steps (5) and/or (6) occur, the order should be 1,[3] on applying the steady state approximation to this mechanism. Actually, the order in II Eq. (2) is 0.7—1.0. This might be explained by assuming the occurrence of bimolecular termination [step (4)] along with unimolecular termination [steps (5) and (6)]. The radical chain may need small energy of activation, thus the temperature dependence of the autoxidation rate is small (E_a=5.9 kcal/mol and ΔS^*=−54 e.u. at 25.0 °C).

Formation of trimethyl phosphate is due to the autoxidation of I but not to the hydrolysis of phosphorus intermediate reported in the reaction of phosphite with chloranil.[11] One-electron transfer occurred in the reaction of trimethyl phosphite with acenaphthenequinone or chloranil, but none in that with phenanthrenequinone or anthraquinone. The different behaviors in these quinones can be attributed to the difference of reduction potentials of quinones,[12] *i.e.*, reduction potentials of quinones: chloranil (0.712 V),[12b] phenanthrenequinone (0.458 V),[12c] anthraquinone (0.157 V),[12d] and acenaphthenequinone (0.78 V). The last has not been reported.

Polymerization. Copolymerization of added styrene-divinylbenzene was initiated during the reaction of trimethyl phosphite with acenaphthenequinone at 60 °C under O_2 or N_2, while formed IV did not initiate the polymerization. This indicates the presence of a free radical in the reaction mixture of trimethyl phosphite with acenaphthenequinone and the fact that the radical has a life long enough to initiate polymerization.

Experimental

Apparatus. The NMR spectra were measured with a JNM-C60-HL model of Japan Electron Optics Laboratory Co., Ltd; IR spectra with a Perkin-Elmer 337 grating infrared spectrophotometer; ESR spectra with a JES-ME1X model of Japan Electron Optics Laboratory Co., Ltd; UV spectra with a Hitachi 124 spectrophotometer; and mass spectra with a Hitachi RMS-4 model. A Yanagimoto GCG 550F gas chromatograph was used for glc analysis, and a Yanagimoto P8-DPR polarograph for the measurement of reduction potentials.

Materials. Trimethyl phosphite (bp 58 °C/116 mmHg; lit,[13] bp 111—112 °C), acenaphthenequinone (mp 261 °C; lit,[14] mp 259—260 °C), chloranil (mp 299 °C; lit,[15] mp 291—293 °C), styrene (bp 49—50 °C/25 mmHg; lit,[16] bp 54 °C/30 mmHg), phenanthrenequinone (mp 210 °C; lit,[17] mp 208.5—210 °C), and solvents were purified before use.

Reaction of Trimethyl Phosphite (I) with Acenaphthenequinone (II). The reaction of I with II was carried out at room temperature in neat or in a dioxane or chloroform solution. The tlc analysis (silica gel/acetone) of the reaction mixture gave two spots, one (R_f=0.59) being detected by $CoCl_2$, and the other (R_f=0.80) by I_2. After separation of formed precipitate by filtration (reaction in neat), the solid

product was washed with water, then extracted by $CHCl_3$. The extract gave a solid which was identified to be 8-[hydroxy (2-oxo-1-acenaphthenylidene)methyl]-1-naphthoic acid δ-lactone (V) mp 274 °C.

Found: C, 82.1; H, 3.52%. Calcd for $C_{24}H_{12}O_3$: C, 82.8; H, 3.47%.

The NMR spectra gave only aromatic protons (in $CDCl_3$). The mass spectra are shown in Table 6. The UV spectra in CH_3CN are as follows: λ_{max} 249 nm (log ε 4.92), 285 nm (4.64), 301 nm (4.61), 316 nm (4.60), and 342 nm (4.53). The crude yield of V was quantitative. The filtrate gave only one peak in glc (Apiezon Grease L 3% on Celite 545), whose structure was confirmed to be trimethyl phosphate (III) by NMR (6.26 τ, doublet, J_{PH}=11 Hz) and IR (P=O; 1267 cm^{-1}, P–O–C; 1035 cm^{-1}). The reaction in dioxane or in $CHCl_3$ gave the same results as described above. The structure of 1:2 adduct (IV) was determined by NMR spectra without purification (1.5—2.5 τ, multiplet, 12H; 6.28 τ doublet, J_{PH}=10.6 Hz, 9H).

Kinetics. A dioxane solution of trimethyl phosphite (2 ml) and a doixane solution of acenaphthenequinone (2 ml) was mixed under 159 mmHg partial pressure of oxygen. The autoxidation rate was measured manometrically.[3] The stoichiometry was determined by the consumed amount of oxygen after being kept standing for a long time.

ESR Spectra. A dioxane solution of acenaphthenequinone was introduced into an ESR tube and frozen out at liquid nitrogen temperature under N_2 flow. A dioxane solution of trimethyl phosphite was then introduced into the tube and also frozen out. Two separate layers were gradually mixed by raising the temperature. The observed broad ESR signal having center at 3150 G soon reached a maximum intensity and then gradually vanished.

Table 6. Mass spectra of δ-lactone (V)

m/e	Relative intensity
126	100
154	85
182	38
320	12
348 (M^+)	30 (100) [a]
349 (M^++1)	(25)
350 (M^++2)	(3.7)

a) Numerals in parenthesis denote relative intensity based on M^+. The calculated intensity of M^++1 and M^++2 is 26.1 and 1.3, respectively ($C_{24}H_{12}O_3$) [J. H. Beynon, "Mass Spectrometry and its Application to Organic Chemistry," Elsevier, Amsterdam (1960), p. 305)].

Polymerization of Styrene. Acenaphthenequinone (0.007 g) was dissolved in a mixture of 4 ml styrene and 0.1 ml divinylbenzene. Bubbling nitrogen gas, 1 ml trimethyl phosphite was added to the mixture at 60 °C and then the tube was sealed. The homo and popcorn polymerization was almost complete after two days, but no such polymerization was observed without trimethyl phosphite and acenaphthenequinone.

Reduction Potential. The reduction potential of quinones was measured in 50% aqueous ethanol containing 0.1M HCl as a saturated solution of substrate at 20 °C by means of a Yanagimoto P8-DPR polarograph potentiostated with a calomel electrode.

The Oxidative Coupling of Alkyl Aryl Ketones by Iron(III) Chloride

Hiroo INOUE, Mitsuya SAKATA, and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi Osaka 591

(Received February 3, 1973)

The oxidative carbon-carbon coupling of two enolizable ketones, propiophenone and butyrophenone, with iron(III) chloride is investigated. The ketones are converted to γ-diketones (II) and 2,5-diphenylfurans (III) in high yields, while iron(III) chloride is reduced to iron(II) chloride. III is produced by the dehydration of II with iron(III) chloride and/or hydrogen chloride. During the reaction, iron(III) chloride is regenerated partially by the oxidation of iron(II) chloride with oxygen in the presence of hydrogen chloride. However, oxygen enhances the formation of III and the polymeric material. The addition of pyridine, calcium oxide, or zinc oxide to the iron(III) chloride-ketone system brings about the selective formation of α-chloroketones. A combination of iron(III) chloride with copper(II) chloride or oxide is effective for the oxidative coupling. Under irradiation, the reactions result both in oxidative coupling and in chlorination at the α-position of the carbonyl group, accompanied by chlorination at the β-position.

The oxidative coupling with phenols of compounds containing the -CH=C(OH)- group has been well known.[1] As the oxidizing agents, $K_3Fe(CN)_6$,[1] $VOCl_3$,[2] VCl_4,[2] Mn(acetylacetonate)$_3$,[3] [Fe(dimethylformamide)$_3$Cl$_2$][FeCl$_4$],[4] and the Cu-amine-O_2 system[1] have been investigated. In recent years considerable attention has been given to the mechanistic aspects of the coupling of phenoxy radicals.[5-7] We

have now examined the oxidative carbon-carbon coupling of enolizable ketones with iron(III) chloride. The carbon-carbon coupling of the compounds containing the activated CH, CH_2, or CH_3 groups has been investigated with a large variety of oxidants.[8] However, no method for the direct coupling of the α-carbon of simple ketones has been reported. We will describe herein a new reaction in which propiophenone (Ia) or butyrophenone (Ib) successfully undergoes carbon-carbon coupling by iron(III) chloride to give the γ-diketones (II) and 2,5-diphenylfurans (III). Furthermore, we will report on the influence of additives, such as pyridine, water, copper(II) chloride, metal oxides, and metal, upon the reactions. Some of the results of this investigation have been reported in a previous communication.[9]

$$+ \underset{\text{III}}{\text{(2,5-diphenylfuran)}} + \underset{\text{IV}}{C_6H_5COCHR}$$

Results and Discussion

Oxidative Coupling. When a solution of anhydrous iron(III) chloride in I was heated without a solvent at 70 °C under an atmosphere of air, γ-diketones (II) were obtained, together with 2,5-diphenylfurans (III) and α-chloroketones (IV). Iron(III) chloride was reduced to iron(II) chloride, which was precipitated as white crystals. The formation curve of the products against the reaction time is shown in Fig. 1. In a separate experiment, it was observed that II was converted to III with the aid of hydrogen chloride and iron(III) chloride. Therefore, III would be produced consecutively by the dehydration of II with hydrogen chloride and/or iron(III) chloride. II was produced parallel with IV without an induction period. In order to investigate whether or not II is produced from IV, a solution of IV in I in the presence of iron(II) or iron(III) chloride was heated at 70 °C. IV was recovered unchanged. This means that II is not produced either by the reductive coupling of IV by iron(II) chloride or by the reaction of IV and the enol of I with iron(III) chloride.

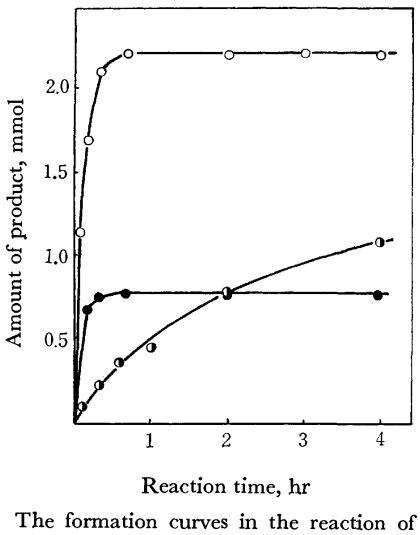

Fig. 1. The formation curves in the reaction of Ia (15 ml) with iron (III) chloride (4.5 mmol) at 70°C.
○: IIa, ◑: IIIa, ●: IVa.

The formation of II and IV together with iron(II) chloride indicates that the initial step involves the oxidation of the ketone by iron(III) chloride, thus leading to the α-keto radical (V). Such a process has also been found in the oxidation of ketones by either manganic or ceric ions.[10-12] The α-keto radicals couple with each other to form II, or are oxidized by the iron(III) chloride to give α-chloroketone (IV).[13]

$$\underset{\text{I}}{} \xrightarrow{FeCl_3} \underset{\text{V}}{[C_6H_5\dot{C}OCHR]} \begin{cases} \xrightarrow{\text{V}} \underset{\text{II}}{} \xrightarrow{FeCl_3\text{-}HCl} \underset{\text{III}}{} \\ \xrightarrow[FeCl_3]{} \underset{\text{IV}}{} \end{cases}$$

When the yields of II, III, and IV were calculated by this equation: 200×(the number of moles of the products/the number of moles of iron(III) chloride), the sum of the yields was higher than 100%, as Table 1 shows.

Effect of Oxygen. The oxidation of iron(II) salts by oxygen in an aqueous or nonaqueous solvent has already been studied.[14-16] We carried out the reaction of Ia with iron(III) chloride under an oxygen atmosphere. As Table 1 shows, the reaction resulted in a decreased yield of IIa and an increased yield of IIIa. In addition, a polymeric material, the IR spectrum of which exhibited bands at 3050, 2900, 1700, 1600, 1495, 1440, 1370, 1000, 750, and 695 cm^{-1}, was isolated. Furthermore, we carried out the experiment of heating a dispersed solution of iron(II) chloride in Ia at 70 °C under a slow flow of oxygen and hydrogen chloride for 30 min. In this case, IIa was obtained in a 54% yield, based on the iron(II) chloride. In the absence of hydrogen chloride and oxygen, IIa and IIIa were not obtained at all. Thus, the presence of oxygen

Table 1. The thermal reaction of Ia or Ib with iron(III) chloride[a)]

Ketone	$FeCl_3$, mmol	Atmosphere	Reaction time, hr	Products, mmol × 10			
				γ-Diketone	Furan	α-Chloro-ketone	$FeCl_2$
Ia	1.5	Air	24	7.2	4.7	1.9	10.2
Ia	0.3[b)]	Air	24	1.8	1.1	1.3	—
Ia	1.5	O_2	5	3.6	5.1	3.0	—
Ia	1.5	O_2	24	3.5	6.5	2.3	9.6
Ia	1.5	N_2-flowed[c)]	2	7.7	0.0	2.8	—
Ia	1.5	N_2-flowed[c)]	24	19.8	3.5	2.4	8.3
Ib	1.4	Air	48	3.4	—	3.8	9.4
Ib	1.4	N_2	48	4.6	—	3.2	—

a) Experiments were carried out without solvent at 70—75°C, using 5 ml of I.
b) The reaction was carried out in 3 ml of Ia.
c) Nitrogen gas was flowed at 30 ml/min.

and hydrogen chloride brought about the regeneration of iron(III) chloride from iron(II) chloride, but the yield of II decreased due to the consecutive formation of III and the polymeric material. The rate of the formation of the products was not accelerated by oxygen.

In order to remove the excess of oxygen and hydrogen chloride, the reaction was carried out with a slow flow of gaseous nitrogen. As Table 1 shows, II was obtained in a high yield, along with III and IV in low yields. The fact that the yield of II was over 100% indicates that oxygen present in the reaction system contributes to the regeneration of iron(III) chloride. Thus, for preventing the consecutive reaction of II it was effective to remove the excess of oxygen and hydrogen chloride.

Effect of Concentration of Iron(III) Chloride. The amounts of II and III produced after a certain reaction time increased with an increase in the concentration of iron(III) chloride up to nearly the saturation point of iron(III) chloride. When iron(III) chloride came to be dispersed in I, however, the amount of IV increased, while the amounts of II and III decreased.

Effects of Solvents. The use of such solvents as benzene and diglyme was not preferred for the oxidative coupling reaction: the reaction of Ia with iron(III) chloride in diglyme gave mainly IVa in an 80% yield (concentration of iron(III) chloride and Ia, 0.33 mol/l; reaction time, 48 hr; reaction temperature, 70—80 °C).

Effects of Additives. Pyridine or Water: When pyridine was added to a solution of iron(III) chloride in I, an iron(III) chloride–pyridine complex was precipitated. The complex was dispersed in I and was then heated at 70—75 °C for 24 or 48 hr. As Table 2 shows, the yield of IV increased with an increase of the pyridine/iron(III) chloride ratio up to the molar ratio of 1—2: 1, accompanied by a decrease in the yields of II and III. At the molar ratio of 5: 1, however, no product was obtained. These facts indicate that II, III, and IV are produced through the coordination of I to iron(III) chloride and that the addition of pyridine to the iron(III) chloride–I system alters the reaction pathway to the course of the formation of IV:

$$\mathrm{I} \xrightarrow{FeCl_3\text{–}C_5H_5N} \mathrm{IV}$$

The reaction pathway was also influenced by the addition of water instead of pyridine. The increase in the water/iron(III) chloride molar ratio brought about a decrease in the yields of II and III, along with a slight increase in that of IV.

Table 2. Effects of pyridine and water on the thermal reaction of I with iron(III) chloride[a)]

Ketone	Additive	Molar ratio Additive /$FeCl_3$	Yields of products, %[b)]		
			γ-Diketone	Furan	α-Chloro-ketone
Ia	C_5H_5N	0	96	63	25
Ia	C_5H_5N	0.5	5	0	69
Ia	C_5H_5N	0.9	0	0	65
Ia	C_5H_5N	2.0	0	0	43
Ia	C_5H_5N	5.0	0	0	0
Ia	H_2O	2.0	42	40	36
Ia	H_2O	6.0	27	23	52
Ib	C_5H_5N	0.5	23	—	18
Ib	C_5H_5N	1.0	0	0	63

a) The starting amount of iron(III) chloride was 1.5 mmol in 5 ml of I. The reactions were carried out under atmosphere at 70—75 °C for 24 hr (Ia) and 48 hr (Ib).
b) The yield was calculated by 200× (the number of moles of the products that of iron(III) chloride).

Copper(II) Chloride, Metal Oxide, and Metal. The reaction of Ia with iron(III) chloride in the presence of copper(II) chloride was carried out under conditions similar to those in the absence of copper(II) chloride. Since copper(II) chloride was insoluble in Ia, it was dispersed under stirring in a solution of iron(III) chloride in Ia. As is shown in Table 3, the maximum yield of IIa, along with low yields of IIIa and IVa, was observed in the iron(III) chloride/copper(II) chloride plus iron(III) chloride ratio of 0.2: 1. The yield, being over 100%, was higher than in the absence of copper(II) chloride. The amount of IIIa produced increased with an increase in the ratio. On the other hand, the reaction of Ia with copper(II) chloride gave only IVa. The amount of IVa produced decreased with the addition of iron(III) chloride to the copper(II) chloride–I system. Thus, the binary iron(III) chloride–copper(II) chloride system was effective for the oxidative coupling reaction, although the mechanism of the action of the binary metal salts is not as yet clear.

Table 3. Effects of copper(II) chloride on the thermal reaction of Ia with iron(III) chloride[a]

$FeCl_3/(FeCl_3+CuCl_2)$[b] ratio	Products, mmol × 10		
	γ-Diketone	Furan	α-Chloroketone
0	0	0	4.0
0.1	1.4	0	1.8
0.2	7.8	1.8	1.5
0.3	7.0	4.2	1.5
0.5	6.1	4.2	1.5
1.0	4.3	3.0	1.1

a) Experiments were carried out under air atmosphere at 70—75 °C for 24 hr, using 3 ml of Ia.
b) The starting amount of iron(III) chloride plus copper(II) chloride was 0.9 mmol.

The presence of CaO and ZnO in the iron(III) chloride–Ia system resulted in the selective formation of IVa in a high yield, although Ia did not react with CaO and ZnO, as is shown in Table 4. In the cases of TiO_2, Fe_2O_3, and Cr_2O_3, IIa, IIIa, and IVa were obtained. The $FeCl_3$–CuO system gave IIa in a high yield, plus IIIa and IVa in low yields. These results also support the idea of the effectiveness of the Fe(III)–Cu(II) combination system for the oxidative coupling reaction. The reaction of Ia with iron(III) chloride in the presence of Fe^0 or Cu^0 resulted in the formation of IVa without IIa and IIIa, as Table 4 shows.

As has been described above, the effects of the concentrations, the additives, and the solvents on the reaction pathway suggest that the course of either coupling or chlorination is governed by the state of an aggregate of iron(III) chloride in the solution—for example, a dimer form of iron(III) chloride, although the details are uncertain. Furthermore, it is interesting to note that a combination of iron(III) chloride and an oxidizing agent is effective for the coupling reaction.

Table 4. Effects of metal oxide and metal on the thermal reaction of Ia with iron(III) chloride[a]

Additive	Product, mmol × 10		
	γ-Diketone	Furan	α-Chloroketone
CaO	0.4	0	8.4
ZnO	0.4	0	7.0
Cr_2O_3	10.9	6.5	2.4
TiO_2	4.9	4.2	2.5
Fe_2O_3	4.8	5.0	5.2
CuO	11.6	0.7	2.2
Fe	0	0	4.6
Cu	0.6	0	4.4

a) The amount of iron(III) chloride used was 1.5 mmol in 5 ml of Ia. The metal oxide or metal /iron(III) chloride molar ratio was 1. The reactions were carried out under air atmosphere at 70—75 °C for 24 hr.

Under Irradiation. A solution of iron(III) chloride in I, which had been placed in a quartz tube, was irradiated with a 100 W high-pressure mercury lamp at a distance of 4 cm under an atmosphere of air at room temperature for 24 hr. During the reaction, white crystals of iron(II) chloride were precipitated. As is shown in Table 5, Ia was converted to IIa, IIIa, and IVa in lower yields than in the case of the thermal reaction. In the case of Ib, however, 3-chlorobutyrophenone (VI), acetophenone, and ethylene were obtained in addition to IIb and IVb. Acetophenone and ethylene were produced after the complete conversion of the iron(III) chloride to iron(II) chloride. The reaction probably proceeded by means of a Norrish Type II process.[17] When pyridine was added to the reaction system in the pyridine/iron(III) chloride molar ratio of 1:1, the reaction resulted in chlorination at the α- and/or β-position of the carbonyl group. In the case of Ib, however, crotophenone (VII) was produced by the dehydrochlorination of VI.

$$\mathrm{Ib} \xrightarrow{h\nu} \mathrm{C_6H_5COCH_3} + \mathrm{CH_2{=}CH_2}$$

$$\mathrm{Ib} \xrightarrow[\mathrm{FeCl_3\text{–}C_5H_5N}]{h\nu} \mathrm{IVb} + \underset{\mathrm{VI}}{\mathrm{C_6H_5COCH_2\overset{Cl}{\overset{|}{C}}HCH_3}} + \underset{\mathrm{VII}}{\mathrm{C_6H_5COCH{=}\overset{}{\overset{|}{C}}HCH_3}}$$

Other Ketones. The reactions of acetophenone and aliphatic ketones, such as acetone, 2-heptanone, and cyclohexanone, with anhydrous iron(III) chloride at 70 °C resulted in aldol condensation, giving the corresponding α,β-unsaturated ketones. That is, the oxidative coupling by iron(III) chloride was specific for the α-methylene group of alkyl aryl ketones.

$$\mathrm{C_6H_5COCH_3} \xrightarrow{\mathrm{FeCl_3}} \mathrm{C_6H_5COCH{=}\overset{CH_3}{\overset{|}{C}}\text{–}C_6H_5}$$

Table 5. The photo-reactions of I with iron(III) chloride

Ketone	Molar ratio[a] $C_5H_5N/FeCl_3$	Yields of products, %[b]				
		γ-Diketone	Furan	α-Chloroketone	β-Chloroketone	$FeCl_2$
Ia	0	40	29	25	—	94
Ia	1	0	0	20	—	—
Ib	0	26	—	26	14	83
Ib[c]	1	0	0	48	14	—

a) The amount of iron(III) chloride used was 1.5 mmol in 5 ml of I. The reactions were carried out under air atmosphere at room temperature for 24 hr.
b) The yield was calculated by 200 × (the number of moles of the products/that of iron(III) chloride).
c) Crotophenone was obtained in 6% yield.

17) J. G. Calvert and J. N. Pitts, Jr., "Photochemistry," John Wiley & Sons, Inc., New York, N. Y. (1967), p. 382.

Experimental

Materials. The aliphatic ketones, acetophenone, metal salts, metal oxides, and metal were purchased from commercial sources. The aliphatic ketones and acetophenone were distilled twice before use. The propiophenone and butyrophenone were prepared by the methods described in the literature.[18] The anhydrous iron(III) chloride was prepared by the sublimation of the commercial iron(III) chloride under the reduced pressure of 1 mmHg at 300 °C. The purity of the iron(III) chloride used was 99—99.8%; it was measured from the content percentage of Fe(III) and chloride ions. Furthermore, the UV absorption spectrum of the iron(III) chloride in dry dioxane coincided with that described in the literature.[19]

Reactions. Similar procedures were used for all the reactions. A solution of 1.3—1.5 mmol of iron(III) chloride in 5 ml of ketones was heated at 70—75 °C or was irradiated with a 100 W high pressure mercury lamp at room temperature for the desired time. II, III, and IV were isolated by gas chromatography after a work-up. The isolation of II and III was carried out by the following method. After a reaction period, dry ether was added to the reaction mixture, the resulting solution was filtered off, and the filtrate was washed repeatedly with water and dried over calcium chloride. After the ether and then the starting ketone and IV had been removed, the residue was distilled under the reduced pressure of 3×10^{-3} mmHg at 100—110 °C. The high-boiling components containing II and III were submitted to chromatography on silica gel (elution with dry carbon tetrachloride), and then to gas chromatography, thus leading to the isolation of II and III.

The NMR spectrum (CCl_4) of IIa showed signals of δ 1.35 and 1.50 (d, 6H, CH_3), 4.25 and 5.60 (q, 2H, CH), and 7.1—8.0 (m, 10H, aromatic protons). The IR spectrum of IIa exhibited strong bands at 1680 cm^{-1} (CO). Mass *m/e*; 266 (parent peak).

Found: C, 81.33; H, 6.80%. Calcd for $C_{18}H_{18}O_2$: C, 81.20; H, 6.76%.

IIb exhibited NMR (CCl_4) signals at δ 0.7—1.3 (m, 6H, CH_3), 1.6—2.1 (m, 4H, CH_2), 4.05 and 5.55 (q and t, 2H, CH), and 6.9—8.0 (m, 10H, aromatic protons), and an IR (liquid film) peak at 1680 cm^{-1} (CO). Mass *m/e*; 294 (parent peak).

Found: C, 81.56; H, 7.55%. Calcd for $C_{20}H_{22}O_2$: C, 81.60; H, 7.53%.

IIIa, mp 52—54 °C, exhibited NMR (CCl_4) signals at δ 2.16 and 2.33 (s, 6H, CH_3), and 7.2—7.8 (m, 10H, aromatic protons). Mass *m/e*; 248 (parent peak).

Found: C, 86.92; H, 6.50%. Calcd for $C_{18}H_{16}O$: C, 87.09; H, 6.45%.

The other products were identified by a comparison of their IR and NMR spectra, the results of elementary analyses of their 2,4-dinitrophenylhydrazones, their retention times in gas chromatography, and their molecular weights with those of authentic specimens.

Analyses. After a reaction period, the iron(II) chloride produced was filtered off, washed by *n*-hexane, dried over calcium chloride, and then weighed. The determination of the iron(III) chloride and iron(II) chloride was carried out by the methods described in the literature.[20] The amounts of the products were determined by means of gas chromatography using a 3 mm×2 m column of 30% high-vacuum Silicone grease on Celite 545 (80—100 mesh).

Reactions of Phenylhydrazinium Thiocyanate with Ketones and Aldehydes

Isamu ARAI

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received February 5, 1973)

Reactions of phenylhydrazinium thiocyanate with various ketones and aldehydes gave 1-phenyl-3-alkyl-5-mercapto-Δ^4-1,2,4-triazoline compounds in 80—90% yield by the cycloaddition of thiocyanic acid to the phenylhydrazones intermediately formed from phenylhydrazine and the ketones or aldehydes. Their structure were determined by elemental analyses, spectral data (IR, NMR, and MS) and chemical reactions. Many 2-phenylthiosemicarbazone and 1-phenyl-1,2,4-triazole derivatives were synthesized in good yields.

We have reported that hydrazinium thiocyanate (I') reacts with aldehydes and ketones to give 1,2,4-triazolidine (II') and triazolo-triazole (III') compounds.[1)]

We considered that the 1,2,4-triazolidine compounds (II') were produced by the cycloaddition of thiocyanic acid to the hydrazones intermediately formed from ketones or aldehydes with hydrazine. Attempts to isolate these intermediate hydrazones from the reaction mixture failed because the hydrazones were not stable and readily changed to the corresponding azines.[2)]

In this paper we deal with the formation of 1,2,4-

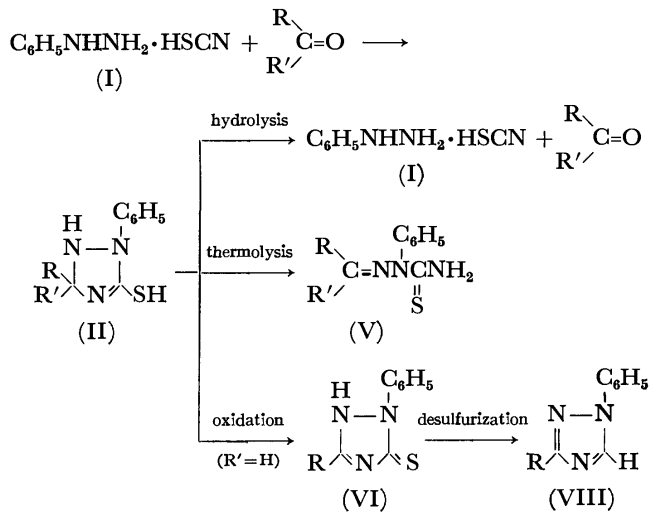
triazolidine compounds and their derivatives, using phenylhydrazine as the starting material instead of hydrazine. New useful methods are given for the preparation of 2-phenylthiosemicarbazone and 1-phenyl-1,2,4-triazole derivatives.

Results and Discussion

When a ketone or aldehyde was added to an aqueous solution of phenylhydrazinium thiocyanate (I) and the mixture was allowed to stand at room temperature, 1-phenyl-3-alkyl-5-mercapto-Δ^4-1,2,4-triazoline (II) was obtained in an 80—90% yield. Elemental analyses (Table 1) and mass spectral data of (II) gave a reasonable molecular formula. The IR spectra of (II) showed absorption bands at 3135—3136 (NH) and 1590—1595 (C=N) cm^{-1}, and the NMR spectral data of (II) also gave a reasonable structure (see Experimental). From these data and the results of chemical reactions (hydrolysis, thermolysis, oxidation, and desulfurization) of (II), the structure was assigned to be 1-phenyl-3-alkyl-5-mercapto-Δ^4-1,2,4-triazoline.



This was also supported by the mass spectral data of (II); *i.e.*, peaks of $C_6H_5NCS^+$ and $C_6H_5NH^+$ at *m/e* 135 and 92 respectively. Fragmentations resulting from the loss of R, R′ or HSCN from the molecular ion were also observed.

The yields of the products are given in Table 2 and those of (IIa) *versus* reaction time in Fig. 1.

From the above results and those of previous work,[1] the following path is proposed for the formation of (II). First the ketone or aldehyde reacts with phenylhydrazine in the presence of an acid catalyst to produce phenylhydrazone (IV). The intermediate then reacts with thiocyanic acid to form (II). Formation of this

of (I) with ketones or aldehydes pass through phenylhydrazone (IV) as an intermediate, and those of (I′) also pass through hydrazone.

Thermolysis of (II) gave 2-phenyl-thiosemicarbazone (V) almost quantitatively. This is a convenient method for synthesizing thiosemicarbazone derivatives since to synthesize them by the conventional method requires several steps.[4]

Oxidation of (IIi—l) gave 1-phenyl-3-alkyl-Δ^3-1,2,4-triazoline-5-thione (VI). This is also a new method to synthesize Δ^3-1,2,4-triazoline-5-thione derivatives and demonstrates the interesting fact that the hydrogen atom attached to a ring carbon of an saturated heterocyclic compound is easily released under mild conditions. Table 4 shows the yields and elemental analyses of (VI).

(VI) was readily methylated with dimethyl sulfate or methyl iodide to give 1-phenyl-3-alkyl-5-methylthio-1,2,4-triazole (VII). (VII) was further desulfurizated with Raney nickel to give 1-phenyl-3-alkyl-1,2,4-triazole (VIII). (VIII) was also prepared by desulfurization of (VI) with Raney nickel. (VIII) was identified by comparison (mp and UV) with an authentic sample.[5] The reactions indicated the presence of a 1,2,4-triazoline skeleton in (II). They also represent a new

useful method for th preparation of 1,2,4-triazole derivatives.

Experimental

All melting and boiling points are uncorrected. The IR spectra were recorded from KBr pellets, using a 215 Hitachi grating infrared spectrophotometer. The NMR spectra were measured in a solution of deuteriochloroform with a JNM C-60HL spectrometer using tetramethylsilane as an internal standard. The mass spectra were obtained on a CEC 21-110B spectrometer at 70 eV.

Reaction of Phenylhydrazinium Thiocyanate (I) with Ketone and Aldehyde. Ketone or aldehyde (0.05 mol) was added dropwise to a solution of phenylhydrazine hydrochloride (7.23 g, 0.05 mol) and sodium thiocyanate (4.05 g, 0.05 mol) in 0.25 M hydrochloric acid (200 ml) with stirring. The solution was stirred at room temperature for 18 hr under shield from light. A white precipitate formed which was filtered and washed with water several times. It was recrystallized with 1,2-dichloroethane to give 1-phenyl-3-alkyl-5-mercapto-Δ^4-1,2,4-triazoline (II).

(IIa): IR; 3150, 2970, 1595, 1490, 1380, 1170, 745 cm^{-1}. NMR; δ 1.50 (s, $-CH_3$), 4.80 (s, –SH), 7.18—8.20 ($-C_6H_5$ and –NH–). Mass spectra; *m/e* 207 ($C_{10}H_{13}N_3S^+$), 192 ($C_9H_{10}N_3S^+$), 148 ($C_9H_{12}N_2^+$), 135 ($C_6H_5NCS^+$), 92 ($C_6H_5NH^+$).

(IIi): IR; 3150, 2960, 1590, 1475, 1400, 1239, 760 cm^{-1}. NMR; δ 1.45 (d, J=6.0 Hz, $-CH_3$), 4.75 (broad s, –SH) 4.92 (q, J=6.0 Hz, =CH–), 7.00—8.20 ($-C_6H_5$ and –NH–). Mass spectra; *m/e* 193 ($C_9H_{11}N_3S^+$), 191 ($C_9H_9N_3S^+$), 178 ($C_8H_8N_3S^+$), 135 ($C_6H_5NCS^+$), 134 ($C_8H_{10}N_2^+$), 92 ($C_6H_5NH^+$).

Phenylhydrazone (IV). To a cooled solution of 0.1 mol of phenylhydrazine in ether (100 ml) were added 0.1 mol of ketone or aldehyde and a few drops of acetic acid and the solution was heated for several minutes. Sodium hydroxide was added to the solution, and it was allowed to stand at room temperature overnight. The ethereal solution was separated from the sodium hydroxide by decantation and then evaporated. The residue was distilled under reduced pressure to give ketone or aldehyde phenylhydrazone (IV).

(IVa); bp 127.0 °C/9.5 mmHg, (IVb); bp 136.5—137.5 °C/7.5 mmHg, (IVc); bp 158.0—160.0 °C/18.5 mmHg, (IVd); bp 156.0—157.0 °C/21.0 mmHg, (IVe); bp 111.8—113.8 °C/1.5 mmHg, (IVf); bp 127.0—128.7 °C/3.0 mmHg, (IVg); bp 157.0—158.0 °C/20.0 mmHg, (IVh); mp 73.0—75.0 °C, (IVi); bp 110.0—111.0 °C/3.5 mmHg, (IVj); bp 126.0—128.5 °C/7.0 mmHg, (IVk); bp 110.0—111.5 °C/2.0 mmHg, (IVl); bp 142.5—144.0 °C/16.0 mmHg.

Reaction of Phenylhydrazone(IV) with Thiocyanic Acid. Sodium thiocyanate (8.10 g, 0.05 mol) was added in one portion to a solution of 0.05 mol of (IV) in acetic acid (40 ml) with stirring. The solution was stirred at room temperature for 18 hr with a light shield. A white precipitate formed which was filtered and washed with water. It was recrystallized with dichloroethane to give 1-phenyl-3-alkyl-5-mercapto-Δ^4-1,2,4-triazoline (II).

Hydrolysis of 1-Phenyl-3,3-dimethyl-5-mercapto-Δ^4-1,2,4-triazoline (IIa). A mixture of 1.0 g of (IIa) in water (30 ml) was refluxed for a few minutes, and distilled at atmospheric pressure until 5 ml of a solution was collected. The distillate was poured into a solution of 2,4-dinitrophenylhydrazine in 6 M hydrochloric acid. A yellow precipitate formed which was filtered and recrystallized from ethanol to give acetone 2,4-dinitrophenylhydrazone, mp 125 °C. The liquor remaining on distillation was evaporated under reduced pressure, and chloroform was added to the residue. An insoluble material (0.40 g) was recrystallized with methanol–ether to give phenylhydrazinium thiocyanate (I), mp 108 °C (decomp). The products were identified by comparison (IR spectra and mp) with an authentic sample.

Thermolysis of 1-Phenyl-3,3-dimethyl-5-mercapto-Δ^4-1,2,4-triazoline (IIa). A solution of 1.0 g of (IIa) in 2-butanol (50 ml) was refluxed for 1.5 hr, and then evaporated under reduced pressure. The residue (1.0 g) was recrystallized from 75 vol% ethanol to give acetone 2-phenylthiosemicarbazone (Va), mp 133.0—134.0 °C (lit,[4] mp 135.0 °C).

Found: C, 57.94; H, 6.32; N, 20.27%. Calcd for $C_{10}H_{13}N_3S$: C, 58.18; H, 6.41; N, 20.23%.

Oxidation of 1-Phenyl-3-alkyl-5-mercapto-Δ^4-1,2,4-triazoline (IIi—l). Oxygen was passed into a mixture of 1.0 g of (IIi—l) in 1 M sodium hydroxide (100 ml) with stirring until (IIi—l) was dissolved. The solution was then acidified with 1 M hydrochloric acid. A white precipitate formed which was filtered and recrystallized from 50 vol% ethanol to give 1-phenyl-3-alkyl-Δ^3-1,2,4-triazoline-5-thione (VI).

IR of (VIi): 3000, 2890, 2700, 1610, 1490, 1225, 1010, 755, 687 cm^{-1}. NMR of (VIi): δ 2.36 (s, $-CH_3$), 7.30—8.25 ($-C_6H_5$ and –NH–).

Methylation of 1-Phenyl-3-methyl-Δ^3-1,2,4-triazoline-5-thione (VIi). 1) With methyl iodide. A solution of 2.0 g of (VIi) and methyl iodide (1.48 g) in ethanol (50 ml) was refluxed for 3.5 hr, and then evaporated under reduced pressure. Fifty milliliters of 1 M sodium hydroxide was added to the residue, and the mixture was extracted with chloroform. The extract was evaporated. The residue (2.07 g) gave 1-phenyl-3-methyl-5-methylthio-1,2,4-triazole (VIIi). (VIIi) was an oil and formed a hydrochloride, mp 141 °C decomp. (from tetrahydrofuran).

Found: C, 49.60; H, 4.87; N, 17.73%. Calcd for $C_{10}H_{12}N_3SCl$: C, 49.69; H, 5.01; N, 17.38%. IR: 2990, 2600, 2470, 1595, 1585, 1505, 1480, 1245, 1025, 770, 690 cm^{-1}. NMR: δ 2.78 (s, $-CH_3$), 3.20 (s, $-SCH_3$), 7.68 (s, $-C_6H_5$).

2) With dimethyl sulfate. To a cooled solution of 0.5 g of (VIi) in 1 M sodium hydroxide (20 ml) was added dropwise dimethyl sulfate (0.33 g). The mixture was then stirred at room temperature for 24 hr and extracted with chloroform. The extract was evaporated and the residue (0.34 g) gave (VIIi).

1-Phenyl-3-methyl-1,2,4-triazole (VIIIi). 1) A mixture of 0.5 g of 1-phenyl-3-methyl-Δ^3-1,2,4-triazoline-5-thione (VIi) and *ca.* 5 g of Raney nickel (W-2) in ethanol (25 ml) was refluxed for 24 hr. The solution of ethanol was then separated from Raney nickel by filtration and evaporated. The residue (0.34 g) was recrystallized with *n*-hexane to give (VIIIi), mp 89.5 °C (lit,[5] mp 89.0 °C).

Found: C, 68.10; H, 6.00; N, 26.27%. Calcd for $C_9H_9N_3$: C, 67.91; H, 5.70; N, 26.40%. IR: 3100, 1600, 1530, 1500, 1310, 765, 695 cm^{-1}. UV λ_{max}^{EtOH} 244 nm (lit,[5] 244 nm). NMR: δ 2.53 (s, $-CH_3$), 7.35—7.90 ($-C_6H_5$), 8.59 (s, =CH–).

2) A mixture of 1.0 g of 1-phenyl-3-methyl-5-methylthio-1,2,4-triazole (VIIi) and *ca.* 10 g of Raney nickel (W-2) was refluxed for 24 hr. It was worked up as in the previous experiment to give (VIIIi), 0.70 g.

The author wishes to thank Professor A. Hagitani, Professor I. Muramatu, and assistant Professor Y. Satoh for many helpful discussions and suggestions during this work, and he also indebted to Mr. S. Kodaka and Mr. T. Shimada for their assistance in the experiments.

Peptides. IV. Racemization Suppression by the Use of Ethyl 2-Hydroximino-2-cyanoacetate and Its Amide

Masumi ITOH

Research Laboratories, Fujisawa Pharmaceutical Co., Ltd. Kashima-cho, Higashiyodogawa-ku, Osaka 532

(Received February 6, 1973)

Racemization suppression by the addition of ethyl 2-hydroximino-2-cyanoacetate (IIIa) or 2-hydroximino-2-cyanoacetamide (IIIb), during coupling stages in peptide synthesis, was studied. The effectiveness of IIIa was compared with these of known additives by the help of Bodanszky's test, which is a simple and accurate method for racemization detection.

There are so many literatures reported about racemization suppression during coupling stages in peptide synthesis.[1,2] These have recommended the use of restricted amount of base,[3] the use of weaker bases which have sufficient basicity to proceed the reaction,[4-6] or the addition of some acidic and nucleophilic compounds for racemization suppression.[7-11] A combination of dicyclohexylcarbodiimide (DCC) with *N*-hydroxysuccinimide (I) practically seems to be an attractive coupling reagent, but it has also known that I is not so stable and that the combination of DCC with I occasionally leads to some side reactions.[12,13] Later 1-hydroxybenzotriazole (II) and its derivatives have been proposed as superior additives than I.[10] In the DCC method using additives, Anderson has concluded that a major factor for racemization suppression was not neutralization of basicity of DCC by an additive, but its nucleophilic reactivity.[14] Some oximes reported as alcoholic components of active esters[15-18] seem to be good nucleophiles, but the reactivity of these esters is somewhat lower than those of other types of active esters. It was expected, therefore, that strongly acidic and nucleophilic oximes, which possess electron-withdrawing groups in the molecule, might be suitable as additives. The author intended to search for more promising additives and alcoholic components of active esters, and now wishes to report the use of strongly acidic oximes, ethyl 2-hydroximino-2-cyanoacetate (IIIa) and 2-hydroximino-2-cyanoacetamide (IIIb), as suitable additives for the same purpose.

Results

The pK_a values of several oximes prepared were compared (Table 1), and acidic oximes, IIIa and IIIb, were chosen as possible additives among them. At the same time several acylamino acid oxime esters shown in Table 2 were prepared and examined their reactivities with ethyl glycinate by the help of thin layer chromatography. It was also shown that those esters with IIIa and IIIb were more reactive than others tested. Both of IIIa and IIIb are stable, acidic compounds and are used in organic syntheses.

H	$COCH_3$	8.4
H	CH_3	>11

Racemization with these additives were examined first by Anderson's test.[19] The coupling reaction of *N*-benzyloxycarbonylglycyl-L-phenylalanine with ethyl glycinate gave no racemate by the use of DCC with IIIa or IIIb in tetrahydrofuran at room temperature, while the control experiment, without additive, gave 8% of racemate. The effectiveness of IIIa was further examined by Young's test.[20] The crude coupling product, ethyl *N*-benzoylleucylglycinate, showed 93.6% optical purity calculated from the optical rotation, which was raised to 97% by recrystallization. This method is not satisfactory for the detection of small

Table 3. Comparison of effectiveness of the additives

Acetyl-L-isoleucine	Ethyl glycinate hydrochloride	Triethylamine	Additive	Extent of racemization (%)[a]
1.0 mmol	1.0 mmol	1.0 mmol	none	35
1.0	1.0	1.0	I 1.2 mmol	2.7
1.0	1.0	1.0	II 1.2	8.8
1.0	1.0	1.0	IIIa 1.2	1.8

a) Racemization during hydrolysis was not subtracted.

quantity of racemate, because it does not give accurate percentage of racemization if the protected dipeptide is contaminated with unconcerned impurities. Therefore, Bodanszky's test[21] was chosen as a more simple and sensitive procedure for racemization detection. For a comparison of additives, I, II, and IIIa, coupling of *N*-acetyl-L-isoleucine and ethyl gylcinate with DCC was carried out in dimethylformamide (DMF), in which significant racemization occurs. The crude product, ethyl *N*-acetylisoleucylglycinate, was hydrolyzed by 6M hydrochloric acid at 110 °C and the hydrolyzate was subjected to amino acid analysis to detect D-alloisoleucine. About 0.7% of racemization occured during hydrolysis of *N*-acetyl-L-isoleucine itself under the same condition. The results obtained are summarized in Table 3, which shows that all of additives examined suppress racemization potently. Unexpectedly, II is less effective than I. Although this is incompatible with previously reported results by König and Geiger,[10] it is difficult to discuss because the racemate detection systems are completely different.

Apart from such a problem the combination of DCC with IIIa seems to be a promising approach in coupling reactions.

Experimental

Capillary melting points were observed on a Hoover "Uni-Melt" apparatus and are uncorrected.

Measurement of pK_a *Values of Several Oximes in Aqueous Solution.* A solution of small amount of sample (2—7 mg) in 0.02 M potassium hydroxide (6.0 ml) was titrated by the use of an automatic titrator, Metrohm E 336. The pK_a values measured are listed in Table 1. Oximes were prepared according to the literatures: ethyl 2-hydroximino-2-cyanoacetate (IIIa),[22] 2-hydroximino-2-cyanoacetamide (IIIb),[22] ethyl 2-hydroximino-2-acetoacetate,[23] diethyl 2-hydroximinomalonate,[24] 3-hydroximinopentan-2,4-dione,[25] and 3-hydroximinopropan-2-one.[26]

Preparation of Esters of Acylamino Acids with Oximes. A typical example is as follows: DCC (1.05 g) was added to a solution of *N*-benzyloxycarbonyl-L-proline (1.25 g) and IIIb (0.56 g) in dioxane (10 ml) at 0 °C. The mixture was allowed to react for 2 hr at the same temperature and to stand for 16 hr at room temperature. After filtration the filtrate was evaporated to dryness. The product was filtered with small amount of 2-propanol and petroleum ether, and was recrystallized from same solvent system; yield 1.5 g (85%); mp 136—138 °C.

Found: C, 55.74; H, 4.71; N, 15.76%. Calcd for $C_{16}H_{18}O_4N_4$: C, 55.81; H, 4.68; N, 16.27%.

The other esters prepared are listed in Table 2.

Investigation of the Effectiveness of IIIa and IIIb for Racemization Suppression. a) Anderson's Test:[19] *N*-Benzyloxycarbonylglycyl-L-phenylalanine (1.78 g, 5 mmol), ethyl glycinate (0.52 g, 5 mmol) and IIIb (0.68 g, 6 mmol) were dissolved in dry tetrahydrofuran (25 ml). DCC (1.20 g, 5.8 mmol) was added to the solution at room temperature and the mixture was stirred for 4 hr. After the addition of acetic acid (0.05 ml), the mixture was filtered. The filtrate was evaporated completely, and the residue was taken up in ethyl acetate, washed with 1 M sodium bicarbonate solution, water, 1 M hydrochloric acid and water, and dried over mag-

nesium sulfate. After evaporation of the solvent crude ethyl *N*-benzyloxycarbonylglycyl-L-phenylalanylglycinate was obtained. Fractional recrystallization from ethanol gave no racemate; yield of pure L isomer, 2.03 g (92%); mp 116—118 °C.

The use of IIIa (0.71 g) in place of IIIb gave similar result. In control experiment, without additive, 8% of racemate, ethyl *N*-benzyloxycarbonylglycyl-DL-phenylalanylglycinate (mp 130—132 °C), was obtained from crude protected tripeptide by fractional recrystallization.

b) Young's Test:[20] DCC (0.52 g, 2.52 mmol) was added to a solution of *N*-benzoyl-L-leucine (0.60 g, 2.55 mmol), free ethyl glycinate (0.30 g, 2.91 mmol) and IIIa (0.35 g, 2.46 mmol) in ethyl acetate (5 ml) at 0 °C. The mixture was stirred for 3 hr at the same temperature, and was filtered. The filtrate was diluted with ethyl acetate, washed with 1 M sodium bicarbonate solution, water, 1 M hydrochloric acid and water, and dried over magnesium sulfate. After evaporation of the solvent the residue was filtered with ether–petroleum ether mixture; yield, 0.73 g; mp 145—152 °C; $[\alpha]_D^{25}$ −30.9° (*c* 3, EtOH). Recrystallization from ethyl acetate–petroleum ether gave 0.61 g of product; mp 151—153 °C; $[\alpha]_D^{25}$ −33.0° (*c* 3, EtOH).

c) Bodanszky's Test:[21] A typical example is as follows: Ethyl glycinate hydrochloride (140 mg, 1.0 mmol) was dissolved in dry DMF (3.0 ml) and neutralized with triethylamine (0.14 ml, 1.0 mmol) under ice-cooling. Then IIIa (170 mg, 1.2 mmol) and *N*-acetyl-L-isoleucine[27] (173 mg, 1.0 mmol) were dissolved in the above solution. A solution of DCC (206 mg, 1.0 mmol) in dry DMF (2.0 ml) was added into the solution, and the mixture was allowed to react for 3 hr at +5 °C. After standing overnight DMF was evaporated completely under nitrogen gas, and the residue was extracted with ethyl acetate. The filtered extract was washed with water, 1 M sodium bicarbonate solution (4 times), water, 1 M hydrochloric acid and water, and dried over magnesium sulfate. After evaporation of the solvent the residue was filtered with small amount of ether–petroleum ether mixture; yield of crude ethyl *N*-acetylisoleucylglycinate, 178 mg (69%). A small amount of the sample was hydrolyzed by 6 M hydrochloric acid at 110 °C in a sealed tube for 16 hr. The hydrolyzate was subjected to an amino acid analyzer, and 1.8% of racemization was detected. The extent of racemization was calculated according to the following formula:

$$\text{Racemization (\%)} = \frac{\text{alloisoleucine} \times 100}{\text{alloisoleucine} + \text{isoleucine}}$$

During hydrolysis of *N*-acetyl-L-isoleucine under the same condition, very small amount of alloisoleucine (0.7%) was formed and detected by following amino acid analysis.

The results obtained are summarized in Table 3.

The author wishes to express his deep gratitude to Professor Miklos Bodanszky of Case Western Reserve University, Cleveland, U.S.A., for his kind advice and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2221—2225 (1973)

Studies of Enamines. III.[1] The Reaction of 4-(1-Piperidyl)- and 4-(1-Pyrrolidinyl)-3-penten-2-ones with Aryl Isothiocyanates

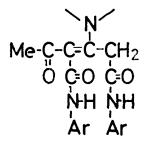
Otohiko TSUGE[2] and Akitaka INABA

Research Institute of Industrial Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

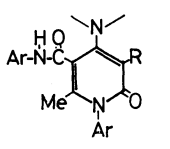
(Received February 7, 1973)

The reaction of enamino ketones, derived from acetylacetone and piperidine or pyrrolidine, with aryl isothiocyanates has been investigated. In contrast with phenyl isocyanates, phenyl isothiocyanates react with the enamino ketones to yield the corresponding 3-phenylthiocarbamoyl derivatives (1 : 1 adducts). The reaction with 1-naphthyl isothiocyanate forms 3-naphthylthiocarbamoyl and/or 2-thiopyridone derivatives, depending on the reaction conditions.

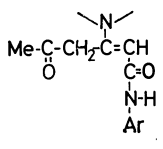
We have reported that 4-(1-piperidyl)- (Ia) and 4-(1-pyrrolidinyl)-3-penten-2-one (Ib) react with phenyl isocyanates to give 3,5-diphenylcarbamoyl (**A**), 2-pyridone (**B**) and/or its 3-phenylcarbamoyl derivatives (**C**), depending on the reaction conditions.[1] The reaction with 1-naphthyl isocyanate afforded the 1 : 1 adduct (**D**).



A



B (R=H)
C (R=CONHAr)



D

The only example involving the reaction of enamino ketones with isothiocyanates was reported by Goerdeler and Keuser;[3] cyclic enamino ketones derived from cyclohexane-1,3-dione and its 5,5-dimethyl derivative reacted with aryl isothiocyanates to yield the corresponding 2-thiocarbamoyl compounds.

For comparison with the reactions of enamino ketones I with isocyanates, and those of cyclic enamino ketones with isothiocyanates, it seemed to be of interest to investigate the reaction of I with isothiocyanates.

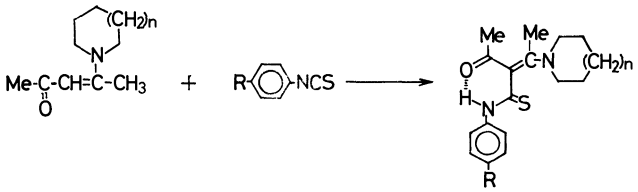
1) Part II of this series: O. Tsuge and A. Inaba, This Bulletin, **46**, 286 (1973).
2) To whom inquiries should be directed.
3) J. Goerdeler and U. Keuser, *Chem. Ber.*, **97**, 2209 (1964).

Results and Discussion

When a solution of equimolar amounts of enamino ketone Ia and phenyl isothiocyanate (IIa) in benzene was refluxed for 5 hr, a 1 : 1 adduct IIIa was obtained in a good yield. Enamino ketone Ia reacted with phenyl isocyanate to give 1 : 2 adduct **A** and its derivatives **B** and **C**.[1] However, the 1 : 1 adduct IIIa was also formed even when excess IIa was employed.

Similarly, the reaction of Ia with *p*-chlorophenyl isothiocyanate (IIb), and that of enamino ketone Ib with IIa afforded the corresponding 1 : 1 adducts IIIb and IIIc, respectively.

The IR spectra of all III exhibited no well-defined bands ascribable to ν_{NH} absorptions, but their structures were assigned to those of the corresponding 3-arylthiocarbamoyl-4-amino-3-penten-2-ones on the basis of their NMR spectral data and chemical conversion. The NMR spectra in deuteriochloroform ($CDCl_3$) displayed signals at δ about 14 (1H, broad, N**H**), and 2.8, 1.8 ppm (each 3H, s, C**H**$_3$), besides methylene and aromatic protons. These observations indicate that III exists as the chelating form[4] as shown in Scheme 1.



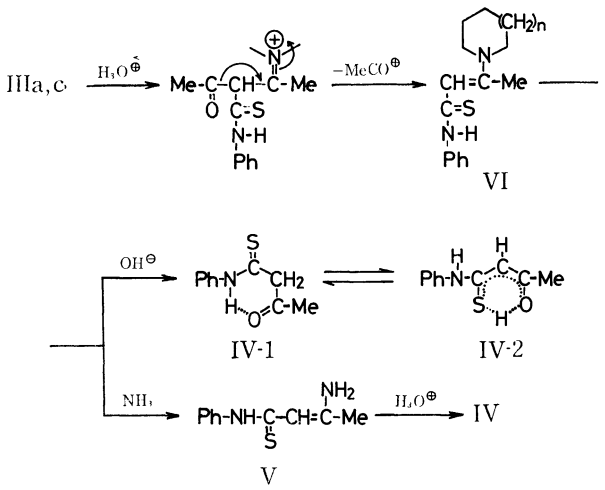
I a: n=1 b: n=0 — II a: R=H b: R=Cl — III a: n=1, R=H b: n=1, R=Cl c: n=0, R=H

Scheme 1

Hydrolysis of both IIIa and IIIc with 18% hydrochloric acid at room temperature for 6 hr, followed by neutralization with aqueous sodium hydroxide, afforded the same product, phenylthiocarbamoylacetone (IV).[5] When the hydrolyzed product of IIIa under same conditions was treated with ammonium hydroxide, 1-phenylthiocarbamoyl-2-aminopropene (V) was obtained; V was transformed into IV on further acidic hydrolysis.

Hydrolysis of III is assumed to proceed *via* the initial formation of 1-phenylthiocarbamoyl-2-(1-piperidyl or 1-pyrrolidinyl)propene (VI) as shown in Scheme 2. 1-Phenylthiocarbamoyl-2-(1-pyrrolidinyl)propene (VIa) was isolated by the hydrolysis of IIIc under mild conditions.

The structures of IV, V, and VIa were confirmed on the basis of their spectral data and microanalyses. The NMR spectrum of IV indicates that IV exists as a 5 : 3 mixture of hydrogen-bonded froms IV-1 and IV-2 in $CDCl_3$; signals appear at δ 1.98 (9/8H, s, C**H**$_3$ in IV-2), 2.34 (15/8H, s, C**H**$_3$ in IV-1), 4.13 (5/4H, s, C**H**$_2$), 5.56 (3/4H, s, =C**H**), 7.20—7.9 (5H, m, aromatic protons), 10.6—10.9 (3/8H, broad, N**H** and O**H** in IV-2), and 14.45 ppm (5/8H, broad singlet, N**H** in IV-1) in the spectrum.



VI — IV-1 — IV-2 — V — IV

Scheme 2.

Treatment of IIIc with hydrazine hydrate afforded 3(5)-methyl-4-acetyl-5(3)-anilinopyrazole (VII), 3,5-dimethyl-4-phenylthiocarbamoylpyrazole (VIII), and hydrazone (IX) of VII. Similarly, IIIa reacted with hydrazine hydrate to give VII, VIII, and IX. The structures of VII and IX were confirmed by their spectral data and microanalyses. The reaction of VII with hydrazine hydrate gave hydrazone IX, which was easily hydrolyzed to VII. Purification of VIII was difficult owing to contamination with sulfur, the NMR spectrum of crude VIII exhibited a signal ascribable to two methyls at δ 2.38 ppm. Acetylation of VIII with acetic anhydride afforded 1-acetyl-3,5-dimethyl-4-phenylthiocarbamoylpyrazole (X) in a good yield. On the other hand, IIIc reacted with phenylhydrazine to form 1-phenyl-3-methyl-5-anilinopyrazole (XI), whose structure was deduced from its spectral data and the mode of its formation (Scheme 3).

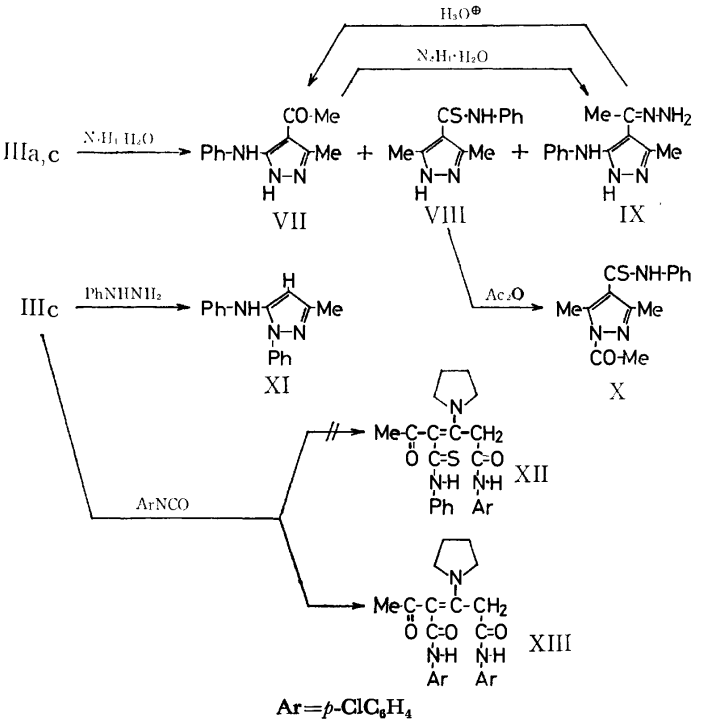
The reaction of IIIc with *p*-chlorophenyl isocyanate afforded bis(*p*-chlorophenylcarbamoyl) derivative XIII, instead of the expected product XII.

3-(1-Naphthylthiocarbamoyl) compound XVa, a product of the same type as III, was obtained, when enamino ketone Ia was treated with 1-naphthyl isothiocyanate (XIV) in refluxing benzene. The structure of XVa was confirmed by its spectral data as well as by its microanalysis. In the same reaction under reflux in xylene two products XVa and XVIa were formed in low yields. Under reflux in both benzene and xylene, however, enamino ketone Ib gave XVIb but not 1 : 1 adduct XVb corresponding to XVa.

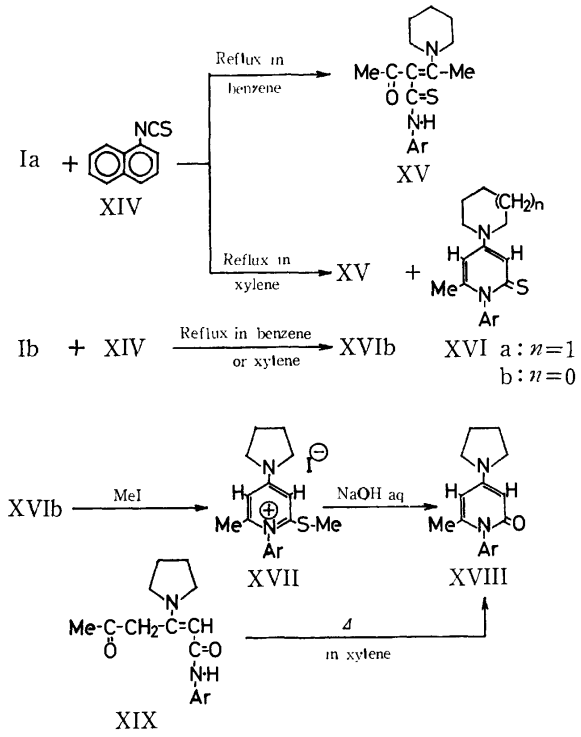
The molecular formulas of XVIa and XVIb corresponded to those of the compounds derived from 1 : 1 adducts with loss of water. The IR spectra of both XVI exhibited bands assignable to $\nu_{C=C}$, but no absorption bands of ν_{NH}. Both NMR spectra displayed two olefinic protons besides methyl, methylene and aromatic protons. Thus, XVI were concluded to be the corresponding 1-(1-naphthyl)-4-amino-6-methylpyrid-2-thiones, whose structures correspond to those derived

4) Goerdeler and Keuser[3] reported that 1-amino-2-arylthiocarbamoylcyclohexen-3-ones exist as double chelating forms.

5) Similarly, hydrolysis of bis(phenylcarbamoyl) derivative **A** afforded 1,3-bis(phenylcarbamoyl)acetone with loss of acetyl group.[1]



Scheme 3.



Scheme 4.

from isomers of XV, 4-amino-5-(1-naphthylthiocarbamoyl)-4-penten-2-ones, with dehydration.

Compounds XVIa and XVIb remained unchanged on both acidic and alkaline hydrolysis under various conditions. The reaction of XVIb with methyl iodide afforded S-methyl pyridinium iodide XVII, which was treated with ethanolic sodium hydroxide to give 1-(1-naphthyl)-4-(1-pyrrolidinyl)-6-methylpyrid-2-one (XVIII). The structure of XVIII was confirmed by its spectral data as well as by identification with an authentic sample prepared from 4-(1-pyrrolidinyl)-5-(1-naphthylcarbamoyl)-4-penten-2-one (XIX).[1] This supports the proposed structure for XVI.

Experimental

All melting points are uncorrected. The IR spectra were measured as KBr pellets by a Nippon Bunko IR-S spectrophotometer, and the NMR spectra were determined at 60 MHz on a Hitachi R-20 NMR spectrometer with TMS as an internal reference. The mass spectra were obtained on a Hitachi RMS-4 mass spectrometer with a direct inlet and an ionization energy of 70 eV. Microanalyses were carried out by Miss M. Akita with a Yanagimoto C.H.N. Corder MT-1.

Materials. 4-(1-Piperidyl)- (Ia) and 4-(1-pyrrolidinyl)-3-penten-2-one (Ib) were prepared from acetylacetone and the corresponding amines.[1] Commercial phenyl (IIa), *p*-chlorophenyl (IIb), and 1-naphthyl isothiocyanate (XIV) were used.

Reaction of 4-(1-Piperidyl)-3-penten-2-one (Ia) with Phenyl Isothiocyanate (IIa). 1.67 g (0.01 mol) of Ia and 1.35 g (0.01 mol) of IIa were dissolved in 50 ml of benzene and the solution was refluxed for 5 hr, and concentrated *in vacuo* to give crystals which, on recrystallization from ethanol, afforded 2.53 g (84%) of 3-phenylthiocarbamoyl-4-(1-piperidyl)-3-penten-2-one (IIIa), mp 135—136 °C (decomp.), as yellow prisms.

Found: C, 67.30; H, 7.60; N, 9.33%. Calcd for $C_{17}H_{22}N_2OS$: C, 67.52; H, 7.33; N, 9.27%.

NMR (in $CDCl_3$) δ ppm: 1.78 (3H, s, CH_3), 1.85 (6H, m, CH_2), 2.80 (3H, s, CH_3), 3.93 (4H, m, CH_2), 7.0—7.95 (5H, m, aromatic protons), 13.98 (1H, broad, NH).

Similarly, the reaction of 4-(1-pyrrolidinyl)-3-penten-2-one (Ib) with IIa gave 3-phenylthiocarbamoyl-4-(1-pyrrolidinyl)-3-penten-2-one (IIIc), mp 131—132 °C (decomp.), as yellow

prisms (from ethanol). Yield, 83%.

Found: C, 66.65; H, 7.03; N, 9.71%. Calcd for $C_{16}H_{20}N_2OS$: C, 66.64; H, 6.99; N, 9.72%.

NMR (in $CDCl_3$) δ ppm: 1.80 (3H, s, CH_3), 2.11 (4H, m, CH_2), 2.73 (3H, s, CH_3), 3.88 (4H, m, CH_2), 7.0—8.0 (5H, m, aromatic protons), 13.89 (1H, broad, NH).

A similar reaction of Ia with *p*-chlorophenyl isothiocyanate (IIb) at room temperature for 10 hr afforded 3-*p*-chlorophenylthiocarbamoyl-4-(1-piperidyl)-3-penten-2-one (IIIb), mp 141—142 °C (decomp.), as yellow prisms (from ethanol). Yield, 44%.

Found: C, 60.85; H, 6.32; N, 8.27%. Calcd for $C_{17}H_{21}N_2OSCl$: C, 60.62; H, 6.24; N, 8.59%.

NMR (in $CDCl_3$) δ ppm: 1.80 (3H, s, CH_3), 1.88 (6H, m, CH_2), 2.81 (3H, s, CH_3), 3.96 (4H, m, CH_2), 7.1—7.9 (4H, m, aromatic protons), 14.04 (1H, broad, NH). Mass spectrum *m/e*: 336, 338 (M^+, rel. intensity 3: 1).

Hydrolysis of 1: 1 Adduct III. *i)* A solution of 1.0 g of IIIa in 10 ml of 18% hydrochloric acid was stirred at room temperature for 6 hr, and neutralized (*a*) with aqueous sodium hydroxide or (*b*) with ammonium hydroxide as follows. (a) The solution was neutralized with aqueous sodium hydroxide and then extracted with diethyl ether. The ether extract was concentrated to give crystals which on recrystallization from ethanol–petroleum ether mixture afforded 0.38 g (60%) of phenylthiocarbamoylacetone (IV), mp 61—62.5 °C (decomp.), as yellow prisms.

Found: C, 62.09; H, 5.75; N, 7.30%. Calcd for $C_{10}H_{11}NOS$: C, 62.16; H, 5.74; N, 7.25%.

IR cm^{-1}: 3290, 3220 (NH or OH), 1630 (C=O or C=C). Mass spectrum *m/e*: 193 (M^+).

(b) The solution was treated with 20% ammonium hydroxide and the resulting precipitate was filtered. Recrystallization from ethanol–petroleum ether mixture afforded 0.25 g (40%) of 1-phenylthiocarbamoyl-2-aminopropene (V), mp 155—157 °C (decomp.), as pale yellow needles.

Found: C, 62.28; H, 6.35; N, 14.50%. Calcd for $C_{10}H_{12}N_2S$: C, 62.48; H, 6.29; N, 14.58%.

IR cm^{-1}: 3300 (NH), 1672 (C=C). NMR (in $CDCl_3$) δ ppm: 1.93 (3H, s, CH_3), 5.32 (1H, s, =CH), 7.0—7.5 (7H, m, aromatic protons (5H) and NH (2H)), 8.0 (1H, broad, NH). Mass spectrum *m/e*: 192 (M^+).

The hydrolysis of V with 18% hydrochloric acid gave IV quantitatively.

ii) A solution of 1.0 g of IIIc in 10 ml of 18% hydrochloric acid was stirred at room temperature for 2 hr, and neutralized with aqueous sodium hydroxide. The resulting precipitate was filtered. Recrystallization from ethanol afforded 0.37 g (43%) of 1-phenylthiocarbamoyl-2-(1-pyrrolidinyl)propene (VIa), mp 156—157 °C, as yellow plates.

Found: C, 68.08; H, 7.42; N, 11.34%. Calcd for $C_{14}H_{18}N_2S$: C, 68.27; H, 7.37; N, 11.37%.

IR cm^{-1}: 3290 (NH), 1580 (C=C).

A trace of IV was obtained from the filtrate by a treatment similar to i)-(a).

Reaction of 1: 1 Adduct IIIc with Hydrazine Hydrate. A solution of 2.35 g of IIIc and 1 ml of hydrazine hydrate in 10 ml of ethanol was stirred at room temperature for 2 hr and then poured into 30 ml of water. The resulting precipitate was collected by filtration. Recrystallization from ethanol–petroleum ether mixture afforded 0.5 g (28.5%) of 3(5)-methyl-4-acetyl-5(3)-anilinopyrazole (VII), mp 236—237 °C (decomp.), as colorless prisms.

Found: C, 66.90; H, 6.14; N, 19.29%. Calcd for $C_{12}H_{13}N_3O$: C, 66.95; H, 6.09; N, 19.52%.

IR cm^{-1}: 3320, 3220 (NH), 1600 (C=O). NMR (in $CDCl_3$) δ ppm: 2.42, 2.53 (each 3H, s, CH_3), 6.85—7.8 (6H, m, aromatic protons (5H) and NH), 9.36 (1H, broad, NH). Mass spectrum *m/e*: 215 (M^+), 200 (M^+—Me), 172 (M^+—COMe), 124 (M^+—PhNH), 104, 77.

The filtrate was concentrated *in vacuo* to leave a residue which was triturated with benzene to give 50 mg of 3,5-dimethyl-4-phenylthiocarbamoylpyrazole (VIII) contaminated with sulfur. Its purification was very difficult.

Crude VIII; mp 148—149 °C (decomp.), yellow prisms. IR cm^{-1}: 3220, 3120—2800 (NH). NMR (in $CDCl_3$) δ ppm: 2.38 (6H, broad singlet, CH_3), 7.0—8.0 (6H, m, aromatic protons (5H) and NH), 9.1 (1H, broad, NH). Mass spectrum *m/e*: 231 (M^+), 198 (M^+—SH), 139 (M^+—PhNH, base peak), 122 (139^+—NH_3), 93, 77.

The benzene solution which was removed VIII was concentrated *in vacuo* to give crystals, which on recrystallization from ethanol–petroleum ether afforded 0.32 g (17%) of hydrazone IX, mp 175—177 °C (decomp.), as colorless prisms.

Found: C, 63.20; H, 6.85; N, 30.36%. Calcd for $C_{12}H_{15}N_5$: C, 62.86; H, 6.60; N, 30.55%.

IR cm^{-1}: 3280, 3150, 3040—2800 (NH), 1640 (C=N). NMR (in $CDCl_3$) δ ppm: 2.1 (6H, broad singlet, CH_3), 4.8—6.0 (3H, broad, NH), 6.5—7.5 (6H, m, aromatic protons (5H) and NH). Mass spectrum *m/e*: 229 (M^+), 198 (M^+—N_2H_3), 137 (M^+—PhNH), 120 (137^+—NH_3), 93, 77.

Similarly, the reaction of IIIa with hydrazine hydrate afforded three pyrazoles VII, VIII, and IX in similar yields to those in the case of IIIc.

1-Acetyl-3,5-dimethyl-4-phenylthiocarbamoylpyrazole (X). A solution of crude VIII (20 mg) in 10 ml of acetic anhydride was stirred at room temperature for 5 hr and then poured into water. The resulting precipitate was filtered. Recrystallization from ethanol–petroleum ether mixture afforded 20 mg of X, mp 163—164 °C (decomp.), as yellow needles.

Found: C, 61.48; H, 5.65; N, 15.17%. Calcd for $C_{14}H_{15}N_3OS$: C, 61.53; H, 5.53; N, 15.38%.

IR cm^{-1}: 3310 (NH), 1730 (C=O). Mass spectrum *m/e*: 273 (M^+), 240 (M^+—SH), 230 (M^+—COMe), 198 (230^+—S), 181 (M^+—PhNH), 139 (181^+—CH_2CO, base peak).

Reaction of 1: 1 Adduct IIIc with Phenylhydrazine. A solution of 1.15 g of IIIc and 0.5 g of phenylhydrazine in 30 ml of ethanol was stirred at room temperature for 7 hr and then concentrated *in vacuo* to leave a solid, which was chromatographed on alumina using benzene as an eluent to give 1-phenyl-3-methyl-5-anilinopyrazole (XI), mp 119—120 °C (decomp.) (lit,[6] mp 120 °C), as red prisms. Yield, 0.3 g (34.7%).

Found: 77.32; H, 6.12; N, 16.70%. Calcd for $C_{16}H_{15}N_3$: C, 77.08; H, 6.06; N, 16.86%.

IR cm^{-1}: 3200 (NH). NMR (in $CDCl_3$) δ ppm: 2.28 (3H, s, CH_3), 5.67 (1H, broad, NH), 5.98 (1H, s, =CH), 6.7—7.6 (10H, m, aromatic protons).

Reaction of 1: 1 Adduct IIIc with p*-Chlorophenyl Isocyanate.* A solution of 1.5 g of IIIc and 1.53 g of *p*-chlorophenyl isocyanate in 30 ml of benzene was refluxed for 5 hr. After cooling, filtration gave crystals, which on recrystallization from benzene afforded 2.0 g (85%) of bis(*p*-chlorophenylcarbamoyl)-4-(1-pyrrolidinyl)-3-penten-2-one (XIII), mp 162—163 °C (lit,[1] mp 162—163 °C), as colorless needles.

Reaction of Enamino Ketone I with 1-Naphthyl Isothiocyanate (XIV). *i)* A solution of 1.67 g (0.01 mol) of Ia and 1.85 g (0.01 mol) of XIV in 30 ml of benzene was refluxed for 5 hr. It was concentrated *in vacuo* to give crystals, which on recrystallization from ethanol afforded 1.58 g (45%) of 3-(1-naphthylthiocarbamoyl)-4-(1-piperidyl)-3-penten-2-one

6) A. Michaelis and E. Grunkel, *Ber.*, **34**, 723 (1901).

(XVa), mp 123—124 °C (decomp.), as yellow needles.

Found: C, 71.73; H, 6.96; N, 7.66%. Calcd for $C_{21}H_{24}N_2OS$: C, 71.57; H, 6.86; N, 7.95%.

NMR (in $CDCl_3$) δ ppm: 1.77 (6H, m, CH_2), 1.82, 2.77 (each 3H, s, CH_3), 3.83 (4H, m, CH_2), 7.2—8.6 (7H, m, aromatic protons), 14.40 (1H, broad, NH).

ii) After a solution of 1.67 g of Ia and 1.85 g of XIV in 20 ml of xylene had been refluxed for 1 hr, it was concentrated *in vacuo* to leave a residue. The residue was chromatographed on alumina using chloroform as an eluent to give 0.26 g (7.8%) of 1-(1-naphthyl)-4-(1-piperidyl)-6-methylpyrid-2-thione (XVIa) and 0.46 g (13%) of XVa.

Compound XVIa; mp 215—217 °C (decomp.), pale orange prisms.

Found: C, 75.62; H, 6.68; N, 8.62%. Calcd for $C_{21}H_{22}N_2S$: C, 75.42; H, 6.63; N, 8.38%.

IR cm^{-1}: 1622 (C=C). NMR (in $CDCl_3$) δ ppm: 1.70 (6H, m, CH_2), 1.87 (3H, s, CH_3), 3.47 (4H, m, CH_2), 6.31, 7.21 (each 1H, d, =CH, J=3 Hz), 7.3—8.1 (7H, m, aromatic protons). Mass spectrum *m/e*: 334 (M^+), 302 (M^+-S).

Similarly, Ib reacted with XIV in refluxing benzene to afford a 17.2% yield of 1-(1-naphthyl)-4-(1-pyrrolidinyl)-6-methylpyrid-2-thione (XVIb), mp 298—300 °C (decomp.), as pale orange prisms.

Found: C, 75.18; H, 6.33; N, 8.55%. Calcd for $C_{20}H_{20}N_2S$: C, 74.99; H, 6.29; N, 8.74%.

IR cm^{-1}: 1620 (C=C). NMR (in $CDCl_3$) δ ppm: 1.88 (3H, s, CH_3), 2.05, 3.45 (each 4H, m, CH_2), 6.14, 7.00 (each 1H, d, =CH, J=3 Hz), 7.4—8.1 (7H, m, aromatic protons). Mass spectrum *m/e*: 320 (M^+), 288 (M^+-S).

1-(1-Naphthyl)-4-(1-pyrrolidinyl)-6-methylpyrid-2-one (XVIII). *i)* A solution of 1.0 g of pyrid-2-thione XVIb in 10 ml of methyl iodide was stirred at room temperature for 2 hr, during which time crystals were precipitated. The crystals were collected by filtration and washed with petroleum ether to give 1.4 g (97%) of *S*-methyl pyridinium iodide XVII, mp 200—202 °C (decomp.), as colorless crystals.

NMR (in $CDCl_3$) δ ppm: 2.12, 2.56 (each 3H, s, CH_3), 2.18, 3.82 (each 4H, m, CH_2), 6.48, 6.99 (each 1H, d, =CH, J=3 Hz), 7.2—8.2 (7H, m, aromatic protons).

XVII was hydrolyzed without further purification. A solution of 1.0 g of XVII in 10 ml of ethanol was stirred with 10 ml of 5 M aqueous sodium hydroxide at room temperature for 5 hr, and then was poured into water to precipitate crystals, which on recrystallization from ethanol afforded 0.48 g (73%) of XVIII, mp 233—234 °C, as colorless prisms.

Found: C, 79.25; H, 6.65; N, 9.22%. Calcd for $C_{20}H_{20}N_2O$: C, 78.92; H, 6.62; N, 9.20%.

IR cm^{-1}: 1655 (C=O). NMR (in $CDCl_3$) δ ppm: 1.78 (3H, s, CH_3), 2.01, 3.37 (each 4H, m, CH_2), 5.53, 5.81 (each 1H, d, =CH, J=3 Hz), 7.3—8.1 (7H, m, aromatic protons). Mass spectrum *m/e*: 304 (M^+).

ii) A solution of 100 mg of 4-(1-pyrrolidinyl)-5-(1-naphthylcarbamoyl)-4-penten-2-one (XIX)[1] in 10 ml of xylene was refluxed for 5 hr, and then concentrated *in vacuo*. The residue was then extracted with petroleum ether. The solvent was removed from the extract to leave crystals. Recrystallization from ethanol gave 25 mg (26%) of colorless prisms, which were identical with XVIII.

The Viscosity *B*-Coefficients of the Anionic Species of Benzoic Acid and Its Monosubstituted Derivatives

Motoo YASUDA and Kiyoshi MIZUTANI
Department of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received March 14, 1972)

The viscosities of aqueous electrolyte solutions have been measured for a large number of electrolytes. According to Jones and Dole,[1] who first measured accurately the viscosity of the aqueous electrolyte solutions up to the range of extremely high dilution, the specific viscosity, η_{sp}, of aqueous solutions of strong electrolytes is related to the solute molarity, c, by the equation:

$$\eta_{sp} = \frac{\eta}{\eta_0} - 1 = A\sqrt{c} + Bc$$

where η and η_0 are the viscosities of the solution and of water respectively. A is a coefficient depending on the ion-ion interaction between the solute ions; it can be calculated theoretically. B is a coefficient depending on the size of the ions and on the interaction between the ions and the surrounding solvent; it is usually called the Jones-Dole's viscosity B-coefficient.

In the course of measurements of the B-coefficients of isomers of metal complexes, we felt that a thorough study of the viscosity of the benzoate anion and its derivatives might supply useful information concerning the contribution of substituents to the viscosity. A study was, therefore, made of the viscosities of the benzoic acid and its derivatives.

Experimental

Measurements. The viscosities were measured with a Cannon-Fenske capillary viscometer with an efflux time of *ca.* 300 seconds for distilled water. The viscosities and densities of the solutions were measured in a water bath maintained at 25±0.01 °C. The efflux times, measured with a stopwatch to 0.1 sec, were easily reproducible to 0.2 sec.

Materials. Samples of benzoic acid and its derivatives of a guaranteed reagent grade were used. From stock solutions, prepared from benzoic acids and potassium hydroxide, solutions containing 0.04—0.15 mol/l potassium benzoate were made by dilution and were then used for the viscosity and density measurements. In each case, the pH value of the solution was controlled so as to be about 2 or 3 pH units higher than the pK value of the parant acid.

Calculations. The B-coefficient was evaluated by plotting $\eta_{sp}/\sqrt{c}$ *vs.* $\sqrt{c}$ (Fig. 1). A straight line was obtained in each case at concentrations below 0.15 mol/l. The intersection of the resulting straight line on the ordinate gives the value of the A-coefficient. In each case, the A-coefficient was found to be zero within the limits of experimental error. The slope of the resulting straight line gives the value of the B-coefficient. As has been discussed by Gurney,[2] the B-coefficient is composed additively of contributions from each of the solute species present in the solution. Moreover, the B-value of the benzoate anion can be obtained by subtracting a correction for the other solute species present in the solution.

Results and Discussion

As the pH value of the solution was at least 2 pH units higher than the pK value of the parent benzoic acid, the contribution of the un-ionized benzoic acid to the viscosity of the solution may be practically neglected. The concentrations of the hydrogen and hydroxide ions are very low compared with that of the benzoate anion in the pH range (5—10) studied here. Moreover, their B-coefficients are themselves quite small compared with that of the benzoate anion,[2] and so their contribution to the viscosity of the solution may also be practically neglected. On the other hand, the concentration of the potassium ion is comparable to that of the benzoate anion. Hence, a correction, a relatively small one, for the potassium ion is necessary, although its B-value is actually the lowest of those of the chemical species under consideration.[2] The B-coefficients studied here are listed in Table 1.

Table 1. Viscosity B-coefficients of benzoate derivatives

Substituent	*o*-	*m*-	*p*-
H		(0.41)	
OH	0.31	0.41	0.45
CH_3	0.49	0.49	~0.49
Cl	0.49	0.47	0.47
NO_2	0.44	0.41	0.41
OCH_3	0.50	—	0.46
COO^-	0.61	0.61	0.61

As has been reported by Charles,[3] the values of η_{sp}/c for the copper chelate with an enforced planar *cis*-configuration about the metal were higher than those found for the corresponding alkyl-substituted chelates with planar *trans*-configurations, evidently the result of the permanent dipole moment associated with the *cis*-configuration. However, as may be seen from Table 1, no essential difference between the B-coefficients of *o*-, *m*-, and *p*-isomers is found, even for COO^--derivatives, with the exception of the OH-derivatives. In the latter case, the B-value of the *o*-hydroxybenzoate, *i.e.*, the salicylate anion, is appreciably lower than that

of its isomers. This may by due mainly to the formation of an intramolecular hydrogen bond, as has been discussed by Davies and Malpass[4] in connection with the difference in *B*-values between maleic acid and its isomer, fumaric acid.

For *o*-phthalic acid, the viscosity measurements were carried out over the 4.4—11.8 pH range. The slope of the straight lines obtained by plotting $\eta_{sp}/\sqrt{c}$ *vs.* $\sqrt{c}$ depend on the pH values lower than about 6. However, for the pH values higher than about 6.7, where phthalic acid, H_2A, is present virtually as the A^{2-} anion the satisfactory agreement of all the points with a single straight line indicates that the *B*-value of the phthalate anion, A^{2-}, is independent of the pH value, as has been expected.

Figure 1 shows two straight lines at the pH values of 4.6 and 7.2. The *B*-coefficient of hydrogenphthalate, HA^-, was tentatively calculated as 0.42 using the data for the lower pH range, where the A^{2-} and HA^- species are present predominantly, together with the *B*-value of A^{2-} and the acid dissociation constants of phthalic acid.

The CNDO-type Molecular Orbital Calculations of MnO_4^-, CrO_4^{2-}, PdX_4^{2-}, and PdX_6^{2-}

Shigeyoshi SAKAKI and Hiroshi KATO*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

**Department of General Education, Nagoya University, Chikusa-ku, Nagoya 464*

(Received August 3, 1972)

Since the molecular orbital (MO) calculations of MnO_4^- and CrO_4^{2-} were presented by Wolfsberg and Hermholz,[1] various MO methods have been used in the MO calculations of transition-metal complexes; the Extended Hückel,[2] SCCC,[3] CNDO-type,[4] INDO-type,[5] *ab-initio*,[6] and the others[7] methods. However, none of these methods was perfectly satisfactory, because an effective method for some compounds can not always give reasonable results in other cases. In order to re-examine the usefulness of the CNDO-type MO calculation of transition-metal complexes except for the estimation of the intra-atomic triplet transition, we calculated the electronic structures of MnO_4^-, CrO_4^{2-}, PdX_4^{2-}, and PdX_6^{2-} (X=halogen), for the CNDO-type approximation avoids the difficulties of the rotation invariance and of the estimation of the one-center exchange integral. The calculated results of the electronic population, the strength of the Pd–X bonds, and the electronic spectra of these complexes will be presented in this paper.

Method

We start from Roothaan's familiar closed-shell SCF equation[8] and separate the Hartree-Fock matrix element, F_{rs}, into the one-electron part, H_{rs}, and the two-electron part;

$$\begin{aligned} &|F_{rs}-\varepsilon S_{rs}| = 0 \\ &F_{rs} = H_{rs} + \sum_{t,u}^{occ} P_{tu}[(rs|tu)-0.5(rt|su)] \end{aligned} \quad (1)$$

where r, s, t, and u denote the atomic orbitals and whose P_{tu} is the t, u density matrix element. Then, the following approximations are introduced into Eq. (1): (I) The zero-differential overlap approximation[9] is introduced:

1) M. Wolfsberg and L. Hermholz, *J. Chem. Phys.*, **20**, 837 (1952).
2) C. J. Ballhausen and H. B. Gray, *Inorg. Chem.*, **1**, 111 (1962).
3) R. F. Fenske and C. C. Sweeney, *ibid.*, **3**, 1105 (1964).
4) a) R. D. Brown, B. H. James, M. F. O'Dwyer, and K. R. Roby, *Chem. Phys. Lett.*, **1**, 459 (1967). b) R. D. Brown, B. H. James, and M. F. O'Dwyer, *Theor. Chim. Acta*, **17**, 262, 279 (1970).
5) a) L. Oleari, G. De Michelis, and L. De Sipio, *Mol. Phys.*, **10**, 111 (1966). b) W. Th. A. M. Van Der Lugt, *Chem. Phys. Lett.*, **10**, 117 (1971).
6) I. H. Hillier and V. R. Saunders, *Proc. Roy. Soc. Ser A*, **320**, 161 (1970).
7) H. Katô, This Bulletin, **45**, 1281 (1972).
8) C. C. J. Roothaan, *Rev. Mod. Phys.*, **23**, 69 (1951).
9) J. A. Pople, D. P. Santry, and G. A. Segal, *J. Chem. Phys.*, **43**, s 129 (1965).

$$S_{rs} = \delta_{rs} \quad (2)$$

$$(rs|tu) = \delta_{rs}\delta_{tu}(rr|tt) \quad (3)$$

(II) The diagonal element, H_{rr}, of the one-electron part can be written as follows:[10]

$$H_{rr} = U_{rr} + \sum_{B \neq A} (B|rr) \quad (4)$$

$$U_{rr} = -I_r - (N_r - 1)(rr|rr) - \sum_{s \neq r}^{A} N_s(rr|ss) \quad (5)$$

$$(B|rr) = -\sum_{s}^{B} N_s(rr|ss) \quad (6)$$

where N_r and I_r represent the number of electrons on the atomic orbital (AO), r, in the neutral atom, A, and the ionization potential of AO r respectively. $\sum^A$ indicates the summation on the A atom.

(III) The off-diagonal element, H_{rs} ($r \neq s$), is approximated according to Wolfsberg and Hermholz:[1]

$$H_{rs} = -0.5kS_{rs}(I_r + I_s) \quad (7)$$

where k is a parameter equal to 1.1.

(IV) The one-center Coulomb repulsion integral (rr|rr) and the two-center Coulomb repulsion integral (rr|ss) are estimated by Pariser's approximation[11] and Ohno's approximation[12] respectively.

In order to calculate S_{rs}, Clementi's AO[13] and Burns' AO[14] were used for ligands and metals respectively. The same orbital exponents were used for s- and p-orbitals. The values obtained by Hinze and Jaffé.[15] were used for the I_r and (rr|rr) values of ligands. The values used for the metals are listed in Table 1.

Table 1. The ionization potential (I_r) and one-center Coulomb repulsion integral (J_{rr})

		I_r(eV)	J_{rr}[18](eV)
Cr	3d	−20.28[16]	14.03
	4s	−14.73	6.80
	4p	−10.31	5.80
Mn	3d	−21.64[16]	14.70
	4s	−15.35	7.09
	4p	−10.62	5.95
Pd	4d	− 8.54[17]	13.87
	5s	− 7.60	7.46
	5p	− 3.84	6.22

Results and Discussion

MnO_4^- and CrO_4^{2-}. For the purpose of comparing our results with previous ones,[4-6] we calculated the MO's of MnO_4^- and CrO_4^{2-}. The net charge on the Mn atom in MnO_4^- was found to be 1.28 from the metal K–X ray spectra.[4b] However, in our results, negative net charge on the Mn atom was obtained. This may be due to the too large electron population of the 4s and 4p orbitals of the Mn atom compared with the results of Oleari *et al.*[5a] and Hillier and Saunders[6] (MnO_4^-; 4s, 0.81 and 4P, 0.78: CrO_4^{2-}; 4s, 0.81 and 4p, 0.78 in our results).

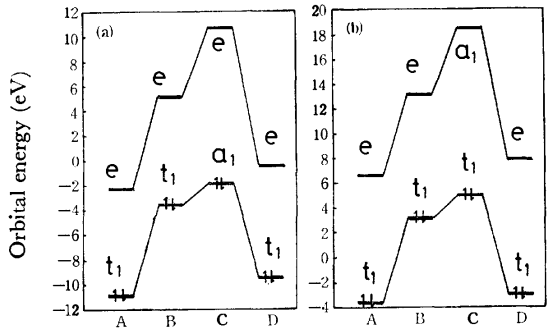

Fig. 1. HOMO and LUMO of MnO_4^- (a) and CrO_4^{2-}(b) by various Methods.
⇅ : HOMO, —; LUMO
A: Oleari *et al.*[5b] by INDO, B: Brown *et al.*[4a] by VE-SCF-CNDO. C: Hillier *et al.*[6] by *ab-initio*, D: ours by CNDO.

The highset occupied (HO) MO and the lowest unoccupied (LU) MO are considered to be represented by t_1[4,5] and e[19] respectively. Our results with respect to HOMO and LUMO are compared with previous ones in Fig. 1. The results of Oleari *et al.*[5a] seem to be quite reasonable. However, the calculation by Brown *et al.*[4b] gave a positive orbital energy for the HOMO of CrO_4^{2-}. Also, in the case of Hillier's calculation,[6] the representations of HOMO and LUMO are not t^1 and e respectively, and the HOMO of CrO_4^{2-} has a positive orbital energy. In contrast to these results, our result are reasonable regarding the orbital energy and the orbital symmetry.

The calculated transition energies are given in Table 2. Our results agree fairly with the experimental results.

PdX_4^{2-} and PdX_6^{2-}. We then calculated the MO's of PdX_4^{2-} and PdX_6^{2-} in order to examine the validity of our method for different types of complexes. The net charge of Pd decreases with a decrease in the electronegativity of halogens, as is shown in Table 3. This tendency agrees with the results obtained by means of photoelectron spectroscopy.[21] However, we obtained a negative net charge on the Pd atom due to the large electron population of 5s- and 5p-orbitals. As is shown in Table 3, the absolute value of the two atomic part of the total energy, $|E_{Pd-Cl}|$,[9] is larger than $|E_{Pd-Br}|$ in PdX_4^{2-} and PdX_6^{2-}, and $|E_{Pd-X}|$ in

The electron configuration of neutral Mn atom is d^5s^2. However, we can not obtain the I_r for d^5s^2 except with I_{4s}, because of the lack of the observed atomic spectra. Therefore we investigated the effect of I_r and choose the suitable values. We show this value in Table 1.

TABLE 2. TRANSITION ENERGIES OF MnO_4^-, CrO_4^{2-}, AND $PdCl_6^{2-}$

	Experimental (eV)		Calculated (eV)	
MnO_4^- [20b]	1.79	$^3T_1$ or $^1T_1$ [20a]	1.44	$^1T_1$
	2.38	$^1T_2$	2.45	$^1T_2+^1E$
			3.65	$^1T_2$
	3.44	$^1T_1$	4.27	$^1T_1$
	4.13	$^1T_2$	4.47	$^1T_2$
CrO_4^{2-} [20c]	3.00	$^1T_1$	3.36	$^1T_1$
			3.78	$^1T_1$
	3.56	$^1T_2$	5.15	$^1T_2$
	4.65	$^1T_2$	6.47	$^1T_2$
	6.20		6.70	$^1T_1$
$PdCl_6^{2-}$ [24]	2.27		3.98	T_{1g}
	3.64		4.13	T_{2g}
			5.94	T_{1u}
	5.17		6.45	T_{2u}

PdX_6^{2-} is larger than $|E_{Pd-X}|$ in PdX_4^{2-}. These results agree with the experimental results.[22]

Though the order of bond strength agrees with the experimental results, we failed to obtain reasonable transition energies for PdX_4^{2-}. The calculated first transition energies seem too small for $PdCl_4^{2-}$ (0.019 eV) and $PdBr_4^{2-}$ (0.028 eV). Furthermore, neither is the d-d transition which is to be expected as the first transition.[23] For $PdCl_6^{2-}$, the calculation gives almost reasonable results, as is shown in Table 2.

As has been described above, by treatment with the same approximation as was used in MnO_4^- and CrO_4^{2-} we can obtain reasonable trends of electron population and bond strength for Pd-halogen complexes, but not successful results for any transition energies except PdX_6^{2-}. Attempts to improve this approximation are under way, for example the inclusion of one-center exchange integrals and further refinements in the parametrization of H_{rs} will be described in the near future.

TABLE 3. ELECTRON POPULATION AND E_{Pd-X} OF PdX_4^{2-} AND PdX_6^{2-}

	Electron Population			Net Charge on Pd			Obsd[22]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2230—2231 (1973)

Catalytic Codimerization of Styrene with Lower Olefins by Rhodium and Ruthenium Catalysts

Hiroshi UMEZAKI, Yuzo FUJIWARA, Kenichi SAWARA, and Shiichiro TERANISHI
Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received July 7, 1972)

We have investigated the codimerization reaction of styrene with lower olefins such as ethylene, propylene or 1-butene in the presence of rhodium(III) or ruthenium(III) compounds as a catalyst.

Results and Discussion

The results are summarized in Tables 1 and 2. We see that the reaction of styrene with ethylene gives 3-phenyl-1-butene (**1**), 2-phenyl-2-butene (**2**) and 2-phenyl-1-butene (**3**) in high yields.[1)]

In order to determine the initial product of codimerization, the relative yields of three phenylbutenes **1**, **2** and **3** were examined as a function of the length of the reaction time. It was possible to monitor the yields as shown in Fig. 1. The rate of formation of **1** is initially high. That of **2** becomes greater after about 3 hr, indicating that the initially formed product from the reaction of styrene and ethylene by rhodium (III) chloride is **1** which is then isomerized to its isomers **2** and **3**.[2)]

We see from Tables 1 and 2 that the codimerization reaction of styrene with lower olefins has the following characteristics: (1) Rhodium(III) and ruthenium(III) catalysts give *internally* phenyl-substituted codimers while palladium(II) catalyst gives *terminally* phenyl-substituted products.[3)] (2) Although accurate comparison is not practical owing to the lack

Table 1. Codimerization of styrene with ethylene

Catalyst	Solvent	Codimer yield, %[a)]		
		1	**2**	**3**
$RhCl_3 \cdot 3H_2O$	Methanol	932	584	84
$RhCl_3 \cdot 3H_2O$	None	482	47	trace
$RhCl_3 \cdot 3H_2O$	Acetic acid	37	121	trace
$RhCl_3 \cdot 3H_2O$	Furfural	37	—	—
$RhCl_3 \cdot 3H_2O$	Benzene+phenol (1 : 1)	21	—	—

$RuCl_3 \cdot H_2O$	Acetonitrile	trace	trace	trace
$[PdCl_2 \cdot \text{styrene}]_2$[c)]	None	*trans*-1-phenyl-1-butene,		1278
		cis-1-phenyl-1-butene,		57
		trans-1-phenyl-2-butene,		170

a) Yields are based on the catalyst used. b) α-phenylethyl acetate was also formed in 293% yield. c) Reference. 3.

Table 2. Codimerization of styrene with propylene and 1-butene

Olefin (5 atm)	Catalyst (1.9 mmol)	Solvent (30 ml)	Product and yield, %[a)]
Propylene[b)]	$RhCl_3 \cdot 3H_2O$	Methanol	CH_3–PhCH–CH=CH–CH_3, 20
Propylene	$RuCl_3 \cdot H_2O$	Methanol	—
Propylene	$[PdCl_2 \cdot \text{styrene}]_2$[c)]	None	Ph–CH=CH–C_3H_7, 72
1-Butene	$RhCl_3 \cdot 3H_2O$	Methanol	—
1-Butene	$RuCl_3 \cdot H_2O$	Methanol	—
1-Butene	$[PdCl_2 \cdot \text{styrene}]_2$	None	Ph–CH=CH–C_4H_9, trace

a) Reactions were performed at 50°C for 6 hr and yields are based on the catalyst used. b) Acetophenone was also formed in 33% yield. c) Styrene dimers were also obtained in 56% yield.

1) Lindsey *et al.*[2)] reported that the rhodium(III) chloride catalyzed codimerization reaction of ethylene with styrene under high pressure (1000 atm) gives only **2** in 40% conversion. The three isomers **1**, **2** and **3** we obtained presumably result from the difference in reaction pressure.

2) T. Alderson, E. L. Jenner, and R. V. Lindsey, *J. Amer. Chem. Soc.*, **87**, 5638 (1965).

3) K. Kawamoto, T. Imanaka, and S. Teranishi, This Bulletin, **43**, 2512 (1970) and the literature therein.

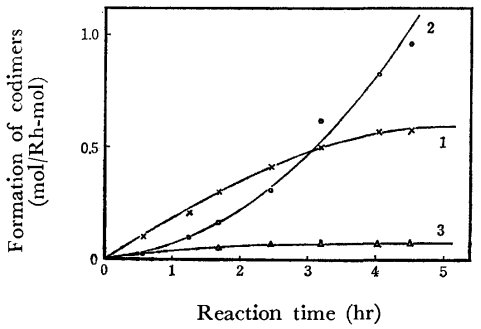

Fig. 1. Formation of 3-Phenyl-1-butene(×), 2-pheny-2-butene (○) and 2-phenyl-1-butene (△) during the reaction of styrene and ethylene with $RhCl_3$-MeOH.

of a solvent which dissolves all of these catalysts, the catalytic activity appears to decrease in the order Pd(II)>Rh(III)>Ru(III) (3) The reactivity of the gaseous olefins decreases in the order ethylene>propylene>1-butene. (4) **1** is the initial codimerization product in the case of the reaction of styrene with ethylene by rhodium(III) chloride.

In the rhodium(III) chloride catalyzed dimerization of olefins, the reaction proceeds through a rhodium hydride from a protonic solvent.[4] Thus, the present codimerization by rhodium(III) chloride seems to proceed also *via* a rhodium hydride as shown in Fig. 2. For the sake of clarity, the case with styrene, ethylene and methanol-d_1 is shown.

A rhodium hydride complex (**4**) would be formed

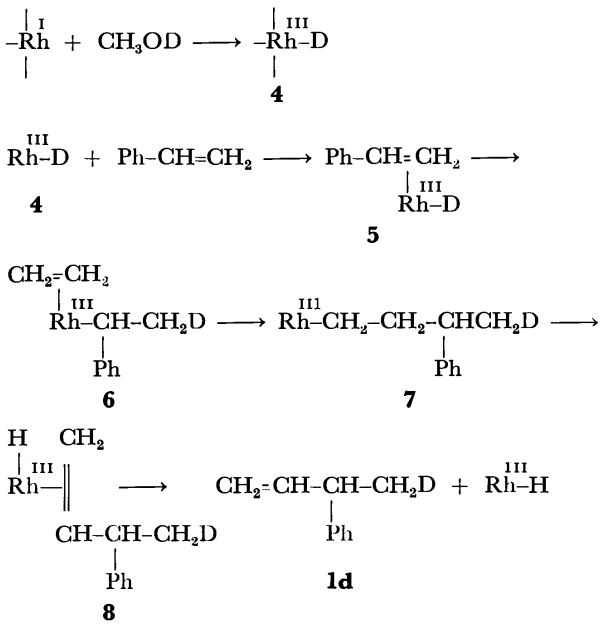

Fig. 2. Mechanism of Codimerization by Rhodium Compound.

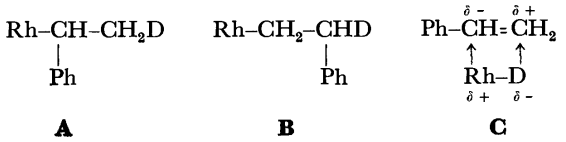
4) R. Cramer, *ibid.*, **87**, 4717 (1965).

5) Since the rhodium-ethylene complex has low catalytic activity (Table 1), styrene could be considered to coordinate first with rhodium.

first and then styrene coordinates with **4** giving a styrene-rhodium hydride π complex (**5**).[5] Complex **5** is transformed into a σ, π complex (**6**) through the addition of Rh-D to styrene, followed by the coordination of ethylene. In this insertion step, there are two modes of addition giving **A** or **B**, the former being favoured because of an electronic effect shown below in **C**.



Complex **6** undergoes rearrangement to a butylrhodium compound (**7**). Finally the elimination of β hydrogen gives **1d** and Rh–H *via* a complex **8**. The reformed rhodium hydride would serve as an active catalyst for codimerization.

Experimental*1

Di-μ-chlorotetrakis(ethylene)dirhodium(I) was prepared according to the method of Cramer.[6]

General Procedure for the Codimerization of Styrene with Lower Olefins by Rhodium Chloride. A glass autoclave was charged with rhodium(III) chloride (1.9 mmol), styrene (27 g, 0.26 mol) and the solvent (30 ml). The autoclave was flushed with ethylene and the pressure was elevated to 5 atm., the mixture being stirred at 50°C for 6 hr. The resulting mixture was distilled under reduced pressure to remove styrene, and then diluted with petroleum ether. The mixture was filtered to remove rhodium(III) chloride, and the filtrate was evaporated. The residue was analyzed and purified by glpc. The products were identified by IR and NMR. 3-phenyl-1-butene (**1**): IR (direct): 990, 910 (-HC=CH_2), 755 and 695 cm^{-1} (-Ph). NMR (CCl_4): 8.66 (d, 3H), 6.58 (m, 1H), 5.04 (m, 2H), 3.77—4.32 (m, 1H) and 2.87 τ (m, 5H). 2-Phenyl-2-butene (**2**): IR (direct): 935 (C=CH–), 752 and 697 cm^{-1} (-Ph). NMR (CCl_4): 8.24 (d, 3H), 8.02 (s, 3H), 4.29 (q, 1H) and 2.02 τ (s, 5H). 2-Phenyl-1-butene (**3**): IR (direct): 893 (CH_2=C<), 780 and 700 cm^{-1} (-Ph). NMR (CCl_4): 8.95 (t, 3H), 7.53 (q, 2H), 5.04 (d, 1H), 4.83 (d, 1H) and 2.76 τ (m, 5H).

Codimerization reactions of styrene with propylene and 1-butene were similarly carried out with use of the same autoclave and reaction conditions as above. *trans*-4-Phenyl-2-pentene; IR (direct): 966 (*trans* HC=CH), 762 and 700 cm^{-1} (-Ph). NMR (CCl_4): 8.72 (d, 3H), 8.36 (d, 3H), 6.68 (m, 1H), 4.55 (m, 2H) and 2.92 τ (m, 5H). *trans*-1-Phenyl-1-pentene: IR (direct): 960 (*trans* HC=CH), 740 and 695 cm^{-1} (-Ph). NMR (CCl_4): 9.03 (t, 3H), 8.51 (m, 2H), 7.82 (q, 2H), 3.78 (m, 2H) and 2.83 τ (m, 5H).

This work was supported by the TAKEDA Science Foundation.

*1 IR spectra were taken on a JASCO Model IR-E spectrometer. NMR spectra were obtained using JNM-4H-100 or JNM-C60HL spectrometers. Rhodium(III) and ruthenium(III) chlorides were of commercial grade.

Polarography of Europium(III)-DL-Tryptophan Complex

Sudarshan LAL

The Thomas Hunt Morgan Institute of Genetics, Inc., 628 N. Broadway, Lexington, KY 40508, U.S.A.

(Received April 1, 1972)

Polarographic studies of europium(III) at the dropping mercury electrode (d.m.e.) in various electrolytes and organic chelating agents have been reported in literature. Holleck[1] claimed that no complexation occurs between Eu(III) and amino acids. However, a recent polarographic study[2] on Eu(III)-L-Proline system indicated definite complexation. In this note, polarographic results on the interaction of Eu(III)-DL-Tryptophan are described.

Experimental

Reagent grade chemicals were used. Solution of europium was prepared by dissolving a weighed amount of Eu_2O_3 (Moly Corp., Colorado) in minimum amount of perchloric acid and diluting with distilled water. M/100 solution of DL-tryptophan (Nutritional Biochem. Corp.) was prepared in double distilled water. The ionic strength was kept constant (μ=0.1) by adding requisite quantity of $NaClO_4$.

PAR Electrochemistry system 170 was used in conjunction with a droptimer for the record of current-voltage curves. The capillary had the characteristics $m^{2/3}t^{1/6}=1.46$ $mg^{2/3}$ $sec^{-1/2}$ in 0.1M $NaClO_4$ in the open circuit. Three electrode circuitry was used with a mercury pool as the counter electrode and voltages measured *vs.* S.C.E. Triple distilled (Bethlehem Instrument) mercury was used for the d.m.e. The temperature of the cell was maintained at 25±0.1C. Linde's prepurified nitrogen was used for deaeration.

Results and Discussion

Solutions containing 0.5 mM Eu(III) with different concentrations of tryptophan (pH=2.4) were polarographed. In each case, a well-defined reduction wave was obtained and $E_{1/2}$ shifted more negatively with increasing concentration of tryptophan. Plots of i_d against h_{eff} were linear depicting it to be a diffusion-controlled process. The plots of log $(i_d-i)/i$ *vs.*$E_{\text{d.e.}}$ were linear but slopes were higher than 59 mV which implied an irreversible process. Although the reduction, in the present case, is diffusion controlled yet is not reversible. $E^r_{1/2}$ (reversible halfwave potential) and kinetic parameters were determined by Gellings[3] method.

The tryptophanate anion [Tr$^-$] concentration at pH=2.4 was calculated with the knowledge of pK value=2.38 of tryptophan. The plot of $E^r_{1/2}$ against $-\log C_x$ is a straight line. Lingane's method[4] for the complex formation studies was applied with the equation:

$$\Delta E_{1/2} = (E^r_{1/2s}) - (E^r_{1/2})_c = \frac{0.0591}{n}\log p + p\frac{0.0591}{n}\log C_x \quad \text{at } 25°C$$

The slope of the plot $(E^r_{1/2})_c$ *vs.* $-\log C_x$ is given by the relation

$$\frac{\Delta E^r_{1/2}}{\Delta \log C_x} = -\frac{0.0591p}{n}$$

and the coordination number, p, is determined. The intercept on the potential axis corresponding to C_x= 1M, gives the instability constant of the complex. In the present case for n=1; p=1 and the intercept= −1.03 V is obtained. The instability constant of the complex $[Eu(Tr)]^{2+}$ is 1.63×10^{-7}.

