When hexamminechromium(III) iodide was heated in an inert gas atmosphere or in a vacuum, the complex decomposed to chromium nitride. The reaction is represented by

$$[Cr(NH_3)_6]I_3 \longrightarrow CrN + 3NH_4I + 2NH_3 \quad (2)$$

It proceeded essentially according to a first-order rate equation, but decomposition was suppressed by the increase of decomposition pressure, as seen for the bromide complex. The first-order rate constants of Reaction (2) were determined by the measurement of initial rates. The activation parameters obtained are given in Table 2.

The order of the thermal stabilities of the hexamminechromium(III) halides heated under the conditions of manometric measurement is as follows:

$$[Cr[NH_3)_6]Cl_3 < [Cr(NH_3)_6]Br < [Cr(NH_3)_6]I_3$$

This differs from that of the thermal stabilities reported by Wendlandt and Chou.[10] The order they obtained from the temperature of initial mass-loss in the air is as follows:

$$[Cr(NH_3)_6]I_3 < [Cr(NH_3)_6]Cl_3 < [Cr(NH_3)_6]Br_3$$
$$(190°C) \qquad (200°C) \qquad (250°C)$$

By heating $[Cr(NH_3)_6]I_3$ in the air, free iodine was observed which is considered to be formed by the reaction of the iodide ion and the oxygen in air.

$[CrI(NH_3)_5]I_2$ was obtained almost quantitatively when $[Cr(NH_3)_6]I_3$ was heated in a sealed capillary tube, in which the decomposition pressure became very high and the whole system was maintained at a furnace temperature. The infrared absorption peaks of the product are given in Table 1, together with those of $[Cr(NH_3)_6]I_3$ and $[CrI(NH_3)_5]I_2$.

Table 1. Wave numbers of the product,[a] $[Cr(NH_3)_6]I_3$ and $[CrI(NH_3)_5]I_2$

	$\delta_d(NH_3)$	$\delta_s(NH_3)$	$\rho_r(NH_3)$
Product	1586	1292	746
$[Cr(NH_3)_6]I_3$	1595	1307	738
$[CrI(NH_3)_5]I_2$	1587	1292	747

a) The product was obtained by heating $[Cr(NH_3)_6]I_3$ at 225 °C for 24 hr in a sealed capillary tube.

Kinetic runs of hexamminechromium(III) thiocyanate in a temperature range of 99 to 116 °C are given in Fig. 3, where α denotes the mole ratio of free ammonia to chromium(III) complex. The reaction is represented by

$$[Cr(NH_3)_6](NCS)_3 \longrightarrow [Cr(NCS)_3(NH_3)_3] + 3NH_3 \quad (3)$$

It proceeded almost independent of the pressure of free ammonia, obeying the Prout-Tompkins equation, $dx/dt=kx(1-x)$, where x denotes fractional decompo-

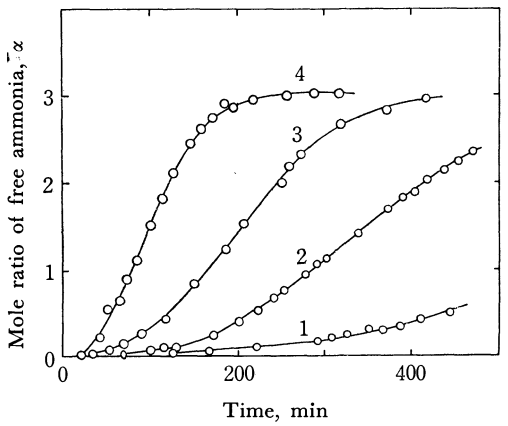

Fig. 3. Kinetic runs of $[Cr(NH_3)_6](NCS)_3$ at (1) 99, (2) 106, (3) 110 and (4) 116°C.

sition. Plots of $\log [x/(1-x)]$ *versus* time are given in Fig. 4, from which the second-order rate constants were determined. The kinetic parameters of Reaction (3) are given in Table 2.

Kinetic runs of $[Cr(NCS)(NH_3)_5](NCS)_2$ in the temperature range 91—105.5 °C are given in Fig. 5. The reaction is represented by

$$[Cr(NCS)(NH_3)_5](NCS)_2 \longrightarrow [Cr(NCS)_3(NH_3)_3] + 2NH_3 \quad (4)$$

This obeys a first-order rate equation although this complex contains thiocyanate ions as in the case of $[Cr(NH_3)_6](NCS)_3$. The kinetic parameters are given in Table 2.

Discussion

Kinetic parameters of amminechromium(III) complexes are given in Table 2. The data of $[Cr(NH_3)_6]Cl_3$, $[CrCl(NH_3)_5]Cl_2$ and *cis*-$[CrCl_2(NH_3)_4]Cl$[2] are also given for the sake of comparison. For $[Cr(NH_3)_6]I_3$, the substituted complexes such as $[CrI(NH_3)_5]I_2$ and $[CrI_3(NH_3)_3]$ could not be obtained under the conditions for manometric measurement, but $[CrI(NH_3)_5]I_2$ was obtained by heating $[Cr(NH_3)_6]I_3$ in a sealed capillary tube. This indicates that the reactions including a partial equilibrium such as

$$[Cr(NH_3)_6]I_3 \longrightarrow [CrI(NH_3)_5]I_2 + NH_3$$
$$[CrI(NH_3)_5]I_2 \rightleftharpoons CrN + NH_3 + 3NH_4I$$

may take place in the case of the iodide complex; the formation of the triammine complex, as seen for $[Cr(NH_3)_6]X_3$ (X=Cl, Br and NCS), is considered to be small because of the steric hindrance, *i.e.*, an iodide ion is too large to form $[CrI_3(NH_3)_3]$.

Thus, it is supposed that the decomposition of all the complexes listed in Table 2 is essentially initiated by substitution of an outer-sphere anion for a coordinated ammonia.

For the hexamminechromium(III) complexes, the order of temperature at which the rate constant is equal to 1×10^{-5} sec^{-1} is as follows:

$$[Cr(NH_3)_6](NCS)_3 \underset{(77°C)}{<} [Cr(NH_3)_6]Cl_3 \underset{(156°C)}{<} [Cr(NH_3)_6]Br_3 \underset{(184°C)}{<} [Cr(NH_3)_6]I_3 \underset{(194°C)}{}$$

It should be noted that the stability of the complexes depends strongly on an outer-sphere ion. The order is quite different from that of the hexamminecobalt(III) complexes whose decomposition is initiated by electron transfer from an outer-sphere anion to a central cobalt(III).[3]

Two types of mechanism are considered for the substitution reaction which includes the replacement of a ligand, dissociation (S_N1) and displacement (S_N2). S_N1 *mechanism*:

$$[Cr(NH_3)_6]X_3 \rightleftharpoons \underset{\text{five coordination}}{[Cr(NH_3)_5]X_3} + NH_3 \longrightarrow [CrX(NH_3)_5]X_2 + NH_3$$

Table 2. Kinetic parameters of the substitution reactions of amminechromium(III) complexes in solid state

Reaction	$k\times10^5$, sec^{-1} (t, °C)	E_a kcal/mol	$\Delta S^{\neq}$ e. u.
$[Cr(NH_3)_6]Cl_3 \rightarrow [CrCl(NH_3)_5]Cl_2+NH_3$	2.97 (170)	30	−12
$[Cr(NH_3)_6]Br_3 \rightarrow [CrBr(NH_3)_5]Br_2+NH_3$	2.16 (192)	43	12
$[Cr(NH_3)_6]I_3 \rightarrow CrN+3NH_4I+2NH_3$	3.0 (204)	49	18
$[Cr(NH_3)_6](NCS)_3 \rightarrow [Cr(NCS)_3(NH_3)_3]+3NH_3$	10.7 (99)	28	−3
$[CrCl(NH_3)_5]Cl_2 \rightarrow [CrCl_2(NH_3)_4]Cl+NH_3$	1.70 (191)	38	1
$[Cr(NCS)(NH_3)_5](NCS)_2 \rightarrow [Cr(NCS)_3(NH_3)_3]+2NH_3$	1.45 (85)	36	15
cis-$[CrCl_2(NH_3)_4]Cl \rightarrow$ *cis, cis*-$[CrCl_3(NH_3)_3]+NH_3$	11.0 (136)	31	−2

S_N2 *mechanism*:

$$[Cr(NH_3)_6]X_3 \rightleftharpoons [CrX(NH_3)_6]X_2 \longrightarrow$$
seven coordination
$$[CrX(NH_3)_5]X_2 + NH_3$$

In the case of S_N1, the rate of deammonation is almost independent of the size of an outer-sphere anion and decreases with the increase of the pressure of free ammonia, while in the case of S_N2, the rate depends strongly on the size of an outer-sphere anion. From the equation

$$\Delta H^{\neq} = \Delta H_1^{\neq} - \Delta H_2^{\neq},$$

where $\Delta H_1^{\neq}$ and $\Delta H_2^{\neq}$ are the enthalpies of activation for bond breaking and bond making, respectively, it is supposed that activation energy of S_N1 is larger than that of S_N2. Moreover, the reaction of S_N1 is considered to have larger entropy of activation from the freedom of the activated complex.

Although it is impossible to assign the reaction of all the complexes listed in Table 2, $[Cr(NH_3)_6]Br_3$ and $[Cr(NH_3)_6]I_3$ might belong to S_N1 and $[Cr(NH_3)_6]Cl_3$ to S_N2 from their kinetic behavior. The reason that $[Cr(NH_3)_6](NCS)_3$ decomposed at the lowest temperature may be due to the fact that the nitrogen atom coordinated directly to chromium(III) is the smallest in size.

The authors wish to thank the Ministry of Education for the financial support granted this research.

Metal Chelates of Aromatic *o,o'*-Dihydroxyazo Compounds. I. The Fluorescence Properties of the Metal Chelates of *o,o'*-Dihydroxyazobenzene and Their Use in Fluorometry

Keizō Hiraki

Department of Chemistry, Faculty of Science and Technology, Kinki University, Kowakae, Higashi-Osaka 577

(Received November 2, 1972)

As fluorometric reagents for the determination of Al, Ga, In, *etc.*, 11 derivatives of *o,o'*-dihydroxyazobenzene were examined in an attempt to determine the most desirable structure of azo compounds. *o,p,o'*-Trihydroxyazobenzene type compounds were more sensitive than *o,o'*-dihydroxyazobenzene; CH_3O-group substitution at the *para* position was also efficient. The SO_3H substitution increased, whereas the Cl substitution decreased the fluorescence of metal complexes, and the CH_3-substituted compound did not form fluorescent metal complexes because of its low solubility in water and because of the steric hindrance. Superchrome Garnet Y and Lumogallion seemed to be excellent fluorometric reagents for Al and Ga; 2-(2,4-dihydroxyphenylazo)-1-hydroxybenzene and 3-(2-hydroxy-4-methoxyphenylazo)-4-hydroxybenzene sulfonic acid were also useful. Therefore, the several conditions for the fluorometric determination of Al and Ga with those compounds were also investigated.

It has been recognized that some azo compounds can be used as fluorometric reagents for aluminum, gallium, and other metal ions. Pontachrome Blue Black R[1] and Eriochrome Red B[2] are widely used for the determination of aluminum, while Lumogallion[3,4] is one of the most sensitive fluorometric reagents for aluminum and gallium and has been employed for the determination of aluminum in sea water.[5] However, few systematic investigations of the usefulness of azo compounds for the fluorometry of metal ions have yet been performed.

Freeman and White[6,7] studied the relationship between the structures of several *o,o'*-dihydroxyazo compounds and the fluorescent characteristics of the metal complexes. However, they did not observe any general regularity, because the fluorescence properties were obtained in an aqueous solution in some cases and in a dimethylformamide solution in other cases, and because the pH of the solution was not always the optimum for the fluorescence.

In this paper, the usefulness of *o,o'*-dihydroxyazo compounds in the fluorometric determination of aluminum and gallium will be discussed. *o,o'*-Dihydroxyazobenzene was chosen as the basic azo compound; ten substituted compounds, in which –OH, $-OCH_3$, $-SO_3H$, –Cl, and/or $-CH_3$ groups were substituted for hydrogen atoms at the *ortho*, *meta*, and *para* positions of azobenzen, were synthesized. Among these compounds, Superchrome Garnet Y,[8] Mordant Blue 31,[9] and Lumogalliion[3] had previously been reported on. The fluorescence measurements were done in an aqueous medium to avoid the complication of the operation and to make the comparison easy, and the usefulness of these azo compounds for the fluorometry was ex-

amined under the optimum analytical conditions.

Reagent and Apparatus

Synthesis of Azo Compounds. The eleven azo compounds used in this investigation are shown in Table 1. These azo compounds were synthesized by the usual diazotization and coupling, and were precipitated from an aqueous solution by adding concentrated hydrochloric acid. The products thus obtained were purified by repeated recrystallizations from 6M hydrochloric acid or an ethanol solution, and were then dried at room temperature on silica gel in a desiccator.

Azo Compound Solutions. A definite weight of each of the azo compounds was dissolved in redistilled water or purified ethanol, and then the solution was diluted to give a 0.1—0.01% solution.

Standard Solutions of Aluminum, Gallium, Scandium, and Indium. The stock solution of aluminum was prepared by dissolving 1.6803 g of aluminum in water containing 5 ml of concentrated hydrochloric acid, and by then diluting the solution to 100 ml. The stock solution was diluted with water to make a standard solution containing 1.00 μg aluminum per ml. The stock solutions of gallium, scandium, and indium were prepared by dissolving 99.99, 99.9, and 99.99% pure oxides respectively with 6M hydrochloric acid; the standard solutions were obtained by the subsequent suitable dilution of the stock solutions.

Rhodamine B Solution. 0.1 g of Rhodamine B was dissolved in water, and then the solution was diluted to 100 ml. The stock solution was diluted with water to make a solution containing 0.168 μg Rhodamine B

Table 1. Chemical formulae of o,o'-dihydroxyazo compounds

Compd. No.	o,o'-Dihydroxyazo compound		Diazonium component	Coupling component
I		2-(2-hydroxyphenylazo)-1-hydroxybenzene		II		2-(2,4-dihydroxyphenylazo)-1-hydroxybenzene		III		3-(2,4-dihydroxyphenylazo)-4-hydroxybenzenesulfonic acid		IV		2-(2,4-dihydroxyphenylazo)-1-hydroxy-4-chlorobenzene		V		3 (2,4-dihydroxyphenylazo)-2-hydroxy-5-chlorobenzenesulfonic acid		VI		3-(2,4-dihydroxyphenylazo)-4-hydroxybenzenecarboxylic acid		VII		3-(2-hydroxy-4-methoxyphenylazo)-4-hydroxybenzenesulfonic acid		VIII		2-(2,4,6-trihydroxyphenylazo)-1-hydroxybenzene		IX		3-(2,4,6-trihydroxyphenylazo)-4-hydroxybenzenesulfonic acid		X		3-(2,4,6-trihydroxyphenylazo)-2-hydroxy-5-chlorobenzenesulfonic acid		XI		3-(2-hydroxy-5-methylphenylazo)-4-hydroxy-1-methylbenzene		
per ml; this solution was employed as the reference fluorescence standard in adjusting the sensitivity of the instrument.

All the other chemicals used were the analytical grade. Ethanol, hydrochloric acid, and ammonia were distilled until they did not show fluorescence.

Apparatus. The spectrofluorometric measurements were made with a Hitachi spectrophotometer, Model EPU-2A, equipped with a Hitachi fluorometric attachment, Model G-3 (exciting source : 150 W Xenon lamp). A Hitachi-Horiba glass electrode pH meter, Model M-5, was used for the pH measurements.

Experimental

The general procedure was as follows. To 15—20 ml of a sample solution containing appropriate amounts of metal ions such as aluminum, gallium, scandium, *etc.*, a certain quantity of a 0.1—0.01% azo compound solution and 2 ml of a 20% ammonium acetate solution or a 20% ammonium chloride solution are added. The pH value is adjusted to a desired one with a dilute hydrochloric acid solution or an ammonia solution, after with the solution is diluted to 25 ml with water. If the reaction is slow, the solution is kept at 50—80 °C for 10 min before the final dilution. The fluorescence intensity is measured at the optimum-excitation and maximum-emission wavelengths, using a Rhodamine B solution as the reference standard.[10]

Results and Discussion

Fluorescence Properties of Metal-o,o'-dihydroxyazo Compounds. Table II summarized the fluorescence behavior of several metal complexes with the *o,o'*-dihydroxyazo compounds synthesized in the present work. As may be seen in the table, metal complexes with Compounds II, III, IV, V, and VII show intense fluorescence, but the complexes with Compounds VIII, IX, X, and XI are weakly fluorescent or non-fluorescent. Compound VI, which is a carboxyl-substituted product, can not be practically used in the fluorometry, because the reagent itself has a strong fluorescence.

The fluorescence intensities of the aluminum complexes obtained under the optimum conditions increase in this order: Compound IV<II=VII<V<III. The weaker fluorescence of the Compound II complex may result from its low solubility in water. The sulfo-substituted compound III forms a strong fluorescent complex, but this reagent fluorescences remarkably. On the other hand, chloro substitution decreases the fluorescence intensity of the complex because of the electron-withdrawing property of chlorine atom. The chloro- and sulfo-substituted compound V, also called Lumogallion, is a very useful and accurate fluorometric reagent for trace amounts of aluminum. This may be the result of the fact that the fluorescence of the aluminum complex decreases a little, while the blank fluorescence decreases markedly, in comparison with Compound III.

Freeman and White pointed out that the fluorescence intensity increased in the presence of an additional hydroxyl group or a methoxyl group on the position *para* to the azo group in *o,o'*-dihydroxyazobenzene. In the order of sensitivity presented above, Compound VII was less sensitive than Compound V. However,

Table 2. Optimum fluorescence conditions of various metal-*o,o'*-dihydroxyazo compound complexes

Compound No.	Ion	$\lambda_{Excitation,\ max.}$ (nm)	$\lambda_{Emission,\ max.}$ (nm)	pH	Standing time	Metal to ligand ratio	Fluorescence intensity[a]

X	—	—	—	—	—	—	—
XI	—	—	—	—	—	—	—

a) Fluorescence intensity was obtained on 1 μg of metal ions. Fluorometer was set at 60 div. with 0.168 μg Rhodamine B/ml standard solution. Longer excitation wavelength was selected.

10) The fluorescence spectra were not corrected, since the present research was done mainly for analytical purposes.

this comparison was made principally for analytical purposes. The sensitivity of the fluorometer was set in such a manner that the fluorescence intensity of the Rhodamine B reference standard gave a definite reading (60 division) under several optimum conditions for every complex. The optimum excitation wavelength and the maximum emission wavelength of the aluminum-Compound VII complex (λ_{ex} : 495 nm, λ_{em} : 570 nm) are somewhat different from those of the Compound-V complex (λ_{ex} : 485 nm, λ_{em} : 576 nm) and of the other complexes (λ_{ex} : 480—485 nm, λ_{em}: 560—580 nm). The Rhodamine B standard shows a higher fluorescence intensity under the measuring condition for the Compound VII complex; accordingly, the sensitivity of the instrument is reduced. When the sensitivity of the instrument is kept constant, the stronger fluorescence of the aluminum complex occurs in the order of V<VII<III.

On the gallium complexes, the effect of the substituent group is similar, but the fluorescence intensity is much weaker than that of the aluminum complexes.

Compounds II and III also form fluorescent complexes with scandium, indium, and magnesium, but their fluorescence is too weak to use for the fluorometry of scandium, indium, and magnesium.

Compound I, VIII, IX, X, and XI do not form fluorescent complexes. Compound I is hardly soluble in water, although the reagent forms fluorescent aluminum and gallium complexes in an alcoholic medium. The water-solubility of Compound XI is also very low, so the fluorescence intensity is reduced. In the case of Compounds VIII, IX, and X, the reasons for the non-fluorescence are not clear.

The excitation and the emission spectra of these complexes are shown in Figs. 1, 2, 3, and 4. The excitation spectra are very similar in shape except in the cases of Compound VII complexes. On the other hand, the emission spectra of the complexes with the same compound are deformed in a certain manner by

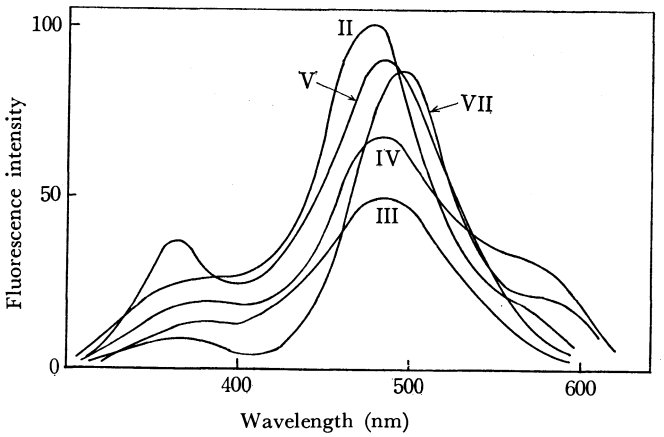

Fig. 1. Excitation spectra of aluminum complexes with *o,o'*-dihydroxyazo compounds.
II: Compound II (*cf.* Table 1, first column), emission monochromator set at 568 nm; III: Compound III, emission monochromator set at 562 nm; IV: Compound IV, emission monochromator set at 576 nm; V: Compound V, emission monochromator set at 576 nm; VII: Compound VII, emission monochromator set at 570 nm

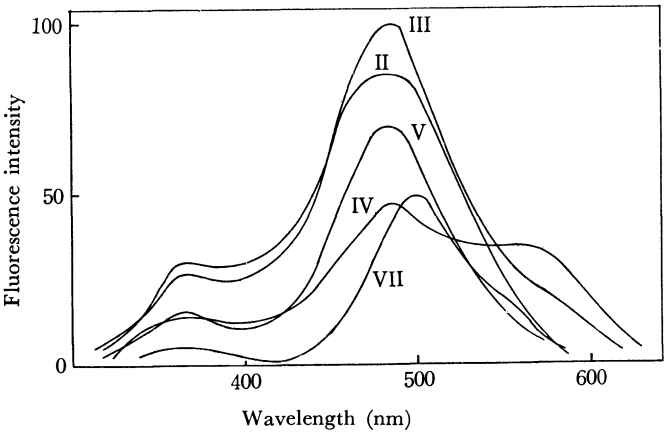

Fig. 2. Excitation spectra of gallium complexes with *o,o'*-dihydroxyazo compounds.

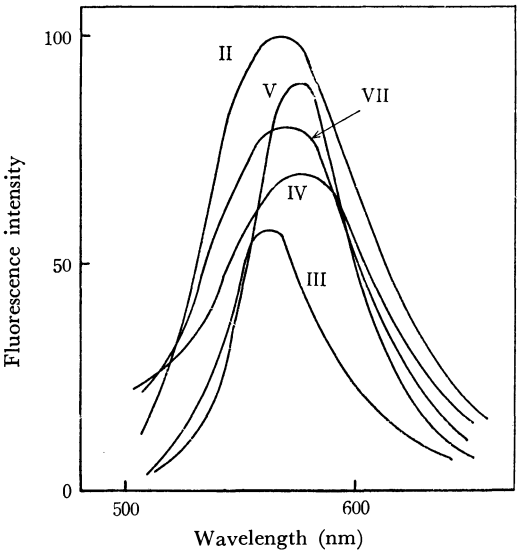

Fig. 3. Emission spectra of aluminum complexes with *o,o'*-dihydroxyazo compounds.
II: Compound II (*cf.* Table I, first column), excitation monochromator set at 480 nm; III: Compound III, excitation monochromator set at 485 nm; IV: Compound IV, excitation monochromator set at 485 nm; V: Compound V, excitation monochromator set at 485 nm; VII: Compound VII, excitation monochromator set at 495 nm

a change in the central metal ions. For example, the emission maximum of the gallium complex shifts to a slightly longer wavelength than that of the aluminum complex.

Fluorometric Determination of Aluminum and Gallium with 2-(2,4-Dihydroxyphenylazo)-1-hydroxybenzene (Compound II) and 3-(2-hydroxy-4-methoxyphenylazo)-4-hydroxybenzene Sulfonic Acid (Compound VII). As has been considered above, Compound III (Superchrome Garnet Y) and Compound V (Lumogallion) are excellent reagents; Compound II and Compound VII

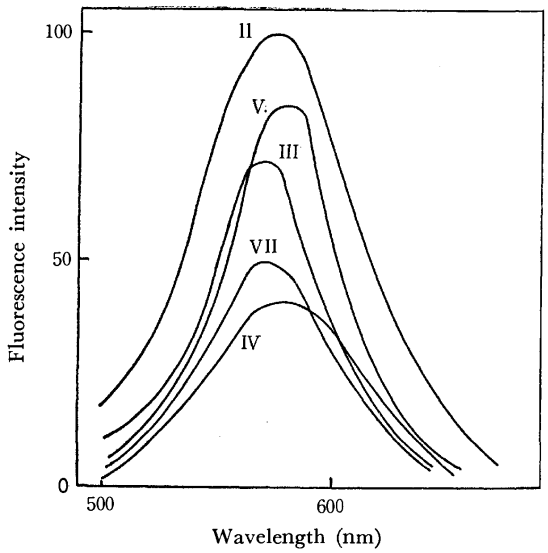

Fig. 4. Emission spectra of gallium complexes with *o,o'*-dihydroxyazo compounds.
II: Compound II (*cf.* Table I, first colum), excitation monochromator set at 485 nm; III: Compound III, excitation monochromator set at 485 nm; IV: Compound IV, excitation monochromator set at 485 nm; V: Compound V, excitation monochromator set at 485 nm; VII: Compound VII, excitation monochromator set at 500 nm

also seem to be useful for the fluorometric determination of aluminum and gallium. Analytical methods using Superchrome Garnet Y and Lumogallion were previously reported; in the present research, the procedures with the latter two reagents were studied.

(a) Effect of Standing Time: The fluorescence of these complexes developed fully within a few minutes after the preparation of the solutions, and it is stable for 2 hr at least.

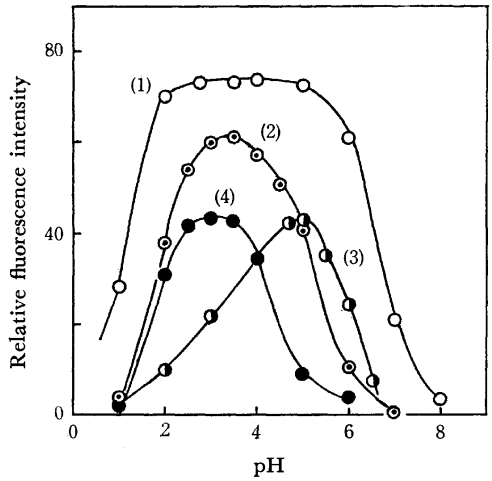

Fig. 5. Effect of pH of solution on fluorescence intensity.
(1) Al complex with compound VII, Al 1.0 μg, 495 nm/570 nm, 50 div. *vs.* 0.168 μg Rhodamine B/ml standard solution; (2) Ga complex with compound VII, Ga 10 μg, 500 nm/570 nm, 100 div. *vs.* 0.168 μg Rhodamine B/ml standard solution; (3) Al complex with compound II, Al 1.0 μg, 480 nm/568 nm, 30 div. *vs.* 0.168 μg Rhodamine B/ml standard solution; (4) Ga complex with compound II, Ga 5.0 μg, 485 nm/575 nm, 40 div. *vs.* 0.168 μg Rhodamine B/ml standard solution

(b) Effect of pH: The effect of the pH on the fluorescence intensities of metal complexes is shown in Fig. 5. The aluminum-Compound VII complex shows its maximum fluorescence in the pH range from 2.7 to 5; the gallium complex, at pH 3.5, the aluminum-Compound II complex, at pH 5, and the gallium complex, near pH 3.

(c) Effect of the Reagent Concentration: Various amounts of the reagent were added to solutions containing an adequate amount of aluminum (2 μg for Compound II and 1 μg for Compound VII) or 10 μg of gallium, after which the fluorescence intensity was measured at the optimum pH. The results, shown in Fig. 6, indicate that 1 ml of a 0.1% Compound VII solution is required for up to 1 μg of aluminum in 25 ml, and 3 ml, for 10 μg of gallium, while 0.5 ml and 0.8 ml of a 0.01% Compound II solution are desirable for 0.05—2 μg of aluminum and 0.5—12 μg of gallium respectively.

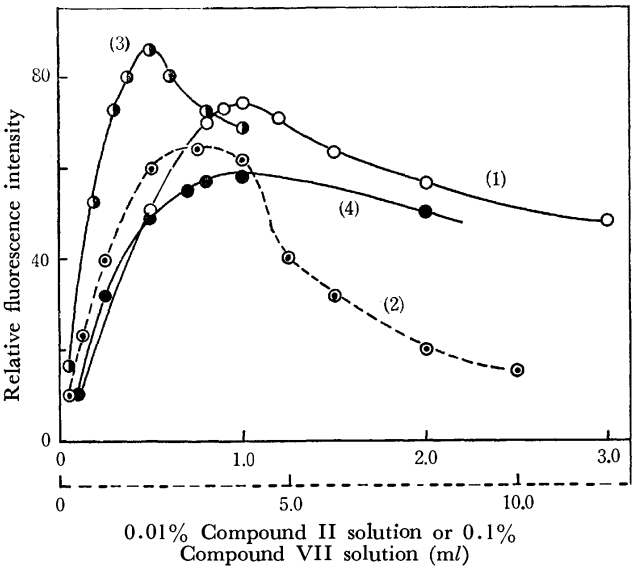

Fig. 6. Effect of reagent concentration.
(1) Al Complex with Compound VII, Al 1.0 μg, 495 nm/570 nm, 50 div. *vs.* 0.168 μg Rhodamine B/ml standard solution; (2) Ga complex with Compound VII, Ga 10 μg, 500 nm/570 nm, 100 div. *vs.* 0.168 μg Rhodamine B/ml standard solution; (3) Al complex with Compound II, Al 2.0 μg, 480 nm/568 nm, 30 div. *vs.* 0.168 μg Rhodamine B/ml standard solution; (4) Ga complex with Compound II, Ga 10 μg, 485 nm/575 nm, 40 div. *vs.* 0.168 μg Rhodamine B/ml standard solution

(d) Calibration Curves: Figure 7 presents the calibration curves for the fluorometric determinations of aluminum and gallium with Compound II and Compound VII; these curves were obtained under the above conditions. The sensitivity of the fluorometer was regulated by setting the fluorescence of the standard Rhodamine B solution (0.168 μg/ml) at a certain reading (40—100 division).

Linear relationships are observed between the fluorescence intensity and the metal-ion concentration; the determinable ranges, within an average error of 3 per cent, are 0.05—1 μg Al/25 ml and 0.5—12 μg Ga/25 ml with Compound II, and 0.05—2 μg Al/25 ml and 2—20 μg Ga/25 ml with Compound VII.

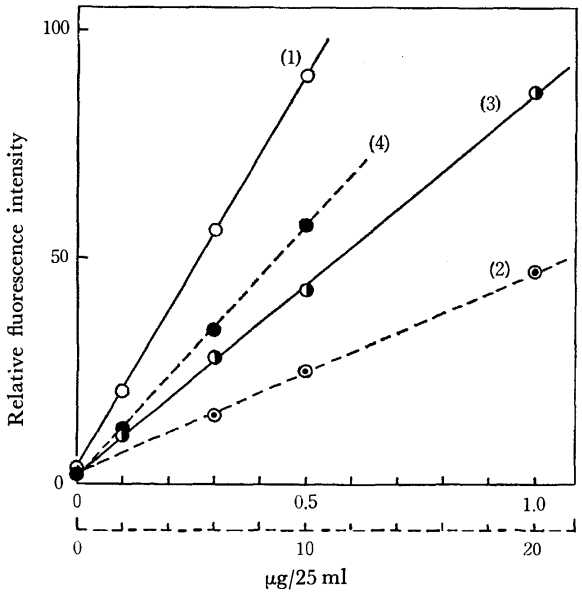

Fig. 7. Calibration curves for aluminum and gallium.
(1): Al-Compound VII system, 495 nm/570 nm, 100 div. *vs.* 0.168 μg Rhodamine B/ml standard solution; (2): Ga-Compound VII system, 500 nm/570 nm, 50 div. *vs.* 0.168 μg Rhodamine B/ml standard solution; (3): Al-Compound II system, 480 nm/568 nm, 60 div. *vs.* 0.168 μg Rhodamine B/ml standard solution; (4): Ga-Compound II system, 485 nm/575 nm, 40 div. *vs.* 0.168 μg Rhodamine B/ml standard solution.

(e) Effects of Diverse Ions: The interference of foreign ions was studied. The following metal ions diminish the fluorescence and give a negative error; in the aluminum-Compound II system, tenfold amounts of cobalt(II), copper(II), iron(III), gallium(III), zirconium(IV), vanadium(V), and chromium(VI); in the aluminum-Compound VII system, hundredfold amounts of cobalt(II), copper(II), nickel(II), tin(II), iron(III), gallium(III), thallium(III), zirconium(IV), titanium(III), vanadium(V), and chromium(VI); for the gallium-Compound II complex, sixfold amounts of copper(II), iron(III), vanadium(V), and molybdenum(VI); and for the gallium-Compound VII complex, twofold amounts of cobalt(II), copper(II), iron (III), and vanadium(V), and fivefold amounts of tin-(II), nickel(III), thallium(III), and chromium(VI).

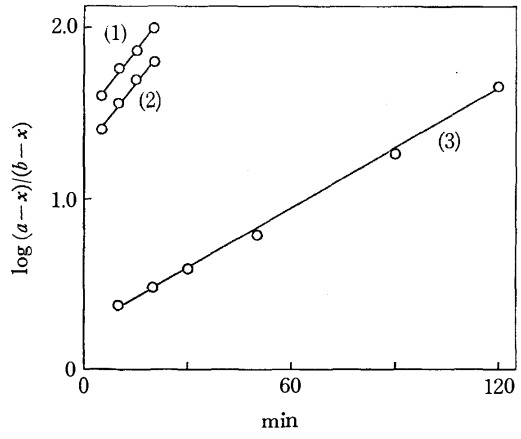

Fig. 8. Kinetics of chelate formation as indicated by fluorescence.
a is initial concentration of aluminum, *b* is initial concentration of compound II, and *x* is concentration of chelate as indicated by fluorescence (at 15 °C).
(1) *a*: 50 μmol, *b*: 5 μmol; (2) *a*: 5 μmol, *b*: 50 μmol; (3) *a*: 5 μmol, *b*: 5 μmol

The aluminum ion gives a positive error in the determination of gallium.

(f) Determination of the Metal-to-Ligand Ratio: Although the existence of the 1 : 1 complex was expected, it could not be confirmed fluorometrically either by the mole-ratio method or by the continuous-variation method. Therefore, the kinetic method was used (reaction temperature—15 °C). Figure 8 shows that the formation of the aluminum-Compound II complex follows the second-order kinetics; this may support the above expected composition. Similar results were obtained in the aluminum-Compound VII, gallium-Compound II, and gallium-Compound VII systems; therefore, the complexes may be said to have the same composition as those of the complexes with Compounds III and V.

The author wishes to express his appreciation to Professor Tsunenobu Shigematsu (Institute for Chemical Research, Kyoto University), Professor Yasuharu Nishikawa (Faculty of Science and Technology, Kinki University), and Professor Masayuki Tabushi (Tohoku Women's College) for their kind advice and suggestions throughout the investigation.

The Infrared Spectra and Normal Coordinate Treatments of X_3M–$Mn(CO)_5$ (X=Cl, Br, and I; M=Si, Ge, and Sn). II.[1]

Satoru ONAKA

Department of Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received November 27, 1972)

The infrared absorption spectra (2200—50 cm^{-1}) have been measured for four metal-metal bonded molecules, Cl_3Si–$Mn(CO)_5$, Cl_3Ge–$Mn(CO)_5$, Br_3Ge–$Mn(CO)_5$, and I_3Sn–$Mn(CO)_5$. Vibrational normal coordinate analyses have been made for each of these molecules on the basis of a modified Urey-Bradley force-field. The calculated frequencies agree closely with validly-assigned frequencies. The metal-metal stretching force constant, K(M–Mn), or the F-matrix element, f(M–Mn), varies with the halogen atom, and increases as the electronegativity of X increases. The force constant, K(M–Mn), or f(M–Mn) depends also on the IVb metal atom, and increases in the order of: $K(Si\text{–}Mn) \geqq K(Ge\text{–}Mn) > K(Sn\text{–}Mn)$, or $f(Si\text{–}Mn) \geqq f(Ge\text{–}Mn) > f(Sn\text{–}Mn)$. However, there is no clear relationship between the electronegativity of M and the K(M–Mn) or (M–Mn). These dependences of K(M–Mn) or f(M–Mn) on X and M are discussed, along with the bonding implications of the M–Mn bonds, on the basis of the sets of the force constants, or the sets of the F-matrix elements, and are interpreted in terms of the predominant σ-bonding framework of the M–Mn bonds.

The nature of metal-metal bonding between a transition metal and a main-Group IV b metal has been studied by a number of spectroscopic techniques, such as IR, NMR, NQR, the Mössbauer effect, *etc.*[1-13]; the common interest of these studies is to clarify the effect of the component-metal atoms or the substituents of the component metal atoms on the nature and/or the strengths of metal–metal bondings in question. Among these techniques, vibrational analyses are quite useful in evaluating the extent of the metal–metal interaction in terms of the force constants. According to a recent report on vibrational analyses by Risen *et al.*,[2b] the metal–metal bond strength in X_3M–$Co(CO)_4$ (M=Ge and Sn, X=Cl, Br, and I) increases linearly with the electronegativity of X and the M–Co bond is predominantly σ in character. In Part I of the present series of studies of metal–metal bondings,[1] the present author studied the effect of L on the Sn–Mn bonding nature for L_3Sn–$Mn(CO)_5$ (L=Cl, Br, and CH_3) and obtained similar result–that the Sn–Mn strength is strongly affected by the electronegativity of L on the tin atom, and that the π-interaction between the Sn and Mn of Cl_3Sn–$Mn(CO)_5$ is more pronounced than that of $(CH_3)_3Sn$–$Mn(CO)_5$.

The present study was undertaken in order to clarify the effects of the Component IV b metal atom and the electronegativity of the X in X_3M group on the M–Mn bonding nature, and in order to facilitate interpretations of Raman-[14] and IR-[15] intensity studies of a series of X_3M–$Mn(CO)_5$ (X=Cl, Br, and I; M=Si, Ge, and Sn) compounds by making vibrational analyses.

Experimental

All the compounds were prepared by the methods in the literatures.[16-21] The purity of the samples was checked by elemental analysis and by IR spectra. The infrared spectra in the CO stretching region were measured with a Jasco model IR-G spectrophotometer in a hexane solution, using a NaCl liquid cell (0.1 mm). The spectra were calibrated by making use of gaseous DCl by means of a superposition method. The Nujol mull samples were also examined with a Hitachi EPI-L spectrophotometer and a FIS-3 double-beam vacuum spectrophotometer in the region from 50 to 700 cm^{-1}. The results are summarized in Table 1 and Figs. 1 and 2.

Spectral Assignments

The molecular structure of Br_3Ge–$Mn(CO)_5$ has been determined by electron-diffraction analysis;[22] its molecular geometry is quite similar to those of $(CH_3)_3Sn$–

$Mn(CO)_5$[23] and $(C_6H_5)_3Sn$–$Mn(CO)_5$[24] (the structures of the latter two compounds were determined by X-ray analyses). According to these reports, the local symmetry around the tin or germanium atom is C_{3v}, while that of the manganese atom is C_{4v}. Similar local symmetries are assumed for I_3Sn–$Mn(CO)_5$, Cl_3Ge–$Mn(CO)_5$, and Cl_3Si–$Mn(CO)_5$ because of the close resemblance of their vibrational spectra and physical and chemical properties to those of Br_3Ge–$Mn(CO)_5$, $(CH_3)_3Sn$–$Mn(CO)_5$, and $(C_6H_5)_3Sn$–$Mn(CO)_5$. In the vibrational analysis, these molecules can be regarded as a symmetric-top molecules, and the vibrational representation is $\Gamma_{vib}=15A_1+2A_2+11E$. This re-

presentation is spanned by symmetrically complete sets of symmetry coordinates, as is detailed in Table 2 for X_3M–$Mn(CO)_5$ molecules. Among the fifteen symmetry coordinates involving C–O stretching, Mn–C stretching, and Mn–C–O deformation vibrations, three C–O stretching, three Mn–C stretching, and four Mn–C–O deformation vibrations can be expected, on the basis of many studies of $LMn(CO)_5$ compounds and previous work on L_3Sn–$Mn(CO)_5$, to be observed above 390 cm^{-1} for each of these molecules of the C_{4v} local symmetry around the manganese atom. Table 1 and Fig. 1 show that the vibrational spectra of Cl_3Ge–$Mn(CO)_5$, Br_3Ge–$Mn(CO)_5$, and I_3Sn–$Mn(CO)_5$ above 390 cm^{-1} are almost identical with one another, and that they are nearly identical with the spectra reported earlier for Cl_3Sn–$Mn(CO)_5$ and Br_3Sn–$Mn(CO)_5$. Therefore, all the bands observed above 390 cm^{-1} are considered to be mainly due to the vibrations of the $Mn(CO)_5$ moiety, and the same assignments of the observed bands as those given previously for Cl_3Sn–$Mn(CO)_5$ and Br_3Sn–$Mn(CO)_5$ are made for Cl_3Ge–$Mn(CO)_5$, Br_3Ge–$Mn(CO)_5$, and I_3Sn–$Mn(CO)_5$. In the spectral region of 150—390 cm^{-1}, three fundamentals which are mainly M–X (A_1+E) and Mn–M (A_1) stretching vibrations can be expected for Cl_3Ge–$Mn(CO)_5$, Br_3Ge–$Mn(CO)_5$, and I_3Sn–$Mn(CO)_5$. Br_3Ge–$Mn(CO)_5$ and I_3Sn–$Mn(CO)_5$ show broad, intense absorptions at 275 and 192 cm^{-1} respectively, with shoulders occur at frequencies higher by 10—20 cm^{-1} than those of the strong bands; these bands are assignable to the Br–Ge and I–Sn stretching vibrations respectively.[16] The spectrum of Cl_3Ge–$Mn(CO)_5$, however, shows a broad, intense absorption at 371 cm^{-1} which is assignable to Ge–Cl stretching vibrations[2a]; the A_1 and E fundamentals of Ge–Cl stretching modes are expected to be overlapped in this spectrum. The spectra of Cl_3Ge–$Mn(CO)_5$ and I_3Sn–$Mn(CO)_5$ display bands with medium intensities at 231 and 155 cm^{-1} respectively. These bands are assigned mainly to Ge–Mn and Sn–Mn stretching vibrations.[2a,16] The spectrum of Br_3Ge–$Mn(CO)_5$, however, shows a weak bands at 190 cm^{-1}; this absorption is assigned mainly to the Ge–Mn stretching vibration of this molecule. The vibrational modes, which are chiefly the X–M–X deformation vibrations and the skeletal C–Mn–C, M–Mn–C, and X–M–Mn deformations, are expected to occur below 150 cm^{-1} for the Cl_3Ge–$Mn(CO)_5$, Br_3Ge–$Mn(CO)_5$, and I_3Sn–$Mn(CO)_5$ molecules. The X–M–X deformation vibrations of Cl_3Ge–$Mn(CO)_5$ are observed at 164 and 126 cm^{-1}; those of Br_3Ge–$Mn(CO)_5$ are observed at 132, 120, and 98 cm^{-1}, and that of I_3Sn–$Mn(CO)_5$ is observed at 70 cm^{-1}.[2] Most of the skeletal C–Mn–C, M–Mn–C, and X–M–Mn deformation vibrations escape detection for these molecules.

As for Cl_3Si–$Mn(CO)_5$, however, the infrared spectrum is quite different from those of X_3Ge–$Mn(CO)_5$ and X_3Sn–$Mn(CO)_5$ in the spectral region above 400 cm^{-1}; that is, only two peaks are observed in the CO stretching region (the E and A_1 (axial) modes are expected to be overlapped) and additional bands with medium intensities are observed at 515 and 497 cm^{-1} in the middle frequency region, besides the Mn–C–O deformation and Mn–C stretching vibrations. According to previous papers on $(CH_3)_nSiCl_{4-n}$[25] and Cl_3Si–$Co(CO)_4$[2a] and the present normal coordinate analysis, these bands are assignable mainly to the Si–Cl stretching vibrations of the E mode (the E mode is supposed to split into two peaks). In the low frequency region, strong bands are observed at 291 and 180 cm^{-1}, and bands with medium to weak intensities are observed at 201, 140, and 120 cm^{-1}. The strong peak at 291 cm^{-1} is assigned mainly to the Si–Mn stretching vibration, while the peaks observed at 180 and 140 cm^{-1} are assigned mainly to $SiCl_3$ deformations.[2a] The bands at 120 cm^{-1} is assigned mainly to C–Mn–C skeletal bending motions, on the basis of the normal coordinate analysis of this molecule.

All the vibrational assignments are presented in Table 1.

Normal Coordinate Analysis

The frequency calculations were carried out on the basis of Wilson's GF matrix method[26] by making use of a modified Urey-Bradley force field.[27] The symmetry and the internal coordinates used were the same as those previously described.[1] The interatomic distances for the $Mn(CO)_5$ moiety used in the calculations were those found in the X-ray analyses of $(CH_3)_3Sn$–$Mn(CO)_5$[23] and $(C_6H_5)_3Sn$–$Mn(CO)_5$.[24] The values of the bond lengths, r(M–X), were taken from the values in Cl_3Si–$Co(CO)_4$,[28] Br_3Ge–$Mn(CO)_5$,[22] and X_4M.[29] The Mn–M bond distances were those found in the structural analyses of Cl_3Si–$Co(CO)_4$,[28] Br_3Ge–$Mn(CO)_5$,[22] and R_3Sn–$Mn(CO)_5$[23,24]: r(Si–Mn) is 2.25 Å, r(Ge–Mn) is 2.44 Å, and r(Sn–Mn) 2.67 Å. Since the trial calculation of Cl_3Sn–$Mn(CO)_5$ revealed that an error of *ca.* 0.17 Å in estimating the r(Sn–Mn) distance causes only negligible changes in the K(Sn–Mn) and other force constants,[30] the use of these metal–metal bond lengths may be

seen to provide a better basis for normal coordinate analyses.

Above 400 cm^{-1}, the infrared spectra of these molecules are almost identical with those of $Cl_3Sn-Mn(CO)_5$, $Br_3Sn-Mn(CO)_5$, and $(CH_3)_3Sn-Mn(CO)_5$. This agreement is strong evidence that the molecular force fields for the $Mn(CO)_5$ moiety are nearly identical, and so the initial force fields were assumed to be identical with those of $L_3Sn-Mn(CO)_5$ in all the four present molecules. Actually, the calculated frequencies closely agree with the observed frequencies above 400 cm^{-1} throughout the $X_3M-Mn(CO)_5$ series of molecules without causing any serious alterations in that portion of the force-field elements which concern the vibrational modes of the $Mn(CO)_5$ moiety. The initial force constants for the MX_3 groups were taken from the MX_4, LMX_3,[31,32] and $X_3Sn-Mn(CO)_5$[1] molecules, while the reasonable starting values of K(M–Mn) was obtained from the K(Sn–Mn) of $Cl_3Sn-Mn(CO)_5$.[1] The initial force-field elements, such as H(MnMX), F(C···M), F(X···Mn), and Y(M–Mn), were transferred from the force constants of $X_3Sn-Mn(CO)_5$ (X stands for Cl and Br).[1] The force constants were adjusted so as to get the best fit of the calculated frequencies with the observed frequencies, with reference to the Jacobian matrix elements. The numerical calculations were carried out by the use of a HITAC 5020 E of the Computation Center of the University of Tokyo; the programs, BGLZ and LSMB, were set up in the laboratory of Professor Takehiko Shimanouchi.

Results

The final sets of the force constants and the F-matrix elements, f(M–Mn), are presented in Table 3, along with those of $Cl_3Sn-Mn(CO)_5$ and $Br_3Sn-Mn(CO)_5$, which are obtained in a previous work.[1] The symbols and the suffixes have the same meanings as have previously been described.[1]

The eigenvectors obtained show that the vibrational modes associated with the M–Mn stretching vibration are extensively coupled with other vibrational modes, especially with the C–Mn–C deformations, X–M and Mn–C stretching and/or X–M–X deformation vibrations. The purities of the vibrational modes of the M–Mn stretching vibrations are evaluated from the potential energy distribution to the M–Mn stretching coordinate (PED). As is shown in Table 4, the vibrational purities of the M–Mn stretching motions in $Cl_3Si-Mn(CO)_5$ and $I_3Sn-Mn(CO)_5$ are significantly low, and a considerable degree of the contribution of the Cl–Si–Cl deformation and C–Mn–C deformation vibrations to the Si–Mn and Sn–Mn stretching vibrations respectively is observed. The separation of the Mn–M stretching motion from other motions increases in accordance with the increase in the mass of M for $Cl_3M-Mn(CO)_5$, while the purity of the Mn–M

stretching motion decreases with the increase in the mass of X in X_3M, as is expected.

Discussion

The principal objective of the present study is to clarify the variation in the force constants, K(M–Mn), K(Mn–C), K(C–O), and so on, and the F-Matrix elements, f(M–Mn), f(Mn–C), and f(C–O), as the metal atom, M, and the halogen atom, X, are replaced by X_3M–$Mn(CO)_5$ molecules. The effect of the X in the X_3M group on these force constants and on f(M–Mn) is exhibited in Table 3 for X_3Sn–$Mn(CO)_5$ (X stands for Cl, Br, and I) and X_3Ge–$Mn(CO)_5$ (X stands for Cl and Br); the K(M–Mn) and the f(M–Mn) values fall in the order of: chloride>bromide (>iodide). That is, the values of K(M–Mn) and f(M–Mn) increase with the increase in the electronegativity of X; especially for X_3Sn–$Mn(CO)_5$, there is a nearly linear relationship between the K(Sn–Mn) or f(Sn–Mn) values and the electronegativity of X, though the values of K(Mn–C) and K(C–O) or f(Mn–C) and f(C–O) remain almost constant in responce to the change in X.[33] The electron-withdrawing ability of the SnX_3 group is expected to increase in accordance with the increase in the electronegativity difference between halogen and tin atoms. This expectation is substantiated by the previous NQR study of X_3Sn–$Mn(CO)_5$; *i.e.*, the halogen NQR study of X_3Sn–$Mn(CO)_5$ has shown that the ionic character (%) of tin–halogen bonds in X_3Sn–$Mn(CO)_5$ falls in the order of: Sn–Cl>Sn–Br>Sn–I,[6] and a good linear relationship exists, as is shown in Fig. 3, between the f(Sn–Mn) or the K(Sn–Mn) values and the ionic character of the Sn–X bond, thus providing evidence that the electron-withdrawing ability of the SnX_3 group is in the order of: $Cl_3Sn>Br_3Sn>I_3Sn$.

In the previous work on L_3Sn–$Mn(CO)_5$,[1] the present author has studied the effect of the substituent, L, on the Sn–Mn bonding nature on the basis of the sets of force constants, K(Sn–Mn), K(Mn–C), and K(C–O); he there concluded that the π-interaction between the tin and manganese atoms of $(CH_3)_3Sn$–

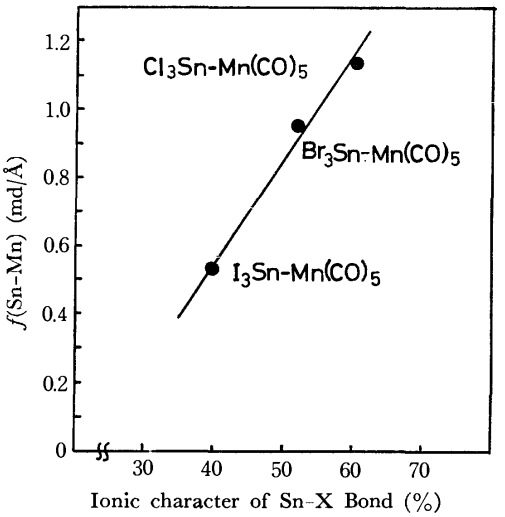

Fig. 3. The relationship between the f(Sn-Mn) and the ionic character of the Sn-X bond.

$Mn(CO)_5$ is weaker than those of X_3Sn–$Mn(CO)_5$ (X=Cl and Br), since not only K(Sn–Mn) but also K(Mn–C) and K(C–O) are changed by the substitution of L from X to CH_3. For the present X_3Sn–$Mn(CO)_5$ and X_3Ge–$Mn(CO)_5$ molecules, it seems that the σ-characters in the Ge–Mn and Sn–Mn bondings predominantly increase with the increase in the electronegativity of X, because the change in X causes no notable amount of variation in K(M–C) and K(C–O) or in f(Mn–C) and f(C–O) in spite of the pronounced dependence of K(M–Mn) or f(M–Mn) on the electronegativity of X (the f(Sn–Mn) of Cl_3Sn–$Mn(CO)_5$ is roughly twice that of I_3Sn–$Mn(CO)_5$). Watters *et al.* have studied X_3M–$Co(CO)_4$ (X=Cl, Br, and I; M=Ge and Sn) by IR and found that the K(Co–M) value decreases monotonously with the decrease in the electronegativity of X, while K(Co–C) and K(C–O) are kept constant.[2b] They have interpreted this similar finding in terms of the difference of the σ-framework of the Co–M bond based on the molecular σ-bonding systems.

Now, let us investigate the effect of M on the M–Mn bondings. As is shown in Table 3, the values of K(M–Mn) or f(M–Mn) increase in accord with the variation in the metal atom, M, from Sn to Si for the corresponding halogen compounds, though the K(Mn–C) and

33) As the manner of the changes in f(Mn–C) and f(C–O) toward the substitution of X or M is quite similar to those of K(Mn–C) and K(C–O), the values of f(Mn–C) and the f(C–O) were eliminated from the Table.

K(C–O) or f(Mn–C) and f(C–O) values remain almost constant.[34] However, there is no clear relationship between the electronegativity of M and the force constant, K(M–Mn) or f(Mn–M). By comparing the sets of force constants, K(M–Mn), K(Mn–C), and K(C–O), or the sets of F-matrix elements, f(M–Mn), f(Mn–C), and f(C–O), it can reasonably be concluded, on the basis of above discussions, that the π-characters in the Si–Mn and Ge–Mn bonds are in the same order as that in the Sn–Mn bond, and that the σ-character of the M–Mn bond is, if anything, primarily responsible for the order of M–Mn bond strength, $f(\text{Si–Mn}) \geqq f(\text{Ge–Mn}) > f(\text{Sn–Mn})$.

34) Although the numerical value of f(Sn–Mn) in Br_3Sn–Mn$(CO)_5$ is slightly larger than that of Br_3Ge–Mn$(CO)_5$, this difference cannot be regarded as significant.

The author wishes to express his deep gratitude to Professor Tastuo Miyazawa for his kind permission to use the far-infrared spectrophotometers.

Kinetic Studies of the Nickel Phthalate Complex Formation in Solution by the Pressure-jump Method

Shoji HARADA, Hideyuki TANABE, and Tatsuya YASUNAGA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received December 22, 1972)

The rate constants of the complex formation and the dissociation of the nickel phthalate (*o*-phthalate) complex have been determined by the pressure-jump method. The thermodynamic parameters of the reaction were obtained from studies at various temperatures between 10 and 30 °C. Upon a comparison of the data on the nickel complexes of the succinate, adipate, maleate, and phthalate, no systematic relationship between the nature of the ligands and the kinetic values has been found; this can be ascribed to the monodentated form of these complexes. The rate-determining step is the loss of the water molecule from the inner-coordination sphere of the nickel ion when the monodentated complex is formed.

Although the equilibrium properties of the nickel dicarboxylate complexes[1] have been well studied, relatively few systematic kinetic studies have been carried out. The development of the relaxation techniques[2] has, however, made it possible to study these fast reactions kinetically. In many of these studies of the complex formation reactions, the relaxation effect has been ascribed to one of the reactions of the step-by-step mechanism proposed by Eigen *et al.*[2] When the nickel complex of the bidentate ligand is formed, two inner-coordinated waters should be replaced by the ligand. Therefore, the mechanism of the bidentated chelate complex formation through the outer-sphere complex and the monodentated complex has usually been proposed. If the complex is stable as a chelate, the rate-determining step can be discussed by two different theories. Nancollas and Sutin[3] and Cavasino[4] have thought that the first bond formation between the nickel ion and the ligand is the rate-determining step. On the other hand, Hoffmann *et al.*[5-8] have considered that the chelate-ring closure is the rate-determining step and have calculated the rate constants of each reaction of the step-by-step mechanism. Nevertheless, if the complex is stable as a monodentated form rather than as a chelate, the same treatment as that carried out in the nickel maleate complex formation[9] will be applied.

The present study was undertaken in an attempt to confirm if one of these theories can be applied to the nickel phthalate complex formation. Another purpose has been to ascertain the ligand effects on the kinetic values of the nickel dicarboxylate complexes where the ligand has a pair of the carboxylate group maintained by the C–C single bond, and the C–C double bond, and the aromatic ring.

Experimental

All of the chemicals used were of a reagent grade. The nickel phthalate solution was prepared by mixing a stoichiometric amount of $NiSO_4$ with phthalic acid. Titration with a solution of $Ba(OH)_2$ was done until all the sulfate ions had precipitated out as insoluble $BaSO_4$. The solid $BaSO_4$ was then removed by filtration. The titration of the solution to pH 6.5 yielded a solution with most of the ligands in the dissociated form. The concentration of the nickel phthalate was determined by dimethylglyoxime titration. The solution to be studied was prepared by the dilution of the standard solution to the desired concentration.

The pressure-jump method with a conductivity readout has been described in considerable detail elsewhere.[10] The time constant of the apparatus was 100 μsec. A small improvement was made by placing a solenoid valve at the gas inlet of the pressure-jump cell. This improvement has resulted not only in making the experiments easier, but also in increasing the signal-to-noise ratio with the improvement of cutting off the entering of the useless gas after the metal diaphragm burst. Because of the use of the conductivity readout, no buffering or supporting electrolytes were added, and so the ionic strength of the solution was varied arbitrarily. In order to determine the kinetic parameters of the reaction, a series of experiments was run covering the concentration range from 0.00051 to 0.051 M of the nickel phthalate and the temperature range from 10 to 30 °C. The relaxation times quoted are the mean values of several runs.

Results

In all the nickel phthalate solutions, the relaxation spectrum was characterised by a single relaxation time. A representative relaxation spectrum is shown in Fig. 1. The experimental conditions and the observed relaxation times at 25 °C are shown in Table 1. In the present studies, the complex formation reaction may be expressed as follows:

$$M^{2+} + L^{2-} \underset{k_d}{\overset{k_f}{\rightleftharpoons}} ML \qquad (1)$$

where M^{2+} is the metal ion, L^{2-} is the ligand, ML is the complex, and k_f and k_d are the rate constants of the complex formation and the dissociation at zero ionic strength respectively. For such a mechanism, the rate constants are related to the relaxation time, τ, by the following equation:

$$1/\tau = k_f\gamma_{\pm}^2(C_M+C_L) + k_d \qquad (2)$$

where $\gamma_{\pm}$ is the mean activity coefficient of the free ions at a finite ionic strength, and where C_M and C_L are the ionic concentrations of the metal ion and the ligand respectively. As may be seen from Eq. (2), the plot of $1/\tau$ against $\gamma_{\pm}^2(C_M+C_L)$ gives k_f and k_d from the slope and the intercept of the line respectively. Such a plot requires the stability constant, K $(=k_f/k_d)$, if we are to calculate the ionic concentrations. Unfortunately, however, an appropriate K was not available, so the values of k_f, k_d, and K were obtained in the following way.

As the first approximation, a value of K which had been estimated from the literature value[11] was used to calculate the ionic concentrations. The activity coefficients of the ions were calculated by the use of the Kielland equation.[12] Then, the $1/\tau$ values were plotted against $\gamma_{\pm}^2(C_M+C_L)$. Here, the ratio between

k_f and k_d should coincide with the first estimated K value. The above procedures were repeated until a constant K value was obtained. The final results at each temperature are shown in Fig. 2. The values of the ionic concentrations, the ionic strengths, and the mean activity coefficients in Table 1 are referred to the final result at 25 °C. The rates and the stability constants obtained at various temperatures are given in Table 2.

The Arrhenius energies of activation, $\Delta E_f^{\neq}$ and $\Delta E_d^{\neq}$, were obtained from the plot of log k_f and log k_d respectively against $1/T$. Other thermodynamic parameters of the complex formation. *i.e.*, the entropy of activation, $\Delta S_f^{\neq}$, the enthalpy of activation, $\Delta H_f^{\neq}$, and the free energy of activation, $\Delta G_f^{\neq}$, were calculated from the following equations; they are listed in Table 3:

$$\log A = \log\frac{eRT}{Nh} + \frac{\Delta S_f^{\neq}}{2.3R} \quad (3)$$

$$\Delta H_f^{\neq} = \Delta E_f^{\neq} - RT \quad (4)$$

$$\Delta G_f^{\neq} = \Delta H_f^{\neq} - T\Delta S_f^{\neq} \quad (5)$$

where A is the frequency factor.

Discussion

The stability constants in Table 4 show that the oxalate, malonate, and malate ligands make very stable five- or six-membered chelate complexes, coordinating their carboxyl group or hydroxyl group to the nickel ion. Meanwhile, the succinate, adipate, maleate, and phthalate ligands make much less stable complexes. A definite difference can also be seen in the complex dissociation rate constant. Since the complexes in the former group are stable as chelates, the characteristics of the ligands, *e.g.*, the carbon number and the substituted groups, may be reflected very much in the stabilities and the dissociation rate constants of the complexes. In the latter group, on the other hand, the dissociation rate constants nearly all have the same value, $(2\sim4)\times10^3$ sec^{-1}, and the differences between the ligands are very small compared to the case of the former group. Moreover, the values are very close to the complex dissociation rate constants, $k_{d'}$ reported by Hoffmann *et al.*:[5-7]

$$Ni(H_2O)_5L \xrightarrow{k_{d'}} Ni(H_2O)_6^{2+} + L^{2-}. \quad (6)$$

These facts imply that the complex is plausible as a monodentated form rather than as a chelate.

The generally accepted mechanism for the complex-formation reactions is a step-by-step mechanism proposed by Eigen *et al.*[2] The scheme may be represented as follows:

$$\underset{\text{(I)}}{M^{2+} + L^{2-}} \overset{K_0}{\rightleftharpoons} \underset{\text{(II)}}{M^{2+}\cdots\overset{H}{\underset{H}{O}}\cdots L^{2-}} \underset{k_{-2}}{\overset{k_1}{\rightleftharpoons}} \underset{\text{(III)}}{M^{+} - L^{-}} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \underset{\text{(IV)}}{ML} \quad (7)$$

where (I) is the free ion, (II) is the outer-sphere complex, (III) is the monodentated complex, (IV) is the bidentated chelate complex, and K_0 is the outer-sphere complex formation constant. If the complex is considered to be very stable as a chelate, the overall rate constants are related to the rate constants of each step in Reaction (7) as follows:

$$k_f = K_0 k_1\left(\frac{k_2}{k_2+k_{-1}}\right) \quad (8)$$

a) The reported rate constants at 20 °C were converted to the value at 25 °C.

$$k_d = k_{-1}\left(\frac{k_{-2}}{k_2+k_{-1}}\right) \quad (9)$$

If a further assumption is made that the first bond formation between the nickel ion and the phthalate ligand is the rate-determining step, Eq. (9) becomes:

$$k_d = k_{-1}\cdot\frac{k_{-2}}{k_2}. \quad (10)$$

This equation shows that if the complex is a stable chelate, *i.e.*, $k_{-2}/k_2 \ll 1$, k_{-1} will be much larger than 10^4 sec^{-1}. This is implausible as a value of k_{-1}. On the other hand, Hoffmann *et al.*[5-8] determined all of the rate constants in Reaction (7) on the assumptions that K_0k_1 is the same for all the nickel dicarboxylates and is equal to the k_d of the adipate, and that k_{-1} can be assumed from the linear correlation between k_{-1} and the basicity of the carboxylate group. If we try to apply the same procedures to the nickel phthalate system, the rate constants will be given as follows: $K_0k_1=8.5\times10^5$ M^{-1} sec^{-1}, $k_{-1}=4\times10^3$ sec^{-1}, $k_2=1.1\times10^4$ sec^{-1}, and $k_{-2}=1.0\times10^4$ sec^{-1} at 25 °C. The result that k_2 is nearly equal to k_{-2}, however, means that the monodentated complex and the chelate complex are present in comparable concentrations; hence, it is in conflict with the above assumption that the chelate complex is very stable.

The stability constant, K, is given by this equation:

$$K = K_0 + K_0K_1 + K_0K_1K_2 \quad (11)$$

where K_0 can be calculated by the Fuoss equation[13] to be 25 M^{-1} at $\mu=0$, and where $K_1=k_1/k_{-1}$ and $K_2=k_2/k_{-2}$. On the assumptions that k_1 is equal to the water-exchange rate constant on the nickel ion,[14] 2.7×10^4 sec^{-1}, and that k_{-1} is found to be 4×10^3 sec^{-1} from the Hoffmann relationship between k_{-1} and the basicity of the ligand, K_1 can be calculated to be about 7. Therefore, Eq. (11) can be rewritten as:

$$K = 25(1+7+7K_2) \quad (12)$$

If the complex is stable as a chelate, *i.e.*, $K_2 \gg 1$; then, K will become much larger than 2×10^2 M^{-1}. In the nickel phthalate system, however, the stability constant obtained is 2.4×10^2 M^{-1}; this means that $K_2<1$, *i.e.*, that the monodentated complex is more stable than the chelate complex. In most of the previous studies of the nickel dicarboxylate complex-formation reactions, the concentration of the monodentated complex has been assumed to be negligibly small in comparison with those of the free ions and the chelate complex, but this assumption can not be properly applied to the nickel phthalate system, just as in the nickel maleate system.[8]

If we assume that the concentration of the chelate complex is negligibly small in comparison with that of the monodentated species, Reaction (7) can be simplified to the following mechanism:

$$\underset{\text{(I)}}{Ni^{2+} + Ph^{2-}} \overset{K_0}{\rightleftharpoons} \underset{\text{(II)}}{Ni^{2+}\cdot\overset{H}{\underset{H}{O}}\,Ph^{2-}} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \underset{\text{(II)}}{Ni^{+} - Ph^{-}} \quad (13)$$

where Ph^{2-} means the phthalate ion. Taking into account the facts that the formation and the dissociation of the outer-sphere complex are very fast and that $K_0\gamma_{\pm}^2(C_{Ni}+C_{Ph})$ is much smaller than unity, the relaxation time of the rate-determining step of Reaction (13) is given by the equation:

$$1/\tau = K_0k_1\gamma_{\pm}^2(C_{Ni}+C_{Ph}) + k_{-1}. \quad (14)$$

Since the concentration of the outer-sphere complex is small, the overall stability constant is given as follows:

$$K = K_0\cdot\frac{k_1}{k_{-1}} = \frac{k_f}{k_d} \quad (15)$$

By comparing Eq. (14) with Eq. (2), the following equations were obtained:

$$k_f = K_0k_1 \quad (16)$$

$$k_d = k_{-1} \quad (17)$$

With the values of k_f and K_0, k_1 was calculated to be 2.5×10^4 sec^{-1}; this value is very close to the water-exchange rate constant on the nickel ion. Moreover, k_{-1}, which is equal to k_d, is equal to the value estimated from Hoffmann's rule and the basicity of the ligand. These good coincidences of the rate constants suggest that the above discussion is correct and that the complex is stable as a monodentated form rather than as a chelate in the case of the nickel phthalate. The rate-determining step of the complex formation is the loss of the water molecule from the inner-sphere of the nickel ion when the monodentated complex is formed.

In addition to the nickel phthalate, pressure-jump studies were also carried out on the nickel complexes of the isophthalate and the terephthalate ligands; however, no relaxation effect was observed in these solutions. This is the same tendency as that observed in the maleate complex and the fumarate complex, where the relaxation effect was observed only in the former solution. From these facts, it may be concluded that the second carboxyl group is not coordinated directly to the nickel ion, but is indispensable in stabilizing the monodentated complex in the nickel complexes of the phthalate and the maleate ligands.

One of the purposes of the present studies has been to ascertain the ligand effect of the seven-membered nickel dicarboxylate complexes. The results obtained above show no systematic relationship between the natures of the ligands and the kinetic values. This may be ascribed to the characteristics of the monodentated form of these complexes.

The Liquid Membranes of the Thiocyanate Ion-Sensitive Electrode

Nobuhiko ISHIBASHI and Kenyu KINA

Department of Applied Analytical Chemistry, Faculty of Engineering, Kyushu University, Higashi-ku, Hakozaki, Fukuoka 812

(Received January 29, 1973)

Ion-selective electrode membranes responsive to the thiocyanate ion were prepared by using ion-association extraction systems. A crystal violet or tetraphenylarsonium cation was used as an ion exchange-site in the liquid nitrobenzene membrane. The liquid membrane electrode exhibits an ideal Nernstian response to the thiocyanate ion down to 10^{-5} *M*. The selectivity of the liquid membrane largely depends on the extractability of the diverse anion into nitrobenzene. The order of the selectivity coefficients, K_j, is as follows:

$$ClO_4^- > IO_4^- > SCN^- > I^- > ClO_3^- > NO_3^- > Br^- > BrO_3^- > Cl^-$$

High selectivities for thiocyanate over SO_4^{2-}, $H_2PO_4^-$, Cl^-, BrO_3^-, and Br^- were observed. The membrane potential is independent of the pH variation in the region from pH 2 to 12.

In recent years many kinds of selective ion-sensitive electrodes have been developed as analytical sensors which are capable of determining the activities of objective ions selectively.

Commercial thiocyanate-sensitive electrodes are usually prepared by using a compacted polycrystalline membrane of silver thiocyanate or a mixture of it with silver sulfide. A bromide-sensitive electrode with a AgBr membrane was also used as a thiocyanate-sensitive electrade,[1] since the thiocyanate ion reacts with a AgBr membrane to form a thin film of insoluble AgSCN on the membrane surface.

Hirsh and Protoch have found that the perchlorate ion-selective electrode of the liquid-membrane type is sensitive to perrhenate and thiocyanate ions; they performed the titration of thiocyanate with mercuric nitrate using this perchlorate ion-selective electrode.[2]

In this work, the thiocyanate-sensitive liquid membranes were prepared by using ion-association extraction systems, and the performance of the liquid membranes was studied.

Experimental

Apparatus and Chemicals. The measurements of the membrane potential were made with a Takeda Riken electrometer, TR-8651. The conductance of the liquid membrane was measured at 25 °C by the use of a Yanagimoto conductivity outfit, MY–7. The crystal violet and tetraphenylarsonium chloride were obtained from the Kishida Kagaku Co. and Wako Pure Chemicals Co. respectively. The thiocyanate stock solution was prepared by dissolving reagent-grade sodium thiocyanate in deionized water and was then standardized titrimetrically by the Volhard method. This stock solution was diluted to the desired concentration.

Preparation of the Liquid Membrane. Both the crystal violet and the tetraphenylarsonium ion were used as anion-exchange sites. By such a large, singly-charged cation, the thiocyanate ion can be extracted into nitrobenzene. The crystal-violet membrane was prepared by extraction with crystal-violet dyestuff in the following manner.

One hundred ml of a 1×10^{-3} M sodium thiocyanate solution and 100 ml of an equimolar crystal-violet solution were transferred into a separating funnel. The resulting aqueous solution was shaken with 100 ml of nitrobenzene for 60 min. The organic phase which was thus separated from the aqueous phase was shaken again with 100 ml of the 1×10^{-3} M sodium thiocyanate solution in order to purify it. After the phase separation had been completed, the organic solution was filtered through a dry filter paper in order to remove droplets of water; it was then diluted to 1×10^{-4} M with nitrobenzene when used as a thiocyanate-sensitive liquid membrane.

The thiocyanate ion was precipitated as white needles from an aqueous solution using the tetraphenylarsonium ion. The tetraphenylarsonium membrane was prepared by dissolving the precipitate in nitrobenzene.

Measurement of the Liquid Membrane Potential. The electromotive force of the following concentration cell was measured by means of the electrometer in order to evaluate the membrane performance:

$$+ \quad \underbrace{\text{SCE/Reference solution/organic liquid membrane/}}_{\text{(Electrode)}} \quad \text{Sample solution/SCE} \quad -$$

The cell assembly was the same as that described elsewhere.[3] The reference solution and the sample solution were separated in the lower part of a U-shaped glass tube by the use of a liquid membrane such as a nitrobenzene solution of tetraphenylarsonium thiocyanate.

Results and Discussion

Membrane Potential. Figure 1 shows the effect of the concentration of the membrane solute on the membrane potential. An increase in the concentration

of the membrane solute beyond about $10^{-3.5}$ M causes a drop in the membrane potential. This is probably due to the elution of the membrane solute on an adjacent aqueous solution. Hence, a dilute organic solution is preferable as the liquid membrane. However, the electrical resistance of the membrane increases with a decrease in the concentration of the membrane solute, and the membrane potential tends to become unstable. Consequently, 1×10^{-4} M was used as the membrane concentration throughout the study.

The membrane potential can be expressed by the following equation:

$$E = (RT/F)\ \ln\ (a'_{SCN}/a''_{SCN}) \qquad (1)$$

where a'_{SCN} and a''_{SCN} denote the thiocyante activities of the reference solution and the sample solution respectively. As the reference solution, we used a 1×10^{-3} M aqueous sodium thiocyante solution. Fig. 2 shows the electrode response to the sample solution at varying concentrations; the figure shows that an ideal Nernstian relationship of the potential against the logarithmic activity of the thiocyanate ion holds down to 10^{-5} M of the sodium thiocyanate solution. No difference was found in the linearity range of the electrode responses between the crystal-violet membrane and the tetraphenylarsonium membrane.

Reference solution: 1×10^{-3} M NaSCN
Membrane solvent: Nitrobenzene

Electrode Response as a Function of the pH. The pH effect on the membrane potential is given in Fig. 3. The pH adjustment was made by the addition of sodium hydroxide or sulfuric acid. The variation in pH has no effect on the membrane potential over the range from pH 2.5 to 12. The crystal-violet membrane showed a somewhat larger decrease of the membrane potential below pH 2 than did the tetraphenylarsonium membrane. The potential decrease in the crystal-violet membrane electrode below pH 2 may be attributed to the conversion of the crystal-violet to its acidic form and to the change in the liquid-junction potential between an agar salt bridge and the sample solution.

The tetraphenylarsonium membrane is affected only by the variation in the liquid-junction potential.

Electrode Response in the Presence of Diverse Anions. The electrode response in the presence of an interfering ion is empirically given by the following equation[4]:

$$E = \text{constant} - 2.303\,RT/F\ \log\ (a''_{SCN} + K_j(a_j'')^{1/z}) \qquad (2)$$

where K_j is the selectivity coefficient of j-ion for the thiocyante electrode and where z is the charge of the j-ion. As can be seen from Fig. 4, the electrode potential is depressed by the presence of diverse ions. A large value of K_j corresponds to a remarkable change in the membrane potential.

The selectivity coefficients can be obtained by the measurement of the membrane potentials in both the presence and absence of diverse ions. The observed values of K_j are listed in Table 1 with respect to the crystal-violet membrane. From the K_j values, the order of interference is found to be:

$ClO_4^- > IO_4^- > I^- > ClO_3^- > NO_3^- > Br^- > BrO_3^- > Cl^-$,
$H_2PO_4^-$, $CH_3CO_2^-$, SO_4^{2-}

The tetraphenylarsonium membrane gave the same selectivity coefficient, K_j. It can be said that the se-

Table 1. Selectivity coefficients of thiocyanate-sensitive liquid membrane electrode (exchange-site: crystal violet)

Anion	K_j	Anions	K_j
ClO_4^-	12.0	Br^-	0.006
IO_4^-	6.7	BrO_3^-	0.002
SCN^-	1.0	Cl^-	$<10^{-4}$
I^-	0.34	$H_2PO_4^-$	$<10^{-4}$
ClO_3^-	0.05	$CH_3CO_2^-$	$<10^{-4}$
NO_3^-	0.03	SO_4^{2-}	$<10^{-4}$

quence of selectivity is independent of the site species in nitrobenzene. The electrode has higher selectivities for the thiocyanate ion over bromide and chloride ions than does the solid-state electrode.[1] From the conductivity measurement of the liquid membrane, it was found that the site and its counter anion in nitrobenzene were in an almost complete dissociation.

According to Eisenman's theoretical treatment[5] of the membrane potential, the selectivity of the electrode with a liquid membrane is determined by the relative partition coefficient and the mobilities between the objective ion and the competitive ion in a limiting case of a complete dissociation. The sequence of K_j values in Table 1 is consistent with the ease of the extraction of the anions into the organic solvent.[6] Hence, the observed selectivity order qualitatively supports Eisenman's theoretical prediction, since there is no large difference among the ionic mobilities.

The authors wish to thank the Ministry of Education for its grant-in-aid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2456—2459 (1973)

The pH-dependent Variation of the Absorption and Circular Dichroism Spectra in Some Ternary Mixed Complexes of Copper(II) Containing Diethylenetriamine and Optically Active Amino Acids

Tasuku MURAKAMI, Tsunenori NOZAWA, and Masahiro HATANO

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980

(Received February 8, 1973)

The absorption and circular dichroism(CD) spectra of some ternary mixed complexes of copper(II) with diethylenetriamine(dien) and various optically active α-amino acids have been measured in an aqueous solution at various pH values. The amino acid may coordinate to one of the planar positions, with its carboxylate or amino group as a unidentate ligand, in a neutral or a very high pH region. On the other hand, from the red shift of the d–d absorption band and the augmentation of the visible CD magnitude, it seems reasonable to expect that a large portion of the amino acid will form a chelate ring with an axial ligation in the pertinent pH region.

In general, coordination compounds of copper(II) typically consist of four nearby donor atoms arranged approximately in a plane about the metal ion, with the possibility of one or two more distant axial donors. The effect of the axial ligation on the spectral feature of copper(II) complexes has been investigated by many workers,[1–4] and it has been clarified that the stronger ligation to the copper ion along the tetragonal axis causes the d–d absorption band to shift to a lower energy and the intensity of the band to increase appreciably. However, little attention has been paid to the formation of the chelate ring containing an axial ligation in an aqueous solution, probably because of the instability of the chelate. Wellman *et al.*[5] detected the axial chelation of potential tridentate α-amino acids by optical rotatory dispersion. Recently, such an axial chelation has been confirmed by Martin and his co-workers.[6]

In a previous communication,[7] we reported that the copper(II) complex of L-alaninamide with dien has its amide nitrogen coordinated to the copper(II) ion at the axial position. Recently, Aiba *et al.*[8] have reported that when diamine or amino acid is added to an aqueous solution of $[Cu(dien)(H_2O)]^{2+}$, the d–d absorption band shifts to a much longer wavelength; this phenomenon suggests the formation of a sort of five-coordinated complex. In this study, we wish to report the pH-dependent variations of the CD magnitude and of the d–d absorption observed in the ternary mixed complexes of copper(II) with dien and various optically active α-amino acids; such knowledge will help to clarify the axial interaction between donor

groups and the copper ion in aqueous solutions.

Experimental

Complex Formations and Measurements. Each solution of the ternary mixed complexes for the spectral observation was prepared by mixing equimolar aliquots of stock solutions of copper(II) nitrate, dien, and amino acids, whose equivalent weights has been checked by titration. The concentrations used here varied over the range from 1.5×10^{-3} to 6.0×10^{-2} M. To follow the same solution with a change in pH, additional drops of 0.1 or 1.0 M NaOH were added. The measurements of the pH of the solutions were performed with a Toa-Dempa HM-8 or Hitachi-Horiba M-5 pH meter.

The following optically active α-amino acids were used: L-alanine(abbreviated to L-alaH), L-valine(L-valH), L-proline(L-proH), and D-phenylglycine(D-phglyH). The D-phenylglycine was supplied by the Ajinomoto Co., Ltd. The CD curves in the region from 400 to 1000 nm were obtained by means of a JASCO J-20A spectropolarimeter at room temperature. The absorption measurements were made on a Hitachi EPS-3T spectrophotometer at room temperature.

Results and Discussion

Some typical absorption spectra observed here for the ternary mixed complexes of dien and α-amino acid are shown in Fig. 1. At pH 6.3, the absorption exhibits a maximum at about 16400 cm^{-1} with ε(molar absorptivity)$\sim$78, a value which almost coincides with that of $[Cu(dien)(H_2O)]^{2+}$. Titration experiments predict that the amino group of the amino acid may be protonated in the neutral pH region in these systems.[9] Consequently, the predominant species in the neutral pH region seem to be those involving dien and an amino acid, which may coordinate to the copper(II) ion only with its carboxylate end as a unidentate ligand. As the pH of the solution is raised, the absorptivity on the lower wavenumber side of the visible absorption band becomes appreciably high and the band, as a whole, shifts to the lower wavenumber side. This spectral feature is nearly identical with those observed in the formation of the five-coordinated complexes, such as $[Cu(NH_3)_5]^{2+}$[10] and $[Cu(dien)(diamine)]^{2+}$.[8]

Figures 2—5 show the variation in the CD spectra of the mixed complexes with the pH values in solution. Each of the mixed complexes except for the L-proline complex exhibits two extrema, at about 13000 and 17000 cm^{-1} in the neutral pH region. As the pH is increased, both of the two CD components become

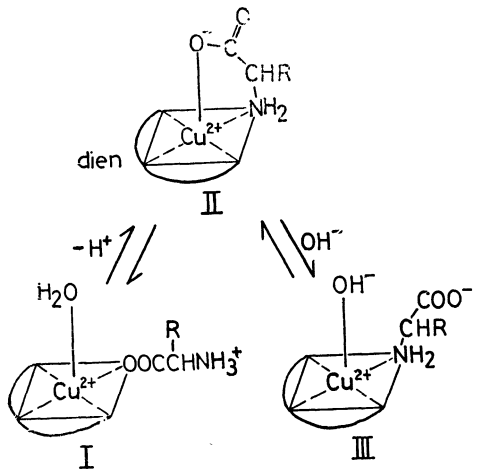

Fig. 7. Proposed equilibrium scheme for the ternary mixed complexes of copper(II) with dien and amino acids in aqueous solution.

very intense.[11] Therefore, the $\Delta\varepsilon$ values of the two components are comparable to those of complexes with optically active amino acids chelated in the square plane about the copper(II) ion, such as $[Cu(L\text{-am})_2]$ and $[Cu(en)(L\text{-am})]^+$ (see Refs. 12 and 13, and Fig. 6). However, as the pH is increased further, the intensities of the CD bands revert to those in the low pH region.

These profiles of the absorption and CD spectra in the mixed complexes can be reasonably explained by assuming the equilibrium scheme shown in Fig. 7. In the present mixed complexes, dien should occupy three coordination positions in the square plane about the copper(II) ion; then the amino acid cannot form a chelate ring in the plane. Therefore, the amino acid would coordinate to the copper(II) ion, with its carboxylate end as a unidentate ligand, in the neutral pH region(species I). In the higher pH region suitable for the deprotonation of the protonated amino group, it is anticipated that a large portion of the amino acid will form a chelate ring with an axial coordination, that is, an axial chelation(five-coordinated species II). Such a chelate formation appears to be a more plausible elucidation for the red shift of the absorption band and

11) When L-lactic acid, which coordinates to copper(II) ion with its carboxylate group as a unidentate ligand, was used instead of the amino acid, the similar spectral behaviors could not be observed. The absorptivity at only higher wavenumber side increases with increase of pH, and the observed CD magnitude remains much small ($\Delta\varepsilon\sim+0.005$).

12) T. Yasui, This Bulletin, **38**, 1746 (1965).

the augmentation of the CD magnitudes. For the following two reasons, the amino group of amino acid instead of the carboxylate group seems to coordinate in the plane, as is illustrated in the five-coordinated species II. The first reason is the tendency of the copper(II) ion to coordinate to strong donor groups in the square plane. The second reason is the labile character of the copper(II) ion, which makes an exchange of ligand groups in the coordination plane possible. As the pH in solution is increased so as to make the concentration of the hydroxide ion comparable to that of the complex ion, a large portion of the carboxylate group at the axial position may be displaced by the hydroxide ion (species III).

The CD curves for the mixed complexes increase in magnitude with an increase in the concentration of complexes. For example, the $\Delta\varepsilon$ values of the higher wave number component in the L-alanine complex are -0.030, -0.045, and -0.055 at about pH 10, corresponding to the concentrations of 1.5×10^{-3}, 1.5×10^{-2}, and 6×10^{-2} M respectively. The concentration dependence seems to be evidence for the preceding scheme that the hydroxide ion would displace the carboxylate group in an axial position, that is, for the (II) $\rightleftharpoons$(III) equilibrium shown in Fig. 7. There seem to be fewer species with other five-coordinated structures in the solution. We say this because, if the amino acids in the ternary mixed complexes, [Cu(dien)(L-am)]$^+$, would chelate in the square plane, we could expect that the CD spectral features would be very similar to those for [Cu(en)(L-am)]$^+$-type complexes. However, this does not seem to be the case.

So far as the donor atoms in the square plane about the copper(II) ion are concerned, when [Cu(N_3O)] is converted to [Cu(N_4)], such as in (I)$\rightarrow$(II) in Fig. 7, the absorption spectrum should shift to a higher wavenumber. However, the difference in the absorption maxima, $\tilde{\nu}_{max}$, for [Cu(N_3O)]- and [Cu(N_4)]-type complexes is not very much— *e.g.*, 16400 cm^{-1} for [Cu(dien)(H_2O)]$^{2+}$ and 16700 cm^{-1} for [Cu(dien)(RNH_2)]$^{2+}$ (R=CH_3– or CH_3CH_2–).[8] In addition, the axial ligation may play a role in shifting the absorption band to a lower wavenumber. Therefore, the more the five-coordinated species(II) are formed in solution, the lower the observed absorption shifts.

Most L-amino acid copper(II) complexes of the [Cu(L-am)$_2$]- and [Cu(en)(L-am)]$^+$-type, except for the L-proline complexes, exhibit a negative main CD band in the higher wavenumber region, with a much smaller positive component at lower wavenumbers.[12,13] The present mixed complexes also exhibit similar CD curves in the neutral or very high pH regions. In both pH regions, L-amino acid coordinates with its carboxylate or amino group as a unidentate ligand. Thus, the unidentate L-amino acids impose a dominant negative CD curve in the d–d band of the copper(II) ion as well as in the case of the chelated L-amino acids. This seems also to be the case with the observed CD cuvres for amino acid complexes of cobalt(III) in aqueous solutions.[14] In the pH region where the five-coordinated species(II) may be formed, the CD magnitude of the lower wavenumber component becomes comparable to that of the higher wavenumber component. Therefore, the chelation containing an axial position seems responsible for the increase in the $\Delta\varepsilon$ of the lower wave number component in particular.

We wish to thank Professor Kazuo Saito and Dr. Junnosuke Fujita for their valuable comments. We wish also to acknowledge the help of the Ajinomoto Co., Ltd., in supplying many amino acids. This research was supported in part by a grant from the Ministry of Education.

A Kinetic Study of the Ligand Substitution Reaction of Tetramethylenediaminetetraacetatocobaltate(II) with Trimethylenediaminetetraacetate

Hiroshi OGINO, Toshiyuki WATANABE, Jong-Jae CHUNG,* and Nobuyuki TANAKA

Department of Chemistry, Faculty, of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received February 26, 1973)

The kinetics of the ligand substitution reaction of tetramethylenediaminetetraacetatocobaltate(II) (cobalt(II)–TDTA) with trimethylenediaminetetraacetate (TRDTA) was investigated by two different polarographic methods. The kinetic data at pH 4.9 to 5.6 were obtained by means of a conventional method in which the reaction was initiated by the mixing of two reactant solutions and was followed polarographically. However, this method could not be applied to solutions with pH values lower than 4.9, for the rate of the reaction is immeasurably fast in such a low pH region. The kinetic data at pH values down to 3.7 were obtained by analyses of the polarographic current which was observed in solutions containing TRDTA and the substitution-inert cobalt(III)–TDTA complex. From these data, it was found that the reaction proceeds through four simultaneous reaction paths, two paths of which are the nucleophilic substitution reactions, while the others are the dissociation reactions of cobalt(II)–TDTA complex ions.

In this paper, the kinetics of the ligand substitution reaction of tetramethylenediaminetetraacetatocobaltate(II) (cobalt(II)–TDTA)[1] with trimethylenediaminetetraacetate (TRDTA) will be studied by the polarographic method. The kinetics of this reaction cannot be investigated by the methods which are usually applied to many other systems. For example, the nuclear magnetic resonance method cannot be applied to this system, for cobalt(II) ions are paramagnetic. As the spectral data of cobalt(II)–TDTA and cobalt(II)–TRDTA are essentially identical, the spectrophotometric method cannot be applied to this reaction either. It will be shown in this paper that polarography provides very useful methods for the kinetic study of this reaction. The results obtained in this work will be compared with the related ones reported previously.[2,3]

Experimental

Reagents. The trimethylenediaminetetraacetic acid (H_4trdta)[4], tetramethylenediaminetetraacetic acid (H_4tdta),[5] and potassium tetramethylenediaminetetraacetatocobaltate(III) (K[Cotdta]·$3H_2O$)[5] were prepared and recrystallized by methods described previously. The preparation and standardization of a solution of cobalt(II) nitrate,[6] disodium dihydrogen trimethylenediaminetetraacetate(Na_2H_2trdta)[7] and disodium dihydrogen tetramethylenediaminetetraacetate (Na_2H_2tdta)[3] were done in ways reported in the literature. All the other chemicals were of an analytical-reagent grade and were used without further purification.

Kinetic Measurement and Apparatus. It has been reported that cobalt(II)–TRDTA shows a polarographic one-electron oxidation wave, with a half-wave potential of +0.05 V *vs.* SCE, in an acetate buffer–potassium nitrate solution.[8] TRDTA, TDTA, and cobalt(II)–TDTA do not show any polarographic waves under these experimental conditions. The kinetic measurements were made by two different methods, both utilizing the anodic wave of cobalt(II)–TRDTA; these methods were designated as Methods A and B.

In Method A, which is a conventional one, the reaction was initiated by the addition of a known amount of cobalt(II)–TDTA solution to an acetate buffer-potassium nitrate solution containing TRDTA in a large excess; the rate of the reaction was measured by following the increase in the anodic current due to the formation of cobalt(II)-TRDTA at +0.15 V *vs.* SCE. The overall reaction of TRDTA with cobalt(II)–TDTA is expressed by Eq. (1):

$$\left\{\begin{matrix}CoY^{2-}\\ \downuparrows\\ CoHY^{-}\end{matrix}\right\} + \left\{\begin{matrix}Z^{4-}\\ \downuparrows\\ HZ^{3-}\\ \downuparrows\\ \vdots\\ \downuparrows\\ H_4Z\end{matrix}\right\} \underset{k^-}{\overset{k^+}{\rightleftharpoons}} \left\{\begin{matrix}CoZ^{2-}\\ \downuparrows\\ CoHZ^{-}\end{matrix}\right\} + \left\{\begin{matrix}Y^{4-}\\ \downuparrows\\ HY^{3-}\\ \downuparrows\\ \vdots\\ \downuparrows\\ H_4Y\end{matrix}\right\} \quad (1)$$

where Y^{4-} and Z^{4-} mean quadridentate TDTA and TRDTA anions respectively; $CoHY^-$ and $CoHZ^-$, hydrogen complexes of cobalt(II)-TDTA and -TRDTA respectively, and k^+ and k^-, the rate constants for the forward and the backward reactions. Under these experimental conditions, the backward reaction can be neglected; therefore, the reaction studied can be treated as a pseudo first-order reaction:

$$\text{Rate} = k^+_{obs}[CoY]_{app} \quad (2)$$

where:

$$[CoY]_{app} = [CoY^{2-}] + [CoHY^-]$$

and where k^+_{obs} means a pseudo-first-order rate constant. Solving the rate law in essentially the same way as has been reported previously,[2] the equation:

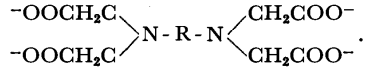
$$\log \frac{\bar{\imath}_e}{\bar{\imath}_e - \bar{\imath}} = \frac{1}{2.303} k^+_{obs}\, t \quad (3)$$

was obtained, where $\bar{\imath}$ and $\bar{\imath}_e$ denote the current at time

---

* Present address: Kyung-Pook National University, Korea.

1) The general formula of the ligands in this paper is:



The abbreviated names of the ligands are:
TDTA (R=$CH_2CH_2CH_2CH_2$), TRDTA (R=$CH_2CH_2CH_2$), EDTA (R=CH_2CH_2), PDTA (R=$CH_2CH(CH_3)$), and *meso*-BDTA (R=$CH(CH_3)CH(CH_3)$).

2) H. Ogino and N. Tanaka, This Bulletin, **40**, 857 (1967). In that paper, 2.303 in Eqs. (7) and (10) should read 1/2.303. The values of k^+ were calculated with the correct equations.

3) H. Ogino, T. Baba and N. Tanaka, *ibid.*, **42**, 1578 (1969).

4) N. Tanaka and H. Ogino, *ibid.*, **37**, 877 (1964).

t and at an infinite time respectively. The values of k^{+}_{obs} were calculated from Eq. (3). The measurements were made in solutions at an ionic strength of 0.2 (KNO_3) and in the pH range from 4.9 to 5.6. All the polarograms were recorded by means of a Yanagimoto PB-4 pen-recording polarograph, using a dropping mercury electrode (DME) which had an m value of 1.16 mg sec^{-1} and a drop time t_d of 6.55 sec in a deaerated 0.1 M acetate buffer–0.1 M potassium nitrate solution containing 0.005% gelatin at 25 °C, −0.50 V *vs.* SCE, and a mercury height of 60 cm.

Method B consists of analyses of the polarographic kinetic current which was observed in solutions containing TRDTA and the substitution-inert cobalt(III)-TDTA complex. The current-time curves during the life of a mercury drop were recorded by means of a Rikendenshi SP-J1 recorder with a DC-201 preamplifier. The DME used had an m value of 1.87 mg sec^{-1} and a t_d value of 4.84 sec in a deaerated 0.1 M potassium nitrate solution containing 0.005% gelatin at 25 °C, −1.0 V *vs.* SCE, and a mercury height of 50 cm. The ionic strength employed was 0.5 (KNO_3), and the pH range was from 3.7 to 4.6.

All the measurements were carried out at 25 °C. Gelatin was added as a maximum suppressor in a concentration of 0.005%. The pH of the solutions was measured with a Hitachi-Horiba F-5 pH meter.

Results

Results Obtained by Method A. The values of k^{+}_{obs} were found to be a linear function of the initial concentration of TRDTA, $[Z]_0$, and of the hydrogen ion concentration, as is shown in Fig. 1, provided that all other experimental conditions were kept constant. Under these experimental conditions, the predominant species of TRDTA was H_2Z^{2-}.[9] On the basis of the above results, the reaction of cobalt(II)-TDTA with TRDTA was considered to proceed through the following four simultaneous reaction paths:

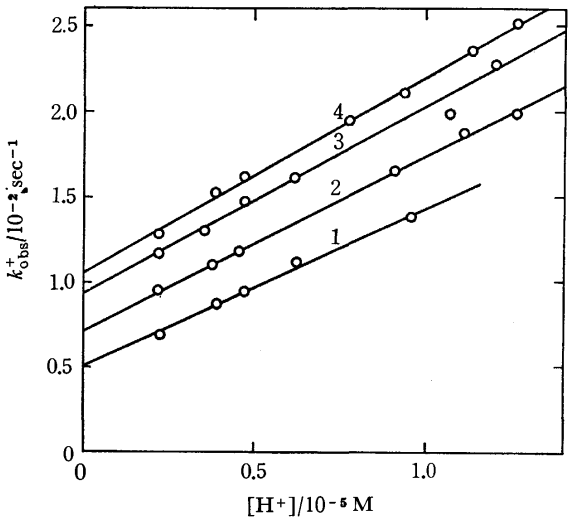

Fig. 1. The value of k^{+}_{obs} as a function of the hydrogen ion concentration at ionic strength 0.2 (KNO_3) and 25 °C containing 0.2 mM cobalt(II)-TDTA, 0.1 M acetate buffer and 0.005% gelatin. Initial concentrations of TRDTA, $[Z]_0$, are: 4 mM (1), 6 mM (2), 8 mM (3), and 10 mM (4).

$$CoY^{2-} + H_2Z^{2-} \overset{k^{CoY}_{H_2Z}}{\rightleftharpoons} CoZ^{2-} + H_2Y^{2-} \quad (4)$$

$$CoHY^{-} + H_2Z^{2-} \overset{k^{CoHY}_{H_2Z}}{\longrightarrow} CoHZ^{-} + H_2Y^{2-} \quad (5)$$

$$CoY^{2-} \overset{k^{CoY}}{\rightleftharpoons} Co^{2+} + Y^{4-} \quad (6)$$

$$CoY^{2-} + H^{+} \overset{k^{CoY}_{H}}{\rightleftharpoons} Co^{2+} + HY^{3-} \quad (7)$$

On the basis of the reaction mechanism, the following equation was derived:

$$k^{+}_{obs} = k^{CoY}_{H_2Z}[H_2Z^{2-}] + k^{CoHY}_{H_2Z}K^{H}_{CoHY}[H^+][H_2Z^{2-}] + k^{CoY} + k^{CoY}_{H}[H^+] = k^{CoY}_{H_2Z}\frac{[H^+]^2}{\alpha_{Z(H)}K_3K_4}[Z]_f + k^{CoHY}_{H_2Z}K^{H}_{CoHY}\frac{[H^+]^3}{\alpha_{Z(H)}K_3K_4}[Z]_f + k^{CoY} + k^{CoY}_{H}[H^+] \quad (8)$$

where:

$$\alpha_{Z(H)} = 1 + \frac{[H^+]}{K_4} + \frac{[H^+]^2}{K_3K_4} + \frac{[H^+]^3}{K_2K_3K_4} + \frac{[H^+]^4}{K_1K_2K_3K_4}$$

$$K^{H}_{CoHY} = \frac{[CoHY^-]}{[CoY^{2-}][H^+]}$$

K_1, K_2, K_3, and K_4 are the acid dissociation constants of H_4Z,[9] and $[Z]_f$ means the total concentration of the uncomplexed ligand, Z. In the pH range of the present experiment, the value of $\alpha_{Z(H)}$ was practically identical with $[H^+]^2/K_3K_4$.[10] Since TRDTA was present in a large excess, $[Z]_f$ was almost the same as its initial concentration, $[Z]_0$, during the reaction process; therefore, Eq. (8) can be rewritten as:

$$k^{+}_{obs} = (k^{CoY} + k^{CoY}_{H_2Z}[Z]_0) + (k^{CoY}_{H} + k^{CoHY}_{H_2Z}K^{H}_{CoHY}[Z]_0)[H^+] \quad (9)$$

Equation (9) clearly indicates that the plots of the values of the intercepts and slopes of the straight lines shown in Fig. 1 against $[Z]_0$ should yield linear relations. They are reproduced in Fig. 2. Each rate constant given in Eq. (9) was determined from the values of the intercepts and the slopes of the straight lines shown in Fig. 2; all are given in Table 2.

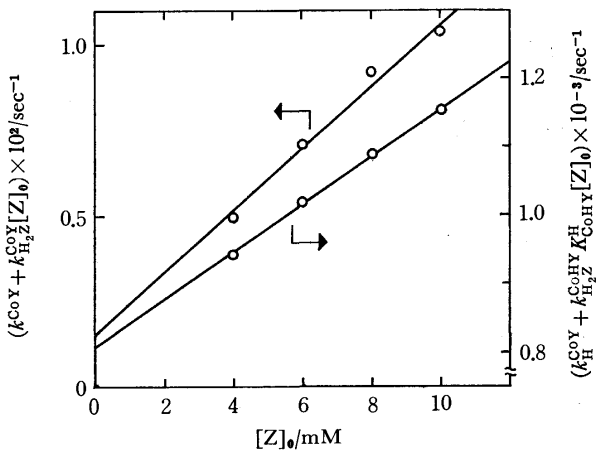

Fig. 2. The plots of $(k^{CoY}_{H} + k^{CoHY}_{H_2Z}K^{H}_{CoHY}[Z]_0)$ and $(k^{CoY} + k^{CoY}_{H_2Z}[Z]_0)$ against $[Z]_0$ at ionic strength 0.2 and 25 °C containing 0.2 mM cobalt(II)-TDTA, 0.1 M acetate buffer and 0.005% gelatin.

9) G. Anderegg, *Helv. Chim. Acta*, **47**, 1801 (1964).

10) The error of this assumption is less than 0.5%.

Results Obtained by Method B. The cobalt(III)-TDTA ion gives a limiting diffusion current corresponding to a one-electron reduction which starts at a more positive potential than the dissolution of mercury. The addition of TRDTA causes a decrease in the limiting current at the potential range more positive than about −0.1 V *vs.* SCE, as is shown in Fig. 3.

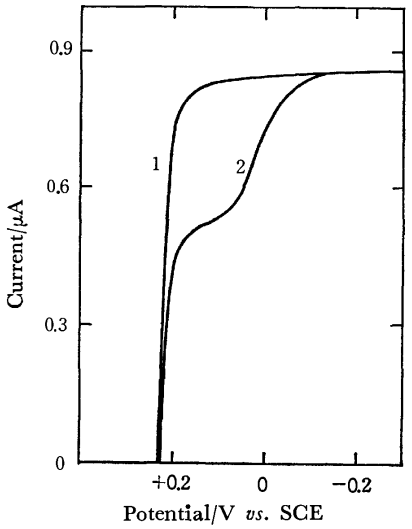

Fig. 3. Polarograms of 0.4 mM cobalt(III)-TDTA in the presence of 40 mM TDTA (curve 1) and 40 mM TDTA +4 mM TRDTA (curve 2) in solutions of ionic strength 0.5 (KNO_3) and pH 3.74 containing 80 mM acetate buffer and 0.005% gelatin.

Table 1. Dependence of the value i_k (at $t=t_d$) on the mercury height

Mercury height/cm	40.7	51.0	60.8
$i_k/\mu A$ (at $t=t_d$)	0.25_5	0.26_1	0.26_0

Measurements were made under the following conditions: 0.4 mM cobalt(III)-TDTA, 8 mM TRDTA, 32 mM TDTA, 80 mM acetate buffer and 0.005% gelatin at ionic strength 0.5 (KNO_3), pH 3.79 and 25 °C. The applied potential was +0.13 V *vs.* SCE.

The value of the instantaneous current at $t=t_d$ corresponding to the decrease in the limiting current, which was denoted as i_k, was found to be independent of the mercury height of DME. This is shown in Table 1, which reveals that i_k is a kinetic current. These phenomena can be interpreted by means of the following equations:

$$\text{Co(III)-TDTA} + e \longrightarrow \text{Co(II)-TDTA} \quad (10a)$$

$$\text{Co(II)-TDTA} + \text{TRDTA} \rightleftharpoons \text{Co(II)-TRDTA} + \text{TDTA} \quad (10b)$$

$$\text{Co(II)-TRDTA} \longrightarrow \text{Co(III)-TRDTA} + e \quad (10c)$$

The electrode process expressed by Eqs. (10a) to (10c) is the so-called ECE mechanism (electrochemical-chemical-electrochemical mechanism), which has previously been treated theoretically.[11] If the concentrations of TDTA and TRDTA are in excess over that of cobalt(II)-TDTA, the substitution reaction (10b) can be expressed as a pseudo first-order reaction:

$$\text{Co(II)-TDTA} \underset{l_b}{\overset{l_f}{\rightleftharpoons}} \text{Co(II)-TRDTA} \quad (11)$$

where l_f and l_b mean the rate constants for the forward and the backward reactions respectively. The apparent equilibrium constant of Reaction (11), K, is given as:

$$K = \frac{l_f}{l_b} = \frac{[\text{Co(II)-TRDTA}]}{[\text{Co(II)-TDTA}]} = \frac{K_{CoZ}[Z^{4-}]}{K_{CoY}[Y^{4-}]} = \frac{\alpha_{Y(H)}K_{CoZ}[Z]_f}{\alpha_{Z(H)}K_{CoY}[Y]_f} \quad (12)$$

where K_{CoY} and K_{CoZ} denote the stability constants for the cobalt(II)-TDTA and cobalt(II)-TRDTA complexes respectively. The value of $(\alpha_{Y(H)}\ K_{CoZ})/(\alpha_{Z(H)}\ K_{CoY})$ was polarographically determined in this work to be $11._8$. The value of K given in Eq. (12) was kept larger than unity by adjusting the concentrations of TDTA and TRDTA. For this condition, the following equation has been derived[11]:

For $K>1$:

$$\left|\frac{i_k}{i_d}\right| = \frac{K}{K-1}\left\{1-\exp(-lt)-2\theta\exp(-K^2\theta^2)\int_\theta^{K\theta}\exp(\lambda^2)d\lambda\right\} \quad (13)$$

where:

$$l = l_f + l_b$$

$$\theta = \sqrt{\frac{lt}{K^2-1}}$$

and where the symbol i_d indicates the diffusion current observed in the absence of Reaction (10b). In this method, the word "current," denoted by i_k or i_d, means an instantaneous current observed four seconds after the beginning of the mercury-drop growth. The rate constants, l_f and l_b, can be determined from Eq. (13) by using the value of $|i_k/i_d|$, which is obtained experimentally.

The pH dependence of the l_f values at various initial concentrations of TRDTA, $[Z]_0$, was also examined, as is shown in Fig. 4; the figure reveals that l_f is a first-

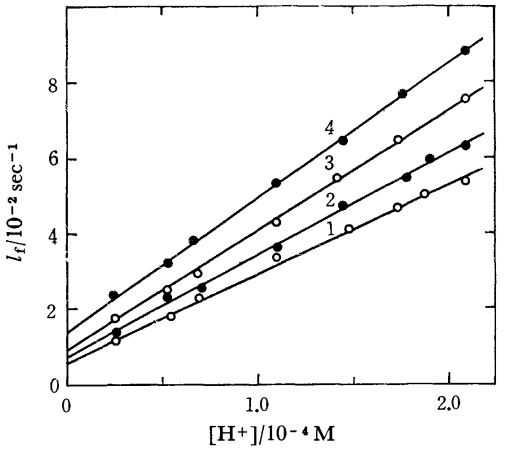

Fig. 4. The value of l_f as a function of the hydrogen ion concentration at ionic strength 0.5 (KNO_3) and 25 °C containing 0.4 mM cobalt(III)-TDTA, 24 mM TDTA, 80 mM acetate buffer and 0.005% gelatin.
Initial concentrations of TRDTA are: 4 mM (1), 6 mM (2), 8 mM (3), and 10 mM (4).

TABLE 2. RATE CONSTANTS OBTAINED BY METHODS A AND B AT 25 °C

Reaction	Rate constant	
	Method A (μ=0.2)	Method B (μ=0.5)
$CoY^{2-} + H_2Z^{2-} \xrightarrow{k^{CoY}_{H_2Z}} CoZ^{2-} + H_2Y^{2-}$	8.9×10^{-1} M^{-1} sec^{-1}	4×10^{-1} M^{-1} sec^{-1}
$CoHY^{-} + H_2Z^{2-} \xrightarrow{k^{CoHY}_{H_2Z}} CoHZ^{-} + H_2Y^{2-}$	$3.5\times10^{4}/K^{H}_{CoHY}$ M^{-1} sec^{-1}	$2.3\times10^{4}/K^{H}_{CoHY}$ M^{-1} sec^{-1}
$CoY^{2-} \xrightarrow{k^{CoY}} Co^{2+} + Y^{4-}$	1.5×10^{-3} sec^{-1}	6×10^{-3} sec^{-1}
$CoY^{2-} + H^{+} \xrightarrow{k^{CoY}_{H}} Co^{2+} + HY^{3-}$	8.1×10^{2} M^{-1} sec^{-1}	$1._3\times10^{2}$ M^{-1} sec^{-1}

order function with respect to both the hydrogen ion concentration and $[Z]_0$. These experimental results are understandable by assuming the same four reaction paths as Eqs. (4) to (7) for Reaction (10b), resulting in the same equation as in the case of Eq. (9)[12]:

$$l_f = (k^{CoY} + k^{CoY}_{H_2Z}[Z]_0) + (k^{CoY}_{H} + k^{CoHY}_{H_2Z}K^{H}_{CoHY}[Z]_0)[H^+] \quad (14)$$

Each rate constant was obtained in the same way as in Method A, on the basis of Fig. 4 and Eq. (14). The results are summarized in Table 2.

Discussion

It was revealed that the reaction of cobalt(II)-TDTA with TRDTA proceeds through four simultaneous reaction paths in the pH range from 3.7 to 5.6; these reaction paths consist of two nucleophilic ligand substitution reactions and two dissociation reactions of cobalt(II)-TDTA. The values of rate constants obtained by the two different methods are, as a whole, in good agreement with each other.

It should be noted that, in a lower pH range, reactions other than (4) to (7), such as:

$$CoY^{2-} + H_3Z^{-} \underset{}{\overset{k^{CoY}_{H_3Z}}{\rightleftharpoons}} CoZ^{2-} + H_3Y^{-} \quad (15)$$

$$CoHY^{-} + H_3Z^{-} \underset{}{\overset{k^{CoHY}_{H_3Z}}{\rightleftharpoons}} CoHZ^{-} + H_3Y^{-} \quad (16)$$

may proceed. However, since the concentration of H_3Z^- is less than 6% of $[Z]_f$ even at pH 3.7, and since the values of $k^{CoY}_{H_3Z}$ and $k^{CoHY}_{H_3Z}$ seem to be smaller than those of $k^{CoY}_{H_2Z}$ and $k^{CoHY}_{H_2Z}$ respectively,[13] it seems reasonable to neglect the contributions of Reactions (15) and (16) to the total reaction.

The dissociation rate constants of cobalt(II)-TDTA and some related complexes are summarized in Table 3. These data show that the cobalt(II)-TDTA complex dissociates easier than the other complexes shown in Table 3. This may be due to the instability of the seven-membered diamine chelate ring which is present in the cobalt(II)-TDTA complex.

TABLE 4. COMPARISON BETWEEN THE OBSERVED AND THE CALCULATED VALUES OF $(k^{Cotdta}_{H}/k^{CoL}_{H})$

Observed	Calculated
$\frac{k^{Cotdta}_{H}}{k^{Cbtrdta}_{H}} = \begin{cases}1._6 \text{ (Method A)}\\ 0.2_6 \text{ (Method B)}\end{cases}$	$\frac{K_{Cotrdta}}{K_{Cotdta}} = 0.69_5$[a]
$\frac{k^{Cotdta}_{H}}{k^{Coedta}_{H}} = \begin{cases}2._7\times10 \text{ (Method A)}\\ 4._3 \text{ (Method B)}\end{cases}$	$\frac{K_{Coedta}}{K_{Cotdta}} = 4._5$[b] or $1._2\times10$[c]

a) This value was determined in this work polarographically. b) Obtained in this work. c) From Ref. 9.

Table 4 compares the ratios of the observed rate constants, k^{CoY}_{H}/k^{CoL}_{H}, and the estimated ones which were calculated on the basis of the method proposed by Bydalek and Margerum.[15] Since TDTA is very similar to EDTA and TRDTA, the k^{CoY}_{H}/k^{CoL}_{H} ratio can be expected to be approximately the same as the reverse ratio of the stability constant, K_{CoL}/K_{CoY}, as has been shown in previous paper.[2,3] The observed ratios are practically identical with the calculated ones.

In Method A, it is necessary to stir and homogenize the solution for at least 5 to 10 seconds when the reaction is initiated. Therefore, it is desirable to measure the reaction which has a longer half-life than 40—50 seconds when DME is used. In this work, the rate of the reaction increases with the decrease in the pH of the solution. The kinetic measurements were not done in the pH range lower than 4.9 by Method A, for the rate of the reaction is immeasurably fast in this pH range. On the other hand, Method B, based on the

12) In this study, it is assumed that $\alpha_{Z(H)}$ is equal to $[H^+]^2/K_3K_4$. The contribution of terms other than $[H^+]^2/K_3K_4$ to $\alpha_{Z(H)}$ is 6% at pH 3.7, and decreases with an increase in the pH to reach 0.7% at pH 4.6.

13) In many kinds of multidentate-ligand substitution reactions, such as $ML+L' \rightleftarrows ML'+L$, which have thus far been investigated, the rate constants decrease in this order: $k^{ML}_{L'} > k^{ML}_{HL'} > k^{ML}_{H_2L'}$. This indicates that a reaction rate decreases with an increase in the extent of the protonation of an attacking ligand.[14] Therefore, it is reasonable to assume that the value of $k^{CoY}_{H_3Z}$ in the Co(II)-TDTA-TRDTA system is much less than that of $k^{CoY}_{H_2Z}$.

14) For instance, M. Kodama, C. Sasaki, and M. Murata, This Bulletin, **41**, 1333 (1968); M. Kodama, *ibid.*, **42**, 2532 (1969).

15) T. J. Bydalek and D. W. Margerum, *Inorg. Chem.*, **2**, 678 (1963).

ECE mechanism, is quite useful for such a fast reaction as long as the following conditions are fulfilled; that is, the rates of the electrode reactions (10a) and (10c) are much faster than the chemical reaction (10b). This indicates that the measurement can be performed even in a pH range lower than 4.9 by utilizing this method.

There seems to be no example of the application of the electrode process, followed by chemical and electrochemical reactions (ECE mechanism), to the multidentate-ligand substitution reaction. In this study, the kinetic treatment over a wider pH range could be carried out by utilizing Method B together with Method A, and it was confirmed that Method B is applicable to the kinetic study of the multidentate-ligand substitution reactions.

Binuclear Metal Complexes. VII.[1] Preparation and Properties of Binuclear Copper(II) and Nickel(II) Complexes of Hydrogen-bridged Macrocycles[2]

Hisashi Okawa, Tadashi Tokii,* Yoneichiro Muto,* and Sigeo Kida
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812
**Department of Chemistry, Saga University, Saga 814*

(Received April 23, 1973)

Two types of binuclear copper(II) and nickel(II) complexes, OK-3(H), 3(H)-M_2 and [OK-m, 3(H)-M_2]ClO_4 (m=2 or 3), have been synthesized, where OK-3(H),3(H) is a macrocycle composed of two 2,6-diformyl-4-methylphenol and four hydroxylamine, and OK-m,3(H) is a macrocycle composed of two 2,6-diformyl-4-methylphenol, one diamine (ethylene diamine (m=2) or 1,3-diaminopropane (m=3)), and two hydroxylamine. It was found that a very strong antiferromagnetic exchange interaction is operating between two copper(II) ions for OK-3(H), 3(H)-Cu_2 and [OK-2,3(H)-Cu_2]ClO_4. The complex [OK-2,3(H)-Ni_2]ClO_4.DMF was found to be a novel-type binuclear nickel(II) complex, in which one nickel(II) ion is diamagnetic and the other is paramagnetic.

In the preceding paper of this series, Okawa and Kida[3] synthesized some binuclear copper(II) and nickel(II) complexes of the macrocycles formulated in Fig. 1. In this paper we report two types of binuclear copper(II) and nickel(II) complexes of new hydrogen-bridged macrocycles (Fig. 2).

The macrocycles were prepared by the combination of 2,6-diformyl-4-methylphenol, hydroxylamine and diamines. The complexes of the macrocycle composed of two 2,6-diformyl-4-methylphenol and four hydroxylamine are abbreviated to OK-3(H), 3(H)-M_2, in which imino nitrogens are connected by two O···H···O bridges. The complexes of the macrocycle composed of two 2,6-diformyl-4-methylphenol, one diamine and two hydroxylamine are abbreviated to [OK-m, 3(H)-M_2]$^+$, where imino nitrogens are connected by one alkylene (ethylene (m=2) or 1,3-propylene(m=3)) chain and one O···H···O bridge.

The structures and properties of the complexes were studied from elemental analyses, infrared and visible spectra, mass spectrum, molar conductivities, and cryomagnetic measurements.

chloride (278 mg) and nickel(II) chloride hexahydrate (475 mg) in 50% ethanol (100 ml), a 10% aqueous solution of sodium hydroxide was added until the solution was neutralized. Soon yellow crystalline powder separated out. It was collected and washed with water.

Found: C, 39.11; H, 3.68; N, 10.13%. Calcd for $C_{18}H_{22}N_4O_9Ni_2$: C, 38.90; H, 3.99; N, 10.01%.

[OK-2,3(H)-Cu$_2$]ClO$_4$. *N,N'*-Ethylenebis(3-formyl-5-methylsalicylaldimino)copper(II)[3] (828 mg), hydroxylamine hydrochloride (278 mg), and copper(II) perchlorate hexahydrate (741 mg) were dissolved in methanol (100 ml). To the clean solution was added dropwise an aqueous solution of sodium hydroxide (160 mg) to give brown prisms. They were collected and washed with ethanol.

Found: C, 39.97; H, 3.46; N, 9.50; Cu, 20.76%. Calcd for $C_{20}H_{19}N_4O_8ClCu_2$: C, 39.65; H, 3.16; N, 9.25; Cu, 20.97%.

[OK-3,3(H)-Cu$_2$]ClO$_4$·H$_2$O. *N,N'-1,3*-Propylenebis(3-formyl-5-methylsalicylaldimino)copper(II)[3] (214 mg), hydroxylamine hydrochloride (70 mg), and copper(II) perchlorate hexahydrate (182 mg) were dissolved in 70% methanol, and were stirred at 50 °C for 3 hr. When the reaction mixture was cooled, dark green prisms separated out. They were collected and recrystallized from methanol.

Found: C, 39.17; H, 4.11; N, 9.22%. Calcd for $C_{21}H_{23}N_4O_9ClCu_2$: C, 39.54; H, 3.63; N, 8.78%.

[OK-2,3(H)-Ni$_2$]ClO$_4$·DMF. *N,N'*-Ethylenebis(3-formyl-5-methylsalicylaldimino)nickel(II)[3] (705 mg), hydroxylamine hydrochloride, (208.5 mg), and nickel(II) perchlorate hexahydrate (384 mg) were dissolved in *N,N*-dimethylformamide (200 ml). To this solution an aqueous solution of sodium hydroxide (180 mg) was added. The reaction mixture was refluxed for 4 hr and concentrated to 30 ml to give orange prisms.

Found: C, 41.70; H, 3.91; N, 10.27%. Calcd for $C_{23}H_{26}N_5O_9ClNi_2$: C, 41.27; H, 3.92; N, 10.46%.

Measurements. Infrared spectra were measured with a Hitachi 215 grating spectrophotometer on a KBr disk. Electronic spectra were measured with a Hitachi EPS-3T recording spectrophotometer. Magnetic susceptibilities were determined by the Gouy method over the range from liquid nitrogen to room temperature. Effective magnetic moments were calculated from the equation

$$\mu_{eff} = 2.83\sqrt{(\chi_A - N\alpha)T},$$

where Pascal's constants were used for correction of diamagnetism. The temperature independent paramagnetism, $N\alpha$, for a nickel(II) ion was estimated to be 193×10^{-6} c.g.s./mol.[4] Molar conductivities were measured in absolute methanol solution (*ca.* 10^{-3} mol) at 25 °C.

Results and Discussion

OK-3(H),3(H)-M$_2$ complexes. Some main infrared absorption bands, ligand field bands and magnetic moments at room temperature of OK-3(H), 3(H)-Cu$_2$ and OK-3(H),3(H)-Ni$_2$·3H$_2$O are given in Table 1.

The band at 1610 cm^{-1} can be assigned to the C=N stretching vibration. The broad band observed in the region 1750—1740 cm^{-1} appears to be similar in its origin to the bands found for Ni(DMG)$_2$[5] and [Co(DMG)$_2$XY]$^{-1}$ (X, Y=Cl$^-$, Br$^-$, NO$_2^-$ or H$_2$O)[6] (DMG=dimethylglyoximate anion), where each of the band was assigned to a strongly hydrogen-bonded OH-vibration. The mass spectrum of OK-3(H),3(H)-Cu$_2$ showed two signals at m/e=510 and 512; these are well corresponding to the molecular ion (mol wt=511.43). Recently we also found two peaks due to the molecular ion for a binuclear copper(II) complexes.[1] The appearance of two (or three) molecular ion peaks, therefore, characteristic of a binuclear copper(II) complex, since naturally occurring copper is composed of ^{63}Cu(69.09%) and ^{65}Cu(30.91%). Judging from these facts we concluded that the complexes possess a binuclear structure constructed with the macrocycle containing hydrogen-bridges shown in Fig. 2a.

The complex OK-3(H),3(H)-Cu$_2$ is practically insoluble even in the solvents of high donar-ability such as pyridine and *N,N*-dimethylformamide. The complex is stable in cold concentrated hydrochloric acid, sulfuric acid, and sodium hydroxide solution. The magnetic moment of the complex at room temperature is subnormal (0.59 B.M.). Its magnetic susceptibility was measured over a temperature range 77—300 K (Fig. 3). Although a deviation was found below 120 K owing to a small amount of paramagnetic impurity, the experimental data are well explained on the basis of the Bleaney-Bowers equation[7]

Table 1. Properties of OK-3(H), 3(H)-M$_2$, and [OK-m, 3(H)-M$_2$]$^+$ complexes

	IR (cm^{-1})				Λ[a]	d-d bands (kK)		μ_{eff} (B.M.)
	O···H···O	C=N	C=O	ClO$_4^-$		solid	methanol	
OK-3(H), 3(H)-Cu$_2$	1750	1610				14.9	—[b]	0.59

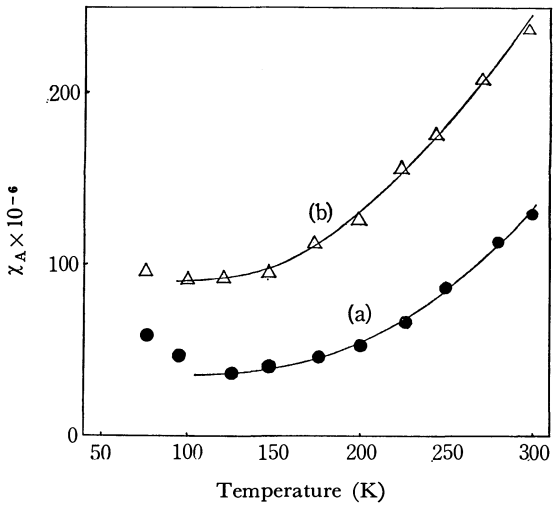

Fig. 3. Variation of molar susceptibility with temperature of (a) OK-3(H), 3(H)-Cu_2, and (b) [OK-2, 3(H)-Cu_2]ClO_4.

$$\chi_A = \frac{Ng^2\beta^2}{3kT}\left[1+\frac{1}{3}\exp(-2J/kT)\right]^{-1} + N\alpha,$$

in which each simbol means the general meaning. By the best fit of the experimental χ_A values to the equation, $-2J$, g, and $N\alpha$ were evaluated to be 870 cm^{-1}, 2.20, and 36×10^{-6} e.s.u./mol respectively. This large $-2J$ value indicates a very strong antiferromagnetic exchange interaction between the copper(II) ions. Generally the more planar the geometry around the copper(II) ion is, the larger the spin-exchange interaction between the copper(II) ions becomes.[8-10]

The reflectance spectrum of OK-3(H),3(H)-Ni_2·$3H_2O$ in Fig. 4 clearly indicates that the geometry around the nickel(II) ion is practically octahedral. The magnetic moment at room temperature is 2.84 B. M., that is slightly lower value compared with most octahedral nickel(II) complexes. The magnetic susceptibility of the complex obeys the Curie-Weiss law (Fig. 5a). The Weiss constant was determined to be -77 K, indicating an antiferromagnetic exchange inter-

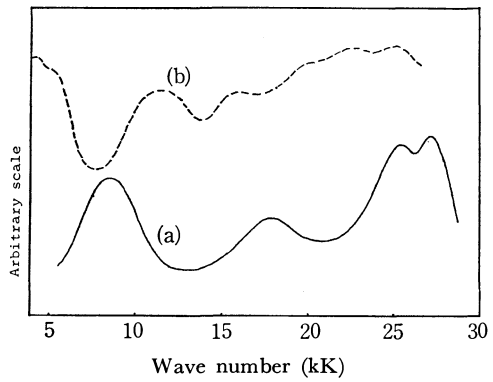

Fig. 4. Reflectance spectra of (a) OK-3(H), 3(H)-Ni_2·$3H_2O$, and (b) [OK-2, 3(H)-Ni_2]ClO_4·DMF.

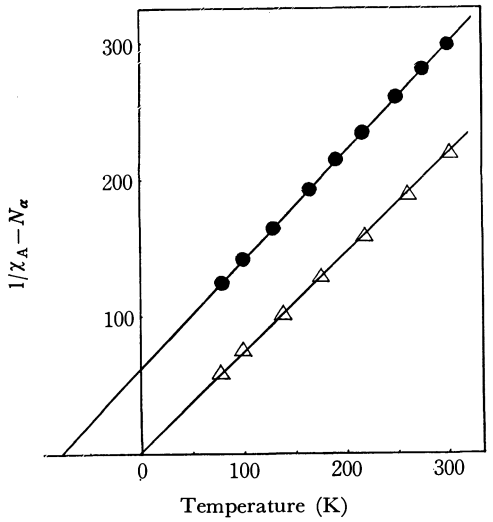

Fig. 5. Plots of the inverse susceptibilities of (a) OK-3(H), 3(H)-Ni_2·$3H_2O$, and (b) [OK-2, 3(H)-Ni_2]ClO_4·DMF per nickel atom as a function of temperature. In the latter case one nickel(II) ion is assumed to be diamagnetic.

action between a pair of nickel(II) ions.

Pilkington and Robson[11] reported that the μ_{eff} value for $LCu_2(ClO_4)_2$·$2H_2O$ (=[OK-3,3-Cu_2]$(ClO_4)_2$·$2H_2O$) was 0.58 B.M. at room temperature and the Weiss constant for LNi_2Cl_2·$2H_2O$ (=[OK-3,3-Ni_2]-Cl_2·$2H_2O$) was -125 K.

[OK-m,3(H)-M_2]$^+$ Complexes. The properties of [OK-m,3(H)-M_2]$^+$ complexes are given in Table 1. Since in the infrared spectra a band due to the O···H···O bond was observed in the region 1780—1760 cm^{-1}, the complexes were assumed to have a binuclear structure of the macrocycle formulated in Fig. 2b. Two bands in the region 1640—1620 cm^{-1} were attributed to the C=N stretching vibrations. This is consistent with the fact that there are two non-equivalent azomethine groups in [OK-m,3(H)-M_2]$^+$ complexes. The broad, strong band near 1110—1070 cm^{-1} was assigned to perchlorate ion.[12] In [OK-2,3(H)-Ni_2]ClO_4·DMF a shoulder was observed at 1635 cm^{-1}, which might be assigned to the $\nu_{C=O}$ mode of coordinated *N,N*-dimethylformamide.

The molar conductivities for [OK-3,3(H)-Cu_2]-ClO_4·H_2O and [OK-2,3(H)-Ni_2]ClO_4·DMF in absolute methanol at 25 °C clearly indicate that they are 1 : 1 electrolytes.

The reflectance spectrum of [OK-2,3(H)-Cu_2]ClO_4 possesses a very broad band around 20—15.5 kK. Similar spectrum was found for [OK-2,3-Cu_2]Cl_2.[3] The broadening of the band will be caused by the superposition of the d–d transition bands of the copper(II) ions, whose geometries are different from each other. The electronic spectrum of [OK-3,3(H)-Cu_2]-ClO_4·H_2O is similar to that of [OK-3,3-Cu_2]Cl_2·H_2O.[3] The splitting of the d–d band (16.4 and 14.3 kK) in methanol has been attributed to the fact[11] that the solvent molecule coordinates to the copper(II) ion to

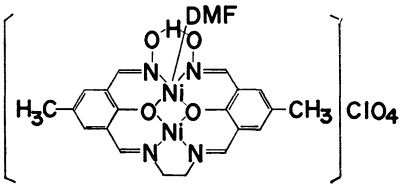

Fig. 6. The probable structure of [OK-2,3(H)-Ni_2]ClO_4·DMF.

form five- or six-coordinate complex.

The magnetic moment for [OK-2,3(H)-Cu_2]ClO_4 at room temperature was very low (0.59 B.M.). Its magnetic susceptibility was measured at various temperatures (Fig. 3b). The χ_A values obeyed the Bleaney-Bower's equation and the magnetic parameters obtained are $-2J=725\ cm^{-1}$, $g=2.10$, and $N\alpha=90\times10^{-6}$ c.g.s./mol.

The reflectance spectrum of [OK-2,3(H)-Ni_2]ClO_4·DMF given in Fig. 4b is markedly complicated; it differs from any of the spectra for octahedral,[13,14] planar,[13,14] and tetrahedral[15] nickel(II) complexes. Since it is evident from infrared spectral data that the strong intramolecular hydrogen-bond is present and that *N,N*-dimethylformamide coordinates to the nickel(II) ion, a tetragonal-pyramidal, five-coordinate structure is naturally assigned to the present complex. Recently many spectroscopic investigations of five-coordinate nickel(II) complexes have been reported,[14,16,17] and it is now well known that most low-spin tetragonal-pyramidal nickel(II) complexes have d–d bands in the region 10—20 kK.[16-18] On the other hand, high-spin, tetragonal-pyramidal nickel(II) complexes show d-d bands in the region 25—5 kK.[16,17] Judging from these facts at least one of the two nickel(II) ions in the complex seems to keep a high-spin, tetragonal-pyramidal geometry. In fact its magnetic moment at room temperature was 2.25 B.M. per nickel atom, indicating the presence of a paramagnetic nickel(II) ion. The relatively small magnetic moment of the complex will be explained in terms of (i) antiferromagnetic exchange interaction between a pair of paramagnetic nickel(II) ions or (ii) a binuclear system composed of one paramagnetic and one diamagnetic nickel(II) ions.

In order to clarify this magnetic phenomenon the magnetic susceptibility was measured at various temperatures (Fig. 5b). Since this complex obeys the Curie-Weiss law and its Weiss constant is very small ($\theta=-2$ K), it is evident that the relatively low magnetic moment is attributed to the novel binuclear system containing one high-spin and one low-spin nickel(II) ions. There are only few reports upon the complexes composed of paramagnetic and diamagnetic nickel(II) ions.[19] The reflectance spectrum given in Fig. 4b, therefore, can be interpreted as the superposition of the spectra of low-spin planar and high-spin tetragonal-pyramidal nickel(II) ions. The solution spectrum in methanol, however, was very simplified and showed a broad band around 15—20 kK. This spectrum resembles that of [OK-2,3-Ni_2]-Cl_2.[3] This fact indicates that in methanol solution the complex is coordinated with neither *N,N*-dimethylformamide nor methanol molecule, and keeps the planar structure.

It is known that *N,N'*-ethylenebis(salicylaldimino)-nickel(II) retains the planar structure in polar solvents such as pyridine.[20] In addition to this Okawa and Kida[3] reported that *N,N'*-ethylenebis(3-formyl-5-methylsalicylaldimino)nickel(II) and OK-2,3-Ni did not add pyridine and *N,N*-dimethylformamide. Therefore, in the present case, it is evident that *N,N*-dimethylformamide molecule coordinates to the nickel(II) ion in the 6–6–6 condensed ring system involving hydrogen-bridge, but not to the nickel(II) ion in the rigid 6–5–6 condensed ring system. Here, it is to be noted that no apical coordination takes place in any polar solvents in the case of [OK-2,3-Ni_2]Cl_2,[3] which has the same ring-system as [OK-2,3(H)-Ni_2]ClO_4·DMF, except that two imino nitrogens are connected with 1,3-propylene bridge instead of –O···H···O– bridge.

The Chemical Structure of Glass of the $NaPO_3$–Sb_2O_4 System

Makoto WATANABE

Department of Industrial Chemistry, Chubu Institute of Technology, Matsumoto-cho, Kasugai-shi, Aichi 487

(Received January 22, 1973)

Glassy substances of the $NaPO_3$–Sb_2O_4 system with P/Sb ratios in the range from 5.0 to 300 were prepared by heating a mixture of $NaPO_3$ glass and Sb_2O_4 at 1000 °C and by then rapidly quenching the melt of the mixture. From the results of the colorimetric determination and the average degree of polymerization of the condensed phosphates, it has been found that the chain length of the phosphates increases with an increase in the P/Sb ratio. When the glass was treated with water, antimony trioxide was deposited. By using these results, a theoretical treatment for the average degree of polymerization of condensed phosphates has been made and it has been concluded that there are P–O–Sb linkages in the glass of the $NaPO_3$–Sb_2O_4 system.

Phosphate glasses containing oxoacid anions of some elements other than phosphorus have attracted the interest of many investigators. In our previous papers,[1,2] we reported the chemical structure of sodium phosphate glass containing antimony tri- or pentoxide. In the present paper, we will examine the structural framework of sodium phosphate glass containing antimony tetroxide by using the same method as in the previous papers.

Experimental

Materials and Procedure. Sodium phosphate glass was prepared by heating monosodium orthophosphate in a platinum crucible at 1000 °C for 3 hr and by then quenching the resulting melt by placing the crucible in ice water. Antimony tetroxide was made by heating antimony trioxide at 800 °C until a constant weight was reached. The increase in the mass was very close to the calculated value of the oxidation of antimony trioxide to tetroxide (98.3%). Glassy products were obtained by heating mixture of the $NaPO_3$–Sb_2O_4 system with P/Sb ratios in the range from 5.0 to 300 in a platinum crucible at 1000 °C for 2 hr and by then quenching the melts rapidly by placing the crucible in ice water. The distribution and the average degree of the polymerization of phosphate species contained in the glasses were measured by using the same method as in the previous papers.[1,2]

Results and Discussion

The ignition loss of a mixture of the $NaPO_3$–Sb_2O_4 system was very close to the calculated value of the reduction of antimony tetroxide to trioxide. When the glassy substances were treated with an alkaline solution, a white substance was deposited; the deposit gave only X-ray diffraction patterns of antimony trioxide. It can be concluded from the results that the valence of antimony in the glasses may be three. The glassy substances are colorless and transparent, and give no X-ray diffraction patterns. The phosphates present in the aqueous solution of the glassy products were separated by paper chromatography and were then determined colorimetrically. As Table 1 shows, the quantities of ortho-, pyro-, and triphosphates decrease with an increase in the P/Sb ratio, while those of higher polyphosphates increase. The quantities of tri- and tetrametaphosphates are very small throughout the full range of P/Sb ratios.

Table 1. Distribution of phosphates of the $NaPO_3$–Sb_2O_4 system with P/Sb ratios of 5.0—300

	Phosphate (P%)					
P/Sb	Ortho	Pyro	Tri	Trimeta	Tetrameta	Higher
5.0	10.6	34.2	10.5	3.7	2.9	38.1
7.0	9.9	15.0	7.7	3.1	3.0	61.3
10	2.1	7.0	5.3	4.9	2.4	78.3
15	1.5	6.4	3.4	3.5	3.8	81.4
20	1.3	5.5	3.3	4.0	3.1	82.8
30	1.3	5.2	3.3	3.6	1.6	85.0
50	1.0	4.1	2.1	4.7	1.7	86.4
80	1.1	1.8	2.9	4.0	1.2	89.0
100	0.9	1.2	2.8	4.0	2.7	88.4
150				3.6	3.7	92.7
200				2.9	3.3	93.8
300				2.8	1.2	96.0

The average degree of polymerization of $NaPO_3$ glass was about 100, while that of the phosphates contained in the glassy products, which was also measured by the pH titration method increases with an increase in the P/Sb ratio, as may clearly be seen in Fig. 1, it can be concluded that sodium phosphate glass may react with antimony oxide to form the P–O–Sb linkage and the valence of the antimony may be reduced to three under these conditions. The

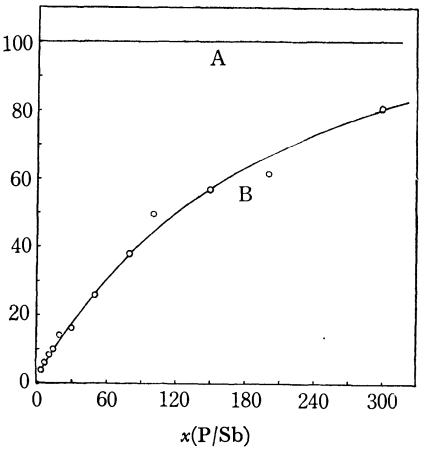

Fig. 1. Variation of average chain length of polyphosphates.
A: Sodium phosphate glass
B: Experimental values of the $NaPO_3$–Sb_2O_4 system

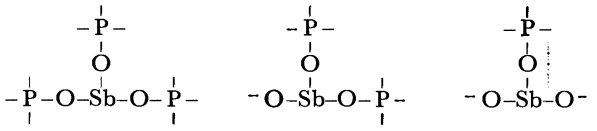
1) M. Watanabe, K. Tanabe, T. Takahara, and T. Yamada, This Bulletin, **44**, 712 (1971).
2) M. Watanabe and M. Kato, *ibid.*, **45**, 1058 (1972).

P–O–Sb linkage may be very much less stable than the P–O–P linkage. Therefore, the P–O–Sb linkage may be rapidly hydrolyzed to produce phosphate ions and antimony trioxide in an aqueous solution.

By using these results as a basis, a theoretical treatment for the average degree of polymerization of the phosphates present in the glassy products can be made. The theory has already been described in previous papers.[1,2] A summary of the theory is as follows. The valence of antimony present in the glasses is considered to be three, and there are three possible types of structures containing P–O–Sb linkages. If x, y, and z are the numbers of phosphorus atoms, P–O–Sb linkages, and Sb–O$^-$ linkages per atom of antimony respectively, the average chain length, $\bar{n}$, of the polyphosphates produced by the hydrolysis of P–O–Sb linkages is given by Eq. (1):

$$(\bar{n}+2)/\bar{n} = (x+y-z)/x \qquad (1)$$

The values calculated by using this equation are listed in Column I of Table 2. When x is larger than 30,



Structure A Structure B Structure C

even the calculated values of $\bar{n}$ based on Structure A are larger than the measured ones. Considering other factors which shorten the chain length of the phosphates present in the glasses, for example, the branching points and impurities, Eq. (1) is modified into Eq. (2):

$$(\bar{n}+2)/\bar{n} = (x+y-z+fx)/x \qquad (2)$$

where f is the factor shortening the chain length of the polyphosphate and is given with respect to an atom of phosphorus. As may clearly be seen in Column II of Table 2, when the f factor is arbitrarily set at 0.015, the calculated values of $\bar{n}$ based on Structure A are very close to the measured ones throughout the range of P/Sb ratios from 5.0 to 300. From these results, it may reasonably be concluded that the structural framework of the glasses of the $NaPO_3$–Sb_2O_4 system with P/Sb ratios larger than 5.0 is Structure A.

Table 2. Average chain length of polyphosphates of the $NaPO_3$–Sb_2O_4 system

		Column I $\bar{n}$ calcd by Eq. (1) Structure			Column II $\bar{n}$ calcd by Eq. (2) (f=0.015) Structure		
x (P/Sb)	$\bar{n}$ Found	A ($y=3$, $z=0$)	B ($y=2$, $z=1$)	C ($y=1$, $z=2$)	A ($y=3$, $z=0$)	B ($y=2$, $z=1$)	C ($y=1$, $z=2$)
5.0	4.1	3.3	10	—	3.3	9.3	—
7.0	5.8	4.7	14	—	4.5	13	—
10	8.8	6.7	20	—	6.3	17	—
15	9.7	10	30	—	9.3	25	—
20	14	13	40	—	12	31	—
30	16	20	60	—	17	41	—
50	26	33	100	—	27	57	∞
80	38	53	160	—	38	73	800
100	50	67	200	—	45	80	400
150	57	100	300	—	57	92	240
200	62	133	400	—	67	100	200
300	81	200	600	—	80	109	171

According to the results described in this paper and in the previous papers,[1,2] when the P/Sb ratio is larger than 5.0, antimony tetr- and pentoxides are reduced to trioxide and the trioxide reacts with $NaPO_3$ glass to form Structure A at 1000 °C. The values of the f factors of the $NaPO_3$–Sb_2O_3 and –Sb_2O_5 systems were 0.02 and 0.01 respectively. The difference in the value of the factor between these systems may be caused by the quantities of impurities contained in the antimony oxides and/or the experimental conditions—for example, the cooling speed of the melts. The f factor of the pure sodium phosphate glass ranges from 0.025 to 0.01, depending on the conditions of the preparation.

Photochemical Reduction of *p*-Quinones with Hydrogen Donors Studied by CIDNP Technique[1,2]

Kazuhiro MARUYAMA, Tetsuo OTSUKI, Akio TAKUWA, and Seiichi ARAKAWA
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606
(Received September 29, 1972)

Photo-reduction of *p*-benzoquinone, 1,4-naphthoquinone, and their methyl- or chloro-derivatives has been investigated by means of CIDNP technique. Strongly polarized PMR signals due to unstable reaction intermediates, *p*-quinones, and hydroquinones were observed during the course of reaction. Structures of the unstable reaction intermediates, none of which accumulated as reaction products, were determined, their polarized PMR signals being compared with those of the unstable reaction intermediates resulting from the deuterated substrates. From these results, a reaction scheme for these photo-reduction was proposed.

Photo-reduction of *p*-benzoquinone or chloranil in the presence of hydrogen donors is well known.[3-5] However, no systematic studies or details of the reaction mechanism have been published.

According to Moore and Waters,[3] chloranil reacted with *p*-xylene to form 2,3,5,6-tetrachloro-4-(4-methylbenzyloxy)-phenol. A similar compound was isolated in the photochemical reaction of chloranil with tetralin.[6] Chemically induced dynamic nuclear polarization (CIDNP) technique affords an effective method for investigating unstable active intermediates as well as stable products produced through radical mechanism even in a very small amount.

A preliminary examination revealed that *p*-benzoquinone and its methyl- or chloro-derivatives dissolved in a suitable solvent are photochemically reduced in the presence of hydrogen donors; *i.e.*, xanthene, 9,10-dihydroanthracene, fluorene, or diphenylmethane, to give hydroquinone, quinhydrone, and/or their methyl- and chloro-derivatives. During the course of photo-reductions, strongly polarized PMR signals due to stable reaction products; *i.e.*, hydroquinones, unstable reaction intermediates, as well as *p*-benzoquinones could be observed.

Photo-reduction of *p*-benzoquinone, 1,4-naphthoquinone, and their methyl- or chloro-derivatives by several types of hydrogen donors was investigated by means of CIDNP technique, and stable photo-reduction products were also investigated in macro scale in the photochemical reaction. Emphasis is laid on the photochemical reaction of *p*-quinones with xanthene.

Results and Discussion

Using the NMR probe shown in Fig. 1 we examined the process of photochemical reaction of *p*-quinones with hydrogen donors *in situ* by NMR spectrometer. Carbon tetrachloride and acetone-d_6 were used as solvents. Light was introduced into the probe from the upper side through a hole, reflected by a mirror. A 500 W high-pressure mercury arc lamp was used.

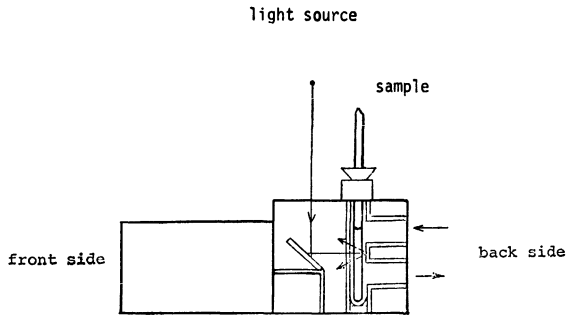


Fig. 1. NMR probe for irradiation.

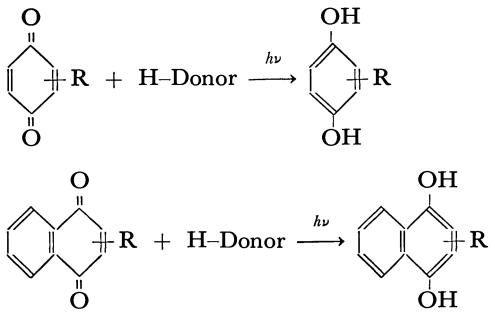
Structures of the *p*-quinones and types of hydrogen donors are shown in the following.



R: H, CH_3, $(CH_3)_2$, $(CH_3)_3$, $(CH_3)_4$, Cl, $(Cl)_2$, $(Cl)_3$ *etc.*

H–Donor: Xanthene, 9,10-Dihydroanthracene, Fluorene, Ether, Alkylaromatics.

Figure 2 shows PMR spectra observed in the reaction of *p*-benzoquinone with xanthene. Spectra (a), (b), and (c) correspond respectively to the PMR spectra observed before irradiation, during the course of irradiation, and after a longer irradiation. Comparing (b) with (a) we find newly appearing strong polarized signals (indicated by arrows). However, when irradiation is stopped they disappear completely with the exception of signal 1 within a few seconds. Since spectrum (c) is obtained after a long photochemical reaction, signal 1 is due to benzene ring protons of hydroquinone which is a stable product. Thus, emission polarized signal 1 in (b) can be assigned to benzene ring protons of hydroquinone. Actually, hydroquinone and bixanthyl are the only stable reaction

products. Bixanthyl gives no polarized PMR signal.[7] None of the unstable intermediates giving the polarized PMR signals [signals 2,3,4,5,6, and 7 in (b)] accumulate in the reaction system.

For the purpose of obtaining information on their structure we have used deuterated xanthene in 9-methylene group and deuterated *p*-benzoquinone (Fig. 3). Spectrum (b) is observed in the reaction of non-deuterated *p*-benzoquinone with xanthene, (d) in that of non-deuterated *p*-benzoquinone with deuterated xanthene, and (e) in that of deuterated *p*-benzoquinone with non-deuterated xanthene. Three absorption polarized signals 2, 5, and 6 appearing in (b) disappear in (d). Thus, we can conclude that they are based on methine proton of xanthene moiety of the active intermediates. On the other hand, signal 7 changes to doublet from triplet (double doublet). Further, comparing (e) with (b), three emission polarized signals 3, 4, and 7 disappear and the absorption polarized signal 5 changes to singlet from doublet. From the results we may assign three structures ([I], [II], and [III]) to the unstable intermediates. Absorption polarized signal 2 might be due to methine proton of xanthene moiety in [I] and emission polarized signals 3 and 4 to two pair protons of hydroquinone moiety in [I]. These two emission polarized signals might be the right half of the AX-type signal and we can not observe the left half hidden behind the other larger signals of aromatic ring protons. Ab-

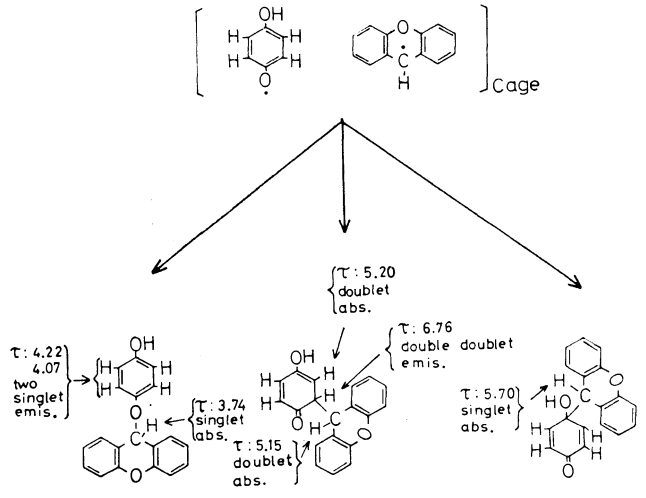
7) We could not observe the polarized PMR signal in the combination reaction of two symmetrical radicals. G. L. Closs and A. D. Trifunac, *J. Amer. Chem. Soc.*, **92**, 2183, 2186 (1970); R. Kaptein and L. J. Oosterhoff, *Chem. Phys. Lett.*, **4**, 195, 214 (1969).

sorption polarized signal 5 may be assigned to methine proton of xanthene moiety in [III] and emission polarized signal 7 to methine proton of *p*-benzoquinone moiety in [III]. Rather weak absorption polarized signal 6 may be due to methine proton of xanthene moiety in [II]. Assignment of signal 6 to [II] can be deduced from a comparison of the polarized PMR signal observed in the photochemical reaction of anthraquinone with xanthene. In this case a sole strongly polarized absorption signal in the corresponding chemical shift region to signal 6 could be observed.[8] The assignments can be further supported by comparison of these results with those observed in the reaction of 1,4-naphthoquinone with xanthene (Fig. 4). PMR spectra (f), (g), and (h) were obtained in the photochemical reaction of 1,4-naphthoquinone with xanthene, (f) being observed before irradiation, and (g) during the course of irradiation. (h) was also observed during the course of irradiation, but in the reaction of 1,4-naphthoquinone with deuterated xanthene in the 9-methylene group. We see that (g) has quite the same pattern of signals as (b) (Fig. 2). Thus, we may assign the three structures described in (g) to the unstable intermediates. As in the photochemical reaction of *p*-benzoquinone, none of these intermediates accumulates in the reaction system, and we obtain only 1,4-dihydroxynaphthalene and bixanthyl as stable products.

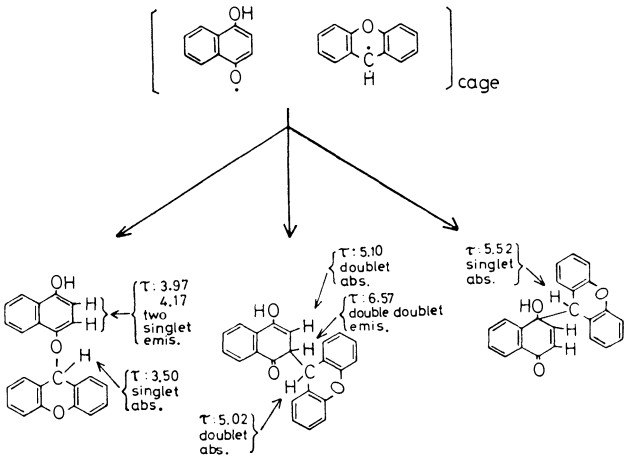
Since only the products which are produced through radical mechanism can give such a polarized PMR signal, photochemical reduction process of *p*-quinones by xanthene can be summarized as follows. Photo-excited *p*-benzoquinone, probably in the triplet state, abstracts hydrogen atom from xanthene and forms

Possible structure of unstable intermediates



Reaction Scheme 1.

Possible structure of unstable intermediates



Reaction Scheme 2.

semiquinone radical and xanthyl radical in a solvent cage. These two radicals may combine in the solvent cage to form three unstable intermediates which finally decompose to solvent separated semiquinone radical and xanthyl radical (Reaction Schemes 1 and 2). Analogous examples which can be observed in photochemical reactions of methyl- or chloro-substituted *p*-quinones are shown in Figs. 5—8. From the PMR spectra observed in the reaction of 2,5-dimethyl-*p*-benzoquinone with xanthene (Fig. 5), we see that PMR signals in the chemical shift region of methyl proton undergo a strong nuclear spin polarization also. When the sample was irradiated in a NMR probe the corresponding numbers of polarized PMR signals 5, 6, 7, and 9 (Fig. 5 (b)) to methyl groups of stable or unstable products could be observed. Thus, the emission polarized signal 5 corresponds to methyl protons of 2,5-dimethylhydroquinone. Methyl protons of quinone themselves also show emission polarized signal. A more typical example of similar phenomena can be found in Fig. 6 (b) (signal 8) and Fig. 7 (b) (signal 8). The other three or more absorption polarized PMR signals 6, 7, and 9 (Fig. 5 (b)) can be observed in the

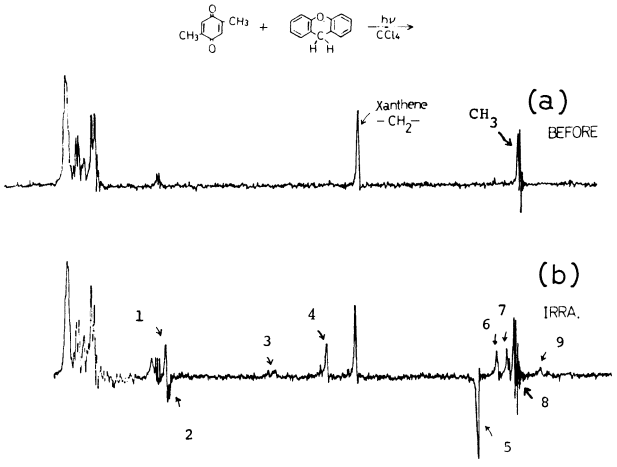


Fig. 5. PMR spectra observed in the photochemical reaction of 2,5-dimethyl-*p*-benzoquinone with xanthene (solvent; CCl_4, 22 °C).
(a): before irradiation, (b): during irradiation

8) From a consideration of their structures, [I], [II], and [III] should be so stable as to be isolated, but none of them accumulated in the photochemical reaction examined. Because of the higher polarity of the solvents used the unstable intermediates might be forced to decompose giving two radicals. In fact we were able to isolate the adducts which might be derived from similar reaction intermediates in the photochemical reaction of 2,3-dichloro- or 2,3-dibromo-1,4-naphthoquinone with xanthene dissolved in cold benzene.

(a): before irradiation, (b): during irradiation,
(c): soon after irradiation (in this case irradiation was stopped)

methyl group region. The signals should be due to methyl protons of the unstable intermediates.

The emission polarized signal 1 in Fig. 6 (b) of the polarized PMR signals observed in the photochemical reaction of 2,6-dimethyl-p-benzoquinone with xanthene is due to the ring protons of quinone. The absorption polarized signals 3, 4, 5, and 6 in Fig. 6 (b) can be assigned to the unstable intermediates. They may be due to the methine proton of xanthene moiety having structures in which xanthene moiety attaches to the oxygen atom or carbonyl carbon. One of the two

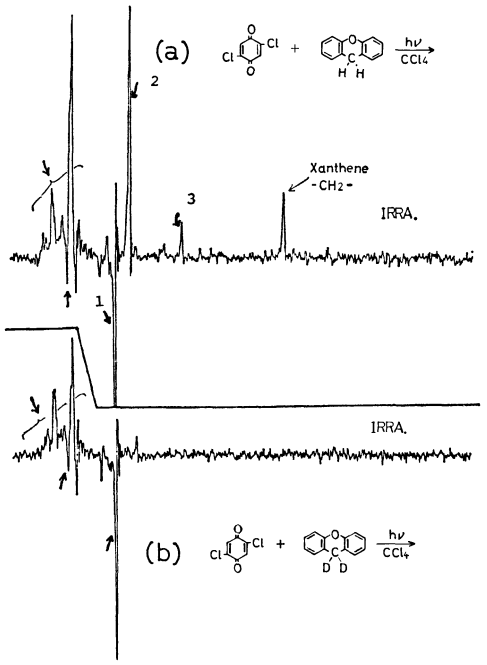

Fig. 8. PMR spectra observed in the photochemical reaction of 2,5-dichloro-p-benzoquinone with xanthene (solvent: CCl_4, 22 °C).
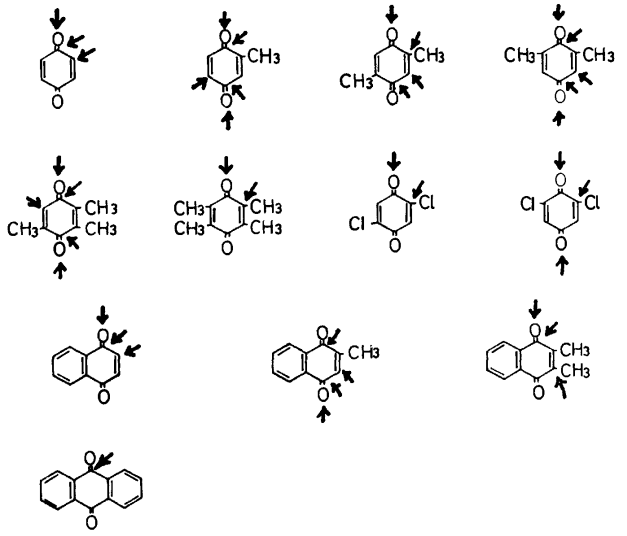
(a): during irradiation, (b): during irradiation, but with use of deuterated xanthene

emission polarized signals (signal 7 in Fig. 6 (b)] in methyl proton region corresponds to methyl group of 2,6-dimethylhydroquinone and the other (signal 8) to the methyl groups of quinone itself. The other three or the more absorption polarized signals 9, 10, and 11 (Fig. 6 (b)) are due to the methyl protons of the unstable intermediates. In Fig. 7 we find a quite analogous example in the photochemical reaction of 2-methyl-1,4-naphthoquinone with xanthene. Several groups of strongly polarized PMR signals containing the strong emission polarized signal 8 due to methyl protons of quinone can be observed. They correspond to the ring proton, the methine proton, and the methyl proton of quinone or xanthene moieties in methyl substituted hydroquinone or in unstable intermediates [signal 7 to CH_3 of hydroquinone, and signals 9, 10, 11 to CH_3's of unstable intermediates]. PMR spectra observed in the photochemical reaction of 2,5-dichloro-p-benzoquinone with xanthene are shown in Fig. 8. Both spectra (a) and (b) are observed during the course of irradiation, (b) being of the deuterated xanthene case. Thus, absorption polarized signals in (a) (signals 2 and 3) are assigned to methine proton of xanthene moiety of unstable active intermediates. Emission polarized signal 1 is due to the ring proton of 2,5-dichlorohydroquinone produced as a stable product.

We can thus decide the attaching position of xanthene moiety to p-quinone moiety to form the unstable intermediates. The positions are indicated by arrows as follows.

For example, 2-methyl-p-benzoquinone forms five unstable intermediates. It is interesting that almost all the possible intermediates having a different structure can be found.



p-Quinone as a starting material, hydroquinone as stable product, and unstable intermediates can give the polarized PMR signal. However, no bixanthyl as the other stable reaction product and no xanthene as the other starting material in the photochemical reaction can give any polarized PMR signal. The photochemical reaction of *p*-quinones with xanthene in carbon tetrachloride or acetone is quite clean and gives only hydroquinones and bixanthyl as the stable reaction products. The photochemical reactions of *p*-quinones with xanthene can be formulated as follows.

$$Q[^0S] \xrightarrow{h\nu} Q[^1S] \longrightarrow Q[T]$$

$$Q[T] + R\text{-}H \longrightarrow [R\text{-}H\cdots Q] \longrightarrow [R\cdot,\cdot QH]_{cage}$$

$$R\text{-}H + Q \longleftarrow$$

$$[R\cdot,\cdot QH]_{cage} \rightarrow \underline{[\text{Unstable Intermediates}]} \rightarrow \cdot QH + R\cdot$$

$$2\cdot QH \longrightarrow \underline{Q} + \underline{QH_2} \qquad \downarrow$$

$$R-R$$

Q: *p*-Benzoquinones.
R-H···Q: Transition state.
·QH: Semiquinone Radicals.
QH_2: Hydroquinones.
The compounds underlined show the polarized signals.

The compounds underlined can show the polarized PMR signals. We can observe analogous polarized PMR signals in the photochemical reaction of *p*-quinones with the other hydrogen donors described above.

Experimental

Materials. Commercial *p*-quinones of guaranteed grade were purified by recrystallization or by sublimation.

TABLE 1. MELTING POINTS OF *p*-QUINONES

p-Quinones	Mp (°C)
p-Benzoquinone	111
2-Methyl-*p*-benzoquinone	66[a]
2,5-Dimethyl-*p*-benzoquinone	123—124[a]

a) Synthesized. b) Sublimed.

When not available, they were synthesized by oxidation of the corresponding phenols with Fremy's salt.[9]

CIDNP Examination. A typical CINDP examination of the photochemical reaction is as follows: a suitable amount of *p*-quinone ($\sim 10^{-2}$—10^{-3} M) and xanthene were dissolved (or suspended) in suitable solvents such as carbon tetrachloride, acetone-d_6, or benzene-d_6[10] in a NMR sample tube made of usual glass.

The sample was irradiated by a 500 W high pressure mercury arc lamp and PMR spectra were observed before, during, and after irradiation. A 60 MHz NMR spectrometer manufactured by JEOL was used.

Products. Photochemical reactions of *p*-quinones with xanthene are so smooth and clean that hydroquinones produced are in general separated out in the sample tube within a few minutes. The same photochemical reactions were examined in a macro scale using a test tube as reaction vessel. The sample was irradiated by a 400W high pressure mercury arc lamp through 10 cm thick of water layer. When the color of *p*-quinone had faded completely, the volume of the sample was reduced to 2~3 ml, and hydroquinone and bixanthyl were separated by short Florisil (100~200 mesh) column. Melting points of hydroquinones produced were: hydroquinone, 170 °C; 2-methylhydroquinone, 126—127 °C; 2,5-dimethylhydroquinone, 217 °C; 2,6-dimethylhydroquinone, 149—151 °C; 2,3,5-trimethylhydroquinone, 168—170 °C; 2,3,5,6-tetramethylhydroquinone, 233 °C; 2,5-dichlorohydroquinone, 170 °C; 2,6-dichlorohydroquinone, 164 °C; 1,4-dihydroxynaphthalene, 173 °C; 2-methyl-1,4-dihydroxynaphthalene, (decn. < 100 °C). Melting point of bixanthyl, 208—209 °C.

10) Photochemical reactions of *p*-quinone with xanthene are so fast that the solvents do not interfere with the photochemical reactions.

Structural Studies of Tryptophan Metabolites by X-ray Diffraction Method. I. The Crystal and Molecular Structure of 5-Hydroxy-DL-Tryptophan

Akio WAKAHARA, Masaru KIDO, Takaji FUJIWARA, and Ken-ichi TOMITA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka 560

(Received December 18, 1972)

5-Hydroxy-DL-tryptophan was crystallized from a methanol solution in the monoclinic space group C2/c, with cell-dimensions of $a=16.765$, $b=5.892$, $c=20.887$ Å, and $\beta=92.06°$. The molecular structure and stereoconfiguration have been elucidated by the direct method for non-primitive space group. A Fourier map, calculated with the largest 198 normalized structure factors as Fourier coefficients, revealed the whole structure which was refined by the least-squares method. The molecule is a zwitterion as in the crystal structure of amino acids, each amino nitrogen atom having an extra proton. The indole ring plane forms a dihedral angle of 40° with that formed by an acid group. With respect to the conformation about the C(α)–C(β) bond, the orientation of C(β)–C(γ) bond is *trans* with respect to the C(α)–COO$^-$. The molecules are arranged in double layers parallel to the *ab*-plane. The layer by polar groups is held together by a series of hydrogen bonds in a three-dimensional network, and by non-polar groups in the other layer, indole rings being stacked by van der Waals forces. The D- and L-forms of 5-hydroxytryptophan are hydrogen-bonded into two types of dimer related by the center of symmetry, one through N–H···O, and the other through O–H···O hydrogen bonding.

5-Hydroxytryptophan (5-HTP) was found as a precursor of 5-hydroxytryptamine (serotonin) in a metabolic pathway of tryptophan.[1-3] In animal tissues 5-HTP is decarboxylated to serotonin,[4] a similar reaction being observed between tryptophan and tryptamine.[5] Bell and Fellows have isolated 5-HTP as a free plant amino acid from seeds of *Griffonia simplicifolia*.[6] X-ray structure determination of tryptophan has been made by several authors because of its biochemical importance. With the exception of tryptophan hydrochloride,[7] their attempts did not succeed due to the difficulty of obtaining a good single crystal.[8-10] The pharmacological action of 5-HTP is also of interest, because of the fact that 5-HTP has excellent radiation protective ability.[11-13] Sano recently showed that 5-HTP is most effective for medical treatment of endogenous depression.[14] As a part of a programme of studies on the crystal and molecular structures of tryptophan metabolites, we performed the structure analysis on 5-hydroxy-DL-tryptophan. A preliminary result has been reported.[15] Refinement based on the three-dimensional photographic data has now been completed.

Experimental

5-Hydroxy-DL-tryptophan (Sigma Chemical Co.) was dissolved in methanol at room temperature and kept at 5 °C. Crystals were very thin colourless laths elongated parallel to the b-axis. Recrystallization of the commercial sample was extremely difficult. The crystal used for the determination of unit-cell parameters and for the collection of intensity data had dimensions of the order $0.03\times0.06\times0.75$ mm. Approximate lattice parameters were determined from oscillation and Weissenberg photographs taken around the b-axis, and were later refined by the precise measurement of the 2θ angles for 8 reflections on a Rigaku Denki manual four circle diffractometer. The systematic extinctions showed that the space group was either C2/c or Cc. From the distribution of the normalized structure magnitudes, a centro-

symmetric space group C2/c was chosen as the correct space group. The crystal and physical data are given in Table 1. Intensity data were recorded on equi-inclination Weissenberg films of *h0l* to *h4l* zones, for a crystal rotating about the b-axis, using Cu$K\alpha$ radiation. Intensities were estimated visually by comparison with a calibrated film strip. These were corrected for spot size, Lorentz and polarization factors. Intensity data of 1084 non-zero reflections were then adjusted to the absolute scale and normalized structure factor E, and $\sum_2$ lists were computed. The statistical averages in Table 2 confirm that the crystal is centro-symmetric.

Determination and Refinement of the Structure

Phases for 5-hydroxy-DL-tryptophan were determined by means of the symbolic addition procedure by Hauptman and Karle. To specify the origin for non-primitive space group C2/c, two structure factors of large magnitude having linearly independent vectors were assigned as having positive signs.[16] Three other reflections whose signs were specified by symbols a, b, and c were chosen among reflections with many $\sum_2$ interactions. This starting set is shown in Table 3. By hand calculation, the phases of additional 193 reflections were determined in terms of the starting signs and letters. The three dimensional E-map, computed with the assignments a=b=c=−, revealed high peaks corresponding to each atom in the molecule.

TABLE 3. STARTING SET FOR SYMBOLIC ADDITION PROCEDURE

h	k	l	Phase	$\|E\|$
3	3	17	+	2.88
8	2	−17	+	2.84
1	3	16	a	4.23
8	2	−14	b	3.61
7	1	−18	c	2.93

The map has no spurious peaks of density greater than that of the 16 non-hydrogen atoms. None of the phases was subsequently found to be incorrect when compared with the phase corresponding to the fully refined structure. The positional coordinates of the sixteen atoms as selected from the E-map were subjected to the structure factor calculation and the three-dimensional Fourier synthesis. At this stage, the discrepancy factor $R=\sum||F_o|-|F_c||/\sum|F_o|$ was 0.32. The structure was refined by successive Fourier syntheses and least-squares method based on only the observed non-zero reflections; using the isotropic thermal parameters for all the nonhydrogen atoms, the R index converged to 0.20 after 5 cycles. The difference synthesis was then computed to obtain the hydrogen atoms. The peaks of the twelve hydrogen atoms clearly appeared on this map, where their heights are within the range 0.3—0.8 e.Å^{-3}. It was confirmed that the molecule of 5-hydroxy-DL-tryptophan exists as a zwitterionic form in crystalline state. The block-diagonal approximation was used for the least-squares refinement. This refinement proceeded including these hydrogen atoms and applying the anisotropic temperature factors for nonhydrogen atoms. Since the shifts in the positional parameters in the final cycle were less than one tenth of the estimated standard deviations, the refinement was terminated at this stage. It was thought that the unfavorable shape of the crystal resulted in a rather high R factor of 0.119. Observed and calculated structure factors from the last cycle are given in Table 4, and the atomic coordinates and thermal parameters with their estimated standard deviations in Table 5. Overall isotropic temperature factor for hydrogen atoms was also refined, the final value being 2.2 Å^2. A difference Fourier map synthesized with the phases by only heavy atom contributions and the final electron density map for the heavy atoms are illustrated in Fig. 1.

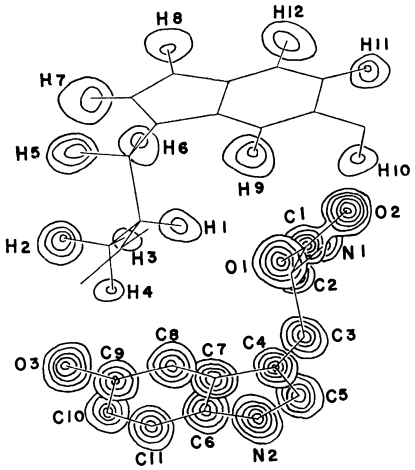

Fig. 1. Superimposed three-dimensional electron-density distribution for the heavy atoms (the lower half) and the hydrogen atoms (the upper half), viewed along the b-axis; contours at intervals of 2 e.Å^{-3} for the heavy atoms, and 0.2 e.Å^{-3} for the hydrogen atoms.

All the numerical calculations were carried out on an NEAC 2200-500 computer of this University, a HITAC 5020 E in the computing center, the University of Tokyo, and a FACOM 230-60 in the data processing center, Kyoto University, using the programs written by Dr. Tamaichi Ashida and by the authors.

Description and Discussion of the Structure

Bond Lengths and Angles. The bond distances and valency angles in the molecule are shown in Fig. 2; the average standard deviations are about 0.012 Å for bonds and 0.8° for angles. The average of six C–C bond lengths in the six-membered ring is 1.382 Å, while that of C–N bonds in the five-membered ring is 1.384 Å. The C(10)—C(11) bond (1.352 Å) is significantly shorter than the mean value taken from other indole derivatives, such a short distance being found only in 5-methoxy-(*N*,*N*)-dimethyltryptamine hydrochloride (1.360 Å).[17] As expected, the molecule is a zwitterion, with an amino nitrogen atom accepting a proton from an acid group and assuming the tetrahedral configuration C–NH_3^+. The value

of 1.491 Å for the C(2)—N(1) bond length is in good agreement with the average value, C–N$^+$ = 1.487 Å, for α-amino acids.[18] In the ionized carboxyl group, the two C–O distances differ significantly, and C(1)–O(2) bond length (1.283 Å) is somewhat longer than that usually observed in many COO$^-$ groups. This might be explained by the fact that the O(2) atom is an acceptor of two short hydrogen bondings. The angle C(α)–C(β)–C(γ) is significantly larger than the tetrahedral value, the value 114.9° being very close to a mean angle of 114° of the examined 27 compounds.[19]

Planarity of the Molecule. As far as tryptophan derivatives are concerned, the conformation of a molecule as a whole can be well described in the two

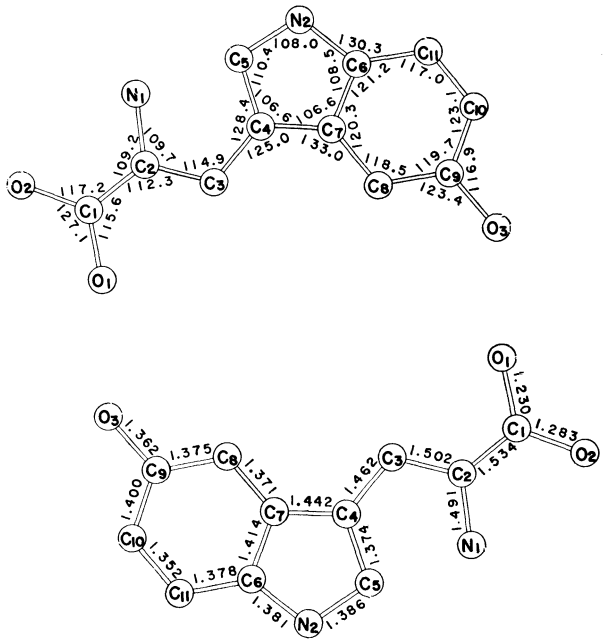

Fig. 2. Bond distances and angles of 5-hydroxy-DL-tryptophan. The standard deviation for the bond lengths ranges between 0.011 and 0.013Å. The standard error for the angles is approximately 0.8°.

planes which consist of the indole ring and the acid group. The equations of the least-squares planes are: for the indole ring, $0.0846X+0.5114Y+0.8552Z=3.8776$ and for the carboxyl group with α-carbon, $0.6536X+0.1469Y+0.7425Z=4.8350$ in rectangular Ångstrom space. These two planes form a dihedral angle of 40.1°, which is considerably differing from 70.6° in L-tryptophan hydrochloride.[7] This is attributed to the difference in conformation of the ionized carboxyl group. The deviations of the individual atoms from the best planes are given in Table 6. It is concluded that nine atoms of indole ring and C(β) atom are almost in a plane within the limit of experimental error.

Table 6. Deviations (Å) of atoms from the best plane

*O (3)	0.070		
*C (3)	0.025		
*C (2)	1.305		
*H (10)	0.290		

* Excluded from the least-squares calculations. The mean deviation from the indole ring is 0.010 Å and that from the acid group 0.007 Å.

However, the O(3) atom of the hydroxyl group is 0.07 Å out of the plane as found in serotonin picrate monohydrate.[20] The amino nitrogen atom is 0.137 Å, being displaced from the acid plane as in α-amino acid, the N(1)–C(2) bond forming an angle of 5.4° with this plane.

Molecular Conformation. As shown in Fig. 3, in the present molecule, the C(β)–C(γ) bond lies at *trans* position to the C(α)–COO^- bond and *gauche* to the C(α)–NH_3^+ bond. Similar conformations have been observed in glycyl-L-tryptophan dihydrate[21] and DL-tryptophan formate.[22] On the other hand, L-tryptophan hydrochloride occurs in a different conformation, and the orientation of C(β)–C(γ) bond moves to *gauche* position with respect to both the C(α)–COOH and C(α)–NH_3^+. In the case of tryptophan, Ramachandran and Lakshminarayanan pointed out that C(γ) atom should take I or III position in Fig. 3.[19] Some torsion angles are given in Table 7.

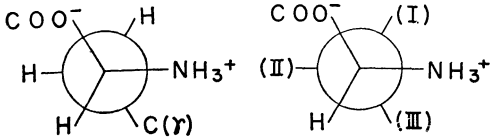

Fig. 3. Newman projections about C(α)–C(β) bond.

Table 7. Torsion angles

C(5)–C(4)–C(3)–C(2)	±110.7°
C(4)–C(3)–C(2)–C(1)	±163.6°
C(4)–C(3)–C(2)–N(1)	± 74.8°
C(10)–C(9)–O(3)–H(10)	±165.9°

Two Modes of Dimers. An interesting aspect of this crystal structure is the hydrogen-bonding scheme. The D- and L-forms of 5-hydroxytryptophan are hydrogen-bonded into two types of dimers related by center of symmetry. Molecule (A) is an original molecule whose coordinates are given in Table 5. Two molecules (A) and (B) or (A) and (C) form DL-dimer in solid state. The A-B type of dimer is a typical cyclic dimer[23] joined through O(3)–H(10)···O(2) hydrogen bonding (2.688 Å). Another type (A-C dimer) is a nonplanar dimer[23] linked together by an N(1)–H(2)···O(2) hydrogen bridge (2.798 Å). This hydrogen-bonded dimer has been found in the crystal structure of DL-valine.[24] Judging from the distances of the hydrogen bonds and the molecular packing in crystals, we suppose that A-B dimers are originally formed in solution and then the crystallization is performed by A-C dimerization.

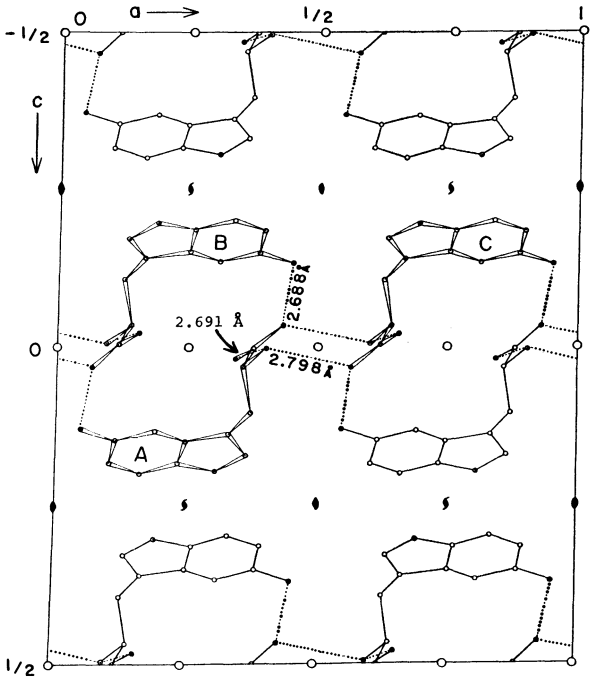

Fig. 4. Molecular packing of 5-hydroxy-DL-tryptophan as seen along the b-axis. The dotted lines show hydrogen bonds.

Packing of the Molecules. The packing in the structure is illustrated in Fig. 4. The molecules are arranged in double layers parallel to (001), and connected through hydrogen bondings described above. The third hydrogen bond of 2.691 Å is observed between the N(1) atom and the O(1) atom (Table 8). By this linkage along b-axis, dimers are connected into an infinite three-dimensional network. It is of considerable interest that the nitrogen atom of the indole ring is not involved in any hydrogen bonds, and nonpolar indole planes are stacked by van der Waals forces. All the intermolecular contacts of less than 3.5 Å between pairs of non-hydrogen atoms are summarized in Table 8. All the atoms other than C(2), C(3), C(4), C(6), and C(7) have one or more intermolecular neighbors within 3.5 Å. Unusually close contact (3.201 Å) is found between C(5) and O(3) of the adjacent molecule. The distance of H(7)···O(3) is 2.24 Å and the C(5)–H(7)–O(3) angle is 153±6°. This might suggest that this short contact arises from hydrogen bonding of the C–H···O type described by Sutor.[25] This work was partly supported by a research grant from the Ministry of Education.

Structural Studies of Tryptophan Metabolites by X-ray Diffraction Method. II. The Crystal and Molecular Structure of Tryptamine Hydrochloride

Akio WAKAHARA, Takaji FUJIWARA, and Ken-ichi TOMITA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka 560

(Received December 18, 1972)

The crystal structure of tryptamine hydrochloride has been solved by the application of the symbolic addition method, and refined by successive Fourier syntheses and least-squares procedures. The crystals are orthorhombic, space group Pbca, with lattice parameters $a=8.545$, $b=10.025$ and $c=24.252$ Å. All the positions of hydrogen atoms were found in the difference Fourier map and included in the refinement. The ethylamine side chain bound to the indole ring is in a folded configuration as found in the crystal structure of serotonin picrate monohydrate. A weakly basic nitrogen atom of the indole ring takes part in the hydrogen bonding with the adjacent ion. Every chloride ion behaves as an acceptor for four hydrogen bonds. This is in line with the absence of any marked cleavage where indole rings are packed together to form a pleated sheet and a three-dimensional network structure is essentially stabilized by the hydrogen bond formation.

Tryptamine, a tryptophan metabolite, was first isolated from shoots and flowers of *Acacia* species.[1] A significant biological implication of this compound lies in its role as starting material for the biosynthesis of alkaloids containing an indole ring. It has been also reported to have anti-radiation ability[2-4] as well as serotonin and 5-hydroxytryptophan. In order to study the correlation between the molecular structure and its pharmacodynamic action, it is necessary to elucidate the stereoconfiguration of the molecule. In the course of studies on tryptamine hydrochloride, we found that the aminoethyl side chain of this molecule is in folded configuration.[5] Extended conformation was reported in the case of a serotonin-creatinine sulphate complex.[6] The same folded configuration was found in the crystal structure of serotonin picrate monohydrate.[7] The present paper gives a more detailed account of the methods and the results of analysis. The structure is compared with that of other tryptophan metabolites, some structural features of radiation protective agents being described.

Experimental

Crystals were prepared by slow evaporation from an aqueous solution, and obtained as transparent yellow prismatic crystals. Preliminary rotation and Weissenberg photographs showed them to be orthorhombic, the space group being uniquely determined as Pbca from the absent spectra. The unit-cell dimensions were finally determined with a Rigaku Denki manual four-circle diffractometer at room temperature. Melting point of this crystal measured with a DSC (differential scanning calorimeter) is in agreement with the reference value.[8] The density was measured by the flotation method in a benzene-carbon tetrachloride mixture. It was confirmed that no solvent of crystallization is contained in the crystal, the result coinciding with DSC results. The physical and crystal data obtained are given in Table 1.

TABLE 1. CRYSTAL DATA OF TRYPTAMINE HYDROCHLORIDE

$C_{10}H_{12}N_2 \cdot HCl$, M.W. 196.68, mp 256—257°C	
Yellowish prism-shaped crystals. Orthorhombic	
$a=8.545(9)$, $b=10.025(8)$, $c=24.252(16)$ Å

	$(h0l)$: $l=2n+1$
	$(hk0)$: $h=2n+1$
Space group; Pbca	

Intensities of 875 independent non-zero reflections were measured visually on equi-inclination Weissenberg photographs of 0 to 7th layers around the b-axis, with the use of Ni-filtered Cu$K\alpha$ radiation. Corrections were made for the Lorentz-polarization factors and spot-shape. No absorption effect was taken into account, since the crystal used was sufficiently small. The data were then adjusted to the absolute scale by means of Wilson's method. The overall temperature factor obtained at this stage was 3.35 Å^2. The SIGMA program was utilized to list the E-values and $\sum_2$ relationships with their probabilities.

Determination and Refinement of Structure

The structure of tryptamine hydrochloride was successfully solved by using the direct method. Reflections with $|E|>1.3$ were selected, five of them being given a sign or a letter symbol as follows.

h	k	l	phase	$\|E\|$
2	2	3	+	3.11
5	4	16	+	2.77
2	5	14	+	2.69

Application of $\sum_1$ formula to reflection (446) indicated that it has a positive sign of 88% probability. It is also included in the initial starting set. The sign

relations between a number of reflections strongly suggested A=B=+. At the end of the process the phases of 157 independent reflections were determined, and a Fourier synthesis was calculated with normalized structure factors as the coefficients (*E*-map). The three dimensional *E*-map showed the sites of all 13 atoms of this molecule. Another 20 spurious peaks of the same height as that of light atoms appeared. The indole ring plane enables us to distinguish true peaks from false ones. The structure was refined by the block-diagonal-matrix least-squares method, first with isotropic thermal parameters and then with anisotropic temperature factors. The estimated parameters of hydrogen atoms were computed in such a way as to give bond angles as close to trigonal or tetrahedral as possible. The distances were assumed to be 1.08 Å for C–H, 1.01 Å for N–H, and 0.97 Å for O–H. The amino nitrogen atom had to be the protonated form, and three hydrogen atoms were placed on it. This nitrogen atom has three chloride neighbors at reasonable hydrogen-bonding distances and angles. Thus, three hydrogen atoms were placed at proper positions on the N···Cl⁻ line. In order to check the expected positions of hydrogen atoms, a difference Fourier synthesis was prepared and all the hydrogen peaks were obtained near the calculated positions as shown in Fig. 1. This may indicate the correctness of the assumed positions of hydrogen atoms and the assignment of hydrogen bonding system. More refinement cycles were performed, which included refinement of the positional and overall isotropic thermal parameters of the hydrogen atoms. Refinement was stopped when parameter shifts were less than one fourth of their standard deviations, giving an *R* value of 0.094. The N–H and C–H bond lengths are in the ranges 0.99—1.11 Å and 1.03—1.17 Å, respectively. The final electron density map is shown in Fig. 2. The final observed and calculated structure factor amplitudes are given in Table 2 and final atomic positional and thermal parameters in Table 3. The scattering factors used throughout the refinement were taken from *International Tables for X-ray Crystallography* (1962). All calculations were done on an NEAC 2200—500 of this University, using programs written by T. Ashida and the authors.

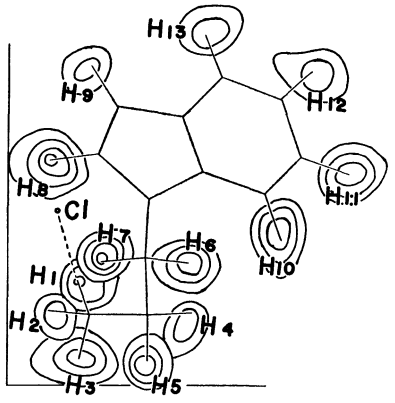

Fig. 1. The location of hydrogen atoms from a three-dimensional difference Fourier map. Contours from 0.2 e.Å^{-3} at intervals of 0.2 e.Å^{-3}.

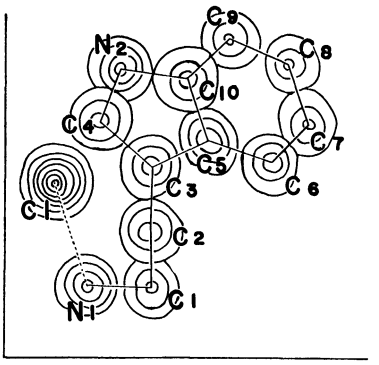

Fig. 2. A composite drawing of the final electron density map, viewed along a-axis. Contour intervals of 2.0 e.Å^{-3} for light atoms and 4.0 e.Å^{-3} for the chloride ion, the first contour begins at 2.0 e.Å^{-3}.

Description and Discussion of the Structure

Molecular Dimensions. The bond lengths and angles are shown in Fig. 3 and Table 4 together with those of the other tryptophan metabolites. The numbering of other metabolites corresponds to that of tryptamine in Fig. 3. We see some interesting structural features of radiation protective agents containing indole ring (indicated with asterisk in Table 4). The C(3)–C(4) bond, 1.342—1.387 Å, is apparently shorter than a normal aromatic C–C bond (1.395 Å). The corresponding bond of four radiation protectors is longer than that of other indole derivatives, and is compatible to 1.381 Å of yohimbane hydrobromide[9] and 1.395 Å of reserpine.[10] On the other hand, the C(2)–C(3) distance of the protector is slightly shorter than that of the other related compounds. The corresponding length of yohimbane and reserpine is 1.489 Å and 1.444 Å, respectively. It is of biological in-

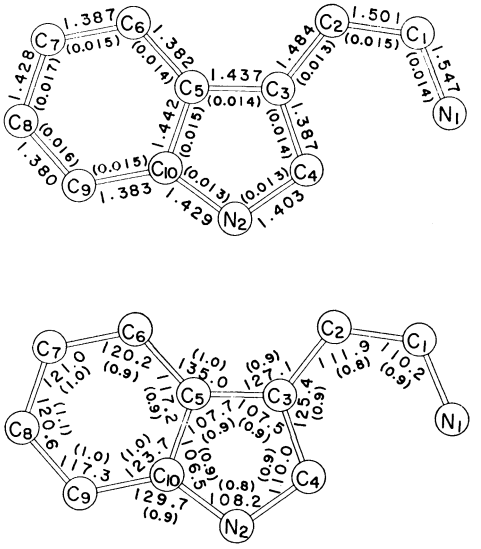

Fig. 3. Bond lengths (Å) and valency angles (°). The standard deviations are given in parentheses.

terest that N(1), C(1) and C(2) atoms of the side chain of tryptamine, and C(3)–C(4) bond of an indole ring take part in the formation of a nonplanar six-membered ring of the alkaloids, yohimbane and reserpine. In the comparison of C(3)–C(4) and C(2)–C(3) bond lengths, we included three more indole derivatives, skatole[11] (1.34 and 1.50 Å), glycyl-L-tryptophan[12] (1.338 and 1.534 Å) and 5-methoxy-dimethyltryptamine[13] (1.365 and 1.509 Å) which had been determined by X-ray analysis. The molecular mechanism of the radiation protective action of these compounds containing an indole ring is still obscure, but the facts mentioned above indicate that the mechanism may be to some

a) Tryptamine hydrochloride, this work, b) 5-Hydroxy-DL-trypophan[14], c) Serotonin picrate monohydrate[7], d) Serotonin-creatinine sulfate complex[6], e) L-Tryptophan hydrochloride[15], f) DL-Tryptophan formate[16], g) 3-Indolylacetic acid[17]. * Radiation protective agents.

extent due to the difference in the localization of electron density distribution or the difference in the resonance structure of a five-membered ring of radiation protective agents compared with other indole derivatives.[18–20] The mean C–C distance in the benzene ring of tryptamine hydrochloride is 1.400 Å, while that of a pyrrole ring 1.422 Å. In all indole compounds, the C(3)–C(5) bond is evidently longer than the standard aromatic C–C bond.

Configuration. Aminoethyl side chain is in a folded configuration. The orientation of the C(2)–C(3) bond is *gauche* with respect to C(1)–NH_3^+ bond, and the torsion angles as defined by Klyne and Prelog[21] are −60.6° (*syn-clinal*) and +110.9° (*anti-clinal*) for the atoms N(1)–C(1)–C(2)–C(3) and C(1)–C(2)–C(3)–C(4), respectively. From conformational studies on tryptamine derivatives applying normal stereochemical rules, Chothia and Pauling proposed two possible values, 180° (*anti-periplanar*) and ±60° (*syn-clinal*), for the former torsion angle, and 0° (*syn-periplanar*) and ±90° (center of *clinal* region) for the latter one.[22] The configurations of 5-hydroxytryptophan and serotonin picrate resemble that of tryptamine. On the other hand, *anti-periplanar* conformation about C(1)–C(2) bond was observed in a serotonin-creatinine sulfate complex (+172.5°) and 5-methoxy-*N*,*N*-dimethyltryptamine hydrochloride (+179.2°). The best plane was computed for the atoms in the indole

a) Excluded from calculation of the plane.

ring and expressed by the equation, $0.8146X-0.4580Y+0.3559Z=2.2578$ in rectangular coordinates in Ångstrom. The indole part of tryptamine molecule is planar, the mean deviation of the atoms from this plane being 0.008 Å and the maximum deviations are +0.0125 and −0.0217 Å for the atoms C(4) and C(5), respectively. The individual deviations of the atoms from this least-squares plane are given in Table 5. The plane formed by N(1), C(1) and C(2) atoms makes a dihedral angle of 83.9° with that of the indole plane. The corresponding angle in serotonin-creatinine sulfate is 12.6°.

The Molecular Environment. The crystal structure viewed along a-axis is given in Fig. 4 and intermolecular distances less than 3.75 Å including hydrogen bonds in Table 6. The side chains of tryptamine are in a folded configuration, and the packing is dominated by a three-dimensional network of hydrogen bonds. The three hydrogen atoms attached to an amino nitrogen atom form three hydrogen bondings with adjacent chloride ions. These three chloride atoms are approximately at three vertices of a regular tetrahedron centered at the N(1) atom, with the C(1) atom directed toward the fourth vertex, the average N–H···Cl

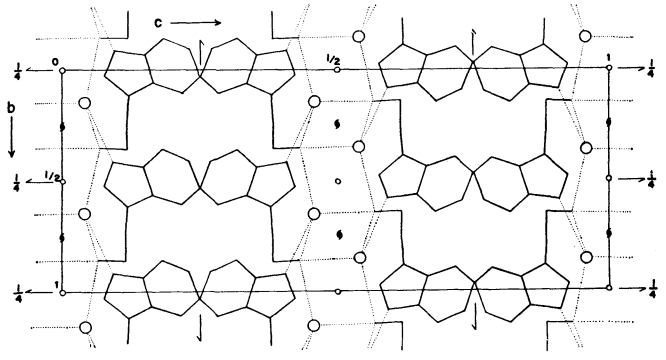

Fig. 4. The crystal structure of tryptamine hydrochloride projected along a-axis.

Table 6. Intermolecular short contacts less than 3.75 Å

C(9)	C(1) (B)	3.722
C(9)	C(6) (B)	3.659
C(8)	C(6) (B)	3.742
C(6)	C(7) (D)	3.671
C(7)	C(1) (E)	3.748
N(2)	C(2) (F)	3.459
C(4)	C(2) (F)	3.688
C(4)	C(1) (F)	3.668

distance being 3.179 Å. Another hydrogen bond is found between the N(2) atom of indole ring and chloride ion, whose distance is 3.235 Å. As a whole, each chloride atom links with the four neighboring tryptamine cations. N(1)–H···Cl hydrogen bonds form infinite columns around the center of symmetry or along the screw axes, and molecules are arranged in a double layered system parallel to *ab*-plane. In the polar part of the molecules, the hydrogen bond formation is substantial to stabilize the molecular packing. The indole rings are packed by van der Waals forces into the non-polar layer. Unusual short contacts are not observed (Table 6).

The authors wish to thank Drs S. Kobayashi and W. Nakamura, National Institute of Radiological Sciences, Chiba, for discussions and interest throughout the course of this investigation. The work was partly supported by a research grant from the Ministry of Education

Photochemical Reaction of Diaryl Thioketones in Ethereal Solutions. A Stable Transient Free-Radical

Noboru KITO and Atsuyoshi OHNO

Sagami Chemical Research Center, Nishiohnuma, Sagamihara-shi, Kanagawa 229

(Received February 1, 1973)

Photochemical reactions of thiobenzophenone and its 4,4′-dimethoxy derivative in ethereal solutions such as tetrahydrofuran and diethyl ether have been studied by means of product analyses and ESR spectroscopy. It was found that the reaction involves quite stable transient free-radicals of the type $Ar_2\dot{C}SR$. The efficiency of free-radical trapping by diaryl thioketones and the reaction mechanism are discussed.

Photo-excited thiobenzophenone abstracts the hydrogen atom from an appropriate solvent through its n,π* triplet state, giving diphenylsulfhydrylmethyl radical.[1,2] The primary process of the reaction is similar to that of benzophenone[3] but products differ to a great extent. In order to obtain further insight into the photo-reaction of thiobenzophenone, we have studied ESR spectroscopy of the transient free-radicals in ethereal solutions. The results are given in this paper. Several studies have been made on detection and positive indication by ESR spectroscopy of transient free-radical species produced by continuous photo-irradiation.[4]

Thiobenzophenone is a good scavenger for free carbon-radicals.[5] The results of the present study also give a direct evidence for the mechanism of scavenging reactions and suggest the availability of thiobenzophenone as a spin-trapping agent.

Results and Discussion

Products. Irradiation with light (>300 nm) on thiobenzophenone in tetrahydrofuran (THF) afforded **1**, **2**, and **3** in 3.1, 35.2, and 54.5% yields, respectively. A similar reaction in diethyl ether gave **1**, **4**, and **5** in 3.6, 37.4, and 52.0% yields, respectively. Their structures were confirmed by spectral and elemental analyses. It was confirmed that no rearrangement from **3** to **2** and from **5** to **4** or *vice versa* took place under the reaction conditions. Compounds **2** and **4** were apparently resulted in by the (in-cage) combination of diphenylsulfhydrylmethyl, **6a**, and the solvent-derived free-radicals, **8**,[1] while **3** and **5** were formed by the reaction of solvent-derived free-radicals with thiobenzophenone, a potential molecular-type scavenger toward carbon-radicals.[5,6] Thus, the analyses of products suggest that the reaction involves three transient free-radicals, **6a**, **7a**, and **8**.

Table 1. Hyperfine splitting constants and g-values for photo-paramagnetic diaryl thioketones-THF system

Starting Thioketone	A_o	A_m	A_p	A_{OCH_3}	$A_{\alpha H}$	g-Value
$(C_6H_5)_2C{=}S$	2.71	0.77	3.10	—	1.16	2.0051
$(4\text{-}CH_3OC_6H_4)_2C{=}S$	2.45	0.70	—	0.35	1.05	2.0053

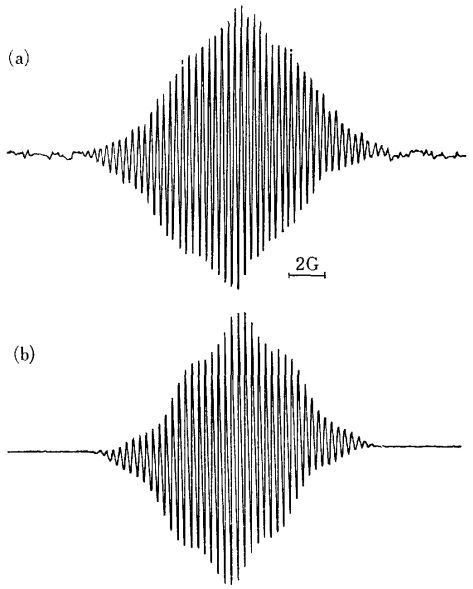

Fig. 2. (a) Observed and (b) calculated ESR spectra of **7b** in THF.

The observed spectra accord well with their computer-simulated ones[7] using the splitting constants, listed in Table 1, with a line width of 192 mG (Fig. 2). They are spectra of neither **8a**[8] nor thioketyls,[9,10] and must be those of **6** or **7**.

When the photo-reaction was carried out in 2-methyltetrahydrofuran (MTHF), the recorded spectrum distinctly showed the absence of double-splittings (Fig. 1b). Figure 3 shows the ESR spectrum of photo-irradiated thiobenzophenone in diethyl ether. The doublet-splittings of 1.12 gauss observed here are again absent when the reaction is carried out in di-

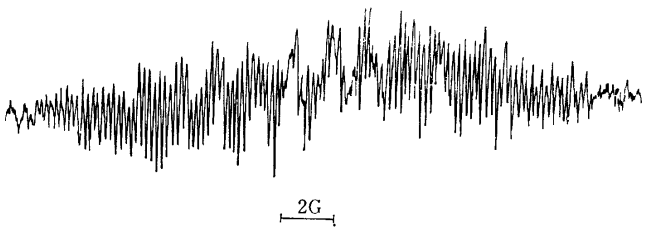

Fig. 3. Observed ESR spectrum of **7a** in diethyl ether.

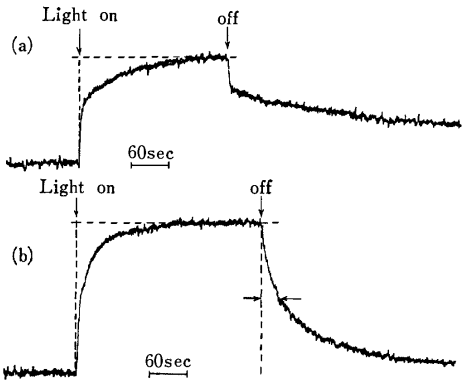

Fig. 4. The change of the intensities of ESR spectra due to the transient free-radicals during the photolyses of (a) thiobenzophenone (10.833 mM) and (b) 4,4'-dimethoxythiobenzophenone (10.173 mM) in THF at 25°C. The spectra were recorded with modulation width of 20 gauss and with response time of 0.1 sec.

isopropyl ether. These results indicate unequivocally that the free-radicals detected on the spectrometer are not **6** but **7**.

It is noteworthy that **7** is a quite stable free-radical. From the decay-curves (Fig. 4), half-lives of **7a** and **7b** (RH=THF) in THF at 25 °C are calculated to be 90 and 29 sec, respectively. Since these values are independent of initial concentrations of diaryl thioketones and irradiation time, the kinetics of the decay is of first-order in **7**. Formation of such a long-lived composite free-radical may make thiobenzophenone a useful reagent for spin-trapping.

Another paramagnetic species is detected from the reaction of thiobenzophenone (Fig. 4a). This accumulates rapidly when the light is turned on and decays instantaneously when it is shut off. We believe that this short-lived species is **6a**. If this were due to **8a**, the absence of such a phenomenon in Fig. 4b cannot be rationalized: since **7b** is less stable than **7a** under experimental conditions, the trapping of **8a** by 4,4'-dimethoxythiobenzophenone should be less effective than that by thiobenzophenone.[11] Thus, both **6a** and **7a** are more stable (or less reactive) than **6b** and **7b**, respectively. The substituent effect observed here is a general trend for the stability of benzyl-type free-radicals.[12]

Thus the mechanism of the photochemical reaction of diaryl thioketones in ethereal solutions is as follows:

$$Ar_2C{=}S \xrightarrow{h\nu} \longrightarrow {}^3(Ar_2C{=}S)_{n,\pi^*}$$

$${}^3(Ar_2C{=}S)_{n,\pi^*} + RH \longrightarrow Ar_2\dot{C}\text{-}SH + R\cdot$$

$$Ar_2\dot{C}\text{-}SH + R\cdot \longrightarrow Ar_2C\begin{matrix}R\\SH\end{matrix}$$

$$Ar_2\dot{C}\text{-}SH + RH \longrightarrow Ar_2CHSH + R\cdot$$

7) The computer program for the simulation of spectra was supplied by The Shionogi Research Laboratory. We wish to express our cordial thanks to Dr. K. Nishikida. The program was run by IBM 360 System.

$$Ar_2C{=}S + R\cdot \longrightarrow Ar_2\dot{C}{-}SR$$

$$Ar_2\dot{C}{-}SR + RH \longrightarrow Ar_2CHSR + R\cdot$$

Since the last two processes constitute a chain reaction, they suggest the possibility that the half-lives of the free-radicals do not necessarily mean the *true* values. However, we believe they are almost true, if not completely so. The concentration of **8a** is too low to be detected, indicating immediate trapping of **8a** by thiobenzophenone. Therefore, if the hydrogen-abstraction by **7** is a fast process, its steady-state concentration may also be too low to be detected after the light is shut off.

Experimental

Materials. Thiobenzophenone was prepared as reported previously.[1] 4,4'-Dimethoxythiobenzophenone was similarly prepared from the corresponding ketone in 88% yield. The thioketone was recrystallized twice from ethanol-chloroform mixture: mp 117—118 °C (lit,[13] mp 116—118 °C).

Solvents were refluxed over calcium hydride under a 50 cm column packed with helics for several days and fractionally distilled. The second distillation was performed just before use over sodium wire after being refluxed for a few hours.

Spectrometry. A 0.25—0.50 M solution of a thioketone placed in a 10 mm o.d. glass tube connected with 1.5—2.0 mm o.d. quartz tube was thoroughly degassed by the usual thawing and freezing method and sealed in a high vacuum (10^{-6} torr). The light from a 100W high-pressure mercury lamp was focused on the sample in the microwave cavity of the ESR spectrometer. The spectra of photochemically generated transient free-radicals were recorded at 25±0.3 °C (room temperature) with a X-band JES-ME-IX type spectrometer (Japan Electron Optics Laboratory Co. Ltd.) with 100 KHz field modulation. In order to obtain well resolved spectra, it was necessary to adjust concentrations of the solution and find the right moment of irradiation with respect to life-time of free-radicals.

Photochemical Reaction of Thiobenzophenone in THF. Prior to the reaction, slow stream of argon gas was passed for 30 min through the THF (60 m*l*) solution of thiobenzophenone (613 mg, 2.59 mmol) in a Pyrex vessel. Irradiation with light from a 400W high-pressure mercury lamp (principal wavelength: 315 and 366 nm) was continued until complete decolorization of the thioketone (19 hr) took place at the temperature of running water. After excess solvent was removed, the residue was chromatographed on a column of silica-gel with elution by a mixture of *n*-hexane and benzene. The following compounds were isolated (mg, % yield, *n*-hexane : benzene ratio): diphenylmethanethiol (**1**) (16, 3.1, 2 : 8), diphenyltetrahydro-2-furylmethanethiol (**2**) (246, 35.2, 3:7), and benzhydryl tetrahydro-2-furyl sulfide (**3**) (381, 54.5, 4 : 6).

2: NMR(δ from TMS, CCl_4) 1.48—2.01 (m, 4H), 2.28 (s, 1H), 3.63—3.97 (m, 2H), 4.65—4.93 (m, 1H), and 7.02—7.55 (m, 10H); mass spectrum (*m/e*) 270 (M^+), 236, 200, 199, 198 (Ph_2CS^+, base), 165, 121, and 71; Found: C, 75.48; H, 6.60; S, 11.80%. Palladium-Catalyzed Coupling Reaction of Aromatic Compounds

Hataaki YOSHIMOTO and Hiroshi ITATANI

Ube Industries, Ltd., Polymer Research Laboratory, Goi, Ichihara-shi, Chiba 290

(Received February 19, 1973)

The oxidative coupling reaction of aromatic compounds proceeds catalytically with palladium salt under oxygen pressure. Yields and isomer distributions are attributed to the reaction variables such as temperature, additives, and the nature of the substituent on a benzene ring. Naphthalene was converted mainly into 1-substituted products and *o*-xylene into 4-substituted products. The coupling of diphenyl ether afforded diphenylene oxide with coupling dimers. An intramolecular two stage dehydrogenation process is proposed.

Palladium compounds have recently attracted much attention from the viewpoint of synthetic organic chemistry and theoretical interest.[1] Van Helden and Verberg[2] reported on the oxidative coupling of benzene derivatives by palladium chloride and sodium acetate in acetic acid solution. Subsequent studies by Davidson and Triggs[3] showed no precipitation of metallic palladium under oxygen pressure. No coupling proceed catalytically since excess acetic acid existed in the reaction system. We have reported[4] on the palladium-catalyzed coupling reaction of styrene with benzene under oxygen pressure in the absence of acetic acid. This paper gives a detailed description of the palladium-catalyzed coupling of aromatic compounds.[5]

Results

Coupling of Alkylbenzenes. Coupling of toluene gave six isomers, 2,2'-, 2,3'-, 2,4'-, 3,3'-, 3,4'-, and 4,4'-dimethylbiphenyls. Yields and isomer distributions of bitolyls at several temperatures are given in Table 1. *Meta*-substituted bitolyls were major products and the yield of *ortho*-substituted bitolyls increased with increasing temperature. However, the system of palladium chloride and sodium acetate[6] accelerated the formation of *ortho*-substituted bitolyls with decreasing temperature. The difference may be due to the reaction process. The former is a catalytic reaction whereas the latter is stoichiometric, precipitating palladium black during the course of reaction. Methyl group shows a high degree of steric effect on the coupling. Namely, yields of biaryls at 150 °C were 7500, 5700, 4100, 400, and zero percent from toluene, *o*-xylene, *m*-xylene, *p*-xylene, and mesitylene as starting material, respectively. The coupling product of *o*-xylene consisted of 1% of 2,3,2',3'-, 24% of 2,3,3',4'-, and 75% of 3,4,3',4'-tetramethylbiphenyls, whereas that of naphthalene contained 43% of 1,1'-, 50% of 1,2'-, and 7% of 2,2'-binaphthyls. The former is contributed by steric requirement and the latter by electronic factor.

Table 1. Yield and isomer distribution of dimethylbiphenyl[a]

Reation		Compositions (%)						
Temp. °C	Press. kg/cm²	2,2'	2,3'	2,4'	3,3'	3,4'	4,4'	yield[c] (%)
120	50	2	12	8	31	36	11	1840

Effect of Palladium Compounds. Various palladium compounds can be used as catalyst (Table 2). Palladium acetylacetonate as well as palladium acetate are effective catalysts. Tetrakis(triphenylphosphine)palladium shows lower activity, precipitating palladium metal during the course of reaction.

Effect of Additives. Addition of an equimolar amount of acetylacetone to palladium acetate increased the yield of the coupling products (Tables 1 and 2). The influence of several β-diketones on the yield of bitolyl is shown in Table 3. Acetylacetone highly activated palladium acetate for the coupling.

Effect of Reaction Variables. Increase in oxygen pressures increases the yields of coupling products but not pressure above 25 kg/cm^2. Under 50 kg/cm^2 of the mixture of nitrogen and oxygen (1 : 1), use of less than 10 mmol/l of palladium acetate is recommended since the overall yield of biaryls does not increase in the presence of excess palladium acetate. Addition of solvent to this system remarkably decreased the yield of coupling products. However, mesitylene or butyl acetate can be applied in as little an amount as possible for the coupling of high melting compounds such as anthracene, phenanthrene, and acenaphthene.

Coupling of Diphenyl Ether. Diphenyl ether was considerably converted into diphenylene oxide, an intramolecular coupling product, with dimerized products. However, the reaction of diphenylmethane involved a small amount of fluorene, an intramolecular coupling product, with dibenzylbiphenyl, benzophenone, and fluorenone. The coupling of anisole gave dimethoxybiphenyl containing only 2% of *ortho*-disubstituted isomer (Table 4).

Table 4. Coupling of diphenyl ether and the related derivatives[a]

Aromatic compound	Products	Yield %[b]
Diphenyl ether	Diphenylene oxide	3080
	Dimers of diphenyl ether	4610
Diphenylmethane	Fluorene	340
	Dimers of diphenylmethane	5010
	Benzophenone	4120
	Fluorenone	230
Anisole[c]	Dimethoxybiphenyl[d]	740

a) Carried out with $Pd(OAc)_2$ (0.15 mmol), acetylacetone (0.15 mmol), aromatic compound (15 ml).
b) Based on $Pd(OAc)_2$ used.
c) Reaction temperature, 120°C.
d) The compositions are 2,2'- 2%, 2,3'- 10%, 2,4'- 21%, 3,3'- 17%, 3,4'- 29%, 4,4'- 21%.

Discussion

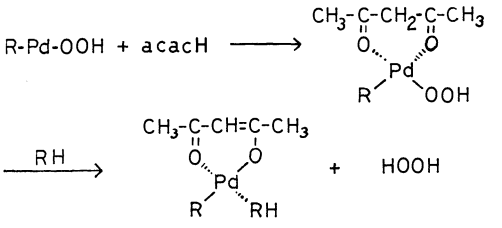
Davidson and Triggs[3] proposed an intermolecular coupling process of σ-phenylpalladium(II) complex on the basis of isolation of palladium(I) complex and measurement of kinetic isotope effect. Unger and Fouty[6] suggested the intramolecular reaction through a diarylpalladium(II) complex for explaining the isomer distribution of bitolyls.

Under oxygen pressure in the absence of acetic acid the coupling reaction is catalytic and thus the yield of biaryl was greatly enhanced. In this system, palladium remaining in the solution can be reoxidized to its active oxidation state by the action of molecular oxygen.

Oxygen adduct complex $Pd(PPh_3)_2O_2$[7,8] takes part in the oxidation of the coordinating triphenylphosphine to triphenylphosphine oxide. Stern[9] explained the mechanism by assuming that the oxygen adduct palladium(0) complex serves to abstract hydrogen from aromatic nucleus and concurrently changes to a σ-arylpalladium(II) complex. By applying this mechanism, the overall process for the palladium-catalyzed coupling can be represented as follows.

$$PdX_2 + 2RH \longrightarrow R\text{-}Pd\text{-}R + 2HX$$
$$R\text{-}Pd\text{-}R \longrightarrow R\text{-}R + Pd$$
$$Pd + O_2 + RH \longrightarrow R\text{-}Pd\text{-}OOH$$
$$R\text{-}Pd\text{-}OOH + acacH \longrightarrow R\text{-}Pd\text{-}acac + HOOH$$
$$R\text{-}Pd\text{-}acac + RH \longrightarrow R\text{-}Pd\text{-}R + acacH$$

where RH denotes an aromatic compound, and acacH acetylacetone. The key step of the mechanism is a reoxidation of palladium(0) with molecular oxygen. The effect of addition of acetylacetone to this system may be explained by assuming the formation of a stable *cis*-diaryl palladium complex which is active on subsequent coupling in analogy with *cis*-hydroxo-olefin complex[1b] known in the Wacker process.



The two stage coupling mechanism was proposed based on the primary isotope effects[10] in the competitive coupling between benzene and benzene-d_6 and also the characteristic isomer distributions of biaryls.

Isomer distribution of the coupling products changes remarkably with the substituent. The coupling of *o*-xylene is attributed to steric effect of methyl group while naphthalene is influenced by polar effect. The

reaction of diphenyl ether affords an intramolecular ring closure which is facilitated *via* a stable transition state of a six π electron system, whereas the reaction of diphenylmethane does not favor a ring formation.

The possibility exists that biphenyl formation may involve homolytic substitution of phenyl radical.[11] However, it is well-known that a radical can not exist in the presence of oxygen. The presence of excess 2,6-di-*tert*-butyl-*p*-cresol does not influence the coupling at all. Thus the reaction mechanism involving free radicals is unlikely.

In contrast to the Wacker process and acetoxylation of olefins, the palladium-catalyzed oxidative coupling is markedly inhibited in the presence of mineral acid, polar solvent, sodium acetate, lithium chloride, and some metal ions. The coupling process favors the simple system consisting of palladium acetate and aromatic compounds under oxygen pressure. For prevention of explosion, oxygen should be diluted with an inert gas.

Experimental

Palladium acetate,[12] palladium acetylacetonate[13] and tetrakis(triphenylphosphine)palladium[8] were prepared according to literatures. Palladium chloride (Nippon Engelhald Co.) and a gaseous mixture of oxygen and nitrogen (1 : 1) (Nippon Sanso Co.) were used. Benzene, toluene, and *o*-xylene were distilled before use. Other chemicals were reagent grade and were used without further purification.

Bis(triphenylphosphine)palladium Acetate. To a stirred solution of palladium acetate (0.224 g) in ether (25 ml) was added a solution of triphenylphosphine (0.786 g) in ether (25 ml). After stirring at room temperature for 1 hr, yellow precipitates formed were collected, washed with ether and dried, mp 118—120 °C. Found: C, 64.77; H, 4.99%. Calcd for $C_{40}H_{36}O_4P_2Pd$: C, 64.14; H, 4.84%.

General Procedure. In a glass vessel (250 ml) were placed palladium acetate, acetylacetone, aromatic compound and some additives when necessary. The glass vessel was inserted into a stainless steel autoclave (300 ml) and subjected to a pressure of 50 kg/cm^2 with a gaseous mixture of oxygen and nitrogen (1 : 1) at room temperature. The autoclave was heated at 150 °C for 4 hr with shaking 35 times per minute. After cooling, the filtrate was analyzed with a Shimadzu GC 4APT gas chromatograph on silicone SE 30 (20% on Diasolid, 1 m long) and Apiezon L (5% on Diasolid, 2 m long) columns using helium as a carrier gas. Products were identified with authentic samples by glc and also by comparison of their melting points (if isolated), IR and mass spectra.[14]

Coupling Reaction of Diphenyl Ether. The reaction was carried out in an autoclave (100 ml). The resulting products were analyzed by glc (SE 30 column). Stilbene was used as an internal standard for diphenylene oxide, and pyrene was used for the coupling dimers. The fraction boiling at 200—240 °C/1 mmHg was collected from the reaction mixture. The mass spectrum shows the molecular ion at *m/e* 338 which is consistent with the dimer of diphenyl ether.

Coupling of Naphthalene. A mixture of naphthalene (50 g), palladium acetate (0.112 g), and acetylacetone (0.050 g) was shaken at 150 °C for 4 hr. The resulting solution was analyzed by glc (SE 30 column) at 240 °C. Triphenylethylene was used as an internal standard. Binaphthyl was obtained in 4500% yield based on palladium acetate used. The composition was shown to be 43% of 1,1′-, 50% of 1,2′-, and 7% of 2,2′-binaphthyls. After removal of naphthalene by distillation, the residue was chromatographed over alumina using benzene as a solvent. Evaporation of benzene gave 6.9 g of crude binaphthyls which was extracted with hot methanol (110 ml) to afford 1,1′-binaphthyl (1.4 g) having mp 157—158 °C. After recrystallization from ethanol, mass spectroscopy showed the molecular ion 254 identical with 1,1′-binaphthyl. The residue was again treated with a mixture of benzene (25 ml) and ethanol (75 ml). The undissolved material (0.3 g) was collected by filtration. Recrystallization from benzene gave 2,2′-binaphthyl mp 182—183 °C. Mass spectroscopy showed the molecular ion to be identical with 2,2′-binaphthyl. 1,2′-Binaphthyl was identified by comparison of glc retention time with that of an authentic specimen prepared from 2-tetralone and 1-bromonaphthalene according to the modified procedure by M. Orchin[15] for the synthesis of 2-ethylbiphenyl.

Studies on Carbamoylation Reactions of Polyethylenimine and Its Low Molecular Weight Analogues with Cyanate Ions

Tsuneo Okubo and Norio Ise

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 22, 1973)

Carbamoylation reaction of ions of polyethylenimine and its low molecular weight analogues, *i.e.*, ethylenediamine, triethylenetetramine, and tetraethylenepentamine, with cyanate ions are investigated in the presence of simple-, micelle-, and poly-electrolytes and in their absence. The rate constants are practically independent of the valency of the cations and are much larger than that previously found for the ammonium cyanate reaction. Both of the activation enthalpy and entropy decrease with increasing valency of the cations. Added electrolytes are found to decelerate the reactions. The reactions of polycations are retarded more strongly by simple cations than by catalyst polycations, whereas those of simple cations are decelerated more effectively by polycations than by simple cations. The kinetic data are discussed thermodynamically in terms of the Brönsted theory and the activity coefficients of the reactant ions. The interaction parameters between reactant electrolyte and added electrolyte are also derived thermodynamically and discussed.

Interionic reactions in the presence of various electrolytes are interesting from the biological point of view and have been studied by many researchers (For a convenient review, see Ref. 1). In a previous paper,[2] we studied quantitatively the catalytic influence of polyelectrolytes for the ionic reaction between oppositely charged ionic species shown in Eq. 1, and also the electrostatic interactions between ions of polyelectrolytes and those of simple electrolytes.

$$NH_4^+ + OCN^- = (NH_2)_2CO \qquad (1)$$

In this paper we obtain quantitative information on ionic reactions between ionic species of various charge types. For this purpose, the carbamoylation reactions of ethylenediamine, triethylenetetramine, tetraethylenepentamine and polyethylenimine with cyanate ions shown in Eqs. (2), (3), (4) and (5) are studied.

$$\overset{+}{N}H_3\text{–}CH_2\text{–}CH_2\text{–}\overset{+}{N}H_3 + 2OCN^- = \underset{\displaystyle CONH_2}{\overset{\displaystyle |}{NH}}\text{–}CH_2\text{–}CH_2\text{–}\underset{\displaystyle CONH_2}{\overset{\displaystyle |}{NH}} \qquad (2)$$

$$\overset{+}{N}H_3\text{–}(\text{–}CH_2\text{–}CH_2\text{–}\overset{+}{N}H_2\text{–})\text{–}H + 4OCN^- = \underset{\displaystyle CONH_2}{\overset{\displaystyle |}{NH}}\text{–}(\text{–}CH_2\text{–}CH_2\text{–}\underset{\displaystyle CONH_2}{\overset{\displaystyle |}{N}}\text{–})_3\text{–}H \qquad (3)$$

$$\overset{+}{N}H_3\text{–}(\text{–}CH_2\text{–}CH_2\text{–}\overset{+}{N}H_2\text{–})_4\text{–}H + 5OCN^- = \underset{\displaystyle CONH_2}{\overset{\displaystyle |}{NH}}\text{–}(\text{–}CH_2\text{–}CH_2\text{–}\underset{\displaystyle CONH_2}{\overset{\displaystyle |}{N}}\text{–})_4\text{–}H \qquad (4)$$

$$\text{–}(\text{–}CH_2\text{–}CH_2\text{–}\overset{+}{N}H_2\text{–})_n\text{–} + nOCN^- = \text{–}(\text{–}CH_2\text{–}CH_2\text{–}\underset{\displaystyle CONH_2}{\overset{\displaystyle |}{N}}\text{–})_n\text{–} \qquad (5)$$

The reactions (2) through (5) are simple reactions like reaction (1). After mixing silver cyanate with aqueous solutions of hydrochlorides of polyethylenimine and its low molecular weight analogues, the precipitate of silver chloride can be isolated from the reaction system. We obtain solutions containing reactant ions only, which is convenient for quantitative investigations. Since all the reactions (2) through (5) proceed between ionic species of unlike charges, the measurement of the electrical resistance of the reaction system offers a convenient and accurate technique for monitoring the reaction.

Experimental

Materials. The details of the preparation of silver cyanate were described earlier.[2] Polyethylenimine (PEI) was furnished by the Dow Chemicals Co., Michigan (Montrek 12). A molecular weight of 4500 was obtained from viscosity determination using an equation proposed by Jones, Langsjoen, Neumann and Zomlefer.[3] Dilute aqueous solutions of PEI were purified by passing them through columns of cation and anion exchange resins. The concentration of PEI was determined by a conductometric method. The fraction of tertiary amino groups was measured by acetylation to be 0.25.

The tertiary amino groups of PEI do not react with cyanate ions. The reaction velocity was determined from the conductance at very low conversions of the reaction in our experiments. The tertiary amines, which are partly responsible for the conductance, were therefore dealt with as reactant ions, in addition to the primary and secondary amino groups. The hydrochloride of PEI (PEI·HCl) was prepared by partial neutralization of PEI solution with HCl (degree of neutralization = 0.92) to prevent the hydrolysis of the PEI salt. Ethylenediamine (ED), triethylenetetramine (TT), and tetraethylenepentamine (TP) were purified by distillation or recrystallization.[4] These bases were partially neutralized with HCl; the degrees of neutralization of ED, TT and TP were 0.77, 0.72, and 0.70, respectively. Sodium polyacrylate (NaPAA) was a product of the Toa Gosei Chemicals Co., Nagoya, Japan. The weight average degree of polymerization was 640. Dilute solutions of NaPAA were converted to the acid form by passing them through ion-exchange resin columns. Completeness of the conversion was assured by checking the atomic absorption spectrum of the solution for sodium ions. A copolymer of diethyldiallylammonium chloride and sulfur dioxide (DECS) was kindly

donated by the Nitto Spinning Co., Koriyama, Japan.[5] Sodium chloride, calcium chloride, and cetyltrimethylammonium bromide (CTABr) were guaranteed reagents.

Kinetic Measurements. A conductometric method was applied to the determination of the reaction rate.[6] The details of the experiments were described earlier.[2] The reactant solutions of ED·OCN, TT·OCN, TP·OCN and PEI·OCN were prepared by mixing hydrochloride solutions of the bases with silver cyanate. In all reaction mixtures, silver chloride, a by-product, was completely removed by filtration. Removal was checked by measuring the concentration of remaining silver chloride using an atomic absorption spectrophotometer. Thus, the filtrate is believed to contain reactant ions only. A cell of the Jones and Ballinger type (cell constant=7.64 cm^{-1}) was used together with a Wheatstone bridge.[8] The maximum experimental error of the resistance was $\pm 0.1\%$. Kinetic measurements were carried out at 30, 40, and 50 °C and within 1% conversion. The error of our measurements was at the highest 3% of the reaction rate. The pH values of the reaction solution were between 5.5 and 7.5 during the reaction.

Results and Discussion

The second-order rate constants k_2 of the carbamoylation reactions are compiled in Table 1. The magnitude of k_2 was about the same for the four reactants studied, whereas it was 20 to 100 fold larger than that for the ammonium cyanate–urea conversion.[9] As is seen from the Table, the k_2 value decreases with increasing concentration and this tendency becomes more distinct with increasing valency of the reactant cations.

PEI·OCN	20.6	8.0	−40.2

a) Concentrations of the reactants are 0.00957, 0.00890, 0.00872 and 0.00957 $mol \cdot l^{-1}$ for ED·OCN, TT·OCN TP·OCN and PEI·OCN, respectively.
b) Okubo and Ise, Ref. 2.

5) S. Harada and K. Arai, *Makromolek. Chem.*, **107**, 78 (1967).

6) It is clearly shown that the conductance method can give the "correct" rate constant of the carbamoylation reaction, even when the side reaction, especially carbonate formation (Eq. (A)) proposed by Wyatt and Kornberg exists.[7] If the carbonate really formed, the rate constant, k, from the conductance method is given by Eq. (B).

$$OCN^- + 2H_2O = HCO_3^- + NH_3 \quad (A)$$

$$\frac{-d\{[NH_4^+]+[OCN^-]+[HCO_3^-]\}}{2dt} = k\left\{\frac{[NH_4^+]+[OCN^-]+[HCO_3^-]}{2}\right\} \quad (B)$$

when the equivalent conductances of NH_4^+, OCN^- and HCO_3^- are approximately equal to each other and when the $[H^+]$ and $[OH^-]$ are negligible, *i.e.*, $[NH_4^+]=a-x$, $[OCN^-]=a-x-y$ and $[HCO_3^-]=[NH_3]=y$, where the notations a, x, and y are the same as those given in Ref. 7, Eq. (B) becomes

$$-\frac{d[NH_4^+]}{dt} = k[NH_4^+]^2 \quad (C)$$

Eq. (C) clearly shows that k obtained from the conductance is apparently "correct". Furthermore, it can be easily shown that the k from the conductance correlates with the rate constant of carbamoylation at infinite dilute, k_{u_0} by Eq. (D).

$$k = k_{u_0} f_1^2 \left(\frac{a-x-y}{a-x}\right) \approx k_{u_0} f_1^2 \quad \text{at} \quad t \approx 0 \quad (D)$$

where f_1 is the activity coefficient of 1-valent ions. For the details of the derivation of Eqs. (C) and (D), the readers should consult the work of Wyatt and Kornberg. Thus, the conductance method is conveninent for the rate determination of the carbamoylation reaction.

8) J. Jones and M. Ballinger, *J. Amer. Chem. Soc.*, **53**, 411 (1931).

9) J. C. Warner and E. L. Warrick, *ibid.*, **57**, 1491 (1935).

For example, the k_2 value of ED·OCN decreases by 40 percent with a ten-fold increase in the reactant concentration, whereas that of PEI decreases more than 80 percent. A quantitative explanation for the decreasing tendency will be described later.

The free energy ($\Delta G^{\ddagger}$), enthalpy ($\Delta H^{\ddagger}$), and entropy ($\Delta S^{\ddagger}$) of activation of the carbamoylation reactions are listed in Table 2. These parameters for the ammonium cyanate–urea conversion are also given in the Table from the previous publication.[2] The $\Delta G^{\ddagger}$ values of the carbamoylation reactions studied in the present work are constant within experimental error, being smaller than that for the NH_4OCN reaction. The $\Delta H^{\ddagger}$ values decrease sharply with increasing valency of the reactant cations. The electrostatic attractive forces between cations and anions become stronger with increasing valency and may decrease the activation energy. As is clearly shown in Table 2, $\Delta S^{\ddagger}$ decreases with increasing valency of the cations. The $\Delta S^{\ddagger}$ value is much smaller than that for the NH_4^+—OCN^- reaction. According to our previous study on the partial molal volume,[10,11] the PEI cation is hydrated electrostrictionally by two water molecules per repeating unit at the full degree of neutralization. On the other hand the ammonium ion is reported to be hydrated by three water molecules from compressibility measurement.[12] If these values are correct, the NH_4^+—OCN^- reaction should have larger $\Delta S^{\ddagger}$ than the polycation reaction. In addition to the dehydration factor, the local accumulation of OCN^- in the vicinity of the polycation by strong electrostatic attractive forces would result in small $\Delta S^{\ddagger}$ values for the PEI^+—OCN^- reaction.

The second-order rate constant for a reaction between ions can be represented as follows by Brönsted,[13,14]

$$k_2 = k_{2o}\gamma_+\gamma_-/\gamma_X \tag{6}$$

where γ_+ denotes the single-ion activity coefficient of the amino groups of the macroion, and γ_- the single-ion activity coefficient of the cyanate anions. X indicates the activated complex. The reference value, k_{2o}, is a limiting velocity constant at zero concentration of the reactant ions. For convenience, we discuss the rate constant by using a reference constant k_2^* which is the rate constant at 0.01 equiv. l^{-1} without foreign salt. The constant k_2^* is correlated with k_{2o} by the equation

$$k_2^* = k_{2o}\gamma_+^*\gamma_-^*/\gamma_X^* \tag{7}$$

where γ_+^*, γ_-^* and γ_X^* are the single-ion activity coefficients of the species indicated by the suffix at the reference concentration. From Eqs. (6) and (7) the following equation is derivable.

$$\log(k_2/k_2^*) = 2\log(\gamma_\pm/\gamma_\pm^*) - \log(\gamma_X/\gamma_X^*) \tag{8}$$

where $\gamma_\pm$ and $\gamma_\pm^*$ are the mean activity coefficients of the reactive groups which are related to the single-ion activity coefficients γ_+, γ_-, γ_+^* and γ_-^* by Eqs. (9) and (10) (see for example, Ref. 15)

$$\gamma_\pm^2 = \gamma_+\cdot\gamma_- \tag{9}$$

$$\gamma_\pm^{*2} = \gamma_+^*\cdot\gamma_-^* \tag{10}$$

The first and second terms of the right-hand side of Eq. (8) denote the changes of the activity coefficients of the reactant ion and activated complex, respectively, in going from the specified state to the reference state.

At this point we wish to try to estimate the activity coefficients of the reactant ions from the kinetic parameter, k_2, using Eq. (8). In the case of interionic reactions between ions of unlike signs and of the same valence (NH_4^+ and OCN^-, for example), the activated complex is considered to be neutral. The second term of the right-hand side of Eq. (8), therefore, can be safely neglected, compared to the first term, because the activity coefficients of neutral molecules are not so sensitive to changes in ionic concentration. In the present case, (Eqs. (2) to (5)), on the other hand, the complex is not neutral except in the final stage of the reaction. However, it is still expected that the second term of the right-hand side of Eq. (8) is much smaller than the first term. Thus we neglect the second term and obtain:

$$\log(k_2/k_2^*) = 2\log(\gamma_\pm/\gamma_\pm^*) \tag{11}$$

It should be noted here that γ is the single-ion activity coefficient of the amino groups of the macroion, and not that of the macroion (to be denoted as $\gamma_{\alpha+}$). The mean activity coefficient of polyelectrolyte ($\gamma_{\alpha\pm}$) is given by the following equation.

$$\gamma_{\alpha\pm}^{\alpha+1} = \gamma_{\alpha+}\cdot\gamma_-^{\alpha} \tag{12}$$

where the effective valency of the macroions is α. Physicochemical measurements such as e.m.f. measurement give $\gamma_{\alpha\pm}$, not $\gamma_\pm$. Thus, the relation between $\gamma_{\alpha+}$ and γ_+ must be given to complete the discussion of the mean activity coefficients of the reaction systems. The chemical potential of the macrocations, $\mu_{\alpha+}$, is given by the sum of the chemical potentials of the reactive group i (the amino groups in the present case), μ_{+i},

$$\mu_{\alpha+} = \sum_{i=1}^{\alpha}\mu_{+i} \tag{13}$$

We assume here that the value of μ_{+i} is not dependent on the location of the group on the cation chain. Then we obtain,

$$\mu_{\alpha+} = \alpha\mu_+ \tag{14}$$

From Eq. (15) we have

$$\gamma_{\alpha+} = \gamma_+^{\alpha} \tag{15}$$

The relation between k_2 and $\gamma_{\alpha\pm}$, is therefore, given by

$$\log(\gamma_{\alpha\pm}/\gamma_{\alpha\pm}^*) = \frac{\alpha}{\alpha+1}\log(k_2/k_2^*) \tag{16}$$

By using Eq. (16), the mean activity coefficients of ED·OCN, TT·OCN, TP·OCN and PEI·OCN in aqueous media were calculated from the observed kinetic data (Fig. 1). The α value equals to Z[D.N.], where, Z and [D.N.] are the valency of reactive cation and the degree of neutralization, respectively. The α values of ED·OCN, TT·OCN, TP·OCN and PEI·OCN were 1.5, 2.9, 3.5 and 96.3, respectively. The

$\gamma_{\alpha\pm}^*$ values at 0.01 mol·l^{-1} were taken from the literature.[4] For comparison, the values of $\gamma_{\alpha\pm}$ from the e.m.f. measurements of the hydrochlorides, *i.e.*, ED·HCl, TT·HCl, TP·HCl and PEI·HCl are also given in the figure.[4] The $\gamma_{\alpha\pm}$ value of ED·OCN coincides with that of ED·HCl very well. The agreement between the $\gamma_{\alpha\pm}$ values of the cyanate and hydrochloride, however, becomes less satisfactory with increasing valency of the cations. This may be due to the fact that μ_{+i} depends for higher valence cations on the location of the reactive group i. Furthermore, the agreement is not good at higher concentrations, perhaps due to the specificity of the anions. Qualitatively, however, the concentration dependence of $\gamma_{\alpha\pm}$ derived from the kinetic data is satisfactory compared with that from the electrochemical measurements.

Now we turn to the catalytic action of added salts on the carbamoylation reactions. Figure 2 shows the decelerating effect of sodium chloride on the ED·OCN, TT·OCN, TP·OCN and PEI·OCN reactions. The data for NH_4·OCN by Warner and Warrick[9] are also given for comparison. The quantity k_2^* denotes the rate constant at $t=0$, at a reactant concentration of 0.01 mol·l^{-1} in the absence of the added salt. As is clearly seen from the Figure, the reactions of the higher valence cations with cyanate anions are retarded more effectively with sodium chloride than those of the lower valence cations.

Let us next discuss the interactions between reactant electrolyte and catalyst salt more quantitatively. For this purpose, it is convenient to use the interaction parameter, β_{23}, defined by Eq. (17).[16]

$$\beta_{23} = (1+\alpha)\partial \ln \gamma_{\alpha\pm}/\partial m_3 \qquad (17)$$

were $\gamma_{\alpha\pm}$ and m_3 denote the mean activity coefficient of the reactant electrolyte and the concentration of sodium chloride, respectively. The β_{23} values obtained from the kinetic data by the use of Eq. (16) are compiled in Table 3. The negative value of β_{23} suggests that the interactions between the reactant electrolyte and the salt are electrostatic (see Refs. 17 and 18). The value of β_{23} increases with increasing concentration of sodium chloride, suggesting a weakening of the electrostatic forces with addition of sodium chloride. As is clearly seen, the magnitude of β_{23} increases strikingly with increasing valency of the reactant cations.

Table 3. Interaction parameter β_{23}
Component 2 : ED·OCN, TT·OCN, PEI·OCN
Component 3 : NaCl

m_3 (mol·l^{-1})	β_{23}			
	ED·OCN	TT·OCN	TP·OCN	PEI·OCN
0.003	−46.6	−151	−326	−11700
0.005	−38.5	−132	−192	−9100
0.01	−29.4	−84	−119	−8000
0.02	−14.7	−63	−93	−6000
0.03	—	−64	−89	—

The dependence of β_{23} on the valency of the reactant cations implies the following. The higher the valency of the reactant cations, the more strongly they attract chloride ions which in turn prevent the cyanate ions from approaching the reactant cations. This shielding effect of the chloride ions becomes greater as the reactant cations are more highly charged.

The catalytic action of a polyelectrolyte on the carbamoylation reactions of ED·OCN, TT·OCN, TP·OCN and PEI·OCN is portrayed in Fig. 3. The decelerating efficiency of DECS was about the same for all of the carbamoylation reactions studied, in contrast to the action of sodium chloride. This suggests that the interactions between the catalyst polyelectrolyte (*i.e.*, DECS) and reactant electrolyte (2–1, 4–1, 5–1,

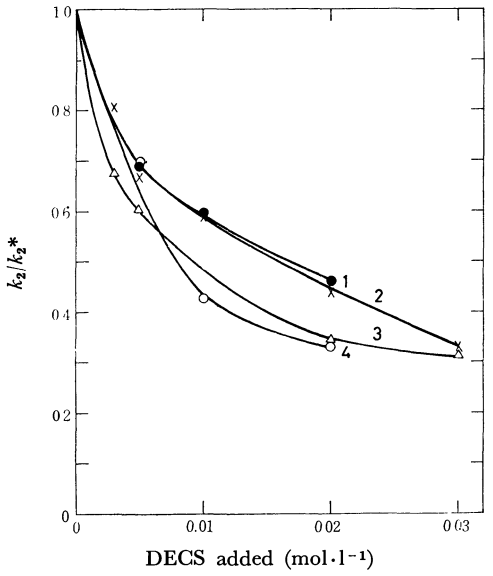

Fig. 3. Decelerating effect of DECS at 30 °C.
[Reactant]=0.01 mol·l^{-1}
Curve 1: ED·OCN 2: TT·OCN
3: TP·OCN 4: PEI·OCN

100–1 valence types) are relatively similar in spite of the large range in the cation valency. The valency of the DECS cations (degree of polymerization about 2000) is much higher than the valencies of the reactant cations (2∼100). The attractive forces between the DECS cations and the cyanate anions, therefore, are much stronger than those between the reactant cations of various valencies and Cl^-. Thus, the difference in the strength of the interactions between the reactant cations and Cl^- may not strongly affect the retarding effects by the DECS cations.

The retarding influences of simple-, micelle-, and polyelectrolytes on the carbamoylation reactions of ED·OCN and PEI·OCN are compared in Table 4. For ED·OCN, the catalytic effect was the weakest for calcium chloride and increased in the order:

$$CaCl_2 < NaCl < CTABr < DECS < NaPAA \quad (19)$$

On the other hand, the retarding effect on the PEI·OCN reaction was in the order:

$$DECS < CTABr < NaCl < CaCl_2 \quad (20)$$

Generally speaking, the retarding action of the added salt is strong when the valencies of reactant cations and salt cations differ greatly from each other. These results are accounted for as follows. The fact that CTABr and DECS are more effective retarders than sodium chloride and calcium chloride in the ED·OCN reaction can be understood if we consider that these macrocations attract cyanate ions more strongly than Na^+ and Ca^{2+}. Sodium chloride is more effective than calcium chloride since the concentration of the chloride ions, which we recall do not favor the approach of cyanate ions to ED cations, is lower in the presence of Ca^{2+} than in the case of Na^+. The ED cations are less effectively shielded by calcium chloride than by sodium chloride, so that the ED·OCN reaction is decelerated less strongly by the former than by the latter.

For the PEI·OCN reaction, the situation is also interpretable by similar considerations. The chloride ion concentration around the PEI cations should be lower in the presence of DECS and CTABr cations than in the case of Na^+ and Ca^{2+} as a result of the attractive interaction between the macrocations and chloride ions, and of the very strong repulsive interaction between the macrocations and PEI cations. Thus, DECS and CTABr are not strong retarders in the PEI·OCN reaction. This situation is consistent with the activity data for the ternary systems, water–polyelectrolyte(2)–salt(3),[1,18] indicating that addition of low molecular weight salts as the third component 3 produces more efficient shielding effect on the polyelectrolyte (component 2) than that of another polyelectroylte (component 3). We have no reasonable explanation for the higher efficiency of calcium chloride as compared to sodium chloride. In summary, we state that the reactions of polycations are more effectively decelerated by coexisting simple cations than by catalyst polycations, whereas reactions of simple cations are retarded more strongly by polycations than by simple cations.

Table 4. Decelerating effect of various salts on the ED·OCN and PEI·OCN reactions at 30 °C
[Reactant]=[Added salt]=0.01 mol·l^{-1}

Added salt	k_2/k_2^*	
	ED·OCN	PEI·OCN
NaCl	0.77	0.31
$CaCl_2$	0.93	0.25
CTABr	0.58	0.36
DECS	0.60	0.43
NaPAA	0.12	—

The authors express their thanks to Drs. W. N. Vanderkooi and J. C. Moore of the Dow Chemical Co., Midland, Mich., and to Dr. S. Harada of the Nitto Spinning Co., Koriyama, Japan, for kindly furnishing polyethylenimine and copolymer of diethyldiallylammonium chloride and sulfur dioxide, respectively.

Studies on the Synthesis of Furan Compounds. XXX.[1] Syntheses and Steric Configurations of 3-(5-Nitro-2-furyl)-2-(5-bromo-2-furyl)acrylic Acid and Its Related Compounds[2]

Ichiro HIRAO, Yasuhiko KATO, and Shiro KOZAKURA

Laboratory of Organic Synthesis, Department of Industrial Chemistry, Kyushu Institute of Technology, Tobata-ku, Kita-Kyushu 804

(Received March 1, 1973)

cis- and *trans*- 3-(5-Nitro-2-furyl)-2-(5-bromo-2-furyl)acrylic acids (II and III) and their functional derivatives have been synthesized in connection with the syntheses and steric configurations of 3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)acrylonitrile and its related compounds. The treatment of *cis*-3-(5-nitro-2-furyl)-2-(2-furyl)-acrylic acid (I) with bromine in refluxing carbon tetrachloride afforded a 1 : 1 mixture of II and III in quantitative yield. II and III afforded methyl (IV and VI) and ethyl (V and VII) esters, *via* each acid chloride (VIII or IX) by treatment with methanol and ethanol, respectively. Similarly, *cis*- and *trans*- 3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)acrylamides (X and XI) were obtained by treatment of VIII and IX with dry ammonia in benzene. Isomerization was observed in the conversion of X into *trans*-3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)-acrylonitrile (XII) upon treatment with phosphoryl chloride, while XI maintained its configuration under similar conditions to afford XII. On the other hand, *cis*-acid and esters (II, IV, and V) were converted into the corresponding *trans* isomers (III, VI, and VII) respectively, by treatment with hydrazine hydrate in refluxing methanol. II was confirmed to be isomerized to III by heating with hydrochloric acid or by irradiation with ultraviolet light (406 mμ). The structures and configurations of these compounds were discussed on the basis of their IR and NMR spectra.

cis-3-(5-Nitro-2-furyl)-2-(5-bromo-2-furyl)acrylonitrile has been prepared by bromination of both *cis*- and *trans*- 3-(5-nitro-2-furyl)-2-(2-furyl)acrylonitriles.[3] It could not be hydrolyzed to *cis*-3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)acrylic acid (II) by heating with 36% hydrochloric acid for 12 hr. Thus, bromination of 3-(5-nitro-2-furyl)-2-(2-furyl)acrylic acid has been carried out with the purpose of preparing II as a raw material in connection with the antibacterial properties of nitrofuran derivatives.[4-11] The present paper deals with the syntheses, steric configurations, and configurational interconversions of *cis*- and *trans*-3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)acrylic acids and their related compounds.

Results and Discussion

A mixture of *cis*- (II) and *trans*-3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)acrylic acid (III) was obtained quantitatively by treatment of *cis*-3-(5-nitro-2-furyl)-2-(2-furyl)acrylic acid (I) with an equimolar amount of bromine in refluxing carbon tetrachloride. It was confirmed to be a 1 : 1 mixture of II (48.9%) and III (51.1%) by NMR analysis, from which II and III were isolated in a 29.8% and a 33.1% yield, respectively, by fractional crystallization from aqueous methanol. In the IR spectra, a C=O stretching absorption appeared at 1690 cm^{-1} in II and at 1710 cm^{-1} in III. The NMR spectra of II and III revealed an olefinic proton signal at δ 7.39 and 6.88, respectively, indicating that the olefinic proton and COOH group are on one side of the ethylene double bond in the molecule of II. Methyl (IV and VI) and ethyl (V and VII) esters were obtained respectively by heating II and III with thionyl

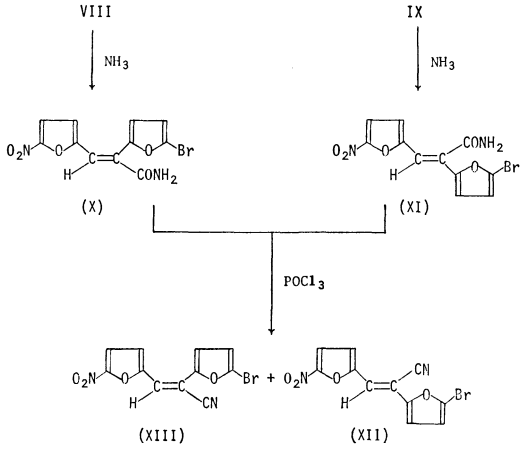
chloride in benzene and treating the resulting acid chlorides (VIII and IX) with methanol or ethanol. These esters were confirmed to retain the steric configuration of each mother acid by a comparison of the NMR spectra of IV and V with those of VI and VII. The olefinic proton signals in IV and V shifted to lower magnetic field than those in VI and VII; this suggests that IV and V are *cis*, and VI and VII are *trans*. In the IR spectra, *cis* esters also exhibited a C=O stretching absorption band at lower frequencies than the corresponding *trans* ester. In a comparison with the IR spectrum of IX, the *cis*-configuration of VIII was suggested by a shift to lower frequencies of the C=O stretching band to be similar to the relation observed between *cis* and *trans* forms of the acid and ester.

When VIII was treated with dry ammonia in benzene at room temperature, *cis*-3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)acryl amide (X) was obtained. Similarly, IX and ammonia produced *trans*-acrylamide (XI) in a good yield, indicating that the configurational interconversion did not take place in the reaction with ammonia under the conditions employed. Isomerization was observed in the dehydration reaction of X. On treatment with hot phosphoryl chloride, X afforded *trans*-3-(5-nitro-2-furyl)-2-(5-bromo-2-furyl)acrylonitrile (XII) as the main product, along with *cis*-acrylonitrile (XIII).[3] While XI maintained its *trans*-configuration giving rise to XII, a part of XI was changed the configuration to produce XIII. The structures of X and XI were supported by their IR and NMR spectra (see Experimental). The *trans*-configuration of XII is clearly shown by comparing its IR and NMR spectra with those of III and XIII.



Scheme 2.

When refluxed with 3/2 equimolar of hydrazine hydrate in methanol for 2 hr, 55% of II, 70% of IV, and 73% of V were respectively converted into III, VI, and VII. Similarly, 64% and 60% of II was isomerized to III on being heated with an equimolar amount of hydrochloric acid in methanol for 1.5 hr and by irradiation with UV light (406 mμ) for 25 hr. The conversion ratio was estimated on the basis of UV or NMR analysis.

Experimental

All the melting points are uncorrected. Elemental analyses were carried out with a Yanagimoto CHN Corder, MT-2 type. The IR spectra were taken on a JASCO IRA-2 grating infrared spectrophotometer by the KBr-disk method. The band positions are expressed in wave number, cm^{-1}. The UV spectra were performed on a Shimadzu photoelectric spectrophotometer, Model QV-50. UV-light irradiation and analyses were also carried out with the same apparatus. The NMR spectra were determined with a Japan Electron Optics Lab. JNM-C-60HL spectrometer. All the spectra were measured in DMSO-d_6 with a concentration of 2 mol% at 60 MHz, with HMDS as an internal reference; the chemical shifts are expressed in δ-values.

cis- *and* trans- *3-(5-Nitro-2-furyl)-2-(5-bromo-2-furyl)acrylic Acid (II and III).* A solution of bromine (50 g, 310 mmol) in carbon tetrachloride (100 ml) was slowly added to a stirred, warmed (70 °C) suspension of I (74.7 g, 300 mmol) in carbon tetrachloride (500 ml). The resulting mixture was then refluxed for 2 hr. After cooling, the precipitated product was filtered, washed with carbon tetrachloride (200 ml), and dried. Thus, 97.6 g (99.2%) of monobromo compound was obtained as brown-colored powder; mp 140—151 °C. The product was determined to be a mixture of II and III with the ratio of 48.9 : 51.1 by a comparison of NMR signal intensities. Fractional crystallization from methanol containing 20% of water afforded 29.3 g (29.8%) of II, 32.6 g (33.1%) of III, and 26.4 g of the recovered mixed-acid.

cis Acid (II); small orange needles, mp 187—189 °C. UV λ_{max}^{MeOH} mμ (ε): 227 (19400), 310 (11200), and 404 (11900). IR: 1690 (C=O). NMR (at 24 °C): 6.69 (d, 1H, J=3.8 Hz, bromofuran ring C_4–H), 6.83 (d, 1H, J=3.8 Hz, bromofuran ring C_3–H), 7.06 (d, 1H, J=4.1 Hz, nitrofuran ring C_3–H), 7.39 (s, 1H, olefinic proton), and 7.65 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H). Found: C, 40.60; H, 1.85; N, 4.26%. Calcd for $C_{11}H_6NO_6Br$: C, 40.24; H, 1.83; N, 4.27%.

trans Acid (III); brown granules; mp 175 °C. UV λ_{max}^{MeOH} mμ (ε): 305 (16400) and 406 (25100). IR: 1710 (C=O). NMR (at 24 °C): 6.69 (s, 2H, bromofuran ring C_3–H and C_4–H), 6.88 (s, 1H, olefinic proton), 6.96 (d, J=4.1 Hz, nitrofuran ring C_3–H), and 7.65 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H). Found: C, 40.16; H, 1.76; N, 4.11%. Calcd: the same value as II above.

cis- *and* trans- *3-(5-Nitro-2-furyl)-2-(5-bromo-2-furyl)acryloyl Chloride (VIII and IX).* A mixture of II or III (each 9.54 g, 30 mmol), thionyl chloride (3.6 g, 30 mmol), *N,N*-dimethylformamide (2 g) and dry benzene (300 ml) was stirred at 70 °C for 3 hr. The resulting solution was brought to dryness *in vacuo* and the residual acid chloride was washed with dry ether (50 ml). The crude chlorides were used in the subsequent experiments without further purification.

cis Acid chloride (VIII); brown powder, mp 137—139 °C. Yield: 9.8 g (97%). IR: 1740 (C=O).

trans Acid chloride (IX); brown powder, mp 97—100 °C. Yield: 9.6 g (95%). IR: 1790 (C=O).

Preparation of Esters (IV, V, VI and VII). VIII or or IX (each 3.4 g, 10 mmol) was dissolved in alcohol (10—20 ml) and the resulting solution was left standing at room temperature for a day. The precipitated product was filtered and recrystallized from alcohols to give pure esters.

cis Methyl ester (IV); brown plates (from methanol), mp 117—119 °C. Yield: 2.8 g (82%). IR: 1715 (C=O).

NMR (at 62 °C): 3.83 (s, 3H, O–CH_3), 6.72 (d, 1H, J=3.8 Hz, bromofuran ring C_4–H), 6.87 (d, 1H, J=3.8 Hz, bromofuran ring C_3–H), 7.09 (d, 1H, J=4.1 Hz, nitrofuran ring C_3–H), 7.44 (s, 1H, olefinic proton), and 7.64 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H). Found: C, 42.35; H, 2.68; N, 4.01%. Calcd for $C_{12}H_8NO_6Br$: C, 42.11; H, 2.38; N, 4.01%.

trans Methyl ester (V); ocherous needles (methanol), mp 106—107 °C. Yield: 2.5 g (73%). IR: 1720 (C=O). NMR (at 24 °C): 3.95 (s, 3H, O–CH_3), 6.73 (s, 2H, bromofuran ring C_3–H and C_4–H), 7.01 (s, 1H, olefinic proton), 7.03 (d, 1H, J=4.1 Hz, nitrofuran ring C_3–H), and 7.65 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H). Found: C, 42.02; H, 2.37; N, 4.02%. Calcd: the same value as IV above.

cis Ethyl ester (IV); ocherous needles (ethanol), mp 80—81 °C. Yield: 3.2 g (90%). IR: 1715 (C=O). NMR (at 62 °C): 1.31 (t, 3H, J=7.5 Hz, C–CH_3), 4.30 (q, 2H, J=7.5 Hz, O–CH_2–C), 6.73 (d, 1H, J=3.8 Hz, bromofuran ring C_4–H), 6.89 (d, 1H, J=3.8 Hz, bromofuran ring C_3–H), 7.09 (d, 1H, J=4.1 Hz, nitrofuran ring C_3–H), 7.43 (s, 1H, olefinic proton), and 7.64 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H). Found: C, 43.52; H, 2.51; N, 3.83%. Calcd for $C_{13}H_{11}NO_6Br$: C, 43.82; H, 2.81; N, 3.93%.

trans Ethyl ester (VII); brown cylinders (ethanol), mp 114—115 °C. Yield: 3 g (84.3%). IR: 1720 (C=O). NMR (at 75 °C): 1.31 (t, 3H, J=7.5 Hz, C–CH_3), 4.45 (q, 2H, J=7.5 Hz, O–CH_2–C), 6.73 (s, 2H, bromofuran ring C_3–H and C_4–H), 7.01 (s, 1H, olefinic proton), 7.03 (d, 1H, J=4.1 Hz, nitrofuran ring C_3–H), and 7.65 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H). Found C, 43.51; H, 2.84; N, 3.99%. Calcd: the same value as VI above.

cis- *and* trans- *3-(5-Nitro-2-furyl)-2-(5-bromo-2-furyl)acrylamide (X and XI).* To a stirred solution of VIII or IX (each 7 g, 20 mmol) in dry benzene (300 ml) was introduced dry ammonia. During the reaction, the temperature was kept below 30 °C. The resulting reaction mixture was filtered and the product was washed with water (200 ml) and then dried. Recrystallization from methanol afforded pure amides.

cis Amide (X); yellow needles, mp 181 °C. Yield: 6 g (81.5%). IR: 3350, 3160 (NH_2), and 1652 (C=O). NMR (at 24 °C): 6.73 (d, 1H, J=3.8 Hz, bromofuran ring C_4–H), 6.85 (d, 1H, J=3.8 Hz, bromofuran ring C_3–H), 6.95 (d, 1H, J=4.1 Hz, nitrofuran ring C_3–H), *ca.* 7.68 (broad s, 2H, NH_2), and 7.68 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H). Found: C, 40.65; H, 2.32; N, 8.22%. Calcd for $C_{11}H_7N_2O_5Br$: C, 40.37; H, 2.14; N, 8.56%.

trans Amide (XI): ocherous needles, mp 173—174 °C. Yield: 5.3 g (78%). IR: 3425—3040 (NH_2 and furan ring C–H) and 1661 (C=O). NMR (at 24 °C): 6.70 (d, 1H, J=3.8 Hz, bromofuran ring C_4–H), 6.72 (s, 1H, olefinic proton), 6.82 (d, 1H, J=3.8 Hz, bromofuran ring C_3–H), 6.93 (d, 1H, J=4.1 Hz, nitrofuran ring C_3–H), 7.72 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H), 7.83 (broad s, 1H, NH), and 8.20 (broad s, 1H, NH). Found: C, 40.20; H, 2.46; N, 8.35%. Calcd: the same value as X above.

cis- *and* trans- *3-(5-Nitro-2-furyl)-2-(5-bromo-2-furyl)acrylonitrile (XIII and XII).* A mixture of X or XI (each 3.3 g, 10 mmol), phosphoryl chloride (40—50 ml) and *N,N*-dimethylaniline (2 drops) was heated at 50—60 °C for 45 min. After cooling, the resulting mixture was poured into crushed ice with agitation. The solidified product was collected, washed with water, and dried. This was identified as a mixture of XII and XIII (63—65 : 37—35) by its NMR spectrum. Yield, 2.6—2.3 g (84—74%); mp 184—189 °C. The mixture was fractionally crystallized from methanol to afford 0.66 g (21.2%) of XII and 0.08 g (2.6%) of XIII.

trans Nitrile (XII); yellow powder, mp 164—166 °C. IR: 2230 (C≡N). NMR (at 97 °C): 6.77 (d, 2H, J= 3.8 Hz, bromofuran ring C_3–H and C_4–H), 7.23 (d, 1H, J= 4.1 Hz, nitrofuran ring C_3–H), 7.25 (s, 1H, olefinic proton), 7.64 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H). Found: C, 42.58; H, 1.61; N, 9.25%. Calcd for $C_{11}H_5N_2O_4Br$: C, 42.72; H, 1.62; N, 9.06%.

cis Nitrile (XIII); orange-red powder, mp 216 °C, undepressed on admixture with the authentic sample.[3] NMR (at 111 °C): 6.72 (d, 1H, J=3.8 Hz, bromfouran ring C_4–H), 6.90 (d, 1H, J=3.8 Hz, bromofuran ring C_3–H), 7.28 (d, 1H, J=4.1 Hz, nitrofuran ring C_3–H), 7.52 (s, 1H, olefinic proton), and 7.64 (d, 1H, J=4.1 Hz, nitrofuran ring C_4–H).