TABLE 1. $E^r_{1/2}$ AND KINETIC PARAMETERS OF Eu(III)-DL-TRYPTOPHAN SYSTEM

Concn ×10³M Tryptophan	Tr ×10⁻³M	$-E^r_{1/2}$V *vs.* SCE	α	$k_s\times10^3$ cm/sec
0.00	0.000	0.654	0.88	6.25
0.005	0.002	0.668		
0.01	0.004	0.685		
0.02	0.008	0.705		
0.05	0.021	0.736		
0.10	0.041	0.747	0.89	5.75
0.20	0.082	0.762		
0.30	0.123	0.780		
0.40	0.164	0.788		
0.80	0.328	0.804	0.88	5.10
1.00	0.411	0.812		
2.00	0.822	0.831		
3.00	1.233	0.842	0.89	4.86
6.00	2.466	0.862	0.88	4.17
8.00	3.288	0.866	0.87	3.34

The rate constants and transfer coefficients of the process have been evaluated and summarized in Table 1. The apparent rate constants tend to decrease with increasing tryptophan concentration and the reduction appears to be quasireversible.[5]

The Absolute Configurations and Optical Rotations of (−)-4-Hydroxy-2-pentanone and (−)-2,4-Pentanediol

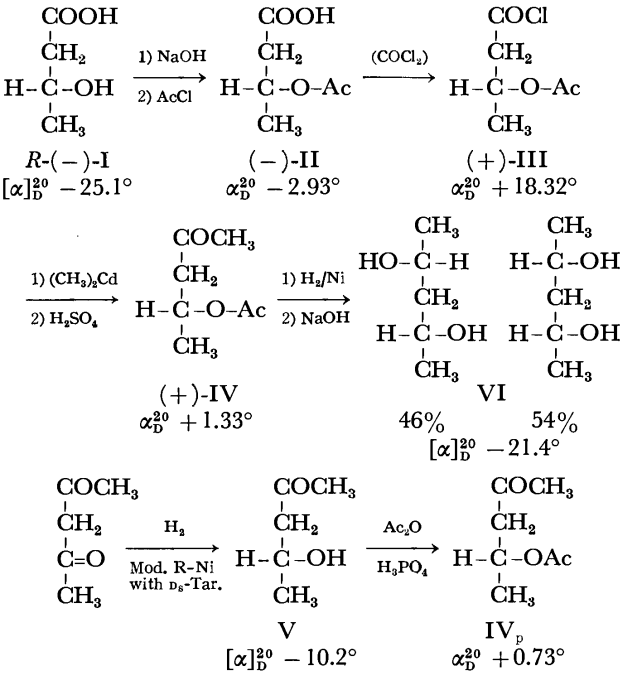
Tadashi TANABE*

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Suita, Osaka 565

(Received September 28, 1972)

In order to calculate the asymmetric yield and the contents of the stereoisomers of the products obtained by the asymmetric hydrogenation of acetylacetone using Raney nickel catalysts modified with L$_s$-glutamic acid and D$_s$-tartaric acid, the absolute configurations and the optical rotations of (−)-4-hydroxy-2-pentanone and (−)-2,4-pentanediol were studied in the present work.

As the direct resolutions of the optical isomers of 2,4-pentanediol were not successful because of difficulty in separating the *racemic* and *meso* compounds, the optical rotation was decided by the following method.



Scheme 1.

Sodium salt of *R*-(D$_s$)-3-hydroxybutyric acid ((−)-I)[1] ([α]$_D^{20}$ −25.1° (*c* 10, water)) was converted into (−)-3-acetoxybutyric acid ((−)-II), which was then treated with oxalyl chloride to yield (+)-3-acetoxybutyryl chloride ((+)-III). By the action of dimethylcadmium, (+)-4-acetoxy-2-pentanone ((+)-IV) was prepared from (+)-III. As IV was a comparatively labile compound under both acidic and alkaline conditions, direct hydrolysis with a base or acid was difficult. (+)-IV was reduced with a Raney nickel catalyst, and the product was hydrolyzed with an aqueous sodium hydroxide solution to yield a mixture of (−)- and *meso*-2,4-pentanediol ((−)- and *meso*-VI). On the other hand, the partially optically-active 4-hydroxy-2-pentanone (V) ([α]$_D^{20}$ −10.2°) obtained by the asymmetric hydrogenation of acetylacetone using a Raney nickel catalyst modified with D$_s$-tartaric acid was acetylated with acetic anhydride in the presence of phosphoric acid to give a partially optically-active IV (IV$_p$) ([α]$_D^{20}$ +0.73°), as is shown in Scheme 1. As (+)-IV and IV$_p$ had the same sign of optical rotation, the absolute configuration of (−)-4-hydroxy-2-pentanone was identified as *R*. From the ratio of the optical rotations of (+)-IV and IV$_p$, and from the optical rotation of V, the optical rotation of *R*-(−)-4-hydroxy-2-pentanone was calculated to be −18°.

The contents of *R*-(−)- and *meso*-VI were determined to be 46 and 54% respectively by means of the glc and NMR spectroscopy of 2,4-*O*-benzylidene-2,4-pentanediol, which had been derived from *R*-(+)-IV. From the contents of *R*-(−)-VI and the optical rotation of the mixture of *R*-(−)- and *meso*-VI, the optical rotation of *R*-(−)-2,4-pentanediol was calculated to be −47°.

Experimental

Determination of the Ratio of racemic *and* meso *2,4-Pentanediols (VI).* *Preparation of* meso-*VI*: A mixture of *racemic* and *meso*-VI was prepared by the hydrogenation of acetylacetone with a Raney nickel catalyst modified with DL-malic acid at pH 5.0, 0 °C.[2] The hydrogenation product was distilled under reduced pressure. Thirty-five grams of the boric ester of VI was prepared from 20 g of VI, 20 g of boric acid, and 4 ml of water according to the method of Nagai *et al.*[3] Twenty grams of the boric ester was recrystallized three times from chloroform; mp 76 °C (lit.,[3] mp 85 °C). Found: C, 45.36; H, 8.61%. Calcd for $C_5H_{11}O_3B$: C, 46.55; H, 8.53%.

Six and a half grams of the boric ester was refluxed with 100 ml of methanol for six hours, and then the methanol and methyl borate were removed under reduced pressure. The residual diol was distilled *in vacuo*. Bp 104 °C/15 mmHg; yield, 3.5 g. Found: C, 56.04; H, 11.90%. Calcd for $C_5H_{12}O_2$: C, 57.66; H, 11.61%. The IR spectrum corresponded with that of *meso*-VI reported in the literature,[3] and the product was used as the standard compound of *meso*-VI.

Preparation of 2,4-O-Benzylidene-2,4-pentanediol (VII): A mixture of 1.2 g of *meso*-VI (or a mixture of *racemic* and *meso*-VI) and 5 ml of benzaldehyde was stirred with 0.5 g of anhydrous zinc chloride[4] for 12 hr at room temperature. The reaction mixture was then distilled two times under reduced pressure, and a fraction with a bp of 130—132 °C/

* Present address: Faculty of Medicine, Kyoto University, Sakyo-ku, Kyoto, 606.

4) L. Zervas, *Ber.*, **64**, 2293 (1931).

16 mmHg was collected.[5] Found: C, 74.25; H, 8.09%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%.

Determination of the Contents of meso *and* racemic *VII by Gas Chromatography*: The gas chromatography of VII was carried out under the following conditions: column, 1.5% PEG 20 M on Chromosorb W, 3 m; temp., 140 °C. The retention times of VII from *meso* and *racemic* VI were 5.3 and 7.1 min respectively. The ratio of the areas of *meso* and *racemic* VII in the gas chromatograph was in good agreement with the ratio of the intensities of the signals from the proton of the methine group $\left(\begin{matrix}C_6H_5\\H\end{matrix}\!\!>\!C\!<\!\!\begin{matrix}O-\\O-\end{matrix}\right)$ in the NMR spectra. This fact shows that the contents of the *meso* and *racemic* VI can be determined by glc like those of VII.

Preparation of the Sample of VII for Gas-chromatographic Analysis. Twenty to thirty milligrams of VI was dissolved in a solution of 0.4 ml of absolute benzene and 0.2 ml of freshly-distilled benzaldehyde, and then 25 mg of anhydrous zinc chloride and 50 mg of anhydrous potassium carbonate were added to the solution. The mixture was shaken for 1 hr and then allowed to stand for 24 hr at 30 °C. Under these conditions, the conversion of VI to VII was found to be quantitative by gas chromatography.

Determination of the Absolute Configurations and Specific Rotations of (−)-4-Hydroxy-2-pentanone ((−)-V) and (−)-VI. Preparation of (−)-3-Acetoxybutyric Acid ((−)-II): Fifty grams of sodium salt of *R*-(D_s)-(−)-3-hydroxybutyric acid ((−)-I) ($[\alpha]_D^{20}$ −25.1° (*c* 10, water)), prepared by the method of Levene *et al.*, and 16 g of anhydrous sodium acetate were dissolved in 100 ml of glacial acetic acid. Forty-two milliliters of acetyl chloride was then stirred into the mixture at 10 °C, after which the stirring was kept up for another hour at room temperature. One hundred and fifty milliliters of ether was then added, and the inorganic salts were removed by filtration. A fraction with a bp of 98—99 °C/1.5 mmHg was collected. 39.3 g $[\alpha]_D^{20}$ −2.93° (without dilution). Found: C, 48.67; H, 6.92%. Calcd for $C_6H_{10}O_4$: C, 49.31; H, 6.90%.

Preparation of (+)-3-Acetoxybutyryl Chloride ((+)-III): Fifteen milliliters of oxalyl chloride[6] was added to 20 g of (−)-II in 10 ml of absolute benzene,[7] and the resulting solution was allowed to stand for 12 hr at room temperature. The benzene was removed under reduced pressure, and the residual liquid was distilled. Bp 79—81 °C/12 mmHg; yield, 21.3 g; $[\alpha]_D^{20}$ +18.32° (neat) IR: 1730, 1800 cm^{-1} (C=O).

Preparation of (+)-4-Acetoxy-2-pentanone ((+)-IV): Nineteen grams of (+)-III in 50 ml of benzene was added at 0 °C, over a period of twenty seconds, to a benzene solution of dimethylcadmium prepared from 6.2 g of magnesium, 20.8 g of methyl iodide, and 26 g of anhydrous cadmium chloride.[8] The reaction mixture was then kept for 15 min at room temperature, carefully decomposed with 80 g of ice water, and acidified with 1.5 M sulfuric acid. The organic layer was separated, washed with water and then with saturated sodium hydrogencarbonate solution, and dried over anhydrous sodium sulfate. After the removal of the benzene, the residue was distilled *in vacuo*. A fraction with a bp of 80—90 °C/14 mmHg was redistilled. Bp 85—90 °C/14 mmHg; yield, 6.3 g.

(+)-IV was obtained by further purification using silica gel column chromatography. (Column: Kiesel Gel, 0.05—0.2 mesh, 1.6×75 cm. Eluent solvent: benzene.) Bp 92 °C/20 mmHg; yield, 2.3 g, $[\alpha]_D^{20}$ +1.33° (neat). Found: C, 56.43; H, 8.33%. Calcd for $C_7H_{12}O_3$: C, 58.31; H, 8.39%.

Preparation of IV from Partially Optically-active 4-Hydroxy-2-pentanone (V) and Calculation of the Specific Rotation of Optically-pure V: Five milliliters of partially optically-active V ($[\alpha]_D^{20}$ −10.2° (d^{20} 0.986), neat), prepared by the asymmetric hydrogenation of acetylacetone using a modified Raney nickel catalyst with D_s-tartaric acid at pH 5.0, 100 °C,[2] was acetylated with 6 ml of acetic anhydride and a catalytic amount of phosphoric acid.[9] After the removal of the acetic acid under reduced pressure, partially optically-active IV (IV_p) was obtained by distillation *in vacuo*. Bp 43 °C/2 mmHg; yield, 4 g, $[\alpha]_D^{20}$ +0.73° (neat).

The specific rotation of (−)-4-Hydroxy-2-pentanone was calculated by the following procedure; $[\alpha]_D^{20}$ of V×($[\alpha]_D^{20}$ of (+)-IV/$[\alpha]_D^{20}$ of IV_p)=−10.2°×(1.33/0.73)=−18°.

Preparation of a Mixture of (−)- and meso*-VI and the Specific Rotation of (−)-VI*: Two grams of (+)-IV ($[\alpha]_D^{20}$ +1.33°) in 5 ml of methanol was reduced using 0.6 g of a Raney nickel catalyst in an autoclave at 70 °C under an initial pressure of 90 kg/cm^2.[10] The product was hydrolyzed with 0.6 g of sodium hydroxide in 0.6 ml of water and 3 ml of methanol. The resulting solution was neutralized with 3 M hydrochloric acid and concentrated *in vacuo*, and then the VI was extracted with acetone. After the acetone had been removed, the residue was distilled. Bp 107—108 °C/17 mmHg; yield, 0.6 g, $[\alpha]_D^{20}$ −21.4° (*c* 10.5, ethanol). Found: C, 56.27; H, 11.57%. Calcd for $C_5H_{12}O_2$: C, 57.66; H, 11.61%. The content of (−)-VI was 46%. The specific rotation of optically-pure (−)-2,4-pentanediol was calculated by means of the following equation: −21.4°×(100/46)=−47° (*c* 10.5, ethanol).

The author wishes to express his thanks to Professor Yoshiharu Izumi for his continuous guidance and encouragement. He also wishes to thank Miss Kiku Koike and Mrs. Nobuko Okuhara for the elemental analyses.

5) As, under these conditions, the conversion of VI to VII was not perfect, and as the distillation process changed the diastereomeric component ratio of VII, the method is inadequate for the preparation of samples for diastereomeric analysis by glc.

Electronic Properties of the Tautomers of Hydroxy-substituted Purines and Pyrimidines

Mamoru KAMIYA

Shizuoka College of Pharmacy, Oshika, Shizuoka-shi 420

(Received September 30, 1972)

The purines and pyrimidines bearing potential amino- or hydroxyl-groups have been the subjects of a number of spectroscopic studies, since they present several interesting problems concerning tautomerism in solution. One of the most useful methods for approaching this problem has been a comparison of the UV spectrum of a given compound with those of the reference compounds, such as the *N*-methyl derivatives. In recent years, the SCF-MO calculation has also been used in the inspection of the correlation between the electronic spectrum and the tautomeric structure of biological purines and pyrimidines.[1-4] These works led to the finding that the P-P-P method, when properly modified, can afford to support fairly well the observations of the predominant tautomers on the basis of the π-electronic transitions and energies. In this work, a more general consideration of the keto-enol tautomerism of purines and pyrimidines was made using the P-P-P method coupled with the variable-β procedure.[5]

The calculations were performed including all singly excited configurations. The variable-β procedure was adopted in order to take account of the remarkable π-bond localization at the keto-tautomers. The parametrizations adopted are analogous to that used previously.[6] The observed transition energies of pyrimidine can be explained well by the present calculation, provided that the second weak band is reduced to $n\rightarrow\pi^*$ in accord with the assignment by Clark and Tinoco.[7] It has been indicated that the 2-, 4-, and 2,4-hydroxypyrimidines take keto-forms in an aqueous solution.[8-10] In this respect, the present calculation of the electronic spectrum shows that the predominant forms of the 2- and 4-isomers are certainly keto-forms, but that of the dihydroxypyrimidine is not necessarily restricted to the diketo-form. In view of the π-electronic energy, the predominance of the diketo-form is supported.

The calculations of purines were performed on the basis of the N(9)H form of purine, since the majority of biological purines exist essentially as derivatives of this form; the calculated data of the electronic spectrum of this form are in good accord with the observed data. The UV spectra of monohydroxypurines in an aqueous solution suggested that the 2- and 8-isomers exist largely in a keto-form type of –CO–NH–, but the 6-isomer is likely to take the enol-form which might contain an intramolecular hydrogen-bond.[11] The above suggestions for the 2- and 8-isomers are well

Table 1. Experimental UV data of purines and pyrimidines

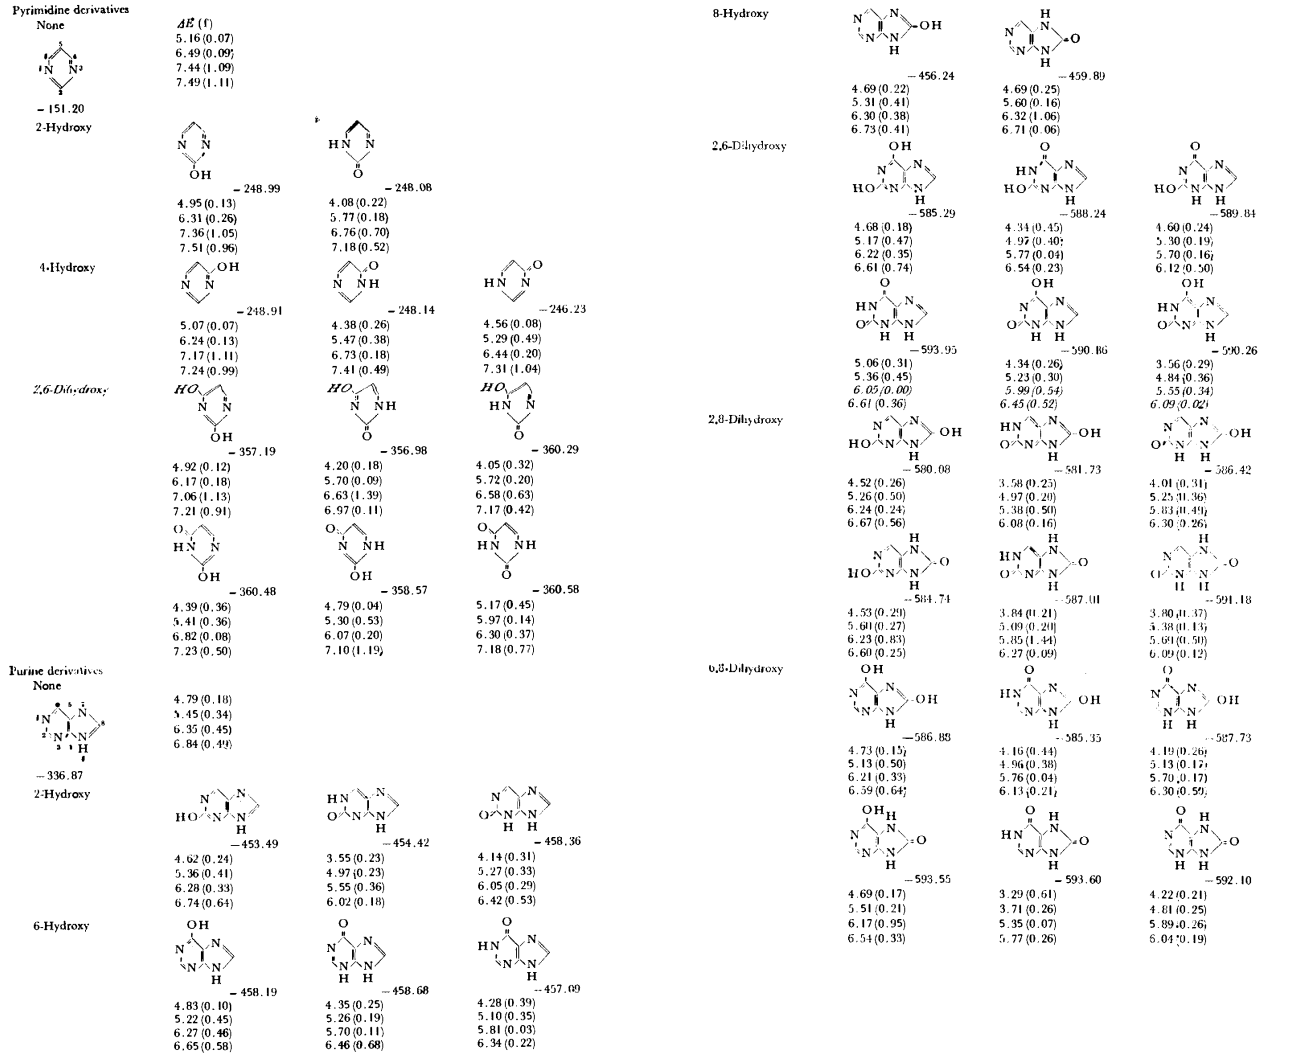
TABLE 2. THEORETICAL DATA OF THE UV SPECTRUM AND π-ELECTRONIC ENERGY



a) ΔE is singlet-singlet transition energy in eV.

b) f is oscillator strength.

c) The valence-state ionization potential and electron affinity are taken as follows:

	=C-	=N-	-N-	=O	-O-
Ionization potential (eV)	11.16	14.12	28.72	17.28	34.75
Electron affinity (eV)	0.03	1.78	11.96	2.01	13.57

The two-center Coulomb integral is evaluated with the Nishimoto-Mataga formula. Parametrization for the evaluation of the core-resonance integral by the variable-β method is as follows:

$\beta_{C-C} = -0.51\, P_{C-C} - 2.04$,

$\beta_{C-N} = -0.53\, P_{C-N} - 2.24$,

$\beta_{C-O} = -0.56\, P_{C-O} - 2.44$.

d) Numerals under the structural formula are π-electronic energies in eV.

supported by the present calculations of the electronic transitions and energies. In the case of the 6-isomer, the predominance of the keto-form –CO–NH–, can not be confirmed by the calculated results. As regards the dihydroxypurines, the calculated data of the electronic spectra of diketo-forms satisfy the relative sequence of the observed first-transition energies. Moreover, the π-electronic energies support the predominance of diketo-forms.

In conclusion, the variable β–P-P-P calculation of the π-electronic transitions and energies was found to be rather useful for the prediction of the predominant tautomers of the compounds in the title.

The calculations were performed on a HITAC 5020-E computer at the University of Tokyo. The author wishes to thank Professor Yukio Akahori for his useful suggestions.

X-Ray Photoelectron Spectra of Copper-Tetracyanoquinodimethane Complexes

Isao IKEMOTO, John M. THOMAS, and Haruo KURODA*

Edward Davies Chemical Laboratories, The University College of Wales, Aberystwyth, U.K.
**Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113*

(Received March 14, 1973)

Copper forms[1] two types of complexes with tetracyano-*p*-quinodimethane (TCNQ). Metathesis of cupric sulphate and Li(TCNQ), and related reactions, yield a solid corresponding to the formula $Cu(TCNQ)_2$, whereas the product formed when the parent TCNQ reacts either with metallic copper or certain cuprous salts, has a composition Cu(TCNQ). From their mode of production it seems reasonable to suppose that these complexes contain cupric and cuprous ions, respectively; the formula have been written as $Cu^{2+}(TCNQ^-)_2$(A) and $Cu^+(TCNQ^-)$ (B). Whilst formulation B is consonant with the observed properties of the complex, there are difficulties associated with A. First, no Cu^{2+} signal is detectable in the ESR spectrum of the $Cu(TCNQ)_2$, and, second, static magnetic susceptibility measurements reveal that the so-called cupric compound is apparently diamagnetic.[2] In addition, the IR absorption spectrum of this compound clearly indicates the presence of TCNQ as well as $TCNQ^-$.[2] Hence feasible alternative representations for A are $Cu^+(TCNQ^-)(TCNQ)$ or $(Cu^+)_2(TCNQ^-)_2(TCNQ)_2$, and it has been suggested[1] that the following equilibria might be set up in the solid state:

$$2Cu^{2+}(TCNQ^-)_2 \rightleftharpoons (Cu^+)_2(TCNQ^-)_2(TCNQ)_2$$
$$\rightleftharpoons (Cu^+)_2(TCNQ^{2-})(TCNQ)_3$$

The X-ray induced photoelectron spectra (ESCA) of the two compounds (hitherto represented as A and B above) have been recorded (on an AEI ES100) under conditions which have been fully descibed[3] for other complexes. The materials were synthesized according to the procedures given in Ref. 1 and the binding energies (Table 1) have been accurately determined using the gold-decoration technique,[4] the subsidiary standard being 84.0 eV for the binding energy of the Au $4f_{7/2}$ level.[5]

TABLE 1. BINDING ENERGIES (eV)

Compounds	Cu $2p_{1/2}$	Cu $2p_{3/2}$	Cu 3s	Cu 3p	Cu 3d	N1s
Cu(TCNQ)	951.0	931.2	121.8	74.8	2.2	398.1
$Cu(TCNQ)_2$	950.4	930.4	121.5	74.5	2.1	(398.3)[a]

a) The peak is broad, and the value is approximate. (Precision throughout is ±0.3 eV).

It is to be expected from other works[6] that a chemical shift of about 1.5 eV occurs between copper in +2 and +1 formal oxidation states, yet the metal core level binding energies for the two complexes are almost coincident. Significantly the shapes and half-widths of the Cu 2p and the Cu 3s peaks (Fig. 1) are indistinguishable for the two compounds, and in each case there are no satellites[7] on the higher-binding energy side of the Cu 2p peaks, nor any signs of spin-spin splitting of the Cu 3s levels that is expected for a $3d^9$ configuration. These facts prove that the copper ion has, in both cases, the $3d^{10}$ configuration.

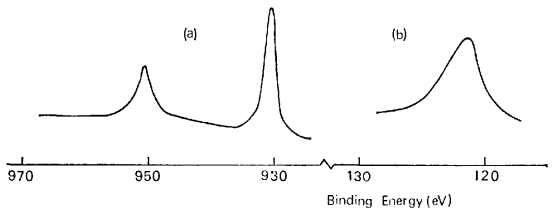

Fig. 1. Copper peaks of $Cu(TCNQ)_2$ (a) Cu 2p (b) Cu 3s.

N1s peaks for the two compounds are, however, revealingly different (Fig. 2). They both exhibit the higher-binding energy satellites, which we have shown elsewhere[3] to be a general feature of TCNQ complexes and which we now know to arise from an intramolecular shake-up (two-electron) mechanism. But of greater significance is the differences in widths of the main peaks. The breadth of the N1s peak in $Cu(TCNQ)_2$ signifies, as does the IR spectra,[2] the presence of two types of nitrogen, namely those due to ($TCNQ^-$) and (TCNQ). Using the N1s peaks observed on TCNQ crystal and K(TCNQ), we synthesized the N1s peak which is expected for the system containing equivalent

9) The observed diamagnetism of this complex seems to be brought from the interaction between ($TCNQ^-$) anion radicals.

amounts of (TCNQ) and ($TCNQ^-$). As shown in Fig. 2, the observed N1s peak of $Cu(TCNQ)_2$ well agrees with the synthesized one. Thus, a possible formulation in place of A is $Cu^+(TCNQ^-)(TCNQ)$ or $(Cu^+)_2(TCNQ^-)_2(TCNQ)_2$.[9]

$Cs_2(TCNQ)_3$ as well as $(Ph_3PMe)(TCNQ)_2$ is also known to be a 'mixed' complex, frequently formulated as $(Cs^+)_2(TCNQ^-)_2(TCNQ)$ and $(Ph_3PMe)(TCNQ^-)$-(TCNQ), but its N1s peak shape is distinctly different from that shown here for the mixed cuprous complex. For these two complexes it is not possible to reproduce the N1s peak by a simple superposition of the N1s peaks of TCNQ and K(TCNQ). If there is a significant electron delocalization between ($TCNQ^-$) and (TCNQ), we should naturally expect a disagreement between synthesized and actual spectra. Thus, the good agreement between the observed and synthesized N1s peaks in the case of $Cu(TCNQ)_2$ seems to indicate small electron delocalization between ($TCNQ^-$) and (TCNQ).

Thanks are due to the S.R.C. for financial support.

A Potentiometric Study on Complex Formation of Oxovanadium(IV) with Malonic Acid

Satoshi Ito,* Hiroshi Tomiyasu,** and Hitoshi Ohtaki***

Department of Electrochemistry, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

***Department of Chemistry, Faculty of Science, Shinshu University, Asahi-machi, Matsumoto 390*

(Received February 1, 1973)

In the previous work we found a protonated oxovanadium(IV)-glycine complex MHGly (where M and Gly denote VO^{2+} and glycinate ions, respectively) along with the MGly and $M(Gly)_2$ complexes (charges are omitted for simplicity) by spectrophotometric measurements.[1] In the present study we employed potentiometric titrations for studying reactions between oxovanadium(IV) ion and malonic acid as another topic of the complex formation of multidentate ligands with metal ions.

Experimental

Reagents. Oxovanadium(IV) perchlorate solution was prepared by the method described in the preceding papers.[1,2] Sodium perchlorate and sodium hydroxide solutions were prepared and purified by the usual methods. Reagent grade malonic acid (Wako Pure Chemicals, Co. Ltd.) was recrystallized twice from distilled water and dried under a reduced pressure in a desiccator over silica gel.

Apparatus. A six-neck titration vessel was used, which was set with a glass electrode and the "Wilhelm" type reference electrode,[3] burets and glass tubes for nitrogen gas inlet and outlet. Nitrogen gas free from carbon dioxide was preequilibrated with 3 M $NaClO_4$ aqueous solution. Glass electrodes of Beckman No. 40498 were used in combination with a Radiometer PHM-4d pH meter (Copenhagen).

Emf measurements were carried out at 25.00 ± 0.01 °C in a paraffin oil thermostat in a room thermostated at 25 ± 1 °C. 3 M sodium perchlorate was used as an ionic medium.

Method of Measurements. Potentiometric titrations were carried out in 3 M $NaClO_4$ aqueous solution at a constant total metal concentration during the course of the titrations. The hydrogen ion concentration at equilibrium [H] was determined by means of emf measurements by the use of the Nernst equation;

$$E = E^\circ + 59.15 \log [H] + E_j \qquad (1)$$

under an assumption of a constant activity coefficient of hydrogen ion. The liquid junction potential E_j was calculated from the relation $E_j = -16.5[H]$ mV/M.[4] Since malonic acid dissociates to some extent even in an acid solution (pH ~2), E° was determined by means of a Gran plot[5] at each titration in a constant ionic solution which contained oxovanadium(IV) perchlorate but no malonic acid in the pH range where oxovanadium(IV) ions did not appreciably hydrolyze. After the determination of E° a suitable amount of malonic acid solution was added to prepare a test solution, the mole ratio of V(IV): malonic acid being controlled to be 1: 10. The concentration of V(IV) covered the range of 0.0007562 to 0.007499 M.

Results and Discussion

Dissociation constants of malonic acid were determined as $pK_1=2.82\pm0.01$ and $pK_2=5.78\pm0.01$ in 3 M $NaClO_4$ at 25 °C. Hydrolysis of oxovanadium(IV) ion in 3 M $NaClO_4$ has been studied by Rossotti and Rossotti[6] who reported values $\log \beta_{11}=-6.0\pm0.1$ and $\log \beta_{22}=-6.88\pm0.04$. In the present work we used these values in preliminary calculations of stability constants of oxovanadium(IV) malonate complexes, although we will briefly discuss whether the values of β_{11} and β_{22} are reasonalbe or not at the final stage of refinement of the results by computer calculations.

Titration curves of mixtures of oxovanadium(IV) perchlorate and malonic acid are shown in Fig. 1.

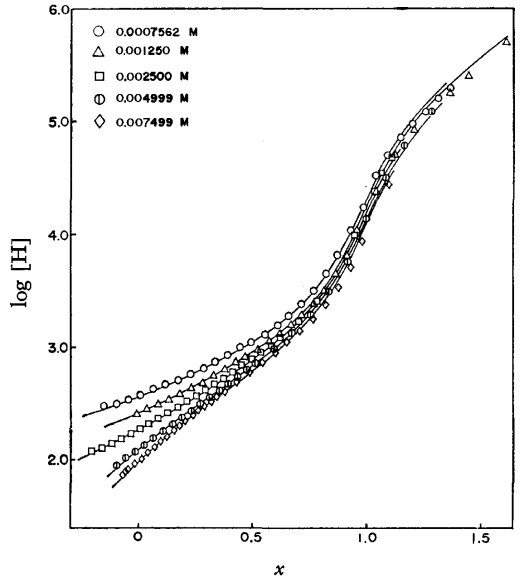

Fig. 1. Titration curves of mixtures of oxovanadium(IV) perchlorate and malonic acid in 3M $NaClO_4$. Curves are plotted against the degree of neutralization of malonic acid, x, at various total oxovanadium(IV) concentrations. Solid lines are calculated titration curves with $pK_1=2.82$, $pK_2=5.78$, $\log \beta_{11}=-6.0$, $\log \beta_{22}=-6.88$, and $\log \beta_{111}=7.41$.

Data obtained in an acid region where no hydrolysis of oxovanadium(IV) ion is expected were used for the first approach of stability constants. Since the concentration of malonate ion A^{2-} could be neglected in the pH range less than 3, the complex formation of oxovanadium(IV) ion with malonic acid may, in general, be described by the following equation:

$$pVO^{2+} + rHA^- + (q-r)H^+ = (VO)_pH_qA_r^{(2p+q-2r)+} \quad (2)$$

The equilibrium constant of the reaction (2) is defined as

$$\kappa_{pqr} = \frac{[M_pH_qA_r]}{[M]^p[HA]^r[H]^{q-r}} \quad (3)$$

The total concentrations of malonic acid (C_A) and proton to be dissociated (C_H) are given as follows:

$$C_A = [H_2A] + [HA] + \sum_r r[M_pH_qA_r] \quad (4)$$

$$C_H = C_A + H = [H] + [H_2A] + \sum_{q-r}(q-r)[M_pH_qA_r] \quad (5)$$

where H represents the analytical excess of hydrogen ion in a test solution. Since C_A is about ten times larger than the total metal C_M in any solution, it is reasonably assumed that the term $\sum_r r[M_pH_qA_r]$ is much smaller than the sum of C_A and H so that [HA] can be obtained, without introduction of any serious error, as follows:

$$[HA] = \frac{(C_A+H-[H])K_1}{[H]} \quad (6)$$

The average number of HA combined with V(IV) in solution $\bar{n}_{M(HA)}$ is given as

$$\bar{n}_{M(HA)} = \frac{C_A-[H_2A]-[HA]}{C_M} = \frac{\sum_r r[M_pH_qA_r]}{C_M} = \frac{\sum_r r\kappa_{pqr}[M]^{p-1}[HA]^r[H]^{q-r}}{1+\sum_p p\kappa_{pqr}[M]^{p-1}[HA]^r[H]^{q-r}} \quad (7)$$

Almost all points of $\bar{n}_{M(HA)}$ plotted against log [HA] fell on a single curve which was drawn by a normalized function $y=x/(1+x)=f(\log x)$ and no systematic scattering of data was observed with varying C_M and [H]. This result showed that Eq. (7) was not a function of [M] and [H] and thus, $p-1=0$ and $q-r=0$. Therefore, we concluded that the complex formed in this pH range was MHA. The equilibrium constant κ_{111} was determined as $10^{1.65}$ by means of curve fitting, or $\beta_{111}=[MHA]/[M][H][A]=10^{7.43}$.

In the range of pH larger than 3, hydrolysis of oxovanadium(IV) must be taken into account in evaluation of stability constants of complexes. If the formula of a complex present in solution is generally described as $M_pH_qA_r$, the mole balances lead to following relations:

$$C_H = 2C_A + H = [H] + [H][A]K_2^{-1} + 2[H]^2[A]K_1^{-1}K_2^{-1} - \beta_{11}[M][H]^{-1} - 2\beta_{22}[M]^2[H]^{-2} + \sum_q q\beta_{pqr}[M]^p[H]^q[A]^r \quad (8)$$

$$C_M = [M] + \beta_{11}[M][H]^{-1} + 2\beta_{22}[M]^2[H]^{-2} + \sum_p p\beta_{pqr}[M]^p[H]^q[A]^r \quad (9)$$

$$C_A = [A] + [H][A]K_2^{-1} + [H]^2[A]K_1^{-1}K_2^{-1} + \sum_r r\beta_{pqr}[M]^p[H]^q[A]^r \quad (10)$$

Since we found the MHA complex in the acid solution, we examined if we could explain whole data by assuming the formation of only the complex. Under the present assumption the following relations could readily be derived from Eqs. (9) and (10):

$$[A] = \frac{C_A}{1+[H]K_2^{-1}+[H]^2K_1^{-1}K_2^{-1}+\beta_{111}[M][H]} \quad (11)$$

$$[M] = [\{(1+\beta_{11}[H]^{-1}+\beta_{111}[H][A])^2 + 8C_M\beta_{22}[H]^{-2}\}^{1/2} - (1+\beta_{11}[H]^{-1}+\beta_{111}[H][A])]/4\beta_{22}[H]^{-2} \quad (12)$$

Successive approximations were repeated until [A] and [M] converged to certain values with which Eqs. (11) and (12) were satisfied simultaneously, β_{111} being known. The average number of malonate ion per oxovanadium(IV) ion $\bar{n}$ is calculated by the following equation after the correction of hydrolysis of oxovanadium(IV) ions;

$$\bar{n} = \frac{C_A-([A]+[H][A]K_2^{-1}+[H]^2[A]K_1^{-1}K_2^{-1})}{C_M-\beta_{11}[M][H]^{-1}-2\beta_{22}[M]^2[H]^{-2}} \quad (13)$$

and was plotted against log [H]+log [A] as seen in Fig. 2. All points fitted very well a normalized curve drawn by the function $y=x/(1+x)=f(\log x)$. This shows that experimental results are satisfactorily explained in terms of the formation of the MHA complex and no other ones, besides the hydrolyzed species MOH and $M_2(OH)_2$, over the whole range of pH and the metal concentration studied.

The stability constants of complexes in solution were refined by means of a non-linear least squares method with the help of an electronic computer. If we set constant K_1, K_2, β_{11}, and β_{22} and variable β_{111}, the value of $\beta_{111}=10^{7.41}$ was obtained as the best one to interprete experimental data. When we set K_1 and K_2 as constants and β_{11}, β_{22}, and β_{111} as variable parameters, a slightly better agreement between calculated

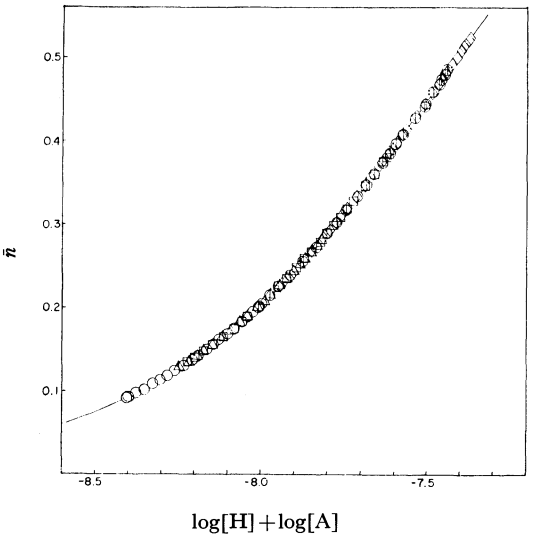

Fig. 2. Relationship between $\bar{n}$ and log [H] + log [A]. A solid line is a curve drawn by a normalized function, $y=x/(1+x)=f(\log x)$ at the position of best fit. Symbols are the same as those used in Fig. 1.

and experimental titration curves was obtained with values of $\beta_{11}=10^{-5.0}$, $\beta_{22}=10^{-6.71}$, and $\beta_{111}=10^{7.50}$. However, the value $10^{-5.0}$ is far beyond the uncertainty of β_{11} estimated by Rossotti and Rossotti,[6] although diversed values of the stability constant of the $VOOH^+$ complex appear in literature.[7] Therefore, we finally adopted the value $\beta_{111}=10^{7.41\pm0.02}$, which is in good agreement with the value obtained in the acid region, instead of $10^{7.50}$. The results were not improved by the assumption of formation of two complexes HMA and MA together with MOH and $M_2(OH)_2$. Thus we concluded that only the MHA complex is formed in solutions we examined. Other complexes such as MA and MA_2 may be formed in more basic solution containing malonic acid of much higher concentration.

The complex MHA is so stable that the complex does not release a proton even at pH$\simeq$6. This fact shows that the dissociation constant of MHA to MA and H must be less than 10^{-6}, which is smaller than K_2. In many protonated complexes of highly charged metal ions, the dissociation of a proton in a complex is usually more enhanced than that of the corresponding free acid by electrostatic repulsion between a leaving proton and the central metal ion. However, the dissociation of a proton in the protonated oxovanadium(IV) malonate complex is not the case. This phenomenon may be interpreted in terms of formation of an intramolecular hydrogen bond between the oxygen atom in VO^{2+} ion and a proton in a malonic acid molecule coordinated as a monodentate ligand to the central metal ion.

A Common Feature in the 2+2 Cycloadditions of Benzyne and $^1\Delta_g$ Molecular Oxygen to Ethylene Derivatives

Satoshi INAGAKI and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received October 2, 1972)

The abnormal behavior of $^1\Delta_g$ molecular oxygen in the cycloaddition reaction previously stimulated our interest in a well-established, close connection between orbital interaction and stereoselection,[1] since the singlet oxygen gives 2+2 and 4+2 cycloadducts, both retaining the configuration of the substrate olefins.[2] A consideration of the orbital interaction scheme[1] was previously found to suggest that the singlet oxygen may approach ethylene, as is represented by Model I.[3] This sort of reaction path for 2+2 cycloaddition was novel and is clearly different from the symmetry-allowed 2_s+2_a process generally proposed for concerted cycloaddition by Woodward and Hoffmann.[4] The preference for this nuclear configuration has been attributed to the fact that the interaction between the highest occupied (HO) molecular orbital (MO) of ethylene as an electron-donor and the lowest unoccupied (LU) MO of the oxygen molecule as an electron-acceptor is most favored in this nuclear configuration. The prediction of the addition mechanism

1) The essence of this concept may be briefly said as follows; a majority of chemical reactions should take place at the position and in the direction where the particular interaction between the frontier orbitals is most favored.

For further particulars on the HOMO-LUMO interaction scheme, see the following articles; K. Fukui, *Accounts Chem. Res.*, **4**, 57 (1971); K. Fukui and H. Fujimoto, "Mechanisms of Molecular Migrations," Vol. 2, ed. by B. S. Thyagarajan, Interscience, New York, N. Y. (1969), p. 118; K. Fukui, "Theory of Orientation and Stereoselection," Springer-Verlag, Heidelberg, (1970).

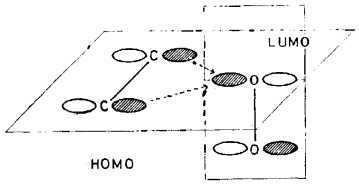
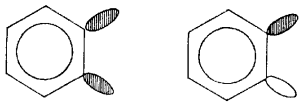
tempts us to seek the most favorable path of the reaction between olefinic C=C double bonds and benzyne, which exhibits a similar behavior toward unsaturated hydrocarbons.[5] Here, this problem will also be probed by means of the HOMO–LUMO interaction scheme.[1]



I

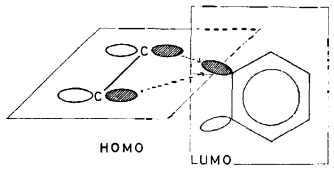
The electronic state of benzyne has been presented in several papers,[6] and it has been shown that the HOMO (II) and the LUMO (III) have the same symmetry property as normal mono-olefins.[6a] Accordingly, it can readily be found that the simple symmetry arguments of the Woodward-Hoffmann method[3] predict that suprafacial-suprafacial[3] cycloaddition is symmetry-forbidden and that the other mode of suprafacial-antarafacial process is not probable for the following reasons. No antarafacial mode on benzyne is conceivable since the particular MO's of benzyne extend their lobes exclusively outward from the benzene nucleus[6a] (see II and III). On the other hand, the antarafacial interaction is possible on the side of ethylene, but this $2\pi_s+2\pi_a$ process ends in the inversion of the ethylene derivative configuration, which is inconsistent with the experimental observations.[5] It follows that the simple application of the Woodward-Hoffmann dichotomy of symmetry-allowed 2_s+2_a and symmetry-forbidden 2_s+2_s processes cannot produce fruitful information on the reaction between benzyne and ethylene.



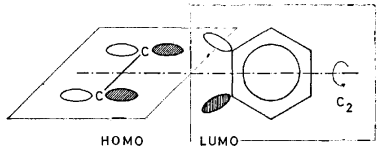
II III

Here, the electronic structure of benzyne, particularly the LUMO with an abnormally low energy or with a negative eigenvalue (the result of *ab initio* calculation),[6b] should be noted; this suggests the strong electrophilicity of benzyne.[7] This characteristic is markedly different from normal olefins, but is similar to the $^1\Delta_g$ oxygen molecule.[4] It may, therefore, be considered that benzyne may also provide the LUMO for the critical orbital interaction with ethylene.

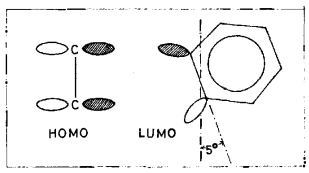
The above discussion allows us to predict the most favorable reaction path, using the degree of interaction between the HOMO of ethylene and the LUMO of benzyne as the primary measure. We will examine the same sorts of models (IV, V, and VI) as with the singlet oxygen. Here, the IV candidate corresponds to that which was predicted to be the most feasible with $^1\Delta_g$ oxygen,[4] in which the benzyne structure lies in the bisecting plane of the ethylenic C–C bond with one of its particular carbon atoms in the vertical plane of ethylene. The V illustration represents some models with C_2 symmetry, including a symmetry-forbidden $2\pi_s+2\pi_s$ process, where the molecular plane of benzyne intersects the plane containing the ethylene π-orbital at the angles of 0°, 30°, and 90°. The last model, VI, is intended for a step-by-step reaction, whether ionic or radical-like. The parallel relation between the C=C bond of ethylene and the C≡C bond of benzyne is broken a little (5°) in the coplane. The overlap integrals between the HOMO of ethylene and the LUMO of benzyne are calculated for each model in order to estimate the degree of orbital interaction between them.[8] The results show that the overlap integral for the IV model is the largest (0.026) among those of the models examined (*cf.* 0.000 for V's and 0.003 for VI).[9] On comparing these values, we see that the IV model is the most appropriate. The prediction made here on the basis of the HOMO–LUMO interaction is consistent with that drawn from the total energy by extended Hückel calculations (−701.501 eV for IV and higher than −701.440 eV for V's and VI).[9]



IV



V



VI

The nuclear configuration IV is also shown to have good grounds for the most probable structure of the transition state or the intermediate structure in the 2+2 cycloaddition between benzyne and ethylene. Here it is

5) For example, see the review, I. Tabushi and H. Yamada, *Yuki Gosei Kyokai Shi*, **28**, 667 (1970).

7) In fact, benzyne readily reacts with a variety of nucleophiles such as anion (alkoxide, metal amide and carbanion), sulfides, phosphorus compounds, amines, ethers, and so on; see the Ref. 5.

8) K. Fukui and H. Fujimoto, This Bulletin, **41**, 1989 (1968).

9) These values are obtained by the calculation on each model where the distance between the relevant C=C bond of benzyne and that of ethylene is 3 Å apart from each other. For more detailed calculation, D. M. Hayes and R. Hoffmann, *J. Phys. Chem.*, **76**, 656 (1972).

noteworthy that good electron-acceptors, *e.g.*, ketenes[10] and tetracyanoethylene,[11] also afford 2+2 cycloadducts with a retention of the configuration. Whether or not these cycloadditions are intrinisically identical with those of $^1\Delta_g$ molecular oxygen and benzyne is a question requiring further study,[12] but it can be expected that this mechanism is pervasive throughout 2+2 cycloadditions between electron-donating and electron-accepting multiple bonds.

The Vibrational Spectra of the Zn-Acrylonitrile Complex

Tomoichi KAMO, Sumio NAGAI, and Masao KIMURA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 6, 1972)

In a previous paper,[1] the present authors reported on the infrared spectra of zinc-halide complexes with acetonitrile; these complexes form σ-bonds between the Zn atom and the N atoms of the nitrile groups. In the present study the infrared spectrum of the zinc chloride-acrylonitrile complex has been investigated; it was also expected to be a σ-complex.

Experimental

The sample of $[ZnCl_2 \cdot CH_2CHCN]_n$ was prepared from $ZnCl_2$ and acrylonitrile by the method described in the previous paper.[1]

The infrared spectra, ranging from 4000 to 96 cm^{-1}, were measured by the mull method on a JASCO IR-G infrared spectrophotometer in the near-infrared region, and on a Hitachi FIS-21 infrared spectrophotometer in the far-infrared region.

Assignment and Normal Coordinate Analysis

A complete assignment for the in-plane vibrational modes of acrylonitrile has been made by Halverson *et al.*[2] and has been supported by Fritz and Schrauzer[3] and also by Devlin *et al.*[4] In the present study, the assignment of bands for the ligand was made by correlation with the spectra for the free acrylonitrile, while that for the skeleton about the Zn atom was made by referring to the spectra of analogous complexes.[1,5]

In order to see the strength of the coordination bond, normal coordinate analyses were carried out in two steps using the simple Urey-Bradley force fields. In the first step (Calculation 1), only the intra-ligand vibrations for the $CH_2 \cdot CH \cdot CN \cdot Zn$ system were treated by assuming them to be separable from the skeletal vibrations about the central Zn atom. The molecular geometry of gaseous acrylonitrile[6] was assumed to be maintained in the complexed ligand. All the force constants associated with the ligand vibrations except for the C≡N stretching, $\nu_{C\equiv N}$, were transferred from those which had been determined by the present authors by applying the overlay technique[4,7] to the observed frequencies for both acrylonitrile and fumaronitrile in the free states. In the second step (Calculation 2), the complex was assumed to be a Cl-bridged dimer of C_{2h} symmetry, in which the two-fold axis was the line connecting the two bridging chlorine atoms and in which the two linear R–C≡N–Zn (R: H_2C=CH) frames are located at *trans* positions on the horizontal plane. The bond distances and angles about the Zn atoms were assumed to be as follows: Zn–Cl=2.30 Å, Zn–N=2.00 Å, and all the valence angles were 109.5°. The force constants, K_{R-C}, $K_{C\equiv N}$, K_{Zn-N}, and $H_{Cl^bZnCl^b}$, were then determined so as to reproduce the observed frequencies by transferring the other force constants from those obtained for the acetonitrile complexes.[1] The observed and calculated frequencies and their assignments are shown in Table 1, while the force constants are shown in Table 2.

Results and Discussion

For comparison, the observed frequencies for the free ligand are reproduced in Table 1. Tables 1 and 2 indicate that the coordination has an appreciable effect only on the $\nu_{C\equiv N}$, and that the slight increase in the $K_{C\equiv N}$ value satisfactorily explains the observed frequencies for the acrylonitrile moiety. Such an effect of coordination has also been observed in the Zn-aceto-

K_{Zn-N}	0.40	$H_{Cl^bZnCl^t}$	(0.075)	$F_{Cl^bCl^t}$	(0.075)
K_{Zn-Cl}	(1.10)	H_{ZnClZn}	((0.025))	$F_{Zn,Zn}$	((0.025))
		H_{CNZn}	(0.025)	$F_{C,Zn}$	(0.0)
		H_{RCN}	(0.12)	$F_{R,N}$	(0.0)

a) Values in parentheses were transferred; see text. Values in double parentheses were assumed.
b) The $K_{C\equiv N}$ for the free ligand, 16.70 mdyn/Å.
c) An effective value obtained by treating the olefinic group as a single mass point.

nitrile complexes; it may be considered to be characteristic of σ-coordination. In Calculation 2, the olefinic group was treated as a single mass point. This treatment produces only an insignificant change in the $K_{C\equiv N}$ value and no change in the K_{Zn-N} value, as compared with the results of Calculation 1. The K_{Zn-N} value was thus determined to be 0.40 mdyn/Å in both calculations, 1 and 2. This value is of the same order of magnitude as that in the Zn-acetonitrile complex, 0.65 mdyn/Å. This suggests that the Zn atom coordinates to the N atom of the nitrile group with a similar bond strength to that of the coordination bonds in the Zn-acetonitrile complexes.[1]

As the geometry of the present complex has not yet been known, we assumed a bridged structure so as to account for the results of the chemical analysis. Then, the three bands observed at 348, 328, and 280 cm^{-1} were assigned to the three Zn–Cl stretching vibrations; the highest frequency band at 348 cm^{-1} may be due to the Zn-terminal Cl stretching, ν_{Zn-Cl^t}, while the

broad band observed at 328 cm^{-1} is probably composed of two bands, one of which originates from the ν_{Zn-Cl^t} and the CCN deformation. Since a Zn atom forms usually a tetrahedral coordination, and since the observed spectra could be interpreted on the basis of a Cl-bridged structure, the assumed structure for this complex seems most probable. In the present normal coordinate calculation, no particular attention was paid to the Zn–Cl stretching vibrations, all the Zn–Cl bonds being assumed to have the same force constant. If different Zn–Cl force constants are used for the terminal- and bridging-Cl atoms, the agreement between the observed and calculated frequencies will be improved. However, no further refinement was made.

Interaction between Lone Pair Electrons on the Nitrogen Atoms in 1,5-Diazabicyclo[3.2.1]octane

Yoshiaki HAMADA, Akiko Y. HIRAKAWA, Masamichi TSUBOI, and Hitoshi OGATA*

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

**Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received January 24, 1973)

In the course of our studies on the electronic spectra of amines,[1-3] we have been interested in the intramolecular interaction between the nitrogen lone pairs. Hoffmann *et al.*[4] made a theoretical study on the interaction of two orbitals (n_1 and n_2) separated by a number of intervening σ bonds. They showed that the interaction should be dependent only on the orientation of the σ bonds between the orbital lobes in question and the orientation of the lobes themselves, but not on the specific molecule. By extended Hückel calculations, they predicted, for example, that in arrangement (a) of Fig. 1, the antisymmetric (n_1-n_2) level should be

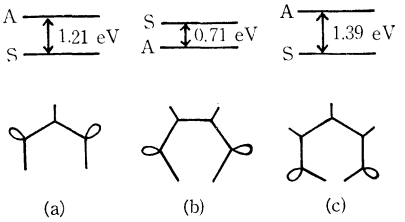

Fig. 1. Interaction patterns in some model arrangements of orbital lobes (n_1 and n_2) and intervening σ bonds, as given by Hoffmann *et al.*[4] The amount of splitting of the S (symmetric, n_1+n_2) and A (antisymmetric, n_1-n_2) levels is given in eV for each model arrangement.

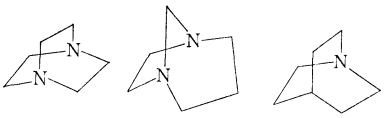
higher by 1.21 eV than the symmetric (n_1+n_2) level, while in arrangement (b) the symmetric level should be higher by 0.71 eV than the antisymmetric level. Therefore, for 1,4-diazabicyclo[2.2.2]octane (I), a splitting of some 2.1 eV ($\fallingdotseq 0.71\times 3$) is expected between the two levels of the lone pair electrons. This was



shown to be the case by Bischof *et al.*[5] They found in the photoelectron spectrum of I two bands at 7.5 and 9.5 eV which are assignable to the ionizations of electrons from two orbitals strongly localized on the nitrogen lone pairs. The assignment was also supported by Dewar and Wasson[6] by the use of a semiempirical SCF MO procedure (MINDO/2).

We now report here the result of our similar examination on 1,5-diazabicyclo[3.2.1]octane (II), in which two nitrogen atoms are connected by three σ-bond-bridges corresponding to arrangements (a), (b), and (c) in Fig. 1 (instead of three type-(b) bridges in I). On the basis of the study of Hoffmann and his collaborators,[4] the amount of splitting should be somewhat smaller in II than in I, and the ordering of the symmetric and antisymmetric levels should be reversed. In Fig. 2, are given the photoelectron spectra of I and II observed in their gaseous states. To help the assignments of the observed peaks, we have made a semiempirical SCF MO (MINDO/2) calculation for quinuclidine (III), as well as for I and II. In the calculation for III, the orbital energy of an MO in which the nitrogen lone pair has the greatest contribution came out to be −8.64 eV, and this is in agreement with the position of the observed peak (8.02 eV) in the photoelectron spectrum of III assignable to the lone pair orbital (highest occupied MO).[5] For I and II, the calculated energy values of the MO's in which the main contributions come from the nitrogen lone

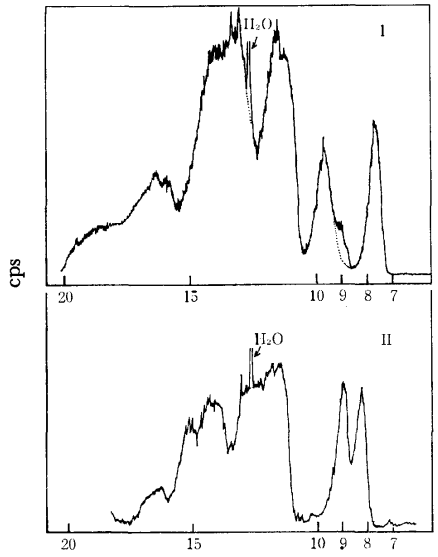

Fig. 2. Photoelectron spectra of I and II. Ordinate is the count rate in arbitrary units. The photoelectron spectrum of I was observed also by Bischof *et al.*,[5] and their result is in a good agreement with ours, shown here. A small peak at 9 eV in the spectrum of I is considered to be caused by an impurity.

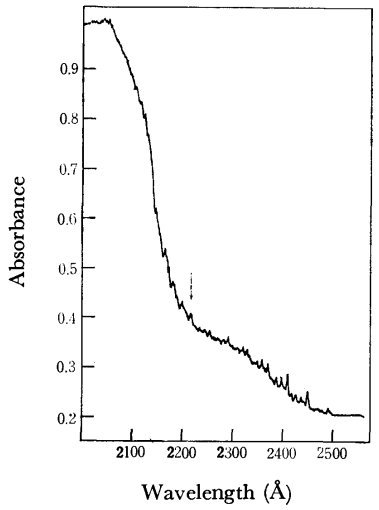

Fig. 3. Ultraviolet absorption spectrum of II in its gaseous state. The arrow indicates a band assigned to 0-0 transition.

pairs are given in Table 1. As may be seen in this table, the calculated values for I are in good agreement with the observed values. In view of such an agreement (both for III and I), we may expect an equally good prediction for our MINDO/2 calculation of the orbital energy in II. Hence, the assignments can be made on the observed peaks in the photoelectron spectrum of II as shown in Table 1. In other words, we may conclude that, assuming the validity of Koopmans' theorem, the two highest occupied MO's of II at −8.24 and −8.95 eV are attributed mostly to the nitrogen lone pairs, the higher one ($E_A = -8.24$ eV) to the antisymmetric MO ($n_1 - n_2$) and the lower one ($E_S = -8.95$ eV) to the symmetric MO($n_1 + n_2$). The amount of splitting ($E_A - E_S$) due to the lone pair interaction is +0.71 eV. This is somewhat smaller than a simple estimate from the study of "basic coupling units" of Hoffmann *et al.*,[4] but slightly greater than the value estimated by our MINDO/2 procedure.

We like to mention here the result of our ultraviolet absorption measurement of II in its vapor phase. This is shown in Fig. 3. The apparent 0—0 transition of the strong absorption band is found at 2216 Å. By adding this transition energy to the orbital energy of the highest occupied MO (−8.24 eV), the approximate orbital energy of the vacant MO now in question is given as −2.64 eV. By a similar procedure, the corresponding orbital energy is found to be −2.77 eV in I and −2.6 eV in III. It is interesting that this vacant MO is located at almost equal height for all of these molecules (I, II, and III).

Experimental

The sample of 1,5-diazabicyclo[3.2.1]octane (II) was prepared from homopiperazine and formaldehyde by the method of Poppelsdorf.[7] Solvent used was toluene, and the product was purified by a recrystallization and sublimation procedure.

The photoelectron spectra were recorded on a Jasco PE-1 High-resolution Photoelectron Spectrometer. Excitation was made by photons from the 584 Å He resonance line. For calibration of the ionization potential (IP), H_2O (IP, 12.61_6 eV), O_2 (12.07_0), and N_2 (15.57_9) were used as internal standards.

The ultraviolet absorption spectrum was observed by the use of a Hitachi EPS-3T spectrometer with a quartz prism. The calibration was made by the absorption lines of the γ system of nitric oxide in the region from 1955 to 2270 Å.

MINDO/2 Calculation

For I and III, a set of the molecular parameters given by Yokozeki and Kuchitsu[8] (N–C, 1.472 Å;

7) F. Poppelsdorf, U.S. 3120336 (Cl. 260—239).
8) A. Yokozeki and K. Kuchitsu, This Bulletin, **44**, 72 (1971).

C–C, 1.562 Å; C–H, 1.110 Å; ∠NCC, 110.2°; ∠CNC, 108.7°; ∠HCH, 111.5°; angle of twisting ϕ defined by Yokozeki and Kuchitsu, 10°) has been used. For II, the following parameters were used: N–C, 1.472 Å; C–C, 1.562 Å; C–H, 1.110 Å; ∠NCN, 109.7°; ∠CNC, 108.7°; ∠NCC, 110.2°; ∠CCC, 109.7°; ∠HCH, 111.5°, dihedral angle HCCH, 0°. The calculation was made by the use of HITAC 5020E. The SCF procedure was repeated until the change in total electronic energy becomes smaller than 0.0005 eV.

The sequence which follows is analogous to that proposed by Kolthoff *et al.*[1]

$$CO_2^- + O_2 \rightleftharpoons O_2CO_2^- \quad (3)$$

$$O_2CO_2^- + Mn^{II}Ox + 2H^+ \longrightarrow H_2O_2 + Mn^{III}Ox + CO_2 \quad (4)$$

$$Mn^{III}Ox \longrightarrow Mn^{II}Ox + CO_2 + CO_2^- \quad (5)$$

The sequence of Reactions (3), (4), and (5) constitutes a chain reaction. The terminating reaction probably occurs *via* Eq. (6):

$$Mn^{III}Ox + CO_2^- \longrightarrow Mn^{II}Ox + CO_2 \quad (6)$$

where $Mn^{II}Ox$ and $Mn^{III}Ox$ indicate the various forms of oxalato-manganese(II) and (III) respectively. The assumption of steady-state concentrations of CO_2^-, $O_2CO_2^-$, and $Mn^{III}Ox$ leads to Eq. (7):

$$[H_2O_2]_{formed} = \sqrt{\frac{kk_4k_5K[O_2][Mn^{II}Ox][Co(C_2O_4)_3^{3-}]}{2k_6}}[H^+]\tau \quad (7)$$

where $k=k_1+k_2[H^+]$, where k_n indicates the rate constant of the reaction (n), where K is the equilibrium constant of Reaction (3), and where τ means the time of standing of the reaction mixtures. It may be presumed that the concentrations, $[O_2]$, $[H^+]$, and $[Mn^{II}Ox]$ are constant under the conditions of Tables 1 and 2. Under these circumstances Eq. (7) predicts a linear relation in the plot of $[H_2O_2]_{formed}/[Co(C_2O_4)_3^{3-}]^{1/2}$ *vs.* τ. This is verified experimentally in Fig. 1. The above reaction mechanisms are properly

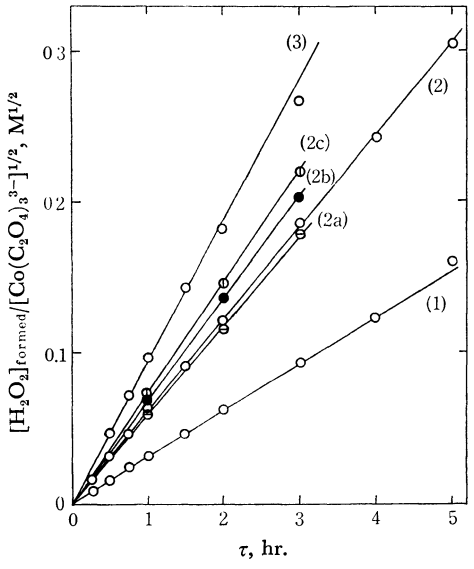

Fig. 1. Plot of $[H_2O_2]_{formed}/[Co(C_2O_4)_3^{3-}]^{1/2}$ *vs.* τ.
Conditions as in Table 1. Concentrations of manganese(II) sulfate are 0.001M (1), 0.01M (2), and 0.1M (3). (2a), (2b), and (2c) are as in (2) except 0.005M, 0.05M, and 0.1M in oxalic acid respectively, instead of 0.01M oxalic acid.

borne out by the fitness of the kinetic treatment. Since the concentration of oxalate does not appear in Eq. (7), the amount of hydrogen peroxide formed must be essentially independent of the concentration of the uncomplexed oxalate ion. However, the following facts should be noted. Manganese(III) as well as manganese(II) forms various complexes with oxalate, and the redox decomposition of Mn(III)Ox occurs at different rates (k_5);[4,5] In acidic solutions under conditions such as are shown in Tables 1 and 2, mono- and di-oxalato complexes of manganese(III) would be presumably predominant species, and the oxalato complexes of manganese(II) may be highly dissociated. The equilibria should be shifted by any change in the concentrations of oxalate and manganese(II) sulfate. Accordingly, the formation of hydrogen peroxide would be dependent on the oxalate concentration. As may be seen in Table 2, a small dependence of

Table 2. Effect of the oxalic acid concentration on the formation of hydrogen peroxide[a]

$[H_2C_2O_4]_{added}$, M[b]	$[H_2O_2]_{formend} \times 10^3$, M Time of standing, hr			
	0.5	1	2	3
0	1.3	2.5	4.4	6.1
0.005	1.7	3.2	5.4	7.3
0.01	1.8	3.4	5.7	7.7
0.05	1.8	3.8	7.2	9.6
0.1	1.8	4.2	7.6	10.4
0.1 M HCOOH instead of $H_2C_2O_4$	1.1	2.2	3.9	5.2

a) Conditions as in Table 1 except for the varied concentrations of oxalic acid and the 0.01 M value of manganese(II) sulfate.
b) The concentrations of oxalic acid listed here indicate those in the initial solutions.

the oxalate concentration was observed. However, the amount of hydrogen peroxide formed at 0.5 hr was practically independent of the concentration of oxalic acid. Finally, formic acid was compared with oxalic acid in respect of the hydrogen peroxide formation. As can be seen in Table 2, the amount of hydrogen peroxide formed does not increase when formic acid is added instead of oxalic acid; rather, it decreases slightly. It appears that the following reactions, (4′) and (5′) hardly occur under these conditions:

$$O_2CO_2^- + Mn^{II} + 2H^+ \longrightarrow H_2O_2 + Mn^{III}(formate) + CO_2 \quad (4')$$

$$Mn^{III}(formate) \longrightarrow Mn^{II} + CO_2^- + H^+ \quad (5')$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2248—2249 (1973)

A Facile, Stereospecific Preparation of Olefins from Pinacols

Tamejiro HIYAMA and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University Yoshida, Kyoto 606

(Received November 30, 1972)

Considerable attention has been drawn to stereospecific or stereoselective olefin syntheses.[1] Among them, the deoxygenation of pinacols constitutes a convenient route to olefins, especially symmetric ones.[2] The desulfurization of thioncarbonates of pinacols with phosphite[3] is well known, but the method requires not-easily-available thiocarbonyldiimidazole as well as a high reaction temperature. The reaction of benzaldehyde acetal of pinacols with *n*-butyllithium[4] proceeds at a low temperature and has been successfully applied to the preparation of *trans*-cyclooctene, but the attempt to prepare stilbene from dihydrobenzoin has been reported to be unfruitful. In contrast, a third method, discovered by Eastwood *et al.*[5], has proven to be quite useful in the preparation of alkylsubstituted stilbenes and cyclic olefins. The present note will describe the experimental details of these new applications.

A mixture of the pinacol **1b**, for example, an excess of ethyl orthoformate, and a catalytic amount of benzoic acid was heated at 100 °C for 2 hr and subsequently at 170—190 °C for 2 hr to afford, stereospecifically, the **2b** olefin in a good yield. The results are summarized in Table 1, which shows that the sequence provides a beneficial route to stilbestrol.[6] Since the pure *threo* diols, **1d** and **1f**, were unaccessible, a mixture of diastereomers was subjected to the reaction in the case of **1d**. The yields of the *trans*-olefins, **2d** and **2f**, were improved by the isomerization of the corresponding *cis*-olefins (**2c** and **2e**).

Experimental

Preparation of trans-*2,3-Diphenyl-2-butene (2b).* A mixture of *dl*-2,3-diphenylbutane-2,3-diol (**1b**, 642 mg, 2.65 mmol), ethyl orthoformate (600 mg, 5.6 mmol), and benzoic acid (20 mg, 0.16 mmol) was stirred at 100 °C for 2 hr. The subsequent evaporation of the produced ethanol and the excess orthoformate *in vacuo* gave the crude 1,3-dioxolane (IR 1120—1050 cm^{-1}). Benzoic acid (300 mg) was then added, and the mixture was heated at 170—190 °C for 2 hr, during which time the evolution of carbon dioxide and the refluxing of ethanol were observed. After cooling, dichloromethane (20 ml) was added, and the solution was washed with saturated sodium bicarbonate (four 5 ml portions) and dried with anhydrous potassium carbonate. Concentration gave crystalline **2b** (593 mg). Recrystallization from methanol afforded an analytically-pure sample (460 mg); mp 103—104 °C (lit,[9] 106 °C). NMR (δ, CCl_4): 1.85 (s, 6H) and 7.15 (s, 10H). Mass spectrum: *m/e* 208 (M^+, 100%).

cis-*2,3-Diphenyl-2-butene (2a)* (402 mg) was obtained from **1a** (484 mg). NMR (δ, CCl_4): 2.10 (s, 6H) and 6.85 (s, 10H).

cis-*3,4-Di*-p-*methoxyphenyl-3-hexene (2c).* The heating of **1c** (660 mg, 2 mmol), ethyl orthoformate (300 mg), and benzoic acid (50 mg) at 170 °C for 1 hr and a subsequent work-up gave **2c** (510 mg); bp 190 °C (bath temperature)/4 mmHg. NMR (δ, CCl_4): 0.90 (t, 6H), 2.44 (q, 4H), 3.52 (s, 6H), 6.40 (d, J=8.4 Hz, 4H), and 6.68 (d, J=8.4 Hz, 4H). Mass spectrum: *m/e* 296 (M^+, 100%).

trans-*3,4-Di*-p-*methoxyphenyl-3-hexene (2d).* An isomer mixture of the **1c** and **1d** pinacols obtained by the redcution[6] of *p*-methoxypropiophenone (2.80 g, 17 mmol) was heated at

5) J. S. Josan and F. W. Eastwood, *Aust. J. Chem.*, **21**, 2013 (1968); G. Crank and F. W. Eastwood, *ibid.*, **17**, 1392 (1964). See also, F. W. Eastwood, K. J. Harrington, J. S. Josan, and J. L. Pura, *Tetrahedron Lett.*, **1970**, 5223.

6) K. Sisido and H. Nozaki, *J. Amer. Chem. Soc.*, **70**, 776 (1948).

7) The glycol **1h** (mp 130—131 °C) was obtained by sodium borohydride reduction of sebacoin. Cf. ref 11).

8) All temperatures are uncorrected. Infrared spectra were taken on a Shimadzu IR-27G, NMR spectra on a JEOL C-60H, mass spectra on a Hitachi RMU-6L. Benzoic acid used was recrystallized from benzene. Commercial orthoformates were distilled before use.

9) J. K. Cline, E. Campaingne, and J. W. Spies, *J. Amer. Chem. Soc.*, **66**, 1136 (1944).

170—180 °C for 2 hr with ethyl orthoformate (4 ml) and benzoic acid (0.5 g). The addition of *n*-hexane precipitated unchanged **1c** (230 mg). The concentration of the filtrate and the recrystallization of the residue (1.8 g) gave **2d** (640 mg); mp 118—120 °C (lit,[6] 124 °C). The mother liquor was concentrated (*ca.* 1.0 g), and dissolved in chloroform (10 ml) and iodine (0.5 g). The solution was then heated under reflux for 3.5 hr, washed thoroughly with aqueous sodium bisulfite and then with water and dried (sodium sulfate). The subsequent concentration of the solution, followed by the recrystallization of the residue, gave additional **2d** (420 mg). A total of 1.06 g of **2d** was obtained. NMR (δ, CCl_4): 0.75 (t, 6H), 2.09 (q, 4H), 3.74 (s, 6H), 6.72 (d, J=8.4 Hz, 4H), and 6.98 (d, J=8.4 Hz, 4H). Mass spectrum: *m/e* 296 (M^+, 100%).

trans-p,p'-*Dimethoxystilbene (**2f**)*. The heating of hydroanisoin (**1e**) (822 mg, 3 mmol) with ethyl orthoformate (900 mg) for 1 hr at 170—180 °C, followed by the evaporation of the excess orthoformate and ethanol *in vacuo*, gave an oil (**2e**) (1.2 g). This oil was heated with iodine (0.50 g) in chloroform (10 ml) under reflux for 3 hr. Work-up and recrystallization (*n*-hexane–acetone) afforded colorless needles (260 mg); mp 216—218 °C (lit,[10] 214—215 °C).

trans-*Cyclooctene (**2g**)*. *trans*-Cyclooctane-1,2-diol (**1g**) (385 mg, 2.7 mmol), methyl orthoformate (0.5 ml), and benzoic acid (20 mg) were heated at 90—100 °C for 2 hr. The methanol and excess orthoformate were then evaporated under reduced pressure. Benzoic acid (50 mg) was added, and the mixture was heated at 160—170 °C. The olefin thus produced was distilled as were carbon dioxide and methanol. The distillate was placed in dichloromethane, washed with aqueous sodium bicarbonate, and dried (sodium sulfate). Concentration gave crude **2g** quantitatively. Distillation at 90—100 °C (bath temperature)/95 mmHg gave **2g** (155 mg). IR (neat): 3020, 1650, and 982 cm^{-1}. Gas-chromatographic analysis (High Vacuum Silicone Grease, 10%, on Celite 545, 2 m, 60 °C) showed a single peak.

cis-*Cyclodecene (**2h**)*. *cis*-Cyclodecane-1,2-diol (**1h**) (860 mg, 5 mmol), methyl orthoformate (1.0 ml), and benzoic acid (50 mg) were heated at 90—100 °C for 2 hr. After concentration *in vacuo*, benzoic acid (100 mg) was added and the mixture was heated at 160—170 °C for 1 hr. Work-up gave **2h** (465 mg); bp 120—130 °C (bath temperature)/106 mmHg. IR (neat)[11]: 706 cm^{-1}.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2249—2251 (1973)

The Catalytic Decomposition of 9-Diazofluorene by Metal Carboxylates

Tamio SHIRAFUJI, Katuzi KITATANI, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received December 14, 1972)

We have found that Cu(II) carboxylates in aq DMF catalyze the decomposition of 9-diazofluorene (I), thus affording fluorenone pinacol diesters (II) in addition to bifluorenylidene (III). The reaction is, therefore, analogous to that of diphenyldiazomethane recorded previously.[1] Though fluorenone pinacol diacetate may alternatively be obtained by treating fluorenone (IV) with zinc and acetyl chloride,[2] the present reaction does furnish a practical, simple method for preparing this class of esters, II.

$$(RCO_2)_2Cu(II) + Ar_2CN_2 \longrightarrow$$
$$\underset{I}{}$$
$$\underset{RCOO\ \ OCOR}{\overset{Ar_2C-CAr_2}{|\quad\ |}} + Ar_2C{=}CAr_2 + Ar_2C{=}O + Ar_2C{=}N\rangle_2$$
$$\underset{II}{}\qquad\qquad\underset{III}{}\qquad\underset{IV}{}\qquad\underset{V}{}$$

Ar_2=2,2′-biphenylene

Table 1 summarizes the reactions of I with Cu(II) carboxylates in aq. DMF to give II, III, and IV. Diacetate IIa was identified by means of the spectral and analytical data, and by the thermal decomposition,[3] which afforded IV and fluorenyl acetate (VI) at 170°C. In contrast to Cu(II) carboxylates such as acetate, propionate, and *n*-butyrate, the Cu(II) isobutyrate afforded IId in an inferior yield, whereas the Cu(II) tartrate gave no pinacol diester, II, but mainly III, along with fluorenone azine (V). Such a difference between Cu(II) carboxylates and the chelate salt may be attributed to the mobility of ligands around the central Cu(II) ion toward the newly-attached fluorenylidene moiety. Chelate ligands are tightly bound to the central metal ion and should be less accessible than simple carboxylate anions.

TABLE 1. REACTIONS OF I WITH Cu(II) CARBOXYLATES IN aq DMF

Cu(II) cabroxylate	Reaction		Products (yield in %)[a]			
	temp (°C)	time (hr)	II	III	IV	V

Table 2. Oxidation of I with various metal acetates

Metal acetate	Reduction potential in water (eV)[a]	Reaction		Solvent	Products (Yield in %)[b]			
		°C	hr		VI	IIa	VII	IV
$Cr(III)(OAc)_3$	−0.41	60	23	aq DMF	9	—	—	55
$Cu(II)(OAc)_2$	+0.15	40	18	aq DMF	—	55	—	15[c]
$Tl(III)(OAc)_3$	+1.21	25	19	CH_2Cl_2	—	—	42	56
$Pb(IV)(OAc)_4$	+1.69	25	25	CH_2Cl_2	—	—	61	30

a) These data were taken from N. A. Lange, "Handbook of Chemistry" 10th ed. McGraw-Hill (1961), p. 1212.
b) Recovery was not considered in calculation of yields. c) A 24% yield of III was obtained.

Being interested in oxidation reactions brought about by metal ions,[5] we then investigated the decomposition of I by means of various other metal acetates, as is shown in Table 2. The Cr(III) acetate catalyzed the decomposition of I to afford VI in a low yield, while the Tl(III) or Pb(IV) acetate gave fluorenone diacetate (VII) as the major product.[6] This behavior is parallel to that of diphenyldiazomethane with the metal acetates.[1]

Experimental

All the melting points are uncorrected. The NMR spectra were obtained on a 60 MHz instrument (JEOL C-60-H spectrometer) in $CDCl_3$ unless otherwise stated. The chemical shifts are given in ppm from the TMS internal standard, and the abbreviations of s, d, t, q, and m are used with their common meanings.

The mass spectra were obtained on a Hitachi RMU 6L spectrometer. The microanalyses were performed by Mrs. K. Fujimoto.

General Procedure of the Catalytic Decomposition of 9-Diazofluorene (I) with Metal Salts. Under N_2, metal salts were dissolved in aq DMF (1:1) or methylene chloride so as to give a *ca.* 0.3 M solution; this solution was then kept at an appropriate reaction temperature (25—60 °C) with stirring. To this we then added, drop by drop, a solution (*ca.* 0.5 M) of I in the same solvent. The molar ratio of diazo compound/metal salt was taken to be 1:1 unless otherwise stated. Heating and stirring were continued until the evolution of N_2 had ceased. The mixture was then worked up as usual. The crude products were separated by glc, recrystallization, or column chromatography, and then identified. The following descriptions will be concerned with cases which are not covered sufficiently by Tables 1 and 2.

Preparation of Fluorenone Pinacol Diesters (II). The diazo compound I was treated with solutions of Cu(II) carboxylates in aq DMF. The chromatography of the reaction mixture on a short silica gel column (benzene elution) gave bifluorenylidene,[7] II, and fluorenone. The spectral

and analytical data of II are shown in Table 3.

Reaction of I with Tl(III) Acetate. I (370 mg, 1.94 mmol) was treated with Tl(III) acetate (1530 mg, 4.0 mmol) in methylene chloride (20 ml) at room temperature for 19 hr. After filtration, the reaction mixture was concentrated *in vacuo*. The products were recrystallized from carbon tetrachloride to give fluorenone diacetate (230 mg, 42%); mp 138—140 °C. IR (Nujol): 1740, 1200, 999 cm^{-1}. NMR (CCl_4, 10%): δ 7.80—7.20 (m, 8H, aromatic) and 2.20 (s, 6H, –OAc). Mass spectrum (relative abundance): *m/e* 180 (100), 152 (36), 105 (15), 76 (20), 43 (84).

Found: C, 72.1; H, 5.0%. Calcd for $C_{17}H_{14}O_4$: C, 72.3; H, 5.0%.

The subsequent concentration of the filtrate gave fluorenone (200 mg, 56%).

Financial support from the Ministry of Education, Japanese Government, and from Toray Science Foundation is acknowledged with pleasure.

The Carbonylation of Furan and Thiophene Mercuric Compounds with Palladium Salt

Taeko IZUMI, Toshio IINO, and Akira KASAHARA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

(Received January 12, 1973)

Heck[1] has reported that diarylketones were formed in moderate yields from arylmercuric salts and carbon monoxide with a transition-metal-salt catalyst. Furthermore, we have ourselves described the carbonylation of 1,1′-bis(chloromercuri)-ferrocene in the presence of a palladium salt.[2] In this report, we wish to report on the carbonylation reactions of chloromercuri-derivatives of furan and thiophene in methanol with a palladium salt.

The carbonylation of 2-chloromercurifuran (I–1) was carried out at 100 °C under a carbon monoxide pressure of 50 atm in the presence of lithium chloropalladite in methanol; the main products were 2,2′-difurylketone (II–1) and methyl furoate (III–1), plus a small amount of 2,2′-bifuryl (IV–1). The carbonylations of 5-methoxycarbonyl-2-chloromercurifuran (I–2) and 2-chloromercurithiophene (I–3) were performed under the same conditions. The mechanism of the formation of II–1 from I–1, as has been pointed out by Heck,[1] probably involves the reaction of an acylpalladium compound with a furylpalladium compound or I–1. III–1 and IV–1 are probably formed by side reactions.

$$ArHgCl + Li_2PdCl_4 \longrightarrow (ArPdCl) + HgCl_2 + 2LiCl$$

$$(ArPdCl) + CO \longrightarrow (ArCOPdCl)$$

$$(ArCOPdCl) + (ArPdCl) \longrightarrow ArCOAr + PdCl_2 + Pd$$

or

$$(ArCOPdCl) + ArHgCl \longrightarrow ArCOAr + HgCl_2 + Pd$$

$$2(ArPdCl) \longrightarrow Ar\text{-}Ar + PdCl_2 + Pd$$

or

$$(ArPdCl) + ArHgCl \longrightarrow Ar\text{-}Ar + HgCl_2 + Pd$$

$$(ArCOPdCl) \longrightarrow ArCOCl + Pd$$

$$ArCOCl + CH_3OH \longrightarrow ArCOOCH_3 + HCl$$

[Ar = furyl]

On the other hand, the carbonylation of 2,5-dichloromercurifuran (V–1) under the same conditions gave a mixture of 5,5′-dimethoxycarbonyl-2,2′-difurylketone (II–2), 2,5-dimethoxycarbonylfuran (III–2), and the keto-ester polymer (VIII). The structure of VIII was identified by means of the measurement of the molecular weight and by means of the spectral data. In the IR spectrum, very intensive absorption bands at 1735 cm^{-1} due to ester streching, at 1630 cm^{-1} due to carbonyl streching, and at 880 cm^{-1} due to the furan ring were observed. However, the carbonylation of 2,5-dichloromercurithiophene (V–2) yielded a mixture of 5,5′-dimethoxycarbonyl-2,2′-dithienylketone (VI) and 2,5-dimethoxycarbonylthiophene (VII).

Experimental

All the melting and boiling points are uncorrected. The IR spectra were recorded on a Hitachi 215 spectrometer, while the NMR spectra were obtained in $CDCl_3$ at 90 MHz with a Hitachi R-22 NMR spectrometer, using TMS as the internal standard.

Materials. The 2-chloromercurifuran (I-1) and 2,5-dichloromercurifuran (V-1) were synthesized by the method of Gilman *et al.*[3] The 2-chloromercurithiophene (I-3) and 2,5-dichloromercurithiophene (V-2) were prepared by the method of Cherbuliez and Giggey.[4]

The 5-methoxycarbonyl-2-chloromercurifuran (I-2) was synthesized from methyl furoate, mercuric chloride, and sodium acetate by a modification of the method of Gilman and Wright[3] Mp 243—245 °C. Yield, 60%. Found: C, 19.69; H, 1.15%. Calcd for $C_6H_5O_3HgCl$: C, 19.95; H, 1.36%.

General Procedure for The Carbonylation of Chloromercuric Compounds. A lithium chloropalladite solution was prepared by stirring 0.84 g (20 mmol) of lithium chloride with 1.77g

(10 mmol) of anhydrous palladium chloride overnight at room temperature in 100 ml of methanol. Into this solution, chloromercuric compound in an equivalent amount was then carbonylated at 100 °C under a carbon monoxide pressure (50 atm) for 6 hr with shaking. The reaction mixture was filtered to remove precipitated palladium, and the solvent was distilled under reduced pressure. The residue was dissolved in benzene and then purified by column chromatography on neutral alumina, or separated by preparative gas chromatography (Hitachi K-53 gas chromatograph, SE-30 column). The structures of the products were confirmed by an observation of the IR and NMR spectra and by comparing the retention time with those of authentic samples. The following results were obtained.

a) The carbonylation of I-1 afforded 2,2′-difurylketone (II-1) (35%, mp 33—34 °C (lit,[5] 33—34 °C)), methyl furoate (III-1) (30%, bp 178—180 °C (lit,[6] 181 °C)), and 2,2′-bifuryl (IV-1) (8%, bp 240 °C/7 mmHg (lit,[7] 240—245 °C/7 mmHg)).

b) The carbonylation of I-2 afforded 5,5′-dimethoxycarbonyl-2,2′-difurylketone (II-2) (40%, mp 95—97 °C, IR 1735, 1640, 880 cm^{-1}, NMR δ 3.88 (s, 6, $-COOCH_3$), 7.15 (d, 2, H on C_3 and $C_{3'}$), 7.34 (d, 2, H on C_4 and $C_{4'}$). Found: C, 56.05; H, 3.53%. Calcd for $C_{13}H_{10}O_7$: C, 56.12; H, 3.62%). 2,5-Dimethoxycarbonylfuran (III-2) (35%, mp 109 °C (lit,[8] 111—112 °C)), and 5,5′-dimethoxycarbonyl-2,2′-bifuryl (IV-2) (7%, mp 218 °C, IR 1728, 878 cm^{-1}, NMR δ 3.89 (s, 6, $-COOCH_3$), 6.87 (d, 2, H on C_3 and $C_{3'}$), 7.22 (d, 2, H on C_4 and $C_{4'}$). Found: C, 57.51; H, 3.96%. Calcd for $C_{12}H_{10}O_6$: C, 57.60; H, 4.03%).

c) The carbonylation of I-3 afforded 2,2′-dithienylketone (II-3) (40%, mp 84 °C (lit,[9] 87—88 °C)), 2-methoxycarbonylthiophene (III-3) (35%, bp 256 °C (lit,[10] 117 °C/30 mmHg)), and 2,2′-bithienyl (IV-3) (10%, mp 30 °C(lit,[11] 33 °C)).

d) The carbonylation of V-1 afforded II-2 (38%), III-2 (30%), and the ketoester polymer (VIII) 7%, IR 1735 (C=O, ester), 1630 (C=O, ketone), 880 (furan ring), mol wt 1212 (in benzene)).

e) The carbonylation of V-2 afforded 5,5′-dimethoxycarbonyl-2,2′-dithienylketone (VI) (36%, mp 210 °C, IR 1710, 1610, 700 cm^{-1}, NMR δ 3.91 (s, 6, $-COOCH_3$), 7.23 (d, 2, H on C_3 and $C_{3'}$), 7.44 (d, 2, H on C_4 and $C_{4'}$), Found: C, 50.25; H, 3.07%; Calcd for $C_{13}H_{10}O_5S_2$: C, 50.33; H, 3.25%), and 2,5-dimethoxycarbonylthiophene (VII), (40%, mp 145 °C (lit,[12] 148—149 °C)).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2253—2254 (1973)

Photochemical Reactions of Some Thiocarbonyl Trimers

Takehiko NISHIO, Michikazu YOSHIOKA, Hiromu AOYAMA, and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

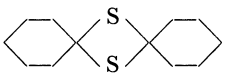
(Received May 24, 1972)

Although the photochemical reactions of diaryl thiocarbonyls have been extensively studied,[1] those of dialkyl or alkyl-aryl thiocarbonyls have not yet been given attention. Generally, monomeric dialkyl or alkyl-aryl thiocarbonyls are unstable and readily trimerize at room temperature. Previously, we reported the photochemical formation of a monomeric thiocarbonyl from the corresponding trimer.[2] In this paper we want to report that the irradiation of some thiocarbonyl trimers give a thiophene, a dithietane, and/or a disulfide.

When the thioacetophenone trimer (**1**) in cyclohexane was irradiated, the solutlon turned blue (λ_{max} 575 nm),[3] showing the formation of thioacetophenone (**7**). After irradiation for 2 hr, the product was treated with cyclopentadiene to give an 1:1-adduct (**8**) of **7** and cyclopentadiene. The NMR spectrum of **8** showed two singlets, at τ 8.49 and 8.39 and in a ratio of 1.9:1.1, assignable to methyl protons at C-3. The product, **8**, was therefore considered to be a mixture of *endo*- and *exo*-isomers. The prolonged irradiation (24 hr) of **1** gave 2,4-diphenylthiophene (**9**) (15%), 9,10-dimethylphenanthrene (**10**) (8%), and an unidentified product (**11**) (3.75%), which was then converted into **9** by distillation (175—178 °C/2 mmHg). The structure of **9** was established on the basis of the results of elemental analysis and the spectral data by comparison with an authentic sample.[4] The formation of **10** seems to proceed through the cyclization of dimethylstilbene,[5] which is photochemically derived from **7**, whlie thiobenzophenone gives tetraphenylethylene on irradiation.[1a]

The irradiation of the thiobenzaldehyde trimer (**2**) in dioxane gave *cis*-stilbene (**12**), *trans*-stilbene (**13**) (combined yield, 3.5%), and phenanthrene (**14**) (3.5%). Compounds **12** and **13** may be derived from a thiobenzaldehyde monomer like **1** and are presumed to be precursors of **14**.[5]

The irradiation of the cyclohexanethione trimer (**3**) in cyclohexane yielded 7,14-dithiadispiro[5.1.5.1]-tetradecane (**15**) (20%) and dicyclohexyl disulfide (**16**)



(**15**)

(10%). The formation of **15** is presumed to proceed through the dimerization of cyclohexanethione, formed from **3** by light, because on irradiation the solution of **3** immediately turns pink (λ_{max} 504 nm),[6] showing the formation of cyclohexanethione. On the other hand, Compound **16** probably arises from **15**, since Berchtold *et al.*[7] reported that the photolysis of 1,4-dithiaspiro[4.5]decane afforded **15** and was followed by the formation of **16**.

The irradiation of the thioacetone trimer (**4**) in cyclohexane yielded 2,2,4,4-tetramethyl-1,3-dithietane (**17**) (35%) and diisopropyl disulfide (**18**) (21%). These photoproducts undoubtedly arise from the thioacetone monomer, which may be formed by an initial C–S bond cleavage of **4**.

The irradiation of other thiocarbonyl trimers (**5**) and (**6**) gave the corresponding disulfides, (**19**) (15%) and (**20**) (20%) respectively. The disulfide **20** was confirmed by unequivocal synthesis from benzylacetone.

30 min. Then H_2S was passed through until precipitation formation came to the end. The precipitates were collected by filtration and were recrystallized from acetone to give 10 g of **6**; mp 130—131 °C. IR: ν_{max}^{KBr} cm^{-1}, 3020, 1600, 1490, 1365, 753, 730, 700. NMR: (τ in $CDCl_3$) 8.17 (s, 9H, 3×Me), 7.86—6.92 (A_2B_2 m, 12H, 6×CH_2), 3.10—2.63 (m, 15H, 3×Ph). Found: C, 73.25; H, 7.51%. Calcd for $C_{30}H_{36}S_3$: C, 73.14; H, 7.37%.

Irradiation of **1**. (a) When a solution of 1 g of **1** in 150 ml of cyclohexane was irradiated with a low-pressure mercury lamp in a quartz tube under nitrogen, the blue color of **7** gradually appeared with time. After irradiation for 2 hr, 1 g of cyclopentadiene was added to the reaction mixture and it was stirred until the blue color disappeared at room temperature. After the removal of the solvent, the residue was chromatographed on a silica-gel column. Elution with *n*-hexane–benzene(9: 1) gave 100 mg of 3-phenyl-3-methyl-2-thianorbornene (**8**); IR: ν_{max}^{film} cm^{-1}, 3050, 1598, 1575, 1490, 765, 748, 702. NMR: (τ in $CDCl_3$) 8.49 (s, 1.9H, *endo*-Me) and 8.39 (s, 1.1H, *exo*-Me), 8.11 (m, 2H, CH_2), 6.63 and 6.03 (m, 2H, 2×CH), 3.90 and 3.68 (m, 2H, vinyl), 3.05—2.2 (m, 5H, Ph). Found: C, 77.24; H, 6.60%. Calcd for $C_{13}H_{14}S$: C, 77.20; H, 6.98%.

(b) A solution of 1 g of **1** in 150 ml of cyclohexane was irradiated for 24 hr. After the removal of the solvent, the residue was chromatographed on a silica gel column with *n*-hexane–benzene (19: 1) to give 150 mg of **9**, 80 mg of **10**, and 37.5 mg of **11**.

(i) 2,4-Diphenylthiophene (**9**); mp 118.5—120.5 °C (lit,[13] 121.0—121.5 °C). UV: $\lambda_{max}^{cyclohexane}$ nm (ε), 223.5 (sh. 19900), 256 (54200), 301 (sh. 11400).

(ii) 9,10-Dimethylphenanthrene (**10**); mp 138—139 °C (lit,[14] 139 °C). NMR: (τ in $CDCl_3$) 8.30 (s, 6H, 2×Me), 2.58—2.30 (m, 4H, aromatic), 2.06—1.78 (m, 2H, aromatic), 1.48—1.20 (m, 2H, aromatic).

Irradiation of **2**. A solution of 1 g of **2** in 150 ml of dioxane was irradiated for 15 hr. After the removal of the solvent, the residue was chromatographed on a silica gel column with *n*-hexane–benzene (9: 1) to give 15 mg of **12**, 20 mg of **13**, and 35 mg of **14**. Each product was identified with the corresponding authentic sample by comparing the spectral data.

Irradiation of **3**. A solution of 1 g of **3** in 150 ml of cyclohexane was irradiated for 15 hr. After the removal of the solvent, the residue was chromatographed on a silica gel column with *n*-hexane–benzene (9: 1) to give 200 mg of **15**, 100 mg of **16**, and 150 mg of unchanged **3**.

(i) 7,14-Dithiadispiro[5.1.5.1]tetradecane (**15**); Recrystallizations from *n*-hexane afforded prisms; mp 131—132 °C (lit,[15] 132—133 °C). NMR: (τ in $CDCl_3$) 9.0—8.18 (m, 12H, 6×CH_2), 8.18—7.62 (m, 8H, 4×CH_2). Mass spectrum: *m/e*, 228 (M^+), 114 ($M-C_6H_{10}S$) and 81.

(ii) Dicyclohexyl disulfide (**16**); bp 125—128 °C/4—5 mmHg (lit,[7,17] 98 °C/2 mmHg, 100 °C/0.01 mmHg). NMR: (τ in $CDCl_3$) 9.40—7.40 (m, 20H, 10×CH_2), 7.30 (br s, 2H, 2×CH). Mass spectrum: *m/e*, 230 (M^+), 148 ($M-C_6H_{10}$), 115 ($M-C_6H_{11}S$) and 83.

Irradiation of **4**. A solution of 1 g of **4** in 150 ml of cyclohexane was irradiated for 20 hr. After the removal of the solvent, the residue was chromatographed on a silica gel column with *n*-hexane–benzene (9: 1) to give 350 mg of **17** and 210 mg of **18**.

(i) 2,2,4,4-Tetramethyl-1,3-dithietane (**17**). Recrystallization from *n*-hexane afforded needles; mp 77—78 °C (lit,[16] 77—77.5 °C). UV: $\lambda_{max}^{cyclohexane}$ nm (ε), 233.5 (180), 303.5 (20). Mass spectrum: *m/e*, 148 (M^+), 74 ($M-C_3H_6S$) and 59.

(ii) Diisopropyl disulfide (**18**); bp 72—75 °C/20 mmHg (lit,[17] 70 °C/20 mmHg). IR: ν_{max}^{film} cm^{-1}, 1380, 1368. NMR: (τ in $CDCl_3$) 8.70 (d, 12H, 4×Me), 7.01 (sep, 2H, 2×CH). Mass spectrum: *m/e*, 150 (M^+), 107 ($M-C_3H_7$), 75 ($M-C_3H_7S$) and 59.

Irradiation of **5**. A solution of 1 g of **5** in 150 ml of tetrahydrofuran was irradiated for 20 hr. After the removal of the solvent, the residual oil was chromatographed on a silica gel column with *n*-hexane–benzene (4: 1) to give 150 mg of diphenethyl disulfide (**19**); bp 159—161 °C/4—5 mmHg (lit,[18] 150—155 °C/1 mmHg. NMR: (τ in $CDCl_3$) 7.05 (s, 8H, 4×CH_2), 2.77 (s, 10H, 2×Ph). Mass spectrum: *m/e*, 274 (M^+), 169 ($M-C_6H_5CH_2CH_2$), 137 ($M-C_6H_5CH_2CH_2S$), 105 ($M-C_6H_5CH_2CH_2SS$) and 91.

Irradiation of **6**. A solution of 1 g of **6** in 150 ml of cyclohexane was irradiated for 15 hr. After the removal of the solvent, the residual oil was chromatographed on a silica gel column with *n*-hexane–benzene (4: 1) to give 200 mg of (1,1′-dimethyl-3,3′-diphenyl)dipropyl disulfide (**20**); bp 185—187 °C/4—5 mmHg. IR: ν_{max}^{film} cm^{-1}, 3030, 2924, 2855, 1605, 1490, 1370, 750, 700. NMR: (τ in $CDCl_3$) 8.67 (d, 6H, 2×Me), 8.42—7.75 (m, 4H, 2×CH_2), 7.27 (t, 4H, 2×CH_2), 7.20 (m, 2H, 2×CH), 2.77 (s, 10H, 2×Ph). Mass spectrum: *m/e*, 330 (M^+), 197 ($M-C_6H_5CH_2CH_2C(Me)H$), 166 ($M-C_6H_5CH_2CH_2C(=S)Me$), 165 ($M-C_6H_5CH_2CH_2CH(Me)S$), 132 ($M-C_6H_5CH_2CH_2CH(Me)SSH$). Found: C, 72.08; H, 7.99%. Calcd for $C_{20}H_{26}S_2$: C, 72.67; H, 7.90%.

Synthesis of **20** *from Benzylacetone*. To a solution of 1 g of $LiAlH_4$ in 30 ml of ether, a solution of 5 g of benzylacetone in 30 ml of ether was added. The solution was refluxed for 20 hr, poured into ice water, and then extracted with ether. The extract was dried over anhydrous Na_2SO_4 and evaporated to leave 4-phenylbutan-2-ol (5 g). The crude alcohol (5 g) was dissolved in 30 ml of DMF, and then thionyl chloride (5 g) was stirred in drop by drop. The whole was stirred for 12 hr, poured into ice water, and extracted with ether. The extract was washed with water, dried (Na_2SO_4), and evaporated. The solution of the crude product (5 g) in 10 ml of alcohol was stirred into a solution of Na_2S_2 (from Na_2S–$9H_2O$ (5 g), S (0.6 g), and H_2O (5 ml)). The whole was then heated to 60 °C, stirred at that temperature for 7 hr, and extracted with *n*-hexane. The extract was then dried and evaporated. When the residual oil was chromatographed on a silica gel column with *n*-hexane–benzene (4: 1), it gave an oil which was subsequently distilled (bp 185—187 °C/4—5 mmHg) and found to be identical with the photoproduct (IR and NMR spectra and tlc) (2.5 g).

Oxosulfonium Salts. II. Nitration of Dimethylphenyloxosulfonium Salt

Kenji KAMIYAMA, Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received February 24, 1973)

The effects of the positively charged substituents of arenes on the rates and isomer distributions in electrophilic aromatic substitution have been studied by various investigators. In connection with the question whether or not the $p\pi$—$d\pi$ resonance exists between aromatic rings of aryl onium salts and the positively charged hetero atoms, electrophilic aromatic substitution of anilinium salts[2] and onium salts of some hetero atoms involving d-orbitals (P, Se, As, and S)[3] have recently been reported. In the substitution reaction of the aryl onium salts of selenium and sulfur the ortho and para substituted products were found in considerable yields, and the existence of $p\pi$—$d\pi$ resonance was proposed in these cases.[4-6]

Oxosulfonio groups, $-\overset{\oplus}{\underset{\underset{O}{\|}}{S}}R_2$, are expected to be more strongly electron-withdrawing than sulfonio groups, $-\overset{\oplus}{S}R_2$. Studies on aromatic substitution of $Ar\overset{\oplus}{\underset{\underset{O}{\|}}{S}}R$ would yield useful information on the presence or absence of resonance between the aromatic ring and the tetrahedral sulfur atom of an oxosulfonio group. Although alkyloxosulfonium salts are fairly reactive with nucleophilic agents and act as methylating agents of thiolate or hydroxide ions, they are very stable toward oxidizing agents and electrophiles. Therefore, it is possible to investigate the electrophilic substitution on oxosulfonio-arenes. However, the electrophilic substitution of aryl oxosulfonium salts has not been reported in the literature, because the preparation of aryl oxosulfonium salts is rather difficult.

In order to determine the electronic effect of oxosulfonio groups on electrophilic aromatic substitution, the nitration of dimethylphenyloxosulfonium salt has been investigated.

Results and Discussion

Product Study. Dimethylphenyloxosulfonium perchlorate (I) remained unchanged when it was heated in concd nitric acid at 70 °C. When a solution of I in a mixture of concd sulfuric acid and fuming nitric acid (*d*, 1.52) (*v*/*v* 2/1) was heated at 80 °C for 3 hr, dimethylnitrophenyloxosulfonium perchlorate (II) was obtained in 80—87% yield. When II was refluxed in a solution of sodium iodide in acetone and the sulfoxide (III) obtained was oxidized to the corresponding sulfone, only the *m*-nitro isomer was found. No *ortho* and *para* isomer were detected with a flame-ionization gas chromatography.

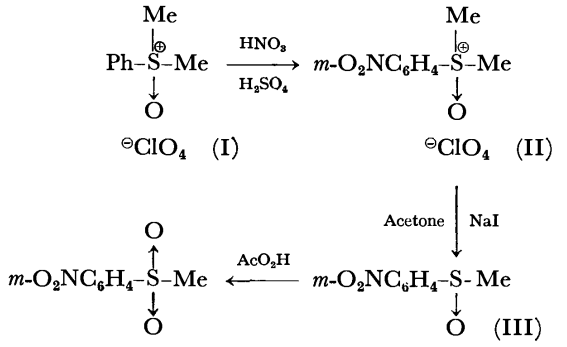

TABLE 1. ISOMER DISTRIBUTION IN THE NITRATION OF SOME AROMATICS POSSESSING POSITIVE POLES

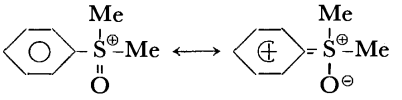
Aromatics	Nitro-aromatics			Reference
	ortho%	*meta*%	*para*%	
$Ph\overset{\oplus}{N}Me_3$	0	89	11	7)
$Ph\overset{\oplus}{P}Me_3$	0	97	3	7)
$Ph\overset{\oplus}{As}Me_3$	0	96	4	7)
$Ph\overset{\oplus}{Se}Me_2$	2.6	91.3	6.1	4)
$Ph\overset{\oplus}{S}Me_2$	3.6	90.4	6.0	4)
	2.18	93.87	3.95	6)
$PhMe_2\overset{\oplus}{S}=O$	0	100	0	This work

The results are shown in Table 1 together with the data on nitration of other onium salts. The nitration of dimethylphenylsulfonium ion gave the *o*- and *p*-nitro derivatives in 5—10% yields, whereas that of dimethylphenyloxosulfonium ion gave no *o*- and *p*- derivatives.

The stretching frequencies of S–O of *p*-substituted phenyldimethyloxosulfonium ions were found to be proportional to the Hammett σ^+ values;[8] this finding suggests a 2p—3p resonance between the benzene ring and the S=O bond.



The fact that only *m*-nitro product was formed in nitration of I is ascribable to the inductive effect of the dimethyloxosulfonio group but also the resonance des-

cribed above. In order to ascertain this, the kinetics of nitration was also investigated.

Kinetic Study. Nitration of I in a mixture of 98% H_2SO_4 and fuming HNO_3 (*d*, 1.52) (*v/v*, 2/1; $[HNO_3]=8.23$ M) was followed by the increase of the UV absorption at 250 nm ascribable to II. (λ_{max} of II, 250 nm, $\varepsilon_{II}=7.063$; ε_I at 250 nm is 328). The reaction was first order in I, and good linear relationship was observed. The rate constants obtained are shown in Table 2.

Table 2. The rate constants of nitration of I in concd H_2SO_4

Temperature (°C)	$10^5 \times k$ (M^{-1} sec^{-1})
40.0	0.917±0.04
50.0	2.11 ±0.06
60.0	4.30 ±0.06

Table 3 compares the rate parameters of nitration of I and dimethylphenylsulfonium ion in concentrated sulfuric acid. The rate of nitration of I is very much smaller than that of the sulfonium ion (by a factor of 500), and this smaller rate is ascribable to the greater activation energy. These data show that the benzene ring of I is considerably deactivated because of the 2p—3p resonance between the ring and the $-\overset{\oplus}{S}(=O)Me_2$.

Very small rates of nitration of I suggest that the σ-value of an oxosulfonio group is very large. When the σ_m-value of $-\overset{\oplus}{S}(=O)Me_2$ was calculated from the rates of nitration at *meta* and *para* positions of $PhN\overset{\oplus}{M}e_3$, $Ph\overset{\oplus}{S}Me_2$, and $PhMe_2\overset{\oplus}{S}=O$, 1.38±0.04 was obtained. This σ-value is the greatest among the σ values known except the values for diazonium ion $-\overset{\oplus}{N}_2$ (σ_m 1.76; σ_p 1.91),[9] and much greater than σ_m of $-\overset{\oplus}{N}Me_3$ (1.01) and $-\overset{\oplus}{S}Me_2$ (1.00). The diazonium group is unstable and reactive whereas the oxosulfonio group is stable and much less reactive. Therefore, the oxosulfonio groups are expected to be very useful for the studies on the effects of substituents on various organic reactions or the properties of various organic compounds.

Experimental

Preparation of Dimethylphenyloxosulfonium Perchlorate (I). After a mixture of mercury(II) iodide (20 g, 44 mmol) and methyl iodide (30 ml) was deaerated in a 100 ml flask by bubbling nitrogen, it was stirred with a magnetic stirrer for 30 min under nitrogen. Then methyl phenyl sulfoxide (20 g, 142 mmol) was added, and the mixture was refluxed for 65 hr. When the excess methyl iodide was removed by distillation and the unchanged sulfoxide was removed by extraction with ether, reddish brown residue was obtained, which crystallized when extraction with ether was repeated few more times. Recrystallization from methanol gave light yellow leaflets of dimethylphenyloxosulfonium mercuritriiodide; yield, 14.0 g; mp 138—139 °C (decomp.); IR, 1230, 750 cm^{-1}; NMR (acetone-d_6), δ, 4.43 (s, 6H), 8.27 (m, 5H).

The mercuritriiodide salt (22.2 g) was dissolved in acetone (200 ml), and an acetone solution of silver perchlorate was added until no more precipitates (AgI, HgI_2) were formed. After the precipitates were filtered off, the acetone was removed under reduced pressure. When the residue was recrystallized from methanol several times, I was obtained as white needles; yield, 5.5 g (73%); mp 158—159 °C; IR, 1230 (ν_{S-O}), 1100, 750 cm^{-1}. Found: C, 37.67; H, 4.31%. Calcd for $C_8H_{11}O_5SCl$: C, 37.71; H, 4.35%.

Table 3. Activation parameters for nitration of sulfonium and oxosulfonium salts in concd H_2SO_4

	E_a (kcal/mol)	ΔS (e.u.)	$10^5 k_{25°C}$ ($M^{-1}sec^{-1}$)	$10^6 k_{0.5°C}$ ($M^{-1}sec^{-1}$)
$Ph-\overset{\oplus}{S}Me_2$	12.9	−28.0	133[a]	150[b]
$Ph-\overset{\oplus}{S}Me_2$ (=O)	16.0	−32.4	0.245	0.218[c]

a) Ref. 6.
b) Determined in the mixed acid used for nitration of $PhMe_2\overset{\oplus}{S}=O$
c) Calculated by use of E_a.

Measurements of the Rates of Nitration of I. A mixture of 98% sulfuric acid and fuming nitric acid (*d*, 1.52) (v/v= 2/1) was used. The concentration of HNO_3 was 8.23 M. A solution of I (about 1 mmol) in the mixed acid (10 ml) was placed in a constant temperature bath, and the samples withdrawn after suitable intervals were diluted with water (1000 times by volume), and the UV absorptions were determined against the reference (the mixed acid diluted by the same factor).