Conversion of II, IV, and V into III, VI, and VII. By Hydrazine Hydrate: A mixture of II, IV, or V (each 5 mmol), 80% hydrazine hydrate (0.47 g, 7.5 mmol), and methanol (100 ml) was stirred under reflux for 2 hr. The resulting solution was brought to dryness *in vacuo* and the residue was washed with water and then dried. A part of the residue was dissolved in DMSO-d_6 and the component ratio was determined by NMR. II was converted into III in 55% yield, IV into VI in 70%, and V into VII in 73%.

By Hydrochloric Acid: A mixture of II (1.64 g, 5 mmol), 36% hydrochloric acid (0.5 g), and methanol (100 ml) was refluxed for 1.5 hr. The resulting solution was brought to dryness *in vacuo*. Work-up as above afforded 64% of the conversion.

By UV-light Irradiation: A methanolic solution of II (10 μg/ml) was irradiated in a quartz cell with ultraviolet light (406 mμ) at room temperature for 25 hr. The conversion ratio was determined by the change of absorbance at 406 mμ. 60% of II was converted into III.

Oxidation of *p*-Tolyl Triphenylmethylhydrazo Sulfone[1]

Minoru KOJIMA, Nobumasa KAMIGATA, Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received March 10, 1973)

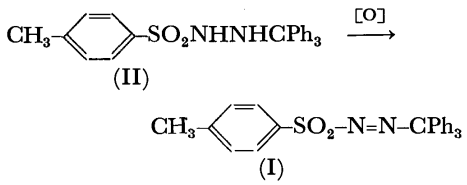
In order to synthesize and study the decomposition of *p*-tolyl triphenylmethylazo sulfone, *p*-tolyl triphenylmethylhydrazo sulfone was oxidized by various oxidizing agents. Although it was oxidized fairly easily by mercury(II) oxide or potassium permanganate, the azo compound formed was unstable and decomposed immediately with evolution of nitrogen. The main products were *p*-tolyl triphenylmethyl sulfone and *p*-tolyl *p'*-benzhydrylphenyl sulfone; both are ascribable to the recombination of *p*-toluenesulfonyl and triphenylmethyl radicals.

Aryl arylazo sulfones yield aryl and arenesulfonyl radicals upon irradiation of light[2] or upon thermolyses in neutral or basic media.[3,4] They yield aryl cations when they are decomposed in acidic media.[5,6]

All the azosulfones studied so far by various investigators are aryl azosulfones, and the decompositions of alkyl azosulfones have not been investigated yet. In an attempt to understand the chemistry of alkyl azosulfones, the synthesis of *p*-tolyl triphenylmethylazo sulfone(I) has been investigated. I is expected to decompose at fairly low temperatures, since both the trityl and *p*-tosyl radicals are resonance-stabilized radicals.

Results and Discussion

Aryl triphenylmethylazo sulfones are not described in the literature. In order to synthesize I, oxidation of *p*-tolyl triphenylmethylhydrazo sulfone (II) was attempted.

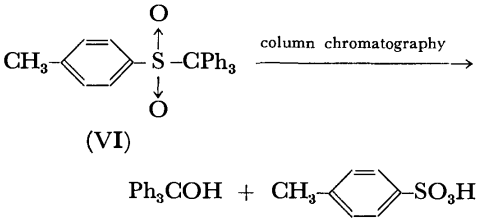


(II) (I)

Although II was oxidized fairly easily by such oxidizing agents as yellow mercury(II) oxide, manganese(IV) oxide, potassium permanganate or bromine, nitrogen was evolved simultaneously, and I could not be isolated.

Oxidation with mercury(II) oxide in benzene did not take place appreciably at room temperature, but proceeded smoothly at the boiling point of the solvent. When the products were subjected to column chromatography on Florisil, the main product was triphenylmethyl alcohol(III) (75% yield). When the oxidation was carried out in air, triphenylmethyl peroxide (IV) was found in 20 mol% yield. Under nitrogen, formation of IV was suppressed, and triphenylmethane (V) was found in 1.5 mol% yield. Mercury(II) *p*-toluenesulfonate precipitated and amounted to 20 mol%. Almost no *p*-toluenesulfinate was contained in the salt which precipitated. When *p*-toluenesulfinic acid was treated with mercury(II) oxide in benzene, the main product was mercury(II) *p*-toluenesulfinate and very little mercury(II) *p*-toluenesulfonate was found; this finding shows that the mercury(II) *p*-toluenesulfonate formed upon oxidation of II is not ascribable to the oxidation of *p*-toluenesulfinic acid which is a possible intermediate.

When the products of oxidation of II with mercury(II) oxide in benzene were not subjected to column chromatography but separated by recrystallizations, the yield of III was only 35% and *p*-tolyl triphenylmethyl sulfonte(VI) was found in 50% yield. A separate experiment showed that on a Florisil, alumina or silica gel column VI was quantitatively converted to III (another main product was *p*-toluenesulfonic acid). Therefore, VI must be one of the main products of oxidation of II in benzene.



(VI) (III)

Since aryl arylazo sulfones undergo heterolysis in acidic media and homolysis in neutral or basic media, it is possible that the decomposition of I produced by oxidation of II is influenced by *p*-toluenesulfonic acid formed as a product. Therefore, II was oxidized with mercury(II) oxide in benzene in the presence of triethylamine (1.5 mol/mol of II). The products isolated by column chromatography were III (44 mol%), V (22 mol%), *p*-benzhydrylphenyl *p'*-tolyl sulfone (VII) (24 mol%) and triethylammonium *p*-toluenesulfonate (23 mol%). These products are quite different from those found in the absence of triethylamine.

When II was oxidized by mercury(II) oxide in pyridine, the oxidation proceeds even at about 30 °C. Nitrogen was evolved in an almost quantitative yield, and the products isolated by column chromatography were III (42—47 mol%), V (7—8 mol%), and VII (25—30 mol%). When the oxidation was carried out in air, IV was found in a small yield (3.6 mol%) in addition to the products described above. When the oxidation products were analyzed by NMR

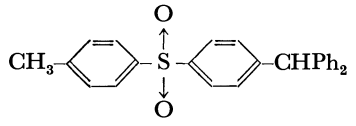
before the column-chromatographic separation, VI and VII were found in 20 and 30 mol% yields, respectively. Therefore, about a half of the total yield of III (after the column chromatography) is ascribable to the hydrolysis of VI during the chromatography, but the other half must have been formed as such directly by the oxidation of II. Since VI does not isomerize to VII even when VI was treated with pyridine, VII must be a primary reaction product.



(VII)

When powdery MgO was used as a base instead of an amine, VI was formed in 50—65% yield and the yield of VII was only 2 mol%. Other products were V (1.5 mol%) and IV (oxidation in air) (10 mol%).

In the oxidation in benzene, no products ascribed to the reactions with benzene were found under varied conditions.

When II was oxidized with potassium permanganate in acetonitrile, oxidation proceeded smoothly and nitrogen was evolved almost quantitatively. The products were III (65 mol%), VI (trace) and an unidentified sulfone (30 wt%; the IR spectrum resembles that of VII but its NMR spectrum does not show the methine proton).

When II was oxidized with manganese(IV) oxide in acetonitrile, oxidation proceeded slowly at room temperature, and it took 10 days before the evolution of nitrogen ceased (70 mol%). The reaction mixture was extracted with an $NaHCO_3$ solution. *p*-Toluenesulfonic acid (49 mol%) was obtained from the aqueous extract, and the evaporation of the organic layer gave almost pure III. The yields of the sulfones (VI or VII) were negligibly small.

Oxidation of II with bromine in acetonitrile proceeded rapidly at room temperature with evolution of nitrogen (90 mol%). When the reaction mixture was diluted with water, extracted with chloroform and the extract was evaporated, almost pure III was obtained. No sulfone (VI or VII) was found.

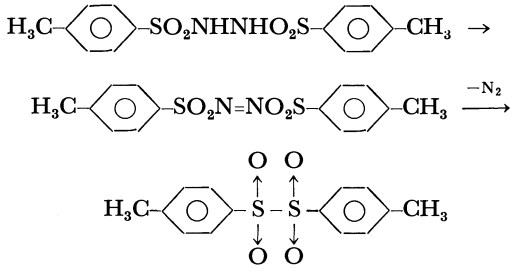
The experimental results described above show that II can readily be oxidized to I but I is very unstable and decomposes with evolution of nitrogen.

Formation of IV shows that triphenylmethyl radical was present and the decomposition of I is homolytic. Sulfone VI is formed by the combination of triphenylmethyl and *p*-tosyl radicals. Since triphenylmethyl radicals are fairly stable, they diffuse out of solvent cage, and form IV upon reaction with oxygen. Part of triphenylmethyl radicals are further oxidized by excess oxidizing agent to III. Part of *p*-tosyl radicals are further oxidized by excess oxidizing agents to *p*-tosyloxy radicals, and then to *p*-toluenesulfonic acid.

Bromine is known to be an efficient radical-scavenger, as exemplified by the efficient trapping of α-cyanoisopropyl radical by bromine in the decomposition of azoisobutyronitrile. Therefore, when II was oxidized with bromine, all the triphenylmethyl radicals were probably converted to triphenylmethyl bromide, which was then hydrolyzed to III. *p*-Tosyl radicals were probably converted to *p*-tosyl bromide, which was then hydrolyzed to *p*-toluenesulfonic acid.

The absence of the products ascribed to the reactions with benzene can be explained in terms of the small reactivity of the resonance-stabilized triphenylmethyl and *p*-toluenesulfonyl radicals. The arenesulfonyl radicals produced by the decomposition of arenesulfonyl iodides did not react with aromatic solvents.[7] Part of the arenesulfonyl radicals formed by the photolysis of aryl α-disulfones attacked aromatic solvents, but the yields of the aromatic substitution products were low.[8]

The oxidation of *N,N'*-diarenesulfonylhydrazine gave the corresponding diimide, which immediately decomposed. The main products were α-disulfone (by recombination in cage), thiolsulfonate and sulfonic acid.[9]



Arenesulfonyl radicals formed in this system also did not react with solvent molecules (benzene, tetrachloroethylene, anisole, *etc*).

The oxidation of II with HgO in the presence of base yielded VII. Formation of VII can be explained by addition of *p*-tosyl radical at a *para* position of triphenylmethyl radical.

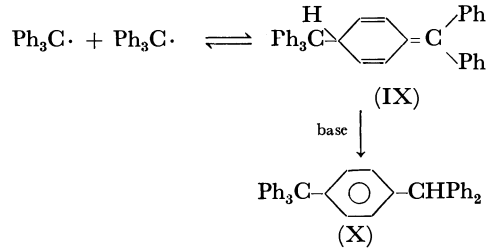
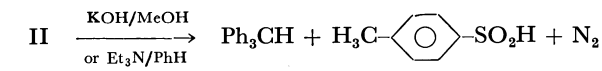
9) Y. Kohara, M. Kobayashi, and H. Minato, *ibid.*, **43**, 2933 (1970).

VII is formed only when a strong base is present. These finding can be rationalized by assuming that the formation of VIII is reversible and VIII is converted to VII by prototropy catalyzed by base. In the absence of base, VIII redissociates to triphenylmethyl and *p*-tosyl radicals, which recombine and form VI. Formation of VIII from triphenylmethyl and *p*-tosyl radicals is analogous to the formation of the Gomberg trityl(IX) from two triphenylmethyl radicals.[10] It is known that IX isomerizes to X with a basic catalyst.[11]



Formation of much triphenylmethane in the HgO-oxidation of II in the presence of triethylamine could be ascribed to abstraction of hydrogen of the amine with triphenylmethyl radical. However, a separate experiment showed that in the presence of a strong base II is converted to triphenylmethane, *p*-toluenesulfinic acid and nitrogen. Therefore, this base-catalyzed decomposition of II appears to be the better explanation for the formation of triphenylmethane in the HgO-base-oxidation of II.



When such stronger oxidizing agents as manganese (IV) oxide were used, the radical pair formed by the decomposition of I were probably further oxidized on the surface of the solid oxidizing agents, and therefore no sulfones were found.

Experimental

Materials. Pyridine and triethylamine were purified by the usual procedures. Yellow mercury(II) oxide was used as received. Manganese(IV) oxide was that used for elemental analyses.

Synthesis of p-*Tolyl Triphenylmethylhydrazo Sulfone(II).* Triphenylmethyl chloride (2.8 g) was added to a chloroform (60 ml) solution of *p*-tosylhydrazine (2.8 g). After 2 hr refluxing, the *p*-tosylhydrazine hydrochloride which precipitated was filtered, and the filtrate was evaporated. Recrystallization of the residue from ethanol gave pure II; mp 136 °C (decomp); yield, 1.6 g (37%). IR, 1160, 1308, 1325 (S–O), 3230, 3280 (N–H) cm^{-1}. NMR, δ, 2.45(s), 4.10(b), 4.95(s), 7.20(m). Found: C, 72.66; H, 5.47%. Calcd for $C_{26}H_{24}O_2N_2S$: C, 72.87; H, 5.64%.

Oxidation of II. The results are summarized in Table 1. Typical examples are shown below.

a) Oxidation of II with HgO in Benzene. A mixture of II (1.290 g, 3.0 mmol), yellow mercury(II) oxide (0.683 g, 3.16 mmol), anhydrous sodium sulfate (1.2 g) and benzene (50 ml) was stirred with a magnetic stirrer at 70 °C. The yellow color of mercury(II) oxide disappeared, and nitrogen was evolved. The mixture was filtered, and the filtrate was evaporated. Crystallization of the residue from benzene–ether yielded crystals of VI (0.618 g, 1.55 mmol; mp 171 °C (lit, 173 °C)) first, and then those of III (0.273 g, 1.05 mmol; mp 160—161 °C(lit, 164.2 °C). They were identified by their IR and NMR spectra.

Table 1. Products of oxidation of $TsNHNHCPh_3$ with HgO

Run	Reactants (mmol)		Solvent	Others	Separation method
	$TsNHNHCPh_3$	HgO			
1	3.00	3.16	PhH	—	Recryst. from Et_2O–PhH
2	6.10	30	PhH	Et_3N 10 mmol	Florisil column

11) R. D. Guthrie and G. R. Weisman, *Chem. Commun.*, **1969**, 1316.

b) Oxidation of II with HgO in the Presence of Triethylamine. Triethylamine (1.0 g, 10 mmol) and mercury(II) oxide (6.487 g, 30.0 mmol) were added to a benzene solution (100 ml) of II (2.609 g, 6.10 mmol), and the mixture was refluxed for 2 hr. It was filtered, and the filtrate was washed with water, dried and then concentrated. Florisil column chromatography of the residue yielded V (0.328 g, 1.35 mmol), III (0.712 g, 2.74 mmol) and VII (0.600 g, 1.5 mmol). The addition of S-benzylisothiourea hydrochloride to the aqueous washings gave crystals of *p*-toluenesulfonate (0.483 g, 1.43 mmol). VII, mp 158 °C; IR; 1150, 1300, 1320 cm^{-1}(S–O); NMR($CDCl_3$), δ, 2.36(s, 3H), 5.55(s, 1H), 6.95~7.89 (m, 18 H); Found: C, 78.19; H, 5.58; S, 8.72%. Calcd for $C_{26}H_{22}O_2S$: C, 78.37; H, 5.57; S, 8.05%.

c) Oxidation of II with HgO in Pyridine. A mixture of II (3.420 g, 8.0 mmol), pyridine (40 ml) and mercury(II) oxide (2.07 g, 9.6 mmol) was stirred at 60—70 °C. After the evolution of gas ceased, the mixture was filtered, and the pyridine was removed by vacuum distillation of the filtrate. The residue was found to contain VI and VII in a 7 : 10 ratio from its NMR spectrum($CDCl_3$). When the residue was subjected to Florisil column chromatography, V (7.1 mol%), IV (2.8 mol%), III (42 mol%), and VII (32 mol%) were isolated. Therefore, the amount of VI present before the chromatography can be calculated as 22 mol% ($32 \times 7/10$).

Reaction between II and Triethylamine. A mixture of II (0.838 g, 1.96 mmoles), triethylamine (1.0 g) and benzene (50 ml) was refluxed for 18 hr. When it was washed with aq Na_2CO_3 and the organic layer was concentrated, V was obtained; 0.460 g, 1.91 mmoles (98 mol%). When the aqueous layer was concentrated and S-benzylisothiourea hydrochloride was added, *p*-toluenesulfinate salt was obtained; 0.423 g, 1.31 mmol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2504—2511 (1973)

Photochemical Reactions of Enamino Ketones[1)]

Kazutoshi YAMADA, Takeo KONAKAHARA, and Hirotada IIDA

Department of Synthetic Chemistry, Faculty of Engineering, Chiba University, Yayoicho, Chiba 280

(Received February 21, 1973)

Photochemical reactions of *N*-aryl enamino ketones including one enone system and one divinylamine system in the molecule were examined. Photochemical behaviours of *N*-aryl enamino ketones differed for the tertiary and secondary amines involved. While 5,5-dimethyl-3-(*N*-methylanilino)cyclohex-2-en-1-one gave an oxidative cyclization product, 3-anilino-5,5-dimethyl-cyclohex-2-en-1-one gave two major products and a minor one. One of the major products was characterized as 3,3-dimethyl-5-hydroxy-3,4-dihydro-1-benzazocines by their elemental analyses and spectroscopic properties. The compounds showed 6π system pseudo aromaticity in their NMR spectra. The temperature-dependent NMR signals for *gem*-dimethyl protons were due to the flapping of the 8-membered ring. The reduction product with diborane was identified as 1,2,3,4,5,6-hexahydro-1-benzazocine by comparison with an authentic sample. The other major product was a ketene adduct and the minor product, a lactone.

N-Aryl enamino ketones involve both a conjugated enone and a divinylamine system in the molecules. Molecular rearrangement reactions of conjugated enones such as cyclohexenones are known as those of cyclohexadienones.[2)] Divinylamines are isoelectronic with pentadienyl anion. The former was reported to give similar cyclization products.[3)] Linschitz and Grellmann[4)] obtained carbazole derivatives on irradiation of *N*-substituted diphenylamines. Chapman and his co-workers[5)] reported on the nonoxidative photocyclization of *N*-methylaniline enamines to give *trans*-hexahydrocarbazoles. However, all the reactions were of *N*-substituted tertiary amines and we could find no report of photoreactions of *N*-unsubstituted secondary enamines, except for that of diphenylamine which is converted into carbazole with a considerable number of side reactions.[4)] Enamino ketones including these two functional groups are also of importance as intermediates in organic syntheses,[6)] and various investigations have been reported.[7-10)] Photoreactions

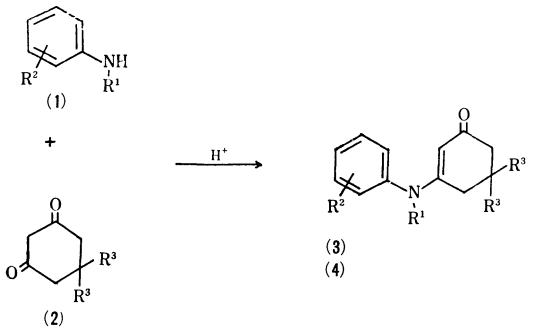
of this type of compound, however, have been investigated only for the photocycloaddition of lycopodine derivatives with allene[11a] or methyl methacrylate,[11b] the photodimerization of 1-methylthymine,[12] photoreduction of kynuric acid with sodium sulfite,[13] and the photoisomerization of 1,2-diphenyl-6-methyl-2,3-dihydro-4-pyridone.[14]

In this paper we wish to report photocyclization reactions of *N*-aryl enamino ketones.[1] Irradiation of 3-(*N*-methylanilino)-5,5-dimethylcyclohex-2-en-1-one in nitrogen-saturated ether gave 2,3-dihydro-2,2,9-trimethylcarbazol-4(1*H*)-one in good yields. No corresponding product was obtained on irradiation of an *N*-unsubstituted 3-anilinccyclohex-2-en-1-one derivative in benzene solution. This compound gave two major and one minor products. One of the major products was characterized as 3,3-dimethyl-5-hydroxy-3,4-dihydro-1-benzazocine by its spectroscopic properties. The reactions of five *N*-unsubstituted enamino ketones (Scheme I) were investigated. The enamino ketones were prepared by the condensation of cyclohexane-1,3-diones with the corresponding anilines in the presence of a trace amount of concentrated sulfuric acid or *p*-toluenesulfonic acid in toluene (see Experimental).

Results and Discussion

Preparation of Enamino Ketones. The enamino ketones (**3** and **4**) were prepared from aniline derivatives (**1**) and 5,5-dimethylcyclohexane-1,3-dione or cyclohexane-1,3-dione (**2**) in the presence of sulfuric acid or *p*-toluenesulfonic acid by azeotropic distillation employing a Dean-Stark trap. The enamino ketones (**4c** and **4b**) were prepared by methylation of the hydroxyl derivatives with diazomethane. Ketones (**3** and **4**) are illustrated in Scheme 1 (for the yields and physical data see Experimental). Their spectral data are in line with the expected structures.



(**3**) $R^1=CH_3$, $R^2=H$, $R^3=CH_3$

(**4**) **a**, $R^1=R^2=H$, $R^3=CH_3$
b, $R^1=H$, $R^2=3'$-Cl, $R^3=CH_3$

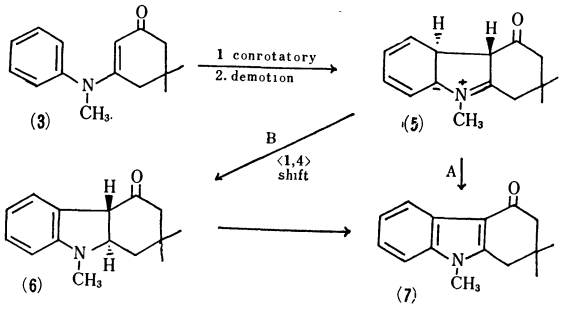
Scheme 1.

Irradiation of 3-(N-Methylanilino)-5,5-dimethylcyclohex-2-en-1-one. Irradiation of 3-(*N*-methylanilino)-5,5-dimethylcyclohex-2-en-1-one (**3**) in ether (5.5×10^{-3} M) with a 450-W Pyrex-jacketed immersion lamp (>3000 Å) under nitrogen gave a major product together with a minor one. The major product (mp 137—138 °C, yield, 38%) isolated after the evaporation of ether and crystallization from *n*-hexane–benzene (4 : 1), was identified as 2,3-dihydro-2,2,9-trimethylcarbazol-4(1*H*)-one (**7**) by comparison of spectroscopic properties with a known sample.[15] A benzene solution of **3** was also irradiated to give the same product. Attempted isolation of the minor product by column chromatography on silica gel was not successful. The photoproduct, which may be a nonoxidative hexahydrocarbazole intermediate, could not be identified or isolated, since it was unstable under these conditions. The oxidative photochemical cyclization can be considered as an electrocyclic reaction of a divinylamine. Its excited-state (probably n,π^* triplet[16]) closure should take a conrotatory course according to the Woodward-Hoffmann rule.[5,17] The initially formed dipolar ion intermediate (**5**) analogous to the observed one in oxidative photocyclization of diphenylamine,[4] seemed to give a final product through two possible reaction paths (Scheme 2).



Scheme 2.

Path A gives the final product directly by oxidation with the residual air in the flask or elimination of two hydrogen atoms due to enolization; path B involves a *trans*-hexahydrocarbazole intermediate (**6**) formed by a thermal, suprafacial<1,4>sigmatropic shift of a hydrogen atom.

In order to examine the molecular orbital implication of this reaction, the bond orders (p_{rs}), frontier densities (f_r), and superdelocalizabilities (S_r) were

11) a) K. Wiesner, I. Jirkovsky, M. Fishman, and C. A. J. Williams. *Tetrahedron Lett.*, **1967**, 1523; b) Z. Koblicova and K. Wiesner, *ibid.*, **1967**, 2563, and analogous reaction was reported by Cantrell (T. S. Cantrell, *Tetrahedron*, **27**, 1227 (1971)).

16) The photoreaction of enamino ketone (**3**) carried out with a low-pressure mercury arc lamp, filtered with a quartz plate (2537 Å), gave the same photoproducts as those obtained with a high-pressure mercury arc lamp but in a lower yield (**7**, 13%). Benzene was employed as the solvent, and the minor product was not isolated.

17) R. B. Woodward and R. Hoffmann, "The Conservation of Orbital Symmetry," Verlag Chemie, GmbH, Academic Press Inc., New York (1970).

calculated for 3-(*N*-methylanilino)-5,5-dimethylcyclohex-2-en-1-one (**3**), and the values compared with experimental results. The usual parameters[18] were used in the calculations. The bond orders in the ground state and in the first excited state between C–3 and C–7 are calculated as follows:

	G	n,π^*	π,π^*
P_{37}	0.0861	0.0785	−0.0540

S_r values for radical reaction are also illustrated in Fig. 1. Since the P_{37} value for the n,π^* excited state is larger than that of π,π^*, the photoreaction occurs more favorably through the former state. This is in good agreement with experimental facts.[16] The S_r and f_r values for radical reaction at C–3 and C–7 indicate that these positions are more reactive than the others.

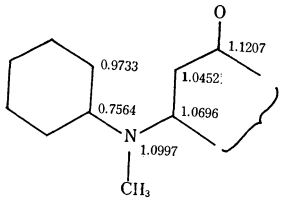

Fig. 1.

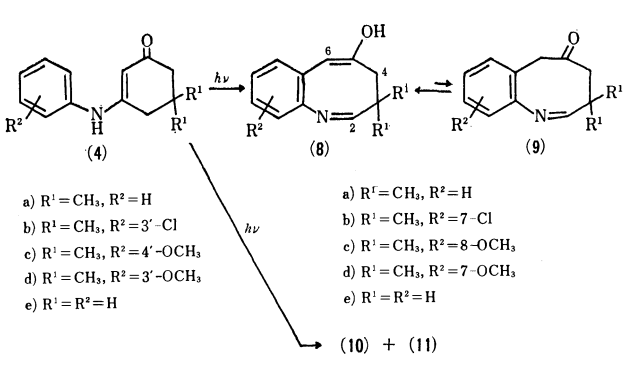
$S_r^{(R)}$ values of the enamino ketone (**3**)

Irradiation of 3-Anilino-5,5-dimethylcyclohex-2-en-1-one. For the irradiation of 3-anilino-5,5-dimethylcyclohex-2-en-1-ones (**4**), a benzene solution was employed because of lower solubility of enamine ketones (**4**) in ether. The solution of **4** was irradiated for 0.5 to 2 hours under the same conditions as for **3** to give two major products (**8** and **10**) and a minor one (**11**) (Scheme 3). Yields of **8a**—**e** are summarized in Table 1. In the case of (**4b**) the tlc R_f values (silica gel, benzene–ethyl acetate 9 : 1) were 0.81, 0.68, and 0.54, respectively. One of the two major products with a R_f value 0.68, **8b**, was characterized as 7-chloro-3,3-dimethyl-5-hydroxy-3,4-dihydro-1-benzazocine by its elemental analysis and physical properties. Elemental analysis and high resolution mass spectrum indicate the molecular formula $C_{13}H_{14}NOCl$, formed by elimination of methylene group from the starting material (**4b**). The molecular formula involves one oxygen atom, but the IR spectrum showed a carbonyl band at 1698 cm^{-1} and a hydroxy-absorption at 3324 cm^{-1}. This coexistence of the carbonyl and a hydroxy-absorption indicates the presence of a keto-enol equilibrium (Scheme 3). Measurements of IR spectra of **8b** in various solvents showed a remarkable change in the ratio $D(\nu_{OH})/D(\nu_{C=O})$ of the absorbance for the two absorption bands (Table 2). This indicates that solvation in polar solvents stabilizes the enol form giving rise to an increase of the ratio $D(\nu_{OH})/D(\nu_{C=O})$. This is also supported by the fact that only absorption due to enol form at 3170 cm^{-1} and 1198 cm^{-1} was observed in tetrahydrofuran solution highly diluted with carbon tetrachloride.

TABLE 1. SUMMARY OF YIELDS OF (**8**)

Compound	Conversion (%)	Yield (%)
8a	25	14
8b	19	12
8c	25	20
8d	90	17
8e	4	3



Scheme 3.

TABLE 2. SUMMARY OF IR SPECTRAL DATA OF **8b** IN VARIOUS SOLVENTS

Solvent	ν_{OH} (cm^{-1})	$\nu_{C=O}$ (cm^{-1})	$\nu_{C=N}$ (cm^{-1})	ν_{C-O} (cm^{-1})	$D(\nu_{OH})/D(\nu_{C=O})$
KBr	3324	1698	1630	1200	0.4
CCl_4	3200	1713	1640	1200	1.0
Dioxane	3175	1713	1632	1198	2.0
THF[a]	3170	1713	1632	1198	2.7
CCl_4[b]	3170	—	—	1198	—

a) THF: tetrahydrofuran.
b) THF solution **8b** was highly diluted with CCl_4. Only the absorption bands at 3170 (strong) and 1198 cm^{-1} (medium) were observed.

The absorption bands at 1382, 1367, and 1215 cm^{-1} indicate the presence of *gem*-dimethyl group. This was further supported in the NMR by the presence of a signal at $\delta(CCl_4, TMS)$ 1.28 (singlet, 6H) and by the absence of a signal assignable to a methine proton in the range δ 2—5 (Table 3). The mass spectrum showed a fragment ion peak ($C_{12}H_{11}NOCl$, 220.0400, base) formed by elimination of methyl radical from the molecular ion ($C_{13}H_{14}NOCl$, 235.0743) with a "flat-topped metastable" ion (m^*=206), indicating the presence of a *gem*-dimethyl group (Scheme 4-1).[18,19] A broad NMR signal at δ 6.18 (1H) exchangeable with deuterium oxide and a singlet-like signal at δ 6.98 (1H) were assigned to the enolic hydroxyl proton at C–5 and vinyl proton at C–6, respectively. An aryl substitution of the vinyl group shifts the *gem*-proton signal downfield to the range δ 6—8.5 compared with that of alkyl substituted one (δ *ca.* 5.5) because of deshielding by the ring. The IR spectra of **8a** and **8e** (753 and 694 cm^{-1}; 753 and 692 cm^{-1}) and their NMR spectra indicate the presence of an *ortho*-

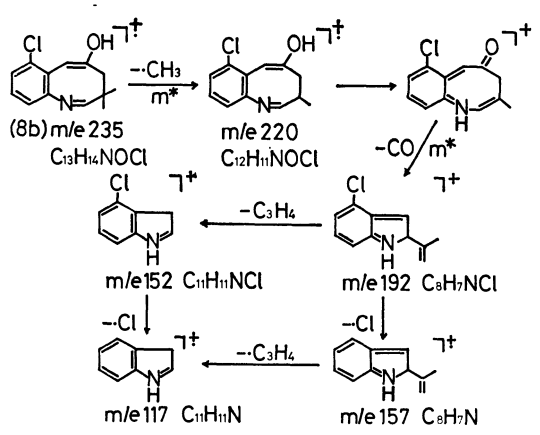
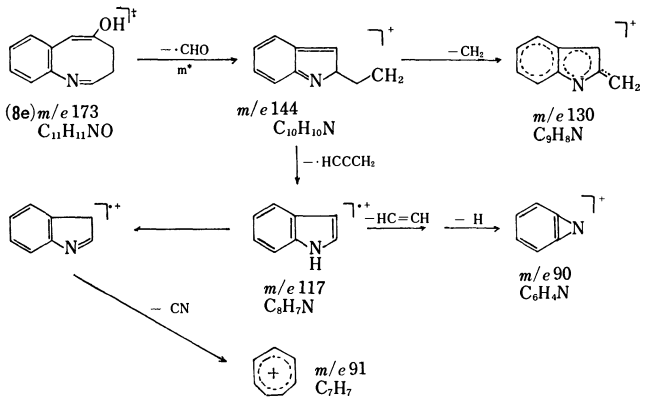


Scheme 4-1.



Scheme 4-2.

disubstituted phenylene group. The latter showed AA'BB' patterns. The spectroscopic data showed 1,2,3-trisubstitution of **8b** and **8d**, and those of **8c** 1,2,4-trisubstitution (see Experimental and Table 3). A strong C–N stretching absorption at 1295 cm^{-1} and a C=N stretching absorption at 1630 cm^{-1} in the IR spectrum of **8b** suggested the presence of an anil system. This was also supported by an NMR signal at δ 6.37 (singlet, 1H) (see Tables 2 and 3). The singlet signal indicated that the carbon adjacent to the anil group was quaternary. The corresponding signal of **8e** at δ 6.59 was a one-proton triplet (J=3.0 Hz), coupled with a two-proton triplet signal at δ 2.62 (J=4.5 and 3.0 Hz) for the methylene protons. The coupling was demonstrated by the double resonance. A two-proton triplet at δ 2.3 (J=4.5 Hz) of **8e**, coupled with the methylene described above, corresponded to a two-proton singlet at δ 2.24 of **8b**.[20,21]

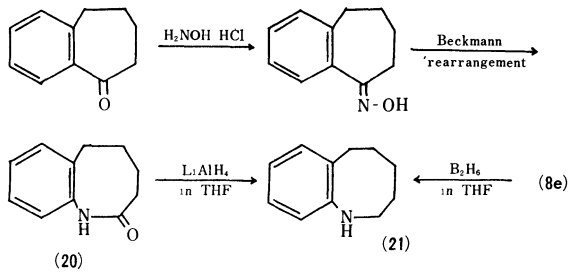
Structure **8** including a dihydroazocine ring, can now be written. Its UV spectrum showed more reasonable absorption maxima (λ_{max} (EtOH) 257 (ε 15800) and 305.5 nm (7010)) for the chromophores compared with those of the related compounds (styrene, λ_{max} (EtOH) 244 (ε 12000) and 282 nm (500); *ortho*-aminostyrene, λ_{max} 240 (ε 10000) and 332 nm (1600); diethylketone-anil, λ_{max} 250 (ε 12000) and 300 nm (2000); 2-methoxyazocine, λ_{max} (isooctane) 214 (ε 8750) and 305 nm (350)).

The mass spectrum of **8b** showed three intense peaks (except isotopic peaks due to ^{37}Cl) at *m/e* 235 (molecular ion $M^{+\cdot}$ peak, 40.5% of base), 220 (base), and 192 (40.2% of base) with some weak peaks (Scheme 4-1). The empirical formula of each fragment ion was determined by means of high-resolution mass spectrometry (see Experimental).

The structure was confirmed by the fact that reduction of **8e** with diborane in tetrahydrofuran gave a product identical with authentic 1,2,3,4,5,6-hexahydro-1-benzazocine (**21**), which was prepared from benzo-2-cycloheptenone oxime (Scheme 5).

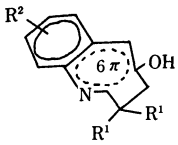
20) No signals assignable to ring-juncture hydrogens for one of the tautomeric isomers, 3,4-dihydro-3,3-dimethylcyclopent[*b*]-indolin-1(2*H*)-one, were found, which were found at δ 3.5 (multiplet) in the spectrum of 1*b*,4-dimethyl derivative.[21]

21) The NMR spectral data were kindly supplied by Prof. Dr. Yoshio Ban (Hokkaido University).



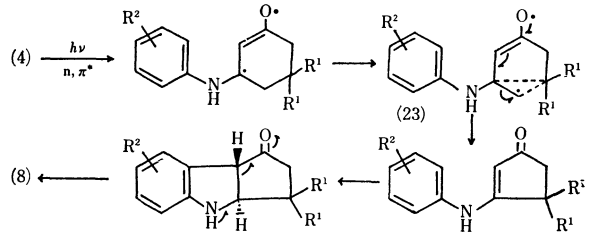
Scheme 5.

Eu(dpm)$_3$-induced shifts in the NMR were used for obtaining information on the conformation of **8b**. The shift-values ($\Delta Eu=\delta_{Eu}-\delta_0$) for the *gem*-dimethyl were 0.93 and 1.01 ppm (in CCl_4) and 1.16 ppm for methylene. The former methyl signal was assignable as *endo*, and the latter as *exo* (Formula **22**). The temperature-dependent NMR signal for the *gem*-dimethyl of **8b** may be considered to be due to the 8-membered ring-flapping of **22**: half height width $b_{1/2}$ 1.25 Hz at 36 °C; 1.75 Hz at −10 °C; 3.65 Hz at −20 °C; 4.90 Hz at −30 °C. The stability of the compounds, the downfield-shifts of signals for protons at 2- and 6-positions, and the stability of the enol-form can be



(**22**)

attributed to the 6π system pseudo aromaticity. The spectra (UV, IR, NMR, and mass) of other derivatives prepared from (**4a**—**e**) were in accord with the structures (**8a**—**e**). A possible reaction path is illustrated in Scheme VI. The higher yield of **4a**—**d** than of **4e** is considered to be due to the stabilization of the radical or charge at the *tertiary* center of (**23a**—**d**, $R^1=CH_3$).



Scheme 6.

Irradiation of hydroxyl derivatives of the enamino ketone (**4**, $R^1=CH_3$, $R^2=3'$ -and 4'-OH) in benzene gave rise to less destruction of the starting material, isolation of traces of similar photoproducts not being possible.

The other major product (**10**) was ketene adduct and the minor one (**11**) a lactone (see Experimental).

Experimental

All melting points and boiling points are uncorrected. Melting points were measured with a Yanagimoto micro melting point apparatus. Ultraviolet spectra were recorded on a Hitachi EPS-3T spectrophotometer. Infrared spectra were recorded on Model IR-G and IR-S (Japan spectroscopic Co., Ltd.) spectrometers. NMR spectra were recorded with JNM 4H-100, Hitachi H-60 and Varian HA-100D high resolution spectrometers for solutions in deuteriochloroform, carbon tetrachloride, or methanol-d_4. The temperature-dependent NMR spectra were measured on a Varian A-60D in a deuteriochloroform solution at −30, −20, −10, and 36 °C. Chemical shifts are reported in δ (internal tetramethylsilane). The mass spectra were obtained with Hitachi RMU-6E (for normal mass spectra), JMS-OlSG (Japan Electron Optics Lab., for high resolution mass spectra), and CEC11OB (for high resolution mass spectra) mass spectrometers at 70 eV. Elemental analyses were performed at the Institute of Physical and Chemical Research.

*Preparation of Enamino Ketones (**3**) and (**4a**).* 5,5-Dimethyl-3-(*N*-methylanilino)cyclohex-2-en-1-one (**3**) and 3-anilino-5,5-dimethylcyclohex-2-en-1-one (**4a**) were prepared from 5,5-dimethylcyclohexane-1,3-dione[22] and anilines (*N*-methylaniline and aniline) in the presence of sulfuric acid by azeotropic distillation with toluene; **3**: mp 80 °C (lit,[9] 84 °C), M^+ 229; **3a**: mp 184—185 °C (lit,[9] 181 °C).

*3-(3'-Chloroanilino)-5,5-dimethylcyclohex-2-en-1-one (**4b**).* *m*-Chloroaniline (1.96 g, 0.015 mol), 5,5-dimethylcyclohexane-1,3-dione (2.14 g, 0.015 mol) and toluene (300 ml) were refluxed in the presence of sulfuric acid in a flask equipped with a Dean-Stark trap for 6 hr. The reaction mixture was treated by the usual method to give 3.34 g (87.0%) of the pure enamino ketone: mp 153 °C (from benzene); UV λ_{max}(EtOH) 230 (ε 8790), 315 nm (24200); IR (KBr) 3100, 1590, 780, and 715 cm^{-1}; NMR ($CDCl_3$, 60 MHz) 6.84—7.35 (m, 5, aromatic and N-H), 5.52 (s, 1, vinyl), 2.32 (s, 2, methylene-4), 2.18 (s, 1, methylene-6), and 1.08 (s, 6); mass spectrum (70 eV) *m/e* (rel. intensity) 251 (27), 249 (81; M^+), 234 (21), 232 (34), 221 (10), 206 (14), 195 (34), 194 (42), 193 (100), 192 (95), 178 (9), 167 (12), 166 (22), 165 (24), 164 (43), 152 (10), 130 (44), 127 (11), 126 (12), 111 (17), 76 (12), 68(28).

Found: C, 67.42; H, 6.60%. Calcd for $C_{15}H_{16}NOCl$: C, 67.32; H, 6.47%.

*5,5-Dimethyl-3-(4'-hydroxyanilino)cyclohex-2-en-1-one (**4**, $R^1=H$, $R^2=4'$-OH, $R^3=CH_3$).* *p*-Aminophenol (1.0 g, 0.01 mol), 5,5-dimethylcyclohexane-1,3-dione (1.4 g, 0.01 mol), and toluene (200 ml) were heated for 4 hr under the same conditions as for **4b**. The resulting solid product was filtered, and washed with cold water. Recrystallization from ethanol gave 0.88 g (37%) of the enamino ketone; mp 227—230 °C; UV λ_{max}(EtOH) 304 nm (ε 17100), mass spectrum *m/e* 231 (M^+).

*5,5-Dimethyl-3-(4'-methoxyanilino)cyclohex-2-en-1-one (**4c**).* To a solution diazomethane[23] in 500 ml of ether, generated from nitrosomethylurea (6.2 g, 0.06 mol), was added 5,5-dimethyl-3-(4'-hydroxyanilino)cyclohex-2-en-1-one (4.10 g, 0.018 mol) in 100 ml of ethanol, allowed to stand overnight in an ice-box. Tlc indicated the presence of the starting material and the product (silica gel with benzene–ethyl acetate 1 : 1, R_f value 0.7 and 0.6, respectively). This was recrystallized from ethyl acetate to give 1.17 g (34%) of the pure enamino ketone (colorless needles): mp 194 °C (lit,[24] 189—190 °C); UV λ_{max} (EtOH) 314 nm (ε 19700); IR (KBr) 3370, 3150, 1610, and 1550 cm^{-1}; NMR methanol-d_4, 100 MHz) δ 7.08 and 6.89 (AA'MM' pattern,

4, $J_{AM}=J_{A'M'}=8$ Hz, aromatic), 5.28 (s, 1, vinyl), 3.75 (s, 3, $-OCH_3$), 2.38 (s, 2, methylene-4), 2.16 (s, 2, methylene-6), and 1.08 (s, 6, *gem*-dimethyl); instead of the N–H proton signal, increase of the OH signal (δ 4.75) of methanol was observed; mass spectrum (70 eV) *m/e* (rel. intensity) 246 (20), 245 (100), 230 (10), 228 (26), 217 (13), 202 (12), 190 (16), 189 (88), 175 (10), 174 (71), 160 (10), 146 (12), 123 (12), 122 (23), 108 (11).

*5,5-Dimethyl-3-(3'-hydroxyanilino)cyclohex-2-en-1-one (**4**, $R^1=H$, $R^2=3'$-OH, $R^3=CH_3$).* Prepared from 5,5-dimethylcyclohexane-1,3-dione (1.4 g, 0.01 mol) and *m*-aminophenol (1.0 g, 0.01 mol) as yellow prisms (from ethanol, 41%): mp 246 °C; UV λ_{max} (EtOH) 314 nm (ε 25500); mass spectrum (70 eV) *m/e* 231 (M^+).

Found: C, 72.28; H, 7.42; N, 5.97%. Calcd for $C_{14}H_{17}NO_2$: C, 72.70; H, 7.41; N, 6.06%.

*5,5-Dimethyl-3-(3'-methoxyanilino)cyclohex-2-en-1-one (**4d**).* Prepared by methylation of 5,5-dimethyl-3-(3'-hydroxyanilino)cyclohex-2-en-1-one (**2**, $R^1=H$, $R^2=3'$-OH, $R^3=CH_3$) with diazomethane as light yellow needles (from benzene, 73.2%): mp 118 °C; UV λ_{max} (EtOH) 314 nm (ε 20400), λ_{max} (acidic EtOH) 301 nm (ε 17700); IR (KBr) 3425, 3245, 1605, and 1583 cm^{-1}; NMR ($CDCl_3$, 100 MHz) 7.2 (m, 1, aromatic proton-2'), 7.1 (broad, 1, N–H), 6.68 (m, 3, aromatic), 5.57 (s, 1, vinyl), 3.72 (s, 3, $-OCH_3$), 2.32 (s, 2, methylene-4), 2.15 (s, 2, methylene-6), and 1.05 (s, 6, *gem*-dimethyl); mass spectrum (70 eV) *m/e* (rel. intensity) 245 (98, M^+), 228 (49), 217 (9), 202 (13), 189 (83), 174 (17), 160 (100), 146 (28), 130 (27), 122 (10), 117 (11), 107 (11) 92 (18), 83 (14), 77 (25).

Found: C, 73.67; H, 7.97; N, 5.52%. Calcd for $C_{15}H_{19}NO_2$: C, 73.47; H, 7.76; N, 5.71%.

*3-Anilinocyclohex-2-en-1-one (**4e**).* Aniline (4.3 g, 0.046 mol), cyclohexane-1,3-dione (5 g, 0.045 mol) and toluene (600 ml) were heated for 5 hr under the same conditions as for **4b**. The product was recrystallized from benzene–ethyl acetate to give 6.36 g (76%) of the pure enamino ketone (**4e**) (colorless prisms): mp 182 °C (lit,[25] 179—181 °C); UV λ_{max} (EtOH) 225 (ε 6650) and 309 nm (18700); IR (KBr) 3245, 1590, 1570, 1530, 750, and 706 cm^{-1}; NMR ($CDCl_3$, 100 MHz) 7.0—7.7 (m, 6, aromatic and N–H), 5.53 (s, 1, vinyl), 2.49 (t, 2, $J_{4.5}=6$ Hz, methylene-4), 2.3 (t, 2, $J_{6.5}=6$ Hz, methylene-6), and 1.96 (p, 2, $J_{5,4}=J_{5,6}=6$ Hz, methylene-5), mass spectrum (70 eV) *m/e* (rel. intensity) 188 (13), 187 (77, M^+), 186 (18), 170 (26), 160(13), 159 (100), 158 (50), 144 (14), 131 (22), 130 (54), 117 (9), 93 (23), 92 (35), 85 (11), 77 (36).

Irradiation of Enamino Ketones. All n,π^* irradiations were carried out in a flask equipped with a Pyrex-jacketed immersion lamp at its center. An Ushio Type UM-452 450-W mercury lamp was used as the light source. π,π^* Irradiations were also carried out in the same manner with a quartz-jacketed immersion lamp (Ushio Type ULI-8BQ 80-W). For the sake of complete dissolution the enamino ketones were agitated in ether or benzene for 30 min with a magnetic stirring bar. Agitation and bubbling of dry nitrogen were continued during the course of preparation of the solution and irradiation. The progress of reaction was monitored by tlc.

*Irradiation of 5,5-Dimethyl-3-(N-methylanilino)cyclohex-2-en-1-one (**3**) in Ether with High Pressure Mercury Arc Lamp.* A solution of enamino ketone (**3**) (500 mg, 2.18 mmol) was irradiated in 750 ml of ether (5.5×10^{-3} M) for 4 hr. Tlc (silica gel) revealed a decrease in the amount of starting material and the presence of one major product and one minor one. Evaporation of the solvent *in vacuo* at room temperature left an oily residue. The product soluble in *n*-hexane was separated to give 75 mg of 2,3-dihydro-2,2,9-trimethylcarbazol-4(1*H*)-one (**7**) (conversion 40%,[24] yield 38%). Recrystallization from *n*-hexane–benzene (4 : 1) gave 41 mg of light-yellow needles: mp 137—138 °C; mass spectrum (70 eV) *m/e* (rel. intensity) 227 (86, M^+), 171 (100, $M-C_4H_8$), 143 (52, $M-C_4H_8-CO$)), 128 (10, C_9H_6N), 115 (15, C_8H_5N).

Isolation of the minor product by column chromatography on silica gel was not possible.

*Irradiation of 5,5-Dimethyl-3-(N-methylanilino)cyclohex-2-en-1-one (**3**) in Benzene with High Pressure Mercury Arc Lamp.* A solution of enamino ketone (**3**) (200 mg, 0.87 mmol) was irradiated in 20 ml of benzene (4.4×10^{-2} M) for 8 hr. Tlc (silica gel) of the product mixture showed the presence of same two products as in the case of irradiation in ether.

*Irradiation of 5,5-Dimethyl-3-(N-methylanilino)cyclohex-2-en-1-one (**3**) in Benzene with Low Pressure Mercury Arc Lamp.* A solution of enamino ketone (**3**) (200 mg, 0.87 mmol) was irradiated in 20 ml of benzene (4.4×10^{-2} M) for 16 hr at *ca.* 10 °C with a low pressure mercury arc lamp. Tlc (silica gel) of the product mixture showed the presence of the same two products as in the case of irradiation with high pressure mercury arc lamp. Column chromatography on silica gel (0.05—0.20 mm, E. Merck) in *n*-hexane containing increasing amount of benzene gave 25 mg of the carbazole (**7**) (13%).

*Irradiation of 3-Anilino-5,5-dimethylcyclohex-2-en-1-one (**4a**).* Four grams of enamino ketone (**4a**) was divided into five 800 mg portions, and each portion was dissolved in 2 l of benzene (2.3×10^{-1} M). After irradiation for 2 hr, the solvent was evaporated to 10 ml *in vacuo* below 30 °C. The resulting light-brown crystals and the starting material (compared with standard material by tlc) were separated by decantation and the mother liquor was evaporated to give 160 mg of the photoproducts. They were composed of 3,3-dimethyl-5-hydroxy-3,4-dihydro-1-benzazocine (**8a**) (one of the two major products), ketene adduct (**10a**), lactone (**11a**) (minor product), and polymerized products (tlc analysis on silica gel; R_f values 0.73, 0.83, 0.69, and 0.0, respectively; benzene–ethyl acetate 4 : 1). The combined mother liquor of five portions (820 mg) were chromatographed over silica gel eluted with *n*-hexane–benzene. The first band gave **10a** recrystallized from *n*-hexane as light-yellow crystals, 11%): mp 177—178 °C, UV λ_{max} (EtOH) 271.5 nm (ε 45600); IR (KBr) 3360, 1630, 1600, 1530, 1500, 750, and 700 cm^{-1}; NMR ($CDCl_3$, 100 MHz) 7.24 (m, 10), 6.10—6.70 (m, 3), 2.35 (q, 1), 1.35 (d, 3), and 1.32 (s, 3); mass spectrum (70 eV, high resolution) *m/e* 304 ($C_{20}H_{20}N_2O$ (M^+, obsd. 304.1575 mu, error from calculated value -0.0030 mu), 289 $C_{19}H_{17}N_2O$ ($M-CH_3$. 289.1339, -0.0029), 261 $C_{18}H_{17}N_2$ ($M-CH_3+CO$), 261.1391, -0.0017), 212 $C_{14}H_{14}NO$ ($M-(CH_3+C_5H_3N)$, 212.1075, -0.0015), 197 $C_{13}H_{11}NO$ ($M-(CH_3+C_5H_3N+CH_3)$, 197.0841, 0.0013), 184 ($C_{13}H_{14}N$ ($M-(CH_3+CO+C_5H_3N)$, 184.1124, $+0.0045$), 169 ($C_{11}H_7NO$ ($M-(CH_3+C_5H_3N+CH_3+C_2H_4)$, 169.0528, -0.0079), 155 $C_{11}H_{12}$ ($M-(CH_3+CO+C_5H_3N+C_2H_2N)$, 144.0940, -0.0056), 118 C_9H_{10} ($M-(CH_3+CO+C_5H_3N+C_2H_2N+C_2H_2)$, 118.0748, -0.0037).

The second band gave 3,3-dimethyl-5-hydroxy-3,4-dihydro-1-benzazocine (**8a**): mp 70—73 °C (light-yellow needles from *n*-hexane), UV λ_{max} (EtOH) 229 (ε 10400) (Sh), 252.5 16200), 306 (4800, sh), and 315 nm (5100); IR (KBr) 3320 (OH), 1708 (C=O), 1630 (C=N), 1385, 1365, 1297 (Ar–N), 1215, 1182, 753, and 694 cm^{-1}; NMR: summarized

25) 300 mg of the starting material was recovered from the residue (insoluble to *n*-hexane).

in Table 3; mass spectrum (70 eV) *m/e* 201 (M^+), 186 ($M-CH_3$), 158 ($M-(CH_3+CO)$), 118 ($M-(CH_3+CO+C_3H_4)$), 77 (C_6H_5).

Found: C, 77.58; H, 7.51; N, 6.96%. Calcd for $C_{13}H_{15}NO$: C, 77.61; H, 7.46; N, 6.97%'

The third band gave a trace of **11a**: mp 100—101 °C (colorless); UV λ_{max} (EtOH) 270.5 nm (ε 27100); mass spectrum (70 eV) *m/e* 229 (M^+).

*Irradiation of 3-(3'-Chloroanilino)-5,5-dimethylcyclohex-2-en-1-one (**4b**).* Enamino ketone (**4b**) (2.11 g, 8.6 mmol) was divided in to three portions, each portion being dissolved in 2 l of benzene. In one case, 702.55 mg was dissolved in 2 l of benzene (1.4×10^{-3} M). The solution was irradiated for 30 min and then concentrated to 10 ml *in vacuo* below 30 °C. Removal of the starting material by the same method as that for **4a** left an oily product. Column chromatography of the combined oily products (409 mg) on silica gel (30 g) in *n*-hexane containing an increasing amount of benzene gave 42 mg of **10b** (24%), 21 mg, of **8b**, and 16 mg of **11b** (9% isolated). **10b**: mp 156 °C (yellow needles from *n*-hexene); UV λ_{max} (EtOH) 274.6 (ε 41960) and 349.5 nm (510): IR (KBr) 3340, 1630, 1599, 1525, 1485, 783, and 700 cm^{-1}; NMR ($CDCl_3$, 60 MHz) 7.22 (s, 2), 6.76—7.15 (m, 6), 6.3—6.7 (broad, 3), and 1.37 (s, 6); mass spectrum (70 eV, high resolution) *m/e* 372 $C_{20}H_{18}N_2OCl_2$ (M^+, obsd. 372.0732 mu, error −0.0065), 357 $C_{19}H_{15}N_2OCl_2$ ($M-CH_3$, 357.0519, −0.0041), 322 ($C_{19}H_{15}N_2OCl$ ($M-(CH_3+Cl)$, 322.0838, −0.0036), 246 $C_{14}H_{13}NOCl$ ($M-(CH_3+Cl+C_5H_2N)$, 246.0667. −0.0019), 231 $C_{13}H_{10}NOCl$ ((*m/e* 246)−CH_3, 231.0467, +0.0016), 218 ($C_{13}H_{13}NCl$ ((*m/e* 246)−CO, 218.0689, −0.0049), 211 $C_{14}H_{13}NO$ ((*m/e* 246)−Cl, 211.0976, −0.0023), 182 $C_{13}H_{12}N$ ((*m/e* 246) NO ((*m/e* 246)−Cl, 211.0976, −0.0023), 182 $C_{13}H_{12}N$ ((*m/e* 211)−CHO, 182.0920, −0.0051), 167 $C_{12}H_9N$ (167.0692, −0.0046), 152 $C_{11}H_6N$ (152.0576, +0.0076).

7-Chloro-3,3-dimethyl-5-hydroxy-3,4-dihydro-1-benzazocine (**8b**) was obtained from the second band: mp 104.5—105 °C (colorless needles from *n*-hexane); UV λ_{max} (EtOH) 257 (ε 15800) and 305.5 nm (7010); IR (KBr) 3324 (strong, OH), 1698 (strong, C=O), 1630 (strong, C=N), 1382, 1367, 1295 (strong, Ar–N), 1215, 1200, and 830 cm^{-1} (strong), and also see Table II; NMR; summarized in Table 3; mass spectrum (70 eV, high resolution) *m/e* 235 $C_{13}H_{14}NOCl$ (M^+, obs. 235.0743, error −0.0021), 220 $C_{12}H_{11}NOCl$ (220.0400, −0.0129), 192 $C_{11}H_{11}NCl$ (192.0434, −0.0146), 157 $C_{11}H_{11}N$ (152.0227, −0.0040), 117 C_8H_7N (117.0570, −0.0009), observed metastable peaks: 235→220 *m**=206 (calcd 206.0) "flat-topped", 220→192 *m**=168 (calcd 167.6) "flat-topped" (Scheme 4–1).

Found: C, 66.41; H, 6.17%. Calcd for $C_{13}H_{14}NOCl$: C, 66.38; H, 5.96%.

The third band gave **11b**: mp 98 °C (from *n*-hexane); UV λ_{max} (EtOH) 274 nm (ε 20000); NMR ($CDCl_3$, 60 MHz) 6.17—7.22(m, 6), 2.26 (broad d, 2), and 1.24 (t, 6); mass spectrum 70 eV) *m/e* 263 (M^+).

Found: C, 63.73; H, 5.40%. Calcd for $C_{14}H_{14}NO_2Cl$: C, 63.75; H, 5.31%.

*Irradiation of 5,5-Dimethyl-3-(4'-methoxyanilino)cyclohex-2-en-1-one (**4c**).* Four grams of enamino ketone (**4c**) were divided into ten portions. Each portion (400 mg) was added to 2 l. of benzene (0.82×10^{-3} M). The solution was irradiated for 4 hr at room temperature and evaporated to 10 ml. This was treated in the same way as for **4a**. 990 mg of the photoproducts were obtained from the combined mother liquor. Column chromatography on silica gel (45 g) in *n*-hexane containing an increasing amount of benzene gave 16.0 mg of 3,3-dimethyl-5-hydroxy-8-methoxy-3,4-dihydro-1-benzazocine (**8c**). This was recrystallized from *n*-hexane for analysis: mp 93—94 °C (light-yellow needles); UV λ_{max} (EtOH) 252 (ε 11700) and 316 nm (2900); IR (KBr) 3350 (strong, OH), 1705 (C=O), 1630 (C=N), 1390, 1369, 1300 (Ar–N), and 1180 cm^{-1}; NMR; summarized in Table 3; mass spectrum (70 eV) *m/e* (rel. intensity) 232 (11), 231 (65, M^+), 217 (17), 216 (100), 189 (6), 188 (38), 173 (5).

Found: C, 72.64; H, 7.44; N, 6.01%. Calcd for $C_{14}H_{17}NO_2$: C, 72.70; H, 7.41; N, 6.06%.

*Irradiation of 5,5-Dimethyl-3-(3'-methoxyanilino)cyclohex-2-en-1-one (**4d**).* Enamino ketone (**4d**) (1.26 g, 5.1 mmol) was added to 2 l of benzene (2.6×10^{-3} M). The solution was irradiated for 4 hr at room temperature and evaporated to 10 ml. After separation of the starting material, the products (1.12 g) were chromatographed on silica gel (50 g) in *n*-hexane containing an increasing amount of benzene to give 12.5 mg of 3,3-dimethyl-5-hydroxy-7-methoxy-3,4-dihydro-1-benzazocine (**8d**) (17%). This was recrystallized from petroleum ether for analysis: mp 84 °C (colorless needles); UV λ_{max} (EtOH) 215 (ε 19000), 252 (10700), and 299.5 nm (3700); IR (KBr) 3340 (strong, OH), 1706 (C=O), 1634 (C=N), 1381, 1365, 1300 (Ar–N), 1218 and 1200 cm^{-1}; NMR; summarized in Table 3; mass spectrum (70 eV) *m/e* (rel intensity) 232 (8), 231 (45, M^+), 217 (17), 216 (100), 189 (7), 188 (45), 173 (5), 148 (6), 77 (11).

Found: C, 72.83; H, 7.56%. Calcd for $C_{14}H_{17}NO_2$: C, 72.70; H, 7.41%.

*Irradiation of 3-Anilinocyclohex-2-en-1-one (**4e**).* Enamino ketone (**4e**) (5.41 g, 29 mmol) was divided into ten portions, and each portion was irradiated for 2 hr in 2 l of benzene (1.45×10^{-3} M). From the combined reaction mixture was recovered 5.20 g of the starting material. A mixture of the photoproducts (210 mg, conversion 3.9%) was chromatographed on silica gel (35 g) in *n*-hexane containing an increasing amount of benzene. Only the second band was isolated to give 5-hydroxy-3,4-dihydro-1-benzazocine (**8e**) (6.25 mg, 3%); mp 101—102.5 °C (yellow needles from *n*-hexane); UV λ_{max} (EtOH) 227 (ε 6700, sh), 254 (11000), 302 (3100, sh), and 313 nm (3400); IR (KBr) 3330 (strong, OH), 1697 (strong, CO=), 1635 (strong, C=N), 1282 (Ar–NO, 753, and 692 cm^{-1}; NMR; summarized in Table 3; mass spectrum (70 eV, high resolution) *m/e* 173 $C_{11}H_{11}NO$ (M^+, obsd. 173.0844 mu. error +0.003 mu), 144 $C_{10}H_{10}N$ (144.0797 −0.0016), 130 C_9H_8N (130.0646, −0.0011), 117 (C_8H_7N (117.0609, +0.0030), 91 C_7H_7 (91.0528, −0.0020), 90 C_6H_4N (90.0429, +0.0085) (see Scheme IV–2).

Cinnamylidenemalonic Acid. This was quantitatively prepared from cinnamaldehyde and malonic acid according to the procedure of Stuart:[27] mp 208—209 °C (decomp., yellow needles, lit, 208 °C decomp.); UV λ_{max} (EtOH) 236 (ε 3900) and 330 nm (14800).

δ-Phenylvaleric Acid. This was obtained by reduction of cinnamylidenemalonic acid with the Raney nickel followed by decarboxylation according to the reported procedure;[28] yield 80%: mp 57.0—58.8 °C(lit,[29] 58—59 °C); UV λ_{max} (EtOH) 238 (ε 72), 244 (95), 249 (136), 254.2 (183), 255.5 (181), 259.8 (213), 261.9 (215), 264.9 (165), and 268.7 nm (171).

Benzo-2-cycloheptenone. The cyclization procedure[26] in phosphoric acid–phosphorus pentoxide was employed. Yield 79%, bp 123—124 °C/6 mmHg (lit,[26] 90~93 °C/1 mmHg);

The Prins Reaction of Cyclooctene and Cyclododecene

Akira UCHIDA, Toyohiro MAEDA, and Sumio MATSUDA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita 565

(Received August 12, 1972)

The reaction products of the sulfuric acid-catalyzed condensation of cyclooctene or cyclododecene with formaldehyde in acetic acid at 40 °C were investigated. The reaction of cyclooctene gave a mixture of 4,5-hexamethylene-1,3-dioxane, 2-cyclooctenylmethyl acetate, and 1-acetoxy-2-acetoxymethylcyclooctane, while the reaction of cyclododecene gave a mixture of cyclic ethers; one was identified as 3-oxabicyclo[10,3,0]-6-pentadecene, and the others were estimated to be 15-acetoxy-3-oxabicyclo[9,3,1]pentadecane and 12,17-dioxatricyclo[13,3,0,$0^{10.14}$]-2-octadecene.

The condensation of cyclopentene or cyclohexene with formaldehyde in the presence of acid-catalysts, Prins reaction, has been the subject of several investigations,[1-5] and the mechanism of the acid-catalyzed reaction of cyclohexene in acetic acid has been studied quite extensively.[2-5] However, the acid-catalyzed condensation of medium-sized cyclic olefins with formaldehyde is almost unknown.

In this report, the sulfuric acid-catalyzed condensation of cyclooctene or cyclododecene with formaldehyde in acetic acid was investigated.

Results and Discussion

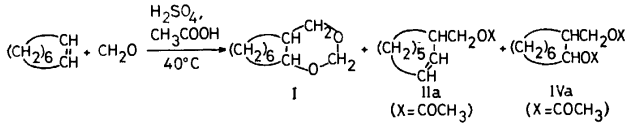
Reaction of Cyclooctene. Cyclooctene was treated with a 1.4-fold molar amount of paraformaldehyde in acetic acid in the presence of sulfuric acid. The reaction gave roughly two fractions. The glpc of the lower-boiling fraction indicated that it consisted of two components, I and IIa, and its IR spectrum demonstrated the presence of an ester group and an ether group in it. By the hydrolysis of the fraction with Claisen alkali, IIa was converted into 2-cyclooctenylmethanol (IIb), while I stayed unchanged. Compounds I and IIb were isolated by column chromatography on alumina. In the IR spectrum of I, the absorption of the ether group was observed at 1150—1030 cm^{-1} but no absorption of the ester group. On the NMR spectrum, there was a quartet at τ 5.1—5.6; this was attributed to the methylene protons adjacent to two oxygen atoms. On the basis of the elementary analysis and the spectroscopic properties of I, compound I was confirmed to be 4,5-hexamethylene-1,3-dioxane.

Compound IIa was isolated from the lower-boiling fraction by preparative glpc or by column chromatography on silica gel. The IR spectrum of IIa indicated the presence of an acetoxy group and a double bond in IIa. The position of the double bond was determined by a comparison of the NMR spectra of IIa and its hydrogenation product (III). The signals in the NMR spectrum of IIa at τ 7.5—7.9, which corresponded to 3H and to the allylic protons, disappeared in that of III. Thus, the double bond was assumed to be adjacent to the tertiary carbon atom. On the basis of the spectroscopic properties of IIa and IIb, they were identified as 2-cyclooctenylmethyl acetate and 2-cyclooctenylmethanol respectively.

The higher-boiling fraction was identified as 1-acetoxy-2-acetoxymethylcyclooctane (IVa). Compound IVa had the typical IR absorption of the acetoxy group at 1710 and 1220 cm^{-1}. In its NMR spectrum, two sharp signals of acetoxy protons at τ 8.80 and 8.10, and two multiplets of methyne and methylene protons at τ 5.3—5.0 and 6.4—6.1, were observed.

To determine the structure IVa was hydrolyzed with Claisen alkali to IVb (X=H); IVb was compared with authentic 2-hydroxymethylcyclooctan-1-ol prepared from cyclooctanone. The spectroscopic data and the glpc-retention times of the two compounds were identical. Thus, IVa was confirmed to be 1-acetoxy-2-acetoxymethylcyclooctane.

On the basis of the glpc of the crude reaction product, the product was found to contain 5 wt% of I, 20 wt% of IIa, 65 wt% of IVa, and 10 wt% of unknown substances.



Reaction of Cyclododecene. The reaction of cyclododecene with a 1.4-fold molar amount of paraformaldehyde in acetic acid in the presence of sulfuric acid was attempted. The fractional distillation of the reaction product gave, roughly, two fractions. The glpc indicated that the lower-boiling fraction consisted of V and that the higher-boiling fraction was a mixture of VIa and VII.

Compound V showed the typical IR absorption of ether group at 1050 and 1020 cm^{-1}, and the NMR signals at τ 6.0—6.4 and 6.5—7.0 were attributed to the oxygen-linked methylene protons. To determine the relative position of the double bond in V, compound V was hydrogenated to VIII and the NMR spectra of V and VIII were compared with each other. The proton counts of allylic protons at τ 7.5—8.2, which disappeared after the hydrogenation of V, were less than 4H; this suggested that the double bond was not flanked by two methylene group, but was, rather, situated adjacent to the tertiary carbon atom. To clarify

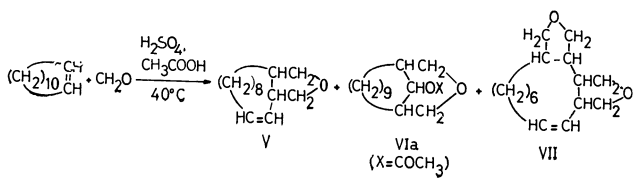
whether compound V had a 3,4-disubstituted tetrahydrofuran ring or a 3,4,5-trisubstituted tetrahydropyran ring, the ether ring in VIII was cleaved with hydrogen iodide and the resultant diiodomethyl compound was treated with lithium aluminum hydride to give IX. Compound IX demonstrated spectroscopic properties and glpc-retention times identical with those of authentic 1,2-dimethylcyclododecane prepared from 2-methyl-2-carbethoxycyclododecanone.

On the basis of the spectroscopic properties of V, VIII, and IX, and from these observations, they were identified as 3-oxabicyclo[10,3,0]-6-pentadecene (V), 3-oxabicyclo[10,3,0]pentadecane (VIII), and 1,2-dimethylcyclododecane (IX) respectively.

Compound VIa was isolated by a preparative glpc of the higher-boiling fraction. On the basis of the elementary analysis and the mass spectrum VIa was determined to be $C_{16}H_{28}O_3$. The IR and NMR spectra of VIa indicated the presence of an acetoxy group and an ether ring in it. To determine the size of the ether ring in VIa, VIa was converted to the tosylate, which was then treated with lithium aluminum hydride to give X.

If compound VIa had the 3,4-disubstituted tetrahydrofuran ring, X might be identical with VIII. Although the elementary analysis and mass spectra of VIII and X were identical, their IR and NMR spectra or their glpc-retention times were different. This obviates the presence of a 3,4-disubstituted tetrahydrofuran moiety in VIa.

Though there was no experimental evidence for the presence of a 3,4,5-trisubstituted tetrahydropyran ring in VI, it seemed reasonable to assume that VIa was 15-acetoxy-3-oxabicyclo[9,3,1]pentadecane, because no other ether ring could be formed from the mechanistic considerations and because such a 3,4,5-trisubstituted tetrahydropyran derivative had previously been obtained by the Prins reaction of cyclohexene.[3,4] Similarly, on the basis of the elementary analysis and mass spectrum compound VII was estimated to be $C_{16}H_{26}O_2$. The IR and NMR spectra justified the presence of two ether rings and a double bond in VII. The allylic protons in VII, which were estimated by a comparison of the NMR spectrum of VII with that of the product of the hydrogenation of VII, amounted to 3H; this suggested that the double bond was adjacent to the tertiary carbon atom. On the basis of the experimental results described here, the relative positions of the two ether rings and, thus, the structure of VII could not be elucidated. However, because no product derived from the carbonium ion formed by a hydride shift was found in any other product described in this paper, the migration of the carbonium-ion center seemed unlikely; it seemed, rather, reasonable to assume that the two ether rings were adjacent to each other. On the basis of these considerations, it was decided that compound VII was 12,17-dioxatricyclo[13,3,0,$0^{10,14}$]-2-octadecene.



The glpc of the reaction product indicated that the product contained 40 wt% of V, 20 wt% of VIa, 30 wt% of VII, and 10 wt% of unknown substances.

Experimental

All of the mps and bps are uncorrected. The IR spectra were recorded on a Hitachi EPI-G2 type grating infrared spectrometer, and the NMR spectra were taken on a JNM-3H-60 (60 MHz) NMR spectrometer (Japan Electron Optics Lab.) with tetramethylsilane as the internal standard. The chemical shifts (τ) were followed by the splitting patterns (s, singlet; d, doublet; t, triplet; m, multiplet) and the relative strengths. For the analyses by glpc, was used a GC-4B type Shimadzu Seisakusho gas chromatograph with a column 2.5 mm i.d. and 2 m in length; this column contained polyethylene glycol 20 M (20%) on Celite 545.

The paraformaldehyde, acetic acid, and sulfuric acid were used as received. The cyclooctene and the cyclododecene (a mixture of *ca.* 45% of the *cis*- and *ca.* 55% of the *trans*-isomer) received from Wako Chemicals were fractionally distilled. The cyclooctanone and cyclododecanone were prepared by the hydroboration of the corresponding olefins, followed by oxidation with hydrogen peroxide.

Prins Reaction of Cyclooctene. To stirred suspension of 24.0 g (0.64 mol) of paraformaldehyde in 92 ml of acetic acid and 15.5 ml of concentrated sulfuric acid, was added gradually a mixture of 50 g (0.46 mol) of cyclooctene and 41 ml of acetic acid at 40 °C; the solution was then stirred for additional 2 hr. After the addition of 100 ml of water and 50 ml of ether, the mixture was transferred to a separatory funnel. The water layer was removed and the organic layer was washed several times with a saturated aqueous sodium bicarbonate solution and twice with water, and then dried over anhydrous magnesium sulfate. The ether was removed *in vacuo*, and the residual oil was fractionally distilled; Fraction 1 (0.8 g, bp 31 °C/15 mmHg), Fraction 2 (14.9 g, bp 76—77 °C/0.4 mmHg), Fraction 3 (21.5 g, bp 110—120 °C/0.4 mmHg), and a residue.

Fraction 1 was identified as the starting olefin.

Hydrolysis of Fraction 2. A solution of 10 g of Fraction 2 in Claisen alkali (10 g of potassium hydroxide in 31.2 ml of methanol and 8 ml of water) was refluxed for an hour, after which the reaction mixture was worked up; 7.4 g of a hydrolyzed product (bp 90—93 °C/0.4 mmHg) was thus obtained. This substance was separated into benzene eluate and methanol eluate by column chromatography on alumina.

The removal of the solvent from the benzene eluate yielded 4,5-hexamethylene-1,3-dioxane; bp 70—71 °C/0.5 mm Hg; IR (neat) 1150, 1080, 1040, 1030 cm^{-1} (CH_2–O–CH_2–O–CH); NMR (CCl_4) τ 5.1—5.6 (q, 2H, O–C$\underline{H}_2$–O), 6.2—6.6 (m, 3H, CH–C$\underline{H}_2$–O+C$\underline{H}$–O), 7.5—9.0 (m, 13H, other $\underline{H}$); MS (*m/e*) 170 (3), 140 (24), 122 (100); Found: C, 70.36; H, 10.94%; Calcd for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66%; mol. wt., 170.24.

The removal of the solvent from the methanol eluate left 2-cyclooctenylmethanol (IIb); NMR (CCl_4) τ 4.3—4.6 (m, 2H, C$\underline{H}$=C$\underline{H}$), 6.5—6.9 (m, 3H, –C$\underline{H}_2$–O$\underline{H}$), 7.8—8.6 (m, 11H, other $\underline{H}$); Found: C, 76.56; H, 11.84%. Calcd for

6) A. P. Krapcho, J. Diamanti, C. Cayen, and R. Bingham, "Organic Synthesis," Vol. 47 (1967), p. 22.

$C_9H_{16}O$: C, 77.09; H, 11.50%.

2-Cyclooctenylmethyl acetate (IIa) was isolated by preparative glpc or by column chromatography; IR (neat) 1720, 1220 cm^{-1} (CH_3COO), 1650 cm^{-1} (C=C); NMR (CCl_4) τ 4.2—4.7 (m, 2H, CH=CH), 6.1—6.4 (m, 2H, $-CH_2-O$), 7.5—7.9 (m, 3H, $CH_2-CH=CH-CH$), 7.9—8.1 (s, 3H, CH_3COO), 8.1—8.9 (m, 8H, other H); MS (*m/e*) 182 (3), 140 (3), 122 (100), 107 (77); mol. wt. for $C_{11}H_{18}O_2$, 182.25.

Fraction 3 was confirmed to be 1-acetoxy-2-acetoxymethylcyclooctane (IVa); IR (neat) 1710, 1220 cm^{-1} (CH_3COO); NMR (CCl_4) τ 5.0—5.3 (broad m, 1H, CH–OCOCH$_3$), 6.1—6.4 (m, 3H, $CH_2-OCOCH_3$+CH–CH_2–), 7.8—9.0 (m, 19H, CH_3CO (s×2)+other H); MS (*m/e*) 212 (8), 199 (2), 182 (10), 164 (13), 154 (14), 140 (100); mol. wt. for $C_{13}H_{22}O_4$, 242.31.

Hydrogenation of IIa to III. In a 200 ml Erlenmeyer flask, were placed a Raney-Ni catalyst (prepared from 5.0 g of Ni–Al alloy (20%)), 50 ml of ethanol, and 5.0 g of IIa. The mixture was stirred with a magnetic stirrer, after which hydrogen was bubbled through it for 1 hr. The catalyst was then removed from the reaction product by filtration.

The removal of the ethanol from the filtrate yielded cyclooctylmethyl acetate (III); IR (neat) 1730, 1230 cm^{-1} (CH_3COO); NMR (CCl_4) τ 6.2—6.3 (d, 2H, CH_2-O), 8.0 (s, 3H, CH_3CO), 8.2—9.0 (m, 15H, other H); MS (*m/e*) 184 (3), 124 (18), 96 (100), 82 (37); Found: C, 64.59; H, 9.32%. Calcd for $C_{11}H_{20}O_2$: C, 64.44; H, 9.16%; mol. wt., 184.27.

Hydrolysis of IVa. When compound IVa was hydrolyzed with Claisen alkali, 2-cyclooctenylmethanol was obtained; IR (neat) 3300, 1020 cm^{-1} (CH); NMR (CCl_4) τ 5.5—5.8 (m, 2H, OH), 5.8—6.3 (m, 1H, CH–OH), 6.3—6.9 (m, 2H, $-CH_2-OH$), 7.8—9.0 (m, 13H, other H); MS (*m/e*) 156 (8), 140 (64), 122 (100); glpc-retention time (220 °C, 67 ml-H_2/min), 11.4 min; Found: C, 68.02; H, 11.60%. Calcd for $C_9H_{18}O_2$: C, 68.31; H, 11.47%; mol. wt., 158.32.

Synthesis of IVb. 2-Carbethoxycyclooctanone[6] was treated with lithium aluminum hydride in tetrahydrofuran. The subsequent work-up of the reaction product yielded authentic IVb. The glpc-retention time and the spectroscopic properties of the authentic sample were identical with those of IVb.

Prins Reaction of Cyclododecene. To a stirred suspension of 9.2 g of paraformaldehyde (0.25 mol) in 35.0 ml of acetic acid and 6.1 ml of concentrated sulfuric acid, was added gradually a mixture of 30.0 g of cyclododecene (0.18 mol), 10.0 ml of acetic acid, and 8.0 ml of ether at 40 °C, after which the mixture was stirred for additional 2 hr. The subsequent work-up of the reaction product yielded 14.2 g of Fraction 1 (bp 53—56 °C/0.5 mmHg), 6.7 g of Fraction 2 (bp 103—105 °C/0.5 mmHg), 11.3 g of Fraction 3 (bp 140—150 °C/0.5 mmHg), and a residue.

Fraction 1 was identified as cyclododecene by glpc and its IR spectrum.

Fraction 2 was identified as 3-oxabicyclo[10,3,0]-6-pentadecene (V); IR (neat) 1050, 1020 cm^{-1} (CH_2-O-CH_2); NMR (CCl_4) τ 4.5—4.9 (m, 2H, CH=CH), 6.0—6.4 (m, 2H, OCH_2), 6.5—7.0 (m, 2H, OCH_2), 7.5—8.2 (m, 4H, allyl H+tertiary H), 8.2—9.5 (m, 14H, other H); MS (*m/e*) 208 (100), 177 (8), 165 (6); mol. wt. for $C_{14}H_{24}O$, 208.33.

Fraction 3 was treated with Claisen alkali, and the resultant oil was separated into the ether eluate and the methanol eluate by column chromatography on alumina. The removal of the solvent from the ether eluate left 12,17-dioxatricyclo-[13,3,0,$0^{10,14}$]-2-octadecene (VII); mp 92—95 °C (methanol); IR (KBr) 1060, 1050 cm^{-1} (CH_2-O-CH_2), 980 cm^{-1} (C=C); NMR (CCl_4) τ 4.4—4.8 (m, 2H, CH=CH), 6.0—7.0 (m, 8H, CH_2-O-CH_2), 7.2—7.9 (m, 3H, allyl H), 7.9—9.4 (m, 13H, other H); MS (*m/e*) 250 (100), 219 (22), 209 (27); Found: C, 76.57; H, 10.69%. Calcd for $C_{16}H_{26}O_2$: C, 76.75; H, 10.47%; mol. wt., 250.23. From the ethanol eluate, a mixture of 3-oxabicyclo[9,3,1]pentadecan-15-ol (VIb, X=H) (*ca.* 67%) and VII (*ca.* 33%) was obtained; NMR (CCl_4) τ 4.4—4.8 (m, CH=CH), 5.8 (m, CH_2-O-CH_2+CH–$OCOCH_3$), 7.3—9.3 (m, OH, which disappeared upon deuterium exchange+other H).

15-Acetoxy-3-oxabicyclo[9,3,1]pentadecane (VIa) was isolated by the preparative glpc of Fraction 3; IR (neat) 1720, 1230 cm^{-1} (CH_3COO), 1060, 1020 cm^{-1} (CH_2-O-CH_2); NMR (CCl_4) τ 5.0—5.3 (m, 1H, CH–$OCOCH_3$), 6.4—6.6 (m, 4H, CH_2-O-CH_2), 8.0—9.0 (m, 23H, CH_3COO (s)+other H); MS (*m/e*) 268 (3), 250 (3), 226 (4), 208 (100); Found: C, 71.61; H, 10.53%. Calcd for $C_{16}H_{28}O_3$: C, 71.60; H, 10.52%; mol. wt., 268.38.

Hydrogenation of V to VIII. The Raney-Ni catalyst prepared from 3.0 g of Ni–Al alloy was used for the hydrogenation of V in 50 ml of ethanol. The subsequent work-up of the product yielded 5.0 g of 3-oxabicyclo[10,3,0]pentadecane (VIII); bp 110—115 °C/2 mmHg; IR (neat) 1110, 1060 cm^{-1} (CH_2-O-CH_2); NMR (CCl_4) τ 6.1—6.9 (q×2, 4H, CH_2-O-CH_2), 7.7—8.2 (m, 2H, CH), 8.2—9.0 (m, 20H, other H); MS (*m/e*) 210 (9), 209 (6), 208 (14), 179 (10), 149 (10), 135 (17), 121 (17), 109 (16), 95 (56), 82 (100); glpc-retention time (230 °C, 47 ml-H_2/min), 44.0 min; Found: C, 79.44; H, 12.65%. Calcd for $C_{14}H_{26}O$: C, 79.93; H, 12.46%.

Conversion of VIII to 1,2-Dimethylcyclododecane (IX). A mixture of 3.0 g of VIII and 25 ml of an aqueous solution of hydrogen iodide (47%) was refluxed for 3 hr. After the subsequent addition of water to the reaction mixture, the product was extracted with three 50-ml portions of ether. The ethereal extract was dried over anhydrous magnesium sulfate. To the stirred suspension of 1.7 g of lithium aluminum hydride in 70 ml of tetrahydrofuran, was added the ethereal extract, and then the mixture was refluxed for 3 hr. The lithium aluminum hydride remaining in the reaction mixture, was decomposed by addition of water, and the resultant solution was filtered. The filtrate was washed with sulfuric acid and water, and dried over anhydrous magnesium sulfate. The ether was removed from the filtrate, and the residual oil was separated into an *n*-hexane eluate and an ether eluate by column chromatography on alumina. From the *n*-hexane eluate, 0.8 g of 1,2-dimethylcyclododecane (IX) was obtained, while from the ether eluate, 1.0 g of VIII was recovered. IX; IR (neat) 2900, 2850, 1440, 720 cm^{-1} (alkane); NMR (CCl_4) τ 8.2—9.0 (m, 22H, H on ring), 9.0—9.4 (m, 6H, CH_3); MS (*m/e*) 196 (100), 182 (10), 168 (32), 139 (36); glpc-retention time (180 °C, 44 ml-H_2/min), 37.0 min; Found: C, 85.34; H, 14.37%. Calcd for $C_{14}H_{28}$: C, 85.63; H, 14.37%; mol. wt., 196.36.

Conversion of VIb to 3-oxabicyclo[9,3,1]pentadecane (X). To a stirred solution of 14.3 g of *p*-toluenesulfonyl chloride in 20 ml of pyridine, which had been cooled in an ice-water bath, was added a solution of 4.0 g of a mixture of VIb (*ca.* 67%) and VII (*ca.* 33%) in 20 ml of pyridine. The reaction mixture was warmed to room temperature and stirred for an additional 15 hr. After the addition of 150 ml of water to the reaction mixture, the product was extracted with ether. The ethereal extract was washed with a 6 M hydrogen chloride solution, a saturated aqueous sodium carbonate solution, and water, and dried over anhydrous sodium sulfate. The resultant ether solution was added slowly to a suspension of 1.3 g of lithium aluminum hydride in 70 ml of tetrahydrofuran. When the resultant mixture was worked up and the less volatile VII was removed by distillation to

yield X; IR (neat) 1080 cm^{-1} (CH_2–O–CH_2); NMR (CCl_4) τ 6.0—7.0 (m, 4H, $C\underline{H}_2$–O–$C\underline{H}_2$), 7.6—9.3 (m, 22H, other H); MS (*m/e*) 210 (9), 209 (9), 208 (17), 179 (9), 135 (17), 121 (22), 109 (39), 95 (69), 82 (100); glpc-retention time (230 °C, 47 ml-H_2/min), 46.5 min; Found: C, 80.15; H, 12.58%. Calcd for $C_{14}H_{26}O$: C, 79.93; H, 12.46%; mol. wt., 210.35.

Hydrogenation of VII. A solution of 5.0 g of VII in 30 ml of ethanol was treated with a Raney-Ni catalyst (from 5.0 g of Ni–Al alloy) in a hydrogen stream at atmospheric pressure; the subsequent work-up of the reaction product yielded 5.0 g of 12,17-dioxatricyclo[13,3,0,$0^{10,14}$]pentadecane; IR (neat) 1060, 1050 cm^{-1} (CH_2–O–CH_2); NMR (CCl_4) τ 6.0—7.2 (m, 8H, $C\underline{H}_2$–CH_2), 7.7—7.9 (m, 1H, H on ring), 7.9—9.2 (m, 19H, other H).

Synthesis of IX. To a solution of 9.3 g of 2-methyl-2-carbethoxycyclododecanone[6] in 20 ml of ethanol, was added 70 ml of 6 M hydrogen chloride solution, after which the mixture was refluxed for 90 hr. The reaction product was then worked up, and 3.1 g of 2-methylcyclododecanone (XII) (bp 85—90 °C/3 mmHg) was thus obtained.

In a 300-ml, four-necked flask fitted with a mechanical stirrer, dropping funnel, a reflux condenser, and a gas-inlet tube, and flushed with nitrogen, were placed 9.8 ml of *n*-butyllithium (15%) in *n*-hexane (0.10 mol) and 40 ml of ether. The solution was stirred vigorously, and then was added 5.5 g of methyltriphenylphosphonium bromide (0.02 mol) and then 3.0 g of XII (0.015 mol). The mixture was subsequently refluxed for 12 hr. When the reaction mixture was worked up, 0.5 g of 2-methyl-1-methylenecyclododecane (XIII) (bp 75—78 °C/2 mmHg) was obtained. A solution of 1.0 g of XIII in 20 ml of ethanol was treated with a Raney-Ni catalyst (from 2.0 g of Ni–Al alloy) in a hydrogen stream at atmospheric pressure; the subsequent work-up of the product yielded 1.0 g of 1,2-dimethylcyclododecane (bp 48—49 °C/25 mmHg). The spectroscopic properties and the glpc-retention time were identical with those described for IX.

The Synthesis and The Configuration of 3-Aminotetrahydrothiophene-3-carboxylic Acids

Minoru HATANAKA and Toshiyasu ISHIMARU

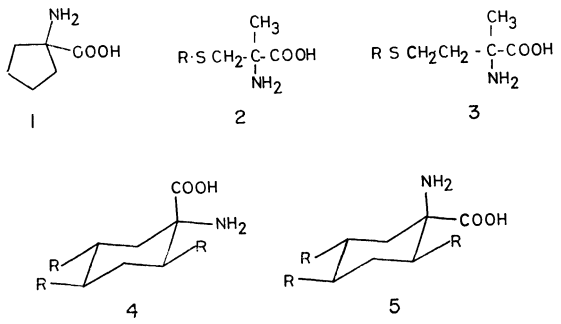
The Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

(Received September 25, 1972)

Several monomethylsubstituted 3-aminotetrahydrothiophene-3-carboxylic acids have been synthesized from the corresponding 3-ketotetrahydrothiophenes by the Strecker and the Bucherer-Bergs syntheses. In each case, the former synthesis leads to one stereoisomer, and the latter, to the opposite stereoisomer. The configurations of 3-amino-2-methyltetrahydrothiophene-3-carboxylic acids have been determined by a study of the NMR spectra; the others have been estimated on the basis of these results. The configurations do not contradict those first assigned to the alkyl substituted 1-amino-1-cyclohexanecarboxylic acids.

The anticancer activity of 1-amino-1-cyclopentanecarboxylic acid (**1**) was first described by Connors *et al.*,[1] and since then several alicyclic α-amino acids have been synthesized from their biological point of view.[2] This paper will deal with the syntheses of 3-aminotetrahydrothiophene-3-carboxylic acids as heterocyclic analogs of **1**. Our interest in these compounds also arises from the fact that some derivatives of DL-α-methylcysteine (**2**) and DL-α-methylethionine (**3**) promote tumor growth.[3]

Munday[4] and Brimelow *et al.*[5] reported that alkylsubstituted cyclohexanones yield, stereospecifically, different isomers of the corresponding α-amino acids, depending on the method of preparation (*i. e.*, the Strecker and the Bucherer-Bergs syntheses). Although their configurations were first assigned by Munday[4] to be **4** for the Strecker products and **5** for the Bucherer products, Cremlyn *et al.*[6] recently reported the opposite assignment. Thus, the configurational assignment remains equivocal because of the absence of conclusive proof.



We attempted both the Strecker and the Bucherer-Bergs syntheses for monomethylsubstituted 3-ketotetrahydrothiophenes. The elucidation of the stereoisomerisms of the two methods in this series is another

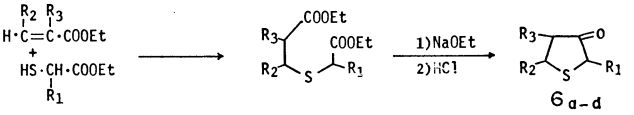
purpose of the present paper.

Results and Discussion

Synthesis. The starting materials, 2-, 4-, and 5-methyl-3-ketotetrahydrothiophenes (**6b–d**, Table 1), were prepared in good yields by means of a modification of the method used by Woodward *et al.*[7] for the synthesis of 3-ketotetrahydrothiophene (**6a**) (Scheme 1).



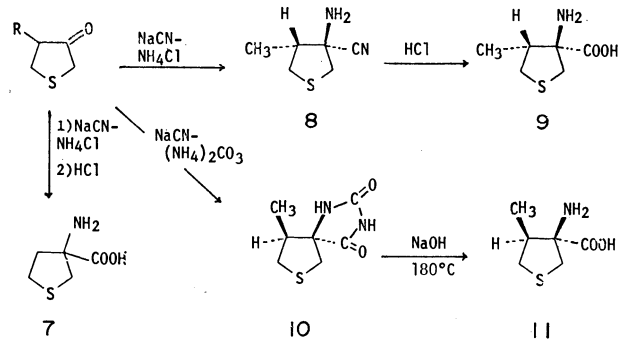
Scheme 1.

TABLE 1. 3-KETOTETRAHYDROTHIOPHENES

No	Compound			Bp °C/mmHg	Yield[a] %	IR[b] $\nu_{C=O}$
	R_1	R_2	R_3			
6a	H	H	H	73—75/16[c]	72[c]	1738
6b	CH_3	H	H	77—84/18	85	1737
6c	H	CH_3	H	77—82/17	77.5	1737
6d	H	H	CH_3	69—70/15	75	1740

a) Based on the mole of ethyl thioglycolate or ethyl thiolactate. b) All spectra were measured in liquid film state. c) Ref. 7: bp 74.5 °C/15 mmHg; 30% yield.

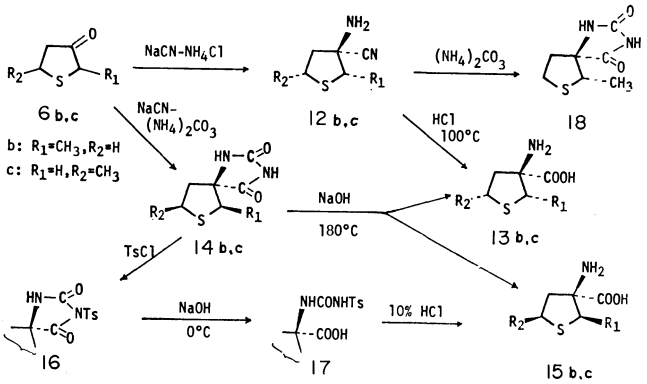
The Strecker reaction with 3-ketotetrahydrothiophene (**6a**) gave a 45% yield of 3-aminotetrahydrothiophene-3-carboxylic acid (**7**), in which case the hydrolysis of the intermediate amino nitrile was conducted by heating it with refluxing 20% hydrochloric acid for 12 hours. However, in the Strecker reaction with the 4-methyl ketone (**6d**) the hydrolysis of the amino nitrile (**8**) under similar conditions produced mainly the corresponding amide; prolonged heating for 2 days was required to give the amino acid (**9**). This resistance to hydrolysis seems to be attributable to the steric effect of the adjacent 4-methyl group. The Bucherer-Bergs reaction with the 4-methyl ketone (**6d**) afforded a 74% yield of the hydantoin (**10**) which was then hydrolyzed by heating with aqueous alkali in an autoclave at 180 °C for 30 hours to produce the amino acid (**11**).



Scheme 2.

The resulting amino acids (**9** and **11**) were indistinguishable from each other by their melting points or by their R_f values upon paper chromatography, but the NMR spectra (Table 2) of their hydrochlorides were obviously different, especially in the signals due to the 4-methyl protons; **9** showed at 1.05 ppm and **11** at 1.15 ppm. Thus, it is apparent that the Strecker product **9** (called the α-form) and the Bucherer product **11** (the β-form) are stereoisomers.

Although the 2-methyl ketone (**6b**) similarly yielded the α-isomer (**13b**) *via* the Strecker reaction, the Bucherer reaction with **6b** followed by the alkaline cleavage of the resulting hydantoin (**14b**) gave a mixture (1 : 1 ratio, on the basis of the signals of the 2-methyl protons in its NMR spectrum) of the isomeric amino acids (**13b** and **15b**). Comparable results were also obtained in the case of the 5-methyl ketone (**6c**); the Strecker reaction gave the α-isomer (**13c**) while the Bucherer reaction produced a 1 : 1 mixture of **13c** and **15c**. This implies that the alkali-induced epimerization of the 2-methyl or the 5-methyl group, occupying the carbon atom adjacent to the sulfur atom, took place *via* carbanion formation during the hydrolysis of the hydantoin. The NMR spectra of the hydantoins (**14b** and **14c**) displayed sharp doublets due to the methyl protons at 1.08 and 1.28 ppm respectively, indicating that they are single isomers. Indeed, when Strecker's amino nitrile (**12b**) was treated with ammonium carbonate, the resulting hydantoin (**18**) was proved by a comparison of the NMR spectra to be isomeric with Bucherer's (**14b**). Therefore, the milder hydrolysis developed by Yamada *et al.*[8] was used for the Bucherer hydantoins (**14b** and **14c**); they were treated with *p*-toluenesulfonyl chloride to form the monotosylates (**16**). The treatment of **16** with cold aqueous alkali followed by the heating of the resulting hydantoic acids (**17**) with 10% hydrochloric acid afforded the desired amino acids (β-isomers), **15b** and **15c** respectively. These amino acids displayed NMR spectra different from those of the corresponding Strecker amino acids (Table 2).



Scheme 3.

In all cases, the stereospecificities of both methods were determined to be >90% on the basis of the signals of the methyl protons in the NMR spectra of the crude products.

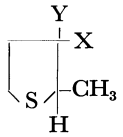
Table 3. Chemical shifts of 2-protons and 2-methyl protons in the derivatives of 2-methyl amino acids (**13b** and **15b**) (60 MHz)



Compound		Concn mg/ml	Solvent	Strecker product		Bucherer product	
X	Y			2-CH_3	2-H	2-CH_3	2-H
NH_3^+Cl	COOH	10	D_2O	1.35	3.68	1.30	4.05
NH_2	$COOCH_3$	7	$CDCl_3$	1.18	3.23	1.19	3.79
NH_2	CH_2OH	7	$CDCl_3$	1.24	3.15	1.23	3.29

The values are in ppm (δ) relative to internal tetramethylsilane.

Configurational Assignment. As has been described above, the amino nitriles (**8** and **12b**) strongly resisted toward hydrolysis. This suggests that the nitrile groups in the Strecker amino nitriles are located *cis* to the methyl groups. Strong support for this assignment is obtained from the studies of the NMR spectra of the 2-methyl amino acids.

For comparison, the 2-methyl amino acids (**13b** and **15b**) were converted to amino esters by treatment with thionyl chloride in methanol, and subsequently to amino alcohols by lithium aluminum hydride reduction. The chemical shifts of the 2-protons and the 2-methyl protons (they appear in the AX_3 pattern) of these compounds are given in Table 3.

In the cases of both the amino acids and the amino esters, the signals due to the 2-protons of the Bucherer products appear at a field lower by 0.37 and 0.56 ppm respectively than those for the Strecker products. It is known that, in a rigid ring system (*e.g.*, a three-membered ring and a rigid bicyclic system such as bicyclo[2,2,2]octane), a carboxyl substituent causes resonances due to the *cis*-vicinal protons to appear downfield of those due to the *trans*-vicinal protons.[9] Also, in the case of a five-membered ring, such an effect has recently been observed.[10] Consequently, our results indicate that the 2-protons are located *cis* to the carboxyl groups in the Bucherer products and *trans* in the Strecker products. In agreement with this assignment, a comparison of the signals of the 2-protons of the amino esters with those for the amino alcohols shows little difference in the case of the Strecker products, but the signal of the amino alcohol shifts 0.5 ppm to a higher field in the case of the Bucherer products.

As a result, the carboxyl group is introduced from the more hindered side of the starting ketone (**6b**) in the Strecker reaction and oppositely from the less hindered side in the Bucherer reaction. Therefore, in the cases of the 4-methyl and the 5-methyl amino acids also it seems to be reasonable to say that the carboxyl groups in the Strecker products are *cis* to the methyl groups, while they are *trans* in the Bucherer products.

These stereochemical results of both reactions are consistent with Munday's conclusion as to the alkyl amino-cyclohexane-carboxylic acids.

Experimental

All the melting points are uncorrected. The IR spectra were measured on a JASCO Model IR-S Spectrometer. The NMR spectra were obtained on a 60 MHz Hitachi R-20 Spectrometer, using tetramethylsilane as the internal standard.

3-Ketotetrahydrothiophenes. A modification of the method of Woodward *et al.*[7] for the preparation of 3-ketotetrahydrothiophene (**6a**) was used for the compounds listed in Table 1; this method, in our hands, gave good yields of these compounds. The preparation of *2-methyl-3-ketotetrahydrothiophene (**6b**)* will be described as an example. To a stirred solution of ethyl thiolactate (53.6 g, 0.4 mol) containing piperidine (0.5 ml), methyl acrylate (38 g, 0.44 mol) was slowly added, while the mixture was maintained at 40—50 °C by occasional cooling. During the reaction, more piperidine (0.5 ml) was added. After the addition of methyl acrylate was complete, the mixture was warmed at 50 °C for 10 min, and then washed with ice water and dried over $MgSO_4$. A mixture of sodium ethoxide [prepared from sodium (11 g) and anhydrous ethanol (30 ml)] in dry benzene (400 ml) was heated at 75—80 °C and a solution of the above Michael-addition product in dry benzene (200 ml) was slowly added over a 1.5-h period. The temperature was then raised to 80—90 °C and the azeotropic mixture (150 ml) of benzene–ethanol was distilled. After cooling, 10% hydrochloric acid (200 ml) was added. The benzene layer was washed with water, dried over $MgSO_4$, and evaporated *in vacuo*. The remaining residue of the Dieckmann product was refluxed with methanol (800 ml) and 20% hydrochloric acid (200 ml) for 4 h. The mixture was cooled in an ice bath, neutralized with a 20% sodium hydroxide solution, and then extracted with methylene chloride (3×100 ml). Drying over $MgSO_4$, the evaporation of the solvent, and the distillation of the residue gave a colorless liquid (39.4 g, 85%); bp 77—84 °C/18 mmHg.

*3-Aminotetrahydrothiophene-3-carboxylic Acid (**7**).* A solution of 3-ketotetrahydrothiophene (6.4 g, 0.063 mol) in methanol (30 ml) was added to a solution of ammonium chloride (8.9 g) and sodium cyanide (7.5 g) in concentrated ammonium hydroxide (51 ml). The mixture was cooled in an ice-salt bath, saturated with ammonia gas, and then shaken at room temperature for 2 days in a tightly sealed bottle. The mixture was diluted with water (100 ml) and extracted with ether (3×50 ml). The extract was washed with water, dried over K_2CO_3, and evaporated *in vacuo*. The remaining residue of the amino nitrile was refluxed with 20% hydrochloric acid (40 ml) for 12 h. After the subsequent evaporation of the solvent *in vacuo*, the residue was dissolved in water (30 ml) and the solution was decolorized with charcoal and again evaporated to dryness *in vacuo*. The resultant solids were extracted with ethanol. After filtration, pyridine was added to the cold filtrate and the mixture was allowed to stand overnight in the refrigerator. The white precipitate was collected by filtration, yielding the amino acid (**7**) (4.6 g, 45%), which was subsequently purified by recrystallization from water. Mp 286.5—287.5 °C (decomp.).

Found: C, 36.34; H, 6.95; N, 8.40%. Calcd for $C_5H_9NO_2S \cdot H_2O$: C, 36.35; H, 6.71; N, 8.47%.

*3-Amino-5-methyltetrahydrothiophene-3-carboxylic Acid (α-Isomer, **13c**).* By the procedure described for **7**, this was prepared from **6c** (5.8 g, 0.05 mol), yielding 2.9 g (36%). Mp 261—262 °C (decomp.).

Found: C, 45.02; H, 7.37; N, 8.95%. Calcd for $C_6H_{11}NO_2S$: C, 44.70; H, 6.87; N, 8.68%.

*3-Amino-4-methyltetrahydrothiophene-3-carboxylic Acid (α-Isomer, **9**).* This was prepared from **6d** (11.6 g, 0.1 mol) by a procedure virtually identical with that described for **7**, but the hydrolysis of the resulting amino nitrile (**8**) to the amino acid (**9**) required heating with 20% hydrochloric acid for 2 days, thus yielding 6.8 g (42%). Mp 281—282 °C (decomp.).

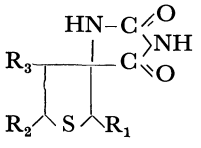
Found: C, 43.26; H, 7.21; N, 8.07%. Calcd for $C_6H_{11}NO_2S \cdot 1/3H_2O$: C, 43.09; H, 7.03; N, 8.37%.

*3-Amino-2-methyltetrahydrothiophene-3-carboxylic Acid (α-Isomer, **13b**).* By the procedure described for **9**, this was prepared from **6b** (11.6 g, 0.1 mol), yielding 6.7 g (41.5%). Mp 319—320 °C (sublime).

Found: C, 44.68; H, 7.21; N, 8.26%. Calcd for $C_6H_{11}NO_2S$: C, 44.70; H, 6.87; N, 8.68%.

*Bucherer Hydantoins, **10**, **14b** and **14c** (β-Isomers).* The usual method was used for the preparation of all the Bucherer hydantoins listed in Table 4. The preparation of *4-methyltetrahydrothiophene-3*-spiro-*5'-hydantoin* (**10**) will be described as an example. A mixture of **6d** (9.2 g, 0.0793 mol), ammonium carbonate (24 g), and 60% aqueous ethanol (130 ml) was warmed at 50 °C; a solution of sodium cyanide (4.1 g) in water (20 ml) was added with stirring. The reaction mixture was stirred at 50—60 °C for 3 h, and then at 85 °C for 1 h. After concentration to 70 ml *in vacuo*, the solution was acidified to pH 6 by the addition of 20% hydrochloric acid and then allowed to stand overnight at 5 °C. The precipitate was collected by filtration and re-

Table 4. Properties of hydantoins



No	Compound			Mp, °C	Yield, %	NMR[a] (Assignment)
	R_1	R_2	R_3			
10	H	H	CH_3	173.5—175	74	0.96, d (4-CH_3)
14c	H	CH_3	H	240—243	72	1.28, d (5-CH_3)
14b	CH_3	H	H	172.5—176	61	1.08, d (2-CH_3) 3.60, q (2-H)
18[b]	CH_3	H	H	180—181.5	35	1.16, d (2-CH_3) 3.40, q (2-H)

a) Measured in DMSO-d_6. Symbols show: d, doublet; q, quartet. b) Prepared from **6b** *via* the amino nitrile (**12b**).

crystallized from aqueous ethanol, yielding 10.9 g (74%).

Found: C, 45.21; H, 5.02; N, 15.15; S, 17.25%. Calcd for $C_7H_{10}N_2O_2S$: C, 45.12; H, 5.40; N, 15.03; S, 17.20%.

*2-Methyltetrahydrothiophene-3-*spiro*-5'-hydantoin(α-Isomer, **18**).* The amino nitrile (**12b**) [prepared from **6b** (3.22 g, 0.0278 mol) *via* the Strecker route] was added to a stirred mixture of ammonium carbonate (8.5 g) and 60% aqueous ethanol (45 ml); the mixture was then stirred at 55—60 °C for 3 h, and subsequently at 85 °C for 1 h. The evaporation of the ethanol, the acidification (to pH 6) of the residue, and the filtration of the precipitate gave the crude hydantoin. Pure **18** was obtained by dissolving it in a 1M sodium hydroxide solution (30 ml); the solution was washed with ethyl acetate and adjusted to pH 6 with 20% hydrochloric acid. The precipitate was collected by filtration, washed with 40% aqueous ethanol, and dried *in vacuo*. Yield 1.82 g (35%).

Found: C, 45.00; H, 5.43; N, 15.12%. Calcd for $C_7H_{10}N_2O_2S$: C, 45.12; H, 5.40; N, 15.03%.

*3-Amino-4-methyltetrahydrothiophene-3-carboxylic Acid (β-Isomer, **11**).* A solution of **10** (10.5 g, 0.0565 mol) in a 1 M sodium hydroxide solution (60 ml) was heated in an autoclave at 180 °C for 30 h, and then decolorized with charcoal and evaporated to dryness *in vacuo*. The residue was suspended in ethanol (50 ml), and lactic acid (6 g) was added. The mixture was stirred at room temperature for 1 h, and then allowed to stand overnight in the refrigerator. The precipitate was collected by centrifuge. The product was purified by dissolving it in 5% ammonium hydroxide (50 ml), and the solution was decolorized with charcoal and concentrated to 10 ml *in vacuo*. The white crystals were collected by filtration, yielding 5.6 g (62%). Mp 281—282 °C (sublime).

Found: C, 44.46; H, 7.03; N, 8.99%. Calcd for $C_6H_{11}NO_2S$: C, 44.70; H, 6.87; N, 8.68%.

*3-Amino-2-methyltetrahydrothiophene-3-carboxylic Acid (β-Isomer, **15b**).* This was prepared by the use of the method of Yamada *et al.*[8] A solution of tosyl chloride (19 g, 0.1 mol) in acetone (50 ml) was slowly added over a period of 6 h to a stirred solution of **14b** (9 g, 0.484 mol) in acetone (150 ml), while the mixture was maintained at pH 9—10 by the dropwise addition of a 1 M potassium hydroxide solution (210 ml). The mixture was then stirred for additional 10 h. The acetone was evaporated *in vacuo* and the precipitate was collected by filtration. The filtrate was acidified with acetic acid and extracted with ethyl acetate. After the evaporation of the ethyl acetate, the residue was combined with the precipitate and the mixture was stirred with 1 M aqueous sodium hydroxide (100 ml) at 0—10 °C for 5 h. The insoluble material was filtered and the filtrate was acidified with 20% hydrochloric acid. The white precipitate of the hydantoic acid (**11**) was collected by filtration and heated with 10% hydrochloric acid (100 ml) at 90—98 °C for 3 h. The mixture was then allowed to stand overnight in the refrigerator. The precipitate was filtered and the filtrate was evaporated to dryness *in vacuo*. The residue was dissolved in ethanol (50 ml), and after the addition of pyridine, the solution was left overnight at 5 °C. The white precipitate was collected by filtration and dried *in vacuo*. Yield 2.6 g (33.4%). Mp 256—257 °C (decomp.).

Found: C, 38.33; H, 7.06; N, 7.47%. Calcd for $C_6H_{11}NO_2S \cdot 3/2\ H_2O$: C, 38.28; H, 7.49; N, 7.44%.

*3-Amino-5-methyltetrahydrothiophene-3-carboxylic Acid (β-Isomer, **15c**).* By the procedure described for **15b**, this was prepared from **14c** (15% yield). Mp 259—260 °C (decomp.).

Found: C, 42.05; H, 7.53; N, 8.17%. Calcd for $C_6H_{11}NO_2S \cdot 1/2\ H_2O$: C, 42.33; H, 7.10; N, 8.22%.

Methyl 3-Amino-2-methyltetrahydrothiophene-3-carboxylate (β-Isomer). A slurry of **15b** (4.28 g, 0.0266 mol) in anhydrous methanol (15 ml) was treated at 0 °C with thionyl chloride (3.3 ml). The mixture was refluxed for 3 h, and then evaporated to dryness *in vacuo*. The residue was shaken for 30 min with dry chloroform (50 ml) saturated with ammonia gas. After filtration, the filtrate was evaporated *in vacuo*. The oily residue was purified through a neutral alumina column with benzene, yielding the amino ester (3.84 g, 82.5%). Tlc indicated the presence of a single component. IR (liquid film): 3300 (NH), 1730 (C=O) cm^{-1}. NMR ($CDCl_3$): see Table 3.

Methyl 3-Amino-2-methyltetrahydrothiophene-3-carboxylate (α-Isomer). By the procedure described above, this was prepared from **13b** (2.36 g, 0.0146 mol), yielding 1.75 g (68%). IR (liquid film): 3300 (NH). 1730 (C=O) cm^{-1}. NMR ($CDCl_3$): see Table 3.

3-Amino-3-hydroxymethyl-2-methyltetrahydrothiophene (β-Isomer). A solution of 3.75 g (0.0212 mol) of the amino ester (β-isomer) in anhydrous tetrahydrofuran (20 ml) was slowly added to an ice-cooled slurry of lithium aluminum hydride (1.2 g, 0.0315 mol) in anhydrous ether (150 ml). The mixture was stirred at room temperature for 2 days and then decomposed with water (3 ml). A 10% sodium hydroxide solution (32 ml) was then added and the aqueous layer was extracted with chloroform containing ethanol. The combined organic layers were dried over $MgSO_4$ and evaporated *in vacuo*. The remaining residue of the amino alcohol was purified through a neutral alumina column with benzene to give a colorless liquid (3.01 g, 96%). Tlc indicated the presence of a single component. IR (liquid film): 3250 (OH, NH) cm^{-1}. NMR ($CDCl_3$): see Table 3.

3-Amino-3-hydroxymethyl-2-methyltetrahydrothiophene (α-Isomer). By the procedure described above, this was prepared from 1.75 g (0.01 mol) of the amino ester (α-isomer), yielding 1.02 g (70%). IR (liquid film): 3250 (OH, NH) cm^{-1}. NMR ($CDCl_3$): see Table 3.

The authors wish to thank Mr. Takuzo Fujino for his microanalysis and Mr. Yoshio Takai for his measurement of the NMR spectra.

Syntheses of Isomaltose, Isomaltotetraose, and Isomaltooctaose

Shinkiti KOTO, Tetsuo UCHIDA, and Shonosuke ZEN

School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108

(Received September 27, 1972)

Ethyl 2,3,4-tri-*O*-benzyl-6-*O*-*p*-nitrobenzoyl-1-thio-α-D-glucopyranoside (I–1) was brominated and subsequently condensed with a deacylated derivative of I–1 in nitromethane in the presence of 2,6-lutidine to give ethyl 2,2′,3,3′,4,4′-hexa-*O*-benzyl-6′-*O*-*p*-nitrobenzoyl-1-thio-α-isomaltoside (I–2) in a 92% yield. These processes were repeated on I–2 to give the blocked tetrasaccharide (I–4) in a 49% yield. Finally, the octasaccharide (I–8) was synthesized in an 11% yield by one more repetition of this reaction cycle. The blocked glycosides, I–2, I–4, and I–8, gave isomaltose, isomaltotetraose, and isomaltooctaose respectively after the sequence of unblocking processes: bromolysis, hydrolysis, methanolysis, and hydrogenolysis.

In synthetic carbohydrate chemistry, it has long been one of the major tasks to synthesize oligosaccharides.[1,2] Since Helferich's gentiobiose synthesis,[3] very many oligosaccharides of various types have been synthesized by all sorts of methods.

At present, there are three general methods for oligosaccharide synthesis: the original and the modified Koenigs-Knorr method,[1,2,4] Kochetkov's ortho ester method,[5] and Lemieux's glycal method.[6] Until recently, however, the fundamental course for the synthesis of relatively higher members of oligosaccharide does not seem to have been laid out or checked, although there were some early investigations.[7] Quite recently, Fréchet and Schuerch started their investigations of the step-by-step oligosaccharide synthesis on polymer support[8] and recorded the synthesis of some higher homologs in excellent yields.[9]

This paper will deal with an approach to the synthesis of the higher oligosaccharide, as in our first program: a series of syntheses of isomaltose,[10] isomaltotetraose, and isomaltooctaose by a systematic repeating scheme in which the condensation between blocks of oligosaccharide was performed as is outlined in Chart 1.[11]

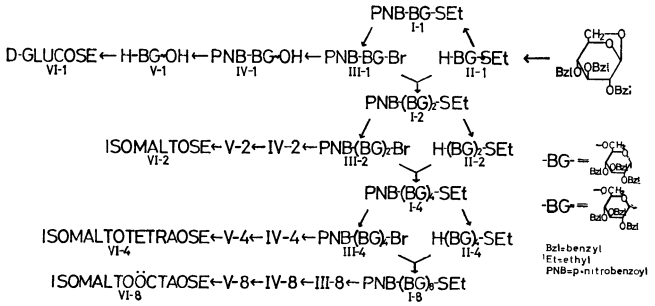


Chart 1.

The anhydro ring of the tri-*O*-benzyl derivative of levoglucosan[12] was cleaved with ethanethiol in the presence of zinc chloride to give the starting ethyl 2,3,4-tri-*O*-benzyl-1-thio-α-D-glucopyranoside (II–1) in a 40% yield. This compound was then converted into the desired *p*-nitrobenzoate (I–1) and also 3,5-dinitrobenzoate (Ia–1) in the usual fashion. I–1 was then bromolyzed by Weygand's method[13] to generate 2,3,4-tri-*O*-benzyl-6-*O*-*p*-nitrobenzyl-α-D-glucopyranoside[14] (III–1) quantitatively.

Throughout this study, glycosidations were carried out by the so-called modified Koenigs-Knorr reaction.[1,2] The choice of the condensing reagent is important for the propagation of the glycoside chain up to a higher degree. 2,6-Lutidine[5] was selected since it is able to form a homogeneous reaction mixture without any activity toward the thio group and without any formation of water during the condensation. As for the solvent, nitromethane might be best for the glycosidation, because of its high polarity to ionize the glycosyl bromide as well as its excellent solvency to various organic materials.

The α-bromide (III–1) was condensed with II–1

in the above reaction system to give the blocked α-linked disaccharide (I–2) in a yield of over 90%. The oily I–2 was characterized as a deacylated crystalline compound, ethyl 2,2′,3,3′,4,4′-hexa-*O*-benzyl-1-thio-α-isomaltoside (II–2). When an analogous condensation was carried out by the use of Ia–1, the yield was about 50%.

I–2 was subjected to this sequence of unblocking processes: (1) bromolysis to split off the ethylthio group, giving a bromide (III–2); (2) hydrolysis to regenerate the hydroxyl group on the head; (3) methanolysis to remove the acyl group on the tail, and (4) catalytic hydrogenolysis to remove the benzyl groups of the body, giving isomaltose. II–2 was also bromolyzed, hydrolyzed, and hydrogenolyzed to give isomaltose.

The bromide (III–2) was condensed with II–2 to give the α-linked tetrasaccharide (I–4) in about 50% yield. The degree of polymerization was confirmed by PMR spectrum. I–4 was unblocked to give isomaltotetraose and was partially unblocked into the deacylated compound (II–4).

The connection of the tetrasaccharide blocks, II–4 and III–4, which had been derived from I–4 by bromolysis, gave the α-linked octasaccharide (I–8) in about 10% yield. The degree of polymerization was confirmed by PMR spectrum. The unblocking processes of I–8 gave isomaltooctaose (VI–8).

The synthesized blocked oligosaccharides, I–2, I–4, and I–8, had an α-linked structure, which was confirmed by their $[M]_D$ values within the range of experimental error as well as by PMR. In their PMR spectra, a doublet of an anomeric proton on the head appeared around 5.4 (J=5 Hz), whereas a signal of an internal anomeric proton(s) was observed around 5.0 (J=3 Hz). The very crucial problem of the propagation of the mixing of glycoside linkages by the formation of the undesired anomer at each condensation step, if any, may by overcome by the purification of the blocked glycosides, such as the I's of II's, before and/or after each condensation.

Turvey and Whelan[15] have investigated the partial hydrolyzate of a *Leuconostoc mesenteroides* dextran and found a linear correlation between the values of $[M]_D$ or R_M and the degree of polymerization (*D.P.*). It was found that all the values of the $[M]_D$'s and R_M's of the synthesized free oligosaccharides had a good linearity to the degree of polymerization (Figs. 1 and 2). In addition the $[M]_D$ values of the blocked oligosaccharides, I, II, IV, and V, also had good correlations to the degree of polymerization, although the ratios of the anomers of IV and V were not determined.

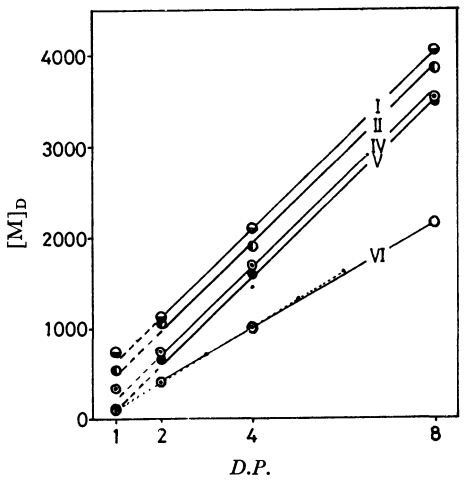

Fig. 1. Relations between *D.P.* and $[M]_D$.
····· Plotted by Turvey and Whelan

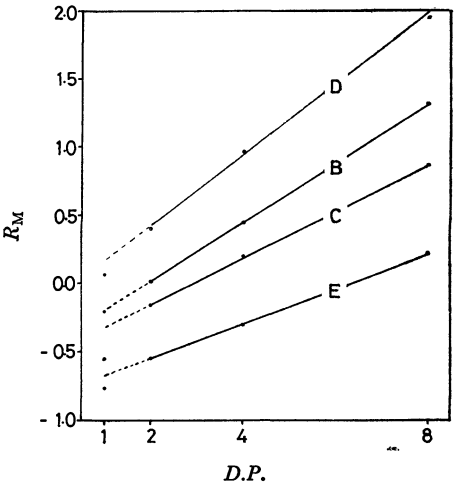

Fig. 2. Relations between *D.P.* and R_M.

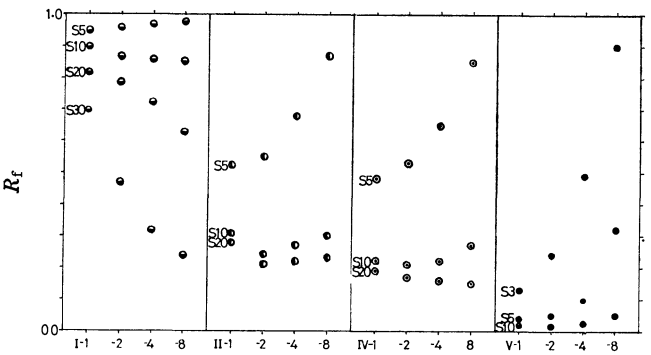

Fig. 3. Relations between *D.P.* and R_f of tlc.

The values of the R_f's in the tlc of the homolog had some correlation to the degree of polymerization (Fig. 3). The R_f's of II, IV, and V, all of which have hydroxy group(s), had roughly an inverse correlation to the degree of polymerization or the molecular size: the ratios of the occupancy of the polar group in the blocked oligosaccharide decrease as the molecular size increases.

Experimental

General Procedures. (1) The solvent systems used for the tlc (silica gel No. 7731, Merck; 10% sulfuric acid spray) and for the column chromatography over silica gel (Kanto Chemical Co.) were as follows: benzene : 2-butanone= (S40) 40 : 1, (S30) 30 : 1, (S20) 20 : 1 (S15) 15 : 1, (S10) 10 : 1, (S7) 7 : 1, (S5) 5 : 1, (S4) 4 : 1, and S(3) 3 : 1, by volume.

(2) The solvent systems used for the paper chromato-

15) J. R. Turvey and W. J. Whelan, *Biochem. J.*, **67**, 49 (1957).

graphy (Toyo filter paper No. 525, unless otherwise stated; ascending development as high as 35 cm at 25 °C; aniline hydrogenphthalate spray) and the column chromatography over cellulose powder (Toyo Roshi Co.,; 100—200 mesh) were as follows: (A) *n*-butanol : acetic acid : water=4 : 1 : 5, (B) *n*-propanol : ethyl acetate : water=6 : 1 : 3, (C) *n*-propanol : nitromethane : water=5 : 2 : 3, (D) *n*-butanol : pyridine : water=6 : 4 : 3, and (E) *n*-propanol : ethyl acetate : water=3 : 1 : 3, by volume.

(3) The melting point was determined by means of a Yanagimoto micromelting point apparatus; uncorrected values are given. The specific rotation was measured in a 1-dm tube by means of an Atago Polux apparatus. The IR spectrum was determined by means of a JASCO IRA-1 infrared spectrometer. The PMR spectrum was measured by means of a Varian S-60T spectrometer in $CDCl_3$, with TMS as the internal standard, unless otherwise mentioned. The elemental analysis was effected by means of a Perkin-Elmer Model 240 Elemental Analyzed apparatus.

(4) The bromolysis was performed by treatment with a bromine solution (Br : petroleum ether=1 : 25, by volume; prepared just before use) in ether (occasionally containing dioxane) at 25 °C for 5 min in a dark place. The bromolyzed mixture was evaporated below 20 °C and then dried at 40 °C. Three co-evaporation with toluene at 40 °C gave a hard yellowish syrup. These operations were performed as quickly as possible, using an oil pump (35 l/min).

Ethyl 2,3,4-Tri-O-benzyl-1-thio-α-glucopyranoside (II-1). A mixture of tri-*O*-benzyl-levoglucosan[12] (7.13 g), zinc chloride (2.08 g), and ethanethiol (35.7 ml) was stirred for 1.5 hr at 25 °C and then poured into iced aqueous sodium bicarbonate. The benzene extract was chromatographed with the S20 solvent to give II-1 after the elution of the unchanged material (1.35 g). Crystallization with *n*-hexane gave colorless needles (3.10 g; 47%); mp 61—63.5 °C, $[\alpha]_D^{25}$ +111° (*c* 1.8, $CHCl_3$). The PMR spectrum contained diagnostic signals of the thioethyl group at δ 1.27 (a triplet; CH_3-) and at δ 2.54 (a quartet; -CH_2-). A doublet of the anomeric proton appeared at δ 5.38, J=5.0 Hz.

Found: C, 70.07; H, 6.88%. Calcd for $C_{29}H_{34}O_5S$: C, 70.42; H, 6.93%.

Ethyl 2,3,4-Tri-O-benzyl-6-O-p-nitrobenzoyl-1-thio-α-D-glucopyranoside (I-1). II-1 (2.00 g) was treated with *p*-nitrobenzoyl chloride (1.23 g) in pyridine (10 ml) at 25 °C overnight. After the hydrolysis of the excess chloride, the benzene extract was chromatographed with the S40 solvent and crystallized with ethanol to give I-1 (2.32 g; 89%); mp 91—92 °C, $[\alpha]_D^{25}$ +116° (*c* 1.0, $CHCl_3$). The IR spectrum (film) showed characteristic bands of the ester group at 1729 cm^{-1} and of the nitro group at 1530 and 1350 cm^{-1}. The PMR spectrum showed the presence of three benzyl groups (δ 7.1~7.5) and one thioethyl group per *p*-nitrobenzoyl group (quasi-quartet, centered at δ 8.18) in I-1.

Found: C, 67.35; H, 5.83; N, 2.06%. Calcd for $C_{36}H_{37}NO_8S$: C, 67.17; H, 5.79; N, 2.18%.

Ethyl 2,3,4-Tri-O-benzyl-6-O-(3,5-dinitrobenzoyl)-1-thio-α-D-glucopyranoside (Ia-1). II-1 (200 mg) was treated with 3,5-dinitrobenzoyl chloride (140 mg) in pyridine (1.0 ml) overnight. After working-up as above, crystallization with diisopropyl ether gave Ia-1 (261 mg; 93%); mp 123—126 °C, $[\alpha]_D^{25}$ +110° (*c* 1.4, $CHCl_3$). The IR spectrum (KBr) had characteristic bands of an ester group at 1725 cm^{-1} and of the nitro group at 1545 and 1348 cm^{-1}. The PMR spectrum showed the presence of three benzyl groups per 3,5-dinitrobenzoyl group (δ 9.0—9.3) in Ia-1.

Found: C, 62.90; H, 5.35; N, 3.84%. Calcd for $C_{36}H_{36}N_2O_{11}S$: C, 62.78; H, 5.27; N, 4.07%.

Ethyl 2,2',3,3',4,4'-Hexa-O-benzyl-6'-O-p-nitrobenzoyl-1-thio-α-isomaltoside (I-2). From I-1. I-1 (0.87 g) was treated with a bromine solution (2.2 ml) in diethyl ether (14 ml) to give a bromide, III-1, $[\alpha]_D^{25}$ +127° (*c* 2.9, $CHCl_3$),[14] which was then condensed with II-1 (0.87 g) in nitromethane (6.0 ml) containing 2,6-lutidine (0.16 ml) for 20 hr. Subsequent chromatography with the S40 solvent gave a homogenous oil of I-2 (1.34 g; 92%), $[\alpha]_D^{25}$ +105° (*c* 2.0 $CHCl_3$). The PMR spectrum showed the presence of six benzyl groups and one thioethyl group per *p*-nitrobenzoyl group in I-2.

Found: C, 69.25; H, 7.22; N, 1.27%. Calcd for $C_{63}H_{65}NO_{13}S$: C, 70.30; H, 6.09; N, 1.30%.

Ethyl 2,2',3,3',4,4'-Hexa-O-benzyl-1-thio-α-isomaltoside (II-2). I-2 (1.32 g) was methanolyzed with dilute sodium methoxide (0.15 M; 20 ml) at 50 °C for 2 hr. Subsequent chromatography with the S20 solvent and crystallization with *n*-hexane gave colorless needles of II-2 (0.96 g; 84%); mp 98—100 °C, $[\alpha]_D^{25}$ +114° (*c* 1.1, $CHCl_3$). The IR(KBr) and PMR spectra indicated the absence of the *p*-nitrobenzoyl group. A couple of doublets of H-1 and H'-1 appeared at δ 5.41, J=4.5 Hz and at δ 5.08, J=4.0 Hz respectively.

Found: C, 72.65; H, 7.02%. Calcd for $C_{56}H_{62}O_{10}S$: C, 72.54; H, 6.74%.