Identification of the Product of Nitration of I. After a mixture of I (318.4 mg), 98% sulfuric acid (2 ml) and fuming nitric acid (1 ml) was heated at 80.0 °C for 3 hr, it was diluted with ice water (20 ml), and the crystals formed were filtered. When the filtrate was made weakly alkaline and an aqueous $NaBPh_4$ solution was added, $O_2NC_6H_4\overset{\oplus}{S}(=O)Me_2$ $Ph_4\overset{\ominus}{B}$ precipitated. The total amount of II isolated (the crystals plus the tetraphenylborate salt obtained from the filtrate) amounted to 87%. Dimethylnitrophenyloxosulfonium perchlorate. Found: C, 32.13; H, 3.40; N, 4.85%. Calcd for $C_8H_{10}O_7ClNS$: C, 32.03; H, 3.36; N, 4.68%.

After the nitrated salt was refluxed in an acetone solution (40 ml) of sodium iodide (0.435 g) for 2 hr, the acetone was removed under reduced pressure, and the residue obtained was heated with 30% hydrogen peroxide (2.0 g) and acetic acid (5 ml) at 70—90 °C for 2 hr. Then the solution was diluted with water, and extracted with dichloromethane. The extracts combined were concentrated, and the residue was subjected to gas-chromatographic analysis (a Hitachi K-51 Gas Chromatograph; column, Silicone XF 1105 on Chromosorb W, 2 m).

Determination of Rates of Nitration of Dimethylphenylsulfonium Perchlorate. In 10.0 ml of the mixed acid used for the nitration of I, about 1 mmol of dimethylphenylsulfonium perchlorate was dissolved, and the mixture was let to react in a constant temperature bath. After suitable intervals, samples were withdrawn and diluted with water (1000 times by volume). The rate constant was calculated from the increase of the UV absorptions at 256 nm (ε of dimethylphenylsulfonium salt is 555, whereas that of the nitrated salt is 7256).[5]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2257—2258 (1973)

$N^2 \rightarrow N^1$ Migration of *s*-Triazinyl Group in the Reaction of N^1-Acetyl-N^2-(*s*-triazinyl)alkylenediamines

Seiichi UNO, Kenji NAKAMURA, Yukio INOUE, Shizen SEKIGUCHI, and Kohji MATSUI

Department of Synthetic Chemistry, Gunma University, Tenjincho, Kiryu, Gunma

(Received August 2, 1972)

A report was given by West and Stewart[1] on the anionic migration of an aryl group in arylhydrazines. We studied the $N^1 \rightarrow N^2$ rearrangement of an s-triazinyl group in N^1,N^1-bis(*s*-triazinyl)-*o*-phenylenediamines.[2] The reactions of N^1-acetyl-N^2-(4,6-dichloro-*s*-triazin-2-yl)alkylenediamines with cyanuric chloride (CC) were carried out in order to obtain information on the migration of an s-triazinyl group in N^2,N^2-bis(*s*-triazinyl)alkylenediamines.

Reaction of N^1-*Acetyl*-N^2-*(4,6-dichloro*-s-*triazin-2-yl)-ethylenediamine with Cyanuric Chloride.* Two moles of cyanuric chloride at −20 °C under alkaline conditions to give N^1-acetyl-N^2-(4,6-dichloro-*s*-triazin-2-yl) ethylenediamine (II). One mole of I was subjected to reaction with two moles of cyanuric chloride at 0—5 °C under alkaline conditions to give N^1-acetyl-N^1,N^2-bis(4,6-dichloro-*s*-triazin-2-yl)ethylenediamine (III). Two singlets appeared at δ 7.91 and 9.00, assignable to N^1-H and N^2-H, respectively, in the NMR spectrum of II, and a singlet at δ 9.00 (assignable to N^2-H in that of III, their structures being shown to be as follows.

$$CH_3CON^1HCH_2CH_2N^2H_2\ (I) \xrightarrow{CC} CH_3CON^1HCH_2CH_2N^2H\text{–}X\ (II) \xrightarrow{CC} CH_3CON^1CHCH_2N^2H\text{–}X\ (III)$$

(X = Cl)

X, A=Cl
Y, A=$N(CH_3)_2$
Z, A=OCH_3

For the sake of confirmation, II and III were treated with excess dimethylamine to give N^1-acetyl-N^2-[4,6-bis(dimethylamino)-*s*-triazin-2-yl]- (IV) and N^1-acetyl-N^1,N^2-bis[4,6-bis(dimethylamino)-*s*-striazin-2-yl] ethylenediamines (V), since II and III are slightly unstable. In the NMR spectrum of IV the two singlets at δ 7.83 and 6.53 are assignable to N^1–H and N^2–H, respectively, and in that of V the singlet at δ 6.53 to N^2–H.

$$II \xrightarrow{NH(CH_3)_2} CH_2CON^1HCH_2CH_2N^2H\text{–}Y\ (IV)$$

$$III \xrightarrow{NH(CH_3)_2} CH_3CON^1CH_2CH_2N^2H\text{–}Y\ (V)$$

(Y)

II and III were treated with excess sodium methoxide to give N^1-acetyl-N^2-(4,6-dimethoxy-*s*-triazin-2-yl)-ethylenediamine (VI) and N^1,N^2-bis(4,6-dimethoxy-*s*-triazin-2-yl)ethylenediamine (VII) under cleavage of an acety lgroup. In the NMR spectrum of VI two singlets appeared at δ 7.83 and 7.92, assignable to N^1–H and N^2–H, respectively, and in that of VII a singlet at δ 7.88 only, assignable to N^1–H (or N^2–H).

$$II \xrightarrow{NaOCH_3} CH_3CON^1HCH_2CH_2N^2H\text{–}Z\ (VI)$$

$$III \xrightarrow{NaOCH_3} Z\text{–}N^1HCH_2CH_2N^2H\text{–}Z\ (VII)$$

The following reactions were carried out to clarify whether cyanuric chloride reacts directly with the N^1–H group to produce III, or with the N^2-H group to produce III *via* the transition state or the intermediate (VIII). It is not clear whether VIII is the transition state or the intermediate. Neither *N*-methyl acetamide nor N^1,N^2-diacetylethylenediamine (XIX) reacted with cyanuric chloride under alkaline conditions, but ethylamine did so under the same conditions to give *N*-(4,6-dichloro-*s*-triazin-2-yl)(IX)[3] and *N,N*-bis(4,6-dichloro-*s*-triazin-2-yl)-ethylamines (X).[4] These results confirm the $N^2 \rightarrow N^1$ migration of a dichlorotriazinyl group.

VIII

$$CH_3CONHCH_3 \xrightarrow{CC} \text{no reaction}$$

$$C_2H_5NH_2 \xrightarrow{CC} CH_3NH\text{–}X\ (IX) \xrightarrow{CC} CH_3N(X)_2\ (X)$$

Cyanuric chloride did not react with *N*-(4,6-dimethoxy-*s*-triazin-2-yl)ethylamine[5] or VI under alkaline conditions. This indicates that cyanuric chloride does not react directly with the N^1-H group and supports the view that the $N^2 \rightarrow N^1$ migration of a dichlorotriazinyl group occurs in the reaction of II with cyanuric chloride.

$$C_2H_5NH\text{–}Z \xrightarrow{CC} \text{no reaction}$$

$$CH_3CON^1HCH_2CH_2N^2H\text{–}Z\ (VI) \xrightarrow{CC} \text{no reaction}$$

The NMR measurement on the reaction of II with triethylamine was carried out in order to determine with which nitrogen atom cyanuric chloride reacts at first. When triethylamine (0.00020 mol) was added to II (0.00010 mol) in DMSO-d_6–$CDCl_3$ (1 : 3 vol) at 0 °C, the peak (N^2-H) at δ 9.16 immediately decreased, but the peak (N^1–H) at δ 8.33 did not change. The area ratio of the peaks at δ 8.33 and 9.16 was

1) R. West and H. F. Stewart, *J. Amer. Chem. Soc.*, **92**, 853 (1970).

2) K. Nakamura, N. Nohara, and K. Matsui, This Bulletin, **45**, 3140 (1972).

3) O. Diels, *Ber.*, **32**, 691 (1899).

4) N. Nohara, S. Sekiguchi, and K. Matsui, *J. Heterocyclic Chem.*, **7**, 519 (1970).

5) K. Stammbach, H. Kilchler, K. Freiedrich, M. Larser, and G. Szekely, *Weed. Red.*, **4(1)**, 64 (1964).

about 2. The ratio remained constant for 25 min after addition of triethylamine, the peak area at δ 8.33 being unchanged. This supports the veiw that cyanuric chloride reacts at first with N^2 atom under alkaline conditions.

Reaction of N^1-*Acetyl*-N^2-*(4,6-dichloro-s-triazin-2-yl)-tri- (XI) or -hexamethylenediamine (XII) with Cyanuric Chloride.* Under alkaline conditions cyanuric chloride reacted with XI and XII to give N^1-acetyl-N^2,N^2-bis(4,6-dichloro-*s*-triazin-2-yl)tri- (XIII) and -hexamethylenediamines (XIV),[6] respectively. A singlet appeared at δ 7.75 only, assignable to N^1–H, in both NMR spectra of the dimethylamino derivatives of XIII and XIV. This indicates that two dichlorotriazinyl groups are attached to N^2 atom in XIII and XIV, no rearrangement of an *s*-triazinyl group taking place. It is therefore concluded that the number of methylene groups in alkylenediamines plays an important role in the $N^2 \rightarrow N^1$ migration of an *s*-triazinyl group in the title reaction.

a) These values agreed with the calculated ones within the usual limit of variation of elemental analysis.
b) Mass spectrometry, *m/e* 446 (medium, attributable to the parent peak; Hitachi RMS-4 mass spectrometre).

N^1-*Acetyl*-N^2-*(4,6-dichloro-s-triazin-2-yl)ethylenediamine (II).* A solution of 6.7 g (0.036 mol) of cyanuric chloride in 70 ml of acetone was added dropwise at −20°C to a stirred solution of 7.5 g (0.073 mol) of I in 100 ml of acetone. After stirring for 2.5 hr, the mixture was poured into 200 ml of ice–water. The precipitate was filtered and dried.

N^1-*Acetyl*-N^1,N^2-*bis(4,6-dichloro-s-triazin-2-yl)ethylenediamine (III).* A solution of 15 g (0.015 mol) of I in 30 ml of acetone was added dropwise at 0—5°C to a stirred solution of 5.4 g (0.029 mol) of cyanuric chloride and then 7.8 ml of a 20% sodium carbonate solution dropwise. After being stirred for 2 hr, the mixture was processed according to the procedure for II.

N^1-*Acetyl*-N^2-*[4,6-bis(dimethylamino)-s-triazin-2-yl]-(IV) and* N^1-*Acetyl*-N^1,N^2-*bis[4,6-bis(dimethylamino)-s-triazin-2-yl]-ethylenediamine (V).* These compounds were prepared from 1.0 g (0.0040 mol) of II and 2.4 g (0.0060 mol) of III, respectively, by the method described previously.[8]

N^1-*Acetyl*-N^2-*(4,6-dimethoxy-s-triazin-2-yl)ethylenediamine (VI).* To a stirred solution of 3.5 g (0.02 mol) of 4,6-dimethoxy-2-chloro-*s*-triazine (CDMT)[9] in 50 ml of acetone was added dropwise at 0—5 °C a solution of 2.1 g (0.020 mol) of I in 20 ml of acetone and then 5.3 ml of a 20% sodium carbonate solution dropwise. After being stirred for 6.5 hr at the same temperature, the mixture was stirred at *ca.* 20°C for 6 hr. The mixture was then concentrated under reduced pressure and cooled. The precipitate was filtered and dried.

N^1,N^2-*Bis(4,6-dimethoxy-s-triazin-2-yl)ethylenediamine (VII).* A solution of 3 g (0.050 mol) of ethylenediamine in 30 ml of acetone was added dropwise at *ca.* 20°C to a stirred solution of 17.6 g (0.10 mol) of CDMT in 100 ml of acetone. After being stirred for 30 min, 26.5 ml of a 20% sodium carbonate solution was added dropwise to the mixture. After being stirred for 4 hr at 30°C, the mixture was poured into 300 ml of ice–water, filtered and dried. Recrystallization from dioxane yielded 17.0 g (quantitative), mp 237.0—237.5°C. Found: C, 42.64; H, 5.64; N, 32.93%. Calcd for $C_{12}H_{18}N_8O_4$: C, 42.60; H, 5.36; N, 33.11%.

N^1-*Acetyl*-N^2-*(4,6-dichloro-s-triazin-2-yl)tri- (XI) and -hexamethylenediamines (XII).* These compounds were prepared from 2.3 g (0.020 mol) of XVII and 4.7 g (0.030 mol) of XVIII in the same manner as for III.

N^1-*Acetyl*-N^2,N^2-*bis[4,6-bis(dimethylamino)-s-triazin-2-yl]-tri- (XV) and -hexamethylenediamines (XVI).* A solution of 4.5 g (0.017 mol) of XI in 80 ml of acetone was added dropwise at 0°C to a stirred solution of 4.8 g (0.026 mol) of cyanuric chloride in 120 ml of dioxane–acetone (1 : 1 vol). After 1.46 g (0.026 mol) of potassium hydroxide in 4 ml of water had been added in small portions, the mixture was stirred for 5 hr at 0—5 °C. The mixture was processed according to the procedure described previously.[8]

Yields and melting points are summarized in Table 1. The results in elemental analysis are within the experimental error. NMR spectral data are in DMSO-d_6

6) Since XIII and XIV were too unstable to be isolated, they were prompty transformed into dimethylamino derivatives.

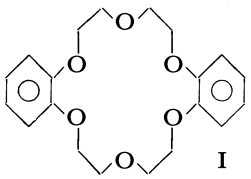
Effect of Crown Ether in the Reduction of Ketones with Sodium Borohydride in Aromatic Solvent

Tsutomu MATSUDA and Kenichi KOIDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received November 28, 1972)

Cyclic polyethers, firstly synthesized by Pedersen[1a] and known as crown ethers, have been attracted much attention because of their unusual capability to form stable complexes with a variety of metallic or non-metallic cations.[1] Asides of their utility in physico-chemical phenomena[1b] they are also interesting in the application of the function to organic synthesis. Pedersen[1a] reported a successful saponification of the sterically hindered esters of 2,4,6-trimethylbenzoic acid with potassium hydroxide in aromatic hydrocarbon in the presence of dicyclohexyl-18-crown-6. Subsequent papers[2] have revealed dominating feature of the cyclic polyethers in enhancement of anion reactivity by com-



I

plex formation with a counter cation in low dielectric solvents. In this paper, we report an effectiveness of dibenzo-18-crown-6 (I) in sodium borohydride reduction of some ketones in aromatic hydrocarbon.

Results and Discussion

Effect of the Addition of Various Ethers. A ketone (0.12 mol) was allowed to react with sodium borohydride (0.03 mol) in 100 ml toluene for 5 hr under reflux in the presence of three ethereal additives (0.03 mol). The results for four ketones were illustrated in Table 1. Table 2 shows the influence of relative amount of I to sodium borohydride in the reduction of cyclohexanone. The presence of 5 mol% of I to the reducing agent was found to be almost as effective as equimolar combination of I. Because of the low solubility of sodium borohydride under the conditions, the ratio of I to sodium borohydride above 5 mol% does not have a practical importance. Use of potassium borohydride required a prolonged reaction period. Sullivan and Hinckley[3] reported that in the reduction of acetophenone tricaprylmethylammonium borohydride afforded a 20% yield of the corresponding alcohol at 25 °C (4 hr) and a 8% at 65 °C (2 hr) in benzene solvent. Present reduction which was carried out at higher temperature and with longer reaction time gave much improved yields, but was inevitably accompanied by the formation of by-product. The by-product in the reduction of cyclohexanone was found to be mostly consisted of 2-(cyclohexen-1-yl)-cyclohexanol (III, a mixture of *cis* and *trans* isomers) and the corresponding ketone (II). Table 3 suggests the occurrence of base-catalyzed condensation of the ketone. 3,3,5-Trimethyl-

	1	9	T	78	6	16	29
	1	3.5	X	41	20	39	34
	1	5	X	4	31	65	32

a) Weight percent for distillate. b) T=toluene, X=*o*-xylene. c) For 2-norbornanone.
d) The reaction was carried out at 100 °C, and the others were under reflux.

cyclohexanone was more resistant to the reduction than less hind ered substituted cyclohexanones; 4-methyl- and 4-*t*-butylcyclohexanone (Table 4). The reduction of 2-norbornanone required a higher reaction temperature to achieve a good conversion and camphor did not react to a measureable extent.

Effect of I on the Stereochemical Course. It is known that the stereochemical course of sodium borohydride reduction is subjected to various factors, such as steric[4] or polar effect[5] in substituted ketones, as well as the nature of solvent.[6] The isomer distributions of the product alcohols obtained in the reduction of substituted cyclohexanones and 2-norbornanone were tabulated in Table 4. Reduction of 4-methyl- and 4-*t*-butylcyclohexanone yielded alcohols in 74 and 77% abundance of *trans* isomer, respectively, which are in good accordance with the reported *trans* contents of 76 and 78% for the reductions in 2-propanol.[5]

In the borohydride reduction of 3,3,5-trimethylcyclohexanone the *cis* alcohol was always an unfavorable isomer in the product and its abundance varies from 27 to 45% depending on the solvent utilized.[6] On the other hand, the *cis* isomer was found to become the predominant product in the present reduction. The present results can be explained in terms of a smaller effective size of reducing agent in nonpolar solvent; toluene. The increased yield (29—34%) of *exo* alcohol from 2-norbornanone as compared to the result in 2-propanol (14%)[4b] can again be accommodated with the idea.

The observed order of facility of reduction in toluene, cyclohexanone $\approx$ 4-substituted cyclohexanones $>$ 3,3,5-trimethylcyclohexanone ($\approx$methyl isopropyl ketone) $>$ 2-norbornanone $\gg$ camphor, also suggests that an unsolvated borohydride anion in toluene still suffers the similar kind of steric hindrance as observed in conventional solvent,[4b] possibly because of close proximity of sodium ion complexed with the cyclic polyether to borohydride anion.

Experimental

Materials. Dibenzo-18-crown-6-(2,3,11,12-dibenzo-1,4,7,10,13,16-hexaoxacyclooctadeca-2,11-diene) was prepared by the procedure described by Pedersen,[1a] mp 163.2—164.5 °C (lit,[1a] 164 °C). 2-Norbornanone[7] and methylisopropyl ketone[8] were obtained by the standard methods. Other liquid ketones used were commercial products and distilled prior to use. Sodium borohydride and camphor were used without purification.

Procedures. A typical procedure is as follows. A mixture of I (10.8 g, 0.03 mol), finely pulverized sodium borohydride (1.13 g, 0.03 mol) and dry toluene (100 ml) was refluxed for 0.5 hr under stirring. Cyclohexanone (11.8 g, 0.12 mol) in toluene (20 ml) was added in a period of 10 min and the mixture was refluxed for 5 hr under stirring. The reaction mixture was cooled and hydrolyzed by addition of dil. hydrochloric acid and let stand at 0 °C. Crystalline I precipitated was removed by filtration and the water layer was extracted three times with ether. The combined organic layer was neutralized, dried and concentrated. Distillation of the concentrate yielded cyclohexanol (6.7 g, 50% bp 89—92 °C/80 mmHg) and a residue (4.4 g). A distillate from the residue (3.9 g, bp 80—100 °C/2 mmHg) was found to be composed mainly of *cis*- and *trans*-2-(cyclohexen-1-yl)-cyclohexanol and small amounts of the corresponding ketone and an unidentified compound by gas chromatography (compared with authentic specimen[9]). Extent of the reduction and isomer ratios of the products were determined by gas chromatography on Ucon Oil HB5100 10%-Celite column or 1,2,3-tris(2-cyanoethoxy)propane 10%-Shimalite column (for isomers of 4-methyl- and 4-*t*-butylcyclohexanol).

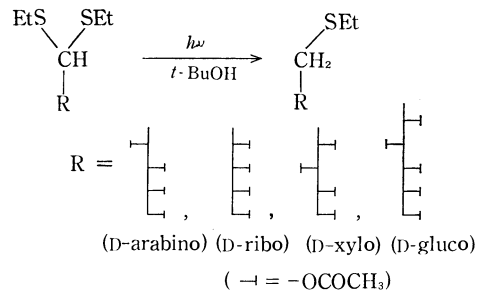
Synthetic Studies of Carbohydrate Derivatives with Photochemical Reaction. VIII.[1] Photochemical Desulfurization of Some Sugar Diethyl Dithioacetal Acetates into the Corresponding 1-*S*-Ethyl-1-thioalditol Acetates

Kazuo MATSUURA, Younosuke ARAKI, and Yoshiharu ISHIDO

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 13, 1973)

In the series of this investigation, a facile photochemical addition of thiols to enoses has briefly been reported from our laboratory.[1,2] As a part of this investigation, the present authors wish to report successively a photochemical desulfurization of some sugar diethyl dithioacetal acetates into the corresponding 1-*S*-ethyl-1-thioalditol acetates since such a conversion has been known solely with respect to D-galactose diethyl dithioacetal which affords 1-*S*-ethyl-1-thiogalactitol.[3] The photochemical desulfurization of diethyl dithioacetal acetates of D-arabinose, D-ribose, D-xylose, and D-glucose are described herewith.



The corresponding 1-*S*-ethyl-1-thioalditol acetates were easily obtained in excellent yields by a chromatography on a column of silica gel (eluting solvent: 1%-acetone–benzene) of each sirup resultant from the concentration of the solution which was obtained by a previous irradiation of a *t*-butyl alcohol solution of the sugar diethyl dithioacetal acetates with a low pressure mercury lamp at room temperature under nitrogen atmosphere for 20 hr; the yields of 1-*S*-ethyl-1-thio-D-arabinitol, -D-ribitol, -D-xylitol, and -D-glucitol acetates were 79.3%, 85.3%, 86.9%, and 84.1%, respectively. The NMR data showed good agreement with their expected structures. According to the result of Horton and Jewell,[3] incidentally, 1-*S*-ethyl-1-thio-D-galactitol was obtained in a 55% yield by irradiation of methanolic solution of D-galactose diethyl dithioacetal with a low pressure mercury lamp (450 W) for 36 hr. The results described here were thus considerably superior to this result with respect to the yields of the photochemical reaction. The superiority may depend on the use of mercaptal acetates and *t*-butyl alcohol as the reaction solvent in place of methanol.

t-Butyl alcohol may probably facilitate the reaction in comparison with the reaction in methanol; 1-deoxy-D-galactitol (L-fucitol) is already produced in the latter case as a result of concomitant process of further elimination of the ethylthiyl radical, and, in addition, the diethyl dithioacetal is yet remained in the reaction mixture.[3]

Two procedures have generally been known for the preparation of 1-*S*-alkyl-1-thioalditols; 1) Partial reduction of sugar mercaptals by the use of an aged Raney nickel as the catalyst.[4] 2) Reduction of 1-halogeno-1-alkylthioalditol derivatives, which was obtained from sugar mercaptals by halogenation, with lithium aluminum hydride.[5] The yield of the product in problem were, however, not so good in these procedures. Consequently, the procedure described in this article can be concluded to be practically feasible for the general synthetic method of 1-*S*-alkyl-1-thioalditols.

Experimental

Melting points are uncorrected. The irradiations were carried out by the use of a low pressure mercury lamp (6 W) of Ushio Electric Co. Inc. at room temperature under nitrogen atmosphere. NMR spectra were taken with a JEOL JNM-H-100 at 100 MHz in deuterochloroform by the use of tetramethylsilane as the internal standard. The acetates of diethyl dithioacetals of D-arabinose, D-ribose, D-xylose, and D-glucose were prepared according to the usual method.[6]

2,3,4,5-Tetra-O-acetyl-1-S-ethyl-1-thio-D-arabinitol: A solution of 2,3,4,5-tetra-*O*-acetyl-D-arabinose diethyl dithioacetal (1.00 g) in *t*-butyl alcohol (170 ml) was irradiated with the UV lamp under nitrogen atmosphere at room temperature for 20 hr. Resultant solution was evaporated *in vacuo* to afford brown sirup, which was subsequently chromatographed on a silica gel column (3×20 cm) by eluting with benzene containing 1% volume of acetone. The starting material (4 mg, 0.4%) was eluted out as the first portion, and 2,3,4,5-tetra-*O*-acetyl-1-*S*-ethyl-1-thio-D-arabinitol was as the second portion. The eluate was concentrated *in vacuo* to a sirup which was soon crystallized on standing at room temperature and is already pure enough for the elemental analysis. Yield

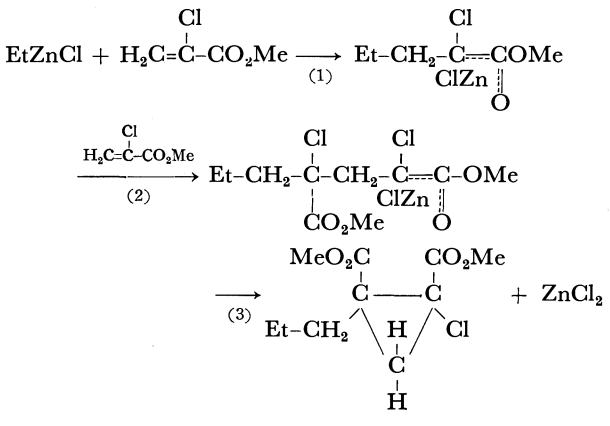
Three-Membered Ring-formation Reactions. V. The Cyclopropane Derivative Obtained from the α-Halogenoacrylic Ester by Means of Zinc Alkyl-Active Methylene Chelate Compounds

Yusuke KAWAKAMI and Teiji TSURUTA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

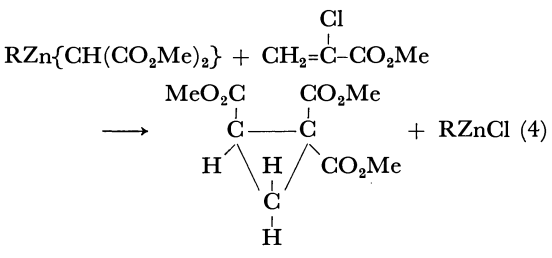
(Received September 16, 1972)

It was previously reported that two molecules of methyl α-chloroacrylate undergo a ring-formation reaction with ethylzinc chloride to produce dimethyl 1-chloro-2-propyl-*cis*-1,2-cyclopropanedicarboxylate (I).[1-3] The reaction was considered to proceed according to a step-by-step mechanism:



(I)

Diethylzinc, instead of ethylzinc chloride, was also effective in the ring-formation reaction.[4] It was further confirmed that the zinc alkyl–active methylene chelate compound[5] behaved in a different fashion from ethylzinc chloride or diethylzinc,[3] as is exemplified by Reaction (4):



(II)

Only one molecule of methyl α-chloroacrylate participates in Reaction (4). Since it was considered that the second active hydrogen atom in the intermediate (A1) may play an essential role as is shown below (Reaction (5)) in the ring-formation reaction (4), we

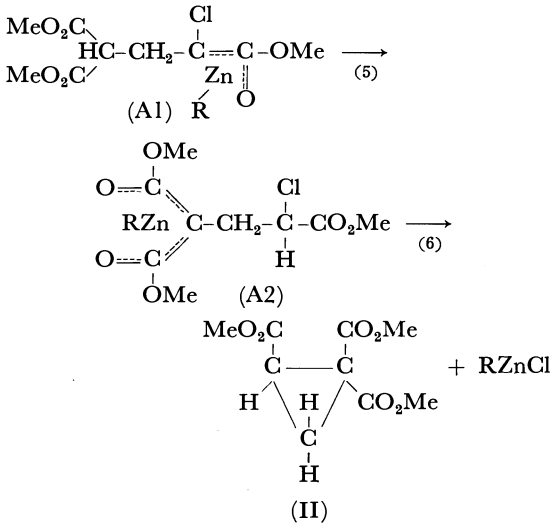
a) Reaction for 2 hr in benzene at 70 °C.
b) MCA, MBA, and MA are methyl α-chloroacrylate, methyl α-bromoacrylate, and methyl acrylate, respectively.
c) The yield was calculated based on 1/2 [MCA].



have undertaken a study of the reactions of methyl α-chloroacrylate with metal alkyl–active methylene chelate compounds, which have substituents on the α-carbon of the active methylene component.

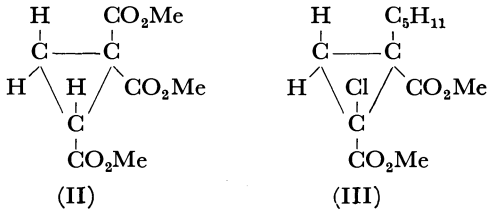
Experimental

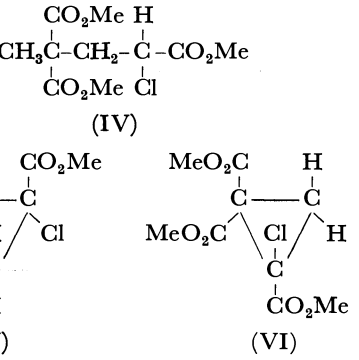
The NMR spectra were recorded at 100 MHz in benzene, TMS being used as the internal standard.

The metal alkyl-active methylene chelate compounds were prepared by a method reported before.[5)] Methyl α-chloroacrylate and methyl α-bromoacrylate were prepared according to the literature.[6)]

To a benzene solution of methyl α-chloroacrylate, equimoles of metal alkyl–active methylene chelate compounds were added at 70 °C. After a given time interval, the reaction was stopped by pouring the reaction system into water containing a small amount of hydrochloric acid. The organic layer was then separated and distilled. The results obtained are shown in Table 1.

The structures of the products in Table 1 were established to be as follows:





Compounds II (n_D^{20} 1.4518, d_4^{20} 1.17, bp 108 °C/1 mmHg) and III (n_D^{20} 1.4618, d_4^{20} 1.08, bp 90 °C/2 mmHg) were identified by comparing their NMR spectra with those reported previously.[1,4)] Compounds IV and V were obtained in 22.5 and 21.5% yields respectively from *n*-butyl(dimethylmethylmalonato)zinc and methyl α-chloroacrylate. Moreover, Compound VI was obtained in a 15% yield from *n*-butyl(dimethyl bromomalonato)zinc and methyl α-chloroacrylate.

IV: n_D^{20} 1.4577, d_4^{20} 1.22, bp 115.5 °C/1 mmHg; NMR: δ 4.50 (1H, t, >CH), δ 3.38, 3.37, 3.32 (9H, s, $-CO_2CH_3$), δ 2.76, 2.47 (2H, q, $-CH_2-$), δ 1.29 (3H, s, CH_3-).

Found: C, 45.36; H, 5.97; Cl, 13.14%. Calcd for $C_{10}H_{15}ClO_6$: C, 45.02; H, 5.67; Cl, 13.30%.

V: n_D^{20} 1.4838, d_4^{20} 1.26, bp 165 °C/1 mmHg.

Found: C, 48.25; H, 5.76; Cl, 9.74%. Calcd for $C_{14}H_{19}ClO_8$: C, 47.92; H, 5.46; Cl, 10.11%.

VI: n_D^{20} 1.4638, bp 116 °C/1 mmHg; NMR: δ 3.28, 3.20 (9H, s, $-CO_2CH_3$), δ 2.09 (2H, q, $>CH_2$).

Found: C, 43.22; H, 4.77; Cl, 14.03%. Calcd for $C_9H_{11}ClO_6$: C, 43.11; H, 4.43; Cl, 14.15%.

Results and Discussion

When dimethyl methylmalonate was used as an active methylene component in the reaction with methyl α-chloroacrylate, the first-step addition product, IV, of dimethyl methylmalonate to methyl α-chloroacrylate was isolated from the reaction mixture along with V. Thus, a close similarity in the mode of formation can be seen between I and V. The results can be reasonably explained in terms of the lack of the exchange reaction (5), because no active hydrogen

6) C. S. Marvel, J. Dec, H. G. Cooke, and J. C. Cowan, *J. Amer. Chem. Soc.*, **62**, 3495 (1940).

atom exists in the intermediate formed by the addition reaction of *n*-butyl(dimethyl methylmalonato)zinc to the acrylate.

When dimethyl α-bromomalonate was used as the active methylene component, an elimination reaction of bromine atom predominate to form VI, because the bromine atom is a good leaving group. In conformity with this, dimethyl α-bromomalonate could undergo a ring-formation reaction, even with methyl acrylate (Table 1, No. 6). In the reaction of *n*-butyl(methyl acetoacetato)zinc with methyl α-chloroacrylate, methyl acetoacetate component did not act as an addendum, but *n*-butyl group underwent the addition reaction, giving dimethyl 1-chloro-2-amyl-*cis*-1,2-cyclopropanedicarboxylate.[4] These results may be ascribed to the chelate ring of methyl acetoacetate being much more stable than that of dimethyl malonate.

Some results on the asymmetric synthesis by zinc alkylactive methylene chelate compounds in the presence of Et_2Zn-*l*-menthol are shown in Table 2.

The rather small value of the optical rotation in II should be ascribed to an exchange reaction (for example, Reaction (5)) between RZn and H groups, which may also be a cause of the racemization around the chiral center in II.

From the results presented above, it seems reasonable to conclude that the mode of the ring-formation reaction of α-halogenoacrylate with alkylzinc–active methylene chelate compounds is strongly influenced by the nature of substituents at the α-carbon atom of an active methylene component, and also by the stability of the chelating systems.

Table 2. Asymmetric synthesis by zinc alkyl–active methylene chelate compounds in the presence of Et_2Zn–*l*-menthol (1.0:1.2) system[a]

$[\alpha]_D^{20}$ in benzene	Chelate	Product

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2265—2266 (1973)

The Light Resistance of the Complex Salts of Flavones and Flavonols

Makoto KANETA and Noboru SUGIYAMA*

Fukushima Technical College, Iwaki-shi, Fukushima 970

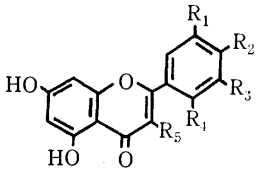
**Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112*

(Received November 22, 1972)

In a previous paper,[1] we showed that flavones, in contrast to flavonols (3-hydroxyflavones), show a high degree of resistance to light, and made clear that dyes from the plants *Arthraxon hispidus*,[2] *Reseda luteola*, and *Miscanthus tinctorius*[3] are superior to dyes from other grasses in their resistance to light because they contain flavones, such as arthraxin, luteolin, and tricin.

Since silk threads normally soaked in a mordant of lye made from leaves and stems of trees, such as *Eurya ochacea* and *Camellia japonica*, after being dyed with dyes from the above-mentioned plants, we examined the light resistance of the complex salts of flavones and flavonols by following the time change in the UV spectra of the following complexes substances: quercetin (**1**), morin (**2**), arthraxin (**3**), luteolin (**4**), and tricin (**5**).

Because of the similarity in the molecular structures of these substances, their molecular extinction coefficients will be considered to be approximately equal.



1 R_1, R_2, R_5=OH R_3,R_4=H
2 R_2,R_4,R_5=OH R_1,R_3=H
4 R_1,R_2=OH R_3,R_4,R_5=H
5 R_2=OH R_1,R_3=OMe R_4,R_5=H

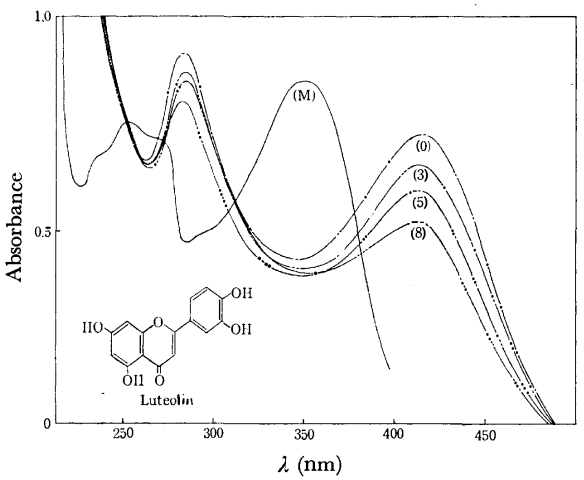


Fig. 1. Time change during irradiation of the spectrum of luteolin complex formed with *Camellia* lye.
(M): Methanol solution of luteolin, (0): 0 hr irradiation, (3): 3 hr irradiation, (5): 5 hr irradiation, (8): 8 hr irradiation.

We can, therefore, measure the light resistance of the substances by means of the decrease in the ratio of the absorption intensity.

3) M. Kaneta and N. Sugiyama, This Bulletin, **45**, 528 (1972).

Fifty ml portions of methanol solutions of the samples were prepared so as to show approximately equal absorption intensities of Band I, with Band I defined as the peak absorption band in the 350—450 nm region. To each solution, we then added a few drops of a saturated solution of salts (Na_2CO_3, $AlCl_3$) or lye of leaves and stems of *Eurya ochacea*, and *Canellia japonica* in order to make a complex.[4] The methanolic solutions of the complexes were irradiated under the same conditions with an immersion-type Taika HLV-A 200-W high-pressure mercury lamp through a quartz glass tube under bubbling air. The UV spectrum of an aliquot was then recorded at intervals of 1, 2, 3, 5, 8, 12, and 24 hr.

The results tabulated in Table 1 indicate that the complex salts of flavones, in contrast with flavonol-salt complexes, show a high power of resistance to the light when air is bubbled into the methanol solution. This result also agrees with the observations reported in a previous paper,[1] so it becomes clear that flavones are more stable than flavonols (3-hydroxyflavone) to irradiation both in the free state and in the complex-salt state.

4) For information about the "complexes" of flavones and flavonols, the reader is referred to T. J. Mabry, K. R. Markham and M. B. Thomas, "The Systematic Identification of Flavonoids," Springer-Verlag, New York (1970), p. 51.

5) The main metals contained in these plants were found to be Na, K, Ca, Mn, Al, Fe, and Cu by Mr. Ryokichi Negishi, Kanagawa Prefectural Industrial Experiment Station.

Application of the RRKM Theory to Energized Ethylene Formed in the Vacuum-ultraviolet Photolysis of *n*-Paraffins

Hajime Akimoto, Kinichi Obi, and Ikuzo Tanaka

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received October 5, 1972)

The Rice-Ramsperger-Kassel-Marcus treatment has been applied to the energized ethylene produced in the vacuum-ultraviolet photolysis of C_2H_6, C_2D_6, C_3H_8, C_3D_8, n-C_4H_{10} and n-C_4D_{10}. The energy spread in the energized ethylene has been evaluated assuming modified statistical distribution of liberated energy among fragment species. The calculated nonequilibrium unimolecular decomposition rate constant for the process $C_2H_4(C_2D_4)\rightarrow C_2H_2(C_2D_2)+H_2(D_2)$ could satisfactorily reproduce the experimental pressure dependence of ethylene to acetylene ratio. Non-statistical kinetic energy E_k seems to appear for the primary decomposition of the n-paraffins. Its value ranges from zero for the elimination of methane and ethane from propane and n-butane, respectively, at 147.0 nm to about 25 kcal mol^{-1} for the elimination of hydrogen from ethane at 123.6 nm.

In the vacuum-ultraviolet photolysis of n-paraffin hydrocarbons in the gas phase, ethylene and acetylene are always among the major products.[1-11] From the analysis of products the following reaction schemes have been proposed[9,12] for the production of ethylene and acetylene in the photolysis of ethane, propane and n-butane.

$$C_2H_6 + h\nu \xrightarrow{\phi_{1a}} H_2 + C_2H_4^{**} \xrightarrow{k_d} C_2H_2 + H_2 \quad (1)$$

$$\xrightarrow{k_s[M]} \xrightarrow{\phi_{1b}} H_2 + C_2H_4^{*} \longrightarrow C_2H_4 \quad (2)$$

$$\xrightarrow{\phi_2} H + C_2H_4 + H \quad (3)$$

$$C_3H_8 + h\nu \xrightarrow{\phi_{1a}} CH_4 + C_2H_4^{**} \xrightarrow{k_d} C_2H_2 + H_2 \quad (4)$$

$$\xrightarrow{k_s[M]} \xrightarrow{\phi_{1b}} CH_4 + C_2H_4^{*} \longrightarrow C_2H_4 \quad (5)$$

$$\xrightarrow{\phi_2} H + C_2H_4 + CH_3 \quad (6)$$

$$n\text{-}C_4H_{10} + h\nu \xrightarrow{\phi_{1a}} C_2H_6 + C_2H_4^{**} \xrightarrow{k_d} C_2H_2 + H_2 \quad (7)$$

$$\xrightarrow{k_s[M]} \xrightarrow{\phi_{1b}} C_2H_6 + C_2H_4^{*} \longrightarrow C_2H_4 \quad (8)$$

$$\xrightarrow{\phi_2} \begin{cases} H + C_2H_4 + C_2H_5 & (9) \\ CH_3 + C_2H_4 + CH_3 & (10) \end{cases}$$

Experimental studies[5,12] revealed that two kinds of ethylene should be obtained through the molecular detachment processes; one which undergoes unimolecular decomposition into acetylene and hydrogen competing with collisional stabilization to ethylene and the other which does not decompose even at very low pressure. These two kinds of ethylene are designated as $C_2H_4^{**}$ and $C_2H_4^{*}$, respectively, their relative yields being referred to as ϕ_{1a} and ϕ_{1b}, respectively. The assumption that the ethylene produced in Eqs. (3), (6), (9) and (10) does not decompose is easily justified in terms of the large endothermicity of the reactions.

With respect to energized ethylene the following points should be clarified: (1) How the unimolecular decomposition rate k_d can be correlated to the internal energy retained in the energized ethylene $C_2H_4^{**}$. How the internal energy can be correlated to the maximum energy available in the processes. (2) The nature of $C_2H_4^{*}$. (3) Whether ethylene is originally produced in the form of ethylidene CH_3CH which then isomerizes to C_2H_4, or it is originally formed as C_2H_4.

By means of the classical Kassel formula,[13] Hampson and McNesby[5] first attempted to correlate the experimentally determined unimolecular decomposition rate to the internal energy of ethylene produced in the photolysis of n-paraffin hydrocarbons, diazoethane and methylketene. Assuming *a priori* that 80% of the maximum energy available in the process would be retained in ethylene, they succeeded in showing reasonably good correlation in a semi-quantitative manner. Their results suggest that energized ethylene $C_2H_4^{**}$ is vibrationally excited ethylene in its ground electronic state. They also suggested that $C_2H_4^{*}$ is a long-lived triplet ethylene.

Kirk and Tschuikow-Roux[14] applied the Rice-Ramsperger-Kassel-Marcus (RRKM) treatment to the decomposition of ethylene produced in the photolysis of 3-methyldiazirine assuming that ethylene is produced in the photolysis with a wide spread of internal energy, whose distribution was selected arbitrarily to fit the experimental data. According to this model ethylene produced in the photolysis has a continuous distribution of internal energy from zero to maximum value allowed in the process, and both $C_2H_4^{**}$ and $C_2H_4^{*}$

can be in the ground electronic state with different amounts of internal energy. Energized ethylene C_2H_4** can then be interpreted as ethylene whose internal energy is greater than a certain critical value necessary to decomposition, and C_2H_4* as that which retains less energy than the critical value.

This model was further developed[15] for ethylene formed in the photolysis of alkanes at 147.0 nm. In order to predict the distribution of internal energy of ethylene more systematically, a statistical model proposed by Campbell and Schlag[16] was employed. Although the RRKM calculation could predict the nonequilibrium unimolecular decomposition rate in fair agreement with experimental data, we had to introduce a correction parameter (A in Eq. (22) of the paper[15]) whose value was hard to reconcile with the statistical model of energy distribution.

This paper presents a modified version of our previous treatment. In the new model a restriction to the statistical calculation for the initial distribution of internal energy of ethylene has been introduced. In order to test the validity of the new model, comparison with experimental data for the photolysis of ethane, propane, and *n*-butane at different excitation wavelengths and also for the photolysis of fully deuterated compounds was made. The new model was found to give good agreement with all sets of data tested and could predict the wavelength effect and isotope effect quantitatively.

Method

Calculation of k_E. Suppose that ethylene with internal energy E is produced through a molecular elimination process in a vacuum-ultraviolet photolysis of *n*-paraffin. A specific rate constant k_E of the decomposition of energized ethylene into acetylene and hydrogen can be given by the RRKM theory[17,18] as follows.

$$k_E = \frac{1}{h}\frac{\sigma}{\sigma^+}\frac{\sum P(E-E_0)}{N(E)} \tag{11}$$

where σ and σ^+ are the symmetry numbers of the active molecule and the activated complex, respectively. $N(E)$ is the energy level density for the active molecule at energy E, $\sum P(E-E_0)$ the energy-level sum for the activated complex and E_0 the critical energy required for the decomposition of energized ethylene into acetylene and hydrogen. A contribution from the change in moment of inertia between the active molecule and activated complex has been neglected since it is known[15] to be small in the case of a hydrogen elimination process.

In the absence of an internal free rotation as is the case here, $N(E)$ and $\sum P(E-E_0)$ can be approximated by

$$N(E) = \frac{(E+aE_z)^{s-1}}{\Gamma(s)\Pi h\nu_i} \tag{12}$$

$$\sum P(E-E_0) = \frac{(E-E+a^\dagger E^\dagger_z)^{s\dagger}}{\Gamma(s^\dagger+1)\Pi h\nu_i^\dagger} \tag{13}$$

as proposed by Whitten and Rabinovitch.[19] In Eqs. (12) and (13) s and $s^\dagger$ are the numbers of vibrational degrees of freedom, E_z and E_z^+ are the zero point energy, and ν_i and $\nu_i^\dagger$ are vibrational frequencies of active molecule and activated complex, respectively. Energy dependence of parameters a and $a^\dagger$ are calculated using analytical expressions given by Whitten and Rabinovitch[19]

An activated complex having a four-membered ring structure has been considered.[15] The activated complex is assumed to be rigid and the frequencies are taken to be equal to those of ground state ethylene except for one CH stretching mode (B_{2u}) which is taken as a reaction coordinate. All the frequencies used are given in the Appendix. Since the pyrolysis of ethylene proceeds through radical chain mechanism rather than molecular elimination of hydrogen,[20,21] no direct experimental data is available for the value of E_0. Benson and Haugen[22] estimated the activation energy of the reverse reaction, $H_2+C_2H_2\rightarrow C_2H_4$, to be 40 kcal mol^{-1}. From this value and the heat of reaction of the process 41.7 kcal mol^{-1}, *ca.* 80 kcal mol^{-1} is obtained for the activation energy of decomposition as a first approximation. The E_0 value of 78 kcal mol^{-1} for C_2H_4 is chosen since it was found to give the most consistent results. Taking into account the difference in zero point energy between the active molecule and the activated complex, 1 kcal mol^{-1} should be raised, giving 79 kcal mol^{-1} for the decomposition of C_2D_4.

Calculation of $f(E)$. It is expected that ethylene molecules produced in the photolyses of *n*-paraffins will have certain energy spread rather than monoenergetic energy. However, at present there exists no *a priori* method to determine the energy distribution of the products of the reactions. In the photolysis of ethane, propane and *n*-butane, molecular elimination of hydrogen, methane and ethane would respectively give rise to energized ethylene. In such a system the maximum energy E_t available for the energized ethylene can be given by

$$E_t = E_p - \Delta H \tag{14}$$

where E_p is the energy of photon used in the photolysis of parent *n*-paraffin and ΔH the heat of reaction of each molecular elimination process. The values of ΔH we used are 32.7, 19.4 and 22.5 kcal mol^{-1} for the photolysis of ethane, propane and *n*-butane, respectively. Energy E_t may either be distributed among each degree of freedom of product fragments more or less statistically or appear as non-statistical kinetic energy of fragments.

During the course of molecular elimination the following type of transition state is expected:

C_2H_6 C_3H_8 n-C_4H_{10}

It is postulated that one of the hydrogen atoms of the methyl group in the "ethylene" part of parent molecule would start to transfer to the adjacent atom while the molecular elimination of H_2, CH_4, and C_2H_6 starts to occur. We assume that the statistical part of the liberated energy would be distributed among "active" vibrational modes which can be defined as vibrational modes whose associated normal coordinates undergo drastic changes during passage through the transition state. The drastic changes mean those of bond length and bond angle for newly formed bond and those of bond angles accompanying a change of hybridization from sp^3 to sp^2. The following vibrational modes should be taken as inactive; three CH stretching modes of "ethylene" part of all n-paraffins; three CH stretching and three CH_3 deformation modes of "methane" part of propane; and five CH stretching, one CC stretching, three CH_3 deformation, one CH_2 scissors, two CH_3 rocking, one CH_2 wagging, one CH_2 twisting and one CH_3 tortional modes of "ethane" part of n-butane. Using a statistical model proposed by Campbell and Schlag,[16] a fraction of the energized ethylene which retains a vibrational energy E out of the total available energy, E_t, can be written as

$$f(E) = \frac{N_{C_2H_4}(E)N_R(E_t-E-E_k)}{\sum N_{C_2H_4}(E_l)N_R(E_t-E_l-E_k)} \quad (15)$$

where E_k is non-statistical kinetic energy, $N_{C_2H_4}(E)$ the energy-level density of the "active" ethylene part of the n-paraffin and $N_R(E_t-E-E_k)$ that of the "active" remaining part of the n-paraffin. The energy-level densities were calculated by means of Eq. (12). All vibrational frequencies used are given in the Appendix.

Comparison with Experiments. Now that the energy distribution of energized ethylene $f(E)$ and the specific rate constant k_E have been calculated, the apparent rate constant k_d can be given[18] by

$$k_d = \frac{\int \frac{k_E}{k_E+\omega} f(E)dE}{\int \frac{1}{k_E+\omega} f(E)dE} \quad (16)$$

where ω is the rate of deactivation of energized ethylene. Throughout this work a strong collision model is assumed, *viz.*, ω is assumed to be equal to the kinetic collision frequency independent of the energy of ethylene. Kinetic treatment[9] of the reaction schemes in Eqs. (1)—(10) gives the relation

$$\frac{\phi(\text{Ethylene})}{\phi(\text{Acetylene})} = \frac{\phi_2+\phi_{1b}}{\phi_{1a}} + \frac{k_s}{k_d}\left(1+\frac{\phi_2+\phi_{1b}}{\phi_{1a}}\right)P \quad (17)$$

which allows us to compare the experimentally determined quantity ϕ(Ethylene)/ϕ(Acetylene) with the calculable quantity of the right hand side of the scheme. In Eq. (17), P is the pressure of n-paraffin, k_s the simple collisional rate constant given by gas kinetics in accordance with the strong collision model ($\omega=k_sP$). The values of k_s we used are 1.43×10^7, 1.58×10^7 and 1.72×10^7 $Torr^{-1}\,s^{-1}$ for ethane, propane and n-butane, respectively. The ϕ_{1a}, ϕ_{1b} and ϕ_2 are defined in schemes (1)—(10). The values of ϕ_2 were determined[2,3,9,11] experimentally. The values we used are given in Table 1 together with the calculated quantities. The values of ϕ_{1a} and ϕ_{1b} are calculated using the energy distribution function $f(E)$, *i.e.* under the restriction of $\phi_{1a}+\phi_{1b}+\phi_2=1$; ϕ_{1a} is put to be equal to the fraction of energized ethylene with energy greater than E_0 and ϕ_{1b} put to be equal to that of energized ethylene with energy less than E_0.

Under the restrictions of all selected values of parameters, only the value of E_k has been left as an adjustable parameter. Selection of the E_k value to give the best fit of calculated curve to the experimental points has been made for each case.

Results and Discussion

The validity of model has been tested by comparing the calculation with the experimental data of the photo-

Table 1. Values of excess energy E_t, relative yields ϕ_{1a}, ϕ_{1b} and ϕ_2, average energy of ethylene $\overline{E}$ and average energy of decomposing ethylene $\overline{E_d}$ associated with non-statistical energy parameter E_k

a) Experimentally determined. See Ref. 9, 15, 23.

lysis of C_2H_6,[11,12] C_2D_6,[23] C_3H_8,[11] C_3D_8,[23] n-C_4H_{10}[11] and n-C_4H_{10}[23] at two exciting wavelengths, 147.0 and 123.6 nm. The data for the photolysis of C_2H_6 at 157.7 nm are also available[9] for comparison. The results are presented in Figs. 1—4. The best fit curves were obtained by varying the value of E_K after selecting all other parameters. It should be noted that except E_K the best fit curves for all data were obtained with a common activated complex model, a systematic way of calculation for $f(E)$, and common values of E_0.

Taking into account the fact that the calculated results are very sensitive to selected parameters, and the range of selection of each parameter is not so wide as regards its physical meaning, successful reproduction of experimental data should not be taken as only fortuitous. Calculated values of relative yields ϕ_{1a} and ϕ_{1b}, average internal energy of ethylene $\overline{E}$ and average energy of decomposing ethylene $\overline{E_d}$ are given in Table I, together with the selected values of E_k. An important feature of the model is the successful reproduction of the curvature of the plots[9] of ϕ(Ethylene)/ϕ(Acetylene) *vs.* P in the photolysis of C_2H_6 at 157.7 nm.

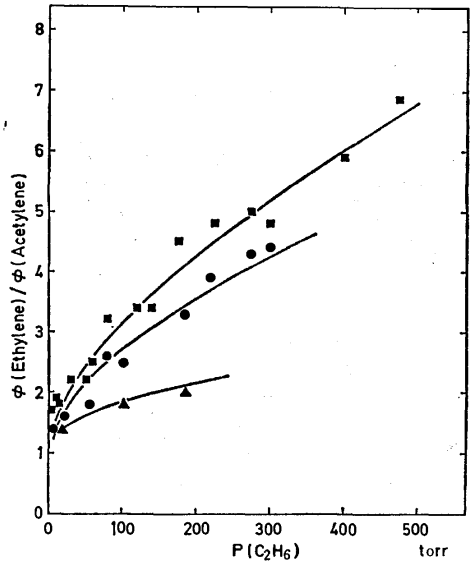

Fig. 1. Calculated ratio of ethylene to acetylene in the photolysis of C_2H_6 (solid lines), compared to experimental results at 157.7 (■), 147.0 (●) and 123.6 nm (▲).

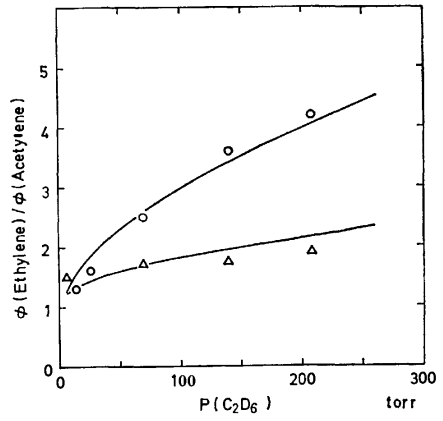

Fig. 2. Calculated ratio of ethylene to acetylene in the photolysis of C_2D_6 (solid lines), compared to experimental results at 147.0 (○) and 123.6 nm (△).

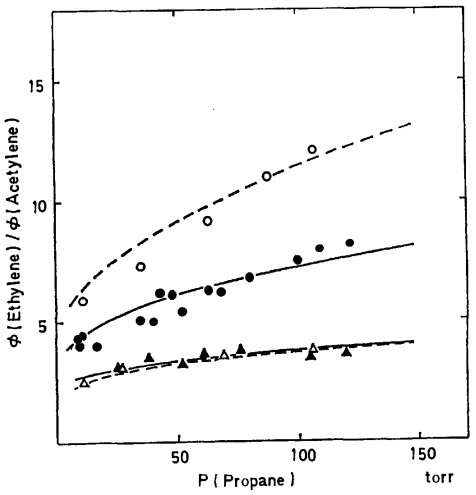

Fig. 3. Calculated ratio of ethylene to acetylene in the photolysis of C_3H_8 (solid lines) and C_3D_8 (dashed lines), compared to experimental results for C_3H_8 at 147.0 (●) and 123.6 nm (▲), and C_3D_8 at 147.0 (○) and 123.6 nm (△).

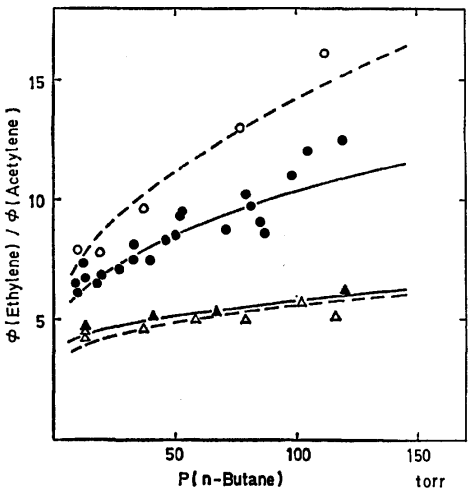

Fig. 4. Calculated ratio of ethyiene to acetylene in the photolysis of n-C_4H_{10} (solid lines) and n-C_4D_{10} (dashed lines), compared to experimental results for n-C_4H_{10} at 147.0 (●) and 123.6 nm (▲) and n-C_4D_{10} at 147.0 (○) and 123.6 nm (△).

According to the present model the curvature results from a very wide spread of internal energy of the energized ethylene formed in the photolysis. Although in all other cases the scatter of experimental points does not allow us to make a clear preference, the non-linear correlation seems to fit the experimental results better than the linear one. The values of ϕ_{1a} and ϕ_{1b} given in Table 1 differ somewhat from those obtained from linear correlation of ϕ(Ethylene)/ϕ(Acetylene) *vs.* pressure plots.[9,12,15] We believe that the linear correlation is true only in appearance and that the k_s/k_d and ϕ_{1a}/ϕ_{1b} values thus obtained are no more than those in a zero approximation. The latter situation has been pointed out by Campbell

23) H. Akimoto and I. Tanaka, unpublished data.

et al.[24] who stated linear plots may not be a sufficient guarantee against a simple two step mechanism.

Production of vibrationally excited polyatomic species in photodissociative processes has been reported in several species. These include the photolysis of cyclobutanone,[16,25] cyclopentanone,[25] methylketene,[26] tetrahydrofuran,[27] 2,3-diazabicyclo[2,2,1]hept-2-ene,[28] *t*-pentyl nitrite,[29] 1-pyrazoline,[30] diazoethane,[31] and 3-methyl diazirine.[32] Generally the excess photon energy has been found to be distributed over the products so that the species formed have a spread of energy. For the case of energized cyclopropane formation, the statistical model which assumes the microscopic equilibration of liberated energy among all degrees of freedom of products, was found[16,30] to be inappropriate to predict the energy partitioning for cyclopropane. Thus the assigned energy for cyclopropane was an underestimate in the case of cyclobutanone and an overestimate in the case of 1-pyrazoline. For the energized ethylene formation in the photolysis of *n*-paraffins,[15] such simple statistical model also failed to predict the energy partition particularly in the case of *n*-butane, where a large negative correction factor was required to reproduce the experimental data. In this work the modified statistical model which introduced an "active" model of energy partitioning was found to be satisfactory at least for the reproduction of experimental data. Although clear justification cannot be made without more information on the potential surface of photodissociation, the assumption we employed is consistent with the general view[29] that a change in an equilibrium bond distance or bond angle during the course of dissociation may lead to preferential excitation of vibrational modes involving the affected bond.

As shown in Table 1 the average energy of decomposing ethylene $\overline{E}_d$ ranges from 97 to 120 kcal mol^{-1}, which is roughly 20—40 kcal mol^{-1} higher than the critical energy E_0. Thus, if an energy quanta transferred by a single collision between *n*-paraffin is as much as 40 kcal mol^{-1}, the strong collision model we used can be justified. Data on an amount of energy transferred by a single collision for deactivation of highly vibrationally excited species are still scarce. Setser *et al.*[33] have shown that ethylene and cyclopropane remove energy from vibrationally excited cyclopropane and methylcyclopropane, respectively, in average steps of at least about 30 kcal mol^{-1} at room temperature. Taking into account the similarity of molecular complexity and the average energy of around 110 kcal mol^{-1} contained in energized cyclopropane and methylcyclopropane in their system, our present system may be analogous to theirs. Thus their conclusion would be applicable to our case and the strong collision assumption may be justified. On the other hand, the photolysis of paraffins in the presence of nitrogen indicates[15] that the collision efficiency of ethane against energized ethylene would be smaller than unity. If this is the case, the best fit of the data is obtained at higher values of E_k, and those given in Table 1 should be taken as a lower limit.

An activated complex model which has the same frequencies as in the ground state molecule except for the reaction coordinate is of course a conventional one. But the selection of the "rigid" model is in accord with the results of quasi-equilibrium theory of ion fragmentation where molecular elimination of hydrogen from a hydrocarbon parent ion is assumed to proceed through a "rigid" activated complex.[34] An activated complex with lower frequencies naturally yields a higher decomposition rate and could not reproduce the experimental data even if other parameters were adjusted.

As shown in Table 1, 13, 20 and 25 kcal mol^{-1} are assigned as suitable values of the non-statistical energy E_k in the photolysis of ethane at 157.7, 147.0 and 123.6 nm respectively. While it is indicated to be close to zero at 147.0 nm in the photolysis of propane and *n*-butane, E_k appears to increase with excitation energy in the case of C_2H_6, and E_k for C_2D_6 appears to be smaller than that for C_2H_6. In the photolysis at 123.6 nm an appreciable amount of E_k may be implied for the elimination of methane from propane and less amount for the elimination of ethane from *n*-butane. Although the assignment of specific values of E_k is difficult for these cases due to the insensitivity of the calculated results to the value of E_k, the trend may be noted that the E_k is smaller for the deuterated compound. Since the reduction of the value of E_0 can be compensated to some extent by the increase of the value of E_k to reproduce experimental data, the value of E_k can not be defined unambiguously. Nevertheless the set of values of E_k would be correct at least relatively (Table 1) since a common value of E_0 was used throughout the calculation.

Non-statistical kinetic energy has been observed in some ion fragmentation processes.[34] Taubert[35] determined experimentally translational energies of some fragment ions after the ionization of paraffins by electron impact. His data suggested that in the elimination of neutral methane from $C_3H_8^+$, the excess energy remains mostly as internal energy of the fragments while in the elimination of a hydrogen molecule from $C_3H_8^+$ and $C_2H_6^+$, part of the excess energy appears as non-statistical kinetic energy to the amount *ca.* 13 and

8 kcal mol^{-1}, respectively.[34] Our results agree with this observation, and the parameter E_k would be justified as non-statistical kinetic energy.

Following the present scheme, C_2H_4* has been interpreted to be an electronic ground state ethylene which contains less vibrational energy than a critical value necessary for decomposition. Since experimental data have been reproduced successfully according to this scheme, it seems unnecessary to invoke another long-lived electronic state of ethylene unless direct evidence indicates the presence of such species.

Energized ethylene formed in Eqs. (1), (2), (4), (5),(7) and (8) has been sometimes quoted[12] as "ethylidene". However, so far there is no experimental evidence that ethylidene is produced in a primary process in the photolysis of *n*-paraffins. We could exclude primary processes such as

$$C_2H_6 + h\nu \longrightarrow H_2 + CH_3CH: \quad (18)$$

$$CH_3CH: \longrightarrow C_2H_4** \quad (19)$$

According to an extended Hückel MO calculation,[36] ground state ethylidene CH_3CH: lies 81 kcal mol^{-1} above the ground state of ethylene. Thus ethylene produced through the isomerization of ethylidene should have at least 81 kcal mol^{-1} of internal energy even if ethylidene formed in Eq. (18) is in the lowest vibrational state. Since E_0 is about 80 kcal mol^{-1}, all of the ethylene thus formed should be able to decompose at low enough pressure and should be interpreted as C_2H_4**. Thus there should be another process which forms exclusively ethylene whose internal energy is lower than 80 kcal mol^{-1}, which would hardly be accepted. Formation of ethylidene in the primary step of the photolysis of *n*-paraffin seems improbable.

Appendix

The vibrational frequencies of C_2H_4 (C_2D_4) are taken[37] to be 3000(2250), 1600(1500), 1350(1000), 1000(800), 3100-(2300), 1250(900), 950(700), 950(800), 3100(2350), 800-(600), 3000(2200), 1450(1100) cm^{-1} for ν_1 to ν_{12} in order. Exactly the same frequencies were used in activated complex, except for ν_9 which was taken as reaction coordinate.

For normal mode frequencies[37] of *n*-paraffin the average values were assigned to the same type of mode. They are given below, where numbers in parentheses are the number of modes, the two successive numbers being the frequencies in cm^{-1} for hydrogenated and deuterated compounds, respectively. For C_2H_6 and C_2D_6: CH strecthing (6), 3000, 2200; CC stretching (1), 1000, 850; CH_3 deformation (6), 1450, 1100; CH_3 rocking (4), 1000, 800; and CH_3 torsion (1), 300, 200. Three CH stretching modes which correlate to ethylene part were taken as inactive for the calculation of $f(E)$. For C_3H_8 and C_3D_8: CH stretching (8), 3000, 2200; CC stretching (2), 1000, 950; CH_3 deformation and CH_2 scissors (7), 1450, 1100; CH_3 rocking (4), 1100, 800; CH_2 rocking (1), 700, 550; CH_2 twisting and wagging (2), 1300, 950; CCC bending (1), 400; 300; and CH_3 torsion (2), 200, 150. Three CH stretching modes which correlate to ethylene part, and three CH stretching and three CH_3 deformation modes which correlate to methane part were taken as inactive for the calculation of $f(E)$. For *n*-C_4H_{10} and *n*-C_4D_{10}: CH stretching (10), 3000, 2200; CC stretching (3), 1000, 950; CH_3 deformation and CH_2 scissors (8), 1450, 1100; CH_3 rocking (4), 1100, 800; CH_2 rocking (2), 700, 550; CH_2 twisting and wagging (4), 1300, 950; CCC bending (2), 400, 300; CH_3 torsion (2) 200, 150; and CH_2CH_2 torsion (1), 100, 90. Three CH stretching modes which correlate to ethylene part and five CH stretching, one CC stretching, four CH_3 deformation and CH_2 scissors, two CH_3 rocking, two CH_2 twisting and wagging and one CH_3 torsion modes which correlate to ethane part were taken as inactive for the calculation of $f(E)$.

Measurement of Negative Ions Formed by Electron Impact. IX. Negative Ion Mass Spectra and Ionization Efficiency Curves of Negative Ions of *m/e* 25, 26, 27, 38, 39, 40 and 50 from Acrylonitrile

Satoru TSUDA, Akira YOKOHATA, and Toshikatsu UMABA

Department of Chemistry, Faculty of Engineering, University of Hiroshima, Senda-machi, Hiroshima 730

(Received November 4, 1972)

Negative ion mass spectra of acrylonitrile were measured for the electron energies of 80, 40 and 9.5 eV. Emphasis was laid on the abundance of the negative ions relative to the positive ions measured for the energies of 80, 40 and 15 eV, respectively. The ionization efficiency (IE) curves were also determined up to 25 eV for the ions of *m/e* 25(C_2H^-), 26(CN^-), 27(HCN^-), 38(C_2N^-), 39($CHCN^-$), 40(CH_2CN^-) and 50(C_3N^-). The electron impact of 80 eV and 40 eV gave almost the same distribution of *m/e* for negative ion mass spectra. Besides the most intense peak of CN^- ions, relatively strong peaks of C_3N^-, C_2H^-, C_2^- and C_2N^- ions were observed. In 9.5 eV, CN^- ions predominated over other ions. Yields of the ions showed a good linearity against the pressure in the range used for usual chemical analysis, irrespective of electron energy. Comparison of the yield of CN^- ions with that of $C_2H_3CN^+$ gave the values 1.2×10^4 and 1.9×10^4 for $C_2H_3CN^+/CN^-$ at 80 eV and 40 eV, respectively, and 47.6 at 9.5 eV (15 eV for the positive ions). The plausible reaction schemes expected to occur at each onset observed in the IE curves were also sought thermochemically by using ΔH_f values of the reactant and products. A value $\gtrsim 2$ eV was obtained for the electron affinity of C_2H.

Studies have been reported on the measurement of negative ion mass spectra by the electron impact method.[1–5] However, they were restricted to a limited number of compounds. Data of ionization efficiency (IE) curves of negative ions are also very limited.[6–10]

IE curves were given for NO_2^-, O^-, $CH_2NO_2^-$, CN^- and CNO^- ions from nitroalkanes,[11] O^- and OH^- ions from *n*-propyl and isopropyl alcohols,[12] O^-, C_2H^- and C_2HO^- ions from tetrahydrofuran,[13] Cl^- ions from alkyl chlorides,[13] CN^-, HCN^-, C_2N^- and $CHCN^-$ ions from methyl and ethyl cyanides.[15] Investigation was extended to acrylonitrile. In this paper we report on negative ion mass spectra for 80eV, 40eV and 9.5 eV, with emphasis on relative abundances to the positive ions for 80 eV, 40 eV and 15 eV, and the IE curves of *m/e* 25(C_2H^-), 26(CN^-), 27(HCN^-), 38(C_2N^-), 39 ($CHCN^-$), 40(CH_2CN^-) and 50(C_3N^-) ions.[16]

Experimental

Experiments were performed on a Hitachi RMU-6D mass spectrometer equipped with a T-2M ion source having a rhenium filament. The ion detector consisted of a ten-stage electron multiplier and a Faraday collector. Experimental conditions: total emission current=20 μA, ion accelerating voltage=3.6 kV, electron multiplier voltage=2.8 kV, sourve pressure $\simeq 10^{-6}$ mmHg. The ionizing current varied from 10.5 μA above 10 eV to 6.4 μA at ~3 eV.[14] The energy scale was calibrated in every measurement by the vanishing current method in comparison with the ionization potential of argon (for positive ions) and the appearance potential of *m/e* 16(O^-) from carbon monoxide, carbon dioxide and oxygen (for negative ions).[11,14] The repeller voltage was adjusted to the best condition to collect positive and negative ions. The sample used was of reagent grade.

Results and Discussion

Negative Ion Mass Spectra. The relative abundances of negative ions for 80 eV, 40 eV and 9.5 eV electron energies are shown in Table 1. Since the data were taken at a pressure of $\sim 10^{-6}$ mmHg in the source, the possibility of ions being induced by ion-molecule reactions may be ruled out. The electron impact of 80 eV and 40 eV gave almost the same distribution of *m/e* for negative ion mass spectra.

The spectra obtained are as follows.

m/e 12(C^-), *m/e* 13(CH^-), *m/e* 14(CH_2^-), *m/e* 24(C_2^-), *m/e* 25(C_2H^-), *m/e* 26(CN^-), *m/e* 27(HCN^-), *m/e* 36(C_3^-), *m/e* 37(C_3H^-), *m/e* 38(C_2N^-), *m/e* 39($CHCN^-$), *m/e* 40(CH_2CN^-), *m/e* 50(C_3N^-), *m/e* 51(HC_3N^-), *m/e* 52($H_2C_3N^-$)

The parent ion (*m/e* 53, $H_3C_3N^-$) was not detected.

16) Recently, the measurement of IE curves of a few ion species was reported. However, no discussion is given on the plausible reaction schemes expected to appear at each onset value (T. Sugiura, Discussion Meeting of the Research Reactor Institute of Kyoto University, January 14, (1968)).

Table 1. Relative abundances of negative ions (normalized to $[CN^-]=100$)

m/e	Probable negative ion	Relative abundances		
		80 eV	40 eV	9.5 eV
12	C	1.46	0.76	
13	CH	0.39	0.85	0.07
14	CH_2	0.06	0.05	0.04
24	C_2	11.20	7.26	0.10
25	C_2H	34.20	36.80	0.91
26	CN	100.00	100.00	100.00
27	HCN	1.47	1.26	1.32
36	C_3	2.39	1.76	
37	C_3H	0.58	0.78	
38	C_2N	2.90	3.55	0.46
39	CHCN	0.89	0.81	2.31
40	CH_2CN	0.04	0.04	0.26
50	C_3N	50.80	61.70	4.45
51	C_2HCN	1.86	2.88	0.78
52	C_2H_2CN	0.47	0.76	0.02

Relatively strong peaks were observed at *m/e* 50(C_3N^-), *m/e* 25(C_2H^-) and *m/e* 24(C_2^-) ions for 80 eV and 40 eV, besides the most intense peak at *m/e* 26(CN^-). The situation is quite similar to that for ethyl cyanide. This shows that C_3N^-, C_2H^- and C_2^- ions are stable, while electron affinities of C_3N and C_2 between them are known to be $EA(C_3N)=2.4$ eV[17] and $EA(C_2)=3.1$ eV.[18] However, the values of $EA(C_2H)$ and $EA(C_2N)$ are not known. The change of relative abundances with electron energies (80→40 eV) was relatively great for C^-, CH^-, C_2^-, C_3^-, C_3HN^- and $C_3H_2N^-$ ions.

Fig. 1. Positive and negative ion mass spectra of acrylonitrile (Pressure in the source, $\sim 10^{-6}$ mmHg).
(a): 80 eV, $C_2H_3CN^+/CN^- \simeq 1.2\times 10^4$
(b): 40 eV, $C_2H_3CN^+/CN^- \simeq 1.9\times 10^4$
(c): 15 eV for positive ions, 9.5 eV for negative ions, $C_2H_3CN^+/CN^- \simeq 47.6$

In 9.5 eV electron energy, *m/e* 26(CN^-) ions predominated over other negative ions. Since the dissociative electron capture process governs the reaction in a lower energy region, the yield should depend on the cross section of each process. The IE curves of CN^-, C_3N^-, C_2H^-, C_2N^-, HCN^-, $CHCN^-$ and CH_2CN^- ions are given.

Figure 1 shows the negative ion mass spectra for 80 eV, 40 eV and 9.5 eV electron energies in relation to the positive ion mass spectra at 80 eV, 40 eV and 15 eV.[19] Comparison of the yield of CN^- ions with

18) C. I. Vedeneyev, L. V. Gurvich, V. N. Kandrat'yev, V. A. Medvedev, and Ye. L. Frankevich, "Bond Energies, Ionization Potentials and Electron Affinities," Bulter Tranner Ltd., London (1966) p. 194.

19) Since the formation of positive fragment ions cannot be expected from the impact of 9.5 eV electrons, the data for 15 eV electrons were used for comparison for the sake of convenience.

that of $C_2H_3CN^+$ ions (the most intense peak among the positive ions) gave $C_2H_3CN^+/CN^- \simeq 1.2\times10^4$ and 1.9×10^4 at 80 eV and 40 eV electron energies, respectively. The ratio of the yield of CN^- ions at 9.5 eV to that of $C_2H_3CN^+$ ions at 15 eV gave the value $C_2H_3CN^+/CN^- \simeq 47.6$.

Effect of Pressure. Figure 2 shows the plot of the yield of *m/e* 26(CN^-), 50(C_3N^-), 38(C_2N^-) and 39($CHCN^-$) ions against pressure, where the electron energy used was 80 eV. All the results showed a good linearity, which are consistent with the findings for *m/e* 1(H^-) ion from hydrogen,[20] *m/e* 39(CH_3CC^-) ion from methylacetylene,[21] *m/e* 46(NO_2^-), 16(O^-), 26(CN^-) and 42(CNO^-) ions from nitroalkanes,[11] *m/e* 26(CN^-), 27(HCN^-), 38(C_2N^-), 39($CHCN^-$) and 40(CH_2CN^-) ions from methyl- and ethylcyanides.[22] The linear correlations against pressure were independent of electron energy. The pressure dependency may become complicated at higher pressures because of the occurrence of ion-molecule reactions.

○ CN^- ⊙ C_3N^- △ C_2N^- □ $CHCN^-$

IE Curves; CN^- ions. Figure 3(a) shows the IE curve of *m/e* 26(CN^-) ions. At least three processes appear to take place. The first process appears at lower energies than 2 eV, the second process at ~3.0 eV[23] and the third process at ~5.8 eV. The shape of the IE curve suggests a dissociative electron capture process except for the part in a higher energy region.

The appearance potential (*AP*) of reaction (1) can be expressed by Eq. (2), if the kinetic energies of the fragment are ignored and the ions formed are in the ground state.

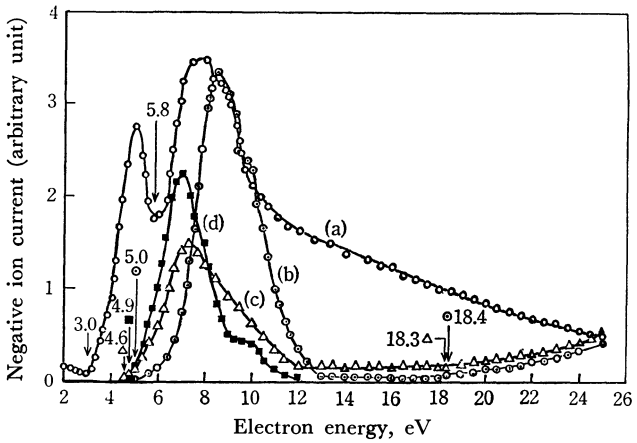

Fig. 3. Ionization efficiency curves of *m/e* 26(CN^-), *m/e* 25(C_2H^-) and *m/e* 38(C_2N^-) ions.
○ CN^- ⊙ C_3N^- △ C_2H^- ■ C_2N^-

$$XYZ + e^- \longrightarrow X^- + YZ \quad (1)$$

$$AP_{calcd} = \Delta H = \Delta H_f(X^-) + \Delta H_f(YZ) - \Delta H_f(XYZ) \quad (2)^{24}$$

In the case of ion pair formation ($XYZ \rightarrow X^-YZ^+$), the following equation holds.

$$AP_{calcd} = \Delta H = \Delta H_f(X^-) + \Delta H_f(YZ^+) - \Delta H_f(XYZ) \quad (3)$$

From Eqs. (2) and (3), schemes of the reactions expected to occur at each onset value (AP_{obsd}) were sought thermochemically.

For the first process, we have

$$C_2H_3CN + e^- \longrightarrow CN^- + C_2H_3 (AP_{calcd} = 1.3\ eV) \quad (4)$$

In the estimation of AP_{calcd}, the values of $\Delta H_f(C_2H_3CN) = 2$ eV,[25] and $\Delta H_f(CN^-) = 0.47$ eV and $\Delta H_f(C_2H_3) = 2.83$ eV[26] were used. The first process appearing at <2 eV would probably correspond to reaction (4). Combining $\Delta H_f(C_2H_3CN) = 2$ eV with $\Delta H_f(CH_2) = 2.5$ eV[26] and $\Delta H_f(CHCN) = 4.2$ eV,[15] we obtain $D(CH_2{=}CHCN) = 4.7$ eV. This is reasonable as compared with $D(CH_2{=}CH_2) = 5.2$ eV.[18] The CN radical is expected to weaken the C=C bond. A previous value $\Delta H_f(CHCN) = 4.2$ eV[15] might also be mentioned.

For the second process, we have

$$C_2H_3CN + e^- \longrightarrow CN^- + C_2H_2 + H \quad (AP_{calcd} = 3.08\ eV) \quad (5)$$

$$\longrightarrow CN^- + C_2H + H_2 \quad (AP_{calcd} = 3.47\ eV) \quad (6)$$

Estimation of each AP_{calcd} value was made with the use[26] of $\Delta H_f(C_2H_2) = 2.35$ eV, $\Delta H_f(H) = 2.26$ eV and $\Delta H_f(C_2H) = 5.0$ eV. A good consistency of $AP_{calcd} = 3.08$ eV with $AP_{obsd} \simeq 3.0$ eV suggests the possibility of the occurrence of reaction (5) rather than (6).

For the third process, we have

20) G. J. Schulz, *Phys. Rev.*, **113**, 816 (1959).
21) T. Sugiura, T. Seguchi, and K. Arakawa, This Bulletin, **40**, 2992 (1967).
22) S. Tsuda, A. Yokohata, and T. Umaba, *ibid.*, **43**, 3383 (1970).
23) Exact determination of appearance potential of the 2nd and 3rd processes is difficult, since the tailing due to the 1st and 2nd processes and their appearance might overlap. In this work, the minimum values in the IE curves have been discussed as by Schulz (G. J. Schulz, *Phys. Rev.*, **113**, 816 (1959)).
24) ΔH (X): heat of formation of X.
25) From $\Delta H_f(C_3H_3N^+) = 12.8$ eV and $IP(C_2H_3CN) = 10.75$ eV, $\Delta H_f(C_2H_3CN) \simeq 2$ eV can be estimated (J. D. Morrison and A. J. C. Nicholson, *J. Chem. Phys.*, **20**, 1021 (1952)).
26) R. R. Bernecker and F. A. Long, *J. Phys. Chem.*, **65**, 1565 (1961).

$$C_2H_3CN + e^- \longrightarrow CN^- + CH_2 + CH \quad (AP_{calcd} = 7.13\ eV)^{27)} \quad (7)$$

$$\longrightarrow CN^- + C_2H + 2H \quad (AP_{calcd} = 7.99\ eV) \quad (8)$$

$$\longrightarrow CN^- + C_2 + H + H_2 \quad (AP_{calcd} = 9.25\ eV)^{28)} \quad (9)$$

However, each AP_{calcd} value does not fit $AP_{obsd} \simeq 5.8$ eV. Reaction (10) might be possible. The value of C_2H_2* can be estimated to be $\sim$2.7 eV.

$$C_2H_3CN + e^- \longrightarrow CN^- + C_2H_2^* + H \quad (10)$$

C_3N^- Ions. Figure 3(b) shows the IE curve of *m/e* 50(C_3N^-) ions with relatively strong peaks. Its shape suggests a dissociative electron capture process and an ion pair formation process. The former appears at $\sim$5 eV and the latter at $\sim$18.4 eV.

On the basis[17] of $\Delta H_f(C_3N) = 131$ kcal/mol and $EA(C_3N) = 55$ kcal/mol,[29] AP_{calcd} values of reactions (11) and (12) can be estimated as follows.

$$C_2H_3CN + e^- \longrightarrow C_3N^- + H_2 + H \quad (AP_{calcd} = 3.57\ eV) \quad (11)$$

$$\longrightarrow C_3N^- + H_2 + H^+ \quad (AP_{calcd} = 17.16\ eV) \quad (12)$$

The difference between AP_{obsd} and AP_{calcd}, $\sim$1.43 eV or $\sim$1.23 eV would be ascribed to an excess energy of C_3N^- ion.

C_2H^- Ions. Figure 3(c) shows the *IE* curve of *m/e* 25(C_2H^-) ions, where the first process appears at $\sim$4.6 eV and the second process at $\sim$18.3 eV. The values of $\Delta H_f(C_2H) \simeq 5$ eV, $\Delta H_f(HCN) = 1.3$ eV and $\Delta H_f(CN) = 3.87$ eV result in $AP_{calcd} = 6.56$ eV for reaction (13) and $AP_{calcd} = 6.87$ eV for reaction (14).

$$C_2H_3CN \longrightarrow C_2H + H + HCN \quad (AP_{calcd} = 6.56\ eV) \quad (13)$$

$$\longrightarrow C_2H + H_2 + CN \quad (AP_{calcd} = 6.87\ eV) \quad (14)$$

If an electron affinity of C_2H is assumed to be 1.96 eV, we have the following schemes.

$$C_2H_3CN + e^- \longrightarrow C_2H^- + H + HCN \quad (AP_{calcd} = 4.6\ eV) \quad (15)$$

$$\longrightarrow C_2H^- + H_2 + CN \quad (AP_{calcd} = 4.91\ eV) \quad (16)$$

$$\longrightarrow C_2H^- + H^+ + HCN + e^- \quad (AP_{calcd} = 18.19\ eV)^{30)} \quad (17)$$

$$\longrightarrow C_2H^- + H + HCN^+ + e^- \quad (AP_{calcd} = 18.46\ eV)^{31)} \quad (18)$$

$$\longrightarrow C_2H^- + H_2 + CN^+ + e^- \quad (AP_{calcd} = 20.04\ eV)^{32)} \quad (19)$$

If we assume $EA(C_2H) = 2.27$ eV we get the following results.

$$C_2H_3CN + e^- \longrightarrow C_2H^- + H + HCN \quad (AP_{calcd} = 4.29\ eV) \quad (20)$$

$$\longrightarrow C_2H^- + H_2 + CN \quad (AP_{calcd} = 4.6\ eV) \quad (21)$$

$$\longrightarrow C_2H^- + H^+ + HCN + e^- \quad (AP_{calcd} = 17.88\ eV) \quad (22)$$

$$\longrightarrow C_2H^- + H + HCN^+ + e^- \quad (AP_{calcd} = 18.15\ eV) \quad (23)$$

$$\longrightarrow C_2H^- + H_2 + CN^+ + e^- \quad (AP_{calcd} = 19.73\ eV) \quad (24)$$

Reaction (19) or (24) might be excluded. This suggests the possibility of reaction (15) rather than reaction (16). Introduction of $EA(C_2H) = 1.96$ eV appears to make the assignment of reactions (15) and (17) or (18) possible. To assume $EA(C_2H) = 2.27$ eV requires 0.31 eV and 0.42 eV or 0.15 eV for an excess energy of C_2H^- ion under the assignment of reactions (20) and (22) or (23). Although the possibility of excess energy of the fragment makes the situation complicated, it should be noted that the value of the electron affinity of C_2H is relatively large and the value of $EA(C_2H) \gtrsim 2$ eV is reasonable.

C_2N^- Ions. As shown in Fig. 3(d), the shape of the IE curve is a little complicated in the range 9—11 eV. We got $AP_{obsd} \simeq 4.9$ eV. The values of $\Delta H_f(C_2N) = 5.3$ eV and $\Delta H_f(CH_3) = 1.39$ eV give a value of 4.69 eV for AP_{calcd} of reaction (25), $AP_{calcd} = 8.06$ eV also for reaction (26).

$$C_2H_3CN \longrightarrow C_2N + CH_3 \quad (AP_{calcd} = 4.69\ eV) \quad (25)$$

$$\longrightarrow C_2N + CH_2 + H \quad (AP_{calcd} = 8.06\ eV) \quad (26)$$

Combining AP_{calcd} (=8.06 eV) with AP_{obsd} ($\simeq$4.9 eV), we have $EA(C_2N) \simeq 3.16$ eV. Judging from $EA(CN) = 3.4$ eV, $EA(C_3N) = 2.4$ eV and $EA(C_5N) = 2.3$ eV, the value of $EA(C_2N) \simeq 3.16$ eV is reasonable, in other words, the following reaction would be assigned.

$$C_2H_3CN + e^- \longrightarrow C_2N^- + CH_2 + H \quad (27)$$

The following ion-pair process was difficult to detect.

$$C_2H_3CN + e^- \longrightarrow C_2N^- + H^+ + CH_2 + e^- \quad (AP_{calcd} \simeq 18.5\ eV) \quad (28)$$

HCN^-. Three processes were observed (Fig. 4(a)). The values of AP_{obsd} were $\ll$2 eV, 3.0 eV and 5.6 eV. Although the possibility of $C_2H_3^-$ ions for *m/e* 27 ions might be considered, combining of AP_{calcd} (=4.7 eV) of reaction (29) with AP_{obsd} lower than 2 eV leads to $EA(C_2H_3)$ larger than 2.7 eV. This seems to be too large to be acceptable. Thus, it can be excluded:

$$C_2H_3CN \longrightarrow C_2H_3 + CN \quad (AP_{calcd} = 4.7\ eV) \quad (29)$$

Using $EA(HCN) \gtrsim 1$ eV[15] and $(C_2H_2)^* = 2.7$ eV (introduced temporarily) the following reactions might be assigned.

$$C_2H_3CN + e^- \longrightarrow HCN^- + C_2H_2 \quad (AP_{calcd} \lesssim 0.65\ eV) \quad (30)$$

$$\longrightarrow HCN^- + C_2H_2^* \quad (AP_{calcd} \lesssim 3.35\ eV) \quad (31)$$

27) $\Delta H_f(CH) = 6.16$ eV (refer to 26).
28) $\Delta H_f(C_2) = 8.52$ eV (refer to 18).
29) $EA(X)$: electron affinity of X.
30) $IP(H) = 13.59$ eV (refer to 26). $IP(X)$: ionization potential of X.
31) $IP(HCN) = 13.86$ eV (refer to 18).
32) $IP(CN) = 15.13$ eV (refer to 18).

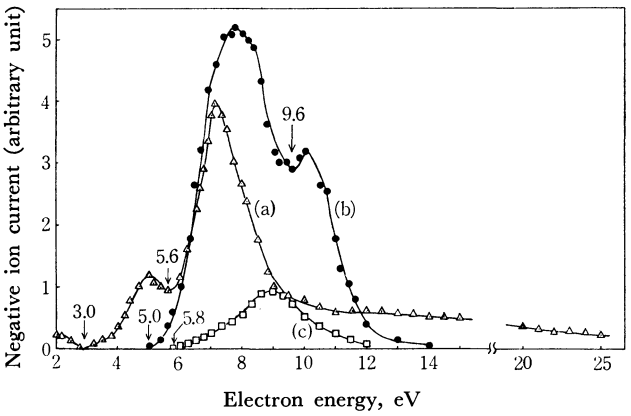

Fig. 4. Ionization efficiency curves of *m/e* 27(HCN^-), *m/e* 39($CHCN^-$) and *m/e* 40(CH_2CN^-) ions.
△ HCN^- ● $CHCN^-$ □ CH_2CN^-

$$\longrightarrow HCN^- + C_2H + H \quad (AP_{calcd} \leq 5.56\ eV) \qquad (32)$$

$CHCN^-$ Ions. Figure 4(b) shows $AP_{obsd}=5.0$ eV and 9.6 eV. By using $\Delta H_f(CHCN)=4.2$ eV[15] we have

$$C_2H_3CN \longrightarrow CHCN + CH_2 \quad (AP_{calcd} = 4.7\ eV) \qquad (33)$$

Moreover, $EA(CHCN) \geqq 1.1$ eV[15] leads to the following result.

$$C_2H_3CN + e^- \longrightarrow CHCN^- + CH_2 \quad (AP_{calcd} \leq 3.6\ eV) \qquad (34)$$

Thus, combining of AP_{calcd} with AP_{obsd} (=5.0 eV) requires a value of $\geqq 1.4$ eV as an excess energy of the fragment.

Next, let us consider the possibility of $C_3H_3^-$ ions.

$$C_2H_3CN \longrightarrow C_3H_3 + N \quad (AP_{calcd} = 5.9\ eV)^{33} \qquad (35)$$

Introduction of $EA(C_3H_3)=0.9$ eV appears to make possible the interpretation of $AP_{obsd}=5$ eV. Since no $C_3H_3^-$ ion from hydrocarbons has been obtained, they may be excluded.

For $AP_{obsd}=9.6$ eV, the following reaction would be assigned.

$$C_2H_3CN + e^- \longrightarrow CHCN^- + CH + H \quad (AP_{calcd} \leq 9.52\ eV) \qquad (36)$$

CH_2CN^- Ions. These ions show only one process having the appearance potential at ~5.8 eV (Fig. 4(c)). $\Delta H_f(CH_2CN)=1.96$ eV,[15] $EA(CH_2CN) \geqq 1.64$ eV[15] and $\Delta H_f(CH)=6.16$ eV give a value of $\leqq 4.48$ eV for AP_{calcd} of the following reaction.

$$C_2H_3CN + e^- \longrightarrow CH_2CN^- + CH \quad (AP_{calcd} \leq 4.48\ eV) \qquad (37)$$

The reaction might also be accompanied with an excess energy of fragments; $\geqq 1.32$ eV.

33) $\Delta H_f(C_3H_3)=3.0$ eV (refer to 26). $\Delta H_f(N)=4.9$ eV (refer to 18).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2277—2279 (1973)

Improvement of Zone Melting Apparatus. I. Zone Melting Apparatus with a Device to Prevent Breakage of a Sample Tube

Nobuko I. WAKAYAMA, Yasuko NAKANO, and Yo-ichiro MASHIKO
National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received November 14, 1972)

A glass sample tube is widely used in zone melting of organic substances since it is transparent, inert to most substances and easily prepared in the laboratory. The glass tube, however, is frequently broken owing to the volume increase of the sample. A new device was worked out to prevent breakage of the sample tube, to purify the sample efficiently and to make replacement of the atmosphere inside the sample tube possible. The apparatus requires much less space than for one ever reported and consists of a sample tube with a set of stainless steel spring and Teflon plug and a new mechanism for carrying it. It was successfully used for biphenyl and *p*-dichlorobenzene.

Zone melting with a sample container is sometimes useful in preparing very pure materials which have high vapor pressure and low surface tension. A glass tube is usually used as a sample container because of its transparency, inertness to most substances and applicability up to 500 °C. However, it undergoes frequent breakage due to volume increase of the sample during zone melting. This paper deals with a new zone melting apparatus which prevents breakage and operates safely and reliably.

The following two methods have been reported to prevent breakage of the sample tube. (a) A glass plug is inserted into the open end of a Teflon sample tube, or a Teflon stick is used as a plug of a glass sample tube for absorbing the volume change of the sample.[1,2] (b) A spring and a tapered glass are put at the bottom of the sample tube for the same purpose.[3]

In order to obtain ultra-pure organic compounds by the zone melting method, gases which react with molten organic compounds and produce some impurities must be removed. Thus for the preparation of the ultra-pure sample for phosphorescence and fluorescence

1) M. J. Joncich and D. R. Bailey, *Anal. Chem.*, **32**, 1578 (1960).
2) N. J. G. Bollen, M. J. van Essen, and W. M. Smit, *Anal. Chim. Acta*, **38**, 279 (1967).
3) F. Ordway, *Anal. Chem.*, **37**, 1178 (1965).

measurement, the atmosphere of the sample tube should be kept under vacuum or replaced by an inert gas. When compounds such as alkali halides, which decompose at melting in the air are to be purified, the atmosphere should be replaced by gases such as halogens.

Thus attention should be focused on replacement of atmosphere as well as protection from breakage of the sample tube. Method (a) is insufficient for replacing atmosphere because of lack in air-tightness.

In our method we used a sealed glass sample tube containing a Teflon plug and a stainless steel spring as a buffer for volume change of sample as shown in Fig. 1 (a), (b). A Teflon plug is more easily made than a glass bar. It is inert to organic compounds and has low thermal conductivity, but is not suitable for use at temperature above 250 °C. When this sample tube is used, each molten zone should be formed first at a point adjacent to the Teflon plug with the heater H 1 in order that the volume increase caused by melting is absorbed by the spring.

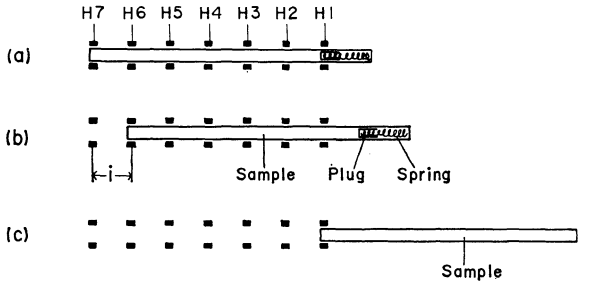

Fig. 1. Reciprocal motion in zone melting. In our mechanism a sample tube reciprocates the distance i between the position (a) and (b). With Sloans' mechanism, at first a sample tube starts from the position (c).

Sloan and McGowan[4] reported a method preventing breakage of the sample tube without the use of a spring and a plug. All the heaters are kept on during the operation in their case. At first a sample tube is located out of the row of the heaters as shown in Fig. 1(c). It slowly moves through the row of the heaters till the left end of the sample tube comes across the left end heater. Then the sample tube reciprocates the distance between the two neighbouring heaters.

We have devised a new mechanism of carriage which requires half the space used by Sloan and McGowan for movement of the sample tube. It operates automatically from beginning to end. First the tube is located at position (a) in Fig. 1. While the heater H 1 is on, it travels one interval i slowly to position (b). The volume increase of molten zone pushes the plug in order to be absorbed by the spring. The tube then returns to the initial position (a) in a few seconds. The zone molten by H 1 is now located at the position H 2. At this moment the heater H 2 is switched on and the sample tube moves from position (a) to (b) again slowly. The heater H 1 makes a new molten zone again. The volume increase of a newly molten zone is also absorbed by the spring. Thus at each return the heaters are switched on one by one, H 1, H 2, H 3, ····· starting from the bottom of the sample tube. After all the heaters are switched on, they are maintained until the end of the zone melting operation.

Even if any buffer is placed at one end of the sample tube, it cannot absorb the volume increase in the middle of the tube when all the heaters are switched on at once. Thus when many heaters are used to improve the efficiency of zone melting, mere insertion of a plug and a spring is unsatisfactory for preventing breakage perfectly. Our new mechanism of carrying the sample tube and switching on the heaters makes the spring absorb every volume increase of a molten zone, thus preventing breakge of the sample tube perfectly, purifying the sample efficiently and requiring much less space than that previously reported. In addition the replacement of atmosphere is accomplished.

Description of Apparatus

A diagram of the sample tube is given in Fig. 1 (a), (b). Tubes with 10 or 25 mm in outer diameter and 1200 mm in length were used. The apparatus is shown in Fig. 2. The sample tube driven by a motor M 1 travels horizontally one interval i (50 mm) for 2/3, 1, 2 or 4 hours and returns rapidly by another motor M 2 through the row of sixteen heaters H and seventeen coolers C. The rate of the tube is changeable by the combination of the gears G 1,2. Water flows through the coolers. The heaters are made of nichrome wire. Switching on the heaters and movement of the tube are controlled by a microswitch Ms. The tube supported by a roller R rotates by a motor M 3 (44 r.p.m.) to make the concentration of liquid zone uniform.

Results and Discussion

Most organic compounds expand when they melt. The apparatus was tested with biphenyl (volume change 12%, mp 71 °C) and *p*-dichlorobenzene (22%, 53 °C) in nitrogen atmosphere. In the case of biphenyl the sample near the plug was colorless and transparent crystals with cracks. Far from the plug yellowish crystals rich in impurities were observed. When biphenyl was zone refined using a 25 mm O. D. sample tube, the movement of the plug was observed. The result was as follows: The number of zone passes 3- the distance of the movement 7 mm, 8—18 mm,

4) G. J. Sloan and N. H. McGowan, *Rev. Sci. Instr.*, **34**, 60 (1963).

13—26 mm, 24—41 mm, 27—50 mm. A similar result was obtained for *p*-dichlorobenzene. The apparatus will be useful for other organic compounds which expand on melting.

The authors are indebted to Mr. K. Tsuji of the Institute for Solid State Physics, the University of Tokyo, for his valuable advice and technical help in the construction of the apparatus.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2279—2284 (1973)

ESR Studies on Radical Anions of Calicene Derivatives

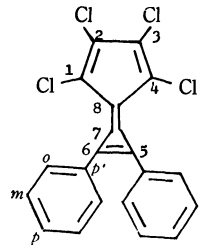
Shiro KONISHI, Shigeya NIIZUMA, Hiroshi KOKUBUN, and Masao KOIZUMI
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received December 18, 1972)

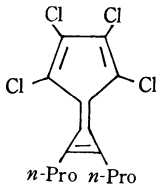
Two calicene derivatives, 1,2,3,4-tetrachloro-5,6-diphenylcalicene and 1,2,3,4-tetrachloro-5,6-di-*n*-propylcalicene, were reduced with an alkali metal in degassed tetrahydrofuran and the ESR spectra of the resluting mono-anion radicals were investigated. It was found that in both anion radicals the unpaired spin does not exist on the five-membered ring, and is localized only on the other part. In the latter anion radical, the five-membered and three-membered rings were found to be twisted toward each other at about 45°, a line width alternation caused by hindered internal rotation of two adjacent *n*-propyl groups being observed. The potential barrier for the hindered rotation was determined to be about 1.5 kcal/mol.

Cycloheptatrienecyclopentadiene, commonly called calicene, has a very unique structure consisting of unsaturated five-membered and three-membered rings bonded to each other. Its derivatives were first synthesized by Kende and Izzo,[1,2] Jones and Pyron[3] and also by Prinzbach and Fischer.[4] Since then, many derivatives have been synthesized, their physical and chemical properties being studied extensively. However, no ESR studies on their ion radicals have yet been reported.

Using two species of calicene derivatives, 1,2,3,4-tetrachloro-5,6-diphenylcalicene [PhC] and 1,2,3,4-tetrachloro-di-*n*-propylcalicene [PrC], we succeeded in preparing their anion radicals. This paper reports the details of ESR studies on these anion radicals which were briefly reported previously.[5]



[PhC]



[PrC]

Experimental

Materials. Two calicene derivatives PhC and PrC were prepared by Ueno *et al.* and Kitahara *et al.*[6,7] Tetrahydrofuran [THF] (Wako Junyaku Co.) was distilled after being refluxed over sodium wire for several hours, dehydrated with sodium-potassium alloy and degassed by freeze-thaw cycles. Sodium (Wako Junyaku Co.) and potassium (Kanto Kagaku Co.) metals were used.

Procedures. Anion radicals were prepared by bringing degassed THF solutions of calicenes into contact below −30 °C with a sodium or a potassium mirror deposited by vacuum evaporation.

In the case of PhC, the solution turned bluish green when it was warmed slowly up to room temperature. The anion radical thus obtained was very stable at room temperature giving a well resolved ESR spectrum. However, it turned reddish brown and lost the ESR signal when kept in contact with the mirror for a long time.

In the case of PrC, the ESR signals observed at low temperatures disappeared rapidly when warmed to room temperature. We therefore introduced the degassed solution previously cooled in a dry ice-methanol bath into a glass capillary also degassed, with an alkali metal mirror deposited on the wall, and immediately inserted the capillary into a low temperature apparatus attached to an ESR cavity. In this way the light yellow solution gave a stable ESR signal below −30 °C where the temperature dependence was reversible. With a gradual rise of temperature above −30 °C, the pattern of the signal changed irreversibly and finally disappeared at room temperature.

A JEOL P-10 type ESR spectrometer (X band, 100 kHz modulation) was used. A NEAC 2200 MODEL 500 Electronic Computer in the Calculation Center of Tohoku University was used for the simulation of ESR spectra and the calculation of spin densities.

Results and Discussion

Hyperfine Structure. Figure 1 shows the observed and simulated ESR spectra of PhC anion radical obtained with the use of sodium and potassium. Only

the right halves of ESR spectra are illustrated because of their symmetry with respect to the central lines. The simulated spectra agree satisfactorily with the observed ones. Simulations were performed by assigning a set of different hfs constants to two sets of four protons and one set of two protons. These protons naturally belong to two equivalent phenyl groups. The total separation of the hyperfine structure due to the protons of the two phenyl groups is about 22 Gauss. This implies that the unpaired spin mainly exists on the two phenyl groups.

Spin Density Calculation of PhC Anion Radical. The unpaired spin densities of PhC anion radical were calculated by the simple Hückel and McLachlan methods to interpret the observed hfs constants, assuming all rings are coplanar. It has been reported that for the calculation of electronic states of PhC neutral molecule, consideration of bond length alternation[8] is desirable; accordingly a similar treatment was also taken into account in the present calculation.

The results are shown in Table 1. It is evident that the unpaired spin does not exist (simple Hückel) or scarcely exists (McLachlan) on the five-membered ring and also on the 7-carbon atom. This conclusion is quite independent of bond length alternation.

According to results from the simple Hückel method,

the orbital occupied by the unpaired spin belongs to a_2, corresponding to the lowest vacant orbital of *cis*-stilbene. Thus the PhC anion radical is almost the same as the *cis*-stilbene anion radical. The ESR of the latter, however, has not yet been reported, the transform being much more stable.

The localization of the unpaired spin on two phenyl groups and on C_5 and C_6 agrees very well with the expectation based on the analysis of ESR spectra. Spin densities evaluated by the four methods are plotted against hfs constants in Fig. 2. A fairly good straight line passing through the origin can be drawn for the values obtained by McLachlan method without bond length alternation. From its slope,

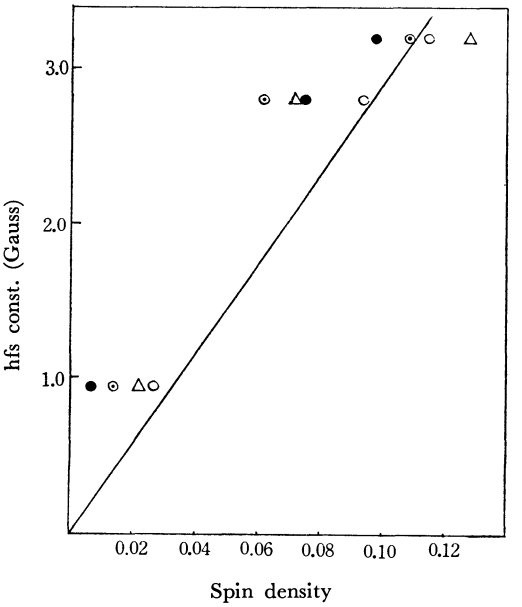

Fig. 2. A plot of hfs constants *vs.* spin densities.

the ordinary McConell's Q-value of 29 Gauss is obtained. Consideration of bond length alternation does not give any improvement. A similar result was reported by Ikegami *et al.* for the case of the tropone anion radical.[9]

The observed and the simulated ESR spectra of PrC anion radical at −51 °C are shown in Fig. 3.

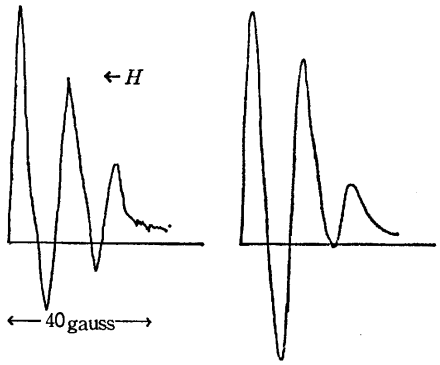

Fig. 3. ESR spectra of PrC anion radical at −51 °C.
left side; observed
right side; simulated

Under over modulation, the spectrum consists of five lines with the approximate intensity ratio 1 : 4 : 6 : 4 : 1. Thus the simulation was carried out by considering four equivalent protons. A hfs constant was found to be 14 Gauss. These must be β-protons of two n-propyl groups.

Generally, a hfs constant of β-protons of an alkyl group a_β^H is given by the following equation.[10]

$$a_\beta^H = B\langle\cos^2\theta\rangle\rho_C$$

where ρ_C is the spin density of carbon atom to which the alkyl group attaches, B is a constant in the range 40∼56 Gauss and θ is the angle between the axis of ring carbon $2p_z$ orbital and the carbon-hydrogen bond both projected on the plane perpendicular to $C_\alpha-C_\beta$ axis. If free rotation of the alkyl group is is allowed, $\langle\cos^2\theta\rangle$ is equal to 1/2. Then from the above equation ρ_C becomes equal to or greater than 1/2 in the present case. Thus we can say that the spin is localized only on C_5 and C_6.

Spin Density Calculation of PrC. In calculating the unpaired spin densities of PrC, we must consider whether the three-membered and five-membered rings are coplanar or not. A molecular model for PrC demonstrates that chlorine atom bonded to C_1 or C_4 and δ-hydrogen atom of n-propyl groups collide with each other if free rotation is assumed for the latter group. To allow this free rotation without collision with chlorine atoms, the three-membered and five-membered rings should be twisted at an angle greater than 45°. In view of the fact that free rotation around the C_7—C_8 bond has been reported for 1-formyl-5,6-di-n-propylcalicene[11] at temperatures higher than room temperature on the basis of NMR data, the above geometry for PrC in our case seems to be quite reasonable although the radical is ionic and the temperature is below room temperature.

Thus, it was assumed that the five-membered and three-membered rings are not in general coplanar. In calculating the spin densities of PrC, a parameter $\cos^2\alpha$ (α is an angle between two rings) was introduced for the resonance integral between C_7 and C_8 and the calculation was made for various α-values. In the case of PhC anion radical, the unpaired spin densities were found to be independent of α, but there is no steric hindrance according to the model constructed, so that all the rings are considered to be coplanar in the PhC anion radical.

The effect of hyperconjugation was taken into account since it is generally believed that the hfs constant of an alkyl group is mainly due to this. In the actual calculation we regarded a n-propyl group as —C≡H_2R and used the following parameters.[12,13]

$$C_{5\,(\text{or }6)} \overset{1.0\beta}{\text{——}} \underset{\alpha-0.1\beta}{C_\beta} \overset{2.5\beta}{\text{═══}} \underset{\alpha-0.5\beta}{H_2R}$$

We considered that the above procedure is sufficient as a first approximation and made no use of other more refined methods.[14,15] Only the result by Hückel method is shown in Fig. 4, because McLachlan method gives an essentially similar result. When α is greater than 40°, the spin densities on C_5, C_6 and on H_2R are respectively 0.42 and 0.076 (Fig. 4). The latter leads to a splitting constant of a methylene proton $508\times0.076\times1/3=12.9$ Gauss which agrees fairly well with the observed value.

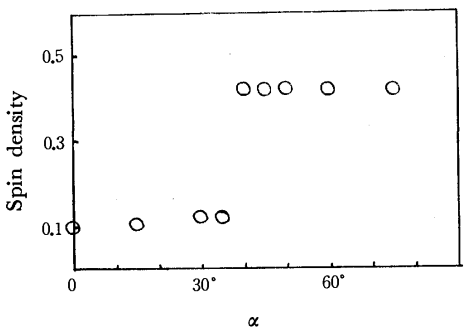

Fig. 4. A plot of spin density on position 5 or 6 *vs.* twisting angle α.