From Ia-1. Ia-1 (100 mg) was bromolyzed in diethyl ether (1.6 ml) with a bromine solution (0.25 ml) to give a bromide, which was then condensed with II-2 (100 mg) in nitromethane (0.97 ml) in the presence of 2,6-lutidine (0.025 ml). Subsequent chromatography with the S40 solvent gave an amorphous disaccharide (76 mg; 47%), which was then methanolyzed with dilute sodium methoxide to give II-2 (52 mg; 39% from Ia-1). Admixture with the above II-2 showed no depression.

Isomaltose (VI-2). From I-2. I-2 (0.14 g) was bromolyzed with the bromine solution (0.22 ml) in diethyl ether (1.5 ml) and then stirred in moist dioxane (10%-H_2O; 10 ml) containing silver carbonate (0.2 g) at room temperature for 1 hr, followed by chromatography with the S15 solvent to give IV-2 (0.084 g; 63%), $[\alpha]_D^{25}$ +72° (*c* 0.5, $CHCl_3$). IV-2 (100 mg) was dissolved in dioxane (1 ml), treated with dilute sodium methoxide (0.15 M; 5 ml), and then chromatographed with the S5 solvent to give V-2 (77 mg; 90%), $[\alpha]_D^{25}$ +73° (*c* 0.5, $CHCl_3$). V-2 (67 mg) was hydrogenolyzed in moist methanol (initial, 2%-H_2O—final, 50%-H_2O), containing five drops of acetic acid over palladium black (20 mg×2)) to give a glass of VI-2 (18 mg; 69%), $[\alpha]_D^{25}$ +126° (*c* 0.8, H_2O)), which was identified with the authentic isomaltose by paper chromatography (Toyo filter paper No. 50; solvents, A, B, and D), as well as by a comparison with β-octa-*O*-*p*-nitro-benzoate[16] (mp 199—201 °C, $[\alpha]_D^{25}$ +97° (*c* 1.4, $CHCl_3$)), using the results of elemental analysis, a mixed-melting point determination, the specific rotation, IR(KBr), PMR, and the R_f's of tlc.

From II-2. II-2 (0.50 g) was bromolyzed in diethyl ether (5 ml) with the bromine solution (0.77 ml), hydrolyzed in moist dioxane (10%-H_2O; 10 ml) in the presence of silver carbonate (140 mg) for 2 hr, and then chromatographed with the S7 solvent to give V-2 (0.23 g; 48%). V-2 (117 mg) was hydrogenolyzed to give VI-2 (35 mg; 77%), which was identified with authentic isomaltose by paper chromatography (Toyo filter paper No. 50; solvents, A, B, and D), and also by comparison of β-octa-*O*-*p*-nitrobenzoate.[16]

16) *Cf.* E. M. Montgomery, F. B. Weakley, and G. E. Hilbert, *J. Amer. Chem. Soc.*, **71**, 1682 (1949). The octa-*O*-*p*-nitrobenzoate prepared from the authentic isomaltose according to their directions melted at 200—202 °C and had $[\alpha]_D^{25}$ +99° (*c* 1.0, $CHCl_3$) (Found: C, 52.90; H, 2.95; N, 7.17%).

Ethyl Dodeca-O-benzyl-terminal-6-O-p-nitrobenzoyl-terminal-1-thio-α-isomaltotetraoside (I-4). I-2 (0.95 g) in diethyl ether (14 ml) was treated with a bromine solution (1.41 ml) to give sirupy III-2, which was then condensed with II-2 (0.95 g) in nitromethane (8 ml) containing 2,6-lutidine (0.10 ml) for 2 days. A crude mixture was chromatographed with the S40 solvent to give a homogenous oil of I-4 (0.84 g; 59%), $[\alpha]_D^{25}$ +108° (*c* 1.0, $CHCl_3$) as the main product. The PMR spectrum showed the presence of 12 benzyl groups and one thioethyl group per *p*-nitrobenzoyl group in I-4.

Ethyl Dodeca-O-benzyl-terminal-1-thio-α-isomaltotetraoside (II-4). I-4 (85 mg) was dissolved in a mixture of methanol (20 ml) and dioxane (5 ml) and treated with dilute sodium methoxide (1.5 M; 0.25 ml) at 50 °C for 2 hr. The mixture was chromatographed with the S15 solvent to give II-4 (77 mg; 98%), $[\alpha]_D^{25}$ +106° (*c* 1.0, $CHCl_3$). The PMR spectrum had no signal of the *p*-nitrobenzoyl group.

Isomaltotetraose (VI-4). I-4 (60 mg) in diethyl ether (1.0 ml) containing dioxane (0.05 ml) was treated with a a bromine solution (0.057 ml) to give 66 mg of II-4, which was then stirred in moist dioxane (13%-H_2O; 4 ml) with silver carbonate (50 mg) for 1 hr. Subsequent chromatography with the S15 solvent gave IV-4 (38 mg; 65%), $[\alpha]_D^{25}$ +91° (*c* 1.0, $CHCl_3$), which was then methanolyzed in methanol (20 ml) containing dioxane (1 ml) with dilute sodium methoxide (1.5 M; 0.25 ml) and chromatographed with the S7 solvent to give V-4 (26 mg; 74%), $[\alpha]_D^{25}$ +91° (*c* 1.0, $CHCl_3$). V-4 (19 mg) was hydrogenolyzed in a mixed solvent of dioxane, methanol, and water (3+1+1 ml, initial→1+1+6 ml, final, containing 5 drops of acetic acid) to give a hygroscopic glass of VI-4 (4.5 mg; 63%), $[\alpha]_D^{25}$ +148° (*c* 0.5, H_2O); it was identified with the authentic isomaltotetraose by paper chromatography with the B, C, and D solvents, as well as by a comparison with β-tetradeca-*O*-benzoate[17] (mp 140.5—145.5 °C, $[\alpha]_D^{25}$ +169° (*c* 0.3, $CHCl_3$)), using the results of elemental analysis, a mixed-melting point determination, IR (KBr), and the R_f's of tlc.

Ethyl Tetracosa-O-benzyl-terminal-6-O-p-nitrobenzoyl-terminal-1-thio-α-isomaltooctaoside (I-8). I-4 (213 mg) was treated in diethyl ether (3.1 ml) containing dioxane (0.4 ml) with a bromine solution (0.16 ml) to give III-4, to which was then added a solution of II-4 (213 mg) in nitromethane (2.0 ml) containing 2,6-lutidine (0.013 ml). After one week, the mixture was chromatographed with the S30 solvent to give I-8 (45 mg; 11%), $[\alpha]_D^{25}$ +110° (*c* 1.1, $CHCl_3$) as the main product. The PMR spectrum showed the presence of 24 benzyl groups per *p*-nitro-benzoyl-group in I-8.

Ethyl Tetracosa-O-benzyl-terminal-1-thio-α-isomaltooctaoside (II-8). I-8 (10 mg) was treated in a mixed solvent of methanol (10 ml) and dioxane (1 ml) with dilute sodium methoxide (1.5 M; 0.15 ml) for 2 hr at 50 °C. Subsequent chromatography with the S20 solvent gave II-8 (8.3 mg; 86%), $[\alpha]_D^{25}$ +110° (*c* 0.8, $CHCl_3$). The IR spectrum (film) showed no absorption of the *p*-nitrobenzoyl group.

Isomaltooctaose (VI-8). I-8 (31.6 mg) was dissolved in a mixed solvent of diethyl ether (0.5 ml) and dioxane (0.1 ml) and then treated with a bromine solution (0.03 ml) to give III-8, which was then stirred in moist dioxane (14%-H_2O; 7 ml) with silver carbonate for 2 hr and chromatographed with the S20 solvent to give IV-8 (17.4 mg; 56%), $[\alpha]_D^{25}$ +99° (*c* 0.5, $CHCl_3$). IV-8 (11 mg) was treated in a mixed solvent of methanol (20 ml) and dioxane (5 ml) with dilute sodium methoxide (1.5 M; 0.25 ml) and chromatographed with the S15 solvent to give V-8 (9.8 mg; 93%), $[\alpha]_D^{25}$ +102° (*c* 0.3, $CHCl_3$).[18] V-8 (8.0 mg) was hydrogenolyzed in a mixed solvent of dioxane, methanol, and water (5+1+0.5 ml, initial→2+0.5+4 ml, final; containing five drops of acetic acid) over palladium balck (10 mg×5) to give a glass of VI-8 (1.8 mg; 59%), $[\alpha]_D^{25}$ +165° (*c* 0.2, H_2O), which had the same R_f values as the eighth spot of the partial hydrolyzate of Dextran T10 (Pharmacia Fine Chemicals Co.), developed with the B and C solvents.

17) *Cf.* Ref. 15; the preparation of the tetradeca-*O*-benzoate from the authentic isomaltotetraose according to their directions gave only an amorphous product (mp 142—146 °C, $[\alpha]_D^{25}$ +164° (*c* 0.9, $CHCl_3$) (Found: C, 68.60; H, 4.58%).

18) *Cf.* E. R. Ruckel and C. Schuerch, *J. Org. Chem.*, **31**, 2233 (1966). The reported value for the blocked polysaccharide with $\overline{DP}_n$=9 is $[\alpha]_D^{25}$ +109° ($CHCl_3$).

Electrochemical Fluorination of Diols and Heterocyclic Compounds[1]

Takashi ABE, Shunji NAGASE, and Hajime BABA

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received November 16, 1972)

Electrochemical fluorination of diols ($HO-CH_2-CH_2-)_2X$ ($X=CH_2$, O, S, NH, NCH_3, NC_2H_5) afforded the corresponding perfluoro-heterocyclic compounds together with the cleaved products as a result of cyclization. Perfluoro-*p*-dioxane, a new compound having boiling point at 22.5—23.0 °C, was obtained from diethylene glycol. Electrochemical fluorination of heterocyclic compounds such as tetrahydropyran, *p*-dioxane, *p*-thioxane and morpholine was carried out and the results were compared with those obtained with diols.

Upon electrochemical fluorination, the formation of five- or six-membered perfluoro-heterocyclic compounds has been known to take place from the straight chain starting material containing a sufficient number of carbon atoms and hetero atom in proper position.[2-4]

We studied the electrochemical fluorination of such diols as 1,3-propanediol and 1,4-butanediol in order to obtain perfluoromalonic acid and perfluorosuccinic acid, respectively.[5,6] From 1,4-butanediol, perfluorotetrahydrofuran, formed as a result of cyclization, was obtained as the main product. It seems of interest to investigate the electrochemical fluorination of the compounds having two functional groups in order to obtain perfluoro-heterocyclic compounds.

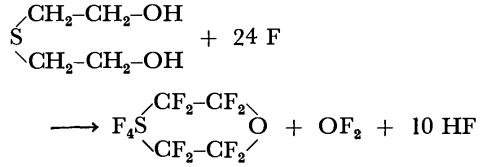
The aim of this work is to examine the ring formation upon electrochemical fluorination of the compounds of the type $(HO-CH_2-CH_2-)_2X$ [$X=CH_2$(I), O(II), S(III), NH(IV), NCH_3(V), NC_2H_5(VI)], comparing the yields with those obtained from the fluorination of corresponding heterocyclic compounds and also to discuss the reaction mechanism. No detailed study has been reported on the fluorination of diols containing hetero atom, while the heterocyclic compounds dealt with in the present work were familiar starting material for the fluorination in electrochemical process.[4,7] As expected ring formed products, $\overline{CF_2CF_2CF_2CF_2CF_2O}$ (XI) was formed from I, $\overline{CF_2CF_2OCF_2CF_2O}$ (XII) from II, $\overline{CF_2CF_2OCF_2CF_2}SF_4$ (XIII) from III, $\overline{CF_2CF_2OCF_2CF_2}NF$ (XVI) from IV, $\overline{CF_2CF_2OCF_2CF_2}NCF_3$ (XV) from V and $\overline{CF_2CF_2OCF_2CF_2}NC_2F_5$ (XVI) from VI, respectively.

Experimental

Materials and Apparatus. All reagents except *p*-thioxane[8] were commercial products and used after purification when necessary. The purity of anhydrous hydrogen fluoride was higher than 99.5%.

All the features of the apparatus (capacity of the electrolytic cell, 1 l; electrodes, Ni plates; effective anodic surface area, 9.2 dm^2) and the procedures were essentially the same as described previously.[5,9,10]

General Procedures. In order to compare the results with those obtained in each experiment, the conditions for fluorination were made to be the same; the electrolysis was carried out by batch (0.34 mol%), and cell temperatures and anodic current density were adjusted to 5—6 °C and 2.7 A/dm^2. The most important setting condition was the amount of electricity passed, *i.e.*, reaction time. Electrolysis was continued until the theoretical amount of electricity required to complete the reaction had passed. This was based on the amount of current assumed to be required to form fluorine which would react with the starting material. Taking an example in III (X=S), the following equation is available.



Thus 4.8 Faraday (128.7 A hr) is required to fluorinate 0.20 mol of the starting material. The value of yield (mol %) of six-membered perfluoro-cyclic ether should coincide with that of the current efficiency of the six-membered perfluoro-cyclic ether by the above equation.

As a typical example, the procedures for the fluorination of pentamethylene-1,5-diol (I) will be described. Anhydrous hydrogen fluoride (about 1 l) was introduced into the cell. Prior to fluorination, electrolysis was carried out in order to remove a trace of impurity until the voltage rose to 6.5 V. The sample (20.8 g) of I was introduced into the cell, and electrolysis was carried out with an anodic current density of 2.7 A/dm^2, at a cell voltage of 4.8—6.1 V, and

a cell temperature of 5—6 °C. Electrolysis was conducted for 130.0 A hr (Theoretical; 128.7 A hr).

Gases evolving from the cell were passed through a reflux condenser kept at −25 °C, over NaF pellets and perfluorocarboxylic acid fluoride absorber[11] (a couple of polyethylene bottles containing water), and then bubbled through an alkaline solution of sodium sulfite containing a small amount of potassium iodide in series of Ichinose gas washers in order to eliminate oxygen difluoride, and finally collected in traps immersed in liquid nitrogen. After electrolysis, the solution drained from the cell was checked, none of perfluorinated compounds being found.[12]

The reaction products (12.9 g) condensed in cold traps were subjected to low temperature distillation and separated into three fractions. Each fraction was subsequently analysed by glc (column; silica gel, Kel F #3 30% on Chromosorb PAW, carrier; He). Compounds in Fractions 1, 2 and 3 were as follows. Fraction 1 (bp∼−77.9 °C, 0.8 g): CF_4,[13] C_2F_6, CHF_3, Fraction 2 (bp −77.8∼−56.5 °C, 1.5 g): C_3F_8, C_2HF_5, CF_3OCF_3, $CF_3OC_2F_5$, Fraction 3 (bp −56.4 °C∼r.t., 10.6 g): $\overline{CF_2CF_2CF_2CF_2CF_2O}$ (XI), $\overline{CF(CF_3)CF_2CF_2CF_2O}$, $\overline{CF_2CF_2CF_2CF_2O}$, C_3F_8, $CF_3OC_2F_5$, n-C_4F_{10}, n-C_5F_{12}. The first two compounds (XI, $\overline{CF(CF_3)CF_2CF_2CF_2O}$) were separated by repetitive glc and were analysed by IR, ^{19}F-NMR, Mass, and fluorine determination.

Results and Discussion

The reaction conditions for the fluorination of diols and heterocyclic compounds are given in Tables 1 and 2, respectively. The results obtained are summarized in Table 3.

We see that the formation of six-membered heterocyclic compounds were observed from corresponding diols, and their yields from diols and also from the fluorination products of heterocyclic compounds were significantly affected by the hetero atom.

Typical features of the fluorination products were observed in the fluorination of I and II. A considerable amount of the five-membered perfluoro-heterocyclic compounds ($\overline{CF(CF_3)CF_2CF_2CF_2O}$ and $\overline{CF_2CF_2CF_2CF_2O}$ from I, $\overline{CF_2OCF_2CF_2O}$ from II) was obtained as well as the expected six-membered compounds (XI from I and XII from II, respectively).

Similarly, ring contraction was observed in the fluorination of tetrahydropyran (VII) and *p*-dioxane (VIII). Thus ring expansion was expected to occur and an attempt was made to obtain XI by the fluorination of 2-methyltetrahydrofuran. When 2-methyltetrahydrofuran was subjected to electrochemical fluorination (reaction conditions: sample, 0.20 mol; anodic current density, 2.7 A/dm²; electricity passed, 102.6 A hr; cell voltage, 4.8—5.1 V; cell temp., 5—6 °C), the product (29.4 g) mainly consisted of perfluoro-

NC_2H_5 (VI)	5.1—5.4	159.6	14.4

11) The products in perfluorocarboxylic acid fluoride absorber were worked up in almost the same way as reported.[5] Perfluoroglutaric acid obtained was converted into silver salt prior to analysis because of its strong hygroscopic character. The perfluorocarboxylic acids obtained were as follows. Silver perfluoroglutarate (0.5 g); mono-basic acid sodium salt (4.6 g) [sodium trifluoroacetate (7 wt%), sodium perfluoropropionate (7), sodium perfluorobutyrate (19), sodium perfluorovalerate (67)].

12) No perfluorinated products were found in the cell drainings throughout experiments.

13) Arranged in the order of decrease in product composition (wt%).

a) Bp 32.0 °C (reported 32 °C).[7a] Found: F, 70.7%. Calcd: F, 71.3%.
b) Bp 26.5—27.0 °C. Found: F, 70.5%. Calcd: F, 71.3%.
c) Bp 67.6 °C. Found: F, 70.3%. Calcd: F, 70.8%.

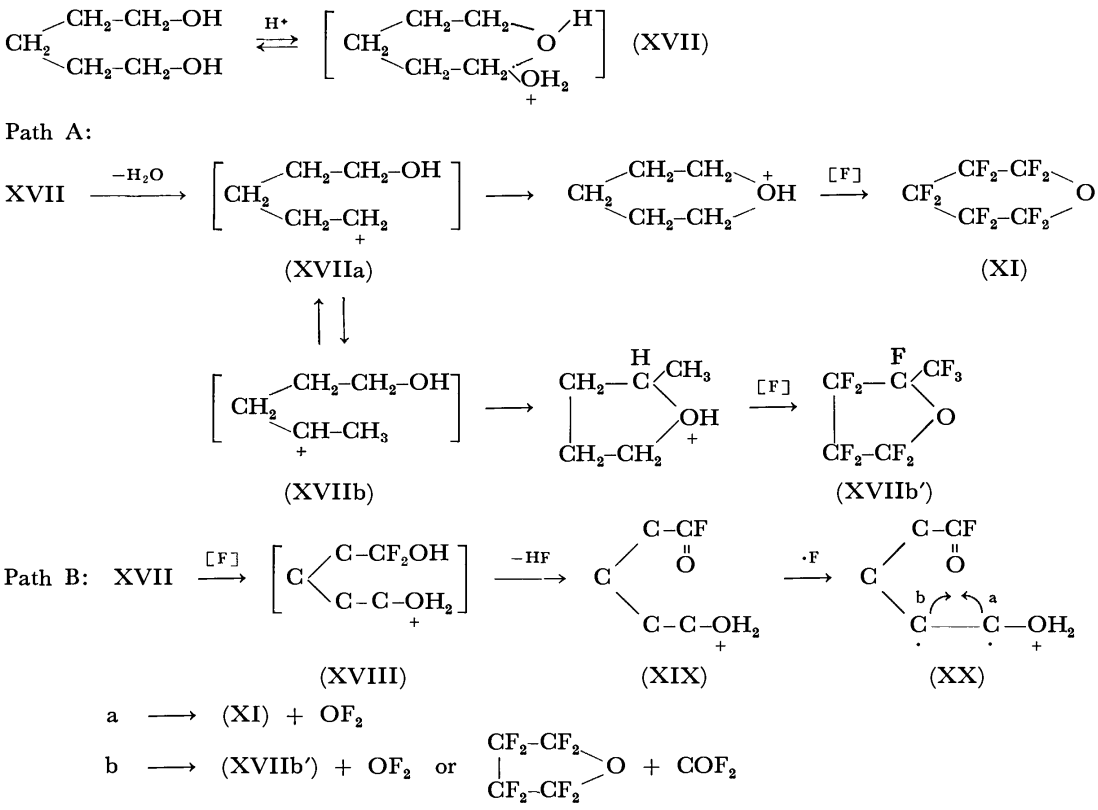
2-methyltetrahydrofuran, and XI produced as a result of the ring isomerization. The yields of the two compounds were 36.1% and 8.5%, respectively.

Perfluoro-*p*-dioxane[14] (XII) was produced as the ring formed product from II, and also the fluorination product of VIII, though the electrochemical fluorination of VIII yielded only perfluoro-1,2-dimethoxyethane as a cleaved product.[7b]

Fluorination of IV afforded a trace of perfluoromorpholine (XIV), which was obtained also in poor yield from morpholine (X). However, when *N*-alkyldiethanolamines (V and VI) were subjected to electrochemical fluorination, the production of an increased amount of the ring formed products (perfluoro-*N*-alkylmorpholines, XV and XVI) was observed as compared with that from IV.[15]

Mechanism. For the formation of perfluoroheterocyclic compounds from diols, there seems to be two conceivable mechanisms operating simultaneously during the course of electrochemical fluorination. One involves cyclization *via* oxonium compound followed by dehydration (Path A), and the other involves cyclization by radicals formed on the carbon chain of the same molecule (Path B). It is well-known that oxonium compounds are formed when alcohols and ethers are dissolved in anhydrous hydrogen fluoride.[16] In the case of pentamethylene-1,5-diol (I), oxonium compound (XVII) is formed when I is dissolved in anhydrous hydrogen fluoride, XVIIa and XVIIb being then formed by dehydration followed by isomerization. Formation of tetrahydropyran including a trace of methyltetrahydrofuran from I in hydrogen fluoride was ascertained in the following experiment, and it is strongly suggested that this type of cyclization (Path A) could occur: 5 g of I was added to 50 ml anhydrous hydrogen fluoride in a 300 ml flask made of poly(chlorotrifluoroethylene), fitted with a reflux condenser (−25 °C). After being left standing 2 hr at room temperature, the solution was diluted with water (200 ml) extracted with ether, the ethereal solution (about 300 ml) being then neutralized by alkaline solution. After removing ether by distillation, the distillation residue (0.5 g) was analysed by glc (column; Carbowax 4000 20% on Celite 545, carrier; He). glc analysis showed the presence of tetrahydropyran (major) and trace of 2-methyltetrahydrofuran.

On the other hand, fluoro-alcohol (XVIII) carrying fluorine atom in α position, which is considered to be formed during the course of electrochemical fluorination of primary alcohol, eliminates hydrogen fluoride and changes into acid fluoride (XIX). The acid fluoride thus obtained may proceed to perfluorocarboxylic acid fluorides[11] (perfluoroglutaryl fluoride, perfluorovaleryl fluoride and other degradaded perfluoroacid fluorides), but part of it (XIX) may be subjected to radical attack by the carbon radical of



14) Bp 22.5—23.0 °C. ^{19}F-NMR (chemical shift from external CF_3COOH); 10.7 ppm (singlet, CF_2). On the other hand, perfluoro-1,2-dimethoxyethane had a bp of 9.0—10.0 °C (reported 13 °C). ^{19}F-NMR; −20.5 ppm (triplet, CF_3), 14.2 ppm (quartet, CF_2).

15) Alkylamines give the corresponding perfluoroalkylamines in the best yield in the case of tertiary amines. *Cf. e. g.*, E. A. Kauck and J. H. Simmons, U. S. 2616927 (1952); Brit. 666733 (1952).

16) See for example, "The Chemistry of Non-Aqueous Solvents," Vol. II, ed. by J. J. Lagowski, Academic Press Inc., New York (1967), p. 81; "Protonated Heteroaliphatic Compounds," by G. A. Olah and A. M. White, *Chem. Rev.*, **70**, 561 (1970).

the same molecule resulting from the hydrogen abstraction by fluorine radical creating the bond in either way, B-a or -b.

Accordingly, Path A may be the first step in the reaction, while Path B may occur during the course of electrochemical fluorination. The usual poor yield of the ring formed products from diols which contain a hetero atom may be explained to be due to an undesirable influence of the protonated hetero atom on the stability of the carbonium ion formed (XVIIIa, XVIIb) and also an easier fission of the bond of the carbon-hetero atom.

The authors wish to express their sincere thanks to Mr. S. Fujii for the ^{19}F-NMR experiment, Mr. K. Kodaira for the Mass measurements, and Dr. K. Inukai of this Institute for his interest in this work.

Research Institute for Polymers and Textiles, Kanagawa-ku, Yokohama 221

(Received February 1, 1973)

The singlet-energy transfer from the phenol to the indole chromophores occurs intramolecularly, with a high efficiency, in the compounds containing these chromophores joined by the methylene and the amide groups. The total emission spectra of the compounds consisted only of those from the indole chromophore, neither the fluorescence nor the phosphorescence of the phenol chromophore contributing to them, and the excitation spectra of the fluorescence were similar to the absorption spectra. The quantitative analysis of the fluorescence-polarization spectra suggested that the ^1L_b transition of the indole chromophore was excited in the energy transfer. The intramolecular interactions between these chromophores in the ground and excited states are discussed.

The fluorescence yield of the protein is very low compared with the contribution to be expected from the constituents of the aromatic amino acids.[1-4] Weber and Rosenheck[5] have suggested that the phenolic hydroxide of the tyrosine residue is hydrogen-bonded to the neighboring carboxylate moieties in the excited state, thus resulting in the non-fluorescent phenolate ion. Cowgill[6] has proposed the hypothesis that the peptide bond enhances the vibrational deactivation of the aromatic ring. The combined action of these effects may be responsible for the reduction of the fluorescence quantum yield of the protein.[7]

The fluorescence of the protein containing the tryptophane residue is the only one attributable to the residue, neither the phenylalanine residue nor the tyrosine residue having any detectable fluorescence. The excitation spectra of the fluorescence indicate the excitation-energy transfer from the tyrosine to the tryptophane residues in some proteins,[8-10] though no such sensitization of any tryptophanyl fluorescence by the tyrosine residue has been observed in other proteins.[1,11] The excitation-energy transfer seems reasonable from the viewpoint of the energy-level sequence of the aromatic amino acids: Phe<Tyr<Trp<Tyr^-; it is primarily due to the long-range dipole-dipole interaction, the theory of which has been developed by Förster.[12]

The measurements of the fluorescence of the compounds which contain the phenol and/or the indole chromophores provide convenient information for studying the fluorescence of the protein. A number of reports have been published concerning the quantum yield,[13-17] the lifetime,[18,19] and the peak position[20-23] of the fluorescence and the intramolecular[10] and intermolecular energy transfer.[24]

In this experiment, a series of compounds, I—VI, containing the phenol or its methyl ether, and the indole chromophores joined by the methylene groups and the amide group were prepared, and the intramolecular interaction between these chromophores was studied in

Recently, the intramolecular energy transfer has been investigated in several donor-acceptor pairs combined by methylene groups.[25] Schnepp and Levy[26] have observed that the efficiency of the singlet-energy transfer from the naphthalene to the anthracene groups is comparable to that of the donor fluorescence, and they have considered a Förster-type mechanism for the transfer. Lamola *et al.*[27] have found that the singlet excitation is transferred from the naphthalene to the benzophenone chromophores with a high, but not total, efficiency, and that the triplet-energy transfer from the latter to the former chromophores occurs with a total efficiency, which the exchange mechanism can account for. The fluorescence from the intramolecular exciplex formed in this pair has also been reported.[28]

Experimental

*1-(3-Indolyl)-2-(*p*-methoxyphenyl)ethane (I).* The ethereal solution of indolylmagnesium iodide was prepared according to the procedure described by Baker.[29] Into 16.5 g of *p*-methoxyphenylethylbromide in ether, we stirred a solution of the Grignard compound of indole (9 g of indole). The reaction mixture was then gently refluxed for about 3 hr. The Grignard compound was decomposed with ice and ammonium chloride, and the compound was extracted with ether. The residue from the ether extract was recrystallized from benzene; mp 113—114 °C.

Found: C, 81.06; H, 6.47; N, 5.24%. Calcd for $C_{17}H_{17}NO$: C, 81.24; H, 6.82; N, 5.57%.

*1-(3-Indolyl)-3-(*p*-methoxyphenyl)propane (II).* This compound was prepared by a procedure analogous to that of 1-(3-indolyl)-2-(*p*-methoxyphenyl)ethane, using a Grignard compound of indole and 3-(*p*-methoxyphenyl)propylbromide in ether. The compound was recrystallized from benzene; mp 80—82 °C.

Found: C, 81.51; H, 7.51; N, 5.14%. Calcd for $C_{18}H_{19}NO$: C, 81.48; H, 7.22; N, 5.28%.

β-(3-Indolyl)vinyl p*-methoxyphenyl Ketone.* To 5.5 g of indole-3-aldehyde and 18 g of sodium hydroxide in water–ethanol (20—15 ml), we added 7.1 g of *p*-methoxyacetophenone. The reaction mixture was then stirred for 8 hr at 60 °C to give a red solution. The solution was concentrated, and the residue was solidified. The compound was subsequently washed with water and recrystallized from benzene; mp 169—173 °C.

Found: C, 78.46; H, 5.31; N, 4.59%. Calcd for $C_{18}H_{15}NO_2$: C, 77.96; H, 5.45; N, 5.05%.

2-(3-Indolyl)ethyl p*-methoxyphenyl Ketone.* The ethanol solution of 5 g of β-(3-indolyl)vinyl *p*-methoxyphenyl ketone was reduced with hydrogen at 10 atmospheres in the presence of Raney nickel at 55 °C for 30 min.[30] The product was collected and recrystallized from ethanol; mp 132 °C.

Found: C, 77.79; H, 6.10; N, 5.17%. Calcd for $C_{18}H_{17}NO_2$: C, 77.39; H, 6.13; N, 5.01%.

*1-(3-Indolyl)-3-(*p*-hydroxyphenyl)propane (III).* According to a modification of the Wolf-Kishner reduction,[31] the carbonyl group of 2-(3-indolyl)ethyl *p*-methoxyphenyl ketone was reduced and its methoxy group was simultaneously demethylated. A paste product was thus obtained, and the compound was repeatedly recrystallized from a water-acetone mixture; mp 108—110 °C.

Found: C, 82.15; H, 6.51; N, 5.34%. Calcd for $C_{17}H_{17}NO$: C, 81.24; H, 6.82; N, 5.57%.

N-p-*Methoxybenzyl-3-indolylacetamide (IV),* N-p-*Hydroxybenzyl-3-indolylacetamide (V), and* N-*2-(3-Indolyl)ethyl-2-(*p*-methoxyphenyl)propionamide (VI).* These compounds were prepared by the method using carbodiimide.[32] The reaction mixture including the corresponding acid and amide components, and *N,N*-dicyclohexylcarbodiimide in acetonitrile was stirred overnight over ice. The filtered solution was evaporated, and the products were recrystallized from benzene.

IV: mp 107—109 °C.

Found: C, 73.02; H, 6.18; N, 9.31%. Calcd for $C_{18}H_{18}N_2O_2$: C, 73.45; H, 6.16; N, 9.52%.

V: mp 184—186 °C.

Found: C, 73.02; H, 5.58; N, 9.67%. Calcd for $C_{17}H_{16}N_2O_2$: C, 72.84; H, 5.75; N, 9.99%.

VI: mp 90—91 °C.

Found: C, 74.93; H, 6.70; N, 8.28%. Calcd for $C_{20}H_{22}N_2O_2$: C, 74.51; H, 6.88; N, 8.69%.

Measurements. The emission and the fluorescence excitation spectra were measured by means of a Hitachi spectrophotofluorometer, Model MPF-2A. The excitation spectra were obtained at 20 per cent of the absorption of the peak maxima, so they could be compared with the absorption spectra.

The efficiency of the energy transfer of the singlet excitation from the phenol or its methyl ether to the indole chromophores, Φ_t, was calculated according to the following considerations.

The fluorescence intensity, $F_N(\lambda)$, of the compounds on excitation at λ nm is represented by this equation:

$$F_N(\lambda) = Q_N \cdot [A_{In}(\lambda) + A_{Ph}(\lambda) \cdot \Phi_t] \quad (1)$$

where Q_N is the fluorescence quantum yield and where A_{In} and A_{Ph} are the quanta absorbed by the indole moiety and the phenol or its methyl ether moiety respectively. It seems reasonable that A_{In} is equal to that of the model compound containing only the indole chromophore: 3-methylindole for I, II, and III; indole-3-acetamide for IV and V, and *N*-acetyltryptamine for VI; it also seems reasonable that A_{Ph} is equal to that of the model compound containing only the phenol or its methyl ether chromophore: *p*-methylanisole for I and II; *p*-cresol for III; *N*-acetyl-*p*-methoxyphenylethylamine for IV; *p*-hydroxyphenylethylamine for V, and *p*-methoxyphenylpropionamide for VI. On these assump-

tions, the ratio of $F_N(\lambda)$ to the fluorescence intensity of the model compound, $F_{In}(\lambda)$, may be represented by an equation in which

$$F_N(\lambda)/F_{In}(\lambda) = \beta \cdot [\{\Phi_t \cdot A_{Ph}(\lambda)/A_{In}(\lambda)\} + 1] \quad (2)$$

β is the ratio of the fluorescence quantum yields. In Eq. (2), the value of Φ_t can be calculated from the measurements of $F(\lambda)$, $A(\lambda)$, and β.

In the study of the temperature dependence of the fluorescence intensity, a quartz tube (3 mm in diameter) containing the sample in EPA was cooled in the temperature of liquid nitrogen and then left in a Dewar flask at room temperature during the course of the measurement. The temperature was monitored by means of a copper-constantan thermocouple injected into the sample tube; it increased monotonously at the average rate of 2.5 °C per minute from −120 to 20 °C.

In order to avoid the depolarization due to the Brownian movement, the fluorescence-polarization spectra were measured at −70 °C in a propylene glycol solution, which forms a rigid glass at that temperature.

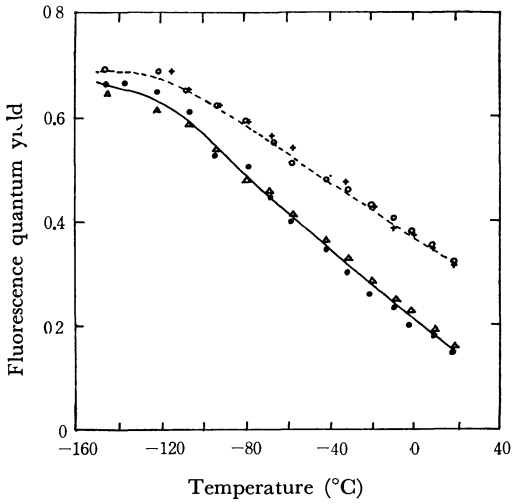

Fig. 2. The temperature dependence of the fluorescence intensities of (+) 3-methylindole, I (○), II (●), and III (△) in EPA.

Results

The total emission spectra of 3-methylindole, *p*-cresol, and an equimolar mixture of them in EPA at 77 K are shown in Fig. 1a. The 0–0 fluorescent emission band of 3-methylindole is located at a longer wavelength than that of *p*-cresol, as in the case of the phosphorescence. The emission spectrum of *p*-methylanisole was analogous to that of *p*-cresol. The excitation wavelength is 280 nm, at which the ratio of the number of the quanta absorbed by 3-methylindole and *p*-cresol is about 1 : 0.3. The emission spectrum of the equimolar (2×10^{-5} M) mixture is superimposed on those of the constituents, as is seen in Fig. 1a.

The total emission spectrum of I at 77 K is shown in Fig. 1b. The spectra of both the fluorescence and the phosphorescence are very similar to those of 3-methylindole. None of the emission from the anisole moiety can be seen in Fig. 1b. This confirms that the excitation energy is transferred from the phenol chromophore to the indole chromophore with a high efficiency. The shapes of the emission spectra of the other compounds were also very similar to that of 3-methylindole, except for the slight blue shift in the spectra of IV, V, and VI, which contain amide groups. The ratio of the intensities of the fluorescence to the phosphorescence of these compounds was little different from that of 3-methylindole.

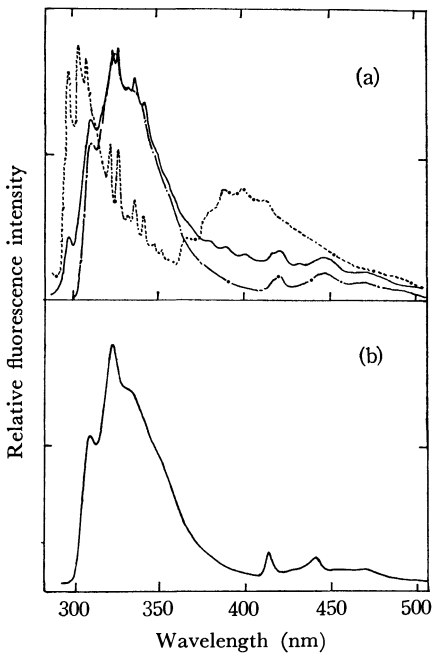

Fig. 1. The total emission spectra in EPA at 77 K, (a): (dotted line) *p*-cresol, (broken line) 3-methylindole, and (solid line) their equimolar (2×10^{-5} M) mixture. (b): I.

The fluorescence characteristics at room temperature in ethanol and in dioxane are listed in Table 1. The positions of the fluorescence peaks are shifted to longer wavelengths in ethanol, the absorption spectra undergoing a very small shift. The pronounced red shift of the fluorescence of indole and its derivatives induced by the polar solvent has been suggested as resulting from the reorientation of the surrounding solvent molecules in the excited state,[20,21] or, alternatively, from the formation of the exciplex with the solvent molecules.[22,23]

The fluorescence spectra of the compounds containing the amide groups (IV, V, and VI) are shifted to somewhat shorter wavelengths than that of 3-methylindole, as is shown in Table 1. These compounds also indicate a slight blue shift in the absorption spectra; they have the same Stokes shift as 3-methylindole. The fluorescence yields of these compounds are low in ethanol, whereas they approach the normal level in dioxane (Table 1). Cowgill[16] has also observed the low fluorescence yields of the tryptophanyl and the tyrosyl derivatives in a polar solvent that can solvate the carbonyl group by hydrogen-bonding.

The fluorescence yields of II and III are about half as high as those of 3-methylindole and I at room temperature, irrespective of the existence of oxygen molecules and of the polarizability of the solvent, as is demonstrated in Table 1. However, the former recover to the same level as the latter at low temperatures (Fig. 2).

Table 1. Relative quantum yields and wavelength maxima of the fluorescence in ethanol and dioxane which are in air and flushed with argon gas

Compound	in Ethanol			in Dioxane		
	Fluorescence Maximum (nm)	Relative Quantum yield		Fluorescence Maxmium (nm)	Relative Quantum yield	
		in Air	Ar		in Air	Ar
3-Methylindole	350	3.3_5	4.8	335	3.4	4.0
I	350	3.4	4.8	335	3.6	4.3
II	350	1.6	2.0	335	1.6	2.0

VI	348	3.0	4.2_5	335	3.1_5	3.9

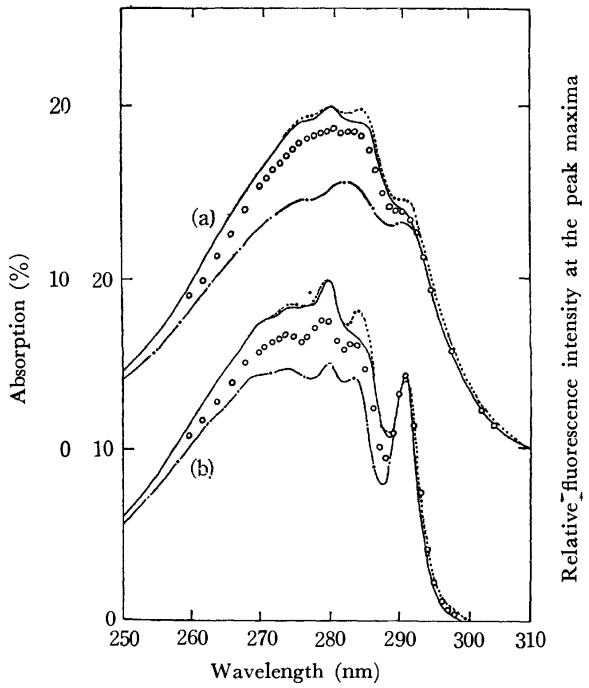

Fig. 3. The absorption and the fluorescence excitation spectra of I (a) in ethanol, and (b) in methylcyclohexane: (dotted line) the absorption spectrum, and (○) the excitation spectrum. The absorption spectra of (broken line) 3-methylindole, and (solid line) the equimolar mixture of 3-methylindole and *p*-methylanisole. The spectra except for that of 3-methylindole were obtained at 20 per cent of the absorption of the peak maxima.

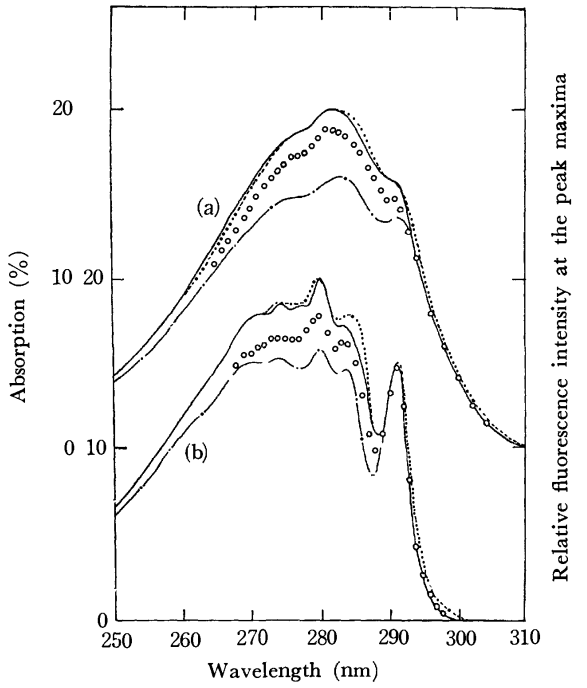

Fig. 4. The absorption and the fluorescence excitation spectra of III (a) in ethanol, and (b) in methylcyclohexane: (dotted line) the absorption spectrum, and (○) the excitation spectrum. The absorption spectra of (broken line) 3-methylindole, and (solid line) the equimolar mixture of 3-methylindole and *p*-cresol. The conditions are the same as those in Fig. 3.

As may be seen in Fig. 2, the fluorescence yields decrease upon an increase in the temperature, the shapes of the fluorescence spectra remaining unaltered. It is known that the nonradiative deactivation process of the indole derivatives is temperature-dependent.[3] From the slope of the straight line obtained by plotting $\log(1/Q_N-1)$ *vs.* the reciprocal of the absolute temperature,[15] the value of the activation energy of the process in I was evaluated to be 2.5 kcal/mol, which was equal to that of 3-methylindole. The fluorescence yields of II and III depend more strongly upon the temperature than do those of 3-methylindole and I (Fig. 2).

The absorption spectra of the compounds and the equimolar mixtures of the model compounds containing the indole chromophore or the phenol (anisole) chromophore alone are shown in Figs. 3—7. The absorption spectra of the compounds show a distinct spectral distortion compared with those of an equimolar mixture of the model compounds, as may be seen in the figures. The spectral difference is more predominant in methylcyclohexane than in ethanol. The absorption spectra of IV, V, and VI in methylcyclohexane were not available because of the poor solubility. The results obtained for II were very similar to those for I.

The fluorescence-excitation spectra are also illu-

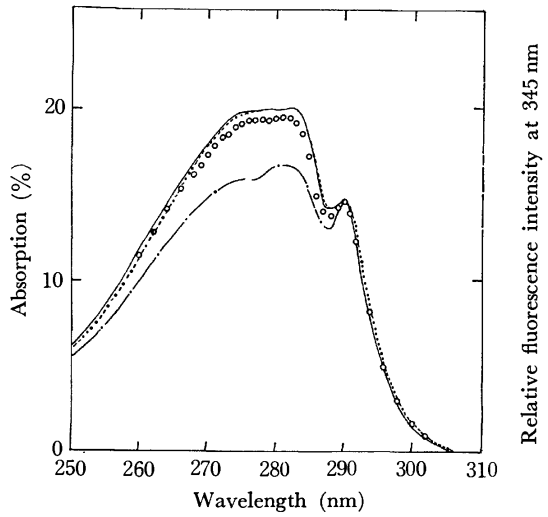

Fig. 5. The absorption spectra of (dotted line) IV, (broken line) 3-acetamidoindole, and (solid line) the equimolar mixture of 3-acetamidoindole and *N*-acety-*p*-methoxyphenethylamine, and (○) the fluorescence excitation spectrum of IV in ethanol. The conditions are the same as those in Fig. 3.

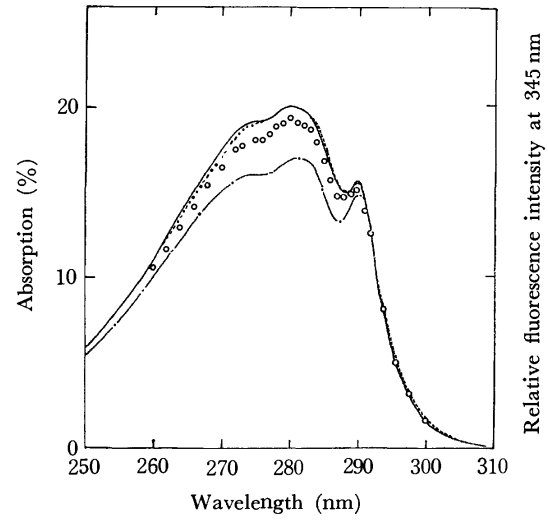

Fig. 6. The absorption spectra of (dotted line) V, (broken line) 3-acetamidoindole, and (solid line) the equimolar mixture of 3-acetamidoindole and *p*-hydroxyphenethylamine, and (○) the florescence excitation spectrum of V in ethanol. The conditions are the same as those in Fig. 3.

strated in Figs. 3—7. They are normalized to the absorption spectra of the equimolar mixtures of the model compounds on the long wavelength edge, in which the incident light is absorbed only by the indole chromophore. They are similar to the absorption spectra of the compounds rather than to those of the equimolar mixtures of the model compounds. However, the excitation spectra never reach the same level as the absorption spectra at wavelengths shorter than 290 nm, where the absorption spectra of the two chromophores overlap.

The values of the efficiencies of the singlet-excitation-energy transfer, Φ_t, which vary from 0.36 to 0.78, are listed in Table 2; they were calculated using Eq. (2). They seem to be subject to experimental error pri-

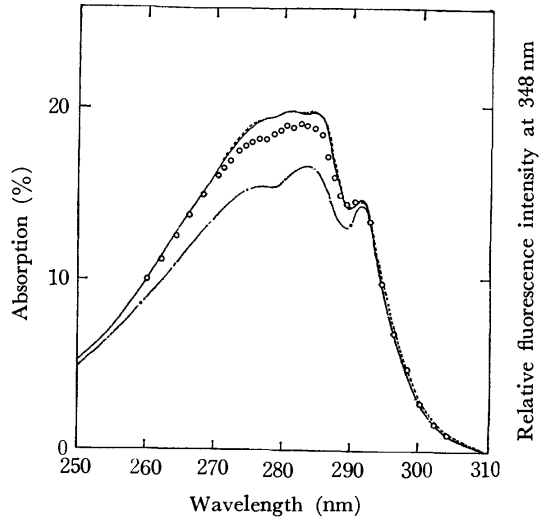

Fig. 7. The absorption spectra of (dotted line) VI, broken line) *N*-acetyltryptamine, and (solid line) the equimolar mixture of *N*-acetyltryptamine and *p*-methoxyphenylpropionamide, and (○) the fluorescence excitation spectrum of VI in ethanol. The conditions are the same as those in Fig. 3.

Table 2. Efficiencies of the intramolecular energy transfer from the phenol to the indole chromophores

Compound	Φ_t in Ethanol	Φ_t in Methylcyclohexane
I	0.63	0.46
II	0.60	0.49
III	0.48	0.36
IV	0.69	—
V	0.56	—
VI	0.78	—

marily because of our neglect of the small spectral differences between the absorption spectra of the compounds and the equimolar mixtures of the model compounds in the long-wavelength band.

The spectra of the fluorescence-excitation polarization in propylene glycol at −70 °C are shown in

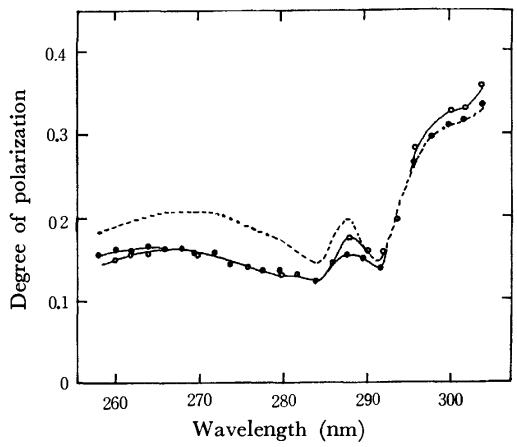

Fig. 8. The fluorescence-polarization spectra in propylene glycol at −70 °C: (dotted line) 3-methylindole, (-○-) I, and (-●-) III. The fluorescence was measured at 360 nm.

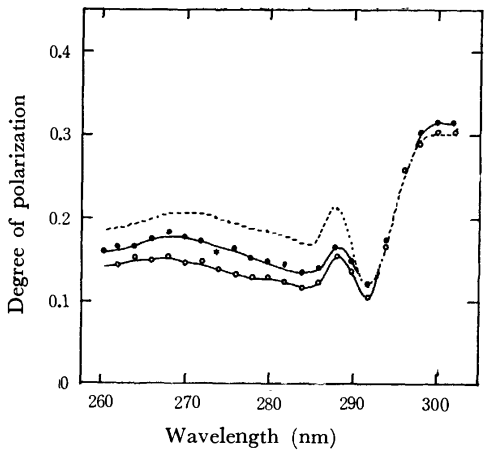

Fig. 9. The fluorescence-polarization spectra in propylene glycol at −70 °C: (dotted line) 3-acetamidoindole, (-○-) IV, and (-●-) V. The fluorescence was measured at 340 nm.

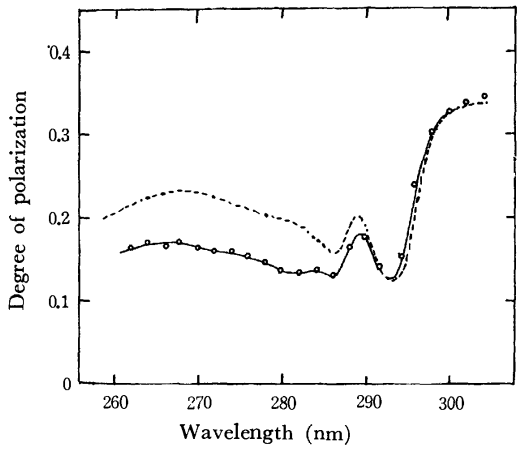

Fig. 10. The fluorescence-polarization spectra in propylene glycol at −70 °C: (dotted line) *N*-acetyltryptamine, and (-○-) VI. The fluorescence was measured at 360 nm.

Figs. 8—10. The spectrum of I exhibits an intense depolarization in wavelengths shorter than 290 nm, while it agrees well with the spectrum of 3-methylindole above 290 nm, as is shown in Fig. 8. The results for II were the same as those for I, and similar results were also obtained for the other compounds (Fig. 8—10).

Discussion

In the near ultraviolet spectra of indole and its derivatives, the ^1L_a and the ^1L_b electronic transition bands overlap strongly.[33-35] It is observed that the ^1L_a transition band is more sensitive to perturbation by solute-solvent interaction than is the ^1L_b transition band. Konev[7] and Strickland *et al.*[34] presented evidence that, on the addition of a drop of butanol to indole and 3-methylindole in hexane, the ^1L_a bands undergo a large red shift and broadening, while the ^1L_b bands undergo only a minor change. The spectral changes are believed to be due to the formation of a hydrogen bond, which severely affects the ^1L_a transition, the moment of which passes through the imino group, but which scarcely at all affects the ^1L_b transition, which is almost perpendicular to the ^1L_a transition.

From the facts that the distortion of the absorption spectra of I—VI is pronounced in the bands to which the absorption of the phenol group contributes little, and is obviously predominant in a non-polar solvent (Fig. 3-7), it may be said to be due to the change in the ^1L_a band of the indole chromophore, a change which is induced by weak intramolecular hydrogen bonding to the phenolic oxygen or the π orbitals of the phenol ring.[36,37] On the other hand, it has been pointed out that the absorption spectra of the adjacent chromophores close to each other differ from the sum of those of the constituents in the peak position and the intensity, mainly because of long-range exciton interaction.[27] The ^1L_b band as well as the ^1L_a band may be expected to change as a result of such interaction.

The low fluorescence yields of II and III at room temperature are anomalous (Table 1 and Fig. 2). The reduction of the population of the singlet state in II and III due to the low probability of the intramolecular energy transfer, due to the enhancement of the intersystem crossing, and due to the photochemical reaction may be excluded, since the efficiencies of the intramolecular energy transfer in II and III were as high as those in other compounds (Table 2), since the ratios of the fluorescence to the phosphorescence of II and III were the same as that of 3-methylindole, and since no detectable absorption change could be observed after irradiation for the fluorescence measurement. Therefore, it may be inferred that the molecular configuration of II and III, in which the two aromatic rings are joined by three methylene groups, is responsible for the fluorescence quenching.

Hirayama's $n=3$ rule states that the aromatic ring pairs combined with three methylene groups have a face-to-face parallel configuration and are likely to form an intramolecular excimer or exciplex as a result of the strong overlap of the two π orbitals.[38] Recently, the temperature dependence of the excimer formation in 1,3-dinaphthylpropane was reported.[39] The disappearance of the excimer emission at low temperature was interpreted in terms of rotation barriers in the methylene chain joining the naphthalene nuclei.

From the fact that the fluorescence yields of II and III approach that of 3-methylindole at low temperatures (Fig. 2), it may be suggested that the quenching of the monomer fluorescence at room temperature has its origin in the formation of the intramolecular com-

plex between the indole group in the excited state and the phenol group in the ground state.

The efficiencies of the energy transfer from the phenol to the indole chromophores in the compounds containing the amide group (IV, V, and VI) remain as high as in the other compounds (Table 2), whereas it has been suggested that the peptide group enhances the internal conversion of the phenol chromophore.[16] On the other hand, there is no evidence that *N*,*N*-dimethylacetamide reduces the efficiencies of the fluorescence or of the intramolecular energy transfer in the compounds containing the phenol chromophore (III and V), although the amide compound intermolecularly quenches the fluorescence of phenol by forming a hydrogen bond.[17] These results indicate that the rate constant of the energy transfer is much greater than those of the radiationless deactivation and of the diffusion-controlled bimolecular encounter.

According to the theory of resonance-energy transfer developed by Förster,[12] the critical radius, R_0, that is, the distance at which the probability of the energy transfer is 50 percent, can be calculated from the experimental parameters. The values of R_0 calculated for the energy transfer from *p*-cresol or *p*-methylanisole to 3-methylindole both in ethanol and in methylcyclohexane are listed in Table 3. The results that the value of R_0 are larger in ethanol (26 and 29 Å for *p*-cresol, and *p*-methylanisole respectively) than in methylcyclohexane (22 and 25 Å) are mainly the result of the more intense overlap integrals and fluorescence yields of the donor molecules in ethanol than in methylcyclohexane. They may agree with the results that the efficiencies of the intramolecular energy transfer are larger in ethanol than in methylcyclohexane, as is shown in Table 2.

Table 3. Calculated critical radii for the resonance energy transfer from *p*-cresol or its methyl ether to 3-methylindole in ethanol and in methylcyclohexane

Donor	Solvent	R_0[a] (Å)
p-Cresol	Ethanol	26
p-Cresol	Methylcyclohexane	22
p-Methylanisole	Ethanol	29
p-Methylanisole	Methylcyclohexane	25

a) The quantum yields of the donor fluorescence were evaluated using that of *p*-cresol which is 0.23 in water.[16] The random orientation of the donor and the acceptor molecules was assumed.

However, it has been suggested that the intramolecular singlet-excitation transfer must be totally efficient in a compound in which the donor-acceptor chromophores are less than ten angstroms apart.[40] The experimental difficulties are responsible for the low transfer efficiencies, as is calculated in Table 2. Higher values might be obtained if the slight spectral distortion in the long-wavelength band could be taken into account.

The depolarization of the fluorescence of the compounds in propylene glycol (Fig. 8—10) may be quantitatively analyzed using the equation formulated by Weber:[41]

$$1/P - 1/3 = [\sum f_i/(1/P_i - 1/3)]^{-1} \quad (3)$$

where P is the degree of the polarization, P_i is that of the ith molecule, and f_i is the fraction of the fluorescence intensity of the ith molecule to the total fluorescence intensity. Now, two types of fluorescence are considered: one ($i=0$) is the fluorescence from the molecule in which the incident quanta are absorbed directly by the indole chromophore, and the other ($i=1$) is the fluorescence from the molecule in which the phenol chromophore is initially excited and the excitation energy is intramolecularly transferred to the indole chromophore. The further sequence of i can be disregarded, since the probability of the reverse transfer of the excitation energy is very low because of the small overlap integral.

Therefore, f_0 and f_1 are represented by the equation: $f_0=A_{\mathrm{In}}/(A_{\mathrm{In}}+\Phi_t\cdot A_{\mathrm{Ph}})$; $f_1=\Phi_t\cdot A_{\mathrm{Ph}}/(A_{\mathrm{In}}+\Phi_t\cdot A_{\mathrm{Ph}})$. The values of P_1, as calculated assuming that Φ_t is 100 percent and substituting the values of P of the model compounds containing only the indole chromophore for the values of P_0, are listed in Table 4. It is remarkable that P_1 indicates the negative polarization on the excitation near 270 nm. This can be expected if the emitting oscillator differs from the exciting one and if $\cos^2\theta<1/3$ is satisfied, where θ is the relative orientation angle.[42]

Table 4. Polarization of the fluorescence on excitation at 270 nm in propylene glycol at −70 °C

Compound	f_0	f_1	P	P_0	P_1[d]
I	0.76	0.24	0.15	0.20[a]	−0.02
II	0.76	0.24	0.16	0.20[a]	0.00
III	0.82	0.18	0.15_5	0.20[a]	-0.07_5
IV	0.80	0.20	0.15	0.21[b]	−0.13
V	0.84	0.16	0.17	0.21[b]	-0.02_5
VI	0.81	0.19	0.16	0.22[c]	−0.12

a) 3-Methylindole. b) 3-Acetamidoindole. c) *N*-Acetyltryptamine. d) Calculated using Eq. (3).

Since the relative orientation of the exciting oscillator in the phenol ring and the emitting one in the indole ring cannot remain unaltered because of the flexibility of the methylene groups combining the two chromophores, the negative polarization cannot be caused by intramolecular energy transfer, which may induce the depolarization of the fluorescence. Therefore, the result may be interpreted on the assumption that the excitation energy absorbed by the phenol group is transferred to the ^1L_b transition oscillator of the indole group, and that it is internally converted to that of the ^1L_a, which is perpendicular to the former and which is known to emit fluorescence in the polar solvent.[33]

These conclusions agree well with the results described by Weber,[24] who observed a small but doubtless negative polarization of indole in the presence of a

large amount of phenol.

The overlap integral of the donor fluorescence and the acceptor absorption spectra, and the relative orientation of the two electronic transition moments, are critical in the intermolecular and intramolecular energy transfers. It is difficult to expect that the ^1L_b transition moment would take an especially favorable orientation in such energy transfers. On the other hand, the ^1L_b band may overlap more strongly with the phenolic fluorescence than the ^1L_a band, since the former is located in the long-wavelength absorption bands of the indole moiety. Thus, the activity of the ^1L_b transition in the energy transfer may be interpreted in terms of the overlap integral factor rather than in terms of the orientation factor.

Anodic Ring Opening Reaction of 2-Methoxy-1-cyclopentene-1-carboxylic Acids

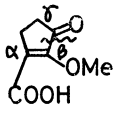
Sigeru TORII, Hideo TANAKA, Tokio FUKUOKA, and Shukuo HIRAI
Department of Industrial Chemistry, Okayama University, Okayama 700

(Received February 12, 1973)

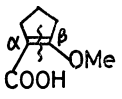
Electrolysis of 2-methoxy-1-cyclopentene-1-carboxylic acids **2** and **12a** gave α,β- or β,γ-ring opening products **4**, **5a**, **7a**, and **15**. Electrolysis of **2** without separation of anode and cathode compartments gave **6a** in a notable yield. **6a** is expected to be formed by the reduction of a key intermediate **8**, which can be rationalized by leading to **4** and **5**. The results from the anodic oxidation of **12** suggest that the C=C double bond function of **12** was initially oxidized giving **14** followed by discharge of the carboxylate anion to afford **15**. A possible mechanism for the anodic reaction of **2** and **12** has been discussed.

During the course of a study on the anodic oxidation of α,β-unsaturated carboxylic acids,[1a-d] it was found that the anodic reaction of α-methoxy-γ,γ-dimethylaconic acid in protic solvents gives lactone carbonate[1c] and the electrolysis of 5-substituted 2-furoic acids affords α,β-unsaturated butenolides along with the ring opening products.[1b,d] In both cases, the C=C double bond functions were initially oxidized to afford dimethoxy derivatives followed by further two electron oxidation of the carboxyl group.

Our interest in the anodic reaction of α,β-unsaturated carboxylic acids led us to investigate the oxidation of substituted cyclic α,β-unsaturated carboxylic acids. We wish here to report on the α,β- and β,γ-ring cleavage reactions of β-methoxy-α,β-unsaturated carboxylic acids (**2** and **12a**) by electrolysis.

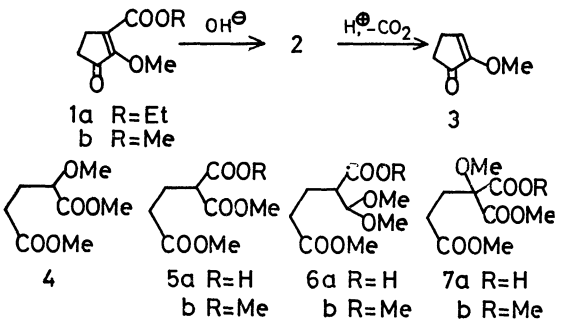


2



12a

Compound **2** obtained by hydrolysis of readily available ethyl ester **1a**[2] was electrolyzed in methanol containing a drop of concentrated sulfuric acid using one or two compartment cells fitted with platinium foil electrodes under a constant current.



In Experiment 1 (Table 1), the major products were **3**[3] and **4**.[4]

In Experiment 2, a prominent portion of acidic component was obtained together with **3** and **4** when electrolysis was interrupted at an early stage. On being treated with diazomethane the acidic products could be converted into methyl esters **1b**, **7**, and a small amount of minor products. However, when a cell without separation of the electrolysis compartments was used, compounds **5b**,[5] **6b**, and **7b** were isolated after esterification (Experiment 3). Details of experimental conditions along with the results are given in Table 1. Identification of products **3**, **4**, **5b**, **6b**, and **7b** were carried out by their spectral data and microanalyses (see Experimental).

Mechanistic consideration suggests that the electrolysis of **2** (Scheme 1), would give rise to a cationic

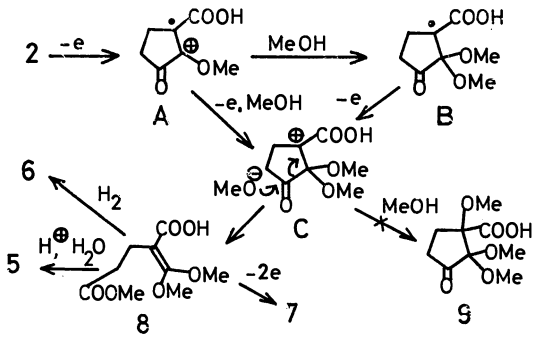
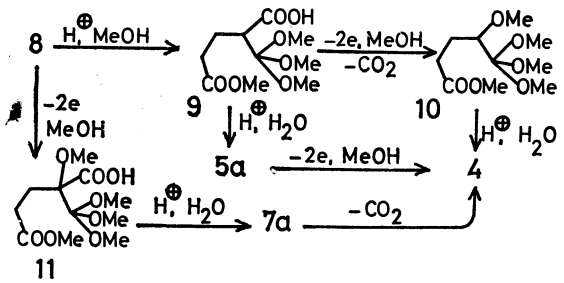
intermediate **C**, which is expected to be formed from either radical intermediate **A** or **B** by one electron oxidation. On the other hand, most of our attempts to isolate a trimethoxy derivative **9** expected to be formed from the intermediate **C** with subsequent reaction with methanol failed. However, the formation of **4**, **5a**, **6a**, and **7a** *via* **8** reveals that the cation **C** would be attacked by a solvent leading to the cleavage of β,γ-bond of the intermediate **C**. Because of the high chemical instability under the acidic work-up conditions **8** was hydrolyzed rapidly to give **5a**. The formation of **8** *in situ* was also demonstrated by the isolation of **6b** as a result of reduction of the double bond when electrolysis was carried out in one compartment cell (Experiment 3).



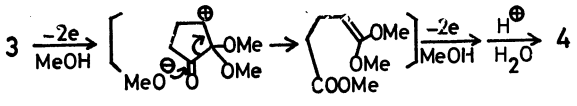
Scheme 1.

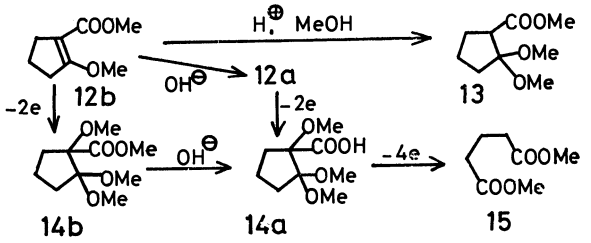
Conversion of **8** into **4** *via* **5a** and **7a** might be also explained as follows (Scheme 2). Most of the ortho ester intermediates **9**, **10**, and **11** would be readily hydrolyzed to **4**, **5a**, and **7a** under acidic conditions, *in situ* or during after treatment.



Scheme 2

Formation of **3** from **2** could be rationalized as the result of acid-catalyzed decarboxylation, since stirring of **2** in methanol containing a drop of concentrated sulfuric acid provided **3** in a moderate yield. The presence of an appreciable amount of **3** in the earlier stage of electrolysis of **2** suggests that the anodic oxidation of **3** would afford **4** as follows. Actually, electrolysis of **3** under the same conditions as in Experiment 1 (Table 1) gave **4** in 57% yield.





Scheme 3.

In order to compare the electrochemical nature of **2** with that of its analogous compound, electrolysis of the acid **12a** prepared by hydrolysis of **12b**[6] was attempted. The reaction conditions and the results are listed in Table 1. As a major product, methyl glutarate **15** was isolated from the neutral product including several minor constituents. On the other hand, electrolysis of **12b** gave **13** and **14b** without producing other notable products. It is clear that the acetal ester **13** was derived from **12b** by acid-catalyzed solvation with methanol (Scheme 3). After hydrolysis of **14b** with aqueous potassium hydroxide, electrolysis of the alkaline solution in acetonitrile gave rise to the ring opening of **14a** to give **15**. These results reveal that **14a** should be precursors of **15** in the case of anodic oxidation of **12a**.

It is considered that the differences in the products resulting from electrolyses of **2** and **12** are apparently consistent with the intrinsic chemical nature of the postulated intermediate **C** and the electrochemical behavior of **14a**.

Experimental[7]

Electrolysis. Procedure A. The cell used was a water-jacketed beaker, 3.2 cm or 5.5 cm in diameter, 10 cm high, fitted with a gas lead pipe, a thermometer, and magnetic stirrer. The electrodes were two platinum foils (1.5×2.0 cm^2) about 1 mm apart from each other. The current was controlled manually, its direction being changed every 30 sec by means of a commutator. The reaction temperature was controlled by cooling externally with circulating water.

Procedure B. Electrolysis was carried out with two platinium foil electrodes (1.5×2.0 cm^2) under a constant current. The cell used consists of two compartments separated by a glas-filter.[1]

2-Methoxy-3-oxo-1-cyclopentene-1-carboxylic Acid (2). A solution of ethyl 2-methoxy-3-oxo-1-cyclopentene-1-carboxylate(**1a**),[2] (1.00 g), Na_2CO_3 (1.00 g), and water (25 ml) was stirred for 24 hr at room temperature. The aqueous solution was washed with ether, neutralized with dilute HCl, and

7) Preparative and analytical glpc were performed with a a partially modified Yanagimoto GCG-550T type apparatus using a column packed with 10% coated SE-30 Silicone grease on Celite 545, 80/100 mesh, 3 m long (4 ϕ), carrier gas H_2 at 120 °C or 140 °C. All melting and boiling points are uncorrected. Infrared spectra were determined with a Hitachi EPI/S2 spectrophotometer. NMR spectra were obtained on a Japan Electron Optics Laboratory Spectrometer (JNM-C-60) in deuterochloroform with TMS as an internal reference. Microanalyses were carried out by Miss M. Harada.

c) Isolated acidic products were treated with diazomethane before analysis.

extracted with chloroform. The extract was washed with water and dried(Na_2SO_4). Evaporation of the solvent gave 0.49 g of **2**, mp 148.5—149.5 °C (Benzene); IR (Nujol) 3450—2200, 1709 (COOH), 1672 (C=O), 1614 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 2.39—2.90 (m, 4H), 4.27 (s, 3H, CH_3O), 8.81 (s, 1H, COOH).

Found: C, 53.83; H, 5.03%. Calcd for $C_7H_8O_4$: C, 53.85; H, 5.16%.

Electrolysis of **2**. *(Procedure B).* A mixture of lithium perchlorate (6.00 g) and concd H_2SO_4 (70 mg) in MeOH (130 ml) was poured into the anode and cathode compartments. The carboxylic acid **2**(1.00 g) was charged in the anode compartment and electrolyzed under a constant current (0.25 A) at 10—12 °C for 1.5 hr. The anode solution was concentrated by suction and taken up in chloroform. The solution was washed with water followed by aqueous $NaHCO_3$ and dried (Na_2SO_4). Removal of the solvent gave a crude liquid (0.90 g). The constituent of the oil was elucidated by glpc as shown in Table, Exp. 1. The major component **4**[4] was isolated by preparative glpc: IR (Neat) 2845 (CH_3-O), 1741 (C=O) cm^{-1}; NMR ($CDCl_3$) δ 1.80—2.20 (m, 2H, CH_2), 2.30—2.60 (m, 2H, CH_2CO), 3.39 (s, 3H, CH_3O), 3.68 (s, 3H, CH_3OOC), 3.77 (s, 3H, CH_3OOC), 3.92 (m, 1H, CH). Microanalyses gave correct results.

The spectral data of **3**[3] (minor product) isolated by preparative glpc are as follows: IR (Neat) 3098 (HC=C), 1715 (C=O), 1631 (C=C) cm^{-1}; NMR ($CDCl_3$) δ 2.98 (broad, 4H, CH_2), 3.76 (s, 3H, CH_3O), 6.39 (t, J=2.5 Hz, HC=C).

(Procedure A). A mixture of **2** (0.96 g) in MeOH (40 ml) containing H_2SO_4 (*ca.* 70 mg) was electrolyzed (Table 1, Exp. 3). The mixture was concentrated under reduced pressure and the residue was taken up in chloroform. The solution was washed successively with water, aqueous $NaHCO_3$, and water, and then dried (Na_2SO_4). Removal of the solvent gave an oil (0.43 g), whose glpc results are shown in Table 1 (Exp. 3). Components **3** and **4** were isolated by preparative glpc from the oil. Spectral data of **3** and **4** were identical with those of the corresponding authentic samples.

The aqueous alkaline solution was acidified with dilute HCl to pH 3—4 and extracted with chloroform. The extracts were washed with water and dried (Na_2SO_4). Removal of the solvent gave the acidic material as an oil (0.38 g). By treating with diazomethane, the acidic fraction was converted into the corresponding methyl esters, whose glpc results[8a] showed the presence of three major compounds: **5b** (Peak area 23%, R_t 8.2 min), **6b** (53%, 9.6 min), and **7b** (15%, 14.2 min) along with several minor peaks (total 9%). The major products **5b**, **6b**, and **7b** were isolated by preparative glpc.

Compound **5b**[5]: IR (Neat) 2850 (CH_3O), 1740 (C=O) cm^{-1}; NMR ($CDCl_3$) δ 2.00—2.60 (m, 4H, CH_2), 3.51 (t, 1H, CH), 3.70 (s, 3H, CH_3OOC), 3.78 (s, 6H, CH_3OOC).

8) a) Carrier gas flow rate: 35 ml/min at 140 °C. b) 20 ml/min at 140 °C.

Compound **6b**: IR (Neat) 2840 (CH_3O), 1741 (C=O) cm^{-1}; NMR ($CDCl_3$) δ 1.80—2.80 (m, 5H), 3.42 (s, 6H, gem CH_3O), 3.73 (s, 3H, CH_3OOC), 3.76 (s, 3H, CH_3OOC), 4.58 (d, J=7.5 Hz, 1H, CH).

Found: C, 51.56; H, 7.75%. Calcd for $C_{10}H_{18}O_6$: C, 51.27; H, 7.75%. Compound **7b**: IR (Neat) 2880 (CH_3O), 1745 (C=O) cm^{-1}; NMR ($CDCl_3$) δ 2.44 (s, 4H, CH_2), 3.43 (s, 3H, CH_3O), 3.73 (s, 3H, CH_3OOC), 3.86 (s, 6H, CH_3-OOC).

Found: C, 48.76; H, 6.60%. Calcd for $C_{10}H_{16}O_7$: C, 48.39; H, 6.50%.

*2-Methoxy-2-cyclopentenone (**3**).* A solution of **2** (0.50 g) in MeOH (40 ml) containing a drop of concd H_2SO_4 was stirred for 5.5 hr 11—13 °C. After removal of the solvent, the residue was taken up in chloroform. The solution was washed with water and aqueous $NaHCO_3$ and dried (Na_2SO_4). Removal of the solvent gave an oil (91 mg), whose glpc[8b] results showed the presence of two major components: **3** (Peak area 70%, R_t 4.3 min), unknown (30%, 6.0 min). Isolation of **3** was carried out by preparative glpc, its structure being confirmed by comparison with the spectral data of an authentic sample.[3]

*Electrolysis of 2-Methoxy-1-cyclopentenone (**3**). (Procedure B).* A mixture of lithium perchlorate (6.00 g) in MeOH containing concd H_2SO_4 (70 mg) was poured into both compartments. In the anode compartment **3** (0.20 g) was charged and electrolyzed under a constant current of 0.25 A at 10.0—11.0 °C for 2.0 hr with stirring. The solution of the anode compartment was then worked up as described above to give a crude oil (230 mg), which was chromatographed on 5 g of silica gel (Wakogel C-200) with AcOEt–Benzene (1 : 5) to give a clean oil (144 mg). Glpc analysis of the oil showed the presence of methyl 2-methoxyglutarate (**4**) (79%). Analytical specimen of **4** was obtained by preparative glpc. IR and NMR spectra of **4** were identical with those of an authentic sample.

*2-Methoxy-1-cyclopentene-1-carboxylic Acid (**12a**).* A mixture of **12b** (10 g),[6] K_2CO_3 (10 g), and water (35 ml) was stirred for 8 hr at room temperature. The resulting solution was cooled to 10 °C and acidified with dilute HCl to pH 6.0—6.5 and extracted with chloroform. The extracts were washed with water and dried (Na_2SO_4). Concentration of the solution gave crude **12a**, 4.5 g (49.4%), mp 148—148.3 °C (Benzene); IR (Nujol) 2600 (COOH), 1670, 1640, 1610, 1600 (C=O, C=C) cm^{-1}; NMR ($CDCl_3$) δ 1.95 (m, 2H, CH_2), 2.40—2.90 (m, 4H, CH_2), 3.89 (s, 3H, CH_3O), 9.57 (s, 1H, COOH).

Found: C, 59.43; H, 7.07%. Calcd for $C_7H_{10}O_3$: C, 59.14; H, 7.09%.

*Electrolysis of 2-Methoxy-1-cyclopentene-1-carboxylic Acid (**12a**). (Procedure A).* A mixture of **12a** (0.50 g) and lithium perchlorate (0.50 g) in MeOH was electrolyzed (Table 1, Exp. 4). The reaction mixture was concentrated *in vacuo* and the residue was taken up in chloroform. The solution was worked up in the usual manner. Removal of the solvent gave an oil (0.31 g), whose glpc results (Table 1) showed the presence of dimethyl glutarate (59.2%) as a major component isolated by preparative glpc.

*Electrolysis of Methyl 2-Methoxy-1-cyclopentene-1-carboxylate (**12b**). (Procedure A).* A mixture of **12b** (4.00 g) and lithium perchlorate (2.00 g) in MeOH (120 ml) was electrolyzed (Table 1, Exp. 5). The mixture was worked up in the usual manner to give an oil (3.95 g), whose glpc results[8] showed the presence of four major components: methyl 2-cyclopentanone-1-carboxylate (Peak area 6%, R_t 4.3 min), **13** (43%, 6.0 min), recovered **12b** (9%, 7.8 min), and **14b** (24%, 10.6 min) along with several minor compounds (18%). The major products were isolated by preparative glpc or by preparative tlc. The structural assignments of methyl 2-cyclopentanone-1-carboxylate, **12b**, and **13** were carried out by comparing their spectral data with those of the corresponding authentic specimen. The physical data of **14b** together with microanalyses are as follows: IR (Neat) 2845 (CH_3O), 1737 (C=O) cm^{-1}; NMR ($CDCl_3$) δ 1.50—2.50 (m, 6H, CH_2), 3.24 (s, 6H, CH_3O), 3.39 (s, 3H, CH_3O), 3.78 (s, 3H, CH_3OOC).

Found: C, 55.04; H, 8.30%. Calcd for $C_{10}H_{18}O_5$: C, 55.03; H, 8.31%.

*Electrolysis of 1,2,2-Trimethoxycyclopentane-1-carboxylic Acid (**14a**). (Procedure A).* A solution of **14b** (215 mg, purity 70%) obtained in the above procedure in 1 M aqueous KOH (1.26 ml) was stirred for 25 hr at room temperature. To this solution was added a mixed solution of acetonitrile (30 ml) and water (10 ml). The mixture was electrolyzed, reaction conditions and results being given in Table 1, Exp. 6.

*Methyl 2,2-Dimethoxycyclopentane-1-carboxylate (**13**).* A mixture of **12b** (0.50 g) and a drop of concd H_2SO_4 in MeOH (30 ml) was stirred at room temperature for 1 hr. The resulting solution was concentrated and taken up in chloroform. The solution was washed with water and dried (Na_2SO_4). Evaporation of the solvent gave an oil (0.31 g), consisting of two components (**13** and **12b**) as elucidated by glpc[8b]: **13** (Peak area 89%, R_t 6.0 min) and recovered **12b** (8%, 7.8 min). Both compounds isolated by preparative glpc were confirmed by comparison with authentic sepcimens.

Synthetic Studies of Carbohydrate Derivatives with Photochemical Reactions. IX.[1] The Photochemical Addition of 1,3-Dioxolane to Several Enoses

Kazuo MATSUURA, Kazunari NISHIYAMA, Koh YAMADA, Younosuke ARAKI, and Yoshiharu ISHIDO

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received February 24, 1973)

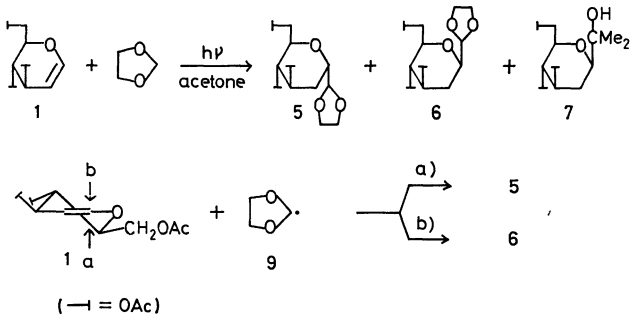
The photochemical addition reactions of 1,3-dioxolane to enoses with an endocyclic or exocyclic double bond, such as 3,4,6-tri-*O*-acetyl-D-glucal, 2,3,4,6-tetra-*O*-acetyl-2-hydroxy-D-glucal, methyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside, and methyl 5-deoxy-2,3-*O*-isopropylidene-β-D-*erythro*-pent-4-enofuranoside, were studied. It was found that the addition of 1,3-dioxolane to the enoses proceeds with great ease, thus affording the corresponding 1,3-dioxolan-2-yl derivatives in excellent yields, and with a considerable regiospecificity and stereoselectivity. The reactions of tetrahydrofuran with the enoses were also studied.

In this series of investigations, the photochemical reaction of sugar derivatives has been studied mainly from a synthetic standpoint of view.[2] Rosenthal and Elad[3] have reported that an acetone-sensitized photochemical addition of 1,3-dioxolane to a terminal olefinic compound affords 2-substituted dioxolane derivatives as the main products, plus its 4-substituted isomers as the minor products. This reaction has also been shown to be applicable to enoses; *i. e.*, 5,6-dideoxy-1,2-*O*-isopropylidene-α-D-*xylo*-hex-5-enofuranose and 3-deoxy-1,2; 5,6-di-*O*-isopropylidene-3-methylene-α-D-*ribo*-hexfuranose, which have a terminal and an exocyclic double bond respectively, thus giving the corresponding equimolar adducts with 1,3-dioxolane in 45 and 55% yields respectively.[4]

In the field of carbohydrate chemistry, it is now an essential problem to obtain an excellent method of synthesizing sugar derivatives with a branched-aldehyde structure; such derivatives can conceivably be derived from such a photochemical addition of 1,3-dioxolane to enoses involving an endocyclic double bond, followed by acid-catalyzed hydrolysis under mild conditions, since the functional group can be converted into a hydroxymethyl group by reduction or into a heterocyclic structure by an appropriate set of reactions, *etc.* In a previous paper,[2a] the present authors briefly reported on the acetone-sensitized photochemical addition of 1,3-dioxolane to 3,4,6-tri-*O*-acetyl-D-glucal (**1**) and 2,3,4,6-tetra-*O*-acetyl-2-hydroxy-D-glucal (**2**); in that study, though, the final structural determination was not achieved. The photochemical additions of **1**, **2**, methyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside (**3**), and methyl 5-deoxy-2,3-*O*-isopropylidene-β-D-*erythro*-pent-4-enofuranoside (**4**) will be described in this article.

Results and Discussion

An acetone-sensitized photochemical addition of 1,3-dioxolane to **1** was carried out by irradiating it with a high-pressure mercury lamp in 1,3-dioxolane under a nitrogen atmosphere. The subsequent chromatographic separation of the sirup obtained by the concentration of the reaction mixture on a column of silica gel afforded 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*arabino*-L-*glycero*-heptose ethylene acetal (**5**) and 4,5,7-tri-*O*-acetyl-2,6-anhydro-3-deoxy-D-*arabino*-D-*glycero*-heptose ethylene acetal (**6**) in 37 and 37% yields respectively, along with 5,6,8-tri-*O*-acetyl-3,7-anhydro-1,4-dideoxy-2-*C*-methyl-D-*arabino*-D-*glycero*-octitol (**7**)[2f] (24% yield). **7** was produced by the nucleophilic



attack of the 2-propanol-2-yl radical (**8**), which had been formed from acetone by the abstraction of a hydrogen atom from 1,3-dioxolane, on the C-1 of **1**. The structural assignments of **5** and **6** were made on the basis of their NMR data, shown in Table 1. In the spectrum of **5**, the signals of H-2, H-3a, and H-3e are observed as multiplets at δ 4.01, 1.79, and 2.22 ppm respectively, while $J_{2,3a}$, $J_{2,3e}$, and $J_{3a,3e}$ have been determined to be 6.0, 4.0, and 14.0 Hz respectively. In the spectrum of **6**, on the other hand, the signals of H-2, H-3a, and H-3e are observed at δ 3.56 as an octet, and those at 1.61 and 2.19 ppm, as multiplets, while $J_{2,3a}$, $J_{2,3e}$, and $J_{3a,3e}$ were determined to be 11.5, 2.2, and 11.5 Hz respectively. The 1,3-dioxolan-2-yl groups at C-2 in **5** and **6** were concluded to be in axial and equatorial orientations respectively, on the basis of the above assignments for H-2s in **5** and **6** being in equatorial and axial orientations respectively. Consequently, the photochemical addition of 1,3-dioxolan-2-yl radical (**9**) to **1** can conceivably

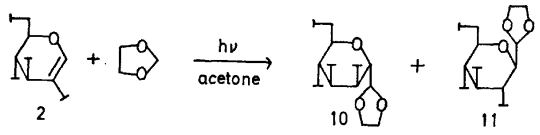
These data were obtained in $CDCl_3$ by the use of tetramethylsilane as the internal standard.

take place regiospecifically at the C-1 of **1** from both the α- and β- sides of the 1-enopyranosyl ring, without any configurational selectivity, thus giving **5** and **6** in a relative ratio of 1 : 1.

The treatment of **2** under similar conditions afforded 3,4,5,7-tetra-*O*-acetyl-2,6-anhydro-D-*glycero*-D-*talo*-heptose ethylene acetal (**10**) and 3,4,5,7-tetra-*O*-acetyl-2,6-anhydro-D-*glycero*-D-*gulo*-heptose ethylene acetal



+ other 3 Products

(**11**) in 17 and 42% yields respectively. Much as in the previous reaction, three products, which are the adducts with **8**, were concomitantly afforded in this case.[5] The NMR spectral evidence for the structural determination of **10** and **11** is demonstrated in Table 1. In the spectrum of **10**, the signals of H-2 and H-3 are observed at δ 3.57 (quartet) and 5.66 (quartet) ppm respectively, and $J_{2,3}$ and $J_{3,4}$ were determined to be 1.3 and 3.2 Hz respectively. Moreover, only one of the four acetyl signals is observed at δ 2.17 ppm. In the spectrum of **11**, on the other hand, the signal of H-2 is observed at δ 3.58 (quartet) ppm, $J_{2,3}$ and $J_{3,4}$ were determined to be 9.1 and 9.2 Hz respectively, and all the acetyl signals are observed in the equatorial region. In **10**, the 1,3-dioxolan-2-yl group and the *O*-acetyl group are concluded to occupy the axial orientation at C-2 and C-3 respectively. In **11**, on the other hand, they are in the equatorial orientation at C-2 and C-3 respectively. The addition of the **9** radical may take place on the C-1 of **2** from the α- and β-sides of the 2-hydroxy-1-enopyranosyl ring, thus giving **10** and **11** respectively; this reaction was thus established to involve the *cis*-addition-type mechanism.

Subsequently, the photochemical addition of 1,3-dioxolane to **3** and **4** respectively under the irradiation of a low-pressure mercury lamp was investigated.[6]

		H-5—H-6′	2.8
		H-6—H-6′	12.5

These data were determined in $CDCl_3$ by the use of tetramethylsilane as the internal standard.

5) Gas Chromatographic examination elucidated the relative ratio of the three products to be 1 : 2 : 1, and the major product to be 4,5,6,8-tetra-*O*-acetyl-3,7-anhydro-1-deoxy-2-*C*-methyl-D-*glycero*-D-*gulo*-octitol. Details with respect to these results will be published elsewhere.

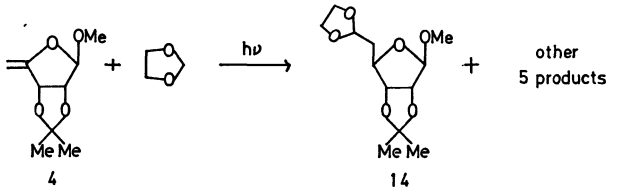
6) It is natural and advantageous to irradiate the reaction mixture with a low pressure mercury lamp in the absence of acetone as the photosensitizer on account of the concomitant formation of the adduct with acetone, by which the yield of the expected product is directly affected, when the reaction was carried out under the irradiation of a high pressure mercury lamp in the presence of acetone. However, the irradiation of **1** or **2** in pure 1,3-dioxolane afforded no product and resulted in the complete recovery of the corresponding starting materials.

The irradiation of **3** afforded methyl 4,6-di-*O*-acetyl-2,3-dideoxy-2-*C*-(1,3-dioxolan-2-yl)-α-D-*erythro*-D-*glycero*-hexopyranoside (**12**) and methyl 4,6-di-*O*-acetyl-2,3-dideoxy-3-*C*-(1,3-dioxolan-2-yl)-α-D-*arabino*-hexopyranoside (**13**) in 39 and 39% yields respectively. The structural determination of **12** and **13** was accomplished by the use of their NMR spectral data (Table 2). In the spectrum of **12**, H-2, H-3a, and H-3e signals are observed at δ *ca.* 2.1 (multiplet), *ca.* 2.1 (multiplet), and *ca.* 1.9 (multiplet) ppm respectively, and $J_{1,2}$ is found to be 4.0 Hz. In the spectrum of **13**, on the other hand, H-2a, H-2e, and H-3 signals are observed at δ 1.68, 1.96, and 2.42 ppm respectively, and $J_{2a,3}$, $J_{2e,3}$, and $J_{3,4}$ are found to be 12.6, 4.3, and 10.5 Hz respectively. On the basis of this evidence, **12** and **13** were concluded to involve a 1,3-dioxolan-2-yl group at C-2 and C-3 respectively in equatorial orientations. It can thus be stated that this reaction affords the thermodynamically more stable stereoisomers selectively in a relative ratio of 1 : 1, since no product with an axial substituent is formed.

Incidentally, similar products could be obtained by carrying out the irradiation with a high-pressure mercury lamp in the presence of acetone as the photosensitizer. However, the reaction was inevitably accompanied by the formation of methyl 4,6-di-*O*-acetyl-2,3-dideoxy-2-*C*-(1-hydroxy-1-methylethyl)-α-D-*erythro*-D-*glycero*-hexopyranoside, which had previously been shown to be formed by the addition of the **8** resulting from acetone to **3**,[2d] in a 10% yield.

The irradiation of **4** with a low-pressure mercury lamp under the conditions employed for **3** was, on the other hand, found by tlc and glc to afford at least six products.

Among these products, only methyl 5-deoxy-2,3-*O*-isopropylidene-β-D-*ribo*-hex-dialdofuranoside 6-ethylene acetal (**14**) was isolated in a 10% yield from the reaction mixture. The structure of **14** was confirmed by its NMR spectral data (Table 3). Such a formation of several products in this case, in contrast with the cases of the other enoses employed in the present study, may be due to the high reactivity of the exocyclic double bond, as is generally accepted,[7] and also to a potential photoisomerization of the photoaddition product once formed.[8]



The photochemical addition of 1,3-dioxolane to the enoses, as far as it has been examined, may be summarized as follows:

1) In the reaction of such enoses as **1**, the addition takes place regiospecifically at C-1 from both the α- and β-sides of the 1-enopyranosyl ring, thus giving the corresponding equimolar adducts, such as **5** and **6** in high yields in a relative ratio of 1 : 1. In the reaction of such enoses as **2**, which have a substituent at their C-2 position, on the other hand, the preferential formation of an isomer such as **11**, which is thermodynamically more stable than a configurational isomer such as **10**, is observed. 2) In the reaction of such 2-enoses as **3**, isomers with thermodynamically stable (*i. e.*, equatorial) substituents, such as **12** and **13**, are produced, although no regioselectivity is observed. 3) The reaction of 4-enoses involving an exocyclic double bond such as **4** proceeds with great ease in comparison with those of the other enoses, although such a reaction lacks regio- and stereoselectivity. 4) On the basis of the results obtained by the reaction of **2**, it can be considered that these reactions proceed in part at least by means of a *cis*-addition mechanism.

In addition to the photochemical addition reaction of 1,3-dioxolane, similar photochemical addition of tetrahydrofuran(THF) to enoses was investigated in view of the reactivity of 1,3-dioxolane, the location of the 2-yl radical of which is established by the adjacent two oxygen atoms.

The irradiation of **3** in THF by means of a low-pressure mercury lamp gave methyl 4,6-di-*O*-acetyl-2,3-dideoxy-3-*C*-(2-tetrahydrofuranyl)-α-D-*arabino*-hexopyranoside (**15**) and methyl 4,6-di-*O*-acetyl-2,3-dideoxy-2-*C*-(2-tetrahydrofuranyl)-α-D-*erythro*-D-*glycero*-hexopyranoside (**16**) in 15 and 32% yields respectively. In this case, 44% of the starting material was recovered. The structure of **15** and **16** were confirmed by com-

These data were obtained in $CDCl_3$ by the use of tetramethylsilane as the internal standard.

a) These signals appeared centering in the vicinity of this chemical shift.

7) Exocyclic double bonds have generally accepted to have higher reactivities than endocyclic double bonds in the free radical addition reaction of thio radicals to double bonds; *cf.* M. Fukuyama, "Yuhriki-no-Kagaku (Chemistry of Free Radicals)," ed. by H. Sakurai and K. Tokumaru, Nanko-do, Tokyo (1967), p. 219.

8) D. Elad and R. D. Youssefyeh, *Tetrahedron Lett.*, **1963**, 2189: in this paper, acetone-induced photoisomerization of 2-substituted 1,3-dioxolanes into the corresponding esters has been reported.

paring their NMR spectra with those of **13** and **12** respectively (*cf.* Table 1).

In the photochemical addition of **4** in place of **3**, the formation of at least five products and the recovery of no starting material were detected by tlc and glc, although their structures could not be determined. **1** was, moreover, recovered quantitatively by treating it under the same conditions. Furthermore, the irradiation of **2** in THF in the presence of acetone as the photosensitizer was carried out by means of a high-pressure mercury lamp to give a mixture of two products, **17a** and **17b**(1 : 1), in a 27% yield.[9] The NMR spectra of these products showed that all the acetyl groups are in an equatorial orientation, and the integration curve demonstrated that these are the corresponding equimolar adducts of **2** with THF, which may correspond to two of the three structures shown in Fig. 1, although their structures could not be confirmed. On the basis of these results, the order of the reactivity of the enoses to THF may be concluded to be (**4**>) **3**>**2**(>**1**).

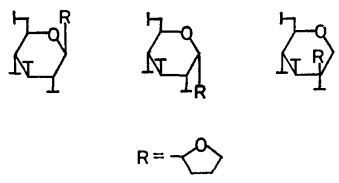

Fig. 1.

In contrast with the cyclic ethers described above, the reactivity of tetrahydropyran was found to be remarkably lower; it gave only a trace of products[10] in reactions with **2** and **3** respectively, and they were recovered almost quantitatively.

Moreover, an acyclic ether such as diethyl ether gave no product at all in spite of a variety of examinations with respect to the potential dependence on the concentration, the effect of the variation in the photosensitizer(such as acetone, 2-butanone, acetophenone, or benzophenone), and irradiation by means of a low-pressure mercury lamp or a high-pressure one in the presence of photosensitizers in reactions with the enoses.

It may thus be concluded with respect to the reactivity of the ethers employed herein that:

1,3-Dioxolane>THF>THP>Diethyl Ether

Experimental

The solvents used for the experiment were purified in the usual manner prior to use. Irradiations were carried out with a high-pressure mercury lamp (450 W) of Ushio Electric, Inc., in a Pyrex-glass tube at a distance of about 5 cm, or with a low-pressure mercury lamp (30 W) of Riko Kagaku Co., Ltd., in a quartz test tube, and with one (6 W) of Ushio Electric, Inc., under a nitrogen atmosphere at room temperature. The tlc's were carried out by the use of Wakogel B-5, and the solvent system of benzene–methanol (9 : 1 v/v) was used for the development. The NMR spectra were taken with a Varian HA-100 apparatus in deuterochloroform using tetramethylsilane as the internal standard. The glc data were obtained with a Hitachi K-53 model; Column: 10% SE-30 on Chromosorb W (60—80 mesh); carrier gas: nitrogen under 1.5 Atm unless otherwise noticed; oven temperature: 200 °C, and injection temperature: 300 °C. The mass spectra were taken with a Hitachi RMU 6E model spectrometer.

4,5,7-Tri-O-*acetyl-2,6-anhydro-3-deoxy*-D-*arabino*-L-glycero-*heptose Ethylene Acetal* (**5**) *and 4,5,7-Tri*-O-*acetyl-2,6-anhydro-3-deoxy*-D-arabino-D-glycero-*heptose Ethylene Acetal* (**6**): A solution of 3,4,6-tri-*O*-acetyl-D-glucal (**1**) (1.00 g) in a solvent system composed of acetone (2 ml) and 1,3-dioxolane (10 ml) was irradiated by means of a high-pressure mercury lamp for 73 hr, after which the reaction mixture was concentrated *in vacuo*.

The residual sirup was chromatographed on a column of silica gel (Mallinckrodt Silica Gel, 100-mesh) by the use of a solvent system of benzene–acetone, whose relative content ratio was changed in turn to 99 : 1 (800 ml), 98 : 2 (800 ml). and 97 : 3 (800 ml) v/v for the elution. **5** (500 mg, 37%), **6** (500 mg, 37%), and 5,6,8-tri-*O*-acetyl-3,7-anhydro-1,4-dideoxy-2-*C*-methyl-D-*arabino*-D-*glycero*-octitol (**7**) (255 mg, 21%) were eluted out in turn separately. The retention volumes of **1**, **5**, **6**, and **7** in glc were 1, 4.4, 4.6, and 2.5 respectively. The specific rotations of these products were as follows; **5**: $[\alpha]_D^{22}$ +28.0° (*c* 1.0, Me_2CO), **6**: $[\alpha]_D^{22}$ +8.0° (*c* 1.0, Me_2CO). Found: C, 52.39 (**5**), and 52.08 (**6**); H, 6.71 (**5**) and 6.60 (**6**)%. Calcd for $C_{15}H_{22}O_9$: C, 52.02; H, 6.40%. The NMR data of **5** and **6** are demonstrated in Table 1.

3,4,5,7-Tetra-O-*acetyl-2,6-anhydro*-D-glycero-D-talo-*heptose Ethylene Acetal* (**10**) *and 3,4,5,7-Tetra*-O-*acetyl-2,6-anhydro*-D-glycero-D-gulo-*heptose Ethylene Acetal* (**11**). A solution of 2,3,4,6-tetra-*O*-acetyl-2-hydroxy-D-glucal (**2**) (1.00 g) in a solvent system composed of acetone (2 ml) and 1,3-dioxolane (10 ml) was irradiated by means of a high-pressure mercury lamp for 54 hr, after which the reaction mixture was concentrated *in vacuo*. The resultant sirup was chromatographed on a column of silica gel by the use of a solvent system of benzene–acetone, whose relative content ratio was changed in turn to 96.5 : 3.5 (1000 ml), 96 : 4 (800 ml), 95 : 5 (800 ml), and acetone (100 ml) v/v, for the elution; this afforded **10** (210 mg, 17%), **11** (510 mg, 42%), and three by-products[5] (equimolar adducts of **2** with acetone, 225 mg, 19%). The retention volumes of **2**, **10**, **11**, and the by-products in glc were, respectively, 2.1, 7.7, 8.1, 3.7, 4.4, and 5.0. Mass spectrum of **11**: *m/e*=404 (M^+), 344[$(M-60)^+$], and 331 [$(M-73)^+$]. Specific rotations: **10**: $[\alpha]_D^{22}$ +22.3° (*c* 1.0, Me_2CO), **11**: $[\alpha]_D^{22}$ −2.0° (*c* 1.0, Me_2CO). Found: C, 50.52 (**10**) and 51.01 (**11**): H, 6.04 (**10**) and 6.04 (**11**)%. Calcd for $C_{17}H_{24}O_{11}$: C, 50.49; H, 5.98%. The NMR data of these products are shown in Table 1.

Methyl 4,6-Di-O-*acetyl-2,3-dideoxy-2*-C-*(1,3-dioxolan-2-yl)*-α-D-erythro-D-glycero-*hexopyranoside* (**12**) *and Methyl 4,6-Di*-O-*acetyl-2,3-dideoxy-3*-C-*(1,3-dioxolan-2-yl)*-α-D-arabino-*hexopyranoside* (**13**). A) A solution of methyl 4,6-di-*O*-acetyl-2,3-dideoxy-α-D-*erythro*-hex-2-enopyranoside (**3**) (1.00 g) in 1,3-dioxolane (25 ml) was irradiated by means of a low-pressure mercury lamp (30 W) for 115 hr, after which the reaction mixture was concentrated *in vacuo*. The residual sirup was chromatographed on a column of silica gel by the use of a solvent system of benzene–acetone, whose relative content ratio was changed in turn to 99 : 1 (1000 ml), 98 : 2 (500 ml), 97 : 3 (500 ml), 9 : 1 (200 ml) v/v, for the elution; this afforded **3** (115 mg, 12% recovery), **12** (510 mg, 39%),

9) Two peaks corresponding to **17a** and **17b** were detected in glc with retention volumes of 8.3 and 8.9, respectively, and their chromatographic separation has not yet been accomplished.

10) The amounts of the corresponding products in the reaction with **2** or **3** were determined as less than 10% yields by means of glc.

and **13** (510 mg, 39%). The retention volumes of **3**, **12**, and **13** in glc were, respectively, 0.8, 2.2, and 2.2. The specific rotations of **12** and **13** were $[\alpha]_D^{22}$ +84.5° (*c* 1.0, Me_2CO) and $[\alpha]_D^{22}$ +55.7° (*c* 1.0, Me_2CO) respectively. Found: C, 52.62 (**12**) and 52.91 (**13**): H, 7.05 (**12**) and 7.12 (**13**)%. Calcd for $C_{14}H_{22}O_8$: C, 52.82; H, 6.97%. The NMR spectral data of these products are shown in Table 2. B) A similar treatment of **3** (1.00 g) in a solvent composed of 1,3-dioxolane (9 ml) and acetone (1 ml) under irradiation with a high-pressure mercury lamp (450 W) for 14 hr, and a similar chromatographic treatment of the sirup obtained by the concentration of the reaction mixture, afforded **12** (420 mg, 32%) and **13** (410 mg, 31%), in addition to methyl 4,6-di-*O*-acetyl-2,3-dideoxy-2-*C*-(1-hydroxy-1-methylethyl)-α-D-*erythro*-D-*glycero*-hexopyranoside[2d] (60 mg, 10%).

*Methyl 5-Deoxy-2,3-O-isopropylidene-β-D-ribo-hexo-dialdofuranoside 6-Ethylene Acetal (**14**).* A solution of methyl 5-deoxy-2,3-*O*-isopropylidene-β-D-*erythro*-pent-4-enofuranoside (**4**) (1.00 g) in 1,3-dioxolane (180 ml) was irradiated by means of a low-pressure mercury lamp (6 W) for 51 hr, after which the reaction mixture was concentrated *in vacuo*. The residual sirup was chromatographed on a column of silica gel by the use of a solvent system of benzene–acetone, whose relative content ratio was changed in turn to 99 : 1 (1000 ml), 98 : 2 (500 ml), and 97 : 3 (500 ml), for the elution, thus affording **14** (140 mg, 10%). Its retention volume in glc was 5.4 with reference to that of **4** (1.0) under 0.8 Atm of nitrogen gas. $[\alpha]_D^{22}$ −70.8° (*c* 1.0, Me_2CO). Found: C, 55.78; H, 7.53%. Calcd for $C_{12}H_{20}O_6$: C, 55.37; H, 7.75%. The NMR data of this product are shown in Table 3.

*Methyl 4,6-Di-O-acetyl-2,3-dideoxy-3-C-(2-tetrahydrofuranyl)-α-D-arabino-hexopyranoside (**15**) and Methyl 4,6-Di-O-acetyl-2,3-dideoxy-2-C-(2-tetrahydrofuranyl)-α-D-erythro-D-glycero-hexopyranoside (**16**).* A solution of **3** (0.500 g) in THF (25 ml) was irradiated by means of a low-pressure mercury lamp (30 W) for 210 hr, after which the reaction mixture was concentrated *in vacuo*. The residual sirup was chromatographed on a column of silica gel by the use of a solvent system of benzene–acetone (98 : 2 v/v, 1000 ml) for the elution, thus affording **3** (220 mg, 44% recovery), **15** (95 mg, 15%), and **16** (205 mg, 32%). The retention volumes of **15** and **16** in glc were 3.2 and 3.4 respectively. The specific rotations of **15** and **16** were as follows: $[\alpha]_D^{22}$ +78.5 (*c* 1.0, Me_2CO) and +66.1° (*c* 1.0, Me_2CO) respectively. The NMR spectral data of **15** and **16** are almost superimposable with those of **13** and **12** respectively, except that the singals of the tetrahydrofuranyl-ring protons are observed at δ *ca.* 1.8—2.0 (4H) and 3.8—4.0 (3H) ppm in both cases. Moreover, these were concluded, on the basis of the relative ratios of the integration curves of their NMR spectra, to be equimolar adducts of **2** with THF.

*Irradiation of 2,3,4,6-Tetra-O-acetyl-2-hydroxy-D-glucal (**2**) in Tetrahydrofuran–Acetone with a High-pressure Mercury Lamp.* A solution of **2** (1.00 g) in a solvent system composed of tetrahydrofuran (22.5 ml) and acetone (2.5 ml) was irradiated with a high-pressure mercury lamp for 150 hr, after which the reaction mixture was concentrated *in vacuo*. The residual sirup was chromatographed on a column of silica gel by the use of the solvent system of benzene–acetone, whose relative content ratio was changed in turn to 97 : 3 (1500 ml) and 91 : 9 (1000 ml) v/v for the elution, thus affording **2** (110 mg, 11% recovery), a mixture of the corresponding equimolar adducts **17a** and **17b** (330 mg, 27%), and the same three by-products (equimolar adducts of **2** with acetone,[5] 460 mg, 40%) as have been described in the second example of this section.

The authors are grateful to Mr. Katsuhiko Kushida, Nippon Electric Varian, and Mr. Asao Murai, Central Research Lab., Ajinomoto Co., Inc., for the NMR and mass spectral determinations respectively, and also to the members of the Laboratory of Organic Elemental Analysis, Tokyo Institute of Technology, for the elemental analyses.

Crystal and Molecular Structure of ω-Amino Acids, ω-Aminosulfonic Acids and Their Derivatives. V. Crystal and Molecular Structure of γ-Guanidino Propane Sulfonic Acid

Yang Bae KIM,* Akio WAKAHARA, Takaji FUJIWARA, and Ken-ichi TOMITA

Faculty of Pharmaceutical Sciences, Osaka University, Toneyama, Toyonaka, Osaka 560

(Received March 8, 1973)

The crystal structure of γ-guanidino propane sulfonic acid was determined by the symbolic addition method with X-ray intensity data on a diffractometer and refined by the least-squares method to an *R*-value 0.069 for 1963 reflections. The crystals were monoclinic, space group $P2_1/c$, $Z=8$, with $a=10.080$, $b=8.013$, $c=19.716$ Å and $\beta=98.17°$. Two independent molecules in the asymmetric unit both have a zwitterionic form, $(NH_2)_2^+$-$CNHCH_2CH_2CH_2SO_3^-$. There are two forms, *trans* zigzag and *cis* ones, which are linked by N(1)H···O hydrogen bonds. The molecules are held together in the crystal by a three-dimensional network of NH···O hydrogen bonds.

γ-Guanidino propane sulfonic acid (GGPSA) is a guanidyl derivative of 3-amino propane sulfonic acid, homotaurine, which has strong activity towards the behavior of neurones when applied extracellularly.[1] Short-chain ω-guanidino acids and homotaurine also depress cortical responses.[2-3] Tsunoo *et al.* reported that homotaurine and γ-amino-β-hydroxy propane sulfonic acid (GABOPSA) act to lower blood pressure, and GGPSA and γ-guanidino-β-hydroxy propane sulfonic acid (GGBOPSA) acts to depress the lowering of blood pressure.[4]

It is of interest to investigate systematically the molecular structure of such compounds and elucidate the relationship between the molecular conformations and their physiological actions.

We previously reported the crystal data of GGBOPSA, GGPSA and γ-guanidino-β-hydroxybutyric acid (GGBOBA),[5] and the molecular and crystal structure of GGBOPSA.[6]

In this paper, we describe a detailed molecular and crystal structure of γ-guanidino propane sulfonic acid (GGPSA) and compare it with that of ω-amino sulfonic acids and amino acid containing guanidyl group, L-arginine.[7]

Experimental

The compound was recrystallized from an aqueous solution as colorless, transparent prismatic crystals.

Crystallographic Measurement. The space group was determined from Weissenberg and precession photographs, and lattice costants were obtained from precise measurement of the 2θ angles for 9 reflections on a diffractometer with Cu*K*α radiation. Density was measured by the flotation method in a mixture of ethylene dibromide and acetonitrile.

Table 1. Crystal data

Molecular formula; $C_4H_{11}N_3O_3S$. M.W. 181.2,	
Colorless transparent prism, Monoclinic system	
$a = 10.080(3)$ Å	$b = 8.013(8)$ Å
$c = 19.716(1)$ Å	$\beta = 98.17(3)°$
Volume of unit cell,	1576.3 Å^3
Density (by flotation)	1.518 g/cm^3
Density (calculated)	1.522 g/cm^3
$Z = 8$	F(000) = 768
Absent spectra; $h0l$ when $l = 2n + 1$	
$0k0$ when $k = 2n + 1$	
Space group; $P2_1/c$ with two independent molecules in an asymmetric unit.	

The crystal data are listed in Table 1.

Three-dimensional intensity data were collected on a computer controlled four-circle diffractometer (Rigaku Denki Co. Ltd.) with Ni-filtered Cu*K*α radiation using a crystal mounted about the *b*-axis. A total of 1963 independent reflections limited within $\sin\theta/\lambda<0.53$ Å^{-1} was scanned by a ω-2θ technique at a scan speed of 4° per minute. During the course of data collection, the intensities for three standard reflections 020, 006, and 500 were measured every 50 reflections in order to check the stability of the electronics or the damage on crystal lattice. All the reflections were recorded and corrected for usual Lorentz and polarization effects, no absorption correction being made.

Structure Determination and Refinement. An approximate scale and the over-all temperature factor were calculated by Wilson's method. The structure determination was tried at first by a heavy atom procedure, but there was some trouble in interpreting the Patterson function owing to too many large peaks. Failing in this, we tried to determine the structure by means of the symbolic addition method proposed by Karle and Karle.

Normalized structure factor, $|E|$, and $\sum_2$ lists ($|E|\geqq1.5$, probability greater than 97%) were calculated by the program "SIGMA" written by T. Ashida. Three-dimensional *E*-maps of 8 possible cases were calculated from the sign relations between four symbols A to D, for 145 reflections. One of them gave the positions of two sulfur atoms reasonably coincident with the corresponding coordinates in the Patterson function. The positions of all the non-hydrogen atoms were found by the following Fourier synthesis with phases of only two heavy atoms. An *R*-index, $\sum||F_o|-|F_c||/\sum|F_o|$, was reduced from 0.32 to 0.27 by successive syntheses with

a constant over-all temperature factor. Refinement was carried out for all reflections by the block-diagonal least-squares procedure with unit weight. The R-index was reduced to 0.14 with isotropic temperature factors for all non-hydrogen atoms and decreased further with anisotropic temperature factors to 0.11. In this state, a calculated difference Fourier synthesis (Fig. 1) revealed the locations of all the twenty-two hydrogen atoms. They were included in the final least-squares cycles with anisotropic temperature factors for non-hydrogen atoms and isotropic one for hydrogen atoms. The final R-value was 0.069. The observed and calculated structure factors for each reflection are listed in Table 2.

Calculations were carried out on an NEAC 2200—700 computer, this University, and a FACOM 230—60 computer, University of Kyoto. The scattering factors were taken from

a) Six reflections, 021, 022, 210, 204, 214, and 244, were excluded from the least-squares refinement probably because of the high extinction effect.

the International Tables for X-Ray Crystallography.[8]

Results and Discussion

The final atomic parameters are given in Table 3, together with their estimated standard deviations. As shown in Fig. 1, there are two molecules (A and B) in an asymmetric unit and one hydrogen atom of a sulfonate group is protonated to the nitrogen atom of a guanidyl group. Thus, the two molecules of GGPSA occur in zwitterionic forms, $(NH_2)_2{}^+CNHCH_2CH_2CH_2SO_3{}^-$, as in the case of GGBOPSA,[6] L-arginine dihydrate,[7] γ-aminobutyric acid (GABA),[9] γ-amino-β-hydroxybutyric acid (GABOB),[10] taurine,[11,12] homotaurine[13] and γ-guanidinobutyric acid hydrochloride (GGBA·HCl).[14]

Bond Distances and Angles. The interatomic distances and angles are listed in Table 4 together with their standard deviations. The bond lengths and angles of the two molecules are similar and acceptable as a whole. However, the length for C(A2)–(A3) (1.523 Å) is shorter than that for C(B2)–C(B3) (1.552 Å), which may be due to the difference in C(3)–N(1) distance.

In the sulfonate group, the averages of three S–O distances, three O–S–O angles and three O–S–C(1) angles are 1.457 Å, 112.3° and 106.5° (molecule A) and 1.456 Å, 112.4° and 106.3° (molecule B), respectively. These values are very similar to those of other compounds containing a sulfonate group; GGBOPSA,[6] taurine[11,12] and homotariune.[13] The deviations of angles around the sulfur atom from tetrahedral angles are probably duc to the van der Waals repulsion by the short contacts of O–O distances which are averaged to be 2.42 Å in both molecules as in the case of GGBOPSA.[6]

In the guanidyl group, the three C–N distances of

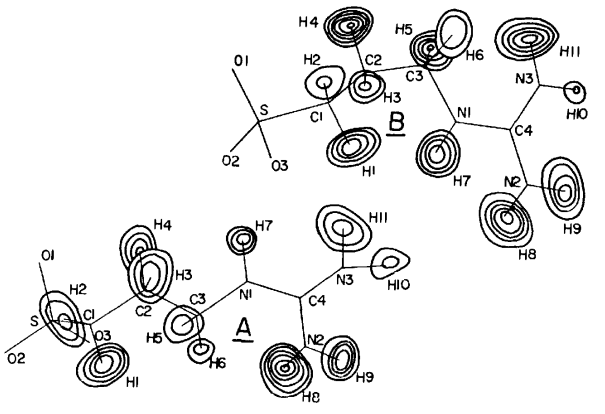

Fig. 1. Difference Fourier map of GGPSA. Contours are drawn at intervals of 0.1 e.Å^{-3}, starting with the contour of 0.3 e.Å^{-3}.

			N(2)-C(4)-N(3)	122.0(7)	120.9(7)

each molecule have normal values. Separations of the guanidyl group from the backbone, *i. e.*, C(3)–N(1) distance, are 1.464 Å (A) and 1.443 Å (B), and are very similar to those of GGBOPSA (1.456 Å), γ-guanidinobutyric acid hydrochloride (GGBA·HCl) (1.477 Å[14]) and L-arginine dihydrate (1.471 Å[7]). The three N–C(4)–N angles are 119.6°, 122.0° and 122.0 118.4° (A) and 119.3°, 120.9° and 119.8° (B). C(4)–N distances are averaged to be 1.329 Å and 1.332 Å for A and B, respectively, indicating to that they have somewhat double bond character. Calculation by Pauling's method[15] indicates that the double bond characters of C(4)–N(1), C(4)–N(2), and C(4)–N(3) bonds are approximately 24%, 37%, and 39% for A, and 29%, 35%, and 36% for B, whereas the corresponding values for GGBOPSA[6] and GGBA·HCl[14] are 32%, 25%, and 43%, and 35%, 29%, and 36%, respectively.

The C–H and N–H distances are within the ranges 0.91 Å—1.29 Å and 0.77 Å—1.09 Å, respectively.

Conformation. Conformations of the two molecules are of great interest, those around C(1)–C(2) and C(2)–C(3) being *gauche-trans* in molecule A, and *trans-gauche* in molecule B (Fig. 2). GGBOPSA,[6] GABA·HCl,[9] GABOB,[10] homotaurine[13] and GGBA·HCl[14] showed *trans-trans* conformations, and GABA[16] a *gauche-trans* form similar to molecule A. The *trans-gauche* conformation of molecule B, however, is a rare one in the derivatives of γ-amino acid and γ-guanidino acid so far investigated. Conformations of the sulfonate group around S–C(1), took the most stabilized forms (Fig. 2).

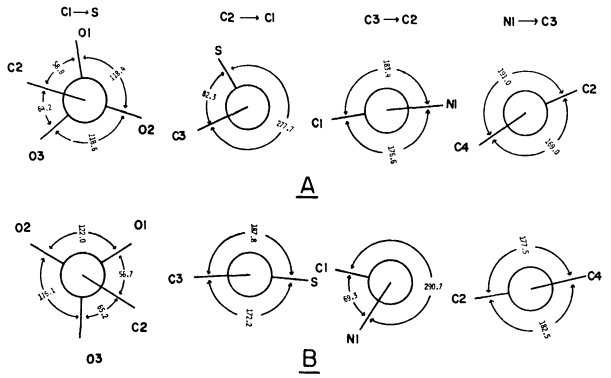

Fig. 2. Newman projection of atoms around four bonds. The arrow indicates the bond direction viewing down from front to back of paper.

The torsion angles around C(3)–N(1) are 169.0° (A) and 177.5° (B), which mean roughly a *trans* conformation similar to that of GGBOPSA[6] and L-arginine dihydrate.[7]

Planarity. The guanidyl groups are essentially planar in both molecules. Equations of the least-squares plane of each molecule through the atoms N(1)–C(4)–N(2)–N(3) and deviations of individual atoms from the corresponding plane are listed in Table 5. The planarity of guanidyl groups in GGPSA is in good agreement with that of GGBOPSA,[6] L-arginine dihydrate[7] and of GGBA·HCl.[14]

The dihedral angles between the plane of a guanidyl group and that passing through C(1)–C(2)–C(3) are 12.95° in molecule A, and 69.87° in molecule B. The corresponding angle of GGBOPSA is 27.4°. Molecule A therefore, has a value nearer that of GGBOPSA, since both have *trans zigzag* conformations.

Crystal Structure. Distances and angles of hydrogen bonds are listed in Table 6. All feasible hydrogen atoms in the molecule are utilized to form hydrogen bonds, the molecules being held together by a three-dimensional network of NH···O hydrogen bonds (Fig. 3).

In molecule A, the guanidyl group is connected with five neighboring molecules by seven hydrogen bonds and the sulfonate group performs the role as an acceptor of six hydrogen bonds. The distances of N(A1) to O(B2) and to O(B3) are 3.215 Å and 3.033 Å, respectively, and the N(A1)–H(A7) bond is directed to bisect these two directions. The distances of N(A3) to O(B3) of the original molecule and to O(A3) of a neighboring molecule translated by operation of (x, $0.5-y$, $0.5+z$) are 3.188 Å and 2.876 Å, respectively, the N(A3)–H(A11) bond bisecting the two directions. Thus, the H(A7) and H(A11) atoms are considered to contribute to form bifurcated hydrogen bonds.

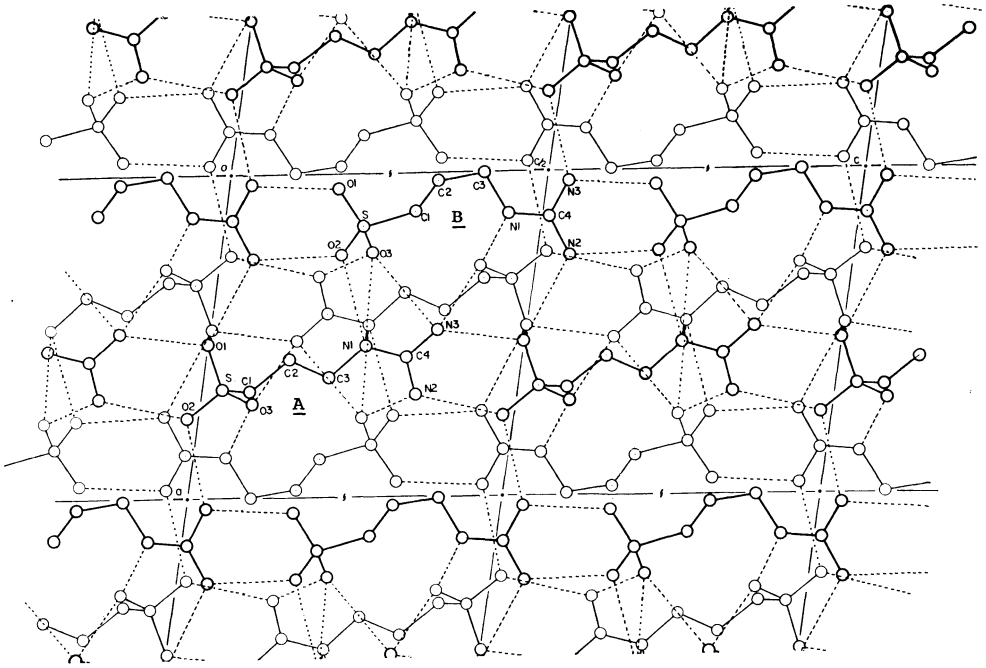

Fig. 3. The crystal structure projected along b-axis.

In molecule B, the guanidyl group is connected with four neighboring molecules by five hydrogen bonds, the sulfonate group fulfilling the role as an acceptor of six hydrogen bonds.

On the other hand, the guanidyl group of GGBOPSA[6] is connected with three neighboring molecules by six hydrogen bonds, and the sulfonate group performs the role of an acceptor of five hydrogen bonds and the N(2)–H bond is bifurcated to O(2) and O(4) of (2-x, 1-y, 1-z).

Homotaurine molecules are jointed to each other with three NH···O hydrogen bonds to form a three-dimensional network, and there are three NH···O intermolecular and one intramolecular hydrogen bonds in taurine.

The intermolecular contacts between adjacemt molecules are kept by normal van der Waals distances.

We wish to thank Prof. S. Tsunoo and Dr. K. Horisaka, Showa Medical School, for valuable adivce and for supply of the sample. This work was partly supported by a research grant from the Ministry of Education.

Effects of *N*-Acyl- and *N*-*s*-Triazinyl Groups on the Rearrangement of *S*-(*s*-Triazinyl)-2-aminothiophenols and *O*-(*s*-Triazinyl)-2-aminophenols

(Received March 20, 1973)

S-*s*-Triazinyl-2-aminothiophenols (I) containing methoxyl and/or dimethylamino groups in the *s*-triazine nucleus gave disulfides of *N*-*s*-triazinyl-2-aminothiophenols upon the S→N migration of the *s*-triazinyl group in the presence of acid; the rate of S→N migration was slow compared to that of the O→N migration of the corresponding *O*-*s*-triazinyl-2-aminophenol. On acylation or *s*-triazinylation, *S*-dimethoxy-*s*-triazinyl-2-aminothiophenol (I-1) and *O*-dimethoxy-*s*-triazinyl-2-aminophenol (II-1) gave *N*-acyl-*N*-*s*-triazinyl- or *N*,*N*-bis (*s*-triazinyl) derivatives upon the S→N or O→N migration of the *s*-triazinyl group. However, *S*-dimethylaminomethoxy-*s*-triazinyl-2-aminothiophenol (I-2), *S*-bis[(dimethylamino)-*s*-triazinyl]-2-aminothiophenol (I-3) and the corresponding derivatives of *o*-aminophenol gave *N*-acyl- or *N*-*s*-triazinyl derivatives, wihtout any migration of the *s*-triazinyl group, by acylation or *s*-triazinylation. The facility of the rearrangement of these *N*,*S*-bis-(*s*-triazinyl)-2-aminothiophenols and *N*,*O*-bis(*s*-triazinyl)-2-aminophenols depended not only upon the substituents in *S*- or *O*-*s*-triazine nucleus, but also upon the substituents in the *N*-*s*-triazine nucleus; the substituents in the *N*-*s*-triazine nucleus of strong electron-attracting and of strong electron-donating substances were not appropriate for the rearrangement in the presence of alkali to give disulfides of *N*-*s*-triazinyl-2-aminothiophenols (III-I) or *N*-*s*-triazinyl-2-aminophenols (III-II).

In previous papers,[1] we have reported that *O*-*s*-triazinyl-2-aminophenols rearrange in protic solvents or photochemically[2] to give the corresponding *N*-*s*-triazinyl-2-aminophenols.

It has been known that not only *O*-aryl-2-aminophenols, but also their *N*-acyl derivatives,[3] undergo the rearrangement of the *O*-aryl groups. Similarly, many *S*-aryl derivatives of *o*-aminothiophenol, their *N*-acyl derivatives,[4] and other related compounds, such as 2-acetamido-2′-nitrodiphenylsulfoxide,[5] 2-acetamido-2′-nitrodiphenylsulfone[4-1] or *o*-*N*-alkylamino sulfides, have been known to rearrange to yield the *N*-nitrophenyl derivatives or the derivatives of phenothiazine.[6] Recently, rearrangements of *s*-triazinyl groups have been reported in the reactions of 1-acylamino- or 1-*s*-triazinylamino-8-hydroxynaphthalene-3,6-disulfonic acid[7] and 3-hydroxy-2-naphthanilide with chloro-*s*-triazines.[8] However, in these papers the effect of *N*-acyl and *N*-triazinyl groups on the rearrangement of the *s*-triazinyl group, and their function in that rearrangement have not been mentioned. This paper will report on the S→N and O→N rearrangement of the *s*-triazinyl group of *S*-*s*-triazinyl-2-aminothiophenols, *N*-acyl, or *N*-*s*-triazinyl derivatives of *S*-*s*-triazinyl-2-aminothiophenols and *O*-*s*-triazinyl-2-aminophenols; the effects of *N*-acyl and *N*-*s*-triazinyl groups and their function in the rearrangement will also be discussed.

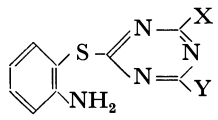
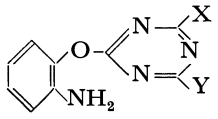
Results and Discussion

S-s-Triazinyl-2-aminothiophenols and *O-s*-triazinyl-2-aminophenols[1b] of the following general formulas were synthesized for this work:



(I)

(1) X=Y=-OCH_3
(2) X=-OCH_3, Y=-$N(CH_3)_2$
(3) X=Y=-$N(CH_3)_2$



(II)

S→N Rearrangement of the s-*Triazinyl Group of* S-s-*Triazinyl-2-aminothiophenols (I-1∼3).* In contrast to the cases of *O-s*-triazinyl-2-aminophenols,[1] the (I) compounds could be easily prepared by treating *o*-aminothiophenol with the corresponding chloro-*s*-triazines in the presence of sodium hydroxide; the success in preparing the (I) compounds by this method is considered to be due to the facts that the nucleophilic reactivity of the thiophenoxide anion is much larger than that of the phenoxide anion[9] and that the rate of the rearrangement of *S-s*-triazinyl-2-aminothiophenols is much slower than that of *O-s*-triazinyl-2-aminophenols in an alkaline solution. Table 1 lists the compounds obtained.

Generally, *S-s*-triazinyl-2-aminothiophenols are much more inactive to rearrangement than the corresponding *O-s*-triazinyl-2-aminophenols. For example, (I-1) could be stored for a long period and scarcely no rearrangement was observed even in an alkaline solution. However, (II-1) gave *N-s*-triazinyl-2-aminophenol upon storage in the laboratory in a solid state. This difference in the facility of the rearrangement agreed with the difference in mobility between -SAr and -OAr as leaving groups in the nucleophilic substitution reactions with amine; the mobility order is known as -OAr>-SAr.[10] However, (I-1) readily gave a disulfide of *N*-(4,6-dimethoxy-*s*-triazin-2-yl)-2-aminothiophenol (III-I-1) when a dilute solution (0.5 g/100 ml acetone) was treated with a small amount of hydrochloric acid, while when a concentrated solution

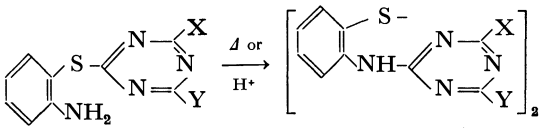
(20 g/100 ml) was used, (III-I-1), *N,N*-bis(*s*-triazinyl)-2-aminothiophenol (IV-I-1-8) and *o*-aminothiophenol were obtained, indicating that an intermolecular migration of the *s*-triazinyl group took place.

Compounds (I-2) and (I-3) are more inactive than (I-1) to the rearrangement, as may be expected; however, they also gave disulfides of the corresponding *N*-*s*-triazinyl-2-aminothiophenols when treated with an acid or when heated above their melting points. The disulfides of *N*-*s*-triazinyl-2-aminothiophenols thus obtained are listed in Table 2.



(I) (III-I)

Rearrangement of the S- *or* O-s-*Triazinyl Group during the Reactions of* S-*Dimethoxy*-s-*triazinyl*-2-*aminothiophenol (I-1) and* O-*Dimethoxy*-s-*triazinyl*-2-*aminophenol (II-1) with Acylating or* s-*Triazinylating Reagents. (a) Reaction of* S-*(4,6-Dimethoxy*-s-*triazin*-2-*yl)*-2-*aminothiophenol (I-1)*: When I-1 was treated with 2-chloro-4,6-dimethoxy-*s*-triazine in acetone under nearly neutral conditions by adding sodium carbonate, *N,N*-bis(*s*-triazinyl)-2-aminothiophenol (IV-I-1-8) was obtained as the main product instead of the expected *N,S*-bis(*s*-triazinyl)-2-aminothiophenol. A similar migration of the *S*-*s*-triazinyl group during the reaction was observed when I-1 was treated with acetic anhydride, benzoyl chloride, cyanuric chloride, or ethyl chloroformate. I-1 reacted readily with phenyl isocyanate (at room temperature) or phenyl isothiocyanate (at 60 °C) in benzene to give *N*-*s*-triazinyl-*N*-phenyl-

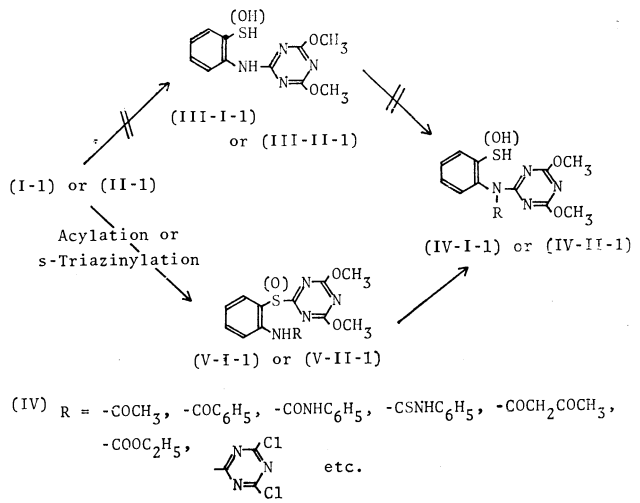
carbamoyl- or *N*-*s*-triazinyl-*N*-phenylthiocarbamoyl-2-aminothiophenol in a good yield. I-1 also reacted with diketene upon heating under reflux in xylene to give *N*-acetoacetyl-*N*-dimethoxy-*s*-triazinyl-2-aminothiophenol. Thus, *N*-acyl- and *N*-*s*-triazinyl-*S*-dimethoxy-*s*-triazinyl-2-aminothiophenols were not obtained in these cases. However, in the reaction of I-1 with acrylonitrile (heated in dioxane in the presence of Triton B) or 2,4-dinitrofluorobenzene (in the presence of triethylamine), merely an *N*-substituted product (V-I-1-1～V-I-1-2) was obtained, without any rearrangement in any case.

Table 3 lists the compounds thus obtained.

(b) Reaction of O-(4,6-Dimethoxy-s-triazin-2-yl)-2-aminophenol (II-1): A similar rearrangement was observed in the reaction of II-1 with 2-chloro-4,6-dimethoxy-*s*-triazine or acetic anhydride, which gave *N*,*N*-bis(*s*-triazinyl)-2-aminophenol or *N*-acetyl-*N*-*s*-triazinyl-2-aminophenol.

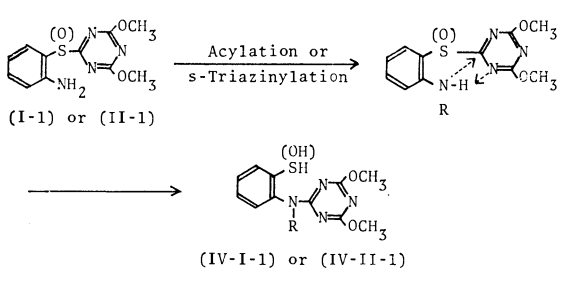
In most of these cases (except the case of diketene), (I-1) and (II-1) are stable under the reaction conditions and scarcely no formation of the rearranged product [(III-I) or (III-II)] was observed when the acylating or *s*-triazinylating reagents were absent. From these results, a process involving the intermediary formation of *N*-*s*-triazinyl-2-aminothiophenol or *N*-*s*-triazinyl-2-aminophenol (III) is not considered for these reactions; the reactions are, assumed to proceed by means of a preferential acylation or *s*-triazinylation of the amino group, followed by a rearrangement giving the end products. This assumption is supported by thin-layer chromatograms of the reaction mixture; for example, in the reaction of II-1 with acetic anhydride in the presence of triethylamine, no spot of *N*-*s*-triazinyl-2-aminophenol (III-II-1) was observed at any time during the course of the reaction (developed on a silica gel layer; developing solvent, chloroform–benzene–ligroin–methanol=15 : 5 : 5 : 5 by volume). A short time after the reaction components were mixed, however, a new, unidentified spot appeared, followed by a spot of *N*-acetyl-*N*-*s*-triazinyl-2-aminophenol (IV-II-1-1). The latter increased gradually with the reaction time; however, the unidentified spot [probably attributable to *N*-acetyl-*O*-*s*-triazinyl-2-aminophenol (V-II-1-1)] was small and remained almost constant throughout the course of the reaction until it disappeared at last.



(IV) R = $-COCH_3$, $-COC_6H_5$, $-CONHC_6H_5$, $-CSNHC_6H_5$, $-COCH_2COCH_3$, $-COOC_2H_5$, etc.

In contrast to the case of I-1, II-1 gave merely *N*-dimethoxy-*s*-triazinyl-2-aminophenol when heated with diketene in xylene or when heated with acrylonitrile. Because of the slow S→N migration, the reaction of (I-1) is assumed to proceed by means of a preferential reaction at the amino group, followed by the rearrangement giving the end product. On the other hand, (II-1) rearranges rapidly upon mere heating; therefore, in the case of II-1 the rearrangement is considered to take place in preference to the reaction of the amino group with the reagent, because the preformed *N*-*s*-triazinyl-2-aminophenol is inert to the attack by diketene or acrylonitrile under the present reaction conditions.

From the results, it is obvious that the introduction of the acyl or *s*-triazinyl group into the amino group very much facilitates the S→N or O→N migration of the *S*- or *O*-dimethoxy-*s*-triazinyl group. Generally, the nucleophilic reactivities of NH-*s*-triazinyl and NH-acyl groups are known to be low. Thus, the rate of the rearrangement of *N*-acyl-*O*-(2,4-dinitrophenyl)-2-aminophenols is much slower than that of the parent aminoether in the absence of alkali.[3] Therefore, it is unlikely that the ready rearrangement of intermediary *N*-acyl or *N*-*s*-triazinyl derivatives (V) merely proceeds by means of a general nucleophilic attack by the NH-acyl or NH-*s*-triazinyl group. However, a process involving the formation of a reactive anion by the abstraction of a proton from the NH-acyl- or NH-*s*-triazinyl group is also unlikely, for, in most of these cases, the acylation and *s*-triazinylation were carried out under nearly neutral conditions; in certain cases, as in the reaction of I-1 with phenyl isocyanate, even though the reactions were carried out without the addition of any base, the rearrangement took place very readily. Consequently, it may be considered that the presence of an acidic –NH– hydrogen atom resulting from the introduction of an acyl or *s*-triazinyl group is important for the ready rearrangement, and that the difference in effect of introducing an acyl group between the nitrophenyl (retardation) and *s*-triazinyl (acceleration) derivatives is attributable to the presence or absence of a ring nitrogen atom in the migrating aryl nucleus. From these considerations, it seems reasonable to assume that the ready rearrangement of *N*-acyl or *N*-*s*-triazinyl derivatives of I-1 and II-1 proceeds by intramolecular four-center electrophilic-nucleophilic processes, as is shown below:



R = Acyl- or s-Triazinyl Group

From the viewpoint of this assumption, it may be considered that the -NH- group of the 2,4-dinitrophenyl derivative is more favorable for the protonation-like process than are the ordinary NH-acyl groups; however, its nucleophilic reactivity is assumed to be too low to attack the *s*-triazine ring carbon. An opposite situation holds for the *N*-β-cyanoethyl derivative.

Reactions of S-*(2-Dimethylamino-4-methoxy-*s*-triazin-2-yl)-2-aminothiophenol (I-2),* O-*(2-Dimethylamino-4-methoxy-*s*-triazin-2-yl)-2-aminophenol (II-2),* S-[*2,4-Bis-(dimethylamino)-*s*-triazin-2-yl]-2-aminothiophenol (I-3), and* O-[*2,4-Bis(dimethylamino)-*s*-triazin-2-yl)-2-aminophenol (II-2) with Acylating or* s-*Triazinylating Reagents, and the Migration of the* s-*Triazinyl Group of* N,S-*Bis(*s-*triazinyl)-2-aminothiophenols and* N,O-*Bis(*s-*triazinyl)-2-aminophenols.* When I-2 or II-2 was treated with acetic anhydride, phenyl isocyanate, benzoyl chloride, ethyl chloroformate, cyanuric chloride, 2,4-dichloro-6-methoxy-*s*-triazine, or 2,4-dichloro-6-methyl-*s*-triazine in manners similar to those described above, an *N*-acyl- or *N-s*-triazinyl-derivative was obtained in every case, without any migration of the *S*- or *O*-triazinyl group. Tables 4 and 5 list the compounds, (V-I-2) and (V-II-2), thus obtained. Similar results were also obtained in the reactions of I-3 and II-3 with acylating or *s*-triazinylating reagents; Tables 6 and 7 list the compounds, (V-I-3) and (V-II-3), thus obtained.

When *N*-chloro-*s*-triazinyl-*O-s*-triazinyl-2-aminophenols [(V-II-2-5)～(V-II-2-7) and (V-II-3-8)～(V-II-3-10)] and *N*-chloro-*s*-triazinyl-*S-s*-triazinyl-2-aminothiophenols [(V-I-2-4)～(V-I-2-6) and (V-1-3-5)

~(V-I-3-7)] were treated with dimethylamine, one or two chlorine atoms were replaced by a dimethylamino group, depending upon the amounts of dimethylamine used and the reaction temperature; the migration of the *O*- or *S*-*s*-triazinyl group was not observed in any case. However, in the reaction with sodium methoxide, not only the replacement of the chlorine atom, but also the migration of the *s*-triazinyl group, took place. For example, V-II-2-5 reacted with an equimolar amount of sodium methoxide to give V-II-2-6. However, with more than two equivalents of sodium methoxide V-II-2-5 gave *N*-(4-dimethylamino-6-methoxy-*s*-triazin-2-yl)-2-aminophenol (III-II-2) under the O→N

rearrangement and the cleavage of one of the *s*-triazinyl groups. III-II-2 was also obtained from V-II-2-7 when it was treated with more than one equivalent of sodium methoxide. Similarly, V-II-3-8 gave V-II-3-9 or III-II-3 when treated with one or more than two equivalents of sodium methoxide. However, when V-II-3-8 was treated with one and a half equivalents of sodium methoxide, even though the reaction mixture was slightly acidic at the end of the reaction, instead of an intermediary *N*-[bis(dimethylamino)-*s*-triazinyl]-*N*-(chloromethoxy-*s*-triazinyl)-2-aminophenol (IV-II-3)′ or *O*-[bis(dimethylamino)-*s*-triazinyl]-*N*-(dimethoxy-*s*-triazinyl)-2-aminophenol (V-II-3)′, the rearranged product of the latter (IV-II-3), which gave III-II-3 in the presence of alkali, was obtained, together with III-II-3. Thus, it is obvious that the reaction of V-II-2-5 or V-II-3-8 with sodium methoxide proceeds by means of a preferential replacement of the chlorine atoms by methoxyl groups, followed by the O→N migration of the *O*-*s*-triazinyl group to give IV-II-2 or IV-II-3, which gave the end product by a cleavage of the dimethoxy-*s*-triazinyl group, as is shown below.

Compound (V-II-3-10), however, unlike V-II-2-7 or V-II-3-9, gave only a replaced product when

treated with sodium methoxide. Similarly, III-I-2 was obtained in the reaction of V-I-2-4 with sodium methoxide; however, V-I-3-5 gave merely a replaced product upon treatment with an excess of sodium methoxide. Thus, although, because of the ready rearrangement *N*-dimethoxy-*s*-triazinyl derivatives of V-I-1～2 and V-II-1～3 types could not be obtained, *N*,*S*- and *N*,*O*-bis(*s*-triazinyl) derivatives of V-I-2～3 and V-II-2～3 types containing such substituents as -Cl, -Cl; -Cl, $-OCH_3$; -Cl, $-CH_3$; -Cl, $-N(CH_3)_2$; $-OCH_3$, $-CH_3$; $-OCH_3$, $-N(CH_3)_2$; $-N(CH_3)_2$, $-N(CH_3)_2$, and $-CH_3$, $-N(CH_3)_2$ in the *N*-*s*-triazine nucleus were prepared as fairly stable compounds, as Tables 4, 5, 6, and 7 show. From these results it has become clear that the facility of the rearrangement of *N*,*S*-bis(*s*-triazinyl)-2-aminothiophenols

Table 8. Rearrangement of *N*,*O*-bis(*s*-triazinyl)-2-aminophenols and *N*,*S*-bis(*s*-triazinyl)-2-aminothiophenols in the presence of sodium hydroxide in acetone

● indicates that the compound was not obtained owing to the rearrangement during the synthesis.

and *N*,*O*-bis(s-triazinyl)-2-aminophenols depends not only upon the substituents in the *S*- or *O*-*s*-triazine nucleus, but also upon the substituents in the *N*-*s*-triazine nucleus; however, no simple relation such as holds in the case of the substituents in the *O*-*s*-triazine nuclues[1b] was observed between the facility of the rearrangement and the substituents in the *N*-*s*-triazine nucleus. As will be mentioned later, some of the compounds, V-I-2∼3 and V-II-2∼3, rearrange in the presence of alkali (*cf.* Table 8). However, these results suggest that the ready rearrangement during the methoxydechlorination proceeds in a manner similar to that mentioned before by means of intramolecular four-center electrophilic-nucleophilic processes, and that, in these cases, the presence of alkali is necessary not for the rearrangement, but for the hydrolytic fission of the *s*-triazinyl group.

Migration of the S- *and* O-s-*Triazinyl Groups of* N-*Acyl*-S-s-*triazinyl*-, N,S-*Bis(*s-*triazinyl)-2-aminothiophenols, and* N-*Acyl*-O-s-*triazinyl*-, N,O-*Bis(*s-*triazinyl)-2-aminophenols in the Presence of Alkali.* The compounds listed in Tables 4∼7 are stable in a neutral or acidic solution. However, in the presence of sodium hydroxide some of these compounds give III-I or (III-II) upon the S→N or O→N migration of the *S*- or *O*-*s*-triazinyl group and the subsequent hydrolytic fission of the acyl group or one of the *s*-triazinyl groups, while *N*-2,4-dinitrophenyl and *N*-*β*-cyanoethyl derivatives of V-I-3 and V-II-3 types fail to give the rearranged products even in the presence of alkali. The results are shown in Table 8.

In the reaction of *N*-acyl derivatives of V-II-2 and (V-II-3) types in the presence of alkali, anions formed by the dissociation of the NH- groups were confirmed to be reactive species, as will be discussed in a subsequent paper;[11] similar reactive species may be assumed in the rearrangement of *N*,*O*-bis(*s*-triazinyl)-2-aminophenols and the corresponding derivatives of 2-aminothiophenol in the presence of alkali. It has been established, from the results on *N*-substituted *o*-amino sulfides and *o*-amino sulfones,[4a,5] that the proper balance of acidity and nucleophilicity of an attacking group is important for the rearrangement in the presence of alkali. However, in these cases it is assumed that a simple relation between acidity and nucleophilicity does not hold among the compounds used, because there is no similarity in the *N*-substituents. Therefore, it may be better to use as *N*-*s*-triazinyl groups a series of *N*-substituents of the same kind in order to make clear the importance of the proper balance mentioned above.

From Table 8 it is obvious that a good correlation holds between the substituents in the *N*-*s*-triazine nucleus ($\sigma_m X+\sigma_m Y$)[12] and the reactivity. Substituents in the *N*-*s*-triazine nucleus of strong electron-attracting or strong electron-donating substances were not appropriate for the rearrangement; this suggests that the balance between the acidity of the NH- group and the nucleophilicity of the anion is important. The failure of the rearrangement of derivatives containing strong electron-attracting substituents may be attributed to the low nuclepohilic reactivities of their anions, while the derivatives containing strong electron-donating substituents are assumed to be too weakly

acidic to provide a sufficient concentration of reactive anions under the present reaction conditions.

Experimental

All the melting points are uncorrected.

The infrared spectra were measured in potassium bromide discs on a Jasco D-301 spectrophotometer. The NMR spectra were recorded on a Varian A-60D spectrometer. The elemental analyses were performed in the Micro-analytical Center of Gunma University.

The identification of the reaction products was performed by means of their NMR and infrared spectra, by elemental analyses, by molecular-weight determinations, by studying the solubility in an alkaline solution, by the color reaction of the -SH or -OH group, and by mixed-melting-point tests with an authentic sample.

Materials. S-s-*Triazinyl-2-aminothiophenols (I-1~3).* S-*(4,6-Dimethoxy-s-triazin-2-yl)-2-aminothiophenol (I-1)*: A solution of 2.5 g (0.02 mol) of *o*-aminothiophenol in 10 ml of a 10% sodium hydroxide solution was stirred, drop by drop, into a solution of 3.5 g (0.02 mol) of 2-chloro-4,6-dimethoxy-*s*-triazine in 30 ml of acetone at room temperature. Stirring was continued for 2 hr at 30 °C, and then the solution was poured into 200 ml of ice water. The precipitate was then filtered and dried. IR (KBr) cm^{-1}, (NH_2) 3440, 3400; (*s*-triazine) 810. NMR ($CDCl_3$), δ 3.90 (s, 6H), 4.18 (s, 2H), 7.30 (m, 4H).

S-*(4-Dimethylamino-6-methoxy-s-triazin-2-yl)-2-aminothiophenol I-2*: The I-2 compound was prepared in a manner similar to that described above by treating *o*-aminothiophenol with 2,4-dichloro-6-methoxy-*s*-triazine, followed by treatment with dimethylamine. IR (KBr) cm^{-1}, (NH_2) 3300, 3190; (*s*-triazine) 790. NMR (DMSO-d_6), δ 2.95 (s, 6H), 3.90 (s, 3H), 5.00 (s, 2H), 7.03(m, 4H).

S-[*4,6-Bis(dimethylamino)-s-triazin-2-yl*]-*aminothiophenol (I-3)*: A solution of 5.0 g (0.04 mol) of *o*-aminothiophenol in 20 ml of a 10% sodium hydroxide solution was stirred, drop by drop, into a solution of 8.0 g (0.04 mol) of 2-chloro-4,6-bis(dimethylamino)-*s*-triazine in 30 ml of dioxane; then the mixture was refluxed with stirring for 12 hr and poured into 200 ml of ice water. The oily precipitate was extracted with benzene, the benzene layer was washed with a sodium hydroxide solution and evaporated *in vacuo*, and the residue was collected. IR (KBr) cm^{-1}, (NH_2), 3400, 3310, (*s*-triazine) 795. NMR (DMSO-d_6), δ 2.95 (s, 12H), 5.20 (s, 2H), 7.00 (m, 4H).

Rearrangement of I in the Presence of Acid. A typical run is the case of *S*-(dimethoxy-*s*-triazinyl)-2-aminothiophenol (I-1). To a solution of 0.5 g of I-1 in 100 ml of acetone, we added 3 drops of concd. hydrochloric acid at room temperature. After it had stood for 24 hr at room temperature, the mixture was poured into ice water and neutralized with sodium carbonate; the precipitate thus formed was filtered and dried. IR(KBr) cm^{-1}; (NH) 3380. NMR (DMSO-d_6), δ 3.85 (s, 6H), 7.60(m, 4H), 9.65 (s, 1H).

Reactions of S-s-*Triazinyl-2-aminothiophenols (I) or* O-s-*Triazinyl-2-aminophenols (II) with Acylating or* s-*Triazinylating Reagents.* Some typical runs are noted below.

i) Reaction of I-1 with Acetic Anhydride to give N-*(Acetyl)*-N-*(dimethoxy-s-triazinyl)-2-aminothiopheonl (IV-I-1-1).* To a stirred solution of 2.6 g (0.01 mol) of I-1 and 6 ml of triethylamine in 50 ml of acetone, we added 2.0 g (0.02 mol) of acetic anhydride at room temperature. After it had stood for 5 hr, the mixture was poured into 200 ml of ice water, and the precipitate thus formed was filtered and dried. NMR (DMSO-d_6), δ 2.04 (s, 3H), 3.85 (s, 6H), 7.50 (m, 4H), 9.38 (s, 1H).

ii) Reaction of I-1 with Benzoyl Chloride to give N-*(Benzoyl)*-N-*(dimethoxy-s-triazinyl)-2-aminothiophenol (IV-I-1-2).* To a stirred mixture of 2.6 g (0.10 mol) of I-1, 30 ml of acetone, and 1.7 g (0.01 mol) of benzoyl chloride, 12 ml of a 5% sodium hydroxide solution was added, drop by drop, while the reaction mixture was kept at a nearly neutral condition at room temperature. After stirring for 5 hr, the mixture was poured into 200 ml of ice water, and the precipitate thus obtained was filtered and dried. NMR (DMSO-d_6), δ 3.85 (s, 6H), 7.70 (m, 9H), 9.55 (s, 1H).

iii) Reaction of I-1 with Cyanuric Chloride to give N-*(Dichloro-s-triazinyl)*-N-*(dimethoxy-s-triazinyl)-2-aminothiophenol (IV-I-1-7).* To a stirred solution of 2.6 g (0.01 mol) of I-1 in 50 ml of acetone, we added 1.8 g (0.01 mol) of cyanuric chloride, a 10 ml portion of a 1 N solution of sodium carbonate was then added, drop by drop, at 0 °C. After it had been stirred for 1 hr, the reaction mixture was poured into 300 ml of ice water, and the precipitate thus formed was filtered and dried. NMR (DMSO-d_6), δ 3.75 (s, 6H), 7.55 (m, 4H), 10.87 (s, 1H).

iv) Reaction of I-1 with Phenyl Isocyanate to give N-*(Dimethoxy-s-triazinyl)*-N-*(phenylcarbamoyl)-2-aminothiophenol (IV-I-1-3).* To a stirred solution of 2.6 g (0.01 mol) of I-1 in 100 ml of benzene, we added 1.2 g (0.01 mol) of phenyl isocyanate at room temperature. After it had been stirred for 3 hr, the precipitate thus formed was filtered and dried. NMR (DMSO-d_6) δ 3.83 (s, 6H), 7.35 (m, 9H), 8.23 (s, 1H), 9.35 (s, 1H).

v) Reaction of II-2 with Phenyl Isocyanate to give N-*(Phenylcarbamoyl)*-O-*(4-dimethylamino-6-methoxy-s-triazin-2-yl)-2-aminophenol (V-II-2-1).* To a solution of 2.6 g (0.01 mol) of (II-2) in 50 ml of benzene, we added 1.2 g (0.01 mol) of phenyl isocyanate at room temperature. After the mixture had been stirred for 5 hr, the precipitate thus formed was filtered and dried. NMR (DMSO-d_6), δ 3.10 (d, 6H), 3.83 (s, 3H), 7.30 (m, 9H), 8.14 (s, 1H), 9.13 (s, 1H).

vi) Reaction of II-2 with 2,4-Dichloro-6-methoxy-s-triazine to give N-*(4-Chloro-6-methoxy-s-triazin-2-yl)*-O-*(4-dimethylamino-6-methoxy-s-triazin-2-yl)-2-aminophenol (V-II-2-6).* To a stirred solution of 2.6 g (0.01 mol) of II-2 and 1.8 g (0.01 mol) of 2,4-dichloro-6-methoxy-*s*-triazine in 100 ml of acetone, we added a solution of 1.0 g (0.012 mol) of sodium bicarbonate in 30 ml of water, drop by drop, at room temperature. After having been stirred for 2 hr, the reaction mixture was poured into 300 ml of ice water; the precipitate thus formed was then filtered and dried. NMR (DMSO-d_6), δ 3.10 (d, 6H), 3.85 (s, 3H), 3.90(s, 3H), 7.40(m, 4H), 10.10(s, 1H).

vii) Reaction of II-3 with 2,4-Dinitrofluorobenzene to yield N-*(Dinitrophenyl)*-O-[*4,6-bis(dimethylamino)-s-triazin-2-yl*]-*2-aminophenol (V-II-3-6).* To a stirred solution of 2.7 g (0.01 mol) of II-3 and 1.0 g (0.01 mol) of triethylamine in 100 ml of benzene, we added 1.8 g (0.01 mol) of 2,4-dinitrofluorobenzene at room temperature. After the mixture had been stirred at room temperature for 8 hr, the benzene was distilled off *in vacuo*; the residue was then washed with water and filtered. NMR (DMSO-d_6), δ 2.99 (s, 12H), 7.40 (m, 7H), 9.91 (s, 1H).

viii) Reaction of II-3 with Ethyl Chloroformate to give N-*Ethoxycarbonyl)*-O-[*4,6-bis(dimethylamino)-s-triazin-2-yl*]-*2-aminophenol (V-II-3-5).* To a mixture of 2.7 g (0.01 mol) (I-3), 1.5 g (0.018 mol) of sodium bicarbonate, and 30 ml of water in 100 ml of acetone, we added a solution of 2.0 g (0.018 mol) of ethyl chloroformate in 50 ml of acetone at room temperature. After having been stirred, for 5 hr at room temperature, the reaction mixture was poured into 500 ml of ice water, and the precipitate thus formed was

filtered and dried. NMR (DMSO-d_6), δ 1.19 (t, 3H), 2.99 (s, 12H), 4.09 (q, 2H), 7.15 (m, 4H), 8.60 (s, 1H).

Reactions of N-*(Chloro-*s*-triazinyl)*-S-*(*s*-triazinyl)-2-amino thiophenols and* N-*(Chloro-*s*-triazinyl)*-O-*(*s*-triazinyl)-2-aminophenols with Neucleophiles.* Some typical runs will be shown in the case of *N*-(4,6-dichloro-*s*-triazin-2-yl)-*O*-[4,6-bis(dimethylamino)-*s*-triazin-2-yl]-2-aminophenol (V-II-3-8).

i) Reaction of V-II-3-8 with Dimethylamine to give N-*(4-Chloro-6-dimethylamino-*s*-triazin-2-yl)*-O-*[4,6-bis(dimethylamino)-*s*-triazin-2-yl]-2-aminophtnol (V-II-3-12).* To a solution of 2.1 g (0.005 mol) of V-II-3-8 in 100 ml of acetone, we added 1.2 ml (0.01 mol) of a 40% dimethylamine solution at 0 °C. After having been stirred for 3 hr at 0 °C, the reaction mixture was poured into 300 ml of ice water; the precipitate thus formed was then filtered and dried. NMR (DMSO-d_6), δ 2.98 (s, 18H), 7.30(m, 4H), 8.60(s, 1H). When the reaction was carried out using 2.5 ml of a 40% dimethylamine solution at 50 °C, the reaction product was V-II-3-13.

ii) Reaction of V-II-3-8 with Sodium Methoxide. ii-a) Reaction of V-II-3-8 with Sodium Methoxide in a Molar Ratio of 1 : 1 to give N-*(4-Chloro-6-methoxy-*s*-triazin-2-yl)*-O-*[4,6-bis(dimethylamino)-*s*-triazin-2-yl]-2-aminophenol (V-II-3-9).* To a mixture of 2.1 g (0.005 ml) of V-II-3-8 in 100 ml of methanol, we added 5 ml of a 1 N methanolic sodium methoxide solution at 0 °C. After it had stood for 1 night, the reaction mixture was poured into 300 ml of ice water. The precipitate thus formed was filtered and dried. (This compound was also obtained by the condensation of I-3 with 2,4-dichloro-6-methoxy-*s*-triazine). NMR (DMSO-d_6), δ 2.85 (s, 12H), 3.85 (s, 3H), 7.40 (m, 4H), 10.10 (s, 1H).

ii-b) When the Above-mentioned reaction was carried out using 15 ml of a sodium methoxide solution, *N*-[4,6-bis-(dimethylamino)-*s*-triazin-2-yl]-2-aminophenol (mp 185—186 °C)[1b] (III-II-3) (yield, 95%) and dimethylcyanuric acid[13] (yield, 82%) were obtained. However, in the reaction of V-II-3-8 with sodium methoxide in a molar ratio of 1 : 1.5, two rearranged products were obtained. One was *N*-[4,6-bis(dimethylamino)-*s*-triazin-2-yl]-2-aminophenol (yield, 33%), and the other was found to be *N*-(4,6-dimethoxy-*s*-triazin-2-yl)-*N*-[4,6-bis(dimethylamino)-*s*-triazin-2-yl]-2-aminophenol. (Mp 95—97 °C, recrystallized from cyclohexane), (yield, 36%). Found: C, 52.66; H, 5.83; N, 30.32%. Calcd for $C_{18}H_{23}N_9O_3$: C, 52.29; H, 5.61; N, 30.49%. NMR (DMSO-d_6), δ 2.97 (s, 12H), 3.83 (s, 6H), 7.55 (m, 4H), 8.98 (s, 1H).

Rearrangement of N,S-*Bis(*s*-triazinyl)-2-aminothiophenols (V-I) and* N,O-*Bis(*s*-triazinyl)-2-aminophenols (V-II) in the Presence of Sodium Hydroxide.* To a solution of 0.2 g of a *N,S-* or *N,O*-bis(*s*-triazinyl) derivative in 30 ml of acetone, we added 3 ml of a 0.5 N sodium hydroxide solution. After having stood (at room temperature in the case of V-II, and at 60 °C in the case of V-I) the reaction mixture was developed on a silica gel layer, using a mixture of benzene and acetone (6 : 1 by volume) as the developing solvent. From the thin-layer chromatogram thus obtained, the rearranged product was eluted with ethanol and thus identified.

Reactions of Diphenylphosphinothioyl Isothiocyanate and Related Compounds with Some Nucleophiles and Carbodiimides

Iwao Ojima,* Kin-ya Akiba, and Naoki Inamoto

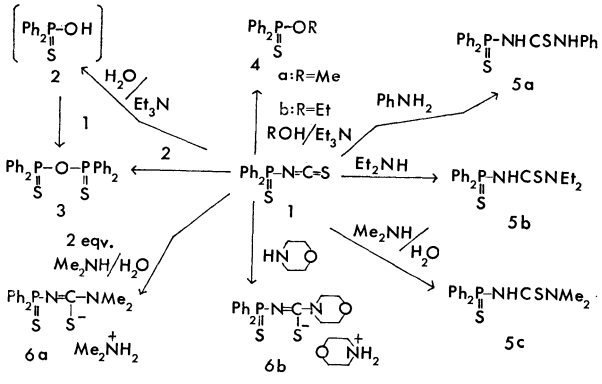
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received March 23, 1973)

Diphenylphosphinothioyl isothiocyanate (**1**) reacted with alcohols, water and diphenylphosphinothioic acid to give the esters and anhydride of diphenylphosphinothioic acid by substitution reaction on the phosphorus atom, but reacted with amines by addition to the isothiocyanate group to afford diphenylphosphinothioylthioureas or their ammonium salts. Diphenylphosphine and *p*-toluenethiol, however, did not react with **1**. On the contrary, diphenylphosphinothioyl isocyanate underwent only addition reaction with water, amine and thiol. Isothiocyanate (**1**) and *p*-toluenesulfonyl isothiocyanate were found to undergo 1,2-cycloaddition reaction with carbodiimides across the C=S bond to produce 1,3-thiazetidine derivatives.

Diphenylphosphinothioyl isothiocyanate (**1**) is an ambident substrate and has two reaction sites on phosphorus and carbon atoms.

This paper describes the reaction sites of **1** in the reactions with some nucleophiles and carbodiimides. Nucleophiles used were water, alcohols diphenylphosphinothioic acid (**2**), amines, diphenylphosphine and *p*-toluenethiol. Reactions of **1** with **2**[1] and diethylamine[2] have been reported. The results of these reactions are summarized in Scheme 1.



Scheme 1.

* Present address: Sagami Chemical Research Center, Nishi-onuma, Sagamihara, Kanagawa 229.

1) I. Ojima, K. Akiba, and N. Inamoto, This Bulletin, **42**, 2975 (1969).

2) I. Ojima, T. Onishi, T. Iwamoto, N. Inamoto, and K. Tamaru, *ibid.*, **44**, 2150 (1971).

It is remarkable that nucleophiles, the center of which is oxygen, attack selectively the phosphorus atom of **1** in the presence of triethylamine. This is attributable to formation of strong P–O bond in the substitution reaction.

The amines added to the carbon atom of the isothiocyanate group to give diphenylphosphinothioylthioureas (**5**) in quantitative yields, whereas diphenylamine did not react with **1** even when reaction temperature was raised up to 120 °C, because of its low nucleophilicity. Thioureas (**5**) can act as bidentate ligands.[2]

The reaction with 40% aqueous dimethylamine shows that the addition reaction with the amine predominates over the substitution reaction with water.

Attack of amines on the phosphorus atom has been reported in the case of diethoxyphosphoryl isothiocyanate.[3]

$$(EtO)_2P(O)-NHCSNR_2 \xleftarrow{R_2NH} (EtO)_2P(O)-NCS \xrightarrow{2R_2NH} (EtO)_2P(O)NR_2$$

In the case of **1**, however, the reactions with two equivalents of dimethylamine or morpholine provided ammonium salts (**6**), no substitution being observed under the present reaction conditions, though a formation of P–N bond by decomposition of **6** is possible.[4]

$$Ph_2P(S)-N(R_2N)-C(S^{\ominus})R_2\overset{\oplus}{N}H_2 \xrightarrow[in\ vacuo]{80-100\,^{\circ}C} Ph_2P(S)NR_2 + R_2\overset{\oplus}{N}H_2\overset{\ominus}{S}CN$$

6

It is curious that diphenylphosphine and *p*-toluenethiol, strong nucleophiles, react not with **1** but with ordinary isothiocyanates.[1,5]

The IR spectrum of **1** displays a strong band at 1960 cm^{-1} (–N=C=S). The value is considerably low as compared with that of ordinary isothiocyanates (2020—2100 cm^{-1}). This phenomenon would be interpreted by a large contribution of a canonical structure (**1′**).

$$>P(S)-N=C=S \longleftrightarrow >P=N-\overset{\oplus}{C}=S \overset{\ominus}{S} \longleftrightarrow \textit{etc.}$$

1 **1′**

The large contribution of **1′** increases the reactivity of the carbon atom of **1** toward nucleophiles, and also the hardness[6] of the carbon atom. The reaction with soft bases, diphenylphosphine and *p*-toluenethiol, may therefore become difficult.

In contrast with the reactions of **1**, diphenylphosphinothioyl isocyanate (**7**) reacted with water and diethylamine to give aminodiphenylphosphine sulfide (**8**) and 1,1-diethyl-3-diphenylphosphinothioylurea (**9**), respectively, no nucleophilic attack on the phosphorus atom being observed. Addition of *p*-toluenethiol to **7** produced a monothiocarbamate (**10**). This is attributable to a higher reactivity of the isocyanate group.

$$[Ph_2P(S)-NHCO_2H] \xrightarrow{-CO_2} Ph_2P(S)-NH_2 \quad (\mathbf{8})$$

$$[Ph_2P(S)-NHCO_2H] \xleftarrow{H_2O} Ph_2P-N=C=O \ (\mathbf{7}) \xrightarrow{Et_2NH} Ph_2P(S)-NHCONEt_2 \quad (\mathbf{9})$$

$$Ph_2P-N=C=O \ (\mathbf{7}) \xrightarrow{p\text{-}MeC_6H_4SH} Ph_2P(S)-NHCOSC_6H_4Me\text{-}p \quad (\mathbf{10})$$

If the contribution of **1′** is large, **1** should undergo 1,4-cycloaddition like thioacyl isothiocyanate.[7] Reactions of **1** with carbodiimides were performed from this standpoint.[8]

When an equimolar mixture of **1** and dicyclohexylcarbodiimide was heated, the adduct (**11a**) was obtained in a nearly quantitative yield. The IR spectrum showed a very strong band at 1640 cm^{-1} (C=N), and the UV spectrum displayed absorption maxima at 223 (log ε 4.81) and 260 nm (sh., log ε 4.23).

$$R^1-N=C=S + R^2-N=C=N-R^2 \rightarrow R^1-N=C(-S-)(-N(-R^2)-)-C=N-R^2$$

1 $R^1=Ph_2P(S)$
14 $R^1=p\text{-}MeC_6H_4SO_2$

11

a : $R^1=Ph_2P(S)$, $R^2=c\text{-}C_6H_{11}$
b : $R^1=Ph_2P(S)$, $R^2=i\text{-}Pr$
c : $R^1=p\text{-}MeC_6H_4SO_2$, $R^2=c\text{-}C_6H_{11}$

12

13

a : $R^1=Ph_2P(S)$, $R^2=c\text{-}C_6H_{11}$
b : $R^1=p\text{-}NO_2C_6H_4$, $R^2=c\text{-}C_6H_{11}$
c : $R^1=p\text{-}MeC_6H_4SO_2$, $R^2=o\text{-}MeC_6H_4$
d : $R^1=p\text{-}NO_2C_6H_4$, $R^2=i\text{-}Pr$
e : $R^1=MeSO_2$, $R^2=Ph$

The spectral data confirm that **11a** is a new 1,3-thiazetidine derivative, and not a 1,3-diazetidine derivative (**13a**) or a 1,4-cycloadduct (**12**), because the strong absorption band at 223 nm is too short to be assigned to the π–π^* transition of a C=S bond[9] and no absorption band caused by n–π^* transition could be detected. Furthermore, **11a** did not catalyse the

decomposition of sodium azide by iodine (Feigl test),[10] indicating the absence of a C=S group.

The reaction of **1** with diisopropylcarbodiimide gave a similar adduct (**11b**).

Ulrich and Sayigh[11] reported that the 1,2-cycloaddition of carbodiimide and isothiocyanate having electron-withdrawing group always gives 1,3-diazetidine derivative (**13**). *p*-Toluenesulfonyl isothiocyanate (**14**) ($\nu_{N=C=S}$ 1890 cm^{-1}) was allowed to react with dicyclohexylcarbodiimide under conditions similar to those used by Ulrich *et al.* Adduct (**11c**), which also gave a negative Feigl test, was obtained in a nearly quantitative yield.

Comparison of the C=N stretching vibrations (1620—1640 cm^{-1}) of 1,3-thiazetidines (**11**) with those of **13** reported by Ulrich and Sayigh[11] also suggests that the adducts (**13**) are 1,3-thiazetidines (see Table 1). Recent work by Ulrich *et al.*[12] supports our results.[8]

Table 1. C=N stretching vibrations of 1,3-thiazetidines (**11**) and "1,3-diazetidines (**13**)" reported by Ulrich *et al.*[11]

	R^1	R^2	$\nu_{C=N}$ (cm^{-1})
11a	$Ph_2P(S)$	*c*-C_6H_{11}	1640
11b	$Ph_2P(S)$	*i*-Pr	1630
11c	*p*-$MeC_6H_4SO_2$	*c*-C_6H_{11}	1620
"**13b**"	*p*-$NO_2C_6H_4$	*c*-C_6H_{11}	1655
"**13c**"	*p*-$MeC_6H_4SO_2$	*o*-MeC_6H_4	1600
"**13d**"	*p*-$NO_2C_6H_4$	*i*-Pr	1655
"**13e**"	$MeSO_2$	Ph	1615

These results show that the cycloaddition of the isothiocyanates having electron-withdrawing group and carbodiimides occurs across the C=S bond of the isothiocyanate to give 1,3-thiazetidines, and not across the C=N bond to give 1,3-diazetidines.

Experimental

All melting and boiling points are uncorrected. IR, UV, NMR and Mass spectra were measured with Hitachi Model EPI-G2, Hitachi Model EPS-3, JEOL-C-60H, and Hitachi Model RMU-6D spectrometers, respectively.

Materials. Diphenylphosphinothioyl isothiocyanate (**1**) was prepared from diphenylphosphinothioyl chloride and ammonium thiocyanate, mp 48—49 °C (lit,[4] 48 °C). *p*-Toluenesulfonyl isothiocyanate (**14**) was prepared from potassium *N*-(*p*-toluenesulfonyl)dithiocarbamate[13] and thionyl chloride, bp 114—118 °C/0.5 mmHg (lit,[14] 115—125 °C/0.65 mmHg).

*Preparation of Diphenylphosphinothioyl Isocyanate (**7**).* A mixture of potassium cyanate (10.0 g, 0.12 mol) and diphenylphosphinothioyl chloride (25.3 g, 0.10 mol) in 400 ml of acetonitrile was stirred at room temperature for 24 hr, and filtered. The filtrate was evaporated and the residue was treated with petroleum ether to give colorless crystals of **7** in an almost quantitative yield. Mp 42—43 °C, IR (Nujol): 2240 cm^{-1} (–N=C=O).

Found: C, 59.97; H, 4.08; N, 5.33; S, 12.62%. Calcd for $C_{13}H_{10}NOPS$: C, 60.23; H, 3.89; N, 5.40; S, 12.37%.

*Reaction of **1** with Water.* A solution of **1** (0.5 g, 1.8 mmol) and water (1 g, 55 mmol) in 100 ml of acetone was heated in the presence of a few drops of triethylamine under reflux for 5 hr. After the solvent was removed, the residue was recrystallized from benzene to give diphenylphosphinothioic anhydride (**3**) in a quantitative yield, mp 197—198 °C (lit,[15] 197—198 °C).

*Reaction of **1** with Ethanol and Methanol.* A solution of **1** (0.75 g, 2.6 mmol) in 100 ml of ethanol was heated under reflux in the presence of a few drops of triethylamine for 2 hr. After the solvent was removed, the residue was dissolved in petroleum ether and recrystallized to give ethyl diphenylphosphinothioate (**4b**) in a quantitative yield, mp 38—39 °C (lit,[16] 42—43 °C). The IR spectrum is identical with that of an authentic sample.

In a similar reaction with methanol, **4a** was obtained in a quantitative yield, mp 83—85 °C (lit,[16] 84.5—85.5 °C).

*Reaction of **1** with Aniline.* Aniline (0.53 g, 5.7 mmol) and **1** (1.5 g, 5.6 mmol) were mixed without solvent and an exothermic reaction occurred. The mixture was then heated at 80—90 °C for a few minutes. White crystals thus obtained were recrystallized from dichloromethane or ethanol to give 3-diphenylphosphinothioyl-1-phenylthiourea (**5a**) in a nearly quantitative yield, mp 143—145 °C.

Found: C, 61.85; H, 4.62; N, 7.38; S, 16.90%. Calcd for $C_{19}H_{17}N_2PS_2$: C, 61.96; H, 4.62; N, 7.62; S, 17.39%.

*Reaction of **1** with Aqueous Dimethylamine.* 40% aqueous dimethylamine (1.0 g, 8.9 mmol) and **1** (3.0 g, 10.9 mmol) were mixed. After an exothermic reaction subsided, the solvent was removed under reduced pressure. The residue was washed with ether to give 1,1-dimethyl-3-diphenylphosphinothioylthiourea (**5c**) in an almost quantitative yield, mp 94—96 °C (lit,[4] 95.5—96 °C).

Use of two equivalents of 40% aqueous dimethylamine gave the corresponding dimethylammonium salt (**6a**).[2]

*Reaction of **1** with Morpholine.* A mixture of morpholine (1.8 g, 20.7 mmol) and **1** (2.8 g, 10.1 mmol) in 50 ml of ether was stirred at room temperature. An exothermic reaction occurred to give ammonium salt (**6b**) in a quantitative yield, mp 135—138 °C (from ethanol).

Found: C, 56.06; H, 6.03; N, 9.41; S, 14.51%. Calcd for $C_{21}H_{28}N_3O_2PS_2$: C, 56.12; H, 6.24; N, 9.35; S, 14.25%.

Equimolar mixture of morpholine and **1** also produced **6b**. No free thiourea derivative could be obtained.

*Reaction of **7** with Water.* A solution of **7** (0.50 g, 1.93 mmol) and 2 ml of water in 50 ml of acetone was heated under reflux for 2 hr. The mixture was allowed to stand overnight at room temperature to afford aminodiphenylphosphine sulfide (**8**) in an almost quantitative yield, mp 99—101 °C (lit,[17] 102—104 °C).

Reaction of **7** *with Diethylamine.* Diethylamine (0.40 g, 5.5 mmol) was added to **7** (1.1 g, 4.25 mmol) without solvent and heated at 50—60 °C for 5 min. Crystals thus produced were recrystallized from cyclohexane to give 1,1-diethyl-3-diphenylphosphinothioylurea (**9**) in a nearly quantitative yield, mp 128—130 °C. IR (Nujol): 3150 (NH) and 1625 cm^{-1} (C=O).

Found: C, 61.41; H, 6.15; N, 8.39; S, 9.51%. Calcd for $C_{17}H_{21}N_2OPS$: C, 61.44; H, 6.33; N, 8.44; S, 9.64%.

Reaction of **7** *with* p-*Toluenethiol.* A mixture of **7** (0.5 g, 1.9 mmol) and *p*-toluenethiol (0.25 g, 2.0 mmol) was heated at 50 °C for one hour without solvent. The resulting solid was recrystallized from benzene-petroleum ether to give *S-p*-tolyl *N*-(diphenylphosphinothioyl)monothiocarbamate (**10**) in a nearly quantitative yield, mp 94—96 °C (dec); IR (Nujol): 3350 sh, 3180 (NH), and 1695 cm^{-1} (C=O).

Found: C, 62.86; H, 4.69; N, 3.51; S, 16.93%. Calcd for $C_{20}H_{18}NOPS_2$: C, 62.64; H, 4.73; N, 3.65; S, 16.72%.

Reaction of **1** *with Dicyclohexylcarbodiimide.* A solution of **1** (0.55 g, 2.0 mmol) and carbodiimide (0.414 g, 2.01 mmol) in 100 ml of dry cyclohexane was heated under reflux for 30 min. After the solvent had been removed, the residue was recrystallized from petroleum ether to give the adduct (**11a**) in a quantitative yield, mp 120—122 °C. IR (Nujol): 1640 cm^{-1} (C=N); $\lambda_{max}^{c\text{-}C_6H_{12}}$: 223 (log ε 4.81) and 260 sh nm (log ε 4.23); MS: *m/e* 481 (M^+, 9%) and 217 (Ph_2PS^+, 100).

Found: C, 64.52; H, 6.41; N, 8.05; S, 13.61%. Calcd for $C_{26}H_{32}N_3PS_2$: C, 64.86; H, 6.65; N, 8.73; S, 13.31%.

When a mixture of **1** and the carbodiimide was heated at 90—95 °C for a few minutes, the adduct (**11a**) was also obtained in a quantitative yield.

Reaction of **1** *with Diisopropylcarbodiimide.* A mixture of **1** (0.577 g, 2.02 mmol) and carbodiimide (0.279 g, 2.21 mmol) was heated without solvent for 2 hr. An oily product was obtained in a nearly quantitative yield. Since the distillation resulted in decomposition, column chromatography on silica gel using petroleum ether was performed to obtain colorless oil (**11b**). IR (neat): 1630 cm^{-1} (C=N).

Found: C, 59.65; H, 5.98; N, 10.63; S, 16.12%. Calcd for $C_{20}H_{24}N_3PS_2$: C, 59.83; H, 6.02; N, 10.46; S, 15.97%.

Reaction of p-*Toluenesulfonyl Isothiocyanate (***14***) with Dicyclohexylcarbodiimide.* A mixture of **14** (1.0 g, 4.72 mmol) and carbodiimide (1.0 g, 4.86 mmol) was heated at 80 °C for 30 min. The resulting solid was recrystallized from petroleum ether to give the adduct (**11c**) in a quantitative yield, mp 144—146 °C. IR (Nujol): 1620 cm^{-1} (C=N); $\lambda_{max}^{c\text{-}C_6H_{12}}$: 229 sh (log ε 4.43), 235 sh (4.50), 248 (4.55), and 262 sh nm (4.46).

(Received March 30, 1973)

The synthesis of five 9-(2′,3′,4′,5′-tetrahydroxycyclopentyl)adenines with 1,2,4/3,5- (**2a**), 1,2,3/4,5- (**2b**), 1,4,5/2,3- (**2c**), 1,4/2,3,5- (**2e**) and all-*cis* configuration (**2d**) are described, by amination of 4-amino-5-nitro-6-chloropyrimidine with the respective 5-aminocyclopentanetetrols (**3a**—**e**), followed by reduction of the nitro group and cyclization with formamide.

Preliminary antifungal properties are reported.

Nucleoside analogs, in which the ribofuranosyl moiety is replaced by the hydrolytically and enzymatically more stable cyclopentane ring, have attained much interest in the past decade[1,3–8], its main stimulus stemming from their possible function as antimetabolites or nucleoside substitutes in nucleic acid metabolism. This allurement was enhanced by the isolation of aristeromycin (**1**), with promising antibacterial and antifungal properties, from natural sources,[5] which, nevertheless, was preceded by a chemical synthesis of the DL-form of **1**.[4]

Since it has been demonstrated in the case of a carbocyclic puromycin analog, that the lack of the ring-*O*-function and the hydroxymethyl group in the ribofuranosyl moiety are not detrimental for bioactivity,[8] it appeared of interest to biologically evaluate adenosine analogs of type **2**, in which the ribofuranose portion is replaced by a tetrahydroxycyclopentane system.

The present report describes the synthesis of five of these 9-(2′,3′,4′,5′-tetrahydroxycyclopentyl)adenines (**2a**—**e**), *i. e.* products that—with respect to the C-2′ and C-3′ arrangement of the OH-groups in adenosine—resemble the *ribo*-configuration (**2a** and **2b**), as well as the *xylo*-(**2a**, **2e**), *lyxo*- (**2d**) and *arabino*-forms (**2b**, **2c**), the latter being conceivably of main interest in view of the antiviral activity of 9-(β-D-arabinofura-

nosyl)adenine.[9]

Since methods are available for the stepwise *de novo* construction of the purine base from a cycloalkylamino function,[1,6-8] the principal problem was the preparation of the respective 5-aminocyclopentanetetrols. All ten theoretically possible isomers being known now in the form of their pentaacetyl derivatives,[10] the more readily accessible compounds **3a**—**e**[10-12] were subjected to complete deacetylation with hydrochloric acid to afford the respective aminotetrols **4a**—

triaminopyrimidines **6a**—**e** in yields above 70%. Without further purification, they were cyclized by refluxing in formamide to give the title compounds, adenine analogs **2a**—**e** (Table 3), featuring the UV absorption characteristics at pH 1, 7 and 13, required for 9-substituted adenine derivatives.[13]

The antiviral properties of compounds **2a**—**e** are being evaluated. With respect to antifungal activity, **2e** showed an inhibition value of 34% against *piricularia oryzae* (strain Kita No. 373), whilst the pentahydroxycyclohexyl-adenines of *scyllo* and *myo*-2 configuration[1] exhibited values of 30 and 41% respectively, in this systems.

Experimental[14]

Melting points were determined in capillary tubes and uncorrected. UV spectral measurements were effected with a Hitachi EPS-2 instrument. Since preparative procedures employed varied only slightly within the different stereoisomers (a—e series, respectively), general procedures are given exclusively.

*5-Amino-1,2,3,4-cyclopentanetetrols (**4a**—**e**) by Deacetylation of Their Pentaacetates.* The respective tetra-*O*-acetyl-5-acetamido-1,2,3,4-cyclopentanetetrol (**3a**,[10] **3b**,[10] **3c**,[11] **3d**[11] and **3e**,[12] 1.0—1.3 g portions) was refluxed in 6 M hydrochloric acid (10 ml) for 1.5—2.0 h and subsequently evaporated *in vacuo*. The residue was taken up in water and triturated with Amberlite IRA-400 for removal of chloride ions. Charcoal treatment and evaporation to dryness yielded a crystalline residue in the case of **4a**, **4c** and **4e**, which was filtered with ethanol to give the crude products, that were directly used for the ensuing reaction. For analytical samples, small amounts were recrystallized from ethanol giving the data in Table 1. The aminotetrols **4b** and **4d** resisted crystallization from the usual solvents. Their sirups were used for further reactions.

*4-Amino-5-nitro-6-(2′,3′,4′,5′-tetrahydroxycyclopentyl)aminopyrimidines (**5a**—**e**).* The crude aminotetrols (**4a**—**e**), as obtained above (500 mg portions), and 4-amino-5-nitro-6-chloropyrimidine[15] (590 mg, 1.05 mol) were refluxed for 8 h in 2-menthoxyethanol (50 ml) containing 3 ml of triethylamine. On allowing the reaction mixture to cool to ambient temperature, crystallization occurred in the case of **5a**, **5d** and **5e**. The crystals were filtered off to give the crude products used for further experiments. In the cases (**5b** and **5c**), the reaction mixture was evaporated *in vacuo*, followed by crystallization of the residue with a small amount of water (**5b**) or by extraction with ethyl acetate (**5c**), to give the crude products. Small samples of each were recrystallized from water to give the data in Table 2.

*4,5-Diamino-6-(2′,3′,4′,5′-tetrahydroxycyclopentyl)aminopyrimidines (**6a**—**e**).* The respective nitropyrimidines **5a**—**e**, as obtained above (600—700 mg portions), were added to a boiling suspension of 15 g of zinc powder in 150 ml of water with vigorous stirring, and the heating was continued for 8 h. The reaction mixture was filtered whilst still hot. On cooling to ambient temperature, crystallization occurred in all cases except **6b**, which required prior concentration to a small volume. Filtration and drying *in vacuo* gave the crude products, used for the subsequent cyclization, as pale yellow crystals except for **6d**, obtained as an amorphous solid; **6a** (mp 255—258 °C, dec; 85%), **6b** (mp 181—187 °C, dec; 72%), **6c** (mp 151—155 °C; 89%), **6d** (mp 200—210 °C, dec; 98%) and **6e** (mp 260—265 °C, dec; 74%).

*9-(2′,3′,4′,5′-Tetrahydroxycyclopentyl)adenines (**2a**—**e**).* The respective triaminopyrimidines **6a**—**e** (400—500 mg portions) were refluxed in formamide (10—20 ml) for 30—60 min, whereafter the mixture was taken to dryness *in vacuo*. The residue was triturated with water or ethanol to give the crude product, which was recrystallized from water, involving charcoal treatment, to give the analytically pure products of Table 3.

The authors wish to express their appreciation to the Japan Ministry of Education for supporting this investigation and to the Japan Society for the Promotion of Science for granting a Visiting Professorship (to F. W. L.). They are also indebted to Mr. Yukio Sakota for assistance in some experiments.

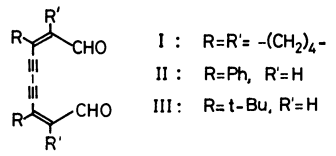
(Received May 1, 1973)

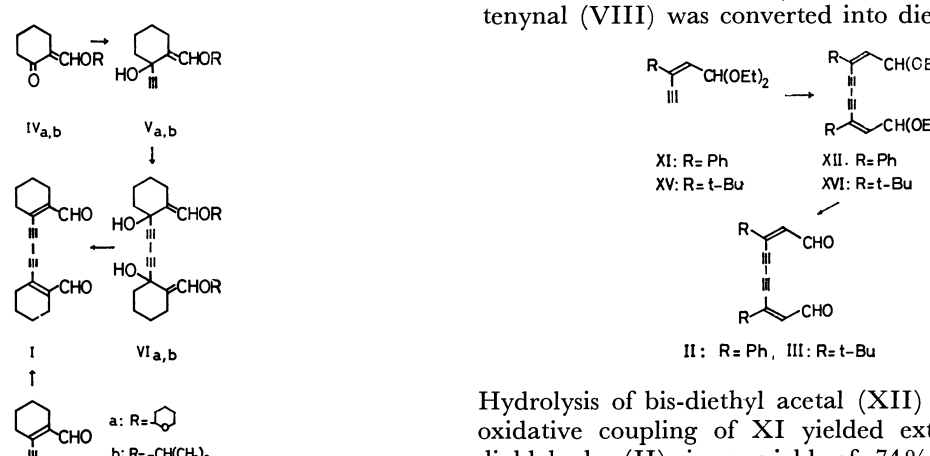
Substituted 2,8-decadien-4,6-diyndials (I, II and III) were synthesized by the oxidative coupling of corresponding substituted pentenynals (VII and XIII) or acetal (XI). It was found that decadiendiyndials (I, II and III) give readily dihydrofuranylidene derivatives (X, XIV and XXV) by the addition of methanol followed by intramolecular cyclization. Thermal reaction of dialdehyde (I, II, and III) afforded difuranylacetylene derivatives (IX, XXI and XXII). 5-Phenyl-2,4-heptadien-6-ynal (XXXII) was prepared from 3-phenyl-2-penten-4-ynal (VIII) or its acetal (XI) by a modified Wittig reaction or by the condensation of ethyl vinyl ether. Oxidative Coupling of XXXII or 5-*t*-butyl-2,4-heptadien-6-ynal afforded 5,10-diphenyl- (XXIX) or 5,10-di-*t*-butyl-2,4,10,12-tetradecatetraen-6,8-diyndial (XXX) which showed no tendency for intramolecular cyclization.

During the course of studies on the syntheses of dehydroannulenes, we have investigated the syntheses of substituted decadiendiyndials (I, II and III) and tetradecatetraendiyndials (XXIX and XXX) which seemed to be potential precursors of dehydroannulenes.

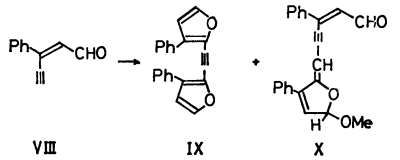


It was found that the dialdehydes (I, II and III) give readily difuranylacetylene derivatives (IX, XXI and XXII) by thermal reaction and dihydrofuranylidene derivatives (X, XIV and XXV) by nucleophilic addition of methanol followed by intramolecular cyclization.

Synthesis. Bis-tetramethylene derivative (I) could be obtained by the reaction sequence outlined in Scheme 1. Acetylenic alcohol (V) obtained by ethynylation of 2-alkoxymethylenecyclohexanone (IV)[1] was treated with cupric acetate in pyridine[2] (the Eglinton's method) to yield hexadiyndiol (VI). Hydrolysis of VI afforded dialdehyde (I). I was also prepared by the Eglinton's oxidative coupling of 1-ethynyl-2-formylcyclohexene[1] (VII) in the presence or absence of methanol. However, the oxidative coupling of 3-phenyl-2-penten-4-ynal (VIII)[3] in the presence of



Scheme 1.



methanol resulted in the formation of bis(3-phenyl-2-furanyl)acetylene (IX, 13%) and dihydrofuranylidene derivative (X, 41%). In the absence of methanol, IX was obtained in a yield of 30.5%. Phenylpentenynal (VIII) was converted into diethyl acetal (XI).

Hydrolysis of bis-diethyl acetal (XII) obtained by the oxidative coupling of XI yielded extremely unstable dialdehyde (II) in a yield of 74%. Formation of appreciable amount of IX was observed when II was allowed to stand for 2 days at room temperature. The Eglinton's reaction of *t*-butylpentenynal (XIII)[4] in the absence of methanol at a low temperature (15—20 °C) afforded dialdehyde (III). However, the re-

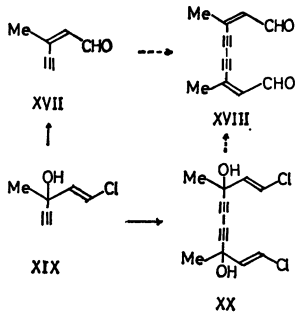
XIII XIV

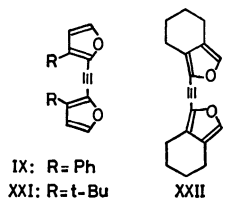
action performed in the presence of methanol gave a mixture of III and dihydrofuranylidene derivative (XIV). NMR spectroscopy revealed that the mixture consists of 50% of III and 10—15% of XIV. III could be obtained by the hydrolysis of bis-diethyl acetal (XVI) which was prepared by the oxidative coupling of diethyl acetal (XV).[5]

Dialdehyde (XVIII) could not be obtained by the Eglinton's reaction of methylpentenynal (XVII)[6] in the presence of methanol, but the UV spectrum of the product (λ_{max}^{EtOH} 247, 285, 357 nm) was found to be similar with that of X. Attempts to prepare XVIII from diacetylenic glycol (XX) obtained by the Glaser reaction of XIX[6] gave fruitless results owing to sluggish anionotropic rearrangement.



XVII XVIII XIX XX

Thermal Cyclization of Dialdehydes (I, II and III). Formation of bis(2-furanyl)acetylene derivatives (IX, XXI and XXII) was observed on heating solutions of dialdehydes (II, III and I) in organic solvents. The results are summarized in Table 1. This results indicate that the formation of IX in the oxidative coupling of phenylpentenynal (VIII) is attributable to a secondary reaction of initially formed dialdehyde (II). The possibility of catalytic action of cupric acetate in pyridine for the cyclization reaction could be excluded by the experiments performed in benzene or ether containing cupric acetate and pyridine (see Experimental). Intramolecular cyclization of acetylenic compounds containing oxygen function has been well-known.[7] However, the formation of difuranylacetylene derivatives (IX, XXI and XXII) from II, III and I seems to be symmetry-allowed thermal process.



IX: R=Ph
XXI: R=t-Bu XXII

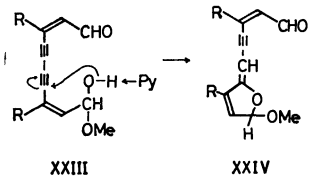
TABLE 1. FORMATION OF DIFURANYLACETYLENES

Dialdehyde	Solvent	Temperature (°C)	Reaction period (hr)	Yield (%)
I	xylene	120	5	XXII 57
II	benzene	50	8	IX 86
III	benzene	60	20	XXI 82
III	pyridine	60	6.5	XXI 54[a]

a) Low yield of XXI can be attributed to gradual decomposition of III in pyridine.

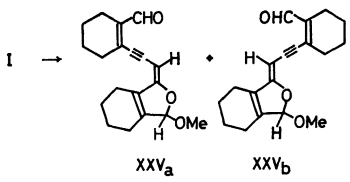
It is to be noted that the mass spectral patterns of II and III were found to be similar to those of IX and XXI indicating facile formation of difuranyl derivatives from II and III prior to the fragmentation.

Formation of Dihydrofuranylidene Derivatives (X, XIV and XXV). The formation of dihydrofuranylidene derivatives (X or XIV) by the Eglinton's oxidative coupling of pentenynals (VIII or XIII) in the presence of methanol can be regarded as a result of secondary reaction of initially formed dialdehydes (II or III), *i. e.*, addition of methanol to carbonyl carbon of dialdehyde forms hemiacetal (XXIII), and nucleophilic attack of oxygen atom of hemiacetal (XXIII) to acetylenic carbon atom gives rise to dihydrofuranylidene compound (XXIV). Because the cyclization reaction did not proceed without pyridine, it is evident that pyridine has a role of proton acceptor.



XXIII XXIV

In the case of dialdehyde (I), no cyclization took place by pyridine–methanol. However, treatment of I in ether with sodium methoxide–methanol at 0 °C afforded dihydrofuranylidene derivative (XXV). Dihydrofuranylidene derivative (XXV) could be separated into *cis*-(XXVa) and *trans*-isomers (XXVb) on chromatography on silica gel.



XXV$_a$ XXV$_b$

It is to be noted that acetylenic compounds with analogous dihydrofuranylidene system (XXVIa, XXVIb and XXVII) have been found in naturally occurring poly-ynes.[8] An intramolecular cyclization of ketoalcohol (XXVIII) in biogenetic path way to form XXVII has been postulated by Bohlmann and Florenz.[9]

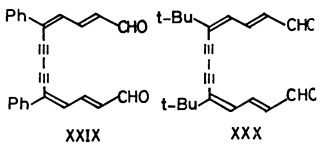
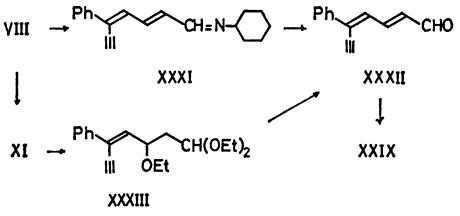
Syntheses of Tetradecatetraendiyndials (XXIX and XXX). Facile intramolecular cyclization observed in decadiendiyndials (I, II and III) can be attributed to the proximate position of oxygen atom of formyl group to acetylenic carbon atom favorable for the formation of stable five-membered ring which is caused by the *cis*-configuration of ethylenic linkage with respect to acetylene and formyl functions. We have prepared diphenyl- (XXIX) and di-*t*-butyltetradecatetraendiyndials (XXX). Expectedly intramolecular cyclization could not be observed in these dialdehydes (XXIX and XXX).



Phenylheptadienynal (XXXII) was prepared by different two routes. Phenylpentenynal (VIII)[3] was treated with diethyl 2-(cyclohexylimino)ethylphosphonate carbanion[10] and the product (XXXI) was hydrolyzed to yield XXXII in a yield of 51%. Condensation of ethyl vinyl ether in the presence of boron trifluoride[11] with acetal (XI) derived from VIII afforded ethoxy acetal (XXXIII) which gave XXXII



on treatment with hydrochloric acid in tetrahydrofuran. Oxidative coupling of XXXII by the Eglinton's method yielded XXIX in a high yield. Di-*t*-butyltetradecatetraendiyndial (XXX) was obtained similarly from 5-*t*-butyl-2,4-heptadien-6-ynal.[6] Quite recently the preparation of 4,5 : 10,11-bis(tetramethylene)-2,4,10,12-tetradecatetraen-6,8-diyndial, a vinylog of I, was reported by Yamamoto and Sondheimer.[12]

Experimental

All the melting points are not corrected. The UV and IR spectra were obtained on a Hitachi EPS-3T and a Hitachi EPI-2 spectrophotometers, respectively. Shoulder was indicated by an asterisk. The NMR and mass spectra were obtained on a Varian A-60 (internal standard, TMS) and a Hitachi RM-50 (ionization energy, 70 eV) spectrometers, respectively. Chemical shifts are recorded in τ-unit. Silica gel (Merck, Kieselgel 60) and alumina (Merck, act. II–III) were used in the chromatography.

2-Tetrahydropyranoxymethylenecyclohexanone (IVa). 2-Hydroxymethylenecyclohexanone (105.6 g, 0.84 mol) was added over 40-min period to freshly distilled pure 2,3-dihydropyran (84 g, 1.0 mol) containing few drops of phosphoryl chloride under stirring and cooling with running water. After being kept overnight at room temperature, the mixture was stirred for 3 hr at 30 °C and then mixed with ether (150 ml), washed successively with saturated sodium carbonate and sodium chloride solutions. IVa was obtained as a colorless liquid, bp 117—130 °C/6×10^{-4} mmHg, 43.5 g (24.7%), IR (neat): 1670, 1660*, 1590, 1195, 1110, 1075, 1035 cm^{-1}.

Found: C, 67.69; H, 8.58%. Calcd for $C_{12}H_{18}O_3$: C, 68.53; H, 8.63%.

1-Ethynyl-2-tetrahydropyranoxymethylenecyclohexanol (Va). To a suspension of lithium acetylide [from acetylene and lithiumamide (lithium 1.89 g, 0.275 g-atom)] in liquid ammonia (300 ml) was added over a period of 30 min a solution of IVa (52.5 g, 0.25 mol) in ether (100 ml). After the mixture had been stirred for 3.5 hr, the ammonia was allowed to evaporate. The residue was mixed with a saturated solution of ammonium chloride and extracted with ether. The extract was worked up by the usual way. Va was obtained as a viscous liquid, bp 142—144 °C/10^{-3} mmHg, 43.15 g (73.0%).

Found: C, 70.72; H, 8.57%. Calcd for $C_{14}H_{20}O_3$: C, 71.16; H, 8.53%.

1-Ethynyl-2-isopropoxymethylenecyclohexanol (Vb). The reaction of 2-isopropoxymethylenecyclohexanone (IVb)[1] with lithium acetylide in liquid ammonia by the procedure used in Va afforded Vb in a yield of 60% as a colorless liquid, bp 76.1—77.0 °C/4×10^{-3} mmHg, n_D^{20} 1.4936.

Found: C, 73.50; H, 9.25%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

2-Ethynyl-1-cyclohexenecarboxaldehyde (VII). To a stirred solution of Va (20 g) in tetrahydrofuran (250 ml) was added 10% aqueous sulfuric acid (35 ml). After being kept at room temperature overnight, the reaction mixture was washed successively with saturated sodium chloride, 10% sodium carbonate and saturated sodium chloride solutions, and dried. Evaporation of the solvent under reduced pressure afforded faint brown crystals, 7.3 g (64%). Vacuum sublimation of the crystals yielded pure VII, mp 50—51 °C [lit. 52—53 °C[13]; 49.5—50 °C[1e]].

Found: C, 80.17; H, 7.51%. Calcd for $C_9H_{10}O$: C, 80.56; H, 7.51%.

Bis(2-formyl-1-cyclohexenyl)-1,3-butadiyne (I). *1) From Va*: A solution of Va (43.0 g, 0.182 mol) in pyridine (150 ml) was added to a mixture of cupric acetate monohydrate (120 g) and pyridine (900 ml). After being stirred overnight at room temperature, the mixture was stirred at 40 °C for 7 hr. Insoluble material was removed by filtration and washed thoroughly with ether. The combined filtrate and washings were concentrated under reduced pressure (bath temp. below 80 °C). The residue was dissolved in ether. After being washed 4 times with saturated sodium chloride solution and dried, the solvent was removed under reduced pressure to give crude VIa. Crude VIa was dis-

solved in a mixture of sulfuric acid (10 ml), water (90 ml) and tetrahydrofuran (900 ml) and the mixture was allowed to stand at room temperature for 22 hr. After being stirred for 1.5 hr at 50 °C, the reaction mixture was worked up by the usual way. The oily residue (29.5 g) obtained by evaporating the solvent *in vacuo* was chilled in a dry ice-acetone bath to result in crystallization. The crystals were filtered and recrystallized from benzine to give pure I, pale yellow crystals, 5.4 g, mp 89.0—90.5 °C; UV: $\lambda_{max}^{95\%EtOH}$ (ε) 205.5 (22150), 231* (10050), 238.5 (13470), 258* (12300), 270 (14550), 290 (15900), 317 (15800), 334(16800), 358(12400) nm, IR (KBr-disk): 1670 (C=O), 1580 (C=C) cm^{-1}, NMR ($CDCl_3$): −0.12 (s, 2H, CHO), 7.62 (m, 8H, allylic CH_2), 8.32 (m, 8H, non-allylic CH_2), Mass (*m/e*): 266 (M^+), 239 (M–29).

Found: C, 80.91; H, 6.95%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

The mother liquors were chromatographed on alumina to yield second crop of I.

2) From VII. a) Oxidative Coupling in the Presence of Methanol: A solution of VII (200 mg, 1.49 mmol) in pyridine (2 ml) was added to a mixture of cupric acetate monohydrate (1.00 g, 5.01 mmol), pyridine (5 ml) and methanol (3 ml). After being stirred for 2 hr at 16 °C, the reaction mixture was poured onto 3 M hydrochloric acid (50 ml) and extracted with ether (20 ml×3). The extract, after being washed and dried, was evaporated under reduced pressure. The crystals thus obtained was chromatographed on alumina. Elution with *n*-hexane–benzene (1 : 1) and benzene afforded pure I, 171 mg (86%).

b) Oxidative Coupling in the Absence of Methanol: To a mixture of cupric acetate monohydrate (1.00 g, 5.01 mmol) and pyridine (7 ml) was added a solution of VII (200 mg, 1.49 mmol) in ether (3 ml). After being stirred for 6 hr at 16 °C, the reaction mixture was worked up to give I, 183 mg (92%).

3-Phenyl-2-penten-4-ynal Diethyl Acetal (XI). A solution of *p*-toluenesulfonic acid monohydrate (0.385 g, 2.02 mmol) in ethanol (2 ml) was added to a mixture of VIII[3] (3.852 g, 24.7 mmol) and ethyl orthoformate (13.25 g, 89.4 mmol). After being stirred for 24 hr at room temperature, the reaction mixture was chilled in an ice-bath and then poured onto ice-water containing sodium hydrogen carbonate, and extracted with ether. The extract, after being washed and dried (potassium carbonate), was concentrated under reduced pressure. The residue was distilled *in vacuo* to yield XI, 4.948 g (87%), bp 93—96 °C/0.005 mmHg, Mass (*m/e*): 230 (M^+), IR (CCl_4): 3321 (C≡CH), 2090 (–C≡C–), 1615 (C=C), 1000—1150 (C–O–C) cm^{-1}. NMR (CCl_4): 2.31—2.82 (m, 5H, phenyl), 3.62 (d, J=7.5 Hz, 1H, olefinic), 4.60 (d, J=7.5 Hz, 1H, acetal), 6.38 (q, J=7.0 Hz, 2H, CH_2), 6.42 (q, J=7.0 Hz, 2H, CH_2), 6.70 (s, 1H, C≡CH), 8.82 (t, J=7.0 Hz, 6H, CH_3).

Elemental analysis gave unsatisfactory result owing to extremely unstable nature of XI to hydrolysis.

3,8-Diphenyl-2,8-decadien-4,6-diyndial (II). To a solution of XI (327 mg, 1.42 mmol) in ether (3 ml) was added a mixture of cupric acetate monohydrate (566 mg, 2.83 mmol), pyridine (6 ml) and ether (2 ml). The mixture was stirred at 15 °C for 17 hr and then poured onto 3 M hydrochloric acid (49 ml), and extracted with ether (20 ml×4). The extract was washed successively with water, saturated solutions of sodium hydrogen carbonate and sodium chloride, and evaporated under reduced pressure. The residue (XII) containing water was mixed with 20% aqueous acetic acid (5 ml) and the mixture was stirred for 15 min at room temperature. The reaction mixture containing light brown crystals was mixed with water (40 ml) and extracted with dichloromethane (30 ml×4). The extract, after being washed and dried, was concentrated under reduced pressure to yield crystals. Chromatography of the crystals on silica gel followed by elution with carbon tetrachloride containing 10—20% dichloromethane afforded pure II, yellow crystals, 163 mg (74%), mp 119.4—120.3 °C, Mass (*m/e*): 310 (M^+), IR (KBr-disk): 2850, 2740 (CHO), 2135 (–C≡C–), 1668 C=O), 1581, 1560 (C=C) cm^{-1}, NMR ($CDCl_3$): −0.27 (d, J=8.0 Hz, 2H, CHO), 2.01—2.68 (m, 10H, phenyl), 3.07 (d, J=8.0 Hz, 2H, olefinic).

Found: C, 84.86; H, 4.57%. Calcd for $C_{22}H_{14}O_2$: C, 85.14; H, 4.55%.

Bis(3-phenyl-2-furanyl)acetylene (IX). A solution of II (93 mg, 0.30 mol) in benzene (4 ml) was kept at 50 °C for 8 hr. The reaction mixture was concentrated unduer reduced pressure and chromatographed on alumina. Elution with carbon tetrachloride–20% dichloromethane afforded IX, colorless crystals, 81 mg (86%), mp 131.5—131.8 °C (from benzene–*n*-hexane), Mass (*m/e*): 310 (M^+), IR (KBr-disk): 3140, 3215 (furan CH), 892 (furan) cm^{-1}, NMR ($CDCl_3$): 2.50 cd, J=2.0 Hz, 2H, α–H of furan), 2.10—2.87 (m, 10H, phenyl), 3.76 (d, J=2.0 Hz, 2H, β–H of furan), UV: λ_{max}^{EtOH} (ε) 231.5, (32900), 258.5* (14800), 342.5 (17500) nm.

Found: 84.84; H, 4.52%. Calcd for $C_{22}H_{14}O_2$: C, 85.14; H, 4.55%.

6-(5-Methoxy-3-phenyl-2-dihydrofuranylidene)-3-phenyl-2-penten-4-ynal (X). a) In the Presence of Pyridine and Methanol: A solution of II (83 mg, 0.26 mmol) in pyridine (5 ml) and methanol (8 ml) was stirred for 2 hr at 30 °C, and then the mixture was poured onto 3 M hydrochloric acid (40 ml). The mixture was extracted with dichloromethane (30 ml×4). The extract, after being washed and dried, was concentrated under reduced pressure. Brownish oily residue was chromatographed on silica gel and eluted with benzene to yield X as pale brown oil, 78 mg (85%), Mass (*m/e*): 342 (M^+), IR (neat): 2180 (–C≡C–), 1662 (C=O), 1620 (C=C) cm^{-1}. The NMR spectrum of X showed complexes pattern owing to the presence of *cis*- and *trans*-isomers.

A solution of 2,4-dinitrophenylhydrazine (97 mg, 0.49 mmol) and phosphoric acid (1.2 ml) in ethanol (0.8 ml) was added to a solution of X (47 mg, 0.13 mmol) in ethanol (8 ml) and the mixture was stirred for 15 hr at room temperature. Red crystals deposited were washed thoroughly with benzene. Red crystals obtained by evaporating the washings under reduced pressure were chromatographed on silica gel. Elution with benzene afforded pure 2,4-dinitrophenylhydrazone of X red crystals, mp 208.4—209.8 °C, 58 mg (81%).

Found: C, 66.61; H, 4.22; N, 10.51%. Calcd for $C_{22}H_{22}N_4O_6$: C, 66.66; H, 4.24; N, 10.27%.

b) In the Absence of Pyridine: A solution of II (108 mg, 0.34 mmol) in methanol (10 ml) and ether (5 ml) was stirred for 28 hr at 30 °C. Brown oily residue obtained by evaporating the solvent was chromatographed on silica gel, and eluted with benzene. IX (39 mg, 36%) was obtained from early fractions and the following fractions afforded II (28 mg, 26%) and then X (35 mg, 29%).

Oxidative Coupling of Phenylpentenynal (VIII). a) In the Presence of Methanol. A solution of VIII[3] (1.00 g, 6.4 mmol) in pyridine (10 ml) and methanol (10 ml) was added to a mixture of cupric acetate monohydrate (5.00 mg, 0.025 mol), pyridine (30 ml) and methanol (10 ml). After being stirred for 30 min at room temperature, the mixture was poured onto 3 M hydrochloric acid (200 ml) and extracted with benzene. The extract was washed successively with water, saturated sodium hydrogen carbonate and sodium

chloride solutions and dried. Chromatography of the residue obtained by evaporating the extract afforded IX, 127 mg (13%) and X, 449 mg (41%).

b) In the Absence of Methanol. To an ice-cooled so-solution of cupric acetate monohydrate (2.00 g, 0.010 mol) in pyridine (20 ml) was added a solution of VIII (1.00 g, 0.0064 mol) in ether (15 ml). After the mixture had been stirred for 12 hr at 15—20 °C, ice-cooled 3 M hydrochloric acid (100 ml) was added and the mixture was extracted with dichloromethane (30 ml×3). The extract, after being washed and dried, was concentrated under reduced pressure. The residue was chromatographed on alumina. The fractions eluted with carbon tetrachloride containing 10—20% of dichloromethane afforded IX (303 mg, 30.5%).

3,8-Di-t-butyl-2,8-decadien-4,6-diyndial (III). a) From XIII: A solution of XIII (945 mg, 6.94 mmol) in ether (12 ml) was added to a mixture of cupric acetate monohydrate (2.10 g, 10.5 mmol) and pyridine (20 ml) and the mixture was stirred for 24 hr at 15—20 °C. The reaction mixture was poured onto 3 M hydrochloric acid (110 ml) and extracted with ether (40 ml×3). The extract was worked up by the usual way. Crude crystals obtained were chromatographed on alumina. Elution with benzene yielded pure III, mp 83.3—84.5 °C (from benzene-*n*-hexane), pale yellow needles, 765 mg (80%), Mass (*m/e*): 270 (M^+), IR (KBr-disk): 2115 (–C≡C–), 1681 (C=O), 1574 (C=C) cm^{-1}; NMR ($CDCl_3$): −0.09 (d, J=7.5 Hz, 2H, CHO), 3.61 (d, J=7.5 Hz, 2H, olefinic), 8.74 (s, 18H, *t*-Bu), UV: λ_{max}^{EtOH} (ε) 224.5* (13200), 232.0 (14400), 253.5 (13200), 264.5 (14300), 280.0 (14100), 303.5* (10500), 322.0 (12200), 343.5 (8300) nm.

Found: C, 80.14; H, 8.20%. Calcd for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%.

b) From XV: To a stirred mixture of cupric acetate monohydrate (50 g) and pyridine (300 ml) was added a solution of XV[5] (9.50 g, 0.045 mol) in pyridine (50 ml) at 50 °C and the mixture was stirred for 2 hr at the same temperature. The cooled reaction mixture was poured onto a mixture of cracked ice and dilute hydrochloric acid, and extracted with ether. The extract, after being washed and dried, was concentrated under reduced pressure to give crude XVI [NMR (CCl_4): 3.19 (d, J=7.0 Hz, 2H, olefinic), 4.86 (d, J=7.0 Hz, 2H, acetal), 6.44 (q, J=7.0 Hz, 4H, CH_2), 6.49 (q, J=7.0 Hz, 4H, CH_2), 8.82 (t, J=7.0 Hz, 12H, CH_3), 8.82 (s, 18H, *t*-Bu)]. Crude XVI was mixed with acetic acid (250 ml) and water (80 ml). After being stirred for 30 min, the mixture was worked up by the usual way and chromatographed on alumina to yield pure III, 6.6 g (55% based on XV).

Oxidative Coupling of XIII in the Presence of Methanol. A mixture of XIII (500 mg, 3.64 mmol), cupric acetate monohydrate (1.706 g, 8.54 mmol), pyridine (15 ml) and methanol (11 ml) was stirred for 22 hr at room temperature. The reaction mixture was worked up by the usual way to give brownish crystals. The crystals were chromatographed on alumina and eluted with benzene. A mixture of III and 6-(5-methoxy-3-*t*-butyl-2-dihydrofuranylidene)-3-*t*-2-penten-4-ynal (XIV was obtained by evaporating the benzene eluate. The approximate composition of the mixture could be estimated to be III, 250 mg (50%) and XIV, 70—75 mg (10—15%) by an NMR spectroscopy.

Oxidative Coupling of 1-Chloro-3-methyl-1-penten-4-yn-3-ol (XIX). A mixture of XIX[6] (2.7 g, 0.0207 mol), methanol (20 ml), cuprous chloride (0.3 g), ammonium chloride (1.7 g) and one drop of concentrated hydrochloric acid was stirred vigorously for 3.5 hr under a slightly elevated pressure of oxygen. Insoluble material was removed by filtration and washed with methanol. The combined filtrate and washings were concentrated under reduced pressure and the residue was extracted with ether. The extract was washed with 5% hydrochloric acid and water, successively, and dried. The residue obtained by evaporating the solvent was chromaotgraphed on alumina. Elution with benzene afforded 1,10-dichloro-3,8-dimethyl-1,9-decadien-4,6-diyn-3,8-diol (XX), colorless crystals, mp 65—70 °C, IR (Nujol mull): 3350, 3090, 3000, 2950, 2880, 2160, 1630, 1485, 1450, 1375, 930, 825 cm^{-1}, NMR (CCl_4): 3.47 (d, J=13.4 Hz, 2H, H^1), 4.00 (d, J=13.4 Hz, 2H, H^2), 6.60 (s, 2H, OH), 8.40 (s, 6H, CH_3).

Found: C, 55.03; H, 4.58; Cl, 27.15%. Calcd for $C_{12}H_{12}O_2Cl_2$: C, 55.62; H, 4.67; Cl, 27.39%.

Treatment of XIX with cupric acetate-pyridine resulted in recovery of the starting material.

Bis(3-t-butyl-2-furanyl)acetylene (XXI). a) Thermal Cyclization in the Absence of Pyridine. A solution of III (82 mg, 0.3 mmol) in benzene (4 ml) was stirred for 20 hr at 60 °C. Concentration of the reaction mixture under reduced pressure afforded yellow crystals (81 mg) which were chromatographed on alumina and eluted with *n*-hexane containing 20—30% of benzene. Evaporation of the eluate yielded XXI, pale yellow crystals, 68 mg (82%), mp 42.0—42.6 °C (from ether-*n*-hexane), Mass (*m/e*): 270 (M^+), IR (KBr-disk): 3130 (furan C–H), 1585 (C=C), 890 (furan) cm^{-1}, NMR ($CDCl_3$): 2.69 (d, J=2.0 Hz, 2H, α–H of furan), 3.62 (d, J=2.0 Hz, 2H, β–H of furan), 8.64 (s, 18H, *t*-Bu), UV: λ_{max}^{EtOH} (ε) 253.0 (16200), 296.0* (19700), 300.5 (20100), 318.5* (12600) nm.

Found: C, 80.20; H, 8.27%. Calcd for $C_{18}H_{22}O_2$: C, 79.96; H, 8.20%.

Bis(3,4-tetramethylene-2-furanyl)acetylene (XXII). a) Cyclization at 120 °C. A solution of I (112 mg) in *p*-xylene (5 ml) was kept at 120 °C for 5 hr. Crystals obtained by removing the solvent under reduced pressure was chromatographed on alumina (5 g). Elution with *n*-hexane–benzene (1 : 1) afforded XXII, colorless crystals, mp 146—147 °C (from benzine), 64 mg (57%), Mass (*m/e*): 266 (M^+, base peak), IR (KBr-disk): 2170 (–C≡C–), 1547 (C=C), 1505 (C=C) cm^{-1}, NMR ($CDCl_3$): 2.87 (s, 2H, α–H of furan), 7.43 (m, 8H, allylic CH_2), 8.29 (m, 8H, non-allylic CH_2).

Found: C, 81.02; H, 6.88%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%.

b) Cyclization at 60 °C. A solution of I (104.5 mg) in benzene (5 ml) was heated to 60 °C for 2 hr. Chromatography on alumina (3 g) of the reaction mixture yielded XXII, 1.9 mg (1.8%) and recovered I, 76.9 mg (73.6%).

Cyclization of III in the Presence of Cupric Acetate and Pyridine. To a mixture of cupric acetate monohydrate (184 mg, 0.92 mmol) and pyridine (4 ml) maintained at 60±2 °C was added a solution of III (198 mg, 0.73 mmol) in benzene (10 ml). The mixture was stirred in nitrogen atmosphere at the same temperature for 5 hr, then poured onto 3 M hydrochloric acid (30 ml) and extracted with ether (30 ml×3). The extract was washed and dried. A mixture of light brown crystals and liquid obtained by evaporating the extract was chromatographed on alumina and eluted with *n*-hexane containing 20% of benzene to yield XXI, 91 mg (46%). The results of reactions performed under different conditions are summarized in Table 2.

cis- and trans-1-(2-Formylcyclohexenyl)-3-(3,4-tetramethylene-5-methoxy-2-dihydrofuranylidene)-1-propyne (XXVa and XXVb). To an ice-cooled solution of I (186 mg, 0.698 mmol) in ether (10 ml) was added 1 M solution of sodium methoxide in methanol (2 ml). After being stirred for 30 min at the same temperature, the mixture was mixed with 3 M hydro-

TABLE 2. FORMATION OF XXI IN THE PRESENCE OF CUPRIC ACETATE

Temp. °C	II (mg)	$Cu(OAc)_2 \cdot H_2O$ (mg)	Solvent (ml)	Reaction time (hr)	XXI (mg) (%)
40	221	250	pyridine 4 + benzene 10	24	92 (41)
50	193	409	pyridine 4 + ether 3	24	109 (56)

chloric acid (1 ml) and extracted with ether (20 ml). The extract, after being washed and dried, was concentrated under reduced pressure. Brownish yellow oily residue was chromatographed on silica gel to yield a mixture of XXVa and XXVb (187 mg, 90%). The mixture was re-chromatographed on silica gel. Elution with benzene resulted in the separation of isomers. XXVa was obtained from early fractions, yellow crystals, mp 115.6—116.2 °C (from benzene-methanol), Mass (*m/e*): 298 (M^+), 267 (M–31), 266 (M–32), IR (KBr-disk): 2160 (–C C–), 1670 (C=O), 1626 (C=C), 1580 (C=C) cm^{-1}, NMR ($CDCl_3$): −0.10 (s, 1H, CHO), 4.26 (s, 1H, hemiacetal), 4.80 (s, 1H, olefinic), 6.58 (s, 3H, OCH_3), 7.25—8.00 (m, 8H, allylic CH_2), 8.29 (m, 8H, non-allylic CH_2), UV: λ_{max}^{EtOH} (ε) 249* (10900), 256 (11200), 286.5 (8750), 360 (20500) nm.

Found: C, 76.33; H, 7.44%. Calcd for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43%.

Evaporation of the following benzene eluates afforded XXVb, yellow crystals, mp 91.5—93.0 °C (from methanol), Mass (*m/e*): 298 (M^+), IR (KBr-disk): 2175 (–C≡C–), 1663 (C=O), 1626 (C=C), 1578 (C=C) cm^{-1}, NMR ($CDCl_3$): −0.27 (s, 1H, CHO), 4.18 (s, 1H, hemiacetal), 5.33 (s, 1H, olefinic), 6.50 (s, 3H, OCH_3), 7.40—8.00 (m, 8H, allylic CH_2), 8.29 (m, 8H, non-allylic CH_2).

Found: C, 75.86; H, 7.42%. Calcd for $C_{19}H_{22}O_3$: C, 76.48; H, 7.43%.

XXVa and XXVb showed closely related mass, IR and UV spectra. However, marked difference of chemical shifts of olefinic protons between XXVa (4.80) and XXVb (5.33) was observed. The structure of XXVa was assigned to the isomer with low τ-value, because the olefinic proton in XXVa is dishielded by the magnetic anisotropy of oxygen atom of dihydrofuran ring.

5-Phenyl-2,4-heptadien-6-ynal (XXXII). a) By the Modified Wittig Reaction: Sodium hydride dispersion in mineral oil (50%, 1.84 g, 0.383 mol) was washed under nitrogen atmosphere with petroleum ether (3 ml×4). The sodium hydride, after being dried *in vacuo*, was mixed with tetrahydrofuran (10 ml) and a solution of diethyl 2-(cyclohexylimino)ethylphosphonate[10] (10.0 g, 0.0383 mol) in the same solvent (30 ml) was added under ice-cooling and the mixture was stirred for 15 min. A solution of VIII (2.00 g, 0.0128 mol) in the same solvent (15 ml) was then added at −15 °C. The mixture was stirred at −10——15 °C for 15 hr, then poured onto ice-water, and extracted with ether (30 ml×3). After being washed and dried, the extract was evaporated under reduced pressure to yield a crude mixture containing XXXI, dark brown oil, 8.07 g. The material was dissolved in benzene (60 ml) and mixed with 1% aqueous solution of oxalic acid (180 ml). After being stirred for 15 hr at 20—25 °C, the organic layer was separated and the aqueous layer was extracted with dichloromethane (20 ml×2). The combined organic layer was washed and dried. The residue obtained by evaporating the solvent was chromatographed on silica gel. Elution with carbon tetrachloride and dichloromethane afforded XXXII, yellow crystals (from carbon tetrachloride–methanol), mp 69.5—70.3 °C, 1.18 g (51%), IR ($CHCl_3$): 3300 (≡C–H), 2085, 2710 (CHO), 1686 (C=O), 1608 (C=C) cm^{-1}, NMR (CCl_4): 0.33 (d, J=7.5 Hz, 1H, CHO), 2.06—2.95 (m, 8H, phenyl and olefinic), 3.75 (dd, J=7.5 and 15 Hz, α-position of CHO), 6.32 (s, 1H, ≡C–H).

Found: C, 85.73; H, 5.48%. Calcd for $C_{13}H_{10}O$: C, 85.69; H, 5.53%.

b) By the Isler's Method: A solution of borontrifluoride etherate (72 mg) in benzene (1 ml) was added to a solution of acetal (XI, 16.98 g, 0.0737 mol) in the same solvent (23 ml). at 40 °C and a solution of ethyl vinyl ether (6.233 g, 0.0864 mol) in the same solvent (10 ml) was slowly added at 40—45 °C. The mixture was kept at the same temperature for 4 hr and then allowed to cool on standing. Finely powdered potassium carbonate was added to the mixture. The filtrate was concentrated under reduced pressure to give crude XXXIII, brown oil, 22.68 g. A mixture of crude XXXIII, tetrahydrofuran (187 ml) and 3 M hydrochloric acid (125 ml) was vigorously stirred at 25 °C for 48 hr. The reaction mixture was extracted with ether. The extract, after being washed and dried, was concentrated under reduced pressure. Oily residue containing crystals was purified by a chromatography on silica gel to yield pure XXXII, 8.168 g (61% based on XI).

5,10-Diphenyl-2,4,10,12-tetradecatetraen-6,8-diyndial (XXIX). To a mixture of XXXII (740 mg, 4.07 mmol), methanol (5 ml) and pyridine (5 ml) was added a solution of cupric acetate monohydrate (3.50 g) in methanol (25 ml) and pyridine (25 ml). After being stirred for 3 hr at 25 °C, the mixture was chilled on an ice-bath, mixed with 3 M hydrochloric acid, and extracted with chloroform (30 ml×3). The extract, after being washed and dried, was concentrated under reduced pressure. The residue was chromatographed on silica gel (30 g) and eluted with carbon tetrachloride–dichloromethane to yield XXIX, yellow crystals, 691 mg (94%). The crystals dissolved in benzene was passed through a short column of alumina. Concentration of the filtrate afforded pure XXIX, orange yellow crystals, mp *ca.* 155 °C (decom.) (from benzene–cyclohexane), IR ($CHCl_3$): 1677 (C=O), 1603 (C=C) cm^{-1}, NMR ($CDCl_3$): 0.31 (d, J=8.0 Hz, 2H, CHO), 1.93—2.78 (m, 16H, phenyl and olefinic), 3.58 (dd, J=8.0 Hz and 15 Hz, 2H, olefinic H^2).

Found: C, 86.56; H, 4.98%. Calcd for $C_{26}H_{18}O_2$: C, 86.16; H, 5.01%.

5,10-Di-t-butyl-2,4,10,12-tetradecatetraen-6,8-diyndial (XXX). A solution of 5-*t*-butyl-2,4-heptadien-6-ynal[5] (1.20 g, 7.4 mmol) in pyridine (10 ml) and methanol (10 ml) was added to a mixture of cupric acetate monohydrate (5.00 g), pyridine (40 ml) and methanol (40 ml). After being kept at 25 °C for 21 hr, the reaction mixture was worked by up by the way used for XXIX. Crude yellow crystals thus obtained were chromatographed on alumina to yield pure XXX, 1.01 g (85%), yellow crystals, mp 154.4—155.7 °C (from benzene–*n*-hexane), IR (KBr-disk): 2745 (CHO), 2230 (–C≡C–), 1677 (C=O), 1604 (C=C) cm^{-1}, NMR ($CDCl_3$): 0.29 (d, J=8.0 Hz, 2H, CHO), 2.39 (dd, J=11 Hz and 15 Hz, 2H, H^3, H^{12}), 3.30 (d, J=11 Hz, 2H, H^4, H^{11}), 3.67 (dd, J=8.0 Hz and 15 Hz, 2H, H^2, H^{13}), 8.73 (s, 18H, *t*-Bu).

Chemical Evidence for the Existence of pπ-dπ Interaction between the Unsaturated Bond and the Sulfur Atom in Allyl and Vinyl Sulfide Systems[1)]

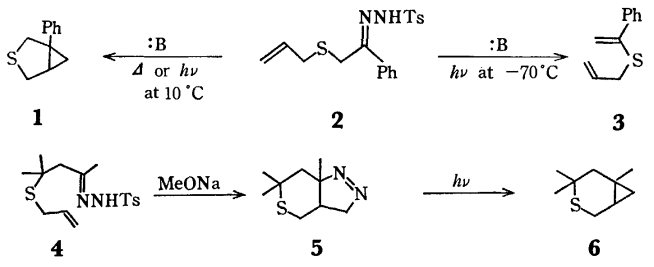
Iwao OJIMA and Kiyosi KONDO*

Sagami Chemical Research Center, Nishi-Onuma, Sagamihara 229

(Received January 26, 1973)

Chemical evidence for the activation of double bonds by the use of 3d orbitals of the sulfur atom was observed in the reaction of allyl benzyl sulfide and phenyl vinyl sulfide with diazomethane. Similar supporting evidence was also obtained in the reaction of acetophenone tosylhydrazone with allyl benzyl sulfide in the presence of sodium methoxide at 150 °C. It was found that there should not be any important role of the oxygen atom of allyl benzyl ether in directing the orientation of the 1,3-dipolarophile.

It is well known that the thermal cycloaddition of diazoalkanes to the simple non-conjugated olefins is a very slow and difficult process.[2,3)] Thus, nowadays the thermal or photochemical formation of cyclopropanes from diazoalkanes and non-conjugated olefins is believed to be a carbenic process.[4)] Certain diazoalkanes bearing an allylthio-substituent have, however, been found to undergo a ready intramolecular cycloaddition to produce pyrazolines, which were thereafter further transformed into cyclopropanes under the same reaction conditions.[5)] 1-Phenyl-3-thiabicyclo[3.1.0]hexane (**1**) was obtained by the thermal decomposition at 150 °C, or by the photolysis at 10 °C, of α-(allylthio)acetophenone tosylhydrazone (**2**) in the presence of sodium methoxide. The carbenic process could be observed in this α-allylthio system when the photolysis was carried out at −70 °C; this process afforded an entirely different product, **3**.[6)] Thus, the formation of **1** may mean that an intramolecular cycloaddition of the diazoalkane moiety to the double bond of the allylthio group and a subsequent elimination of molecular nitrogen really do occur under the present reaction conditions. Conclusive evidence for the intramolecular thermal cycloaddition of the diazoalkane was observed when 4-allylthio-4-methylpentan-2-one tosylhydrazone (**4**) was used as a substrate. Thus, the bicyclic pyrazoline, **5**, was actually isolated in the thermal decomposition of **4** in the presence of sodium methoxide; the pyrazoline, **5**, was then further converted to the 3-thiabicyclo[4.1.0]heptane, **6**, by irradiation.[5)] These facts seem to indicate that the intramolecular thermal cycloaddition is a ready process even at 10 °C and that the subsequent elimination of nitrogen is also an effective process under the photolytic conditions. The high efficiency of the intramolecular cycloaddition to the isolated double bond may be partly due to some kind of activating effect of the sulfur atom in the molecule as well as to the *intramolecular* nature of the reaction.



Scheme 1.

In order to clarify the activating effect of the sulfur atom, *intermolecular* cycloadditions of diazoalkanes to allyl sulfide and vinyl sulfide systems were investigated. This paper will deal with the evidence for the existence of pπ–dπ interaction between the sulfur atom and the unsaturated bond.

Results and Discussion

Acetophenone tosylhydrazone was thermally decomposed in the presence of an equivalent of sodium methoxide and two equivalents of allyl benzyl sulfide in diglyme at 150 °C. The products were separated by column chromatography on silica gel to give 1-(benzylthio)methyl-2-methyl-2-phenylcyclopropane (**9**) in a 28% yield (**9a**/**9b**=29/71). The formation of the cyclopropane, **9**, can be accounted for either by the attack of a carbene intermediate on the olefin or by the 1,3-dipolar cycloaddition of phenylmethyldiazomethane to the unsaturated bond, followed by the loss of a nitrogen molecule. The former possibility seems to be less likely, for recent investigations have shown that the reaction of allylic sulfides with carbene or carbenoid species appears to involve mainly a [2.3]sigmatropic rearrangement of the intermediately-formed allyl sulfonium ylides.[7)] Moreover, in the above system, the generated carbene is prone to be converted to acetophenone azine or styrene smoothly.[8)] Though the reaction mixture was carefully examined, the sulfide, **7**, could not be detected in the product.

These considerations lead us to speculate that the cyclopropanes (**9a** and **7b**) were formed through the pyrazoline (**8a** or **8b**), and that subsequently the

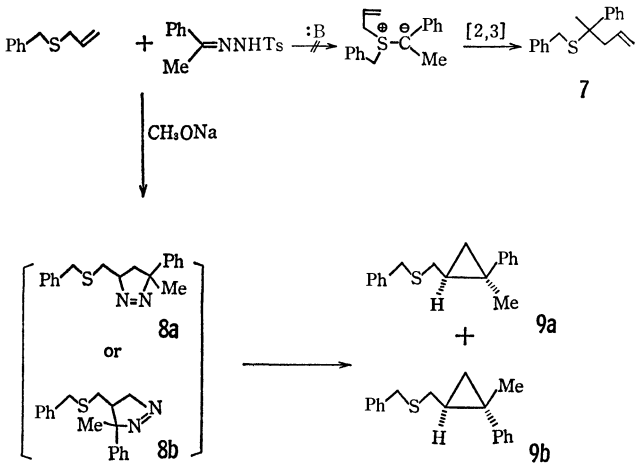
molecular nitrogen was eliminated, as is shown in Scheme 2. The observed ratio of the **9a** and **7b** isomers seems to reflect the relative degree of their thermodynamic stabilities, supporting the intermediacy of the 1,3-diradical produced by the thermal fragmentation of **8** under the present reaction conditions.[5,9]



Scheme 2.

In order to elucidate the orientational effect of hetero atoms in the allylic systems, the thermal reactions of allyl benzyl sulfide and allyl benzyl ether with diazomethane were examined. Thus, allyl benzyl sulfide was allowed to react with diazomethane in ether at room temperature for a week in a sealed tube. The reaction mixture was then purified by column chromatography on silica gel to give 3-(benzylthio)-methyl-Δ^1-pyrazoline (**10**) in a 79% yield; this substance subsequently afforded a cyclopropane derivative, **11**, on irradiation with a high-pressure mercury lamp. The structure of the pyrazoline **10** was determined by studing its NMR spectrum. The NMR spectrum of the pyrazoline displayed three multiplets, at τ 8.80 (1H), at τ 8.40 (1H), and in the τ 6.18—5.35 (3H) region. The former two can be assigned to the resonance of non-equivalent H^b methylene protons, and the latter, to that of the H^a methine proton and of H^c methylene protons.[10] If the structure of the pyrazoline is 4-benzylthiomethyl-Δ^1-pyrazoline (**12**), H^a protons should appear as a double AB quartet (4H) in the region near τ 6.00, and the H^b proton, as a multiplet (1H) in a higher field (see the Experimental section for the case of **13b**). Thus, the structure of the pyrazoline obtained can be assigned to 3-(benzylthio)methyl-Δ^1-pyrazoline (**10**).

In contrast with the observed specific orientation in the case of the allyl sulfide system, the reaction of allyl benzyl ether with diazomethane under similar conditions afforded a mixture of two Δ^1-pyrazolines, **13a** and **13b** (**13a**/**13b**=67/33), in a 74.5% yield. These pyrazolines could fortunately be separated and purified by column chromatography on silica gel, and their structures were established by means of their NMR spectra. The fact that two different adducts were obtained in the case of allyl benzyl ether implies that

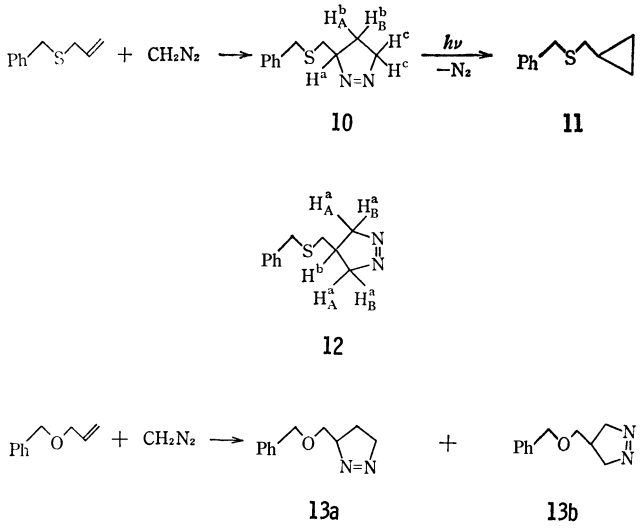

Scheme 3.

the oxygen atom plays no important role in directing the orientation of the 1,3-dipolarophile.

It has recently been suggested that the through-space $p\pi$–$d\pi$ conjugation between the double bond and the sulfur atom is operative in the reactions of allyl aryl sulfones with diazomethane.[11] The exclusive nucleophilic attack of diazomethane on the terminal carbon found in the present investigation appears to provide chemical evidence for the existence of homoallylic $p\pi$–$d\pi$ conjugation even in the case of a simple allyl sulfide system.

A similar activating effect of the hetero atom on the double bond can also be expected to emerge in the case of vinyl sulfides. Both vinyl ethers and sulfides are known to be electron-rich olefins because of the contributing structures, such as **14A** and **15A**. Thus, these compounds can easily be hydrolyzed under acidic conditions.[12] It is also known, however, that the sulfur atom has the ability to stabilize a carbanion on the α-position using its 3d orbitals.[13]

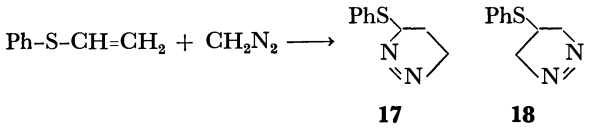
Thus, the contribution of another resonance structure, **15B**, also seems to be important in determining the character of the double bond in a vinyl sulfide, but no such effect of the sulfur atom in withdrawing electrons in such a way has been observed in cycloaddition reactions. D'yakonov has reported that the reaction of *n*-butyl vinyl ether with diazomethane produced 4-butoxy-Δ^1-pyrazoline (**16**).[14] This result is apparently consistent with the importance of the **14A** resonance structure.

Phenyl vinyl sulfide was allowed to react with an excess of diazomethane in ether at room temperature in a sealed tube for a week to give 3-phenylthio-Δ^1-pyrazoline (**17**) in a 40.4% yield; no formation of 4-phenylthio-Δ^1-pyrazoline (**18**) could be observed. This finding is to be expected in view of the predominant contribution of the canonical structure, **15B**, in preference to that of **15A**, to the resonance hybrid of the sulfide, and it well corresponds to the case of vinyl sulfones.[15]



17 **18**

Scheme 5.

It is sufficient to note at this point that both nucleophilic and electrophilic attacks on allyl and vinyl sulfides tend to occur at the terminal carbon. Such a versatile character of the olefinic sulfides seems to be associated with the large polarizability of the molecule due to the participation of the 3d orbitals of a sulfur atom.

Experimental

Measurements. The melting points and boiling points are uncorrected. The infrared spectra were recorded on a Hitachi-Perkin-Elmer Model 337 Infracord or a Hitachi EPI-G3 spectrophotometer, using samples as neat liquids or KBr disks or Nujol mulls. The nuclear magnetic resonance spectra were obtained by the use of a Varian HA-100 or Hitachi R20-B spectrometer, using TMS as the internal standard. The mass spectra were measured by means of a Hitachi RMU-6E spectrometer at 70 eV. Photolyses were carried out using a 450-W high-pressure mercury lamp (Ushio Electric Inc.).

Materials. The allyl benzyl sulfide,[16] and allyl benzyl ether[17] were prepared according to the reported method. The phenyl vinyl sulfide[18] was prepared from β-chloroethyl phenyl sulfide[19] by treatment with potassium hydroxide in ethanol. The acetophenone tosylhydrazone was prepared by the condensation of acetophenone and tosylhydrazide; mp 148—150 °C (lit,[20] 147.5—150 °C).

Thermal Decomposition of Acetophenone Tosylhydrazone in Allyl Benzyl Sulfide in the Presence of Sodium Methoxide. In 50 ml of diglyme, 1.64 g (10.0 mmol) of allyl benzyl suifide and 1.44 g (5.0 mmol) of acetophenone tosylhydrazone and 300 mg of sodium methoxide were dissolved. The mixture was heated in an oil bath at 150 °C for 1 hr. After the precipitated sodium *p*-toluenesulfinate had then been filtered off, the filtrate was distilled under reduced pressure to remove the solvent. The residue was submitted to column chromatography on silica, using *n*-hexane as the eluent; 1-(benzylthio)methyl-2-methyl-2-phenylcyclopropane (**9**) (375 mg, 28% yield) was thus obtained. The isomer ratio of the cyclopropane, **9**, was determined to be *cis*(**9a**)/*trans* (**9b**)=29/71 by glpc analysis, using 20% SE-30 on chromosorb W at 200 °C.

An X-Ray Study of Coal Tar Pitch

Minoru SHIRAISHI and Kazuo KOBAYASHI

National Research Institute for Pollution and Resources, Kawaguchi, Saitama 332

(Received September 27, 1972)

The diffuse X-ray scattering from coal tar pitch has been investigated by using Fourier transformation for the 002 band and Diamond's least-squares method for the 11 band. From the results of this investigation, the layers were found to be stacked parallel to each other, partly in groups of 8—9 layers, the average number of the layers being 2.46. The distribution of the layer size showed a peak at the diameter of 8.4—10 Å, the average layer size was 8.9 Å, which corresponded to 25 atoms per layer.

It has been known that the properties of synthetic carbon depend largely on the structure of the starting materials and also on the condition of heating up to about 600 °C. However, not only the mechanism of the pyrolysis of the starting materials, but also the physical features of starting materials, have not yet been clarified. Therefore, it is valuable to clarify the structure of pitch from the viewpoint of the utilization of pitch as the starting material for synthetic carbon.

It has been known that the fundamental structure of coal tar pitch consists of various sizes of aromatic-ring systems.[1,2] However, the X-ray diffraction pattern of coal tar pitch shows only a small, diffuse scattering, corresponding to the 002, 100, and 110 reflections of graphite. The analysis of such diffuse scattering as is shown in coal and coal tar pitch is painstaking and difficult in the selection of its method.

In the present paper, the Fourier transformation, which Hirsch[3] used first and which Diamond[4] developed for the analysis of coal, was applied to the analysis of the 002 band of pitch. Moreover, Diamond's method[4,5] was used for the analysis of the 11 band of pitch. The size of the aromatic layer and the thickness of the aromatic layer stacking were estimated by using those methods.

Experimental

Sample. The sample was coal tar pitch which had already been treated at 390 °C. Table 1 shows some properties of the pitch used.

TABLE 1. SOME PROPERTIES OF PITCH USED

Ultimate analysis	C	92.1%
	H	4.5%
Specific gravity		1.31
Softening point		82.2 °C
Temperature of processing		390 °C

Experimental Procedure. The X-ray scattering was measured for a powdered sample using a diffractometer, a scintillation counter, a pulse-height analyser, and Cu$K\alpha$ radiation. Monochromation was carried out with balanced filters of Ni and Co.

The X-ray intensity was measured in two ranges, $0.01 \leqq s \leqq 0.44$ and $0.66 \leqq s \leqq 0.96$ Å^{-1} ($s = 2\sin\theta/\lambda$). The same experimental conditions of the slit system and of the electric power of the X-ray tube were adopted for both ranges of s.

The intensity of X-rays in the high-angle range ($0.66 \leqq s \leqq 0.96$ Å^{-1}) was measured by point counting or a fixed time method using the balanced filters. The intensity curve in the high-angle range was obtained by plotting the average value of two or more measurements. In the low-angle range ($0.01 \leqq s \leqq 0.44$ Å^{-1}), the X-ray intensity was recorded by a scanning method.

The observed intensity was then corrected for polarization, absorption, and geometrical factors. The absorption factor, $A(\theta)$, was obtained from Milberg's equation:[6]

$$A(\theta) = 1 - \frac{1}{\alpha}(1 - e^{-\alpha}) \tag{1}$$

$$\alpha = 2\rho'\left(\frac{\mu}{\rho}\right)\cdot A \cdot \mathrm{cosec}2\theta$$

with $A = 0.1614$ cm, $\rho' = 0.7$ g/cm^3, and $\mu/\rho = 4.60$ cm^2/g, where ρ' is the bulk density of the sample, where μ/ρ is the mass absorption coefficient for Cu$K\alpha$ and where A is the breadth of the X-ray beam.

Diamond's Method. The analysis derived by Diamond[4,5] was used for the 11 band, in which a linear combination of theoretical intensity curves from small layers of different sizes and from amorphous carbon atoms was fitted to the experimental curve over the range from 0.66 to 0.96 Å^{-1} by the method of least-squares. By means of a matrix transformation, the distribution, λ_i, in proportion by weight of the material, in each of the specified-layer-size groups, which are 5.8, 8.4, 10, 15, 20, and 30 Å in diameter, and of the amorphous atom, is derived by means of the following equation:

$$\lambda_i = \sum_j h_{ij} I_j \tag{2}$$

where h_{ij} is an element of the matrix calculated theoretically and where I_j is the observed intensity. The average layer diameter, $\bar{L}$, is defined by the relation:

$$\bar{L} = \sum_i' \lambda_i L_i / \sum_i' \lambda_i \tag{3}$$

where L_i is the specified layer size and where the prime denotes the omission of the term for amorphous carbon atoms. The relation between the layer size, L, and the number, N, of atoms in the layer of that size is given by the equation:

$$L = 2.5\sqrt{N/2} \tag{4}$$

Fourier Transformation. In the region of $s \leqq 0.40$ Å^{-1}, the main diffraction pattern is the 002 band, which is inter-

preted by analogy with pure carbons as being due to the stacking of parallel layers. The scattering curve was analyzed by the Fourier transformation method of Hirsch[3] and Diamond.[4] The Fourier transform of the following form:

$$P(u) = 2\int_0^\infty \frac{I_{002}}{f^2}\cos 2\pi us\,ds \qquad (5)$$

gives the probability of finding a layer at a distance of u along the normal to a given layer. In Eq. (5), I_{002} is the intensity of the 002 band, f is the atomic scattering factor for the carbon atom, and s is the reciprocal distance. The interlayer spacing, d, was obtained from the periodicity in the transform $P(u)$. This function can be used to determine stacking distribution using the second differences of the peak weights above a smooth background curve following the minima in $P(u)$, in the manner of Hirsch.[3] If $P(n)$ is the weight of the nth peak from the origin in the transform, the probability, $f(n)$, that a given stack contains n layers ($n \geqq 2$) is given by the following equation:

$$f(n) = P(n) - 2P(n+1) + P(n+2) \qquad (6)$$

The following procedure was used to determine I_{002}. The experimentally-observed intensity was corrected for geometrical, polarization, and absorption factors. The intensity of I_{obs} in absolute units was obtained by dividing the above corrected intensity by the value of $\sum\lambda$ determined by Diamond's method. The Compton scattering was subtracted from I_{obs} in order to obtain the coherent scattering, I_{coh}. The Breit-Dirac recoil factor to the 2/3 power was considered to be correct for the Compton scattering. The minimum value of I_{coh}/f^2 in the neighourhood of $s=0.40$ Å^{-1} was subtracted from I_{coh}/f^2 in the region of $s \leqq 0.44$ Å^{-1}. I_{002} was estimated as the product of the above difference and s:[7]

$$I_{002} = s\cdot\left(\frac{I_{coh}}{f^2} - A\right) \qquad (7)$$

$$A = (I_{coh}/f^2)_{s\fallingdotseq 0.4}$$

Results

002 Band. In Fig. 1 the observed X-ray intensity, I_{obs}, is plotted in the range of s values smaller than 0.44 Å^{-1}. Fig. 1 shows that the corrected intensity of the 002 band reaches 55 electron units at $s \approx 0.29$ Å^{-1}. The intensity curve of the 002 band, I_{002}, obtained by Eq. (7), is given against s in Fig. 2.

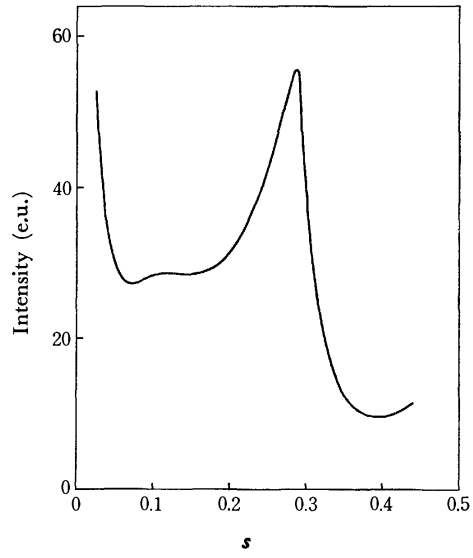

Fig. 1. X-ray intensity curve of coal tar pitch in low angle range.

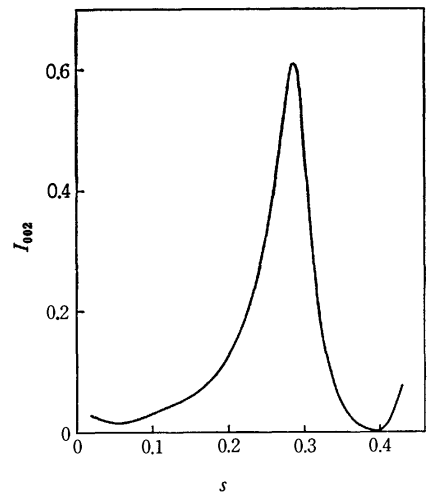

Fig. 2. X-ray intensity curve for 002 band of coal tar pitch.

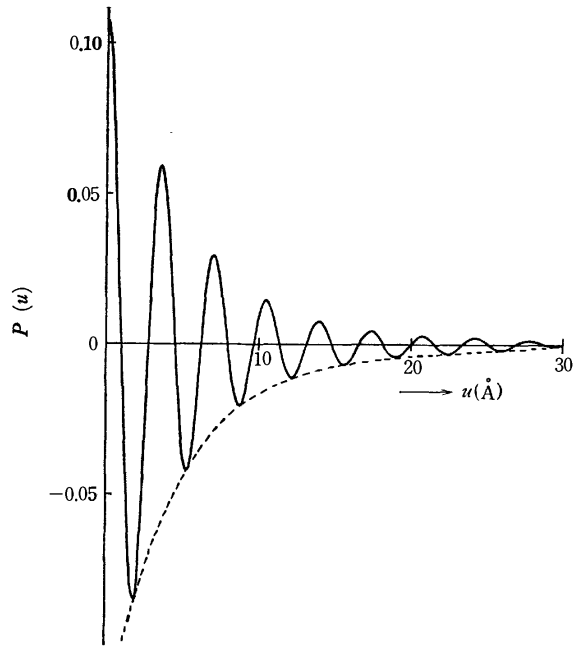

Fig. 3. Fourier transform of I_{002}.

The integration in Eq. (5) was replaced by a summation over the range from $s=0.01$ to $s=0.40$ corresponding to the minimum intensity of I_{002}. The results of the transform for coal tar pitch are shown in Fig. 3. The amplitude of oscillation is observed up to the 9th peak from the point of origin. The number of 9 corresponds to the maximum number of layers which may be considered to be packed parallel to each other at nearly equal distances. (Table 2)

A histogram of the stacking of the layers is given in Fig. 4. The layers per stack were observed up to 9 layers, but the fraction of stacks containing 8 and 9 layers was not obtained because $P(10)$ and $P(11)$ in Eq. (6) were unknown. Apart from the singly-occurring layers, the most frequently occurring groups contain two (55 wt%) or three (26 wt%) layers in the pitch

7) W. Ruland, *Carbon*, **2**, 365 (1965).

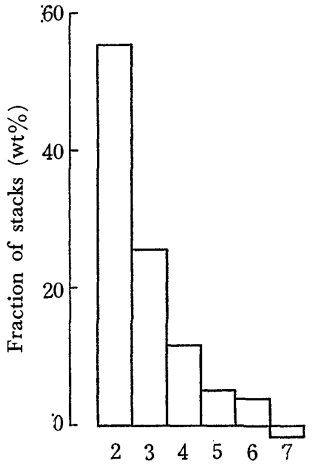

Fig. 4. Histogram of stack heights in coal tar pitch.

Table 2. Structural parameters of pitch used

Interlayer spacing	d	3.44 Å
Average number of layers per stack	$\bar{n}$	2.46
Thickness of stack	L_c	8.45 Å
Average layer size	$\bar{L}$	8.87 Å
Average number of atoms per layer	$\bar{N}$	25.2

used. The interlayer spacing, d, the average thickness of layer stack, L_c, and the average number of layers per stack other than the single layer, $\bar{n}$, are given in Table 2.

It is interesting to note that the interlayer spacing (3.44 Å) is equal to that in the non-graphitic carbons[8] and slightly smaller than that derived from the peak in Fig. 2.

11 Band. The X-ray intensity curve in electron units, obtained by dividing the collected X-ray intensity by $\Sigma\lambda_i$, is shown in Fig. 5 over a range extending from $s=0.66$ to 0.96 Å^{-1}. As is shown in Fig. 5, the intensity of the 11 band is weak in comparison with

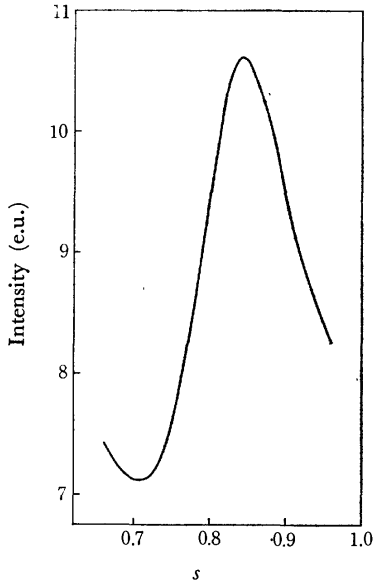

Fig. 5. X-ray intensity curve of coal tar pitch in high angle range.

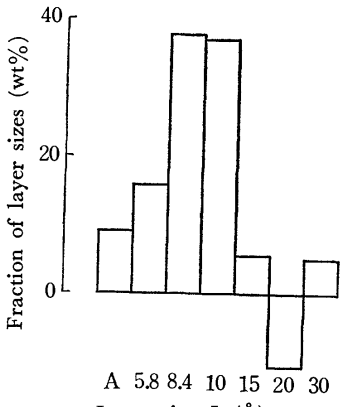

Fig. 6. Layer size histogram for coal tar pitch. The size group A is amorphous (single) carbon atoms.

the background scattering. The peak has a value of about 10.7 e.u.

A layer-size histogram of the coal tar pitch is given in Fig. 6. The fraction of amorphous matter is about 9%, and the fractions of the layer size in 8.4 and 10 Å are 38% and 37% respectively. The fraction of the layer size in 20 Å shows a minus value. The average layer size was 8.87 Å, and the number of carbon atoms per layer, $\bar{N}$, was 25.2.

Discussion

The transform, $P(u)=2\int(I_{002}/f^2)\cos 2\pi us ds$, is in principle the most general way for estimating the stacking distribution. There is a problem, however, in the determination of I_{002}. Diamond[4] derived two transforms as follows:

$$P_1(u) = 2\int\frac{s^2I}{f^2}\cos 2\pi us ds \tag{8}$$

and

$$P_2(u) = 2\int\frac{I}{f^2}\cos 2\pi us ds \tag{9}$$

The first gives the probability of finding a layer at a distance of u along the normal to a given layer; it thus represents a projection of the density of the interatomic vectors to the normal to the layers at any given point in the specimen. The second function corresponds to a projection of the density of the interatomic vectors along an arbitrary radius with random orientation.

Franklin[9] and Diamond[4] considered that the function, s^2I/f^2, in Eq. (8) was the best plot for the evaluation of the 002 reflection and the stacking distribution determined. However, when an undistorted profile is desired, an sI/f^2 plot is preferable to an s^2I/f^2.[7] Therefore, Eq. (7) was adopted for the best evaluation of the 002 reflection in this paper.

On the other hand, Fig. 1 shows a weak peak of $s\approx 0.1$ Å^{-1}, the existence of which implies that there may be a variation in the density in this region. There are two possible explanations of the variation in density.[3,10] First, the spacing of the peak may be due to some repeat distance of the structure; secondly, the peak may be due to the internal structure of the unit, which, for ex-

a) Included single layers

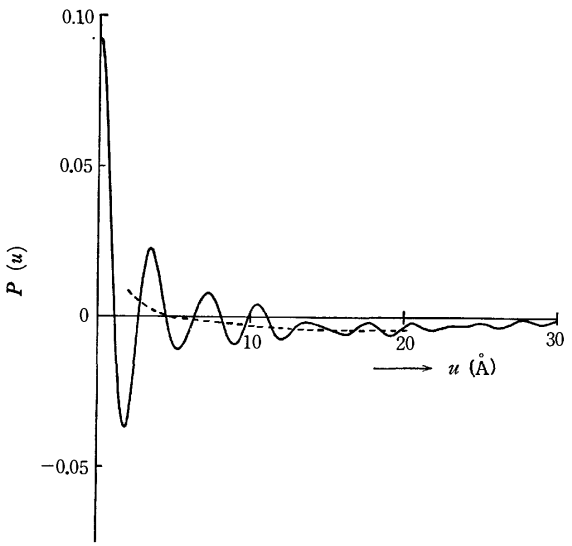

Fig. 7. Fourier transform of I_{coh}/f^2.

ample, has a greater than average density in its core and a less than average density in its peripheral regions. Therefore, the transform, $P_2(u)$, in Eq. (9) of this pitch was tried. As is shown in Fig. 7, there appear about five rapid oscillations due to the layers, but no maximum of the slow modulation of the transform appears. (The modulation is a dotted curve on Fig. 7) Accordingly, although Fig. 1 shows a peculiar region of $s \approx 0.1$, a distinct order with a distance of *ca.* 10 Å is not observed in this pitch from an analysis of the Fourier transformation.

Cartz[11] has examined a specimen of pitch for which structural parameters had been determined by Van Krevelen, using the statistical structure analysis. (Table 3). The carbon and hydrogen contents of the coal tar pitch used in the present experiment are nearly equal to those of the sample used by Van Krevelen and Cartz. However, the histograms of the stacking of the layers and the layer sizes are different in shape. Although the histogram of the layer size obtained by Diamond's method contains a negative term and does not give directly the true proportion of layers of the sizes indicated, the comparison with the shape of the histogram is more significant[4] and the average layer size, $\overline{L}$, is quite accurate.[12] Since C_{ar} stands for the average number of aromatic carbon atoms per cluster unit, the value of C_{ar} is compared with the number of atoms in a coherently-diffracting layer as deduced from X-ray data, $\overline{N}$. The average number of atoms per layers (25.2) in this pitch is found to be larger than the result, $\overline{N}$, by Cartz and slightly smaller than that, C_{ar} obtained by Van Krevelen.