Reason for a Sudden Spin Density Change at around 40°. An unusual dependence of spin density on α appears, increasing only very little from $\alpha=0$ to $\alpha<40°$, but suddenly jumping at 40° and then remaining constant. The reason for this is as follows.

The PrC anion radical is a 21 π-electron system including hyperconjugation of two n-propyl so that the unpaired electron occupies the 11th orbital. According to results obtained by the simple Hückel

calculation the energy for two types of orbitals either depends or does not depend on angle α. These orbitals belong to b_1 and a_2 respectively, assuming PrC molecule has C_{2v} symmetry. The 11th orbital occupied by the unpaired electron at $\alpha=0$ belongs to the former and the 12th orbital to the latter. The energy of the 11th orbital increases with the increase in α, moving above the 12th level for $\alpha>40°$. Inversion occurs at 40° between 11th and 12th levels. Thus when α exceeds 40°, the unpaired electron occupies the 12th orbital (when $\alpha=0$) whose energy is independent of α. The angle α at which the inversion occurs depends slightly on the parameters of hyperconjugation. The increase of the total electronic energy due to twisting is about 0.42 β/mol which is equal to 6.9 kcal/mol at $\alpha=45°$ if resonance integral β is assumed to be 16.5 kcal/mol.[8]

Observation of Line Width Alternation. In the ESR spectrum of PrC anion radical (Fig. 3), the second line from the right is broader than the others. We examined the temperature dependence of ESR spectra, the results for potassium and sodium reduction being given in Figs. 5 and 6. Line width changes remarkably only in the second line. The temperature dependence is almost completely reversible, and is considered to be due to the line width alternation.

Hindered Rotation as a Cause of Line Width Alternation. The line width alternation might be attributed to the hindered rotation of two *n*-propyl groups. The molecular model constructed shows that the free rotation

of each *n*-propyl group around C_α–C_β, $C_{\alpha'}$–$C_{\beta'}$ axis is not allowed because of mutual steric hindrance of the two groups. It is expected that certain stable conformations exist and the transformation from one to another occurs with characteristic frequencies determined by the potential barriers between them. In the frozen state at −150 °C, PrC anion radical gives a spectrum with the intensity ratio 1 : 2 : 1, suggesting that the spectrum arises mainly from only two equivalent protons and that the other protons have fairly small hfs constants. This implies that the C_β—H or $C_{\beta'}$—H bond belonging to the former group has a small angle to the axis of $2p_z$ orbital of C_5 or C_6 and the one belonging to the latter a large angle.

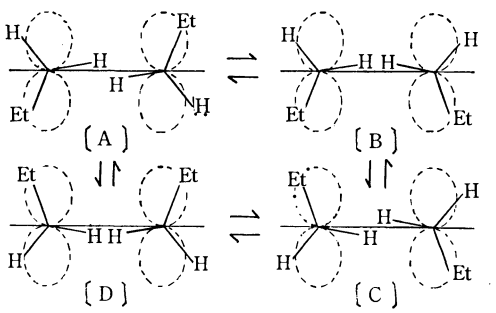

Fig. 7. Equilibrium four conformations.

The four conformations shown in Fig. 7 are most plausible as stable ones. All other conformations conceivable can be eliminated because of a strong steric hindrance between two R-groups.

Simulation Analysis of Line Width. In order to analyze the present result we made use of a theory developed and applied successfully to a similar system to ours.[16,17] According to the theory, the average magnetization to the four conformations (Fig. 7) is expressed as follows.

$$\langle\overline{G}\rangle = -i\omega_1 M_0 \times \left\{ \frac{(2+3\eta\tau)(2+2\eta\tau)+\tau^2(1+\eta\tau)(\eta_C\eta_D+\eta_A\eta_B)}{2\eta+3\eta^2\tau+\tau(1+2\eta\tau)(\eta_C\eta_D+\eta_A\eta_B)+\tau^3\eta_A\eta_B\eta_C\eta_D} \right\}$$

where $\omega_1 M_0$ is a constant intensity factor, subscripts A, B, C, D refer to the four conformations and τ[18] is the lifetime of each conformation. The η's are defined by the following expression.

$$\eta_A = 1/T_2 - i(\omega_0 - \omega + \omega_A)$$
$$2\eta = \eta_A + \eta_B = \eta_C + \eta_D$$

where $1/T_2$ is the line width in the absence of conformation change, ω_0 the Larmor precession frequency of the electron in the absence of hyperfine interaction and ω_A the shift in resonance frequency due to interactions with protons in conformation A. The imaginary part of $\langle\overline{G}\rangle$ gives an absorption spectrum. In the present case ω_A's were determined for each state of sixteen nuclear spin states and $1/T_2$ was equated to the observed line width of the end line. For simulation the absorption line was converted into the first differential by numerical differentiation for comparison with the observed spectra. Calculations were made by use of an electronic computer.

In the case of potassium reduction (Fig. 5), a constant quantity of absorption, about 1/20 of the total, should be added to the central line in order to get a good agreement with the experiment. This may be due to an impurity or a certain radical produced by some side reaction. Simulation spectra agree very well with the observed ones. Simulation was similarly made for sodium reduction (Fig. 6). For the end line and its adjacent line the agreement between observed and simulated ones is good. However, the simulated spectra differ from the observed ones in the central region where the latter is more intensive and has a small shoulder. The disagreement may be due to the same reason as in the case of potassium reduction. This is supported by the fact that strength of the central line increases and the shoulder becomes remarkable with the rise in temperature, and that this is not reversible. The best values for the hfs constants of protons are 24 and 4 Gauss for both potassium and sodium reduction and are quite consistent with the conformation in Fig. 7.

Potential Barrier Height of Hindered Rotation. The potential barrier height of the hindered rotation of *n*-propyl groups can be determined from the temperature dependence of lifetime τ or the first-order rate constant k $(=1/\tau)$. A plot of $\log_{10}(1/\tau)$ against $1/T$ is given in Fig. 8. The linearity is satisfactory. Activation energies E_A and frequency factors k_0 are determined from the slopes and the intercepts of two lines, the values being 1.6_5 kcal/mol, 1.3×10^{11} s^{-1} for potassium reduction and 1.4_1 kcal/mol, 6.2×10^{10} s^{-1} for sodium reduction. The difference in values for the two cases may be due to the difference in the perturbation by cations.

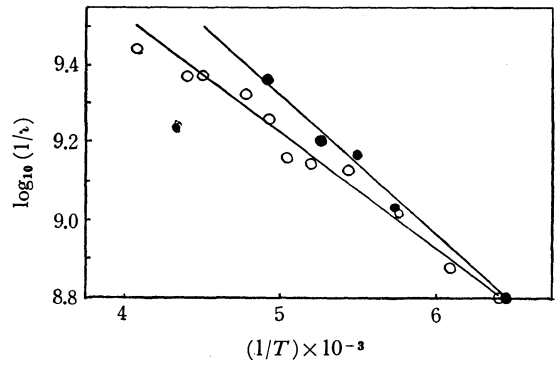

Fig. 8. A plot of $\log_{10}(1/\tau)$ *vs.* $1/T$.
○: Na reduction, ●: K reduction

Stone and Maki[19] discussed the internal rotation of an alkyl group of nitroalkane anion radical in solution from a quantum mechanical viewpoint. According to them the height of the potential barrier for internal rotation is 1.4 kcal/mol, and the spin density on nitrogen atom to which an alkyl group links is 0.7±0.1. Ishizu *et al.* also reported a similar equilibrium conformation for 2,2′-dialkylbiphenyl.[20]

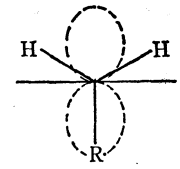

Fig. 9. Possible equilibrium conformation for RCH_2-Ar.

The conformation is given in Fig. 9. The hindered rotation of the present system is similar to that of this compound. Miyagawa and Itoh[21] obtained 3.6±0.2 kcal/mol and $(10\pm4)\times10^{12}$ s^{-1} as the value of E_A and k_0 respectively for rotation of a methyl group in $CH_3\dot{C}HCOOH$ radical produced in a single crystal of L-alanine by γ-ray irradiation. Iwaizumi and Isobe[22] have reported on the inversion of two benzene ring planes in 4,5,9,10-tetrahydropyrene anion radical (non-planer molecule) $2.0—9.0\times10^{-6}$ s (−90 °C)

Bond Distortions and Related Phenomena in *Peri*-Condensed Tetracyclic Nonbenzenoid Aromatic Hydrocarbons

Azumao TOYOTA and Takeshi NAKAJIMA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received December 25, 1972)

On the basis of the second-order Jahn-Teller effect and SCF MO method, we have examined the geometrical structures with respect to bond length and the ground-state multiplicity and stability of *peri*-condensed tetracyclic nonbenzenoid aromatic hydrocarbons. It was found that of the molecules examined, dibenzo[cd, gh]pentalene (III) and its seven-membered analogue (IV) should have a triplet ground-state, exhibiting no appreciable double-bond fixation in the peripheral carbon skeleton. The other molecules were predicted to suffer the first-order or second-order bond distortions, showing a more or less marked double-bond fixation. The electronic spectra were calculated using the bond distances obtained on the basis of SCF MO method.

In a previous paper[1] we developed a symmetry rule for predicting the stable molecular shapes with respect to C–C bond length in the ground and electronically-excited states of conjugated molecules. The symmetry rule[2–7] is based on the second-order Jahn-Teller effect, occurring when a certain bond distortion mixes two electronic states which are nearly degenerate in the symmetrical nuclear arrangement. On the basis of this theory, we examined the bond-length distributions and stabilities of a large number of non-alternant hydrocarbons.

In this paper we examine the bond distortions and related phenomena in *peri*-condensed tetracyclic nonbenzenoid aromatic hydrocarbons containing a pentalene or a heptalene nucleus (Fig. 1). Of these systems, the dianion of dibenzo[cd, gh]pentalene(III) has recently been synthesized by Trost and Kinson.[8]

There are two equilibrium nuclear arrangements in the ground state for pentalene, the closest derivative of which, 1-methylpentalene, has recently been synthesized by Bloch *et al.*[9] and for heptalene, which has already been synthesized by Dauben and Bertelli.[10] One belongs to molecular symmetry group D_{2h} which exhibits only a slight degree of double-bond fixation in the peripheral carbon skeleton, and the other to molecular symmetry group C_{2h} exhibiting a marked double-bond fixation.[1,11–15] It was revealed that the latter is energetically more stable than the former. These predictions are in good agreement with experimental results.[9,10] This aroused our interest in an examination of the stable nuclear arrangements and molecular symmetries of condensed hydrocarbons containing a pentalene or a heptalene nucleus.

One interesting prediction of molecular orbital theory is the possibility that certain symmetrical molecules may have a triplet ground state. For example, in the case of 1.2-5.6-dibenzopentalene, the triplet state is predicted to be more stable than the closed-shell singlet state in the symmetrical C_{2v} conformation (Fig. 2). However, in this molecule the closed-shell singlet interacts strongly with the first excited singlet state through the b_2 nuclear displacement because of the small energy gap between them.[1] As a result, the ground state turns out to be a singlet with C_s conformation.

Breslow *et al.*[16] observed a thermally accessible triplet state of pentaphenylpentadienyl cation in equilibrium with a singlet state, and also the stable triplet ground state of pentachlorocyclopentadienyl cation. Van Willigen *et al.*[17] observed the triplet ground states of triphenylbenzene dianion, triphenylene dianion *etc.*, and suggested that in triphenylene dianion the trigonal symmetry is lost. The origin of the molecular sym-

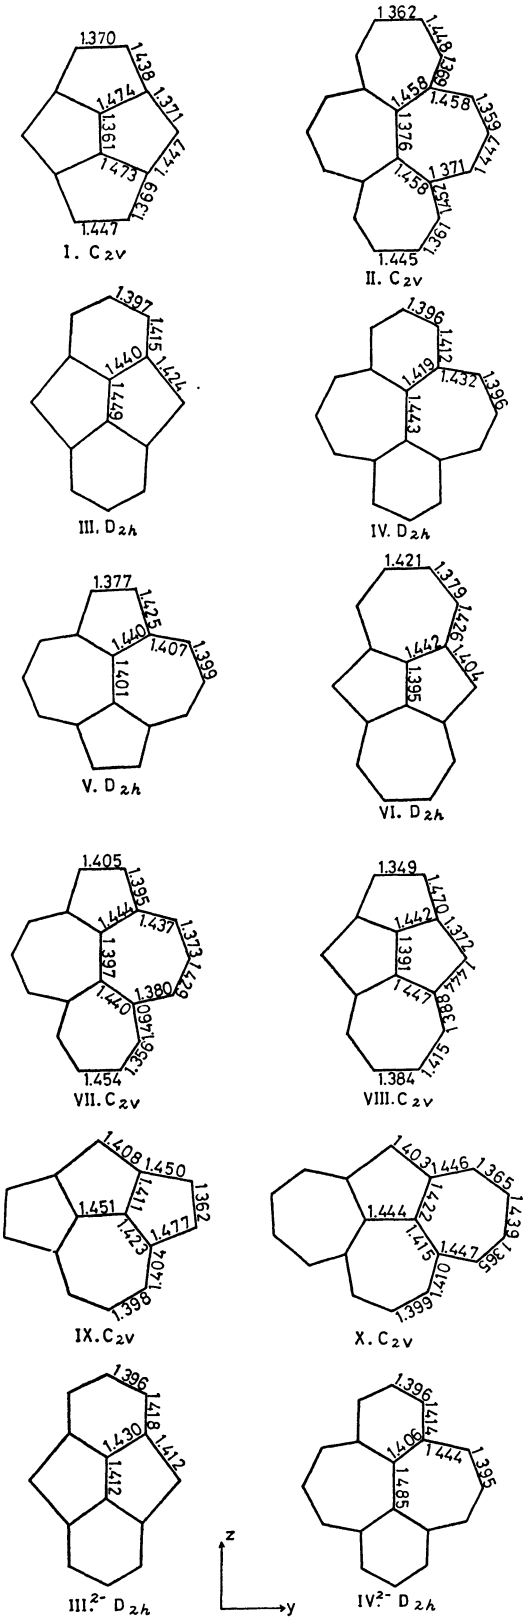

Fig. 1. Molecular symmetry groups, bond lengths (in Å), and choice of axes.

metry reduction has been ascribed to the perturbing effect of alkali counterions, since in this molecule the energy gap between the lowest triplet ground and the first excited triplet states is relatively large, and

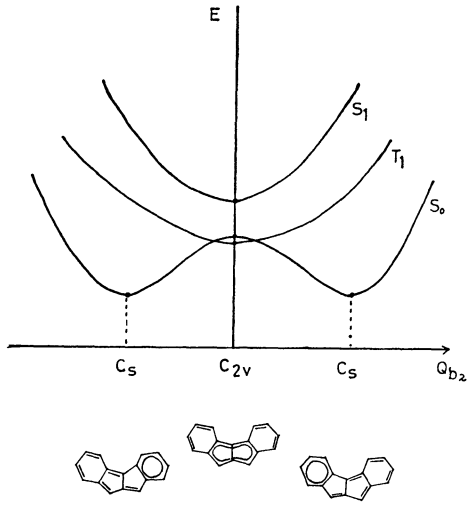

Fig. 2. The potential energy curves for the lowest singlet (S_0), the first singlet excited (S_1) and the lowest triplet states (T_1) of 1.2-5.6-dibenzopentalene.

there is no possibility for the second-order Jahn-Teller distortion to occur.[18,19]

The purpose of this paper is to predict the ground-state multiplicities, energetically most favorable symmetry groups and the equilibrium bond length of the *peri*-condensed nonalternant hydrocarbons, using the symmetry rule which is based on the second-order perturbation theory and the variable bond length SCF MO method.[20] The ground-state π-electronic properties and the electronic spectra were also examined.

Theoretical

We start by assuming a particular symmetrical nuclear configuration for a molecule. This will place the molecule in a certain fully-symmetrical point group. We treat the nuclear displacements as perturbations and use the second-order perturbation theory. On the basis of the same approximation as used previously, we find that the force constant for the ith normal nuclear-displacement in the ground state may be written as

$$f_0{}^i = k - 2\sum_n{}' \frac{\left|\langle\psi_n\left|\frac{\partial H_\pi}{\partial Q_i}\right|\psi_0\rangle\right|^2}{(E_n - E_0)}$$

where k and H_π are the force constant for an sp^2 hybridized C–C σ-bond and the Hamiltonian for π-electrons, respectively. ψ_0 and ψ_n represent the ground and the nth excited wavefunctions with respective energies E_0 and E_n.

The symmetry rules for predicting the stable molecular shapes in the ground state are as follows: the symmetry of the normal nuclear displacement with

18) J. A. M. van Broekhoven, H. van Willigen, and E. de Boer, *Mol. Phys.*, **15**, 101 (1968).
19) J. L. Sommerdijk and E. de Boer, *J. Chem. Phys.*, **50**, 4771 (1969).
20) H. Yamaguchi, T. Nakajima, and T. L. Kunii, *Theoret. Chim. Acta*, **12**, 349 (1968).

the smallest force constant is identical with that of the lowest excited state, ψ_1. If the energy gap ($E_1 - E_0$) is smaller than the critical value, about 1.2 eV, the molecule would be distorted into a less symmetrical nuclear configuration. The most favorable type of bond distortion is predicted by examining the distribution of the transition densities ρ_{01} over the molecular skeleton.

The symmetry rule gives only the type of most favorable bond distortion since it is based on the second-order perturbation theory. In order to obtain information on the actual magnitudes of distortions or the equilibrium bond lengths at which the nuclei of the real molecule will settle, we use the variable bond-length SCF MO method.[20]

Results and Discussion

Ground-State Molecular Symmetries and Multiplicities. The symmetries and energies (measured from the lowest singlet state) of the first excited singlet states for the fully-symmetrical nuclear arrangements of the *peri*-condensed hydrocarbons and some of their dianions are given in Table 1, and the two-center components of the transition densities for some selected molecules in Fig. 3.

Table 1. Symmetries and energies of first excited singlet states of *peri*-condensed nonalternant hydrocarbons

Molecule (Point group)	First excited state	
	$E_1 - E_0$ (eV)	Symmetry
I (D_{2h})	0.91	B_{2u}
II (D_{2h})	0.39	B_{2u}
III (D_{2h})	1.13	B_{3g}
III^{2-} (D_{2h})	3.28	B_{3g}
IV (D_{2h})	1.09	B_{3g}
IV^{2-} (D_{2h})	1.10	B_{2u}
V (D_{2h})	1.81	B_{3g}
VI (D_{2h})	1.86	B_{3g}
VII (C_{2v})	1.45	B_2
VIII (C_{2v})	1.34	B_2
IX (C_{2v})	1.34	B_2
X (C_{2v})	1.19	B_2

Molecule II was predicted to have a triplet ground state in the fully-symmetrical D_{2h} conformation. However, in molecules I and II, the energy gap between the lowest singlet and first excited singlet states $E_1 - E_0$ is small, as compared with the critical value 1.2 eV for the molecular symmetry reduction in the ground state. Thus, these molecules might undergo the second-order bond distortions making their ground-state molecular symmetry groups reduced to C_{2v} from D_{2h} by the interaction of the lowest state with the first excited state through the b_{2u} normal displacement.

We may predict that molecules V, VI, VII and VIII undergo no second-order Jahn-Teller distortion, since the energy gap is relatively large as compared with the critical value.

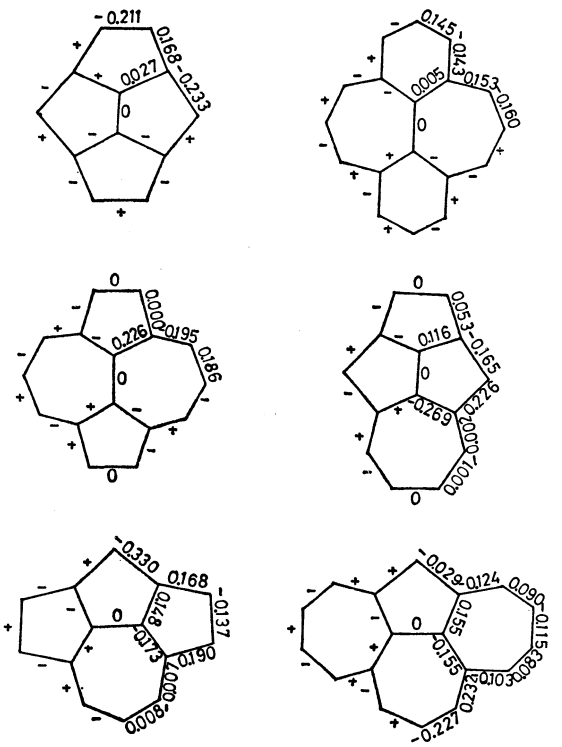

Fig. 3. Two-center components of transition densites (ρ_{01}).

The energy gap in III and IV is comparable with the critical value, and in the symmetrical D_{2h} conformation the ground state is not singlet but triplet.

The energy gap in molecules IX and X is also comparable with the critical value, but the ground state is singlet in the symmetrical C_{2v} conformation.

In order to investigate the ground-state molecular-symmetry groups, geometries and multiplicities, we have performed the SCF calculation, taking into account a distorted structure as the starting geometry.[21] The form of the displacement vector has been estimated from the distributions of two-center components of transition density ρ_{01} (Fig. 3).

SCF MO calculations revealed that molecules I and II undergo the second-order bond distortion, as predicted from the symmetry rule, their ground-state molecular symmetry groups being lowered from D_{2h} to C_{2v}. The prediction is in good agreement with the theoretical investigation of Binsch.[22] The stabilization energies which favor the lower-symmetry nuclear arrangements are estimated to be 3.1 and 17.5 kcal mol^{-1}, respectively. It is of interest to note that the second-order effect in molecules containing the seven-membered rings is greater than that in its five-membered analogues, as in the case of heptalene and pentalene.[23]

On the other hand, it turns out that III and IV undergo no second-order bond distortions. Thus, we may conclude that both their stable ground states are triplet states ($^3B_{1u}$), which are energetically more stable than the singlet states by 3.9 and 8.5 kcal, respectively.

22) G. Binsch, "Aromaticity, Pseudoaromaticity and Antiaromaticity." The 3rd Jerusalem Symposium, The Israel Academy of Sciences and Humanities, Jerusalem (1971), p. 25.
23) T. Nakajima, A. Toyota and H. Yamaguchi, *ibid.*, p. 227.

V, VI, VII, VIII, IX, and X were predicted not to undergo second-order bond distortions and all the ground-state molecular symmetries to belong to the fully-symmetrical group.

Dianions of III and IV undergo no second-order bond distortions, both their ground-state multiplicities being singlet.

Ground-State π-Electronic Properties. The calculated equilibrium bond length at the energetically favorable geometrical structures of the molecules examined are shown in Fig. 1. Since all the stable conformations of I, II, VII, VIII, IX and X belong to the molecular symmetry group C_{2v}, they have dipole moments in the ground state. The dipole moments calculated using the theoretical charge densities are 1.16, 1.23, 2.30, 2.70, 2.05, and 1.12 D, respectively

Concerning the distribution of bond length, it is of interest to note that in molecules I and II there is a marked double-bond fixation in the periphery and vinyl segment located at the center of molecule, but no appreciable one in III and IV. The bond lengths of the two benzene rings are very much smoothed out as those of the free benzene molecule.

In V and VI, the C–C skeleton is composed of two distinguishable parts: one in which bond lengths are highly equalized (in a pentalene or a heptalene core), and the other in which there is a marked double-bond fixation (in the remainder of the periphery).

In VII and VIII, a strong first-order double-bond fixation exists in the peripheral C–C skeleton, the bond length of vinyl segment located at the center of molecule being 1.4 Å.

In IX and X, there is a moderate first-order double-bond fixation in the peripheral C–C skeleton.

In dianions of III and IV, the bond lengths of a pentalene or a heptalene core are almost same as those of the free pentalene or heptalene dianion in which bond lengths are nearly equal throughout the whole molecular skeleton.

Electronic Spectra. In calculating electronic spectra, configuration mixing of the singly excited states is partially included: the number of configuration interactions considered is 28 for each molecule. The lower singlet transition energies and intensities calculated using the geometrical structures corresponding to the energetically most stable nuclear configuration are summarized in Table 2. The transition symmetries are also included. Unfortunately, there are at present no experimental spectral data available for a direct comparison of theory and experiment.

(Received December 28, 1972)

Time-resolved fluorescence spectra and the fluorescence rise and decay curves have been measured for *p*-(*N*,*N*-dimethylamino)-benzonitrile. The results demonstrate the relaxation process to be due to the interaction between the solvent and the ^1L_a state of the solute, leading to dual fluorescence.

In some molecules such as *p*-(dimethylamine)benzonitrile (DMABN)[1] and indole[2] the lowest excited singlet state is a slightly polar state of the ^1L_b type, and the highly polar ^1L_a state is not far from it. In such a case, there is a possibility that the solvent effect causes the inversion of two different energy states since the solvent effect on these two excited states seems to differ considerably. In relation to such a solvent effect, the fluorescence of DMABN has been studied in detail.[1]

In a nonpolar solvent such as cyclohexane, DMABN shows only one fluorescence band due to the transition from the ^1L_b state. However, in a polar solvent, fluorescence spectra have two peaks, since the ^1L_a state can be strongly stabilized in the excited equilibrium state because of the large dipole-dipole interaction and turn out to be the lowest excited state. Actually, from the solvent shift of the fluorescence, the dipole moment of the ^1L_a state, $\vec{\mu}(^1L_a)$,has been evaluated to be 23 D.[1]

So far no direct confirmation of the above relaxation process has been made. We have undertaken to observe the process by means of ns time-resolved fluorescence spectroscopy.

Experimental

The fluorescence rise and decay curves as well as time-resolved fluorescence spectra were obtained by exciting the solution with a 337 nm light pulse of nitrogen gas laser. Details of the apparatus were described elsewhere.[3] For the measurement of ordinary luminescence spectra, calibrated Aminco-Bowman and Hitachi MPF-2A spectrophotofluorometers were used. The absorption spectra were measured with Cary 15 and Shimadzu MPS-50L spectrometers. The temperature of a solution was controlled by a constant flow of cold nitrogen gas in a metal Dewar with quartz windows.

DMABN was recrystallized several times from cyclohexane. 2-Methyltetrahydrofuran (MTHF) was refluxed over metallic sodium wire, fractionally distilled and finally distilled under vacuum in the presence of lithium aluminum hydride. Spectrograde benzonitrile and cyclohexane were used without further purification.

Results and Discussion

DMABN shows ^1L_b fluorescence (F_b) at 365 nm and ^1L_a fluorescence (F_a) at 425 nm in MTHF solution at room temperature. The fluorescence quantum spectra at several temperatures are given in Fig. 1.

When the temperature of the solution is lowered from room temperature to −110 °C, F_a shows a remarkable red shift while F_b shows no shift at all. The former can be ascribed to the very polar structure of the ^1L_a state and increase of solvent polarity by temperature lowering, and the latter to the nonpolar nature of the ^1L_b state.[1]

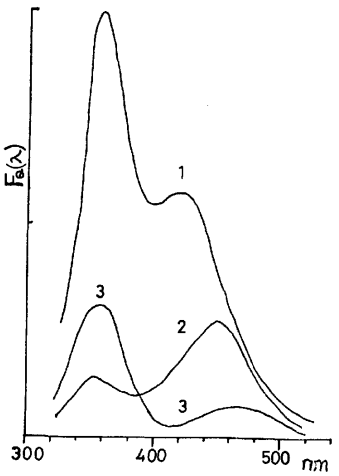

Fig. 1. Fluorescence quantum spectra of DMABN in MTHF at various temperatures.
1: room temperature (~20 °C), 2: −50 °C, 3: −110 °C

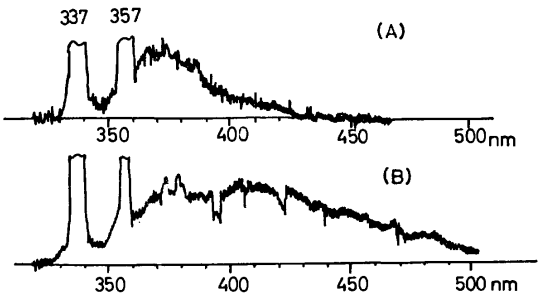

Fig. 2. Time-resolved fluorescence spectra of DMABN in MTHF at −115 °C.
(A) T_d=2.0 ns, (B) T_d=7.0 ns.
The spectra are not corrected, and the correction will shift the F_a band to the longer wavelength side. The lines at 337 and 357 nm are due to the scattered exciting pulse.

In order to observe directly the solvent relaxation process leading to dual fluorescence, we have made the time-resolved fluorescence measurements as shown in Figs. 2 and 3. It can be seen that at the delay time (T_d) of 2 ns from the exciting pulse the F_b band is predominant and the intensity of the F_a band is very weak (Fig. 2). At $T_d=7$ ns, the intensity of the F_a band becomes comparable with that of the F_b band. The relaxation process can be demonstrated also by measuring the fluorescence rise and decay curves of the F_b and F_a bands. We see that the fluorescence rise time of the F_a band measured at 460 nm is longer than that of the F_b band, in agreement with the results in Fig. 2. The decay times of both bands are approximately the same, which seems to indicate the equilibrium or reaction between the two states, ^1L_b and ^1L_a. The results prove unambiguously the solvation process of the ^1L_a state which causes the dual fluorescence. The results given in Figs. 2 and 3 were obtained at −115 °C, but we have made measurements on the same system also at room temperature where the relaxation process is much faster than that at −115 °C. Thus even at small delay times, the intensity of the F_a band is fairly strong. Nevertheless, we observed that the intensity ratio $I(F_b)/I(F_a)$ at a small T_d value is larger than that at a large one.

In relation to the very polar nature of the ^1L_a state of DMABN, we have examined the possibility that the ^1L_a DMABN forms the complex with benzonitrile by electrostatic dipolar interaction. Such a possibility has already been examined by Chandross and Thomas[4] in the case of DMABN-propionitrile system in methylcyclohexane. They observed three fluorescence maxima upon successive additions of propionitrile to a methylcyclohexane solution. We studied the effect of temperature upon the fluorescence of the DMABN-benzonitrile system in cyclohexane, the results of which are shown in Fig. 4.

4) E. A. Chandross and H. T. Thomas, *Chem. Phys. Lett.*, **9**, 397 (1971).

At 70 °C, we observed only one fluorescence band which may be ascribed to a free DMABN molecule. The spectra at room temperature seem to be a superposition of the band due to the free DMABN and that of the complex. At 0 °C as well as at −10 °C, we can clearly recognize two bands, the shorter being ascribable to the free DMABN and the longer to the complex. The fluorescence band due to the complex shows a remarkable red shift by temperature lowering. Presumably, the spectra of the complex at lower temperatures are not due to the 1 : 1 dipolar complex but can be attributed to a 1 : n complex or a 1 : 1 complex strongly solvated by benzonitrile.

We also examined temperature effect on the cyclohexane solution of DMABN itself. At low temperatures, this system shows a long wavelength fluorescence band with peaks at 390 and 460 nm together with the ^1L_b band of the free DMABN. Since the positions of the long wavelength fluorescence peaks and the ratio of their intensities do not change with temperature lowering or with the increase of DMABN concentration, the long wavelength band might be ascribed to the 1 : 1 dipolar complex (self-complex) of DMABN.

The fluorescence decay time at 390 and 460 nm was about 9 ns, while that measured at F_b band was shorter than 5 ns. A slightly longer lifetime of the long wavelength fluorescence may be explained based on the above dimer model. We assume the sandwich dimer configuration where the dimethylamino group comes over the cyano group, and take the excition type wavefunction $\Psi_\pm=(\Psi_1^a\Psi_2^o\pm\Psi_1^o\Psi_2^a)/\sqrt{2}$, assuming the perturbation Hamiltonian of the dipole-dipole interaction, where Ψ^a represents the ^1L_a state. Thus, the energies of these states may be written as $E_+=E_a-\{(|\vec{\mu}_e|\cdot|\vec{\mu}_g|+\mu_t^2)/R^3\}$, $E_-=E_a-\{(|\vec{\mu}_e|\cdot|\vec{\mu}_g|-\mu_t^2)/R^3\}$, where E_a is the energy of the ^1L_a state, $\vec{\mu}_e$ and $\vec{\mu}_g$ the dipole moments of the ^1L_a state and the ground state, respectively, and $\vec{\mu}_t$ the transition moment. Thus, $E_+<E_-$ and the transition between the ground state

$\Psi_1^\circ \cdot \Psi_2^\circ$ and Ψ_+ is forbidden. Presumably, this sort of exciton type interaction in addition to the permanent dipole-dipole interaction is responsible for making the lifetime of the long wavelength band a little longer.

In view of the above results of complex formation, short range dipolar interactions might be important even in the case of the interaction between ^1L_a DMABN and MTHF.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2290—2292 (1973)

Mass Spectrometric Study of the Primary Processes in Photochemical Reactions I. Photodecomposition of 1,1′-Azopropane

Shigeru YAMASHITA and Teruo HAYAKAWA

Department of Chemistry, Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received January 11, 1973)

Primary processes of the photolysis of 1,1′-azopropane were studied using a high intensity light beam and a collision-free photochemical reactor incorporated in the ion-source of a mass spectrometer. The photofragments produced by the following three one-bond fission primary processes were found.

$$CH_3CH_2CH_2N_2CH_2CH_2CH_3 + h\nu \longrightarrow CH_3CH_2CH_2N_2CH_2 + CH_2CH_3 \quad (1)$$

$$CH_3CH_2CH_2N_2CH_2CH_2CH_3 + h\nu \longrightarrow CH_3CH_2CH_2N_2 + CH_2CH_2CH_3 \quad (2)$$

$$CH_3CH_2CH_2N_2CH_2CH_2CH_3 + h\nu \longrightarrow 2\,CH_3CH_2CH_2N \quad (3)$$

The lifetime of these photofragments seems to be longer than 50 μs considering the experimental conditions.

Several mass spectroscopic instruments have been reported for the study of primary processes of photochemical reactions. The essential part of these instruments is the photolysis reactor connected with the ion source of the mass spectrometer for prompt detection of photofragments produced in the primary processes.[1-4] Information has been obtained for many reaction systems.

However, in these mass spectroscopic intruments, collision of the photofragments with each other and with the reactor wall is inevitable. Most reaction products detected were molecular species and a few free radicals in certain cases.[5-7]

One of us reported on the photolysis of mercaptans and alkyl sulfides with a mass spectrometer connected with a fast-flow reactor.[8,9] We were interested in the use of molecular flow of reactant in the photolysis reactor involved in the ion source of the mass spectrometer. A mass spectrometric investigation of the primary processes in the photolysis of 1,3-butadiene with a pulsed flash-lamp and the molecular beam of the reactant vapor was reported by Bergmann and Demtröder.[10]

We attempted the use of steady illumination with a high-intensity light beam and the molecular flow type gas-lead of a Pyrex glass tube in the ion source of a mass spectrometer for studying primary processes of photochemical reactions.

From an interest in re-examination of the primary processes of 1,1′-azopropane, we carried out the photolysis of azopropane using the above instrument. The present paper describes the results.

The primary process was found to be[11]

$$CH_3CH_2CH_2N{=}NCH_2CH_2CH_3 + h\nu \longrightarrow 2\,CH_3CH_2CH_2 + N_2 \quad (a)$$

indicating simultaneous two-bond-splitting. Gowenlock *et al.* pointed out the possibility of the single bond-splitting process in their electron impact study of azo-*n*-alkanes,[12] suggesting that the products ($2\,CH_3CH_2CH_2 + N_2$) in process (a) might be derived from a preceding state ($CH_3CH_2CH_2N_2 + CH_3CH_2CH_2$).

We expected to find photofragments such as $CH_3CH_2CH_2N_2$ produced by single bond-rupture with a collision-free reactor incorporated in the ion source of the mass spectrometer. Collisions during the time between the photon impact and the detection of the photofragments could be neglected provided that the experimental conditions for the molecular flow of the reactant were satisfied by use of proper arrangement of gas-leak orifice and reservoir pressure.

Experimental

Figure 1 shows a schematic diagram of the photolysis reactor and ion source. The mass spectrometer was a modified Hitachi RMU-5 type instrument, the ion current being detected by a ten-stage secondary electron multiplier.

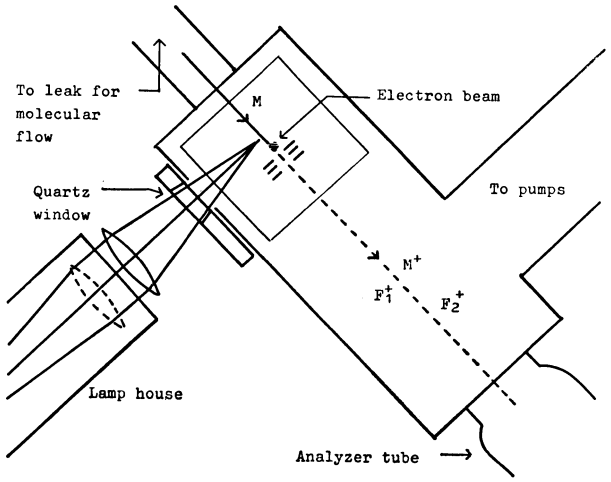

Fig. 1. Illustration of the reactor in the ion source. M means the reactant azopropane, M^+ denotes the ion from unreacted azopropane and F_1^+, F_2^+ show the ions from the photofragments.

Molecular flow of the reactant azopropane was supplied from a 5-l gas reservoir kept in the dark into the ion source through an orifice and a Pyrex glass gas-lead. The pressure in the reactor was about 10^{-5} Torr.

The light source for the photolysis was a USH-500D 500W high-pressure mercury lamp (Ushio Electric Co.). The light output was collimated in a housing fitted with a condensing lens system and a spherical mirror to obtain maximum intensity. The total light flux was estimated by ferrioxalate actinometer to be about 3×10^{18} quanta/s. The light flux from the lamp house was focused on the molecular flow of the reactant in the Pyrex gas-lead tube through a quartz window fixed on a side hole of the ion source block. In order to cut off wavelengths shorter than 300 nm, a Toshiba UV-29 filter was installed before the quartz window. Most of the incident light-quanta into the reactor were of 365 nm with small contribution from that of 334 nm. No light-exit window[10] was installed in this work, but the effect of scattered light was considered insignificant because of the fact that several metal pieces of the ionization chamber effectively shield the scattered light.

The mass spectrum obtained for each run was a superposition of the cracking patterns of the photofragments and that of unreacted azopropane. The mass spectrum of the photofragment mixture was obtained after subtracting the contribution from unreacted azopropane.

For detecting the signal of the photofragments, sufficient concentration of the photofragments relative to that of unreacted azopropane was necessary. This could be achieved by using a highly intense light beam focused on the molecular flow of the reactant and by using a reactant with a very high molecular extinction coefficient in the wavelength range of the light source. Since azopropane has absorption in near ultraviolet (Fig. 2), the high-intensity mercury lamp was proved to be effective for detecting the photofragments from azopropane.

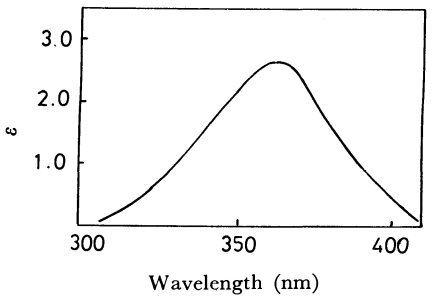

Fig. 2. Absorption spectrum of 1,1'-azopropane CH_3CH_2-$CH_2NNCH_2CH_2CH_3$ (gas phase).

Results and Discussion

The procedure to obtain the mass spectrum of the photofragment mixture from the recorded mass spectrum is given in Table 1. By subtracting the contribution from unreacted azopropane (third column) from the recorded peak height (second column), we obtain the residue Δ, the sum of the mass spectrum of the photofragments. Only the residues of significant magnitude are shown. Subtraction was done by normalizing at the mass number 114, the parent peak of azopropane.

Table 1. Mass spectrum of the photolyte flow of 1,1'-azopropane
(in arbitrary units)

m/e	Peak height	Azopropane contribution	Δ	Assignment
27	7.5	6.4	1.1	
28	75.0	75.0	—	
29	46.5	37.2	9.3	C_2H_5
30	14.0	13.0	1.0	
39	26.3	27.2	—	
41	99.0	97.4	1.6	
42	27.1	25.2	1.9	
43	239.5	231.0	8.5	C_3H_7
56	3.8	3.0	0.8	
57	5.6	3.1	2.5	C_3H_7N
71	7.9	6.9	1.0	$C_3H_7N_2$
85	2.1	1.6	0.5	$C_3H_7N_2CH_2$
114	20.0	20.0	—	Azopropane

The residue at *m/e* 28 was found to be negligible, indicating that N_2 was not a primary product. Some process preceding (a) might be expected.

The residues at *m/e* 85, 71 and 57 (Table 1) could be assgined as the ion peaks of $CH_3CH_2CH_2N_2CH_2$, $CH_3CH_2CH_2N_2$ and $CH_3CH_2CH_2N$, respectively. Presumably these photofragment radicals were produced in the following primary processes:

$$CH_3CH_2CH_2N_2CH_2CH_2CH_3 + h\nu \rightarrow CH_3CH_2CH_2N_2CH_2 + CH_2CH_3 \quad (1)$$

$$CH_3CH_2CH_2N_2CH_2CH_2CH_3 + h\nu \rightarrow CH_3CH_2CH_2N_2 + CH_2CH_2CH_3 \quad (2)$$

$$CH_3CH_2CH_2N_2CH_2CH_2CH_3 + h\nu \rightarrow 2\,CH_3CH_2CH_2N \quad (3)$$

a) Peak heights are normalized to unity at *m/e* 71.

The ion peak at m/e 43 was due to the unreacted azopropane whose concentration is several tens of times higher than the sum of the concentration of photofragments. Thus fluctuation of the peak height of *m/e* 43 affected its Δ-value of photofragments to such an extent to make it unreliable.

The residues at lower mass numbers were taken for mass spectral fragment ion peaks of the primary photofragments induced by electron impact. There was contribution from the ions of the photofragments $CH_3CH_2CH_2$ and CH_3CH_2 at *m/e* 43 and 29.

The results are summarized in Table 2, where the peak heights are normalized to unity at *m/e* 71. Assuming the same sensitivity for the three of photofragments of the mass numbers 85, 71 and 57, the probability of the occurrence of the primary processes (1), (2) and (3) seems to be approximately comparable with each other.

From the geometry of the instrument and the experimental conditions, the lifetime of these photofragments seems to be longer than 50 μs.

The Crystal Structure of Dinicotinic Acid

Fusao TAKUSAGAWA, Ken HIROTSU and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received January 13, 1973)

The crystal structure of dinicotinic acid has been determined by X-ray diffraction method. Two kinds of twinning crystals were obtained by changing the pH of the aqueous solution by recrystallization. The crystals are monoclinic with the space group of $P2_1/c$ and with cell dimensions of $a=9.702$, $b=11.153$, $c=6.587$ Å, and $\beta=107.8°$. The crystal structure was solved by an inspection of the sharpened Patterson map. The final R value is 5.93% for 1181 observed reflections. The dinicotinic acid molecule takes an intermediate structure between the neutral molecule and the zwitter ion with an approximate C_{2v} symmetry. The bond lengths and angles related by the C_{2v} symmetry are equal within the limits of experimental error for those of the two carboxyl groups. The C(2)–N(1)–C(6) bond angle is 119.8°, which lies between those of protonated and unprotonated species of the pyridine ring. The molecules lie approximately on planes parallel to the (001) plane at $z=1/4$ and 3/4. Each molecules on the same plane is joined through two kinds of hydrogen bonds (O–H···O; 2.594 Å, O···H···N; 2.515 Å), related by two-fold screw axes, with four neighboring molecules. In the O···H···N hydrogen bond, the hydrogen bonding distance and angle are 2.515 Å and 174° and the O–H and N–H distances are 1.23 and 1.29 Å, which are equal within the limits of experimental error. Therefore, it may be considered as an example of the single minimum hydrogen bond of the O–H···N hydrogen-bond type. The existence of two kinds of twins may be interpreted on the basis of the layer structure.

This work is a part of a series of studies on the O–H···N hydrogen bonding by the X-ray crystal structure analyses of several carboxylic acids with a pyridine ring. In their crystal structures studied hitherto, the O–H···N or $^+$N–H···O hydrogen bonds are found to play an important role without exception. Thus, this type of hydrogen bond is formed in nicotinic acid,[1] although the formation of the O–H···O hydrogen bond might also be plausible between carboxyl groups, as has been found in isoelectronic benzoic acid.[2] The same situation has also been revealed in dipicolinic acid,[3] which has a framework similar to that of isophthalic acid.[4] This dipicolinic acid has two bulky carboxyl groups in both α-positions so as to shield the nitrogen atom in a pyridine ring from the hydrogen-bond donor group, but it forms a hydrogen bond between nitrogen and oxygen atoms with the aid of a water molecule. The dinicotinic acid in the present

study is also isoelectronic with isophthalic acid, and it will be of interest to elucidate the effect of the nitrogen atom in a pyridine ring on the hydrogen-bond formation in solids. Furthermore, the melting point of this compound is the highest of the six pyridine-dicarboxylic acids. Therefore, a rather strong hydrogen bond might be expected to exist in this crystal.

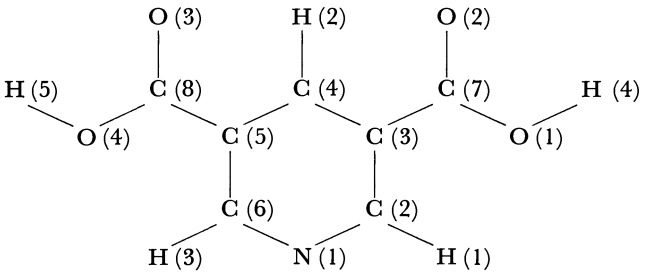
Experimental

Two kinds of crystals were obtained by changing the pH of the aqueous solutions by recrystallization, one in the form of colorless pillars from an aqueous solution and the other in the form of colorless prisms from an aqueous solution containing a few drops of HCl. Weissenberg photographs showed that the crystals recrystallized from an aqueous solution had the a^*b^* twinning plane, and that the other crystals recrystallized from an aqueous acidic solution has the b^*c^* twinning plane. The intensity ratio of the two individuals in the former twin is about 1.0 to 1.0, while that in the latter is 1.0 to 0.15.

The crystals were monoclinic with the space group of $P2_1/c$. The cell dimensions were measured from zero-layer Weissenberg photographs, which were calibrated with superimposed Al powder lines. They are given, along with other crystal data, in Table 1. One of the crystals which had the b^*c^* twinning plane was shaped to a sphere with the average diameter of 0.4 mm. The intensity data were collected for the 0—9 layers around the b axis and the 0—2 layers around the c axis by the use of the multiple-film equi-inclination-integrating Weissenberg technique, using Cu$K\alpha$ radiation. The intensities of the diffraction spots were estimated visually by comparison with an intensity standard. The intensities of the overlapped spots were estimated from $I \times 0.87$, where I is the intensity of the overlapped spot and where 0.87 is $1.0/(1.0+0.15)$. Of the possible 1555 reflections within the Cu$K\alpha$ sphere, 1289 independent reflections were measured; 108 were too weak to be observed. No absorption correction was applied.

Table 1. Crystal data for dinicotinic acid

Molecular formula	$C_7H_5NO_4$
Molecular weight	167.12
Crystal size	$\sim 0.4\times0.4\times0.4$ mm
Crystal system	Monoclinic
Space group	$P2_1/c$
Cell dimensions;	
a	9.702 ± 0.004 Å
b	11.153 ± 0.007
c	6.587 ± 0.004
β	$107.80\pm0.05°$
V	$678.5\ \pm0.7$ Å^3
Z	4
Density (calculated)	1.636 g/cm^3
Density (observed)	1.63
Radiation	Cu$K\alpha$ ($\lambda=1.5418$ Å)
Linear absorption coefficient	13.65 cm^{-1}
Number of independent reflections	1289
Atom numbering	



Structure Determination and Refinement

The crystal structure was solved by an inspection of the sharpened Patterson map, which was resolved sufficiently enough to give the orientation and the location of molecules in the unit cell. The first postulated structure gave an R value of 42%, which decreased to 13% in three cycles of least-squares refinement with individual isotropic thermal factors. Since the 0 0 2 reflection was seemingly influenced by the strong extinction effect, this reflection was removed from the later refinements.

The coordinates and anisotropic thermal parameters were refined by the block-diagonal least-squares procedure, minimizing the function $\Sigma w(F_o-F_c)^2$, where:

$w=0.5$ for $|F_o|\leqq 0.5$,

$w=1.0$ for $0.5<|F_o|<6.0$ and

$w=6.0/|F_o|$ for $6.0\leqq|F_o|$.

The atomic scattering factors used were those listed in the International Table for X-ray Crystallography for C, N and O atoms and the spherical scattering factors proposed by Stewart, Davidson, and Simpson[5] for the H atom. At the stage of $R=7.9\%$, a difference Fourier map was computed, from which five hydrogen atoms were located (Fig. 1). With anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms, the final R value was 5.93%, excluding unobserved reflections. The observed and calculated structure factors are listed in

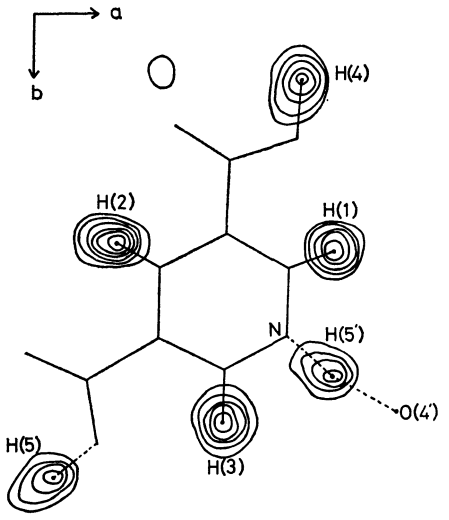


Fig. 1. A composite drawing of the electron density associated with the hydrogen atoms. The contours at intervals of 0.1 e·Å^{-3}, beginning with 0.2 e·Å^{-3} contour.

Table 2. The fractional coordinates and thermal parameters are listed in Table 3.

Results and Discussion

Molecular Structure. The bond lengths and angles are shown with their estimated standard deviations in Fig. 2. Figure 1 shows the difference Fourier map along the *c* axis, in which there is no high peak except for those due to the hydrogen atoms. Figure 3 shows the anisotropic thermal ellipsoids of non-hydrogen atoms and the isotropic thermal ellipsoids of hydrogen atoms.

The dinicotinic acid molecule in the crystal was found by this study to have a structure intermediate between the neutral molecule and the zwitter ion, as

TABLE 3. THE FINAL PARAMETERS AND THEIR ESTIMATED STANDARD DEVIATIONS (IN PARENTHESES)

The coordinates of non-hydrogen atoms have been multiplied by 10^4; those of the hydrogen atoms by 10^3. The anisotropic thermal parameters of non-hydrogen atoms are of the form $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$ and have been multiplied by 10^4. For the hydrogen atoms the values listed are isotropic thermal parameters B (Å^2).

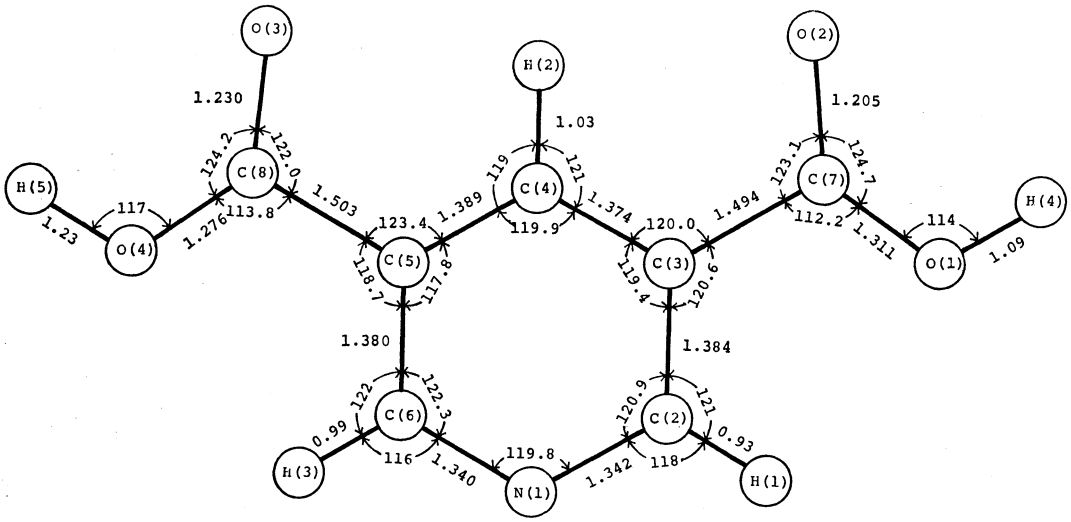

Fig. 2. Dimensions of dinicotinic acid molecule.
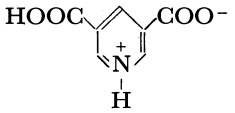
The estimated standard deviations are as follows:
X-X=0.003−0.004 Å X-H=0.03−0.04 Å
X-X-X=0.2−0.3° X-X-H=2°
where X and H are non-hydrogen atom and hydrogen atom, respectively.

is shown below;



The existence of the molecule in this form is evident from the position of the hydrogen atom in the difference Fourier map. It is also confirmed by the C(2)–N(1)–C(6) bond angle of 119.8 (2)° and the O(4)–H(5) and H(5)–N(1) bond lengths, which are 1.23(4) and 1.29 (4) Å, respectively (the values in parentheses denote the e.s.d.'s in the last digits).

A dinicotinic acid molecule is approximately planar, with the maximum deviation of 0.229 Å, and its pyridine ring is essentially planar and the maximum deviation of a ring atom from the least-squares plane is 0.002 Å. The equations of the two planes through twelve non-hydrogen atoms of a molecule and six non-hydrogen atoms of the pyridine ring are:

$$0.0523X+0.0736Y+0.9951Z=2.3097 \quad \text{and}$$

$$0.0677X+0.0906Y+0.9936Z=2.4951,$$

respectively, where X, Y and Z are coordinates in Å referred to an orthogonal set of axes and parallel to the a, b, and c^* axes respectively; this coordinate system

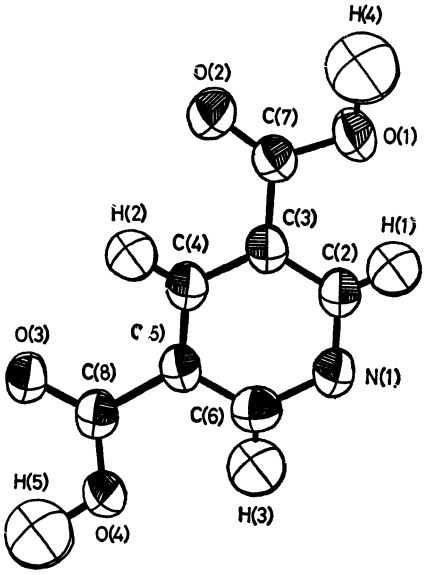


Fig. 3. The anisotropic thermal ellipsoids of non-hydrogen atoms and the isotropic thermal ellipsoids of hydrogen atoms. Ellipsoids are scaled to include 74% probability.

is used throughout this paper. The displacements of all the atoms from the planes are listed in Table 4.

Roughly speaking, the molecule in the crystal has the C_{2v} symmetry, as is shown in Fig. 2. The bond lengths and angles related by the C_{2v} symmetry are equal within the limits of experimental error except for

Table 4.

* The N···H distance was not determined.
\+ The corresponding N···H bond was not found.

those of the two carboxyl groups. The bond lengths in a pyridine ring are in good agreement with those pyridine itself, but the bond angles are not. The C-(2)–N(1)–C(6) bond angle is 119.8(2),° which lies between the pyridine[6] (116.8°) not protonated at the nitrogen atom and some pyridine derivatives[7–9] (~125°) protonated at the nitrogen atom. The C–N–C bond angles and C–N and N···H bond lengths of several pyridine derivatives are listed in Table 5. The C–N–C bond angle seems to be inversely proportional to the N···H distance, as is shown in Table 5.

Each carboxyl group consists of C–O(H) and C=O groups. The differences between two C–O(H) lengths, C(7)–O(1) and C(8)–O(4), and between two C=O bond lengths, C(7)–O(2) and C(8)–O(3), are 0.035(3) and −0.025(3) Å respectively; these differences are significant in view of their estimated standard deviations. The former difference may be explained by the increase in the double-bond character of the C(8)–O(4) group, which participates in a very short O···H···N hydrogen bond, as will be seen later. On the other hand, the latter difference may be due to the fact that the O(3) atom takes part in the hydrogen bond, while the O(2) atom does not, although there will be a decrease in the double-bond character in the C(8)–O(3) bond corresponding to the increase in this character in the C(8)–O(4) bond. A similar situation is observed also in quinolinic acid[9] and cinchomeronic acid.[9] Therefore, the longer C–O distance in the carbonyl group may be related to the participation of this group in the hydrogen bond. One carboxyl group (C(7)O(1)-O(2)H(4)) twists by 6.7° out of the plane of the pyridine ring, while the other twists by 12.1°.

Molecular Arrangement and Hydrogen-bond System. The crystal structure is shown in Figs. 4 and 5. The distances and angles of hydrogen bonds are listed in Table 6. The molecules lie approximately on the planes parallel to the (0 0 1) plane at $z=1/4$ and 3/4, with a spacing of 3.136 Å. The best plane through the carbon, nitrogen, and oxygen atoms of the 1 and 2 molecules, related to each other by the two-fold screw axis at $z=1/4$, is calculated by the least-squares analysis to be:

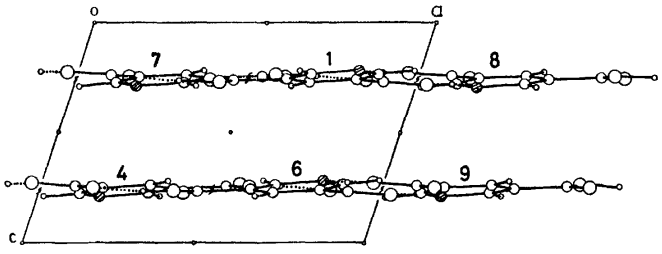

Fig. 4. A view of the crystal structure down the *b* axis. The hydrogen bonds are shown by broken lines. The numbers on pyridine rings correspond to those of the symmetry codes shown in Table 6.

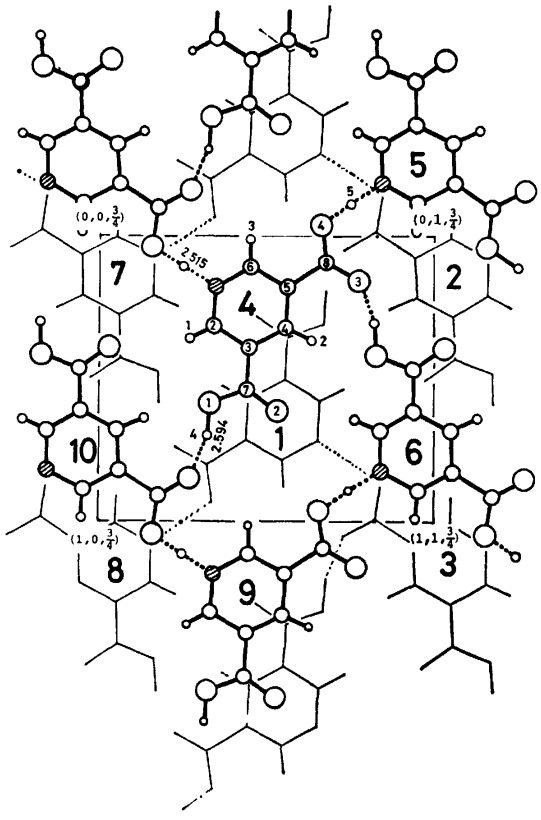

Fig. 5. A view of the crystal structure along the normal to the (001) plane, showing the relative orientation of the molecules in two adjacent layers parallel to the (001) plane. The hydrogen bonds are shown by broken lines. The numbers in pyridine rings correspond to those of the symmetry codes shown in Table 6.

$$0.0279X+0.0240Y+0.9939Z=1.8942.$$

The dihedral angle which it makes with the (0 0 1) plane is 2.1°. Figure 4 shows the crystal structure down the *b* axis. Figure 5 shows a view normal to the (0 0 1) plane and illustrates the relative orientation of the molecules in two neighboring layers. The upper layer of the molecules drawn with heavy lines in this figure involves the molecules on the plane at $z=3/4$.

Each molecule on the same plane is joined through two kinds of hydrogen bonds related by the two-fold screw axes, with four neighboring molecules, and forms a sheet parallel to the (0 0 1) plane. The sheets are related by the center of symmetry and are not linked by the hydrogen bond, but only by the van der Waals forces.

One carbonyl oxygen atom (O(3)) participates in a hydrogen bond (O(3)···H(4)–O(1); 2.594(3) Å), while the other (O(2)) does not. The nitrogen atom in a pyridine ring, however, takes part in a hydrogen bond (N(1)···H(5)···O(4); 2.515(3) Å), as in the crystals of nicotinic acid, dipicolinic acid, quinolinic acid, and cinchomeronic acid. This fact suggests that the O–H···N or $^{+}$N–H···O hydrogen bond is energetically more favored than the O–H···O hydrogen bond in these compounds.

In the O(4)···H(5)···N(1) hydrogen bond, the angle is 174(3)°, which indicates a straight hydrogen bond, and the distance between the O(4) and N(1) atoms is

5=(−1+x, 3/2−y, 1/2+z); 6=(x, 3/2−y, 1/2+z); 7=(1−x, −1/2+y, 1/2−z);
8=(2−x, −1/2+y, 1/2−z); 9=(2−x, 1−y, 1−z); 10=(x, 1/2−y, 1/2+z)

2.515(3) Å, which is very short in the O–H···N type of hydrogen bond. The O(4)···H(5) and N(1)···H(5) bond distances are 1.23(4) and 1.29(4) Å, which are equal within the limits of experimental error. Therefore, this bond may be considered as an example of the single minimum hydrogen bond[16] of the O–H···N type of hydrogen bond. This may also be confirmed by the C(2)–N(1)–C(6) bond angle of 119.8(2)°.

Figure 6 shows the models proposed for two kinds of twins. In the twin(Fig. 6(a)) which has the directions of the *a* and *b* axes in common, the transition may take place across the (0 0 1) plane, since the molecules are arranged in layers closely parallel to this plane and since these layers are stacked together with a spacing of about 3.136 Å. On the other hand, the twin(Fig. 6(b)) which has the directions of the *b* and *c* axis in common may depend on the change in the torsional angle, O(3)–C(8)–O(4)–H(5). Such a twist causes only a little change in the angle and distance of the O(4)···H(5)···N(1) hydrogen bond. Furthermore, no abnormal approach between the intermolecular atoms is found in this twin model because of the layer structure. Therefore, the main reason for the existence of two kinds of twins may be the layer structure in this crystal. It is not easy to explain conclusively the relation between the twinning patterns and the pH of aqueous solutions on recrystallization, since it may be characterized by many factors. However, the formation of two types of twins seems to be related with the amounts of ⩾N, +⩾N–H, —O–H and —O⁻ on the crystal surfaces, which themselves depend on the pH of the aqueaus solution on recrystallization.

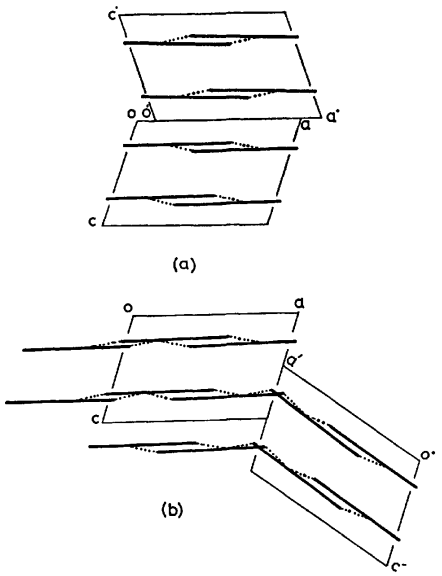

Fig. 6. The model proposed for two kinds of twins. A molecule is shown by a heavy line, and hydrogen bonds are shown by broken lines. (a): This twinning crystal has the directions of *a* and *b* axes in common, and it is obtained from an aqueous acidic solution. (b): This twinning crystal has the directions of *b* and *c* axes in common, and it is obtained from an aqueous solution. In both models, the origins, O and O′, have same value of *y* coordinate, *y*=0.

Computer Programs. All the calculations were performed on a FACOM 270-30 computer at the Computer Center of Osaka City University, using the following programs—RSLC-3 (cell constant),[10] RSSFR-3 (Fourier synthesis),[11] HBLS-IV (block diagonal least-squares refinement),[12] DAPH(bond length, bond angle and least-squares plane),[13] SCALE (film factor, Lp and layer scaling),[14] and TE-I(thermal ellipsoid).[15]

The Molecular and Crystal Structure of the Cyclic Pentamer of Formaldehyde, 1,3,5,7,9-Pentoxecane

Yozo CHATANI and Katsuki KITAHAMA*

Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received January 22, 1973)

The crystal structure of the cyclic pentamer of formaldehyde, 1,3,5,7,9-pentoxecane, has been determined by the X-ray diffraction method. The unit cell is orthorhombic, with $a=8.154$ Å, $b=10.673$ Å, $c=7.666$ Å. The space group is Pbcn, and there are four molecules per unit cell. The structure was refined by the block-diagonal least-squares method to a final discrepancy factor, R, of 0.049, using 712 reflections observed with an automatic four-circle single-crystal diffractometer. The molecules in the crystals are ten-membered rings with an exact C_2–2 symmetry; the torsion angles of the five independent C–O bonds are 72.9°, −118.7°, 84.2°, −123.4°, and 69.8°, and the two halves of the molecule are related by a twofold rotation axis. The averaged C–O bond length is 1.410 Å, and the averaged C–O–C and O–C–O bond angles are 115.6° and 111.8° respectively. The close intramolecular H···H distances are 2.17 Å and 2.20 Å.

In a previous paper,[1] the molecular and crystal structure of the cyclic hexamer of formaldehyde, 1,3,5,7,9,11-hexoxecane $(-CH_2-O-)_6$, was reported. The cyclic pentamer, 1,3,5,7,9-pentoxecane $(-CH_2-O-)_5$, is also of interest from the viewpoint of molecular conformation. To date, many investigations have been made with regard to the structure determination of ring compounds of the $(-X-)_m$ or $(-X-Y-)_m$ type. However, little is known of ten-membered ring compounds with such a sequence. Pentoxecane is also interesting with respect to the radiation-induced solid-state polymerization.[2,3] Pentoxecane undergoes a ring-opening polymerization in the crystalline state to form linear polyoxymethylene $(-CH_2-O-)_n$ under irradiation. The polymer resulting from the solid-state polymerization is highly crystalline, just as in the cases of trioxecane $(-CH_2-O-)_3$,[4-6] tetroxocane $(-CH_2-O-)_4$,[7] and hexoxecane $(-CH_2-O-)_6$.[1] The preferred orientations of the resultant polymer crystals are, however, characteristic for each cyclic oligomer. In the present paper, the molecular and crystal structure of pentoxecane will be reported, and the relationship between the crystal structure and the solid-state polymerization will be discussed briefly.

Experimental

The pentoxecane was obtained through the courtesy of Drs. Miyaka and Yamauchi of Mitsui-Toatsu Chemicals, Inc. The melting point of pentoxecane is 61.3 °C. Crystals were grown as rhombohedrons by the slow evaporation of a methanol solution. The crystals were found to sublime slowly when exposed to the atmosphere. To prevent the sublimation of the samples, single crystals were sealed in thin-walled Lindemann glass capillary tubes. The cell constants were determined from Weissenberg photographs and θ values measured with a single-crystal diffractometer.

Crystal data:

1,3,5,7,9-pentoxecane, $(-CH_2-O-)_5$

Molecular weight 150.1

Orthorhombic $a=8.154\pm0.005$ Å

$b=10.673\pm0.009$

$c=7.666\pm0.005$

Volume of the unit cell: $V=661.8$ Å^3

Density, calculated with $Z=4$: $D_x=1.494$ g/cm^3; measured: $D_m=1.49$ g/cm^3

Number of electrons per unit cell: $F(000)=320$

Absorption coefficient for $\lambda_{MoK\alpha}$ (=0.7107 Å): $\mu=1.62$ cm^{-1}.

The systematic absences of $0kl$ for k odd, of $h0l$ for l odd, and of $hk0$ for $h+k$ odd indicate that the space group is Pbcn.

Intensity measurements were performed using a Rigaku-Denki automatic four-circle single-crystal diffractometer with MoKα radiation. The crystal used for intensity measurements was $0.2\times0.2\times0.3$ mm^3 in size. The integrated intensities were measured for all reflections in the sphere of the radius $\sin\theta/\lambda<0.65$ Å^{-1}, using the θ—2θ (moving crystal, moving counter) technique. The procedures used in getting the observed structure factors were similar to those used in the case of hexoxecane.[1] A total of 749 independent reflections were examined, and 712 reflections were observed. No correction was made for absorption. In a previous paper,[2] the solid-state polymerization of pentoxecane by X- or γ-irradiation was reportod. The polymer yield depends upon the irradiation temperature. The present intensity measurements were performed at 16 °C, and, judging from the constancy of the intensities of three reference reflections measured every 25 reflections, such a polymerization was found to be suppressed during the measurements. Therefore, it was unnecessary to correct the observed structure factors for any decrease caused by polymerization.

Structure Determination

The space group Pbcn possesses eight general equivalent points. Since there are four molecules in the unit cell, the molecules themselves have one kind of twofold symmetry. The possible symmetry of the molecule which can possess in the space group Pbcn is either a center of symmetry or a twofold rotation

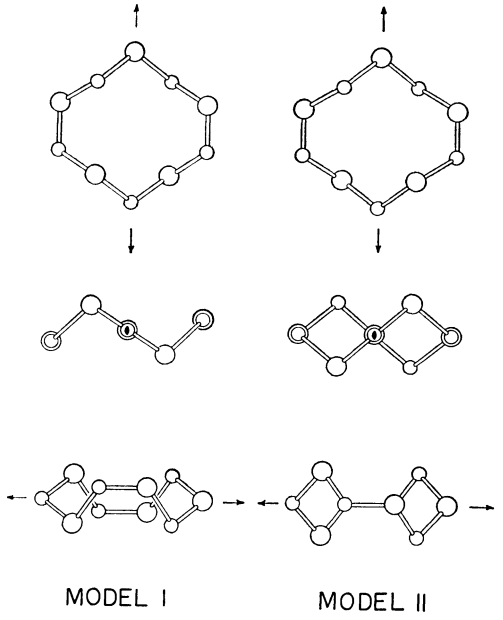

Fig. 1. Two models of a pentoxecane molecule.

axis. Since the ten-membered cyclic molecules of pentoxecane cannot have a center of symmetry, they must possess a twofold rotation axis. In the pentoxecane ring, the twofold rotation axis can pass through a carbon atom and an oxygen atom lying across the ring from each other. Two typical possible models which can satisfy the twofold rotation symmetry are shown in Fig. 1. The conformation of Model I is denoted by the sequence of $G\bar{S}CS\bar{G}\bar{G}SC\bar{S}G$, and Model II, by $\bar{G}S\bar{G}S\bar{G}\bar{G}S\bar{G}S\bar{G}$, or their enantiomers, C is a *cis*-form (the torsion angle is defined as 0°), G and S are a clockwise *gauche*-form and a *skew*-form respectively, and $\bar{G}$ and $\bar{S}$ are a counter-clockwise *gauche*-form and a *skew*-form respectively. Since the twofold rotation axis in the molecule coincides with the twofold rotation axis parallel to the *b* axis, the two models were selected by a comparison of the F_o and F_c of (*h*0*l*) reflections, varying the rotation angle of the molecule about the twofold rotation axis. Model I was easily excluded. Therefore Model II was refined three-dimensionally by a block-diagonal least-squares program of Dr. Ashida using a NEAC 2200 electronic computer at Osaka University. The five independent hydrogen atoms were revealed unambigously by a difference Fourier synthesis, as is shown in Fig. 2, the maxima being between 0.6 and 0.7 e/Å^3. The coordinates of these peaks were introduced into the refinement as hydrogen atoms and were given isotropic thermal factors. The weighting scheme used in the least-squares calculation was:

$$w = 0 \text{ for } F_o = 0$$
$$w = 0{\cdot}4 \text{ for } 0 < |F_o| \leq F_{min}$$
$$w = 1{\cdot}0 \text{ for } F_{min} < |F_o| \leq 4F_{min}$$
$$w = (4F_{min}/|F_o|)^2 \text{ for } |F_o| > 4F_{min}$$
$$F_{min} = 30 \text{ in the scale of Table 2.}$$

The atomic scattering factors used for carbon and

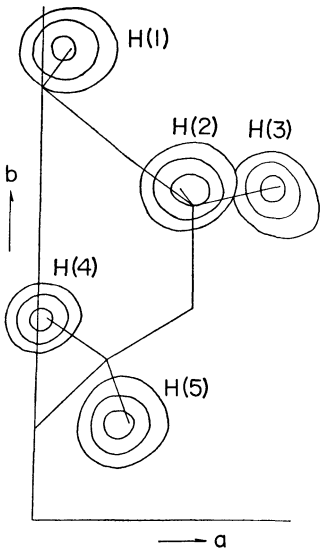

Fig. 2. Composite difference Fourier map. Contours are at intervals of 0.2 e/Å^3, begining at 0.2 e/Å^3.

oxygen were those[8] in the International Tables for X-ray Crystallography, Vol. III, while for hydrogen the bonded values of Stewart *et al.*[9] were used. A set of final structure factors for all the observed reflections shown in Table 2 was calculated on the basis of the final positional and thermal parameters shown in Table 1. The discrepancy factor, $R(= \Sigma(|F_o| - |F_c|)/\Sigma|F_o|)$, for the observed reflections was 0.049.

Results and Discussion

Molecular Structure and Thermal Motion. Figure 3 shows the molecular structure of pentoxecane. The ten-membered ring molecule has a C_2–2 symmetry; the twofold rotation axis passes through C(1) and O(3). The bond lengths, bond angles, and torsion

H(2)–C(2)–H(3)	112(2)		
Torsion angles (°)			
C(1)–O(1)	−72.9	O(2)–C(3)	123.4
O(1)–C(2)	118.7	C(3)–O(3)	−69.8
C(2)–O(2)	−84.2		
Intramolecular H···H distances (Å)			
H(2)···H(4)	2.17(3)	H(1)···H(2)	2.20(3)

Estimated standard deviations shown in parentheses refer to the last decimal positions.

angles derived from the final atomic parameters are listed in Table 3 and are also shown in Fig. 3. The rings have five independent C–O bonds, and their lengths range from 1.402 Å to 1.420 Å and are averaged to be 1.410 Å. The O–C–O bond angles range from 110.7° to 112.9° and are averaged to be 111.8°. The C–O–C bond angles range from 115.1° to 116.0° and are averaged to be 115.6°. The five independent torsion angles are −72.9°, 118.7°, −84.2°, 123.4°, and −69.8°, which indicate approximately either a *gauche*-form or a *skew*-form.

Table 4 shows the molecular dimensions of some cyclic oligomers of formaldehyde: trioxecane, pentoxecane and hexoxecane. In the trioxecane molecule, the O–C–O and C–O–C bond angles are close to the tetrahedral angle of 109.5°. The average C–O–C bond angles in both pentoxecane and hexoxecane are about 6° larger than the tetrahedral angle. In the hexoxecane molecule, the O–C–O bond angle is also 4.5° larger than the tetrahedral angle. Such large departures from the tetrahedral angle can be attributed to the effect of close H···H overlapping; the resultant close intramolecular H···H distances are 2.17 Å and 2.20 Å for pentoxecane, and 2.13 Å for hexoxecane.

Hendrickson[13] examined many possible molecular conformations of cyclodecane in terms of the strain energy: bond angle bending strain, torsional strain, and nonbonded interactions of hydrogen atoms. The conformation of the pentoxecane ring is similar to Model XXIX in his article. In the case of cyclodecane, however, he ignored Model XXIX, since the model is incapable of escaping serious nonbonded H···H interactions.

Table 5 lists the root mean square vibration amplitudes and the direction cosines of the principal axes of the thermal ellipsoids to the crystallographic *a*, *b*, and *c* axes (see Fig. 4). In the case of hexoxecane,[1] the rigid body approximation[14,15] was undertaken for the molecule of the $\bar{3}$ symmetry, but a reasonable result could not be obtained. In the cases of hexoxecane and also pentoxecane, the thermal ellipsoids suggest that there are considerable intramolecular motions, *i.e.*, torsional motions. Therefore, no corrections of the bond lengths and bond angles for thermal motions were made.

Crystal Structure. Two projections of the crystal structure of pentoxecane, viewed along the *c* and *b* axes, are shown in Fig. 5. Some close intermolecular atomic distances, less than 3.8 Å for the C···O pair and less than 4.2 Å for the C···C pair, are listed in Table 6. There are no abnormal distances between

the molecules.

As has already been mentioned, the solid-state polymerization of pentoxecane by X- or γ-irradiation was successful. The single crystal habit of pentoxecane is retained at the completion of polymerization, and the orientation of the resultant polyoxymethylene crystallites is governed by the symmetry of the parent pentoxecane crystal. The polymer chains grow along the two face-diagonal axes, [110] and [$\bar{1}$10], which are equivalent to each other, as if the crystals were "twinned crystals." In addition to the crystals, a small amount of crystallites with another preferred orientation is formed, that is, the polymer chains are oriented along the [101] and [$\bar{1}$01] axes, which are equivalent to each other. The details of the orientation of polymer crystals have already been reported.[2)]

a: x, y, z; b: $x, 1-y, -\frac{1}{2}+z$; c: $-\frac{1}{2}+x, \frac{1}{2}-y, 1-z$; d: $1\frac{1}{2}-x, \frac{1}{2}-y, \frac{1}{2}+z$; e: $1\frac{1}{2}-x, \frac{1}{2}+y, z$

It has also been noted that the polymer formation can be detected by irradiation at 20 °C. The polymerization rate increases with the elevation of the irradiation temperature, and the maximum rate is found at about 50 °C. No polymer is obtained by irradiation above the melting point, 61.3 °C. In order to clarify such specificities of the solid-state polymerization, many physicochemical investigations are necessary.

The authors wish to thank Professor H. Tadokoro of Osaka University for his interest in the work and his constant encouragement. The thermal ellipsoids of the pentoxecane molecule were drawn with a plotter by the use of the universal crystallographic computation program system 5020 UNICS of the University of Tokyo.

Magnetic Susceptibilities of Solid Oxygen-Argon Mixtures

Yoshihiro MORI,* Akira SAKAKIBARA,** and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo 106

(Received February 3, 1973)

The magnetic susceptibility in solid oxygen-argon mixtures has been obtained as a function of the temperature from 12 K to the melting point. In case of the 95% O_2–5% Ar system, the behavior of the magnetic susceptibility was similar to that of pure oxygen except for some dynamical effects caused by the addition of argon to the oxygen lattices. In the composition range between 92% and 66% O_2, the appearance of a novel phase, δ, was observed from the magnetic susceptibility measurements; its temperature and concentration dependence was discussed qualitatively on the basis of the crystal structure.

The magnetic susceptibility of solid oxygen was first measured from 2 K to its melting point by Kanda *et al.*[1] Since then, the magnetic properties of solid oxygen have been studied by various methods, such as crystallographic analysis,[2] optical-absorption measurements in relation to magnon excitation,[3] and electronic 'double' transitions.[4]

It has been clarified through these studies that there exists an antiferromagnetic spin ordering over a long range in the lowest-temperature α phase; in this sample the crystal structure is monoclinic and nearly closed-packed in both [001] and [$\bar{2}$01] planes. On the other hand, in the higher-temperature phases, β (23.8—43.8 K) and γ (43.8—54.4 K), the order is only short range because of the nearest-neighbor interactions.

In the present study, the results of magnetic susceptibility measurements of oxygen-argon mixtures with oxygen contents between 66% and 95% will be reported and the effects of the addition of diamagnetic argon atoms will be discussed.

Experimental

The magnetic susceptibitily measurements were carried out from 12 K to the melting point in each of the oxygen-argon mixtures by the Faraday method, as has previously been described.[5] The magnetic field was set at about 9×10^3 Gauss throughout the measurements. The field strength was calibrated by measuring the susceptibility of sucrose, the mass susceptibility of which was taken to be -0.566×10^{-6} emu/g.

The preperation method and the thermal history of the sample were as follows. Gaseous mixtures of oxygen and argon in various ratios containing 5—10 mg of oxygen were condensed into a small quartz tube cooled at the temperature of liquid helium, and then the tube was sealed off. The quartz ampoule (5 mm in diameter and 15 mm in length) was suspended by a Pyrex glass string from the arm of a Saltorius Electrono Microbalance, cooled to about 80 K, and kept at this temperature for more than ten minutes in order to liquefy and mix the gases. This liquid mixture was then solidified at about 50 K. After this treatment, it was cooled to 12 K within less than 15 min.

The temperature was measured with an Au : Co–Cu

thermocouple placed below the ampoule. The temperature of the sample was calibrated by the phase-transition temperatures of pure solid oxygen and also by measuring several times the susceptibilities of the paramagnetic salts whose suscepitibilities are known, Mohr's salt ($Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$) and Tutton's salt ($Mn(NH_4)_2(SO_4)_2 \cdot 6H_2O$), under the same conditions.

Results and Discussion

Figure 1 shows the temperature dependence of the magnetic susceptibility at each oxygen molar ratio, corrected for the diamagnetism of the argon and the quartz ampoule.

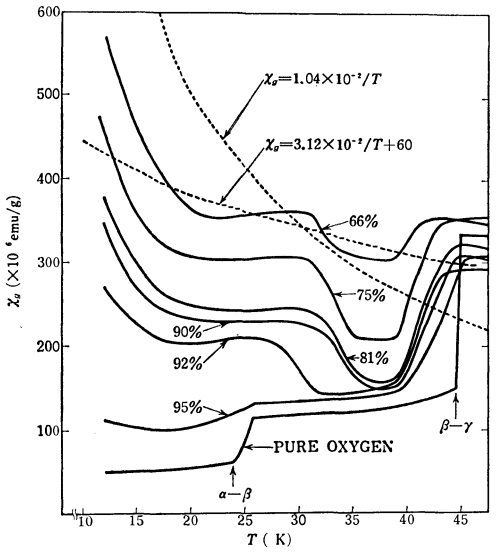

Fig. 1. The magnetic susceptibility of solid oxygen-argon systems.

In case of the 95% O_2, the behavior of the magnetic susceptibility was very similar to that of pure oxygen. This shows that the antiferromagnetic properties characteristic of each crystalline phase, α, β, and γ, of solid oxygen are not so much affected at these low concentrations of argon.

From the viewpoint of the dynamics of crystallization, however, this solid was found to behave differently from pure oxygen. The transformation temperatures from β to γ are lowered to about 40 K. The transformation process was also observed to be less discontinuous; an abrupt change in the susceptibility at each transition temperature, as in pure solid oxygen, was not observed in this mixture even at the slowest of temperature increases (1 °C/min), which was controlled by changing the vacuum in the Dewar vessel. Because of this experimental design, the susceptibility did not reach equilibrium during the transformation. These dynamical effects resulting from the addition of argon to the oxygen lattice have been previously observed in a determination of the oxygen-argon system by Barrett *et al.*,[6] and also through the measurement of the specific heat.[7]

On the other hand, with a further increase in the argon content, the magnetic susceptibilities showed some behavior very different from that of pure oxygen and the 95% O_2 mixture. They are consistent with an interesting phenomenon discovered by Barrett,[5] namely, that a novel homogeneous phase, 'δ', different from the phase of pure oxygen and pure argon, exists in the composition range between 55 and 80% O_2, while the monoclinic phase disappears. Furthermore, the upper limit of oxygen content at which the δ phase appears can be extended to 90% when the mixture is cooled from the γ phase down to the temperature of liquid hydrogen within less than an hour.

The stable-temperature region of this phase was estimated from the decrease in the susceptibility to be below 30—31 K for the 90%, 81%, 75%, and 66% oxygen mixture. In the case of the 92% O_2 and 8% Ar samples, a similar decrease in susceptibility was observed, but at a slightly lower temperature, about 26 K. These transformation temperatures do not agree in detail with those of the phase diagram.[6] According to this, the δ phase containing 80—90% O_2 is transformed to the β phase via a two-phase $\delta+\beta$ region at temperatures between 25 and 29 K, and that of 66—80% is transformed to the hexagonal closed-packed phase of argon + the β phase via the $\delta+\beta$ region at 29 K. This discrepancy may arise from the fact that the magnetic susceptibility measurements can not give such a sensitive indication of these complex transformation processes as X-ray diffraction analysis.

The temperature and concentration dependence of the susceptibility in the δ-phase region can be interpreted on the basis of the crystal structure. A possible structure of the δ phase was also determined by Barrett.[8] According to their work, unit cell has a body-centered cubic lattice with $a=13.23\pm0.02$ Å and $Z=64$, which is a super lattice of the γ structure

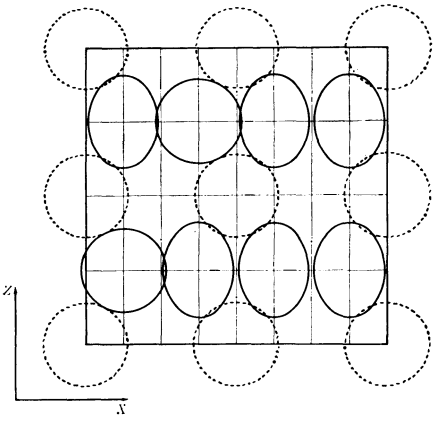

Fig. 2. The [010] plane of unit cell of the δ structure belonging to the space group I_{2_13}. The solid and dotted circles represent argon atoms with a diameter of 3.75 Å. The ellipses represent oxygen molecules with a major axis of 3.18Å.[10] The tilting of the molecular axis is postulated to be in this plane. The corner's argon represented by a dotted circle is displaced by 0.005, 0.005, 0.005 from each position along the threefold axis.

of pure oxygen, with $a=6.83\pm0.05$ Å and $Z=8$. The position of the argon atoms in the δ structure has not been exactly determined, but some plausible models have been suggested. One of them is illustrated in Fig. 2. In this model, the argon and oxygen molecules are placed in a periodic sequence as; $\cdots Ar,O_2,O_2,O_2\cdots$ in the rows across the middle of the cube faces denoted 'γ rows.' The distance between the oxygen molecules in a γ row is 3.31 Å, which is equal to the nearest-neighbor distance in β-O_2 and about 0.1 Å shorter than in γ-O_2. Therefore, we can expect that there exists a fairly strong antiferromagnetic exchange interaction between these three oxygen molecules $(O_2)_3$ in a γ row. Consequently, the total spin moment of this trimer of the form $(O_2)_3$ decreases and becomes one in the antiferromagnetic short-range ordered state.

The paramagnetic increase below about 20 K is dependent on the argon content and seems to obey a Curie-Wiess law. A qualitative interpretation can be given in terms of weak antiferromagnetic interactions between the corner or the body-center's oxygens and the trimer in a γ row. The exchange interaction for these oxygen molecules, separated by about 3.8 Å, estimated to be equal to or less than 2 K from the 'statistical' Weiss temperature obtained for oxygens dispersed into the f.c.c. lattice of argon.[9] If the argon ratio is increased, some of the sixteen oxygen molecules at the corner and body-center's sites are successively replaced by argon, that is, 0 for 81% O_2, 4 for 75% O_2 and 10 for 66% O_2, so that the exchange interaction is weakened. Furthermore, as the neighboring trimers are separated by more than 4.1 Å, the magnetic susceptibility increases, obeying a Curie-Weiss law with a nearly zero Weiss temperature and also a smaller total spin moment. This is represented in the limiting form, $\chi(\text{emu/g})=C'/T+\theta$, where θ is the Weiss temperature and where C' equals 1.043×10^4, that is, the value of 1/3 of 3.128×10^4 for a free oxygen molecule. A quantitative treatment, however, was not attempted because it was not possible to estimate the contributions of residual phases, such as the α and β phases of solid oxygen, and of oxygens randomly dispersed in the segregated argon matrix.

Some interesting phenomena due to δ-phase transformation have also been observed from magnetic susceptibility measurements in solid oxygen-fluorine systems. These results will be reported elsewhere.

Thermoluminescence from the UV-Irradiated Solution of Triphenylmethane at Low Temperature

Naoto YAMAMOTO, Michio MATSUMURA, and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 22, 1973)

Triphenylmethane, irradiated in the near ultraviolet region in a non-polar rigid medium at 77 K, showed thermoluminescence consisting of three bands, fluorescence and phosphorescence of triphenylmethane and fluorescence of triphenylmethyl radical. With the increase of solute concentration the yield of the emissions from triphenylmethane decreased while that of the emission from the radical increased. It was concluded that the emissions from triphenylmethane were due to the recombination between triphenylmethane cation and the photo-ejected electron, and that the fluorescence from the radical was mainly due to the electron transfer reaction between triphenylmethane cation and triphenylmethyl anion. Detailed emission processes inlcuding electron transfer and energy transfer processes were discussed.

Thermoluminescence from low temperature UV-irradiated solution of aromatics has been investigated by many authors.[1-4] It has been recognized that the luminescence in many cases is caused by recombination of the charged species generated by the photo-ionization of aromatic molecules. Gibbons *et al.*[3] found that the thermoluminescence from an irradiated solution of toluene comprises the fluorescence and the phosphorescence of toluene together with the fluorescence of the benzyl radical. The former two emissions were concluded to be caused by the recombination of the solvated electron with the toluene cation, while the mechanism for the last one was left untouched.

In this paper, we have investigated the thermoluminescences from triphenylmethane irradiated in non-polar organic rigid solutions and give an explanation for the emission mechanism.

(TMPD) was described previously.[5] Isopentane and methylcyclohexane were purified by passing through 1 m silica gel columns. Solutions of triphehylmethane in a 2 : 1 mixture of isopentane and methylcyclohexane (hereafter called MP) were deaerated by purging with nitrogen. Irradiation of the solution in the UV region was carried out at 77 K with a high pressure mercury lamp (250 W) through a Toshiba UV-D25 glass filter and an aqueous solution of 2.0 M nickel sulfate. Infrared light was obtained from the same lamp using a Toshiba VR-67 glass filter. The thermoluminescence from the irradiated solution was measured with a Shimadzu GF 16 monochromator and an RCA 1P28 photomultiplier. Details of the measurement are described elsewhere.[6] The absorption spectra were measured with a Cary Model 15 spectrophotometer.

Results

Change of the absorption spectrum of an MP solution of triphenylmethane by UV-irradiation is shown in Fig. 1. The bands lying in the range 25—35 kK and around 20 kK were in fairly good agreement with those of triphenylmethyl radical assigned by Adam and Weissman.[7] Formation of the triphenylmethyl radical was found to be proportional to the square of the intensity of UV-light from the absorption intensity measurement. It is therefore concluded that the radical is produced by a bi-photonic mechanism.[4,8] The irradiated solution showed weak luminescence on warming. A thermoluminescence spectrum is shown in Fig. 2. The band with maximum at 34.5 kK corresponds to the fluorescence of triphenylmethane, and that at 24.4 kK to the phosphorescence of the same

molecule. The band at 19.4 kK agrees well in shape and position with the normal fluorescence of triphenylmethyl radical ($^2E\leftarrow{}^2A_2$ transition).[9]

The intensity of thermoluminescence was measured for each emission band as functions of time after the irradiated solution was taken out from the Dewar (Fig. 3). Curves (a) for fluorescence and (b) for phosphorescence of triphenylmethane are similar in shape, while curve (c) for fluorescence of the triphenylmethyl radical differs considerably, suggesting that the latter appears by a different mechanism from that for the emission of triphenylmethane. It was also found from simultaneous observation of the glow curves and the change of absorption with warming that the radical survives after the emission from the radical already fades out.

The emission intensities change markedly with experimental conditions such as concentration of the solution and UV-irradiation time. Figure 4 shows the emission yield (obtained by integrating the thermal

glow curve with time) for the three bands of the thermoluminescence against the concentration of the solute. Concentrated solutions (10^{-3}—10^{-2} M) absorbed almost all the UV-lights (the cell used was 13 mm thick) and therefore gave nearly constant amounts of triphenylmethyl radical in the media for the irradiation time of 10 min. For solutions with concentrations below 10^{-3} M, part of the light passes through the solution. Such solutions were irradiated until the yield of the radical became equal to that of the concentrated solutions. As is obvious from Fig. 4, the emission from triphenylmethane were strong at lower concentration and weak at higher concentration. On the other hand, the fluorescence from the radical, hardly observable at concentration of 2×10^{-4} M, became strong at concentration above 10^{-3} M.

No absorption band of triphenylmethane cation was found for the irradiated solution in the visible and near infrared region.[10]

We also measured the thermoluminescence for the MP rigid solution containing TMPD (1.5×10^{-5} M) and triphenylmethane (7×10^{-3} M). Strong thermoluminescence was observed and its spectrum was found to consist of three bands, *i.e.*, the fluorescence and phosphorescence of TMPD and the fluorescence of triphenylmethyl radical (Fig. 5, curve a). The fluorescence of triphenylmethyl radical was 11 times stronger in intensity than that obtained for an MP solution containing only 7×10^{-3} M triphenylmethane where the irradiation time was 5 min for both cases. For the irradiated TMPD-triphenylmethane solution, the TMPD cation and triphenylmethyl radical were proved to be present by absorption measurement, but no absorption band was found in the visible region ascribable to triphenylmethyl anion.[11]

The thermoluminescence was also studied for a UV-irradiated solution of triphenylmethane after being exposed to infrared light. The emissions from triphenylmethane became weak but the fluorescence from the radical was only slightly affected (Table 1).

Discussion

Emission Mechanism. It is evident from UV absorption spectra studies that the triphenylmethyl radical is formed in the UV-irradiated solution of triphenylmethane at 77 K. The radical is presumably formed by the following bi-photonic excitation.[4,8]

$$\phi_3CH \xrightarrow{h\nu_1} {}^3[\phi_3CH] \xrightarrow{h\nu_2} \phi_3C\cdot + H\cdot \qquad (1)$$

The ionization potential of triphenylmethane is 8.80 eV in the gas phase,[12] and its triplet state energy is 3.58 eV higher than that of the ground state. Therefore, if it is photo-ionized by the bi-photonic process as are many aromatics in the low temperature matrices,

$$\phi_3CH \xrightarrow{h\nu} {}^3[\phi_3CH] \xrightarrow{h\nu'} [\phi_3CH]^+ + e \qquad (2)$$

10) T. Shida and W. H. Hamill, *J. Chem. Phys.*, **44**, 2375 (1966).
11) K. K. Brandes, R. Suhrmann, and R. J. Gerdes, *J. Org. Chem.*, **32**, 741 (1967).
12) V. V. Sorokin, *Zh. Fiz. Khim.*, **40**, 2332 (1966).

the second step needs a photon energy equal to or higher than 5.2 eV in the gas phase. Due to polarization energy, the necessary energy for the second step in the matrix may be smaller. As the light source used in the present work has an energy distribution in the range 5.2—3.4 eV, such a photo-ionization is assumed to take place to a small extent, though we could not observe the absorption bands for the triphenylmethane cation.

The triphenylmethyl radical formed is expected to capture the electron ejected in the medium because of its large electron affinity.

$$e + \phi_3C\cdot \longrightarrow \phi_3C^- \quad (3)$$

The anion and other charged species frozen at 77 K become mobile when the solution is warmed. The triphenylmethane cation and the solvated electron will recombine causing emissions from triphenylmethane as follows:

$$\phi_3CH^+ + e_{solv} \longrightarrow {}^1\phi_3CH^* \text{ or } \phi_3CH^* \quad (4)$$

$${}^1\phi_3CH^* \longrightarrow \phi_3CH + h\nu_F \quad (5)$$

$${}^3\phi_3CH^* \longrightarrow \phi_3CH + h\nu_P \quad (6)$$

On the other hand, the triphenylmethyl anion will react with the triphenylmethyl cation and emit fluorescence of the triphenylmethyl radical as follows:

$$\phi_3CH^+ + \phi_3C^- \longrightarrow \phi_3CH + {}^2\phi_3C\cdot^* \quad (7)$$

$${}^2\phi_3C\cdot^* \longrightarrow \phi_3C\cdot + h\nu_F' \quad (8)$$

As the first excited doublet state of the radical is energetically the lowest of all the excited states of triphenylmethane and the radical formed, the fluorescence from it will prevail as the result of the electron transfer and energy transfer processes.

Variations in the intensities of the emission bands with concentration (Fig. 4) can be explained as follows. In dilute solutions, reactions (1) and (2) by irradiation occur uniformly in the cell, while in concentrated solutions they take place mostly near the surface of the irradiated side of the cell, the concentration of the triphenylmethyl radical thus becoming much higher at that part of the solution. As the concentration of the radical becomes higher, the ratio of the photo-ejected electrons captured by the radical compared with those trapped in the matrix become higher.[6,13] Consequently, as reactions (4), (5) and (6) are dominant so are the emissions from triphenylmethane at low concentrations, while as reactions (7) and (8) become dominant so do the emissions from the radical at high concentrations. This fits the trends of curves in Fig. 4.

For the case of TMPD-triphenylmethane solution, it is most probable that the electrons generated mainly by the photo-ejection from TMPD are captured by triphenylmethyl radicals, and the electron transfer reaction between TMPD cation and triphenylmethyl anion leads to the fluorescence from the radical. That the emissions from triphenylmethane were weakened by illumination in the infrared to a greater extent than the emission from the radical seems to result from the fact that the electron is bound by the radical more tightly than in the matrix (Table 1).

The emission from benzyl radical observed for the irradiated solution of toluene might be due to the reaction between benzyl anion and toluene cation.[3,14]

Electron transfer and energy transfer on recombination. We have concluded that the combination of triphenylmethane cation with triphenylmethyl anion leads to emission from the triphenylmethyl radical.

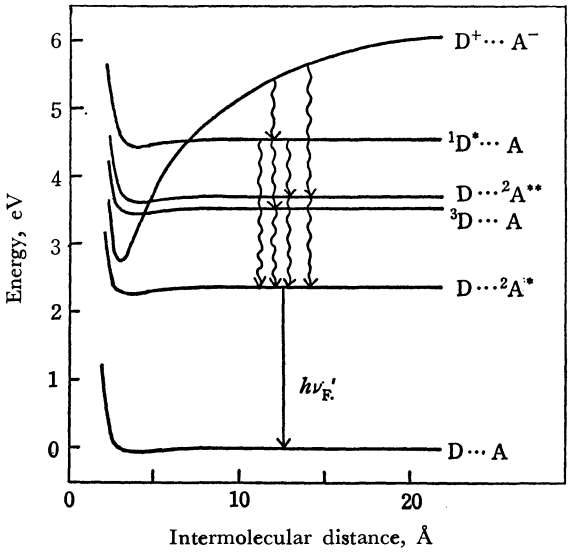

Fig. 6. The potential energy curves for the various states of a system made of triphenylmethane cation (D^+) and trimethyl radical anion (A^-).

The triphenylmethyl anions are expected to be distributed at fairly large distances (~100 Å)[13,15] from the triphenylmethane cations at 77 K. As the matrix is warmed, the anion is mobilized and is drawn near the cation by the Coulombic force along the $D^+\cdots A^-$ curve in Fig. 6. The velocity of the anion should be determined by the Coulombic force $e^2/\varepsilon r^2$, and the resisting force by $6\pi\eta bv$ according to the Stokes' law, where ε and η are respectively the dielectric constant and viscosity of the medium, and b and v the radius and velocity of the anion, respectively. Thus we have

$$v = e^2/6\pi\eta b\varepsilon r^2 \quad (9)$$

In order to estimate the distance between the ions at which the electron transfer reaction occurs at the maximum rate, it is necessary to derive the absolute value of the reaction rate as a function of the distance. The probability of the electron transfer from the anion to the cation P_{CT} is proportional to the amount of charge transfer interaction V_{CT}.

$$P_{CT} = 2|V_{CT}|/h \quad (10)$$

$$V_{CT} = \langle \Phi_f | H | \Phi_i \rangle \quad (11)$$

where Φ_i and Φ_f are, respectively, the wave functions for the initial and final states of the system and H is

the total Hamiltonian. We roughly estimate the value of the right side of Eq. (11), using a simple model consisting of two carbon monocations C_A^+ and C_B^+ fixed at a distance of r and an electron. Assuming that the electron is initially localized on C_A^+ and transferred to C_B^+, the initial and the final electronic wave functions are the atomic orbitals of the each atom represented by Φ_A and Φ_B, respectively. In this case, the matrix element in Eq. (11) can be simply written as follows.

$$\langle \Phi_f | H | \Phi_i \rangle = \langle \Phi_B | H | \Phi_A \rangle \quad (12)$$

Assuming that it is proportional to the overlap integral of the orbitals, approximated to be proportional to $\exp(-3.07\times10^8 r)$, and taking the value of 2.4 eV for the element at $r=1.40$ Å, as suitable for the usual MO calculation of π-electron systems, we obtain

$$P_{CT} = 8.48 \times 10^{16} \exp(-3.07\times10^8 r) \quad (13)$$

By taking the probability of existence of unreacted ion-pair to be p, and assuming the initial distance between the cation and the anion to be very much greater than the distance at which the electron transfer reaction takes place predominantly, the extermination of the ion-pairs due to the electron transfer can be represented as a function of distance:

$$\begin{aligned} dp/dr &= -(P_{CT}/v)p \\ &= -6.94\times10^{36}\,\eta b\varepsilon r^2 \exp(-3.07\times10^8 r)p \end{aligned} \quad (14)$$

The most probable distance for the reaction corresponds to the distance making dp/dr the maximum. Hence, the following equation is obtained, taking $d^2p/dr^2=0$

$$\begin{aligned} &-(2-3.07\times10^8 r_{max})/r_{max}^3 \\ &= 6.94\times10^{36}\eta b\varepsilon \exp(-3.07\times10^8 r_{max}) \end{aligned} \quad (15)$$

It is found that the r_{max} determined from Eq. (15) is rather insensitive to η, b and ε. Saturated hydrocarbons at 77 K have viscosities of the order of 10^{12} P.[16] At the temperature of maximum thermoluminescence, the viscosity is definitely higher than 10^3 P. We calculated r_{max} using the values of 10^{12} and 10^3 P for the viscosity of the solvent. Taking 4.0 Å for b and 2.5 for ε, the distances obtained are 7.6 Å for $\eta=10^3$ P and 14.8 Å for $\eta=10^{12}$ P.

The primary electronic state thus formed by the electron transfer reaction, which should have a total energy equal to the CT state at that distance, may be such as D**···A, D···A** etc., where D** and A** are higher excited states of triphenylmethane and triphenylmethyl radical. The energy relaxation due to intra-molecular radiationless transitions is thought to be very quick. The inter-molecular energy transfer, such as transition from either ^{1}D* or ^{3}D* to ^{2}A*, depends strongly on the inter-molecular distance. Since the dipole-dipole transition from ^{1}D* to ^{2}A* is spin-allowed, this process should take place very effectively at the distances considered.[17] The transition from ^{3}D* to ^{2}A*, although it is spin-forbidden, seems also to be effective because the triplet state of D is long-lived at low temperatures. These radiationless processes are represented in Fig. 6 by the wave lines. The fluorescence from the radical observed is understandable as due to the electron transfer followed by energy transfer reactions (Fig. 6).

Molecular Structure of Ethane. Comparison of the Structure Parameters of CH_3CD_3 in the Torsionally Excited State and in the Ground State

Takao IIJIMA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 10, 1973)

The structure parameters of ethane have been re-examined by the use of the spectroscopic moments of inertia and the electron diffraction results, on the basis of the large amplitude theory for the torsional motion. The results have been applied to the CH_3CD_3-species in order to see whether or not the change of the moment of inertia in the torsionally excited state observed by Hirota and Matsumura is consistent with the theoretical prediction on the deformation of the molecular frame upon torsion proposed by Veillard. The conclusion has been affirmative. The elongation of the C–C distance by 0.0028 Å and the decrease of the HCH angle by 0.05° in the torsionally excited state as expected from the theoretical calculation have been found to be consistent with the experimental result of microwave spectroscopy.

According to several experimental results obtained by microwave spectroscopy[1–3] and a series of theoretical studies,[4–7] it seems that the torsional motion of molecules involves sizable deformations of the frame and/or the top. Meyer and Wilson[2] extensively investigated the rotational constants of torsionally excited states

of ethyl formate and two other compounds. They concluded that observed changes of rotational constants upon torsional excitation could not be explained without allowing distortions of the molecular geometry upon torsion. An *ab-initio* molecular Hartree-Fock calculation of ethane was carried out by Veillard,[4] where the C–C distance and the HCH angle were optimized. The barrier hindering internal rotation was calculated to be 3.07 kcal/mol, which was very close to the experimental value 2.93 kcal/mol. The C–C distance of the eclipsed conformation was found to be longer than that of the staggered conformation by 0.019 Å, and the HCH angle was smaller by 0.34°. It was not necessary to vary the C–H distance.

In order to get experimental confirmation of this theoretical prediction, ethane is naturally the most suitable molecule. However, since ordinary ethane is inactive in microwave, the rotational constant of the torsionally excited state had not been available. Recently, Hirota and Matsumura[3] made successful observation of the microwave spectrum of CH_3CD_3 species and obtained the rotational constants of both the ground state and the torsionally excited state. The present study is an analysis of the structure parameters of ethane, especially for the purpose of seeing whether or not the theoretical calculation by Veillard is consistent with the experimental observation by Hirota and Matsumura. The conclusion of the present study is that they are consistent with each other. This is also to support the theoretical implication of Veillard's calculation that the electron correlation is not important in the barrier to internal rotation, contrary to the binding energy in which the effect of electron correlation (molecular correlation) is considerable.[8] The deformation of molecular geometry upon torsion is to give an additional correction in the structure determination by a joint use of spectroscopic and diffraction data, since the observed values of diffraction experiment are averaged quantities over torsionally excited state. The force constants determined by Nakagawa and Shimanouchi[9] were used throughout this work.

Analysis

Changes of the Structure Parameters between the Ground State and the First Excited State of Torsional Motion. On the basis of Veillard's calculation, the changes of the C–C distance and the HCH angle for different torsional states were estimated by assuming that the variation of the structure parameters follows the trigonometric function as that of the torsional potential, *viz.*,

$$\Delta r = \frac{c}{2}(1-\cos 3\phi) \qquad (1)$$

where c is 0.019 Å for the C–C distance and −0.34 Å for the HCH anlge, and ϕ is the torsional angle. The average value of Δr for the torsional state τ was evaluated by

$$\langle \Delta r \rangle_\tau = \frac{9}{4} c \langle \phi^2 \rangle_\tau \qquad (2)$$

where the $\langle \phi^2 \rangle$ was calculated by a harmonic approximation.

The values of $\langle \Delta r \rangle$ calculated by Eq. (2) are summarized in Table 1 for the ground state ($\tau=0$) and the first excited state ($\tau=1$). The thermal average values $\tau=T$ at the room temperature are also shown. A similar table for the HCH angle are shown also in the Table 1. From the values in Table 1, it is expected that the structure parameters of CH_3CD_3 for the first excited state of torsion is different from those of the ground state in such a way that the C–C distance is longer by 0.0028 Å and the HCH angle is smaller by 0.05°.

Table 1. Changes of the C–C distance and the HCH angle for different torsional states

	CH_3CH_3	CD_3CD_3	CH_3CD_3
$\langle \Delta r \rangle_0$	17(−31) [b]	12(−22)	14(−25)
$\langle \Delta r \rangle_1$	51(−92)	36(−65)	42(−76)
$\langle \Delta r \rangle_T$ [a]	27(−49)	26(−47)	25(−45)

a) Thermal average values at $T=288$ K
b) Values in the parentheses are the corresponding averages of the HCH angle in 10^{-3} degree units.

Even without the detailed analysis described in the following section, it can be seen that the b-axis moments of inertia I_b obtained by Hirota and Matsumura show a trend which is consistent with the estimation mentioned above. The increase in the C–C distance of 0.02% roughly corresponds to an increase in I_b of 0.04%. Observed value of I_b for the excited state is 0.03% as large as the I_b for the ground state (see Table 2).

Since the thermal average values $\langle \Delta r \rangle_T$ are almost equivalent for all the isotopic species, the isotope effect originating from the torsional distortion can not be expected to appear in r_g values obtained by electron diffraction. On the other hand, the small differences in $\langle \Delta r \rangle_0$ will be the isotope effect of this origin upon r_a^0 or r_z, *i.e.*, the zero-point average distances. More important is the difference between $\langle \Delta r \rangle_T$ and $\langle \Delta r \rangle_0$ which should be included in the correction of r_g to r_a^0 in the joint analysis of electron-diffraction and spectroscopic data on the basis of the zero-point average structure.[10]

Structure Parameters. The structure parameters of CH_3CH_3 and CD_3CD_3 were previously determined by Kuchitsu[10] by means of a joint use of electron diffraction data and spectroscopic moments of inertia. In his treatment, the torsional motion was regarded as a small-amplitude vibrational motion, which was valid since the torsional amplitudes of these molecules are not very large. In the present study, the structure parameters of h_6 and d_6-species were re-determined on the basis of the large amplitude theory for a molecule containing a single internal rotor,[11] simply in order to apply the obtained parameters to the torsionally excited state of CH_3CD_3 in which the small-amplitude approximation would probably fail. In fact the determined parameters of h_6 and d_6-species have shown

b) The r_g-parameters consistent with the r_z-values of the set II are equivalent to the electron diffraction results of Ref. 17, except for the HCH and DCD angles or the non-bonded C···H and C···D distances, which are 2.196_4 Å for C···H and 2.190_9 Å for C···D.
c) To be applied to all the isotopic species. Note that these are uncertainties in the absolute values of the parameters and that the uncertainties in the relative scale are much smaller.
d) Torsionally excited state.

no significant discrepancy from those by Kuchitsu, if the difference in the operational definitions of the parameters is taken into account in the comparison.[12]

In Table 2 are listed the observed values of moments of inertia, the vibrational corrections calculated by the method reported elsewhere,[11,16] and the zero-point average moments of inertia I_z(SP). The moments of inertia calculated by the use of the r_α^0-parameters obtained from the electron diffraction result by Bartell and Higginbotham[17] are compared as I_z(ED). Although a trend that I_z(ED) was systematically larger than I_z(SP) by 0.02% was observed in the analysis by Kuchitsu, it is not seen in the present result. This is partly because of the correction for the torsional deformation included in the conversion of r_g into r_α^0.

A comparison of I_z(ED) and I_z(SP) suggests that a slight adjustment of HCH angle would lead to a set of parameters consistent with the I_z(SP). The values of I_z calculated by the adjusted parameters are listed in the column I_z^{calcd} of Table 2, while the values of the parameters are shown in Table 3.

The structure parameters for the ground state of CH_3CD_3 were then determined as follows. The C–C distance was set equal to the average of those of h_6 and d_6-species. The HCH and DCD angles were transferred from h_6 and d_6-species, respectively. The agreement of the calculated I_z^{calcd} with the observed I_z(SP) is satisfactory. For the torsionally excited state, the C–C distance and HCH (DCD) angle were varied according to the estimation described in the preceding section. The agreement of the calculated value of the moments of inertia with the observed is remarkable. It may be said that the theoretical prediction on the deformation of molecular frame upon torsion has been

12) The zero-point average structure in Ref. 10 is a representation of the atomic positions averaged over all zero-point motions including torsion, while the torsional motion is not included in the averaging in the present treatment. The effect of this difference appears mainly in the structure parameters related to hydrogen atoms.

15) H. C. Allen and E. K. Plyler, *ibid.*, **31**, 1062 (1959).

16) In order to reduce the off-diagonal term of the moments of inertia tensor in the kinetic energy Hamiltonian, the molecular-fixed coordinate-axes for h_6 and d_6-species were chosen in such a way that the torsion of an angle ϕ was represented by a rotation of $\phi/2$ of both ends in the opposite directions. For CH_3CD_3, the rotations of the two tops CH_3 and CD_3 were chosen to be inversely proportional to the moment of inertia of each top around the axis.

17) L. S. Bartell and H. K. Higginbotham, *J. Chem. Phys.*, **42**, 851 (1965).

given quantitative confirmation by experimental observation.

In the present analysis, the secondary isotope effect in the C–C distance was retained as originally reported in the electron diffraction study.[17] If this isotope effect is ignored and an average of the C–C distances in the h_6 and d_6-species is taken as the diffraction value, a slightly different set of structure parameters can be obtained, although the difference is of no significance. However, there would be no revision in the conclusion about the comparison of the ground state and the torsionally excited state of the CD_3CH_3 species.

As for the estimation of the uncertainties of the determined parameters, the present study has nothing to revise the values reported in Ref. 10, which are reproduced in Table 3. However, these are the uncertainties in the absolute values of the parameters, and the uncertainties in the relative scale, *i.e.*, the difference between the torsionally excited state and the ground state, are much smaller.

The author wishes to thank Professor Masao Kimura, Hokkaido University, for his encouragement. Numerical calculations were carried out on a FACOM 230—60 of the Hokkaido University Computing Center, and on a FACOM 270—20 of Professor Kimio Ohno's laboratory, to whom the author's thanks are also due.

Microwave Spectrum of Arsenic Trifluoride in the Excited Vibrational State

Toshio CHIKARAISHI and Eizi HIROTA

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received April 5, 1973)

The microwave spectrum of arsenic trifluoride was observed in the excited states of all the normal vibrations. The rotational constant at the equilibrium state was determined, and the equilibrium As–F distance was calculated to be 1.704_4 Å assuming the FAsF angle to be 95°58′. The *l*-type doubling constant, q_4, and the asymmetry parameter, η, of the As nuclear quadrupole coupling constant were determined in the $v_4=1$ to be 10.24 ± 0.02 MHz and $-0.00_5\pm0.01$, respectively.

Kisliuk and Geschwind[1] have measured the $J=2\leftarrow1$ transitions of arsenic trifluoride and have determined the ground-state rotational constant, the nuclear quadrupole coupling constant, and the vibration-rotation interaction constants, α_2^B and α_4^B, for a symmetric and a degenerate bending vibration, v_2 and v_4. Reichman and Overend[2] have analyzed the infrared v_1 band of arsenic trifluoride and determined the ground-state rotational constant and the α_1^B constant. Mirri[3] has obtained the force field of AsF_3 by the combined use of the vibrational frequencies and the centrifugal stretching and Coriolis' coupling constants. On the other hand, Konaka[4] and Konaka and Kimura[5] have determined the thermal-average distance, r_g(As—F), by gas-phase electron diffraction and has calculated the zero-point average distance, r_z(As—F). In the present work the microwave spectrum in the excited states of all the normal vibrations was observed to obtain the equilibrium structure of arsenic trifluoride. The *l*-type doubling transitions in the v_4 state were also observed to determine the *l*-type doubling constant and to examine the asymmetry of the quadrupole coupling constant of the As nucleus induced by the degenerate bending vibration, v_4.

Experimental

A sample of arsenic trifluoride was donated to us by the courtesy of Dr. S. Konaka of Department of Chemistry, Hokkaido University, and it was purified through vacuum distillation. The spectrometer used was of conventional Hughes-Wilson type with 120 kHz sine-wave and square-wave Stark modulators. The spectrum was recorded while pumping the sample through the cell because of decomposition of arsenic trifluoride in the waveguide.

Results

The $J=1\leftarrow0$ transitions in the ground vibrational state and four excited vibrational states, v_1, v_2, v_3,

a) Errors are standard deviations. b) Ref. 2. c) Ref. 1. d) From the $J=5\leftarrow4$ transition. e) In calculating α_4^B the ground-state rotational constant of 5879.08 MHz (Table 4) is used, which is determined by using the transitions of $J=2\leftarrow1$ through $5\leftarrow4$.

and $2\nu_2$, were measured. The observed frequencies are listed in Table 1. The rotational constants and the nuclear quadrupole coupling constants were determined using the following equation, Eq. (1):

$$\nu = 2B_v(J+1)+\Delta W_Q^{(1)}, \quad (1)$$

where $\Delta W_Q^{(1)}$ is the first-order contribution of the quadrupole effect. The vibration-rotation interaction constants were calculated by $\alpha_v^B=B_0-B_v$. The molecular constants determined are listed in Table 2. The ν_4 spectra were not resolved from those of the ground state in the $J=1\leftarrow0$ transition, but a hyperfine component $F=11/2\leftarrow9/2$ of the $J=5\leftarrow4$, $K=3$ transition was observed at 58773.09 MHz, which was higher than the ground state line by 1.65 MHz, and thus the α_4^B constant was calculated to be -0.16_5 MHz. This is in good agreement with the value of Kisliuk and Geschwind.[1] On the other hand, the α_2^B constant is much improved in accuracy compared with that reported in Ref. 1. Using all the four α^B constants thus obtained the equilibrium rotational constant, B_e, was calculated to be 5893.20 ± 0.30 MHz.

Because both arsenic and fluorine nuclei have only one stable isotope, no isotopic species of arsenic trifluoride are available. It is known that the effect of the intramolecular vibrations on the bond angle is relatively small, and therefore, taking the zero-point average bond angle θ_z(FAsF), 95°58′, obtained by Konaka[4] as the equilibrium value, the equilibrium length was calculated to be r_e(As—F)$=1.704_4$ Å. If the error in the angle is assumed to be ±1°, that of the bond length is ±0.0013 Å, where the double signs should be taken in the same order.

The l-type doubling transitions in the ν_4 vibrational state were observed for $J=2\leftarrow1$ through $J=5\leftarrow4$. A general expression for the frequencies of the lower and upper doublet components is given for the $J+1\leftarrow J$ transition by [6-8]

$$\begin{aligned}\nu^{\pm} &= 2B_4(J+1)\pm q_4(J+1)+(eqQ)_{v_4=1}\\ &\times[\{3/[(J+1)(J+2)]-1\mp(1/2)\eta\}f(I,J+1,F_f)\\ &-\{3/[J(J+1)]-1\mp(1/2)\eta\}f(I,J,F_i)] \quad (2)\end{aligned}$$

where B_4 and q_4 denote the rotational constant and l-type doubling constant, respectively, in the $v_4=1$ state, η (referred to as the asymmetry parameter) the asymmetry in the electric field gradient induced at the arsenic nucleus by the ν_4 mode, and $f(I,J,F)$ Casimir's function. The frequencies of the $K=\pm1$, $l_4=\mp1$ component are given by

$$\begin{aligned}\nu_0 &= 2B_4(J+1)+(eqQ)_{v_4=1}[\{3/[(J+1)(J+2)]-1\}\\ &\times f(I,J+1,F_f)-\{3/[J(J+1)]-1\}f(I,J,F_i)] \quad (3)\end{aligned}$$

By using Eqs. (2) and (3) the following equation is derived.

$$\begin{aligned}\Delta\nu^{\pm} &= \nu^{\pm}-\nu_0\\ &= \pm q_4(J+1)\mp(1/2)\eta(eqQ)_{v_4=1}\\ &\times[f(I,J+1,F_f)-f(I,J,F_i)] \quad (4)\end{aligned}$$

The lines of the ground vibrational state and the $K=\pm1$, $l_4=\mp1$ components of the ν_4 vibrational state are overlapped with each other, except for a hyperfine component of the $J=5\leftarrow4$ transition mentioned above. The effect of the l-type resonance[9] has not been ob-

served definitely. In calculating $\Delta\nu^-$ the center frequencies ν_0 of the ν_4 state were estimated by fixing B_4 to 5879.24 MHz, which was obtained from the α_4^B constant and the ground-state B value of 5879.08 MHz, the latter being determined using the $J=2\leftarrow1$ to $5\leftarrow4$ transitions. The observed frequencies of the l-type doubling transitions and $\Delta\nu^-$ are listed in Table 3. The upper components ν^+ are overlapped by the ν_2 satellites and are not resolved clearly because of the broad line width. The frequencies of the l-type doubling transitions were fitted to Eqs. (2) and (4) by a least-squares method, where the centrifugal distortion in the ν_4 state was assumed to be the same as in the ground vibrational state. The constants thus obtained are shown in Table 4. The l-type doubling constant is 10.24±0.02 MHz. The value of the As nuclear quadrupole coupling constant in the ν_4 state was also listed in Table 4. The difference in the hyperfine structure pattern of the ground state and the ν_4 state is hardly noticeable, and electric field gradient at the arsenic nucleus remains almost unaffected by the excitation of the ν_4 vibration. The asymmetry parameter is zero within experimental error.

Transmission of Substituent Effects through the Oxygen and Sulfur Atoms. IV. CNDO/2 Charge Distributions in Vinyl and Divinyl Ethers and Sulfides

Okitsugu KAJIMOTO, Masaru KOBAYASHI, and Takayuki FUENO

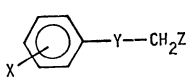
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received April 13, 1973)

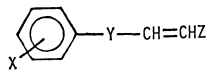
Charge distributions in vinyl methyl and divinyl ethers and their sulfur homologs bearing a polar substituent at the *trans*-β position were calculated by the CNDO/2 method. It was found that the effect of substituents on charge distribution is transmitted primarily through the successive π-polarization of the ethylenic units involved. In the divinyl compounds, the sulfur atom on the spd basis is calculated to transmit the substituent effects more effectively than the oxygen atom. The greater transmission efficiency of the sulfur atom is interpreted in terms of the pπ-dπ-pπ conjugation.

The reaction constant ρ of the Hammett equation is a useful experimental probe into the mode and efficiency of the transmission of the electronic effects of substituents in aromatic side-chain reactions.[1,2] A systematic examination of the ρ-values often permits quantitative comparison of the transmission efficiencies of the atoms or groups which intervene between reaction center and substituents.[3]

In the preceding papers of this series,[4-6] we compared the roles of the oxygen (Y=O) and sulfur (Y=S) atoms in transmitting the effects of ring-substituents (X) to the properties of the side-chain groups (CH_2Z and CH=CHZ) in two types of compounds I and II:



I (Y = O or S)



II (Y = O or S)

The properties investigated were the ^1H chemical shifts of the terminal hydrogen (Z=H),[4] the ^{13}C shifts of the aliphatic carbons (CH_2Z and CH=CHZ with Z=H),[5] and the ionization equilibrium constants of the carboxylic acids (Z=COOH).[6] It was found that, while in compounds I the sulfur atom is apparently a less efficient transmitter of the substituent effects than the oxygen atom, it becomes a more efficient transmitter in compounds II in which it is interposed between two unsaturated groups. The enhancement of the transmission efficiency of the sulfur atom was interpreted in terms of the pπ–dπ–pπ interaction, i.e., the "through-conjugative" contribution[7]

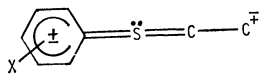
of the sulfur 3d-orbitals to the π-conjugation as can be represented by III.



III

The purpose of the present paper is to rationalize the qualitative view stated above. Thus, we have undertaken to calculate the CNDO/2 charge distributions in various β-substituted derivatives of methyl vinyl (IV) and divinyl (V) ethers and their corresponding sulfur homologs, which may be regarded as the model compounds of I and II, respectively.

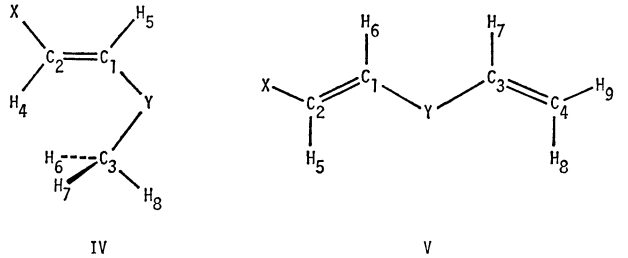
IV (Y = O or S) V (Y = O or S)

The results of calculation based on the spd basis set for the sulfur atom were found to be compatible with the substituent effects observed.

Method

Pople's CNDO/2 method[8] was used without modification. The sulfur atom was treated on both the sp and spd bases; the integral parameters were those determined by Santry and Segal.[9]

The molecular geometries and atomic numberings of IV and V are shown in Fig. 1. IV was assumed to be in the *s-cis* conformation[10] with the methyl C–H bonds directed as shown in Fig. 1, while V was assumed to have the *s-trans,s-trans* conformation which should apparently be the most stable planar form. In both IV and V, the β-substituent X was placed at a position *trans* to the atom Y. The substituents chosen for this study were the CH_3O, CH_3, H, F, and Cl atoms or groups. For the Cl atom, the 3d-orbitals were included throughout. All the necessary bond lengths were taken from the literature.[8]



IV V

Fig. 1. Molecular geometries and atomic numberings of IV and V. The carbon atoms were assumed to have either sp^2 or sp^3 valence angles, and the CYC bond angles were assumed to be 110 and 105° for Y=O and Y=S, respectively.

Calculations were carried out on a NEAC 2200 computer at the Osaka University Computation Center. The outputs were required to be self-consistent to within 10^{-4} for all the atomic-orbital densities.

Results

The charge distributions calculated for the various derivatives of IV and V are summarized in Tables 1 and 2, respectively. The entries there are the net charge densities, both total and π, defined by

$$Q_r = n_r - q_r \quad (1)$$

where q_r is the pertinent electron density on atom r and where n_r is the number of its relevant valence electrons. The spd basis set was used for the sulfur atom, but, for the sake of comparison, calculations based on the sp basis were also carried out for divinyl sulfides. The results of the latter calculations are given in parentheses (Table 2).

Discussion

A. Charge distribution in Unsubstituted Compounds. Previous studies[3–5] on the ^1H and ^{13}C chemical shifts in ethers and sulfides have shown that an oxygen atom apparently behaves as a π-donor-σ-acceptor while a sulfur atom tends to act as a π,σ-acceptor. The view can readily be tested by analyzing the π and σ-charge densities on the oxygen and sulfur atoms. In Fig. 2, the amount of electronic charge transferred to or from these atoms in divinyl ether and sulfide are illustrated.[11] It can be seen that the oxygen atom strongly with-

10) N. L. Owen and N. Sheppard, *Trans. Faraday Soc.*, **60**, 634 (1964).

11) The amount of electronic charge transferred *from* the pπ-orbital of the oxygen or sulfur atom *to* one of the ethylenic π-bonds can be obtained by dividing the π charge density Q_Y^π (Table 2) by 2. Likewise, one half the σ charge density on Y ($Q_Y^\sigma = Q_Y - Q_Y^\pi$) may be defined as the amount of the σ charge migration *from* Y *to* one of the olefinic groups.

a) The data given in parentheses are those obtained by using the sp basis set for the sulfur atom.

draws σ-electron from the neighboring carbon atoms but donates π-electron to the ethylenic π-bond. On the other hand, the sulfur atom (spd) accepts a small fraction of electron from both the σ and π orbitals of ethylene. The π-electron-accepting property of the sulfur atom is ascribable to the participation of its 3d-orbitals in π-conjugation; the sulfur atom on the sp basis is predicted to be π-electron-donating, as can be seen in Fig. 2.

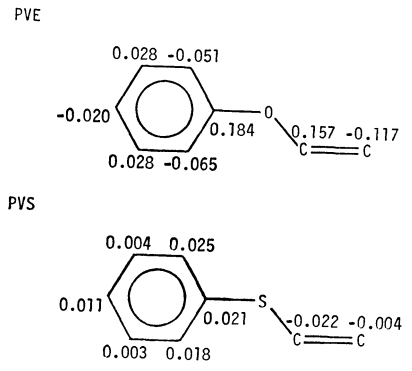

Fig. 3. The charge density distributions in phenyl vinyl ether (PVE) and sulfide (PVS).

Figure 3 shows the calculated total charge densities on the skeletal carbon atoms in phenyl vinyl ether (PVE) and sulfide (PVS). The charges in the vinyl moiety of these compounds are much the same as those in divinyl compounds. This endorses the validity of using the divinyl compounds as the model for PVE and PVS. In both types of compounds, the α-carbon atom of the sulfides are calculated to have a greater electron density than the β-carbon, in contrast to the greater electron density on the β-carbon in the unsaturated ethers.

The charge distributions shown in Fig. 3 are also to be compared with the ^{13}C chemical shift data presented previously.[5] In Fig. 4 the total electron densities q_τ of the various carbon atoms in PVE and PVS are plotted against the ^{13}C chemical shifts. For the purpose of comparison, the data of benzene[12] has also been plotted. The points for the PVS derivatives gather in the vicinity of the plot for benzene, while those for PVE's are spread in a relatively wide range of q_τ. The latter points are roughly fitted by a straight line with the slope of 175 ppm/electron, which is in fair agreement with the value 155 ppm/electron reported by Tokuhiro and Fraenkel[13] for azines.

B. Substituent Effects in Divinyl Ethers. The electronic effects of *trans*-β substituents on the charge distribution in divinyl ethers are expected to resemble those of *para* substituents in phenyl vinyl ethers. In Fig. 5, the π, σ, and total electron densities (q^π, q^σ, and q, respectively) on the α- and β-carbons of the various divinyl ether derivatives are plotted against the Hammett constants for *para* substituents, σ_p. Although the substituents studied are limited in number, it appears that all the calculated densities are linearly correlated with σ_p.

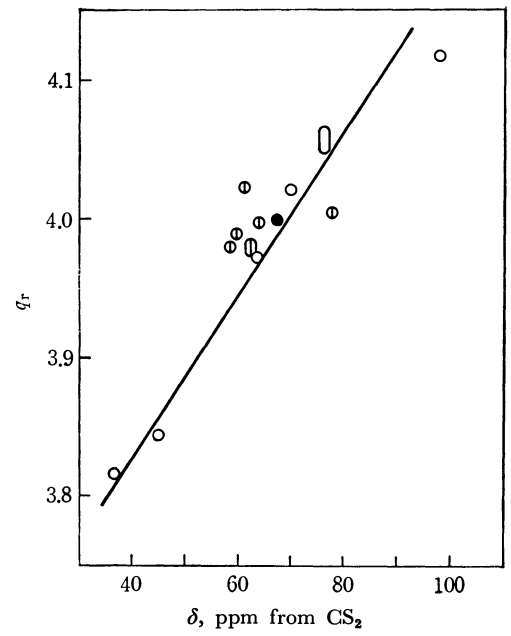

Fig. 4. Parallelism between the ^{13}C chemical shifts and the calculated total electron densities on carbon atoms of phenyl vinyl ether (PVE) and sulfide (PVS). ○, PVE; ⊖, PVS; ●, Benzene.

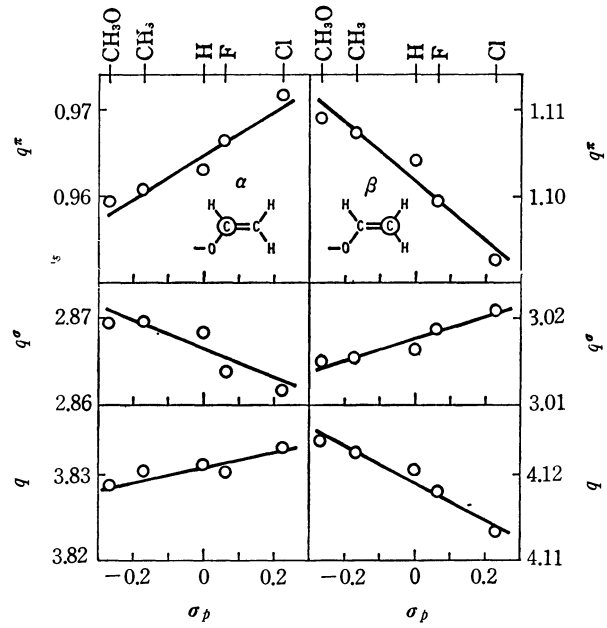

Fig. 5. The π, σ and total electron densities on the α- and β-carbons of substituted divinyl ethers.

The linear relationship shown in Fig. 5 are worthy of note in two important respects. First, the effects of substituents on the total electron density at the α- and β-carbons (q_α and q_β) are opposite in direction to each other; the electron-donating substituents tend to diminish q_α whereas they clearly enhance q_β. The results are in line with our previous observation that the ^{13}C chemical shifts, δ, of the α-carbon of PVE shows a Hammett-type dependence on ring substituents with a positive slope of $\rho_\alpha = 3.10\ \delta/\sigma$, in contrast to a "nor-

12) R. T. C. Brownlee and R. W. Taft, *J. Amer. Chem. Soc.*, **90**, 6537 (1968).

13) T. Tokuhiro and G. Fraenkel, *ibid.*, **91**, 5005 (1969).

mal" negative slope of $\rho_\beta = -4.84\ \delta/\sigma$ for the β-carbon.[5] A similar phenomenon, which was referred to as the "inverse" substituent effects, was observed for the γ- and δ-carbon atoms in *trans*-1-substituted-1,3-butadienes and rationalized in terms of the CNDO/2 total charge density.[14]

The second point which should be noted is that the substituent effects on the total electron density, q, is governed primarily by those on the π-electron density, q^π. The plots of the σ-electron density, q^σ, give slopes opposite in sign to those of q^π, and their dependence on substituents is relatively small. This would mean that, at least in the side-chain sp^2 carbons, any increase in q^π effected by substituents should be accompanied by a compensating decrease in q^σ which should, however, be overshadowed by the increase in q^π. In effect, therefore, the π-framework is considered to constitute a main route for the transmission of substituent effects in the case of unsaturated compounds. The electronic effect of substituents should thus be transmitted along the bonds through successive π-polarization of the ethylenic unit.[15] This in turn accounts for the inverse substituent effects as has been discussed in the last paragraph.

C. Transmission Efficiencies of the Oxygen and Sulfur Atoms. We now compare the efficiencies of the oxygen and sulfur atoms in transmitting the substituent effects. For this purpose, we will plot the total electron densities, $q_r(S)$, calculated for given positions (r) of the various derivatives of vinyl or divinyl sulfide against those obtained for the corresponding ethereal derivatives, $q_r(O)$. If such "O–S plots" are linear over the substituents studies, their slopes, *viz.*,

$$R_r = dq_r(S)/dq_r(O) \qquad (2)$$

may be regarded as a theoretical measure of the transmission efficiency of the sulfur atom relative to the oxygen atom.

Figure 6 shows the O–S plots for the terminal hydrogens H_8 and H_9 in vinyl methyl (IV) and divinyl compounds (V), respectively. The slope for the former hydrogen is $R_8=0.825$, indicating that the sulfur atom is a less efficient transmitter of substituent effects onto this particular hydrogen atom. By contrast, the *trans*-β hydrogen (H_9 of V in the spd approximation) has a slope of $R_9=1.139$, indicative of a greater transmission efficiency of the sulfur atom. It should be noted that the sulfur atom is calculated to be a less efficient transmitter ($R_9=0.956$) when its 3d-orbitals are left out of consideration (dashed line).

The O–S plots for the β-carbon atom in divinyl compounds are shown in Fig. 7. The slope is found to be $R_\beta=1.020$ when the spd basis set was used for the sulfur atom, while it is $R_\beta=0.885$ in the case of the sp approximation. Thus, the sulfur atom cannot be a more efficient transmitter of substituent effects than the oxygen atom, unless the 3d-orbitals of sulfur partake in the construction of the molecular orbitals.

In previous papers,[4-6] we demonstrated experimentally that the sulfur atom can transmit the substituent effects more efficiently than the oxygen atom, when it is interposed between two unsaturated groups. It was then inferred that the 3d-orbitals of the sulfur atom should play an essential and decisive role in this enhancement in the transmission efficiency. The theoretical results given in Figs. 6 and 7 are well in line with these experimental deductions. This reinforces our concept that the through-conjugative participation (III) of the sulfur 3d-orbitals in π-conjugation, *i.e.*, the $p\pi$–$d\pi$–$p\pi$ conjugation, is of distinct importance to the transmission of substituent effects in the compounds in which the sulfur atom is interposed between two unsaturated groups.[4,5]

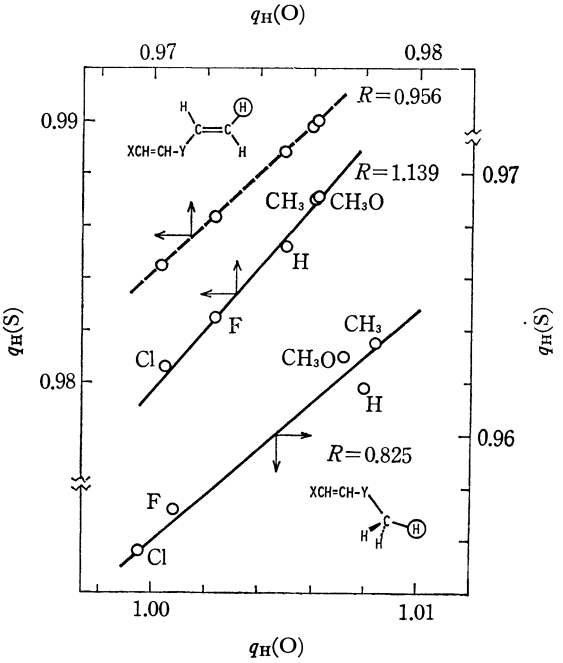

Fig. 6. "O-S plots" of the electron densities for the terminal hydrogens. R denotes the slope of each line. ——, spd basis; ----, sp basis.

14) O. Kajimoto and T. Fueno, *Tetrahedron Lett.*, **1972**, 3329.

15) The successive polarization of π-bondings is a well-known characteristics of conjugated molecules in general. The intervention of an oxygen atom does not affect this mode of transmission of the substituent effects.

Nuclear Quadrupole Effects in the Microwave Spectrum and Dipole Moment of Aniline*

Aritada HATTA,** Masao SUZUKI, and Kunio KOZIMA***

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 25, 1972)

The quadrupole hyperfine structure was resolved and analyzed for the vibrationally-ground state of the NH_2 species. The quadrupole coupling constants are: $\chi_{aa}=2.34$, $\chi_{bb}=1.86$, and $\chi_{cc}=-4.20$ MHz. The rotational constants obtained from the quadrupole corrected frequencies are as follows: $A=5617.67$, $B=2593.88$, and $C=1777.04$ MHz. The rotational constants of the ND_2 species in the vibrationally-ground state were also determined. By the use of the moments of inertia of both species, the non-planarity of this molecule was ascertained. The dipole moments of the NH_2 and the ND_2 species were determined to be 1.15 ± 0.02 D and 1.13 ± 0.01 D respectively.

In 1966 Lister and Tyler[1] reported their preliminary findings on the microwave spectra of aniline and its amino-monodeuterated species, and pointed out the non-planarity of the molecules. The detailed results have since been presented by Lister alone.[2] However, they did not observe the spectra due to the nuclear quadrupole coupling of nitrogen or those for the electric dipole moment.

In order to determine the value of the dipole moment, it seemed necessary to ascertain the effect of the ^{14}N quadrupole coupling on the spectra. For this purpose we have carried out this research.

Experimental

The microwave spectrometer used in this study was improved by adding a stabilized Klystron sweep system, since the longer time constants of 8~20 seconds were required to observe the hyperfine structure due to the ^{14}N quadrupole coupling. The measurements were made in the frequency range from 7.8- to 25-GHz at room temperature by using a 6-m absorption cell.

The sample of aniline, obtained from a commercial source, was purified by vacuum distillation before use. The amino-deuterated aniline, $C_6H_5ND_2$, was prepared by mixing the NH_2 species with D_2O. For measuring the spectrum of the ND_2 species, the waveguide was flushed several times with D_2O.

Results and Discussion

Only the a-type transitions were observed. As is shown in Table 1, the quadrupole hyperfine structures for the NH_2 species could be observed for some of the low-J R-branch transitions and all the Q-branch transitions of the vibrationally-ground state. The bracketed transitions in the table could not be well resolved. By using the transitions marked with asterisks in the table, the nuclear quadrupole coupling parameters, χ_{aa}, χ_{bb}, and χ_{cc}, were determined by a least-squares fitting according to the method of Bragg and Golden.[3] The quadrupole corrected frequencies, $\nu_{obsd}^{correct}$, were calculated by using these parameters. As the rigid-rotor approximation holds for these frequencies, the rotational constants, A, B, and C, were calculated from these frequencies by means of a least-squares fitting. The differences, Δ, between $\nu_{obsd}^{correct}$ and the frequencies calculated from the rotational constants, ν_{calcd}^{rigid}, are given in the last column of the table. It was ascertained that, for the bracketed transitions in the table, the splittings are within 0.3 MHz. The values of the rotational constants and those of χ_{gg} (g=a, b, or c) are listed in Table 2, where the a axis is nearly along the C–N bond and where the c axis is nearly perpendicular to the plane of the C_6H_5N fragment. The rotational constants obtained agreed very well with those reported by Lister and Tyler,[1] although their values were calculated from the high-J R-branch transition frequencies.

For the ND_2 species the low-J R-branch transition frequencies of the a-type in the vibrationally-ground state were also observed and assigned as shown in Table 3. By using the rigid-rotor approximation, the rotational constants were calculated by a least-squares fitting from the frequencies of the same transitions as those which are unresolved for the NH_2 species. The results are shown in Table 2.

By using a procedure similar to that of Kraitchman, and by choosing a z axis perpendicular to the plane of the C_6H_5N fragment, the z coordinate of the H or the D atom of the amino group was calculated to be 0.35 Å from the moments of inertia of the two species. The valency angle of $\angle$H–N–H and the angle between the C–N bond extended and the $\angle$H–N–H bisector were estimated as 112.3° and 38° respectively, by assuming only the N–H bond length to be 1.00 Å.

By using transition frequencies which are hardly affected at all by the ^{14}N quadrupole coupling, the dipole moments were measured for both the NH_2 and the ND_2 species. For the transitions used, the Stark energies are 10~20 times larger than the quadrupole coupling energies. Therefore, the Stark levels were calculated as in a strong-field case[4,5] and are those

determined for the asymmetric rotor without the quadrupole coupling effects. The value of the dipole moment of the NH_2 species agreed with that of the ND_2 species within the range of experimental uncertainty. As was expected, the component, μ_c, which is nearly perpendicular to the plane of the phenyl group, is zero for the NH_2 or the ND_2 species within the range of experimental uncertainty.

The value of the dipole moment of the NH_2 species is markedly different from that of 1.48 D obtained from the dielectric constant measurements at the temperature of 459 K in vapor.[6] It is certain that the value of this study is more accurate, for the difference between the values of the moment is probably due to the incorrect value of the sum of the atomic and the electric polarization as estimated from the molar refraction. The atomic polarization of this molecule may be anomalously large.

The Photoconductivity of Poly(*N*-vinylcarbazole). III. Photoconductivity in a Sandwich-type Cell.[1)]

Kenichi Okamoto*, Shigekazu Kusabayashi* and Hiroshi Mikawa

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received March 21, 1972)

Photoconductivity in a sandwich-type cell of a PVCz film was investigated in a high vacuum and in the air. A large photocurrent was observed in the π–π^* absorption region and a small photocurrent in the visible region. The former showed the following interesting points in its behavior. In low applied fields, no difference was found between the photoconductivity with positive-electrode illumination and that with negative-electrode illumination. In moderate or high fields, however, the photoconductivity with positive-electrode illumination was significantly different from that with negative-electrode illumination. The former showed a superlinear dependence on the applied field (consequently, $i_{ph}^{+} \gg i_{ph}^{-}$) and a spectral response coinciding with the absorption spectrum. This photoconductive behavior was explained by assuming the mechanism of carrier generation, namely, the field-assisted thermal dissociation of exciplexes and the detrapping of trapped carriers by singlet excitons. Carriers are supposed to migrate through the overlap of π-electrons of neighboring carbazyl rings in the same polymer chain.

Many investigations of the photoconductive properties of poly-*N*-vinylcarbazole (PVCz) have been reported in recent years.[2)] Most of them, however, have been carried out in the air. It is well known that ambient oxygen affects the photoconductive properties of molecular crystals.[3)] It is, therefore, necessary to investigate the photoconductive properties of PVCz in a high vacuum. In a previous paper the present authors reported on the photoconductivity in a surface-type cell, especially the effect of ambient oxygen on the photoconductivity and the effect of the pre-irradiation of UV light or γ-rays.[4)] In the present investigation the authors studied the photoconductivity in a sandwich-type cell of a fresh film of PVCz in a high vacuum (10^{-7} mmHg) as well as in the air.

Experimental

The method of preparing a sandwich-type cell of a PVCz film (area of electrode: 1 cm^2) and the method of electrical measurement were described in the previous paper.[5)] A 500W xenon lamp was used as the light source; it was monochromatized by a grating monochromator. The purity of the monochromatic light was 5–10 mμ in the half width; its intensity was changed by means of neutral filters. The light intensity was measured by means of a thermopile (Kipp and Zonen CA 1) or an actinometer by the use of potassium ferrioxalate. The following data were taken for a fresh cell which had stood for several hours in the dark under an applied DC voltage.

Results

Unless otherwise noted, the results were obtained in a high vacuum with freshly cast films 15 μ thick. Although an asymmetrical Metal-PVCz-Nesa sandwich-type cell was used for the following experiments, a symmetrical Au-PVCz-Au sandwich-type cell showed similar results.

Time Dependence of Photocurrent. The response curves of the photocurrent changed with both the applied voltage and the light wavelength. Representative response curves (Types A, B and C) are illustrated in Fig. 1. In low applied fields, the illumination with the weakly-absorbed light (λ>360 mμ) induced a photocurrent of the A type, while the illumination with the strongly-absorbed light (λ<360 mμ) induced that of the B type. In the latter case, the difference in magnitude between the peak and the steady-state photocurrents becomes smaller with an increase in the applied voltage. The photoresponse curve of the B type seems to be attributable to some effect of non-homogeneously-distributed space charges which are built up by the illumination with the strongly-absorbed light.

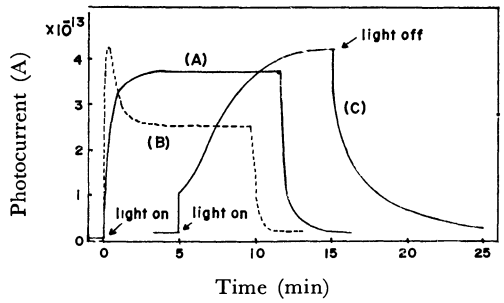

Fig. 1. Representative photoresponse curves in a PVCz sandwich-type cell (Types A, B and C).

In middle applied fields as large as 35000 V/cm, with negative-electrode illumination a photoresponse curve of the B type was observed only at 300—310 mμ. On the other hand, with positive-electrode illumination it was still observed at 270—340 mμ. In high applied fields as large as 150000 V/cm, every photoresponse curve, with one exception, belonged to the A type, and the response times of the rise and decay curves of the

photocurrent were too small to be measured by means of a vibrating-reed electrometer (below 1 sec). The illumination of 230—280 mμ or 350—370 mμ light on a positive electrode or of 350—360 mμ light on a negative electrode induced a photocurrent consisting of two components with different response times (C type), as is shown in Fig. 1. One has a very small response time (below 1 sec), and the other, a fairly large one (5—20 min). Similar behavior was observed in the decay part of this photocurrent. The subsequent re-illumination of the same light induced a photocurrent with the same behavior and also consisting of two components.

The results to be presented below were obtained for the steady-state values of the photocurrent, unless otherwise noted.

Voltage Dependence of Photocurrent. Figure 2 shows the voltage dependence of the photocurrent. In applied fields lower than 2000 V/cm the photocurrent was proportional to the applied voltage regardless of either the polarity of the illuminated electrode or the wavelength of the illuminating light, although some photocurrent (photovoltaic current) was observed without any applied voltage. In low fields the observed photocurrent apparently consists of both a photovoltaic current and a true photocurrent.

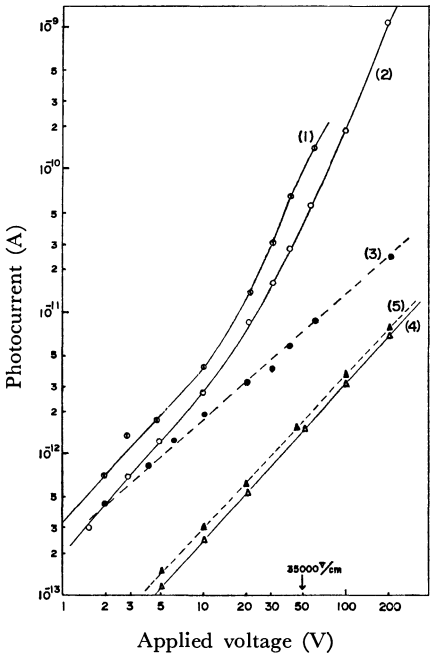

Fig. 2. Voltage dependence of photocurrent in an Ag-PVCz-Nesa sandwich-type cell. In high vacuum with nesa electrode illumination.
(1) peak value of i_{ph}^{+} at 330 mμ, (2) steady state value of i_{ph}^{+} at 330 mμ, (3) steady state value of i_{ph}^{-} at 330 mμ, (4) i_{ph}^{+} at 500 mμ, and (5) i_{ph}^{-} at 500 mμ.

In applied fields higher than about 7000 V/cm the voltage dependence of the photocurrent, however, varied with both the polarity of the illuminated electrode and the wavelength. In the case of negative-electrode illumination the photo-current (abbreviated to i_{ph}^{-}) was proportional to the applied voltage in every wavelength region over the whole range of voltage applied (0—150000 V/cm). On the other hand, in the case of positive electrode illumination the photocurrent (abbreviated to i_{ph}^{+}) changed with the n-th power of the applied voltage (n=1.4—2.0) in the UV region shorter than 360 mμ, although it was proportional to the applied voltage in the visible region longer than 360 mμ. It should be noted that the wavelength of 360 mμ corresponds to the absorption edge of a film 15 μ thick. The superlinearity of the photocurrent on the applied voltage was observed not only for the steady-state photocurrent, but also for the peak value of the photocurrent of the B type, as is shown by Curve (1) in Fig. 2. This voltage dependence of the photocurrent was not affected by the electrode materials, such as Au, Ag, Cu, Al, and nesa coating.

Light-intensity Dependence of Photocurrent. The photocurrent was always proportional to the light intensity (10^{12}—10^{14} photons/cm² s) regardless of the applied voltage, the wavelength (300—600 mμ), the polarity of the illuminated electrode, and the ambient oxygen, as is shown in Fig. 3. In a surface-type cell the photocurrent showed a linear dependence on the light intensity in a high vacuum and a sublinear dependence in the air. This lowering of the light-intensity dependence of the photocurrent was attributed to the introduction of some shallow hole trap levels by the air.[4] The effect of the hole trap levels due to oxygen molecules in the air may not be significant in a sandwich type cell.

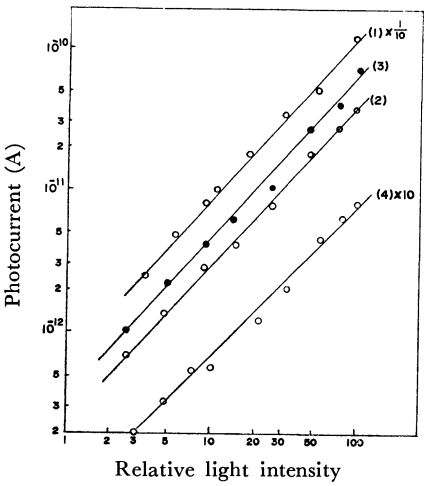

Fig. 3. Light intensity dependence of photocurrent in an Au-PVCz-Nesa sandwich-type cell. With positive Au electrode illumination.
(1) 350 mμ, 150000 V/cm in high vacuum; (2) 350 mμ, 35000 V/cm in high vacuum; (3) 350 mμ, 35000 V/cm in the air and (4) 450 mμ, 35000 V/cm in high vacuum.

Spectral Dependence of Photocurrent. The spectral dependence of the photocurrent shown in Figs. 4 and 8 was obtained by normalizing the observed photocurrent values to the values for the light intensity of 2×10^{13} photons/cm² s according to the light-intensity dependence. The spectral dependence of the photocurrent varied with the polarity of the illuminated electrode, the applied voltage, and the film thickness, but it was not affected by either air or the electrode materials. As is shown by the dotted line in Fig. 4,

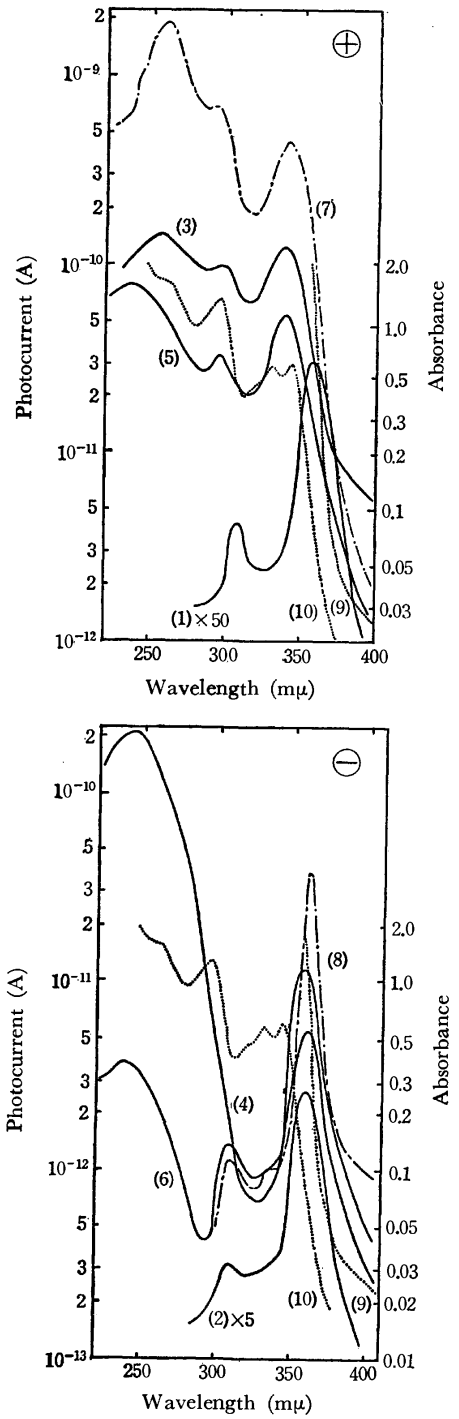

Fig. 4. Spectral dependence of photocurrent in an Au-PVCz-Nesa sandwich-type cell. Film thickness 15 μ. With positive Au electrode illumination; (1) 2 V (3) 50 V and (5) 50 V. With negative Au electrode illumination; (2) 2 V (4) 50 V and (6) 50 V. With positive nesa electrode illumination; (7) 200 V. With negative nesa electrode illumination; (8) 200 V. (1)~(4) and (7)~(8), in high vacuum. (5) and (6), in the air. (9) absorption spectrum of a PVCz film 15 μ thick. (10) absorption spectrum of a PVCz film about 1 μ thick.

the absorption spectrum of PVCz has its absorption maxima at 344.8, 331.8, 297, and 262.8 mμ and its absorption minima at 338, 312, and 282 mμ.

In low fields no difference was observed between i_{ph}^+ and i_{ph}^- either in magnitude or in the positions of the peaks and the minima. The photocurrent peaks were observed at 360, 310, and 250 mμ, and the photocurrent minima, at 330 and 290 mμ. This spectral dependence of the photocurrent corresponds inversely to the absorption spectrum except for the 250 mμ peak. This behavior is similar to that reported by Klöpffer *et al.*.[6] The 360-mμ photocurrent peak was observed at the absorption edge. The 330-mμ photocurrent minimum was observed in the region of the 344.8- and 331.8-mμ absorption peaks, which were unresolved in the photocurrent spectrum, probably because of both the fairly large half-width of the monochromatic light and the small difference in the extinction coefficients in this region.

In the middle applied fields as large as 35000 V/cm, a marked difference of photocurrent was observed both in magnitude and in the positions of the photocurrent peaks and minima, depending on whether the positive or the negative electrode was illuminated. With negative-electrode illumination the spectral dependence of the photocurrent was similar to the case of the low applied field; that is, it corresponded inversely to the absorption spectrum. With positive-electrode illumination, however, the photocurrent peaks shifted to a shorter wavelength and were observed at 340, 295—300 and 240—250 mμ, while the photocurrent minima were observed at 315 and 285 mμ. The spectral dependence of i_{ph}^+ thus corresponded just to the absorption spectrum. The magnitude of i_{ph}^+ in the UV region was 20—100 times larger than the corresponding value of i_{ph}^-. This is apparently attributable to the superlinear dependence of i_{ph}^+ on the applied voltage in the middle and high fields.

In the high fields as large as 150000 V/cm the spectral dependence of the photocurrent was the same as in the case of a middle applied field. The i_{ph}^+/i_{ph}^- ratio in the UV region was 70—500. This value of the ratio is 3—10 times larger than that in the middle applied fields. These results were obtained for a film 15 μ thick. As is shown in Fig. 8, in a thick film (0.5 mm thick) the 360 mμ photocurrent peak for the film 15 μ thick shifted to 370—380 mμ, which corresponds to the absorption edge of the thick film.

The above-mentioned spectral dependence of i_{ph}^+ is a new observation, one very different from those reported by others.[6]

In a high vacuum with a negative illuminated metal electrode a large photocurrent with no activation energy was observed in the region shorter than 300 mμ, as is shown by Curve (4) in Fig. 4. This is attributable to the photoemission current from the electrode metal into a high vacuum, independent of PVCz.

Temperature Dependence of Photocurrent. Figure 5 shows the temperature dependence of the photocurrent. Log i_{ph} *vs* $1/T$ plots gave straight lines over the whole temperature range (20—160 °C).

In a middle field, 35000 V/cm, the activation energy of the photocurrent (ΔE_{ph} in the equation: $i_{ph} \propto \exp(-\Delta E_{ph}/kT)$) was 0.07—0.15 eV in the visible

region and 0.18—0.22 eV in the UV region. The latter is larger than the former by about 0.09 eV. In a high field, 150000 V/cm, ΔE_{ph} in the UV region was 0.07—0.10 eV, smaller by about 0.11 eV than the corresponding ΔE_{ph} value at 35000 V/cm.

There is no significant difference between the photoconductive properties mentioned above in a high vacuum and those in the air.

Photovoltaic Current. Even without applied voltage a fairly large photocurrent was observed in a short circuit, the spectral response of which is shown in Figs. 6(a) and (b). In the cell which had not been exposed to air after the evaporation of a metal electrode in a high vacuum, the photocurrent always flowed in the bulk from a metal electrode to a nesa electrode, regardless of whether the nesa or the metal electrode was illuminated. This photocurrent cannot be explained by the Dember effect, the difference in the carrier mobilities, but seems to be caused by a photovoltaic effect resulting from the contact interface between the electrode and the PVCz film. The authors called this photocurrent a "photovoltaic current."

The photovoltaic current is changed irreversibly by the introduction of air. In the air, with metal electrode illumination the photovoltaic current flowed in the bulk from a metal to a nesa electrode, as in the case of a high vacuum. With nesa electrode illumination, however, it flowed oppositely in the region shorter than 360 mμ, as is shown in Fig. 6(b). Furthermore, the photovoltaic current in the air was much smaller than that in high vacuum. When a cell exposed once to air after the evaporation of an electrode was put back into a high vacuum, the photovoltaic current was not restored to its original value.

It seems that the phenomena mentioned above can be interpreted by supposing that there is a large potential barrier at the interface between a metal electrode and a PVCz film, such as the well-known barrier in a metal—P type semiconductor system.[7] This potential barrier may determine the photovoltaic current in a high vacuum. The potential barrier is lowered by the

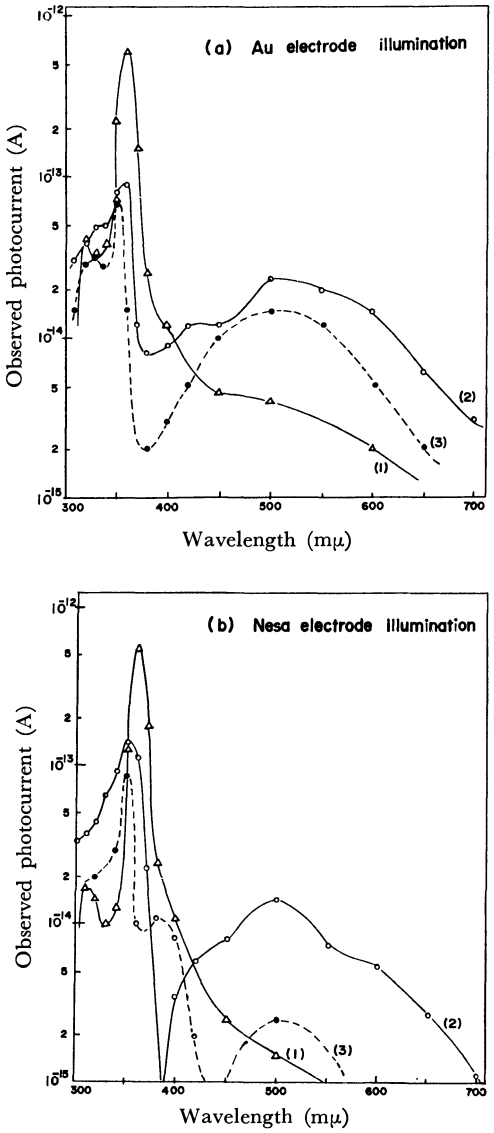

Fig. 6. Photovoltaic current in an Au-PVCz-Nesa sandwich-type cell.

air, as is observed in a metal—P type semiconductor system. If so, in the air the photovoltaic current seems to be determined mainly by the Dember effect.

Hole Injection into a PVCz Film from a Metal Electrode. The photoemission of holes from various metals (Au, Al and Cu) into a PVCz film has been observed by Lakatos *et al.*[8] Hole emission was observed also in an

7) L. E. Lyons, "Physics and Chemistry of the Organic Solid State," Vol. 1. ed. by D. Fox, M. M. Labes and A. Weissberger, Interscience Publishers, New York (1963), p. 788.
8) A. I. Lakatos and J. Mort, *Phys. Rev. Lett.*, **21**, 1444 (1968).

Au-PVCz-Nesa sandwich-type cell and was found to be significantly affected by the air. When a cell was not exposed to air after the evaporation of a gold electrode in a high vacuum, no photocurrent due to hole injection from the gold electrode was observed. The photocurrent in the visible and the near IR regions with the gold positive electrode showed values similar to those of the negative gold electrode as is shown in Fig. 7. If a cell was exposed to air after the evaporation of a gold electrode in a high vacuum, it showed a fairly large current due to hole emission both in the air and in a high vacuum; that is, the photocurrent in the visible and the near IR regions with the positive gold electrode increased significantly and was much larger than the photocurrent with the negative gold electrode, as shown in Fig. 7.

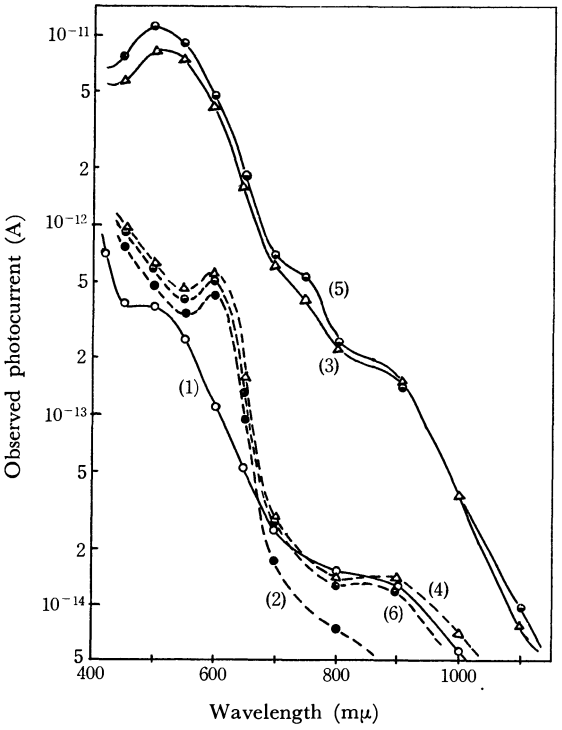

Fig. 7. Effect of air on photocurrent in the visible and the near IR regions in an Au-PVCz-Nesa sandwich-type cell.
With illuminated Au electrode biased positively (1, 3 and 5) or negatively (2, 4 and 6), under 35000 V/cm. (1) and (2); in high vacuum, for the cell which has not been exposed to air after the evaporation of an Au electrode. (3) and (4); in the air. (5) and (6); in high vacuum, for the cell having been exposed to air.

The above-mentioned effect of air on the hole emission current can probably be interpreted in terms of a decrease in the contact potential barrier, just as in the case of the photovoltaic current discussed above.

Effect of the Crystallinity on Photocurrent. Untreated PVCz has poor crystallinity, but the crystallinity was improved by appropriate heat-treatment.[9] The relation between the crystallinity and the photoconductivity was studied. The powder of the polymer was compressed to a disk (1 cm in diameter and 2—3 mm thick), which was then hot-pressed under various conditions to a film with varied crystallinity. Gold semitransparent electrodes were evaporated on both sides of the film. The photocurrent was measured for the Au-PVCz-Au sandwich-type cell thus obtained; it is shown in Fig. 8 and in Table 1. Judging from the crystalline peak at $2\theta=8°15'$[9,10] in the X-ray diffraction curves shown in Fig. 9, the I film is highly crystalline, while II is moderately and III, poorly so.

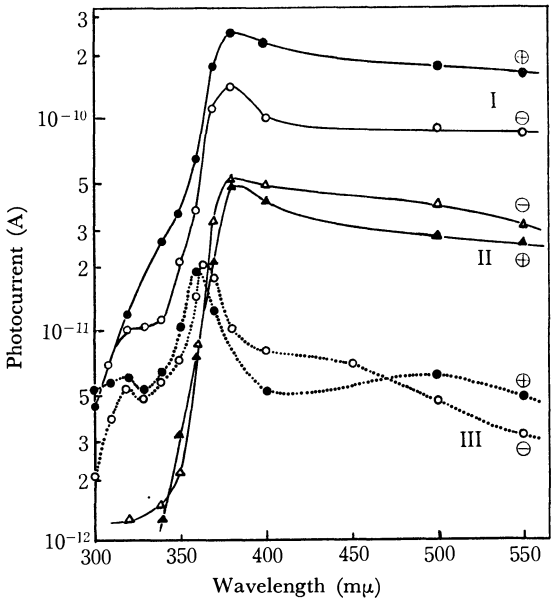

Fig. 8. Effect of the crystallinity of a PVCz film on photocurrent. In high vacuum, 8000 V/cm. ⊕; positive-electrode illumination, ⊖; negative-electrode illumination.
I, a film annealed under a hot-press (240° C, 150 kg/cm², 40 min), highly crystalline, 0.5 mm thick. II, a film annealed under a hot press (240 °C, 100 kg/cm², 15 min), moderately crystalline, 0.4 mm thick. III, a film cast from a benzene solution, poorly crystalline, 0.07 mm thick.

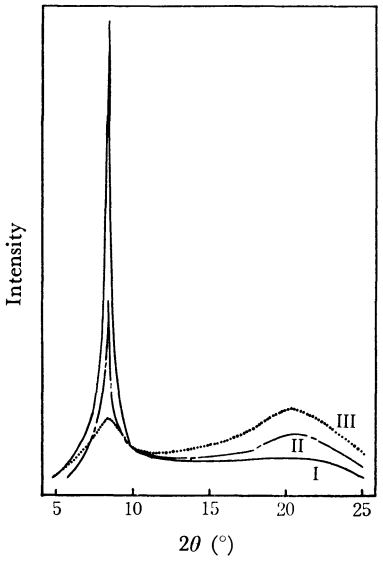

Fig. 9. X-ray diffraction patterns of PVCz films. I, II and III are the same films as described in Fig. 8 and Table 1.

10) R. G. Crystal, *Macromolecules*, **4**, 379 (1971).

The magnitude of the photocurrent could not be compared directly in these three kinds of films because the spectral response curves changed slightly with the film thickness, as is shown in Fig. 8. As the red shift of the photocurrent peak in the longer wavelength π–π^* absorption region is mainly due to the change in the absorption edge of a film with the film thickness, the magnitude of the photocurrent maximum at this wavelength was compared in order to examine the correlation between the crystallinity and the photocurrent. As is shown in Table 1, the higher the crystallinity of a film, the larger the photocurrent.

Although the results shown in Table 1 may not be attributable to only the difference in crystallinity because of the effect of heat-treatment on the concentration of impurity in a film, they seem to suggest a correlation between the crystallinity and the photoconductivity. A similar correlation has been reported for the γ-ray induced current in polyethylene films.[11]

Table 1. Effect of the crystallinity of PVCz films on photocurrent

Film No.	Thickness (mm)	Crystallinity	Absorption edge (mμ)	Photocurrent[a] i_{ph}^+	Photocurrent[a] i_{ph}^-
III	0.5	very good	380	7.4	12.5
III	0.4	moderate	380	2.6	2.4
III	0.07	poor	360	1	1

a) Relative value of photocurrent at the peak wavelength, film III being a standard. Under 8000 V/cm in high vacuum.

Discussion

Sharp reported on the photoconductivity of *N*-isopropylcarbazole, a model compound of PVCz.[12] No photocurrent was observed in the π–π^* absorption region longer than 280 mμ, although some intrinsic photoconduction was observed in the region shorter than 280 mμ. Furthermore, i_{ph}^- was larger than i_{ph}^+. An acceptor such as picryl chloride does not sensitize the photocurrent and acts only as a trapping center for an electron, the majority carrier. It has also been reported that the photoconductivities of *N*-vinylcarbazole and some alkylcarbazoles are smaller than that of PVCz, and that the light in the lower π–π^* absorption region is not effective for photoconduction.[13]

As is shown in Fig. 4, PVCz shows, however, a large photocurrent both in the lower and higher π–π^* absorption regions as well as a small photocurrent in the visible region. Furthermore, i_{ph}^+ is much larger than i_{ph}^- in moderate and high applied fields and a hole is expected to be the majority carrier. These photoconductive properties of PVCz are thus in sharp contrast with the photoconductivity of the related compounds.

Carrier Generation. The photocurrent in the visible region must be due to the optical reexcitation of trapped carriers, as has been reported previously.[4] Now, we are interested in carrier generation in the π–π^* absorption region of PVCz.

We have found that PVCz, a fairly strong electron donor, interacts easily even with a very weak electron acceptor, such as dimethyl terephthalate or chloroform, to form a so-called exciplex.[14] This suggests the possibility of the existence of some impurity in a PVCz film, which can form an exciplex under UV illumination. As the singlet exciton created by the π–π^* absorption in PVCz covers many pendant carbazyl groups during its lifetime,[14,15] a fairly high exciplex-forming efficiency can be expected by the π–π^* excitation. The carrier generation *via* the exciplex may be considered.

$$D^* + A \rightarrow (D^+\cdots A^-)^* \rightarrow D^+ + A^-, \quad (1)$$

$$A^- + D \text{ or } D^* \rightarrow D^- + A, \quad (2)$$

where D is the ground state of PVCz; D*, a singlet excited state; A, an impurity with an electron accepting property, and A^-, an impurity anion (immobile). $(D^+\cdots A^-)^*$ are an exciplex, D^+ and D^- are ion radicals of PVCz (*i.e.*, mobile charge carriers). Equation (1) shows the ionization of an exciplex (ion pair) into a mobile carrier ion in a film. Equation (2) shows the excitation of an electron donor (A^-) thermally or by a singlet exciton. The excitations of trapped carriers and/or of acceptors by singlet excitons may also be considered.

$$\begin{aligned} M^+ + D^* &\rightarrow M + D^+, \\ M^- + D^* &\rightarrow M + D^-, \end{aligned} \quad (3)$$

where M^+ is a trapped hole or an acceptor, and M^-, a trapped electron or a donor. The detrapping of trapped carriers by singlet excitons has been examined in anthracene.[16]

The dissociation of an exciplex (or ion pair) has been discussed in connection with the photoconductivity in aromatic hydrocarbon crystals. The energy required for the separation of an ion pair is evaluated roughly as 0.5 eV for anthracene.[17] The dissociation of an ion pair in a molecular crystal will need a fairly large activation energy. It may usually be difficult for an exciplex to dissociate into free ions in a film with a low dielectric constant. This dissociation may, however, be possible under conditions which reduce the energy required for the separation of an ion pair,—for example, under a strong electric field, as has been proposed by Lyons.[18] The following two kinds of fields[19] may be considered as strong electric fields in a PVCz film: (a) the local field surrounding an ion already produced (or a trapped carrier), and (b) the field near the surface which may act as a part of a diffuse double layer.

In a PVCz sandwich-type cell both carriers are not

replenished with a metal or a nesa electrode.[13,21,22] Both carriers must be discharged at each electrode according to the electroneutral condition. The magnitude of photocurrent will be limited by the smaller value of either the number of holes having reached a negative electrode through the bulk or the number of electrons having reached a positive electrode. For the understanding of the photoconductive behavior, it is important to know how this number changes with the applied voltage, the polarity of the illuminated electrode, or the wavelength of the illuminating light.

If the processes represented by Eqs. (1), (2) and (3) are supposed to be carrier generation processes in the UV region in a PVCz sandwich-type cell, the photoconductive behavior can be explained favorably as follows.

In low applied fields, the exciplex will dissociate into free ions only in the local field surrounding an ion (or a trapped carrier), because the field near the surface will be small. The carriers will also be created by Process (3). In a PVCz film, impurities, A, and trapped carriers (or acceptors) will exist not only at the surface layer but also in the bulk. In homogeneous carrier generation, (1) recombination of the carriers will occur with a lower probability because of the lower concentration of the carriers than that in the case of surface carrier generation; (2) both carriers migrate in the bulk and can contribute to the photocurrent, and (3) space charge effects will be smaller because of the relatively homogeneous distribution of trapped carriers. Therefore, in general, homogeneous carrier generation in the bulk seems to be favored rather than the generation at surface. With an increase in the absorption coefficient of a film, the illuminating light is absorbed only in the region near the surface and the favorable conditions in the homogeneous carrier generation gradually disappear. Therefore, the spectral response of the photocurrent corresponds inversely to the absorption spectrum and the photocurrent peak in the longer wavelength region shows a red shift with an increase in the film thickness, unless there is an additional condition favoring the surface carrier generation. There is no significant difference either in magnitude or in the spectral dependence between i_{ph}^+ and i_{ph}^- in low fields.

When a higher voltage is applied, the field near the surface becomes larger and may be supposed to be large enough to assist the thermal dissociation of an exciplex. With positive-electrode illumination, hole carriers generated will be swept away before recombining with the immobile A^- ion. A mobile electron is generated from an A^- ion by Process (2). Thus, the thermal dissociation of an exciplex assisted by the field near the surface may act as a primary carrier generation process. Therefore, with an increase in applied voltage, significantly more carriers are generated, more favorably in the vicinity of an illuminated positive electrode rather than in the bulk. Consequently the spectral response of the photocurrent corresponds to the absorption spectrum with positive-electrode illumination in moderate and high applied fields. During the migration in the bulk to the opposite negative electrode, the hole carriers are frequently trapped and gradually fill hole traps in the same manner as has been mentioned previously.[4] As a result of the hole traps being filled, the effective mobility of a hole may become larger. With positive-electrode illumination, the number of holes reaching the negative electrode will become significantly larger with the applied voltage;—i_{ph}^+ in the UV region has, therefore, a superlinear dependence on the applied field.

On the other hand, in the case of negative-electrode illumination, most of the hole carriers generated by the same process as in positive-electrode illumination remain near the surface, without discharging at a negative electrode, and recombine with the immobile A^- ion. With negative-electrode illumination, the thermal dissociation of an exciplex assisted by the field near the surface seems not to act as a carrier generation process and the bulk carrier generation seems to be predominant even above a middle applied field. The i_{ph}^- neither shows a superlinear dependence on the applied voltage nor a spectral response corresponding to the absorption spectrum, even in high applied fields.

Photoresponse Curves. With positive-electrode illumination, as the carriers are generated preferentially at the surface, some effect of space charges distributed nonhomogeneously in a film may be more significant than in the case of the negative-electrode illumination. For this reason, a photoresponse curve of the B type is observed with positive-electrode illumination by the UV light, even in middle applied fields.

In high applied fields, the B type is not observed and the C type as well as the A type is observed. This may be explained as follows. At a high applied voltage, the effective hole mobility increases with the filling of hole traps and finally becomes equal to the value of the hole mobility which would be observed in the absence of any traps. With this gradual increase in the effective hole mobility, the photocurrent gradually increases during the illumination. In high fields the homogeneous illumination gives a photoresponse curve of the C type in Fig. 1, while the nonhomogeneous illumination gives an A or C type.

Activation Energy of Photocurrent. As the photocurrent in the visible region is due to the optical reexcitation of the carriers trapped by deep trap levels,[4] no significant activation energy seems to be needed for the carrier generation. The activation energy, ΔE_{ph} (0.07—0.15 eV at 35000 V/cm), in the visible region seems to be the energy required for the carrier migration. In a middle field (35000 V/cm) ΔE_{ph} in the UV region is assumed to be the sum of the activation energy for carrier migration and that for carrier generation. The former is estimated to be less than the value of ΔE_{ph} in the visible region, because under UV illumination a steady-state Fermi level for the hole[20] is lowered much more than in the case of visible illumination. The latter may be the energy required for the field-assisted thermal dissociation of an exciplex. In a high field as large as 150000 V/cm, the value of ΔE_{ph} in the UV region was lowered by about 0.1 eV. This lowering of the ΔE_{ph} value may be due to the filling up of the hole traps mentioned above, and the ΔE_{ph} value observed in high fields may not be the

20) A. Rose, *RCA Rev.*, **1951**, 362. *Phys. Rev.*, **97**, 322 (1955).

energy required for the carrier migration, but only that required for the carrier generation. The energy required for the field-assisted thermal dissociation of an exciplex may, consequently, be estimated to be about 0.1 eV.

Comparison with Pulse Photoconductivity Data. The transient pulse photocurrent in a PVCz film has been reported on by Regensburger,[21] Szymanski,[22] and Pai.[23] Their results, which were obtained under high applied fields, agree with each other in the following two points. The efficiency of hole carrier generation increases significantly with an increase in the applied field; the hole carrier mobility also increases significantly with both the temperature and the applied field, suggesting that the hole carrier migration process involves the field-assisted thermally-activated jump. These results correspond to the finding of the superlinearity of the voltage dependence of i_{ph}^{+}, which was observed in the steady-state photocurrent in the present investigation. The activation energy for hole carrier generation obtained from the transient measurements is nearly the same as the value (about 0.1 eV) observed in the present steady-state measurements. The activation energy for hole carrier migration obtained from the transient measurement (0.36 eV[23] or 0.4—0.7 eV[21] in air) is much larger than that (about 0.1 eV at 35000 V/cm and nearly zero at 150000 V/cm) observed in the present investigation. This may be attributed to the fact that, under the steady-state conditions, most of the hole traps are filled by holes, while under the conditions of the transient measurements the hole traps remain empty during the experiment.

Carrier Migration. From the X-ray analysis,[9,10] NMR spectra[24,25] and electron diffraction[10] the structure of solid PVCz has been suggested to be as follows. The crystalline nature of PVCz is sensitive to heat treatment. In a specimen stretched under a hot-press, the crystalline diffraction peak at $2\theta=8°15'$ is sharp and strong and the amorphous peak shows an appreciable decrease in its intensity. Thus, an annealed or stretched film is crystalline and takes a pseudo-hexagonal packing structure of a rigid rod-like molecule, with a cross sectional diameter of about 12.6 Å with only a chain-to-chain order. This chain may have isotactic 3/1 and syndiotactic 2/1 helix parts in a stereo-block manner.

From the structure of solid PVCz, it seems most probable that carriers can move primarily along the chain from a carbazyl group to another adjacent carbazyl group, through the overlap of the π-electron systems of carbazyl rings in the same polymer chain. This carrier migration process is supported by the correlation between the crystallinity and the photocurrent and also strongly by the significant decrease in the photocurrent in the copolymers of *N*-vinylcarbazole with a small amount of another monomer, which severs the overlap of the π-electron systems of carbazyl rings in the same polymer chain, thereby significant hindering the migration of the carriers.[26]

The authors wish to acknowledge the financial support of the Fuji Photo Co. for this work.

The Vibrational Assignments of Propyl Bromide and Its Two Asymmetrically-Deuterated Species

Michiro HAYASHI, Keiichi OHNO, and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received November 30, 1972)

The vibrational assignments of the observed spectra of propyl bromide and its two asymmetrically-deuterated species have been worked out. Since the two *gauche* isomers come not to be equivalent for the asymmetrically-deuterated species, the infrared bands of the *gauche* isomer can be expected to be split into doublets, while the bands of the *trans* isomer remain singlets. The observed infrared bands for the *gauche* isomer were actually the doublets for the C–Br stretching and two CH_2 rocking modes. The C–D stretching and deformation modes of the β-deuterated species were also in the expected spectral patterns. In order to confirm the vibrational assignments, the normal vibration calculation was carried out using a modified Urey-Bradley force field for the parent and two asymmetrically-deuterated species.

Brown and Sheppard[1] studied the rotational isomerism of propyl bromide using the infrared spectra in the liquid and crystalline states.

Komaki *et al.*[2] also studied the infrared and Raman spectra of this substance in relation to the rotational isomerism. They concluded that the *trans* and *gauche* isomers co-exist in the gaseous and liquid states, while only the *trans* isomer persists in the crystalline state. The conclusion as to the molecular forms of the isomers by Komaki *et al.* had been drawn on the basis of the normal vibration calculation and the vibrational product rule of the skeletal vibrations between isomers.

The molecular forms of the isomers have also been confirmed by Sarachman by means of microwave spectroscopy.[3]

McDevitt *et al.*[4] studied the far-infrared spectra of this substance. As for the vibrational assignments, they worked them out for only the skeletal and some CH_2 rocking vibrations.

Recently, Tanabe and Saëki[5] have worked out the vibrational assignments of propyl bromide and chloride on the basis of absorption intensity measurements. They have also carried out the normal vibration calculation in the local-symmetry force field.

In this paper, we will deal with vibrational assignments of propyl bromide based on a comparison of the spectra with those of its two asymmetrically-deuterated species and on the results of the normal vibration calculation. Our assignments of the spectra are almost the same as those by Tanabe and Saëki except for several points which will be discussed in the future.

For the determination of the molecular forms of the rotational isomers, the asymmetrically-deuterated species of the original molecule usually gives useful information. as Neu and Gwinn,[6] de Hemptinne,[7] and Bernstein *et al.*[8] have shown for the case of 1,2-dibromoethane.

For propyl bromide, since the two *gauche* isomers come not to be equivalent for asymmetrically-deuterated species, such as the CH_3CHDCH_2Br and CH_3CH_2-$CHDBr$ species, the infrared bands of the *gauche* isomer are expected to be split into doublets, while the bands of the *trans* isomer remain singlets.

In order to find the molecular forms for a molecule with a structure similar to propyl bromide, such as propyl mercaptan, it is useful to find which asymmetrically-deuterated species gives better splitting patterns of the spectra, thus making possible an easier discrimination of the results. This is the second purpose of the present investigation of propyl bromide and its asymmetrically-deuterated species.

Experimental

The sample of the parent propyl bromide used in the measurements was a commercial product purified by redistillation. The α-deuterated species, CH_3CH_2CHDBr, was prepared by a method similar to that used in the preparation of α-deuterated butyl alcohol;[9] that is, propionaldehyde was reduced to α-deuterated propyl alcohol by $LiAlD_4$ in ethyl ether, and the resultant alcohol was brominated by PBr_3. The β-deuterated species, CH_3CHDCH_2Br, was prepared by the addition of propylene and DBr, with benzoylperoxide as the catalyst.[10] The purities of the deuterated species were found to be better than 90% by both gas chromatography and a study of the infrared spectra.

The infrared spectra in the region from 200 to 4000 cm^{-1} were recorded with a Perkin-Elmer instrument (model 621). For the measurements in the crystalline state, the vapor of the sample was directly condensed on a CsI plate in a cell cooled with liquid nitrogen in a vacuum and was then annealed several times in order to keep the sample from reaching the supercooled liquid state.

Vibrational Assignment

As is shown in Fig. 1, for the parent species there are equivalent two *gauche* isomers, and they produce

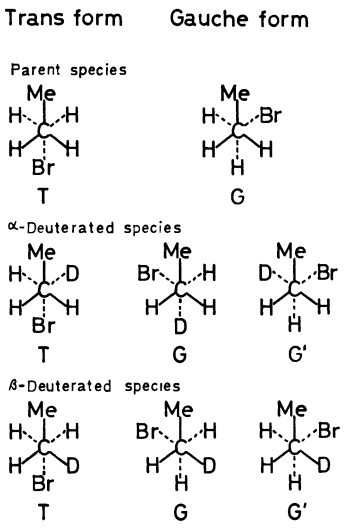

Fig. 1. Rotational isomers of propyl bromide and its asymmetrically-deuterated species.

two non-equivalent pairs of the four *gauche* forms if one of the hydrogens in the CH_2 groups is replaced by a deuterium, while the *trans* isomer produces two equivalent forms. Therefore, the infrared bands for the *gauche* isomers may be expected to be split into doublets for the asymmetrically-deutetrated species.

Spectra in the Region from 300 to 1000 cm^{-1}. In Fig. 2, the observed infrared spectra in the region from 300 to 1000 cm^{-1} are shown; the solid and the dotted lines indicate the spectra in the liquid and crystalline states respectively.

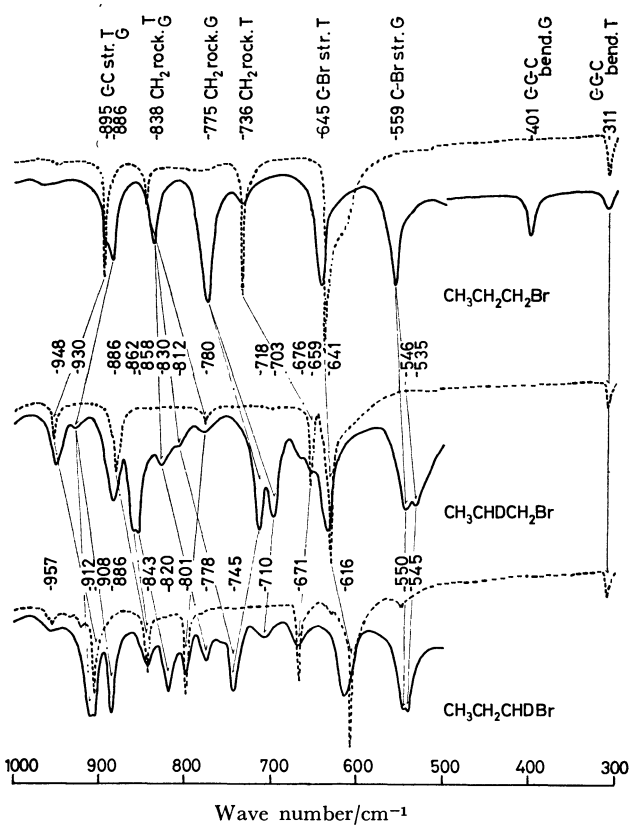

Fig. 2. Observed infrared spectra in the 300—1000 cm^{-1} region for the parent, β-deuterated, and α-deuterated species of propyl bromide. Solid and dotted lines indicate the spectra in the liquid and the crystalline states, respectively.

According to the reported vibrational assignments,[1,2] the strong infrared bands at 645 and 559 cm^{-1} of the parent species are the C–Br stretching vibrations for the *trans* and *gauche* isomers respectively. For the α- and β-deuterated species, the corresponding bands are found with nearly equal frequencies, and the band vanishing in the crystalline state appears to be a doublet, as is expected, while the band persisting in the crystalline state is a singlet.

As Shimanouchi and Suzuki[11] have already pointed out in their paper on dichloromethylene, upon asymmetrical deuteration the CH_2 rocking mode keeps its original mode, with relatively smaller modifications than the other hydrogen deformation modes. In the case of propyl bromide, the shifts of the CH_2 rocking modes are also expected to be relatively simple, though the shifts of the other vibrational modes between the parent and the deuterated species may be complicated.

For the parent species of propyl bromide, according to the reported assignments,[2] one of the two CH_2 rocking modes is the band at 736 cm^{-1} persisting in the crystalline state for the *trans* isomer and the band at 775 cm^{-1} appearing in the liquid state for the *gauche* isomer.

For the asymmetrically-deuterated species, there are two kinds of CH_2 rocking modes; they can be regarded as the CHD and CH_2 rocking modes, though a larger mutual mode mixing is expected. The CHD rocking mode is expected to be at a lower frequency than the CH_2 rocking mode.

For the β-deuterated species, the band at 659 cm^{-1} persisting in the crystalline state can be assigned to the CHD rocking mode for the *trans* isomers, which is a singlet. For the *gauche* isomer, the doublet around 710 cm^{-1} can be easily assigned to this mode.

For the α-deuterated species, the band at 671 cm^{-1} persisting in the crystalline state can be assigned to this mode for the *trans* isomer, which is a singlet. For the *gauche* isomer, although the band at 710 cm^{-1} appearing only in the liquid state can be easily assigned to one of components of the doublet of this mode, there are two possibilities for the other component of the doublet; that is, either the band at 710 cm^{-1} is the unsplit doublet or the band at 745 cm^{-1} appearing only in the liquid state is another component of the doublet.

Since the band at 710 cm^{-1} is too weak to be regarded as the unsplit doublet when comparison is made with the corresponding doublet of the β-deuterated species, the band at 745 cm^{-1} must be the component of the doublet with the band at 710 cm^{-1}. The present assignments are also supported by the result of the normal vibration calculations, as will be described later.

The doublet spacing for the *gauche* isomer of the α-deuterated species (35 cm^{-1}) is larger than that for the β-deuterated species (15 cm^{-1}), according to the

11) T. Shimanouchi and I. Suzuki, *J. Mol. Spectrosc.*, **8**, 222 (1962).

present assignments, in the same manner as the calculated spacings (the calculated spacings are 32 and 4 cm^{-1} respectively).

From the tendency found in the frequency separations between the two CH_2 rocking modes for a series of molecules with $-CH_2-CH_2-$ groups, as has already been reported,[12] the bands around 840 cm^{-1} for the parent species can be assigned to another CH_2 rocking mode, which corresponds to the CH_2 rocking mode for the deuterated species. The bands at 780 and 801 cm^{-1} for the β- and α-deuterated species respectively can be assigned to the corresponding CH_2 rocking mode for the *trans* isomer.

However, the assignment cannot be made immediately for the *gauche* isomer. For the β-deuterated species, there is no possible band if the corresponding mode for the *gauche* isomer is considered to have a lower frequency than that for the *trans* isomer, as is the case in the parent species. If bands at higher frequencies are permitted for this mode, there is a weak doublet around 820 cm^{-1} with a reasonable spacing for this mode.

For the α-deuterated species, there is a single band at a lower frequency than that for the *trans* isomer; in explaining this, there are three possibilities: 1) this band may be regarded as an unsplit doublet; 2) another component may overlap with the band at 745 cm^{-1}, which is assigned to the CHD rocking mode for the *gauche* isomer, and 3) this unknown component may have a higher frequency than that for the *trans* isomer.

In order to find the correct assignments in view of the above possibilities, the results of the normal vibration calculation are useful, as is shown in Tables 5—7.

From the calculation, the localization of the higher-frequency mode of two CH_2 rocking vibrations is found to be rather worse than that of the lower-frequency mode, though both of them are well localized from the other mode, as is to be expected. Furthermore, if the rocking modes for the *trans* and *gauche* isomers are designated as T and G respectively, they are possibly arrayed in the order of GTGT from higher to lower frequencies for the β-deuterated species, while for the α-deuterated species they are arrayed in the same order (TGGT) as that for the parent species.

Therefore, for the β-deuterated species, the doublet around 820 cm^{-1} can be assigned to this mode, while for the α-deuterated species, the band at 745 cm^{-1} can be regarded as containing one of the components of the doublet which has the band at 778 cm^{-1} as another component with reasonable spacing.

There are two C–C stretching modes for one isomer; one of them can be expected around 900 cm^{-1}. For the parent species, the bands at 895 and 886 cm^{-1} can be assigned to this mode for the *trans* and *gauche* isomers respectively.

For the deuterated species, one of the two CH_2 twisting modes, which should be more properly called a CD deformation mode,[11] can also be expected in the same region for the C–C stretching mode. In this region, there are two distinct bands in the crystalline state for both α- and β-deuterated species.

For the β-deuterated species, the bands at both 886 and 948 cm^{-1} persisting in the crystalline state accompany the bands in the liquid state on the lower-frequency side. The band accompanying the band at 886 cm^{-1} is a strong doublet with a small spacing, while the band accompanying the band at 948 cm^{-1} is a shoulder and seems to be a singlet.

According to the normal vibration calculation, the CD deformation mode should not only have a lower frequency for both the *trans* and *gauche* isomers, but should have a larger spacing of the doublet for the *gauche* isomer than that for the C–C stretching mode. Therefore, the band at 886 cm^{-1} and the doublet around 860 cm^{-1} can be assigned to the CD deformation mode for the *trans* and *gauche* isomers respectively, while the bands at 948 and 930 cm^{-1} can be assigned to the C–C stretching mode for the *trans* and *gauche* isomers respectively.

For the α-deuterated species, the calculation indicates that: 1) the C–C stretching mode has a higher frequency than the CD deformation mode; 2) both the C–C stretching and CD deformation modes have relatively large spacing of the doublet for the *gauche* isomer, and 3) one of the components of the doublet of the C–C stretching mode for the *gauche* isomer has a higher frequency than that for the *trans* isomer.

Taking the above results into account, for the *trans* isomer the bands at 843 and 908 cm^{-1} can be assigned to the CD deformation and the C–C stretching modes respectively. The band at 820 cm^{-1} can be assigned to one of the components of the doublet for the CD deformation mode for the *gauche* isomer, where the other component can be regarded to overlap the band at 843 cm^{-1} for the *trans* isomer. The band at 886 cm^{-1} assigned to the C–C stretching mode for the *gauche* isomer forms a doublet with a reasonable spacing and with a shoulder of the band at 908 cm^{-1} of the *trans* isomer.

Spectra in the Region from 1000 to 1200 cm^{-1}. In this region, one of the C–C stretching modes and two of the CH_3 rocking modes can be expected for one isomer. Actually, three bands exist, at 1022, 1036, and 1097 cm^{-1}, in the crystalline state for the parent species; they can be assigned to the C–C stretching mode, the CH_3 rocking mode belonging to the A″ species, and that belonging to the A′ species for the *trans* isomer respectively, taking into account the results of the calculation.

There are three corresponding bands, at 1017, 1064, and 1143 cm^{-1}, in the crystalline state for the β-deuterated species.

For the α-deuterated species, the band for the C–C stretching mode is at 1020 cm^{-1} in the crystalline state. However, the assignments cannot be made immediately for the two CH_3 rocking modes. As no other mode is possible in the expected region from 1000 to 1200 cm^{-1} for these two CH_3 rocking modes, some of the four bands appearing in the crystalline state are probably the modes in question. Among these

12) M. Hayashi, Y. Shiro, and H. Murata, This Bulletin, **39**, 112 (1966).

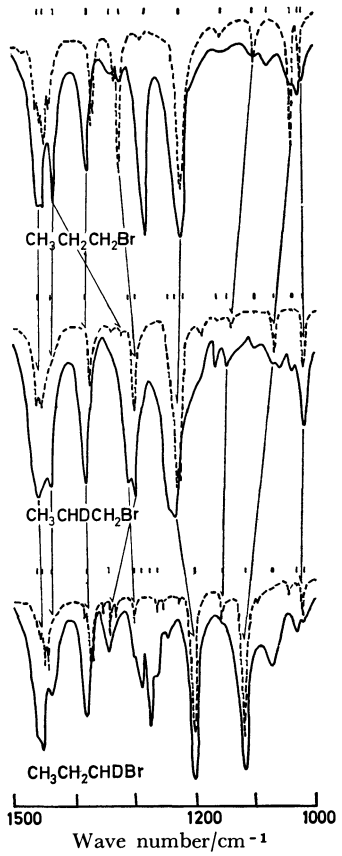

Fig. 3. Observed infrared spectra in the 1000—1500 cm^{-1} region for the parent, β-deuterated, and α-deuterated species of propyl bromide. Solid and dotted lines indicate the spectra in the liquid and the crystalline states, respectively.

four bands, the strongest band, at 1118 cm^{-1}, may be assigned to the CH_3 rocking mode corresponding to the strong band belonging to the A″ species for the parent species, though the difference between the calculated and observed frequencies seems to be a little large.

This assignment seems suspect because the band at 1118 cm^{-1} is too strong compared with the corresponding bands for the parent and the β-deuterated species. However, a similar strong band has also been found in this region for the monodeuterated ethyl bromide, CH_3CHDBr, reported by Bak *et al.*[13] Therefore, this may be a permissible assignment.

Another CH_3 rocking mode corresponding to the mode belonging to the A′ species for the parent species may be assigned to either the weak band at 1154 cm^{-1} or the band considered to overlap the band at 1118 cm^{-1}. There is no way to find which is correct, since the calculated frequency is probably not reliable. Therefore, we will tentatively assign the band at 1154 cm^{-1} to the CH_3 rocking mode.

For the *gauche* isomer, the tentative assignments for the C–C stretching and the two CH_3 rocking modes are shown in Tables 5—7; they have been made taking into account the results of the calculation and the assignments of the *trans* isomer.

Spectra in the Region from 1200 to 1500 cm^{-1}. In this region, there are nine CH_2 and CH_3 hydrogen deformation modes for one isomer.

For the deuterated species, since one of the CH_2 groups is replaced by a CHD group, when the results for $CHDCl_2$ described earlier are taken into account the set of CH_2 hydrogen deformation modes can be expected to change in their characteristic and to be more or less shifted to a lower-frequency side.

Among these shifted modes, the CHD rocking mode and the CD deformation mode originating from the CH_2 twisting mode have previously been assigned. The CHD scissoring mode and the CH deformation mode originating from the CH_2 wagging mode can be expected around 1290 and 1220 cm^{-1} respectively.

On the assignments of the spectra for the parent species, the potential energy distributions of the normal vibrations for propyl chloride calculated by Snyder and Schachtschneider[14] give a suitable point of reference, though they did not report any explicit assignments of the observed spectra.

The CH_2 wagging modes can be assigned to the strong bands at 1224 and 1326 cm^{-1} in the crystalline state for the *trans* isomer and to a strong band at 1282 cm^{-1} and a weak band at 1326 cm^{-1} in the liquid state for the *gauche* isomer.

As is shown in Table 5, judging from the calculated frequency it seems better to regard the CH_2Br wagging mode for the *gauche* isomer as overlapping the strong band at 1224 cm^{-1}. However, if this assignment is chosen, the intensity change of the band at 1282 cm^{-1} between the liquid state and the crystalline state cannot be understood unless the band for the CH_2 twisting mode exhibits a drastic intensity change between that for the *trans* isomer and that for the *gauche* isomer.

As for the two CH_2 twisting modes, since the spectra are expected to be weak and since, actually, no remarkable bands exist in the expected region, it is not easy to make any definite assignments. Therefore, the weak bands and the shoulders in this region are only tentatively assigned to these modes.

Only one band, at 1380 cm^{-1}, exists in the liquid state in the expected region for the CH_3 symmetric deformation mode; this band appears in the crystalline state at 1378 cm^{-1} as a doublet due to the crystalline field. As the difference in the molecular forms is considered to have a negligible influence on this mode, these may be regarded as overlapping bands due to the *trans* and *gauche* isomers.

Around 1440 cm^{-1}, there exist complicated bands which correspond to the CH_3 asymmetric deformation and CH_2 scissoring modes, where the lowest band at 1435 cm^{-1} existing in the liquid and crystalline states is probably one of the CH_2 scissoring modes due to both the *trans* and *gauche* isomers, in view of the finding on ethyl chloride reported by Miller and Kiviat.[15]

For the β-deuterated species, the strong bands at 1230 and 1295 cm^{-1} can be easily assigned to the CH_2 wagging mode and the CH deformation mode originating from the CHD wagging mode for the *trans* isomer.

14) R. G. Snyder and J. H. Schachtschneider, *J. Mol. Spectrosc.*, **30**, 290 (1969).

15) F. A. Miller and F. E. Kiviat, *Spectrochim. Acta*, **25A**, 1363 (1969).

For the *gauche* isomer, the CH_2 wagging mode and the CH deformation mode can be assigned to the bands at 1230, 1235, and 1308 cm^{-1}, taking into account the results of the calculation where the band at 1308 cm^{-1} is regarded as the overlapping band of two spectra due to two kinds of *gauche* isomers.

Since one of the CH_2 twisting modes (CD deformation mode) is shifted to the lower-frequency side around 900 cm^{-1}, there is one CH_2 twisting mode for one isomer which can be assigned to the shoulder at 1210 cm^{-1} for the *trans* isomer. For the *gauche* isomer, as the calculation indicates that only a slight frequency shift can be expected for the CH_2 twisting mode among the one *trans* isomer and the two kinds of *gauche* isomers, and as the lower-frequency side of the band at 1230 cm^{-1} seems to be too broad, the other weak band assigned to the CH_2 twisting mode may be considered to be hidden somewhere near the foot of the band.

Corresponding to the CH_2 scissoring mode at 1435 cm^{-1} for the parent species, either the band at 1319 or 1331 cm^{-1} in the crystalline state can be regarded as the CHD scissoring mode for the *trnas* isomer. Though there is no way to decide which is the correct assignment, the band at 1319 cm^{-1} may be considered to be preferable on the basis of the results of the calculation.

For the *gauche* isomer, since the band around 1295 cm^{-1} is too much weakened in the crystalline state, the band may consist of several overlapping bands due to the *gauche* isomer. Therefore, the CHD scissoring modes for the *gauche* isomers can be regarded as overlapped on this band.

For the α-deuterated species, the strong band at 1200 cm^{-1} can be easily assigned to the CH deformation mode originating from the CHD wagging mode for the *trans* isomer on the basis of a comparison of the spectra with those for CH_3CHDBr.

There are several weak bands in the crystalline state in the expected region for the higher-frequency CH_2 wagging mode. As the corresponding band at 1296 cm^{-1} for the β-deuterated species is also not very strong, the weak band can be assigned to this mode. However, in this region, the CHD scissoring and CH_2 twisting modes are expected, both of which are also expected to be weak. As the results of the calculation indicate that the CH_2 wagging mode has the highest frequency, while the CH_2 twisting mode has the lowest, if the relatively stronger bands are selected from the observed bands in this region, the bands at 1341, 1296 and 1260 cm^{-1} can be assigned to the CH_2 wagging, CHD scissoring, and CH_2 twisting modes respectively.

For the *gauche* isomer, though the assignments become more ambiguous than those for the *trans* isomer, the tentative assignments shown in Table 7 have been made taking into account the results of the calculation.

The assignments of the other modes, such as the CH_3 symmetric deformation, CH_2 scissoring, and CH_3 asymmetric deformation modes, are obtained from a comparison of the spectra with those for the other species.

Spectra for the C–H and C–D Stretching Modes. As is shown in Fig. 4, the C–H and C–D stretching vibrations are found in the regions around 2950 and 2200 cm^{-1} respectively.

A comparison of the spectra between the parent and deuterated species and between those in the liquid and crystalline states leads to the conclusion that the band at 2848 cm^{-1} is due to the β–CH_2 group of the *gauche* isomer, while the band at 3003 cm^{-1} is due to the α-CH_2 group of the *trans* isomer. For the β-deuterated species, one of the two C–H stretching modes of the β–CH_2 group is shifted to the region around 2200 cm^{-1} by replacing one of the hydrogens with a deuterium. The shifted bands consist of three bands; one of them (2197 cm^{-1}) persists in the crystalline state and can be assigned to the *trans* isomer, while the two other bands, which vanish in the crystalline state, can be assigned to the *gauche* isomer. Again, the spectra assigned to the *gauche* isomer are doublets, as is seen for the spectra below 900 cm^{-1}.

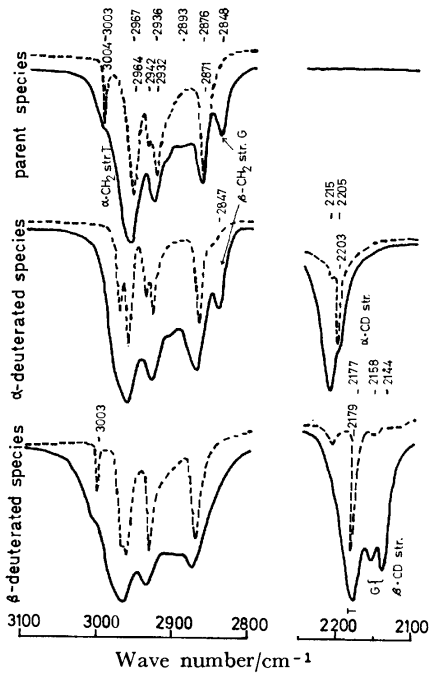

Fig. 4. Observed infrared spectra of the C-H and C-D stretching vibrations for the parent, α-deuterated, and β-deuterated species of propyl bromide. Solid and dotted lines indicate the spectra in the liquid and the crystalline states, respectively.

For the α-deuterated species, though the shifted bands are seen at 2215 and 2205 cm^{-1}, and though the band at 2215 cm^{-1} can be assigned to the *gauche* isomer, the band for the *gauche* isomer seems to be a singlet, although it may be an unresolved doublet with a smaller spacing.

Spectra in the Region below 550 cm⁻¹. As for the skeletal deformation and torsional modes, McDevitt *et al.*[4] have already reported the observed infrared and Raman spectra in the liquid state below 400 cm^{-1}, along with the assignments for the parent species. However, the assignments in Table 1 are very different from those reported by McDevitt *et al.*

They made their assignments on the basis of a comparison of the spectra of propyl chloride and bromide with those of isopropyl and *t*-butyl chlorides and bromides in the liquid state. Not only does this comparison of the spectra seem to us to be inadequate, but the lack of the spectra in the crystalline state leads to incorrect assignments for the rotational isomers.

a) See footnote a) of Table 1.

The incorrectness of their assignments can be clearly seen if their assignments for propyl chloride are compared with those reported by Komaki *et al.* and by Snyder *et al.*

The assignments in Table 1 have been obtained from a comparison of the spectra of propyl bromide with those of propyl chloride, both in the liquid and crystalline states, and have been confirmed from the normal vibration calculations to be described in the next section.

Normal Vibration Calculation

In order to confirm the vibrational assignments, a normal vibration study based on a modified Urey-Bradley force field has been carried out.

The bond lengths used in the calculation were transferred from those of ethyl bromide determined by microwave study by Flanagan and Pierce.[16] They were $r(C-Br)=1.950$, $r(C-C)=1.518$, $r(C-H)_{CH_3}=1.093$, and $r(C-H)_{CH_2}=1.087$ Å. On the other hand, all of the valency angles were assumed to be tetrahedral in disregard of the observed values. The internal symmetry coordinates were taken from those given in the papers by Takahashi[17] and by Clark.[18]

At first, the force constants were transferred from those for propane[19] and for ethyl bromide[20] in the simple Urey-Bradley force field; the force constants for ethyl bromide were obtained in order to fit the calculated frequencies to the observed frequencies for the parent ethyl bromide and its three deuterated species, CH_3CD_2Br, CD_3CH_2Br, and CD_3CD_2Br, by the least-squares technique.

The internal rotation force constant for the skeletal torsion was assumed to be the value obtained from the reported far-infrared band for the CH_3 torsion of ethyl chloride.[15] This value of the force constant corresponds to the barrier height of 3.49 kcal/mol. The force constant for the CH_3 torsion was assumed to be the value obtained from the barrier height of 2.77 kcal/mol. This barrier height is the average of the observed barrier height of the CH_3 group in the *trans* and the *gauche* isomers of propyl fluoride, as determined by means of microwave spectroscopy.[21]

However, the calculated frequencies could not reproduce the observed frequencies well enough, especially for the CH_2 deformation, C-Br stretching, and C-H stretching modes.

Therefore, the force field was modified as follows: 1) the *trans* and *gauche* coupling terms between the CH_3 and CH_2C groups and between the CH_2C and CH_2Br groups were added; 2) the C-H bond interac-

Table 4. Force constants for propyl bromide[a] ($F' = -0.1F$)

K(C–Br)	1.784	(1.874)[e]	$\kappa(CH_2Br)$	−0.032	(−0.047)
K(C–C)	2.695	(2.568)	$\kappa(CH_2C)$	−0.045	
K(C–H), CH_2Br	4.401	(4.499)	$\kappa(CH_3)$	−0.036	(−0.010)
K(C–H), CH_2C	4.115		$Y(CH_2–CH_2)$	0.109[b]	
K(C–H), CH_3	4.209	(4.229)	$Y(CH_2–CH_3)$	0.087[c]	
H(C–C–Br)	0.033		F(C···C···Br)	0.669	
H(C–C–H)	0.258		F(C···C···H)	0.406	
H(H–C–Br)	0.164	(0.192)	F(H···C···Br)	0.303	
H(H–C–H)	0.352		F(H···C···H)	0.250	
H(C–C–C)	0.275[d]		F(C···C···C)	0.335[d]	
$t(CH_3, CH_2)$	0.056		$g(CH_3, CH_2)$	−0.018	
$t(CH_2, CH_2)$	0.001		$g(CH_2, CH_2)$	−0.033	
			p(C–H)	−0.144	(−0.128)

a) The units of the force constants are in mdyn/Å for stretching, K; bending, H; repulsion, F; and bond interaction, p; and in mdyn·Å for intramolecular torsion, k; internal rotation, Y; *trans* coupling, t; and *gauche* coupling, g.
b) The value of Y is assumed from the barrier height of 3.49 kcal/mol.
c) The value of Y is assumed from the barrier height of 2.77 kcal/mol.
d) Force constants are transferred from propane, Ref. 19.
e) ( ) indicates the values for ethyl bromide.

a) See a) of Table 6.

tion constants were introduced; 3) the C–H stretching force constants of the CH_2 groups were considered to be not necessarily equal for the CH_2C and CH_2Br groups, and 4) the stretching force constants of K(C–C) and K(C–Br), the bending force constant of H(H–C–Br), and the intramolecular torsions were also considered to be different from the values transferred from similar molecules.

These force constants were determined by the least-squares technique in order to reproduce the observed frequencies for the parent species. They are shown in Table 4, together with the other transferred force constants. The calculated and observed frequencies for the parent and two asymmetrically-deuterated species are given in Tables 5—7, together with the potential energy distributions. A good agreement has been obtained between the calculated and observed frequencies for the two deuterated species as well as for the parent species. Since the force constants were adjusted for the parent species, this agreement for the deuterated species is considered to indicate the reasonableness of the present assignments.

From the potential energy distributions, for the parent species larger mode mixings are obvious between the two CH_2 scissoring modes, between the C–C stretching and CH_3 rocking modes, and between the two CH_2 rocking modes.

Although the mode mixing has been found to be relatively large between two skeletal bending vibrations, as had been expected, the mode designations in the internal coordinates still seem to be valid for this molecule. Therefore, the designations of the C–C–C and C–C–Br bending modes are more adequate for the description of the actual modes of the vibrations than the designations of the symmetric and antisymmetric deformation modes of the two skeletal bendings.

Discussion

Mizushima *et al.*[22] pointed out that when a heavier atom or group, such as the halogen atom or the CH_3 group, occupies the position *trans* to the halogen atom, the stretching vibration of the carbon-halogen bond is observed at a higher frequency than in the other configurations.

This tendency is also found in the cases of the deuterated species and the parent species of propyl bromide. That is, the C–Br stretching vibrations for the *trans* isomers of the three isotopic species were always observed at higher frequencies than those for the *gauche* isomers. Furthermore, even for the two different *gauche* isomers of the α- and β-deuterated species, the C–Br stretching vibration appears at a higher frequency for the *gauche* isomers with the deuterium atom at the posittion *trans* to the bromine atom than that for the other, *gauche* isomer with its hydrogen atom at the posittion *trans* to the bromine atom.

As for the frequency splittings of the *gauche* isomers resulting from the asymmetrical deuteration, the bands in the range from 500 to 1000 cm^{-1} give more obvious patterns of the doublets than the bands in the other range. Although the spacings of the doublets for the CH_2 deformation modes are found to be larger, in general, for the α-deuterated species than for the β-deuterated species, the patterns of the doublets seem to be more distinct for the β-deuterated species than for the α-deuterated species. Therefore, the β-deuterated species may be preferable in the determination of the molecular forms of the rotational isomers for the $XCH_2CH_2CH_3$-type molecules.

The authors wish to express their thanks to Dr. Kazutoshi Tanabe and Dr. Shinnosuke Saëki of the Government Chemical Industrial Research Institute of Tokyo for their pre-publication information on their vibrational assignments.

Studies of the Preparation and Physical Properties of Multivalent Metal Condensed Phosphates. V.[1] The Grinding of Various Aluminum Phosphates

(Received December 1, 1972)

Changes in the structures of various aluminum phosphates as a result of grinding were studied by a variety of physical methods—X-ray analysis, DTA, TGA, infrared absorption spectroscopy and electron microphotography, and their acidic properties were investigated in order to obtain information on the surface activity of the compounds. The X-ray diffraction patterns indicated that the A, B, and C types of $Al_4(P_4O_{12})_3$ and $AlPO_4$ (Berlinite) did not become completely amorphous even after grinding for 72 hr; this shows that the crystal structures of these compounds were relatively stable to grinding. Substance K was structurally more fragile than the other aluminum phosphates ($Al_4(P_4O_{12})_3$, $AlPO_4$), becoming completely amorphous on being ground for 72 hr. On DTA and TGA, the ground aluminum phosphates exhibited an endothermic peak, accompanied by a weight loss due to the loss of adsorbed water in the vicinity of 100 °C. A further weight loss at higher temperatures was presumably due to dehydration caused by the condensation of P–OH. The amounts of acids on the ground aluminum phosphates were almost independent of the acid strength, which was around $+1.5$ (pK_a). The amounts of acids of the A, B, and C types and of $AlPO_4$ tended to increase slightly with the grinding time. The amount of acid of the K substance reached a maximum after 6 hrs' grinding but decreased slowly when grinding was continued for longer than 15 hr.

Grinding is known to cause changes in the structure, composition, and properties of substances.[2-6] The present authors have previously reported the formation conditions and the acidic properties of various aluminum phosphates.[7,8] The present paper will describe an investigation of the change in the structure and acidic properties of various aluminum phosphates on grinding.

Experimental

Apparatus and Method. An Ishikawa grinder, model AGA (agate mortar), was used; grinding was carried out at room temperature and at a relative humidity of 20~25%. X-Ray analysis was carried out with a Rigaku Denki Geigerflex X-ray diffractometer, using Ni filtered Cu$K\alpha$ radiation. Hitachi EPI-S2 and EPI-G2 spectrophotometers were used for the infrared spectroscopy, spectra being taken by means of a KBr tablet or on Nujol mulls. A Rigaku Denki differential thermogravimetric analyzer, 8002 HD, was used for the DTA and TGA. The method reported by Tanabe and his co-workers[9,10] was used for measuring the acidic properties of various aluminum phosphates. The amount of water was determined by both the Karl-Fischer method and TGA.

Preparation of Various Aluminum Phosphates. *1) $AlPO_4$ (Berlinite)*: Aluminum hydroxide (hydrargillite type) or γ-alumina and phosphoric acid were mixed to give a Al_2O_3/P_2O_5 (R) molar ratio of 1.0/1.0. The mixture was then dehydrated over a small flame with vigorous agitation to complete the reaction; the product was heated at 500 °C for 20 hr in a thermostated electric furnace to prepare the sample. The heated product was proved to be $AlPO_4$, Berlinite, by the X-ray diffraction method.

2) A, B, and C types of $Al_4(P_4O_{12})_3$: α-Alumina and ammonium dihydrogen phosphate were mixed thoroughly to give a molar ratio of R=1/3~1/4. The A type product was obtained by heating the mixture at 750 °C for 20 hr in an electric furnace; the B type, by heating it at 500~550 °C for 20 hr, and the C type, by heating it at 650~700 °C for 20 hr. The products were thoroughly washed with water to remove the excess phosphoric acid and dried at 80 °C for 20 hr. The X-ray diffraction patterns of the A, B, and C types of $Al_4(P_4O_{12})_3$ were identical with those of the respective ASTM cards.

3) K Substance (the substance which we tentatively designated previously as the K substance has characteristic X-diffraction peaks at $2\theta=11.2$, 18.0, 26.8°): α-Alumina and phosphoric acid were mixed to give a molar ratio of R=1/3~1/4. The mixture was heated at 300 °C for 20 hr and then treated in a manner similar to that described above.