Since the layers deduced from the high-angle diffraction pattern are diffracted effectively coherently in the 11 and the 20 region, all that may be said about the average layer size, $\overline{L}$, is that it represents the lower limit of the actual size of the imperfect sheet and the upper limit of the size of the perfect region of the layer. Therefore, the average layer size, $\overline{L}$, cannot necessarily be identified with the aromatic molecule as determined by statistical structural analysis. Notwithstanding the above reservation, the average number of atoms per layer, $\overline{N}$, is rather closer to the number of aromatic carbon atoms, C_{ar}, obtained by the statistical structural analysis than the $\overline{N}$ obtained by Cartz using X-ray analysis. The above discussion indicates that the average layer size, $\overline{L}$, obtained in this pitch is smaller than the aromatic molecule in this pitch.

On the other hand, the number of layers in the stacks were obtained from the area under the peaks of the Fourier transform by a second difference method. The proportion of single layers can not, however, be derived by the same method, since the origin peak in the transform is not accurate. In view of the height of the minima in the experimental curve, it seems that an appreciable proportion of the layers are unassociated.

Conclusion

On the basis of the results of the present experiments, the aromatic layers of the coal tar pitch used can be said to be distributed mostly at layer sizes of 8.4—10 Å. The average layer size which diffracts effectively coherently had a diameter of 8.9 Å and contained 25 atoms per layer. It was found that such aromatic layers stacked parallel to each other up to 8—9 layers. The average number of layer stacking was 2.46, excluding an isolated single layer and the interlayer spacing was 3.44 Å.

Therefore, it can be concluded that the crystallite size of the coal tar pitch was 8.9 Å in diameter and 8.5 Å in thickness.

The authors wish to thank Dr. S. Toyoda for countless discussions and a thorough review of the paper, and Dr. K. Ouchi, Dr. T. Yamakawa and Dr. Y. Sanada for much encouragement and many suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2579—2580 (1973)

The Simulation Analysis of Dipeptide Hydrolysis Catalyzed by Divalent Metal Ions

Katsutoshi OHKUBO and Hiroyuki SAKAMOTO

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received June 7, 1972)

Some quantitative studies of the kinetics of peptide hydrolysis in the presence of metal ions have been hitherto recorded, and such divalent metal ions (M^{2+}) as Co(II)[1] and Cu(II)[2,3] have been pronounced as effective catalysts for the following reactions of dipeptide (A–B) hydrolysis:

$$\text{A–B}^{\pm} \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} \text{A}\frown\text{B} \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} \text{B–A}^{\pm} \quad (1)$$

$$\text{A–B}^{\pm}(\text{or B–A}^{\pm}) \rightleftharpoons \text{A–B}^{-}(\text{or B–A}^{-}) + \text{H}^{+} \quad (2)$$

$$\text{A–B}^{-}(\text{or B–A}^{-}) + \text{M}^{2+} \rightleftharpoons \text{A–B}\text{---}\text{M}^{+}(\text{or B–A}\text{---}\text{M}^{+}) \quad (3)$$

$$\text{A–B}\text{---}\text{M}^{+}(\text{or B–A}\text{—}\text{M}^{+}) \underset{\text{H}_2\text{O}}{\overset{K}{\rightleftharpoons}} \text{M}^{2+} + \text{A} + \text{B} \quad (4)$$

where A⌒B denotes the dioxopiperazine intermediate. Recently, Long *et al.*[4,5] have noted that the rate of glycyl-glycine hydrolysis is directly proportional to the concentrations of Co(II), Ni(II), Zn(II), and/or Mn(II) over the pH range of 3.8—6.0.

In the present paper, the simulation analysis was performed on the rate of dipeptide hydrolysis catalyzed by Zn(II), Co(II), and/or Ni(II) by means of a computer technique based on the kinetic method;[6] also the mechanism for the divalent metal ion-catalyzed dipeptide hydrolysis will be briefly discussed on the basis of ASMO-SCF and extended Hückel MO calculations.[7]

Results and Discussion

Let us first discuss the simulation results on Zn(II)-catalyzed hydrolyses of dipeptides; glycyl-L-leucine (G–L), glycyl-L-alanine (G–A), and glycyl-glycine (G–G). As can be seen from Fig. 1, the time conversions of the dipeptide concentrations calculated with the rate constants listed in Table 1 were satisfactorily in accordance with those[5] obtained experimentally. In the absence of the Zn(II) ion, only the acid H^+ (pH 5.6) accelerates a little the rate of G–L hydrolysis.

In regard to the cleavage of peptide bond in G–L G–A, and G–G, the order of the bond fission caused by the Zn(II) ion, G–G>G–A>G–L, was not directly related to that of the bond populations of their peptide bonds (G–G=1.036; G–A=1.035; G–L=1.035); this may be ascribed to the difference in the steric hindrances of the substituents (R_1 and R_2) in $H_3\overset{+}{N}CH(R_1)C(=O)NHCH(R_2)CO_2^-$ to the interaction of the Zn(II) ion.

Next, let us discuss the rate constant, k, of Reaction (3) in G–G hydrolysis with Zn(II), Co(II), and/or Ni(II). Fig. 2 shows the k values obtained experimentally[4] (k_{obsd}) and those calculated (k_{calcd}) by means of Arrhenius and activated complex theories on the basis of least-squares error analysis. Both the k_{obsd} and k_{calcd} values were found to be identical within the limits of technical error. As may be seen from Fig. 2, the Zn(II) ion seems to be predominant as a catalyst for the G–G hydrolysis. This distinctive catalytic nature of the Zn(II) ion is well reflected in the distinctive kinetic data of the Zn(II) ion (see Table 2).

Finally, the mechanism for the metal ion-catalyzed hydrolysis will be briefly discussed. The electronic structure of G–G in a weak acid solution, $H_3\overset{+}{N}CH_2C$-

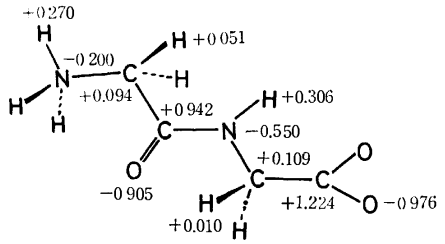

Fig. 3. Electronic structure of G-G in weak acid solution.

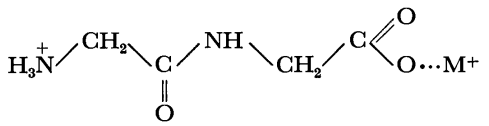
(=O)$NHCH_2CO_2^-$, is[8] presented in Fig. 3 by the use of the formal charges calculated by the ASMO-SCF method: the highest occupied (HO) MO of G–G± is strongly localized by the nonbonding lone-pair oxygen 2p-orbital of the CO_2^- group. Bearing in mind that the divalent metal ion behaves as an electron acceptor against G–G±, an assumed complex, A–B···M^+ (or B–A···M^+), in Eqs. (2) and (3) may be represented by the following interacting system:



The distinctive nature of the Zn(II) ion mentioned above may be the result of the low-lying, lowest-unoccupied (LU) AO level of the Zn(II) ion; In view of the orbital energies of the LU AOs of the metal ions (−9.39 eV[9] for the Zn(II) p-orbital; −7.86 eV[9] for the Co(II) d-orbital; −7.633 eV[9] for the Ni(II) d-orbital) and the HOMO of the nonbonding lone-pair 2p-orbital of oxygen (−10.50 eV) in the terminal CO_2^- group, it seems from the energetic point of view[10] that the Zn(II) ion may interact easily and strongly with G–G± in the above interacting system. Therefore, the nucleophilic attacking of the H_2O molecule on the more positively-charged carbonyl carbon in the peptide bond may be expected in the case of G–G—Zn^+.

10) In an aqueous solution, the divalent metal ion may react with dipeptides as an aquo-complex involving a fixed number of water molecules.[11] Therefore, we should take into consideration the lability order of aquo-complexes in the water substitution with the dipeptide. In this respect, the lability order, Zn(II)≫Co(II)>Ni(II),[12] and/or the order of the rates in water-molecule exchange, Co(II)≧Ni(II),[13] are closely related to that of the rates in the dipeptide hydrolyses by the divalent metal ions.

CNDO/2 Calculation of the Valence Electron Contribution to the Intermolecular Potential of Some Ground State Closed Shell Molecules

Masao HASHIMOTO and Taro ISOBE

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Sendai 980

(Received August 4, 1972)

The empirical or semiempirical theories of intermolecular forces seem to be able to yield satisfactory results for the problem of the stability of solids and for that of conformation of polymers, but in the quatitative calculation of the interaction energy they have more or less been clouded by ambiguous parameters or factors. This is also the result of the artificial distinction between a long- and a short-range force in the usual calculations of the interaction energy in the region of the van der Waals minimum. Thus, it is necessary now to seek a method by which these forces can be unified.

The possibility that a molecular orbital theory could yield an attractive interaction between two closed-shell atoms or molecules has often been discussed.[1] A careful CI calculation for He···He was done recently[2] using very elaborate multiconfigurational wavefunctions, and successful result was thus obtained. However, it is doubtful that this method can be practically applied to larger systems.

The energy of interaction, $U(M\cdots M)$, is generally defined as follows:

$$U(M\cdots M) = E(M\cdots M) - 2E(M) \quad (1)$$

where M is a molecule or an atom and where $M\cdots M$ is a dimer.

Assuming that intermolecular bonding is mainly brought about by an overlap between two molecular orbitals, we will calculate $U(M\cdots M)$ by means of the CNDO/2 SCF MO method[3] and will study the applicability of this method to the molecular-interaction problem by considering the contribution to the lattice energy of the molecular crystal.

The molecules treated in the present work are N_2, C_2H_2, and CO_2, which form crystals belonging to Pa3 space group, and C_2H_4, which forms a crystal belonging to the $P2_1/n$ space group.

Theoretical

Dimer Orbitals and Energies Obtained by the CNDO/2 Method. In this work, the dimer can be treated as one species, and there is essentially no difference between the intermolecular bond and the intramolecular bond so long as the LCAO MO approximation is used. The dimer orbitals and energies can, then, be obtained in the usual way, like the monomer orbital, from the following matrix elements:

$$F_{rr} = -\frac{1}{2}(I_r+A_r) + \left[(P_{AA}-Z_A) - \frac{1}{2}(P_{rr}-1)\right]\gamma_{AA} + \sum_{B(\neq A)}(P_{BB}-Z_B)\gamma_{AB} \quad \text{(orbital } r \text{ on atom } A) \quad (2)$$

$$F_{rs} = \frac{1}{2}S_{rs}(\beta_A+\beta_B) - \frac{1}{2}P_{rs}\gamma_{AB} \quad (r \text{ on } A,\ s \text{ on } B). \quad (3)$$

The total electronic energy of the dimer is expressed as follows:

$$E_{\text{elec}} = \frac{1}{2}\sum_{r,s} P_{rs}(H_{rs}+F_{rs}). \quad (4)$$

The Coulombic repulsion energy between cores is as follows:

$$E_{\text{core}} = \sum_{A\neq B} Z_A Z_B / R_{AB}. \quad (5)$$

The total dimer energy, $E(M\cdots M)$, is, therefore:

$$E_{\text{total}} = E_{\text{elec}} + E_{\text{core}}. \quad (6)$$

The intermolecular interaction energy is, then:

$$U(M\cdots M) = E_{\text{total}}(M\cdots M) - 2E_{\text{total}}(M). \quad (7)$$

The pair interaction energy (7) was summed over all the pairs in the crystal, assuming the pairwise additivity of the intermolecular forces. One half of the above sum was compared with the experimental heat of sublimation.

The assumption of the pairwise additivity is based upon the finding[4] that, in the system of He_3, the non-additive contribution in the neighbourhood of the van der Waals minimum is negligible.

Modification of Slater Atomic Functions at Larger Value. Simple Slater atomic orbitals are usually used for the calculation of the electronic states of molecules; they are expressed, for example, as follows:

$$\chi_{2p_z} = (\alpha^5/\pi)^{1/2}\exp(-\alpha r) r\cos\theta \quad (8)$$

χ in (8) gives a satisfactorily correct charge distribution when r is small, but it gives incorrect results when r becomes large.

One of the atomic functions accurate also in the region of large r values is the linear combination of (8) with different orbital exponent α's:

$$\chi'_{2p_z} = r\cos\theta\sum a_i(\alpha_i^5/\pi)^{1/2}\exp(-\alpha_i r) \quad (9)$$

The coefficients, a_i's, and orbital exponents, α_i's, have been determined by the Hartree–Fock–Roothan Method by Clementi.[5] In the present paper the above types of Clementi's atomic orbitals will be used as basic functions, unless otherwise stated.

The CNDO/2 parametrization was done as usual[3] except for the use of Slater's μ-values; the FORTRAN program for CNDO/2 written by Kikuchi[6] was modified so as to be applicable to Clementi's AO basis.

In the present work, μ-values appear, for example, as α_i in (9).

All the numerical calculations were done on a NEAC-2200 model 700 computer system at the Computer Center of Tohoku University.

Results and Discussion

Figures 1 and 2 indicate the dependency of the $U(M\cdots M)$ of C_2H_4 on the intermolecular distance, R, when the two molecules have a parallel and perpendicular configuration respectively.

The summation of (7) over all the pairs of molecules in the crystal was approximated by that over the nearest and the second-nearest neighbour molecules,

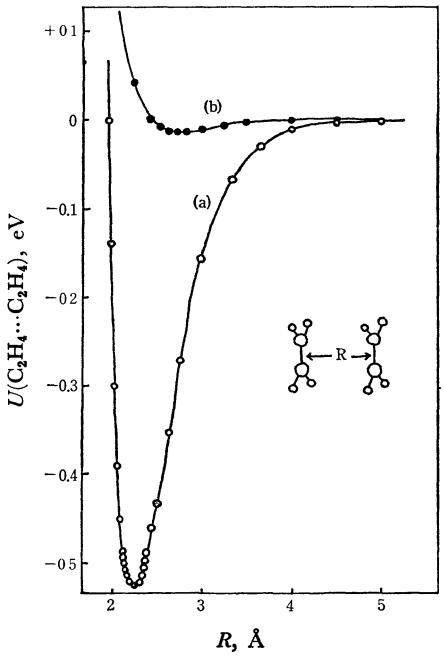

Fig. 1. The dependency of $U(M\cdots M)$ of C_2H_4 on intermolecular distance R when the two molecules have a parallel configuration.
(a) using Clementi's AO; (b) using simple Slater's AO.

C_2H_2	−0.24834	−0.23851[13)]
C_2H_4	−0.11360	−0.18213[14)]
CO_2	−0.28465	−0.28621[15)]

a) In electron volt, error ±0.00025

since the third-nearest neighbour molecules in the crystal are from 11.1 to 19.4 Å away from the central molecule and in this region the $U(M\cdots M)$ might be negligible, as may be seen from Figs. 1(a) and 2. More or less similar situations are observed for the other crystals.

In Table 1, the experimental heat of sublimation, which does not include the zero-point energy, and a half of the calculated interaction energy summed over the nearest and the second-nerarest neighbour molecules in the crystals are compared. The consistency seems to be quite good.

In Fig. 1 the $U(M\cdots M)$ (a) calculated by using Clementi's AO is compared with that (b) calculated using the simple Slater AO.

The overlap integrals among the simple Slater AOs are very small and negligible in the region of the intermolecular distances. However they become effective if Clementi's AOs are used.

To show the partial reliability of the present work, we wish to cite two example: 1) Many authors have examined the refinement of Bunn's crystal structure for ethylene,[7)] and it is known today to have $P2_1/n$ space group.[8)] If the $\sum U(M\cdots M)$ of C_2H_4 is calculated for Bunn's structure, it becomes +3.37 eV and is strongly repulsive. This does not explain the formation of the stable crystal. 2) The lower-temperature form of the crystalline acetylene has already been suggested to be Cmca.[9,10)] The present calculation of $\sum U(M\cdots M)$ of C_2H_2 for the Cmca structure is −0.51456 eV, surely lower that of the high-temperature form, −0.49668 eV.

Furthermore, the *staggered* configuration of CH_3OH molecule was found to have an energy lower by 0.04486 eV or 1.03 kcal/mole than the *eclipsed* configuration. This is in good agreement with the experimental value of 1.07 kcal/mole.[11)]

The authors wish to thank Dr. Enrico Clementi of the IBM Research Laboratory for his kind offer of the table of atomic functions.

Circular Dichroic Evidence for the Cholesteric Phase in Solid Films of Poly-γ-methyl-glutamate

Taro TACHIBANA and Etsuko ODA

Chemical Laboratory, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112

(Received October 21, 1972)

Concentrated solutions of synthetic polypeptides are known to have a cholesteric liquid crystal structure.[1] Samulski and Tobolsky[2] presented evidences for such a structure in solid films of poly-γ-benzyl-L-glutamate (PBLG) made by casting from solution. The structure in the solid films was inferred from swelling and birefringence studies and X-ray observation. Thus, if the solid films in which the periodicity is comparable to the wavelength of light can be prepared, it is reasonable to expect them to show the cholesteric colors, since the cholesteric liquid crystal exhibits selective reflection of circularly polarized light. Such an example has been reported[3] only for a concentrated solution of poly-γ-ethyl-glutamate in ethyl acetate.

Recently a patent[4] was published in which it was described that solid films with iridescent colors were obtained from poly-γ-methyl-D(or L)-glutamate (PMDG or PMLG). In order to confirm our presumption that the colors are due to cholesteric color, we have performed circular dichroic studies with colored films.

Experimental

Concentrated solutions (24 wt%) of PMDG and PMLG (D. P., *ca* 230) in 1,2-dichloroethane (provided from Central Research Laboratories, Ajinomoto Co., Inc.)[5] were used after being diluted to 8 weight percent with the same solvent. A small amount of the solution was spread as thin films on the surface of a plate glass, rubbed in one direction with a glass rod. The solvent was then allowed to evaporate freely in air at room temperature. After being dried completely, thin solid films were formed on the glass surface. They were then stripped off the glass surface by introducing the film-covered glass plates into water. Solid films 10 to 30 micron thick were preferred for the optical study. Although they were more or less opaque and colorless for transmitted light, they assumed a uniform reflection color varying from blue to red depending on the angle of view and incidence. The color depended also on the initial concentration of solution and the evaporation rate; when the rate was slower, the color was displaced from blue to red when viewed at a certain angle.

Samples with uniform thickness and area suitable for measuring the circular dichroism were cut out from the films and mounted on a holder with a window, 6 mm×6 mm. Circular dichroism was measured by using a JASCO Automatic Recording Spectropolarimeter Model J-10. Unless otherwise stated, incident light was cast at right angle to the sample film.

Results and Discussion

As expected, circular dichroism (CD) was observed for the sample films reflecting blue to red light. Typical circular dichroic curves for a PMDG film are illustrated in Fig. 1, where the CD (ordinate) is

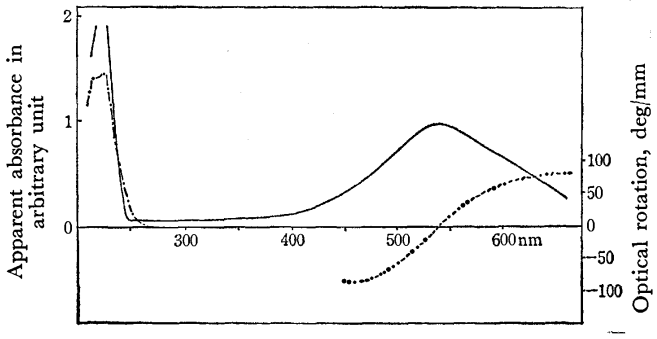

Fig. 1. Circular dichroism (——) and optical dispersion (····) of solid films (20 μ thick) of PMDG.
Line (-·-·-) shows a CD curve of dilute solution (0.04 wt%) of PMDG in 1,2-dichloroethane.

expressed as the apparent absorbance of the left circularly polarized light minus that of the right one. The CD curve exhibited a large band with a peak in the region 450—650 nm and a small band with a peak in the region 220—230 nm. The latter band, also observed for the solutions of PMDG in chloroform, was the same as the CD band which has been attributed to the n–π* transition in the α-helix of PMDG molecules.[6] The 450—650 band is due to selective reflection of circularly polarized light of one sense in that wavelength region, since no absorption is found here for the solution. Since the apparent absorbance is actually due to the reflection, it is concluded from Fig. 1 that the PMDG films reflect selectively the left circularly polarized light. On the other hand, the PMLG films were found to give the CD curve of the opposite sense. The result indicates the presence of a cholesteric liquid crystal structure in the solid films of PMDG or PMLG.

Liquid crystals in the cholesteric phase are well-known to form a macroscopic helical structure. Polarizing microscope examination showed that the birefringence of the film of PMDG or PMLG is optically negative and the optical axis is almost normal to the

4) N. Okuda, S. Mori, Y. Takagi, and Y. Takeda, Japanese, No. 5154 (1970).

5) PMG was prepared by ring-opening polymerization of γ-methyl-glutamate NCA in 1,2-dichloroethane using *N,N*-dimethylethylenediamine as initiator (S. Mori and N. Iwatsuki, private communication).

6) G. Holzwarth and P. Doty, *J. Amer. Chem. Soc.*, **87**, 218 (1965).

film surface, *i.e.* the axis of the macrohelix is almost vertical to the film surface. Thus, for normal incidence, the pitch p of the macrohelix is inferred from the equation[7] $\lambda_m = n \cdot p$, where λ_m is the wavelength of the maximum reflection and n is the average refractive index. The value for λ_m was obtained from the peak of the CD curve and n was experimentally estimated as about 1.4. For a sample which showed the CD curve of Fig. 1, the pitch was estimated as 350 nm by using $\lambda_m = 500$ nm and $n = 1.4$.

The helical sense can be deduced from the sense of the circularly polarization of the reflected light or from the sign of the optical rotatory dispersion; a left-handed helical structure reflects left circularly polarized light and it shows negative optical rotation on the short wavelength side of the reflection band[7,8,9,10]. Figure 1 shows that the PMDG films reflect left circularly polarized light and that they show negative optical rotation at the short wavelength side of the inversion. It is thus concluded that the PMDG films have a left-handed macrohelix. For the PMLG films a right-handed macrohelix was found. Since the molecular helix (α-helix) of PMDG (or PMLG) is known to be left-handed (or right-handed), this result indicates that the sense of the macrohelix is the same as that of the molecular helix of each enantiomer.

The dependence of the reflection on the angle of incidence was also measured. The wavelength peak was compared with the value calculated by Fergason's formula[11] which gives the wavelength of maximum reflection as a function of the angle of incidence and of reflection for cholesteric liquid crystal. The observed value of the peak was in good agreement with the value calculated by assuming that the reflection planes are placed parellel to the film surface. This shows that the reflection planes of the cholesteric phase are parallel to the film surface, being consistent with the result of the polarizing microscope examination.

The cholesteric structure of the films was so heat-resistant that it was not destroyed until near the decomposition temperature of this polymer.

The colors of the solid films of PMDG were found to change reversibly by absorbing organic vapor such as chloroform or benzene. With the progress of absorption, the color turned red, becoming finally faint. Corresponding to the visual color change, the peak of the CD curve shifted to longer wavelength region. This indicates the increase of the pitch of the macrohelix by absorbing organic vapor between the planes in which the molecules lie, since the change of the refractive index is not so sensitive in this case.

Colored films were not obtained from a racemic mixture of PMDG and PMLG. Among polyglutamate esters, PBLG is also reported to form a solid film with a cholesteric structure,[2] but it did not exhibit cholesteric color. Formation of the solid film with cholesteric color was most favorable from solutions of PMDG or PMLG which was prepared according to the method in Ref. (5). This explanation is still not clear.

The result we presented has a new significance for the observation[12] that the light reflected from certain iridescent beetles is also circularly polarized, suggesting the presence of a cholesteric structure in their cuticles.

10) Here it should be noted that confusion occurs regarding the sense of circular polarization in the literature. For example, according to Conners' paper (*J. Opt. Soc. Amer.*, **58**, 875 (1968)), a right-handed helix reflects left circularly polarized light. Then, he adopted a definition contrary to the normal usage for the sense of circularly polarized light.

Studies on Microcapsules. XV. Electrophoretic Behavior of Carboxylated Polyphthalamide Microcapsules Containing Aqueous Solutions of Polyelectrolytes

Motoharu SHIBA, Suiichi TOMIOKA, and Tamotsu KONDO*

Research Laboratory, Chugai Pharmaceutical Co., Ltd., Toshima-ku, Tokyo 171

** Faculty of Pharmaceutical Science, Scinence University of Tokyo, Shinjuku-ku, Tokyo 162*

(Received November 24, 1972)

In an earlier paper of this series,[1] we reported that polyphthalamide microcapsules containing aqueous solution of anionic or cationic polyelectrolytes move towards the anode or cathode in an electric field according to the sign of charge on the encapsulated polyelectrolyte though the microcapsule membrane itself has no charge at all. Polyphthalamide microcapsules containing amphionic polyelectrolyte migrate either to the anode or to the cathode depending on the pH of the medium, showing the existence of an isoelectric point. All these findings indicated that the direction of electrophoresis of microcapsules containing aqueous solution of polyelectrolyte is determined by the sign of electric charge on the encapsulated polyelectrolyte.

However, if a certain portion of encapsulated polyelectrolyte molecules is supposed to have been chemically incorporated into the microcapsule membrane during the microencapsulation to give the membrane an electric charge, the direction in which microcap-

1) M. Shiba, Y. Kawano, S. Tomioka, M. Koishi, and T. Kondo, *Kolloid-Z. Z. Polym.*, **249**, 1056 (1971).

sules move in an electric field does not necessarily reflect the sign of charge on the encapsulated polyelectrolyte. Thus, for example, polyphthalamide microcapsules containing aqueous solution of bovine serum albumin migrated to the anode even at a lower pH than that of the isoelectric point of the protein.[2] This was interpreted as follows: A portion of the encapsulated bovine serum albumin molecules participates in the interfacial polycondensation reaction between diamine and acid dichloride, giving the membrane a negative charge since the protein has many amino groups reactive with acid dichloride and the charge on the encapsulated, unreacted protein molecules is screened by the charge of outer surface of microcapsule membrane.

The present study is aimed at confirming the dependence of the net charge of aqueous microcapsules containing polyelectrolyte upon the surface charge of their membrane. Poly-L-lysine phthalamide microcapsules containing aqueous solution of polyelectrolytes were prepared and their electrophoretic mobilities were determined at various hydrogen ion concentrations. The aqueous carboxylated polyphthalamide microcapsules containing polyelectrolyte are superior to the above-mentioned polyphthalamide microcapsules containing aqueous solution of bovine serum albumin in that the charge can be safely assumed to be uniformly distributed in the membrane since it consists of a single component and a free choice of polyelectrolyte to be encapsulated can be made.

Experimental

Materials. The polyelectrolytes were sodium heparinate (Daiichi Chemical Medicine Ind. Co., Tokyo) and 2-methyl-5-vinylpyridine–methyl acrylate–methacrylic acid copolymer (abbreviated hereafter as MPM) (Tanabe Pharmaceutical Co., Ltd., Osaka). Polyvinylpyrrolidone (PVP) was also used as electrically neutral polymer to be encapsulated.

L-Lysine of the highest purity available (Ajinomoto Co., Ltd., Tokyo) was used.

Preparation of Microcapsules. Poly-L-lysine phthalamide (PLPA) microcapsules containing aqueous polyelectrolyte solution were prepared by the same procedure as in a previous work.[3]

Measurements of Electrophoretic Mobilities. Electrophoretic mobility measurements on the carboxylated polyphthalamide microcapsules containing polyelectrolyte solution were carried out at room temperature in a quartz flat microelectrophoretic cell. For each measurement 40 microcapsules were timed in each direction to eliminate the polarization effect of the electrodes. The dispersion media were HCl-CH_3COONa (pH 2—3), acetate (pH 3—6), and phosphate (pH 6—8) buffers, the ionic strength of which was maintained at 1×10^{-1} or 2×10^{-3} with NaCl.

The samples for electrophoretic measurement were prepared by pipetting a few drops of the microcapsule suspension into a large volume of the dispersion media.

In view of the size of microcapsules (about 3 μm in diameter) and the ionic strength of the dispersion media (2×10^{-3} and higher), mobilities were converted into zeta-potentials ζ by means of the simple Smoluchowski equation

$$\zeta = \frac{4\pi\eta v}{D}$$

where v is the mobility, η and D are the viscosity and dielectric constants, respectively, of dispersion medium.

Results and Discussion

In Fig. 1 is shown the variation of the zeta-potential with the pH of the medium for PLPA microcapsules containing aqueous solution of PVP and for those containing aqueous solution of sodium heparinate. The electrophoretic behavior of PLPA microcapsules con-

taining PVP was almost the same as that of those containing no polymer.[3] This is reasonable because PVP is electrically neutral and the zeta-potential of PLPA microcapsules is, therefore, determined solely by the charge of microcapsule membrane. In contrast, sodium heparinate seems to play an important role in determining the zeta-potential of PLPA microcapsules at low pH. Since the dissociation of carboxyl groups of PLPA should decrease with increasing hydrogen ion concentration, screening of the charge of the polyelectrolyte by the microcapsule membrane would be less significant with the lowering of pH of the medium. At high pH, the zeta-potential of PLPA microcapsules containing the polyelectrolyte was slightly less negative than that of those containing PVP. This may be due to the higher counter ion concentration near the membrane surface.

Figure 2 gives the plot of the zeta-potential against the pH of the medium for PLPA microcapsules containing aqueous solution of MPM, an amphionic polyelectrolyte having an isoelectric point at pH 4. The zeta-potential varied with both pH of the medium and the concentration of MPM. At low concentrations of MPM, PLPA microcapsules migrated to the anode independent of pH. When the microcapsules contained high concentrations of MPM, the direction in which they moved in an electric field reversed at low pH, while they still migrated towards the anode at high pH. This may result from the fact that some of MPM molecules are absorbed on the inner surface of microcapsule membrane to give it a positive charge which surpasses the negative charge of the outer membrane surface at low pH. We see from the figure that an increase in the concentration of MPM gives rise to a decrease in the absolute value of the zeta-potential of negatively charged PLPA microcapsules. The decrease in the zeta-potential may be caused by the increasing concentration of counter ions liberated from the encapsulated polyelectrolyte molecules.

ESR of Hot Ions: Ni(I) Complex Ions Produced in Ni(II) Complexes by γ-Irradiation

Chikara AMANO, Tokuko WATANABE, and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 6, 1972)

X- or γ-Irradiation has been shown to produce in solids metal ions with uncommon valence and geometrical configuration.[1-4] In this paper a report is given on the ESR spectra of monovalent nickel complex ions with the $3d^9$ electron configuration and a discussion on the electronic state of the Ni(I) complex ions in terms of observed g-values.

Forty-six Ni(II) complexes were synthesized by standard methods (Table 1).[5] Nickel(II) chloride hexahydrate, the starting material, was purified by an anion exchange method to remove a trace of cobaltous and cupric ions. The polycrystalline complexes ($\sim$100 mg) were γ-irradiated at room temperature with a γ-ray dosage of 1×10^7 R with dose rate of 5×10^5 R/h, and at 77 K with a γ-ray dosage of 1×10^6 R with dose rate of 5×10^4 R/h. ESR spectra were recorded at 77 K on a JEOL 3BSX spectrometer.

Of the forty-six complexes examined, nine gave strong signals upon γ-irradiation (Table 2). Other complexes gave only weak absorptions at $g\sim2$ probably due to radicals produced from ligand molecules.

γ-Irradiated $[Ni(en)(H_2O)_4]SO_4\cdot H_2O$, $[Ni(en)_2(H_2O)_2](ClO_4)_2$, $[Ni(l\text{-ala})_2(H_2O)_2]2H_2O$, and $[Ni(succinimde)_2(H_2O)_4]4H_2O$ give broad ESR absorptions (line width$\sim$100 G) of an approximately axial pattern. The other complexes in Table 2 shows several narrower absorptions. It is to be noted that in both these cases relatively large g-shifts ($\Delta g=0.2$—0.3) are observed, suggesting that the paramagnetic centers produced upon γ-irradiation are due to nickel ions. In the case of irradiated $[Ni(en)(H_2O)_4]SO_4\cdot H_2O$, $[Ni(en)_2(H_2O)_2](ClO_4)_2$ and $[Ni(l\text{-ala})_2(H_2O)_2]\text{-}2H_2O$, it is observed that $g_{\parallel}>g_{\perp}>2$, which is expected for a d^9 electron configuration with tetragonally elongated octahedral symmetry (ground state $^2B_{1g}$). According to ligand field theory a d^7 electron configuration in the ground state $^2B_{1g}$ is also consistent with this observation. However, as far as we know, complex ions

a) Ethyleneglycol: water=2 : 1 v/v. b) g-value for the most intense line.

with the d^7 electron configuration always give the relation $g_\perp > g_\parallel \sim 2$.[6-9] Therefore it may be concluded that in the above complexes, monovalent nickel complex ions are produced through reduction of Ni(II) complexes by γ-irradiation. On the other hand, in irradiated $[Ni(succinimide)_2(H_2O)_4]4H_2O$ we find $g_\perp > g_\parallel \sim 2$, which is expected for d^9 ions with tetragonally compressed octahedral symmetry (ground state $^2A_{1g}$).

Each of the remaining five complexes in Table 2 gives several absorptions which are most likely due to Ni(I) complex ions from their relatively large g-shifts, such shifts being due to heavy atoms, *i.e.* nickel ions in the present case. A preliminary investigation on a single crystal of $Na_2[Ni(CN)_4]3H_2O$ shows that the number of paramagnetic species is greater than that of inequivalent sites in the host crystal. In X-irradiated nickel(II) acetate tetrahydrate, Morton-Blake observed seven monovalent nickel complex ions with different g-values.[1]

It should be noted that for $[Ni(en)(H_2O)_4]^+$ and $[Ni(CN)_4]^{3-}$ g-values observed in the lattice of the host complexes are considerably larger than in rigid solutions (Table 2). This suggests that the structure of the Ni(I) complex ions is different in these two matrices. The yield of the Ni(I) species produced by γ-irradiation is strongly dependent on the counter ions and crystal structure of the complexes. ESR spectra of Ni(I) can be observed in irradiated $[Ni(en)(H_2O)_4]SO_4\cdot H_2O$ and $[Ni(en)_2(H_2O)_2](ClO_4)_2$, but not in $[Ni(en)(H_2O)_4](NO_3)_2$ and $[Ni(en)_2(H_2O)_2](NO_3)_2$. In the latter two complexes the yield of paramagnetic species, if exist at all, should be lower at least by two orders of magnitude.

We would like to thank Mr. Shingo Katsura, γ-ray Irradiation Center, for his assistance, and also Dr. Yoji Arata for helpful discussions and remarks in the preparation of this paper.

The Structure of Ordered β V_2D as Determined by Means of the Deuteron Magnetic Resonance

Keikichi NAKAMURA

National Research Institute for Metals, Nakameguro, Meguro-ku, Tokyo 153

(Received December 26, 1972)

According to the V–D phase diagram,[1,2] there are three types of ordered phases: β V_2D, $\delta(\alpha'')$, and $\gamma(\alpha''')$ V_4D_3. The β form is body-centered tetragonal, with $c_0/a_0 \simeq 1.1$, and it is stable up to +140 °C. The δ and γ forms are pseudocubic and stable from −60 to −120 and below −120 °C respectively.

We have measured the deuteron magnetic resonance of the V–D system over wide ranges of the deuterium concentration and the temperature. The results confirm the published V–D phase diagram.[1,2] The deuteron quadrupole coupling constants have been measured as 68.6±1.2 KHz (R.T.) for β V_2D and 37.5±0.4 KHz (−130 °C) for γ V_3D_4. The asymmetry parameters were approximately zero for both forms. These values agree well with the recent NMR results.[3] The observed deuteron quadrupole coupling constants and the asymmetry parameter of δ, γ V_4D_3 are approximetely the same as those for β Nb_4D_3. In view of this fact and the similarity of neutron diffraction pattern between γ V_4D_3 and β Nb_4D_3,[4] it may be assumed that the deuteriums in γ V_4D_3 occupy tetrahedral intersticies such as those in the β Nb_4D_3.

The deuteron quadrupole coupling constant of β V_2D is roughly twice those of γ V_4D_3, β Nb_4D_3,[5] and β Ta_2D[6,7]. The c_0/a_0 ratio of β V_2D is about 1.1, which is different from the pseudocubic character of the other forms, — e.g., 1.008 for Ta_2D. In spite of the relatively large lattice expansion along the c axis, the asymmetry parameter is approximately zero. This is comparable to that of β Ta_2D ($\eta \simeq 0.24$).[6,7] These considerations clearly indicate the site of deuterium in β V_2D. Firstly, the EFG of the site must be symmetry with respect to the c axis. Secondly, the deuterium must repel the two nearest-neighboring vanadium atoms along the c axis so as to deform the cubic cell to tetragonal. Thirdly, the V–D distance in this form must be shorter than that in γ V_4D_3. The only possible site which satisfies the above three conditions is the octahedral site (o-site), whose EFG is symmetric with respect to the c axis.

Next, let us determine the ordered deuterium arrangement in β V_2D. Consider that there are n deuterium atoms and $6n$ o-sites in a ordered V_2D unit cell. However, it is necessary to consider only $2n$ o-sites because of their symmetry with respect to the c axis. Thus, the problem can be reduced to a manner of selecting n o-sites from $2n$ o-sites.

Consider a linear array of vanadium atoms with a spacing of c_0 along the c axis. The o-sites are at the middle of the V–V axis, standing in a line with the same spacing of vanadium:

-V-O-V-O-V-O-V-O-V-O-V-O-V-O-V-

If a deuterium atom occupies an o-site, it would displace the two nearest-neighboring vanadium atoms by $\pm z$. Consequently, it becames geometrically difficult for deuterium to occupy the two nearest-neighboring o-sites and the array of deuterium atoms will be:

-V-D-V-E-V-D-V-E-V-D-V-E-V-D-V-E-V-D-V-E-V-

where E means that the site is empty. A translation of the above one-dimensional lattice points by $\pm 1/2$ 1/2 1/2 determine the array of atoms on the next side. Thus, we obtain a three-dimensional arrangement of deuterium, as is shown in Fig. 1. This structure is

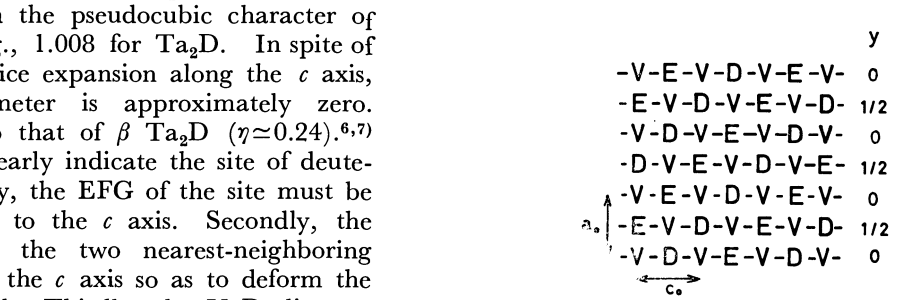

Fig. 1. Three-dimensional arrangement of β V_2D, a projection onto (010) plane.

consistent with the results of a recent neutron diffraction study[8] except for the existence of a small proportion of tetrahedral occupation in that study.

It should be noted that there are $4n$ tetrahedral sites (t-sites) whose EFG is symmetric with respect to the c axis. Therefore, the occupation of these t-sites by deuterium may not be negligible. However, at high temperatures, this effect does not change the principal axis directions and the asymmetry parameter of the EFG, but changes only the principal value of the EFG.

Table 1.

$K\times10^{-8}$ cm	$\lvert(eq)_{tet}\rvert/\lvert(eq)_{oct}\rvert$
1.8	0.412
1.5	0.449
1.0	0.511

Thus, from the temperature dependence of the deuteron quadrupole coupling constant, we can, in principle, determine the proportion of the *t*-occupation of the deuterium. It has been shown that about 5% of deuterium atoms are in the *t*-sites.[8] Since the sign of the EFG of the *t*-site is the reverse that of the *o*-site, the following simple relation may be hold:

$$[(e^2qQ/h)^{\beta}_{oct}\times0.95]-[(e^2qQ/h)^{\beta}_{tet}\times0.05]=(e^2qQ/h)_{\beta}=68.6\text{ KHz (R.T.)}$$

where $(e^2qQ/h)^{\beta}_{oct}$ and $(e^2qQ/h)^{\beta}_{oct}$ are the quadrupole coupling constants for the *o*- and *t*-sites of the tetragonal β V_2D respectively. With the $(e^2qQ/h)^{\beta}_{tet}\simeq(e^2qQ/h)_T=37.5$ KHz approximation, $(e^2qQ/h)^{\beta}_{tet}$ is calculated to be 74.2 KHz, larger by about 10.8% than the observed value.

It is of interest to compare the experimental quadrupole coupling constant ratio $(e^2qQ/h)_T/(e^2qQ/h)^{\beta}_{oct}\simeq0.5$ with that calculated from the simple electrostatic model used in the previous paper.[7] With a_0 3.00 Å and c_0 3.1 Å for β V_2D (*o*-site) and with $a_0=3.16$ Å for γ V_4D_3 (*t*-site), the calculated ratio for three values of the screening constant is shown in Table 1. A comparison of the values in the table with the experimental one shows that $K=1.1\times10^8$ cm^{-1} is suitable in this case. However, it has elsewhere been shown[7] that a value of $K=1.8\times10^8$ cm^{-1} is most suitable for the Ta-D system if the charge on the Ta ion is 5. Thus, the discrepancy in the K value seems to indicate the limit of the application of the electrostatic model to the high-concentration interstitial systems.

The author wishes to express his deep gratitude to professor Shizuo Fujiwara and Dr. Ichiro Morimoto for their helpful advice and encouragement.

Model Complexes of Catalyzers for Asymmetric Hydrogenation. I. Crystal Structure of β-Cyanoethyl(D(−)-*erythro*-1,2-diphenyl-2-hydroxyethylamine)bis(dimethylglyoximato)cobalt

Yuji OHASHI, Yoshio SASADA, Yasuhisa TASHIRO, Yoshiaki OHGO, Seiji TAKEUCHI, and Juji YOSHIMURA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 28, 1972)

It has recently been shown that the complexes of bis(dimethylglyoximato)cobalt(II) and optically active amine (abbreviated to $Co(DMG)_2$-amine) catalyze asymmetric hydrogenation of olefins, α-diketones and α-keto carboxylic esters.[1-5] Optical yields vary with the amine and solvent. From chemical consideration and CD and NMR spectra, these complexes seem to have a structure[5] as shown in Fig. 1. The $Co(DMG)_2$ plane is twisted by hydrogen bonding between one of the oxygen atoms of DMG and the hydroxyl group of amine. The direction of this twist is determined by the absolute configuration of the optically active amine. Asymmetry around the cobalt atom caused by the twisted plane is transferred to the products at a certain stage of catalytic reaction. The present work has been undertaken to examine this hypothesis and to give a structural explanation to the mechanism of asymmetric hydrogenation.

The crystal structure of the title compound $C_{25}H_{33}N_6O_5Co$ was determined by X-ray method. Crystal data; $M=556.51$, monoclinic with $a=13.31$, $b=8.84$, $c=23.90$ Å, $\beta=108.0°$, $V=2673.2$ Å^3, $Z=4$. The density calculated is 1.37 g/cm^3, while that measured by flotation is 1.38 g/cm^3. Systematic absence of reflections is $0k0$ for $k=2n+1$, the space group being $P2_1$. The molecular arrangement, however, seems to have an approximate $P2_1/c$ symmetry because $h0l$ reflections are very weak for $l=2n+1$. A total of 2127 independent reflections were collected on Weissenberg photographs using Cu$K\alpha$ radiation. Intensities were measured visually. Correction for Lorentz and polarization factors was applied as usual but not that for absorption.

4) Y. Ohgo, Y. Natori, and J. Yoshimura, Presented at the 26th Annual Meeting of Chemical Society of Japan, April, 1972. Preprints p. 1010.

5) S. Takeuchi, Thesis, Tokyo Institute of Technology (1972).

At first an approximate $P2_1/c$ symmetry was tentatively assumed. Atomic positions were easily obtained by the heavy atom method and refined by block-diagonal least-squares. After three cycles of the least-squares, an electron density was calculated, where the peaks for the amine were broader and lower than those of the others. This suggests that in the two crystallographically independent complexes the β-cyanoethyl and the $Co(DMG)_2$ groups are related almost strictly by a c-glide plane, but not the amine ligands. Thus a trial structure based on $P2_1$ was constructed, in which the atomic parameters of the former two groups were taken from the refinement based on $P2_1/c$, those of the optically active amine being obtained by resolving the average structure. Further refinement was carried out by block-diagonal least-squares. Anisotropic temperature factors were taken into account for the cobalt atom and all other atoms were constrained to isotropic motion. The final R factor was 0.14. The estimated standard deviations of bond distances and angles are 0.02—0.04 Å and 2—3°, respectively.

Structures of two crystallographically independent complexes are identical to each other within standard deviations. Figure 2 shows one of these complexes

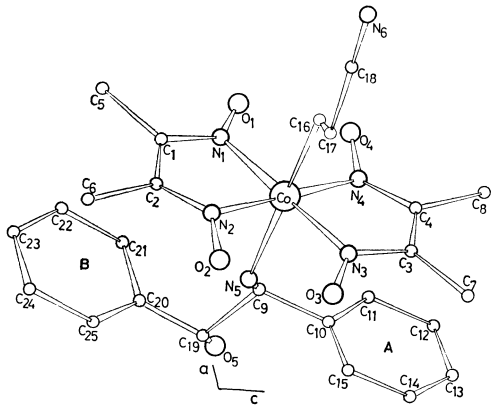

Fig. 2.

projected along the b axis. The $Co(DMG)_2$ groups are planar within standard deviations except for the methyl groups. Two methyl groups above the two benzene rings are slightly shifted upward to avoid short contact with the benzene rings. Figure 3 shows the complex viewed along N(1)—N(2). The plane of $Co(DMG)_2$ except the methyl groups makes angles of 13° and 15° with the benzene ring A and B, respectively. The distances from the centers of the rings to the $Co(DMG)_2$ plane are 3.59 Å for A and 3.91 Å for B. The average Co–N distance and N–Co–N

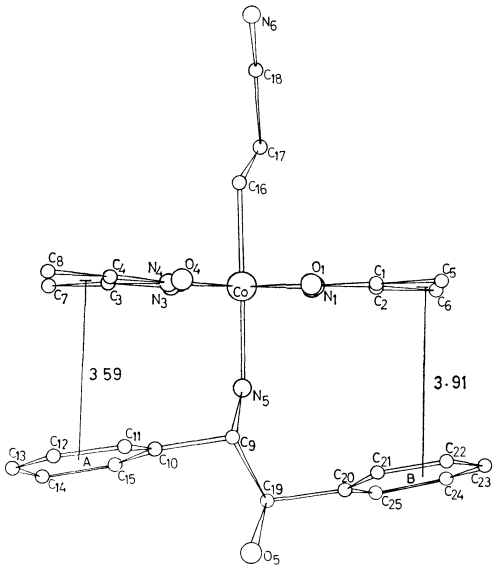

Fig. 3.

angle for the equatorial ligands are 1.89 Å and 82°, respectively. The axial Co–N distance is 2.08 Å and the Co–C distance is 2.04 Å. These distances and angles are close to those of alkyl cobaloxime.[6] The axial Co–N and Co–C bonds make angles of 84° and 85° with the $Co(DMG)_2$ plane, respectively. The other distances and angles also agree with the values published.

As to the conformation of amine, O(5) and N(5) atoms are *trans* as shown in Fig. 3. Thus contrary to expectation, there is no hydrogen bonding between the oxygen atom of DMG and the hydroxyl group of amine. The hydroxyl group does not make any hydrogen bonding with neighbouring complexes.

Any distance between non-bonded atoms, within the complex and between neighbouring ones, is not abnormally shorter than the usual van der Waals contact.

The structure of the complex obtained here is different from the assumed structure shown in Fig. 1. However, it does not seem that the mechanism of asymmetric induction could be revealed with the present structure, since the asymmetry of amine would have no effect on active site of the cobalt atom. An alternative explanation might be as follows. The complex coordinated by the amine of *gauche* conformation probably exists in solution, which might catalyze asymmetric hydrogenation.

ESR and Optical Spectra of Ion Radicals of Some Triptycene Derivatives

Fumio TANAKA and Noboru MATAGA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received December 28, 1972)

It is important to study the delocalization interactions between the groups when a molecule contains two or more π-electronic groups separated by saturated chemical bonds. The mechanisms of CT (charge transfer) complex formation and of electron transfer reaction are cases closely connected with this problem. Hillier and Rice[1] studied theoretically the electronic state of *para*-cyclophane anion radicals and predicted appearance of a charge resonance band at 9000 cm^{-1} when the distance between the two molecular plane is *ca.* 3A. Ishitani and Nagakura[2] measured the optical and ESR spectra of 2,2'-*para*-cyclophane anion and showed that the absorption band at 760 nm could be interpreted as a charge resonance spectrum. If the two π-electronic systems are different, it might be possible, by means of ESR and optical measurements of the ion radicals, to examine directly the extent of the charge transfer in the ground state and the appearance of the CT band for a definite separation between the π-electronic groups. We have conducted such studies for 1,4-quinone triptycene anion (I) and dimethoxytriptycene cation (II).

Synthesized and purified samples of triptycene derivatives (supplied by Dr. F. Ogura of this University) were used without further purification. I was produced by reduction of corresponding molecule with metallic potassium in THF or DME solution. II was prepared by dissolving the molecule in concd sulfuric acid.

Optical absorption spectra were measured with Cary 14 and Cary 15 spectrophotometers. The ESR spectra were recorded with a JES-3BX spectrometer using X-band.

The absorption spectra of I in DME were almost the same as those of *p*-benzoquinone anion radical in the same solvent. No new absorption band which might be attributed to the interaction between the *p*-benzoquinone group and other parts of I was found in the spectra of I. We come across quite similar circumstances in the case of II, *viz.* absorption bands which correspond to the 437 nm and 282 nm bands of 1,4-dimethoxybenzene cation radical can be observed, but none due to the interaction between the dimethoxybenzene cation group and the other groups. Thus, the excess electron in I and the positive hole in II seem to be fairly well localized at quinone and dimethoxybenzene groups, respectively.

The same conclusion has been reached also from the ESR measurements. The ESR spectra of both I and II show no hfs due to the delocalization interaction between the component groups, *viz.*, the spectra of I shows the hfs due to the two protons in the quinone group, and the hfs constants of II are very close to the corresponding ones[3] of *cis*-form 1,4-dimethoxybenzene cation radical. In the case of free 1,4-dimethoxybenzene cation radical, both *cis*- and *trans*-isomers can exist in solution.[3] However, the 1,4-dimethoxybenzene group in II take only the *cis*-form owing to the barrier due to the bridge-head proton.

The fact that there are no significant intramolecular delocalization effects in the case of the above ion radicals may be of some interest from the viewpoint of the electronic structures of ions and molecular complexes in solution. According to recent experimental and theoretical studies,[4] it has become clear that the electronic structure of many TCNB (1,2,4,5-tetracyanobenzene) complexes with various aromatic hydrocarbons in the S_1 state can be considered to be a contact ion-pair with no significant delocalization interaction between the component TCNB anion and hydrocarbon cation. In the case of the TCNB complex in the S_1 state, quantum chemical calculations indicate clearly that it has a symmetrical overlapping structure where the intermolecular overlap integral is very small and the ion-pair structure may be stabilized strongly by solvation.[4] The intermolecular overlap integrals between the constituent groups of I and II may be rather small in view of their geometrical structure. On the other hand, the delocalization interaction between two identical aromatic groups is sufficiently strong for the "fast transfer" of the excess electron to occur when they are separated by one or two methylene groups.[5,6] In the case of I and II, we are concerned with the charge transfer between different groups, where the trapping of the excess electron or the positive hole at one group occurs very easily. The trapping may be facilitated by strong solvation of the ion radical groups.

The Catalytic Oxidation of Hydrogen on Zirconium Dioxide

Takuya HAMAMURA, Yoshito ONISHI, and Yasuo IIZUKA*

Department of Chemistry, Faculty of Industrial Arts, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606

(Received January 24, 1972)

The previous paper was concerned with the catalytic oxidation of carbon monoxide on zirconium dioxide.[1] The experimental results were there compared with those for anatase and rutile[2~5] in order to examine the correlation between zirconium dioxide and titanium dioxide with respect to their catalytic actions. It was found that the reaction mechanism could be explained in entirely the same manner as that on titanium dioxide.

The oxidation mechanism of hydrogen on titanium dioxide was extremely analogous to that of carbon monoxide,[4] and titanium and zirconium belong to the same group in the periodic table. Therefore, the oxidation mechanism of hydrogen on zirconium dioxide can also be expected to be similar to that of carbon monoxide.

Experimental

Two kinds of samples of ZrO_2-1 (3.8 m^2/g) and ZrO_2-2 (1.0 m^2/g) used in the previous experiment were again employed.[1] The apparatus, procedure, and method of pretreatment of the catalysts used were essentially the same as before.[2] The reaction rate was measured by using a mixed gas with a composition of $H_2/O_2=2/1$ in the temperature range of 450—600 °C and under pressures of 10^{-1}—10^{-3} mmHg.

Results and Discussion

The oxidation rate of hydrogen on zirconium dioxide was nearly of the first order with respect to P_{H_2} and was independent of P_{O_2}. Consequently, the reaction rate can be expressed by the following equation:

$$d(H_2O)/dt = k \cdot P_{H_2} \quad (1)$$

where k is a constant. The Arrhenius plots of k on ZrO_2-1 and -2 are given in Fig. 1, together with those on anatase and rutile.[4] The ZrO_2-1 and -2 show almost the same values in their catalytic activities. The activation energy of zirconium dioxide is the value of 22.6 kcal/mol, intermediate between anatase, 29.2 kcal/mol, and rutile, 17.8 kcal/mol.

When instead of a mixture of H_2 and O_2, hydrogen, at a pressure of about 10^{-2} mmHg, was introduced into the reaction system, it reacted with the surface oxygen of the catalyst and the water vapor thus formed was caught in the trap. The rate of the formation of water was found to be proportional to P_{H_2}:

$$d(H_2O)/dt = k_{H_2} \cdot P_{H_2} \quad (2)$$

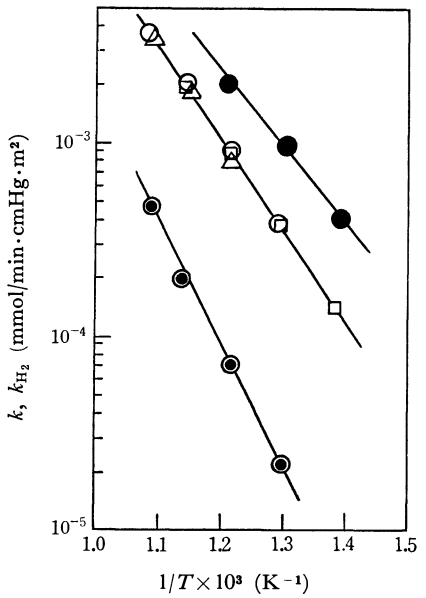

Fig. 1. Effect of temperature on the reaction rate constant.
□: ZrO_2-1 ○: ZrO_2-2 ◉: Anatase ●: Rutile

where k_{H_2} is the reduction rate constant of zirconium dioxide by hydrogen. The Arrhenius plots of k_{H_2} on ZrO_2-1 are shown in Fig. 1 by the mark △. It is obvious that k_{H_2} agrees with k. It was reported in the preceding paper that the oxygen-uptake rate of the reduced zirconium dioxide was much faster than the reduction rate of zirconium dioxide.[1]

From all these results, the mechanism of the oxidation of hydrogen on zirconium dioxide can be expressed as follows. The reaction consists of the following two steps;

$$H_2(g) + O(s) \xrightarrow{A} H_2O(g) + (s) \quad (3)$$

$$(s) + 1/2\,O_2(g) \longrightarrow O(s) \quad (4)$$

where O(s) refers to the surface oxygen of the catalyst and (s) the oxygen defect on the surface. Step (4) is much faster than Step (3), so the overall reaction rate is proportional to P_{H_2}. This reaction mechanism is extremely analogous to that of the oxidation of carbon monoxide.

The activation energies of the oxidations of carbon monoxide and hydrogen on anatase, rutile, and zir-

Table 1. Activation energies for the oxidations of CO and H_2 and those for the thermal desorption of surface oxygen from the catalysts (kcal/mol)

Catalysts	Oxidation of CO	Oxidation of H_2	Thermal desorption of surface oxygen
Anatase	16.0	29.2	57.8
Rutile	6.7	17.8	38.4
ZrO_2	12.5	22.6	44.0

conium dioxide are summarized in Table 1, together with the activation energies of the thermal desorption of the surface oxygen from these three catalysts.[1,2,4,5] The values of activation energies in each column of Table 1 decrease in this order: anatase, zirconium dioxide, and rutile. These facts suggest that the activation energies of the two oxidation reactions are connected with the bond strength between the surface oxygen and the catalyst surface.

Elimination Reactions of Propylene Chlorohydrins over Solid Acids

Yasuhide ANJU, Isao MOCHIDA*, Akio KATO, and Tetsuro SEIYAMA
Department of Applied Chemistry, Faculty of Engineering, Kyushu University, Fukuoka 812
(Received August 31, 1972)

In a previous paper, the elimination reactions of ethylene chlorohydrins over solid acids, solid bases, and metals supported by silica gel were investigated and the reaction mechanism was discussed.[1] In the present paper, the elimination reactions of propylene chlorohydrins over solid acids are studied in order to elucidate the effect of the methyl group on the reactivities and in order to examine the validity of the mechanism proposed for the reaction of ethylene chlorohydrin.

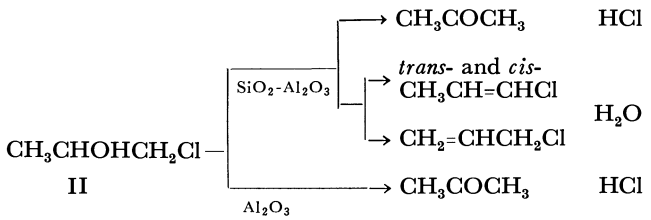
Experimental

Silica–alumina and alumina were described in a previous paper.[2] 2-Chloro-1-propanol(I) and 1-chloro-2-propanol (II) were separated from commercial 1-chloro-2-propanol (Tokyo Kasei Co., E. P. grade; *ca.* 20% 2-chloro-1-propanol) by gas chromatography with a PEG column. The reaction rates were measured by the microcatalytic gas-chromatographic technique at 300°.[1-3] Hydrogen gas was used as the carrier. TCP (4 m, 60°) and Tween 80 (2 m, 80°) were used in a column in the reaction of 1-chloro-2-propanol and 2-chloro-1-propanol respectively. The conversions were reproduced from a pulse to a pulse, indicating that the elimination reactions of propylene chlorohydrins over the solid acid were catalytic.

Results and Discussion

The Reactivities of Propylene Chlorohydrins. The elimination reactions of propylene chlorohydrins on silica–alumina and alumina are summarized as follows:

Reactant	Catalyst	Product	Eliminated group
$CH_3CHClCH_2OH$ (I)	SiO_2-Al_2O_3	CH_3CH_2CHO	HCl
		CH_2=$CHCH_2OH$	
	Al_2O_3	CH_3CH_2CHO	HCl
		CH_2=$CHCH_2OH$	



where allyl alcohol was not detected. The reaction rates are shown in Table 1, together with the elimination rates of some related reactants for the sake of comparison.[1,3] The dehydrochlorination reactivities of these reagents on both catalysts are summarized as follows:

$$\underset{\text{Cl OH}}{\text{CH}_3\text{CH–CH}_2} \gg \underset{\text{OH Cl}}{\text{CH}_3\text{CH–CH}_2} \simeq \underset{\text{OH Cl}}{\text{CH}_2\text{–CH}_2} \gg \underset{\text{Cl Cl}}{\text{CH}_3\text{CH–CH}_2}$$

(primary-chlorine elimination)

The dehydration reactivities on silica–alumina were:

$$\underset{\text{OH Cl}}{\text{CH}_3\text{CH–CH}_2} \gg \underset{\text{Cl OH}}{\text{CH}_3\text{CHCH}_2} \simeq \underset{\text{Cl OH}}{\text{CH}_2\text{–CH}_2}$$

It should be noted that alumina did not show any dehydration activity for 1-chloro-2-propanol(II). Over silica–alumina, the dehydrochlorination of 1,2-dichloropropane gave the same reaction products as the dehydration of 1-chloro-2-propanol(II). The product distributions of the two reactants are compared in Table 2, where the same tendency is observed on silica–alumina.

The Reaction Mechanism. 1) *Silica–Alumina*: The authors have proposed a carbonium-ion mechanism for the dehydrochlorination of ethylene chlorohydrin on silica–alumina in a previous paper:[1]

$$\text{CH}_2\text{OHCH}_2\text{Cl} \xrightarrow{-\text{Cl}^-} \text{CH}_2\text{OHCH}_2^+ \xrightarrow{-\text{H}^+} \text{CHOH=CH}_2 \longrightarrow \text{CH}_3\text{CHO}$$

CH_2ClCH_2OH[a]	1100	0	3300	0
$CH_3CHClCH_2Cl$[b]				
→ $CH_3CH{=}CHCl$ / $CH_2{=}CHCH_2Cl$	950	—	220	—
→ $CH_3CCl{=}CH_2$	0	—	30	—
$CH_3CHOHCH_2OH$	—	0	—	1
CH_2ClCH_2Cl[a]	3.2	—	14.2	—

a) Ref. 1. b) Ref. 3.

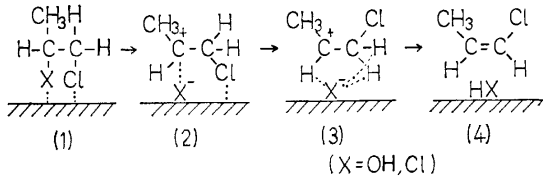
Table 2. The product distribution of the reaction:

$$CH_3CHXCH_2Cl \begin{cases} \nearrow CH_3CH{=}CHCl + HX & (X=Cl \text{ or } OH) \\ \searrow CH_2{=}CHCH_2Cl + HX & (X=Cl \text{ or } OH) \end{cases}$$

Catalyst	Ratio: Allyl chloride / 1-Chloropropylene (X=OH)	Allyl chloride / 1-Chloropropylene (X=OH)	*trans*-1-Chloropropylene / *cis*-1-Chloropropylene (X=OH)	*trans*-1-Chloropropylene / *cis*-1-Chloropropylene (X=Cl)
Silica-alumina	1.10	0.61	0.25	0.14
Alumina	—	0.18	—	0.024

where the carbonium-ion formation may be the rate-determining step. The reactivity order above shown can be understood in terms of the stability order of carbonium-ion intermadiates: $CH_3\overset{+}{C}HCH_2OH \gg \overset{+}{C}H_2CHOHCH_3 \simeq \overset{+}{C}H_2CH_2OH > \overset{+}{C}H_2CHClCH_3$ and $CH_3\overset{+}{C}HCH_2Cl \gg CH_3CH_2Cl\overset{+}{C}H_2 \simeq CH_2Cl\overset{+}{C}H_2$. The lack of any dehydration reaction of 2-chloro-1-propanol(I) on silica–alumina may also be understood by this mechanism. To understand the two series of reactivity orders, $CH_3CHClCH_2OH > CH_3CHCl$-$CH_2Cl$ (the secondary chlorine elimination) and CH_3-$CHOHCH_2Cl \gg CH_3CHClCH_2Cl$ (the primary chlorine elimination) which are due to the effects of the β-substituent, the strong adsorption ability of the hydroxyl group onto the solid acid may have to be taken into account in addition to the stability of the carbonium ion as has been described in the previous paper.[1]

The product distributions can also be understood by the carbonium-ion mechanism as follows. It may be natural that the product distributions in the dehydration of 1-chloro-2-propanol(II) and the dehydrochlorination of 1,2-dichloropropane are similar for the same carbonium ion ($CH_3\overset{+}{C}HCH_2Cl$) can be assumed as the intermediate for both reactions. Taking into account the steric hindrace as indicated by Tominaga *et al.*,[4] and the nonstereospecificity of the carbonium-ion mechanism in the dehydrohalogenation on solid acids,[5] the highly preferential formation of *cis*-1-chloropropylene may be explained by the interaction between the eliminating anion and proton to be abstracted;



The chlorine atom and the hydroxyl group may interact with surface acid sites at the initial stage (1), and then the carbonium ion may be formed by the abstraction of the hydroxyl group (2) because dehydration is now considered. The abstracted anion may interact with the hydrogen to be eliminated, resulting in methyl and Cl groups in a *cis*-position to each other (3). The subsequent cleavage of β-hydrogen results in the *cis*-olefin.

Alumina: The facts that no dehydration of 1-chloro-2-propanol occurred on alumina in spite of the secondary position of the hydroxyl group and that alumina had a greater activity for the dehydrochlorinations of halohydrins than silica–alumina indicate the characteristics of alumina as a catalyst. The former fact can not be explained by the carbonium-ion mechanism. We assume that the elimination reaction on alumina proceeds through a concerted mechanism.[2,6] It has been reported that the chlorine atom is more easily removed than the hydroxyl group in the S_N2 reaction.[7] The higher reactivity of chlorine may be true if the C–X bond still exists in the intermediate. This mechanism corresponds to the concerted one in the elimination reaction. The higher dehydrochlorination activity of alumina may be partly due to this mechanism.

The Crystal Structure of Rb(TCNQ)-II

Ichimin SHIROTANI and Hayao KOBAYASHI*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

**Department of Chemistry, Faculty of Science, Toho University, Narashino, Chiba 275*

(Received January 24, 1973)

X-Ray studies of several TCNQ salts have revealed that the planar TCNQ molecules are stacked face-to-face to form columns in most of these crystal structures. The infinite columns hitherto reported consist of tetradic, triadic, diadic, and monadic units of TCNQ molecules.[1-6]

Rb(TCNQ) is polymorphic at room temperature.[7,8] The crystals of Rb(TCNQ)-I are monoclinic. The $TCNQ^-$ radical ions form columns contructed from diadic units of $TCNQ^-$. The crystal structure of Rb(TCNQ)-II will be reported in this paper.

Experimental

The dark purple crystal of Rb(TCNQ)-II was kindly supplied by Sakai. The cell dimensions were determined from Weissenberg photographs. The shape of the crystal used for the collection of the intensity data was approximate parallelepiped, with a maximum dimension of 0.3 mm. Equi-inclination Weissenberg photographs were taken around the c axis up to the third layer with Cu$K\alpha$ radiation ($\lambda=1.5418$ Å); the multiple film technique was used. In all, 811 reflections were observed. The intensities were estimated visually by comparison with a standard film strip and were converted to $|F(hkl)|$ by applying the usual Lorentz, polarization, and shape corrections.

The crystal data of Rb(TCNQ)-II are: $Rb^+(C_{12}H_4N_4)^-$, F.W. 290, triclinic, $a=9.914\pm0.001$, $b=7.196\pm0.003$, $c=3.390\pm0.002$ Å, $\alpha=92.70\pm0.10$, $\beta=86.22\pm0.11$, $\gamma=97.73\pm0.07$, $v=275.20$Å^3, $D_x=1.757$, $Z=1$, space group $P\bar{1}$, $F(000)=137$

Determination of the Structure and Discussion

The space group $P\bar{1}$ was assumed tentatively and was then indeed verified at a later stage of the refinement. The trial structure was readily deduced from the three-dimensional Patterson synthesis. The atomic parameters were refined anisotropically by the block-diagonal least-squares method. The calculated positions of all the hydrogen atoms were included. The weighting scheme adopted was; $w=1$ for $F>3.5$ and $w=0.2$ for $F<3.5$. The final R value was 0.130.

The final positional and thermal prameters are given

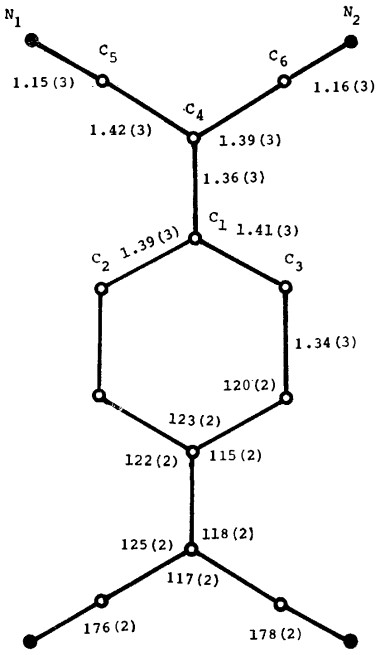

Fig. 3. Bond lengths (Å) and angles (°) with their standard deviations (in parenthses).

in Table 1. The observed and calculated structure factors are given in Table 2.[9] The structure within one unit cell is shown in Figs. la and 1b as viewed along the c axis and the b axis respectively. $TCNQ^-$ ions are stacked in a plane-to-plane manner and form columns of monadic units. This columnar structure is very similar to those found in the crystals of *N*-methylphenazinium(TCNQ).[1] The inter-planar spacing of TCNQ is 3.43 Å. The mode of overlapping is illustrated in Fig. 2. This type of overlapping has been observed in various TCNQ salts.[1-6] The bond lengths and angles of the $TCNQ^-$ are shown in Fig. 3. These values show that the $TCNQ^-$ ion has a quinoid character. It is known that crystals of Rb-(TCNQ)-I have monoclinic symmetry and that $TCNQ^-$ ions are stacked face-to-face to form columns of diadic units of $TCNQ^-$. Within a column, two different intermolecular spacings, 3.159 and 3.484 Å, appear alternately.[10]

Table 3. The pysical properties of both Rb(TCNQ)

	Rb(TCNQ)-II	Rb(TCNQ)-I
Electrical resistivity Ω cm (R. T.)	10^2	10^5
Activation energy eV	0.16∼0.19	0.53∼0.41 below the transition point 0.37∼0.28 above the transition point
Transition temperature K	230	374
The electrical anomalies at high pressure Kbar	unobservable	1, 3.5
Absorption peaks cm^{-1}	6250 16250, 26380	8500 15750, 26500

The physical properties of both Rb(TCNQ) substances are summarized in Table 3.[7] The resistivity of Rb(TCNQ)-I is about 10^3 times that of Rb(TCNQ)-II. The near-infrared absorption band of salt-II, which is due to the inter-radical charge transfer in the crystal, shifted toward a longer length than that of salt-I. The difference in the physical properties may arise from the difference in the columnar structures.

The authors are grateful to professor Saito for his interest in this study and his kind advice. They are also indebted to Dr. Sakai for kindly supplying the crystals of Rb(TCNQ).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2597—2598 (1973)

Polymerization of Methyl Methacrylate with the Chlorocarbonylbis-(triphenylphosphine)rhodium(I)-Organic Halides System[1)]

Noriyuki KAMEDA and Noriko ITAGAKI

Department of Chemistry, Faculty of Science and Engineering, Nihon University, Narashinodai, Funabashi, Chiba 275

(Received May 8, 1972)

Recently it has been reported that zero-valent transition-metal complexes conjugated with organic halides act as effective radical initiators of methyl methacrylate (MMA).[2,3)] Bamford and his co-workers[2)] found that metal carbonyls in the presence of organic halides can initiate the free-radical polymerization of MMA and that the polymers thus obtained are more stereospecific than those obtained in the usual free-radical polymerization. In this case, the valency, state of metal appears to play an important role in the free-radical initiation of MMA.

In a previous paper,[4)] we reported that some low-valent metal complex, *trans*-$PtHCl\{P(C_2H_5)_3\}_2$ (Pt complex) and the alkyl halide system can serve as radical initiators of MMA and styrene. Chlorocarbonylbis(triphenylphosphine)rhodium(I) (Rh complex) has been known as hydrogenation catalysts of ethylene and acetylene,[5)] and in the presence of organic halides they may serve much like the Pt complex in initiating the polymerization of MMA.

This paper will describe the results of the polymerization of MMA with a system composed of the Rh complex and organic halides, and also the results of kinetic studies of the polymerization with the system composed of the Rh complex and carbon tetrachloride.

Experimental

Methyl methacrylate (MMA) was purified by an ordinary method and was stored in a refrigerator until use.

The organic halides were purified by distillation or recrystallization.

Chlorocarbonylbis(triphenylphosphine)rhodium (I) (Rh complex) was synthesized according to the method in the literature[6)] and then purified by recrystallization from a benzene solution. It had an mp of 194—196 °C (lit,[6)] 195—197 °C).

The other reagents were purified by ordinary methods.

The polymerization was carried out in a sealed glass tube (30 ml) containing a given amount of the Rh complex (18 mg) dissolved in benzene (5 ml); MMA (5 ml) and the required amount of organic halides (solution=3 ml; solid=3 g) were placed in it, and then the air in the tube was replaced with nitrogen before sealing. Polymerization was carried out in a tube in a thermostat maintained at a given temperature. After polymerization, the contents of the tube were poured into a large amount of methanol in order to precipitate the polymer. The conversion was calculated from the weight of the dried polymer thus obtained.

The number-average molecular weight ($\bar{M}_n$) of the resulting polymers was calculated from the intrinsic viscosity, [η], in chloroform at 25 °C according to the following equation[7)]:

$$[\eta] = 3.4 \times 10^{-5}\bar{M}_n^{0.83}.$$

The rate of polymerization (R_p) was measured by the dilatometric method, using a dilatometer with a capacity of 10 ml as the reaction vessel. The Rh complex was weighed and placed in the reaction vessel, and then benzene was added. After the Rh complex had been solved, the atmosphere of the apparatus was replaced with nitrogen and the reaction vessel was filled with a known amount of MMA and carbon tetrachloride. The dilatometer was placed in a constant-temperature bath, and the rate of contraction in volume was followed up by the use of a cathetometer.

Results and Discussion

Effect of Organic Halides. The results of the polymerization of MMA with the Rh complex in the presence of various kinds of organic halides (carbon tetrachloride, carbon tetrabromide, chloroform, bromoform, iodoform, methylene chloride, hexachloroethane, chlorobenzene, and benzyl chloride) at 60 °C for 7 hr. The initiating activity of the halides was shown only by carbon tetrachloride and carbon tetrabromide, the polymer yields of which were 30.8% ($\bar{M}_n=6.4\times10^4$) and 9.0% ($\bar{M}_n=2.6\times10^4$) respectively. The nuclear magnetic resonance spectra of poly(methyl methacrylate) obtained with these initi-

ator systems showed that its tacticity was similar to that obtained with the conventional radical polymerized poly(methyl methacrylate). No polymer was obtained by the use of the Rh complex alone.

Kinetic Studies of the Polymerization with the System of the Rh complex and Carbon Tetrachloride. Figure 1 shows the relationship between the R_p and the concentration of the Rh complex at constant concentrations of both MMA and carbon tetrachloride.

From this figure, the rate was found to be proportional to the square root of the concentration of the Rh complex. The plots of R_p against the concentration of carbon tetrachloride at constant concentrations of both the Rh complex and MMA are shown in Fig. 2, in which the rate is indicated to be proportional to the square root of the concentration of carbon tetrachloride. The square-root dependence of the concentration of carbon tetrachloride on the rate was observed only in the concentration range lower than 5×10^{-3} mol/l. When the concentration of carbon tetrachloride becomes higher than this, the rate becomes constant and independent of the concentration of carbon tetrachloride.

Figure 3 shows the relationship between the R_p and the concentration of MMA at constant concentrations of both the Rh complex and carbon tetrachloride. From this figure, it is clear that the rate is proportional

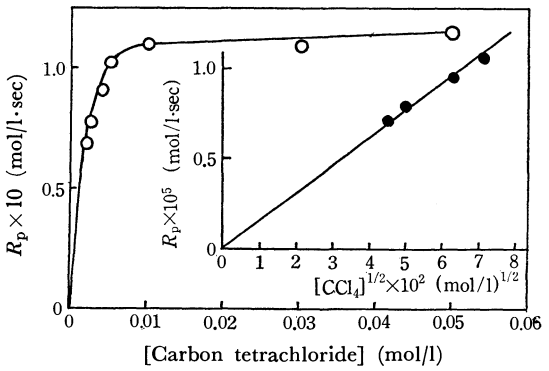

Fig. 2. Relationship between R_p and the concentration of carbon tetrachloride: [MMA]=4.65 mol/l, [Rh complex] $=10^{-3}$ mol/l, in benzene at 50 °C.

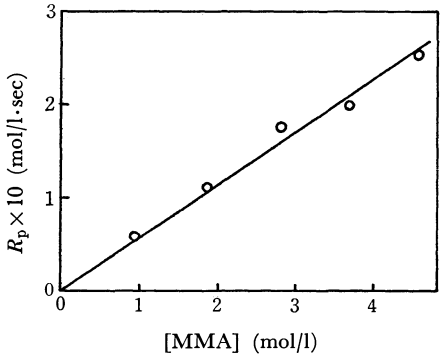

Fig. 3. Relationship between R_p and the concentration of MMA: [Rh complex] $=10^{-3}$ mol/l, [Carbon tetrachloride] =2.05 mol/l, in benzene at 50 °C.

to the concentration of MMA. This finding indicates that MMA does not participate in the initiation of the radical production.

Effect of Radical Inhibitor. The effects of several radical inhibitors on the polymerization with the system of the Rh complex and carbon tetrachloride were investigated. α,α-Diphenyl-β-picrylhydrazyl (5×10^{-3} mol/l) and *p*-benzoquinone (5×10^{-3} mol/l) inhibit the polymerization.

Mechanism of MMA Polymerization with the Rh Complex and the Organic Halids System. The results on the polymerization kinetics and on the radical inhibitor, indicate that the polymerization of MMA with the Rh complex and carbon tetrachloride proceeds through a radical mechanism. From the fact that the rate of polymerization is proportional to the square root of the concentration of the Rh complex and of carbon tetrachloride, it can be presumed that free radicals are produced by the reaction of the Rh complex and carbon tetrachloride. These free radical are considered to be trichloromethy radicals, because of the fact that hexachloroethane is found by gas-chromatographic analysis. Trichlorocarbonylbis(triphenylphosphine)rhodium(III) was also found from the infrared spectra in the reaction of the Rh complex and carbon tetrachloride at 60 °C for 3 hr.

Further investigation is required for the elucidation of the mechanism of the Rh complex reaction.

The Polymerization of Vinyl Monomers in the Presence of Surface-active Agents. V. The Copolymerization of Methyl Methacrylate with Styrene

Yoshikazu ARITA, Shinsaku SHIRAISHI, Manabu SENŌ, and Teruzo ASAHARA
Institute of Industrial Science, University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received November 30, 1972)

In the previous papers of this series, we have reported the polymerization of methyl methacrylate (MMA)[1,2] and styrene (St)[3] in the presence of a surface-active agent in an aqueous medium without any ordinary initiators. The polymerization reactions were considered to proceed via a radical mechanism, because the polymerizations were inhibited by the addition of hydroquinone or diphenylpicrylhydrazyl and also by passing air continuously into the reaction system during the reaction period. In this paper we will present the results of the copolymerization of MMA with St; we attempted this in order to confirm that the present reaction proceeds *via* a radical mechanism and also to ascertain some particular aspects of this reaction system if possible.

Experimental

Materials. MMA and St were purified by ordinary procedures and were stored in a refrigerator until use. The sodium tetrapropylenebenzenesulfonate(ABS from the Lion Fat & Oil Co.) was purified by recrystallization from aqueous acetone.

Copolymerization. The copolymerization of MMA with St was carried out in a manner similar to that described in a previous paper.[2]

Characterization of the Copolymers. The composition of the copolymers was determined by the IR technique. The calibration curve for the quantitative analysis was prepared by measuring the intensity of the C=O absorption at 1725 cm^{-1} of 1% chloroform solutions of mixtures of poly(MMA) and poly(St) in various ratios by using a cell 0.268 mm thick. The curve was expressed by this equation:

$$\log (I_0/I) = 0.61[C]$$

where I_0 is the percentage transmission of the solvent only, where I is that of the solution, and where [C] is the concentration of the MMA component in copolymers (g/100 ml of a chloroform solution).

The composition of the copolymers was also determined by elementary analyses, which gave the same results as obtained by the IR techniques afore-mentioned.

The NMR spectra were measured at 34 °C with 3% solutions in carbon tetrachloride using a Hitachi-Perkin Elmer R-20A Spectrometer working at 60 MHz, with tetramethylsilane as the internal standard.

Results and Discussion

The copolymerization of St(M_1) with MMA(M_2) has been widely investigated, and the monomer reactivity ratios have been reported to be $r_1=0.52$ and $r_2=0.46$ for a bulk polymerization at 60 °C,[4] $r_1=0.54$ and $r_2=0.42$ for a solution polymerization in benzene at 60 °C,[5] and $r_1=0.56$ and $r_2=0.50$ for an emulsion polymerization at 35 °C.[6] In the present report, the copolymerization of St with MMA in the presence of ABS without any ordinary initiators will be examined. The results are summarized in Table 1. As is shown in Table 1, the rate of the copolymerization of St with MMA is much smaller than that of the polymerization of MMA. This phenomenon has also been observed in the usual radical copolymerization of St with MMA. Therefore, the propagation reaction may proceed in the same way as the usual radical copolymerization, though the initiation reaction may be different from usual in the point of the necessity for the micelles to be formed in our present polymerization system.

TABLE 1. COPOLYMERIZATION OF MMA WITH St

MMA/St[a]	Conversion (%)	$[\eta]$[b]
∞	52.3	8.20

The polymers obtained were fractionated by precipitation from a 2% benzene solution by ethanol; all of the polymers in the solution precipitated out in the precipitation range (volume ratio of the precipitant to the polymer solution) of 0.9 to 1.2, which indicated that the polymer was exclusively the copolymer of the two monomer components.[7] The dependence of the composition of the copolymers on initial ratio of monomers was examined. The composition of the resulting copolymers was determined by the IR technique using the calibration equation described above. The copolymer composition curve

Water 100 g, ABS 1 g, comonomer 0.1 mol, 80 °C, 2 hr, under nitrogen atmosphere.

thus obtained is shown in Fig. 1.

The apparent monomer reactivity ratios (mrr) were calculated to be $r_1=0.71\pm0.03$ and $r_2=0.40\pm0.03$ by Mayo and Lewis' intersection method. These values were very different from Mayo's data.

According to Wall's investigation into the solubility of St and MMA in water,[6] we calculated the monomer ratios in the oil phase in the present system and corrected the copolymer composition curve and reactivity ratio. The corrected values were $r_1=0.61\pm0.03$ and $r_2=0.48\pm0.03$, which apparently approached Mayo's data. The values were still slightly different from the usual mrr, but it is considered that these values show that the copolymerization proceeds *via* a radical mechanism.

8) K. Ito and Y. Yamashita, *J. Polym. Sci., Part B*, **3**, 625 (1965).

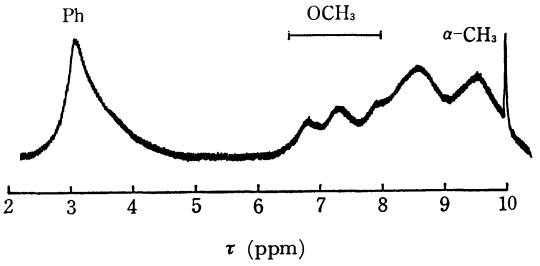

Fig. 2. NMR spectrum of MMA-St cooplymer of reactant mole ratio 1.0 at 60 MHz, at 34 °C in CCl_4 solution.

The NMR spectrum of the copolymer gave results similar to those of Yamashita's investigation.[8] As is shown in Fig. 2, the α-methyl proton resonance of the MMA unit appears at 9.2—9.1 ppm and the methoxy proton resonance is resolved into three peaks, which is a characteristic feature of the copolymers of St and MMA formed through a radical mechanism.

The results presented above and those of the previous reports[1,2,3] definitely confirmed that the polymerization of our reaction system proceeds *via* a radical mechanism. It was also clarified that, in the emulsion copolymerization, the mrr of each monomer component obtained by the usual copolymerization technique must be modified by considering their solubility parameters, especially the distribution coefficient.

Rearrangement of 2-Aryloxybenzazoles

Takeshi NAGAI, Yoshiaki FUKUSHIMA, Toshio KURODA, Hiroshi SHIMIZU, Shizen SEKIGUCHI, and Kohji MATSUI

Department of Synthetic Chemistry, Gunma University, Tenjincho, Kiryu, Gunma 376

(Received January 22, 1973)

O-Acylphenols are known to undergo rearrangement in the presence of Lewis acid[1] or photochemically[2] to give *o*- and/or *p*-acylphenols. Similarly, aryloxy-*s*-triazines give *o*- and/or *p*-hydroxyaryl-*s*-triazines on irradiation.[3] However, aryloxy-*s*-triazines containing 2-amino groups undergo rearrangement to give o-hydroxyarylamino-*s*-triazines in protic solvents in the dark[4] or on irradiation with ultraviolet light in aprotic solvents.[5] This paper reports on the rearrangement of 2-aryloxybenzazoles (benzoxazole, benzothiazole, and benzimidazole).

Preparation of 2-Aryloxybenzazoles. 2-Aryloxybenzazoles having the following general formula were synthesized by the condensation of 2-chlorobenzazoles with the corresponding phenolates. 2-(2-Aminophenoxy)benzothiazole was obtained by the hydrogenation of the corresponding nitro compound. In the hydrogenation of 2-(2-nitrophenoxy)benzoxazole, however, 2-(2-hydroxyanilino)benzoxazole was obtained as the main product instead of 2-(2-aminophenoxy)benzoxazole. 2-Aryloxybenzazoles thus obtained are listed in Table 1.

Rearrangement in the Dark. 2-Aryloxybenzazoles (*ca.* 5.0 g) were heated at 150 °C for 24 hr in nitrobenzene (300 ml) with aluminum chloride in a 1 : 1 molar ratio, but no 2-(hydroxyaryl)benzazoles, Fries rearranged products, were producd. Failure of rearrangement in these cases is attributed to the preferential coordination of aluminium chloride to the ring nitrogen atom instead of the aryloxy oxygen. By heating at 200 °C for 5 hr, no reaction took place in 2-aryloxy-benzoxazoles or -benzthiazoles, 2-aryloxybenzimidazoles being decomposed with cleavage of phenol. However, 2-(2-aminophenoxy)benzthiazole underwent rearrangement slowly in methanol or ethanol to give 2-(2-hydroxyanilino)benzthiazole, a Smiles rearranged product, although it did not react in such aprotic solvents as benzene, cyclohexane, carbon tetrachloride, and butyl ether. The Smiles rearrangement of 2-(2-aminophenoxy)benzthiazole took place readily in the presence of a small amount of hydrochloric acid to give a rearranged product quantitatively; the catalytic effect by acid is attributable to the lowering of electron-density of the ring carbon atoms by the protonation at the ring nitrogen atom. Thus, the formation of 2-(2-hydroxyanilino)benzoxazole by hydrogenation of 2-(2-nitrophenoxy)benzoxazole indicates the ready O→N migration of the 2-benzoxazolyl group of preformed 2-(2-aminophenoxy)benzoxazole.

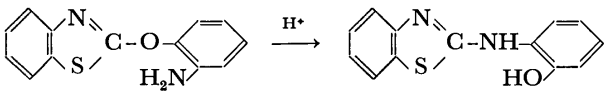

Photo-rearrangement of 2-Aryloxybenzazoles. Irradiation of 2-aryloxybenzazoles (*ca.* 5.0 g) in cyclohexane or ethanol (300 ml) with low pressure mercury lamp gave 2-(2- and/or 4-hydroxyphenyl)benzazoles.[6] The photo-rearranged products thus obtained are listed in Table 2. However, under similar conditions

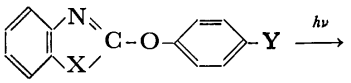
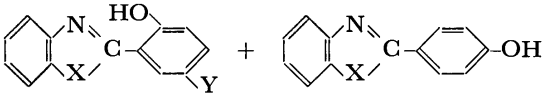


Y=-H, -CH_3, -Cl



Y=-H, -CH_3, -Cl Y=-H

2-anilinobenzazoles gave no rearranged 2-(2- or 4-aminophenyl)benzazoles. On the other hand, when 2-(2-aminophenoxy)benzthiazole was irradiated in cyclohexane, no 2-(2-aminohydroxyphenyl)benzthiazole, a photo-Fries rearranged product, was obtained, but 2-(2-hydroxyanilino)benzthiazole, a photo-Smiles rearranged product, was obtained in a good yield.

Quantum Yields for the Product Formation from 2-Aryloxybenzazoles. The quantum yields of the product for

6) In the photo-rearrangement of 2-aryloxybenzazoles, several by-products other than rearranged ones were produced (see Experimental). For example, 12 hr's irradiation of 5 g of 2-(4-chlorophenoxy)benzoxazole in 300 ml of ethanol gave 2-(5-chloro-2-hydroxyphenyl)benzoxazole (11%), benzoxazole (1%), *p*-chlorophenol (27%), benzoxazolone (30%), and 2-ethoxybenzoxazole (<1%). In this paper discussion is restricted to rearranged products.

mation from 2-aryloxybenzazoles were measured. The values obtained in ethanol are as follows: 0.084 for 2-(4-methylphenoxy)benzoxazole, 0.025 for 2-(4-methylphenoxy)benzthiazole, and 0.15 for 2-(4-methylphenoxy)benzimidazole. The quantum yields of the product formation from 2-(4-methylphenoxy)benzoxazole at 2537 Å did not change with concentration ($<\sim 7\times10^{-3}$ mol/l) and irradiation time (2~9 min) in the presence of piperylene as a triplet quencher ($10^{-4}\sim 2\times10^{-2}$ mol/l). Similar results were also obtained with 2-(4-methylphenoxy)benzthiazole and -benzimidazole. The results are in line with the general photo-Fries-rearrangement involving the intramolecular process *via* the lowest excited singlet state.

Experimental

Preparation of 2-Aryloxybenzazoles. 2-Aryloxybenzazoles were prepared by the condensation of 2-chlorobenzazoles with the equimolar corresponding phenolates. Typical procedures are described in the case of 2-(4-methylphenoxy)-, 2-phenoxy-benzthiazoles and 2-phenoxybenzoxazole.

2-(4-Methylphenoxy)benzthiazole. After 17 g (0.100 mol) of 2-chlorobenzthiazole and 17.4 g (0.133 mol) of sodium *p*-methylphenoxide in 50 ml of *p*-methylphenol had been heated at 130 °C for 24 hr, the mixture was poured into a large amount of aqueous sodium hydroxide solution. After the mixture had been extracted with benzene, the benzene solution was concentrated and the residue was distilled under reduced pressure (bp 178—178.5 °C/3 mmHg) and recrystallized from ethanol. 2-Phenoxybenzthiazole (bp 178—180 °C/8 mmHg) was prepared by a similar method.

2-Phenoxybenzoxazole. After 15.3 g (0.100 mol) of 2-chlorobenzoxazole and 17.4 g (0.15 mol) of sodium phenoxide in 50 ml of phenol had been heated at 120 °C for 20 hr, the mixture was poured into a large amount of aqueous sodium hydroxide solution and filtered out. The precipitate was recrystallized from ethanol. Other aryloxybenzazoles except for the above-mentioned three aryloxybenzazoles were prepared by similar methods.

Hydrogenation of 2-(2-Nitrophenoxy)benzoxazole: A mixture containing 50 ml of dioxane, 5 g (0.020 mol) of 2-(2-nitrophenoxy)benzoxazole, and 3 g of Raney Nickel was stirred for 12 hr under a pressure of 120 kg/cm² of hydrogen at room temperature. After the catalyst had been removed by filtration and the solvent evaporated, the residue was dissolved in 200 ml of 3% aqueous sodium hydroxide. After filtration the filtrate was neutralized with dilute hydrochloric acid, filtered, and dried to give 3.5 g (80%) of crude 2-(2-hydroxyanilino)benzoxazole. Recrystallzation from ethanol–water gave an analytical sample, mp 176—177 °C. Found: C, 68.72; H, 4.28%. Calcd for $C_{13}H_{10}O_2N_2$: C, 69.01; H, 4.46%.

Smiles and Photo-Smiles Rearrangements of 2-(2-Aminophenoxy)-benzthiazole (2APB): To a solution of 0.5 g (0.002 mol) of 2APB in 10 ml of acetone or ethanol was added a small amount of concd hydrochloric acid (*ca.* 0.08 g). After the mixture had been allowed to stand at room temperature for 2 days (for Smiles rearrangement) or 21 days (for photo-Smiles rearrangement), it was poured into 50 ml of ice-water, filtered, and dried. Recrystallization from benzene gave 2-(2-hydroxyanilino)benzthiazole quantitatively, mp 178.5—179 °C; NMR (DMSO-d_6) τ 0.2(s, OH), 1.7(s, NH). Found: C, 64.70; H, 4.46%. Calcd for $C_{13}H_{10}ON_2S$: C, 64.66; H, 4.16%.

After a solution of 5 g (0.02 mol) of 2APB in 300 ml of ethanol had been irradiated at room temperature with a low pressure mercury lamp (30W) for 7 days, the solvent was distilled off, and the residue was dissolved in 300 ml of benzene. The benzene solution was extracted with 200 ml of 4% sodium hydroxide solution. The aqueous solution was neutralized with hydrochloric acid and extracted with 200 ml of benzene. Column chromatography and recrystallization of the former benzene solution afforded 3.6 g of 2APB and 0.4 g (28.9%, based on the reacted 2APB) of benzthiazolone, and 0.7 g (50%, based on the reacted 2APB) of 2-(2-hydroxyanilino)benzthiazole from the latter benzene solution.

Photo-rearrangement and Actinometry: A low pressure mercury lamp was used as the 2537 Å radiation source with a Vycor glass filter. Irradiation was continued for 7 to 10 days. Actinometry was carried out with a ferric oxalate solution,[7] throughly degassed on a high vacuum line by the freeze-pump-thaw method.

Structural assignments of all products were performed by means of NMR, IR, UV, MS and elemental analyses. The results of the elemental analysis of all new products were within the experimental error.

Fluorescence Lifetime of Pyrene in Different Solvents

Akira NAKAJIMA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received March 12, 1973)

As has been reported in a previous paper,[1] the forbidden components in the vibrational structures of the absorption and fluorescence spectra of aromatic hydrocarbons are markedly enhanced in very polar solvents. These intensity enhancements have been shown to be well correlated with the dielectric property of the solvent. It is known that the radiative lifetime of the fluorescence can be estimated using the theoretical relation[2-4] from the integral of the corresponding absorption spectrum. Experimentally it is determined from the observed fluorescence lifetime and quantum yield.[2] It is supposed that the intensity enhancements by solvents may be accompanied by a decrease in the radiative lifetime. Under these circumstances, it is of interest to study the applicability of the relation

Table 1. Fluorescence lifetimes (τ) of pyrene in three solvents

Excitation	τ (ns)		
	Air-gap discharge	Ruby laser	
Concentration	9.7×10^{-6} M	9.7×10^{-6} M	1.07×10^{-4} M
Cyclohexane	408± 5	338± 9	369±11
1,2-Dichloroethane	202± 3	170±12	187± 4
Dimethyl sulfoxide	275±11	233± 8	238± 6

and the change in the radiative rate.

In this work, the fluorescence lifetimes were measured at various vibronic bands in three representative solvents, and the radiative rate constants calculated from the observed lifetimes and quantum yields were compared with those estimated from the integrated absorption spectra. In addition, on the basis of the constancy of the fluorescence lifetimes over the vibronic band system, it was confirmed that there was no appreciable specific interaction between the solute and solvent molecules.

Experimental

The fluorescence lifetimes were measured by excitation with the frequency-doubled light pulses from a Q-switched ruby laser (a duration of ~20 ns, 3472 Å) and with the UV light pulses from an air-gap discharge (a duration of ~10 ns). An about 2% mesh filter was used for attenuation of the strong exciting laser light. The fluorescence emission was detected with a Hamamatsu TV R-446 photomultiplier through a Hitachi G-3 grating monochromator. The slit width of the monochromator was less than 3 mμ for the laser excitation and 10 to 30 mμ for the discharge excitation. The fluorescence decay curves were displayed on an Iwasaki SS-112 synchroscope and photographed. The lifetimes were estimated from the photographs, the analyses of which gave most part of errors of about 10 ns.

The fluorescence spectra were measured with a Hitachi MPF-2A spectrofluorometer. The absolute quantum yields of pyrene fluorescence in various solvents were calculated assuming the value of 0.65[5] in a degassed cyclohexane solution from the relative yields, which were evaluated from the areas under the corrected fluorescence spectra.

The concentrations of the solutions were 9.7×10^{-6} and 1.07×10^{-4} M. The solutions used were thoroughly deaerated by the usual method of freeze-pump-thaw cycles.

Pyrene was purified by recrystallization, zone-refining, and vacuum sublimation. Super-special grade cyclohexane, G. R. grade 1,2-dichloroethane, and spectroscopic grade dimethyl sulfoxide were used without further purification. The purities of pyrene and these solvents were checked by measuring the fluorescence and excitation spectra.

Results and Discussion

Since there are two kinds of components, solvent-sensitive and insensitive, in the vibronic band system, the possibility can be considered that the fluorescence decay times might be different between these components in various solvents. Thus, the lifetimes of pyrene fluorescence were measured at several vibrational band peaks in three solvents of different polarities. Table 1 gives the fluorescence lifetimes averaged over the vibronic band system with the maximum deviations. As seen from Table 1, the lifetimes measured by the laser excitation were appreciably shorter than those measured by the discharge excitation. This phenomenon may be much related to the bimolecular decay process due to the interaction between the excited molecules found by excitation at a high photon density.[6,7] In fact, a slight deviation from the single exponential curve could be observed in the initial time region. In cyclohexane and 1,2-dichloroethane by the laser excitation, the lifetimes in 1.07×10^{-4} M solutions are about 10% longer than those in 9.7×10^{-6} M solutions. This may be caused by the dissociation of excimers formed in a small amount due to the low viscosity of these solvents and the somewhat high concentration of the solutions. Weak excimer emission was actually observed in 1.07×10^{-4} M cyclohexane solutions.

In view of the considerable errors in the decay time analysis, the lifetimes given in Table 1 should be regarded as taking almost the same values in the whole region of the fluorescence spectrum in each solvent. If the solvent-enhanced bands are assumed to arise from some species such as a specifically solvated solute molecule or more unlikely, a complex formed between the solute and solvent molecules, the lifetimes observed at the solvent-sensitive bands might differ from those observed at the solvent-insensitive bands. However, the constant lifetimes obtained over the whole vibronic band system indicate the participation of a single species responsible for both these bands, in accord with the conclusions derived from the fluorescence spectra by excitation at different wavelengths and the excitation spectra by monitoring at various vibrational bands.

Since the intensities of the forbidden bands change in various solvents, the corresponding changes in the radiative rate can be expected. In general, the radiative rate constant, k_0, can be calculated from the observed fluorescence lifetime, τ, and the quantum yield, η, by the following relation:[2]

$$k_0 = \eta/\tau . \tag{1}$$

On the other hand, k_0 can also be estimated from the absorption spectrum of the first electronic transition by the well-known equation:[2-4]

$$k_0 = 2.88 \times 10^{-9} n^2 \bar{\nu}_0^2 \int \varepsilon d\bar{\nu} , \tag{2}$$

where ε is the molar extinction coefficient and n is the

Dimethyl sulfoxide	2.0×10^6	2.6×10^6

refractive index of the solvent. $\bar{\nu}_0$ was taken to be the wave number of the 0–0 band. This simplified formula[2] was used in view of the accuracy of the present results.

In Table 2, the values of the radiative rate constants evaluated by Eqs. (1) and (2) are given. In spite of the large errors inherent to the evaluations, the agreement between the values obtained by these two different methods is good. Though the applicability of Eq. (2) to weak or forbidden transitions may be questionable,[3] it can be well employed for an order estimation, including the cases of enhancements by solvents.

As seen from Table 2, the k_0 values increase appreciably on going from cyclohexane to dimethyl sulfoxide, corresponding to the enhancements of the forbidden bands with the increase in the solvent polarity. In a highly polar solvent, the contribution of the forbidden components to the vibronic band system can be comparable to that of the vibronically allowed components, indicating that the intermolecular perturbation by solvent can become as important as the intramolecular perturbation due to vibronic coupling.

(Received November 20, 1972)

Determination of arsenic in trace amount is often necessary in connection with pollution. Accuracy of the determination of arsenic can be fairly enhanced by introduction of arsenic as arsine gas into argon-hydrogen flame.[1–4] Chu *et al.*[5] have recently described a flameless atomic-absorption spectrophotometric method for arsenic determination involving chemical conversion of arsenic into arsine. We showed that antimony and selenium can be rapidly determined by introducing stibine or hydrogen selenide gas into argon-hydrogen flame.[6,7]

This paper deals with a method for the rapid, sensitive and accurate determination of arsenic by atomic-absorption spectrophotometry in combination with the argon-hydrogen system. Arsine was rapidly evolved from arsenic(III) or aresenic(V) solutions by reduction with zinc powder tablets, stannous chloride and potassium iodide. With the combined use of these reagents, both optimum hydrochloric acidity and interference of diverse ions in the reduction process could be reduced to a considerable extent.

Experimental

Reagents. All solutions were prepared with Chemicals of analytical reagent grade and deionized water, the aqueous solutions being stored in polyethylene bottles.

Standard Arsenic(III) Solutions: Prepared by dissolving 1.320 g of diarsenic trioxide (As_2O_3) in 10 ml of water containing 4 g of sodium hydroxide, and diluting it to 1000 ml with water. An aliquot of this solution was diluted with water to give a concentration of 0.2 ppm immediately before use.

Standard Arsenic(V) Solution: Prepared by dissolving 2.403 g of potassium dihydrogen arsenate in water and diluting it to 1000 ml with water. An aliquot of this solution was diluted with water to give a concentration 0.2 ppm immediately before use.

Stannous Chloride Solution: Prepared by dissolving stannous chloride dihydrate in 10 M hydrochloric acid to give a concentration of 10%(w/v).

Potassium Iodide Solution: Prepared by dissolving potassium iodide in water to give a concentration of 40% (w/v).

Zinc Tablets 50 g of arsenic-free zinc powder (200 mesh), 4 g of kaolin powder, and 10 ml of water were mixed in a mortar to make a paste. This was moulded into small tablets, 8 mm in diameter, 3 mm in thickness and about 0.5 g in weight, and dried in an electric oven.

Apparatus. The atomic-absorption was measured with a Nippon Jarrell-Ash Model AA-1 EW atomic-absorption spectrophotometer equipped with a Westinghouse arsenic hollow cathode lamp. The apparatus used for generation and collection of arsine was the same as that reported.[6,7]

Recommended procedure: Transfer into a reaction bottle a sample solution less than 20 ml in total volume and

containing not more than 1 μg of arsenic. Add 2 ml of 12 M hydrochloric acid, 1 ml of the potassium iodide solution and 2 ml of the stannous chloride solution. Dilute the mixture to 25 ml with water. Swirl the solution to mix thoroughly and stand it at room temperature for 15—30 min. After adding two zinc tablets, immediately connect the reaction bottle to the collection unit and allow the reaction to take place for 90 sec at room temperature by agitating the mixture with a magnetic stirrer. Turn the four-way stopcock to "sweep" forcing the hydrogen and arsine into the burner mixing chamber, and also introducing argon into the system to sweep the gases into the flame. Simultaneously record the absorption signal on a recorder. Finally return the stopcock to "bypass".

The working conditions are: wavelength 1937 Å, slit-width 0.10 mm, lamp current 15 mA. Flow rates of gases for a standard 10-cm slot burner: argon 8.0 l/min (1.5 kg/cm²G), hydrogen 7.0 l/min (0.4 kg/cm²G) using air-acetylene regulator system, respectively, auxiliary argon 4.0 l/min (2.0 kg/cm²G).

Results and Discussion

In the conventional method for arsenic determination by colorimetry, granular zinc metal is used as the reducing agent. Evolution of arsine has to be continued for about half an hour because the reaction proceeds gradually. Holak[1] used granular zinc for arsine generation and collected the arsine by freezing in a liquid nitrogen trap. It was then introduced into an air-acetylene flame after being brought to room temperature and swept with nitrogen. The procedure required considerable time. It was found[2–4] that it is not necessary to wait for the reaction to complete since almost all the hydrides are formed during the early period of the reaction when smaller granular zinc (20 mesh) is used. We have reported[6,7] that zinc powder tablets are effective for rapid and quantitative evolution of stibine and hydrogen selenide.

We also found that the use of the zinc tablets together with stannous chloride and potassium iodide considerably accelerate the reduction even in a lower acidic medium. Conditions were investigated for the quantitative production of arsine by use of a mixture of reagents.

The mechanism of the conversion of trivalent and pentavalent arsenic into arsine appears to be very complicated. It is therefore of interest to investigate the role of potassium iodide and stannous chloride in the overall reduction process. It is known[8] that both potassium iodide and stannous chloride are highly effective not only for the complete reduction of arsenic from the pentavalent to the trivalent state, but also for the suppression of the interference of diverse metal ions in the overall reduction process. A potassium iodide solution (0—3.0 ml) and a stannous chloride solution (0—6.0 ml) were added respectively to arsenic(III) and arsenic(V) solutions, each containing 1.0 μg of arsenic with a final acidity of 2 M. It was found that potassium iodide and stannous chloride enhanced to a great extent the recovery of arsenic as arsine from the trivalent state (KI with 0.8% $SnCl_2$, 4-fold; $SnCl_2$ with 1.6% KI, 3-fold) when at least 0.3 ml of the potassium iodide and 0.5 ml of the stannous chloride solutions were added. Thus the potassium iodide or stannous chloride concentration was usually kept at 1.6% or 0.8%. As a result, the same values in the atomic-absorption signal were obtained when evolution of arsine took place either from trivalent arsenic or pentavalent arsenic state.

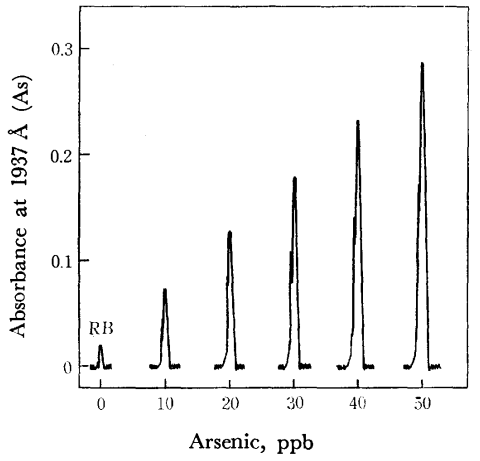

Fig. 1. Absorption signal *vs.* concentration of arsenic. (RB is a reagent blank)

The optimum range of acidity was about 1.5—2.5 M in hydrochloric acid. Addition of at least one zinc tablet was enough to obtain a highest and constant recovery of arsenic as arsine.

After addition of the reagents no distinct evolution took place appreciably for a few seconds, during which time we could connect the reaction bottle to the gas collection unit without any loss of arsine. Arsine was vigorously generated by grinding the tablets by agitating the mixture with a magnetic stirrer. A constant and maximum sharp signal was obtained for only one minute gas sampling. The calibration curve was constructed by the procedure described above by use of arsenic(III) standard solution. An example is shown in Fig. 1. An appreciable value of absorbance is observed in the reagent blank. This can be attributed to the arsenic contained in the zinc tablets as impurities. The same results were obtained by using the arsenic(V) solution as a standard. The sensitivity for 1% absorption of the signal was estimated to be 0.001 ppm of arsenic and the linearity of absorption *vs.* concentration was good over the range 0.01—0.05 ppm. The precision was estimated to be 3% from the results of ten solutions with 1 μg of arsenic. The effect of diverse cations on the reduction process was studied using a solution containing 1.0 μg of arsenic(III). The following ions did not interfere at the 250 ppm level: chromium(III), manganese(II), iron(III), aluminium, cobalt(II), nickel(II), copper(II), zinc, silver, cadmium, mercury(II), sodium, potassium, magnesium, and calcium. The maximum permissible amount of the other ions was as follows: lead and antimony(III) 10 ppm, selenium 0.4 ppm.

The authors thank Mr. R. Tsujino, Nippon Jarrell-Ash Co. Ltd., for his assistance in the device of the apparatus for the evolution of arsine.

The Crystal and Molecular Structure of *trans*-2,2′-Dichloroazobenzene

Masayuki KOMEYAMA*, Shunzo YAMAMOTO, Norio NISHIMURA, and Shigeo HASEGAWA
Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received February 2, 1973)

In a previous paper,[1] the dipole moment and spectral data of substituted azobenzenes have been presented. The dipole moment and the intensity of the π–π^* band are apparently reduced by the introduction of methyl groups into ortho position with respect to azo group. This has been interpreted as due to the reduced conjugation by the twisting of the molecule. In this connection, it became desirable to obtain information about the molecular structure of 2,2′-disubstituted azobenzene in crystal. Recently, the crystal and molecular structures of 4,4′-disubstituted azobenzenes were determined and it was found that the molecules are nearly planar.[2-4] However, for 2,2′-disubstituted ones, no such information is available as yet. This paper presents the three-dimentional X-ray structure analysis of 2,2′-dichloroazobenzene.

Experimental

2,2′-Dichloroazobenzene was prepared from *o*-chloroaniline,[5] and recrystallized by slow evaporation from a benzene–ligroin solution. The compound crystallized as red plates having a predominant (001) face.

Crystal data: $C_{12}H_8N_2Cl_2$; M=251.1; mp=138—139 °C, monoclinic, a=13.651(8), b=3.946(8), c=11.626(4) Å, β=114.40(3)°, U=570.4 Å^3, D_m=1.47, D_x=1.46 g cm^{-3}, Z=2. Absorption coefficient for Cu$K\alpha$; μ=48.8 cm^{-1}. F(000)=256.

Absent spectra: $h0l$ when h is odd and $0k0$ when k is odd. Space group is $P2_1/a$.

Using Cu$K\alpha$ radiation, multiple-film equi-inclination Weissenberg photographs were taken for the layers from $0kl$ to $9kl$ and from $h0l$ to $h2l$. A total of 995 independent non-zero reflections was recorded. The intensities were estimated visually. After Lorentz, polarization and spot-shape corrections were made, the intensities of various layers were adjusted to the same relative scale by making use of all the common reflections. The relative values were converted to an absolute scale by Wilson's method. No corrections were applied for absorption and extinction effects.

Structure Determination

In the space group $P2_1/a$, four is the minimum number of asymmetric units necessary to fulfill the symmetry operation, while there are only two molecules in the unit cell. Hence it must be that the molecules themselves are centrosymmetric, and occupy the position of a center of symmetry of the cell.

Approximate x,y,z parameters for all non-hydrogen atoms were easily determined from a three-dimensional Patterson map. The structure was refined by the block-diagonal least-squares method[6] with isotropic thermal parameters to an R value of 0.17 and with anisotropic ones to the R of 0.10. The difference Fourier synthesis showed the locations of all the four hydrogen atoms. Furthermore, six cycles of calculation were made with anisotropic thermal parameters for the non-hydrogen atoms and with isotropic thermal parameters (initially set at B=3.5 Å^2) for the hydrogen atoms using unit weight for all the observed reflections. The final R index was 0.087 for all the observed reflections. The final positional and thermal parameters are given in Table 1. The numerical calculations were performed with the aid of a HITAC 5020E computer of the Computer Center of the University of Tokyo, a FACOM 230—60 computer of the Data Processing Center of Kyoto University. The atomic scattering factors were taken from Ref. (7).

Results and Discussion

The bond lengths and angles are shown in Fig. 1. The average C–C bond length in the benzene ring is 1.389 Å. The bond angles in benzene ring range from 118.6 to 121.4°. The other bond lengths and angles are listed in Table 2, together with the corresponding bond lengths and angles of azobenzene and other related compounds. As shown in Table 2, the N=N, N–C and C–Cl bond lengths and the N=N–C

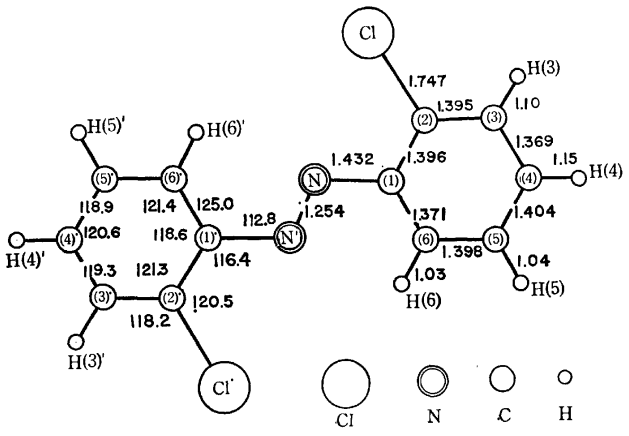

Fig. 1. Bond lengths and angles. Estimated standard deviations are 0.007—0.010 Å for lengths not involving H, 0.07 Å for C–H lengths and 0.5—0.7° for angles not involving H.

C(4)	0.010*	0.029	Cl	0.001*	−0.585
C(5)	0.000*	0.286			

Least-squares plane is determined by the atoms with asterisk.
Dihedral angle between the two plane is 12.8°.
The numbering of each atom is the same as that in Fig. 1.

TABLE 4. INTERMOLECULAR CONTACTS

Atom	Neighbour atom	Distance	Atom	Neighbour atom	Distance
(1) I···II			(4) II···IV		
C(4)	Cl	3.54 Å	H(3)	H(3)	2.55 Å
H(4)	Cl	3.02	H(3)	C(3)	3.01
(2) I···III			Cl	H(3)	3.00
Cl	H(3)	3.00	(5) III···IV		
H(3)	H(3)	2.55	Cl	H(4)	3.08
H(3)	C(3)	3.01	Cl	H(5)	3.08
(3) I···V					
Cl	Cl	3.95			
Cl	C(2)	3.63			

Perpendicular distance from benzene ring (I) to benzene ring (V) is 3.62 Å

Key for position of molecules
I: x, y, z; II: $1/2+x$, $1/2-y$, z; III: $1/2-x$, $1/2+y$, $1-z$; IV: $1-x$, $-y$, $1-z$; V: x, $1+y$, z

and N–C–C (*cis* and *trans* relative to the central double bond) bond angles are well consistent with the corresponding values of the related compounds.

The intramolecular distance between Cl and N atoms (2.98 Å) is considerably shorter than the sum of the van der Waals radii of Cl and N atoms (3.3 Å). Hence the steric repulsion between these two atoms must exist. As mentioned above, however, the bond lengths and angles are hardly affected by the introduction of Cl atom into *ortho* position with respect to azo group.

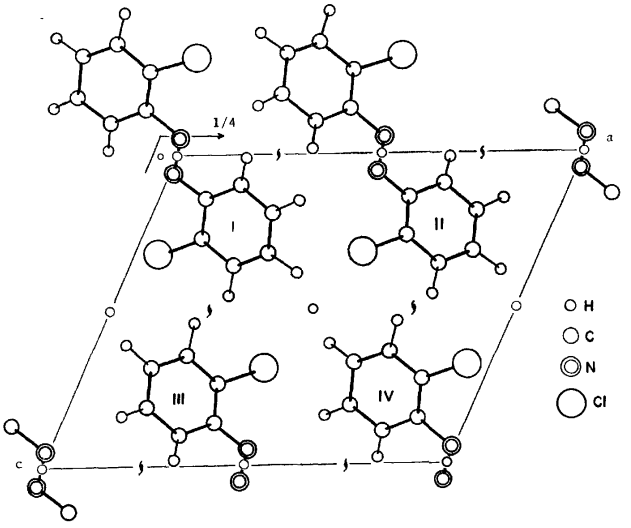

Fig. 2. The projection of the crystal structure along the b-axis.
Key for molecules I: x, y, z; II: $1/2+x$, $1/2-y$, z; III: $1/2-x$, $1/2+y$, $1-z$, IV: $1-x$, $-y$, $1-z$.

As shown in Table 3, the benzene ring including N and Cl atoms is planar within 0.02 Å. This plane (plane 1) makes a dihedral angle of 12.8° with the N=N–C plane (plane 2). From the inspection of Table 3, it can be concluded that the dihedral angle between these two planes is the twisting angle of the benzene ring around the N–C bond. As mentioned in the section of structure determination, this compound has the center of symmetry. The two benzene rings must be symmetrically twisted around the azo group. This is in accord with the previous suggestion that the molecule is twisted in the same manner. The cause of the twist has already been discussed in some detail.[1)]

The mode of packing of the molecules in the crystal can be seen in Fig. 2. The short intermolecular contacts are summarized in Table 4. They show the normal van der Waals interaction.

The authors wish to express their deep gratitude to Professor Masao Haisa and Mr. Setsuo Kashino for their kind guidance and valuable adivce.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2608—2609 (1973)

Derivatives of 1,2-Dithiole-3-thione. II. Thermal Rearrangement of Iminothiocarbonyl Compounds.

Seizo TAMAGAKI, Keishi SAKAKI, and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

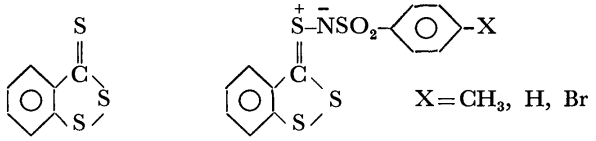
(Received February 20, 1973)

The synthesis[1] and cyclization mechanism[2] of thiocarbonyl ylides have recently attracted considerable attention. A solution of thiourea in chloroform reacts rapidly and exothermically with 2,2-dicyano-3,3-bis-(trifluoromethyl)oxirane, giving dicyanomethylene sulfonium dicyanomethylide in a high yield.[3] Certain thiocarbonyl compounds have been found to give the olefins by a similar treatment. The initial step of the reaction seems to be the formation of ylides, which collapses to a three-membered ring, giving rise to expulsion of sulfur to afford the final product.

We have synthesized the terminal *N*-analog of thiocarbonyl ylide for the first time and found it to undergo similar rearrangement. This report deals with the nature of the thermal rearrangement of thiocarbonyl imines(B).[4]

Results and Discussion

When trithione(A) was treated with chloramine-B or corresponding substituted chloramines in methanol, thiocarbonyl imines(B) were obtained as red-colored precipitates in nearly quantitative yields.



(A) (B)

When compound(B) (X=H) thus obtained was heated by refluxing in various solvents or kept standing at room temperature for a month without solvent, the rearranged imine (*N*-benzenesulfonyl-1,2-benzodithiole-3-imine)(C) was obtained. The analytical data are summarized in Table 1.

In order to clarify the mechanism of rearrangement we carried out kinetic measurements at about 60 °C. The rate of the rearrangement was followed by the disappearance of the absorption band due to thiocarbonylimine, appearing at 472—506 nm. In every case the reaction follows first-order kinetics. The relevant data are collected in Tables 2 and 3.

The marked change in rate with solvents indicates that the reaction rate sequence is not parallel at all with the ordinary polarity scale such as dielectric constant or dipole-moment. Instead, a relatively better correlationship can be found with $1/\lambda_{max}$ for the thiocarbonyl imine itself (Fig. 1). Accordingly, it should be pointed out that rearrangement involves a transition structure like the state of photoexcitation in

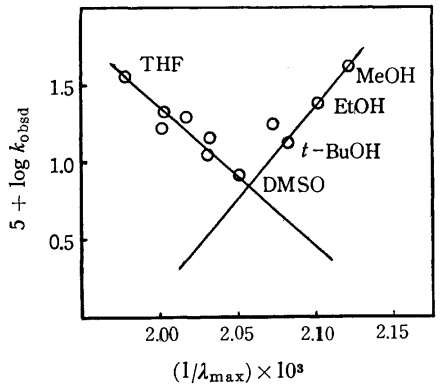


Fig. 1. Plot of log k_{obsd} *vs.* $1/\lambda_{max}$.

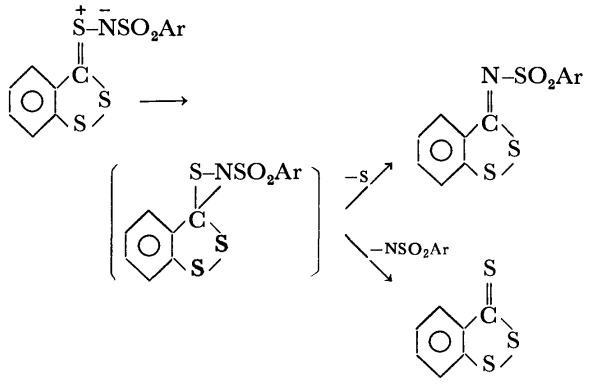
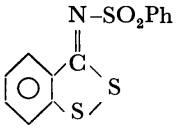
which the charge-separation initially existing completely disappears due to the charge-transfer photoexcitation.[5] The significant increasing change in entropies of activation on going from the reaction in THF to that in CH_3CN also implies that the extent of desolvation on proceeding from the initial state to the transition state is larger in the latter solvent. We can thus conclude that the rearrangement takes place through the initial ring closure to a three-membered thiaziridine ring, followed by the loss of sulfur. The following mechanism would be fully compatible with the negative ρ-value, *i.e.*, -0.56 (Table 3).



As for the reaction in protic solvents we see that the plot (Fig. 1) against solvent such scale as either $1/\lambda_{max}$ or E_T (not given here) displays a behavior essentially different from that of the reaction in aprotic solvents. The reaction is facilitated in more polar alcohols. The lower value of activation energy of 11 kcal/mol as compared with that in aprotic solvents (20 kcal/mol) would support the view that the reaction is brought by nucleophilic interaction of the oxygen atom of alcohol with the tetravalent sulfur atom of thiocarbonyl imine, giving a relatively large charge-separation. The slightly positive rho value of $+0.13$ also supports this.

Experimental

Products. The thermal reaction was carried out by the following procedure. Thiocarbonylimine (339 mg, 1.0 mmol) was heated in various solvents or in neat until thiocarbonyl imine disappeared. The solvent was then evaporated *in vacuo* and the residual crystals were dissolved in a small amount of $CHCl_3$. The residue was chromatographed on silica gel using benzenel. The rearranged product obtained was purified by recrystallization from benzene. The yields of products are given in Table 1.



Mp 176—177 °C, elemental analysis: Found: C, 50.65; H, 2.73; N, 4.55%. Calcd for $C_{13}H_9O_2NS_3$: C, 50.88; H, 2.93; N, 4.56%.

Kinetics. Thiocarbonyl imine (1.5 mg) was dissolved in 50 ml solvent. The solution was kept at 60.1 °C in a thermostat. Every ten minutes 3 ml of the solution was pipetted out and poured into the UV cell which was cooled previously in order to stop the reaction. The reaction rate was obtained by determining the intensity of UV spectra due to thiocarbonyl imine (493 mn in CH_3CN). The results are collected in Table 2.

The Oxidation of α- and β-Methylstyrenes by Manganese(III) Acetate

Akira KASAHARA, Ryu-ichi SAITO, and Taeko IZUMI

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

(Received January 26, 1973)

Earlier studies established that, in acetic acid at 135 °C, α-methylstyrene (I) and β-methylstyrene (II) reacted with manganese(III) acetate to give lactone (III and IV),[1] which could also be obtained with the same reactions in refluxing acetic acid–acetic anhydride.[2] Heiba *et al*[1] suggested that the $\cdot CH_2COOH$ radical is produced directly by the thermolysis of the complex and that the great selectivity of $\cdot CH_2COOH$ radical toward addition to the olefin over allylic hydrogen abstraction leads to high yields of lactones. On the other hand, Gilmore and Mellor[3] reported that, in the presence of potassium bromide, cyclohexene reacts with manganese(III) acetate at 70 °C in acetic acid, thus leading to the formation of cyclohexenyl acetate as the major product. The finding that the potassium bromide-catalyzed oxidation of cyclohexene proceeded *via* allylic hydrogen atom abstraction led us to examine the reactions of I and II under similar conditions.

At 80 °C in acetic acid, I reacted slowly with manganese(III) acetate, but the addition of potassium bromide led a rapid reaction and to the formation of β-phenylallyl acetate (V) as the major product (70%); no evidence for any lactone formation was obtained. Using this same set of conditions, from II cinnamyl acetate (VI) (62%) and α-phenylallyl acetate (VII) (10%) were obtained. These results indicate that potassium bromid-catalyzed oxidation of allylic olefin by manganese(III) acetate proceeds *via* allylic hydrogen abstraction rather than *via* $\cdot CH_2COOH$ radical addition to the olefin.

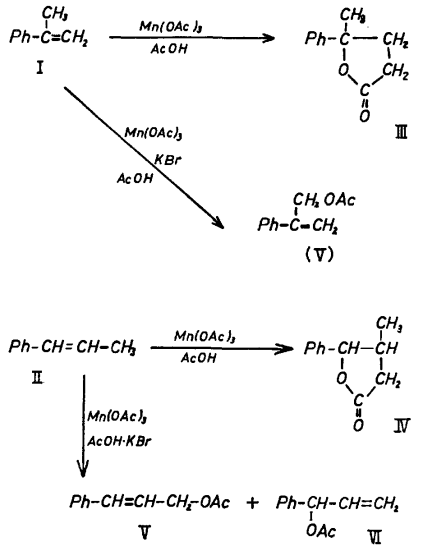

Fig. 1.

Experimental

Manganese(III) acetate was prepared by a modification of Christiansen's procedure.[3,4] β-Phenylallyl acetate (V) was prepared from α-methylstyrene by selenium dioxide oxidation;[5] bp 115—117 °C/7 mmHg (lit.[5] 112—113 °C/5 mmHg). Cinnamyl acetate (VI) was synthesized by esterifying cinnamyl alcohol with acetic anhydride (bp 124 °C/5 mmHg (lit.[6] bp 113 °C/2.4 mmHg)), while α-phenylallyl acetate (VII) was prepared by the esterification of the alcohol (from acrolein and phenylmagnesium bromide) with acetic anhydride (bp 106 °C/6 mmHg (lit.[6] bp 92 °C/2 mmHg)). Gas-chromatographic analyses were carried out on a column, silicon SE 30 (5% on celite), 1 m at 100 °C, with a Hitachi K-53 gas-chromatograph.

Oxidation of α-Methylstyrene (I). Manganese(III) acetate (5.0 g) in acetic acid (60 ml) was heated at 80 °C under nitrogen. To the stirred solution we then added I (1.2 g) and potassium bromide (0.25 g), and the solution was maintained at 80 °C until the color disappeared (*ca.* 6 hr). The reaction mixture was added to 500 ml of ether, which was then extracted four times with ice water. The ether layer was dried over anhydrous magnesium sulfate, filtered, and stripped on a rotary evaporator. The residual oil was distilled under reduced pressure, and the distillate was purified by gas-chromatography and identified as V (70% yields) by comparing the retention time on the gas-chromatogram and the infrared and NMR spectra with those of an authentic sample.

Oxidation of β-Methylstyrene (II). The oxidation of II was carried out in the manner described for I. On work-up, the reaction products contained VI (62% yields) and VII (10% yields), the infrared and NMR spectra and the retention time of which were identical with those of an authentic sample.