Results and Discussion

1) Changes Caused by Grinding of the A, B, and C Types of $Al_4(P_4O_{12})_3$. As an example, Fig. 1 shows the changes in the X-ray diffraction pattern of the A type caused by grinding. It can be seen that the X-ray diffraction peaks become weaker with the grinding time, as the destruction of the crystal structure to give an amorphous form progresses. However, as the X-ray diffraction pattern indicates that the A type does not become completely amorphous even after grinding for 72 hr, it can be seen that the crystal structure of the A type is relatively more stable when ground than sodium phosphates.[2,3] Changes in the X-ray diffraction patterns of the B and C types are similar

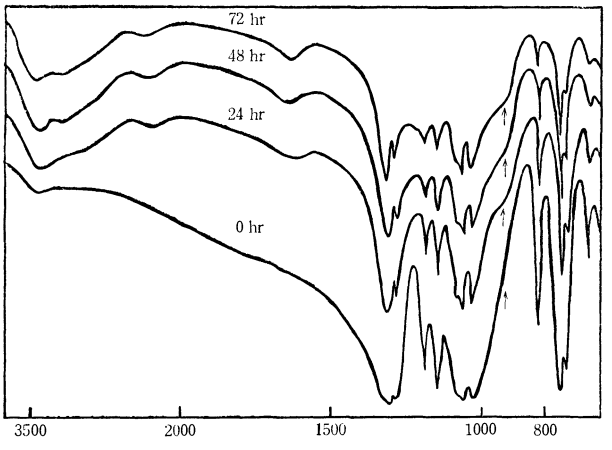
Fig. 1. The changes in X-ray diffraction pattern of type A of $Al_4(P_4O_{12})_3$ on grinding.

to that with the A type, though the results indicate that the crystal structure of the B type breaks down somewhat more easily than those of the A and C types. The changes in the infrared absorption spectrum of the A type caused by grinding are shown in Fig. 2. Although the changes are not appreciable, a new absorption (shoulder) due to grinding appears near 940 cm^{-1}, corresponding to a P–OH bending absorption.[11,12] Since absorptions due to the stretching and bending of P–OH groups appear at 2500~3000 and near 900 cm^{-1} respectively, it is assumed that P–OH is formed by the cleavage of the P–O–P or P–O–Al linkages on grinding. The absorptions at 3400~3600 and near 1600 cm^{-1} increase with the grinding time, presumably because of the adsorption of water onto active sites formed by grinding.



Wave number (cm^{-1})

Fig. 2. The changes in infrared absorption spectra of type A of $Al_4(P_4O_{12})_3$ on grinding.

2) *Changes Caused by Grinding of $AlPO_4$ (Berlinite).* Changes in the X-ray diffraction pattern and IRS of $AlPO_4$ on grinding show the same tendencies as those for the A, B, and C types. The X-ray diffraction pattern of $AlPO_4$ does not indicate a completely amorphous state even after having been ground for 72 hr, showing that the crystal structure is somewhat stable to grinding. A shoulder appears near 940 cm^{-1} in the IRS when the sample is ground for 48~72 hr, presumably because of the formation of P–OH by the cleavage of the P–O–Al linkage.

3) *Changes Caused by Grinding of the K Substance.* Changes in the X-ray diffraction pattern of the K substance on grinding are shown in Fig. 3. The change in structure to an amorphous form is greater than those of the A, B, and C types of $Al_4(P_4O_{12})_3$ and $AlPO_4$

(Berlinite), a completely amorphous form resulting after 72 hr's grinding. The crystal structure of the K substance is, therefore, more unstable than those of the A, B, and C types and $AlPO_4$. Fig. 4 shows the change in the IRS of the K substance on grinding. The K substance shows two sharp absorption peaks near 3600 cm^{-1} due to water of crystallization, and a broad absorption at 2600~2700 cm^{-1} due to P–OH. On grinding, the two sharp absorption peaks near 3600 cm^{-1} become smaller; the appearance of a broad absorption at a slightly lower wave number indicates that water of crystallization is released by the destruction of the crystal structure on grinding, and water molecules are adsorbed onto active sites of the surface of the ground K substance. Generally, water of crystallization is released when hydrated substances are ground, and their crystal structures break down easily.[4,13,14] The K substance contains water of crystallization and follows this general rule. It is, therefore, believed that the K substance is more unstable to grinding than the A, B, and C types and $AlPO_4$.

4) *Change in the Particle Size of the K Substance on Grinding.* The results of electron microphotography are shown in Fig. 5. It may be seen that particles of the K substance become very small after being ground for 6~15 hr. However, the particles gradually become larger again when grinding is continued for longer than 24 hr. This can be explained as resulting from the adsorption of moisture by the initially formed small-sized particles, leading to their subsequent agglomeration,[15] though this phenomenon is not seen with particles of the A, B, and C types or $AlPO_4$.

5) *Changes in the DTA and TGA of Various Aluminum Phosphates on Grinding.* Changes in the DTA and TGA of the K substance are shown in Fig. 6. The A, B, and C types and $AlPO_4$ show almost identical tendencies, an endothermic peak accompanied by weight loss due to the dehydration of adsorbed water around 100 °C. The endothermic peak and the weight loss increase with the grinding time, suggesting that the amount of water released increases with grinding.

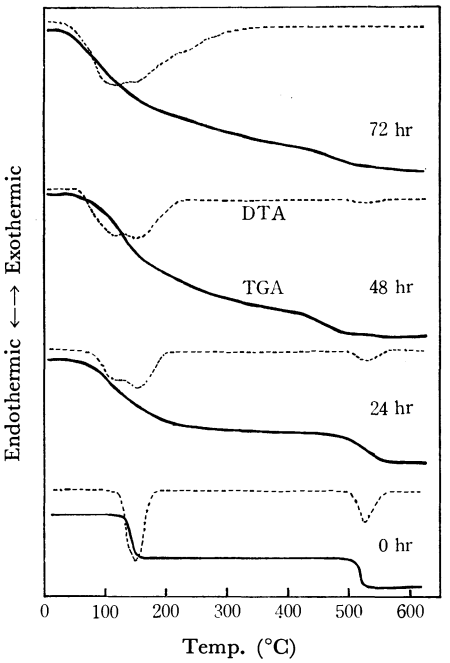

Fig. 6. The changes in DTA and TGA of substance K on grinding.

When the temperature is further increased, a further weight loss occurs, presumably because of dehydration caused by the condensation of the P–OH group. The unground K substance exhibits large endothermic peaks in the vicinity of 150~160 °C (the first endothermic peak, due to the dehydration of water of crystallization) and in the vicinity of 540 °C (the second endothermic peak, presumably due to the dehydration caused by the condensation of P–OH). However, the first endothermic peak becomes broader with an increase in the grinding time and overlaps with the endothermic peak due to the dehydration of adsorbed water, while the second endothermic peak gradually becomes smaller as the grinding time increases, and disappears almost completely after 48~72 hr's grinding. This again shows that the structure of the K substance is easily broken down by grinding. The changes in the water content on grinding are shown in Fig. 7, which shows the changes in the dehydration quantities of ground A, B, and C types, $AlPO_4$, and the K substance when they are heated to 650 °C. The K substance has a moisture content of about 16~17% in its original state, but the moisture content increases gradually with grinding.

13) I. B. Bleeker, *Chem. News*, **101**, 30 (1910).
14) Y. Arai, and T. Yasue, *Kogyo Kagaku, Zasshi*, **74**, 1343 (1971).
15) A similar tendency was observed when the surface area was measured by the BET method, though this point is being studied further because of problems in the measurement of the surface area of these aluminum phosphates.

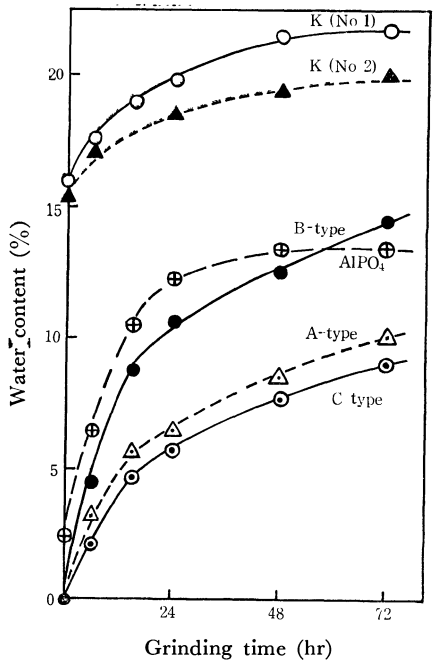

Fig. 7. The changes in water content of various aluminum phosphates on grinding.

The moisture contents of the A, B, and C types and $AlPO_4$ also increase gradually with grinding, and at a faster rate than for the K substance.

6) *Changes in the Acid Strength and Amounts of Acid of the A, B, and C Types of $Al_4(P_4O_{12})_3$ and $AlPO_4$ on Grinding.* The amounts of acid were not changed by the acid strength when the A, B, and C types and $AlPO_4$ were ground. The amounts of acid contained in unground samples of these aluminum phosphates are very small, but they increase slightly with the grinding time. It is considered that the increase in the amounts of acid is due to both the increase in surface area and the formation of P–OH by the cleavage of the P–O–P or P–O–Al linkages on grinding.

7) *Changes in the Acid Strength and Amount of Acid of the K Substance on Grinding.* As with the A, B, and C types and $AlPO_4$, almost no change in the amount of acid was observed upon a change in the acid strength when the K substance was ground. The amount of acid of the unground K substance is much larger than those of the A, B, and C types and $AlPO_4$. The changes in the amount of acid of the K substance on grinding are shown in Fig. 8. The amount of acid becomes very large when the sample is ground for 6 hr, but it gradually decreases with further grinding. This may be explained as follows. On grinding, the particles initially become smaller and the surface area of the sample increases, so there is an increase in the amount of acid per unit weight. However, upon more prolonged grinding the crystal structure breaks down and the agglomeration of the amorphous particles occurs, with a consequent decrease in the surface area and, hence, in the acidity of the K substance.

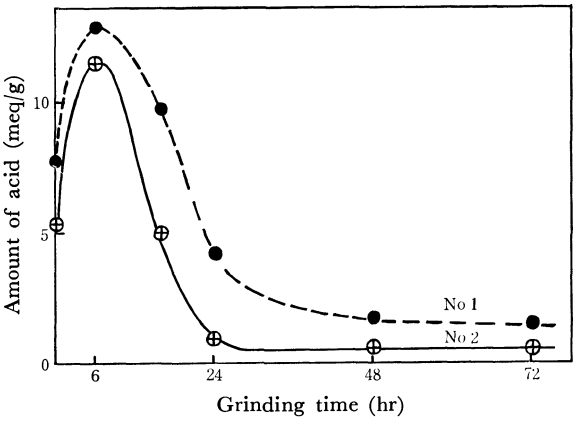

Fig. 8. The changes in amount of acid of substance K on grinding.
Amount of acid is the value at $pK_a = 1.5$

The Electron-scavenging Process in 3-Methylhexane Glass at 77 K Studied by ESR

Koichi OKA, Hideo YAMAZAKI, and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received December 4, 1972)

The effect of various additives, *i.e.*, nitrous oxide, sulfur hexafluoride, methyl chloride, and sulfur dioxide, on the yield of the trapped electrons produced in the γ-irradiated 3-methylhexane (3MHX) glass at 77 K have been investigated by the ESR technique. The yields of the trapped electrons were reduced by the addition of all the solutes examined; the efficiency of electron scavenging was found to be in the order of $SF_6 > CH_3Cl > N_2O > SO_2$. The concentration dependence of the electron scavengers showed that the efficiency of the electron scavenging in the glassy state had values intermediate between those in the gas and liquid phases. The high efficiency observed in the glassy state suggests that the non-solvated electrons before being trapped move about rapidly in the glassy matrix as the form of quasi-free electrons. The ESR-power saturation of the trapped electrons was considerably reduced by the addition of N_2O; a possible mechanism of the relaxation of the ESR is proposed.

The electron-scavenging process is one of the most important problems in radiation chemistry. To examine this problem, physical methods, such as optical absorption measurement by means of pulse radiolysis,[1] ESR studies,[2,3] and luminescence measurement,[4] have been used as well as the chemical method of product analysis. A considerable number of experiments have been made on electron scavenging by chemical analysis in the gas[5,6] and the liquid phases;[7-9] however, there has been little work in the glassy state.[10] The main difficulties of the product analysis in the glassy state at low temperatures are the fact that the spatial distribution of solutes may be nonhomogeneous and the fact that the overall reactions are not isothermal. Therefore, the kinetic treatment based on the homogeneous distribution of reactants and on the isothermal condition is not applicable. The physical methods may still give some insight into this problem, though concerning the nature of the trapped electrons, the spatial distribution has been studied by photobleaching[11] and by the microwave-power saturation of ESR.[12,13] The structure of the trapped electrons has also been studied by means of pulse radiolysis[1,14] and by ESR.[3,15] However, little study has been done on the electrons before being trapped. These electrons should resemble those photo-released from the trapped states,[16] 'mobile electrons,' but they may be different in energy.

In the present work, ESR has been used to measure the trapped electrons in 3-methylhexane (3MHX) glass and to obtain information on the electrons before they were trapped by the scavenger technique. The energy of electron attachment has been said to be different in each electron scavenger[17-20] in the gas phase, so that the electrons are scavenged even in the solid phase. The ESR technique is expected to be useful for testing the efficiency of electron attachment in the solid phase. The electron scavengers (N_2O, SF_6 and CH_3Cl) used in the present work are well known, but SO_2 is not usually used in the gas and the liquid phases. In the present work, N_2O, one of the most important electron scavengers, has been studied in detail.[21] The trapped electrons decreased upon the addition of N_2O to the hydrocarbon matrix and also changed in their nature; the ESR-power saturation of the trapped electrons was remarkably reduced by the addition of N_2O.

Experimental

Pure-grade 3MHX (Aldrich Chemical Co.) was purified by passing it through an activated silica gel column; it was degassed by the freeze-pump method and stored in sodium-potassium alloy for more than a day before use. The gaseous materials, SF_6, CH_3Cl, N_2O and SO_2 (Matheson Co.) were

commercially obtained and were used without purification.

In a mercury-free system, 3MHX was measured with a measuring capillary (2 mm i.d.), and the amounts of gaseous material added were determined by means of an oil manometer with a flask of a constant volume. The Ostwald absorption coefficients of various electron scavengers in liquid 3MHX at room temperature were used to determine the concentration of the solutes in 3MHX glass at 77 K. The samples were sealed in a Suprasil quartz ESR tube (3 and 5 mm, i.d.) and irradiated for 20 min—4 hr by ^{60}Co γ-rays at 77 K in the dark, at a dose rate of 0.8×10^{6} r/hr. After the irradiation, the ESR spectra of the samples were immediately measured in the dark by means of a JEP-1 X-band ESR spectrometer with a field modulation of 100 kHz. A multimode microwave cavity was used to determine the signal intensity by referring to a standard sample. After the initial measurement, bleaching experiments were performed with infrared light (>1000 nm) from a tungsten lamp through two Toshiba glass filters (V-B46 and IR-RIA).

In the saturation study the microwave power of ESR was measured by means of a thermistor power meter in the range of 0.01—10 mW. The magnetic field, H_1, of the microwaves in the cavity under the present operating conditions was given approximately by the following relationship: $H_1=2.0\times10^{-2}P^{1/2}$, where P is the microwave power in mW and where H_1 is that in gauss.[22] The power saturation curve was measured in the $1-10^{-3}$ mW range by the use of multimode microwave cavity at the modulation frequency of 100 kHz. The ratio of the saturation factor, Z, was directly measured from the signal-intensity ratio of the sample to a DPPH crystal, because the signal of the DPPH crystal was not entirely saturated under the conditions of the measurement.

Results

The ESR spectrum of γ-irradiated 3MHX glass is shown in Fig. 1. The singlet spectrum at the center is due to the trapped electrons (e_t^-) and is photobleached by the irradiation of infrared light. The remaining spectrum is due to a free radical. The line shape of e_t^- is close to a gaussian. The line width of e_t^- between the maximum slope is about 3.5±0.2 gauss and is broadened at a high microwave power. The singlet ESR spectrum of e_t^- was well resolved from that of the free radicals by photobleaching with infrared light. The microwave-power saturation of e_t^- was measured at various total doses. The experimental values coincide with the theoretical curves calculated by the saturation factor, as is shown in Fig. 2. With the irradiation doses between $(0.83-10)\times10^{19}$ eV/g, the saturation curve moves gradually to the side of a high microwave power at high total dose, but the curvature does not change.

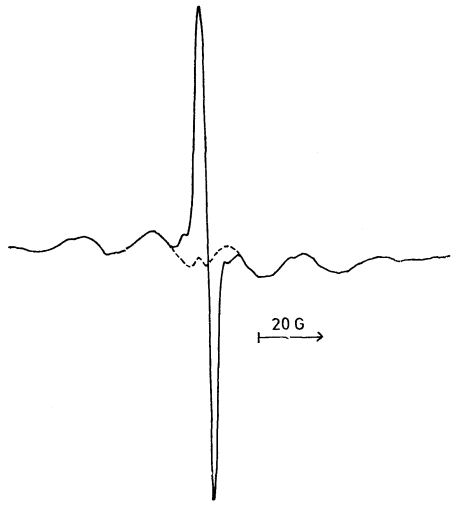

Fig. 1. ESR spectra of pure 3-methylhexane glass γ-irradiated to a dose of 9×10^{18} eV/g at 77 K. Solid curve; immediately after the irradiation, dotted curve; after the photobleaching by infrared light.

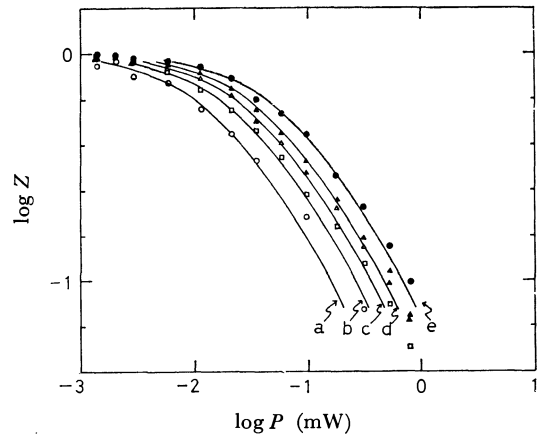

Fig. 2. Experimental values and theoretical curves of microwave-power saturation for e_t^- in 3-methylhexane glass at 77 K. The saturation factor, Z, is plotted as a function of microwave power, P, and the experimental values correspond to ○; 8.3×10^{18}, □; 17×10^{18}, △; 33×10^{18}, ▲; 50×10^{18}, ●; 10×10^{19} eV/g and the calculated curves correspond to a) $T_1=1.3\times10^{-2}$, b) 7.6×10^{-3}, c) 5.6×10^{-3}, d) 4.4×10^{-3}, e) 3.0×10^{-3} s.

A study was made of the scavenging of e_t^- in γ-irradiated 3MHX glass at 77 K as a function of the electron-scavenger concentration. It is well known that the electron scavengers reduce the formation of e_t^-. The signal intensity of e_t^- decreased rapidly with the concentration of SF_6 (Fig. 3) and disappeared completely at a relatively low concentration compared with the cases of the other electron scavengers. The addition of SF_6 did not alter the line shape of the e_t^- signal and did not produce any new signal. The

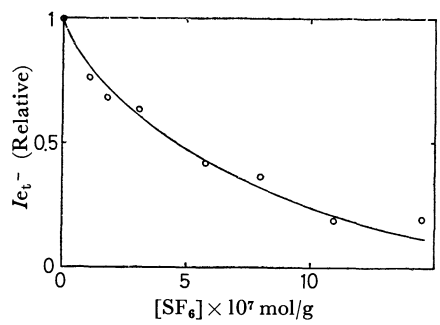

Fig. 3. Effect of addition of SF_6 on the relative signal intensity of e_t^- in 3-methylhexane glass at 77 K γ-irradiated to a dose of 2.0×10^{19} eV/g.

22) C. P. Poole, Jr., "Electron Spin Resonance," Interscience Publishers, New York (1967), p. 341.

microwave-power saturation curve of e_t^- shifted slightly to the side of the low power upon the addition of SF_6.

When N_2O was added, the signal intensity of e_t^- decreased at the low microwave power. At a high microwave power, the signal intensity of e_t^- increased with the concentration of N_2O and then decreased, as is shown in Fig. 4. The line shape and the width of the e_t^- signal did not change upon the addition of N_2O, and the signal could be photobleached by the infrared light at any concentration of N_2O. However, when N_2O was added, the microwave-power saturation curve shifted to the side of the high power and the shape of the saturation curve changed, as is shown in Fig. 5.

Figure 6 shows the ESR spectrum of γ-irradiated 3MHX glass containing CH_3Cl. The signal at the center is due to e_t^-, and the quartet signal, to CH_3. The microwave-power saturation curve of e_t^- did not shift upon the addition of CH_3Cl. After the photobleaching, the signal of e_t^- disappeared and that of

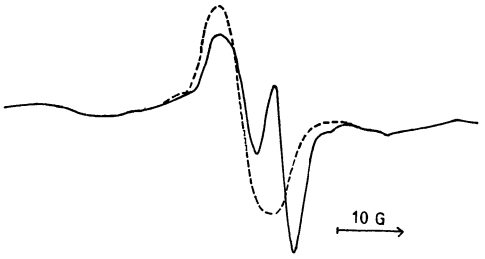

Fig. 8. ESR spectra of 3-methylhexane glass containing 5.4×10^{-6} mol/g SO_2 γ-irradiated to a dose of 9×10^{18} eV/g at 77 K. Solid curve; immediately after the irradiation, dotted curve; the photobleaching by infrared light.

CH_3 increased. As is shown in Fig. 7, the signal intensity of e_t^- decreased, while the quartet signal of CH_3 increased, with the concentration of $CHCl_3$, which underwent a dissociative electron attachment.

The ESR spectrum of γ-irradiated 3MHX glass containing SO_2 is shown in Fig. 8. A new singlet signal (g=2.007, ΔH_{msl}=8 gauss) appeared in the presence of SO_2, and the signal increased when the e_t^- was photobleached. The signal seems to be due to SO_2^-; the ESR signal of SO_2^- formed from the adsorbed SO_2 on MgO has been measured by another method.[23] The broad linewidth is probably due to the anisotropy of SO_2^-. Figure 9 shows that the signal

intensity of e_t^- decreased, and that of SO_2^- increased, with the concentration of SO_2. Even at high concentrations of SO_2, the signal of e_t^- did not completely disappear.

The electron-scavenging studies of e_t^- in 3MHX by various electron scavengers are summarized in Fig. 10, which shows that the efficiency of electron scavenging obtained from the initial slope of the curves is in the order of $SF_6>CH_3Cl>N_2O>SO_2$ and that the curvature of each scavenger is different from all others.

Discussion

In the absence of electron scavengers, the liberated electrons are either recombined with parent cations or trapped by physical sites in the glassy matrix:

$$3MHX \rightsquigarrow 3MHX^+ + e^- \quad (1)$$

$$e^- + 3MHX^+ \xrightarrow{k_n} 3MHX \quad (2)$$

$$e^- + \text{physical site} \xrightarrow{k_t} e_t^- \quad (3)$$

where k_n and k_t are the rate constants of neutralization and of electron trapping. In the presence of the electron scavenger, S, a part of the electrons can be scavenged before the recombination or the trapping:

$$e^- + S \xrightarrow{k_s} S^- \quad (4)$$

where k_s is the rate constant of electron scavenging. The measurement was made only of the decrease in the trapped-electron yield by the addition of the scavengers in this experiment. The reaction of electron attachment competes with those of electron trapping and neutralization. If the reaction of the electron scavenging and the electron trapping are treated by homogeneous kinetics, the following equations are obtained:

$$G_0(e_t^-)/G(e_t^-) = 1 + (k_s/\tau)S \quad [1]$$

$$\tau = k_n[M^+] + k_t[T.S.] \quad [2]$$

where $G_0(e_t^-)$ is the G-value of e_t^- at zero scavenger concentration and where [T.S.] is the concentration of the physical trapping site. Because the ion pairs neutralize geminately, the local concentration of parent cations, $[M^+]$, is a dose-independent constant in Eqs. [1] and [2], it is expressed microscopically as a function of the distance between the electrons and the parent cations. The concentration of the physical trapping sites was estimated to be larger than 10^{-3} mol/l from the total dosage effects.[24] The relative rate constants of electron scavenging, k_s/τ, are obtained from the initial slope of the curves in Fig. 11, in which the plots for SF_6 and CH_3Cl are almost linear and in the curves for N_2O and SO_2 are concave downwards. The deviation of the plots from the straight line may be due to the fact that these reactions are not homogeneous. When k_s is very large, the concentration of scavengers can be relatively small in the measurement and the heterogeneity of the competition reaction may be ignored. The reciprocal concentration at which the yield of e_t^- decreases to a half, $1/S_{1/2}$, and the k_s/τ ratio are shown in Table 1. The values of k_s/τ and $1/S_{1/2}$ are the same sequences of series, and the $1/S_{1/2}$ ratio is almost ten times larger than k_s/τ. To express the efficiency of electron scavenging, the values of k_s/τ seem to be more adequate than that of $1/S_{1/2}$. The electron-scavenging efficiency of SF_6 in the liquid phase is found to be almost the same as that of N_2O by the measurement of the hydrogen depression,[25] because the electrons were solvated and the efficiencies were determined by a diffusion-controlled process. In the gas phase, the ratio of efficiencies between SF_6 and

a) This work in 3MHX glass; b) From the measurement of hydrogen depression in liquid cyclohexane, α is equivalent to $1/S_{1/2}$ from Ref. 9; c) From the measurement of N_2 formation in gaseous propane by the addition of N_2O; d) Electron-attachment cross section by thermal electron from Ref. 17; e) Electron-attachment cross section by electrons of E_{max} from Refs. 17 and 19.

N_2O was measured[6] and found to be about 10^4 and the electron-attachment cross sections were measured directly by the methods of mass spectrometry for negative ions,[17-19] as is shown in Table 1. The electron scavenging in the glassy state seems to have an intermediate character between those in the gas and liquid phases with respect to the ratios and the absolute values of $1/S_{1/2}$. These experimental results indicate that, before being trapped, the electrons interact with a solvent weaker than the solvated electrons in the liquid phase.

The formations of SO_2^- and CH_3 were observed by the use of ESR in the presence of SO_2 and CH_3Cl. The electron scavengers, SO_2 and CH_3Cl, attach to the electrons produced by γ-irradiation or by photobleaching of e_t^-, and the negative ions or the free radicals appear by means of those reactions:

$$e_t^- \xrightarrow{h\nu} e^- \quad (5)$$

$$e^- + SO_2 \longrightarrow SO_2^- \quad (6)$$

$$e^- + CH_3Cl \longrightarrow CH_3 + Cl^- \quad (7)$$

On the other hand, the electron scavenging by SF_6 and N_2O produces no negative ions or free radicals. The solute, SF_6, attaches to the electrons as intermediate species:

$$e^- + SF_6 \longrightarrow [SF_6^-] \quad (8)$$

The pair of SF_6^- and the parent cation is unstable and is neutralized by electron jumps from the negative ions or by the migration of negative ions in the matrix. In the CH_3Cl solution, however, the dissociative electron attachment by CH_3Cl takes place,[26] and an ion pair of Cl^- and the parent cations forms near the CH_3 radicals by means of the cage effect of a glassy matrix. The ion pair must be unstable and must be neutralized to leave CH_3 radicals. In the experimental results of low-pressure mass spectrometry, SO_2 and N_2O attach dissociatively to electrons with some energy by the formation of O^-:

$$e^- + SO_2 \longrightarrow SO + O^- \quad (9)$$

$$e^- + N_2O \longrightarrow N_2 + O^- \quad (10)$$

The cage effect in glassy matrix disturbs the dissociative electron attachment of SO_2, and SO_2^- is formed. However, N_2O^- dissociates easily, and the parent cations are neutralized by O^- migration in the matrix. Therefore, no negative ion were trapped in the matrix by the addition of N_2O.

The energy distribution of electrons, $p(E, t)$, is the function of the electron energy, E, and the time, t. When the electrons are thermalized, the spatial distribution, $D(r)$, is the integrated product of the degradation factor, $R(E, r)$, and the initial energy distribution, $\int R(E, r)p(E, O)dE$, where r is the distance between electrons and the parent cations. If the electrons are trapped after a complete thermalization and if the concentration of trapping sites is very large, the portion of ionic species being trapped is the integrated product, $4\pi\int r^2D(r)\phi(r/r_t)dr$,[27] where $\phi(r/r_t)$ is the probalility of electron trapping, where r_t is $e^2/\varepsilon V_t$, where ε is the dielectric constant, and where V_t is the depth of the physical or chemical site. When r is larger than r_t, $\phi(r/r_t)$ can be expected to be large. The chemical site is usually deeper than the physical site. When the concentration of electron scavengers is small, the electron-scavenging efficiency, k_s, is proportional to the integrated cross section of electron attachment, $\int\sigma(E)P(E)Q(E)dE$, where $\sigma(E)$ is the cross section of electron-scavenging as a function of the electron energy, $p(E)=\int p(E, t)dt$ is the time-average distribution of electrons, and $Q(E)$ are the portions of electrons which should have been physically trapped in the absence of the electron scavengers. In a glassy matrix, $Q(E)$ will be small for the electrons near the thermal energy, because the electrons in the low-energy population will geminately recombine with the parent cation and will not contribute to the reaction with the scavengers. Therefore, $P(E)Q(E)$ in the glassy state will more likely be the energy distribution function in the gas phase than that in the liquid phase, where the collisional deactivation is easier than in the glassy state, so that energy is distributed only

26) "Fundamental Processes in Radiation Chemistry," Ed. by J. E. Willard and P. Ausloos, New York, Interscience Publishers (1968), p. 620.

27) If the function, $\phi(r/r_t)$, is similar to Onsager's equation, Laplace transformation of yield of trapped species as a function of various scavengers, r_t, will be obtained as the function, $D(r)$. Assumption of Magee's process, other functions $P(E)$ and $p(E, t)$, can be written as function of $D(r)$.

near the thermal energy in the liquid phase. In the electron-scavenging process, it is important to know what percentage of the total ionization is trapped. By the ESR and photoabsorption methods, the *G*-value of electron trapping, $G(e_t^-)$, in 3MHX glass at 77 K is 0.9.[15] In the gas phase, however, the yield of ionization has been estimated from the *W*-value[28] to be 4. If the ionization efficiency is the same in the gas and solid phases, the portion of electrons being trapped in the 3MHX glass, $\int P(E)Q(E)dE = 4\pi\int r^2D(r)(r/r_t)dr$, is estimated to be 0.2 ($\simeq$0.9/4). Recently, however, the quasi-free electron model[29] has successfully been applied to the behavior of electrons in the condensed phase, so the electron-scavenging process should be reexamined from this point of view. In the gas phase, the cross section of electron attachment with scavengers has been measured as a function of the electron energy. For example, the electron energies for the maximum cross section, E_{max}, of SF_6, N_2O, and CH_3Cl are, respectively, 0.02,[17] 2.25,[18] and 0.02eV,[19] while the E_{max} of SO_2 has two values, 5 and 8 eV.[20] When E_{max} is small, for example, in the cases of SF_6 and CH_3Cl, k_s is reduced to being proportional to $\int\sigma(E)dE$, considering that $P(E)Q(E)$ is constant in the range of near-thermal energies, in contrast with the rapid change of $\sigma(E)$ in this region. Even at high concentrations, SO_2 can not scavenge a part of the electrons, because the $\sigma(E)$ of SO_2 is nearly zero at a small electron energy.

The saturation study of ESR also provides information on the structure of e_t^-. The rapid and fast passage and the nonadiabatic condition ($H_1/H_m\omega_m \ll \sqrt{T_1T_2}$, $\omega_m T_1 \gg 1$, $\gamma H_1^2 \ll \omega_m H_m$)[30] are given by the data of Tsuji and Williams[12]; T_1 is about $10^{-2}-10^{-3}$, T_2 is about $10^{-7}-10^{-8}$, $\sqrt{T_1T_2}$ is about $10^{-5}-10^{-6}$, the angular frequency of magnetic-field modulation, ω_m, is $2\pi\times10^5$, and the peak modulating magnetic field, H_m ,is about 1 gauss in this experiment, where H_1 is the component of the rotating magnetic field, perpendicular to the z-direction and where γ is the gyromagnetic ratio. The spin-lattice relaxation time, T_1, given by the equation of the saturation factor, $Z=(1+2\gamma H_1^2T_1/\pi H_m)^{-1}$,[30] is not accurate because of the error in H_1 values, but the relative values give useful information regarding the structure. The higher microwave-power saturation curve of e_t^- in pure 3MHX (Fig. 2) agrees with the equation of Z, and shift to a microwave power shows the decrease in T_1 with an increase in the total dose. However, the shift to the higher microwave power in Fig. 5 shows the decrease in T_1 with the concentration of N_2O. In addition to the shift, the shape of the saturation curve changes when N_2O is added. Because the variation in T_1 and T_2 values due to the addition of N_2O affects the conditions of the power-saturation measurement, a different type of equation for the saturation factor should be applied. The singlet signal of the trapped electrons produced by the addition of N_2O is different from that in pure 3MHX glass and has the following properties: 1) the signal has the same ESR linewidth at any concentration of N_2O and is photobleached by the infrared light much like the trapped electrons in pure 3MHX glass; 2) the signal disappears at a large concentration of N_2O; 3) in the presence of N_2O, the absorption spectrum shows a broad near-infrared band which shifts to a slightly shorter wavelength than that in pure 3MHX[31]; 4) no such shift of the absorption band or change in the ESR relaxation time can be observed in a polar matrix such as 2-methyltetrahydrofuran.[31] These phenomena must result from the formation of trapped electrons in a slightly different structure, and must not be due to negative species such as N_2O^-.

The spin-lattice relaxation mechanism is partly due to the spin-orbit coupling of the Van Vleck theory,[32] partly to the modulation of the spin-spin interaction by the lattice vibrations (Waller theory),[33] and partly to the cross relaxation by the spin-spin interaction.[34] The transition due to the spin-orbital interaction of the trapped electrons in pure 3MHX must be small; it has the same value for any sample, no matter the total dose, but the geometrical change in the structure of the trapping site should affect this value. When N_2O is added, the electrons may be trapped near the N_2O molecule and the field in the trapping sites appears to be perturbed by N_2O, so that the spin-orbit interaction increases. However, the spin-spin interaction is related to the overlapped area of the ESR spectra; therefore, the interaction of the e_t^-—e_t^- type is greater than that of the e_t^-—R (free radical) type. In the Waller mechanism, the e_t^-—e_t^- interaction may dominate the e_t^-—R interaction. The cross relaxation depends on the facts that the spins of R are in good contact with the lattice and that those of e_t^- are in poor contact. Therefore, the cross relaxation takes place *via* the spin-lattice relaxation of R by the mutual spin flip between e_t^- and R. At any rate, the spin-lattice relaxation increases with an increase in the concentrations of the spins due to the e^- and free radicals, whose concentrations are related to the total doses of irradiation. The addition of SF_6 decreases the concentrations of e_t^- and free radicals, and the rate of spin-lattice relaxation is decreased. When CH_3Cl is added, the concentration of e_t^- decreases and that of CH_3 increases, so that the decrease in the spin-lattice relaxation by the Waller mechanism of the (e_t^-—e_t^-) type will be partially compensated for by the increase in that of the (e_t^-—R) type caused by the cross relaxation. Therefore, the total amounts of spin-lattice interaction seem to be almost the same.

Modified CNDO 2 Calculations of Ionization Potentials for Some Unsaturated Hydrocarbons

Koichi OHNO,* Tomohiko HIROOKA, Yoshiya HARADA, and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo 106

**College of General Education, The University of Tokyo, Komaba, Tokyo 153*

(Received December 16, 1972)

The orbital energies of several unsaturated hydrocarbon molecules have been calculated using a modified CNDO/2 method, with the electron repulsion integrals evaluated from Klopman's formula and the σ–π separation factor proposed by Tinland and Jaffé. The empirical parameters are determined to reproduce the observed ionization potentials for ethylene and benzene *via* Koopmans' theorem. The results are shown to agree well with the available experimental ionization potentials and with the assignments of the photoelectron spectra.

Photoelectron spectroscopy provides much information on the ionized states of molecules; not only are the adiabatic first ionization potentials and the higher ionization potentials determined by the measurement of the excess kinetic energies of photoelectrons,[1-7] but also information on the symmetry of ionized states can be obtained from the observed angular distribution of photoelectrons.[8] On the other hand, based upon Koopmans' theorem,[9] the development of molecular orbital methods made it possible to compare the observed vertical ionization potentials with the calculated orbital energies not only for π-electrons but for σ-electrons. They also enable us to compare the assignments of the electron energy levels expected from the observed angular distribution of photoelectrons with those derived from the symmetry of molecular orbitals. However, the methods have not been sufficient to give reasonable interpretation of the observed photoelectron spectra.

Although the all-electron *ab initio* methods have also been advanced, the calculations are time consuming and not always more reliable than the semi-empirical calculations.

In the present paper, we modified the CNDO method introduced by Pople *et al.*[10,11] and established a simpler and more reliable method for the assignment and prediction of photoelectron spectra of unsaturated hydrocarbon molecules.

Method and Parametrizations

The method used here is almost the same as the CNDO/2 method proposed by Pople and Segal;[11] the following semi-empirical parametrizations are taken.

(1) The electron repulsion integrals, γ_{AB}, are evaluated from Klopman's formula:[12]

$$\gamma_{AB} = e^2/\sqrt{R_{AB}^2 + G_{AB}^2}$$

and:

$$G_{AB} = \frac{e^2}{2}(\gamma_{AA}^{-1} + \gamma_{BB}^{-1})$$

where R_{AB} is the interatomic distance between A and B. For one-center repulsion integrals, the semi-empirical values are used:

for carbon atoms, $\gamma_{AA}(C) = 11.144$ eV,

and

for hydrogen atoms, $\gamma_{AA}(H) = 12.845$ eV.

(2) The resonance integrals, β_{AB}, are determined by the use of the following formula;

$$\beta_{AB} = \frac{\beta_A^\circ + \beta_B^\circ}{2} S_{AB},$$

where S_{AB} is the overlap integral between the two atomic orbitals. β_A° is an empirical parameter depending upon the kind of atom. For carbon atoms, we introduced another parameter, k, which is a σ–π separation factor proposed by Tinland[13] and Jaffé[14];

$$\beta^\circ(C\pi) = k\beta^\circ(C),$$
$$\beta^\circ(C\sigma) = \beta^\circ(C).$$

Now, we have three unknown empirical parameters, $\beta^\circ(H)$, $\beta^\circ(C)$, and k, for unsaturated hydrocarbon molecules. These parameters must be determined in order to reproduce the observed spectra. As the simplest parametrization, we chose the first three levels of ethylene, (πb_{1u}), (σb_{1g}), and (σa_g), and the first two levels of benzene, (πe_{1g}) and σe_{2g}), as the standards; they should be fitted to the first three observed ionization potentials of ethylene and the first two of benzene respectively.

The orbital energies of ethylene and benzene were calculated as a function of the unknown parameters, the ranges of the parameters, -10.0 eV$\geqq\beta^\circ(C)\geqq -14.0$ eV, -6.0 eV$\geqq\beta^\circ(H)\geqq -10.0$ eV, and $0.2\leqq$

$k \leqq 0.6$, the calculated orbital energies were arranged as (πb_{1u}), (σb_{1g}), (σa_g), (σb_{2u}), ··· for ethylene, and as (πe_{1g}), (σe_{2g}), (πa_{2u}), ··· for benzene, and no interchanges of the orders were found. Although the optimization was not completely carried out, a set of the following values for the parameters leads to satisfactory results with regard to the standard levels;

$$\beta^\circ(C) = -12.0\,eV, \quad \beta^\circ(H) = -7.0\,eV,$$

and $$k = 0.40.$$

With these parameters, the orbital energies of other unsaturated hydrocarbon molecules were calculated by means of a FACOM-270-20/30 Computer.

Results and Discussion

The parameter values determined in the previous section were used in the calculations of the orbital energies of ethylene, *trans* 1,3-butadiene, benzene, naphthalene, and azulene. Based upon Koopmans' theorem, the absolute values of the calculated orbital energies were compared with the (vertical) ionization potentials obtained from the available data of the photoelectron spectra, and also with the calculated values by Dewar[15] and others.[16-21] The results are shown in Tables 1—5. As can be seen in the tables, the calculated ionization potentials smaller than 16 eV agree, in general, with the observed values. Especially for ethylene and butadiene, our results seem much better than the MINDO calculations by Dewar. From the present results, it may be concluded that both of the first two levels for *trans* 1,3-butadiene are to be attributed to π-electrons, as has been previously reported.[22,23] Furthermore, we are encouraged by the fact that the assignment of the photoelectron spectra for benzene from the calculated orbital energies and their symmetries completely coincides with the recent assignment from the angular distribution data of the photoelectrons reported by Carlson and Anderson.[8] These assignments are not only consistent with the analysis of the vibrational structure by Turner;[3] they also agree with the order of the orbital energies predicted by Jonsson and Lindholm.[5] In addition, since the three lowest IP bands of naphthalene are sharp,[3,6,7] it seems reasonable to assign these bands to the three highest occupied π-orbitals, as assigned in Table 4. In the case of azulene, our calculation also explains the first three bands as π-excitations.

The general conclusion of our results is that the calculated π-electron ionization potentials are in comparatively good agreement with those obtained by the MINDO calculations, but that the calculated ionization potentials for σ-electrons are quite different from these obtained by MINDO. It seems that the introduction of the fairly small σ–π separation factor has led to appropriate separations between the σ-

electron levels and the π-electron levels. Moreover, the parameters, β°(C) and β°(H), were adjusted to reproduce the shallow levels for ethylene and benzene; thus, it is natural that the present results are plausible for the ionization potentials smaller than about 16 eV. Although the physical meaning of the choice of the empirical parameters is not very clear, the present method may provide, as in the sense of the Pariser-Parr-Pople calculations for the electronic spectra of π-electron system, a complementary means for interpreting or predicting the photoelectron spectra of unsaturated hydrocarbon molecules.

Kinetic Studies of the Solvent Extraction of Metal Complexes. II. The Rate of the Extraction of Iron(III) with Thenoyltrifluoroacetone into Carbon Tetrachloride

Tatsuya SEKINE, Jun-ichi YUMIKURA, and Yū KOMATSU

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received January 18, 1973)

The rate of the solvent extraction of iron(III) in 4.0 M perchlorate ionic media with 2-thenoyltrifluoroacetone (TTA) into carbon tetrachloride has been measured under various conditions. The rate was found to be first order with respect to the concentration of iron(III) in the aqueous phase, first-order with respect to TTA in the organic phase, but independent and inversely first-order with respect to the hydrogen-ion concentration. From these results, it was concluded that the rate-determining step in this extraction is the formation of the first complex between the undissociated form, TTA(HA), and Fe^{3+} in the higher acid concentration range, but that the reaction between the anionic form, TTA(A^-), and Fe^{3+} also becomes a rate-determining step as the acid concentration decreases. It was also found that chloride ions accelerate the extraction; this was interpreted by more rapid reactions between TTA (in the both forms, HA and A^-) and an iron(III) chloride complex. From these results, the rate constants for the rate-determining reactions were calculated to be $K_{HA}=10^{0.57}$ M^{-1} min^{-1} and $K_A=10^{6.84}$ M^{-1} min^{-1} in 4.0 M(H, Na)ClO_4 at 25 °C by means of these equations: $-d[Fe^{3+}]/dt=K_{HA}[Fe^{3+}][HA]$ (where [HA] is the total concentration of both enol and keto forms of uncharged TTA in the aqueous phase) and $-d[Fe^{3+}]/dt=K_A[Fe^{3+}]\cdot[A^-]$. The $FeCl^{2+}$ species reacts with both HA and A^- more rapidly than does the Fe^{3+} species, and the rate constants of the reactions of the former are in both cases higher than those of the latter by a factor of 28.

It has been pointed out that the rate of the reaction of metal ions in aqueous solutions is low when the charge is larger and/or when the radius is small; this has been explained as being due to the slow substitution of the hydrated water on such ions with the reactant. As examples of these metal ions, Be^{2+}, Al^{3+} and other strongly-hydrolysing metal ions were cited by Eigen.[1] In the previous paper of the present series,[2] it was reported that the solvent extraction of beryllium(II) with 2-thenoyltrifluoroacetone(TTA) in carbon tetrachloride is extremely slow because of the slow formation of the first complex of this metal ion in the aqueous phase with a TTA anion. In the course of another experiment of the present laboratory,[3] it was found that the extraction of iron(III) with TTA in chloroform was rather slow. The slow extraction of iron(III) with TTA has been reported by Bolomey and Wish[4] and by Adin and Newman.[5] It has been reported by Dyrssen[6] that the extraction of iron(III) with β-isopropyltropolone(IPT) is slow; the rate of this IPT extraction was studied more quantitatively by McClellan and Menis.[7] The extraction of iron(III) with alkylphosphoric acid has been studied kinetically by several workers, as Coleman and Roddy summarized in their review.[8]

The present study has been undertaken in order to make quantitative measurements of the rate of iron(III) extraction with TTA and in order to clarify the details of the mechanism of this slow extraction. The organic phase used is carbon tetrachloride, and the aqueous phase employed is perchlorate ionic media, 4.0 M(H, Na)ClO_4, except in a few cases. This aqueous phase was chosen in order to use the equilibrium data obtained for this aqueous solution in Ref. 3 for the analysis of the results. Since it has been found that the rate of extraction is accelerated by the addition of the chloride ion,[5,8] this effect was also measured.

Experimental

Reagents. The stock solution of iron(III) was prepared as follows. A weighed amount of analytical-grade metallic iron was dissolved in warm perchloric acid; the mixture was then stored as the stock solution. A working solution containing 1.0×10^{-2} M iron(III), 1.0 M perchloric acid, and 3.0 M sodium perchlorate was prepared from the above stock solution. The TTA was obtained from Dojindo & Co. The sodium perchlorate was prepared from sodium carbonate and perchloric acid, and it was recrystallized three times from water. All of the other reagents were of a reagent grade.

Procedures. The details of the procedures are essentially the same as those described in the previous paper[2] except that the amount of the metal ion was determined by colorimetry in the present study. The aqueous phase was prepared so as to contain 1.0×10^{-3} M of iron(III), 4.0 M of the perchlorate ion, and various amounts of sodium and hydrogen-ions. Some experiments were also carried out in order to ascertain the effect of coexisting salt on the rate of extraction by changing the sodium perchlorate concentration. The organic phase was carbon tetrachloride containing TTA. The initial volume of each phase was always 5.0 ml. The two phases were placed in stoppered glass tubes (volume, 20 ml) and vigorously agitated at 25±0.3 °C. The shaking speed was chosen so as to be high enough that no acceleration of the rate of extraction was observed upon a further increase in the agitation speed; thus, the effects due to the transport of materials and to any interfacial re-

action could be eliminated from consideration, as has been described in the previous paper.[2] After a certain interval, the two phases were centrifuged. A certain portion of the organic phase was pipetted out, and the content of the iron(III)–tris TTA chelate was determined by colorimetry. The absorption was determined at 500 nm; the molar extinction coefficient at this wavelength was found to be 3.7×10^3. It was found that Beer's law held, at least until a concentration of 2.0×10^{-4} M of the iron(III)–TTA chelate in carbon tetrachloride. The amount of aqueous iron(III) was estimated from the difference between the iron(III) concentration in the initial aqueous phase and that in the organic phase at equilibrium. The hydrogen-ion concentration was calculated from the amount of perchloric acid added.

Statistical

The rate of the extraction of Fe^{3+} ion with an acidic extractant, HA, may be written, in many cases, as follows:

$$-\frac{d[Fe^{3+}]}{dt} = k_0[Fe^{3+}]^a[HA]_{org}^b[H^+]^c \quad (1)$$

When the extractant and the hydrogen-ion are present in a large excess to iron(III), Eq. (1) can be written as follows:

$$-\frac{d[Fe^{3+}]}{dt} = q[Fe^{3+}]^a \quad (2)$$

Here, q is the multiplication of the rate constant, k_0, and the other two concentrations in Eq. (1), which are kept at certain values throughout a series of experiments. When the reaction order with respect to iron(III) is unity, as in the case of the present study, the following simplified statistical treatment is possible. Assuming that the value of a in Eq. (2) is unity, it can be written by integration as:

$$-\log[Fe^{3+}] = q't + C_0 \quad (3)$$

where C_0 is a constant and where q' is $q\times\log e$. Equation (3) shows that when a is unity, the $-\log[Fe^{3+}]$ *vs.* t plot should be a straight line with a slope of q'.

The reaction order with respect to the other two elements in Eq. (1) can be determined from the measurements when one of these two concentrations is kept at a certain value. For example, when the concentration of the hydrogen-ion is kept at h, the quantity, q_{HA}, can be written, in the first step, as follows:

$$\log q_{HA} = \log k_0h^c + b\log[HA]_{org} \quad (4)$$

As can be seen from Eq. (4), the reaction order with respect to the extractant, b, can be determined from the slope of the $\log q_{HA}$ *vs.* $\log[HA]_{org}$ plot.

Since the reaction order with respect to the hydrogen-ion, c, was found in the present study to change from minus one to zero upon an increase in the hydrogen-ion concentration, the following more general equation, containing a term in which the reaction order with respect to the hydrogen-ion concentration is zero, was employed:

$$-\frac{d[Fe^{3+}]}{dt} = k_0[Fe^{3+}][HA]_{org}^b(1+K_H[H^+]^{-1}) \quad (5)$$

On the other hand, when the concentration of the extractant is kept at a certain value, ha, the q_{H^+} quantity is obtained as:

$$\log q_{H^+} = \log k_0(ha)^b + \log(1+K_H[H^+]^{-1}) \quad (6)$$

Furthermore, since the addition of the chloride ion was found to accelerate the extraction, the following statistical treatment was made for this effect. Under the conditions where the concentrations of the extractant and hydrogen-ion are kept constant at h and ha, but where the aqueous phase contains a certain amount of the liquid, Cl^-, the rate may be represented by the following equation (the higher terms with respect to Cl^- are not given here and the b value is always unity in Eq. (6)):

$$-\frac{d[Fe^{3+}]}{dt} = q_L[Fe^{3+}] \quad (7)$$

where q_L is

$$\log q_L = \log k_0(ha)(1+K_Hh^{-1}) + \log(1+K_{Cl}[Cl^-]) \quad (8)$$

The constants in Eqs. (6) and (8) can be determined by a curve-fitting method.[2,9-11]

When the initial concentration of the extractant in the organic phase is denoted by $C_{HA(org)}$, the following equations are obtained if the volumes of the two phases are the same and if $[A^-]\ll C_{HA(org)}$:

$$K_a = [H^+][A^-][HA]^{-1} \quad (9)$$

$$K_d = [HA]_{org}[HA]^{-1} \quad (10)$$

$$C_{HA(org)} = [HA]_{org} + [HA] + [A^-] \quad (11)$$

$$[A^-] = C_{HA(org)}K_a(K_d+1)^{-1}[H^+]^{-1} \quad (12)$$

The values of these constants in the carbon tetrachloride–4.0 M (H, Na)ClO_4 system have been reported to be $\log K_a=-6.57$ and $\log K_d=1.93$.[2] Since $K_d\gg1$, and since, thus, $C_{HA}\simeq[HA]_{org}$, Eq. (12) can be written as:

$$[A^-] = [HA]_{org}K_aK_d^{-1}[H^+]^{-1} \quad (13)$$

Results

Iron(III) was always added initially to the aqueous phase. Since the data used for the analysis were only those obtained from the experiments in the early stage of extraction, the effect of the back extraction may be negligible.

Reaction Order with Respect to Fe^{3+}. In all the experiments, each of the $-\log[Fe^{3+}]$ *vs.* t plots always gave a staright line. Thus, as can be seen from Eq. (3), the reaction order with respect to iron(III) is always unity.

Reaction Order with Respect to TTA(HA). The rate of extraction was determined in the TTA concentration range between 0.05 M and 0.3 M and at the hydrogen-ion concentration of 1.0 M. The $\log q_{HA}$ *vs.* $\log[HA]_{org}$ plot is given in Fig. 1. As may be seen from the figure, the plot obtained is a straight ling with a slope of +1; thus, the rate of extraction was concluded to be proportional to the TTA concentration under these conditions.

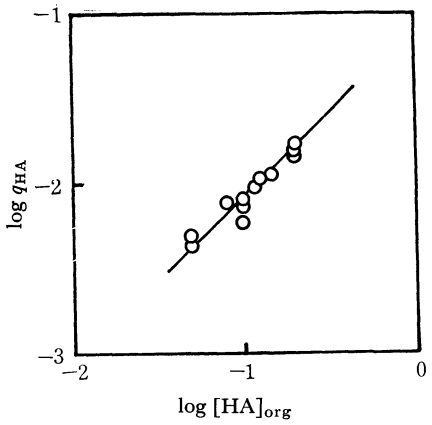

Fig. 1. Dependence of the rate of Fe(III) extraction on the TTA concentration in the organic phase (q_{HA} *cf.* Eq. (4)).

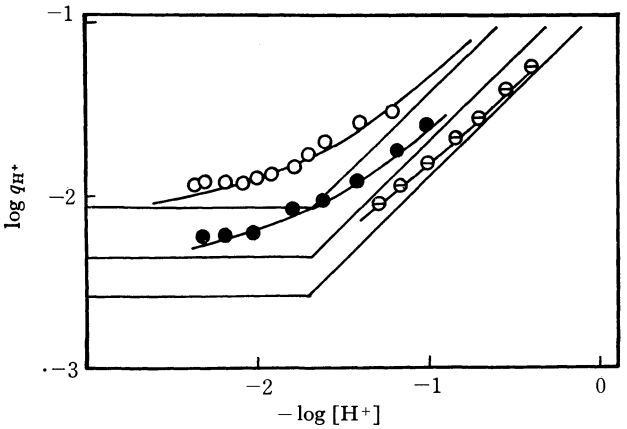

Fig. 2. Dependence of the rate of Fe(III) extraction on the hydrogen-ion concentration (q_{H^+} *cf.* Eq. (6)). ○: CCl_4 containing 0.2 M TTA, ●: CCl_4 containing 0.1 M TTA and ⊖: CCl_4 containing 0.05 M TTA. The two straight lines for each plot are the two asymptotes; $Y=\log k_0(ha)$ and $Y=\log k_0K_H(ha)$ $-\log[H^+]$, and the solid curve is calculated by introducing the rate constants in Table 1 into Eq. (6).

Reaction Order with Respect to H^+. The rate of extraction was determined in the range of hydrogen-ion concentrations from 2.0 M to 0.04 M and at the TTA concentrations of 0.05 M, 0.1 M, and 0.2 M. Figure 2 gives the log q_{H^+} *vs.* $-\log[H^+]$ plot. As may be seen from Fig. 2, the slope for the plot approaches zero in the lowest $-\log[H^+]$ region, but it increases with the increase in $-\log[H^+]$ until it approaches unity. From this fact, it was concluded that there are two mechanisms for the extraction and that they can be represented by Eq. (6).

The rate constants in the absence of chloride ions were determined from these results by the curve-fitting method; they are listed in Table 1(a).

Effect of the Chloride Ions. The rate was determined as a function of the chloride-ion concentration in the aqueous phase when the TTA concentration was 0.1 M and when the hydrogen-ion concentration was 1.0 M. Figure 3 gives the log q_L plot where L is Cl^-; the rate is accelerated by the chloride ion, and it becomes almost proportional to the chloride concentration in the higher range. The constant, K_{Cl}, in Eq. (8) was determined from this plot by the curve-fitting method; it is listed in Table 1.

Table 1. Summary of constants

(a) Constants for the equation:

$$-d[Fe^{3+}]/dt = k_0[Fe^{3+}][HA]_{org}(1+K_H[H^+]^{-1})(1+K_{Cl}[Cl^-])$$

$\log k_0 = -1.36$ $(M^{-1}\,min^{-1})$

$\log K_H = -0.30$ (M)

$\log K_{Cl} = 2.32$ (M^{-1})

(b) Reaction constants$(M^{-1}\,min^{-1})$ defined by Eqs. (14) and (15).[a)]

$\log K_{HA} = 0.57$

$\log K_A = 6.84$

$\log K_{HA-Cl} = 2.01$

$\log K_{A-Cl} = 8.28$

a) Rate constant for the reaction between Fe^{3+} and HA (K_{HA}) which has been computed by using the total concentration of HA in the aqueous phase, Fe^{3+} and A^-(K_A), $FeCl^{2+}$ and HA(K_{HA-Cl}), and $FeCl^{2+}$ and A^-(K_{A-Cl}).

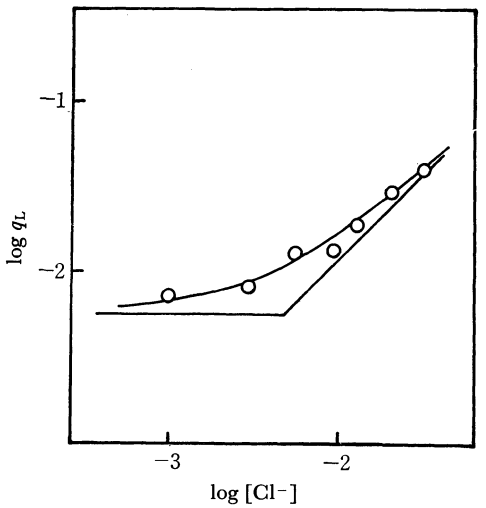

Fig. 3. Dependence of the rate of Fe(III) extraction on the chloride ion concentration. The straight lines are two asymptotes; $Y=\log C$ and $Y=\log CK_{Cl}+\log[Cl^-]$ where C is equal to $\log k_0(ha)(1+K_Hh^{-1})$ in which ha is 0.1 M and h is 1.0 M. The solid curve was obtained by introducing the constants in Table 1 into Eq. (8).

In order to consider the effect of the chloride ion on the rate of extraction further, the rate was determined with 0.1 M TTA in the organic phase in the presence of the chloride-ion at a certain concentration, 5×10^{-3} M, but in the presence of the hydrogen-ion at various concentrations. Figure 4 shows these results. As may be seen from Fig. 4, the addition of chloride always increases the rate by a factor of $10^{0.24}$. Thus, it can be concluded that both mechanisms, one independent of, and the other inversely first-order dependent on the hydrogen-ion, are affected by the chloride-ion in the same manner. From the amounts of the chloride complexes, $FeCl^{2+}$ and $FeCl_2^+$, in the aqueous phase, which were computed by using the stability constants in 4.0 M (H, Na)ClO_4,[3)] that is, $\log\beta_1=0.88$ and $\beta_2=0.80$, the rate constants for the extraction in the presence of chloride-ion were determined to be

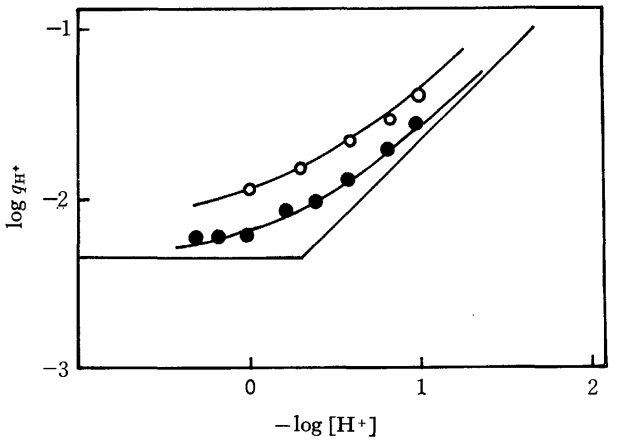

Fig. 4. Dependence of the rate of Fe(III) extraction on the hydrogen ion concentration in the presence of 5×10^{-3} M chloride-ion (○) and its absence (●) in the aqueous phase when the TTA concentration in the organic phase is 0.1 M. The two straight lines are the same as those given in Fig. 2. The curve for the full circle is $Y=\log k_0(ha)\,(1+K_H[H^+]^{-1})$ and that for the open circles is $Y=\log k_0(ha)(1+K_{Cl}[Cl^-]_a)(1+K_H[H^+]^{-1})$ in which ha is 0.1 M and $[Cl^-]_a$ is 5.0×10^{-3} M.

as listed in Table 1 (b).

Since the rate of the extraction of iron(III) with IPT has been reported to be dependent on the concentration of the coexisting sodium perchlorate,[7] the dependence of the rate on the sodium perchlorate concentration was also determined. The results are given in Table 2. As may be seen from the table, the rate is not very much affected by the change in the salt concentration.

Discussion

Since the rate of extraction is always first-order with respect to TTA, and zero and inversely first-order with respect to the hydrogen-ion, and since the effect of interfacial reaction is negligible in the present study, Eq. 5 may, by introducing Eq. (13), be written as:

$$-\frac{d[Fe^{3+}]}{dt}=K_{HA}[Fe^{3+}][HA]+K_A[Fe^{3+}][A^-] \quad (14)$$

where $K_{HA}=k_0K_d$ and where $K_A=k_0K_HK_dK_a^{-1}$. Equation (14) shows that the rate of extraction is controlled by two reactions, one between Fe^{3+} and HA and the other between Fe^{3+} and A^- in the aqueous phase.

Table 2. The effect of ionic strength adjusted by sodium perchlorate on the rate of extraction at two hydrogen ion concentrations (q_{H^+} *cf.* Eq. (6))

Ionic strength	log q_{H^+} at $[H^+]=1.0$ M	log q_{H^+} at $[H^+]=0.05$ M
4.0 M	−2.18	−1.32
3.0 M	−2.17	−1.28
1.0 M	−2.20	−1.22
0.1 M		−1.09

The effect of the chloride-ion can, then, be treated from Eqs. (8) and (14) and the stability constant of the $FeCl^{2+}$ species as follows:

$$-\frac{d[Fe^{3+}]}{dt}=K_{HA}[Fe^{3+}][HA]+K_A[Fe^{3+}][A^-]+K_{HA-Cl}[FeCl^{2+}][HA]+K_{A-Cl}[FeCl^{2+}][A^-] \quad (15)$$

where $K_{HA-Cl}=K_{HA}K_{Cl}\beta_1^{-1}$ and where $K_{A-Cl}=K_AK_{Cl}\beta_1^{-1}$.

By using the constants in Table 1(a) and these relations, the values of these constants were calculated to be as given in Table 1(b).

Adin and Newman[5] determined the rate of the extraction of iron(III) with TTA and reported that the TTA extraction of iron(III) takes place by way of two mechanisms; one is independent of, and the other is dependent on, $[H^+]^{-1}$. They also reported an acceleration of the extraction by the chloride-ion. These results are summarized in Table 3. Their results are similar to those obtained in the present study, although the solvent is different and the electrolyte concentration and the background cation are different. These authors, however, explained the inversely first-order dependence of the rate on the hydrogen-ion in terms of the hydrolysis of iron(III); in other words, they assumed that the $FeOH^{2+}$ species reacted with the HA-form TTA much faster than did the Fe^{3+} species, and they assumed that the $FeOH^{2+}$ species reacted much faster than the $FeCl^{2+}$ species. According to these authors, the $FeOH^{2+}$ species reacts with the HA-form TTA faster than does the Fe^{3+} species by a factor of 10^4.

Statistically, it is impossible to distinguish whether this inversely first-order dependence on the hydrogen-ion which has been observed in both the previous and the present studies is due to a $Fe^{3+}+A^-\rightarrow FeA^{2+}$ re-

Table 3. Previous work on the rate of iron(III) extraction with chelating extractants

Chelate	Organic phase	Aqueous phase	k ($M^{-1}min^{-1}$)	Ref.	Remarks
TTA (room temparature)	C_6H_6	—	—	4	Slow extraction at pH 4.5 but rapid back extraction
TTA (25 °C)	C_6H_6	1.0 M (H, Li)ClO_4	30	5	$Fe^{3+}+(HTTA)_{enol}\rightarrow FeTTA^{2+}+H^+$
			2.6×10^4		$FeOH^{2+}+(HTTA)_{enol}\rightarrow FeTTA^{2+}$
			1.2×10^3		$FeCl^{2+}+(HTTA)_{enol}\rightarrow FeTTA^{2+}+H^++Cl^-$
IPT (21±1 °C)	$CHCl_3$	1.0 M (H, Na)ClO_4 $[H^+]=1.0$	1.5×10^{10}	7	$Fe^{3+}+IPT^-\rightarrow Fe(IPT)^{2+}$ First-order dependence on $NaClO_4$ when its concentration is 1—4 M and zeroth-order dependence on H^+ in the range $[H^+]$ 1—5 M were also observed.

action or to a $FeOH^{2+}+HA \rightarrow FeA^{2+}+H_2O$ reaction. The present authors, however, believe that the former mechanism is dominant in the system studied in this paper, because, as may be seen from Fig. 4, the rate of extraction is always increased by the chloride-ion by a factor of $10^{0.24}$ at 5×10^{-3} M; that is, the increase is the same for lower $-\log[H^+]$ region, where the reactions between HA and the Fe^{3+} and $FeCl^{2+}$ species are dominant, and for the higher region, where the reactions between A^- and the Fe^{3+} and $FeCl^{2+}$ species are also dominant.

According to the viewpoint of previous authors,[5] the rate of extraction can be represented by:

$$-\frac{d[Fe^{3+}]}{dt}=k[HA]([Fe^{3+}]+K'[FeCl^{2+}]+K''[FeOH^{2+}])$$
$$=k[Fe^{3+}][HA](1+K'\beta_1[Cl^-]+K''K_h[H^+]^{-1}) \quad (16)$$

where $K_h=[FeOH^{2+}][H^+][Fe^{3+}]^{-1}$. Thus, when the chloride concentration is zero and a certain value, L_1, and when the concentration of the extractant in the aqueous phase was a certain value of ha_1, the rates may be represented by:

$$-\frac{d[Fe^{3+}]}{dt}=k(ha_1)[Fe^{3+}](1+K''K_h[H^+]^{-1}) \quad (17)$$

$$-\frac{d[Fe^{3+}]}{dt}=k(ha_1)[Fe^{3+}](1+K'\beta_1L_1+K''K_h[H^+]^{-1}) \quad (18)$$

From these equations, it is obvious that the ratio of the two rates, which can be obtained by dividing Eq. (18) by Eq. (17), changes with the change in the hydrogen-ion concentration; this is not observed in the results in Fig. 4.

Although the hydrolysis does not seem to be the reason for the inversely first-order dependence of the rate on the hydrogen-ion shown in Figs. 3 and 4, hydrolysis seems to accelerate the rate of extraction. Unfortunately, since the rate in the higher $-\log[H^+]$ region, where the effect can be expected, is too high to be measured accurately by the experimental method employed here, the quantitative relation between the rate and the degree of hydrolysis could not be determined.

The conclusion drawn in the present study is somewhat similar to that reported by McCllelan and Menis for the extraction of Fe^{3+} with IPT.[7] They described that the extraction is proportional to $[HIPT]_{org}$ and $[H^+]^{-1}$, and they explained these dependences in terms of the $Fe^{3+}+IPT^- \rightarrow FeIPT^{2+}$ reaction. At the same time, they described that the rate is independent of $[H^+]$ when it is from 1.0 M to 5.0 M, although they did not give any rate constant for this latter reaction. They also reported that the rate at 0.1 M $[H^+]$ shown a first-order dependence on the concentration of the coexisting sodium perchlorate. In the present study, however, the effect of the change in the sodium perchlorate concentration on the rate of TTA extraction was found to be only slight, as may be seen from Table 2.

The results in Table 1 can be compared with those obtained with regard to beryllium(II) TTA extraction from a 4.0 M sodium perchlorate solution into carbon tetrachloride.[2] The rate constant of the formation of the first beryllium(II)–TTA complex in 4.0 M sodium perchlorate, $-d[Be^{2+}]/dt=k[Be^{2+}][A^-]$, was obtained as $10^{4.3}$ M^{-1} min^{-1}, which is about one three-hundredth of the rate constant of the first iron(III)–TTA complex under the same conditions. It is remarkable that the rate of the TTA extraction of beryllium(II) is only slightly affected by the formation of $BeCl^+$ species. For example, when the chloride concentration in a 4.0 M Na(Cl, ClO_4) medium is 1.0 M, about 25% of the total beryllium(II) is assumed to be in the $BeCl^+$ and $BeCl_2$ forms ($\beta_1=10^{-0.85}$ and $\beta_2=10^{-0.70}$)[12], but the difference in the rate of the TTA complex formation in the presence of the 1.0 M chloride-ion from that in its absence is small (Fig. 4 in Ref. 2).

It is remarkable that the TTA anion reacts with the hydrated Fe^{3+} ion much faster than does the undissociated TTA. Since it is known that the enol-form TTA in the aqueous phase reacts with a metal ion much faster than does the keto-form, and since the concentration of the enol-form is only one-sixtieth of the keto-form,[13] we may reasonably assume that the rate constant for the reaction which actually takes place, $Fe^{3+}+HA(enol) \rightarrow FeA^{2+}+H^+$, is about $10^{2.4}$ (M^{-1} min^{-1}) (60 times the K_{HA} value in Table 1(b) and that the $Fe^{3+}A^- \rightarrow FeA^{2+}$ reaction is thus $10^{4.5}$ times faster than the reaction with the enol-form undissociated TTA.

The authors are grateful to Mr. Toshihiro Tetsuka of the present laboratory for his experimental aid and valuable discussions.

Variational Calculation of Atoms and Molecules by a Modified Hassé Method Using Hulthén Functions.[1] III. Long-range Interactions between Hydrogen Atom and Proton and between Two Hydrogen Atoms

Tokio YAMABE, Shingo ISHIMARU, and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 2, 1973)

The variation method using the wave function of the modified Hassé form is applied to the problem of long-range interactions between hydrogen atom and proton and between two hydrogen atoms. The interaction energy is also related to the perturbation energy under the Unsöld approximation by the use of several pertinent approximations, and an "improved second-order Unsöld energy," which will be higher than the exact second-order perturbation energy, is newly proposed. The numerical results show that the present trial wave function is quite effective; particularly, at $R \gtrsim 10$ (a.u.), the dispersion energy between hydrogen atoms is better than that of Hirschfelder-Linnett, which might be the best variational result at a large nuclear separation. Furthermore, the importance of considering the degeneracy in treating the induction energy is numerically disclosed for an example of H–H$^+$ interaction. The coefficients in the asymptotic form of the dispersion energy between two hydrogen atoms are briefly discussed, and, finally, a new method for the calculation of the second-order energy is suggested.

It is desirable that an expression of the long-range interaction energy between atoms and molecules has the following properties: (1) the result is an upper or lower bound to the exact value, (2) it is given in a simple analytical closed form, and (3) it gives a reasonable asymptotic form when expanded in inverse powers of the nuclear separation, R. Many works have been devoted to obtaining an energy which satisfies the above conditions, particularly for such simple but essential systems as H—H$^+$, H—H and He—He. Among these, one of the most brilliant successes is the exact second-order perturbation energy, E_2, of H—H$^+$ obtained by Dalgarno and Lynn.[2] On the other hand, within the framework of the Unsöld approximation,[3] exact analytical expressions of the second-order perturbation energy, $\overline{E}_2$(Unsöld), which satisfies the latter two properties, have been derived by several authors[4,5] for the above molecular systems. Moreover, in our own previous paper,[6] the results of two hydrogen atoms and two helium atoms were examined and it was found that, at a large R value, the analytical formula gives an energy which is almost an upper bound to the exact one, if the absolute value of the energy in the ground state, E_0, of the isolated system, H_0, is applied to the average excitation energy, $\langle \Delta E \rangle_{\mathrm{Av}}$, in:

$$\overline{E}_2\,(\text{Unsöld}) = -\frac{(H_1^2)_{00} - (H_1)_{00}^2}{\langle \Delta E \rangle_{\mathrm{Av}}}, \qquad (1)$$

where H_1 is the non-expanded perturbation and where $(F)_{00}$ signifies the expectation value, $\langle \phi_0 | F | \phi_0 \rangle$, of the operator, F, concerning the unperturbed wave function of the ground state, ϕ_0. The charge overlap effect, which was extensively discussed by Kreak and Meath,[7] is automatically involved in $\overline{E}_2$(Unsöld). Therefore, considering that the Unsöld approximation corresponds to the following form for the first-order perturbation function:[8]

$$\phi_1 \sim AH_1\phi_0\,, \qquad (2)$$

the variational function including the above first-order wave function may be expected to give a fairly good interaction energy, especially at a large R value. Indeed, in order to get the result which is an upper bound and which, besides, includes the preferable properties at a large R value, the following variational function was employed in treating the problem of the long-range interaction between two atoms:[9]

$$\phi = (1 + AH_1)\phi_0. \qquad (3)$$

An approximate upper bound can thus be obtained, provided that $(H_1H_0H_1)_{00}$ and $(H_1^3)_{00}$ are small enough compared with $(H_1^2)_{00}$.

It has been pointed out by several authors,[10,11] however, that the variational function of Eq. (3) often gives unreasonable results for the perturbation energy; for example, if H_1 is the exact Coulombic interaction and if ϕ_0 is a 1s-like atomic orbital, $(H_1H_0H_1)_{00}$ and $(H_1^3)_{00}$ are infinite, as will be demonstrated in the case of H—H$^+$. To overcome this type of difficulty, the present authors[11] previously proposed a modified Hassé form and, in the atomic cases of hydrogen and helium, showed that the divergence of the above integrals can not only be easily removed, but that the variational function applied is quite effective. The wave function will be also favorable for the calculation of the long-range interaction energy, because the correction is mainly brought about for the exponentially decreasing terms and the asymptotic behavior through the third-order energy is retained.

Another type of variational function[12] usually involves ionic and polarization terms, and the effect of the electron exchange and the associated Laguerre function or the Slater-type orbital are often used for the radial part of the trial function. However, if the exact perturbation is applied in the calculation, this wave function gives only exponentially decreasing terms and a part of the correct asymptotic form, so the potential will be rather higher than the true one at a large nuclear separation.

Therefore, in the present article, we will investigate the long-range interaction energy by using the wave function of the modified Hassé form and by sorting the results into perturbation energies, which makes it possible to discuss the reliability of the Unsöld-type perturbation energy. Two cases of H—H$^+$ and H—H systems will be examined numerically.

The Variation Method Applied and Its Relation to the Perturbation Method

We assume the perturbation acting between two atoms to be the sum of the Coulombic interactions:

$$H_1 = \frac{Z_a Z_b}{R} - \sum_{j=1}^{n_a} \frac{Z_b}{r_{bj}} - \sum_{k=1}^{n_b} \frac{Z_a}{r_{ak}} + \sum_{j=1}^{n_a}\sum_{k=1}^{n_b} \frac{1}{r_{jk}} \tag{5}$$

where $n_{a(b)}$ is the number of electrons of the atom a(b) with a nuclear charge, $Z_{a(b)}$ and where $r_{bj(ak)}$ is the distance between the nucleus of the b(a) atom and the $j(k)$ electron belonging to the atom a(b) (all in atomic units). In order to remove the divergence difficulty mentioned in the introduction, we replace H_1 in Eq. (3) by the following function:[11]

$$\bar{H}_1 = \frac{Z_a Z_b}{R} - \sum_{j=1}^{n_a} \frac{Z_b(1-e^{-m_b r_{bj}})}{r_{bj}} - \sum_{k=1}^{n_b} \frac{Z_a(1-e^{-m_a r_{ak}})}{r_{ak}} + \sum_{j=1}^{n_a}\sum_{k=1}^{n_b} \frac{(1-e^{-k r_{jk}})}{r_{ik}}, \tag{6}$$

in which m_a, m_b, and k are supposed to be positive parameters, and use the variational function of the modified Hassé form:

$$\bar{\psi} = (1 + A\bar{H}_1)\phi_0 . \tag{7}$$

The upper bound, $\bar{E}$, of the total energy, E, of the perturbed system, H, is then obtained as follows:

$$\bar{E} = E_0 + E_1 + \frac{2A[(\bar{H}_1 H_1)_{00} - E_1(\bar{H}_1)_{00}] + A^2(\bar{H}_1(H_0 - E_0 + H_1 - E_1)\bar{H}_1)_{00}}{1 + 2A(\bar{H}_1)_{00} + A^2(\bar{H}_1^2)_{00}} \geqq E, \tag{8}$$

where $E_0 = (H_0)_{00}$ and $E_1 = (H_1)_{00}$. $\bar{E}$ is further classified into the second- and third-order perturbation energies by regarding $A\bar{H}_1\phi_0$ as the approximate first-order perturbation function, $\bar{\phi}_1$. That is, following the variation-perturbation theory, the upper bound, $\bar{E}_2$, of the second-order energy is given by:

$$\bar{E}_2 = 2\langle\bar{\phi}_1|H_1 - E_1|\phi_0\rangle + \langle\bar{\phi}_1|H_0 - E_0|\bar{\phi}_1\rangle \tag{9}$$

$$= 2A[(\bar{H}_1 H_1)_{00} - E_1(\bar{H}_1)_{00}] + A^2(\bar{H}_1(H_0 - E_0)\bar{H}_1)_{00} \tag{10}$$

$$= 2A[(\bar{H}_1 H_1)_{00} - E_1(\bar{H}_1)_{00}] + \frac{1}{2}A^2(\nabla H_1)_{00}^2 \geqq E_2, \tag{10'}$$

which gives the minimum:[13]

$$\bar{E}_2 = -\frac{[(\bar{H}_1 H_1)_{00} - E_1(\bar{H}_1)_{00}]^2}{(\bar{H}_1(H_0 - E_0)\bar{H}_1)_{00}} \geqq E_2 \tag{11}$$

when

$$A = -\frac{(\bar{H}_1 H_1)_{00} - E_1(\bar{H}_1)_{00}}{(\bar{H}_1(H_0 - E_0)\bar{H}_1)_{00}} . \tag{12}$$

The third-order energy is, approximately:

$$\bar{E}_3 = -2A\bar{E}_2(\bar{H}_1)_{00} + A^2(\bar{H}_1(H_1 - E_1)\bar{H}_1)_{00} . \tag{13}$$

The residue in $\bar{E}$, hence, consists of the fourth- and higher-order terms. At a large R value, the results of Eq. (8) can also be related to the perturbation energy with the Unsöld approximation by the use of several pertinent approximations; *i.e.*, we may put

$$(\bar{H}_1)_{00} \sim (H_1)_{00} \tag{14}$$

$$(\bar{H}_1^2)_{00} \sim (\bar{H}_1 H_1)_{00} \sim (H_1^2)_{00} , \tag{15}$$

because the discrepanicies between them are of the order of e^{-2R}. For instance, the relative magnitudes of these integrals in the case of H—H$^+$, which we will discuss in the next section, are presented in Table 1. The results show that these assumptions are reasonable. Moreover, considering that the denominator of Eq. (8) is almost unity,[6] and using the relations, $|E_0| \gg |E_1|$ and $(H_1^2)_{00} \gg (H_1)_{00}$, Eq. (8) can be approximated by:

$$\bar{E} \sim E_0 + E_1 + \frac{(H_1^2)_{00} - (H_1)_{00}^2}{E_0 - \Delta} \gtrsim E, \tag{16}$$

where

$$\Delta = \frac{(\bar{H}_1 H_0 \bar{H}_1)_{00} + (\bar{H}_1 H_1 \bar{H}_1)_{00}}{(H_1^2)_{00} - (H_1)_{00}^2} . \tag{17}$$

Equation (16) shows that, if the $E_0 - \Delta$ value is chosen as $-\langle\Delta E\rangle_{Av}$, Eq. (1) gives almost an upper bound. Δ is considered to be a correction depending on the R value and the variational parameters (in our previous derivation of the upper bound,[6] Δ was neglected). Ex-

TABLE 1. THE RELATIVE MAGNITUDES OF SEVERAL INTEGRALS IN THE CASE OF H–H$^+$ INTERACTION

R (a.u.)	m	$(\bar{H}_1)_{00}/(H_1)_{00}$	$(\bar{H}_1 H_1)_{00}/(H_1^2)_{00}$	$(\bar{H}_1^2)_{00}/(H_1^2)_{00}$	$(H_1)^2_{00}/(H_1^2)_{00}$

12) L. O. Hirschfelder and J. Y. Linnett, *J. Chem. Phys.*, **18**, 130 (1950).

13) Dalgarno got an upper bound to E_2 using the function of the type of Eq. (2) in the perturbation-variation theory as follows:

$$-\frac{[(H_1^2)_{00} - (H_1)^2_{00}]^2}{(H_1(H_0 - E_0)H_1)_{00}} \gtrsim E_2 .$$

See A. Dalgarno, "Quantum Theory," Vol. 1, ed. by D. R. Bates, Academic Press Inc., New York (1961), p. 193.

panding $1/(E_0-\Delta)$ into the power series of Δ/E_0 and neglecting the higher-order terms than Δ/E_0, one obtains another expression:

$$\bar{E} \sim E_0 + E_1^+ + \frac{(H_1^2)_{00}-(H_1)_{00}^2}{E_0} + \frac{(\bar{H}_1H_0\bar{H}_1)_{00}+(\bar{H}_1H_1\bar{H}_1)_{00}}{E_0^2}. \quad (18)$$

Although $(\bar{H}_1H_1\bar{H}_1)_{00}/E_0^2$ in Eq. (18) is a part of the third-order energy, $(\bar{H}_1H_0\bar{H}_1)_{00}/E_0^2$ should be included in the second-order energy, as may be seen in Eq. (10). Indeed, under the same order of the approximation as the above, Eq. (10) gives:

$$\bar{E}_2 \sim \frac{(H_1^2)_{00}-(H_1)_{00}^2}{E_0} + \frac{(\bar{H}_1H_0\bar{H}_1)_{00}}{E_0^2} \gtrsim E_2, \quad (19)$$

which may be called "the improved second-order Unsöld energy" and which is plausible when compared with the modified form of the exact second-order energy given by Lennard-Jones:[14]

$$E_2 = \frac{(H_1^2)_{00}-(H_1)_{00}^2}{E_0} + \sum_i{}' \frac{(H_1)_{0i}E_0^i(H_1)_{i0}}{E_0(E_0-E_0^i)}, \quad (20)$$

where E_0^i is the i-th eigenvalue of H_0(*i.e.*, $H_0\phi_0^i=E_0^i\phi_0^i$ ($\phi_0^0=\phi_0$, $E_0^0=E_0$)) and where $\sum'$ means that the summation does not include the case of $i=0$. Equation (19) corresponds to the results obtained by replacing $E_0-E_0^i$ by $-\langle\Delta E\rangle_{Av}=E_0$ and by deleting the divergence difficulty. It should be noticed that the second-order energy of Eq. (1) with $\langle\Delta E\rangle_{Av}=-E_0$ differs from that of the (perturbation-) variation method by the amount of $(\bar{H}_1H_0\bar{H}_1)_{00}/E_0^2$, though the correction does not affect the first leading term of the asymptotic form of Eq. (1), as will be shown below.

H–H$^+$ Interaction

As the simplest example, let us first consider the interaction between a hydrogen atom with a nucleus, a, and a proton, b. The perturbation may be obtained from Eq. (5) as follows:

$$H_1 = \frac{1}{R} - \frac{1}{r_{b1}}. \quad (21)$$

If one applies the variational function of Eq. (3), with the 1s atomic orbital as the unperturbed wave function, the $(H_1^3)_{00}$ and $(\bar{H}_1H_0\bar{H}_1)_{00}$ appearing in the expression of the total energy become infinite because of the divergence of integrals:

$$(r_{b1}^{-3})_{00} = \lim_{\varepsilon\to 0} 4\left(-\log\varepsilon+1-\log 2\gamma+\frac{1}{2R}\right)e^{-2R} - \frac{2}{R} - 2e^{2R}Ei(-2R) + 2e^{-2R}Ei(2R), \quad (22)$$

$$(r_{b1}^{-4})_{00} = 4e^{-2R}\lim_{\varepsilon\to 0}\frac{1}{\varepsilon}, \quad (23)$$

where:

$$Ei(-x) = -\int_x^\infty \frac{e^{-t}}{t}dt, \quad Ei(x) = -\int_{-x}^\infty \frac{e^{-t}}{t}dt$$

and where $\log\gamma$ is the Euler constant, 0.5772156649···. However, if one uses the variational function of Eq. (7), in which $\bar{H}_1$ is, in the present example, given by:

$$\bar{H}_1 = \frac{1}{R} - \frac{1-e^{-mr_{b1}}}{r_{b1}}, \quad (24)$$

$(\bar{H}_1H_1\bar{H}_1)_{00}$ and $(\bar{H}_1H_0\bar{H}_1)_{00}$ become finite by the cancellation of singularities so long as m is finite. For large m values, these values are, respectively, approximated by:

$$(\bar{H}_1H_1\bar{H}_1)_{00} \sim -4e^{-2R}\log m \quad (25)$$

$$(\bar{H}_1H_0\bar{H}_1)_{00} \sim 4me^{-2R}, \quad (26)$$

which diverge to negative and positive infinity as $m\to\infty$.

Thus, the divergence characters are included in the exponentially decreasing terms, which can not be obtained unless exact calculations are performed. The conventional perturbation calculation with the Unsöld approximation[15] did not solve this problem since the perturbation is usually expanded in powers of R^{-1} and the exponentially decreasing terms are completely omitted. Nevertheless, the conventional calculation is considered to be reliable, because, according to our correction, the divergence character has been excluded and so exerts little influence on the part expressed in the inverse powers of R.[16]

Now, let us calculate the interaction energy, $\bar{E}-E_0$. All of the integrals in Eq. (8) can be written as follows:

$$(H_1)_{00} = \left(1+\frac{1}{R}\right)e^{-2R} \quad (27)$$

$$(\bar{H}_1)_{00} = (H_1)_{00} + \left(\frac{e^{-mr_{b1}}}{r_{b1}}\right)_{00} \quad (28)$$

$$(H_1^2)_{00} = \frac{1}{R^2} - \frac{2}{R}\left(\frac{1}{r_{b1}}\right)_{00} + \left(\frac{1}{r_{b1}^2}\right)_{00} \quad (29)$$

$$(\bar{H}_1H_1)_{00} = (H_1^2)_{00} + \frac{1}{R}\left(\frac{e^{-mr_{b1}}}{r_{b1}}\right)_{00} - \left(\frac{e^{-mr_{b1}}}{r_{b1}^2}\right)_{00} \quad (30)$$

$$(\bar{H}_1^2) = 2(\bar{H}_1H_1)_{00} - (H_1^2)_{00} + \left(\frac{e^{-2mr_{b1}}}{r_{b1}^2}\right)_{00} \quad (31)$$

$$(\nabla H_1)_{00}^2 = \left(\frac{[1-e^{-mr_{b1}}]^2}{r_{b1}^4}\right)_{00} - 2m\left(\frac{e^{-mr_{b1}}[1-e^{-mr_{b1}}]}{r_{b1}^3}\right)_{00} + m^2\left(\frac{e^{-2mr_{b1}}}{r_{b1}^2}\right)_{00} \quad (32)$$

14) J. E. Lennard-Jones, *Proc. Roy. Soc. Ser. A*, **129**, 598 (1930).

15) A. Dalgarno and J. T. Lewis, *Proc. Phys. Soc. Ser. A*, **69**, 57 (1956).

16) For example, assuming $r_{a1}<R$ and α is a constant not equal to zero,

$$\left(\frac{e^{-\alpha r_{b1}}}{r_{b1}^3}\right)_{00} = \sum_{l=0}^\infty\sum_{m=0}^\infty\sum_{n=0}^\infty (2l+1)\int \frac{r_{a1}^{m+n}}{\sqrt{r_{a1}\bar{R}}\,R^{m+n+2}} \times P_l(\cos\theta)\,P_m(\cos\theta)\,P_n(\cos\theta)\,I_{l+1/2}(\alpha r_{a1})\,K_{l+1/2}(\alpha R)\,\phi_0^2 d\tau$$
$$= \frac{2e^{-\alpha R}}{(\alpha R)^3}\left[\frac{\alpha^2}{(2-\alpha)^2}-\frac{\alpha^2}{(2+\alpha)^2}\right] + \frac{4e^{-\alpha R}}{(\alpha R)^4}\left[\frac{2\alpha^3}{(2+\alpha)^3}+\frac{2\alpha^3}{(2-\alpha)^3}+\frac{\alpha^2}{(2+\alpha)^2}-\frac{\alpha^2}{(2-\alpha)^2}\right] + \frac{16e^{-\alpha R}}{(\alpha R)^5}\left[\frac{\alpha^4}{(2-\alpha)^4}-\frac{\alpha^4}{(2+\alpha)^4}\right] + e^{-\alpha R}O([\alpha R]^{-6}),$$

where θ is the angle between r_{a1} and R and $I_\nu(z)$ and $K_\nu(z)$ are well-known Bessel functions of purely imaginary argument. This integral can be neglected for large R.

a) Ref. 17.

$$(\overline{H}_1H_1\overline{H}_1)_{00}=\frac{1}{R^3}-\frac{1}{R^2}[2(\overline{H}_1)_{00}+(H_1)_{00}]+\frac{1}{R}[2(\overline{H}_1H_1)_{00}+(\overline{H}_1^2)_{00}]-\left(\frac{[1-e^{-mr_{b1}}]^2}{r_{b1}^3}\right)_{00}. \quad (33)$$

The integrals on the right-hand sides are given in Appendix A. The interaction energies, optimized at each R value with respect to m, are listed in Table 2. The results are comparable with those obtained through the second-order perturbation energy under the Unsöld approximation and without the resonance effect.[17] That the values of m are finite means that the divergence difficulty is deleted and that, as expected, A approaches $1/E_0=-2.0$ at large R values.

Next, let us examine the second- and third-order perturbation energies in connection with the above variational calculation. At large enough R values, exponentially decreasing terms can be neglected and $(H_1^2)_{00}$ and $(\overline{H}_1H_0\overline{H}_1)_{00}$ can be simplified only to the parts which are the origin of the well-known expression of a power series of R^{-1}, namely:

$$(H_1^2)^{L}_{00}=-\frac{1}{R^2}+\left(1+\frac{1}{2R}\right)e^{-2R}Ei(2R)+\left(1-\frac{1}{2R}\right)e^{2R}Ei(-2R) \quad (34)$$

$$\sim\sum_{n=1}^{\infty}\frac{4(n+1)(2n)!}{(2R)^{2n+2}}, \quad (34')$$

$$(\overline{H}_1H_0\overline{H}_1)^{L}_{00}=\frac{1}{2R^2}+\left(\frac{1}{2}-\frac{3}{4R}\right)e^{-2R}Ei(2R)+\left(\frac{1}{2}+\frac{3}{4R}\right)e^{2R}Ei(-2R) \quad (35)$$

$$\sim\sum_{n=1}^{\infty}\frac{2n(2n+2)!}{(2R)^{2n+4}}. \quad (35')$$

From Eq. (1),

$$\overline{E}_2^{L}(\text{Unsöld})=-2(H_1^2)^{L}_{00} \quad (36)$$

and from Eq. (19),

$$\overline{E}_2^{L}=\frac{4}{R}\left[\frac{1}{R}-e^{-2R}Ei(2R)+e^{2R}Ei(-2R)\right]. \quad (37)$$

According to the results of Dalgarno and Lynn,[2] the exact second-order energy without exponentially decreasing terms is given by:

$$E_2^{L}=\frac{1}{R^2}\left[\frac{5}{2}-(R+1)^2e^{-2R}Ei(2R)-(R-1)^2e^{2R}Ei(-2R)\right]. \quad (38)$$

On expanding the exponential integrals, Eqs. (36)—(38) are reduced to:

$$\overline{E}_2^{L}(\text{Unsöld})\sim-\sum_{n=1}^{\infty}\frac{(n+1)(2n)!}{2^{2n-1}R^{2n+2}} \quad (36')$$

$$\overline{E}_2^{L}\sim-\sum_{n=1}^{\infty}\frac{2(2n)!}{2^{2n-1}R^{2n+2}} \quad (37')$$

$$E_2^{L}\sim-\sum_{n=1}^{\infty}\frac{(2n+1)(n+2)}{4n}\frac{(2n)!}{2^{2n-1}R^{2n+2}}. \quad (38')$$

From Eqs. (37′) and (38′), it may easily be seen that $\overline{E}_2^{L}$ is higher than E_2^{L} in all terms of the series, that is, that the relation of Eq. (19) is still kept for the non-exponentially decreasing terms:

$$\overline{E}_2^{L}>E_2^{L}. \quad (39)$$

$\overline{E}_2^{L}$(Unsöld) is, however, so only in the first term, probably because the higher multipole transition has a larger excitation energy than does the lowest dipole transition. The numerical results, presented in Table 3, show that the non-exponentially decreasing terms are negligible and that the expressions of $\overline{E}_2^{L}$(Unsölid)

a) Ref. 12.

and $\overline{E}_2{}^{\mathrm{L}}$ are quite effective.

Similarly, the third-order energy in Eq. (18) is approximated by:

$$\overline{E}_3{}^{\mathrm{L}} = (\overline{H}_1H_1\overline{H}_1)^{\mathrm{L}}{}_{00}/E_0{}^2 = 4\left[\frac{2}{R}-\frac{2}{R^3}-\left(2-\frac{3}{R}-\frac{3}{2R^2}\right)e^{-2R}Ei(2R) + \left(2+\frac{3}{R}-\frac{3}{2R^2}\right)e^{2R}Ei(-2R)\right], \quad (40)$$

which is, in the form of a power series of R^{-1}:

$$\overline{E}_3{}^{\mathrm{L}} \sim -\sum_{n=1}^{\infty}\frac{n(n+2)(2n+2)\,!}{2^{2n+1}R^{2n+5}} \quad (41)$$

and which leads to the same result as that of Dalgarno and Lewis[15] except for the difference in the average energy. The numerical results are also listed in Table 3.

H–H Interaction

In the case of two hydrogen atoms, the perturbation is given by:

$$H_1 = \frac{1}{R}-\frac{1}{r_{b1}}-\frac{1}{r_{a2}}+\frac{1}{r_{12}}. \quad (42)$$

According to Eq. (6), $\overline{H}_1$ is written as follows:

$$\overline{H}_1 = \frac{1}{R}-\frac{1-e^{-mr_{b1}}}{r_{b1}}-\frac{1-e^{-mr_{a2}}}{r_{a2}}+\frac{1-e^{-kr_{12}}}{r_{12}}. \quad (43)$$

In Table 4, the interaction energy optimized with respect to m and k is shown, together with the best variational results for large separations calculated by Hirschfelder and Linnett[12] (HL) using the exact perturbation and the trial function, which consists of the 1s atomic orbital with a variable exponent and which is corrected by considering the ionic states, the polarization effect, and the electron exchange. As a matter of course, the values of HL are better than ours at $R\leqq8$, where the exchange effect plays an important role. However, at a longer distance, where only the Coulombic interaction is dominant, the present energy becomes lower than that of HL in spite of its simple expression.

In Table 5, the perturbation energies through the third-order are listed and the second-order perturbation energy is compared with the result previously obtained by the present authors.[6] The second-order energy of the Unsöld type approaches $\overline{E}_2$ at large R values; this is consistent with the previous observation.[6]

Following our calculation, the third-order energy, $\overline{E}_3$, is positive, while the asymptotic form[18] gives a negative value ($-3986\,R^{-11}$). The difference may be partly due to the fact that the present result includes the charge-overlap effect,[19] which is usually repulsive in the order of e^{-2R}, and partly to the fact that, in the calculation of $(\overline{H}_1H_1\overline{H}_1)_{00}$, we neglected the $-(e^{-kr_{12}}/r_{b1}r_{12}r_{a2})_{00}+(e^{-mr_{b1}}e^{-kr_{12}}/r_{b1}r_{12}r_{a2})_{00}$ terms, which are of the e^{-2R} order and which are totally negative (the $\overline{E}_3$ and $\overline{E}$ thus obtained are, accordingly, higher than the respective exact values). Therefore, it is not strange that $\overline{E}_3$ is positive for not sufficiently large nuclear distances.

For such large R values that the exponentially decreasing terms can be neglected, the non-exponentially decreasing terms of $(H_1{}^2)_{00}$, which are the same as those in $(\overline{H}_1H_1)_{00}$ and $(\overline{H}_1{}^2)_{00}$, were obtained in our previous paper[6] as follows:

$$(H_1{}^2)^{\mathrm{L}}{}_{00} = \frac{1}{R^2}-\frac{7}{12}+e^{2R}Ei(-2R)\left(\frac{11}{16R}-\frac{11}{8}-\frac{R}{2}+\frac{R^2}{6}\right) + e^{-2R}Ei(2R)\left(-\frac{11}{16R}-\frac{11}{8}+\frac{R}{2}+\frac{R^2}{6}\right). \quad (44)$$

Hence, $\overline{E}_2{}^{\mathrm{L}}$(Unsöld) is in the expanded form:

$$\overline{E}_2{}^{\mathrm{L}}(\text{Unsöld}) = \frac{1}{E_0}(H_1{}^2)^{\mathrm{L}}{}_{00} \sim -\frac{1}{3}\sum_{n=1}^{\infty}\frac{n(n+7)(2n+4)\,!}{(2n+3)(2R)^{2n+4}} \sim -\frac{6.0}{R^6}-\frac{135.0}{R^8}-\frac{3937.5}{R^{10}}-\cdots. \quad (45)$$

Moreover, the second-order perturbation energy of Pauling and Beach[20] is:

$$E_2{}^{\mathrm{L}} = -\frac{6.49903}{R^6}-\frac{124.399}{R^8}-\frac{3285.828}{R^{10}}-\cdots. \quad (46)$$

By comparing Eqs. (45) and (46), it may easily be seen that, as in the case of H–H$^+$, the Unsöld approxima-

18) Y. M. Chan and A. Dalgarno, *Mol. Phys.*, **14**, 101 (1968).

19) At $R=10$, for example, $e^{-2R}=0.2\times10^{-8}$ and $-3986\,R^{-11}=-4\times10^{-8}$. So the effect of the charge overlap will surpass that of the asymptotic form in the region $R<10$.

tion with $\langle\Delta E\rangle_{Av}=-E_0$ tends to underestimate the coefficient of the first leading term, while overestimating those of the higher-order terms. Therefore, if one chooses the average excitation energy so that correct coefficient of R^{-6} may be obtained, the adjustment unfortunately increases errors in the coefficients of the second- and higher-order terms.[21] On the other hand, the correction terms, $(\overline{H}_1H_0\overline{H}_1)^L{}_{00}$, is:

$$(\overline{H}_1H_0\overline{H}_1)^L{}_{00}=\frac{5}{12}-\frac{1}{R^2}+e^{2R}Ei(-2R)\left(\frac{R^2}{6}+\frac{R}{2}-\frac{7}{8}-\frac{25}{16R}\right)+e^{-2R}Ei(2R)\left(\frac{R^2}{6}-\frac{R}{2}-\frac{7}{8}+\frac{25}{16R}\right), \quad (47)$$

which is written in the following power series:

$$(\overline{H}_1H_0\overline{H}_1)_{00}\sim\frac{2}{3}\sum_{n=1}^{\infty}\frac{n(n+1)(n+5)(2n+4)\,!}{(2R)^{2n+6}}. \quad (48)$$

Hence, from Eqs. (19), (44) and (47), $\overline{E}_2{}^L$ is obtained as follows:

$$\begin{aligned}\overline{E}_2{}^L&=\frac{1}{6}-\left(\frac{R^2}{3}-\frac{9}{4}-\frac{7}{8R}\right)e^{2R}Ei(-2R)-\left(\frac{R^2}{3}-\frac{9}{4}+\frac{7}{8R}\right)e^{-2R}Ei(2R)\\&\sim-4\sum_{n=1}^{\infty}\frac{n(n+3)(2n+2)\,!}{(2R)^{2n+4}}\\&\sim-\frac{6.0}{R^6}-\frac{112.5}{R^8}-\frac{2835.0}{R^{10}}-\cdots.\end{aligned} \quad (49)$$

Equation (49) gives the upper values for all orders of R^{-1}, as in the case of H–H$^+$.

Discussion

It has been stressed by several authors[7,15,22] that the major factor limiting the accuracy of the long-range interaction energy between the hydrogen atom and the proton is the neglect of the degeneracy arising from the identity of the nuclear fields. Therefore, let us now examine the energy, including the effect of the degeneracy. The wave function for the $1s\sigma_g$ is given by:

$$\overline{\phi}_{1s\sigma_g}=(1+P)(1+A\overline{H}_1)\phi_0 \quad (50)$$

where P is a usual projection operator which interchanges the two nuclei, a and b. Performing the integration analytically with some manipulations, and optimizing with respect to m in $\overline{H}_1$, the results shown in Table 6 are obtained. It is remarkable that the present result is, for all nuclear distances, superior to that calculated by Dalgarno and Lynn[17] by the use of a modification of a trial function given by HL for the H–H system. That there is a great discrepancy between the results in Tables 1 and 6 demonstrates the importance of considering the degeneracy particularly in treating the induction force, because, as has been mentioned above, the present dispersion energy for H–H, even without any exchange effect, is better than that of HL for $R\gtrsim10$.

It is of interest that Eq. (49) gives good coefficients when multiplied by the value of 6.499/6.0 so that the coefficient of the first leading term may become the

exact value; that is:

$$\frac{6.499}{6.0}\bar{E}_2^{\mathrm{L}} \sim \frac{6.499}{R^6} - \frac{121.9}{R^8} - \frac{3070.8}{R^{10}} - \cdots . \quad (51)$$

This coincidence implies the utility of the conditions in Eq. (19). However, the correction for the coefficient of R^{-6} should be essentially brought about by use of the sum in Eq. (20),[14] which corresponds to $(\bar{H}_1H_0\bar{H}_1)_{00}/E_0^2$ in the present treatment, whereas, as is shown in Eq. (48), $(\bar{H}_1H_0\bar{H}_1)_{00}/E_0^2$ does not include the term of R^{-6}, but begins with R^{-8}. The difference may be caused by the average energy approximation applied. Followingly, it seems more legitimate to correct the result of Eq. (45) by adding $-(\bar{H}_1H_0\bar{H}_1)_{00}/E_0\langle\Delta E\rangle_{\mathrm{Av}}$, in which $\langle\Delta E\rangle_{\mathrm{Av}}$ is adjusted so as to give the preferable coefficient of R^{-8}. Indeed, if the value of 2.122 is adopted for $\langle\Delta E\rangle_{\mathrm{Av}}$, the coefficients of R^{-8} and R^{-10} become 124.4 and 3417.9 respectively; the latter is better than the value, 3724, obtained by Starkschall and Gordon.[21]

Furthermore, one can easily improve the numerical accuracy by the combination of our method with that presented by Goodisman,[24] who also treated the divergence problem in the calculation of $(\bar{H}_1H_0\bar{H}_1)_{00}$. If the complete set of eigenfunctions $\{\phi_0{}^i\}$ of the unperturbed Hamiltonian H_0 is available, the following first-order variational function, $\bar{\phi}_1{}^{(n)}$, can be used instead of $\bar{\phi}_1$:

$$\bar{\phi}_1{}^{(n)} = A[\bar{H}_1\phi_0 - \sum_{i=1}^{n}\bar{V}_i\phi_0{}^i] - \sum_{i=1}^{n}\frac{V_i\phi_0{}^i}{\varepsilon_i}, \quad (52)$$

where:

$$V_i = \langle\phi_0{}^i|H_1|\phi_0\rangle \quad (53)$$

$$\bar{V}_i = \langle\phi_0{}^i|\bar{H}_1|\phi_0\rangle \quad (54)$$

$$\varepsilon_i = E_0{}^i - E_0 . \quad (55)$$

Substituting Eq. (52) into Eq. (9) gives:

$$\bar{E}_2{}^{(n)} = -\sum_{i=1}^{n}\frac{V_i{}^2}{\varepsilon_i} + 2A[(\bar{H}_1H_1)_{00} - E_1(\bar{H}_1)_{00} - \sum_{i=1}^{n}\bar{V}_iV_i] + A^2[(\bar{H}_1(H_0-E_0)\bar{H}_1)_{00} - \sum_{i=1}^{n}\varepsilon_i\bar{V}_i{}^2] \geqq E_2 . \quad (56)$$

which is reduced to Eq. (10) when the terms of the summation concerning i are omitted and to the exact value when $n=\infty$. Minimizing Eq. (56) with respect to A, one obtains:

$$\bar{E}_2{}^{(n)} = -\sum_{i=1}^{n}\frac{V_i{}^2}{\varepsilon_i} + \frac{[(\bar{H}_1H_1)_{00} - \sum_{i=1}^{n}\bar{V}_iV_i]^2}{\sum_{i=1}^{n}\varepsilon_i\bar{V}_i{}^2 - (\bar{H}_1(H_0-E_0)\bar{H}_1)_{00}} \geqq E_2 . \quad (57)$$

In the above equation, no divergence difficulty appears in the denominator. The improvement made possible by applying this expression is now under investigation in our laboratory.

Distribution of Uranyl Nitrate between 1- or 2-Butanol and Aqueous Phases

Norio Yui, Yōichi Kurokawa, and Taketoshi Fujita

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980

(Received February 2, 1973)

The distribution of uranyl nitrate between 1- or 2-butanol and aqueous phases and the effect of nitric acid or sodium nitrate on the distribution at 25 °C have been studied. Conductance measurements have been carried out for the butanol solutions of uranyl nitrate. It was found that high water content in the butanol phase gives rise to the dissociation of the salt. Semi-empirical relations hold for the distribution considering the dissociation of salt in the butanol phase. Observed and calculated slopes agree in the plots of distribution ratio *vs.* nitrate concentration. The results were discussed in comparison with distribution data in literature.

A study of the distribution of electrolyte between aqueous and organic phases provided a method of investigating the thermodynamic properties of organic solutions. However, such a study has been limited to organic solvents almost immiscible with water. Isomeric butanol has a moderate dielectric constant and is miscible with water to a greater extent. Thus, water seems to play an important role in the distribution. The extraction of uranyl nitrate was discussed in some detail.[1] In most cases, the electrolyte was considered to be completely dissociated in aqueous phase and completely associated in the organic phase. Previous conductance measurements on the 1-butanol phase containing alkali halides indicated that these salts were considerably dissociated.[2,3] A marked deviation from thermodynamic distribution ratio could occur depending upon the degree of association in the butanol phase. We investigated the equilibrium composition of alkali halide–1-butanol–water system. A semi-empirical treatment of the distribution of alkali halides was performed, assuming that these salts in the butanol phase are dissociated.[4] This study was undertaken to examine how far the above treatment is applicable to the distribution of uranyl nitrate between the butanol and aqueous phases.

Experimental

Materials. Uranyl nitrate hexahydrate, sodium nitrate, nitric acid, 2-butanol, and 1-butanol were of reagent grade and used without further purification.

Procedure. The electric equipment, conductance cell (flask type) and methods were essentially the same as before, except for the conductance bridge which was of a YOKOGAWA BV-Z-103B type.[2,3] A quartz flask type cell with lightly platinized electrodes was used. The cell constant was determined to be 0.1893 cm^{-1} with 0.1 M KCl. All measurements were carried out in a thermostat at 25±0.01 °C. The conductance of the solute was determined by subtracting the conductance of the solvent from that of the solution. Since the specific conductance of pure 1-butanol was 9.12×10^{-9} ($ohm^{-1}\cdot cm^{-1}$) at 25 °C, solvent correction in pure 1-butanol system was not necessary even for very dilute solution.

100 ml each of aqueous and butanol solutions were taken into a flask with a stopper, and shaken in a thermostat for a few hours. A portion of the solution was then taken from both phases for analysis. In the presence of nitric acid or sodium nitrate, the distribution equilibrium was established within half an hour. The initial concentration of uranyl nitrate in the aqueous phase ranged from 10^{-4} to 10^{-2} M, and that of nitric acid or sodium nitrate from 0.05 to 3 M.

Analysis. *Uranyl Ion*: The method was essentially the same as that reported.[5-7] A sample solution (1—5 ml) from each phase was evaporated to dryness below 80 °C to avoid loss of uranyl salt. A buffer solution of pH 5 and 0.1% solution of neothorin was added to the sample solution.

The absorbance of the solution was then measured at 600 mμ against a reference solution.

Sodium Ion: This was analyzed by the potentiometric or EDTA method.[8] The former is as follows. The sample solution was passed through a resin column converted into hydrogen ion form. It was eluted by 2 M HCl. The effluent was evaporated to dryness to remove hydrochloric acid and the residue was dissolved in a small amount of water. The solution was analyzed for chloride by the potentiometric method.

Nitrate Ion: This was analyzed by spectrophotometry.[9]

Hydrogen Ion: This was titrated with sodium hydroxide solution using phenolphthalein as an indicator.

Solvent Composition: Equilibrium compositions in the absence of solute were determined by gas chromatography.[4]

Results and Discussion

Mutual solubilities of 1-butanol–water and 2-butanol–water systems are given in Table 1. Dielectric constant ε was estimated from the values for water and butanol assuming that ε of the mixtures is a linear function of the weight fraction as in the cases of ethanol–water mixture.[10] Both butanols are miscible with water and consequently both butanol phases have high dielectric constants.

Table 1. Mutual solubilities of 1-butanol–water and 2-butanol–water systems at 25 °C (wt %)

	1-Butanol–Water			2-Butanol–Water		
	Water	1-Butanol	ε	Water	2-Butanol	ε
Aqueous phase	92.7	7.3	73	80.5	19.5	67
Butanol phase	20.3	79.7	23	37.5	62.5	38

The conductance of uranyl nitrate $\Lambda(\text{ohm}^{-1}\cdot\text{cm}^2)$ in a few kinds of pure alcohol and 1-butanol–water(11.0 wt%) isgiven in Fig. 1, by means of the plots Λ *vs.* the square root of concentration. Conductance decreases in the order ethanol(24.3)>propanol(20.1)>1-butanol (17.1) over all concentrations, the order being in line with that of dielectric constant (given in parentheses). The plots show a marked deviation from linearity as in the case of LiI and NH_4I.[12] This indicates that uranyl nitrate behaves as a weak electrolyte. Addition of water to pure 1-butanol causes a large change in conductance. A sharp rise on approaching infinite dilution suggests a possibility of the following dissociation:

$$UO_2(NO_3)_2 = UO_2(NO_3)^+ + NO_3^- \quad (1)$$

However, concentrated uranyl nitrate solution might not be dissociated in pure 1-butanol. Association constants were not calculated because of a sharp increase in conductance at infinite dilutions. A plot by Shedlowsky's method is not linear for the 1-butanol–water (11 wt%) system. It seems that dissociation in two stages occurs to some extent. Trzebiatowska obtained an association constant of 1.44×10^4 in ethanol and concluded that covalency participates in uranyl nitrate from the very small Bjerrum parameter *a*.[11] However, interpretation of such an adjustable parameter is too uncertain to draw a clear conclusion.

Distribution of Uranyl Nitrate between 1- or 2-Butanol and Aqueous Phases. The results are shown in Fig. 2 with the plots $K_d(U)$ *vs.* $\log(NO_3^-)_a$. The distribution ratio of uranyl nitrate $K_d(U)$ is defined by $\Sigma(UO_2)_a/\Sigma(UO_2)_b$, where subscripts a and b refer to the aqueous and butanol phases, respectively. Curve III gives the distribution of uranyl nitrate between

1-butanol and aqueous phases, and curve IV that between 2-butanol and aqueous phases. The distribution showed the same trend as in the acids, namely it approaches a constant value at higher concentration.[13] This indicates that uranyl nitrate tends to be transferred into the butanol phase with increasing concentration. The ionization constants of uranyl nitrate were determined in various solvents by means of the Walden rule, a slight dissociation being found to take place. However, notable dissociation was found in 1-butanol.[14] Uranyl nitrate showed an appreciable conductivity in diethyl ether on being dissolved in the form of hexahydrate.[15] The relatively high water content in the butanol phase causes the dissociation of salt. Water content is 38 wt% in 2-butanol phase and 20 wt% in 1-butanol phase, causing an increase of conductance (Fig. 1). The first stage of dissociation might therefore occur in the butanol phase. $K_d(U)$ of the 1-butanol system is larger than that of the 2-butanol system over all concentrations. The difference is principally due to the difference in water contents. It seems that water plays the principal role in the distribution of uranyl nitrate. We assume that uranyl nitrate in both phases is dissociated into free ions as follows, the species extracted being the same over all concentrations:

$$(UO_2^{2+})_a + 2(NO_3^-)_a \overset{K}{\longleftrightarrow} (UO_2NO_3^+)_b + (NO_3^-)_b \quad (2)$$

$$K = \frac{[UO_2NO_3^+]_b[NO_3^-]_b}{[UO_2^{2+}]_a[NO_3^-]_a^2} \propto \frac{1}{K_d(U)^2(NO_3^-)_a} \quad (3)$$

If this is the case, the slope of the plot $K_d(U)$ *vs.* $\log(NO_3^-)_a$ should be -0.5 (Eq. 3). The observed values for 1-butanol and 2-butanol systems are about -0.5 and -0.3, respectively. The lower value for 2-butanol system might be due to the second stage dissociation because of high water content of the butanol phase, indicating that mixed species $UO_2NO_3^+$ and UO_2^{2+} are involved. In the case of the solvent extraction with a reagent such as TBP, the slope is -2.[16] Since no data are available concerning activity coefficients in this system, the activity is replaced by concentration.

Distribution of Uranyl Nitrate Coexisting with Nitric Acid or Sodium Nitrate. Use of a salting-out agent is common in solvent extraction. Nitrate is generally chosen for the extraction of uranyl nitrate.[17] Salting effects of nitric acid and sodium nitrate on the distribution of uranyl nitrate were investigated in the concentration range 0.06—3 M. The results are given in Fig. 2, in which curve I denotes the distribution of uranyl nitrate coexisting with nitric acid and curve II that with sodium nitrate. We see that the effect is enhanced. Distributions of nitric acid and sodium nitrate are given in Fig. 3 by means of logarithms of distribution ratio *vs.* solute concentration in aqueous phase. $K_d(H)$ is the distribution ratio of nitric acid defined by $(H^+)_a/(H^+)_b$ and $K_d(NO_3)$ is that of sodium nitrate by $(NO_3^-)_a/(NO_3^-)_b$, where (H^+) denotes the acid concentration and (NO_3^-) the sodium nitrate concentration in each phase. Nitric acid is extracted into butanol phase more than other mineral acids,

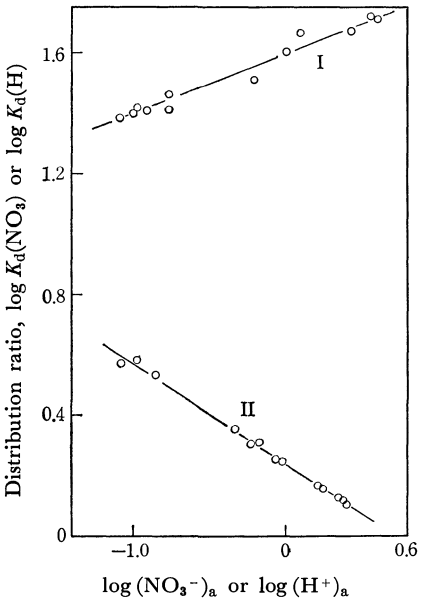

Fig. 3. Distribution ratio of sodium nitrate *vs.* nitrate ion in aqueous phase and that of nitric acid *vs.* acid in aqueous phase.
I: sodium nitrate, II: nitric acid

indicating its strong interaction with butanol. This may be ascribed to the weak electrolytic behavior and conspicuous covalent character of the acid.[18] Alcock *et al.* studied the extraction of mineral acids from an aqueous solution by TBP and showed that perchloric acid is a strong electrolyte in TBP, but not other acids.[19] In the case of nitric acid, a volume change occurred at the expense of the aqueous phase, apparently due to a much higher uptake of water by the butanol phase which certainly facilitates ionization. We assume that the first stage dissociation occurs in the butanol phase, the species extracted are the same and the concentration is represented in the observed one not in the activity. The following relation is obtained for the system coexisting with nitric acid.

$$K_d(U) \propto K_d(H) \cdot (NO_3)_a^{-1} \quad (4)$$

$K_d(H)$ is determined to be $K_d(H) \propto (NO_3)_a^{-0.3}$ from Fig. 3. By combining this relation and Eq. (4), a slope of -1.3 equal to the observed value is obtained. In the same way, the following relation can be obtained

$$K_d(U) \propto K_d(NO_3) \cdot (NO_3)_a^{-1} \quad (5)$$

Since $K_d(NO_3)$ is proportional to $(NO_3)_a^{0.2}$ (Fig. 3), the plot $K_d(U)$ *vs.* $(NO_3)_a$ yields a slope of -0.8 by combining this relation with Eq. (5). This is in good agreement with the observed slope -0.8. The degree of ionization of sodium nitrate in TBP is higher than that of uranyl nitrate at an equal solute concentration by an order of magnitude.[20] The ionization in the butanol phase would be still higher because of its high water content. We assumed that the solvent composition remains approximately constant inde-

pendent of solute concentration. However, the observed phenomenon was more complicated and involved a change of solvent composition accompanied by the solute. Dielectric constant change in the butanol phase caused by solute and water and that in aqueous phase caused by the butanol salted out might affect the equilibrium to a great extent. The distribution of uranyl nitrate in the butanol–water system was given by Morrison and Freiser.[21] They treated the distribution in terms of complex formation in the butanol phase, but their results are not in line with ours. Good agreement was obtained between the observed and calculated slopes by a semi-empirical treatment. This might indicate that distribution is associated with the predominance of ion species in the butanol phase. At a higher concentration the treatment is probably no longer valid. Changes in solvation, association and solvent composition should be taken into consideration.

The Crystal Structure of Quinolinic Acid

Fusao TAKUSAGAWA, Ken HIROTSU, and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received February 8, 1973)

The crystal structure of quinolinic acid (2,3-pyridinedicarboxylic acid) has been determined by the method of X-ray diffraction. The crystal is monoclinic, with a space group of $P2_1/c$ and with cell dimensions of $a=7.421$, $b=12.729$, $c=7.850$ Å, and $\beta=116.96°$. The crystal structure was solved by the inspection of a Patterson map. The final R value was 6.78% for 1224 observed reflections. The quinolinic acid molecule takes the form of a zwitter ion in the crystal. The pyridine ring in the molecules shows a significant deformation from the C_{2v} symmetry of idealized geometry. The lengths of the two C–C bonds joining the carboxyl groups to the ring are longer than the normal value. There is an intramolecular hydrogen bond between the adjacent carboxyl groups. The bond lengths in the two C–O groups which participate in this intramolecular hydrogen bond are longer than those of the other two C–O groups. One of the two carbonyl oxygen atoms participates in a hydrogen bond, while the other is free from it. The molecules are arranged in layers closely parallel to the (0 1 0) plane. Each molecule on the same plane is hydrogen-bonded to form an endless chain along the a axis. These chains are packed by the van der Waals forces. The thermal diffuse scattering observed on Weissenberg photographs can be explained by this hydrogen-bond system.

This work is a part of series of O–H···N hydrogen bonding studied based on X-ray crystal structure analyses of some carboxylic acids with a pyridine ring. The O–H···N or $^+$N–H···O hydrogen bond has been found in all the crystals of dipicolinic acid,[1] dinicotinic acid,[2] and cinchomeronic acid[3] thus far studied, without exception. It seems that it would be of interest to elucidate the effect of a nitrogen atom in a pyridine ring on the hydrogen-bond formation in solids.

The melting point of a quinolinic acid crystal is the lowest of those of the six pyridine dicarboxylic acids, and this molecule has adjacent carboxyl groups. These facts suggest that there is some hydrogen bond which acts not between molecules, but within a molecule. Such an intramolecular hydrogen bond is known in 3,4-furandicarboxylic acid,[4] which has an aromatic five-membered ring. On the contrary, while the crystal structures of five carboxylic acids which have adjacent carboxyl groups substituted on a benzene ring(phthalic acid,[5] trimellitic acid,[6] hemimellitic acid,[7] pyromellitic acid,[8] and mellitic acid[9]) have previously been determined by the X-ray method, no intramolecular hydrogen bond between the adjacent carboxyl groups has been found in their crystal structures. If the geometrical configuration plays an important role in the formation of an intramolecular hydrogen bond between the adjacent carboxyl groups substituted on the aromatic six-membered ring, it may be impossible to form this type of hydrogen bond in crystal. In this regard, it will also be of interest to find out the mode of the hydrogen bond in this crystal.

Experimental

The crystals were obtained in the form of light yellow prisms by recrystallization from an aqueous solution. Weissenberg

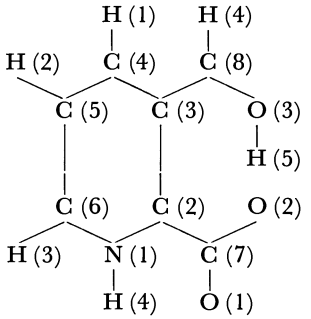
Linear absorption coefficient	14.17 cm^{-1}
Number of independent reflections	1371
The atom numbering	



photographs showed the crystal to be monoclinic, with a space group of $P2_1/c$. The cell dimensions were measured from zero-layer Weissenberg photographs, which had been calibrated with superimposed Al powder lines. They are given, along with other crystal data, in Table 1. There are four molecules in a unit cell, corresponding to the density of 1.66 g/cm^3 observed by the flotation method. One of the crystals was in the shape of a sphere with the average diameter of 0.3 mm. The intensity data were collected for the 0—10 layers around the b axis and the 0—2 layers around the c axis by the use of the multiple-film equi-inclination integrating Weissenberg technique with Cu $K\alpha$ radiation. The intensities of the diffraction spots were estimated visually by comparison with intensity standard. Of the possible 1513 reflections within a Cu $K\alpha$ sphere, 1371 independent reflections were measured; 147 were too weak to be observed. The absorption coefficient is 14.17 cm^{-1} for Cu $K\alpha$ radiation, and no absorption correction was applied. Appreciable thermal diffuse scattering was observed along the directions of the b* and c* axes on Weissenberg photographs.

Structure Determination and Refinement

The crystal structure was solved by the inspection of a sharpened Patterson map which had been resolved enough to give the orientation and location of the molecules in the unit cell. The first postulated structure gave an R value of 41%, which decreased to 15% after three cycles of least-squares refinement with individual isotropic thermal factors. Since the 0 4 0 reflection seemed to have a strong extinction effect, this reflection was removed from the later refinements.

The coordinates and anisotropic thermal parameters were refined in a block-diagonal least-squares procedure, minimizing the function $\Sigma w(F_o-F_c)^2$, where:

$$w = 0.5 \text{ for } 0.5 \geqq |F_o|,$$

$$w = 1.0 \text{ for } 6.0 > |F_o| > 0.5 \text{ and}$$

$$w = 6.0/|F_o| \text{ for } |F_o| \geqq 6.0.$$

The atomic scattering factors used were those listed in the International Table for X-ray Crystallography for C, N and O atoms and the spherical scattering factors proposed by Stewart, Davidson, and Simpson[10] for the H atom. At the stage of R=9.6%, a difference Fourier map was computed, and from it the positions of the five hydrogen atoms were located (Fig. 1). With anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms, the final R value was 6.78%, excluding unobserved reflections. The observed and calculated structure factors are listed in Table 2. The fractional coordinates and thermal parameters are listed in Table 3.

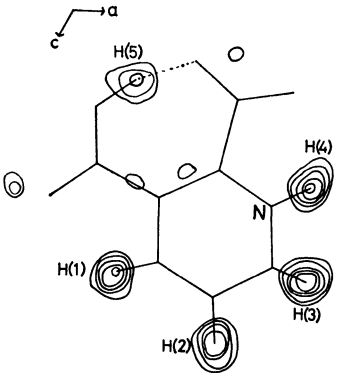


Fig. 1. A composite drawing of the electron density associated with the hydrogen atoms. The contours are at intervals of 0.1 e·Å^{-3}, beginning with the 0.2 e·Å^{-3} contour.

Results and Discussion

Molecular Structure. The bond lengths and angles are listed, along with their estimated standard deviations, in Table 4, and they are shown in Fig. 2. Figure 1 shows a difference Fourier map along the b axis, in which there is no high peak except those due to hydrogen atoms. Figure 3 shows the anisotropic thermal ellipsoids of the non-hydrogen atoms and the isotropic thermal ellipsoids of the hydrogen atoms. The net charges and π-bond orders calculated by the CNDO/2 method[11] are shown in Fig. 4.

Table 3. The final parameters and their estimated standard deviations (in parentheses)

The coordinates of the non-hydrogen atoms have been multiplied by 10^4; those of the hydrogen atoms, by 10^3. The anisotropic thermal parameters of non-hydrogen atoms are of the form $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$, and have been multiplied by 10^4. For the hydrogen atoms, the values listed are isotropic thermal parameters $B(\text{A}^2)$.

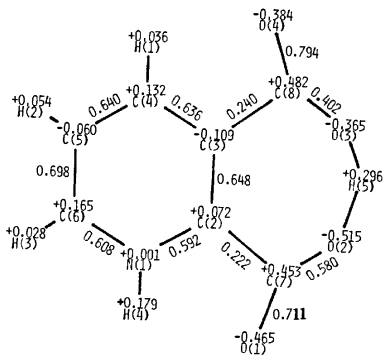

Fig. 4. The net charges and π-bond orders calculated by the CNDO/2 method.

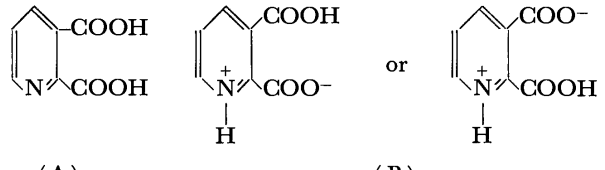
The quinolinic acid molecule may be a mixture of the following two forms:



(A) (B)

However, the present study shows that the molecule takes the zwitter ion(B) in the crystal. The existence of the molecule in this form is quite evident from the assignment of a hydrogen atom in the difference Fourier map. It is also confirmed by the C(2)–N(1)–C(6) bond angle of 125.3(2)° and by the four C–O bond lengths of 1.216 (4), 1.258(4), 1.265(4), and 1.230(4) Å in the two carboxyl groups (the values in parentheses denote e.s.d.'s in their last digits).

The quinolinic acid molecule is approximately planar, with a maximum deviation of 0.242 Å. The pyridine ring is planar, the maximum deviation of a ring atom from the least-squares plane being 0.013 Å. The equations of the two planes through twelve non-hydrogen atoms of a molecule and six non-hydrogen atoms of a pyridine ring are:

$$0.0551X+0.9983Y+0.0215Z=1.8705 \quad \text{and}$$

$$0.0117X+0.9998Y+0.0156Z=1.6535$$

respectively, where X, Y, and Z are coordinates in Å referred to an orthogonal set of axes and parallel to the a, b, and c^* axes respectively. The displacements of all the atoms from these two planes are listed in Table 5.

The pyridine ring in the molecule shows a significant deformation from the C_{2v} symmetry of idealized geometry. The differences between the corresponding bond lengths, the N(1)–C(2) and N(1)–C(6), the C(2)–C(3) and C(5)–C(6), and the C(3)–C(4) and C(4)–C(5) bonds, are 0.019(3), 0.014(4), 0.022(4) Å respectively. The bond lengths of the side which has both carboxyl groups are longer than those of the other side. This difference may depend on the asymmetric substitution of two carboxyl groups, because no such difference has been found in dipicolinic acid[1] and

Table 5.

dinicotinic acid,[2] in which two carboxyl groups are substituted symmetrically on the pyridine ring.

The lengths of the two C–C bonds joining the carboxyl groups to the ring are 1.548(4) and 1.518(4) Å, longer than the normal value(about 1.48~1.50 Å for sp^2—sp^2 bond); the difference between these two bond lengths, 0.030(4), is significant, judging from their estimated standard deviations. The two C–O bond lengths in each carboxyl group are slightly different from each other. In carbonyl groups, the difference between the C(7)–O(1) and C(8)–O(4) bond lengths, 0.014(4) Å, is due to the fact that the O(4) atom participates in the hydrogen bond, while the O(1) atom is free from it. Similar differences were also observed in dinicotinic acid[2] and cinchomeronic acid.[3] On the other hand, the C(7)–O(2) and C(8)–O(3) bond lengths, 1.258(4) and 1.265(4) Å, are equal within the limits of experimental errors. Their average value, 1.262 Å, is shorter than the normal bond length between the carbon and hydroxyl oxygen atom, and lies between the values of the C=O and C–O(H) bond lengths. The reason for these abnormal C–O(H) bond lengths is the formation of an intramolecular hydrogen bond which joins the O(2) and O(3) atoms at a very short distance, 2.399(3) Å. A similar tendency was observed in carboxyl groups of 3,4-furandicarboxylic acid.[4] The H(5) atom is bonded to the O(3) atom rather than to the O(2) atom in this analysis, corresponding to the slight difference between C–O distances related to these two oxygen atoms. In connection with this finding, it is desirable to locate the position of this hydrogen atom by neutron-diffraction study, since there has been a speculation that the hydrogen atom might be placed symmetrically between the oxygen atoms when they are joined by a short hydrogen bond. There is a good correlation between the π-bond orders and the observed bond lengths, as is shown in Fig. 4. The C(3)–C(2)–C(7) and C(2)–C(3)–C(8) bond angles deviate greatly from 120° due to the sp^2 hybridization of the C(2) and C(3) atoms. These deviations are caused by the formation of an intramolecular hydrogen bond. Both carboxyl groups are twisted by −8.3° (C(7)O(1)O(2)) and 10.8° (C(8)O(3)O(4)) out of the plane of the pyridine ring, as is shown in Fig. 3, so that the O(2) and O(3) atoms approach each other.

The intramolecular hydrogen bond between the adjacent carboxyl groups was found in 3,4-furandicarboxylic acid,[4] with an aromatic five-membered ring. However, the intramolecular hydrogen bond of this type has not thus far been found in the crystal structures of carboxylic acids with a benzene ring and another aromatic six-membered ring. From a geometrical point of view, the formation of the hydrogen bond of this type seems to be more difficult in the carboxylic acids with an aromatic six-membered ring than in those with a five-membered ring. Hence it may be noted that the hydrogen bond of this type has been found in the crystal of quinolinic acid, which has an aromatic six-membered ring.

Molecular Arrangement and Hydrogen-bond System. The crystal structure is shown in Figs. 5 and 6. The distances and angles of hydrogen bonds are listed in Table 6. The molecules are arranged in layers closely parallel to the (0 1 0) plane at $y=1/8$, 3/8, 5/8 and 7/8. These planes have a spacing of 3.182 Å. The dihedral angle which the best plane of a molecule makes with the (0 1 0) plane is 3.3°. Figure 5 is a view parallel to the (0 1 0) plane. Figure 6 is a view normal to the (0 1 0) plane and illustrates the relative orientation of the molecules in two neighboring layers. Figures 6(a) and 6(b) show the relation between the planes

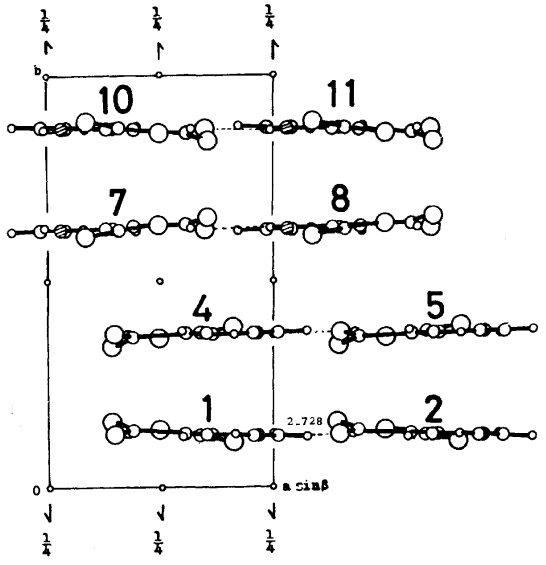

Fig. 5. A view of the crystal structure down the *c* axis. The hydrogen bonds are shown by broken lines.

at $y=1/8$ and 3/8, and 3/8 and 5/8. In Figs. 5 and 6, the same numerals designate the same molecules. The symmetry codes of the molecules with these numbers are shown in Table 6.

Each molecule on the same plane is joined, through the N(1)-H(4)···O(4) hydrogen bond, with two neighboring molecules and forms an endless chain along the a axis. The carbonyl oxygen atom, O(4), participates in a hydrogen bond(O(4)···H(4)-N(1); 2.728(3) Å), while another atom (O(1)) is free from the hydrogen bond. Similar situations are observed also in nicotinic acid,[12] dinicotinic acid,[2] and cinchomeronic acid.[3] Those facts suggest that the O-H···N or $^+$N-H···O hydrogen bond is more energetically favored than the O-H···O hydrogen bond in solids.

There is no hydrogen bond between the chains on the same plane, those on the planes at $y=1/8$ and 3/8 related by the c-glide plane at $y=1/4$, and those on the planes at $y=3/8$ and 5/8 related by the center of symmetry at $y=1/2$. These chains are packed together only by the van der Waals forces. Therefore, there is an anisotropy of the bonding forces joining the molecules in this crystal. The appreciable thermal diffuse scattering along the directions of the b^* and c^* axes may be caused by this anisotropy of the bonding forces. Similar patterns were observed in dipicolinic acid monohydrate[1] and other crystals in which molecules are joined by this type of hydrogen bond.[13]

Computer Programs. All the calculations were performed on a FACOM 270-30 computer at the Computer Center of Osaka City University by the use

Studies on Intermolecular Complex Formation. III. Crystal Structure of Thymine-*N*,*N*-Diethylmelamine Complex Monohydrate

Chihiro TAMURA, Tadashi HATA, and Sadao SATO

The Central Research Laboratories of Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

(Received February 14, 1973)

The crystal and molecular structure of the thymine-*N*,*N*-diethylmelamine complex monohydrate has been solved by means of the direct method. The crystals are monoclinic, with the space group of $P2_1/c$ and with $a=7.167$, $b=16.123$, $c=13.179$ Å, and $\beta=104.2°$. The final *R*-factor for 1612 reflections is 0.087. These two components are hydrogen-bonded by a NH···N and two NH···O bonds with distances of 2.881, 2.821, and 3.006 Å. The complex formation ability for thymine and uracil has also been tested for some other organic compounds with amino and nitrogen heterocycles.

Intermolecular interactions in crystalline fields have recently come into focus after Hoogsteen displayed some model complexes of DNA.[1] The pairing mechanism has been interpreted as being due to special features in the purine and pyrimidine structures, in which the atoms in these molecules are arranged in appropriate combinations of so-called "complementary hydrogen bond."[2-18] Such arrangements would have a bearing on the biological duplication mechanism. Subsequently, we have been trying to determine some role for the intermolecular complex formation between nucleotide bases and organic compounds.[19,20] It has been found that cytosine and adenine exhibit a rather strong affinity for many organic compounds, while thymine and/or uracil are less reactive and bind only with a few organic compounds that have a $-\underset{\displaystyle NH_2}{\underset{|}{C}}=N-\underset{\displaystyle NH_2}{\underset{|}{C}}=N-$ grouping or a few other basic groups. In this paper we wish to describe the crystal structure of the thymine–*N*,*N*-diethylmelamine monohydrate complex and the general ability of complex formation in some organic compounds that can produce a complex with thymine and/or uracil. The biological importance of the melamine molecule and its derivatives has already been discussed in several places.[21,22] These studies may make it possible to project an illustrative intermolecular spatial system.

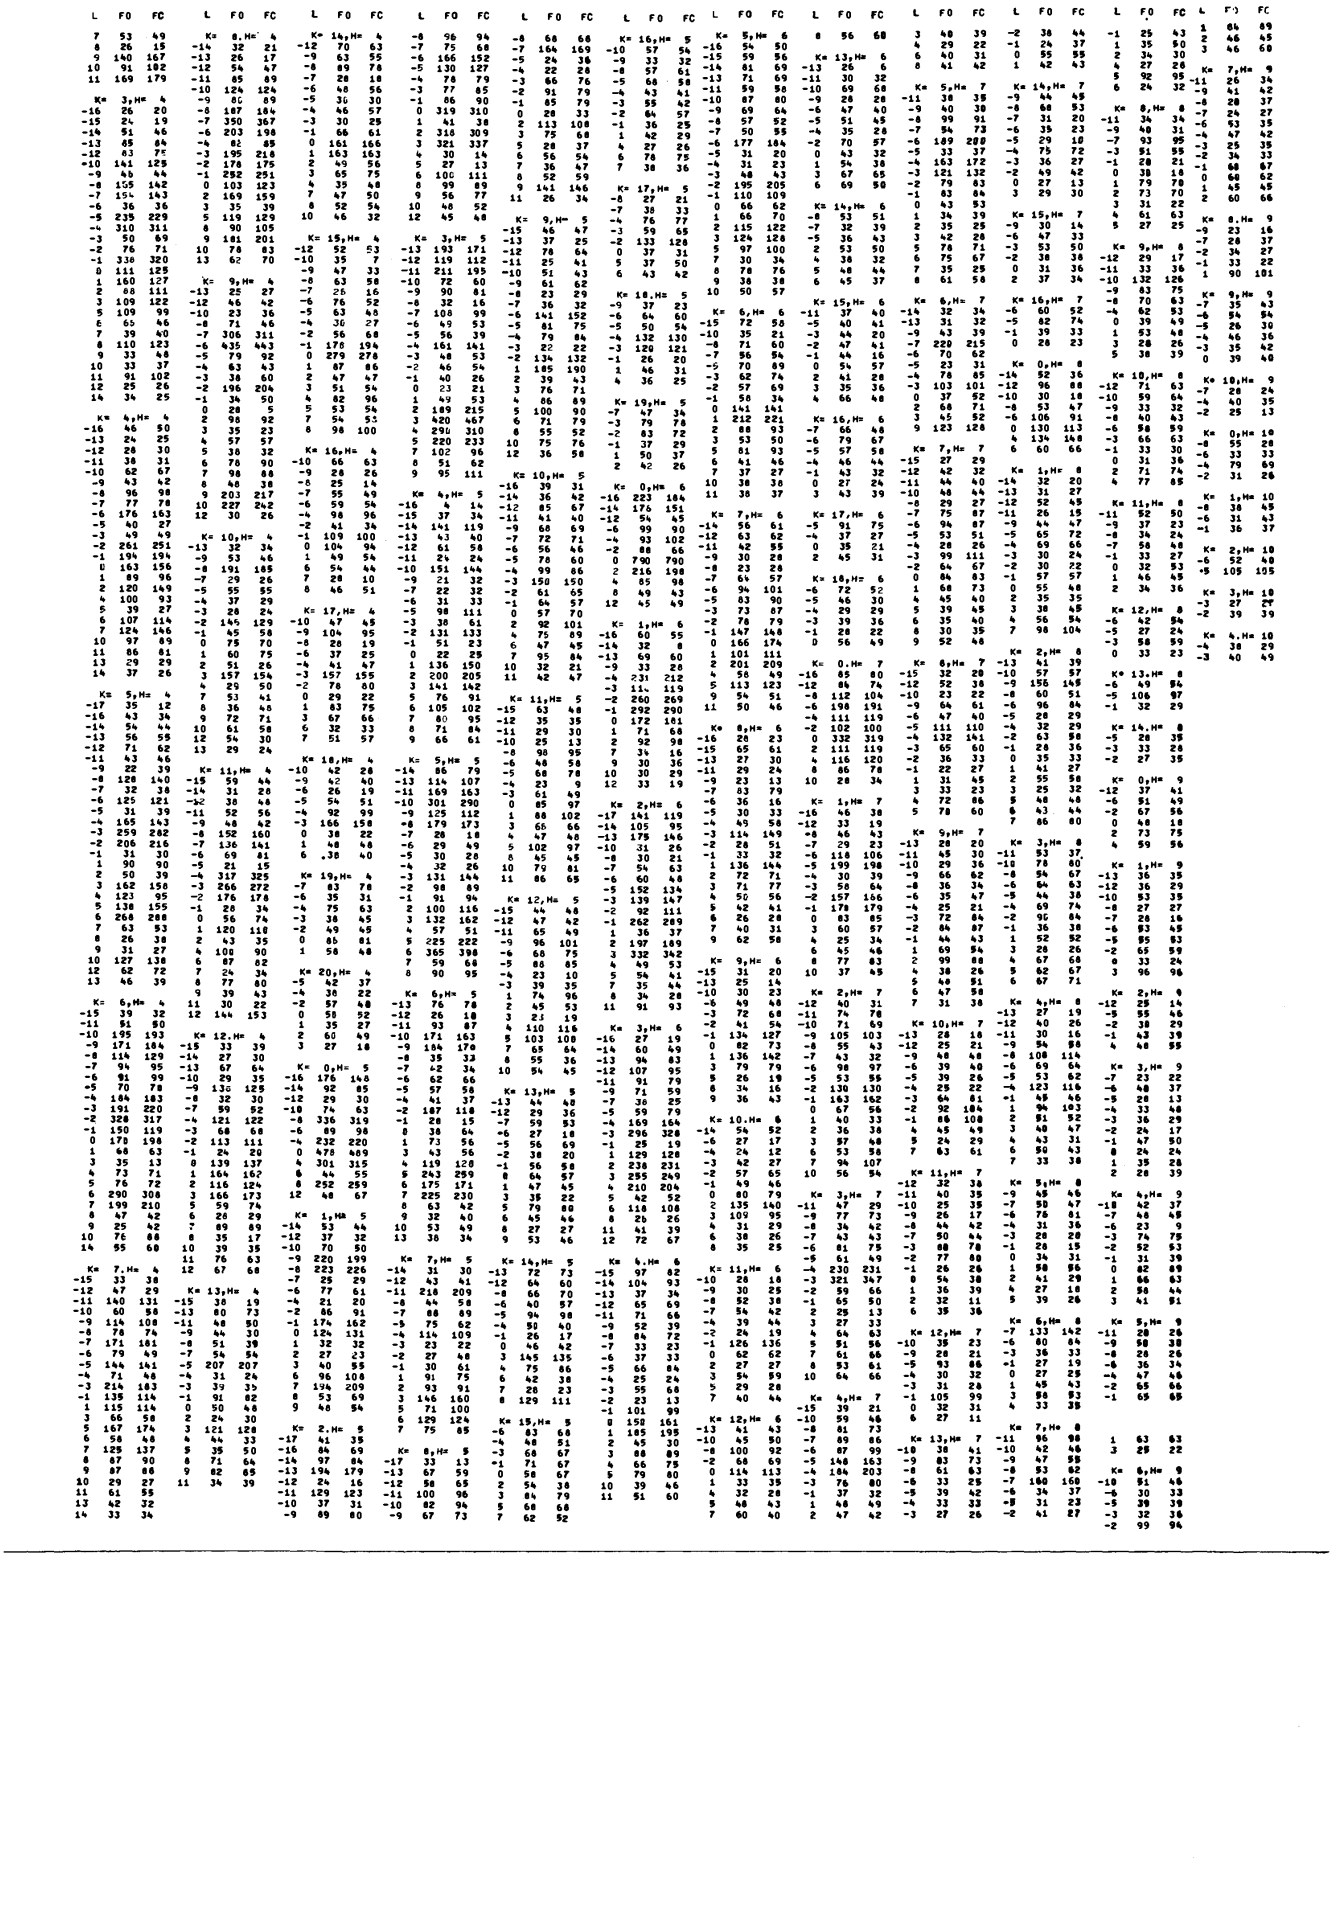
TABLE 1. STRUCTURE FACTOR DATA ($\times 10$) FOR THE OBSERVED REFLECTIONS

TABLE 1. (Continued)



Experimental

Equivalent moles of nucleotide bases and some nitrogen heterocycles were dissolved in hot 70% aqueous ethanol, and then allowed to stand for several days in a refrigerator. The X-ray diffraction of the materials obtained and of each component were measured up to $2\theta=50°$ (Cu Kα) with a Rigaku model D6C diffractometer.

The single crystals of thymine–*N*,*N*-diethylmelamine thus obtained, which were suitable for X-ray analysis, were used for the intensity measurements. A crystal measuring $0.5\times0.3\times0.2$ mm was chosen for recording the crystal data and the intensities. Preliminary Weissenberg photographs showed that the crystals belong to the monoclinic system, with the space group of $P2_1/c$. The lattice parameters from the diffractometer are: $a=7.167(9)$, $b=16.123(18)$, $c=13.179(15)$ Å, $\beta=104.2(1)°$, $D_{obsd}=1.39$, and $D_{calcd}=1.44$ g/cm^3. The three-dimensional intensities were collected on a Rigaku Denki four-circle automatic diffractometer with a FACOM-R computer system up to a 2θ limit of 60° using Mo Kα radiation and the $2\theta/\theta$ scan mode at a scan speed of 2° min^{-1}. A crystal was mounted along the *a*-axis, and a total of 1612 independent reflections were collected. Three standard reflections were used to monitor the crystal stability during the measurement. The data were corrected for the usual Lorentz and polarization factors, but no corrections were made for absorption.

Structure Analysis and Refinement

The reiterative application of Sayre's equation[23] was used to determine the phases of 270 reflections having $E\geqq1.50$. Three reflections (1,2,−3; 1,3,−3; 3,14,0) were chosen for specifying the origin, and three other reflections (0,0,16; 0,0,3; 5,5,6), were denoted by the symbols A, B and C respectively. The B and C symbols were uniquely determined to be −A and A respectively by subsequent calculations. Then the structure was satisfactorily solved by an interpretation of the *E*-map based on these phases. The atomic parameters were refined by the method of least-squares, using the block-diagonal least-squares program. When the *R*-factor was reduced to 0.18, the difference synthesis was calculated in order to determine the positions of the hydrogen atoms; the six atoms attached to C(11) and C(13) were vague because of disorder. The final *R*-factor reached was 0.087 for the structure factors listed in Table 1. The atomic parameters are given in Tables 2, 3 (a), and 3 (b).

Results and Discussion

Intermolecular Interactions and Hydrogen-bond Systems. The cytosine and adenine molecules have a strong tendency to bind with acidic organic compounds, especially with molecules containing a carboxylic acid moiety. However, few organic compounds can bind with thymine or uracil under these experimental conditions. In such circumstances, we have tried to un-

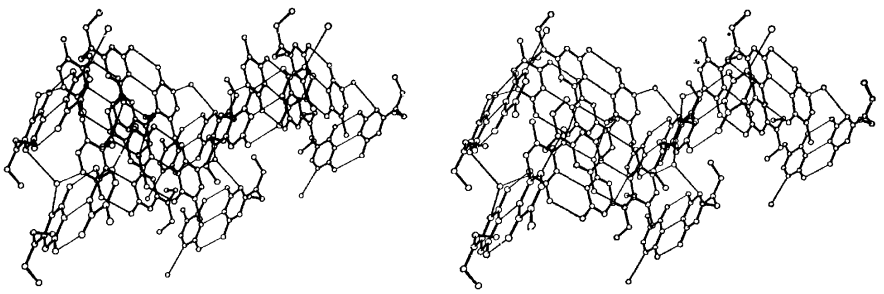

Fig. 1. Stereoscopic view of the packing and hydrogen bonding. Molecular bonds are drawn thick and hydrogen bonds thin.

cover some specific atomic arrangement or any molecule that can associate with thymine or uracil by means of hydrogen bonding. Table 4 shows the materials tested in this experiment. Some molecules with a number of exocyclic amino groups in combination with endocyclic –N= parts, especially in an arrangement which corresponds to a  group, were found to be able to associate with these molecules. Therefore, combining this finding with the results for cytosine and adenine, it can be said that at least a partially molecular basicity or acidity plays an important role in binding the two components, presumably a so-called acid-and-base interaction. From this point of view, adenine, cytosine, thymine, and uracil can be classified into two groups; cytosine and adenine act as basic nucleotide bases which can bind with acidic components, such as carboxylic acids, while the other two are acidic nucleotide bases which can bind with basic components, such as melamine. However, the binding force is sometimes seriously affected by some other molecular

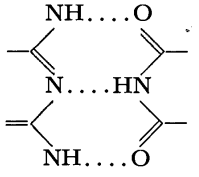
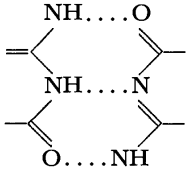
feature; thus, not all similar molecular structures can always bind with each other. The local atomic basicity or acidity may be considered to be appropriate for association at each specific site, but steric hindrance may be the determining factor in the formation of molecular complex crystals. Detailed molecular geometry can be evaluated only by X-ray analysis.

Description of the Crystal Structure. The crystal and molecular structure is shown in a stereographic plot in Fig. 1, while a projectional view along the *a*-axis is shown in Fig. 2. The thymine and melamine molecules are associated with each other mainly by means of two NH···O hydrogen bonds (2.821 and 3.006 Å) and one NH···N bond (2.881 Å). This hydrogen-bond system is defined as consisting of the specific nitrogen and oxygen atoms in both molecules, which form the tips of the capital letter "W"; two such molecules bind with each other, with both tops of the letter, thus forming three hydrogen bonds.



I (A)



I (B)

There are several analogous three-hydrogen bond ystems, I(A) and I(B), which are summarized in

Table 5. The molecular complexes of similar hydrogen-bonding arrangements have been reported by Sobell *et al.*[14] and Rich *et al.*[18] These facts suggest that an atomic arrangement such as that in I(A) is one of the fundamental combination schemes for binding among molecules. The paired-molecular complex formed in this manner is connected by the remaining

NH···O hydrogen bond at a distance of 2.931 Å, and such units are stacked in such a way that they are parallel to the alternate (0, 1, 1, and 0,1,–1) crystallographic planes. One water molecule is associated by means of hydrogen bonds between these triazine-ring systems in the direction of the *a*-axis. The component molecules are almost coplanar, and the dihedral angle of both least-squares planes is 4.9°. Parallel sheets of the component molecules are separated from each other at an average spacing of 3.35 Å, since the maximum deviation between the atoms in some charge-transfer complexes is 3.26 Å.[24] Therefore, for the complex formation of this series, in some way the molecular stacking or van der Waals forces are second-order in importance. Sakurai *et al.*[25,26] reported some charge-transfer complexes between the molecules of thymine and quinone, which would imply that stacking forces between these hygroscopic moieties play an important role in the complex formation.

In the three-hydrogen-bond system the distances of the two bondings on the outside differ by about 0.2 Å even though *N*,*N*-diethylmelamine is a fairly symmetric molecule. It is hard to explain why hydrogen bonding between the atoms N(8) and O(20) is weak in such symmetrical three-hydrogen bonds. The other intermolecular atomic distances are shown in Table 6.

Description of the Molecular Structure. The intramolecular atomic bond lengths and angles are shown in Figs. 3(a) and 3(b) and in Table 7. As was discussed earlier, the existence of a hydrogen atom attached to nitrogen may be indicated by its bond angle, in the manner of Singh;[27] the usual –NH– angle is 125°, while for –N= it is 116°. In this complex both components agree well with this hypothesis, since the mean C–N–C bond angle of melamine is 114.4° and that of thymine is 124.7°. The difference synthesis at the *R*-factor, 0.14, indicated that there are no protons around the triazine nitrogen hetero-atoms, while there are two protons attached to N(14) and N(18) in the thymine molecule. The bond lengths of the endocyclic part of thymine differ significantly from those found in the literature; *i.e.* the C=O distances of 1.209 and 1.205 Å are slightly shorter than those found in thymine monohydrate[28] (1.234 and 1.231), methylthymine[29] (1.237 and 1.214 Å) and uracil (1.230 and 1.241 Å). The mean bond length of all the N–C distances in *N*,*N*-diethylmelamine is 1.330 Å, and that in thymine is 1.356 Å. These values are slightly shorter than the expected values between 1.37 and 1.38 Å observed for uracil,[30] thymine monohydrate,[28] barbiturate derivatives,[31,32] but they are compatible with those in melamine[33] and purine,[34] with values from 1.34 to 1.35 Å. The deviations of atoms from each molecular plane are listed in Table 8.

Studies on Intermolecular Complex Formation. IV. Crystal Structure of Cytosine-Resorcylic acid 2 : 1 Complex monohydrate

Chihiro TAMURA, Sadao SATO, and Tadashi HATA

The Central Research Laboratories of Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

(Received February 14, 1973)

The crystal and molecular structure of a cytosine and resorcylic acid complex monohydrate has been solved by the direct method. The molecular complex is formed by two moles of cytosine and one mole of resorcylic acid. The crystals are monoclinic, with a space group of $P2_1/n$, and with $a=8.335$, $b=20.605$, $c=10.159$ Å, and $\beta=95.5°$. The final R-factor for 1820 reflections is 0.100. Resorcylic acid is hydrogen-bonded to one of the cytosine molecules with one hydrogen bond, and to the two cytosine molecules with one hydrogen bond, and the two cytosine molecules are associated with three hydrogen bonds in a system similar to that of the guanine-cytosine hydrogen bond in the Watson-Crick model.

Recently the biological significance and drug activity of several molecular complexes have been investigated.[1-26] Since we surveyed a number of organic compounds interacting with nucleotide bases, some molecules with specific atomic constellations have been found to form complexes with cytosine and/or adenine.[25] Some of those complex structures have already been solved by means of single-crystal analysis. Herein we wish to describe the crystal structure of the resorcylic acid–cytosine monohydrate complex.

Experimental

Cytosine and resorcylic acid were dissolved in 70% aqueous ethanol at room temperature and crystallized as single crystals after the solution had been cooled in a refrigerator. The mass spectrometry of this complex revealed that both components were present. Preliminary oscillation and Weissenberg photographs showed that the crystals belong to the monoclinic system, space group of $P2_1/n$, and the density of the crystals was determined to be $1.34\,g\cdot cm^{-3}$ by the flotation method. The lattice parameters are $a=8.335$ (10), $b=20.605(18)$, $c=10.159(11)$ Å, and $\beta=95.5$ (1)°. The results of the elemental analysis and the calculation of the molecular weight from the cell constants and the measured density were compatible with a 2 : 1 molar ratio for cytosine and resorcylic acid with one water molecule.

Three-dimensional intensity data were collected on a Rigaku Denki auto-diffractometer up to a 2θ limit of 60°, using Mo Kα radiation with the $2\theta/\theta$ scanning mode at a scan speed of $2°\,min^{-1}$. The intensities were reduced to structure factors by correcting for the Lorentz-polarization factors using a program attached to this equipment. Because of the small size of the crystals, no corrections were made for absorption. The 1830 independent observed structure factors thus obtained were used for structure analysis.

Structure Analysis

The normalized structure factors, E, were calculated from the observed structure factors, F, which were put on an absolute scale by the use of Wilson's statistics.[27] A trial structure was obtained using the symbolic addition procedure. The reflections of 267 with $|E|$ values greater than 1.30 were obtained using the $\Sigma 2$ of Hauptman and Karle.[28] Three linear independent reflections (5,6,−6; 7,0,1; 0,5,2), each with a large number of interactions, were assigned to be +, three other reflections (1,15,5; 2,7,7; 7,1,2) were denoted by the symbols A, B, and C. After the symbolic addition procedure, the A, B, and C symbols are uniquely determined to be all −. A Fourier synthesis using these signs for the E-values showed over 38 large peaks. From a knowledge of the geometry of the molecules, the peaks corresponding to 27 atoms could easily be recognized. The initial structure factor calculations for the 27 atoms gave an R-factor of 0.38, with an isotropic temperature factor. After five cycles of block-diagonal least-squares refinements, the R-factor was reduced to 0.24. The remaining water molecules

were found from the subsequent Fourier synthesis. Then difference synthesis was carried out in order to obtain the positions of the hydrogen atoms, which appeared satisfactorily on the map. The eight subsequent refinement cycles used the anisotropic temperature factor for C, N and O and the isotropic factor for H gave a final *R*-factor of 0.100 for all the observed reflections.

Results and Discussion

The final atomic parameters are given in Tables 1 and 2 and the corresponding structure factors, in Table 3. The bond lengths and angles are shown in Table 4, while Fig. 1 shows a diagram of the atomic notation. The crystal structure and hydrogen-bond system of the molecules are shown in Fig. 3, while a stereographic view is illustrated by the ORTEP plot in Fig. 2. Some important intermolecular atomic distances are listed in Table 5. The average estimated standard deviations for bond distances are: for C–C within 0.020 Å; for C–N and C–O within 0.013 Å; and for bond angles, 1.0° for all the heavy atoms.

Description of Crystal and Molecular Structure. As is shown in the stereographic plot (Fig. 2), two approximately coplanar cytosine (A and B) molecules are coupled to each other, with two NH···O (2.889, 2.778 Å) and one NH···N (2.815 Å) hydrogen bonds forming

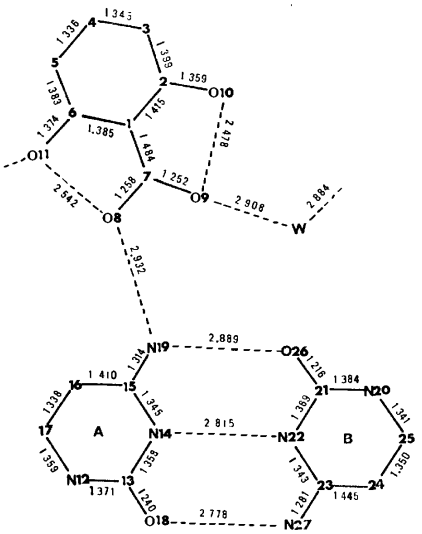

Fig. 1(a). Interatomic distances in cytosine-resorcylic acid (2 : 1) complex monohydrate.

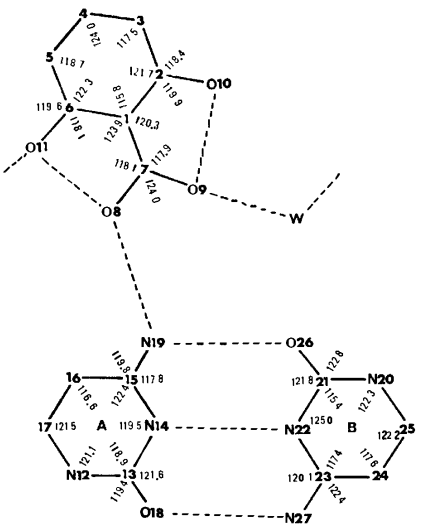

Fig. 1(b). Interbond angles in cytosine-resorcylic acid (2 : 1) complex monohydrate.

TABLE 2(a). ANISOTROPIC THERMAL PARAMETERS IN CYTOSINE-RESORCYLIC ACID (2:1) COMPLEX MONOHYDRATE
The thermal parameters are given in the form $T=\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+2B_{12}hk+2B_{13}hl+2B_{23}kl)]$.

a pseudo-dimer, while to the amino group in one of the cytosines, A, the carboxylic acid group in resorcylic acid is bound by one hydrogen bond (2.932 Å). Further, these three molecules make a coplanar net-work. The other component, the water molecule, associates with the O(9) of the carboxyl and the O(11) of the phenolic groups of the neighboring resorcylic acid molecule in the crystal packing. These distances are 2.908 Å for O(9)···W and 2.884 Å for O(11)···W. There are two intramolecular hydrogen bonds at a distance of 2.478 for O(9)–O(10) and 2.542 Å for O(8)–O(11); these values agree well with the case of *o*-salicylic acid.[29,30] Although the amino groups of the two cytosine molecules, C(15)–N(19) of A and C(23)–N(27) of B, seem to have the same bond lengths, the values of the two molecules are significantly different; the values are 1.341 and 1.281 Å for A and B respectively. This significant shortening of the bond length in the B molecule can be attributed to the double-bond character in this specific portion. A few examples of the C=NH double bond lengths have been reported, *e.g.*, that in 1,3-dimethyl-4-imino-5-oxo-2-thione-imidazolidine is 1.25 Å.[31] The two cytosine molecules, A and B, are actually not identical, since B has no proton at N(22); A has a proton at the corresponding atom N(14), forming a cationic structure. This extra proton in the A molecule is the one which has migrated from the resorcylic acid proton. Furthermore, the bond lengths of the carboxyl groups are 1.258 Å for C(7)–O(8) and 1.252 Å for C(7)–O(9); these values correspond to the usual carboxyl acid anion structure observed in many aminoacids.[32] In the difference map, there are no hydrogen peaks around the carbonyl oxygen atoms. These facts indicate that the resorcylic component molecule is anionic. A similar phenomenon has been observed in the *N*-benzoyl glycine–cytosine complex, in which the proton from the acid moiety migrates to the base moiety. However, in the molecular complex of caffeine with 5-chlorosalcylic acid, the proton is retained in the acid moiety.[11] Thus far, no such anion-cation structure has been found for binding between a carboxylic acid and a basic compound. Interestingly, the cytosine B molecule is neutral and has no extra proton. Consequently, the actual nomenclature of this complex is cytosinyl-cation-cytosine-resorcylic acid anion-monohydrate.

The mean value of the C–N bonds in the cytosine-ring system is 1.359 Å which corresponds to those of

isocytosine,[33] thymine monohydrate,[34] uracil[35] barbituric acid,[36] and cytosine monohydrate[37] (1.354, 1.372, 1.361, 1.369 and 1.361 Å respectively), but which is slightly longer than those of the completely-conjugated systems of melamine,[34] pyrimidine[35] and purine[36] (1.343, 1.326, and 1.337 Å respectively). The bond lengths of C(16)–C(17), 1.338 Å, and C(24)–C(25), 1.350 Å, are clearly shorter than the fully-conjugated C=C double bond of 1.395 Å. The deviations of the atoms from each molecular plane are listed in Table 6; the inter-plane angles of the individual molecules are 7.23° for cytosine(A)–cytosine(B) and 5.14° for cytosine(B)–resorcylic acid.

A particularly interesting phenomenon in this analysis is the fact that the two cytosine molecules could form three hydrogen bonds in which they are bound to each other, with the formation of a pseudo-dimer of A and B. Such a hydrogen-bonding scheme resembles that of the guanine–cytosine three-hydrogen-bond system in the Watson-Crick model and its model complex.[2] Furthermore, it is reminiscent of the crystal structure of isocytosine[33] reported by McConell, in which tautomeric isomers of two cytosine molecules are bound by three hydrogen bonds. The present analysis of the complex is structurally different, but the

combination scheme between these two molecules is very similar in manner when the proton is introduced from resorcylic acid, as is shown in Fig. 4. The crystal structures of cytosine and cytosine monohydrate have been determined to contain two hydrogen bonds which are of the  type; this has been established using NH···O and NH···N hydrogen bonds, as is shown in Figs. 5(a) and (b).[30] On the other hand, in crystals of cytosine-5-acetic acid (5-acetic-cytosine) and the

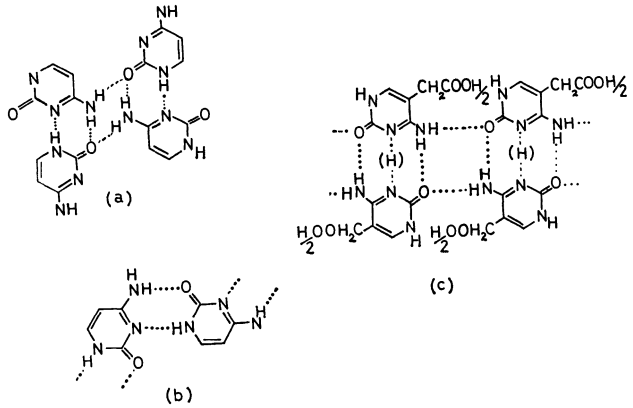

Fig. 5. Various hydrogen-bonding scheme in cytosine and its derivatives. (a) Cytosine[41] (b) cytosine monohydrate[37] (c) cytosine-5-acetic acid[42].

present complex which contain carboxylic acid moieties, the crystals form three hydrogen bonds (Fig. 5(c)).[42] These facts indicate that the change in the internal electronic states in the molecules is caused by a proton in the crystals involving a catalytic effect. The three-hydrogen-bond scheme resembles the Watson-Crick model between cytosine and guanine. In biological paths of RNA or DNA, the protonation of the bases may occur in many instances; thus, the cytosine–cytosine three-hydrogen-bond system might be said to be an interaction potentially important as a genetic proto-type in dynamic biological processes.

Optical and Magnetic Studies of $CuSeO_3 \cdot 2H_2O$ Based on the Refined Crystal Structure

Takeshi Asai and Ryôiti Kiriyama

Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received March 2, 1973)

Magnetic, IR and electronic spectral studies were made on $CuSeO_3 \cdot 2H_2O$, its crystal structure being refined. The IR band at 927 cm^{-1} was found to be due to a rocking vibration of a water molecule. The H-bonding scheme was suggested. The electronic spectrum shows a maximum of the d-d transition bands at *ca.* 14000 cm^{-1}. This was explained on the basis of a square pyramidal coordination of a Cu ion. Above 100 K the magnetic susceptibility obeys the Curie-Weiss law with $\theta = -92._6$ K and $\mu_{eff} = 2.00\,\beta_B$. At lower temperatures it shows a broad maximum at *ca.* 45 K, a sharp peak at $26._4$ K corresponding to T_N. The behaviour could be explained from the antiferromagnetic superexchange interactions of Cu cations through the σ-bonds of SeO_3^{2-} anions. The small anisotropy and the number of cations intermediated by each anion give rise to the 1-dimensional character. A linear Heisenberg model and the molecular field model gave J/k values of -33 and -31 K, respectively. The latter model also gave the observed ratio of $|\theta|/T_N$.

Magnetic properties of transition metal compounds have attracted the attention of many workers and studies have been carried out according to several different methods. The compounds studied can be classified into (a) those with highly anisotropic structures of a linear chain or a sheet arrangement of metal ions since the theories are expected to be phenomenologically applicable and (b) those in which the simple anions like halide or oxide anions coordinate to a metal atom since the quantum mechanics is useful for an explanation of the mechanism. They have given information on the nature of the chemical bond and the superexchange interaction. Studies on the compounds which belong to neither (a) or (b) do not seem to have been carried out. They are desirable because of their utility for testing the theories. The present study has been carried out with $CuSeO_3 \cdot 2H_2O$, the easiest system for application to the theory. The trigonal-pyramidal oxo-anion SeO_3^{2-} is potential to form MO's of both a σ- and a π-type character with metal cations. However, the nature of the bonds and the mechanism of magnetic interactions depend to a great extent on the conformation attained in the crystal lattice.

Experimental

Preparation. The hydrated sample was obtained by the usual method[1] and was confirmed by powder X-ray diffractometry[2] and also by chemical analysis of Cu content. A deuterated sample for IR study was obtained in a sealed tube at 120 °C with fully dried $CuSO_4$ and Na_2SeO_3 dissolved into D_2O. The powder X-ray diffraction pattern of the deuterate was the same as that of the hydrate.

IR and Electronic Spectra. IR spectra were recorded in the region 4000—400 cm^{-1} on a JASCO DS-402G spectrometer. Both KBr pellets and nujol mulls were employed. Diffuse reflectance spectra were obtained in the range 8250—35000 cm^{-1} with Hitachi EPU-2 and EPS-3T spectrometers with MgO as a standard. The spectra were recorded on a pure sample and one diluted with MgO to 80 wt.-%. Dilution was confirmed to have no effect on the position of absorption maxima.

Magnetic Measurement. Magnetic susceptibility was measured on powder samples by a Faraday balance. Temperatures were varied from 4 K to room temperature. $Co-Hg(SCN)_4$ was used as a reference substance of susceptibility.[3] Corrections were made for diamagnetism[4] but not for TIP.

Refinement of the Crystal Structure. The space group and lattice constants of Gattow[2] were confirmed; the space group is D_4^2–$P2_12_12_1$(No. 19) and lattice constants are $a = 6.664$, $b = 9.156$ and $c = 7.369(\pm 0.005)$ Å with $Z = 4$. Intensity data were collected using a Rigaku Denki four-circle X-ray diffractometer with a scintillation counter and Mo$K\alpha$ radiation. A total of 2311 reflections in two octants were measured within $\sin\theta/\lambda$ of 0.85. By averaging intensities of symmetry-related reflections in two octants,[5] intensities for 1347 independent reflections were obtained, of which 75 reflections had less than 2σ, the e.s.d. of $|F_o|$, and were taken to be zero. Intensities were corrected for Lorentz and polarization effects, but not for absorption and extinction effects. Dimensions of the crystal were $0.05 \times 0.08 \times 0.12$ mm^3; $\mu R = 1.19$.

Using atomic parameters of Gattow's analysis[2] and isotropic temperature factors of 1.0 for all atoms[6] as initial parameters, four cycles of the least-squares refinements were carried out. Anisotropic temperature factors were then introduced and four more cycles were repeated. Shifts of atomic parameters and temperature factors in the last cycle were less than 0.1 σ and 0.2 σ, respectively, with the exception of y-parameter of O_w1(0.14σ) and a temperature factor $B12$ of Cu(0.52σ). The final R-value ($R = \sum||F_o| - |F_c|| \sum|F_o|$) was 0.045 (0.038 excluding $|F_o| = 0$). In the earlier stages the weights were 1.0 for all reflections. In the later stages the following weights were used.

If $|F_o| \leqq 8.9$, $w = 0.25$,
if $|F_o| > 83.3$, $w = 1/|F_o|$,
and otherwise, $w = 1.0$.

3) B. N. Figgis and R. S. Nyholm, *J. Chem. Soc.*, **1958**, 4190.

4) P. W. Selwood, "Magnetochemistry," 2nd Ed., Interscience Publishers, New York (1956).

5) Since this space group lacks the center of symmetry, 2311 reflections were taken to be independent at first and refinements were performed including imaginary parts of the anomalous dispersion. The atomic parameters for the two sets of indexing were the same within the e. s. d., and their R values were 0.080 and 0.068. The difference in the intensities of I_{hkl} and $I_{h\bar{k}l}$ were therefore taken to be an error in measurement and the average values of I_{hkl} and $I_{h\bar{k}l}$ were used for the later work, which is reported here.

6) Only the atomic parameters were taken because of negative temperature factors.

Atomic scattering amplitudes used in these calculations were those of Cu^+, Se and O^-.[7] Corrections for the real parts of the anomalous dispersion were included. All calculations were performed with the aid of UNICS PROGRAM HBLS-IV and RSDA-4 on NEAC 2200/500 and 700 computers at the Computer Center, Osaka University.

Results and Discussion

IR Spectra. IR spectra of $CuSeO_3 \cdot 2H_2O$ and the dideuterate are shown in Fig. 1. The spectrum of the hydrate is in good agreement with that published by Sathianandan *et al.*[8] They assigned the band at 927 cm^{-1} to a bending vibration of Cu–O–Se. Since this band disappeared on deuteration, hydrogen atoms should take part in it. It can be assigned to a rocking vibrational mode of a water molecule. The corresponding band of a deuterate is not obvious because of its overlap with Se–O stretching bands. If we take a new band at 659 cm^{-1} as a rocking mode of D_2O, it gives 0.71 for the frequency ratio $\nu(D_2O)/\nu(H_2O)$, which is comparable to the observed ratios of $\nu(OD)/\nu(OH)$ and $\delta(D_2O)/\delta(H_2O)$ (0.73—0.74). Since the rocking vibration of a water of crystallization often appears at 800—700 cm^{-1},[9] this is a rare example of its appearing at a higher frequency.

Electronic Spectrum. The spectrum shown in Fig. 2 presents a broad *d-d* transition band at *ca.* 14000 cm^{-1} and an intense charge transfer band above 25000 cm^{-1}. The *d-d* transition band has a maximum at 13500 cm^{-1} and a shoulder at 10500 cm^{-1}. It is resolved into three components if we assume a Gaussian line shape with a common half width (Table 1).

A copper(II) cation is in an almost regular square pyramid composed of five oxygen atoms with a slight rhombic distortion (*vide post*). This configuration lacks the center of symmetry, explaining the high intensity of the absorption band. In this C_{2v} environment the 3*d* orbital levels are all split, three transitions being symmetry-allowed. The transition of $d_{x^2-y^2} \leftarrow d_{xy}$ is still forbidden, but the vibronic mechanism can bring forth the band of this transition.

Observed (——) and resolved components (----).

Table 1. Resolution and assignment of the *d-d* transition bands

Energies (cm^{-1})	Relative intensity	Assignment[a]
10000	1.4	$^2A_1 \leftarrow {}^2A_2$
13200	1.7	$^2A_1 \leftarrow {}^2A_1'$
16300	1.3	$^2A_1 \leftarrow {}^2B_1, {}^2B_2$

a) Notations are given with an approximation of the C_{2v} point symmetry. A_1 and A_1' correspond to $d_{x^2-y^2}$ and d_{z^2} orbitals, respectively.

Since distortion is very small, it can be said that the energy difference between d_{xz} and d_{yz} orbitals is too small to be detected in the powder reflectance spectrum. Some polarized electronic spectra[10] show that this difference is less than 1500 cm^{-1} and that the transitions occur at 14200—16800 cm^{-1}. The component at 16300 cm^{-1} can therefore be assigned to the $d_{x^2-y^2} \leftarrow d_{xz}, d_{yz}$ transitions. This is also confirmed in the following estimation.

Copper(II) complexes in an environment of a tetragonally distorted octahedron of oxygen atoms give transitions of $d_{x^2-y^2} \leftarrow d_{z^2}$ in a wide range of energy. This energy was shown to be related to the axial Cu–O bond length.[11] Smith[12] succeeded in explaining the relationship from the molecular orbital formation between copper and ligand atoms and the electrostatic crystal field energy. His treatment was modified[12,13] for a square pyramidal coordination with the C_{4v}

symmetry, giving the energies 12900, 11400 and 15100-17600 cm^{-1} for $d_{x^2-y^2} \leftarrow d_{z^2}$, $d_{x^2-y^2} \leftarrow d_{xy}$ and $d_{x^2-y^2} \leftarrow d_{xz}, d_{yz}$, respectively. These values are in good agreement with those of resolved components. π-bonding between copper and basal oxygen atoms were involved in this estimation. Since these quantities were treated only as parameters to fit the data by Smith, the agreement between resolved and estimated values does not necessarily mean the presence of the π-bonding. It might be negligible in this compound.

Refined Crystal Structure. The final atomic parameters, temperature factors and $|F_o|$'s and $|F_c|$'s are given in Tables 2, 3 and 4, respectively. The projection of the refined structure to the (100) plane is shown in Fig. 3. Interatomic distances and angles are given in Table 5.

The gross feature of the structure is the same as that of Gattow,[2] but significant shifts (0.06—0.15 Å) of oxygen atoms were found. Thus the selenium and copper atoms attain more regular coordinations.

The bond lengths and angles show that the copper atom is located in the square pyramid of oxygen atoms rather than in the distorted octahedron as stated by Gattow[2] and Handlovič[14] for the isomorphous $CuHPO_3 \cdot 2H_2O$. Four oxygen atoms forming the basal plane are planar, the deviations being within 0.030 Å. The copper atom is 0.137 Å above this plane as is often the case in the copper complexes of a square pyramidal configuration. Three interatomic distances (mean 1.952 Å) of basal Cu–O(SeO_3) bonds are the same within the e.s.d., but the basal Cu–O_w1 distance is significantly longer. The apical Cu–O_w2 distance became longer than that of Gattow's structure (2.27→2.323 Å), whereas the next-nearest oxygen atom O_w2' came closer than before (3.21→3.117 Å). In spite of the shortened Cu–O_w2' distance this oxygen atom should be excluded from coordination to the copper atom, not only because it is much longer than the longest one in the square pyramid but also because the copper atom has three next-nearest neighbours of uncoordinating Se atoms at 3.128—3.182 Å. This configuration is in good agreement with that of $CuHPO_3 \cdot 2H_2O$,[14] $Cu(NH_3)_4SO_4 \cdot H_2O$[15] and $Cu(NO_3)_2 \cdot CH_3NO_2$.[16]

A selenite anion forms a very slightly distorted trigonal pyramid. Its average dimensions are Se–O= 1.70_6, O–O=2.60_7 Å and O–Se–O=99.7° with the selenium atom 0.80_3 Å above the basal plane. These values are comparable to those of $ZnSeO_3 \cdot 2H_2O$,[17] $MgSeO_3 \cdot 6H_2O$,[18] H_2SeO_3,[19] $Na_3H(SeO_3)_2$[20] and $K_3H(SeO_3)_2$.[21] A selenite anion coordinates to three different copper atoms, with each oxygen atom towards a single copper atom, and connects the CuO_5 pyramids into a three-dimensional network.

No hydrogen atoms could be found in the analysis. However, consideration of interatomic distances and angles around O_w1 and O_w2 led to the sole probable scheme of hydrogen bonds of water molecules. A water molecule H_2O 1 may direct its hydrogen atoms towards O 1 and O 3 belonging to the two neighbouring CuO_5 pyramids and its negative dipole towards the copper atom (Table 5). The water molecule H_2O 2 has two copper neighbours. The angle Cu–O_w2–Cu' and also an electrostatic repulsion between hydrogen and copper atoms suggest a configuration in which two lone pairs direct towards two copper atoms and one hydrogen atom to O 2 atom belonging to another CuO_5 neighbour. Another hydrogen atom may be free from the hydrogen bonding or incorporated to

a weak bent hydrogen bonding to H_2O 1. The situations of water molecules H_2O 1 and H_2O 2 belong to the D- and B-types, respectively, of Chidambaram *et al.*[22] The IR spectrum showed three ν_{OH} bands at 3490, 3175 and 2880 cm^{-1}, indicating three O–H···O distances of *ca.* 2.92, 2.77 and 2.69 Å.[23] These values are in good agreement with the observed ones for the scheme mentioned above. The hydrogen atoms seem to point to one of the lone pairs of the acceptor oxygen atoms.

Magnetic Susceptibility. The magnetic susceptibility and its reciprocal are plotted against temperature in Fig. 4. Above 100 K the Curie-Weiss law holds, giving a Weiss temperature θ of $-92._6$ K and a magnetic moment μ_{eff} of 2.00 β_B. At lower temperatures the susceptibility shows two maxima, one rounded and appearing at *ca.* 45 K and the other sharp and located at $26._4$ K. Below 10 K it seems to have a constant value. These features resemble those of $Cu(HCOO)_2 \cdot 4H_2O$,[24,25] a blue modification of $Cu(HCOO)_2$,[26] $Cu(C_4H_4N_2)Br_2$ and other similar compounds.[27] The broad maxima were explained to be due to the one- or two-dimensional magnetic interaction and the sharp maxima to the onset of the antiferromagnetic ordering of spins throughout the crystal at the Néel temperature T_N. Constant sus-

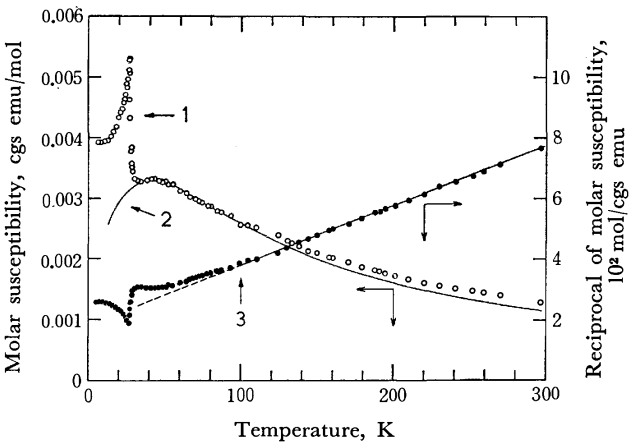

Fig. 4. Molar magnetic susceptibility and its reciprocal plotted against temperature.
1: Observed molar susceptibility, 2: calculated one for a linear Heisenberg spin system with $g=2.00$ and $J/k=-33$ K, 3: reciprocal of the observed one.

ceptibilities below T_N were observed, and in the case of $Cu(HCOO)_2\cdot 4H_2O$[25] the magnetization was measured to be 3% of the moment of a Cu(II) ion originating from the canting of the spins. The magnetic susceptibility of $CuSeO_3\cdot 2H_2O$ can also be explained in a similar manner.

The possible paths of superexchange interaction between magnetic ions were sought in the crystal structure. A linear path of Cu–H_2O···Cu along the crystallographic b axis is most apparent and a conformable path of magnetic interaction is known for $Cu(NH_3)_4SO_4\cdot H_2O$.[28] However, the interaction through an H_2O molecule is very weak as is evident from the small θ and J values found in $Cu(NH_3)_4SO_4\cdot H_2O$[28] and $CuSO_4\cdot 5H_2O$,[29] and cannot explain the observed maximum at high temperatures. The other paths should involve SeO_3^{2-} anions. Each SeO_3^{2-} anion combines three different CuO_5 square pyramids and forms a three-dimensional network. Interatomic distances and angles concerning three Se–O–Cu paths are almost the same. If these paths contribute equally to the magnetic interaction, $CuSeO_3\cdot 2H_2O$ should be a three-dimensional ferromagnet or antiferromagnet. As a matter of fact, a broad maximum of susceptibility characteristic of the one- or two-dimensional magnet is observed. There must, therefore, be a certain difference between the three paths of Cu–O–Se–O–Cu. The environments of three oxygen atoms of an SeO_3^{2-} anion are schematically projected along the pseudosymmetry axis of the anion in Fig. 5. These oxygen atoms are also a proton acceptor. Bond angles which are made by Se, Cu and a hydrogen-donor atoms are very close to 120° except O_w1_4–O 3_2–Cu_2. These values suggest that the orbitals of oxygen atoms are the sp^2 hybrid ones and that one of them is used for a σ-bond with the Se atom while the other two lone pairs are

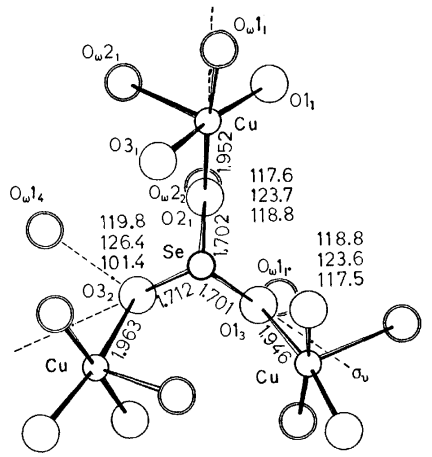

Fig. 5. Environment around an SeO_3^{2-} anion viewed along the pseudo-symmetry axis of the anion. Three numbers given for each oxygen atom of the anion are the angles of Se-O-Cu, Se-O-O(hydrogen donor) and Cu-O-O (hydrogen donor), respectively, in their order. Interatomic distances are given in Å and angles in degree.

directed towards Cu and a hydrogen-donor atoms. These sp^2 orbitals may extend within the plane normal to the basal plane of an anion and passing through the Se and O atoms, since in this conformation the oxygen atoms are bound most tightly to the Se atom by the additional formation of π-bonds. The p_π orbitals of oxygen atoms may then direct midway between the z- and x-(or y-) axes of Cu coordinate system and have only a negligible effect on the superexchange interaction between Cu atoms. The main paths of the superexchange interaction may thus involve an O–Se–O σ-bond, and the path Se–O–Cu may be weaker than the other two since the deviation of the Cu atom from the sp^2 lobus is the greatest for this oxygen atom (Fig. 5). The path Cu–O 1–Se–O 2–Cu···makes up a helical one-dimensional spin system along the crystallographic a axis. Though the difference between the three Se–O–Cu paths brings forth a linear magnetic system, the Se–O 3–Cu path may introduce a three-dimensional interaction between Cu(II) ions because the difference is not serious.

The magnetic susceptibility of $CuSeO_3 \cdot 2H_2O$ can be explained qualitatively on the refined crystal structure. Some of the parameters concerning the magnetic interactions were estimated phenomenologically. For a one-dimensional spin system there are two formalisms of magnetic susceptibility based on the Ising[30] and Heisenberg[31] spins. The Ising model could not explain the temperature dependence of the susceptibility above 30 K, while the Heisenberg model gave a fair agreement. The g and J/k values giving the best fit are 2.00 and -33 K, respectively (Fig. 4). On the other hand, the molecular field theory[32,33] gives the relationships among θ, T_N, and J values. If a single J value is assumed for three O–Se–O paths, the observed θ gives $J/k = -31$ K, agreeing excellently with the value obtained by the Heisenberg model. The results also show that the difference in magnitude of superexchange interactions is very small. The ratio $|\theta|/T_N$ was estimated to be 3.0 using the above J value, which is comparable with the observed one (3.5). The g value of 2.00 seems smaller for a Cu(II) compound and the difference between two J/k values appears too small to give the magnetic behaviour of a linear spin system. An explanation for this may be as follows. Since each SeO_3^{2-} anion intermediates three copper(II) ions antiferromagnetically, the spin at each copper(II) cation is required to be "up" by the Cu′–O 1–Se–O 3–Cu interaction and at the same time to be "down" by the Cu″–O 2–Se–O 3–Cu interaction. The two interactions may be almost cancelled to give the observed features. The treatment is only approximate and the individual values cannot be taken to be accurate. Agreement as a whole indicates that the explanation is adequate.

In this mechanism the σ-bonds play an important role for the superexchange interaction. In $Ba_2Cu(HCOO)_6 \cdot 4H_2O$[34] and a blue modification and a royal blue one of $Cu(HCOO)_2$[26] the σ-bonds of an $HCOO^-$ anion induce a ferromagnetic spin ordering and the π-bonds an antiferromagnetic one. If these schemes for formates are applied to the present system, $CuSeO_3 \cdot 2H_2O$ should be ferromagnetic, which is contrary to observation. In the nuclear spin-spin coupling in a high resolution NMR,[35] the sign of the multibond coupling is known largely to depend on the molecular conformation even in the saturated hydrocarbons, as well as on the number of intermediate bonds. It means that the spin-spin coupling of the magnetic ion depends on the species of the intervening oxo-anions and on their conformations in the crystal structure. In fact, the very simple model without any account for the conformation leads to the antiferromagnetic coupling of two Cu(II) spins through only the σ-bonds of SeO_3^{2-} anion. Thus, it is not astonishing that $CuSeO_3 \cdot 2H_2O$ shows antiferromagnetic behaviour without any superexchange interaction through π-bonds of the anion.

The authors wish to thank Prof. Y. Shimura and Dr. S. Kaizaki, Osaka University, for their help in the measurement of diffuse reflectance spectra.

A New Method for the Precise Measurement of the Polarographic Current and Its Application in Digital Polarography

Sadato SAKURAI, Hideko SHIRAI, and Eiji NIKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo 113

(Received October 31, 1972)

In order to increase polarographic precision and sensitivity, the oscillopolarographic current was digitized and stored in a 100-channel pulse-height analyzer (PHA) operated in the multi-scaler mode (MS mode). An oscillopolarograph which could sweep the DC potential rapidly was combined with the PHA. The digitized oscillopolarographic current was repeatedly stored in the PHA, so that the statistical noise was reduced and the signal-to-noise ratio of the oscillopolarographic current was increased. Also, the drift due to the change in the experimental conditions was removed effectively by shortening the measurement time. Therefore, precision was efficiently improved by means of accumulation. The relative deviation was 0.25% at the concentration of the 5×10^{-7} M cadmium ion. As an example of the application, trace amounts of copper, lead, and cadimum in 99.99% indium metal were analyzed.

Recent developments in electronics have resulted in various improvements of polarography, such as those of radio-frequency polarography and pulse polarography. Besides, digital accumulation and processing[1] have been introduced to permit a high rate of data collection and greater accuracy, resolution, and precision. A small computer[2] has been employed on-line in an electrochemical system to provide semi-automated polarographic measurements.

Recently several reports have been published concerned with the precise measurement of the polarographic current at a low concentration using an accumulator or a digital computer. Perone and Harrar *et al.*[3] applied a rapid potential sweep and thus repeatedly accumulated the polarographic current. The relative deviation of their result was 0.1% at the concentration of 1 mM and 1.3% at the concentration of 2×10^{-7} M. Matsuda and Tamamushi[4] reported that the long-term integration of diffusion currents was reasonably accurate even at concentrations as low as 10^{-6} M. Shults, Fisher and Schaap[5] demonstrated that a precision and accuracy of about 0.1% could be obtained by using the mode of comparative polarography and by measuring the difference between the diffusion currents of unknown and standard solutions. Lingane[6] measured the diffusion current up to 0.1% and integrated it over an exactly known time which covered 50 or more mercury drops.

The detection limit in square-wave polarography is about 10^{-8} M, restricted by the capillary effect. If the statistical noises arising from the power supply, the capillary effect, etc. are sufficiently reduced by means of accumulation, a sensitivity of more than 10^{-8} M can be expected.

In this experiment, the oscillopolarographic current was digitized and a train of pulses proportional in number to the current was accumulated in the PHA. The statistical noise decreases in proportion to $1/\sqrt{n}$, where n is the number of repeated samplings. The coefficient of the variation in the oscillopolarographic current was improved by the accumulation.

Experimental

General. A block diagram of the apparatus is shown in Fig. 1. The rapid DC potential sweep, on which the square-wave voltage is superimposed, is used; the alternating faradaic current is measured through the gate circuit, which is used to eliminate the charging current. After the alternating faradaic current is rectified, amplified, and converted into the voltage, the output voltage is changed into a train of pulses proportional in number to its voltage by using a digital voltmeter. The train of pulses is stored in the 100-channel PHA. The beginning of the channel scanning of the PHA is synchronized with the start of the potential sweep, so that each oscillopolarographic current in the same state of the mercury drops and at the same applied potential is repeatedly stored in the same channel of the PHA. Therefore, the channel advance corresponds to the potential sweep

and the accumulated numbers of the pulses correspond to the oscillopolarographic current at a given value of the applied potential. The numbers of pulses stored in each channel of the PHA are printed out by a digital printer at the end of a predetermined number of scannings. The digital data thus obtained can be plotted as is shown in Fig. 5. The time sequence of the operation is shown in Fig. 2.

Instrumentation. *Oscillopolarograph (Yanagimoto digital polarograph PE 21)*: An oscillographic square-wave polarogram and an oscillographic direct-current polarogram can be measured. A mercury drop is detached by the drop dislodger, and the start time of the potential sweep is synchronized with the dislodgement of the mercury drop. The oscillopolarographic current is converted into voltages from 0 mV to +50 mV, which is proportional to its current.

Digital Voltmeter (Takeda Riken 6154 B digital voltmeter): In this experiment, the digital voltmeter is used as a voltage-to-frequency converter. The output voltage from the oscillopolarograph is introduced into the digital voltmeter and then converted into a train of pulses proportional in number to its voltage. This digital voltmeter converts the input voltage of 100 mV into the frequency of 10 kHz. The height of the output pulse from the digital voltmeter is 4 V, and the rise time of the pulse is about 1 μs.

Multichannel Pulse-height Analyzer: A Toshiba 100-channel PHA (EDS-34206) is connected to a plug-in unit M (type UE 730-007); thus, the measurement can be performed in the multi-scaler mode (MS mode). The train of pulses from the digital voltmeter is stored in the PHA from the lst channel to the 100th channel. In Fig. 3 the time sequence of the operation of the PHA is shown. The capacity of the PHA is (10^5-1)pulses/channel.

Experimental Conditions. In order to reduce the fluctuation of the current arising from the depleting effect,[7] which was caused by the fact that the concentration of the depolarizer in the vicinity of the electrode decreased during the electrolysis, the actual measurement was started after electrolysis over 10 mercury drops using the same potential

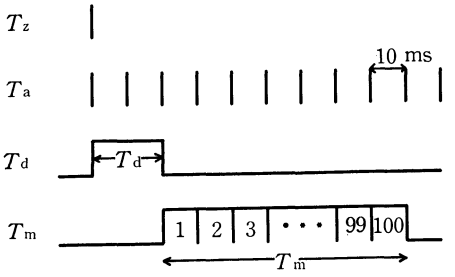

Fig. 3. The time sequence of the operation of the PHA.

T_a: The signal for the channel advance.
T_d: The delay time of the scanning of the PHA.
T_m: The operating time of the PHA. When the sweep reaches the 100th channel, it goes back to the 1st channel and waits for the next T_z signal.
All the time of the PHA refers to the clock signal generated by a 1 M Hz Xtal oscillator.

sweep as the actual measurement. The decrease due to the depleting effect was most marked at the beginning of the electrolysis; it reached a constant value after 10 mercury drops.[7] Also, gelatin was added at 0.01% in order to decrease the variation in the current arising from the fluctuation of the solution. The temperature was controlled within ±0.01 °C by surrounding the cell with lagging material in order to limit the variation in the oscillopolarographic current due to temperature change within 0.015%. All the solutions were deoxygenated by passing pure nitrogen through for at least 10 min.

Results and Discussion

It is impossible to avoid the error arising from quantization when the train of pulses is sampled repeatedly at definite intervals. The relation between the coefficient of the variation and the number of repeated samplings is shown in Fig. 4. In the actual measurement, other statistical noises arising from the power supply, the capillary effect, etc. are added. In order to measure the oscillopolarographic current at a low concentration, the residual current had to be elimi-

nated. At first, the solution of the supporting electrolyte was scanned and the digitized residual current was stored in the PHA, whose channels were related to the applied potential. Next, after changing the sign of the memory, the solution containing the supporting electrolyte plus the sample was scanned under the same conditions as in the first scan. Consequently, an oscillopolarogram in which the residual current had been subtracted could be obtained. Table 1 shows the precision of the current measurements on solutions containing various concentrations of the cadmium ion. The relative deviation was 0.05% at a concentration of the 1 mM cadmium ion; this value was obtained by integrating the oscillographic square-wave polarographic current over 10 mercury drops. The relative deviation was 0.25% at a concentration of the 5×10^{-7} M cadmium ion; this value was obtained by accumulating the oscillographic square-wave polarographic current over 25 mercury drops. It is evident that the statistical noise was reduced efficiently by accumulation. The change in the time constant of the square-wave oscillator, which changed the wave form of the superimposed SW voltage, had little effect on the precision of the current measurement (Table 2). The change in the amplitude of the superimposed SW voltage also had little effect on the precision of the current measurement (Table 3). Therefore, it is profitable to use the large amplitude of the superimposed SW voltage (30 mV), because the square-wave polarographic current is in proportion to the amplitude of the superimposed SW voltage. Table 4 indicates that the precision of the current measurement decreased as the rate of the potential sweep increased. Therefore, the sweep rate of 0.2 V/s was used in this experiment. As an example of application, trace amounts of copper, lead, and cadmium in 99.99% indium metal were analyzed. The indium metal was dissolved in concentrated nitric acid. The solution which contained the indium ion was heated until the indium nitrate had crystallized. The reduction potentials of the cadmium ion and the indium ion are

close together, and the waves overlap in almost all the supporting electrolytes. However, indium forms a complex with phosphate ions in phosphoric acid,[8] so the half-wave potential of the indium complex deviates from that of the indium ion. Fig. 5 shows an oscillographic square-wave polarogram of the cadmium ion, the lead ion, and the indium ion in 0.025 M indium nitrate plus 1 M phosphoric acid. The appearance of the indium peak may be attributed to the fact that the quantity of indium is so large that the complex formation can not mask the indium peak completely.

8) A. Holroyd and J. E. Salmon, *J. Chem. Soc.*, **1956**, 269.

However, if 0.54 M nitric acid is added, the cadmium peak appears distinctly (Fig. 5). The half-wave potentials of indium and cadmium differ by 63 mV in 1 M phosphoric acid, while the half-wave potentials differ by 88 mV in 1 M phosphoric acid plus 0.54 M nitric acid. In Figs. 6 and 7, oscillographic square-wave polarograms of the copper(I) ion and the lead ion in 0.025 M indium nitrate plus 1 M phosphoric acid are shown. The oscillographic square-wave polarograms of the supporting electrolyte are shown at the same time. It is obvious that very small amounts of the copper(I) ion and the lead ion are present in 1 M phosphoric acid. In Fig. 8 the relation between the accumulated numbers of the pulses and the concentrations of the cadmium ion is shown. Table 5 shows the quantitative analytical data of trace amounts of copper, lead, and cadmium in 99.99% indium metal.

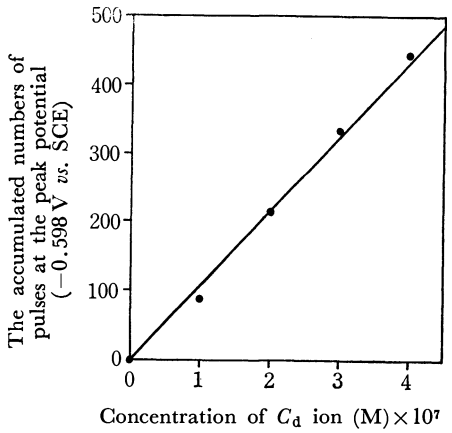

Fig. 8. The relation between the concentrations of cadmium ion and the accumulated numbers of pulses.

Table 5. The quantitative analytical data of trace amounts of copper, lead, and cadmium in 99.99% indium metal

Metal	Contents (ppm)
Cu	16
Pb	129
Cd	6

Conclusion

As has been indicated in the quantitative analysis of a trace amount of cadmium in indium metal, the precise measurement of 10^{-7} M could be performed in this experiment. If the statistical noise is decreased sufficiently, a sensitivity as high as 10^{-8} M or even higher can be expected in the near future.

Investigation on Low-spin Cobalt(II) Complexes. III. Structural, Optical and Magnetic Properties of Five-coordinate Complexes

Yuzo NISHIDA and Hideharu SHIMOHORI

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received December 18, 1972)

ESR and reflectance spectra of low-spin five-coordinate cobalt(II) complexes $[CoXdpe_2]Y$, where dpe represents 1,2-bis(diphenylphosphino)ethane and X,Y are Cl^-, Br^-, NCS^-, NO_3^- and ClO_4^- anions, were measured. From the results it was inferred that the structures of $[CoCldpe_2]ClO_4$ and $[CoBrdpe_2]ClO_4$ are distorted trigonal bipyramids whereas those $[CoNCSdpe_2]ClO_4$ and $[CoNO_3dpe_2]NO_3$ are square pyramids.

In the last few years several papers have appeared on the low-spin five-coordinate cobalt(II) complexes,[1-3] the syntheses, electronic spectra and magnetic data of which have increased. However, ESR data are considered to be most reliable for understanding the relation between structure, electronic spectrum and magnetic moment of these complexes. We measured the ESR and reflectance spectra of low-spin five-coordinate cobalt(II) complexes $[CoXdpe_2]Y$, where dpe represents 1,2-bis(diphenylphosphino)ethane and X,Y are Cl^-, Br^-, NCS^-, NO_3^- and ClO_4^- anions. From results we discussed their structural, optical and magnetic properties.

Experimental

1,2-bis(diphenylphosphino)ethane, dpe, was prepared by the method of Hewertson and Watson.[4]

$[CoXdpe_2]Y$ (X=Cl^-, Br^-, NCS^-, Y=ClO_4^- and X=NO_3^-, Y=NO_3^-) were prepared by the method of Sacco and Gorieri.[5] They reported a brown crystal for $[CoNCSdpe_2]ClO_4$ but we obtained a green one. (Found: C, 62.94; H, 5.18; N, 1.44. Calcd for $[CoNCSdpe_2]ClO_4$: C, 62.80; H, 4.78; N, 1.38) $[CoBrdpe_2]ClO_4 \cdot 2CHCl_3$ was obtained as a red prism by recrystallization of green $[CoBrdpe_2]ClO_4$ from a hot chloroform solution. (Found: C, 50.88; H, 4.10%. Calcd for $[CoBrdpe_2]ClO_4 \cdot 2CHCl_3$: C, 50.92; H, 3.96%).

The ESR spectra were measured with a JEOL ESR-apparatus model JES-MX-3X at various temperatures using X- and K-bands. Manganese(II) doped in MgO was used as a standard marker. The infrared spectra were recorded with a Hitachi EPI-S2 spectrophotometer in the region 4000~650 cm^{-1} on a KBr disk. The reflectance spectra were measured with a Hitachi EPS-3T recording photometer at room temperature.

Theoretical

For the five-coordinate metal complexes, the two geometries of the highest symmetry are (a) trigonal bipyramid(D_{3h}) and (b) square pyramid(C_{4v}). For (a) the chromophore has C_{3v} symmetry if the axial ligands are not the same and/or the metal lies in the plane of equatorial ligands. For (b) the chromophore naturally retains C_{4v} symmetry, even when the metal lies out of the plane of four basal ligands (it generally lies above it).

Splittings of 3d orbitals in both five-coordinate chromophores have been studied experimentally and theoretically.[6-8] Application of the angular overlap model to MX_5 chromophores of trigonal bipyramidal and square pyramidal geometries gives the pattern shown in Fig. 1 for the energy of antibonding "d" molecular orbital.[9] The crystal field model gives a similar pattern.

Since the electronic structure of a cobalt(II) ion is $3d^7$, low-spin trigonal bipyramidal cobalt(II) complexes should be more or less distorted from a perfect D_{3h} symmetry, because of the Jahn-Teller effect on the degenerate ground state.

The probable ground state of low-spin cobalt(II) complex with a distorted trigonal bipyramidal geometry

Table 1. Electronic repulsion energy of low-spin five-coordinate cobalt(II) complexes

$\|(z^2)^+(z^2)^-(xy)^+\|$	$3F_0-8F_2+33F_4$
$\|(z^2)^+(z^2)^-(x^2-y^2)^+\|$	$3F_0-8F_2+33F_4$
$\|(z^2)^+(z^2)^-(yz)^+\|$	$3F_0+7F_2-42F_4$
$\|(z^2)^+(z^2)^-(xz)^+\|$	$3F_0+7F_2-42F_4$
$\|(x^2-y^2)^+(x^2-y^2)^-(z^2)^+\|$	$3F_0-8F_2+33F_4$
$\|(x^2-y^2)^+(x^2-y^2)^-(xy)^+\|$	$3F_0+12F_2-67F_4$
$\|(x^2-y^2)^+(x^2-y^2)^-(yz)^+\|$	$3F_0-3F_2+8F_4$
$\|(x^2-y^2)^+(x^2-y^2)^-(xz)^+\|$	$3F_0-3F_2+8F_4$

is $(d_{z^2})^2(d_{x^2-y^2})^1$ or $(d_{z^2})^2(d_{xy})^1$, if we assume that in the d^3 configurations d_{z^2} remains the lowest orbital for the vacancies and consequently in a S=1/2 configuration is doubly occupied.

On the other hand in the case of a square pyramidal cobalt(II) complex, the predicted ground state is only $(d_{xy})^2(d_{z^2})^1$. No other states are likely for the ground state, even though the electronic repulsion energy is taken into account.

We calculated theoretical three g-values for both predicted ground states according to the methods given previously.[10] For a trigonal bipyramidal complex, we tentatively assumed the ground state to be $(d_{z^2})^2(d_{x^2-y^2})^1$, but found that the same results were also obtained for $(d_{z^2})^2(d_{xy})^1$.

1) The case where the ground state $(d_{z^2})^2(d_{x^2-y^2})^1$ is assumed.

By applying the spin-orbit interaction Hamiltonian $k\zeta ls$ to the zeroth-order Kramers doublet $(d_{z^2})^2(d_{x^2-y^2}^+)^1$ and $(d_{z^2})^2(d_{x^2-y^2}^-)^1$ as a perturbation, the ground state doublets are written by means of perturbation theory as follows.

$$\left.\begin{aligned}\Psi_a^+ &= N_a\{|(d_{z^2})^2(d_{x^2-y^2}^+)^1| - ika_1|(d_{z^2})^2(d_{xy}^+)^1| \\ &\quad + \frac{1}{2}ika_2|(d_{z^2})^2(d_{yz}^-)^1| - \frac{1}{2}ka_3|(d_{z^2})^2(d_{xz}^-)^1|\} \\ \Psi_a^- &= N_a\{|(d_{z^2})^2(d_{x^2-y^2}^-)^1| + ika_1|(d_{z^2})^2(d_{xy}^-)^1| \\ &\quad + \frac{1}{2}ika_2|(d_{z^2})^2(d_{yz}^+)^1| + \frac{1}{2}ka_3|(d_{z^2})^2(d_{xz}^+)^1|\}\end{aligned}\right\} \quad (1)$$

where N_a, ζ and k represent normalization constant, one-electron spin-orbit coupling constant for 3d orbitals and orbital reduction factor, respectively. Coefficients a_1, a_2 and a_3 denote $\zeta/\Delta[(x^2-y^2)-xy]$, $\zeta/\Delta[(x^2-y^2)-yz]$ and $\zeta/\Delta[(x^2-y^2)-xz]$, respectively, where $\Delta[(x^2-y^2)-xy]$ denotes the energy difference between the states $(d_{z^2})^2(d_{x^2-y^2})^1$ and $(d_{z^2})^2(d_{xy})^1$. Configurations which do not contribute to g-values were neglected. By means of the usual methods,[10] we obtain the following results in the first order.

$$\left.\begin{aligned}g_z &= 2N_a^2[1-4k^2a_1] \\ g_x &= 2N_a^2[1-k^2a_2] \\ g_y &= 2N_a^2[1-k^2a_3]\end{aligned}\right\} \quad (2)$$

This indicates that $g_z > g_x \approx g_y > 2$, since a_1, a_2 and a_3 have negative values.

2) The case where the ground state $(d_{xy})^2(d_{z^2})^1$ is assumed.

By the same procedure we obtained the perturbed ground state wave functions

$$\left.\begin{aligned}\Psi_b^+ &= N_b\left\{|(d_{xy})^2(d_{z^2}^+)^1| + \frac{\sqrt{3}}{2}ikb_1|(d_{xy})^2(d_{yz}^-)^1| \right. \\ &\quad \left. + \frac{\sqrt{3}}{2}ikb_2|(d_{xy})^2(d_{xz}^-)^1|\right\} \\ \Psi_b^- &= N_b\left\{|(d_{xy})^2(d_{z^2}^-)^1| + \frac{\sqrt{3}}{2}ikb_1|(d_{xy})^2(d_{yz}^+)^1| \right. \\ &\quad \left. - \frac{\sqrt{3}}{2}ikb_2|(d_{xy})^2(d_{xz}^+)^1|\right\}\end{aligned}\right\} \quad (3)$$

which include only terms which contribute to g-values. Three g-values are calculated as follows.

$$\left.\begin{aligned}g_z &= 2N_b^2 \\ g_x &= 2N_b^2[1-3k^2b_1] \\ g_y &= 2N_b^2[1-3k^2b_2]\end{aligned}\right\} \quad (4)$$

where N_b, b_1 and b_2 represent normalization constant, $\zeta/\Delta[z^2-yz]$ and $\zeta/\Delta[z^2-xz]$, respectively. g_z is shown to be nearly equal to 2, and g_x and g_y greater than 2.

It is thus predicted that the two possible geometries of low-spin five-coordinate cobalt(II) complexes can be discriminated by means of ESR spectroscopy.

Results and Discussion

Structures and ESR Spectra. Figure 2 shows the ESR spectra of polycrystalline samples of $[CoCldpe_2]ClO_4$ and $[CoNCSdpe_2]ClO_4$, obtained at room temperature using the K-band. For $[CoCldpe_2]ClO_4$, $g_\parallel=2.345$, $g_\perp=2.097$, for $[CoNCSdpe_2]ClO_4$, $g_\parallel=1.998$, $g_\perp=2.225$ are calculated according to the methods of Kneubühl[11] and Sands.[12] The ESR data $[CoXdpe_2]Y$ are summarized in Table 2. It is evident that the ESR patterns can be divided into two classes, (A) complexes with the relation $g_\parallel > g_\perp$ and (B) those with the relation $g_\parallel < g_\perp$.

We see from Eqs. (2) and (4) that the structures of (A) $[CoCldpe_2]ClO_4$ and $[CoBrdpe_2]ClO_4$ are distorted trigonal bipyramids, whereas those (B) $[CoNCSdpe_2]ClO_4$ and $[CoNO_3dpe_2]NO_3$ are square py-

ramids. This seems to be in line with the results of electronic spectra. The reflectance spectra of A and B complexes shown in Figs. 3 and 4, respectively, are seen to differ completely. The reflectance spectra of A complexes are very similar to the spectrum of [CoClQP]BPh$_4$,[13] whose structure has been determined by X-ray analysis[14] to be trigonal bipyramid, while those of B complexes are similar to that of [CoBrPNNP]BPh$_4$[15] with a square pyramidal geometry. A good agreement was observed between the results of ESR, electronic spectra and the structures of low-spin five-coordinate cobalt(II) complexes.

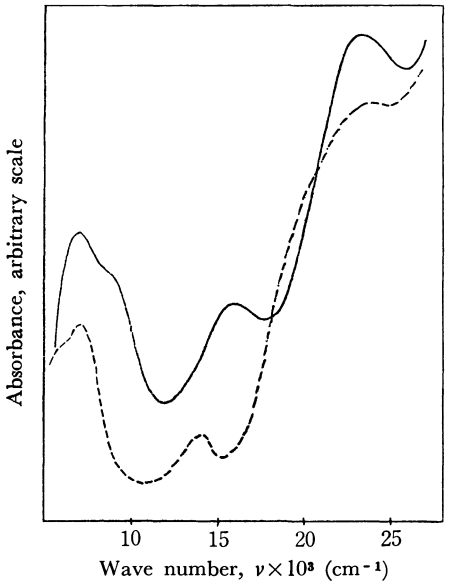

Fig. 4. Reflectance spectra of [CoNCSdpe$_2$]ClO$_4$ (——) and [CoNO$_3$dpe$_2$]NO$_3$ (----).

Although ESR studies of low-spin square pyramidal cobalt(II) complexes have been published, this is the first report on an ESR spectrum of a distorted trigonal bipyramidal cobalt(II) complex. Our ESR data of [CoCldpe$_2$]ClO$_4$ and [CoBrdpe$_2$]ClO$_4$ are similar to those of [CoCldpe$_2$]Cl and [CoBrdpe$_2$]Br, by Horrocks, Van Vecke and Hall,[16] who discussed them on the assumption that the ground state of the latter complexes is $(d_{xy})^2(d_{x^2-y^2})^1$.

Electronic Spectra. In order to interpret the electronic spectra A complexes, the energy difference between the d_{xy} and the $d_{x^2-y^2}$ orbitals, degenerate in the perfect D_{3h} symmetry should be determined. This can be estimated from the results of ESR spectra.

From Eq. (2) we obtain the following result for [CoCldpe$_2$]ClO$_4$.

$$8N_a^2k^2\zeta/\Delta[(x^2-y^2)-xy] \simeq 0.345$$

If we assume N_a^2, $k^2 \approx 1$ and use the value of free ion, $-515\ cm^{-1}$ for ζ, $\Delta[x^2-y^2)-xy]$ is calculated to be $11800\ cm^{-1}$. However, as it is known that k is reduced from unity in the metal complexes[17] and also ζ is reduced from free ion value, it is reasonable to assign the peak at $6500\ cm^{-1}$ and the shoulder at

10000 cm^{-1} for the electronic transitions, $d_{xy} \rightarrow d_{x^2-y^2}$ and $d_{yz}, d_{xz} \rightarrow d_{x^2-y^2}$, respectively, on the basis of the results of ESR, the splittings of 3d orbitals and the selection rules of the electric dipole transition in D_{3h} symmetry (Table 3).

The electronic spectra of a low-spin trigonal bipyramidal nickel(II) complex show two peaks in the range 15000—25000 cm^{-1}. One peak of large intensity ($\log \varepsilon \sim 3$) in the lower energy region and the another peak of small intensity($\log \varepsilon \sim 2$) in the higher energy region have been assigned to the electronic transitions d_{xy}, $d_{x^2-y^2} \rightarrow d_{z^2}$ and d_{yz}, $d_{xz} \rightarrow d_{z^2}$, respectively.[18] This remarkable difference in the transition probability of two peaks can be explained in terms of selection rules for these electric dipole transitions (Table 3). Using the above results, two peaks at 14000 and 20000 cm^{-1} observed for A complexes can be assigned to the electronic transitions $d_{x^2-y^2} \rightarrow d_{z^2}$ and $d_{xy} \rightarrow d_{z^2}$, respectively. The energy difference between two peaks (14000 and 20000 cm^{-1}) is about 6000 cm^{-1}, which is consistent with the conclusion that the peak at 6500 cm^{-1} can be assigned to the electronic transition $d_{xy} \rightarrow d_{x^2-y^2}$. The peaks due to the electronic transitions $d_{yz}, d_{xz} \rightarrow d_{z^2}$ are observed at 23000 cm^{-1}. Our assignment is partially the same as that of Norgett *et al.*[19] for the complex $[CoNO_3QP]^+$, but they did not observe the electronic transition $d_{xy} \rightarrow d_{x^2-y^2}$.

In order to interpret the electronic spectra of B complexes, we used the results of the electronic spectra of square planar complex $[Codpe_2](ClO_4)_2$ and distorted octahedral complex $[Codgm_2(Ph_3P)_2]$,[20] since the assumed ground state of the latter two complexes is $(d_{xy})^2(d_{z^2})^1$.[21] The absorption peak due to the electronic transition $d_{z^2} \rightarrow d_{xy}$ is observed at 22000 cm^{-1} and 10500 cm^{-1} for $[Codpe_2](ClO_4)_2$ and $[Codgm_2(Ph_3P)_2]$, respectively. It is therefore reasonable to assign the peaks at 16000 cm^{-1} of $[CoNCSdpe_2]ClO_4$ and 14000 cm^{-1} of $[CoNO_3dpe_2]NO_3$ to the electronic transition $d_{z^2} \rightarrow d_{xy}$. Other peaks at 7000, 9000 and 23000 cm^{-1} of $[CoNCSdpe_2]ClO_4$ are assigned to the electronic transitions $d_{yz}, d_{xz} \rightarrow d_{z^2}$, $d_{x^2-y^2} \rightarrow d_{z^2}$ and $d_{yz}, d_{xz}, d_{x^2-y^2} \rightarrow d_{xy}$, respectively. The intensities of these peaks are also elucidated in terms of selection rules of electric dipole transitions in C_{4v} symmetry (Table 3).

Novel Configurational Change. We found a novel configurational change by adduct formation of chloroform for the complex $[CoBrdpe_2]ClO_4$. From the results of ESR and electronic spectra, the structure of green $[CoBrdpe_2]ClO_4$ is assumed to be a distorted trigonal bipyramid. When this green complex was recrystallized from a hot chloroform solution, red prisms were obtained. The result of elemental analysis is compatible with that of the adduct of chloroform of the parent complex $[CoBrdpe_2]ClO_4 \cdot 2CHCl_3$. The results of infrared spectra of the green and the red complexes also support the empirical formula. Two molecules of chloroform of the red complex can be removed at 110 °C in a vacuum, the color turning green. The ESR and reflectance spectra are shown in Figs. 5 and 6, respectively. It is estimated that the structure of the red complex is a distorted square pyramid and ground state is $(d_{xy})^2(d_{z^2})^1$, since the reflectance spectrum is quite similar to the spectra of B complexes and the ESR spectrum shows a small in-plane anisotropy.

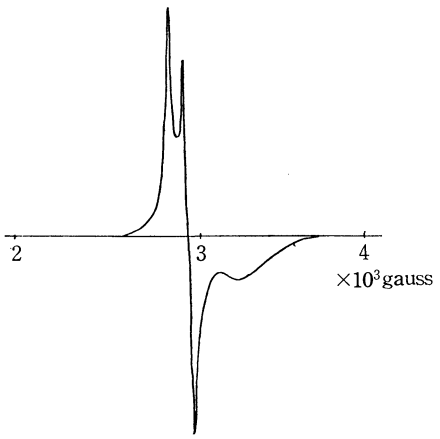

Fig. 5. ESR spectrum of $[CoBrdpe_2]ClO_4 \cdot 2CHCl_3$ polycrystalline sample at room temperature (X-band).

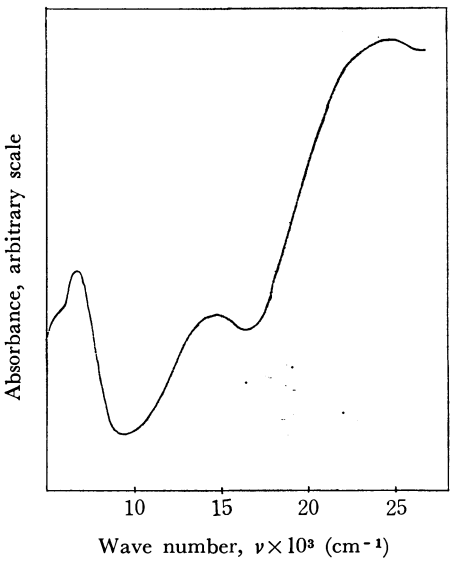

Fig. 6. Reflectance spectrum of $[CoBrdpe_2]ClO_4 \cdot 2CHCl_3$.

ESR Spectra of Glasses. The ESR spectra of $[CoCldpe_2]ClO_4$, $[CoNCSdpe_2]ClO_4$ and $[CoNO_3dpe_2]NO_3$ in CH_2Cl_2 glasses at 150 K are similar to those of polycrystalline samples. However, the situation differs for $[CoBrdpe_2]ClO_4$. The ESR spectrum of green $[CoBrdpe_2]ClO_4$ in CH_2Cl_2 glass at 150 K shows a typical rhombic symmetry, very similar to that of red $[CoBrdpe_2]ClO_4 \cdot 2CHCl_3$ in CH_2Cl_2 glass at 150 K (Fig. 7). This might be attributed to the existence of both, the trigonal bipyramid and the square pyramid in a solution.

Magnetic Moments. The magnetic moments of these low-spin five-coordinate cobalt(II) complexes $[CoXdpe_2]Y$ fluctuate in the range 2.0—2.3 B.M., which is lower than that of square planar complexes, and higher than that of the octahedral complexes.[10] This can be elucidated according to the equation of Van Vleck, using the results of ESR and electronic spectra.

Conclusion

It was confirmed that two possible geometries, the trigonal bipyramid and the square pyramid, of low-spin five-coordinate cobalt(II) complexes can be discriminated by means of ESR spectroscopy.

The electronic spectra of both geometries have been characterized by means of ESR spectra and selection rules for electric dipole transitions. The absorption peak due to the electronic transition $d_{xy} \rightarrow d_{x^2-y^2}$ of a trigonal bipyramidal complex has been identified from the result of an ESR spectrum.