The Synthesis of the Salts of L-Aspartic Anhydride with Alkylsulfuric Acid and Their Use in the Preparation of Aspartylphenylalanine Methyl Ester

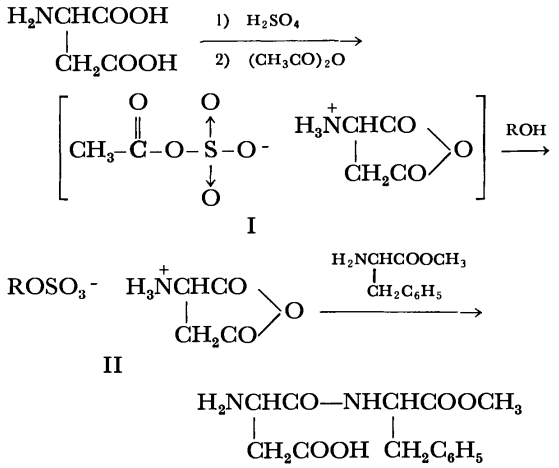
Yasuo ARIYOSHI, Tetsuo YAMATANI, and Yohko ADACHI

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki-ku, Kawasaki 210

(Received January 25, 1973)

In our previous paper,[1] α-L-aspartyl-L-phenylalanine methyl ester (α-APM), which has a sweet taste,[2] has been conveniently prepared by the condensation of L-aspartic anhydride hydrochloride with methyl L-phenylalaninate, followed by the separation of α-APM from a mixture of α- and β-APM. In the present paper, we will describe the synthesis of the salts of L-aspartic anhydride with alkylsulfuric acid and their use in the preparation of α-APM.

By bringing L-aspartic acid into contact with an excess molar amount of concentrated sulfuric acid in ethyl acetate, we obtained L-aspartic acid sulfate, which, on dehydration with two molecular equivalents of acetic anhydride in ethyl acetate, gave the corresponding anhydride (I). Although the anhydride (I) could not be isolated, its structure was assumed to be the salt of L-aspartic anhydride with mixed acetic-sulfuric anhydride (I). The treatment of the anhydride (I) with an equimolar amount of an alcohol, such as methanol, 2-propanol, or cyclohexanol, gave the salts of L-aspartic anhydride with alkylsulfuric acid (II) (Table 1). The reaction of the anhydride (I) with an alcohol took place exclusively at the sulfuric acid moiety of I. The results of the elemental analyses of the reaction products agreed with the values calculated for the anhydrides (II) (Table 1). All of the salts of L-aspartic anhydride with alkylsulfuric acid were practically stable and were used successfully in the preparation of α-APM. In order to increase the formation of the desired α-isomer, the reaction conditions, such as the temperature, the solvent effects, and the molar ratios of both reactants, were investigated. It was found that the reaction could be effected by adding carbon dioxide, by employing an excess of methyl L-phenylalaninate, and by conducting it at a low temperature.



The treatment of L-aspartic anhydride isopropylsulfate with 4 molecular equivalents of methyl L-phenylalaninate in the presence of carbon dioxide in ethylene dichloride at −20 °C gave a mixture of α- and β-APM, from which α-APM was isolated in a 45% yield by separation through its hydrochloride salt, followed by neutralization and subsequent column chromatography.

Experimental

All the melting points are uncorrected. The determination of α- and β-APM by paper electrophoresis was carried out according to the method described in a previous paper.[3] The IR spectra were recorded in Nujol mull with a Jasco IR-S spectrometer. The NMR spectra were obtained with a Varian T-60 spectrometer at 60 MHz; the chemical shifts are given from sodium 2,2-dimethyl-2-silapentane-5-sulfonate, used as the internal reference.

L-Aspartic Acid Sulfate. A mixture of L-aspartic acid (60 g), concentrated sulfuric acid (52.5 ml), and ethyl acetate (200 ml) was stirred for 48 hr at room temperature. The crystals were then collected by filtration and dried *in vacuo* over phosphorus pentoxide; yield, 99 g (95%), mp 151—152 °C. Found: C, 20.59; H, 3.87; N, 6.00; S, 13.71%. Calcd for $C_4H_7O_4N \cdot H_2SO_4$: C, 20.78; H, 3.80; N, 6.06; S, 13.85%.

The Salts of L-Aspartic Anhydride with Alkylsulfuric Acid. In a typical procedure (No 1 in Table 1), a mixture of L-aspartic acid sulfate (11.55 g), ethyl acetate (10 ml), acetic

anhydride (12.8 g), and concentrated sulfuric acid (0.5 g) was stirred for 4 hr at room temperature. Anhydrous methanol (24 ml) was then added to the solution with stirring and cooling in an ice-bath. After stirring for 30 min in an ice-bath, the crystals thus formed were collected by filtration, washed with anhydrous ethyl acetate, and dried *in vacuo* over phosphorus pentoxide and sodium hydroxide pellets; yield, 10.5 g (93%); $[\alpha]_D^{26}$ +15.3° (*c* 2, 6 M HCl); NMR (D_2O, DSS): δ 3.22(d, 2H, J=5.5 Hz), 3.80(s, 3H), 4.50 (t, 1H, J=5.5 Hz).

The data are given in Table 1.

Synthesis of α-APM. Carbon dioxide (8.8 g) was introduced into a solution of methyl L-phenylalaninate (71.6 g) in ethylene dichloride (750 ml) containing 8 ml of methanol at −10 °C. To the stirred solution, L-aspartic anhydride isopropylsulfate (22.7 g) was added, portion by portion, at −20 °C. After stirring for 30 min at this temperature, hot water (300 ml, 70—80 °C) and sodium carbonate (6.3 g) were successively added to the solution. After the removal of the excess of methyl L-phenylalaninate by two extractions with 150-ml portions of ethylene dichloride, the aqueous layer was acidified to pH 3 with dilute hydrochloric acid. The solution was found to contain 20.3 g (61%) of α-APM and 5.8 g (19%) of β-APM by paper electrophoresis. The solution was concentrated *in vacuo* to 135 ml and kept in a refrigerator overnight to give crystals (α-APM·HCl, 20 g, 55%), which were then dissolved in water (150 ml). The solution was adjusted to pH 4.8 with a 5% aqueous sodium carbonate solution while being stirred at 50 °C, and then it was kept in a refrigerator overnight to give crystals (α-APM, 14 g, 46%). The crystals were dissolved in water (500 ml) and passed through a column (1×20 cm) of Dowex 1×4 (acetate form) while being maintained at 45 °C, and then the column was washed with water (20 ml). The eluate and washings were concentrated *in vacuo* to give α-APM, which was recrystallized from water; yield, 12.6 g (42%); mp 235—236 °C (decomp.); $[\alpha]_D^{26}$ +31.5° (*c* 1, acetic acid). lit,[1] mp 235—236 °C; $[\alpha]_D$ +32° (*c*, 1, acetic acid); lit,[2] mp 190 °C and 246—247 °C. lit,[4] mp 245—247 °C. Found: C, 55.46; H, 6.24; N, 8.96%. Calcd for $C_{14}H_{18}O_5N_2 \cdot 1/2H_2O$: C, 55.44; H, 6.31; N, 9.24%.

The Photoconductivity of Poly(*N*-vinylcarbazole). V.[1] The Doping Effects of Various Materials on the Photoconductivity[2]

Kenichi OKAMOTO,* Shigekazu KUSABAYASHI,* and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received June 21, 1972)

The photoconductivity and fluorescence spectra of poly(*N*-vinylcarbazole) (PVCz) films doped with various materials were investigated. The photoconductive properties of doped films may be grouped into three classes according to the kind of dopant. The doping of an electron donor, such as tetramethyl-*p*-phenylenediamine and 1,5-diaminonaphthalene, reduced the photocurrent in all the wavelength regions by a factor of 10^2 to 10^4 because of the hole-trapping effect of the dopant molecule. The exciplex formed between the donor and PVCz does not seem to contribute to the photocurrent. The doping of an acceptor, such as TCNE and dimethyl terephthalate, on the other hand, enhanced the photocurrent. The field-assisted thermal dissociation of an excited CT complex formed between PVCz and an acceptor seems to be a carrier generation process. The doping of anthracene or perylene quenched the fluorescence of PVCz by a factor of 10 to 30 and reduced the photocurrent in the UV region by a factor of 2 to 7, while it enhanced the photocurrent in the absorption region of the dopant.

In their previous papers[1,3] the present authors have examined the photoconductivity of PVCz and explained it by assuming that the carriers were generated through the field-assisted thermal dissociation of an exciplex formed with a fairly good efficiency between PVCz and some impurity with an electron-accepting ability, and also through the detrapping of trapped carriers by singlet excitons, and that the carriers migrated through the overlap of the π-electrons of the neighboring carbazyl rings in the same polymer chain.

In the present paper the doping effects of various materials on the photoconductivity and the fluorescence spectra of PVCz were examined.

Experimental

Materials. *PVCz*: The preparation of PVCz was described in a previous paper.[3]

Carbazole: A commercial product was subjected to a Diels-Alder reaction with maleic anhydride in order to remove a trace of anthracene[4], and was then purified by repeated recrystallizations from *o*-dichlorobenzene and subsequently from acetone.

Anthracene: A commercial product of a scintillation grade was recrystallized three times from benzene.

Perylene, Tetracyanoethylene (TCNE) and Dimethyl terephthalate (DMTP): Commercial products were recrystallized two or three times from benzene and subsequently sublimed *in vacuo*.

*Tetramethyl-*p*-phenylenediamine (TMPD) and 1,5-Diaminonaphthalene (DAN)*: A commercial product of the HCl salt was reprecipitated twice from an aqueous solution of ammonia and then recrystallized three times from *n*-hexane or benzene under a nitrogen stream.

p-*Nitroaniline (PNA)*: A commercial product was recrystallized three times from methanol. The solvents were purified by the ordinary method.

Measurements. Doped films were prepared by casting a 5 wt% benzene solution of PVCz with a certain amount of a dopant onto a quartz plate in a manner similar to that described previously.[3] The films of the following doping amounts were used in the measurements: carbazole 2.0 mol% (per carbazole unit in PVCz), anthracene 3.0 mol%, perylene 1.4 mol%, TMPD 1.8 mol%, DAN 2.7 mol%, TCNE 1.8 mol%, DMTP 1.8 mol%, and PNA 1.9 mol%. The thickness of the films was about 15 μ for the electrical measurements and about 1—2 μ for the fluorescence measurements. The preparation of a sandwich-type cell of a film (area of electrode, 1 cm^2) and the electrical measurement were carried out in a manner similar to that described previously.[3] The ESR spectrum of PVCz powder doped with TCNE (8 mol%) was also measured under illumination with UV or visible light from a 500 W superhigh pressure Hg lamp as well as in the dark.

Results

Dark Conductivity. Carbazole, anthracene, perylene, DMTP, TMPD, and PNA did not have any significant effect on the conductive properties (the magnitude of the dark current, the voltage dependence, and the activation energy) of a PVCz film in the dark.[5]

On the other hand, the doping of DAN or TCNE changed the conductive properties. The dark current for a film doped with DAN was much smaller than that of an undoped film by a factor of ten to a hundred. It was ohmic over the applied fields (0—100000 V/cm). Its activation energy (ΔE_d in the $i_d \propto \exp(-\Delta E_d/kT)$ equation) was 0.9 eV below 100 °C and 1.5 eV above 100 °C, as is shown in Table 1. The former value is similar to that of an undoped film, while the latter is considerably larger. The doping of TCNE enhanced the dark current by a factor of several hundreds to a thousand and lowered the value of ΔE_d (0.8 eV) a little.

Shape of the Photoresponse. The doping of carbazole, anthracene, perylene, or PNA did not have any effect on the photoresponse behavior. The films doped with these materials showed photoresponse curves

Table 1. Activation energies of photo and dark conductivities

Doping material	ΔE_d (eV)	ΔE_{ph} (eV)	Wavelength of illuminating light (mμ)
Carbazole	1.1	0.17	350
Anthracene	1.1	0.14	360
		0.13	380
Perylene	1.0	0.12	350
		0.15	440
TMPD	0.93—1.2	0.24 (below 80 °C)	360
		0.50 (80—140°C)	360
DAN	0.9 (below 100 °C)	0.25 (below 100 °C)	350
	1.3—1.6 (100—140 °C)	0.44 (100—140 °C)	350
TCNE	0.82	0.22	350
		0.24	550
DMTP	1.0—1.1	0.19 (below 90 °C)	350
		0.33 (90—160°C)	350
PNA	—	0.23	360
		0.25	430
Undoped	1.0—1.3	0.13—0.22	UV
		0.07—0.16	Visible

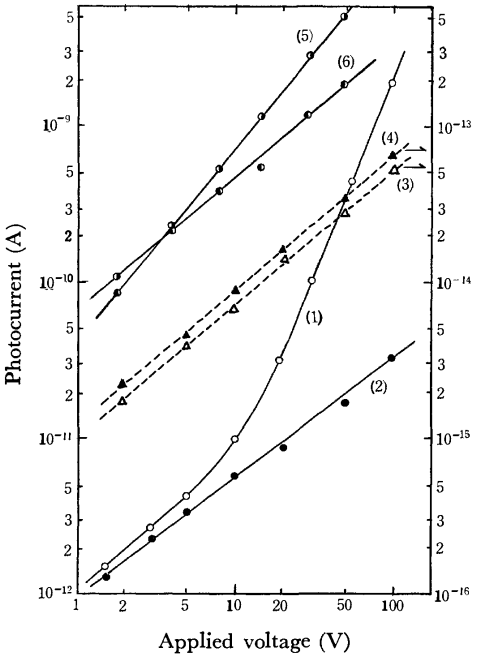

Fig. 1. Voltage dependence of photocurrent in doped films at 20 °C in high vacuum.
(1) perylene, i^+_{ph}, 350 mμ; (2) perylene, i^-_{ph}, 350 mμ; (3)DAN, i^+_{ph}, 360 mμ; (4) DAN, i^-_{ph}, 360 mμ; (5) TCNE, i^+_{ph}, 350 mμ, and (6) TCNE, i^+_{ph}, 550 mμ.

similar to those observed in an undoped film.

The doping of DMTP did not have any effect in the photoresponse behavior when a negative electrode was illuminated (this photocurrent is abbreviated to i^-_{ph}) or when a positive electrode was illuminated by the light of longer wavelength than 360 mμ, but it caused a considerable space charge effect on the photocurrent when a positive electrode was illuminated by UV light (this photocurrent is abbreviated to i^+_{ph}). i^+_{ph} in the region shorter than 360 mμ reached a peak value soon after light-on and decreased slowly with time until it leveled off to a steady-state value after 10—40 min. The steady-state value was much smaller than the peak value, especially when the light of the wavelength corresponding to the absorption peak was used. This difference between the peak and the steady values was quite large as compared with the case of an undoped film.

In a film doped with TCNE or DAN, the normal photoresponse curve (A type in the previous paper[3]) was observed at every wavelength irrespective of the polarity of the illuminated electrode.

Light-intensity Dependence of the Photocurrent. In every doped film except TCNE, the photocurrent was found to be proportional to the light intensity, irrespective of both the polarity of an illuminated electrode and the wavelength of light. This is the same as the case of a PVCz film. In a film doped with TCNE, the photocurrent was found to be proportional to the 0.8-th power of the light intensity.

Voltage Dependence of the Photocurrent. In films with dopants other than TMPD and DAN, the photocurrent showed a voltage dependence similar to that observed in an undoped film, as is shown in Fig. 1. In applied fields higher than 15000 V/cm, i^+_{ph} was proportional to the n-th power of the applied voltage (n=1.4—2.0) in the UV region shorter than 360 mμ, although it was proportional to the applied voltage in the visible region. The i^+_{ph} in applied fields lower than 15000 V/cm and the i^-_{ph} were proportional to the applied voltage, irrespective of the wavelength of light. In these films i^+_{ph} was larger than i^-_{ph} in high fields, although they were roughly equal to each other in low applied fields. This behavior is similar to the case of an undoped film.

On the other hand, in a film doped with TMPD or DAN both i^+_{ph} and i^-_{ph} were proportional to the applied voltage over the whole voltage region, and the super-linear dependence of i^+_{ph} in the high-field region was not observed. There was no significant difference in magnitude between i^+_{ph} and i^-_{ph} in these films, as is shown in Fig. 2(b). It should be noted that these dopants are fairly strong electron donors.

Spectral Dependence of the Photocurrent. The spectral dependence of the photocurrent in the doped films shown in Figs. 2(a—d) was obtained by normalizing the observed photocurrent values to the values for the light intensity of 2×10^{13} photons/cm^2 s according to the light-intensity dependence. The photocurrent values in Fig. 2 were obtained from the cells which showed the representative values of photocurrent among several cells. The magnitudes of the photocurrents in Figs. 2 can be compared directly with each other. The dopants are grouped according to both their spectral dependence and the magnitudes of the photocurrents. Figures 2(a—d) also show the absorption spectra of the undoped and doped films used in the photoconductivity measurements. No new absorption

band was observed in the doped films except in the case of TCNE. The film doped with TCNE shows the charge-transfer (CT) absorption bands, as is well known.[6]

Group A. Carbazole, anthracene, and perylene belong to this group. The spectral dependence of the photocurrent is almost the same as that observed in an undoped film, as is shown in Figs. 2(a) and (c). The spectral dependence of i^+_{ph} corresponds to the absorption spectrum, while that of i^-_{ph} corresponds inversely to it. In the film doped with anthracene or perylene, new photocurrent peaks are observed in the absorption region of the dopant. This sensitized photocurrent in the film doped with perylene showed a spectral dependence similar to that in the π-π^* absorption bands of PVCz. The doping of carbazole hardly changed the magnitude of the photocurrent at all in any of the wavelength regions. The doping of anthracene or perylene reduced the photocurrent in the absorption region of PVCz by a factor of 2 to 7, while it enhanced the photocurrent in the lowest absorption band of the dopant by factors of 10 for i^+_{ph} and 2—3 for i^-_{ph}.

Group B. TMPD, DAN, and PNA belong to this group. As is shown in Fig. 2(b), both i^+_{ph} and i^-_{ph} showed the same spectral dependence, one which corresponded rather inversely to the absorption spectrum, and both were significantly reduced in magnitude by doping.

In a film doped with TMPD or DAN, both i^+_{ph} and i^-_{ph} significantly decreased in all the wavelengthr egions. The decrease in the photocurrent was 1/1000—1/10000 for i^+_{ph} or 1/30—1/300 for i^-_{ph} in the case of DAN, while it was 1/100—1/10000 or 1/5—1/20 in the case of TMPD, respectively. Thus, i^+_{ph} decreased much more than i^-_{ph}; hence, i^+_{ph} was almost equal to i^-_{ph} in magnitude in all the wavelength regions. It is very interesting that the photocurrent decreased by a factor of 10^2—10^4 by the doping of small amount (1—3 mol%) of TMPD or DAN.

In a film doped with PNA, the photocurrent in the absorption region of PVCz decreased by a factor of 10—100 for i^+_{ph} and by one of 5—10 for i^-_{ph}. The value of i^+_{ph} was, however, still larger than i^-_{ph}, although the i^+_{ph}/i^-_{ph} ratio in the UV region (4—30 in this case) was considerably smaller than the corresponding ratio of an undoped film (50—500). In a film doped with

7) J. Tanaka, This Bulletin, **36**, 833 (1963).

PNA, the incident light of wavelength shorter than 385 mμ was absorbed almost completely. Consequently, a photocurrent peak was not observed at 360 mμ, but at 390 mμ. In the wavelength region from 380 mμ to about 500 mμ, the photocurrent was a little larger than that of an undoped film.

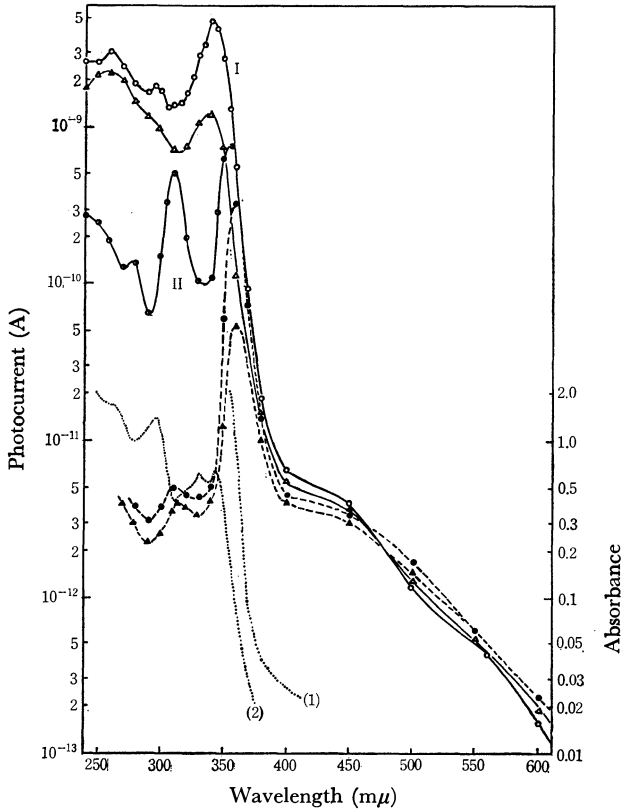

Fig. 2(c). Spectral dependence of photocurrent in a sandwich-type cell of both a PVCz film and a PVCz film doped with DMTP under 35000 V/cm in high vacuum at 20 °C.
PVCz; —△— for i_{ph}^{+}, and ---▲--- for i_{ph}^{-}.

The absorption spectra of the PVCz films are given by the dotted lines. (1) doped with DMTP and (2) an undoped film 1 μ thick.

Group C. DMTP belongs to this group. In a film doped with DMTP the spectral dependence of i_{ph}^{-} was almost the same as that observed in an undoped film. The spectral dependence of i_{ph}^{+}, however, changed with the measurement conditions, as is shown in Fig. 2(c), because of a considerable space charge effect. In Fig. 2(c) Curve I shows the spectral dependence of i_{ph}^{+} measured under conditions which make the space-charge effect as small as possible. In order to release space charges formed by the previous UV illumination, the visible light of wavelengths longer than 400 mμ was used for a long time in each case before UV light was used for the measurement. Curve II shows the spectral dependence of i_{ph}^{+} measured after space charges were built up by the preillumination of the UV light of wavelengths shorter than 330 mμ. In Curve I the spectral dependence was similar to that of an undoped film, and the magnitude of i_{ph}^{+} in the UV region was considerably larger than the magnitude of i_{ph}^{+} in an undoped film; that is, the chemical sensitization of the photocurrent was observed. On the other hand, in Curve II the spectral dependence corresponded inversely to the absorption spectrum, and the magnitude of i_{ph}^{+} in the UV region, especially at the absorption peaks, was considerably smaller than that of an undoped film.

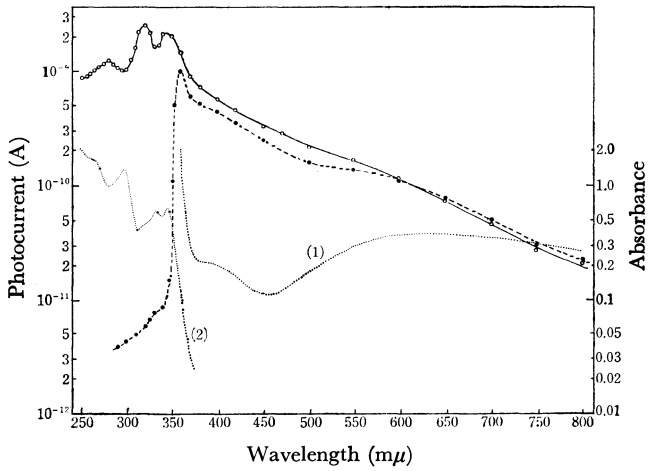

Fig. 2(d). Spectral dependence of photocurrent in a sandwich-type cell of a PVCz film doped with TCNE under 35000 V/cm in high vacuum at 20 °C.
—○— for i_{ph}^{+}, and ---●--- for i_{ph}^{-}.
The absorption spectra of the PVCz films are given by the dotted lines. (1) doped with TCNE and (2) an undoped film 1 μ thick.

Group D. TCNE belongs to this group. The peaks of i_{ph}^{+} were observed at 340 and 320 mμ, and the minima, at 330 and 295 mμ, as is shown in Fig. 2(d). The i_{ph}^{-} showed only a peak at 360 mμ and showed neither a clear peak nor a minimum in the wavelength region shorter than 350 mμ. The doping of TCNE enhanced both i_{ph}^{+} and i_{ph}^{-} a little in the UV region and significantly in the visible region. The degree of increase in the photocurrent in the UV region was 10—20 fold at 360 mμ, 3—4 fold at 350 mμ, and 2 fold at 330 mμ. Thus, the doping of TCNE caused not only the spectral sensitization, but also the chemical sensitization of the photocurrent.

Activation Energy of Photocurrent. The activation energies of the photocurrent (ΔE_{ph}) in doped films are listed in Table 1. In a film doped with carbazole, anthracene, or perylene, the value of ΔE_{ph} (0.15—0.20 eV) was almost the same as that observed in an undoped film. In a film doped with PNA, or TCNE, the value of ΔE_{ph} was 0.2—0.3 eV, a little larger than that of an undoped film. In a film doped with TMPD, DAN, or DMTP, the photocurrent showed clearly different temperature dependences in the high- and low-temperature ranges, as is shown in Fig. 3. In these films, ΔE_{ph} was 0.19—0.25 eV in the low-temperature range and 0.35—0.50 eV in the high-temperature range, the latter being fairly large. Although the values of ΔE_{ph} mentioned above were the values for the photocurrent in the absorption region of PVCz, similar values of ΔE_{ph} were also obtained for the spectrally-sensitized photocurrent.

Fluorescence Spectra of the Doped Films. Information

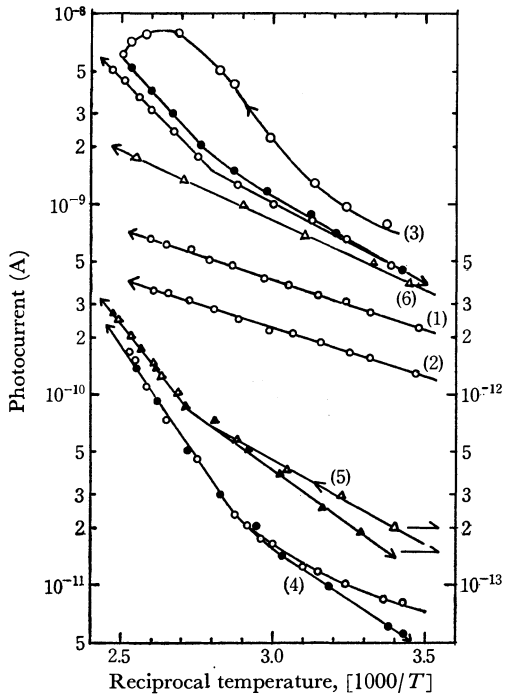

Fig. 3. Temperature dependence of photocurrent in a sandwich-type cell of the doped PVCz films under 35000 V/cm with positive electrode illumination in high vacuum. (1) perylene, 350 mμ, (2) perylene, 440 mμ, (3) DMTP, 360 mμ, (4) TMPD, 360 mμ, (5) DAN, 350 mμ, and (6) undoped, 350 mμ.

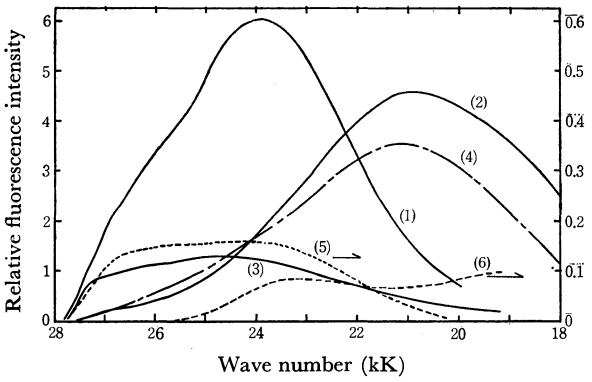

Fig. 4. Fluorescence spectra of the doped PVCz films. Excitation wavelength; 313 or 334 mμ, film thickness; 1 μ, atmosphere; air. (1) undoped, (2) doped with DMTP, (3) DAN, (4) TMPD, (5) TCNE, and (6) PNA.

concerning the electronic interaction between PVCz and a dopant molecule is necessary for understanding the photoconductive properties in doped films, so the fluorescence spectra of doped films excited by 313 or 334 mμ light were measured; they are shown in Fig. 4.

In a film doped with carbazole, the fluorescence spectrum was the same as that of an undoped film, no significant quenching of fluorescence being observed. When PVCz was doped with anthracene or perylene, energy transfer occurred from the excited singlet state of a carbazole chromophor of PVCz to the dopant molecule,[8] and the fluorescence of PVCz was significantly quenched and much fluorescence was emitted by the dopant. For instance, in films doped with 0.3 or 1.4 mol% of perylene the fluorescence of PVCz was quenched by a factor of 6 or 15 respectively.

The fluorescence of perylene in three films with the same doping amount was examined by directly exciting a perylene molecule with 405 mμ light. The films examined were a PVCz film, an *N*-vinylcarbazole (VCz)–vinyl acetate copolymer (VCz 81 mol%) film, and a polystyrene film. The relative intensities of the total fluorescence emission of perylene were as follows: a polystyrene film, 1.0; a VCz-vinyl acetate copolymer film, 0.92, and a PVCz film, 0.82. Thus, the intensity of the total fluorescence emission of perylene doped in a PVCz film is a little smaller than that in a polystyrene film. There may be some interaction between the excited molecule of perylene and a PVCz molecule.

In a film doped with TCNE or DAN, the fluorescence of PVCz was quenched by a factor of 30 in the case of TCNE or by one of 5 in the case of DAN, and no new emission band was observed. In a film doped with TMPD, DMTP, or PNA, the fluorescence of PVCz was quenched by a factor of from 10 to 100 and a new broad emission band was observed at about 21000 cm^{-1}. TMPD being a strong electron donor, the fluorescence of an exciplex between TMPD and perylene[9] or α-methylnaphthalene[10] has been observed in the same wavelength region. The new broad emission band may, therefore, be attributed to the fluorescence of the exciplex. The quenching of the fluorescence of PVCz in a film doped with DAN seems to be due to a similar process. A new broad emission band at about 21000 cm^{-1} in a film doped with DMTP may be attributed to the fluorescence of an exciplex. A similar emission band has been reported in the PVCz–DMTP system in solution.[11] In a film doped with PNA, the fluorescence of PVCz was quenched almost completely and a new weak emission band was observed in the visible region. As the ionization potential of gaseous PNA is 8.85 eV,[12] it is probable that PNA acts as a weak electron acceptor to PVCz. The new emission band may be due to the formation of an exciplex.

Discussion

It is useful to know the relative energy levels of the highest occupied and the lowest unoccupied π molecular orbitals of both the dopants and PVCz in understanding the photo and dark conductivities of the doped films. The dopants used in the present study are molecules with many π electrons, the gaseous ionization potentials of which have been measured by various methods.[12] These values of ionization potential were

used as a measure of the highest occupied π molecular orbital. The energy level of the lowest unoccupied π molecular orbital was estimated from the energy of the lowest absorption band, which may be attributed to the transition from the highest occupied to the lowest unoccupied π molecular orbitals except in the case of PNA. The lowest absorption band of PNA is due to the intramolecular CT band.[7] The energy levels of both dopants and PVCz thus obtained are shown in Fig. 5. From Fig. 5, the dopants used in this study may be grouped into three categories: donor, acceptor, and neutral. The photoconductive properties and fluorescence spectra of doped films may also be classified into these three groups.

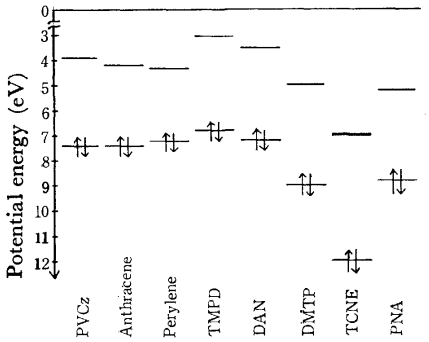

Fig. 5. Relative energy levels of the highest occupied and the lowest unoccupied π molecular orbitals of the dopant molecules and of PVCz.

Donors (TMPD and DAN). Films doped with these donors are characterized by the following three points; a significant decrease in the photocurrents ($i^+_{ph}=i^-_{ph}$) in all the wavelength regions, the disappearance of the superlinear dependence of i^+_{ph} on the applied voltage, and a large activation energy of the photocurrent in the high-temperature range.

As the formation of an exciplex $(PVCz^-\cdots D^+)^*$ is clear from the fluorescence spectra, the following Eqs., (1) and (2), are conceivable as carrier generation processes.

$$PVCz^* + D \longrightarrow (PVCz^-\cdots D^+)^* \longrightarrow PVCz^- + D^+ \quad (1)$$

$$D^+ + PVCz\ (\text{or } PVCz^*) \longrightarrow D + PVCz^+ \quad (2)$$

where D is a donor molecule; $(PVCz^-\cdots D^+)^*$, an exciplex; D^+, an immobile cation of a donor, and $PVCz^-$ and $PVCz^+$, ion radicals of PVCz (*i.e.*, mobile charge carriers). Equation (1) shows the ionization of an exciplex into a mobile carrier. Equation (2) shows the excitation of an electron from PVCz (or PVCz*) to an electron acceptor, D^+. A similar process has been presented in order to explain the photoconductive properties of a PVCz film,[3] although in that case PVCz acts as an electron donor. In the present case, excited PVCz molecules acting as electron acceptors, these processes do not seem to occur, judging from the significant decrease in the photocurrent in the doped films. This may be due to the ease of recombination between $PVCz^-$ and D^+ in Eq. (1), probably because of the small electron mobility in PVCz films. If so, the formation of an exciplex may have only the effect of decreasing the efficiency of the extrinsic carrier generation through the reduction of the life-time of the excited singlet state of PVCz.

Figure 5 suggests that the highest occupied π molecular orbital of a donor may act as a hole trap level and may reduce the effective hole mobility significantly. Both the increase in the ΔE_{ph} value and the disappearance of the superlinear dependence of i^+_{ph} on the applied voltage can be explained in terms of this hole trapping effect of a donor.

Acceptors (TCNE, DMTP, and PNA). In a film doped with TCNE, a sensitization of the photocurrent was observed in the absorption region of PVCz as well as in the CT absorption region. The apparent quantum yield of the photocurrent was determined as the ratio of the number of electrons flowing in the external circuit to the number of the photons absorbed by the film. It was in the order of 10^{-3}—10^{-2} at the CT bands and in that of $\sim 10^{-4}$ in the UV region. The former is much higher than the latter. The carrier generation *via* the excited CT state, such as that presented by the following equations, seems to contribute considerably to the photocurrent:

$$PVCz^* + TCNE \longrightarrow (PVCz^+\cdots TCNE^-)^*$$

$$(PVCz\cdots TCNE) \xrightarrow{h\nu_{CT}} \downarrow \quad (3)$$

$$PVCz^+ + TCNE^-$$

$$TCNE^- + PVCz^* \longrightarrow TCNE + PVCz^- \quad (4)$$

The film doped with TCNE showed an ESR signal even in the dark. This ESR signal was enhanced a little by illumination both with UV light and with visible light. The ESR signal must be due to the radical ion of TCNE or PVCz. This supports the carrier generation represented by Eqs. (3) and (4).

Although the doping of DMTP had no effect on the photocurrent in the visible region, a significant influence was observed on the photocurrent in the absorption region of PVCz. Both the peak photocurrent and the steady-state photocurrent in the UV region measured under the conditions which made the space charge effect as small as possible were fairly sensitized by doped DMTP; there was no influence on the other properties of the photocurrent, such as the large value of the i^+_{ph}/i^-_{ph} ratio, the spectral dependence, and the superlinearity of i^+_{ph} on the applied voltage. It is clear from the fluorescence spectrum that, in this film, the exciplex $(PVCz^+\cdots DMTP^-)^*$ is formed with a good efficiency by the UV light illumination in spite of the small concentration of DMTP. The exciplex thus formed seems to be responsible for the chemical sensitization of the photocurrent. The field-assisted thermal dissociation of the exciplex $(PVCz^+\cdots A^-)^*$ assumed in the previous paper as an extrinsic carrier generation mechanism in a PVCz film must be a primary carrier generation process under UV illumination in this doped film. This is represented by the following Eqs., (5) and (6):

$$PVCz^* + DMTP \longrightarrow (PVCz^+\cdots DMTP^-)^* \longrightarrow PVCz^+ + DMTP^- \quad (5)$$

$$PVCz^* + DMTP^- \longrightarrow PVCz^- + DMTP \quad (6)$$

In the PNA doped film the photocurrent (i^{+}_{ph}) decreased significantly in the UV region, although the exciplex seemed to be formed. Although the reason for this is not clear, it is conceivable that this can be attributed to the effect of the product of the hydrogen abstracting reaction of PNA[13] or to the presence of a small amount of an impurity such as *p*-diaminobenzene, a strong donor, in PNA.

Neutral Materials (Carbazole, Anthracene, and Perylene). Doping of carbazole had no effect on either the photocurrent or the fluorescence spectrum of PVCz.

In a film doped with anthracene or perylene (doping amount, 1—3 mol%), the fluorescence of PVCz was quenched by a factor of from 10 to 30, while the photocurrent in the absorption region of PVCz decreased by a factor of from 2 to 7. Judging from the quenching of the fluorescence of PVCz, the lifetime of the singlet exciton of PVCz and, consequently, the number of the carbazole rings covered with the singlet exciton during its lifetime may be estimated to decrease by a factor of from 10 to 30 as compared with the case of the undoped film. Therefore, in the doped film the efficiency of extrinsic carrier generation will decrease by the same factor. The decrease in the photocurrent in the absorption region of PVCz was, however, much smaller than the decrease presumed from the degree of the fluorescence quenching. This may be due to the contribution of carrier generation through the excited state of the dopant molecule.

In the doped film, the sensitized photocurrent was observed in the proper absorption region of anthracene or perylene. The apparent quantum yield of this photocurrent was from a tenth to a fifth of that of the photocurrent in the proper absorption region in a PVCz film (the quantum yield of PVCz in this region is, for instance, 1×10^{-4} for i^{+}_{ph} at 330 mμ under 35000 V/cm in the film of 15 μ thick). Some interaction between the dopant molecule in the excited state and PVCz in the ground state, which is probable from the fluorescence spectra mentioned above, may be responsible for the photocurrent sensitized spectrally with anthracene or perylene.

Doped anthracene or perylene may be expected from Fig. 5 to act as a hole trap center It has been reported that, in an anthracene single crystal doped with tetracene, the dopant molecule acts as a hole trap center.[14] Such a trapping effect by the dopant was not, however, observed in the film doped with anthracene or perylene.

The authors wish to thank the Fuji Photo Film Co. for its financial support of this work.

Some Doping Effects on the Semiconducting Properties of Gd_2CuO_4

Tadao KENJO and Seishi YAJIMA

The Oarai Branch, The Research Institute for Iron, Steel and Other Metals, Tohoku University, Oarai, Ibaraki 311-13

(Received August 28, 1972)

Some doping effects on the semiconducting properties of the Gd_2CuO_4 compound were investigated. The ZrO_2 or ThO_2 (0.5 mol%) lowered the resistivity of the Gd_2CuO_4 at room temperature by a factor of 10^4. The thermoelectric powers of the same samples were negative. These were explained as being due to the Cu^+ ions formed by the dopants. The CaO dopant lowered the resistivity by a factor of ten and converted the sign of the thermoelectric power from negative to positive. The resistivity of the BaO-doped samples increased with an increase in the dopant concentration up to 0.5 mol%, and decreased with an increase in the dopant concentration in the concentration region lower than that. This suggested that the dopant of BaO was less effective on the resistivity-lowering than was the CaO. The samples doped with the ZrO_2 and CaO simultaneously gave a trend similar to those doped with the BaO in the concentration dependence of the resistivity. Silver oxide and indium oxide were also employed as dopants, but no doping effects were observed on either resistivity or the lattice parameters.

The Ln_2CuO_4 compounds (Ln=Gd, Sm, Nd, and Pr) are semiconductive, and their resistivities increase with an increase in the atomic number of Ln.[1] It has been suggested that the most important electron-carriers come from cuprous cations, Cu^+, probably formed by a thermal decomposition of cupric cations, Cu^{2+}.[1] The trend for the resistivities to increase with an increase in the atomic number of Ln was explained as being due to: (1) a variation in the number of the donor centers or (2) a variation in the activation energy.[1] However, it is not known which factor is more important.

As is well known, some dopants introduce donor

1) T. Kenjo and S. Yajima, This Bulletin, **46**, 1329 (1973).

centers.[2,3,5,6] If the dopants do not change the activation energy very greatly, any electrical effects due to the dopants can be ascribed to the first case. The X-ray diffraction data indicated that the lattice parameters for the Gd_2CuO_4 did not shift with doping, suggesting no variation in the activation energy. Therefore, the comparison of the doped to undoped Ln_2CuO_4 in the semiconducting properties may give an answer to the above problem.

Dopants usually lower the resistivity. Therefore, the most marked doping effect can be expected for the compound whose resistivity is the greatest. Since the Gd_2CuO_4 showed the greatest resistivity in the Ln_2CuO_4 series, it was chosen as the compound to be doped.

Donor centers are formed when the valence of the dopant is greater than that of the site.[2,3,5,6] Zirconium oxide, ZrO_2, and thorium oxide, ThO_2, were chosen as dopants which could be expected to occupy the Gd^{3+} sites, because they are chemically similar to the rare earth oxides.

Acceptor centers will be formed by dopants whose valences are smaller than those of the site. The most probable acceptor centers in this case are the Cu^{3+} or the Gd^{4+} cations. Since both of them are unstable and are not well known, it would be of interest to see if doped divalent cations lower the resistivity of the Gd_2CuO_4. Alkaline earth oxides are most suitable for the above purpose, because they are chemically similar to Gd_2O_3 and because they are expected to occupy the Gd^{3+} sites. Barium oxide, BaO, and calcium oxide, CaO, were employed as the dopants here.

Silver oxide, Ag_2O, and indium oxide, In_2O_3, were expected to occupy the Cu^{2+} sites and to form acceptor and donor centers respectively. They were also used as dopants.

Experimental

Reagents and Materials. An aqueous solution of $Gd(NO_3)_3$ was prepared by dissolving Gd_2O_3 (Nippon Yttrium Co., Ltd., 99.9%) in nitric acid (Wako Pure Chemical Co., Ltd., GR grade). The maximum contents of the impurities contained in the Gd_2O_3 used were Fe_2O_3, 10 ppm; CuO, 10 ppm; CaO, 30 ppm; ZrO_2, 10 ppm and ThO_2, 10 ppm.[7] An aqueous solution of $Cu(NO_3)_2$ was prepared by dissolving GR-grade $Cu(NO_3)_2 \cdot 3H_2O$. The maximum contents of the impurities contained in the $Cu(NO_3)_2$ used were; Fe, 30 ppm; Zn, 50 ppm; Ni, 40 ppm; Ba, 20 ppm; Ca, 4.5 ppm; Zr, 10 ppm, and Th, not detected.[8] The aqueous solutions of the nitrates of Zr, Ag, and Th were prepared by dissolving GR-grade $ZrO(NO_3)_2$, $AgNO_3$, and $Th(NO_3)_4$ respectively. The aqueous solutions of $Ca(NO_3)_2$, $Ba(NO_3)_2$, and $In(NO_3)_3$ were obtained by dissolving GR-grade $CaCO_3$, $BaCO_3$, and EP-grade In_2O_3 respectively in nitric acid. The concentration of the $AgNO_3$ solution was determined gravimetrically. The concentrations of the other solutions were determined chelatometrically against a standard EDTA solution.

Procedure. The samples were prepared by the same method as in a previous work.[1] Aliquot portions of $Gd(NO_3)_3$, $Cu(NO_3)_2$, and the nitrate of the dopants were mixed, and a sodium hydroxide solution (1M) was stirred in. After the mixture had stood overnight, filtering-washing was repeated until no sodium ion was detected in the filtrate by the flame test. The mixed hydroxides thus obtained were dried at 120 °C and preheated at 750 °C for 4 hr in air. The lumped oxide mixtures were milled, pressed into 15-mmϕ pellets, and heated at 1000 °C for 15 hr in air. The pellets thus obtained were removed from the furnace and cooled to room temperature. These samples thus obtained were cut into rods 12—13 mm long and 3—4 mm thick for the electrical measurements. The resistivity was measured by the 4-probe method using Du Pont No. 4622 Conductive Silver Coating Materials. The thermoelectric power was measured by means of the method of the previous work.[1] The bulk densities of the samples thus obtained were essentially the same as those of the undoped Gd_2CuO_4.

Results

The concentrations of the dopants are expressed as a mol% of the dopants against the total moles of the Gd_2CuO_4 and the dopants used. The signs for the values of the thermoelectric power are the same as in the previous work, being positive for a *p*-type and negative for an *n*-type.

Figures 1, 2, 3, and 4 show the data for the ZrO_2- or ThO_2-doped Gd_2CuO_4. As will be described in a later section, the mole ratio of raw oxide mixtures was: Gd_2O_3: CuO: $ZrO_2 = 1-x : 1 : x$. The sample containing 5 mol% ZrO_2 gave only the X-ray diffraction pattern of the Gd_2CuO_4 phase, while the ZrO_2 phase was found for the sample containing 10 mol% ZrO_2. This indicated that the solubility of ZrO_2 in Gd_2CuO_4 was between 5 and 10 mol%.

The resistivity, ρ, particularly at room temperature, decreases with an increase in the concentration of ZrO_2 up to 0.5 mol%. Beyond this concentration, however, the resistivity increases with an increase in the concentration of ZrO_2 (Fig. 1). Figure 2 shows the temperature dependence of the resistivity for the various contents of ZrO_2. The resistivity-lowering due to the dopant is the most marked at room temperature. The log ρ *vs.* $1/T$ plots for the samples of $x<0.5$ mol% show shoulders in the high-temperature region. As is indicated by the black squares in Fig. 2, the resistivity of the less dense specimen is ten times that of the denser one (open circles); the bulk density of the former is 0.64 of the theoretical value, while that of the latter is 0.90 of the same value. The curves for the two specimens are parallel. Figure 3 indicates that the ZrO_2-doped Gd_2CuO_4 are *n*-type semiconductors.

The solubility of ThO_2 in the Gd_2CuO_4 was between 15 and 20 mol%. The ThO_2-doped samples are similar to the ZrO_2-doped ones in the dependence of the resistivity on the dopant concentration and in the thermoelectric power data; the resistivity is at a minimum at 0.5 mol% ThO_2, and the thermoelectric power is negative.

Figures 5, 6, and 7 give the data for the CaO- or BaO-doped Gd_2CuO_4. The solubility of CaO in the Gd_2CuO_4 was between 1 and 5 mol%. Figure 5 shows that the resistivity decreases with an increase in the dopant concentration, but not so markedly as in the case of the ZrO_2- or ThO_2-doping. The log ρ *vs.* $1/T$ plots (Fig. 6) indicate that the ρ values for the CaO-doped samples, as well as their slopes, approach those for the undoped Gd_2CuO_4 in the high-temperature region. Figure 7 shows that the thermoelectric

power was changed from negative to positive values by doping the CaO.

The solubility of BaO in the Gd_2CuO_4 was between 2.5 and 5 mol%. The plots of the resistivity *vs.* the dopant concentration (Fig. 5) show the maximum resistivity value at 0.5 mol% BaO. Figure 6, showing the temperature dependence of the resistivity, is similar to the plots for the CaO-doped samples. The samples containing large amounts of BaO give positive thermoelectric powers, except in the high-temperature region (Fig. 7). The sample containing 0.5 mol% BaO, the resistivity of which is the maximum (Fig. 5), changes its sign of the thermoelectric power at 180 and 580 °C.

Figures 8, 9, and 10 show the data for the Gd_2CuO_4 doped both with ZrO_2 and with CaO simultaneously with a constant total mole value of the ZrO_2 and CaO.

△: ZrO_2= 0.1 mol%, CaO=0.9 mol%, ●: ZrO_2=0.2 mol%, CaO=0.8 mol%, ◇: ZrO_2=0.3 mol%, CaO=0.7 mol%, ◆: ZrO_2=0.4 mol%, CaO=0.6 mol%, ○: ZrO_2= 0.5 mol%, CaO=0.5 mol%, ▲: ZrO_2=0.6 mol%, CaO= 0.4 mol%.

Figure 8 shows the dependence of the resistivity on the composition of ZrO_2–CaO in mol%. The ρ value is at its maximum at the concentrations of 0.2 and 0.8 mol% of ZrO_2 and CaO respectively. The CaO- and ZrO_2-rich samples show essentially the same trend as the CaO-doped and ZrO_2-doped samples respectively in the temperature dependence of their resistivities.

Discussion

The lattice sites occupied by a dopant can be estimated by the use of an X-ray diffractometer when the dopant concentration is higher than its sensitivity limit. When the ZrO_2, for example, is doped, the mole ratio of the raw oxide mixtures, $CuO: Gd_2O_3: ZrO_2$, is $1: 1-x: x$ or $1-x: 1: x$, where x is the dopant concentration. The former ratio is used when the ZrO_2 is expected to occupy the Gd^{3+} sites; the dopant in the latter case is expected to occupy the Cu^{2+} sites. If the ZrO_2 occupies the Gd^{3+} sites, the ZrO_2 phase will be found in the samples prepared in the latter fashion. If the ZrO_2 occupies the Cu^{2+} sites, the same phase will be found in the former samples. The X-ray diffraction data indicated that ZrO_2 phase was present in the samples when $CuO: Gd_2O_3: ZrO_2 = 1-x: 1: x$, and that no ZrO_2 phase was present when $CuO: Gd_2O_3: ZrO_2 = 1: 1-x: x$; $x<0.1$ for both cases. Consequently, the doped ZrO_2 or the ThO_2 was found to occupy the Gd^{3+} sites in the concentration region of $0.1>x>0.05$.

The X-ray diffraction data described above still leave two problems: (1) it is not known which sites are occupied by the dopants in the $x<0.05$ concentration region, and (2) a small amount of the ZrO_2 or ThO_2 may be present in the Cu^{2+} sites, although an X-ray diffractometer does not detect them. It is difficult to give a clear answer to the above problems, but the following assumptions may be made: (1) the ZrO_2 or ThO_2 occupies the Gd^{3+} sites also in the $x<0.05$ concentration region, and (2) the fraction of the Cu^{2+} sites which might be occupied by the dopants is so small that the electrical effects due to them are negligibly small. The above two assumptions seem reasonable, because the sites occupied by the dopants are unlikely to depend upon the dopant concentration, and because the ZrO_2 or ThO_2 is chemically more similar to Gd_2O_3 than to CuO.

The doped Gd_2CuO_4 decreases in its resistivity with an increase in the concentration of ZrO_2 up to 0.5 mol%. This suggests the presence of donor centers. The doped Zr^{4+} cations occupy the Gd^{3+} sites and may be initially reduced to Zr^{3+} cations to minimize the strain energy due to the oxygen vacancies, but the Zr^{3+} cations formed, if they were fixed at the sites, do not act as donor centers because they are on the Gd^{3+} sites, where an appreciable electron-overlapping cannot be expected.[1] The Cu^+ ions, on the other hand, seem to be more probable donor centers, because they are on the Cu^{2+} sites, where an electron-overlapping *can* be expected.[1] The Cu^+ ions are formed by the reduction of the Cu^{2+} ions while the Zr^{3+} ions are oxidized to Zr^{4+} ions—that is, $Cu^{2+}+Zr^{3+}=Cu^+ + Zr^{4+}$. This reaction is an electron-transfer from the Zr^{3+} to Cu^{2+} ions, and results in excess positive and negative charges at the Zr^{4+} and Cu^+ ion respectively. It is electrostatically unstable. However, the electrostatic energy needed for the electron-transfer is compensated for by the energy difference between the Cu^+ formation and the excitation of the Zr^{3+} to the Zr^{4+} ion, because the Cu^+ ion seems to be more stable than the Zr^{3+} ion.

The increase in the resistivity with the increase in the concentration of ZrO_2 beyond 0.5 mol% is unexpected. An increase in the resistivity is usually ascribable to a decrease in the number of carriers or to a decrease in the mobility.[3,5,6] In this case, however, a decrease in the number of carriers is not likely, because such a doping effect as would decrease the number of carriers cannot be expected. A decrease in the mobility is not likely either, although the mobility might be lowered because of the electron scattering by the lattice vacancies. Therefore, some changes in the grain boundary are more likely to be causes of the above fact. As can be seen in Fig. 2, the less dense specimen is greater than the denser one in its resistivity, while the slopes in the log ρ *vs.* $1/T$ plots are the same. This is simply because the less dense sample is smaller than the denser one in the contacting area of the grains. The ZrO_2 dopant, on the other hand, enhances not only the resistivity but also the slopes of the plots. Therefore, a decrease in the contacting area of the grains, which is one of the changes in the grain boundary, is not a cause of the increase in the resistivity with the increase in the concentration of ZrO_2. Another possible change in the grain boundary would be a deposit of some insulators on the grain boundary. A small amount of ZrO_2, for example, one too small

to be detected by an X-ray diffractometer, might increase both the resistivity and the activation energy of the samples.

The previous work[1] revealed that the resistivity of Ln_2CuO_4 decreases with a decrease in the atomic number of Ln. This fact was explained as being due to: (1) a variation in the activation energy, or (2) a variation in the number of the donor centers formed by the thermal decomposition of the Cu^{2+} to the Cu^{+} ions. However, it is not known which factor is the more important. The activation energy corresponds to the energy gaps between the split 3d-electron energy levels of the Cu^{2+} ions, which are affected by the ligand-field strength at the Cu^{2+} sites.[1] The ligand-field strength is determined by the distance between the Cu^{2+} ions and the closest neighbors. Since no change is indicated in the lattice parameters of the doped Gd_2CuO_4, the distance described above may also be unchanged by doping. On the basis of the above discussion and the X-ray diffraction data, it seems reasonable to assume that the ligand-field strength at the Cu^{2+} sites is unchanged by doping; therefore, the doping method varies the number of donor centers without a great variation in the activation energy. The activation energy is related to the thermoelectric power by this equation: $\alpha \propto -E/T$, for the Maxwell distribution, where α is the thermoelectric power; E, the activation energy, and T, the temperature.[1,3] Therefore, the dopants are expected to lower the resistivity without a great variation in the thermoelectric power. In fact, Fig. 2 shows that the Gd_2CuO_4 doped with 0.5 mol% ZrO_2 is lower than the Pr_2CuO_4[1] in its resistivity, while the former is greater than the latter in its thermoelectric power. The $\alpha \propto -E/T$ relationship is applied to the data for the Ln_2CuO_4 compounds. If the trend for the resistivity of the Ln_2CuO_4 to decrease with a decrease in the atomic number of Ln was simply due to an increase in the number of donor centers, and not to a variation in the activation energy, the thermoelectric powers of the Ln_2CuO_4 compounds would not depend upon the atomic number of Ln. However, their thermoelectric powers increase with an increase in the atomic number of Ln,[1] suggesting that the above trend is ascribable to an increase in the activation energy. The X-ray diffraction data seem to support this suggestion; the lattice parameter of the tetragonal Ln_2CuO_4, c/a, increases with a decrease in the atomic number of Ln.[1,4]

Figure 5 shows that the resistivity decreases with an increase in the concentration of CaO, suggesting a formation of acceptor centers. It has been suggested on the basis of the X-ray diffraction results that the doped Ca^{2+} or Ba^{2+} ions occupy the Gd^{3+} sites. If they occupy the Gd^{3+} sites without oxygen vacancies, the doped alkaline earth cations would be forced to be in a trivalent state. Trivalent alkaline earth cations, however, are very unstable. The Cu^{2+} ions, on the other hand, seem to be more readily oxidized to Cu^{3+} ions, although the Cu^{3+} ions may still be unstable. As in the case of the Cu^{+} formation, the formation of the Cu^{3+} ions is an electron transfer from the Cu^{2+} ions to the Ca^{3+} ions which might be initially formed. This electron-transfer is again electrostatically unstable. The electrostatic energy needed for the electron-transfer may be compensated for by the energy difference between the formation of the divalent alkaline earth cations and the excitation of the Cu^{2+} to Cu^{3+} ions. The Cu^{3+} ions would not be very stable, so many acceptor centers cannot be expected to be formed. This may be one of the reasons why the CaO-doping is not so effective on the resistivity-lowering as the ZrO_2- or ThO_2-doping. The presence of the acceptor centers is directly suggested by the positive thermoelectric power (Fig. 7).

The number of acceptor centers formed at a given dopant concentration is such a number as will minimize the total energy of the strain due to the oxygen vacancies and that of the excitation of the Cu^{2+} to Cu^{3+} ions. The strain energy may be made smaller by doping larger cations. Therefore, the number of acceptor centers formed at a given dopant concentration can be made smaller by doping larger cations. The experimental results for the BaO-doped Gd_2CuO_4 show the expected behavior (Figs. 5—7). The resistivity increases with an increase in the dopant concentration in the concentration region of $x<0.5$ mol%. The sample doped with 0.5 mol% BaO shows a medium trend between the undoped and 2.5 mol% BaO-doped samples in the temperature dependence of the thermoelectric power. These data suggest that the donor centers initially formed by the thermal decomposition are recombined with the acceptor centers formed by doping the BaO, and that the former still number more than the latter. In concentration region of $x<0.5$ mol%, the CaO-doped samples are p-type semiconductors and decrease in resistivity with an increase in the concentration of the CaO. These results indicate that the BaO dopant at a given concentration produces a smaller number of acceptor centers than the CaO dopant. In the concentration region of $x>0.5$ mol%, the BaO-doped samples behave much like the CaO-doped ones; the resistivity decreases with an increase in the concentration of BaO, and the thermoelectric power is positive, over the temperature range investigated. These facts suggest that the acceptor centers number more than the donor centers in this concentration region.

The recombination of the donors with the acceptors can be made by doping the ZrO_2 and CaO simultaneously. Since the donor centers consist of Cu^{+} ions formed by the ZrO_2-doping and those formed by the thermal decomposition of the Cu^{2+} ions, the dopant concentration where the resistivity is at its maximum will shift to a CaO-rich composition because of the donor centers formed by the thermal decomposition. Figure 8 shows the expected results; the maximum resistivity can be seen at CaO=0.8 mol% and ZrO_2= 0.2 mol%. The thermoelectric power data correspond to the resistivity data; the sign is changed at the same concentration.

On the basis of the series of data shown in Figs. 5 to 10, it can be concluded that the most important donor centers in the Ln_2CuO_4 compounds are the Cu^{+} ions formed by the thermal decomposition of the Cu^{2+}

ions.

An attempt to dope Ag_2O and In_2O_3 was unsuccessful. This failure may be partly due to too great a difference in the ionic radii between the Cu^{2+} ion and either the Ag^+ or the In^{3+} ion ($Cu^{2+}=0.72$ Å, $Ag^+=0.97$ Å, and $In^{3+}=0.81$ Å) and partly to too small a latitude of the Cu^{2+} site for the ionic size. This may be related to the covalent nature of the Cu–O bonds.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2625—2629 (1973)

Kinetic Study of Triplet-Triplet Energy Transfer in Fluid Solution by Means of Laser Pulse Photolysis[1)]

Takeshi TAKEMURA, Hiroaki BABA, and Masahisa FUJITA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received September 26, 1972)

The kinetics of triplet-triplet (T-T) energy transfer in fluid solution has been studied by means of laser pulse photolysis with acetophenone as the energy donor and naphthalene as the acceptor. Decay curves of phosphorescence of the donor and rise-and-decay curves of sensitized T-T absorption of the acceptor were obtained. These were analyzed to determine the unimolecular and bimolecular rate constants (denoted by k_1 and k_2 respectively) for the deactivation processes of the triplet state of donor or acceptor and the rate constant (k_t) for the T-T energy transfer. In isooctane at room temperature these rate constants were found to be: $k_1=0.67\times10^6$ sec^{-1} and $k_2=2.0\times10^{10}$ M^{-1} sec^{-1} for acetophenone, $k_2'=1.6\times10^{10}$ M^{-1} sec^{-1} for naphthalene, and $k_t=1.0\times10^{10}$ M^{-1} sec^{-1}. The k_t value obtained from the donor phosphorescence is in good agreement with that from the acceptor T-T absorption. The experimental results suggest that T-T transfer and T-T annihilation processes are not strictly diffusion-controlled.

Triplet-triplet (T-T) energy transfer between molecules in fluid solution has been extensively investigated since the work of Bäckström and Sandros.[2-9)] It is generally believed that, when the transfer is exothermic by at least 3 kcal/mol, the transfer rate is nearly equal to the encounter frequency predicted by the Debye equation for diffusion-controlled kinetics, provided that the solvent viscosities are greater than 3 cP.[5)]

On the other hand, Nordin and Strong pointed out on the basis of computational analysis that an energy difference greater than 3 kcal/mol between donor and acceptor triplet states does not necessarily lead to diffusion-controlled quenching.[6)] Wagner and Kochevar also indicated that the triplet energy transfer is not totally diffusion-controlled in solvents of low viscosity.[7)]

T–T energy transfer has so far been studied through spectroscopic and photochemical experiments performed by either steady excitation or the usual flash photolysis method in which the flash duration is of the order of microseconds.[10,11)] Such a duration is too long for direct observation of the T–T transfer process in fluid solution.

In an attempt to obtain detailed information on energy transfer and other rate processes associated with the donor and acceptor triplet states, we re-examined T–T energy transfer in solution by using a frequency-doubled ruby laser with a pulse duration of 25 nsec. Acetophenone was chosen as the energy donor and naphthalene as the acceptor, and isooctane was used as a solvent of low viscosity. We utilized the fact that acetophenone shows a phosphorescence emission of appreciable intensity even in a fluid solution, provided that the solvent is fully degassed. In this way we were able to measure both the phosphorescence of the donor and the sensitized T–T absorption of the acceptor, and hence it was possible to investigate the dynamic behavior of the donor and acceptor triplet species simultaneously.

Experimental

Reagents were obtained from Wako Pure Chemical Industries, Osaka. Acetophenone was purified by high-vacuum distillation. Spectro-grade isooctane was used without further purification. Sample solutions consisted of acetophenone of a constant concentration (1.0×10^{-2} M) and naphthalene of varying concentrations ($\sim10^{-4}$ M), with isooctane as the solvent. Each solutions was degassed repeatedly by freeze-thaw cycles until the phosphorescence intensity of acetophe-

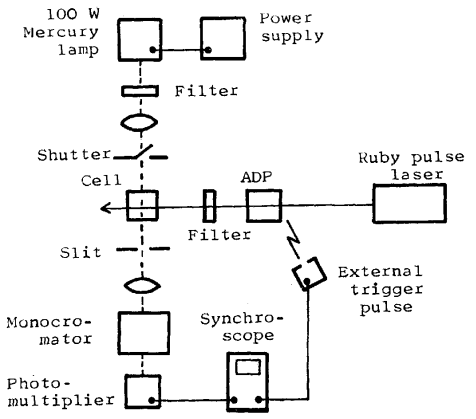

Fig. 1. Diagrammatic representation of the apparatus for laser pulse photolysis.

none reached a maximum.

Phosphorescence spectra were measured at room temperature with a Hitachi MPF-2A fluorescence spectrophotometer.

The apparatus for laser pulse photolysis is schematically shown in Fig. 1. A Japan Electron Optics Laboratory JLS-R3A giant pulse ruby laser with a peak output of 150 MW and pulse width of 25 nsec was used. The sample in a 10-mm square quartz cell was excited by the second harmonic (347 mμ) of the ruby laser generated by an ADP crystal. It should be noted that only the donor molecule of acetophenone absorbs at 347 mμ. To observe the rise and decay of T–T absorption, light from a 100-W extra-high pressure mercury lamp was passed through the cell at right angles to the laser beam, dispersed by a grating monochromator, and was then detected by an RCA 1P28 photomultiplier and an Iwasaki 100 MHz oscilloscope. In order to measure the phosphorescence decay, the emission from the solution excited by the frequency-doubled laser pulse was detected instead of the light from the mercury lamp (Fig. 1).

The exciting pulse of the second harmonic had an energy of 4×10^{-7} einstein/pulse, which was reproducible within an error of ±10 %. Since the principal source of error is the variation in energy of the pulse, the overall experimental error may safely be assumed to be ±20 %.

Most of the measurements were made with the above-mentioned exciting pulse (hereafter called normal- or high-intensity pulse). For certain purposes, we used an exciting pulse whose energy was reduced to 1 % of the energy of the normal-intensity pulse by means of a suitable system of glass filters (hereafter called low-intensity pulse).

The donor phosphorescence was observed at 420 mμ, and the acceptor T–T absorption at 410 mμ, unless otherwise stated. All the emission and absorption measurements were made at room temperature (about 20 °C).

Results and Discussion

Kinetic Scheme. Creation and degradation of triplet states in fluid solution involving intermolecular triplet-triplet energy transfer may be expressed by the following mechanisms:

$$^1D \longrightarrow {}^3D^* \qquad (1a)$$

$$^3D^* \xrightarrow{k_1} {}^1D \qquad (1b)$$

$$^3D^* + {}^3D^* \xrightarrow{k_2} {}^1D^* + {}^1D \qquad (1c)$$

$$^3D^* + {}^1A \xrightarrow{k_t} {}^1D + {}^3A^* \qquad (1d)$$

$$^3A^* \xrightarrow{k_1'} {}^1A \qquad (1e)$$

$$^3A^* + {}^3A^* \xrightarrow{k_2'} {}^1A^* + {}^1A \qquad (1f)$$

where ^1D, $^3D^*$ and ^1A, $^3A^*$ represent the ground and triplet states of donor (D) and acceptor (A), respectively; k_1 or k_1' is the sum of the rate constants for all unimolecular decay processes including both radiative and nonradiative transitions; k_2 or k_2' is the bimolecular rate constant for T–T annihilation, and k_t is that for T–T energy transfer. The formation of the triplet excited dimer can be neglected, since it has only a small rate constant[12] and does not appreciably contribute to the triplet decay.

The rate equations for the donor-acceptor system after pulse excitation are given by

$$-\frac{d[^3D^*]}{dt} = (k_1+k_2[^3D^*] + k_t[^1A])[^3D^*] \qquad (2)$$

$$\frac{d[^3A^*]}{dt} = k_t[^1A][^3D^*] - (k_1'+k_2'[^3A^*])[^3A^*] \qquad (3)$$

Although these equations cannot be solved exactly, we can determine the rate parameters if we choose appropriate experimental conditions.

Rate Constants Derived from the Donor Phosphorescence. The phosphorescence spectrum of acetophenone in isooctane at room temperature is similar in location and shape to the spectrum of that in a rigid-glass solution at low temperature (Fig. 2).[13]

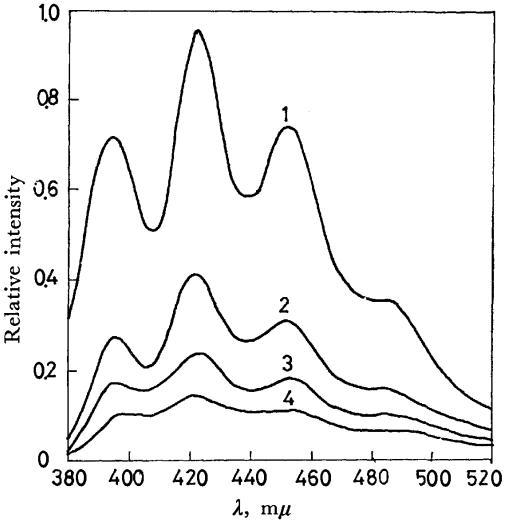

Fig. 2. Phosphorescence spectra of acetophenone–naphthalene system obtained by steady excitation at 340 mμ in isooctane. The concentrations of naphthalene: (1) 0; (2) 0.8×10^{-4}; (3) 2.0×10^{-4}; (4) 4.0×10^{-4} M.

When the acetophenone–naphthalene system was excited at 347 mμ by the normal-intensity pulse, the phosphorescence of the donor generally showed non-exponential decay. On the other hand, excitation by the low-intensity pulse led to a phosphorescence decay curve which was exponential within the limit of experimental errors. These observations indicate that the importance of the term involving k_2 on the right hand side of Eq. (2) largely depends upon the intensity of the exciting light.

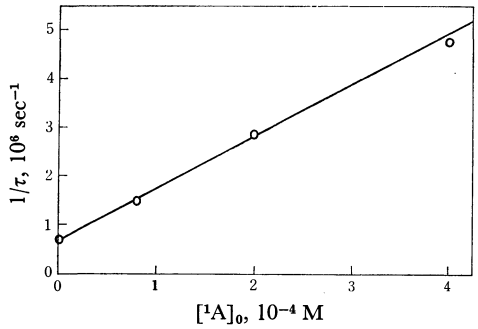

Fig. 3. Plot of $1/\tau$ *vs.* $[^1A]_0$ for acetophenone–naphthalene system in isooctane.

The phosphorescence lifetime τ as obtained from the decay curve corresponding to the low-intensity pulse decreases with increase in the amount of naphthalene added as an acceptor. The plot of $1/\tau$ against the initial acceptor concentration $[^1A]_0$ is found to be linear within the limit of experimental errors (Fig. 3). With the low-intensity pulse, the term involving k_2 can be neglected in Eq. (2), and $[^1A]=[^1A]_0-[^3A^*]$ can be replaced by $[^1A]_0$, so that $1/\tau$ is expressed as

$$1/\tau = k_1 + k_t[^1A]_0$$

The linear relation in Fig. 3 can thus be understood. From the intercept and slope of the straight line, we at once obtain

$$k_1 = 0.67\times 10^6 \text{ sec}^{-1}$$
$$k_t = 1.1\times 10^{10} \text{ M}^{-1}\cdot\text{sec}^{-1}$$

In the case of the normal-intensity pulse, the term neglected before should be included, but Eq. (2) should be simplified at the instant of pulse excitation, that is, at $t=0$. Thus, if the phosphorescence intensity of the donor is denoted by I, Eq. (2) can be written in the form:

$$-\left[\frac{1}{I}\frac{dI}{dt}\right]_{t=0} = k_1 + k_2[^3D^*]_0 + k_t[^1A]_0 \qquad (4)$$

where $[^3D^*]_0$ is the concentration of the initially produced triplet state of the donor, *i.e.* $[^3D^*]$ at $t=0$.

Figure 4 shows a plot of $-[(1/I)(dI/dt)]_{t=0}$ against $[^1A]_0$, which gives a straight line as expected from Eq. (4). From the intercept of the line, we obtain $k_1+k_2[^3D^*]_0=2.5\times 10^6$ sec^{-1}. It will be shown later that $[^3D^*]_0=0.90\times 10^{-4}$ M. Thus, recalling that $k_1=0.67\times 10^6$ sec^{-1}, we obtain

$$k_2 = 2.0\times 10^{10} \text{ M}^{-1}\cdot\text{sec}^{-1}$$

Further, from the slope of the straight line, we obtain

$$k_t = 0.90\times 10^{10} \text{ M}^{-1}\cdot\text{sec}^{-1}$$

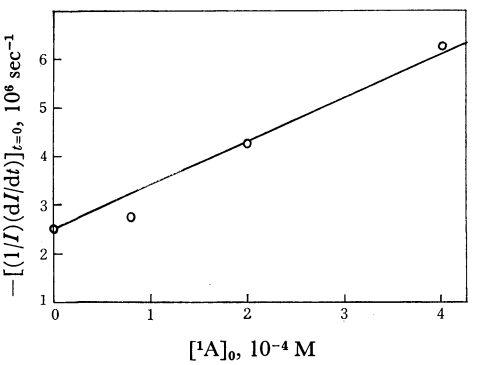

Fig. 4. Plot of $-[(1/I)(dI/dt)]_{t=0}$ *vs.* $[^1A]_0$ for acetophenone–naphthalene system in isooctane.

We here refer to spectral data resulting from the steady excitation on the usual spectrophotometer. The intensity of the phosphorescence spectrum of acetophenone, obtained by steady excitation at 340 mμ, decreases with the increasing amount of naphthalene (Fig. 2). The phosphorescence quenching is interpreted to be due to the T–T energy transfer from acetophenone to naphthalene.

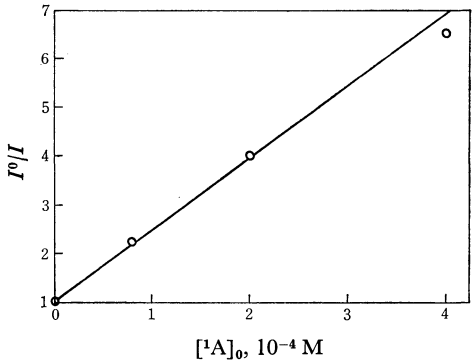

Fig. 5. Stern-Volmer plot for the quenching of phosphorescence of acetophenone by naphthalene in isooctane.

A Stern-Volmer plot for the quenching of acetophenone phosphorescence is given in Fig. 5. The plot is linear as expected. In the case of steady excitation, T–T annihilation can be disregarded on account of the low intensity of exciting light. Consequently, the following equation of Stern-Volmer type is obtained by reference to Eq. (2):

$$I^0/I = 1 + k_t[^1A]_0/k_1 \qquad (5)$$

where I^0 and I are the steady intensities of the donor phosphorescence in the absence and presence of the acceptor, respectively. From the slope of the straight line in Fig. 5, $k_t/k_1=1.5\times 10^4$ M^{-1} is obtained; hence, by use of the known value of k_1, it follows that

$$k_t = 1.0\times 10^{10} \text{ M}^{-1}\cdot\text{sec}^{-1}$$

Rate Constants Derived from the Acceptor T–T Absorption. Figure 6 represents typical examples showing the time behavior of the transient absorption at 410 mμ obtained for a mixture of acetophenone and naphthalene in isooctane by excitation with a normal-intensity laser pulse. The intensity of absorption first rises rapidly, reaches a maximum or a peak, and then decays rather slowly. The maximum intensity value increases with the amount of naphthalene, provided that the concentration of acetophenone is kept constant.

We made a series of measurements, changing the wavelength at which the transient absorption was monitored, and plotted the absorption intensity at a definite time after the pulse excitation as a function of the monitoring wavelength. The resulting spectrum agreed well with the T–T absorption spectrum of naphthalene in literature. No transient absorption could be detected from a solution of acetophenone

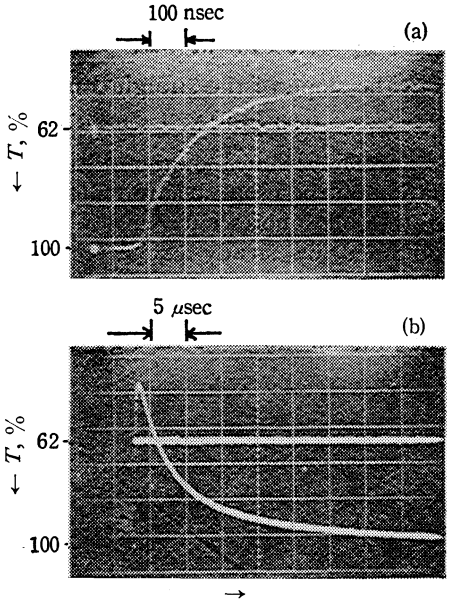

Fig. 6. Rise and decay of the sensitized T–T absorption of naphthalene. (a) rise curve; (b) rise-and-decay curve. $[^1A]_0=2.0\times10^{-4}$ M.

alone or of naphthalene alone in isooctane under the present experimental conditions.

The foregoing observations clearly indicate that the transient absorption as given in Fig. 6 is due to the T–T transition in triplet naphthalene molecules produced by T–T energy transfer in which acetophenone acts as a donor and naphthalene as an acceptor. We note that the wavelength of 410 mμ corresponds to a peak in the T–T absorption spectrum of naphthalene.

The absorbance for the transient T–T absorption at a particular wavelength, *i.e.* 410 mμ in the present experiment, will be denoted by A_b, or by $A_b(t)$ when it is desirable to show explicitly that the absorbance is a function of time. There is, of course, the following relation between A_b and $[^3A^*]$:

$$[^3A^*] = A_b/\varepsilon l \qquad (6)$$

where ε and l are the molar extinction coefficient for the T–T absorption of acceptor and the effective absorbing path length, respectively.

Let us denote the time at which the peak occurs in the $A_b(t)$ curve by t_p. Then, at any time t later than t_p by at least three microseconds, the decay curve of $A_b(t)$ is represented by the following relation between $[^3A^*]$ and t:

$$1/[^3A^*] = k_2't + C \qquad (7)$$

where C is a constant. At the time under consideration $[^3D^*]$ is so small that the first term on the right-hand side of Eq. (3) can be neglected; k_1' also is negligible because of its relatively small magnitude.[12] Equation (3) is thus simplified to give Eq. (7).

A plot of $1/[^3A^*]$ against t is shown in Fig. 7. The values of $[^3A^*]$ were derived on the basis of Eq. (6) from experimental data for A_b; the ε value at 410 mμ was taken to be 1.4×10^4,[14] and l was estimated to be

14) S. G. Hadley and R. A. Keller, *J. Phys. Chem.*, **73**, 4356 (1969).

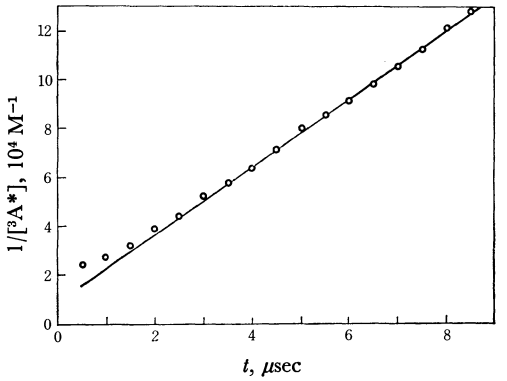

Fig. 7. Plot of $1/[^3A^*]$ *vs.* t for acetophenone–naphthalene system in isooctane. $[^1A]_0=2.0\times10^{-4}$ M.

0.7 cm. We see that the relation of $1/[^3A^*]$ to t can be satisfactorily expressed in the form of Eq. (7) for $t>3$ μsec. From the slope of the straight line we obtain

$$k_2' = 1.6\times10^{10}\ \mathrm{M^{-1}\cdot sec^{-1}}.$$

Let us consider the rate of rise of absorbance at the instant of excitation (*cf.* Fig. 6a). At $t=0$, Eq. (3) becomes

$$\left[\frac{d[^3A^*]}{dt}\right]_{t=0} = k_t[^1A]_0[^3D^*]_0 \qquad (8)$$

Therefore, a plot of the initial slope of the $[^3A^*]-t$ curve, $(d[^3A^*]/dt)_{t=0}$, against the initial acceptor concentration, $[^1A]_0$, should yield a straight line with a slope of $k_t[^3D^*]_0$. This is valid as may be seen in Fig. 8. As will be shown later, $[^3D]_0$ is evaluated as 0.90×10^{-4} M. Hence, from the slope of the straight line, we obtain

$$k_t = 1.0\times10^{10}\ \mathrm{M^{-1}\cdot sec^{-1}}$$

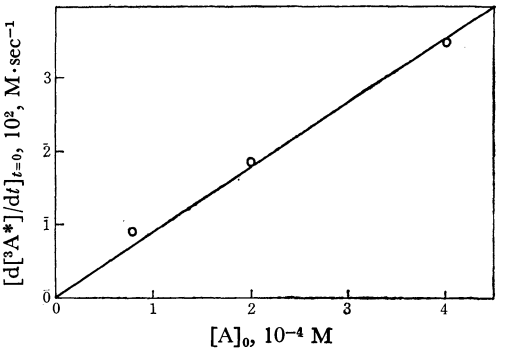

Fig. 8. Plot of $[d[^3A^*]/dt]_{t=0}$ *vs.* $[^1A]_0$ for acetophenone–naphthalene system in isooctane.

This is in good agreement with the k_t values derived from the data on donor phosphorescence.

Evaluation of $[^3D^*]_0$. The initial concentration of the donor triplet $[^3D^*]_0$ immediately after the excitation with the normal- or high-intensity laser pulse is important in determining rate parameters.

The experiments related to Figs. 4 and 8 were carried out under the same conditions with respect to the intensity of exciting pulse. According to the definition of t_p, we have $d[^3A^*]/dt=0$ at $t=t_p$. Thus by neglecting the term of k_1' it follows from Eq. (3) that

TABLE 1. RATE CONSTANTS OF VARIOUS PROCESSES OF TRIPLET ENERGY DEACTIVATION AND TRANSFER FOR ACETOPHENONE–NAPHTHALENE PAIR IN ISOOCTANE AT ROOM TEMPERATURE

Observation	$k_1\times10^{-6}$ sec^{-1}	$k_2\times10^{-10}$ $M^{-1}\cdot sec^{-1}$	$k'_2\times10^{-10}$ $M^{-1}\cdot sec^{-1}$	$k_t\times10^{-10}$ $M^{-1}\cdot sec^{-1}$	α
Donor phosphorescence (steady excitation)				1.0	0.76
Donor phosphorescence (laser pulse excitation)	0.67	2.0		1.1	0.83
				0.9	0.61
T–T absorption of A (laser pulse excitation)			1.6	1.0	0.76

$$[^3D^*]_{t_p} = k_2'[^3A^*]^2_{t_p}/k_t[^1A]_{t_p} \quad (9)$$

The values for rate constants k_2' and k_t have already been obtained without the knowledge of $[^3D^*]_0$, $[^1A]_{t_p}$ being equal to $[^1A]_0-[^3A^*]_{t_p}$. For $[^1A]_0=2.0\times10^{-4}$ M, $[^3A^*]_{t_p}$ is found to be 0.39×10^{-4} M from the A_b value at t_p. Hence $[^3D^*]_{t_p}$ is determined to be 0.15×10^{-4} M from Eq. (9). On the other hand, the ratio between $[^3D^*]_{t_p}$ and $[^3D^*]_0$ can be obtained by use of the decay curve of the donor phosphorescence. Thus, for $[^1A]_0=2.0\times10^{-4}$ M, we find that $[^3D^*]_{t_p}/[^3D^*]_0=0.17\pm0.02$. This along with the value of $[^3D^*]_{t_p}$ leads to

$$[^3D^*]_0 = 0.90\times10^{-4}\ M$$

Considerations on the Values of Rate Constants. The rate constants determined by various procedures are summarized in Table 1. It is obvious that the values of k_t obtained from the donor phosphorescence caused by steady or laser-pulse excitation and from the sensitized acceptor T–T absorption caused by laser-pulse excitation are in good agreement within the limit of experimental errors. This indicates that the behavior of triplet states in less viscous solvents can be satisfactorily described by the reaction scheme given in Eq. (1).

The triplet-triplet energy transfer process given in Eq. (1d) can be represented by a more detailed mechanism involving an encounter complex:

$$^3D^* + {}^1A \underset{\overleftarrow{k}}{\overset{\overrightarrow{k}}{\rightleftharpoons}} [^3D^*\ldots{}^1A] \xrightarrow{k_{et}} {}^1D + {}^3A^*$$
$$\text{(I)} \qquad\qquad \text{(II)}$$

Process (I) corresponds to the encounter of a donor molecule in the excited triplet state and an acceptor molecule in the ground state. Process (II) represents the energy transfer from the donor to the acceptor in the encounter complex. It can then be shown that k_t in Eq. (1d) is expressed as

$$k_t = \alpha\vec{k} \quad (10)$$

with

$$\alpha = k_{et}/(\overleftarrow{k}+k_{et})$$

The encounter between donor and acceptor molecules can be regarded as a diffusion-controlled process. Thus, if the Debye equation is applicable to such a process, the rate constant $\vec{k}$ is given by

$$\vec{k} \equiv k_{dif} = \frac{8RT}{3000\eta} \quad (11)$$

Using the $\vec{k}$ value obtained from this equation and the observed k_t values, α is calculated to be less than unity from Eq. (10), as is shown in Table 1.

The fact that the parameter α is less than unity leads to the view that the overall energy-transfer process as given by Eq. (1d) is not diffusion-controlled in a strict sense. Because of the assumptions involved in the evaluation of k_{dif}, too much reliance cannot be placed on the value of α. However, in our recent experiments on the temperature dependence of T–T energy transfer for acetophenone–1,4-dibromonaphthalene pair in isooctane, it was found that the value of α decreases with the decreasing solvent viscosity caused by the rise in temperature; for example, $\alpha(0\ ^\circ C)=0.57$ and $\alpha(65\ ^\circ C)=0.26$. This shows the value of k_{et} to be comparable to that of $\overleftarrow{k}$ and thus gives evidence in favor of the above-mentioned view.

A similar result is also obtained for the T–T bimolecular annihilation process: when the values of k_2 and k_2' described before are compared with twice the diffusion-controlled rate constant k_{dif} evaluated from Eq. (11), it can be seen that k_2 and k_2' are about seven-tenths as large as $2k_{dif}$. This factor 0.7 corresponds to the parameter α given in Eq. (10), and is comparable to the values of α shown in Table 1.

Studies of the DNA–Acridine Complexes. I. Fluorescence Depolarization

Yukio KUBOTA

Department of Chemistry, Yamaguchi University, Yamaguchi 753

(Received December 15, 1972)

The motion of the DNA–acridine complexes in solution was studied by the fluorescence depolarization method. Five derivatives of 3,6-diaminoacridine were used in order to investigate the effect of amino substituion on the depolarization results. A linear relation between the reciprocal polarization ($1/P$) and T/η was obtained by varying the temperature of a native DNA–acridine solution. The limiting polarization (P_0) and the mean rotational relaxation time (ρ_h) of the complex were evaluated from these data. The ρ_h value of the complex (30—50 nsec) was much larger than the value of free acridine in water, but it was much too small to correspond to the rotation of the whole DNA molecule. Further, it was found that the values of P_0 and ρ_h for 3,6-bis(diethylamino)-acridine are much smaller than those for other acridines. This may result from some steric hindrance of the binding by bulky diethylamino groups.

The interaction of aminoacridines and their derivatives with DNA has been extensively studied by various techniques. Interest in this topic has been stimulated by the biological activity of the acridines and by their structural similarity to carcinogens, such as polycyclic hydrocarbons and benzacridines. At present, it is generally accepted that acridine molecules bind to DNA to form two types of complexes; one (Complex I) results from the acridine-acridine interaction on the outside of the DNA helix at low values of the molar ratio of nucleotides to acridine molecules (N/A),[1,2] while the other (Complex II) occurs at high N/A values, where the acridine-nucleotide interaction is involved.[3] Lerman[4,5] proposed that, in Complex II, acridine molecules are intercalated in a sandwich-like way between adjacent base pairs in the double-stranded helix. Evidence in support of this model includes the data of viscosity,[4] the chemical reactivity of bound acridines,[6] polarized fluorescence,[5] sensitized fluorescence,[7] *etc.* On the other hand, Peacocke and his co-workes[8,9] proposed a modified intercalation model in order to interpret the effects of denaturation and the ionic strength on the interaction of acridines with DNA. In this model, the positively-charged nitrogen of the acridine ring associates closely with the negatively-charged phosphate group of DNA, and the flat acridine ring is inserted between adjacent bases on the same polynucleotide chain. In both models, the structure of acridine derivatives can be expected to influence their binding to DNA. Therefore, it is important to study the effect of the acridine structure on the interaction between acridines and DNA by using various acridine derivatives and various techniques.

In the present study, the DNA–acridine complexes were investigated by the fluorescence depolarization method,[10–13] using five derivatives of 3,6-diaminoacridine. The aims of this study are: (1) to obtain some information on the characteristics of the complex related to the rotation or internal motion of the bound acridine and (2) to reveal the relation between these properties and the structure of 3,6-amino groups.

Experimental

Materials. A highly-polymerized calf thymus DNA was purchased from the Worthington Biochemical Corporation. The concentration of DNA was determined spectrophotometrically at 259 nm, with an extinction coefficient per molar DNA phosphate ($\varepsilon_P=6600$). The hyperchromicity was 35% at room temperature and at an ionic strength of 0.01; this means that the DNA used was native. The thermal denaturation of DNA was performed by heating the DNA solutions for 20 min in boiling water and by then rapidly cooling them in ice water.

Acridine orange (AO) and proflavine (PF) were obtained from Chroma and British Drug Houses respectively. 3,6-Bis(methylamino)acridine ($Ac[NHMe]_2$), 3,6-bis(ethylamino)acridine ($Ac[NHEt]_2$), and 3,6-bis(diethylamino)-acridine ($Ac[NEt_2]_2$) were prepared according to the method described by Albert.[14] These acridines were purified by repeated recrystallizations and by chromatography.

Measurements. The solutions of the complexes were made up in a 0.005 M phosphate buffer (ionic strength of 0.01) at pH 6.8. This low ionic strength was used to minimize the amount of unbound acridine molecules. The acridine concentrations were $(1—2.5)\times10^{-6}$ M.

The absorption spectra were measured with a Shimadzu MPS-50L spectrophotometer.

The fluorescence spectra and polarization were measured with a Hitachi MPF-2A spectrophotofluorometer, with a pair of Polacoat dichroic filters as the polarizer and the analyzer. With the incident beam vertically polarized, the degree of polarization (P) is given by:[15,16]

$$P = \frac{I_{VV} - GI_{VH}}{I_{VV} + GI_{VH}} \quad (1)$$

where I_{VV} and I_{VH} are the measured fluorescence intensities with the analyzer vertically and horizontally oriented; the correction factor, $G = I_{HV}/I_{HH}$, is obtained with the incident beam horizontally polarized.

The fluorescence lifetimes were measured by means of a JASCO FL-10 phase fluorometer equipped with a 500-W xenon lamp and a CT-20P prism monochromator; the cut-off color and interference filters were used to select appropriate emission bands. The arrangement was similar to the one described in detail in an earlier paper.[17] The light emerging from the monochromator was modulated at a frequency of 13.56 MHz. The phase shifts of the fluorescent samples were measured by comparison with the phase shift of light scattered from a colloidal solution of silica.[18]

The measurements of the flow dichroism were carried out at 25 °C by the use of a Shimadzu QV-50 spectrophotometer equipped with an attachment. The datails of the theory and the experiment procedures have previously been reported by Wada and Kozawa.[19]

All the measurements except those of the flow dichroism were made at temperatures from 10 to 70 °C.

Results and Discussion

A typical fluorescence polarization spectrum is shown for the DNA–Ac[NHMe]$_2$ complex in Fig. 1. No change in the P value was observed at the wavelengths from 400 to 490 nm; this indicates that only one electronic transition exists in this wavelength region.[7,20] The other complexes gave similar polarization spectra. Therefore, the complexes were excited in this wavelength region. Further, no significant change in the P value was observed at N/A values higher than *ca.* 100. Our equilibrium dialysis and absorption data[21] showed that almost all the acridine molecules are bound to DNA at a high N/A value and even at elevated temperature up to 65 °C. Accordingly, the value of P at a sufficiently high N/A value can be expected to reflect the rotational characteristics of the unit to which

Table 1. Polarization of the DNA-acridine complexes at 25 °C

Actridine	Native DNA		Denatured DNA	
	N/A	P	N/A	P
PF	270	0.34_2	300	0.27_4
AO	260	0.34_5	240	0.27_6
Ac[NHMe]$_2$	240	0.35_7	270	0.28_1
Ac[NHEt]$_2$	260	0.35_4		
Ac[NEt$_2$]$_2$	240	0.32_3		

an acridine molecule is attached. The polarization of the complex at 25 °C is tabulated in Table 1. At every temperature investigated, the value of P in the case of denatured DNA was lower than that in the case of native DNA, and the value of P for Ac[NEt$_2$]$_2$ was smaller than those for other acridines.

For plane-polarized exciting light, the Perrin equation[10] relates the value of P to the molecular characteristics on the assumption that the molecule undergoing the Brownian rotation is spherical:

$$1/P - 1/3 = (1/P_0 - 1/3)(1 + RT\tau/\eta V) \quad (2)$$

where P_0 is the limiting value of P when $T/\eta = 0$; R, the gas constant; T, the absolute temperature; τ, the lifetime of fluorescence; η, the viscosity of the solvent, and V, the molar volume of the rotating molecule. The rotational relaxation time of this molecule (ρ_0) equals $3V\eta/RT$. If the molecule is ellipsoidal in shape the expression for P is given by:[11-13]

$$1/P - 1/3 = (1/P_0 - 1/3)(1 + 3\tau/\rho_h) \quad (3)$$

where $\rho_h = 3\eta V_e/RT$ is the harmonic mean of the three principal rotational relaxation times and where V_e is the effective hydrodynamic volume of the molecule.

If V and τ are constant, both equations predict a linear relation between $1/P$ and T/η, and the rotational relaxation time can be calculated by the determination of the slope (β) of such a plot:

$$\rho_h = 3(1/P_0 - 1/3)/(\beta \times T/\eta) \quad (4)$$

If V changes with the temperature, or if two or more rotational units of distinctly different volumes are present, deviations from linearity are to be expected.[11]

Figures 2 and 3 show some results of the plots of $1/P$ against T/η; η was assumed to be that of water and was interpolated from the values given in the literature.[22] For all the native DNA-acridine complexes studied in this work, there exists a linear relation between $1/P$ and T/η over the temperature range from 10 to *ca.* 60 °C. However, there is an abrupt increase in the value of $1/P$ above *ca.* 60 °C; this implies that the bound acridine now reflects the new rotational unit associated with the denaturation of DNA. The $1/P$ *vs.* T/η curves of the complexes are similar in shape to those reported by Anufrieva *et al.*[23] for DNA–AO complexes and by Ellerton *et al.*[24] for DNA–PF complexes. However, all the P values of Anufrieva

□ ■: Ac[NEt$_2$]$_2$ (2.2×10^{-6} M, N/A=240)

et al. are much lower than ours and those of Ellerton *et al.*

On the other hand, the value of P in the case of denatured DNA remarkably decreased with an increase in the temperature. As may be seen in Fig. 2, the plots of $1/P$ *vs.* T/η showed a marked departure from linearity. This phenomenon is probably due to the structural change in denatured DNA resulting from the collapse of the double-helical regions at elevated temperatures.[25]

The results obtained on cooling the solutions of the complexes from the maximum temperature (69 °C in all systems) are shown in Figs. 2 and 3. The temperature effects were in general reversible between 10 and 69 °C; a further elevation of the maximum temperature led to an irreversibility of the temperature

□: native DNA–Ac[NEt$_2$]$_2$ (N/A=240)

effects. This implies that, under the present experiment conditions, the tertiary structure of native DNA is not significantly lost as the polarization of the bound acridine is altered.

Next, the fluorescence lifetimes of the complexes were measured under each of the experimental conditions in order to ascertain the proper values for use in calculating the rotational relaxation times. Figure 4 shows the dependence of the fluorescence lifetimes on the temperature for the DNA–PF, DNA–AO, and DNA–Ac[NEt$_2$]$_2$ complexes. The value of τ for each complex declines very slowly with the temperature up to *ca.* 60 °C, but it sharply decreases above *ca.* 60 °C; this temperature coincides with the temperature at which the value of P rapidly decreases. Similar results were obtained in the cases of Ac[NHMe]$_2$ and Ac[NHEt]$_2$. Since almost all acridine molecules are bound to DNA under the present experiment conditions, the decrease of τ above *ca.* 60 °C may be ascribed to a certain change in the binding site associated with the denaturation of DNA. Further studies of the variation in τ with the temperature are in progress.

Table 2. Depolarization results at 25 °C

Acridine	N/A	τ (nsec)	P_0	ρ_h (nsec)
PF	470	6.1	0.43_5	$52._6$
	270	6.1	0.43_9	$52._0$
AO	930	5.2	0.44_4	$47._9$
	260	5.2	0.44_0	$48._4$
Ac[NHMe]$_2$	420	4.0	0.44_2	$47._9$
	240	4.0	0.43_9	$48._3$
Ac[NHEt]$_2$	260	4.0	0.43_5	$45._4$
Ac[NEt$_2$]$_2$	240	4.0_5	0.42_0	$32._1$

Because of the small variation in the value of τ below *ca.* 60 °C, the mean rotational relaxation times were evaluated by Eq. (4), using an average value of τ for each system and the slope of the linear portion of the $1/P$ *vs.* T/η plots. The calculated values are summarized in Table 2. The depolarization results in Table 2 show that: (1) the values of P_0 and ρ_h are independent of N/A, (2) the value of ρ_h is of almost the same order of magnitude except for Ac[NEt$_2$]$_2$,

(3) the value of ρ_h for $Ac[NEt_2]_2$ is much smaller than those for the other acridines, and (4) the value of P_0 for $Ac[NEt_2]_2$ is also lower than those for the others.

The ρ_h value of the bound acridine (30—50 nsec) is much larger than the value for the free acridine in water (a few tenths of 1 nsec), but it is much too small to correspond to the rotation of the whole DNA molecule.[26] Since almost all acridine molecules are bound and are very fara part under the present experimental conditions (high N/A value and low ionic strength), any depolarization due to the free acridine or energy transfer between bound acridine molecules may be ruled out. Furthermore, it has previously been shown[27] that the rate constant of an intercalation reaction between native DNA and PF is about 10^4—10^2 sec^{-1}; therefore, the dissociation of the bound acridine could not occur during the lifetime of the excited state (4—6 nsec).

From the measurements of the nanosecond anisotropy, Wahl *et al.*[28] determined the rotational relaxation time of DNA–ethidium bromide (EB) in water to be 28 nsec; this value is also much too small for the rotation of the whole DNA molecule. Wahl *et al.* proposed that the depolarization is due either to a restricted motion of the EB molecule in its binding site on DNA, without any motion of the DNA, or to a local deformation motion of the DNA, and they showed that the latter is the only likely hypothesis that fits the restraints of the intercalation model.[4,29]

On the other hand, studies of the fluorescence quenching[30] and equilibrium dialysis[31] of the DNA-acridine complexes showed that the binding constants of PF, AO, $Ac[NHMe]_2$, and $Ac[NHEt]_2$ are of the same order of magnitude, while that of $Ac[NEt_2]_2$ is much smaller than those of the others. This suggsets that the bulky diethylamino groups produce some steric hindrance of the binding.

Table 3. Flow dichroism at 25 °C[a]

Acridine	λ_{max}[b] (nm)	$B(\alpha)$[c] at λ_{max}
PF	462	−0.84
AO	502	−0.82
$Ac[NHMe]_2$	475	−0.84
$Ac[NHEt]_2$	476	−0.82
$Ac[NEt_2]_2$	508	−0.70

a) The molar concentration of DNA phosphate (M_P) is 1.38×10^{-3} M_P. $N/A=15$ to 50.
b) The maximum wavelength of absorption spectrum of the complex in the visible region.
c) The reduced dichroism at a perfect orientation. The value of $B(\alpha)$ was obtained according to the method described by Wada.[32]

In view of these findings, the depolarization results of $Ac[NEt_2]_2$ in Table 2 can be interpreted to show that the $Ac[NEt_2]_2$ molecule, when intercalated between base pairs, leads to a larger local change in the DNA helix and, hence, a larger local deformation motion than the other acridines. If this is the case, some difference in the orientation of the bound acridines can be expected to occur between $Ac[NEt_2]_2$ and the others. In practice, preliminary results on flow dichroism reveal that the magnitude of the dichroism for the DNA–$Ac[NEt_2]_2$ complex is much smaller than those for the other complexes (see Table 3). Further studies by flow techniques are now in progress to clarify the orientation of the bound acridines; the results will be presented in a subsequent paper.

This work was supported in part by a Grant for Scientific Research by the Ministry of Education.

Near-infrared Spectroscopic Studies of the States of Water in Lyotropic Liquid Crystals

Masuo AIZAWA and Shuichi SUZUKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 21, 1972)

The states of water in lyotropic liquid crystals of the polyoxyethylene–nonylphenylether and water system were investigated by means of near-infrared spectroscopic measurements. The states of water were classified into nonbonded, singly-hydrogen-bonded, and doubly-hydrogen-bonded states, and their relative concentrations were calculated from the intensities of the combination bands of $2\nu_1+\nu_3$ and $\nu_1+\nu_2+\nu_3$ in the temperature range from 25 to 50 °C. An increase in the hydrogen-bonded water species was found for the liquid crystal. Furthermore, the nonbonded and singly-hydrogen-bonded water species decreased, while the doubly-hydrogen-bonded water species increased in the liquid crystal structure, as compared with ordinary water. The structural properties of the liquid crystal are discussed.

Liquid crystalline structures may be prepared thermally from one component (thermotropic systems) or by the treatment of certain compounds with a controlled amount of water or other polar solvent (lyotropic systems). Lyotropic liquid crystals are strongly birefringent and may vary in texture from a turbid free-flowing fluid to a waxy substance or clear gel. A solvent is responsible for the formation of the lyotropic liquid crystals. Especially in the biological system, water plays an important role in the formation of the lyotropic liquid crystals.[1] The states of water in lyotropic liquid crystals, however, have not yet been clarified. We reported previously that the states of water involved in macromolecular gels should be classified into at least three groups, because most of the so-called free water has been found to be fairly restricted.[2-4] The present investigation was undertaken in order to determine the states of water in the lyotropic liquid crystals.

Various measurements, such as infrared and Raman spectroscopy, NMR, X-ray diffraction, and dielectric relaxation measurements, have been used in the studies of the structure of water. These methods have also been extended to aqueous solutions, and a number of structural models have been postulated for liquid water.[5] These models are generally classified into multi-state models and uniform-state models. For both a multi-state model and a uniform-state model, the degree of association of water has been the main subject of study. The vibrational spectroscopic investigation is effective, because it is extremely sensitive to the strength and extent of hydrogen bonding. The frequency of OH stretching vibrations is known to decrease in a regular manner with the strength of the hydrogen bonding. Therefore, Raman or infrared fundamental, overtone, and combination bands, which involve OH stretching, may serve as a probe of hydrogen bonding. As has been pointed out by Falk,[6] the frequencies of bending vibrations increase upon hydrogen bonding, but the shifts are much smaller, and, hence, somewhat less useful as a structural probe. As the combination bands involving OH stretching have been used successfully in quantitative investigations of the hydrogen bonding of water,[7-11] near-infrared spectroscopic analysis was carried out in this work.

The combination of nonionic surfactants and water being a typical example of how the lyotropic liquid crystals are formed, the polyoxyethylene–nonylphenylether and water system is used in this investigation. The water molecules are presumed to be strictly restricted in the lyotropic liquid crystal, because polyoxyethylene–nonylphenylether may be highly ordered and their hydrophilic sites may be hydrated. In view of the hydrogen-bonding association, the states of water in a lyotropic liquid crystal can be classified into three states: the nonbonded, singly-hydrogen-bonded, and doubly-hydrogen-bonded states. The concentrations of the nonbonded, singly-hydrogen-bonded, and doubly-hydrogen-bonded water species were calculated for this system by near-infrared spectrum analysis in the 900—1300 nm region.

Experimental

Materials. The polyoxyethylene–nonylphenylether was supplied by the Kao Atlas Co., Ltd. The average polymerisation degree of the oxyethylene residue is 13.2. This nonionic surfactant is denoted as C_9Ph_{13} in this paper.

Near-infrared Spectra. The spectra were recorded with a Shimazu SV-50A spectrophotometer. All the measurements were made with water or an aqueous solution in a 1-cm cell and with an empty cell in the reference beam. Temperature control for the sample and the reference cells was achieved with circulating water at a fixed temperature.

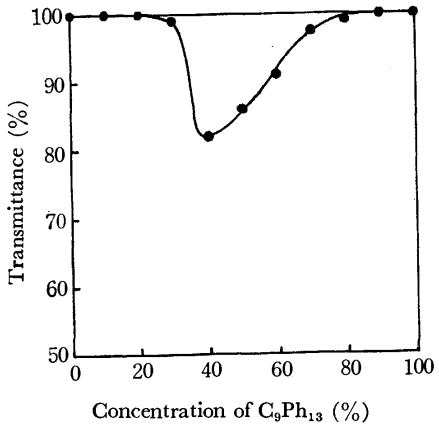

Fig. 1. Concentration dependence of transmittance at 900 nm.

Results

Near-infrared Spectra of Water in Lyotropic Liquid Crystals. Polyoxyethylene–nonylphenylether (C_9Ph_{13}) is known to form a smectic liquid crystal with less than approximately 75% of water. The transmittance measured at 900 nm in this experiment is shown in Fig. 1 for various C_9Ph_{13} contents. The transmittance becomes poor in the concentration range from 40 to 60% of C_9Ph_{13}. In the above concentration range, these mixtures form a gel at room temperature. The rheological properties of these mixtures have been reported elsewhere.[8]

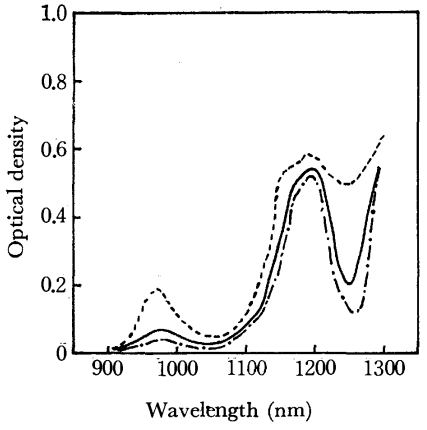

Fig. 2. Spectra of water in liquid crystals containing 60% (——), 80% (—·—) of C_9Ph_{13}, and pure water (·····) at 25 °C.

The near-infrared spectra of water in liquid crystals containing 60 and 80% of C_9Ph_{13} at 25 °C are presented in Fig. 2. The spectrum of pure water is illustrated as a reference. As has been reported by Buijs and Choppin,[7] the absorption band at 977 nm can be assigned to the combination band of $2\nu_1+\nu_3$, and the bands at 1160 and 1200 nm, to that of $\nu_1+\nu_2+\nu_3$, where ν_1 (symmetric stretching), ν_2 (bending), and ν_3 (asymmetric stretching) are the fundamental vibrations. As for the bands around 1200 nm, the three peaks at 1160, 1200, and 1250 nm were assigned to the bands of the water species involving 0, 1, and 2 hydrogen bondings respectively.[7] As the temperature is raised, the bands have been observed to become sharper and to shift toward the blue, so as to approach a constant wavelength asymptotically. On the contrary, the formation of hydrogen bonding is known to shift the water bands toward the red.[9–10]

As is shown in Fig. 2, the peak of $2\nu_1+\nu_3$ in the lyotropic liquid crystals was observed to shift to a longer wavelength compared with that of ordinary water. In addition, the peak height at 1160 nm attributed to the monomeric water species is suppressed. These spectra suggest that the monomeric water species decrease in the liquid crystals. The association degree of water in the liquid crystals was surveyed by the quantitative analysis of both the $2\nu_1+\nu_3$ and $\nu_1+\nu_2+\nu_3$ bands.

Hydrogen Bonding of Water in the Liquid Crystal. The band of $2\nu_1+\nu_3$ was analysed in order to estimate the association degree of water. As has been described above, the band of $2\nu_1+\nu_3$ can be expected to shift to a longer wavelength in the liquid crystals because of the decrease in monomeric water species.

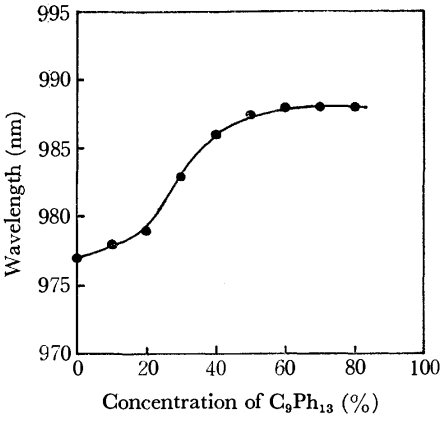

Fig. 3. Concentration dependence of the wavelength at $2\nu_1+\nu_3$ band.

The concentration dependence of the $2\nu_1+\nu_3$ band is shown in Fig. 3. The maximum of the $2\nu_1+\nu_3$ band shifts to a longer wavelength with an increase in the C_9Ph_{13} concentration, reaching approximately 988 nm. This indicates that the association degree of water increases in the liquid crystals in which the C_9Ph_{13} concentration is more than approximately 30%.

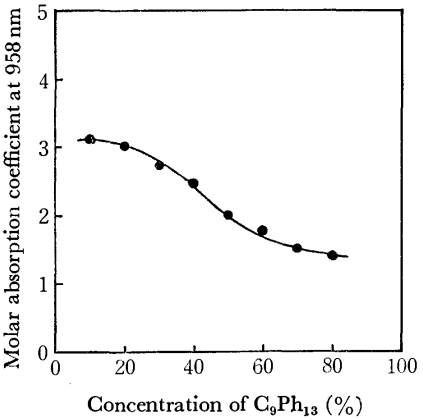

Fig. 4. Molar absorption coefficients at 958 nm for various concentrations of C_9Ph_{13}.

As the characteristic band for liquid monomeric water has been reported to be 958 nm, the absorbance at 958 nm may serve as a measure of the amount of liquid monomeric water. If the hydrogen-bonding association increases in the liquid crystals, the molar absorption coefficient at 958 nm can be expected to decrease in the liquid crystals. In Fig. 4, the molar absorption coefficient at 958 nm is shown for various concentrations of C_9Ph_{13} at 25 °C. A marked suppression of the molar absorption coefficient at 958 nm was observed in the liquid-crystal phase. Thus, it is reasonable to state that most of the monomeric water species disappear because of the strong interaction between C_9Ph_{13} and water in the liquid crystals.

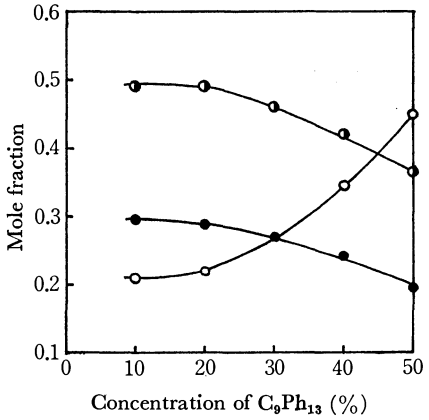

Fig. 5. Mole fractions of nonbonded (—●—), singly-bonded (—◑—), and doubly-bonded (—○—) water species in various concentrations of C_9Ph_{13}.

The relative amounts of nonbonded, singly-bonded, and doubly-bonded water species can be calculated according to the method of Buijs and Choppin.[7] In Fig. 5, C_0, C_1, and C_2, which are the relative concentrations of nonbonded, singly-bonded, and doulby-bonded water species respectively, are presented for various C_9Ph_{13} concentrations at 25 °C.

A baseline in the range from 1100 to 1300 nm was constructed so as to deduct the contribution of the strong band of water at 1447 nm and the sharp band of C_9Ph_{13} at 1200 nm. The baseline was calculated from a sum of the exponentials, $A=A_1e^{d_1(\lambda-\lambda_0)}+A_2e^{d_2(\lambda-\lambda_0)}$, for the band at 1447 nm[7] and by multiplying the observed molar absorption coefficients of C_9Ph_{13} at 1160, 1200, and 1250 nm with the molar concentration of the liquid crystals. The molar absorption coefficients of C_9Ph_{13} were then determined in the temperature range surveyed. The influence of the band at 980 nm was disregarded. The quantitative correction becomes difficult in the concentrated liquid crystals because of the marked disturbance by the band of C_9Ph_{13}. Therefore, C_0, C_1, and C_2 were calculated in the concentration range from 0 to 50% of C_9Ph_{13}.

As was expected, not only C_0 but also C_1 decreases with an increase in the C_9Ph_{13} concentration. A decrease in C_0 and C_1 was observed in the liquid crystals containing more than 30% of C_9Ph_{13}. In contrast with C_0 and C_1, an increase in C_2 was found in the above liquid crystals. Thus, most of the water in the liquid crystals is singly- or doubly-hydrogen-bonded and the monomeric water species are reduced compared with ordinary water. An increase in the doubly-bonded water species is characteristic in this system.

Temperature Effect on the States of Water in the Liquid Crystal. The physicochemical properties, such as the viscosity and birefringence of the liquid crystal, show a drastic change at approximately 40 °C. Such a drastic change may be caused by the structural change in the liquid crystal. Therefore, the states of water can be expected to show anomalous changes accompanying the above changes.

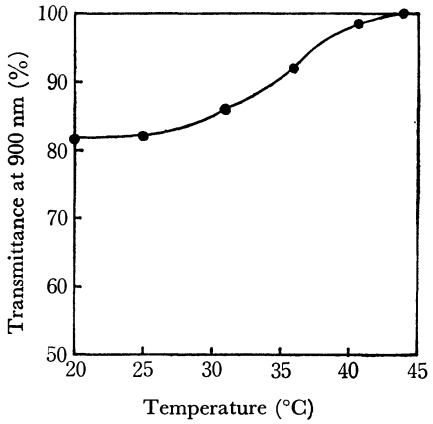

Fig. 6. Temperature dependence of transmittance at 900 nm for the liquid crystal containing 40% of C_9Ph_{13}.

The transimittance at 900 nm is a suitable measure for following the structural transition of the liquid crystal. The temperature dependence of the transmittance at 900 nm is shown in Fig. 6 for the liquid crystal containing 40% of C_9Ph_{13}. Though this liquid crystal shows a poor transmittance at room temperature, it gives excellent transparency above approximately 40 °C. A kind of structural transition may occur around this temperature.

If such a structural transition is caused by dehydration, the relative concentration of the monomeric water species, C_0, will increase. The temperature effect on the relative concentrations of nonbonded, singly-bonded, and doubly-bonded water species is shown in Fig. 7

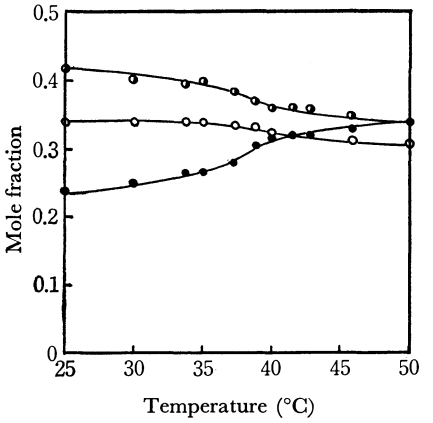

Fig. 7. Temperature dependence of mole fractions of nonbonded (—●—), singly-bonded (—◑—), and doubly-bonded (—○—) water species in the liquid crystal containing 40% of C_9Ph_{13}.

for the liquid crystal containing 40% of C_9Ph_{13}. The relative concentration of the nonbonded water species, C_0, increases gradually with an increase in the temperature. Accompanying the temperature dependence of C_0, the relative concentrations of the singly-bonded and doubly-bonded water species, C_1 and C_2, decrease with an increase in the temperature. These changes indicate that a marked dehydration of C_9Ph_{13} occurs with the structural transition in this temperature range.

Discussion

The spectrum analysis of the combination bands, $2\nu_1+\nu_3$ and $\nu_1+\nu_2+\nu_3$, has revealed that the degree of hydrogen-bond association increases in the lyotropic liquid crystals compared with ordinary water. For instance, in the liquid crystal containing 50% of C_9Ph_{13}, only 18% of the water is nonbonded, whereas approximately 32% of the water is nonbonded in ordinary water at 25 °C. In addition, the relative concentration of the doubly-hydrogen-bonded water species exceeds that of the singly-hydrogen-bonded ones in the liquid crystal. Such an increased degree of hydrogen-bond association, especially doubly-hydrogen-bond association, may be closely related to the mechanism of the liquid-crystal formation.

One of the possible explanations for the increase in the doubly-hydrogen-bonded water species is the hydration to the ether bonds of the polyoxyethylene chain. Each hydrogen atom of water can be linked with the oxygen atom of an ether bond in the polyoxyethylene chain. Water molecules may be bridged between two polyoxyethylene chains by hydrogen bonding. Gel formation may be caused by such a water bridge. This explanation is supported by the temperature dependence of the concentration of the doubly-hydrogen-bonded water species. The hydrogen bonds dissociate markedly around 40 °C, at which temperature the gel recovers fluidity. Moreover, it has been reported that this liquid crystal changes its birefringence from positive to negative with a phase transition of the liquid crystal at approximately 40 °C.[9] Therefore dehydration is thought to occur around 40 °C and to give fluidity.

The C_9Ph_{13} and water system is known to form smectic liquid crystals. The molecules in the smectic structure may be arranged in neat rows within individual layers or the molecules within a layer may be randomly distributed. The orientation of the C_9Ph_{13} and water molecules, however, cannot be determined by this method. The mobility and orientation of water molecules in lyotropic liquid crystals are now under investigation.

Emission Spectra of Benzene, Toluene, and Xylenes by Controlled Electron Impact

Teiichiro OGAWA, Masaharu TSUJI, Minoru TOYODA, and Nobuhiko ISHIBASHI

Faculty of Engineering, Kyushu Unviersity, Hakozaki, Fukuoka 812

(Received January 11, 1973)

The emission spectra of gaseous aromatic hydrocarbons under electron impact excitation (60—300 eV) were measured in the 220—450 nm region at very low pressures. A characteristic band was observed in all cases in the 240—340 nm region; this band was assigned to the transition from the lowest excited singlet state to the electronic ground state. Photoemissions from the fragment species, such as H (Balmer series) and CH (A→X, B→X), were also observed. The excited species were concluded, from the relations of the emission intensities to the electron-beam current and to the gas pressure, to be produced by one-electron processes. The relative intensity and the vibrational structure of the observed spectra were examined and compared with those of the fluorescence spectra produced by photo-excitation.

The electric discharge method has been one of the most effective ways of studying excited molecules and their emission spectra. Although the methods are very useful in the detection of unstable species, however, the complicated character of the discharge is a major obstacle for any detailed analysis of the mechanism of fragmentation and excitation of the species concerned. The ideal way to produce excited molecules by means of electrons is, in this respect, the crossed electron and molecular-beam method,[1] in which the photoemission of excited species can be obtained at very low pressures, where the effect of molecular collision is greatly reduced and the energy of electrons can be controlled. However, the disadvantage of this method is the low intensity of photoemission. Although recent developments in instrumentation have made the study of smaller molecules feasible, little has been done on complicated organic molecules.

Extensive studies have been carried out in recent years on the excited species of the aromatic hydrocarbons. The fluorescence spectra in the gas phase

1) T. Horie, T. Nagura, and M. Otsuka, *J. Phys. Soc. Jap.*, **11**, 1157 (1956).

at low pressures have been observed for benzene,[2-5] toluene,[5,6] and other aromatic molecules.[5] Electron impact is an effective alternate method for exciting molecules at low pressures in the gas phase. The spectroscopic investigation of the electron-molecule collisions of these molecules would not only give the emission spectra by a different excitation method, but would also reveal the mechanism of the collision and fragmentation.

The emission spectra of fragment species of methane and chlorinated methanes[7] and methanol[8] under electron impact excitation have been reported. The emission spectra of benzene by controlled electron impact have been measured in the 240—300 nm region, and the lifetime of the $^1B_{2u}$ state has been studied.[9] The emission spectra of toluene and anisole[10] and of xylenes[11] in the 250—450 nm region obtained by this method have also been communicated by the present authors. In the present report, detailed results on benzene, toluene, and xylenes will be described and the relationship between the emission spectra obtained by the controlled electron impact method and the fluorescence spectra obtained by photo-excitation will be discussed.

Experimental

The sample vapor was crossed so as to collide with an electron beam in a chamber, as is shown schematically in Fig. 1. The cell was made of glass and was about 4.5 cm in diameter and about 40 cm in length. The electron was emitted from a tungsten filament (a), was accelerated by three electrodes (c, d, e), and was introduced into the collision chamber through a slit (2×15 mm) in the center of one of the electrodes (c). Two electromagnets (h) were placed so as to collimate the electron beam. The voltages of the two electrodes in the collision chamber (b, c) were set equal for the quantitative measurements. After being purified in a vacuum line (j) by repeated freezing and pumping, the sample was jetted into the collision chamber through a nozzle 0.1—1.0 mm in diameter (g). The chamber was evacuated (i) continuously to a high vacuum; a Penning gauge attached to the chamber indicated a pressure of the order of 10^{-4}—10^{-5} mmHg during the electron-impact measurements. The actual pressure in the impact region was expected to be higher than the value indicated and smaller than 10^{-2} mmHg. The sample vapor was excited by the collision with the electron, and the photoemission was observed through a quartz window (f). An electron beam of 10—1000 μA at 60—300 eV was used for the excitation. The energy distribution of the incident electron was not measured;

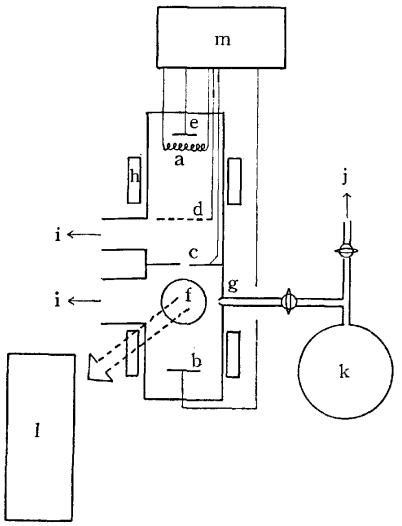

Fig. 1. Schematic diagram of the collision chamber. Controlled electron beam was introduced through a slit (c) and sample vapor was jetted through a nozzle (g). Photoemission at the collision region was observed through a quartz window (f). (a) tungsten filament, (b) electron target, (c) electrode with a slit in its center, (d) electrode, (e) electrode, (f) quartz window, (g) nozzle, 0.1—1.0 mm in diameter, (h) electromagnet, (i) to diffusion pump, (j) to vacuum line for the sample preparation, (k) gas reservoir to store sample vapor before use, (l) monochromator, (m) power supply.

however, it is expected to be no less than the voltage used for heating the filament (6—9 V).

The fluorescence spectra under photon-excitation were taken by the use of a standard quartz cell (10×10 mm) placed just in front of the entrance slit. The sample vapor in the cell was irradiated with a Hamamatsu TV L299 low-pressure mercury lamp.

The spectra were obtained with a Jarrell-Ash JE25 monochromator equipped with two 1200 groove/mm gratings blazed for 300 and 600 nm, and it had a reciprocal dispersion of about 33 Å/mm. The photons were detected photoelectrically with an EMI 9558QB photomultiplier and a Burr-Brown 3421J OP amplifier. The wavelength was calibrated by means of a low-pressure mercury lamp. The further details of the apparatus have been described elsewhere.[12]

All the compounds used were of a JIS specially pure reagent grade and were obtained from either Wako Pure Chemical Ind. or the Kishida Chemical Co.

Results and Discussion

A typical emission spectrum of benzene by electron impact is shown in Fig. 2. The impact voltage was 200 V and the electron-beam current was 1 mA in this measurement. The bands in the 250—300 nm region agreed well with those of Smith[9] and were assigned to the vibronic band of the forbidden $^1B_{2u}$—$^1A_{1g}$ transition. The transitions from vibrationally-excited states of the upper electronic level such as $6_1^0 1_0^2$ [13] (255 nm) and $6_1^0 1_0^1$ (260 nm) are quite intense.

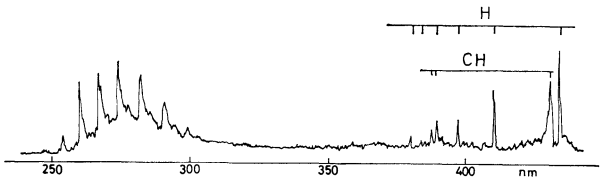

Fig. 2. Emission spectrum of benzene by electron impact. 200 V impact at 1 mA.

Balmer series of the hydrogen atom and the $B^2\Sigma^- - X^2\Pi$ transition and the $A^2\Delta - X^2\Pi$ transition of the CH radical were found in the 370—440 nm region. The Swan system of C_2 and Schüler's T spectrum of $C_4H_2^+$ were also observed in the 430—550 nm region.

The fluorescence spectra of benzene in the gas phase were taken at various excitation wavelengths; several different resonance spectra have been reported at such a low pressure as 0.2 mmHg, where collisional deactivation is not complete.[4,5] A comparison of those spectra with the present spectrum under electron-impact excitation reveals several points of interest. The equilibrated fluorescence[4] (the emission spectra of 0.2 mmHg benzene with 40 mmHg hexane, in which the Boltzmann equilibrium is established in the $^1B_{2u}$ state) shows no remarkable band above 267 nm, whereas the present spectrum has a strong band head at 261 nm ($6_1^0 1_0^1$). Since the pressure in the impact chamber was very low in the present study, molecular collisions were not so frequent that photoemission from vibrationally excited states was observed. The resonance spectra excited by irradiation with a monochromatic light[4,5] consist of only a few strong progressions and appear to be simpler than the present spectrum. This finding is probably connected with the facts that the excitation energy of the electron impact is higher and the energy distribution of the electron beam is broader than those in the case of the photon excitation with a monochromatic light. The variation in impact voltage between 60—300 V did not, however, induce any remarkable change in the appearance of the spectrum under the resolution of the spectrometer used. It seems

that the molecule received enough excess energies even when excited with electrons of 60 V; a similar emission spectrum was observed upon excitation by electrons with higher energies.

The dependence of the emission intensity on the electron-beam current was measured; the results are shown in Figs. 3 and 4. The intensities of the photoemission of the excited parent species of benzene and of the fragment species (H and CH) were proportional to the electron-beam current. Thus, the excitation of a π electron of benzene is concluded to be a one-electron process, as is that of fluorobenzene.[14] The fragmentations of benzene to H and to CH are also concluded

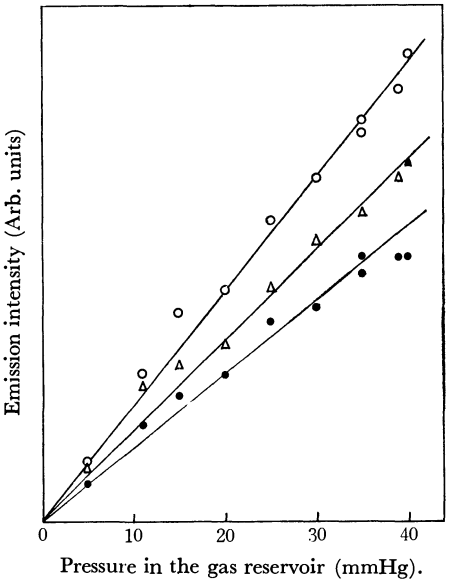

Fig. 5. Dependence of photoemission intensity on the gas pressure in the gas reservoir. Emission of excited benzene molecules. Impact voltage 200 V; electron beam current 70 μA.

to be one-electron processes; an identical conclusion has previously been obtained in the case of methane.[7]

The relationship between the emission intensity and the gas pressure in the gas reservoir was also measured in the case of benzene; the results are shown in Figs. 5 and 6. The intensities of the photoemission of the excited parent species and of the fragment species (H and CH) were found to be proportional to the gas pressure in the gas reservoir. The gas pressure in the gas reservoir can be expected to be proportional to the pressure in the impact region since the gas is jetted through a small nozzle; this presumption was confirmed in the case of nitrogen by measuring the pressure in the impact chamber. This finding indicates that intermolecular quenching processes by collisions are not important.