Acknowledgment: We wish to express our sincere thanks to Professor S. Kida for his valuable discussion. We also thank Professor S. Misumi and Dr. T. Isobe for use of the ESR apparatus and Professor Y. Murakami and Dr. Y. Matsuda for ESR measurement by the K-band.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2410—2416 (1973)

Metal Complexes Containing Six-membered Chelate Rings. III. Preparation and Structure of Mono- and Bis(2,4-Pentanediamine)cobalt(III) Complexes Containing Acetylacetonate or Oxalate Ion[1]

Fujio Mizukami, Haruko Ito, Junnosuke Fujita, and Kazuo Saito

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received December 18, 1972)

New cobalt(III) complexes $[Co(acac)_2(2,4\text{-ptn})]^+$, $[Co(acac)(2,4\text{-ptn})_2]^{2+}$ and $[Co(ox)(2,4\text{-ptn})_2]^+$ have been synthesized, resolved into optical isomers and their structures determined; 2,4-ptn=optically active (*RR* and *SS*) and *meso* (*RS*) 2,4-pentanediamine, acac=acetylacetonate ion, ox=oxalate ion. The patterns of circular dichroism spectra of these complexes in the first absorption band region are very similar to those of the corresponding α-diamine cobalt(III) complexes.

Kawaguchi *et al.*[2] recently determined the absolute configuration of $(-)_{589}$-$[Co(acac)(tn)_2]^{2+}$ (tn=trimethylenediamine) as *Δ*. This complex shows a main circular dichroism (CD) band with positive sign in the first absorption band region. The result agrees with that of a number of chiral complexes of cobalt(III) containing such five-membered chelate rings as ethylenediamine (en). The CD curve of *Δ*-$[Co(tn)_3]^{3+}$ is known to differ greatly from that of *Δ*-$[Co(en)_3]^{3+}$ in the first absorption band region.[3] Mason[4] proposed a new regional rule for a metal complex to account for such a difference. We have reported[1] that the *tris*-cobalt(III) complexes of *meso*(*RS*)- and optically active (*RR* or *SS*)-2,4-pentanediamine showed CD curves differing from those of both $[Co(en)_3]^{3+}$ and $[Co(tn)_3]^{3+}$, while the optically active 2,4-pentanediamine chelate gave vicinal contribution to the CD similar to that of the optically active propylenediamine (pn) chelate. In order to elucidate the optical activity of metal complexes, therefore, it is desirable to accumulate CD data on those complexes containing six-membered chelates.

This paper deals with preparation of optically active cobalt(III) complexes containing 2,4-pentanediamine and acetylacetonate or oxalate ion and their stereochemistry on the basis of CD and pmr spectra.

Experimental

Optically active-(*RR* and *SS*) and *meso*-(*RS*) 2,4-pentanediamine were synthesized according to the method reported previously.[5]

Δ-$(-)_{546}$-$[Co(acac)_2(RR\text{-}2,4\text{-}ptn)](ClO_4)$. This was synthesized according to a method similar to that for the cor-

responding ethylenediamine complex.[6] Charcoal (1.5 g) and *RR*-2,4-pentanediamine (0.66 g) were added to a 20% aqueous methanol solution (80 ml) of $Na[Co(acac)_2(NO_2)_2]\cdot 5H_2O$[7] (3 g) with stirring at room temperature. After 20 min, the charcoal was filtered off and washed with 10 ml of water. The filtrate and washings were combined, and then evaporated to about 35 ml at about 50 °C under reduced pressure. The solution was passed through a column containing cation exchanger Dowex 1-X4 in sodium form. The column was washed with water to remove tris(acetylacetonato)cobalt(III). At this stage the column gave two separated bands, violet and red ($[Co(acac)(RR\text{-}2,4\text{-}ptn)_2]^{2+}$). The violet band was eluted with 0.3 M sodium perchlorate solution, but the two diastereoisomers did not separate in the column. Thus, each fraction was checked by its CD and absorption spectrum. Fractions showing similar spectral data were collected, and evaporated under reduced pressure. Crystals thus obtained were recrystallized fractionally from water until the CD exhibited a constant curve. Less soluble crystals seemed to be a pseudo-racemate of Δ and Λ isomers, and only the more soluble $(-)_{546}$-isomer was obtained as pure optically active diastereoisomer, its yield appearing to be greater (>60%) than that of the other.

Found: C, 39.01; H, 6.14; N, 5.95%. Calcd for $C_{15}H_{28}N_2O_8CoCl$: C, 39.27; H, 6.15; N, 6.11%.

Δ-$(-)_{589}$-[Co(acac)(RR-2,4-ptn)$_2$](ClO$_4$)$_2$. To an aqueous solution (25 ml) of *trans*-$[CoCl_2(RR\text{-}2,4\text{-}ptn)_2]ClO_4$[1] (1 g) was added sodium acetylacetonate (0.28 g). The solution was stirred for half an hour at 60 °C, and cooled to room temperature. A red powder was precipitated by addition of sodium perchlorate (5 g) in 3 ml of water, filtered off and air dried. More complex was obtained by evaporating the filtrate in a desiccator over diphosphorus pentoxide under reduced pressure. Total yield: 1.2 g (93%). The crude complex was a mixture of Δ and Λ diastereoisomers, and separated into optical isomers by fractional recrystallization from water. Pure $(-)_{589}$-isomer (0.7 g) was obtained, but $(+)_{589}$-isomer was always accompanied by a small amount of $(-)_{589}$-isomer. The pmr spectrum of the crude complex showed that the $(-)_{589}$-isomer was obtained in much greater yield (>75%) than the $(+)_{589}$-isomer.

Found: C, 31.98; H, 6.28; N, 9.94%. Calcd for $C_{15}H_{35}N_4O_{10}CoCl_2$: C, 32.10; H, 6.29; N, 9.98%.

Δ,Λ-[Co(acac)$_2$(RS-2,4-ptn)](ClO$_4$). To a 20% aqueous ethanol solution (125 ml) of $Na[Co(acac)_2(NO_2)_2]\cdot 5H_2O$ (5 g) were added 2.5 g of charcoal and 1 g of *RS*-2,4-pentanediamine. The solution was stirred for 15 min at room temperature, and the charcoal was then filtered off and washed with 30 ml of water. The filtrate and washings were combined, and 35 g of sodium perchlorate in 30 ml of water was added. After a while, a red powder ($[Co(acac)(RS\text{-}2,4\text{-}ptn)_2](ClO_4)_2$) precipitated was filtered off. To the filtrate was added more sodium perchlorate (35 g). On cooling the solution at 0 °C for 1.5 hr, more $[Co(acac)(RS\text{-}2,4\text{-}ptn)_2](ClO_4)_2$ was precipitated almost completely, and then filtered off. The filtrate was cooled again at 0 °C for 5 hr. Purple crystals thus formed were filtered off, and recrystallized from hot ethanol. Yield: 1.3 g.

Found: C, 39.01; H, 6.34; N, 6.40%. Calcd for $C_{15}H_{28}N_2O_8CoCl$: C, 39.27; H, 6.15; N, 6.11%.

Λ-$(+)_{546}$-[Co(acac)$_2$(RS-2,4-ptn)]$^+$. Δ,Λ-$[Co(acac)_2(RS\text{-}2,4\text{-}ptn)](ClO_4)$ (1 g) and sodium hydrogendibenzoyltartrate (0.45 g) (2 : 1 mole ratio) were dissolved in 100 ml of water with stirring at about 80 °C. The solution was cooled gradually to room temperature. A purple powder was precipitated, filtered off, washed with a small amount of water and air dried. (0.7 g). This was dissolved in an appropriate amount of ethanol containing an excess mole of silver perchlorate. The silver hydrogen dibenzoyltartrate was filtered off, and the filtrate was evaporated to dryness. The residue was dissolved again in a small amount of water, and filtered. The filtrate was gradually evaporated to remove less soluble racemic perchlorate which was filtered off occasionally. Evaporation was continued until the ratio of $\Delta\varepsilon$ and ε values of the filtrate became constant. From the final filtrate, more soluble optically active perchlorate was obtained crystalline but it was contaminated with silver perchlorate which could not be removed completely. Thus the quantitative CD curve of this isomer was determined with the aid of the ε values of the racemate.

Δ,Λ-[Co(acac)(RS-2,4-ptn)$_2$](ClO$_4$)$_2\cdot H_2O$. To a suspension of *trans*-$[CoCl_2(RS\text{-}2,4\text{-}ptn)_2]Cl$ (5 g) in 50 ml of water was added an aqueous solution (50 ml) of sodium acetylacetonate (2 g), and this was warmed at 70 °C for 2 hr. After cooling, the solution was filtered and excess sodium perchlorate was added to the filtrate. Red crystals were precipitated, filtered off and recrystallized from water (75 °C). The complex thus obtained was assigned tentatively to *cis-cis* isomer of three possible geometrical isomers. Attempts to resolve this complex into optical isomers with sodium hydrogendibenzoyltartrate were only partially successful.

Found: C, 31.02; H, 6.91; N, 9.36%. Calcd for $C_{15}H_{37}N_4O_{13}CoCl_2$: C, 31.10; H, 6.44; N, 9.67%.

trans-cis-*Δ,Λ-[Co(ox)(RS-2,4-ptn)$_2$]Cl·2H$_2$O (less soluble isomer in water).* A solution of $[Co(NO_2)_2(RS\text{-}2,4\text{-}ptn)_2]NO_2$[8] (2.2 g) and oxalic acid (2 g) in 70 ml of water was warmed at 60—70 °C for 1 hr. To this was added 10 ml of concentrated hydrochloric acid dropwise over a period of 2 hr with warming at 60—70 °C, which was then cooled to room temperature. Pink flakes were filtered off, washed with a small amount of water and ethanol, and air dried. Yield: 1 g. This complex is hardly soluble in water. The other geometrical isomer, *cis-cis*-$[Co(ox)(RS\text{-}2,4\text{-}ptn)_2]Cl$ was highly soluble in water and was obtained from the filtrate.

Found: C, 33.75; H, 7.62; N, 13.25%. Calcd for $C_{12}H_{32}N_4O_6CoCl$: C, 34.09; H, 7.63; N, 13.25%.

Δ-$(-)_{510}$- and Λ-$(+)_{510}$-trans-cis-[Co(ox)(RS-2,4-ptn)$_2$]ClO$_4\cdot 2H_2O$. To a suspension of Δ,Λ-*trans-cis*-$[Co(ox)(RS\text{-}2,4\text{-}ptn)_2]Cl\cdot 2H_2O$ (0.8 g) in 50 ml of water was added silver nitrate (0.3 g) with stirring. After 30 min, silver chloride was filtered off, and washed with 50 ml of water. The filtrate and washings were combined, and stirred with sodium hydrogendibenzoyltartrate (0.38 g) for 2 hr at 60 °C. A pink powder was precipitated upon cooling at room temperature and filtered off to give crude dibenzoyltartrate salt of $(-)_{510}$-isomer (0.6 g). The filtrate was stored to obtain $(+)_{510}$-isomer. The crude dibenzoyltartrate was converted into perchlorate by treating with 99% acetic acid saturated with magnesium perchlorate. The crude perchlorate of $(-)_{510}$-isomer was recrystallized from water fractionally until the CD showed a constant curve. The pure optically active perchlorate is much more soluble in water than the racemate. The filtrate free of pink powder was stirred with an excess of anion exchanger Dowex 1-X4 in

perchlorate form for 4 hr at room temperature. The anion exchanger was filtered off, and washed with a small amount of water. The filtrate and washings were combined, evaporated to 40 ml at 55 °C under reduced pressure and filtered to remove less soluble racemate. Crystals were obtained fractionally from the filtrate by evaporation in a vacuum desiccator over diphosphorus pentoxide. Each fraction was checked by its CD, and pure perchlorate salt of $(+)_{510}$-isomer was obtained by repeating such fractional recrystallization.

Found: C, 29.85; H, 6.47; N, 11.78%. Calcd for $C_{12}H_{32}N_4O_{10}CoCl$: C, 29.61; H, 6.59; N, 11.51%.

*cis-cis-Δ,Λ-[Co(ox)(*RS*-2,4-ptn)$_2$]Cl·6H$_2$O (more soluble isomer in water).* A suspension of *trans*-[$CoCl_2$(*RS*-2,4-ptn)$_2$]Cl (6 g) and oxalic acid (2.1 g) in 110 ml of water was warmed at 70 °C for 2.5 hr and cooled to room temperature. A mixture of *cis-cis*- and *trans-cis*-isomer was obtained, and separated by recrystallization from 50 ml of hot water. More soluble *cis-cis*-isomer was condensed in the filtrate, and crystallized by evaporation in a vacuum desiccator over diphosphorus pentoxide. A pure complex was obtained by recrystallizing from hot water. Yield: *cis-cis*-isomer 7.2 g. *trans-cis*-isomer 0.3 g.

Found: C, 29.14; H, 7.48; N, 11.39%. Calcd for $C_{12}H_{40}N_4O_{10}CoCl$: C, 29.13; H, 8.15; N, 11.32%.

*Δ-(+)$_{510}$- and Λ-(−)$_{510}$-cis-cis-[Co(ox)(*RS*-2,4-ptn)$_2$]-ClO$_4$·4H$_2$O.* To a solution of *Δ,Λ-cis-cis*-[Co(ox)(*RS*-2,4-ptn)$_2$]Cl·6H$_2$O (1 g) in 50 ml of water was added sodium hydrogendibenzoyltartrate (0.44 g) in 20 ml of water. The solution was stirred for 2 hr at 60 °C. A red powder was precipitated upon cooling at room temperature and filtered off. The powder was crude dibenzoyltartrate of $(+)_{510}$-isomer, and converted into perchlorate as in the case for the *trans-cis*-isomer. The filtrate was stirred with anion exchanger Dowex 1-X4 in perchlorate form (3 g) for 4 hr at room temperature. The anion exchanger was filtered off and washed with a small amount of water. The filtrate and washings were combined, and crystallized fractionally by evaporation of the solution in a vacuum desiccator over diphosphorus pentoxide. Fractions which exhibited similar CD were combined and recrystallized from water until the CD of $(-)_{510}$-isomer became constant.

Found: C, 27.99; H, 6.86; N, 10.50%. Calcd for $C_{12}H_{36}N_4O_{12}CoCl$: C, 27.57; H, 6.94; N, 10.72%.

*Λ-(+)$_{546}$-[Co(ox)(*SS*-2,4-ptn)$_2$]ClO$_4$.* A solution of *trans*-[$CoCl_2$(*SS*-2,4-ptn)$_2$]ClO_4 (1 g) and oxalic acid (0.5 g) in 30 ml of water was warmed at 65 °C for 2 hr, and evaporated to dryness at 50 °C under reduced pressure. The residue, a mixture of *Δ* and *Λ* isomer, was separated into diastereoisomers by fractional recrystallization from water. Both isomers were very soluble in water, only less soluble *Λ*-isomer with a constant CD being obtained crystalline.

Found: C, 30.55; H, 6.14; N, 12.19%. Calcd for $C_{12}H_{30}N_4O_9CoCl$: C, 30.75; H, 6.45; N, 11.95%.

Measurements. Visible and ultraviolet absorption spectra were recorded with a Hitachi 124 recording spectrophotometer. The CD curves were recorded with a Model ORD/UV-5 spectrophotometer of JASCO with its CD attachment. PMR spectra in D_2O and in a mixed solvent of D_2O and pyridine were obtained with a Varian T-60 spectrometer using Na-TMS as internal standard. All the measurements were carried out at room temperature.

Results and Discussion

Structure of the Complexes. A pair of diastereoisomers *Δ* and *Λ* are possible for the complexes [Co(acac)$_2$(*RR*-2,4-ptn)]$^+$ and [Co(acac)(*RR*-2,4-ptn)$_2$]$^{2+}$. However, only one pure isomer was obtained for each complex. Purity can be checked by pmr spectra, since the pairs of isomers are not enantiomeric with each other and the stereochemical environments of the protons on the chelate rings may differ for the two diastereoisomers.

Figure 1a shows the pmr spectrum of $(-)_{546}$-[Co(acac)$_2$(*RR*-2,4-ptn)]$^+$ in D_2O. A sharp doublet at 1.2 ppm, a doublet at 2.2 ppm and a singlet at 5.8 ppm are assigned to the methyl signal of the diamine chelate,[1] two kinds of methyl signals Me_1 and Me_2 (Fig. 2b) and the methylene signal of the acetylacetonato chelate,[9] respectively. The appearance of a single doublet of the methyl signal on the diamine chelate may indicate that the complex ion has C_2 symmetry, and that the diamine chelate takes a *λ*-skew boat conformation with two equatorial methyl groups (Fig. 2b). The pmr spectrum of unresolved [Co(acac)$_2$(*RR*-2,4-ptn)]$^+$ is more complex than that of the $(-)_{546}$-isomer, and reveals itself as a mixture of the two diastereoisomers (Fig. 1b).

A similar difference is seen between $(-)_{546}$-[Co(acac)(*RR*-2,4-ptn)$_2$]$^{2+}$ and a mixture of the two diastereoisomers. Each diastereoisomer should have two kinds of methyl groups Me_1 and Me_2 in the diamine chelate, whenever the chelates are in a *λ*-skew boat conformation (Fig. 2g). However, the spectrum of the $(-)_{546}$-isomer at 60 MHz shows no such presence (Fig. 3a). This might be due to the small difference in chemical shift between Me_1 and Me_2. A mixture of the two diastereoisomers gives a quartet signal due to the methyl groups of the diamine chelates. The mole ratio of the two isomers can be determined by the intensity of each peak (Fig. 3b).

[Co(acac)$_2$(*RS*-2,4-ptn)]$^+$ has no symmetry element except C_1, even thought the *RS*-2,4-pentanediamine chelate takes a fixed chair conformation with two equa-

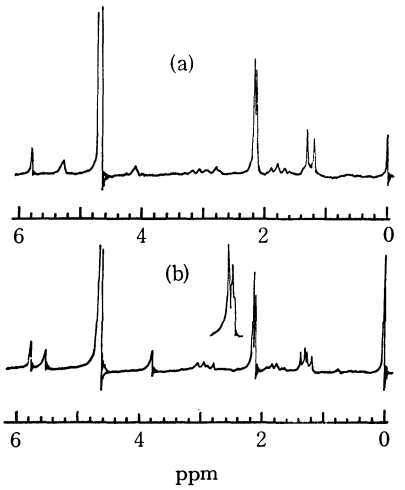

Fig. 1. a) PMR spectra of *Δ*(−)$_{546}$-[Co(acac)$_2$(*RR*-2,4-ptn)]$^+$, b) *Δ,Λ*-[Co(acac)$_2$(*RR*-2,4-ptn)]$^+$ in D_2O.

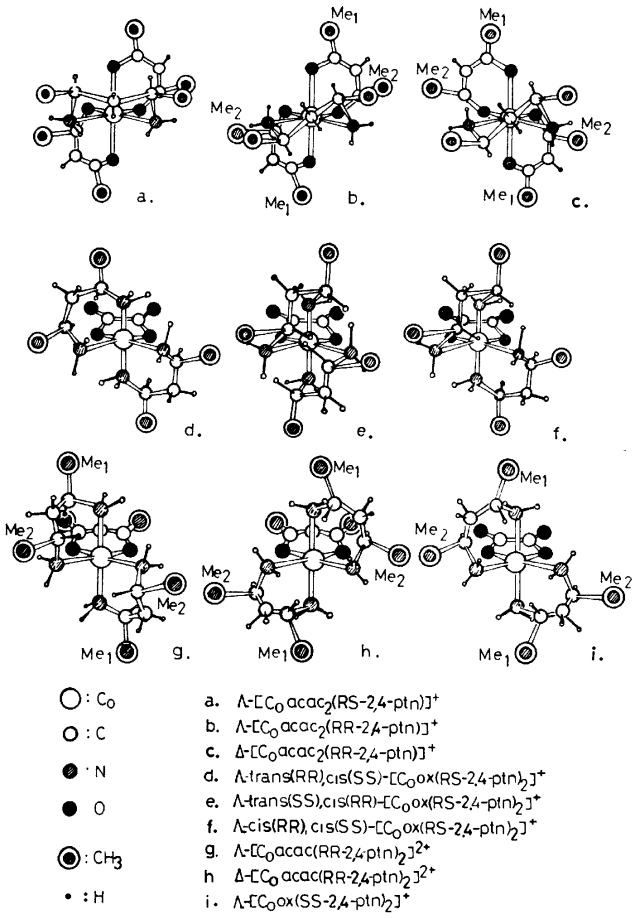

Fig. 2. Schematic structures of $[Co(AA)_{2,1}(2,4\text{-ptn})_{1,2}]$ (AA =acac$^-$, ox^{2-}).

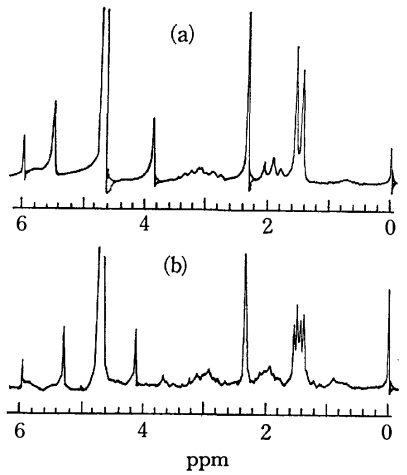

Fig. 3. PMR spectra of a) $\Delta(-)_{589}$-$[Co(acac)(RR\text{-}2,4\text{-ptn})_2]^{2+}$, b) Δ,Λ-$[Co(acac)(RR\text{-}2,4\text{-ptn})_2]^{2+}$ in D_2O.

torial methyl groups.[10] Therefore, the two methyl groups of the diamine chelate and the four methyl and the two methyne groups of the acetylacetonato chelates should all be in different environments. However, the pmr spectrum of the complex shows such a clear difference only on the methyne signal (Fig. 4a).

For the complexes of the type $[Co(AA)(RS\text{-}2,4\text{-ptn})_2]$ (AA=acac$^-$, ox^{2-}), three geometrical isomers can exist with respect to the location of the asymmetric carbon atoms of the diamine. These isomers are designated as *cis(RR)cis(SS)*, *trans(RR)cis(SS)* and *trans(SS)cis(RR)* (Fig. 2d, e, f). Each geometrical isomer has two optical isomers Δ and Λ, Of these six isomers, an enantiomeric pair, *Λ-trans(SS)cis(RR)* and *Δ-trans(RR)cis(SS)*, seems to have steric hindrance between the diamine chelates (Fig. 2e). Accordingly, two enantiomeric pairs, *Λ-cis(RR)cis(SS)* and *Δ-cis(SS)cis(RR)*, and *Λ-trans(RR)cis(SS)* and *Δ-trans(SS)-cis(RR)*, may be formed.

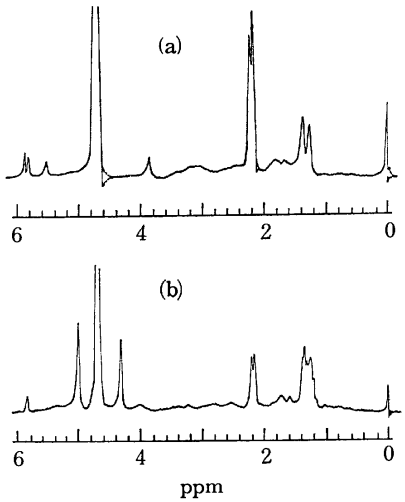

Fig. 4. PMR spectra of a) $\Delta\Lambda$-$[Co(acac)_2(RS\text{-}2,4\text{-ptn})]^+$, b) Δ,Λ-$[Co(acac)(RS\text{-}2,4\text{-ptn})_2]^{2+}$ in D_2O.

We have obtained two geometrical isomers of racemic $[Co(ox)(RS\text{-}2,4\text{-ptn})_2]^+$, *cis-cis*(more soluble isomer in water) and *trans-cis*(less soluble isomer in water) isomer, and resolved them into optical isomers.

For $[Co(acac)(RS\text{-}2,4\text{-ptn})_2]^{2+}$, only a *cis-cis* geometrical isomer has been obtained, its optical resolution being only partially successful (see Experimental).

Since the *RS*-2,4-pentanediamine chelate would be in a chair conformation, the symmetries of *cis-cis* and *trans-cis* isomers are C_1 and C_2, respectively (Fig. 2). Thus the former has four unequivalent methyl groups and the latter two kinds of methyl groups on the diamine chelate. We see from Fig. 5b that the pmr spectrum of *Λ*-$(+)_{510}$-*cis(RR)cis(SS)*-$[Co(ox)(RS\text{-}2,4\text{-ptn})_2]^+$ in a mixed solvent of pyridine and D_2O (1 : 4 in volume) clearly exhibits an octet signal due to the methyl groups of the diamine, although the *Λ*-$(+)_{510}$-*trans(RR)cis(SS)*-$[Co(ox)(RS\text{-}2,4\text{-ptn})_2]^+$ gives a triplet signal which seems to be an accidental overlapping of two doublet signals (Fig. 5a). Thus we can determine the geometrical structure of the isomers by pmr spectra. A mixed solvent of pyridine and D_2O is more effective for the present complexes than D_2O, since it makes the difference in chemical shifts of the unequivalent methyl groups greater. The pmr spectrum of *Λ*-$(+)_{510}$-*trans(RR)cis(SS)*-$[Co(ox)(RS\text{-}2,4\text{-ptn})_2]^+$ in D_2O shows only a doublet methyl signal (Fig. 5c).

The only isomer of $[Co(acac)(RS\text{-}2,4\text{-ptn})_2]^{2+}$ we obtained can be assigned to the *cis-cis* structure, since its pmr spectrum shows two kinds of methyl signals for

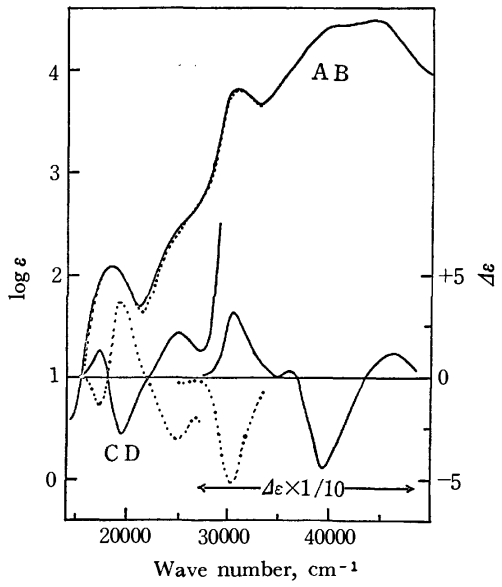

Fig. 9. Absorption (AB) and CD spectra of (——) $\Lambda(-)_{546}$-[Co(acac)$_2$(*RR*-2,4-ptn)]$^+$, (·····) $\Lambda(+)_{546}$-[Co(acac)$_2$(*RS*-2,4-ptn)]$^+$ in water.

other hand, Λ-[Co(*RR*-2,4-ptn)$_3$]$^{3+}$ [13] and Δ-[Co(*RR*-2,4-ptn)$_3$]$^{3+}$ [14] give a single CD band with positive and negative signs, respectively,[1] in agreement with the sign of the main CD band of [Co(en)$_3$]$^{3+}$. However, the CD magnitudes of these two diastereoisomers differ greatly (Λ-isomer: +2.69; Δ-isomer: −0.55), even when the vicinal contribution of the optically active *RR*-2,4-pentanediamine chelate is taken into account.[1] Thus, the CD spectra of tris-β-diamine complexes differ more or less from those of tris-α-diamine complexes.

On the other hand, the CD spectrum of Δ-(b)$_{589}$-[Co(acac)(tn)$_2$]$^{2+}$ whose absolute configuration was determined by the X-ray method[2] is very similar to that of the corresponding ethylenediamine complex, [Co(acac)(en)$_2$]$^{2+}$. Although the absolute configuration of the latter is assigned on the basis of its CD sign in the first absorption band region,[15] such a similarity suggests that a difference in the CD between six-membered and five-membered diamine complexes is not so marked for the present bis-type complex as in the tris-type complex. (−)$_{589}$-[Co(acac)(*RR*-2,4-ptn)$_2$]$^{2+}$ gives a CD curve very similar to that of Δ-[Co-

(acac)(tn)$_2$]$^{2+}$ in the entire region, and can be safely assigned to Δ configuration (Fig. 6). For [Co(acac)-(*RS*-2,4-ptn)$_2$]$^{2+}$, complete optical resolution was not achieved, but the complex shows a CD pattern similar to that of the corresponding RR-2,4-pentanediamine complex.

No report has been published on the absolute configuration of any oxalato-bis-α-diamine complex by the X-ray method.[16] However, such a configuration may be assigned without ambiguity on the basis of the CD sign in the first absorption band region, since the CD is usually very similar to that of [Co(en)$_3$]$^{3+}$. Stereospecifically formed Λ-oxalato-bis-diamine type complexes give a main CD band with the positive sign in this region.[17] The main CD bands of both $(+)_{510}$-*cis-cis* and $(+)_{510}$-*trans-cis* isomers of [Co(ox)(*RS*-2,4-ptn)$_2$]$^+$ are positive and almost enantiomeric with those of Δ-[Co(ox)(α-diamine)$_2$]$^+$ (α-diamine=en, R-pn) (Fig. 7).[15] Therefore, the $(+)_{510}$- and $(+)_{510}$-isomers can be assigned to *Λ-cis(RR)cis(SS)* and *Λ-trans(RR)-cis(SS)* structure, respectively. The *Λ-cis(RR)cis(SS)* isomer has one positive CD band, while the *Λ-trans-(RR)cis(SS)* isomer has one very weak negative and one strong positive band from longer to shorter wave length, but the origin of this difference is unknown.

In a similar way, less soluble $(+)_{546}$-isomer of [Co-(ox)(*SS*-2,4-ptn)$_2$]$^+$ is assigned to Λ configuration (Fig. 8). The CD spectrum of $(-)_{546}$-[Co(acac)$_2$(*RR*-2,4-ptn)]$^+$ is shown in Fig. 9. It is almost enantiomeric with the spectra of $(+)_{546}$-[Co(acac)$_2$(en)]$^+$ [18] and $(+)_{546}$-[Co(acac)$_2$(NH$_3$)$_2$]$^+$ [18] which are assigned to Λ configuration from the sign of their CD in the first absorption band region.[19] Therefore, $(-)_{546}$-[Co-(acac)$_2$(*RR*-2,4-ptn)]$^+$ can be assigned to Δ configuration. $(+)_{546}$-[Co(acac)$_2$(*RS*-2,4-ptn)]$^+$ gives a CD curve enantiomeric with that of $(-)_{546}$-[Co(acac)$_2$-(*RR*-2,4-ptn)]$^+$, and is assigned to Λ configuration (Fig. 9). Thus, the CD spectra of bis-acetylacetonato-β-diamine cobalt(III) complexes are essentially the same as those of the corresponding ethylenediamine complexes.

All the results lead to the conclusion that the mono- and bis-β-diamine complexes of the types given in this paper show CD spectra similar to those of the corresponding α-diamine complexes, and their absolute configuration may be assigned on the basis of their CD sign in the first absorption band region as well as the α-diamine complexes.

It is to be noted that the assignment of structures for the present bis-diamine complexes on the basis of pmr and CD spectra is consistent with that deduced from the studies with molecular models; the smaller the steric interaction among chelate rings in a complex, the greater the formation of a diastereoisomer. For example, the steric interaction for the Δ-$(-)_{589}$-isomer of [Co(acac)(*RR*-2,4-ptn)$_2$]$^{2+}$ seems to be smaller than that for the Λ-isomer, and the former is always formed to a much greater extent than the latter.

We are grateful to the Ministry of Education for a Grant-in-aid for studies on optically active complexes.

16) $(-)_D$-[Co(ox)(en)$_2$]$^+$ has been assigned to Δ configuration by the X-ray analysis. T. Aoki, K. Matsumoto, S. Ooi, and H. Kuroya, This Bulletin, **46**, 159 (1973).

Racemization and Isotopic Exchange of Tris(acetylacetonato)silicon(IV) Perchlorate in Organic Solvents

Tomoaki INOUE and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received 26 December 1972)

Racemization of trisacetylacetonatosilicon(IV) ions and their isotopic exchange reaction with acetylacetone-^{14}C (Hacac) have been studied in tetrachloroethane (TCE) and acetonitrile (AN). No solvolysis takes place at least below 60 °C, and the racemization rate R is expressed as follows: $R=$[complex] $(k_1+k_2$[acid]) (in TCE) and $R=$[complex] $(k_3+k_4$[base]) (in AN). The rate constants and activation parameters at 50 °C are as follows: rate constants, 4.79×10^{-6} s^{-1}, 1.35×10^{-4} M^{-1} s^{-1}, 3.87×10^{-5} s^{-1} and 1.19×10^{-1} M^{-1} s^{-1}, activation enthalpy ($\Delta H^{\neq}$/kcal mol^{-1}) 31.6±0.1, 29.3±1.9, 25.7±0.2 and *ca.* 18, and activation entropy ($\Delta S^{\neq}$/cal mol^{-1} K^{-1}) 14.6, 14.2, 0.53, −5.75, respectively, for k_1, k_2 (for trichloroacetic acid), k_3 and k_4 (for 2,6-lutidine). No isotopic exchange is observed within 6 hr at 60 °C in the solvents. The racemization should proceed intra-molecularly and presumably *via* an intermediate of coordination 5 with one of the ligands as unidentate.

Dynamic properties of β-diketonato complexes of metal ions have been studied from various viewpoints. Geometrical isomerization of the complexes with asymmetric β-diketones was studied mainly by measuring their NMR signals.[1] Trisacetylacetonato- and trisbenzoylacetonatocobalt(III) were partly resolved and their racemization and geometrical isomerization discussed in detail.[2] All the work was centered around intra-molecular rearrangement of the complexes. We have conducted kinetic studies of isotopic exchange of some acetylacetonato complexes of typical and transition metal ions, and discussed the intermolecular course of reaction in organic solvents.[3,4] Since these studies have been limited to those of chargeless complex species, we thought it desirable to extend the studies to silicon(IV) which gives univalent cationic complex with three β-diketonato ligands.

Silicon(IV) compounds with tetrahedral structure have been studied extensively, but much less is known about those with co-ordination number six. Phthalocyaninato,[5] tropolonato[6] and β-diketonato[7] complexes were synthesized and their structures discussed. However, reaction kinetics has been studied only with the tris-β-diketonatosilicon(IV) ion.

Dhar, Doron and Kirschner[8] first resolved trisacetylacetonatosilicon(IV) $[Si(acac)_3]^+$ and studied its hydrolysis, methanolysis and racemization. They concluded that the loss of optical activity is mainly due to solvolysis.[9] Pearson, Edgington and Basolo considered an S_N2 displacement mechanism for the base hydrolysis.[10] From the difference in the rates of loss of optical activity and the hydrolysis, participation of intrinsic racemization was suggested.[9] Muetterties and Wright studied the base hydrolysis of a similar complex with dibenzoylmethane $[Si(dbm)_3]^+$ in ^{18}O-labelled water, and suggested nucleophilic attack of hydroxide ions on the carbon atom adjacent to the coordinated oxygen.[11]

We found that $[Si(acac)_3]^+$ undergoes racemization in carefully dehydrated organic solvents without being involved in other reactions such as hydrolysis, and studied the reaction kinetics of the non-catalyzed and acid- or base-catalyzed reaction path in 1,1,2,2-tetrachloroethane (TCE) and acetonitrile (AN). The result has been compared with that of intermolecular isotopic exchange of the complex with ^{14}C-labelled acetylacetone, and the mechanisms of racemization discussed.

Experimental

Materials. *Preparation and Resolution of the Complex*: Trisacetylacetonatosilicon(IV) hydrogen dichloride $[Si(acac)_3]Cl\cdot HCl$ was prepared by Dilthey's method[12] and resolved by Dhar *et al*'s method[8] with slight modification. Crystals of hydrogen-dibenzoyl-*d*-tartrate salt of this complex $(-)_D$-$[Si(acac)_3]$-$(-)_D$-$C_{18}H_{13}O_8$ were filtered off from the aqueous solution, and the crystals of $(+)_D$-$[Si(acac)_3]$-ClO_4 precipitated with sodium perchlorate from the filtrate. The resolution was partial but the racemization rate was independent of the degree of resolution. $(-)_D$-$[Si(acac)_3]\cdot C_{18}H_{13}O_8$ was converted into $(-)_D$-$[Si(acac)_3]ClO_4$ with the anion exchange resin Dowex 1-X8 by the batch method. $(+)_D$-$[Si(acac)_3]ClO_4$ was recrystallized from chloroform solution with ether and used for the kinetic runs. This complex is stable for several months in dry air below 15 °C, and for 2 weeks at *ca.* 30 °C. The perchlorate is soluble in nitriles, ketones, carboxylic acids, alcohols, and some haloalkanes, but insoluble in ethers, hydrocarbons and water. The dibenzoyltartrates are very stable, and soluble in carboxylic acids, some alcohols and haloalkanes, but insoluble in ethers, hydrocarbons and water.

circular dichroism (CD) of $\Delta(-)_D$-[Si(acac)$_3$]-(−)$_D$-$C_{18}H_{13}O_8$ and $\Lambda(+)_D$-[Si(acac)$_3$]ClO_4 were −162 and +180 at 302 and 304 nm at 25 °C, respectively. The specific rotation was +866° for the Λ-[Si(acac)$_3$]ClO_4 at the D-line at 25 °C.

Solvents: 1,1,2,2-Tetrachloroethane (TCE) was dehydrated with anhydrous calcium sulfate in a dry box and gently distilled. The procedure was repeated three times; the product contained 0.001 M water. Careless procedure gives rise to the increase in water content. Acetonitrile was refluxed with diphosphorus pentoxide and distilled. The procedure was repeated and finally distilled with potassium carbonate. The product contained 0.002 M water. Anhydrous calcium sulfate was also useful for its dehydration. Acetophenone was dehydrated with calcium sulfate and distilled under a reduced pressure. The water content was 0.002 M.

Other Reagents: Pyridine and its derivatives were dehydrated with anhydrous calcium sulfate and distilled. The water content was less than 0.01 M. Trichloroacetic acid was sublimed *in vacuo*. The labelled acetylacetone was prepared by Miss Kazuyo Masuda.[3)]

Experimental Procedure. Racemization: The optically active perchlorate (≃0.1 g) was dissolved in the solvent (25 ml) in a dried vessel in a dry box. Whenever necessary, a given volume of the acid or the base solution was added to make the concentration 0.001 to 0.1 M. The product was sealed in five small test tubes. They were placed in a thermostat (±0.02 °C) and picked up one by one at proper intervals. They were cooled in a mixture of table salt and ice, and the optical rotation measured at the Na–D line. They were then diluted and the u.v. absorption examined. The runs were carried out in the temperature range 30—60 °C.

The rate constant was calculated by the equation

$$k_{obsd} = [\ln(\alpha_0/\alpha_t)]/2t \quad (1)$$

where α_0 and α_t are the optical rotations at time zero and t, respectively.

Isotopic Exchange Kinetics: The complex (0.04—0.08 g) and acetylacetone-^{14}C (0.01—0.02 g) were dissolved in TCE or AN in a long-necked flask in a dry box and kept in a thermostat (60±0.02 °C). Aliquots were withdrawn at appropriate intervals, and poured into cooled diethylether. The complex precipitated at once free from Hacac, filtered off with a small piece of filter paper, washed with diethylether and dried *in vacuo*. The β-activity of the precipitate (10 mg) on the paper was counted with a 2π gas flow counter with Q-gas.

Apparatus. A JASCO DIP-SL polarimeter and a Hitachi 124 spectrometer were used for the measurement of optical rotation and u.v. absorption spectrum, respectively. JASCO model ORD/UV-5 was used for recording the circular dichroism spectrum. Aloka FC-1E counter was used for the β-activity counting of ^{14}C. The water content was measured by the Karl Fischer method.

Results

The Kinetic Formula in TCE. The change in absorbance at 305 nm and optical rotation at the Na–D line of the reaction mixture are shown in Fig. 1. The constant absorbance indicates the absence of decomposition of the complex. Hence the decrease in optical rotation should be due to racemization of the complex. The dependence of k_{obsd} on the complex concentration is illustrated in Fig. 2. The rate constant remains unchanged in the range 0.005—0.05 M and the racemization rate is given by

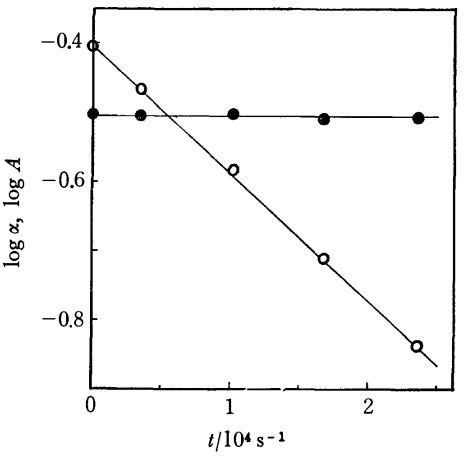

Fig. 1. Change of optical rotation at Na-D line and absorption spectrum at 305 nm in TCE. (● absorption, ○ rotation)

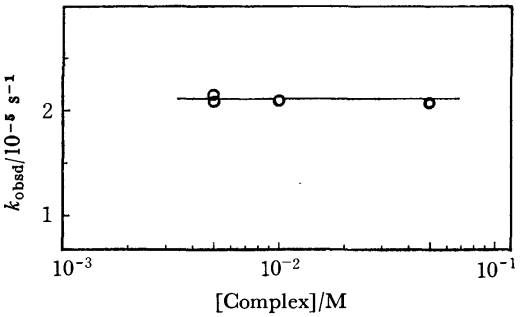

Fig. 2. Influence of the complex concentration upon k_{obsd} in TCE.

$$R - k_{obsd}[\text{complex}] \quad (2)$$

Free acetylacetone gave no effect on the rate of racemization (Fig. 3). The racemization is catalyzed by trichloroacetic acid as shown in Fig. 4. The straight lines have intercepts, which coincide with k_{obsd} values obtained in the absence of acid at the given temperature. Weaker acids do not give catalytic action. Hence k_{obsd} is given by

$$k_{obsd} = k_1 + k_2[\text{trichloroacetic acid}] \quad (3)$$

The results are summarized in Table 1. The catalytic action of trichloroacetic acid is reckoned as acid catalysis for the following reason. When equimolar

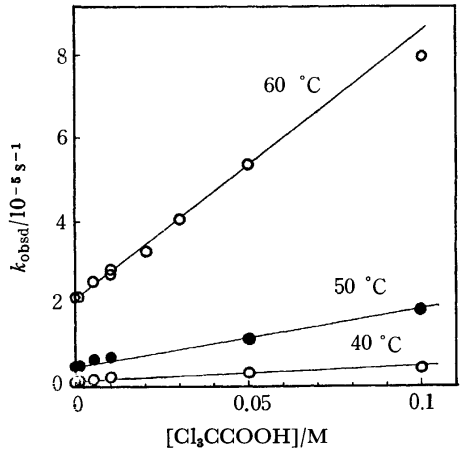

Fig. 4. Influence of concentration of trichloroacetic acid in TCE.

amounts of trichloroacetic acid and pyridine were added to the TCE solution, the k_{obsd} decreased as compared with that in the presence of trichloroacetic acid alone. On the other hand, the electric conductivity of the equimolar mixture was greater than those of pure solutions of trichloroacetic acid and pyridine in TCE. This fact shows that the dissociation of trichloroacetic acid was facilitated by the addition of pyridine. If the trichloroacetate anion had been the catalyzing species, the equimolar mixture should have exhibited greater catalytic activity. Hence, the proton seems to be the catalyzing species.

The fact that pyridine shows catalytic activity in AN (see below) but not in TCE can be interpreted by considering that pyridine is capable of forming hydrogen bonding with TCE[14] and does not behave as a base in this solvent.

No isotopic exchange was observed within 6 hr at 60 °C regardless of the presence or the absence of trichloroacetic acid.

In Acetonitrile. Plots of the rotation and the absorbance *vs.* time disclosed that racemization is not involved in decomposition of the complex. Independence of the rate constant of the concentrations of the complex and of free acetylacetone indicates that a relationship similar to Eq. (2) also holds in this solvent. Water in the concentration range 0.002—0.01 M and trichloroacetic acid gave no influence upon the rate of racemization. The racemization is catalyzed by bases such as strychnine, 2,6-lutidine, γ-picoline, pyridine and pyridine *N*-oxide, the extent decreasing in this order. The catalytic activity of pyridine was quenched by the addition of an equimolar amount of trichloroacetic acid, and the acceleration seems to be due to the base catalysis. The plot of k_{obsd} values *vs.* the concentrations of these bases gave straight lines with intercepts, which coincide with the k_{obsd} values in the absence of the bases (Fig. 5). Thus the rate constant is given by

$$\text{Rate} = k_{obsd}[\text{complex}] = [\text{complex}](k_3 + k_4[\text{base}]) \quad (4)$$

The data are listed in Tables 1 and 2. The k_4 values are not sufficiently reproducible and the plots gave different gradients according to the batch of a given base, although the intercepts were always equal. It

appears as if some unidentified compounds in the pyridine bases give catalytic action on top of that of the bases themselves. Hence only approximate values of k_4 are listed in Table 2. Nevertheless, they increase with increase in basicity of the bases. There was no influence of water and trichloroacetic acid upon the rate.

No appreciable isotopic exchange was observed within 20 hr at 60 °C both in the absence and the presence of bases.

In Acetophenone. The results are given in Table 1. No influence was observed in the presence of different amounts of water and free acetylacetone.

Discussion

All experimental results are summarized in Table 1. The absence of isotopic exchange clearly indicates that the racemization takes place *via* an intramolecular mechanism. Since no net chemical reaction is involved during the course of racemization, some kind of twisting mechanism should be operating.

Intra-molecular racemization can proceed either with or without break of one of the metal-oxygen bonds between silicon(IV) and acetylacetonate. The latter mechanism maintaining coordination number 6 was interpreted by Ray and Dutt[15] and by Bailar[16] in slightly different ways. However, racemization of $[Si(acac)_3]^+$ is subject to acid catalysis in TCE and to base catalysis in AN. Such catalytic actions are more easily understood by considering an intermediate with coordination number 5, because twist mechanism without bond break will be less sensitive towards acid and base catalysis.

An intermediate with coordination number 5 can be either trigonal bipyramid or square pyramid but should have a plane of symmetry with the unidentate ligand at the apical position. When one of the bonds of a ligand is broken, a trigonal bipyramidal intermediate seems to be easily formed without involving drastic intra-molecular rearrangement. (Fig. 6) On the other hand, if a square pyramidal intermediate were to be formed, the intra-molecular rearrangement would be more substantial and require bigger enthalpy of activation. Stability of trigonal bipyramidal and square pyramidal structure was compared both theoretically and experimentally by several authors.[17] It seems that

former is energetically more favorable although the energy difference does not appear very big. This does not necessarily imply that the energy barrier to be overcome is also small; however, we are inclined to presume the trigonal bipyramidal intermediate to be more feasible.

Two possible rate-determining steps can be encountered whenever an intermediate with coordination number 5 is involved. One is to assume that the bond breaks to give the intermediate as rate-determining step and the intra-molecular rearrangement proceeds fast. An alternative is to regard that one of the bonds of a given ligand breaks and forms quickly and the intra-molecular rearrangement to be the rate-determining step. So far as the intermediate has trigonal bipyramidal structure, the intra-molecular rearrangement will not require big enthalpy, and we can presume that the break of the first bond of one of the ligands will be the rate-determining step. From kinetic studies in ^{18}O-labelled water, Muetterties and Wright[11] suggested that the rate-determining step for the aquation of $[Si(dbm)_3]^+$ is the break of one of the ligands facilitated by the attack of water upon the carbonyl carbon. This is in line with our result, although the reaction environment differs.

If the break of one of the bonds of a ligand were the rate-determining step, the acid and base catalysis should be understood in such a way that acid or base will affect the metal ligand bond to facilitate its break. Such an action will give lower $\Delta H^{\neq}$ values as compared with those in the absence of catalysis. The $\Delta H^{\neq}$ values for k_1 and k_2 path are 31.6±0.1 and 29.3±1.9 kcal per mole, respectively. Although the difference is only slightly bigger than the experimental error, acid catalysis can be understood as to facilitate the bond break at the rate-determining step. The difference in $\Delta H^{\neq}$ values in the presence and the absence of base catalysis is more marked, although the experimental error must be bigger. Primary and secondary amines change the absorption spectrum of the reaction mixture and seem to bring about net chemical reaction. As Table 2 shows, there is an overall trend that the greater the basicity of a given pyridine base, the greater the catalytic activity with smaller $\Delta H^{\neq}$ and $\Delta S^{\neq}$ values. This may suggest that the base catalysis operates bimolecularly. The possible attack can take place on either the central silicon or the ligand. Bulky molecules such as *l*-strychnine and 2,6-lutidine give remarkable catalytic action, and the attack upon silicon is less likely. Optically active *l*-strychnine catalyzed both Δ- and Λ-complex equally.

In the absence of catalytic action, the racemization proceeds faster in AN(and acetophenone) than in TCE. Such a solvent effect could be understood by considering that AN, as a weak base, gives more marked solvation than TCE, and facilitates the break of the Si–O bond in the rate-determining step.

Heterocyclic Azomethine Compounds and Their Reduction Products as Analytical Reagents. I. Syntheses and Acid Dissociation Constants of Picolinaldehyde 2-Hydroxyanil and Its Derivatives and Their Reactions with Metal Ions

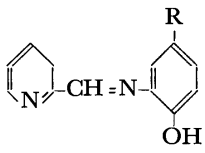
Makoto OTOMO and Kazunobu KODAMA

Department of Synthetic Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received December 20, 1972)

Picolinaldehyde 2-hydroxyanil and its methyl, chloro and nitro derivatives at the 5-position of benzene nucleus were synthesized for the purpose of investigating their applicability as an analytical reagent. The acid dissociation constants were determined by means of potentiometric titration in aqueous dioxane of various concentrations. It was found that the basicity of donor atoms of the parent compound increases with the introduction of a methyl group and decreases with that of a chloro or nitro group. The three compounds other than the nitro derivative are light-colored and react with many divalent metal ions in slightly basic media to form strongly colored chelates, which can be extracted into organic solvents such as partially halogenated hydrocarbons. The distribution coefficients of the three compounds between chloroform and water were also determined spectrophotometrically, that of the chloro derivative being the largest.

The analytical use of heterocyclic azo compounds in color forming reactions with metal ions is very familiar. 2-Pyridylazo compounds, which are strongly colored and have a hydroxy group in *ortho*-position to the azo group, have been proved to be very useful as spectrophotometric reagents and also as metal indicators. However, in spite of the easiness of preparation, only a limited number of azomethine analogs have been used analytically. It is important to note that the stability constants of some metal chelates with picolinaldehyde 2-hydroxyanil are of the same order of magnitudes as those of 4-(2-pyridylazo)-resorcinol.[1] Both compounds have three donor groups capable of coordinating to metals and act as a terdentate ligand. 2-(2-pyridylazo)phenyl (*o*-PAP) also reacts with many metal ions over a wide range of pH to form strongly colored chelates.[2] A series of azomethines represented by the general formula(1) have been synthesized and their applicability to the spectrophotometric determination of copper(II) examined.[3] However, no attempt seems to



R=H, CH_3, Cl, C_6H_5

(1)

have been made so far to elucidate the stability of the chelates formed. Picolinaldehyde 2-mercaptoanil, a thio analog of picolinaldehyde 2-hydroxyanil, shows a marked selectivity towards metals which form brightly colored insoluble sulfides.[4] Some azomethine derivatives of 8-hydroxyquinoline have also been synthesized.[5]

We have synthesized four azomethine compounds, picolinaldehyde 2-hydroxyanil (I), -2-hydroxy-5-methylanil(II), -2-hydroxy-5-chloroanil(III) and -2-hydroxy-5-nitroanil(IV), in order to study quantitatively the effects of substituents at the 5-position of the benzene nucleus on the acid dissociation constants and the stability of metal chelates, and to obtain information on their applicability as an analytical reagent. It is found that the basicity of the imino and pyridine nitrogens, as well as of the phenolic oxygen, is greatly affected by the introduction of an electron-releasing or -withdrawing group into the ring. These compounds except for (IV) may be conveniently used as an extractive spectrophotometric reagent for some divalent metal ions.

Experimental

Preparations. Compound (I) is prepared as follows: To a solution of 10 g of *o*-aminophenol (purified by sublimation) in 80 ml ethanol is added a solution of 11 g of freshly distilled picolinaldehyde in 20 ml ethanol. The mixture is kept at 60—70 °C for 2 hr, and the ethanol is evaporated under reduced pressure. The resulting brown residue is recrystallized from ligroin to give 10 g of pale yellow-orange needle-like crystals.

The other azomethine compounds are prepared similarly from substituted *o*-aminophenols. The melting points and analytical data of the synthesized compounds together with the IR data are given in Table 1.

Sodium perchlorate is prepared by neutralization of a sodium carbonate solution with perchloric acid, followed by shaking with 1-(2-pyridylazo)-2-naphthol (PAN) in benzene to remove heavy metals which may be present and concentrating the aqueous phase until bulk of sodium perchlorate has crystallized out. The crystals are collected and recrystallized from water.

Apparatus. A model HM-6A pH meter (Toa Dempa Co., Ltd.) equipped with a combination electrode, type GC-125, is calibrated at pH 6.88 and 4.01 with standard buffer solutions (Toa Dempa Co., Ltd.). The pH meter readings are corrected according to the method described by van Uitert and Haas.[6] A Hitachi model 181 spectrophotometer

a) Although all the melting points are uncorrected, the reported values for I, II, and III in Refs. 1 and 3 seem to be too low.

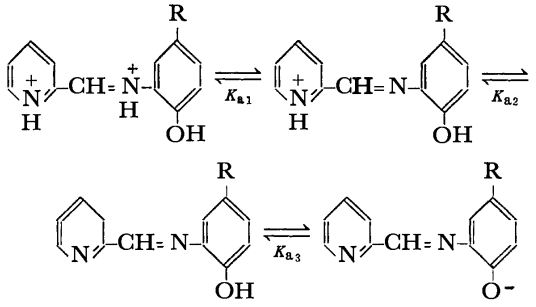
and a Hitachi model 124 double-beam spectrophotometer are used for measurement of absorbance in quartz cells of 10 mm pathlength.

Determination of Acid Dissociation Constants. Since all the azomethine compounds synthesized are almost insoluble in water, potentiometric titration is carried out in aqueous dioxane of various concentrations. A solution containing the sodium salt of each ligand (5×10^{-3} M) and sodium perchlorate (0.1 M) is titrated with 0.2 M perchloric acid at 25±0.1 °C under CO_2-free nitrogen atmosphere.

Determination of Distribution Coefficients. The distribution coefficients of the three compounds other than (IV) are determined spectrophotometrically. Extraction is carried out in a 50 ml centrifuging tube fitted with a glass stopper. A 10 ml portion of 0.1 M sodium perchlorate solution containing appropriate amounts of sodium hydroxide is vigorously shaken with 10 ml each of 1×10^{-3} M reagent in chloroform for 10 min at 25±0.5 °C. After equilibration, the pH of the aqueous phase is determined, and the absorbance of the organic phase is then measured at the absorption maximum, 358 nm for (I), 370 nm for (II), or 367 nm for (III).

Results and Discussion

Acid Dissociation Constants. The acid dissociation constants of the four compounds are determined in aqueous dioxane of various concentrations. The potentiometric titration curves in 50 v/v% aqueous dioxane are shown in Fig. 1. Each titration curve exhibits only one pH inflection at $a=1$. This shows that the dissociation of proton from the phenolic oxygen occurs independently in the alkaline region, whereas the dissociation of protons from the pyridine and azomethine nitrogens overlaps in the acidic region:



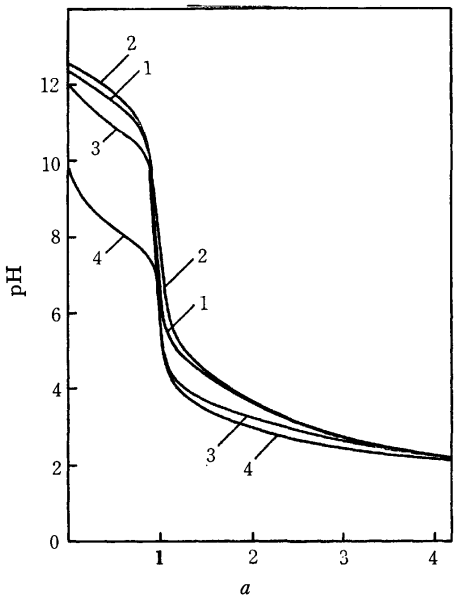


Fig. 1. Potentiometric titration curves of the azomethine compounds in 50 v/v% aqueous dioxane solution, $\mu=0.1$, 25 °C; abscissa a represents mol of acid added per mol of ligand (sodium salt).
Curve 1. Picolinaldehyde 2-hydroxyanil
2. Picolinaldehyde 2-hydroxy-5-methylanil
3. Picolinaldehyde 2-hydroxy-5-chloroanil
4. Picolinaldehyde 2-hydroxy-5-nitroanil

The acid dissociation constants are calculated as follows. For dissociation of a tribasic ligand acid, we have the relation[7]

$$R[H^+]^3 + (R-1)K_{a1}[H^+]^2 + (R-2)K_{a1}K_{a2}[H^+] + (R-3)K_{a1}K_{a2}K_{a3} = 0 \quad (1)$$

where $R=\{(3-a)C_L+[H^+]-[OH^-]\}/C_L$, C_L is the concentration of the ligand, and a the degree of neutralization. Since pK_{a1} and pK_{a2} are obviously close in magnitude whereas pK_{a3} is much larger, values for the first two dissociation constants are obtained conveniently by transforming Eq. (1) into the linear forms

$$\frac{(1-R)[H^+]}{R-2} = \frac{R[H^+]^2}{R-2}\cdot\frac{1}{K_{a1}} + K_{a2} \quad (2)$$

and

$$\frac{2-R}{R[H^+]^2} = \frac{R-1}{R[H^+]}\cdot\frac{1}{K_{a2}} + \frac{1}{K_{a1}K_{a2}} \quad (3)$$

and solving them to obtain K_{a1} and K_{a2} as the reciprocals of the calculated slopes. The value of K_{a3} is calculated from the approximate equation, $K_{a3}=(R-2)[H^+]/(3-R)$.

The plots of pK_{a1}, pK_{a2}, or pK_{a3} thus obtained *vs.* the mole fraction of dioxane, n_2, are linear in every case. The values of pK_{a1} and pK_{a2} decrease and that of pK_{a3} increases with increasing mole fraction of dioxane. These are summarized in Table 2. The value of pK_{a1} for (II) can not be estimated since hydrolysis takes place below pH 4. The acid dissociation constants of (I) in 50 v/v% aqueous dioxane agree well with the values reported by Geary, Nickless and Pollard ($pK_{a1}=3.05$, $pK_{a2}=4.45$ and $pK_{a3}=11.80$[1]).

7) H. Irving and J. J. R. F. da Silva, *J. Chem. Soc.*, **1963**, 448.

Table 2. Acid dissociation constants of the azomethine compounds
At 25 °C, $\mu=0.1$

Compound	pK_{a1}	pK_{a2}	pK_{a3}
(I)	$3.69-3.62n_2$	$4.80-2.47n_2$	$9.99+8.68n_2$
(II)	—	$5.03-2.82n_2$	$10.31+8.22n_2$
(III)	$3.43-3.56n_2$	$4.08-3.33n_2$	$9.52+8.05n_2$
(IV)	$2.81-4.37n_2$	$3.98-3.97n_2$	$7.12+6.49n_2$

It can be seen from Table 2 that the basicity of the donor atoms of the parent compound (I) is increased by the introduction of an electron-releasing group into the benzene ring and *vice versa* by the introduction of an electron-withdrawing group. As may be expected, the basicity of (II) is the highest. A good linear relationship holds between the pK_{a3} values for these compounds and the Hammett σ_p values for the benzene series.[8] The value of pK_{a2} may be ascribed to the dissociation of the –NH= group of pyridine nucleus.[9] The pK_{a2} and pK_{a3} values for (I) and (II) are higher than those of the corresponding azo compounds, *o*-PAP[4] and 2-(2-pyridylazo)-4-methylphenol (PAC),[10] respectively. This means that one would expect metal complexes of (I) and (II) to be more stable than those of *o*-PAP and PAC, respectively. The pK_{a2} and pK_{a3} values for (II) are also higher than those of 2-(2-thiazolylazo)-4-methylphenol (TAC).[11]

Distribution Coefficients. In the range of pH investigated (9.90—11.80), the following equation might hold for reagent extraction.

$$\log D_L = \log K_{DL} - \log(K_{a3}/[H^+]+1) \quad (4)$$

where D_L is the distribution ratio. The value of the distribution coefficient K_{DL} for a given compounds is obtained from Eq. (4). The results are given in Table 3. It is apparent that the log K_{DL} value varies with the substituent in the order $Cl>CH_3>H$ ($\gg NO_2$). These compounds show weak flluorescence in chloroform.

Table 3. Distribution coefficients of the azomethine compounds
At 25 °C, $\mu=0.1$

Compound	log K_{DL}
(I)	1.53±0.04
(II)	2.18±0.06
(III)	2.38±0.04

Reaction with Metal Ions. Many metal ions react with the synthesized compounds in the neutral or slightly basic region to give orange to orange-red color. Of these only divalent metal ions form chelates extractable into organic solvent such as chloroform, 1,2-dichloroethane, and *o*-dichlorobenzene, suggesting that uncharged 1 : 2 metal-ligand chelates are extracted. It is noteworthy that the extracted metal chelates are red to reddish violet in color, fairly differing from those observed in an aqueous dioxane solution; *e.g.*, the nickel(II) chelate of (I) in 20 v/v % aqueous dioxane at pH 9.3 has an absorption maximum at about 455 nm, while the peak of the chloroform extract is located at 529 nm. Metal chelates of (IV), however, can not be extracted into any organic solvent examined, although a potentiometric titration curve of a mixture of nickel(II) and (IV) in 50 v/v % aqueous dioxane with a standard sodium hydroxide solution clearly shows a 1 : 2 metal-ligand complex being formed. The absorption maxima and the apparent molar absorptivities of the divalent-metal chelates extracted into chloroform are given in Table 4. The spectrum of each chelate shows a broad, intense band well separated from that of the reagent, the shift being larger than 100 nm. The band for a metal shifts toward longer wavelength in the order $CH_3>Cl>H$.

Cadmium(II) and zinc(II) are found to form the most strongly colored chelates with these compounds. The cobalt(II) chelates change in color from red to violet during the course of extraction with chloroform

in a slightly basic solution, a precipitate appearing on the boundary of the two phases even in the presence of perchlorate ion. The reaction of nickel(II) with these compounds proceeds rapidly at the pH given in Table 4 and the chelates formed can be readily extracted into chloroform. However, the rate decreases markedly with decrease in pH of the solution. The comparatively lower molar absorptivities of the copper(II) chelates give rise to structural interest. The results imply that the azomethine compounds may be useful as a reagent for extractive spectrophotometric analysis of zinc(II), cadmium(II) and mercury(II). Their behaviors which are similar to those of *o*-PAP and PAR, suggest that these compounds act as a terdentate ligand toward metals to form two five-membered chelate rings.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2424—2428 (1973)

The Crystal Structure of $(-)_{589}$-Acetylacetonatobis(trimethylenediamine)cobalt(III) Arsenic(V) (+)-Tartrate Monohydrate

Keiji MATSUMOTO, Hiroshi KAWAGUCHI,* Hisao KUROYA, and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received January 8, 1973)

The crystal structure of $(-)_{589}$-[Co acac tn_2][As-(+)-tart]$_2\cdot H_2O$ has been determined by the X-ray diffraction method. The crystals are monoclinic, with lattice constants of $a=12.02(1)$ Å, $b=13.73(2)$ Å, $c=9.02(1)$ Å, and $\beta=107.4(3)°$, and with the space group of $P2_1$, containing two formula units in a cell. The structure was determined by the application of Patterson and Fourier techniques and was refined by the least-squares method to an R factor of 10.4%. The absolute configuration of $(-)_{589}$-[Co acac tn_2]$^{2+}$ can be denoted as Δ. The two Co-tn chelate rings assume the chair form, and the Co-acac chelate ring is almost planar. The geometry of [As-(+)-tart]$_2^{2-}$ is identical with that of [Sb-(+)-tart]$_2^{2-}$.

Several investigations have been made regarding the assignment of the CD spectrum of $\Delta(+)_{589}$-[Co tn_3]$^{3+}$ in the region of the octahedral T_{1g} absorption. Those who studied the solution spectra of the complex have identified the negative CD peak in the lower frequency as the E_a component.[1-3] On the other hand, Judkins and Royer indicate that the E_a component has a positive CD peak in the shorter wavelength region,[4] and they support the distortion theories.[5-7]

According to Mason *et al.*,[8] the single CD peak of $(-)_{589}$-[Co acac tn_2]$^{2+}$ in the visible region has the same negative sign as the E_a component of the parent trigonal complex, $\Delta(+)_{589}$-[Co tn_3]$^{3+}$. If the absolute configuration of $(-)_{589}$-[Co acac tn_2]$^{2+}$ is determined, it will be possible to assign the E_a component of $\Delta(+)_{589}$-[Co tn_3]$^{3+}$ on the basis of Mason's rule.[8] Therefore, we carried out the crystal-structure determination of $(-)_{589}$-[Co acac tn_2][As-(+)-tart]$_2\cdot H_2O$ by the X-ray method. A preliminary report of this work has been published.[9]

Experimental

The brownish-yellow, plate-like crystals of $(-)_{589}$-[Co-acac tn_2]][As-(+)-tart]$_2\cdot H_2O$ were prepared by Hiroshi Kawaguchi and Shinichi Kawaguchi. Using Ni$K\alpha$ radiation, the unit-cell dimensions were obtained from a least-squares treatment of 29 θ-values on $0kl$ and $h0l$ Weissenberg photographs calibrated with aluminum powder ($a=4.0494$ Å). The systematic absences of $0k0$ for k odd suggest that the space group is $P2_1$ or $P2_1/m$. However, since the compound is optically-active, $P2_1$ was chosen. The crystal data are as follows:

monoclinic
$a=12.02(0.01)$Å
$b=13.73(0.02)$Å
$c=9.02(0.01)$Å
$\beta=107.4(0.3)°$
space group $P2_1$
$Z=2(D_m=1.79, D_c=1.79$ g.cm$^{-3})$
μ(Ni$K\alpha$)$=54.4$ cm^{-1}

Multiple-film, equi-inclination Weissenberg photographs were taken for the 0—7 and 0—6 layers about the b and a axes with Ni$K\alpha$ radiation ($\lambda=1.6591$ Å). For both sets of films, prismatic specimens ($\sim 0.1\times 0.2\times 0.5$ mm) were used. The intensities were estimated by visual comparison with the calibrated intensity scales. After correction for the ususl

Lp factor and the spot shape,[10] the structure amplitudes were placed on a common arbitrary scale by internal correlation. A total of 2241 independent reflections were collected, but 454 of these were too weak to be observed. Therefore, they were assumed to be zero. No correction for absorption was applied.

Determination of the Crystal Structure

The initial coordinates of the cobalt and two arsenic atoms were deduced from a three-dimensional Patterson function. A three-dimensional Fourier synthesis phased on these heavy atoms revealed the positions of nine light atoms of the complex cation and five oxygen atoms of tartrate anions. Three cycles of refinement were carried out for the positional and thermal parameters by the least-squares method, and the resulting parameters were used to compute a Fourier function, which gave the probable positions of the three chelate rings around the cobalt atom, but not those of all the atoms of tartrate ions. The subsequent Fourier synthesis phased on these atoms showed the coordinates of all the remaining non-hydrogen atoms. The three cycles of block-diagonal least-squares refinement yielded an R factor of 12.5%, isotropic temperature factors being used for all the atoms. Three more cycles of refinement, in which anisotropic temperature factors were applied for the three heavy atoms, reduced the R factor to 10.4% for 1787 observed reflections. The following weighting scheme was employed:

$w=0.3$ for $F_0<12.2$

$w=1.0$ for $12.2\leq F_0\leq 93.5$

$w=93.5/F_0$ for $F_0>93.5$

Throughout the refinement, atomic scattering factors taken from the International Tables for X-ray Crystallography[11] were used. A difference Fourier synthesis obtained at this stage did not show any peaks attributable to hydrogen atoms. The final atomic coordinates and thermal parameters are given in Table 1. The observed and calculated structure factors are preserved by the Chemical Society of Japan.[12]

The absolute structure of the crystal was assigned on the basis of the known configuration of the (+)-tartrate ion,[13] and was found to correspond to the inversed set of the atomic coordinates given in Table 1; the Δ configuration has been assigned to the complex cation on the basis of the present X-ray study.

Discussion

The crystal consists of the $(-)_{589}$-[Co acac tn_2]$^{2+}$ cations, the [As-(+)-tart]$_2^{2-}$ anions, and water molecules, which are held together by N–H···O and O–H···O hydrogen bonds. Projections of the absolute structures viewed along b and c axes are presented in Figs. 1 and 2 respectively. Possible hydrogen bonds are summarized in Table 2. All the hydrogen atoms of N(3) and N(4) and one of the hydrogen atoms linked to N(1) and N(2) participate in the N–H···O hydrogen bonds. The interatomic distance between O(H_2O) and O(10) is 3.10 Å, and that between O(H_2O) and O(4), 2.86 Å. The O(4)–O(H_2O)–O(10) angle is

92°. Therefore, both hydrogen atoms of the water molecule seem to take part in the O–H···O hydrogen-bond formation.

A perspective view of the complex cation is shown in Fig. 3. The cobalt atom is octahedrally coordinated by the four nitrogen atoms of the two trimethylenediamine molecules and the two oxygen atoms in the enolate chelate of acetylacetone. The complex cation has no two-fold axis, in contrast with the case of the $(-)_{589}$-$[Co(NCS)_2tn_2]^+$ complex.[14]

III $1-x, y, z$ IV $1-x, 1/2+y, 1-z$

The positions of the hydrogen atoms were computed on the assumption that the $>NH_2$ groups have the tetrahedral geometry and the N–H bond distances are 1.03 Å.

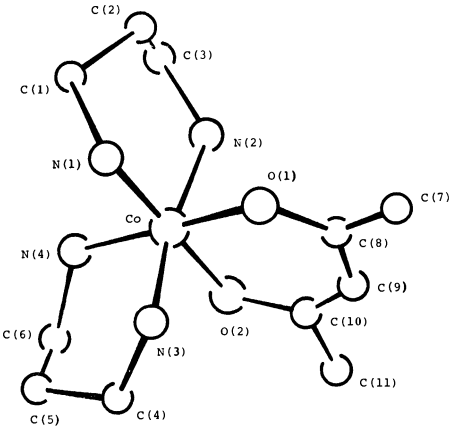

Fig. 3. Perspective view of the complex cation.

It was previously indicated that the rotational strengths of the E_a transitions of $\Lambda(-)_{589}$-[Co en_3]$^{3+}$ and $\Lambda(+)_{589}$-[Co tn_3]$^{3+}$ are negative in sign,[1-3] that the $(-)_{589}$-[Co acac en_2]$^{2+}$ complex shows a single CD band with a negative sign in the visible region, and that it is mainly derived from the dominant E_a component of $(-)_{589}$-[Co en_3].[3+ 8] On this basis, the $(-)_{589}$-[Co acac en_2]$^{2+}$ complex was concluded to have the Λ configuration.[8] Likewise, the Cotton effect of $(-)_{589}$-[Co acac tn_2]$^{2+}$ in the first-absorption-band region is negative in sign (Fig. 4), suggesting that the Λ configuration should be assigned to it; actually, this has been found to be the case. Thus, the spectral assignment for $(+)_{589}$-[Co tn_3]$^{3+}$ made by several workers[1-3] is quite compatible with the results of the present X-ray study.

However, Judkins and Royer identified the positive CD band of $\Lambda(+)_{589}$-[Co tn_3]$^{3+}$ in the region of the octahedral T_{1g} transition as E_a component.[4] If their assignment of the CD peak is correct, the Λ configuration should be given to $(-)_{589}$-[Co acac tn_2]$^{2+}$; this is inconsistent with our result. Piper's model for optical activity is not supported in this case, either.[15]

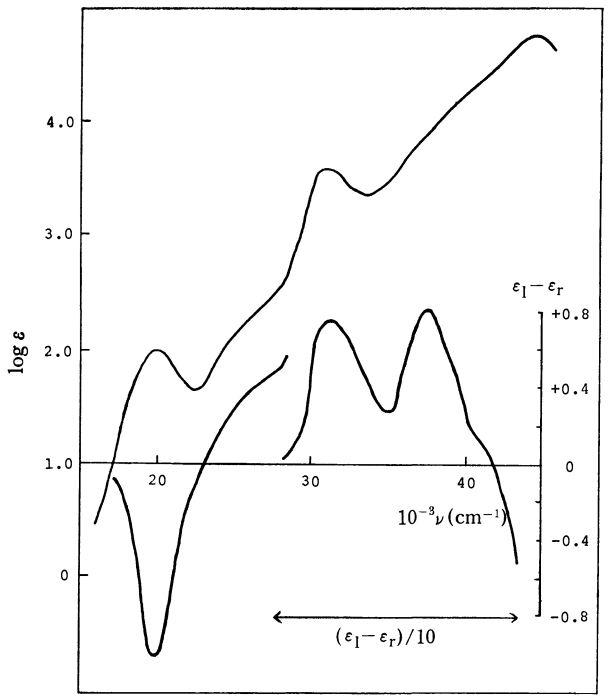

Fig. 4. Absorption and circular dichroism spectra of $(-)_{589}$-[Co acac tn_2]$^{2+}$ in water.

Recent conformational analyses of the chelate ring formed by trimethylenediamine (tn) provide an interesting basis for the interpretation of the CD spectrum of $(+)_{589}$-[Co tn_3]$^{3+}$. Those who computed its conformational preference derived significantly different results from one another,[16-18] but they all joined in suggesting that the energy difference between the tris-chair form and the tris-lel-skew-boat form is quite small. It seems that, in soluton, a conformational equilibrium involving significant amount of two or more conformers prevails, as has been pointed out by Woldbye.[18,19] This is possibly the case with $\Delta(-)_{589}$-[Co acac tn_2]$^{2+}$, whose CD spectrum shows a single negative peak in the visible region. Though such a conformational equilibrium is to be expected in solution, the absolute configuration of $\Delta(-)_{589}$-[Co acac tn_2]$^{2+}$ was found to be related to that of $\Delta(+)_{589}$-[Co tn_3]$^{3+}$ in terms of Mason's rule.[8] Therefore, the CD spectrum of $\Delta(+)_{589}$-[Co tn_3]$^{3+}$ in water should have a negative peak in the region of $A_{1g}\rightarrow E_a$ transition.[20]

The two six-membered diamine chelate rings of $(-)_{589}$-[Co acac tn_2]$^{2+}$ assume the chair form in the crystal. The coordination angles in both chelate rings are 96°, slightly larger than those (94°) found in $(-)_{589}$-[Co tn_3]$^{3+}$.[21] The Co-acac chelate ring is almost planar, the maximum deviation from the best

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2428—2430 (1973)

Absorption Band in the Near-Ultraviolet Region Observed for Binuclear Copper(II) Complexes

Sigeo KIDA, Yuzo NISHIDA, and Masatomi SAKAMOTO

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812

(Received December 28, 1972)

Elucidation of the origin of near-ultraviolet absorption believed to be characteristic of binuclear copper(II) complexes was attempted. The absorption was attributed to charge transfer transitions from nonbonding orbitals of bridging oxygen atoms to the vacant metal *d*-orbital. Appearance of the band in the near-ultraviolet region was interpreted in terms of the red-shift due to the decreasing *s*-character of the nonbonding orbitals enforced by the steric requirement of the complex. On this basis, the spectra of dialkoxo- or dihydroxo- bridged complexes and of copper alkanoates can consistently be explained.

It is well-known that copper(II) alkanoates of a binuclear structure always show an absorption at about 27 kK.[1] A number of investigations have been carried out for the origin of this absorption,[2~7] but the results are still in considerable controversies. A relatively intense absorption band ($\varepsilon=1\sim3\times10^3$) was observed at about 28 kK for many binuclear copper(II) complexes bridged by two alkoxo groups.[8] It was assumed that the band is characteristic of the binuclear structure.

By making use of CD and absorption spectra, we have tried to give a detailed explanation of the origin of the near-ultraviolet bands believed to be characteristic of the binuclear structures of both the copper(II) acetate- and the μ-dialkoxo- types.

Experimental

Optically active N-(3-hydroxypropyl)-(−)1,2-propanediamine $NH_2CH(CH_3)CH_2NH(CH_2)_3OH$ (=pn-prol) and its copper(II) complex $[Cu_2(pn\text{-}prol')_2](ClO_4)_2$ were prepared by the method reported,[8] where pn-prol′ represents deprotonated anion of pn-prol.

The CD and absorption spectra were measured with a JASCO ORD-UV/5 optical rotatory dispersion recorder with a CD attachment. Absorption measurements were carried out over the temperature range 24~−32 °C with a Hitachi EPS-2 spectrometer, a special device being used for temperature control.

Discussion

$[Cu_2(pn\text{-}prol')_2]^{2+}$ has the structural formula as shown in Fig. 1. Its CD and absorption (AB) spectra in methanol are shown in Fig. 2. The band at 28.2 kK is a typical absorption considered to be characteristic of binuclear structure. This band increases in intensity with the lowering of temperature (Fig. 2),

indicating that it is due to the transition from the ground singlet state. A positive CD band was observed at nearly the same position, and a negative CD band relatively small intensity at 24.8 kK. The temperature dependence of this band could not be confirmed because of experimental difficulty.

Since $[Cu\ pn_2](ClO_4)_2$ has no CD band in the region 23~30 kK,[9] both CD bands are unlikely to be due to d-d transitions and are most probably attributable to charge transfer transitions from the nonbonding orbitals of bridging oxygen atoms to the empty copper d-orbitals.

Although the structure of this compound has not been determined, its skeltal structure can be analogized in high probability with that of $[Cu_2(aca\text{-}prol')_2]$, in which two copper ions, all the coordinating atoms and two carbon atoms bonded with bridging oxygen are practically coplanar, where aca-prol′=$^-OC(CH_3)$-$CHCHC(CH_3)NCH_2CH_2CH_2O^-$.[10] Thus nonbonding orbitals on the oxygen atoms, denoted by p_z and p_π', should be pure 2p-orbitals normal to the coordination plane. The CT-transitions will, therefore, occur from $p_+(=p_\pi+p_\pi')$ or $p_-(=p_\pi-p_\pi')$ to $d_+(=d_{x^2-y^2}+d_{x^2-y^2}')$ or $d_-(=d_{x^2-y^2}-d_{x^2-y^2})$, where p_+, p_-, d_+ and d_- indicate bonding (+) and antibonding (−)-orbitals with respect to the p_π-p_π' and the $d_{x^2-y^2}$·$d_{x^2-y^2}'$ interactions, respectively. However, the transition to the d_+ orbital can not be the origin of the band at 28.2 kK, because the band is attributable to the transition only from the ground singlet state, as demonstrated by measurements of the spectra. This would be understood more easily in terms of electron-formulism, *i.e.*, the possible singlet-singlet CT transitions would be from the $(d_-)^\alpha(d_-)^\beta$ state to the $(d_-)^\alpha(p_-)^\beta$ and the $(d_-)^\alpha(p_+)^\beta$ states, where α and β refer to $m_s=+1/2$ and $-1/2$ respectively; no transitions from the low-lying excited states could be compatible with the fact that the intensity of the band increases with lowering of temperature. Since p_+ and p_- are bonding and antibonding with respect to the p_π-p_π' interaction, the $p_+\leftrightarrow d_-$ and the $p_-\leftrightarrow d_-$ transitions may be assigned to the band at 28.2 and 24.8 kK, respectively. The energy difference between the two bands may be compatible with the energy of the p_π-p_π' interaction considered from the estimated distance 2.3 Å.[10]

Irreducible representations under various symmetries are shown in Table 1 for the p_+, p_- and d_- orbitals together with the direct products of those orbitals. In C_2-symmetry both electric- and magnetic-dipole transitions are allowed for $p_+\leftrightarrow d_-$ and $p_-\leftrightarrow d_-$ transitions, but in D_{2h}-symmetry no electric-dipole transition is allowed for both transitions. In C_{2h}-symmetry, which is a fairly good approximation for the compound, electric-dipole transition is allowed for only the $p_+\leftrightarrow d_-$ transition. Thus, it is clear that assignment of the 28.2 kK band to the $p_+\leftrightarrow d_-$ transition best elucidates the observed intensity ($1\sim3\times10^3$). Accordingly, the $p_-\leftrightarrow d_-$ transition may be assigned to the band at 24.8 kK, since p^+ and p_- are bonding and antibonding with respect to the $p_\pi\cdot p_\pi'$ interaction. The energy difference between the two bands may be compatible with the energy of the p_π-p_π' interaction considered from the estimated O–O distance 2.3 Å.[10] This assignment is also consistent with the fact that the absorption at 24.8 kK is so weak as to be hidden by the lower part of the intense band at 28.2 kK, and that CD intensity of the latter band is very small relative to AB intensity. However, it is safer not to form a final

Table 1. Irreducible representations of p_+, p_- and d_- orbitals and selection rules for the transition between these orbitals under various symmetries

	D_{2h}	C_{2h}	C

conclusion for the origin of the 24.8 kK band until the temperature dependence of the CD band is confirmed, though the present assumption is in harmony with Dubicki's observation of single-crystal spectra of copper(II) acetate.[7]

It is well-known that electronegativity of a nonbonding electron-pair on an oxygen atom is highly dependent on the degree of hybridization of 2s and 2p orbitals. For the present complex, the nonbonding orbital on the oxygen atom can be regarded to be a practically pure $2p_z$ orbital. Accordingly, the CT bands shift to the near-ultraviolet region, as characteristic bands of the binuclear structure. This could be interpreted as follows. In the case of a simple coordination of alkoxo or hydroxo group, the two nonbonding electron pairs should have a considerable *s*-character as has been proved for free water and some similar molecules,[11,12] so that CT bands are observed at a relatively high frequency region. On the other hand, in the case where oxygen atoms function as a bridge in a binuclear complex, the oxygen atoms may be forced to form sp^2 hydridized σ-bonds by steric requirement, leaving p_z-orbital as a nonbonding orbital. Thus the CT band appears in a relatively lower frequency region, frequently showing a distinct peak.

Thus it follows that even in the case of a mononuclear complex an absorption band similar to that observed for binuclear complexes can appear at the near-ultraviolet region, granted that nonbonding orbitals on negatively charged oxygen (or nitrogen) atoms are of mainly *p*-character. In fact, some bis(β-diketonato) copper(II) complexes show a shoulder at 25.8 kK.[13]

Copper(II) Alkanoates. Recently Dubicki measured single-crystal spectra over the temperature range 287~4.2 K and found that the near-ultraviolet spectrum of copper(II) acetate consists of two bands at 27.8 and 30.8 kK, polarized parallel and perpendicular to copper-copper axis, respectively, the two bands being identified as singlet-singlet transitions from the fact that their intensities increase with lowering of temperature. Dubicki assigned these bands to the CT transitions $b_{2u}(p_y) \leftrightarrow b_{1g}(d_{x^2-y^2})$ and $e_g(p_x) \leftrightarrow b_{2u}(d_{x^2-y^2})$, where $b_{2u}(p_y)$ and $e_g(p_x)$ are nonbonding ligand molecular orbitals composed of out-of-plane and in-plane (with respect to the $-C\begin{smallmatrix}O-Cu-\\ \vdots \\ O-Cu-\end{smallmatrix}$ plane) oxygen 2p-orbitals, respectively. However, our conclusion on the elucidation of near-ultraviolet spectra of copper(II) acetate, though being the same as Dubicki's in attributing the band to the CT transitions from nonbonding oxygen orbitals to vacant metal d-orbitals, differs in that only p_x (out-of-plane) orbitals are taken into consideration as the orbitals from which an electron transfers. The in-plane nonbonding orbital (p_y) is regarded as a sp^2-hybridized orbitals, whose energy is much lower than that of the out-of-plane p-orbitals and is thus neglected.

Thus, the bands at 27.8 and 30.8 kK should be assigned to some transitions from the out-of-plane π-orbitals to the metal d-(b_{2u}) orbital. Judging from the observed intensities ($\varepsilon > 100$), the absorptions are not likely to be symmetry-allowed ones.

It should be noted that the appearance of CT bands in such a relatively low-frequency region can also be interpreted in terms of a high *p*-character of the nonbonding orbitals of the negatively charged oxygen atoms.

Possibility of Double Excitations. The possibility of double excitation of d–d transitions for copper(II) acetate and other binuclear metal complexes has been pointed out.[5,14,15] Dubicki could not ignore this possibility, though his discussion appeared in favor of the CT-transition origin.[7] However, in the case of chromium(II) acetate it seems improbable that the double excitations are the origin of the near-ultraviolet bands (ν_{max}=29.2 and 30.8 kK),[4] apart from the problem of absorption intensity, because any combination of the d–d transitions which are most probably distributed within the range 17~25 kK could not account for the observed frequencies 29.2 and 30.8 kK. Similar relations are observed in the case of μ-dialkoxodicopper(II) complexes, *i.e.*, frequencies of the near-ultraviolet bands (~28 kK) are too low to be assigned to some combinations of the d–d transitions (15~18 kK).[18] These facts imply that the near-ultraviolet band is better interpreted in terms of CT transitions than double excitations of d–d transitions at least for the binuclear copper(II) complexes discussed in this paper.

Studies of the Ruthenium(III) Complex. V. Aquation and Anation Reactions of Halogenoacetatopentaammineruthenium(III) Complexes in Aqueous Solutions

Akira OHYOSHI, Satoshi SHIDA, Shuichi IZUCHI, Futoshi KITAGAWA, and Katsutoshi OHKUBO

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received January 10, 1973)

The kinetics of aquation and anation reaction have been studied with pentaammineruthenium(III) complexes containing halogenoacetates (fluoro-, monochloro-, dichloro-, trichloro-, bromo-, and iodoacetates). It has been found that the aquation reaction proceeds through two kinds of paths, *i.e.* the acid-catalysed path and the acid-uncatalysed path, except the cases of dichloro- and trichloroacetate complexes. The aquations of dichloro- and trichloroacetate complexes are not catalysed by a proton because these ligand acids are strong acids. The equilibrium constants between $[RuH_2O(NH_3)_5]^{3+}$ and $[RuO_2CRX(NH_3)_5]^{2+}$ (O_2CRX=halogenoacetate), K_{eq}, were calculated from the anation and aquation rate constants. The k_{aq} and K_{eq} values for the fluoro-, chloro-, dichloro-, trichloro-, bromo-, and iodoacetatocomplexes are, respectively: k_{aq}, 10×10^{-5}, 7.5×10^{-5}, 19.1×10^{-5}, 49.0×10^{-5}, 6.8×10^{-5} and 6.7×10^{-5} sec^{-1}; K_{eq}, 5.2×10^{-3}, 3.6×10^{-3}, 9.0×10^{-3}, 23×10^{-3}, 3.5×10^{-3}, and 3.3×10^{-3} M, at 60 °C. The free energy plot, log k_{aq} *vs.* log K_{eq}, gave a straight line with a gradient of 1.0. It has been concluded that the acid-uncatalysed reaction proceeds via a S_N1 mechanism, while the acid-catalysed reaction seems to take place with a S_N2 mechanism. Some remarks have been made on the molecular interaction between the complex and the acid catalyst.

In a previous paper we reported on the kinetics of acid-hydrolysis for carboxylatopentaammineruthenium-(III) complexes.[1] It was found that one of the reaction paths, *i.e.*, the acid-uncatalysed one, proceeded through a dissociative mechanism; however, the mechanism for the acid-catalysed path was not clear. We have now extended the study to obtain further information concerning the reaction mechanism. Thus, the aquation and anation rate constants were measured, and the reaction mechanisms were discussed on the basis of the free-energy relationship.[2]

Experimental

Materials. All the chemicals used were of a reagent grade. Twice-distilled water was used in all kinetic runs. The ionic strength and the acidity of the reaction solution were adjusted with *p*-toluenesulphonic acid and its sodium salt.

Chloropentaammineruthenium (III) chloride was prepared by the method of Allen *et al.*[3),4)] from ruthenium trichloride and hydrazine hydrate.

Found: H, 5.08; N, 23.75%. Calcd for $[RuCl(NH_3)_5]Cl_2$: H, 5.19; N, 23.98%.

Aquopentaammineruthenium(III) perchlorate was prepared by the method of Endicott and Taube.[5)]

Found: H, 3.20; N, 13.74%. Calcd for $[Ru(H_2O)(NH_3)_5](ClO_4)_3$: H, 3.42; N, 13.94%.

Halogenoacetatopentaammineruthenium(III) perchlorates were prepared by the method of Stritar and Taube[6)] from chloropentaammineruthenium chloride, a halogenoacetate buffer solution, and a zinc amalgam.

Found: C, 5.06; H, 3.40; N, 15.00%. Calcd for $[RuO_2CCH_2F(NH_3)_5](ClO_4)_2$: C, 5.19; H, 3.68; N, 15.15%.

Found: C, 4.77; H, 3.50; N, 14.86%. Calcd for $[RuO_2CCH_2Cl(NH_3)_5](ClO_4)_2$: C, 5.02; H, 3.59; N, 14.63%.

Found: C, 4.73; H, 3.18; N, 13.73%. Calcd for $[RuO_2CCHCl_2(NH_3)_5](ClO_4)_2$: C, 4.68; H, 3.12; N, 13.65%.

Found: C, 4.58; H, 2.86; N, 12.83%. Calcd for $[RuO_2CCCl_3(NH_3)_5](ClO_4)_2$: C, 4.39; H, 2.74; N, 12.79%.

Found: C, 4.40; H, 3.08; N, 13.14%. Calcd for $[RuO_2CCH_2Br(NH_3)_5](ClO_4)_2$: C, 4.59; H, 3.25; N, 13.38%.

Found: C, 4.30; H, 2.85; N, 12.17%. Calcd for $[RuO_2CCH_2I(NH_3)_5](ClO_4)_2$: C, 4.21; H, 2.98; N, 12.28%.

Kinetic Runs. The aquation rate was measured spectrophotometically as previously has been described.[1)]

The rate of anation is expressed by the ordinary second-order rate formula:

$$dx/dt = k_{an}(a-x)(b-x) - k_{aq}x \quad (1)$$

where x is the concentration of the $[RuO_2CRX(NH_3)_5]^{2+}$ ion at time t, and where a and b are the initial concentrations of $[RuH_2O(NH_3)_5]^{3+}$ and the halogenoacetate ion respectively. The last is known from the formal concentration and the acid dissociation constant under the given conditions. When the value of a is negligibly small as compared with b, Eq. (1) can be integrated to give;

$$\ln[(x_\infty - x)/x_\infty] = -(k_{aq} + bk_{an})t \quad (2)$$

where the suffix ∞ denotes the equilibrated state. When the anation is measured by a spectrophotometric method, Eq. (2) is replaced by;

$$\ln[(A_\infty - A_t)/(A_\infty - A_0)] = -(k_{aq} + bk_{an})t \quad (3)$$

where A_0, A_t, and A_∞ are the extinctions of the reaction mixture in the initial state, at time t, and in the final state respectively. By plotting $\log(A-A_t)$ vs. t, the apparent rate constant, k_{obs}, can be obtained. The equilibrium quotient, K_{eq}, was calculated from the value of k_{aq} and k_{an}.

Results and Discussion

Aquation Reactions. The pseudo first-order rate constants, k_{obs}, for the aquation of complexes were measured at different hydrogen-ion concentrations of the reaction solution. As is illustrated in Fig. 1, the plots of k_{obs} *vs.* the hydrogen-ion concentration gave straight lines for all the complexes. The observed rate constant, k_{obs}, can be expressed by Eq. (4);

○ fluoroacetato-, ● iodoacetato-, ◐ dichloroacetato-, ◑ trichloroacetato- complex.

$$k_{obs} = k_{H_2O} + k_H[H^+] \quad (4)$$

where k_{H_2O} is the acid-independent rate constant and where k_H is the acid-dependent rate constant. In the cases of dichloro- and trichloro-acetatocomplexes, the contribution of the k_H path in Eq. (4) was negligible compared with the k_{H_2O} path; therefore, the rate constant of aquation, k_{aq} could be approximated as equal to k_{H_2O}. The calculated k_{H_2O} and k_H values are listed in Table 1, together with the pK_a values of the ligand acids.

Table 1. Rate constants of acid-catalysed and uncatalyzed paths in the aquation reaction of halogenoacetatopentaammineruthenium(III) complexes at $\mu=1.0$

Complexes	temp. °C	pK_a [a] (35 °C)	$k_{H_2O} \times 10^4$, sec^{-1}	$k_H \times 10^4$, M^{-1} sec^{-1}

Trichloroacetato-	60.1	0.70	4.90	—

a) These values obtained from Ref. 7.

The rates of aquation increase with an increase in the ionic strength. Applying the Brønsted-Bjerrum-Christiansen formulation[8] (Eq. 5), the dependence of the ionic strength on the k_H value was investigated.

$$\ln k_H = \ln k_{H,0} + \frac{2AZ_1Z_2\sqrt{\mu}}{1+B\sqrt{\mu}} \quad (5)$$

where k_H is the acid-dependent rate constant, $k_{H,0}$ is the same for infinite dilution, Z_1 and Z_2 are the charges on the two reactants, μ is the ionic strength, A is a constant equal to 0.509 for water at 25 °C, and the B constant is of the order of the magnitude of unity.

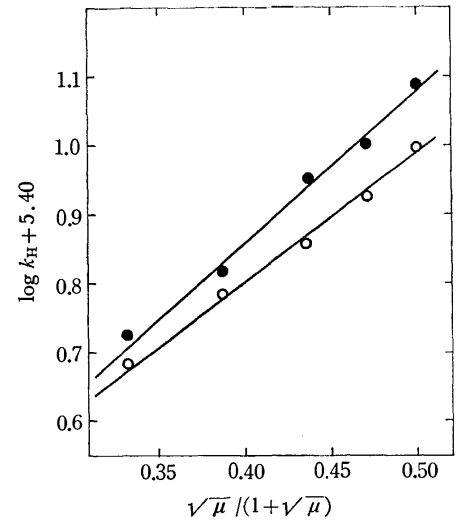

Fig. 2. Relationship between the acid-catalysed rate constant k_H and the ionic strength of the solution. (60 °C, [H$^+$]=0.025 M)
○ Fluoroacetato complex, ● Iodoacetato complex
temp: 60 °C, [H$^+$]=0.025 M

Figure 2 shows the relationship; between the k_H values and μ according to the simplified equation, Equation (5). Since the present experiment was carried out at $\mu=1.0$, this relationship is not sufficiently reliable; however, the slopes of the straight lines in Fig. 2 are both nearly +2, and these facts suffice to show the role of the proton at the transition state in the acid-dependent path. These results show that the aquation rate of the complex is dependent on the hydrogen-ion concentration and that the two reaction paths are involved in the reaction. This can be expressed by Eq. (6) for one path and by Eqs. (7) and (8) for the other path:

$$[(NH_3)_5Ru\text{–}O\overset{\overset{O}{\|}}{C}RX]^{2+} + H_2O \xrightarrow{k_6} [(NH_3)_5RuOH_2]^{3+} + RXCO_2^- \quad (6)$$

$$[(NH_3)_5Ru\text{–}O\overset{\overset{O}{\|}}{C}RX]^{2+} + H^+ \xrightarrow{K_h} [(NH_3)_5Ru\text{–}O\overset{\overset{OH}{|}}{C}RX]^{3+} \quad (7)$$

7) G. Kortüm, W. Vogel, and K. Andrussow, "Dissociation Constants of Organic Acid in Aqueous Solution," Butterworths, London (1961), p. 291—295.

8) F. Basolo and R. G. Pearson, "Mechanisms of Inorganic Reactions", 2nd ed., John Wiley and Sons Inc., New York (1967), p. 34.

$$[(NH_3)_5Ru\text{-}\overset{OH}{\overset{|}{O}}CRX]^{3+} + H_2O \xrightarrow{k_8}$$
$$[(NH_3)_5RuOH_2]^{3+} + RXCO_2^- + H^+ \quad (8)$$

The rate constant of the uncatalysed path (Eq. (6)), k_6 corresponds to k_{aq}. Equations (7) and (8) indicate the acid-catalysed path, the rate constant, k_H, of which can be expressed by Equation (9);

$$k_H = k_8 K_h \quad (9)$$

This relationship for the hydrolysis of similar complexes of Co(III), Rh(III), and Ir(III) has previously been reported.[9-13]

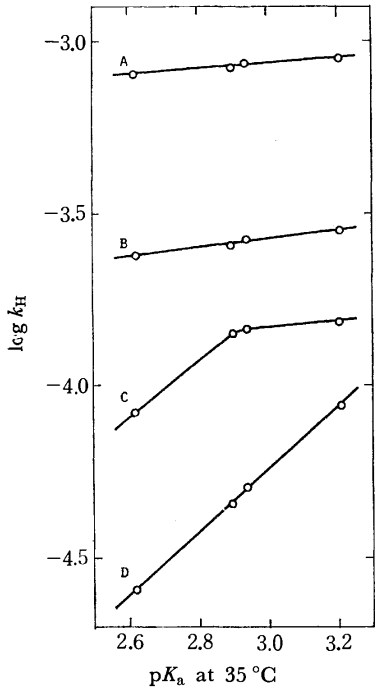

Fig. 3. Relationship between k_H of aquation reactions and pK_a of the ligand acids.
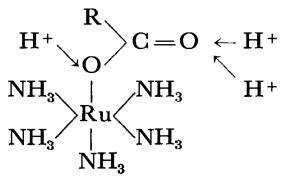
A: 70 °C, B: 60 °C, C: 50 °C, D: 40 °C

As is shown in Fig. 3, the plot of log k_H *vs.* the pK_a value of the ligand acid gives a straight line, with a gradient almost unity at lower reaction temperatures, while the gradient is about zero at higher temperatures, therefore, the weak acid seems to behave as the strong acid. The smaller k_H values of fluoroacetatocomplex compared to these of the iodoacetatocomplex (Table 1) may be due to the smaller tendency of forming a protonated intermediate shown by Eq. (7); that is, the electrostatic effect of the halogen atom is reflected in the constant, K_h, of Eq. (7), which is important in determining the k_H values.

Some remarks should be made here on the molecular interaction between carboxylatopentaammineruthenium(III) complexes ($(NH_3)_5RuOC(=O)R^{2+}$) and the acid catalyst, H^+. Three distinctive modes of interaction can be allowed in view of the orbital symmetry and orbital energies of the two species:



Ru-O=2.5 Å; Ru-N=2.23 Å; N-H=1.031 Å; C-O=1.28—1.43 Å, ∠RuOC=105°; ∠OCO=122.4—130°

The preliminary calculations of the all-valence-shell-electron extended Hückel MO on the above interacting system of $(NH_3)_5RuOC(=O)R^{2+}$—H^+ [14] have demonstrated that the most plausible interaction of the H^+ catalyst occurs predominantly in the direction of the orbital expansion of the nonbonding lone-pair 2p-orbital on the oxygen atom of the Ru–O bond in terms of the weakening of the Ru–O; in the case of $(NH_3)_5$-$RuOC(-O)H^{2+}$, the bond population of Ru–O (0.085) is lessened to 0.073 by the electrophilic attack of the H^+ catalyst (H^+—$0 \gtrsim 0.97$ Å).

It is worthy of emphasis that the single C–O bond is not weakened by the attack of the catalyst and that, in some measure, the solvent of H_2O participates in the weakening of the Ru–O bond; the details of this will be discussed precisely in a succeeding paper.

As is shown in Table 1, an antiparallel relationship is found between the k_{H_2O} values and the pK_a values of the halogenocarboxylic acids. Similar results were obtained for the carboxylato-[9] and amino acido-[13] pentaamminecobalt(III), and analogous ruthenium-(III) complexes.[1] These results indicate that the aquation takes place via the S_N1 (lim) mechanism because the rupture of the metal-ligand bond depends on the bond strength predicted by the pK_a of the carboxylic acids.

Anation Reactions and the Free-Energy Relationship. The anation reaction of aquopentaammineruthenium (III) complexes with halogenoacetate ions may be written as;

$$[RuH_2O(NH_3)_5]^{3+} + RXCOO^-$$
$$\rightleftarrows [RuO_2CRX(NH_3)_5]^{2+} + H_2O \quad (10)$$

and the rate constant, k_{obs}, may be expressed by the following equation;

$$k_{obs} = k_{aq} + k_{an}[RXCOO^-] \quad (11)$$

The k_{an} is obtained from the slope of the linear plot of k_{obs} vs. $[RXCOO^-]$, as is shown in Fig. 4. The equilibrium quotient, K_{eq}, is expressed by:

$$K_{eq} = k_{aq}/k_{an} \quad (12)$$

The values of k_{an} and K_{eq} are listed in Table 3.

Langford[2], Haim[15] and Murakami *et al.*[13] examined the linear free-energy relationship between the equilibrium quotient and the rate constant for aquation reactions of various acidopentaamminecobalt(III) complexes and obtained a gradient unity in their log-log plot;

$$\Delta \ln k_{aq} = \alpha \Delta \ln K_{eq} \qquad (13)$$

This value suggests a similarity between the transition state and the product. When this value is unity, the state of the ligand is the same as that in the product.

A similar plot of our results for the halogenoacetatopentaammineruthenium(III) complexes is shown in Fig. 5. An apparent α value of 1.0 is obtained from the gradient of the straight line. Thus, it can be concluded that the halogenoacetate ligand in the transition state for the aquation reaction is very similar to solvated anions; that is, the aquation reaction proceeds by the S_N1 mechanism.

Haim[15] gives Eq. (14) in discussing the relation between k_{aq} and K_{eq} for the auqations of the pentaammine series of cobalt(III) complexes:

$$\log k_{aq} = \log k_x K_0 - \log K_{eq} \qquad (14)$$

where K_0 is the ion-pair or outer-sphere complex formation constant between the aquopentaammine ion and the incoming ligand, and k_x, the inner sphere-outer sphere interchange velocity of the ion pair.

In the present study, a similar discussion is possible for the anation and aquation mechanisms. Since $K_{eq}=K_0k_x/k_{aq}$, the gradient of 1.0 in the $\log k_{aq}$ *vs.* $\log K_{eq}$ plot (Fig. 5) implies that the first term on the right-hand side of Equation (14) is independent of the nature of the incoming ligand, $RXCO_2^-$, in Reaction (10). The $\log k_xK_0$ term will be constant if the individual values of k_x and K_0 remain constant as the ligand $RXCO_2^-$ is varied. Since the value of K_0 is determined by the charge of the ligand, Langford's linear correlation for the $RXCOO^-$ ligands implies that the values of k_x are independent of the nature of the ligand. As is shown in Table 2, the observed rate constants for various anation reactions are practically the same; that is, there is little assistance by the incoming ligand in the outer sphere-inner sphere interchange reaction. In other words, this interchange is the rate-determining step for the anation reaction.

Kinetic Studies of Thermal Decomposition Reactions of Amminechromium(III) Complexes in Solid State.

Kenzo NAGASE and Nobuyuki TANAKA*

College of General Education, Tohoku University, Kawauchi, Sendai 980

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received January 22, 1973)

Kinetics of the thermal decomposition reactions of $[Cr(NH_3)_6]X_3$ (X=Br, I and NCS) and $[Cr(NCS)(NH_3)_5](NCS)_2$ in solid state were studied by the manometric method. The rate constants, activation energies and activation entropies of the substitution reactions of outer-sphere anions for coordinated ammonia molecules were presented, and possible reaction mechanisms were discussed.

It is well-known that the decomposition of chromium(III) complexes having volatile ligands such as ammonia, water and ethylenediamine is initiated by substitution of an outer-sphere anion for ligand; for example, $[Cr(NH_3)_6]Cl_3$ liberates ammonia to form $[CrCl(NH_3)_5]Cl_2$.[1,2] This behavior differs entirely from that of many cobalt(III) complexes of which the decomposition is initiated by electron transfer from a ligand or an outer-sphere anion to a central metal ion.[3,4]

Investigations on these substitution reactions of chromium(III) complexes have been reported, but the mechanisms are not clear. This might be attributed to the lack of kinetic measurements. There are a few works on kinetic measurements: Wendlandt and Bear[5] obtained isothermal kinetic data for the deaquation of $[Cr(H_2O)(NH_3)_5]X_3$ (X=Cl, Br, I and NO_3), and Tanaka and Nagase[2] those for deammonation of $[Cr(NH_3)_6]Cl_3$, $[CrCl(NH_3)_5]Cl_2$ and *cis*-$[CrCl_2(NH_3)_4]Cl$. Tsuchiya and his coworkers also obtained kinetic data for the deaquation of $[Cr(H_2O)(NH_3)_5]X_3$ (X=Cl, Br, I, NO_3, SO_3 and SO_4) from the DTG and DTA curves.

We have studied kinetics of the thermal decomposition of $[Cr(NH_3)_6]X_3$ (X=Br, I and NCS) and $[Cr(NCS)(NH_3)_5](NCS)_2$ by the manometric method, and discussed the mechanisms on the basis of kinetic data.

Experimental

Apparatus and Procedure. Pressure-time curves were obtained by the apparatus described previously.[3] Details of the procedure were reported.[2]

A Hitachi EPI-2G infrared spectrophotometer and a Hitachi EPS-3T spectrophotometer equipped with a standard integrating sphere attachment were used for the measurements of the infrared absorption spectra and diffuse reflectance spectra, respectively.

Materials. The complexes $[Cr(NH_3)_6]Cl_3$[7] and $[Cr(H_2O)(NH_3)_5]Cl_3$[8] were prepared according to literature. $[Cr(NH_3)_6]Br_3$ and $[Cr(NH_3)_6]I_3$ were obtained by adding HBr and HI, respectively, to the aqueous solution of $[Cr(NH_3)_6]Cl_3$. $[Cr(NCS)(NH_3)_5](NCS)_2$ was prepared by a modified Werner's method.[9] A mixture of 15 g of $[Cr(H_2O)(NH_3)_5]Cl_3$ and 20 g of KNCS was dissolved in a solution of 10 ml of glacial acetic acid in 50 ml of water. The filtrate was cooled and orange crystals were separated by filtration. For the preparation of $[CrI(NH_3)_5]I_2$, the solution containing $[Cr(H_2O)(NH_3)_5]Cl_3$ and HI was heated on a water bath until purple crystals were separated. $[Cr(NH_3)_6](NCS)_3$ was prepared as follows: the mixture of $[Cr(NH_3)_6]Cl_3$ and methanol saturated with KNCS was left standing overnight at room temperature, and filtered off. The yellow filtrate was evaporated until crystals of $[Cr(NH_3)_6](NCS)_3$ were separated.

Results

Hexamminechromium(III) bromide loses one mole of ammonia to form $[CrBr(NH_3)_5]Br_2$ as shown by

$$[Cr(NH_3)_6]Br_3 \longrightarrow [CrBr(NH_3)_5]Br_2 + NH_3 \quad (1)$$

Pressure-time curves of $[Cr(NH_3)_6]Br_3$ in the temperature range of 213 to 232 °C are given in Fig. 1. Reaction (1) proceeded essentially according to a

first-order rate equation, but deammonation was suppressed by the increase of decomposition pressure. In the case of $[Cr(NH_3)_6]Cl_3$ the deammonation proceeded almost independently of the decomposition pressure.[2] On the pressure-time curve, there is an inflection point at 232 °C, indicating that the reaction

$$[CrBr(NH_3)_5]Br_2 \longrightarrow [CrBr_3(NH_3)_3] + 2NH_3$$

follows Reaction (1). In fact, the sample heated at 232 °C for 90 min was confirmed to be a mixture of $[CrBr(NH_3)_5]Br_2$ and $[CrBr_3(NH_3)_3]$ from its infrared and reflectance spectra. The infrared spectrum also showed the formation of a small amount of ammonium bromide.

When $[Cr(NH_3)_6]Br_3$ was heated at 230 °C in a vacuum (the system was continuously evacuated with a rotary pump), the main product was not $[CrBr_3(NH_3)_3]$ but chromium nitride. This shows that $[CrBr_3(NH_3)_3]$ is stable above 230 °C in the presence of free ammonia. This was also observed for $[CrCl_3(NH_3)_3]$. In the case of iodide complex, $[CrI_3(NH_3)_3]$ could not be obtained even when the sample was heated in the presence of free ammoria, $[CrI(NH_3)_5]I_2$ only being obtained by heating the sample in a sealed capillary tube.

Plots of $\log(1-x)$ *versus* time are given in Fig. 2, where x denotes fractional decomposition. The kinetic parameters for Reaction (1) are given in Table 2.