The proportionality between the emission intensity and the amount of electrons and molecules mentioned above is also found in the photoemission of various molecules.[7,14] This result seems to indicate that the excitation and the fragmentation take place through one-electron processes, such as;

$$X \xrightarrow{\text{electron}} X^* \qquad (1)$$

$$X \xrightarrow{\text{electron}} X^{**} \begin{cases} \xrightarrow{\text{fast}} X^* \\ \xrightarrow{\text{fast}} H^*, CH^* \cdots \end{cases} \qquad (2)$$

where X stands for benzene, where * indicates the lower electronically excited state from which the photoemission was observed, and where ** indicates highly excited states, which are probably some kinds of superexcited states.[15] Although the relative importance of the two processes, (1) and (2), could not be determined in the present study, the observation of the Balmer series of hydrogen implies the importance of the second process, since the excitation energy of a typical line of this series (12—13 eV) is more than the typical ionization potential of aromatic hydrocarbons (*ca.* 9 eV). The role and the importance of the superexcited states have also been discussed in the case of the electron impact of CH_4[16] and in the field of radiation chemistry[15] and mass spectrometry.[17]

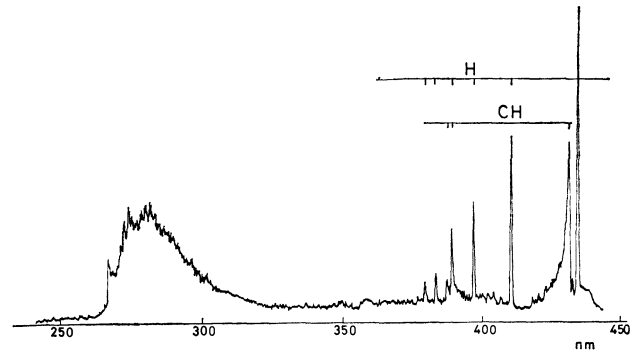

Fig. 7. Emission spectrum of toluene by electron impact. 300 V impact at 1 mA.

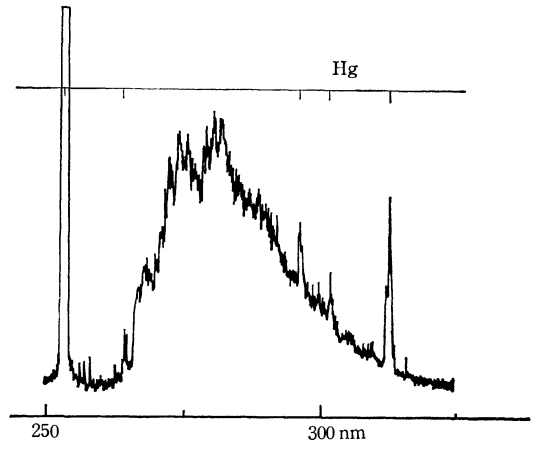

Fig. 8. Emission spectrum of toluene under photon excitation by a low-pressure mercury lamp (2537 Å). vapor pressure, about 10 mmHg.

A typical emission spectrum of toluene under electron-impact excitation is shown in Fig. 7, and that under photon excitation in Fig. 8. A characteristic band was observed in the 270—320 nm region, and the band in Fig. 7 is very similar to that in Fig. 8. The photoemission of H and CH was also observed in the case of electron impact. Since the symmetry of the molecule is C_{2v} for toluene, the 0—0 transition (267 nm) is allowed, unlike the case in benzene. The characteristic band of toluene is located in a longer wavelength region than that of benzene. This band is broader than that of benzene; however, several fine structures between 267—300 nm could be observed above the non-resolved background.

The fluorescence spectra of toluene in the gas phase were observed at 0.1 mmHg[5] and at 20 mmHg.[6] The location and the shape of the present spectrum

under electron-impact excitation are similar to those of the latter, as is shown in Fig. 8. The most striking features of the former experiment are the loss of structure and the increase in the fraction of the background as the excitation energy is increased to higher vibronic levels. Blondeau and Stockburger[5] concluded that vibrational rearrangement dominated at higher vibrational levels and that discrete bands no longer were observable. Their spectrum excited at 932 cm^{-1} above the 0—0 level almost lost its vibrational progression. On the other hand, the present spectrum keeps some of its vibrational features even when the molecule is excited at 200 V. This finding is noteworthy, since the pressure in the impact chamber of the present study is extremely low. However, a detailed comparison of their spectra with the emission spectra obtained by electron impact would require a further improvement in the resolution of the present spectra. The fluorescence spectrum of toluene in solution[18] was found to correspond well to the emission spectrum obtained by electron impact.

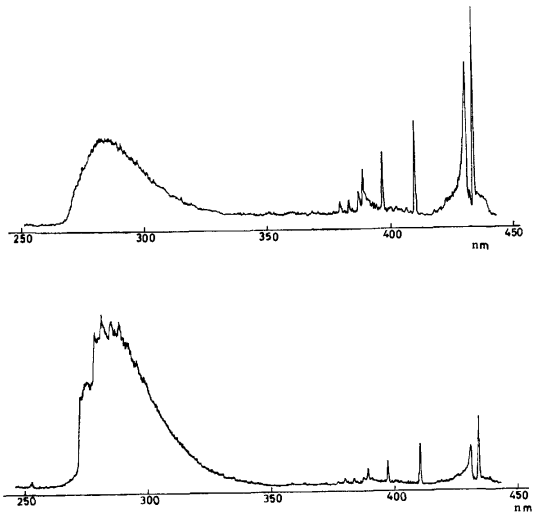

Fig. 9. Emission spectra of xylenes by electron impact.
Top; *o*-xylene, 300 V impact at 1 mA.
Bottom; *p*-xylene, 200 V impact at 1 mA.

Typical emission spectra of xylenes under electron-impact excitation in the 250—450 nm region are shown in Fig. 9. The spectrum of *m*-xylene is similar to that of *o*-xylene. A characteristic band is observed in the 270—340 nm region in all cases, though its location and the vibrational structures differ from each other. Thus, such aromatic molecules as benzene, toluene, xylenes, cumene,[19] and cymene[19] show a characteristic band in this region, and it may well be concluded that this band is a feature common to all aromatic hydrocarbons. The fluorescence spectra of aromatic hydrocarbons in dilute solutions[18] were found to correspond well to the emission spectra by electron impact for various molecules. Thus, all the characteristic bands observed in the present study were assigned to the transition from the lowest excited singlet state to the electronic ground state, as in the case of the fluorescence spectra. Although the energy of the electrons in the present study is much larger than that of the photons in the fluorescence study, the spectra under electron-impact excitation are in many cases similar to those under photon-impact excitation. This is superficially correlative to the fact that the electron-impact (energy-loss) spectra are closely related to the photoabsorption spectra of the same molecules.[20]

The spectrum of *p*-xylene has more vibrational structures and is less diffuse than that of *o*-xylene. This difference in the appearance of the spectra of the two molecules was also observed in the fluorescence in the gas phase[5] and in solution.[18] The relative intensities of the bands of the parent species over the hydrogen Balmer series are also remarkably different in the two spectra, as is shown in Fig. 9. (The cross sections for the formation of excited hydrogen atoms are reported to be almost the same for the different hydrocarbons.[16]) The fluorescence yield of *p*-xylene has been reported to be larger than those of *o*- and *m*-xylenes.[21] It can be concluded that molecules with higher symmetry have sharper and stronger bands than those with less symmetry in the emission spectra obtained by electron impact, just as in the fluorescence. In molecules with high symmetry, there are less vibrational modes which may interact with the electronic level than in those with low symmetry. The more complicated structure and the higher intensity of the emission band of *p*-xylene are probably to be ascribed to the difference in this vibronic interaction. The de-

pendence of the intensity of the photoemission of *p*-xylene on the electron-beam current was measured. The four features of the band of the parent species at 277, 286, 302, and 312 nm showed a linear relationship, as is shown in Fig. 10. This linear relationship indicates that the excitation of a π electron of *p*-xylene is a one-electron process. The identical relationship was also observed for the photoemission of the hydrogen atom and the CH radical just as in the case of benzene.

In the emission spectra under electron-impact excitation, the photoemission from the small fragments of large molecules was usually observed more easily than that from the large parents themselves. It seems likely that larger species have more freedom of motion and of fragmentation and that non-radiative processes become more predominant. The aromatic molecules are exceptional molecules in that the excited large parent species give intense photoemission. The intensities of the photoemission of all the species mentioned above were found to be proportional to the electron-beam current and to the gas pressure. These results indicate that intermolecular quenching processes by collisions are unimportant and that superexcited states may be involved in the excitation.[14]

The few examples which have been discussed in this paper show that the electron-impact method is a useful one for studying electronic excited states. Further research with a higher resolution would reveal even more details on the mechanism of the excitation.

The authors wish to thank Professor Emeritus Kozo Hirota of Osaka University for his interest and encouragement, and Professors Tadao Horie and Tsuruji Iwai and Dr. Seiji Tsurubuchi of Osaka University for their advice on the design of the collision chamber. We also wish to thank Mr. Taketoshi Sonoda for his technical assistance. This work was supported by funds of the Ministry of Education (General research C, 1972)

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2642—2646 (1973)

A Theoretical Consideration of the Electron-scavenging Process in Liquid Hydrocarbons. IV. Integral Transforms in the Prescribed Diffusion Approximation

Hideo YAMAZAKI and Kyoji SHINSAKA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received January 26, 1973)

The relations of the integral transforms and the integral form between various distribution functions have been discussed in the prescribed diffusion approximation for the Smoluchowski equation. The initial electron distribution from the central-ion cluster in a spur or a track, $\omega(r, 0)$; the time dependence of the central value of the electron distribution, $\omega(0, t)$; the time dependence of the space-averaged electron concentration, $N(t)$, after pulse irradiation, and the scavenger-concentration dependence of the relative G-value of electron scavenging, $G_s(k_sC_s)$, as a function of the scavenger concentration, C_s, and the rate constant, k_s, are shown to be connected by this diagram of the Laplace transforms and the integral form:

$$\begin{array}{ccc} \omega(0, t) & \xleftarrow[\text{Laplace transform}]{} & \omega(r, 0) \\ \text{Integral form} \downarrow & & \\ N(t) & \xrightarrow[\text{Laplace transform}]{} & G_s(k_sC_s) \end{array}$$

By the use of this relation, the various distribution functions are evaluated from the generalized Gaussian initial distribution. The square-root relationship of the $G_s(k_sC_s)$ to the scavenger concentration is discussed.

The experimental and theoretical approaches to the electron-recombination process in the radiolysis of hydrocarbons have indicated that the various quantities measured are interconnected. Hummel[1] and Schuler[2] proposed that the scavenger-concentration dependence of the G-value for electron scavenging was connected with the time dependence of the charged species after pulse radiolysis by means of a Laplace transform. Recently, Mozumder[3] extended the prescribed diffusion approximation of the Smoluchowski equation to the multiple-ion spur, blob, and track. He obtained various relationships, namely, the time dependence of the concentration of the charged species after pulse irradiation as well as the G-value of electron scavenging, as functions of the scavenger concentration, using the initial Gaussian distribution of the thermalized electrons. Sato and Oka[4] and Tachiya[5] obtained the relation between the G-value of electron scavenging and the initial spatial distribution of the thermalized electrons by ignoring the effect of diffusion. In a

previous paper,[6] in which the diffusion term of the Smoluchowski equation was neglected, the present authors showed a square-type flow chart of interconnection by means of Laplace transforms among four characteristic functions, the initial spatial distribution of thermalized electrons, the scavenger-concentration dependence of the relative G-value of electron recombination, the time dependence of the electron concentration after pulse irradiation, and the life-time spectrum of the decay of the electron concentration after pulse irradiation. In this paper it will be shown that a similar square diagram of the flow chart of the characteristic functions is present in the prescribed diffusion approximation of the Smoluchowski equation. Various explicit expressions of the characteristic functions for the generalized Gaussian distribution of the thermalized electrons will be given using these relations of the integral transforms in the flow chart.

Theory

The Extended Form of the Smoluchowski Equation and its Prescribed Diffusion Approximation. The extended form of the Smoluchowski equation[7] for the time-dependent spatial distribution of electrons without any electron scavenger in spherical geometry or in cylindrical geometry is expressed by:

$$\frac{\partial C}{\partial t} = D(1/r^n)\frac{\partial}{\partial r}\left(r^n\frac{\partial C}{\partial r}\right) + \frac{u}{r^n}\frac{\partial}{\partial r}\left(r^n C\frac{\partial \psi}{\partial r}\right) \quad (1)$$

($n=2$, spherical geometry; $n=1$, cylindrical geometry),

where $C(r, t)$ is the distribution function, D is the diffusion constant, u is the mobility, and ψ is the static electric potential.

The electric-field strength is given thus for spherical geometry:

$$F_n = \frac{e\partial\psi(r,t)}{\partial r} = -e^2(N^+(r,t) - N(r,t))/\varepsilon r^2 \quad (2)$$

and thus for cylindrical geometry:

$$F_n = \frac{e\partial\psi(r,t)}{\partial r} = -2e^2(N^+(r,t) - N(r,t))/\varepsilon r \quad (3)$$

where the plus sign of the superscript denotes quantities for positive ions, ε is the dielectric constant, and $N^+(r, t)$ and $N(r, t)$ are given by:

$$N^+(r,t) = \int_0^r C^+(r,t)\mathrm{d}v \quad (4)$$

and:

$$N(r,t) = \int_0^r C(r,t)\mathrm{d}v \quad (5)$$

where $\mathrm{d}v$ is a volume element. For the sake of simplicity it is assumed that the positive ions are localized at the origin or in the z-axis:

$$C^+(r,t) = N(t)\delta(r) \quad (6)$$

where $\delta(r)$ means the Delta function of r; the prescribed diffusion approximation is used for the distribution of electrons:

$$C(r,t) = N(t)\omega(r,t) \quad (7)$$

where $\omega(r, t)$ is a solution for the corresponding diffusion equation. Equations (2) and (3) may then be rewritten as:

$$F_n = \frac{e\partial\psi(r,t)}{\partial r} = -e^2N(t)\left(1-\int_0^r\omega(r,t)\mathrm{d}v\right)\Big/\varepsilon r^2, \quad (8)$$

$$(\mathrm{d}v = 4\pi r^2\mathrm{d}r)$$

and:

$$F_n = \frac{e\partial\psi(r,t)}{\partial r} = -2e^2N(t)\left(1-\int_0^r\omega(r,t)\mathrm{d}v\right)\Big/\varepsilon r, \quad (9)$$

$$(\mathrm{d}v = 2\pi r\mathrm{d}r)$$

According to the analysis of Mozumder,[3] the electron decay by recombination is to be expressed in terms of the central value of the electron distribution, $\omega(0, t)$, for spherical and for cylindrical geometry:

$$\frac{N(t)}{N(0)} = 1\Big/\left[1+4\pi Dr_cN(0)\int_0^t\omega(0,t)\mathrm{d}t\right] \quad (10)$$

where $N(0)$ is the initial number of electrons in a spur or in a unit length of track and where $r_c(=e^2/\varepsilon kT)$ is the Onsager length. The details of the more general calculation for evaluating Eq. (10) are given in the Appendix. Inversely, the central value, $\omega(0, t)$, in a spur or in a track is given by the electron-decay function for recombination:

$$\omega(0,t) = \frac{\mathrm{d}}{\mathrm{d}t}\left\{\frac{1}{4\pi Dr_c}\left(\frac{1}{N(t)}-\frac{1}{N(0)}\right)\right\} \quad (11)$$

Relations of Laplace Transforms. Since $\omega(r, t)$ is the solution of a diffusion equation, the central values of distributions in a spherical spur and in a cylindrical track are expressed in terms of the initial distribution:

$$\omega(0,t) = \frac{4\pi}{(2\sqrt{\pi Dt})^3}\int_0^\infty \exp(-r^2/4Dt)\omega(r,0)r^2dr \quad (12)$$

and:

$$\omega(0,t) = \frac{2\pi}{(2\sqrt{\pi Dt})^2}\int_0^\infty \exp(-r^2/4Dt)\omega(r,0)r\mathrm{d}r \quad (13)$$

The relation between the initial distribution and the central value of distribution in spherical geometry can be conveniently described by the Laplace transform:

$$\omega(0, 1/4D\tau)\sqrt{\pi}/2\sqrt{\tau}^3 = \int_0^\infty \exp(-\xi\tau)\omega(\sqrt{\xi}, 0)\sqrt{\xi}\,\mathrm{d}\xi \quad (14)$$

and:

$$\omega(\sqrt{\xi}, 0)\sqrt{\xi} = \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}\omega(0, 1/4D\tau)\frac{\sqrt{\pi}}{2\sqrt{\tau}^3}\exp(\xi\tau)\mathrm{d}\tau \quad (15)$$

where τ and ξ are the substitutions of $1/4Dt$ and r^2 respectively, and where c is taken as having a larger real value than the conversion axis. Similarly, the Laplace transforms in cylindrical geometry are:

$$\omega(0, 1/4D\tau)/\tau = \int_0^\infty \exp(-\xi\tau)\omega(\sqrt{\xi}, 0)\mathrm{d}\xi \quad (16)$$

and:

$$\omega(\sqrt{\xi}, 0) = \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}\omega(0, 1/4D\tau)\frac{1}{\tau}\exp(\xi\tau)\mathrm{d}\tau \quad (17)$$

According to Hummel,[1] Schuler,[2] and Mozumder,[3] the G-value, G_s, of electron scavenging is expressed by the Laplace transform of $N(t)/N(0)$:*1

6) H. Yamazaki and K. Shinsaka, This Bulletin, **45**, 1335 (1972).

7) H. Yamazaki and K. Shinsaka, *ibid.*, **43**, 2713 (1970).

*1) In a previous paper,[6] the relative G-value of the electron recombination was used instead of $G_s(\beta)$, that of electron scavenging.

$$G_s(\beta) = \beta\int_0^\infty N(t)/N(0)\exp(-\beta t)\mathrm{d}t \quad (18)$$

where β is the product of the rate constant, k_s, of the electron scavenging and the scavenger concentration, C_s. Using the inverse Laplace transform, $N(t)/N(0)$ is given by:

$$N(t)/N(0) = \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}\frac{G_s(\beta)}{\beta}\exp(\beta t)\mathrm{d}\beta \quad (19)$$

As a summary of these transforms of the four characteristic functions, the following flow chart of the transformations is given by Fig. 1. A similar flow chart of the linear response of the four characteristic functions was given in a previous paper[6] using the potential control approximation.

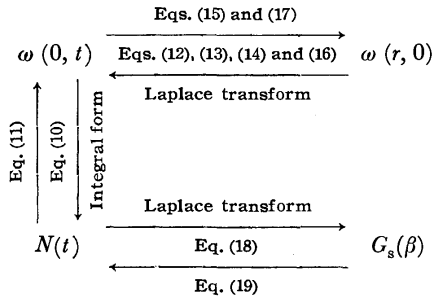

Fig. 1. Flow chart of Laplace trasform and integral form of the four characteristic functions: $\omega(r, 0)$, $\omega(0, t)$, $N(t)$ and $G_s(\beta)$.

Examples of Distribution Functions. To evaluate the explicit form of the four characteristic functions, a generalized Gaussian distribution for the thermalized electrons in the spherical spur will be considered:

$$\omega(r, 0) = A_m r^m \exp(-r^2/b^2) \quad (20)$$

where A_m is a normalization constant and where b is a constant of the spread of the distribution:

$$A_m = 1\Big/\int_0^\infty 4\pi r^{m+2}\exp(-r^2/b^2)\mathrm{d}r \quad (21)$$

Similarly, the initial distribution in cylindrical geometry is expressed by Eq. (20) with the normalization constant of:

$$A_m = 1\Big/\int_0^\infty 2\pi r^{m+1}\exp(-r^2/b^2)\mathrm{d}r \quad (22)$$

By using Eqs. (12), (13), (14), and (16), the central values in the distribution of electron can be obtained for spherical and cylindrical geometries:

$$\omega(0, t) = (4Dt)^{m/2}/\{\pi^{3/2}(4Dt+b^2)^{(m+3)/2}\} \quad (23)$$

and:

$$\omega(0, t) = (4Dt)^{m/2}/\{\pi(4Dt+b^2)^{(m+2)/2}\} \quad (24)$$

By means of Eq. (10) the time dependence of the concentration in spherical geometry is expressed in terms of the incomplete beta function:

$$\frac{N(t)}{N(0)} = 1\Big/\left\{1+\frac{r_c N(0)}{b}B\left(\frac{1}{2}, \frac{m+2}{2}; \frac{4Dt}{b^2}\right)\right\} \quad (25)$$

where the incomplete beta function is defined by:

$$B(p, q; x) = \int_0^x \frac{x^{q-1}}{(1+x)^{p+q}}\mathrm{d}x \quad (26)$$

By the use of the Laplace transform, Eq. (18), the G-value of electron scavenging is obtained:

$$G_s(\beta) = \beta\int_0^\infty 1\Big/\left\{1+\frac{r_c N(0)}{b}B\left(\frac{1}{2}, \frac{m+2}{2}; \frac{4Dt}{b^2}\right)\right\} \times \exp(-\beta t)\mathrm{d}t \quad (27)$$

For dilute concentrations of a scavenger, $G_s(\beta)$ can be expanded as the power series of β for the Gaussian distribution ($m=0$):

$$G(\beta) = \frac{1}{1+K} + \frac{\sqrt{\beta}\,K\sqrt{\pi}}{\sqrt{\alpha}(1+K)^2}\{\exp(\beta/\alpha)\,Erfc(\sqrt{\beta/\alpha})\} - \frac{\beta K^2}{\alpha(1+K)^3}[\exp(\beta/\alpha)\,Ei\{-(\beta/\alpha)\}] \quad (28)$$

where $Erfc$ and Ei are the error function and the exponential integral function,[8]*2) and where K and α denote $2r_cN(0)/(\sqrt{b\pi})$ and $4D/b^2$ respectively. The leading term in the low concentration of the scavenger is $\beta^{1/2}$, which corresponds to the square-root dependence proved by various experiments. The coefficient of the $\beta^{1/2}$ term is:

$$\frac{K\sqrt{\pi}}{\sqrt{\alpha}(1+K)^2} = \frac{r_c N(0)}{\sqrt{D}(1+2r_cN(0)/\sqrt{\pi}\,b)^2} \quad (29)$$

which corresponds to α in Schuler's expression.[2]*3)

Similarly, in cylindrical geometry $N(t)/N(0)$ is given for the Gaussian distribution ($m=0$) for the thermalized electrons by:

$$N(t)/N(0) = 1/\{1+r_cN(0)\ln(1+4Dt/b^2)\} \quad (30)$$

$G_s(\beta)$ is evaluated by[8] means of the Laplace transform:

$$G_s(\beta) = \beta\int_0^\infty\{1-r_cN(0)\ln(1+\alpha t)+r_c^2N^2(0) \times(\ln(1+\alpha t))^2\cdots\}\exp(-\beta t)\mathrm{d}t = 1-\exp(\beta/\alpha)\,Ei(-(\beta/\alpha))+\cdots \quad (31)$$

Therefore, the square-root law does not hold for the electron-recombination process with the Gaussian distribution of thermalized electrons in the cylindrical track. After a long interval, however, the cylindrical track is converted to the 'isolated' ion-pair geometry after recombination in the track. Therefore, the final state can be expressed by the spherical coordinate and

8) For example, H. Beteman, "Table of Integral Transforms. I," McGraw-Hill Book Co., New York (1954).

*2) The error function and exponential integral function are given by:

$$Erfc(x) = \frac{2}{\sqrt{\pi}}\int_x^\infty\exp(-v^2)\mathrm{d}v$$

and:

$$-Ei(-x)\int_x^\infty\exp(-v)/v\mathrm{d}v$$

*3) In Schuler's expression[2], $G_s(\beta)$ can be written as:

$$G_s(\beta) = g_{fl} + g_{gl}\{\sqrt{\alpha\beta/k_s}/(1-\sqrt{\alpha\beta/k_s})\}$$

where g_{fl} and g_{gl} are the relative G-values of free electrons and of geminate electrons:

$$g_{fl} = G_{fl}/(G_{fl}+G_{gl})$$

and:

$$g_{gl} = G_{gl}/(G_{fl}+G_{gl})$$

Schuler's expression can be expanded in the series of β:

$$G_s(\beta) = g_{fl} + g_{gl}\sqrt{\alpha\beta/k_s} + \cdots$$

From Eq. (28), the coefficients of the first and second terms are found to be:

$$g_{fl} = 1/(1+K)$$

and:

$$g_{gl}\sqrt{\alpha/k_s} = \frac{r_cN(0)}{\sqrt{D}(1+2r_cN(0)/\sqrt{\pi}\,b)^2}$$

the square-root law is valid.[3] The contribution of the spherical spurs to the whole process of recombination can be estimated by the factor of $\sigma(=1/\{(2r_cG_i)\text{-}(-dE/dx)\})$, where r_c is the Onsager radius, G_i is the G-value of the total ionization, and $(-dE/dx)$ is the average LET in the radiation track. For example, the α beam of 20 Mev and the ^{4+}N beam of 80 Mev, which are used for the study of the LET effect in hydrocarbons,[9] the factor σ, is evaluated as 2×10^{-2} and 4×10^{-3} respectively, assuming that G_i is 3 and r_c is 100 Å. Therefore, the contribution of the square-root dependence is negligibly small in these cases.

In this paper, the integral transforms in the prescribed diffusion approximation have been discussed. The prescribed diffusion approximation, one of the most common approximations, has been used since the initial stage of the development of the theroy of radiation chemistry. However, the real importance of the integral transforms is that the transforms can also be applied to the other forms of approximation.[5,10-12] On the other hand, in their preliminary stages of development these approximations should be considered as of equal importance.

The authors wish to thank Professor Shoji Shida and Dr. Shin Sato of Tokyo Institute of Technology and Dr. Kenji Fueki of Nagoya University for reading the preliminary manuscript of this paper and for their helpfull discussions, and Miss Toshiko Kitagawa for typing the manuscripts of this series.

Appendix

Introduction of a Finite Reaction Radius. It is reasonable to consider the finite radius, r_0, of the reaction between central-ion clusters and the surrounding electrons, because to consider ion clusters as a point or an axis is not a realistic view of the models, as has been discussed in connection with other approximations,[10,13] and the origin of coordinate is a singular point of the Smoluchowski equation. The solution of the diffusion equation, $\partial v/\partial t = D\Delta^2 v + \delta(r-r')\delta(t)$, is given by,[14]

$$v(r,t) = \frac{1}{8(\pi Dt)^{3/2}} \exp\{-(r-r')^2/4Dt\} \qquad \text{(A-1)}$$

If the reaction radius, r_0, is used, then the value, $\omega(r_0, t)$, at the reaction radius can be used instead of the central value, $\omega(0, t)$. In spherical coordinates, $\omega(r_0, t)$ can be expressed by the initial distribution, $\omega(r, 0)$, by using the super position of the solutions of Eq. (A-1) outside of the ion cluster*4):

$$\omega(r_0,t) = \frac{2\pi}{(2\sqrt{\pi Dt})^3}\int_{r_0}^{\infty}\int_0^{\pi} \exp(-d^2/4Dt)\omega(r,0)r^2 dr \sin\theta d\theta \qquad \text{(A-2)}$$

where d is the distance between the ion and the electron:

$$d^2 = r^2 + r_0^2 - 2rr_0\cos\theta \qquad \text{(A-3)}$$

Similarly, in the cylindrical geometry of a track in cylindrical coordinates, $\omega(r_0, t)$ is given by:

$$\omega(r_0,t) = \frac{1}{(2\sqrt{\pi Dt})^2}\int_{r_0}^{\infty}\int_0^{2\pi} \exp(-d^2/4Dt)\omega(r,0)r dr d\theta \qquad \text{(A-4)}$$

After integration, Eqs. (A-2) and (A-4) are transformed to:

$$\omega(r_0,t) = \frac{2\pi}{(2\sqrt{\pi Dt})^3}\exp(-r_0^2/4Dt)\int_{r_0}^{\infty}\exp(-r^2/4Dt) \times\omega(r,0)r^2\frac{2Dt}{rr_0}\left\{\exp\left(\frac{rr_0}{2Dt}\right)-\exp\left(-\frac{rr_0}{2Dt}\right)\right\}dr$$
$$= \frac{1}{\sqrt{\pi Dt}}\exp(-r_0/4Dt)\int_{r_0}^{\infty}\exp(-r^2/4Dt) \times\omega(r,0)\frac{r}{r_0}\sinh\left(\frac{rr_0}{2Dt}\right)dr \qquad \text{(A-5)}$$

and

$$\omega(r_0,t) = \frac{1}{4Dt}\exp(-r_0^2/4Dt)\int_{r_0}^{\infty}\exp(-r^2/4Dt) \times\omega(r,0)I_0\left(\frac{rr_0}{2Dt}\right)r dr \qquad \text{(A-6)}$$

where I_0 denotes the modified Bessel function. For the outside of the ion cluster ($r>r_0$), $N^+(r, t)$ and $N(r, t)$ can be expressed by:

$$N^+(r,t) = N^+(t) \qquad \text{(A-7)}$$

and
$$N(r,t) = N(t)\Delta + N(t)\int_{r_0}^{r} 4\pi\omega(r,t)r^2 dr \qquad \text{(A-8)}$$

or
$$N(r,t) = N(t)\Delta + N(t)\int_{r_0}^{r} 2\pi\omega(r,t)r dr$$

where Δ is a correction factor of the electron probability in the ion cluster and is given by:

$$\Delta = 4\pi\int_0^{r_0}\omega(r,t)r^2 dr \qquad \text{(A-9)}$$

or
$$\Delta = 2\pi\int_0^{r_0}\omega(r,t)r dr$$

Then, by the use of Eqs. (2) and (3), Eqs. (8) and (9) can be corrected by:

$$\frac{\partial\psi}{\partial r} = -\frac{e}{\varepsilon r^2}N(t)\left\{1-\Delta-\int_{r_0}^{r}\omega(r_1,t)4\pi r_1^2 dr_1\right\} \qquad \text{(A-10)}$$

in the spherical geometry and:

$$\frac{\partial\psi}{\partial r} = -\frac{2e}{\varepsilon r}N(t)\left\{1-\Delta-\int_{r_0}^{r}\omega(r_1,t)2\pi r_1 dr_1\right\} \qquad \text{(A-11)}$$

in the cylindrical geometry. Considering that $\omega(r, t)$ is a solution of the diffusion equation:

$$\frac{\partial\omega(r,t)}{\partial t} = \frac{D}{r^n}\frac{\partial}{\partial r}\left(r^n\frac{\partial\omega}{\partial r}\right) \qquad \text{(A-12)}$$

where $n=1$ for the cylindrical geometry and $n=2$ for the spherical geometry, the Smoluchowski equation can be expressed by:

$$\frac{dN(t)}{dt}\omega(r,t) = -\frac{N(t)u}{r^2}\frac{\partial}{\partial r}\left\{\omega(r,t)\frac{e}{\varepsilon}N(t) \times\left(1-\Delta-\int_{r_0}^{r}\omega(r_1,t)4\pi r_1^2 dr_1\right)\right\} \qquad \text{(A-13)}$$

13) M. G. Robinson and G. R. Freeman, *ibid.*, **55**, 5644 (1971).
14) For example, H. S. Carslaw, and J. C. Jaeger, "Conduction of Heat in Solids," Clarendon Press, Oxford (1959), p. 256.

*4) It is possible to use the solution of the diffusion equation with the boundary condition:

$$(\partial\omega(r,t)/\partial r)_{r=r_0} = 0$$

in the prescribed diffusion approximation. In this case, however, the solution assumes a more complicated expression, so, for the sake of simplicity, the present solutions for the diffusion equation were used instead.

in the spherical geometry and:

$$\frac{dN(t)}{dt}\omega(r,t) = -\frac{N(t)u}{r}\frac{\partial}{\partial r}\left\{\omega(r_1,t)\frac{2e}{\varepsilon}N(t) \times\left(1-\Delta-\int_{r_0}^{r}\omega(r_1,t)2\pi r_1 dr_1\right)\right\} \quad \text{(A-14)}$$

in the cylindrical geometry.

By integration outside of the ion cluster, Eqs. (A-13) and (A-14) become:

$$\frac{d}{dt}\left(\frac{1}{N(t)}\right) = \left\{4\pi u\Big/\left(4\pi\int_{r_0}^{\infty}\omega(r_1,t)r_1^2 dr_1\right)\right\} \times\left\{\omega(r_0,t)\frac{e}{\varepsilon}(1-\Delta)\right\} = 4\pi ue\omega(r_0,t)/\varepsilon \quad \text{(A-15)}$$

and:

$$\frac{d}{dt}\left(\frac{1}{N(t)}\right) = \left\{2\pi u\Big/\left(2\pi\int_{r_0}^{\infty}\omega(r_1,t)r_1 dr_1\right)\right\} \times\left\{\omega(r_0,t)\frac{2e}{\varepsilon}(1-\Delta)\right\} = 4\pi ue\omega(r_0,t)/\varepsilon \quad \text{(A-16)}$$

After integration over time, Eqs. (A-15) and (A-16) are transformed to the same expression for both the spherical and cylindrical geometries. $N(t)$ can be obtained from $\omega(r_0, t)$ instead of $\omega(0.\, t)$:

$$\frac{N(t)}{N(0)} = \frac{1}{1+4\pi Dr_c N(0)\int_0^t \omega(r_0,t_1)dt_1} \quad \text{(A-17)}$$

If r_0 is converged to zero, Eq. (A-17) is reduced to Eq. (10).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2646—2650 (1973)

Mechanism of Hydrogenolysis. III. Thermal Hydrogen Exchange and Demethylation of Toluene-2-d_1, -3-d_1, and -4-d_1

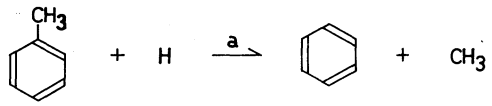
Yoshiki SATO and Akira AMANO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aoba, Aramaki, Sendai 980

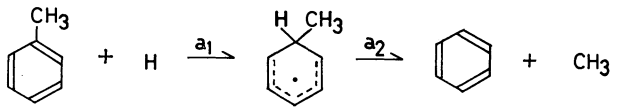
(Received February 5, 1973)

Rates of gas phase thermal hydrogen exchange and hydrogenolytic demethylation of toluene-2-d_1, -3-d_1, and -4-d_1 are evaluated using flow apparatus at temperatures 675—750 °C in the presence of a large excess molecular hydrogen. Both the exchange and the demethylation obey three-halves order rate law indicating the chain mechanism carried by hydrogen atom, the former being found slightly faster than the latter. Rate parameters of the two reactions taking place concurrently are then correlated with the extended Hückel superdelocalizability values appropriate to methylcyclohexadienyl transient formation. Overall applicability of the dynamic index as a measure of reactivity of deuteriotoluenes toward hydrogen atom attack is taken as an additional support for the generally accepted chain mechanism whose rate-determining step consists of electroneutral hydrogen atom addition to aromatic nucleus.

Gas phase demethylation of a series of methyl substituted benzenes in a stream of a large excess hydrogen has been a subject of numerous investigations.[1] General features of the reaction including product distribution and kinetic behavior can be accounted for by the free radical chain mechanism in which the following atomic cracking process (*reaction a*) assumes the rate-controlling role.[2]



The process may be looked upon as consisting of the addition of attacking hydrogen atom to the phenyl carbon adjacent to methyl group followed by the elimination of methyl radical through the intermediary formation of methylcyclohexadienyl radical.



It has been shown that the rate of the consecutive sequence described above is determined by addition (*reaction* a_1).[3] Attempts had hitherto been made to correlate either the atom localization energy[4] or the maximum free valence[5] with observed free radical addition rate constants, showing that these *static reactivity indices* were in limited practical use. However, the ease with which the key reaction proceeds could be predicted by the modified superdelocalizability values, the *dynamic reactivity index* $S_r(R)$ proposed by Fukui

et al.[6] of the ring carbon atom at which the addition-elimination takes place.[1]

The extended Hückel calculation on toluene, however, gives the values of $S_r(R)$ which indicate that phenyl hydrogen is more susceptible to substitution than methyl group upon hydrogen atom attack. A qualitative evidence for this has been provided by Burr *et al.* in their study on the pyrolysis of deuterium laveled toluene.[7] Isotopic distribution in the product observed can only be explained on the assumption that hydrogen-deuterium exchange is slightly faster than demethylation.

In the present work, rate of hydrogen-deuterium exchange relative to that of demethylation has been evaluated using toluene-2-d_1, -3-d_1, and -4-d_1 as reactants. Results are then correlated with the relevant $S_r(R)$ values. In so doing, we expect to extend the applicability of the concept of the superdelocalizability to radical substitutions and also to provide an additional support for the mechanism of hydrogenolysis. Some characteristic features of the key reaction are envisaged during the course of the present approach and will also be reported.

Experimental

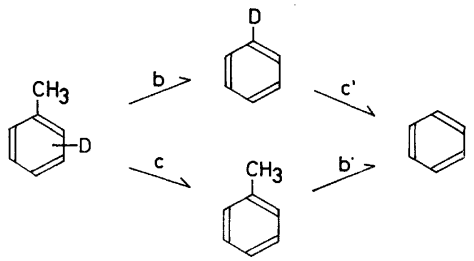
Toluene-2-d_1, -3-d_1 and -4-d_1 were prepared by the methods of Fukuda *et al.*[8] and Weldon *et al.*[9] with minor modifications from *o*-chloro, *m*-bromo and *p*-bromo derivatives of toluene, respectively. Gas chromatographic analysis revealed that the synthetic materials purified through conventional distillation consisted of more than 99.8 mol% toluene fraction accompanied by a trace amount of ether. Infrared absorption spectra were in good agreement with those of toluene-d_1's reported by Turkevich *et al.*[10] and by Tiers.[11] The synthetic materials were passed through a reaction vessel and the fraction collected as unreacted toluene was used in the subsequent rate measurements. Cylinder hydrogen, 99.9 mol% purity as analyzed by mass-spectrometry, was used after conventional purification.

Rates of the reaction of each toluene-d_1 were measured by a flow apparatus specially designed for sufficient accuracy in both temperature and residence time. Details of the apparatus and procedures were described elsewhere.[12]

Liquid products were introduced into a gas chromatographic apparatus with a 3 *m*-Apiezon Grease L packed column for analysis of total isotopic benzenes. A Perkin-Elmer 337 Infrared Spectrometer, equipped with KBr optics and effective slit width of approximately 25 microns, was then used to analyze toluene fraction for deuterium distribution at wave lengths 21.62, 21.93, 22.10 and 22.12 mμ for toluene, toluene-2-d_1, toluene-3-d_1 and toluene-4-d_1, respectively.

Results and Discussion

Stoichiometry. Liquid products from each of the three isomeric toluene-d_1's mainly consisted of benzene, benzene-d_1 and toluene together with unreacted toluene-d_1. No intramolecular migration of deuterium in toluene-d_1 was detected. Hydrocarbons of higher molecular weight were also present, but they did not amount to more than a few percent of toluene-d_1 reacted. The gas phase thermal reaction of toluene-d_1 thus consists of simultaneous hydrogenolytic demethylation (*reactions b* and *b'*) and hydrogen-deuterium exchange (*reactions c* and *c'*).



Kinetics. The results of the rate measurements for both demethylation and exchange of toluene-2-d_1, toluene-3-d_1, and toluene-4-d_1 are listed in Tables 1, 2, and 3, respectively. They exhibit validity of the overall

three-halves order rate law for exchange (*reaction c*) as well as demethylation (*reaction b*), kinetics of the latter being in accord with those of methylbenzenes.[1] The values of $k_{1.5}$'s are then fitted into the Arrhenius formulation giving rise to the values of A-factor and activation energy (Table 4). The rate of exchange relative to that of demethylation at 700 °C, at which experiments have been carried out, is also given. The kinetic parameters of demethylation observed for three isomeric toluene-d_1's are in good agreement within error limits with each other and also with those of toluene.[12]

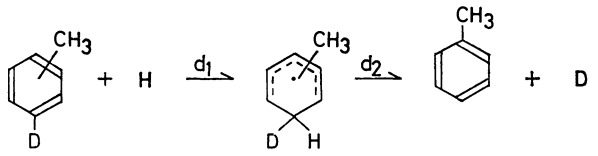
Kinetic Isotope Effects. Neither the secondary kinetic isotope effect nor the effect exerted by deuterium atom at different positions toward thermal demethylation has been detected. This is not surprising in view of the negligibly small effect caused by the introduction of deuterium in place of hydrogen on the electronic structure of the ring carbon atom at which substitution takes place. A similar conclusion was drawn for electrophilic nitration[13] and also for radical alkylation[14] of benzene.

Mechanism of Hydrogen-Deuterium Exchange. A similarity in demethylation (*reaction b*) and exchange (*reaction c*) with respect to the reaction order as well

13) W. M. Lauer and W. E. Noland, *J. Amer. Chem. Soc.*, **75**, 3689 (1953).

14) E. L. Eliel, Z. Welvart, and S. H. Wilen, *J. Org. Chem.*, **23**, 1821 (1958).

as the values of kinetic parameters indicates that these two reactions proceed through similar pathways. Since the key reaction in the free radical chain of the demethylation is the atomic cracking (*reaction a*), the corresponding version of the exchange would be as follows.



The transient structure may be looked upon as methylcyclohexadienyl radical possessing sp^3-hybridized carbon atom which links both incoming hydrogen and outgoing deuterium. It is thus expected that the rate of *reaction d* is influenced by methyl substituent according to its position relative to deuterium in the same molecule, just as in the case of polymethylbenzenes where the demethylation rate is affected by other methyl substituents. The effect exerted by the methyl group upon *reaction d* may be conveniently correlated with $S_r(R)$ proved to be an appropriate reactivity index for the demethylation.[1b] Details of the definition and evaluation of the superdelocalizability values have been described.[1b] In executing the computation, it is assumed that molecular geometry of toluene-d_1 is identical with that of toluene and the valence state ionization potential of deuterium atom is taken to be equal to that of hydrogen. A slight alteration in the values of these structural parameters does not affect the final results in any significant amount. As an example, 10% change in the ionization potential produces uncertainty in the fifth digit of the final $S_r(R)$ values. The results of the extended Hückel calculation are summarized in Table 5. The linear relation obtained for the plots

Table 5. Reactivity indices of toluene by extended Hückel method

Position	Modified superdelocalizability			Atomic bond population
	$S_r(R)$	$S_r(E)$	$S_r(N)$	
1	0.4029	0.2749	0.5309	0.7744
2	0.4149	0.3255	0.5044	0.8243
3	0.4125	0.2836	0.5414	0.8276
4	0.4086	0.3246	0.4926	0.8276

of logarithmic rates of the exchange relative to that of demethylation at 700 °C *vs.* the values of $S_r(R)$ are given in Fig. 1. Other superdelocalizability values, *i.e.* $S_r(E)$ and $S_r(N)$, and also atomic bond population (Table 5), show no linearity with the observed reactivity ratios. This can be taken as an additional support not only for our mechanistic interpretation of the exchange reaction, but also for the use of $S_r(R)$ as reactivity index for thermal substitutions in general. The best explanation so far for the factor influencing the reactivity of atomic cracking (*reactions* a_1 and d_1) is found in the mechanism assuming electroneutral hydrogen atom attack and rehybridization of sp^2 ring carbon atom to the sp^3-state in a concerted manner.

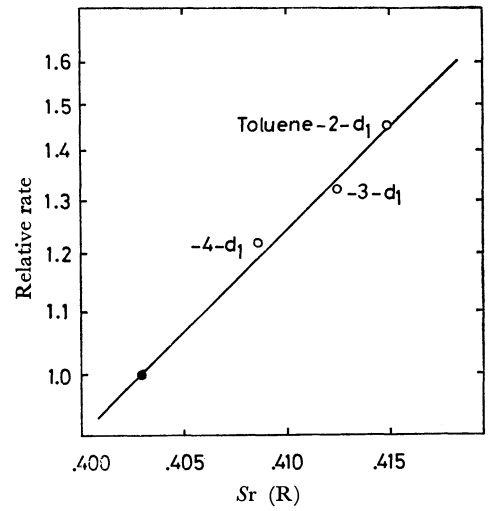


Fig. 1. Correlation between observed relative reactivity and modified superdelocalizability. ●: Demethylation, ○: Exchange.

Hydrogen Atom Addition to Aromatics and Olefins. Gas phase reactions of hydrogen atom with a series of mono-substituted benzenes have been investigated using pulse-radiolytic technique.[15] The results indicate that the addition took place to form cyclohexadienyl-type transients, the latter presumably decomposing to benzene at higher temperatures.[16] The rate of the adduct formation was found to obey the Hammett rule with slightly negative ρ-values (−0.7——0.8). These results suggest that the attacking hydrogen atom could be more conveniently classified as electrophilic reagent. However, according to the theoretical implications of the Hammett rule, ρ-values are by far the more sensitive towards ionic substitutions and are not suitable for classifying reactions consistently.[17] In fact, the data available for radical alkylation of benzene give ρ-values in the range from −1.0 to +1.0. The radiolytic reactions might involve substrates with electrons populated at energy states higher than those usually encountered in thermal reactions. It is therefore possible in the former that the attacking hydrogen atom tends to be more electrophilic.

In this connection, it is interesting to refer to results reported on reactions of hydrogen atom with olefins. According to Cvetanović,[18] the lack of parallelism between hydrogen atom and electrophilic oxygen atom in the rates of addition to a series of olefins was taken as an evidence for support of the electroneutral nature of the former. In spite of the above, hydrogen atom addition to propene, but-1-ene and isobutene has been reported as being somewhat electrophilic, based on the parallelism between the values of $S_r(E)$ and the observed overall rates of the hydrogenolysis.[19] Electronic be-

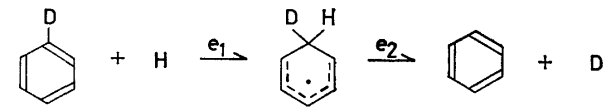
havior of the hydrogen atom toward addition should therefore be reckonned as still controversial.

Comparison between Exchange and Demethylation. In agreement with the qualitative result obtained by Burr *et al.*,[7] we found that exchange (*reaction d*) was faster than demethylation (*reaction a*) by a factor of about 1.3. The converse would most probably be the case if elimination (*reactions* a_2 and d_2) played the rate-controlling role in the overall substitution, since *reaction* d_2 is more endothermic than *reaction* a_2 by about 14 kcal/mol. Our estimated ΔH_f values at 700 °C, based on thermochemical data (Table 6) are −16.1 and approximately −18 kcal/mol for the rate-controlling *reactions* a_1 and d_1, respectively. These values are in accord with the present results, and indicate, on the basis of LFER concept, that the tranistion-state structures for both *reactions* a_1 and d_1 resemble cyclohexadienyl transient.

According to the mechanistic analysis given quite independently by Benson *et al.* in their study of the pyrolysis of 1,3-cyclohexadiene in the presence of benzene and toluene,[20] *reaction* a_1 was found to be faster than the addition of hydrogen atom to benzene-d_6 (*reaction* e_1) by a factor of 1.5.



Reactivity ratio of *reactions* a_1 and e_1 in the range 0.3—0.7 has, however, been obtained on the hydrogen-deuterium exchange of benzene-d_1 both in the presence and in the absence of toluene. If we assume the latter ratio, the rates are in the order $d_1 > e_1 > a_1$. This coincides with what is expected from the calculated values of $S_r(R)$.

Simulation Analysis of the Acid-catalyzed Hydrolysis of Carboxylatopentammineruthenium(III) Complexes

Katsutoshi OHKUBO, Hiroyuki SAKAMOTO, Futoshi KITAGAWA, and Akira OHYOSHI

Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received February 5, 1973)

The mechanism of the acid-catalyzed hydrolysis of $(NH_3)_5RuO_2CR^{2+}$ (R=H, CH_3, C_2H_5, $(CH_3)_2CH$, CH_2OH, and/or CH_2NH_2) has been established by the trapezoidal simulation analyses with a computer. The proposed reaction sequences of S_N1 combined with S_N2 mechanisms involving a quasi-stable intermediate $(NH_3)_5Ru^{3+}$ have proved to be plausible, and the kinetic parameters (rate constants, $\Delta H^{\neq}$, $\Delta S^{\neq}$, *etc.*) have been given for all of the elementary reactions. The aquation rate has been determined by the solvent-assisted, heterolytic dissociation of $(NH_3)_5RuO_2CR^{2+}$ and follows this order: formato>acetato>propionato>isobutyrato>glycolato>glycinato.

In the previous paper,[1] the acid hydrolyses of alkyl-, hydroxyl-, and/or amino-substituted-carboxylatopentaammineruthenium(III) complexes ($(NH_3)_5RuO_2CR^{2+}$) have been proved to proceed in the pseudo first-order fashion:

$$(NH_3)_5RuO_2CR^{2+} + H_2O \xrightarrow[k_{obs}]{H^+} (NH_3)_5RuOH_2^{3+} + RCO_2^- \quad (1)$$

The pseudo first-order rate constant, k_{obsd}, can be represented by the acid-dependent and acid-independent rate constants, k_H and k_d respectively, with a good analytic fit:[1]

$$k_{obs} = k_H[H^+] + k_d \quad (2)$$

The kinetic relationship of Eq. (2) has also been established in the aquation of pentaammine-amino acid cobalt(III) complexes.[2,3] The mechanism of such an aquation reaction has been interpreted, in terms of the reaction paths involving the protonated complex, as:

$$(NH_3)_5MOC(=O)R^{n+} + H^+ \overset{K}{\rightleftharpoons} (NH_3)_5MOC(-OH)R^{(n+1)+} \quad (3)$$

$$(NH_3)_5MOC(-OH)R^{(n+1)+} + H_2O \xrightarrow{k} (NH_3)_5MOH_2^{(n+1)+} + RCO_2^- + H^+ \quad (4)$$

where M denotes the central transition metal.

The aquation mechanism, however, has not yet been strictly established, since Reactions (3) and (4) cannot well explain the kinetic expression of Eq. (2).[4]

The present study was undertaken in order to elucidate the mechanism of the acid-catalyzed hydrolysis of $(NH_3)_5RuO_2CR^{2+}$ (R=H, CH_3, C_2H_5, $(CH_3)_2CH$, CH_2OH, and/or CH_2NH_2) using the technique of computer simulation.

Simulation Results and Discussion

Elementary Reactions of Aquation. In view of the kinetic relationship expressed by Eq. (2), Reaction (1) may be considered to consist of the following two reaction paths involving a quasi-stable intermediate of $(NH_3)_5Ru^{3+}$ (*i.e.*, acid-catalyzed S_N2 and acid-independent S_N1 reactions):

$$(NH_3)_5RuO_2CR^{2+} \xrightarrow[k_H]{H^+} (NH_3)_5Ru^{3+} + RCO_2^- \quad (5)$$

$$(NH_3)_5RuO_2CR^{2+} \xrightarrow{k_d} (NH_3)_5Ru^{3+} + RCO_2^- \quad (6)$$

$$(NH_3)_5Ru^{3+} + H_2O \underset{k_e}{\overset{k_{H_2O}}{\rightleftharpoons}} (NH_3)_5RuOH_2^{3+} \quad (7)$$

The corresponding differential terms (rate equations) derived from Eqs. (5)—(7) are:

$$d[(NH_3)_5RuO_2CR^{2+}]/dt = -d[RCO_2^-]/dt = -(k_H[H^+]+k_d)[(NH_3)_5RuO_2CR^{2+}] \quad (8)$$

$$d[(NH_3)_5Ru^{3+}]/dt = (k_H[H^+]+k_d)[(NH_3)_5RuO_2CR^{2+}] + k_e[(NH_3)_5RuOH_2^{3+}] - k'_{H_2O}[(NH_3)_5Ru^{3+}] \quad (9)$$

$$d[(NH_3)_5RuOH_2^{3+}]/dt = k'_{H_2O}[(NH_3)_5Ru^{3+}] - k_e[(NH_3)_5RuOH_2^{3+}] \quad (10)$$

where k_{H_2O}' stands for the pseudo first-order rate constant derived from $k_{H_2O}[H_2O]$. Assuming the stationary-state for the concentration of $(NH_3)_5Ru^{3+}$, Eq. (2) can be reproduced as:

$$-d[(NH_3)_5RuO_2CR^{2+}]/dt = d[(NH_3)_5RuOH_2^{3+}]/dt = \{k_H[H^+]+k_d\}[(NH_3)_5RuO_2CR^{3+}] \quad (11)$$

Some remarks on Reactions (5) and (6) should be made here in connection with the molecular interaction between $(NH_3)_5RuO_2CR^{2+}$ and H^+ and/or the H_2O solvent. From the results of the extended Hückel MO calculations of the above interacting systems, the most plausible interactions of H^+ and H_2O with $(NH_3)_5RuO_2CR^{2+}$ occur, respectively, in the direction of the orbital expansion of the nonbonding lone-pair 2p-orbital on the oxygen atom of the Ru–O bond and in that of the lowest-unoccupied, antibonding dp-σ orbital on the Ru–O bond axis, which leads to a weakening of the Ru–O.[5] The acid-catalyzed and the solvent-assisted dissociation processes (reactions (5) and (6) respectively) are energetically comparable with the heterolytic cleavage of the Ru–O (see the $\Delta H^{\neq}$ values in Table 2). It is worthy of emphasis that the constants

3) T. Murakami, K. Ogino, H. Kobayashi, H. Yamasaki, and K. Saito, *ibid.*, **44**, 120 (1971).

4) The present extensive study corrects and unveils some discrepancies in the aquation mechanism proposed previously in Ref. 1.

5) The discussions referred to in the remarks made above will be developed in detail in a succeeding paper.

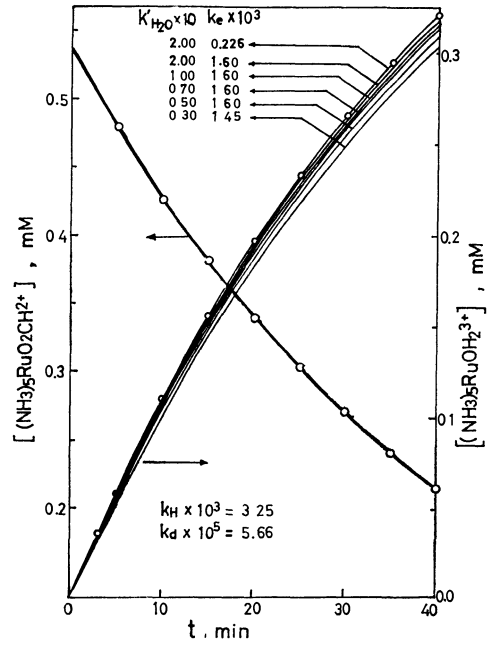

Fig. 1. Variations in time conversions of $[(NH_3)_5RuO_2CH^{2+}]$ and $[(NH_3)_5RuOH_2^{3+}]$ with various sets of values of k_H, k_d, k'_{H_2O}, and k_e at 61°C: $[(NH_3)_5RuO_2CH^{2+}]_i=0.536$ mM; $[H^+]=0.1$ M; $\mu=0.1$.
——: Simulation, ○: Experiment

of k_H and k_d seem to be pseudo rate constants, *i.e.*, $k_H'[H_2O]$ and $k_d'[H_2O]$ respectively.

Determination of the Rate Constants. We will determine the rate constants of the elementary reactions expressed by Eqs. (5)—(7) on the basis of the simulation analysis. Figure 1 indicates the dependence of the time conversions of $[(NH_3)_5RuO_2CR^{2+}]$ and $[(NH_3)_5RuOH_2^{3+}]$ upon various values of k_H, k_d, $k_{H,O}'$, and k_e for the formato-complex. The values of k_H and k_d obtained experimentally[1] for the formato-complex show a good analytic fit, while the best values of $k_{H,O}'$ and k_e were found to be 2.00×10^{-1} M^{-1} s^{-1} and 2.26×10^{-4} s^{-1} respectively; the latter k_e value was obtained

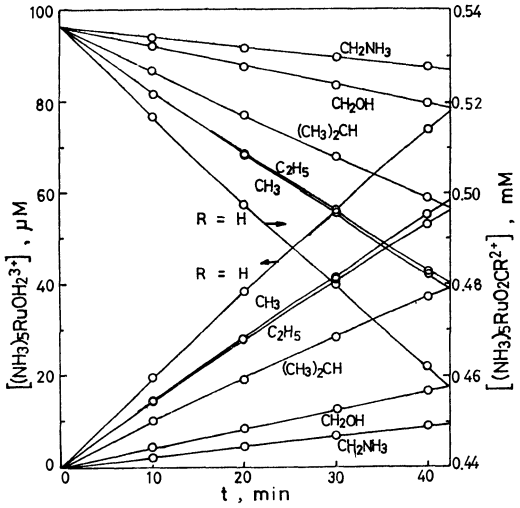

Fig. 2. Simulated time-conversions of $[(NH_3)_5RuO_2CR^{2+}]$ and $[(NH_3)_5RuOH_2^{3+}]$ *vs.* experimental ones: $[(NH_3)_5RuO_2CR^{2+}]_i=0.536$ mM; $[H^+]=0.1$ M; $\mu=0.1$; $T=40$ °C.
——: Simulation, ○: Experiment

from the anation studies[6] of $(NH_3)_5RuOH_2^{3+}$ under the same reaction conditions. The validity of the above values of $k_{H,O}'$, k_e, k_H, and k_d will be tested in the acid hydrolysis of $(NH_3)_5RuO_2CR^{2+}$, where R denotes an alkyl group. As can be seen from Fig. 2, the simulated time conversions of $[(NH_3)_5RuO_2CR^{2+}]$ and $[(NH_3)_5RuOH_2^{3+}]$ are in satisfactory accordance with the experimental values. Table 1 shows the values of k_{obsd}, k_H, k_d, $k_{H,O}'$, and k_e in the Arrhenius-type equations, which were determined by a further simulation analysis of the complex-hydrolyses in the acid solution ($[H^+]=0.025$—0.1 M) at the temperatures of 40, 50, and 70 °C under the condition of $\mu=0.1$. As may be seen from Table 1, the relationship shown by Eq. (2) is completely accounted for.[7]

Reaction Sequences. Now, let us discuss the validity of the reaction schemes represented by Eqs. (5)—(7). From the rate equations of Eqs. (8)—(10), the time-dependence of the [reactant], the [intermediate], and/or the [product] can be reproduced by the non-steady-state analysis:

$$[(NH_3)_5RuO_2CR^{2+}] = [(NH_3)_5RuO_2CR^{2+}]_i e^{-\lambda_1 t} \quad (12)$$

$$[(NH_3)_5Ru^{3+}] = [(NH_3)_5RuO_2CR^{2+}]_i[(1-e^{-\lambda_1 t}) - k'_{H,O}(e^{-\lambda_1 t}-e^{-\lambda_1 t})/(\lambda_2-\lambda_1) - (e^{-\lambda_1 t}-1)/\lambda_2] \quad (13)$$

$$[(NH_3)_5RuOH_2^{3+}] = k'_{H,O}[(NH_3)_5RuO_2CR^{2+}]_i \times [(e^{\lambda_2}-e^{\lambda_1})/(\lambda_2-\lambda_1) - (e^{\lambda_2}-1)/\lambda_2] \quad (14)$$

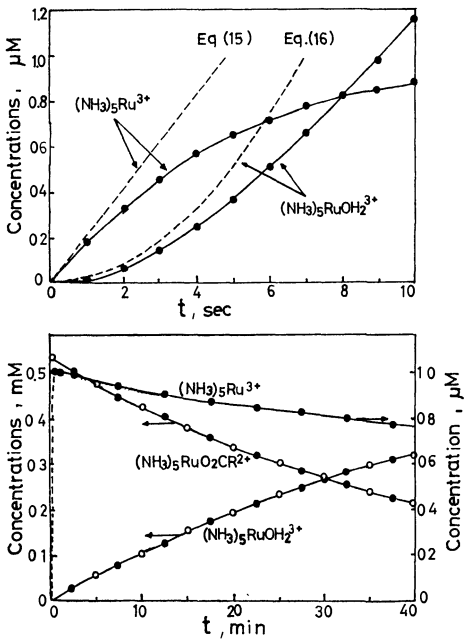

Fig. 3. Time conversions of $[(NH_3)_5RuO_2CR^{2+}]$, $[(NH_3)_5Ru^{3+}]$, and $[(NH_3)_5RuOH_2^{3+}]$ for formato-complex. (Reaction conditions were the same ones in Fig. 1.)

6) A. Ohyoshi, S. Shida, S. Izuchi, F. Kitagawa, and K. Ohkubo, This Bulletin, **46**, 2431 (1973).

7) Strictly speaking, Eq. (2) can be adopted at $t\gtrsim20$ s (see Fig. 3). At $t\gtrsim20$ s, the stationary-state treatment for [intermediate] is possible. In Table 1, the relative errors of the sum of $k_H[H^+]$ and k_d values against k_{obsd} ones (*viz.* $(k_{obsd}-(k_H[H^+]k_d))/k_{obsd}\times100\%$) fall in the range of 0.06—1.15% except in the cases of the propionate- and glycinate-complexes (below 4.60 and 7.45% respectively).

Table 1. The rate constants for the acid-catalyzed hydrolyses of $(NH_3)_5RuO_2CR^{2+}$

$(NH_3)_5RuO_2CR^{2+}$ (R)	Over-all reaction k_{obsd} s^{-1}	Reaction (5) k_H $M^{-1}s^{-1}$	Reaction (6) k_d s^{-1}
H	$5.757\times10^{8}e^{-18580/RT}$	$2.493\times10^{9}e^{-18130/RT}$	$2.277\times10^{10}e^{-21820/RT}$
CH_3	$2.198\times10^{10}e^{-21060/RT}$	$1.361\times10^{10}e^{-18700/RT}$	$2.000\times10^{10}e^{-24790/RT}$
C_2H_5	$8.061\times10^{10}e^{-21800/RT}$	$5.016\times10^{9}e^{-19490/RT}$	$9.723\times10^{15}e^{-30290/RT}$
$(CH_3)_2CH$	$1.547\times10^{11}e^{-22440/RT}$	$2.643\times10^{10}e^{-20180/RT}$	$5.127\times10^{12}e^{-25360/RT}$

CH_2NH_2	24.75±0.12	3.23±0.37	32.62±0.82	−18.9±2.58	24.34±0.05	4.58±0.15

For Reaction (7), Forward: $\Delta H^{\ddagger}=1.44\pm0.05$kcal/mol; $-\Delta S^{\ddagger}=57.67\pm0.02$ e.u.
Backward: $\Delta H^{\ddagger}=6.22\pm0.00$ kcal/mol; $-\Delta S^{\ddagger}=56.87\pm0.01$ e.u.

where $\lambda_1=k_H[H^+]+k_d$, $\lambda_2=k_{H,O}'+k_e$, and the subscript i=initial state. As Fig. 3 indicates, the time conversions of the [component] calculated from Eqs. (12)—(14) are in complete agreement with those obtained from the experimental and simulation results. It may be deduced, therefore, that the acid-catalyzed hydrolysis of $(NH_3)_2RuO_2CR^{2+}$ proceeds *via* the reaction sequences proposed (Eqs. (5)—(7)).

Remark should be here made on the concentration-change of components produced during the initial short stage of the reaction. From Eqs. (13)—(14), the [component] values may be approximated as:

$$[(NH_3)_5Ru^{3+}] \approx k'_{H,O}[(NH_3)_5RuO_2CR^{2+}]_i\times\lambda_1 t \quad (15)$$

$$[(NH_3)_5RuOH_2^{3+}] \approx k'_{H,O}[(NH_3)_5RuO_2CR^{2+}]_i\times\lambda_1 t^2/2 \quad (16)$$

As can be seen from Fig. 3, Eqs. (15) and (16) reproduce the reaction for at least 1.0 s after the start of the reaction. Moreover, the initial rates of the formation or consumption of the components, $r_i[C]$, can be represented by extended analysis[8] in the case of a formato-complex:

$$r_i[(NH_3)_5RuO_2CR^{2+}] \approx -1.53\times10^{-3}[(NH_3)_5RuO_2CR^{2+}]_i^{0.975}[H^+]_i^{0.699} \text{ M/s}$$

$$r_i[(NH_3)_5Ru^{3+}] \approx 3.12\times10^{-4}[(NH_3)_5RuO_2CR^{2+}]_i^{1.000}[H^+]_i^{0.702} \text{ M/s}$$

$$r_i[(NH_3)_5RuOH_2^{3+}] \approx 1.57\times10^{-3}[(NH_3)_5RuO_2CR^{2+}]_i^{1.000}[H^+]_i^{0.704} \text{ M/s}$$

Kinetic Parameters of Activation for Elementary Reactions. Mention should be made here of the enthalpy and entropy of activation, $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$, for each elementary reaction. Using the rate constants listed in Table 1, the least-squares calculations of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values were performed by means of a computer. Table 2 shows the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values for all the elementary reactions. Judging from the $\Delta H^{\ddagger}$ values in Table 2, the reaction step of Eq. (6) may be said to determine the over-all reaction rate, except in the case of the glycinato-complex; the reaction rates follow this order: formato>acetato>propionato>isobutyrato>glycolato >glycinato.

Procedure of Simulation

The procedure of non-steady-state simulation will now be interpreted briefly. According to the trapezoidal simulation method,[9] the series of increments ($D(i)$, $i=1$—4) may be defined by the following terms on the basis of Eqs. (5)—(7):

$$D(1) = k_H[H^+][(NH_3)_5RuO_2CR^{2+}]dt$$

$$D(2) = k_d[(NH_3)_5RuO_2CR^{2+}]dt$$

$$D(3) = k_{H,O}[H_2O][(NH_3)_5Ru^{3+}]dt = k'_{H,O}[(NH_3)_5Ru_2^{3+}]dt$$

$$D(4) = k_e[(NH_3)_5RuOH_2^{3+}]dt$$

According to the rate equations of Eqs. (8)—(10), we obtain:

$$D[(NH_3)_5RuO_2CR^{2+}]_{av} = -D(1)_{av} - D(2)_{av}$$

$$D[RCO_2^-]_{av} = D(1)_{av} + D(2)_{av}$$

$$D[(NH_3)_5Ru^{3+}]_{av} = D(1)_{av} + D(2)_{av} - D(3)_{av} + D(4)_{av}$$

$$D[(NH_3)_5RuOH_2^{3+}]_{av} = D(3)_{av} - D(4)_{av}$$

where the average increments, D_{av}, are evaluated from $(D_t+D_{t+dt})/2$, by the use of the increments at the reaction times of t and $t+dt$, as D_t and D_{t+dt} respec-

8) The analytical method was similar to that described in detail in Ref. 9.

9) K. Ohkubo and T. Hashimoto, This Bulletin, **45**, 3350 (1972).

tively.

The desired concentrations of the components, C (reactant, intermediate, and product), $[C]_t$, at the reaction time, t, can be calculated by:

$$[C]_t = [C]_i + \sum^{n} D[C]_{av} \qquad (ndt = t)$$

where $[C]_i$ and $D[C]_{av}$ are, respectively, the initial concentration of the component, C, and the over-all increment (or decrement) changing with t. In this paper, the $[C]_t$ values were evaluated every 0.1 s (in the case of the initial short stage of the reaction, dt=0.02 s).

Emission Processes in Cadmium Photosensitization

Shigeru TSUNASHIMA, Tsutomu TOYONO, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 15, 1973)

The possibility of the cadmium-photosensitized luminescence of NH_3, CO_2, CO, and CH_4 was examined at 250 °C. In the case of NH_3, a very strong band emission was observed at 432 nm, with a band width of about 100 nm. The sensitized luminescence of NH_3 was attributed to the emission from an excited complex between triplet cadmium and NH_3. In the case of CH_4, a weak emission was observed at about 420 nm. In the cases of CO_2, CO, and N_2, however, no positive evidence of the sensitized luminescence was obtained. From the pressure dependence of the quenching of the 326.1 nm resonance line, the efficiencies of CO_2, CO, NH_3, and N_2 for quenching the triplet cadmium atoms were estimated to be 0.16, 0.03, 3.3×10^{-4}, and 4.9×10^{-5}, respectively, the efficiencies of *cis*-2-butene being assumed to be unity.

In spite of there having been many investigations of the mercury photosensitization, there have been only a few investigations of the cadmium photosensitization.[1] Since the nature of the $Cd(^3P_1)$ atoms is similar to that of the $Hg(^3P_1)$ atoms except for the amount of available excitation energy, a comparison of the two photosensitized reactions will give further information about the detailed mechanism of photosensitization.

It is known that the triplet mercury atoms cause: (a) an electronic energy transfer to molecules which have low-lying triplet states, such as olefins, aromatics, and ketones; (b) a hydrogen-atom abstraction reaction with paraffins, and (c) the conversion of the electronic energy to a luminescence emission.[1-4] Since Penzes, Strausz, and Gunning reported that CH_4, NH_3, and H_2O give a mercury-photosensitized luminescence in the spectral regions of 240—280, 290—400, and 254—320 nm respectively, many investigations of the mercury-photosensitized luminescence have been made with NH_3, H_2O, amines, alcohols, and rare gases by Gunning *et al.*,[2] Phillips *et al.*,[3] and Callear *et al.*[4] Phillips *et al.* attributed the sensitized luminescence to an excited complex between the $Hg(^3P_0)$ atom and a substrate.[3]

In the cadmium photosensitization, processes similar to (a) and (b) have been shown to occur in the reactions of olefins, acetylene, benzene, ketones, and hydrogen.[5] A process similar to (c) was recently reported to occur in the cadmium-photosensitized reactions of NH_3.[6] By analogy with the Hg–NH_3 system, Phillips *et al.* assigned the observed band emission at 430 nm to the emission from an excited complex between $Cd(^3P_0)$ and NH_3.[6]

The present paper will report the results of an independently-undertaken study of the cadmium-photosensitized luminescence and of the quenching for the 326.1 nm resonance line, using NH_3, CH_4, CO, CO_2, and N_2 as the substrates.

Experimental

Apparatus. A diagram of the experimental arrangement is shown in Fig. 1. The light source used was a home-made, U-shaped cadmium lamp (50 cm long and 8 mm o.d.) made of Pyrex; the emitted light was longer than 300 nm. The cylindrical quartz reaction cell was 20 mm in diameter and 50 cm long, with two flat planes. To minimize the intensity of the reflected light on the cell wall, several black-painted aluminum plates were inserted vertically between the lamp and the cell. The cell, the lamp, and the plates were kept in an electric furnace at 250 ± 1 °C. The light

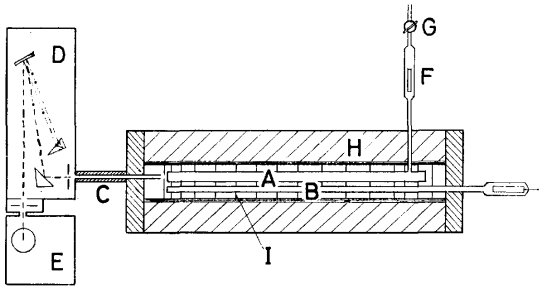

Fig. 1. Experimental system for studying the sensitized emission. A. Quartz Reaction Cell; B. Pyrex Cd Lamp; C. Light Guide; D. Monochromator; E. Photomultiplier; F. Cd Stopper; G. Stop-cock to Vacuum System; H. Furnace; I. Aluminum Plates.

from the cell was detected by means of an 1P28 photomultiplier tube through a light guide and a monochromator. The light guide used was a black-painted porcelain tube 5 mm in i.d. and 30 cm long. The monochromator and the photomultiplier used was a Hitachi Photoelectric Spectrophotometer, model EPU-2A. The emission intensity was measured by means of the photometer of the spectrophotometer and was recorded on a Yokokawa Laboratory Recorder, Type 3043. The reaction cell, containing a few pieces of cadmium metal, was connected to a mercury-free vacuum system through a cadmium stopper, which prevented the cadmium vapor from escaping from the cell. The glass tube between the furnace and the cadmium stopper was heated at about 290 °C by means of an electric heating tape in order to avoid the deposit of cadmium vapor. Some deposits of cadmium were, however, found on the tube at the insulator of the furnace. The pressure of the gas was measured by means of a W & T model 62-075 pressure gauge supplied by the Nagano Keiki Co.

A few experiments on the cadmium-photosensitized decomposition of NH_3 were carried out using a cell 5 cm long and 5 cm in diameter. The experimental details have previously been described.[5]

Materials. The cadmium metal used was high-purity cadmium (99.9999%) manufactured by the Osaka Asahi Metal Co. Pure-grade NH_3, CO_2, and *cis*-2-butene (Takachiho Shoji Co.) were used after degassing at the temperature of liquid nitrogen. Pure-Grade CH_4 and CO (Takachiho Shoji Co.) were used after having been passed through a trap at the temperature of liquid nitrogen. Pure-grade N_2 (Suzuki Shokan Co.) was used after having been passed through a molecular sieve trap at -110 °C.

The light intensity absorbed by cadmium was measured by using the cadmium-photosensitized *cis-trans* isomerization of *cis*-2-butene, assuming the quantum yield of the *trans*-isomer formation to be 0.5.[5] A typical light intensity absorbed in the cell used in the emission study was 6.8 ± 0.4 μEinstein min^{-1}.

Results

Emission Spectrum. When the empty cell only was illuminated by means of the cadmium lamp, line spectra were observed at 326, 340, 347, 361, 468, 480, and 509 nm with the entrance slit of 0.04 mm. These line spectra coincided with the emission spectra of the lamp used. These line spectra may be due to the scattered light on the cell wall. An attempt to minimize the intensity of the scattered light was unsuccessful.

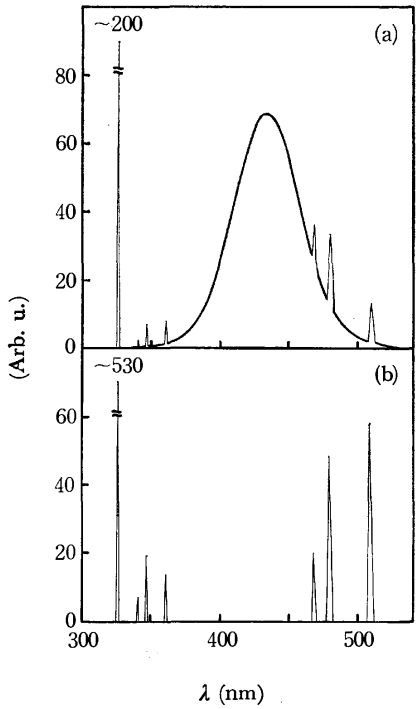

Fig. 2. Observed emission intensity distributions in the presence of 31 Torr of NH_3 (a) and in the absence of NH_3 (b); entrance slit is 0.04 mm and the spectra are not corrected for the sensitivity of the photomultiplier.

In the presence of the cadmium vapor in the cell at 250 °C and *ca.* 4.8×10^{-3} Torr, the intensity of the 326 nm emission increased, but those of the other lines remained almost constant.[7] When 31 Torr of NH_3 was added, as is shown in Fig. 2, the 326 nm line was quenched and a new band emission, with a band width of about 100 nm, was observed at 432 nm. Such a new band emission could not be observed when NH_3 alone was illuminated by the cadmium lamp. When CO_2, CO, or N_2 was the added gas, no emission other than the scattered light was observed in the 300—550 nm region, even when the entrance slit was opened up to 0.8 mm. In the case of CH_4, a very weak emission was observed at about 420 nm. The intensity at 420 nm was about 600 times less than that observed in the case of NH_3. The emission at 420 nm was very faint and decreased with the increase in the irradiation time. A similar tendency was also observed in the intensity at the 326 nm line. Beacuse of the low emission intensity and the large irradiation time dependence, no further study of the case of CH_4 was performed.

Pressure Dependence on the Emission in the NH_3–Cd System. In the case of NH_3, the profile of the band emission at 432 nm was almost the same at 3.0, 31, and 47 Torr, while the intensity at 432 nm increased

7) "C. R. C. Handbook of Chemistry and Physics," **50**, D167 (1969—1970).

Table 1. Irradiation time dependence of the emissions at 326.1 and 432 nm in the presence of 63.5 Torr of NH_3.

b) cell volume 95 ml, light intensity 0.194 μEinstein min^{-1}.
c) cell volume 160 ml, light intensity 6.8 μEinstein min^{-1}.

with the increase in pressure. As is shown in Table 1, the intensity at 432 nm decreased with the increase in the irradiation time. The rate of the decrease increased with the increase in pressure. The emission intensities at 432 nm extraporated to zero irradiation time are plotted in Fig. 3. In this case, the entrance slit of the monochromator was kept at 0.05 mm; this corresponds to the band width of about 0.7 nm at 432 nm.

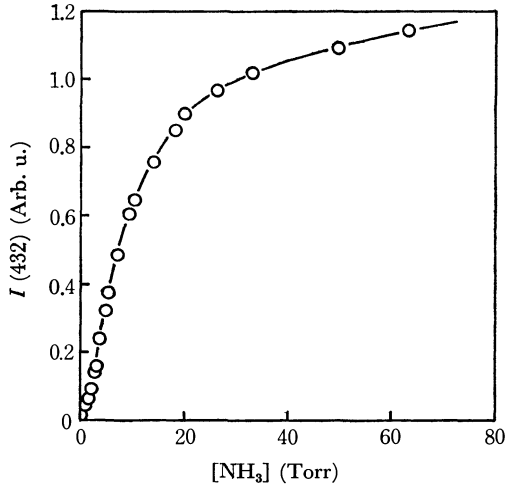

Fig. 3. The emission intensity at 432 nm as a function of NH_3 pressure.

Decomposition of NH_3. After the irradiation of NH_3 in the presence of the cadmium vapor with the cadmium lamp, hydrogen and nitrogen were observed as the decomposition products. We were unsuccessful in trying to detect hydrazine, a possible reaction product, using a gas chromatograph. The relative yield of hydrogen and nitrogen was 3.7 ± 0.8. The apparent quantum yields of the product formation are listed in Table 2.

Quenching of the 326.1 nm Resonance Line. The efficiencies of N_2, NH_3, CO, and CO_2 in quenching the triplet cadmium were studied using the quenching of the 326.1 nm resonance line. The emission intensities at 326.1 nm were measured as a function of the pressure. In order to obtain a good reproducibility, the intensities were measured with a low sensitivity of the photomultiplier and with an entrance slit of 0.5 mm, which corresponds to the band width of 4 nm.

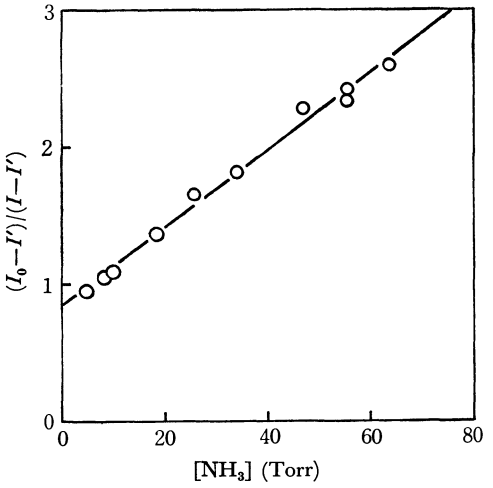

Fig. 4. Stern-Volmer plots of NH_3 for quenching 326.1 nm resonance line.

A typical plot of $(I_0-I')/(I-I')$ against the pressure is shown in Fig. 4, where I_0 and I are the emission intensities at 326.1 nm in the absence and in the presence of a quencher gas respectively. I' is the scattered light intensity at 326.1 nm. On the assumption that 140 Torr of CO quenches the triplet cadmium completely, I' was estimated to be 0.91% of the I_0. In the case of N_2, CO, or CO_2 as the quencher gas, no irradiation time dependence of the emission intensity was observed. In the case of NH_3, however, the intensity decreased with the increase in the irradiation time, as was observed in the case of the 432 nm emission. The irradiation time dependences in both cases agreed well, as is shown in Table 1. In this case, the value of the initial emission intensity was estimated by an extrapolation of the observed intensity to zero irradiation time.

As is shown in Fig. 4, a straight line was obtained. From the intercept and the slope of the straight line, the half-quenching pressure was estimated to be the intercept divided by the slope. The values of the intercept and of the half-quenching pressure are listed in Table 3.

Table 3. Half-quenching pressures and intercepts of Stern-Volmer plots for quenching 326.1 nm resonance line at 250 °C.

Quencher	Intercept	Half-quenching Pressure (Torr)
N_2	0.96±0.01	220 ±3
NH_3	0.85±0.03	29.8 ±1.4
CO	0.84±0.22	0.34 ±0.09
CO_2	0.55±0.27	0.060±0.030

Discussion

Emitting Species in the Cadmium-photosensitized Emission of NH_3. In the case of the vacuum ultraviolet photolysis of NH_3, it has been shown that the NH and NH_2 radicals formed emit their fluorescence at about 324 and 400—600 nm respectively.[8,9] In the case of the cadmium photosensitization, the available energy is only 87.7 kcal mol^{-1}, which is comparable to the N–H bond energy of NH_3 (103 kcal mol^{-1})[10] if the CdH formation is taken into account. The $NH_3 \rightarrow NH + H_2$ (ΔH=89.7 kcal mol^{-1})[9] reaction is energetically impossible in the cadmium photosensitization. When an excited NH_2 radical is assumed to emit the 432 nm band emission, it is necessary to assume the reexcitation of the NH_2 radical by the direct absorption of light and/or the energy transfer from triplet cadmium. A mechanism which includes these processes fails to explain the pressure dependence of the observed emission intensities. The assumption that the emitting species was CdH, which is a possible reaction intermediate in the cadmium-photosensitized reactions of NH_3 and CH_4, was also excluded for the same reason.

In the case of mercury photosensitization, the 350 nm band emission has been attributed to the emission from the complex between the $Hg(^3P_0)$ atom and the NH_3 molecule.[3] Phillips *et al.*, using a phase-modulation method, found a band emission at 430 nm in the cadmium-photosensitized reactions of NH_3.[6] By analogy with the Hg–NH_3 system, they attributed the emitting species to a complex between $Cd(^3P_0)$ and NH_3.[6]

Pressure Dependence of the NH_3 Emission. The pressure dependence of the emission intensity at 432 nm, shown in Fig. 3, was not completely explained by the mechanism proposed by Phillips *et al.*[6] In their mechanism, it was assumed that there were bimolecular and termolecular reactions between $Cd(^3P_0)$ and NH_3 involved in the formation of the complex.[6]

One of the mechanisms which can explain the observed pressure dependence of the emission is shown below:

$$Cd + h\nu(326.1) \longrightarrow Cd(^3P_1) \qquad k_a \qquad (1)$$

$$Cd(^3P_1) \longrightarrow Cd + h\nu(326.1) \qquad k_0 \qquad (2)$$

$$Cd(^3P_1) + A \longrightarrow CdA^{*\prime} \qquad \alpha k_q \qquad (3)$$

$$\longrightarrow \text{other reactions} \qquad (1-\alpha)k_q \qquad (4)$$

$$CdA^{*\prime} + A \longrightarrow CdA^* + A \qquad k_s \qquad (5)$$

$$CdA^{*\prime} \longrightarrow Cd + A \qquad k_d \qquad (6)$$

$$CdA^* \longrightarrow Cd + A + h\nu' \qquad k_f \qquad (7)$$

$$CdA^* + A \longrightarrow Cd + 2A \qquad k_m \qquad (8)$$

Here, $CdA^{*\prime}$ and CdA^* represent, respectively, an unstabilized and a stabilized complex between the triplet cadmium and NH_3. NH_3 is denoted as A. In this mechanism, it is assumed that the unstabilized complex does not radiate the emission. It is also assumed that the $Cd(^3P_1)$ atoms are responsible for the formation of the complex, because the participation of $Cd(^3P_0)$ in the cadmium photosensitization has not been established.[1] If, however, the $Cd(^3P_0)$ is responsible for the complex formation, Reaction (3) should be replaced by Reactions (9) and (10):

$$Cd(^3P_1) + A \longrightarrow Cd(^3P_0) + A \qquad \alpha k_q \qquad (9)$$

$$Cd(^3P_0) + A \longrightarrow CdA^{*\prime} \qquad (10)$$

The steady-state treatment of the above mechanism gives the following relation:

$$1/I = (1+k_0/k_q[A])(1+k_d/k_s[A])(1+k_m[A]/k_f)/\alpha I_a. \qquad (I)$$

Here, I represents the total emission intensity arising from the stabilized complex. Since the emission profile was almost the same at all pressures examined, the observed emission intensity at 432 nm ($I(432)$) may be proportional to the total emission intensity (I) *i.e.*, $I(432)=cI$. The proportional factor, c, may depend on the geometry of the apparatus and on the sensitivity of the photomultiplier used. At the pressures high enough for $(1+k_d/k_s[A])\approx 1$, Eq. (I) can be reduced to this form:

$$1/I(432)(1+k_0/k_q[A]) = (1+k_m[A]/k_f)/c\alpha I_a. \qquad (II)$$

Assuming a value of k_0/k_q equal to the half-quenching pressure of NH_3 (Table 3), the left-hand side of Eq. (II) is plotted against the pressure of NH_3 in Fig. 5. As is shown in Fig. 5, a straight line was obtained in the high-pressure region. At the pressures low enough for $(1+k_m[A]/k_f)\approx 1$, Eq. (I) can be reduced to this form:

$$1/I(432)(1+k_0/k_q[A]) = (1+k_d/k_s[A])/c\alpha I_a. \qquad (III)$$

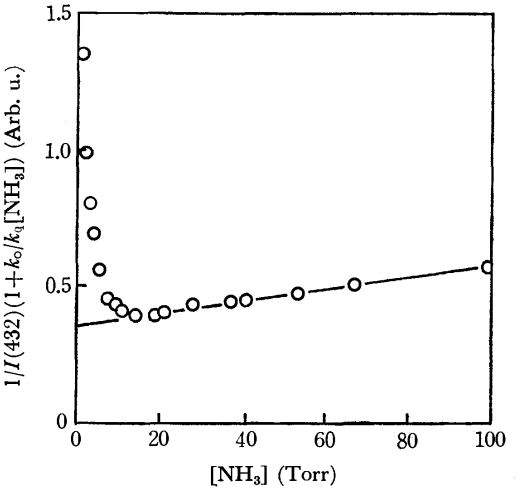

Fig. 5. The plots of $1/I(432)(1+k_0/k_q[A])$ as a function of NH_3 pressure.

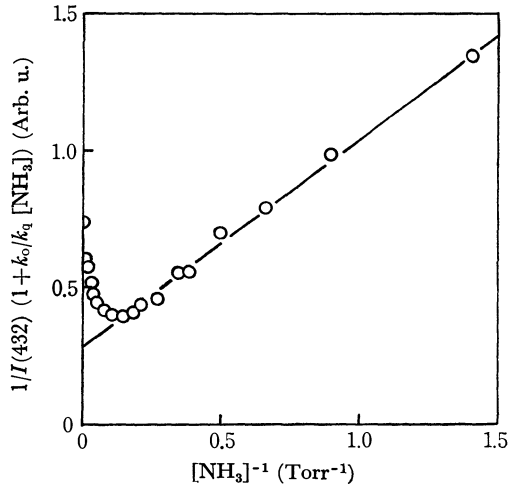

Fig. 6. The plots of $1/I(432)(1+k_o/k_q[A])$ as a function of reciprocal of NH_3 pressure.

The left-hand side of Eq. (III) is plotted against the reciprocal of the pressures in Fig. 6. As is shown in Fig. 6, the plots show a straight line in the low-pressure region. The intercepts of the straight lines coincided with each other within the limits of experimental error. From the intercepts and the slopes of the straight lines, the values of k_m/k_f and k_d/k_s were calculated to be $(1.2\pm0.2)\times10^{-2}$ Torr^{-1} and 2.8 ± 0.2 Torr respectively.

Assuming the cross section of 9 Å^2 for Reactions (5) and (8),[11] which corresponds to $k_m=k_s=1.4\times10^{11}$ l mol^{-1} s^{-1} at 250 °C, the lifetimes of the unstabilized complex and the stabilized complex were calculated to be 8.2×10^{-8} and 2.9×10^{-9} s respectively. The finding that the lifetime of the unstabilized complex is longer than that of the stabilized complex seems somewhat strange. It may, however, be explained by one of the following chains of reasoning: (a) If the total spin is conserved during Reactions (3) or (10), the unstabilized complex, CdA*', should be in a triplet state. Because the lifetime of $\sim10^{-9}$ s is a typical value for a fluorescence emission, the stabilized complex, CdA*, may be in an excited singlet state. Generally, an excited singlet state has a shorter lifetime than an excited triplet state. The difference in the spin multiplicity might explain the estimated shorter lifetime of the stabilized complex. (b) If the following reactions are considered to occur in the mechanism:

$$CdA^* + A \longrightarrow Cd + 2A \qquad k_m' \qquad (8)$$

$$\longrightarrow CdA_2^* \qquad k_m \qquad (11)$$

$$CdA_2^* \longrightarrow CdA^* + A \qquad (12)$$

where CdA_2^* represents a dimer complex between the triplet cadmium atom and two NH_3 molecules, the value of k_m should be smaller than that of k_s. A small value of k_m gives a large value for the lifetime. If k_m'/k_m is larger than 30, the lifetime of the stabilized complex should be longer than 9×10^{-8} s.

Effects of Decomposition Products. The formations of hydrogen and nitrogen in the cadmium-photosensitized reactions of NH_3 may be explained in terms of the following reactions:

$$Cd + h\nu(326.1) \longrightarrow Cd(^3P_1) \qquad (1)$$

$$Cd(^3P_1) \longrightarrow Cd + h\nu(326.1) \qquad (2)$$

$$Cd(^3P_1) + NH_3 \longrightarrow CdH + NH_2 \qquad (13)$$

$$CdH \longrightarrow Cd + H \qquad (14)$$

$$H + NH_3 \longrightarrow H_2 + NH_2 \qquad (15)$$

$$2NH_2 \longrightarrow NH + NH_3 \qquad (16)$$

$$2NH \longrightarrow H_2 + N_2 \qquad (17)$$

The CdH formation is assumed because of the small excitation energy of the triplet cadmium. The reactions of NH and NH_2 radicals are still in question, because the reaction of the hydrogen atom and hydrazine, one of the products, is considered to explain the formation of nitrogen and hydrogen in the mercury-photosensitized decomposition of NH_3.[12]

As will be shown later, the efficiency of hydrogen in quenching the triplet cadmium is about 2×10^3 times that of NH_3. One of the products, hydrogen, will compete with NH_3 in quenching the triplet cadmium, even in the presence of 0.05% of NH_3.

$$Cd(^3P_1) + H_2 \longrightarrow CdH + H \qquad (18)$$

$$\longrightarrow Cd + H_2 \qquad (19)$$

Here, again the CdH formation is assumed.[5] If Reaction (18) is included in the mechanism, the apparent quantum yield of the decomposition should increase with the increase in the irradiation time, while the observed emission intensities at 326.1 and 432 nm should decrease at the same rate. These effects explain well the results shown in Tables 1 and 2.

Using the values of the quantum yield and the half-quenching pressure of NH_3, it was estimated that Reaction (13) accounts for only about 2% of the quenching for the triplet cadmium. This value is about one order of magnitude smaller than that obtained in the mercury photosensitization, in which the available excitation energy is much higher than that in the cadmium photosensitization.[12]

Quenching of the 326.1 nm Resonance Line. In the usual Stern-Volmer plots, the intercept of the straight line is expected to be unity. The intercept obtained here, however, was less than unity for every case examined (Table 3 and Fig. 4). Similar results were obtained by Phillips *et al.* in the mercury-photosensitized luminescence of NH_3.[4] They explained the deviation from unity in terms of the effect of the Lorentz broadening of the resonance line; *i.e.*, the absorbed light intensity increases with the increase in the pressure.[3] To check this possibility in the present study, the Lorentz breadth and the Doppler breadth of the resonance line were compared using the following equations:[13]

$$\Delta\nu_D = 2\nu_0(\sqrt{2R\ln 2}/c)\sqrt{T/M} \qquad (IV)$$

$$\Delta\nu_L = 2\sigma_L^2 N\sqrt{2RT/\pi\mu} \qquad (V)$$

11) "C. R. C. Handbook of Chemistry and Physics," **50**, F151 (1969—1970).

12) C. C. McDonald and H. E. Gunning, *J. Chem. Phys.*, **23**, 532 (1955); S. Takamuku and R. A. Back, *Can. J. Chem.*, **42**, 1426 (1964); M. Z. Hoffman, M. Goldmaster, and R. L. Damour, *J. Chem. Phys.*, **47**, 2195 (1967).

13) A. C. G. Mitchell and M. W. Zemansky, "Resonance Radiation and Excited Atoms," Cambridge University Press, London (1934), p. 99, 170.

Here, $\Delta\nu_D$ and $\Delta\nu_L$ are, respectively, the Doppler breadth and the Lorentz breadth for the resonance line. ν_0 and σ_L^2 are, respectively, the frequency of the resonance line and the effective cross-section for the Lorentz broadening. R, T, M, μ, and N are the gas constant, the temperature, the mass, the reduced mass, and the number of foreign gas molecules in 1 cm^3 respectively. The Doppler breadth of the 326.1 nm resonance line was estimated to be $1.4\times10^9\ s^{-1}$ at 250 °C. The Lorentz breadth was $6.4\times10^8\ s^{-1}$ at 250 °C in the presence of 100 Torr of NH_3, assuming the cross-section for the Lorentz broadening to be 40 $Å^2$. That is, the effect of the Lorentz broadening may be ignored in the present study.

Bender observed in his study of the quenching for the cadmium resonance line, that the absorbed light intensity in the evacuated system was lower than that in the presence of a quencher gas.[14] He explained this in terms of the low vapor pressure of cadmium; *i.e.*, in the evacuated system, the faster distillation of the vapor to the colder part of the apparatus causes a lowering of the vapor pressure.[14] As was mentioned in the Experimental section, the deposit of cadmium was observed in this study. If this effect is operative in the present study, the absorbed light intensity in the evacuated system should be smaller than that expected in the presence of a quencher gas. Even in the presence of 0.1 Torr of a quencher, the mean free path of cadmium is expected to be about two orders of magnitude smaller than that in the evacuated system, in which the pressure may be smaller than the vapor pressure of cadmium (4.8×10^{-3} Torr).[7] This effect may explain the small value of the intercept shown in Table 3.

The relative quenching efficiencies of CO_2 and H_2 have been estimated to be, respectively, 0.16 and 0.8 times that of *cis*-2-butene.[5] Using these values and the values of the half-quenching pressure (Table 3), the efficiencies of H_2, CO_2, CO, NH_3, and N_2 in quenching the triplet cadmium were estimated to be 0.8, 0.16, 0.03, 3.3×10^{-4}, and 4.9×10^{-5} respectively, when the efficiency of *cis*-2-butene was assumed to be unity. The order of the efficiencies obtained is in good agreement with that obtained by Lipson and Mitchell and by Steacie and LeRoy.[15,16] The values of NH_3 and N_2 are, however, much smaller than those obtained by them. This deviation may be mainly due to the presence of a small amount of impurities and/or decomposition products which can quench the triplet cadmium efficiently, such as hydrogen.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2659—2662 (1973)

Relationship between Self-Diffusion and Interdiffusion in Gaseous Systems

Hiromasa HIRAKAWA, Yoshinobu KAMEI, Masayasu SUGISAKI, and Yasumichi OISHI

Department of Nuclear Engineering, Faculty of Engineernig, Kyushu University, Fukuoka 812

(Received February 20, 1973)

Self-diffusion coefficients of oxygen and interdiffusion coefficients were measured for the O_2–He system at 25 °C under 760 Torr. The interdiffusion coefficients obtained were compared with theoretical values calculated by the kinetic theory and by Darken's phenomenological theory. The phenomenological equation was tested in comparison with the kinetic theory by making use of the results and the data reported by other investigators. A criterion determining the magnitude or error of the phenomenological equation was given.

The interrelation between self-diffusion[1] and interdiffusion coefficients for gaseous systems has been described by rigorous kinetic theory. However, calculation has been successful only for dilute gaseous systems, the kinetic theory failing to describe satisfactorily the interdiffusion for condensed systems in terms of self-diffusion coefficients. So far the data of interdiffusion have been analyzed only by means of the phenomenological equation. Darken[2] introduced the concept of intrinsic diffusion flux density for the respective components to explain the Kirkendall effect observed in the interdiffusion of a metallic alloy system and derived a phenomenological equation. This has been widely applied in the analysis of interdiffusion in binary metallic systems. Essentially the same equation was also derived by Hartley and Crank[3] and tested by many

1) "Self-diffusion coefficient" is defined as the diffusion coefficient for diffusion in a homogeneous system where no chemical concentration gradient exists. The term is used for the diffusion coefficient not only in a pure system of single component but also in a homogeneous multicomponent system. Thus, the effective diffusion coefficient defined by the kinetic theory and the intradiffusion coefficient defined by Albright and Mills (*J. Phys. Chem.*, **69**, 3120 (1965)) and McCarty and Mason (*Phys. Fluids*, **3**, 908 (1960)) are included in the present definition.

2) L. S. Darken, *Trans. AIME*, **175**, 184 (1948).

3) G. S. Hartley and J. Crank, *Trans. Faraday Soc.*, **45**, 801 (1949).

authors for various organic binary solutions. The simple form of Darken's equation has the advantage that it can be easily extended to diffusion in the systems of more than two components. An extension to the ternary system has been made for a Ne^{20}–Ne^{22}–CO_2 system with satisfactory results.[4] The Kirkendall effect has also been observed in the interdiffusion in gaseous systems.[5] In Darken's equation the diffusion flux density relative to the external frame is given as a sum of the intrinsic diffusion flux density and the mass flow term. The intrinsic diffusion coefficients are assumed to be equal to the self-diffusion coefficients for the ideal systems, and the interdiffusion coefficient is given by

$$D_{AB} = N_B D_A^* + N_A D_B^* \quad (1)$$

where D_{AB} is the interdiffusion coefficient, N mole fraction, D^* the self-diffusion coefficients, and subscripts A and B refer to components A and B, respectively.

McCarty and Mason[6] and Miller and Carman[7] examined the validity of Darken's equation for the interdiffusion in gaseous systems and found that Eq. (1) was less accurate than the following equation derived from the kinetic theory.

$$\frac{1}{D_A^*} = \frac{N_A}{D_{A^*A}} + \frac{N_B}{D_{AB}} \quad (2)$$

McCarty and Mason further pointed out that Eq. (1) is consistent with Eq. (2) only in the case

$$\frac{D_{AB}^2}{D_{A^*A} D_{B^*B}} = 1. \quad (3)$$

Deviation of the ratio from unity can be a measure for the error resulting from application of the phenomenological equation to a gaseous system for which the kinetic theory holds.

In the present paper, the criterion by means of $D^2_{AB}/D_{A^*A}D_{B^*B}$ has been transformed into mass and potential terms. Thus the magnitude of a possible error coming from the phenomenological equation when applied to an actual system can be estimated with thermodynamic data without knowing the self-diffusion and interdiffusion coefficients. The derived criterion was tested with various binary systems. Necessary self-diffusion coefficients and interdiffusion coefficients were measured by a conventional diaphragm-cell method.

Experimental

Experiments were carried out by means of a Ney-Armistead type[8] diaphragm-cell technique. The cell constant was determined by using the self-diffusion coefficient of carbon dioxide determined by Winn[9] as a standard. The details of the apparatus have been described elsewhere[4].

Commercial helium gas and oxygen gas both of 99.99% purity (Osaka Sanso Co., Japan) were used without further purification. The isotope ratios of these gases were of natural abundance. The O^{18}-enriched oxygen gas was obtained from O^{18}-enriched water by electrolysis. CO_2 gas was O^{18}-enriched with the use of exchange reaction between $CO^{16}O^{16}$ and 5% O^{18}-enriched oxygen on the surface of a red-hot iron wire. Gas mixtures of O_2 and He having the required compositions were prepared in separate storage vessels, transferred into the diffusion cells by means of a Toepler pump, and a diffusion run was then performed. In the measurements of self-diffusion coefficients of O_2 in binary mixtures of O_2 and He, both sides of the diffusion couple were made to have the same chemical composition and one side enriched with O^{18}. For measurements of interdiffusion coefficients the composition difference between the diffusion couple was taken to be approximately 0.2 mole fraction of He. In all experiments the denser gas mixture was placed in the lower cell. Measurements were carried out at 25 ± 0.5 °C under 760 Torr.

The compositions of the binary mixtures of O_2 and He and the isotope ratios of $^{16}O_2$ and $^{17}O_2$ were determined with a mass spectrometer.

Results

Self-diffusion coefficients of O_2 in the binary system of O_2 and He were measured for several compositions. The results are summarized in Table 1. Interdiffusion coefficients for the binary system of O_2 and He were also measured for three compositions. The results are summarized in Table 2. The reciprocals of these diffusion coefficients are plotted as a function of the mole fraction of He in Fig. 1. Equation (2) shows that the reciprocal of the self-diffusion coefficient of one component in a binary system is dependent linearly upon its mole fraction, if the interdiffusion coefficient is independent of composition. The relation holds in the results for O_2 (Fig. 1). The self-diffusion coefficients of He in the binary system of O_2 and He (chain line) were estimated from Eq. (2) by using the value of the self-diffusion coefficient of He in the pure He system D_{B^*B},[10] where the self-diffusion coefficient of He for

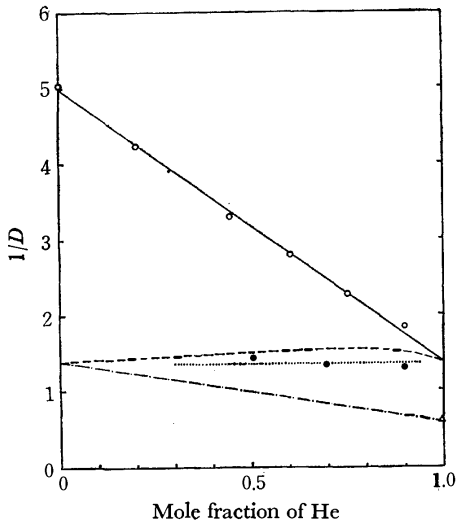

Fig. 1. Reciprocal of diffusion coefficients for the O_2–He system; ○, experimental self-diffusion coefficients of O_2; ●, experimental interdiffusion coefficients; ·-·-·, estimated self-diffusion coefficients of He; △, experimental value by Bendt[9]; ——, theoretical interdiffusion coefficients by the phenomenological equation; ·····, theoretical interdiffusion coefficients by the kinetic theory.

zero mole fraction of He should be equal to the interdiffusion coefficient for the same composition.

The value of the interdiffusion coefficient D_{AB} calculated by Eq. (2) is 0.721, which agrees closely with the average of our values, 0.736. Seager *et al.*[11] and Wasik *et al.*[12] also reported the values, 0.729, 0.736, respectively. The interdiffusion coefficients for the O_2–He system were calculated by the kinetic theory for cases in which the various data[13] of potential parameters were available. The calculation gives a maximum 0.751 and minimum 0.708. The average value, shown in Fig. 1 by a dotted line, agrees well with the experimental results. For the sake of comparison, the results obtained by Eq. (1) are also shown (broken line), maximum deviation from experimental result being approximately 14.7%. This deviation should be attributed to the approximation made in the derivation of Darken's equation.

Discussion

A Criterion for Comparison of the Phenomenological Equation with the Kinetic Theory. For the case where the rigorous kinetic theory is valid, the applicability of Eq. (1) can be tested by whether the ratio $D^2_{AB}/$

11) S. L. Seager, L. R. Geertson, and J. C. Giddings, *J. Chem. Eng. Data*, **8**, 168 (1963).
12) S. P. Wasik and K. E. McCulloh, *J. Res. Nat. Bur. Std.*, **73A**(2), 207 (1969).
13) The potential parameters were obtained according to the combining rule from the force constants data determined by viscosity and 2nd virial coefficients measurements at various temperatures (see also Ref. (15)).

$(D_A{}^*{}_A D_B{}^*{}_B)$ is unity or not, as mentioned by McCarty and Mason. For the O_2–He system at 25 °C, we obtain

$$\frac{D_{AB}^2}{D_A{}^*{}_A D_B{}^*{}_B} = \frac{(0.729)^2}{(0.199)(1.69)} = 1.57$$

The deviation from unity may be taken as a measure for the deviation of the interdiffusion coefficient obtained by the phenomenological equation from the correct value, the square root of 1.57 indicating the deviation.

This criterion can be further simplified and rewritten by use of the rigorous kinetic theory. In order to simplify the derivation, we let $D_A{}^*{}_A$ and $D_B{}^*{}_B$ equal to D_{AA} and D_{BB} respectively. The interdiffusion coefficient D_{ij} is then expressed as follows:[14]

$$D_{ij} = 0.00092916 \frac{T^{3/2}\sqrt{(m_i+m_j)/m_i m_j}}{P\sigma_{ij}^2 W_{ij}^{(1)}(1:\varepsilon_{ij}/kT)} \text{ [cm}^2\text{/s]} \qquad (4)$$

where P is pressure [atm], T temperature [K], σ_{ij} and ε_{ij} the potential parameters, m_i and m_j molecular masses, and $W_{ij}^{(1)}$ $(1:\varepsilon_{ij}/kT)$ the term associated with the collision integral. Thus, we obtain

$$\frac{D_{AB}^2}{D_{AA}D_{BB}} = \frac{(m_A+m_B)}{2\sqrt{m_A m_B}}\left[\frac{\sigma_{AA}^2 W_{AA}^{(1)}\sigma_{BB}^2 W_{BB}^{(1)}}{(\sigma_{AB}^2 W_{AB}^{(1)})^2}\right] \qquad (5)$$

Values of $D^2{}_{AB}/D_{AA}D_{BB}$ for various systems were calculated by use of experimental data and compared with $(m_A+m_B)/2\sqrt{m_A m_B}$. Some of the examples are listed in Table 3. It is noted that the values of Ω,[15] *i.e.* the term in the brackets in Eq. (5) are close to unity, so $D^2{}_{AB}/D_{AA}D_{BB}$ may be approximated to $(m_A+m_B)/2\sqrt{m_A m_B}$, if a few percent error is allowed. Thus the discrepancy of the phenomenloogical equation from Eq. (2) is ascribed mostly to the deviation of $(m_A+m_B)/2\sqrt{m_A m_B}$ from unity.

Charge Transfer in Acetonitrile-Halogen Complexes

Hisao NEGITA, Kaoru SHIBATA, Yoshihiro FURUKAWA, and Koji YAMADA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received February 26, 1973)

The charge transfer in acetonitrile-halogen complexes was examined by means of the nuclear quadrupole resonances resulting from the relevant nuclei. ^{14}N NQR parameters ($|e^2Qq|=3.6000$ MHz and $\eta=0.0183$) and ^{35}Cl NQR parameters ($|e^2Qq|=107.44$ and 108.50 MHz) were obtained for the acetonitrile-chlorine complex, whereas ^{14}N NQR parameters ($|e^2Qq|=3.5439$ MHz and $\eta=0.0043$) and a ^{81}Br NQR parameter ($|e^2Qq|=640.52$ MHz) were obtained for the acetonitrile-bromine complex. From these parameters, the charged states of the nitrogen, chlorine, and bromine atoms in these charge-transfer complexes were calculated by means of the Townes and Dailey theory. In the case of the acetonitrile-bromine complex, the charge loss at the nitrogen atom was not equal to the gain at the bromine atom, as long as the charge was assumed to be transferred only to the p-orbital of the latter. This discrepancy was explained by assuming some d-hybridization at the bromine atom. The charged states of the nitrogen atoms in these complexes were qualitatively in good agreement with the electron affinities of the chlorine and bromine molecules. Moreover, the temperature dependences of the ^{14}N and ^{81}Br nuclear quadrupole coupling constants in the acetonitrile-bromine complex were investigated in the range from -196 to -60 °C.

The charge-transfer (CT) complexes of nitriles or amines with halogens have been investigated by various spectroscopic methods. The NQR method is particularly useful for investigating the charge distribution in the CT complexes. However, NQR data have been reported only on the halogen atoms in electron acceptors. Therefore, we planned to examine ^{14}N NQR in some weak CT complexes, including the CT complexes of acetonitrile with the chlorine and bromine molecules. The crystal structure of the acetonitrile-bromine complex was recently determined to be as is shown in Fig. 1.[1] The open and shaded circles represent atoms at $y=0$ and $y=\pm 1/2$ respectively. The intramolecular bonds are represented by the solid lines, while the intermolecular bonds are represented by the broken lines. The distance between the nitrogen and bromine atoms in the acetonitrile-bromine complex is shorter by 0.61 Å than the sum of their van der Waals radii. Therefore, it may be considered that there is a weak interaction between the acetonitrile and bromine molecules. A similar intermolecular interaction may be expected to exist between the acetonitrile and chlorine molecules.

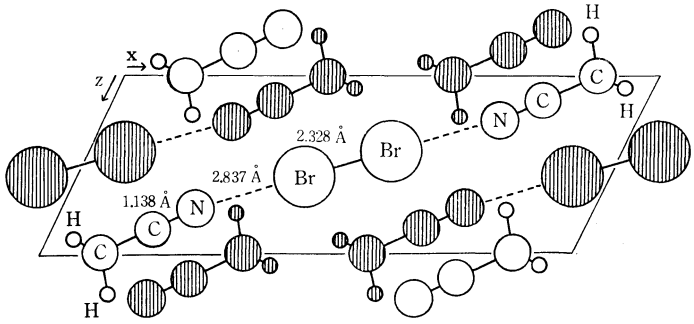

Fig. 1. The crystal structure of the acetonitrile-bromine complex.

Experimental

The ^{14}N NQR spectra of these CT complexes were obtained by the use of a frequency-modulated spectrometer described previously,[2] whereas the ^{35}Cl and ^{81}Br NQR spectra of these CT complexes were obtained by the use of a superregenerative spectrometer. The resonance frequencies were measured by means of two heterodyne-type frequency meters, BC-221 and TS-175C/U, whose frequencies were checked by means of a frequency counter, TR-5578, of the Takeda Riken Co. The measurements were carried out at the temperature of liquid nitrogen, but the studies of the temperature dependences were performed by blowing the vapour of the liquid nitrogen from a Dewar bottle. The temperatures were measured by the use of a thermocouple.

Preparation of the Acetonitrile-chlorine Complex. Gaseous chlorine was generated by the reaction of hydrogen chloride with manganese dioxide, and was liquefied by the use of a mixture of acetone and dry ice as the coolant. Then acetonitrile obtained from commercial sources was mixed with liquid chlorine in the mol ratio of 2: 1 at about −70 °C.

Preparation of the Acetonitrile-bromine Complex. Commercial acetonitrile was mixed with commercial bromine in the mol ratio of 2: 1 at about −40 °C.

Results and Discussion

Generally a pair of ^{14}N NQR frequencies, ν_I and ν_{II}, are observed as follows:

$$\nu_I = |e^2Qq|(3-\eta)/4, \quad (1)$$

$$\nu_{II} = |e^2Qq|(3+\eta)/4. \quad (2)$$

On the other hand, the ^{35}Cl or ^{81}Br NQR frequency, ν_0, is obtained according to the following equation:

$$\nu_0 = |e^2Qq|(1+\eta^2/3)^{1/2}/2, \quad (3)$$

where $|e^2Qq|$ and η are the quadrupole coupling constant and the asymmetry parameter respectively. Our sample of the acetonitrile-chlorine complex revealed a pair of ^{14}N resonance lines and two ^{35}Cl resonance lines, with an intensity ratio of about 5: 3, as is shown in Fig. 2. We attributed the resonance line of 53.72 MHz to the ^{35}Cl nuclei in the CT complex, and that of 54.25 MHz, to the ^{35}Cl nuclei in the non-reacted chlorine molecules. The acetonitrile-bromine complex showed a pair of ^{14}N resonance lines and a ^{81}Br resonance line, as is shown in Fig. 2. The ^{14}N nuclear quadrupole coupling constant in the acetonitrile-bromine complex is lower than that in the acetonitrile-chlorine complex. This seems to suggest that the interaction between the nitrogen and bromine atoms is stronger than that between the nitrogen and chlorine atoms in the CT complexes. The quadrupole coupling constants and asymmetry parameters derived by substituting these resonance frequencies into Eqs. (1), (2), and (3) are listed in Table 1.

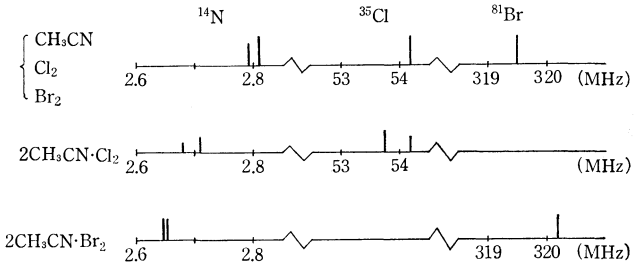

Fig. 2. NQR absorption lines in acetonitrile-halogen complexes.

The orbitals at the nitrogen atom or halogen atoms have the general form listed in Table 2, where the value of s is 0.5 in the case of the nitrogen atom[3] and 0 in the cases of the halogen atoms. The occupation numbers of these orbitals at the nitrogen atom in acetonitrile are denoted by a, a, b, and 2, whereas those in the CT complexes denoted by a, a, b', and x. The quadrupole coupling constant has been related to

Table 1. NQR parameters in acetonitrile-halogen complexes

Complex		ν (MHz)	$\lvert e^2Qq\rvert$ (MHz)	η (%)
$2CH_3CN\cdot Cl_2$	^{14}N	2.6835;2.7165	3.6000	1.83
	^{35}Cl	53.72 54.25	107.44 108.50	—
$2CH_3CN\cdot Br_2$	^{14}N	2.6541;2.6618	3.5439	0.43
	^{81}Br	320.26	640.52	—

Table 2. Orbitals and their occupation numbers at the nitrogen atom

Orbital	Occupation number[a]	
$\varphi_1=\chi_{P_x}$	a	(a)
$\varphi_2=\chi_{P_y}$	a	(a)
$\varphi_3=\sqrt{s}\,\chi_s+\sqrt{1-s}\,\chi_{P_z}$	b	(b')
$\varphi_4=\sqrt{1-s}\,\chi_s-\sqrt{s}\,\chi_{P_z}$	2	(x)

a) The numbers in the parentheses are those in the complex.

the occupation numbers of p-orbitals (N_x, N_y, and N_z) by Townes and Dailey:[4]

$$|e^2Qq/e^2Qq_p| = N_z - (N_x+N_y)/2, \quad (4)$$

where $|e^2Qq_p|$ is the quadrupole coupling constant produced by one p-electron in the outmost occupied shell. From Table 2, the N_x, N_y, and N_z values of the nitrogen atom in an acetonitrile molecule are found to be a, a, and $(b+2)/2$ respectively, while those in the CT complexes are found to be a, a, and $(b'+x)/2$ respectively. Therefore, the electron number transferred from the nitrogen atom, δ, is shown by the following equation:

$$\delta = (b+2) - (b'+x)$$
$$= 2(|e^2Qq_{compound}| - |e^2Qq_{complex}|)/|e^2Qq_p|. \quad (5)$$

The electron numbers transferred to the halogen atoms are calculated from their coupling constants. The $|e^2Qq_p|$ values of the nitrogen, chlorine, and bromine atoms are 10, 109.74,[5] and 643.03 MHz[6] respectively.

Table 3. The values of δ in acetonitrile-halogen complexes

Complex	Value of δ	
	Nitrogen	Halogen
$2CH_3CN\cdot Cl_2$	+0.028	−0.021
$2CH_3CN\cdot Br_2$	+0.029	−0.004

Table 3 lists these values of δ in the CT complexes. In spite of the rough approximations, the values of δ at the nitrogen and chlorine atoms in the acetonitrile-chlorine complex are complementary. However, the value of δ at the bromine atom in the acetonitrile-bromine complex is about one-seventh of that at the nitrogen atom. This discrepancy can be interpreted by theorizing that a part of the charge transferred from the nitrogen atom enters the d_{z^2}-orbital of the bromine atom, which has less effect on the coupling constant than the p_z-orbital. This interpretation is along the same lines as that for the bromine molecular crystal, where the d-orbital of the atom has been taken by Kojima *et al.*,[7] to be used for the intramolecular bond. The recently-reported values of the electron affinities of the chlorine and bromine molecules are 2.52±0.17 and 2.87±0.14 eV respectively,[8] these values are parallel with the values of δ at the nitrogen atoms. According to the crystal structure of the acetonitrile-bromine complex, the bromine-bromine length, 2.328 Å, is longer than that observed in the free molecule, 2.284 Å.[1] This indicates that the negatively-charged bromine atoms repel each other.

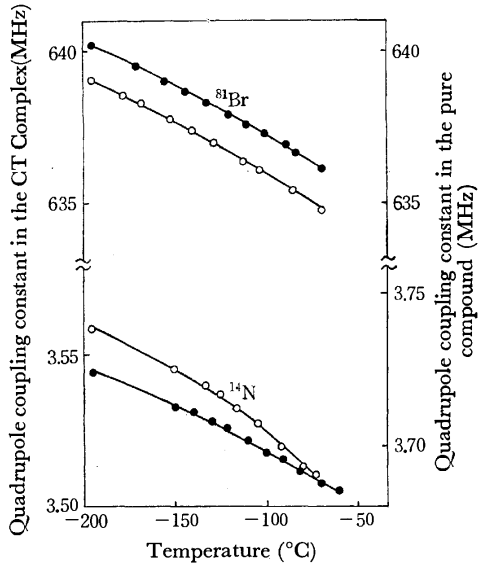

Fig. 3. The temperature dependences of ^{14}N and ^{81}Br quadrupole coupling constants in acetonitrile (○), bromine (○), and acetonitrile-bromine complex (●).

The temperature dependences of the ^{14}N and ^{81}Br quadrupole coupling constants in acetonitrile, bromine, and the acetonitrile-bromine complex are shown in Fig. 3. No phase transition is observed in the range from −196 to −60 °C. The temperature dependence of the ^{14}N quadrupole coupling constant in the CT complex is smaller than that in acetonitrile. Therefore, we see that the vibration of an acetonitrile molecule in the CT complex is suppressed by the interaction with the bromine atom. On the other hand, the temperature dependence of the ^{81}Br quadrupole coupling constant in the CT complex is nearly the same as that in solid bromine. This suggests that the bromine molecule interacts with its neighboring molecules to some extent, even in the molecular crystal, as is to be expected from its crystal structure.[9]

Variations of Heat of Immersion of Ferric Oxyhydroxides in Water with Structural Changes by Heating

Tatsuo ISHIKAWA and Katsuya INOUYE

Department of Chemistry, Faculty of Science, Chiba University, Chiba 280

(Received March 1, 1973)

The relationship between the activity of ferric oxyhydroxides (α-, β-, and γ-FeOOH) and structural changes has been investigated by determining the heat of immersion in H_2O and H_2O vapor adsorption. For each ferric oxyhydroxide, the monolayer capacity of H_2O adsorption and the heat of immersion decreased with the progress of transformation into α-Fe_2O_3. Above the transformation temperature the heat of immersion increased with the outgassing temperature. The heat of immersion of α-Fe_2O_3 obtained by outgassing each ferric oxyhydroxide at 400 and 500 °C increased with the accompanying increase in crystallite size. β-FeOOH showed higher heat of immersion and larger monolayer capacity per unit surface area than other ferric oxyhydroxides. It is presumed that the higher heat of immersion and larger monolayer capacity observed for β-FeOOH are ascribed to micropores in β-FeOOH crystals produced by the removal of molecular water originally contained.

Although ferric oxyhydroxides and oxides are commonly known as significant corrosion products of iron, the surface property in view of the structure of these compounds still remains unclarified. The surface activity of ferric oxyhydroxide, for instance, is expected to vary with the degree of its structural transformation into other compounds. Jurinak[1] reported that the adsorptive activity of α-FeOOH to H_2O suddenly decreases at the transformation temperature into α-Fe_2O_3. The present authors have studied the SO_2 adsorption on ferric oxyhydroxides[2] and ferric oxides at various outgassing temperatures[3] in order to show that β-FeOOH chemisorbs a larger amount of SO_2 than other ferric oxyhydroxides and that the amount of chemisorbed SO_2 by each ferric oxyhydroxide, regarded as a measure of reactivity, decreases with the progress of transformation into α-Fe_2O_3.

It appears that a knowledge of the interaction between H_2O and ferric oxyhydroxides is essential to understand the surface properties of ferric oxyhydroxides as main corrosion products of iron. Several investigators[4-6] have suggested that the surface activity of ferric oxides, evaluated by the heat of immersion in water and H_2O vapor adsorption, depends upon the temperature of heat treatment and the number of hydroxyl groups on the surfaces of resulting ferric oxides. We found that the heat of immersion of ferric oxides of different particle size (50 to 650 Å in diameter) is independent of particle size.[7] However, there has been no investigation into the change of heat of immersion of ferric oxyhydroxides with structural transformation. In the present work, the heat of immersion in water and H_2O adsorption isotherms are determined and discussed for α-, β-, and γ-ferric oxyhydroxides with outgassing at various temperatures up to 500 °C in order to confirm the change of activity towards H_2O with the structural changes.

Experimental

Materials. The preparation of ferric oxyhydroxides has been described in detail[3]. α-FeOOH(α-1) was prepared by the hydrolysis of 0.1 M ferric oxalate solution at 100 °C with the initial pH 6.6. More crystalline α-FeOOH(α-2) was obtained by the hydrolysis of ferric sulfate solution at 50 °C with the adjusted pH 13.6. β-FeOOH(β-1) prepared by hydrolysing 0.1 M ferric chloride solution containing urea at 100 °C is more crystalline than other β-FeOOH(β-2) obtained by heating 0.1 M ferric chloride solution at 75 °C. Crystalline γ-FeOOH(γ-1) was prepared by the oxidation of ferrous hydroxide suspension with $NaNO_3$, and amorphous γ-FeOOH(γ-2) by the oxidation of ferrous sulfate solution in the presence of $Na_2S_2O_3$.

Procedure. The heat of immersion in water was measured at 30.0 °C by means of a twin-type microcalorimeter (Oyodenki Kenkyujo, CM-204S) consisting of a pair of calorimeters, one of them being the reference. Prior to the immersion experiments, approximately 200—300 mg of the sample was heated up to 110, 150, 200, 300, 400, and 500 °C at a heating rate of 8 °C/min in a glass ampule under 10^{-5} Torr and outgassed for 5 hr at each temperature. After outgassing, the glass ampule was sealed off in a vacuum and set in the calorimeter. When the calorimeter attained thermal equilibrium, the ampule was broken in order to immerse the sample in water.

The water adsorption experiment was performed gravimetrically at 30.0 °C by means of a quartz spring balance.

The surface area of the sample was determined by a conventional volumetric method by nitrogen adsorption according to the BET method. The pretreatment of the sample in the H_2O adsorption and surface area determinations was identical to that in the heat of immersion measurement.

The X-ray diffraction patterns were obtained by the powder method with a diffractometer (Rigaku Denki Co., 2001) by use of Mn-filtered Fe$K\alpha$ at 30 kV and 10 mA.

Results and Discussion

The X-ray diffraction patterns of ferric oxyhydroxides are shown in Fig. 1.

The changes of X-ray diffraction patterns of α-2, β-1, and γ-1 with outgassing at various temperatures

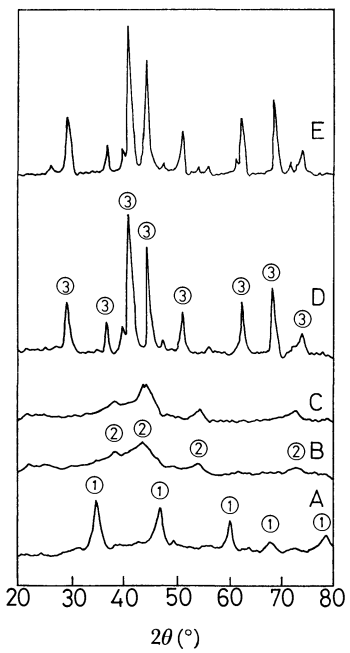

Fig. 4. X-ray diffraction patterns of γ-1 at various outgassing temperatures: ①, γ-FeOOH; ②, γ-Fe_2O_3; ③, α-Fe_2O_3; A, 150 °C; B, 200 °C; C, 300 °C; D, 400 °C; E, 500 °C.

are shown in Figs. 2, 3, and 4 respectively, illustrating the mode of transformation of each ferric oxyhydroxide into α-Fe_2O_3 at particular temperature ranges. α-FeOOH is transformed into α-Fe_2O_3 at 200 °C. β-FeOOH changes to an amorphous mixture, composed of β-FeOOH and α-Fe_2O_3, in the temperature range 200—300 °C, and is further transformed into the crystalline α-Fe_2O_3 above 400 °C. γ-FeOOH is transformed into γ-Fe_2O_3 at 200 °C and is converted into crystalline α-Fe_2O_3 at 400 °C. These results show that all ferric oxyhydroxides are transformed into α-Fe_2O_3 above 400 °C.

The weight loss accompanying the change of ferric oxyhydroxide to α-Fe_2O_3 is 10% corresponding to the dehydration formula; $2FeOOH \rightarrow Fe_2O_3 + H_2O$. To obtain the variations of weight loss with outgassing temperature (Fig. 5), the samples were subjected to heat treatment in the same manner as those in the H_2O adsorption and the heat of immersion measurements. For α-2 and γ-1, the weight loss increases with the rise of temperature up to 200 or 300 °C, followed by almost constant weight above 300 °C. The total weight loss at 500 °C corresponds to 11.2 and 12.8% for γ-1 and α-2, respectively. These values are somewhat larger than the theoretical value (10%), because of the dehydration of adsorbed water and the "bound"

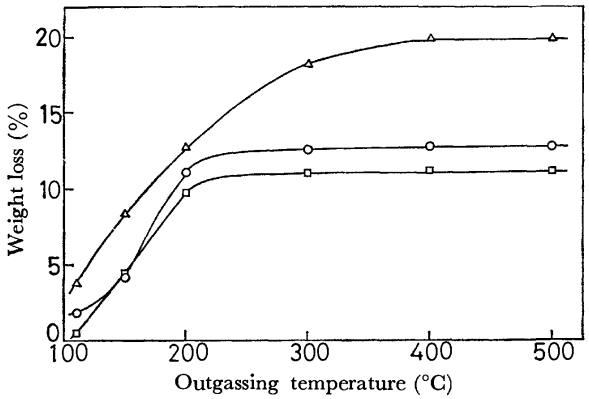

Fig. 5. Relation between weight loss and outgassing temperature: ○, α-2; △, β-1; □, γ-1.

water supposedly contained in the ferric oxyhydroxide crystals.[8] Although the X-ray diffraction patterns obtained for these samples (α-2 and γ-1) remain almost unchanged up to 150 °C, an approximate 4.5% weight loss is observed. This indicates that α-2 and γ-1 are partially transformed into amorphous ferric oxide below 150 °C. On the other hand, the weight loss of β-1 increases with the rise in outagssing temperature up to 400 °C, reaching a total weight loss of 20% at 500 °C. This large weight loss is due to the removal of chlorine and molecular water originally contained in β-FeOOH crystals.[3]

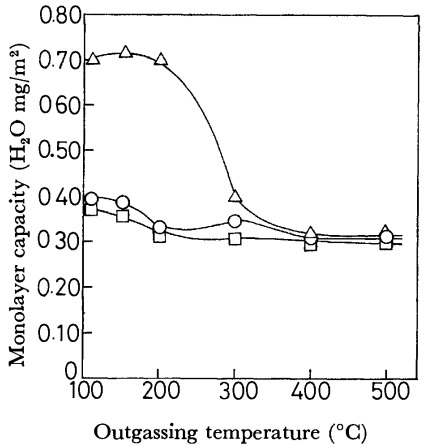

Fig. 6. Effect of outgassing temperature on monolayer adsorption capacity: ○, α-2; △, β-1; □, γ-1.

H_2O adsorption isotherm is the BET-II type for each sample. The monolayer capacity (A_m) of H_2O adsorption per unit BET surface area, calculated from the N_2 adsorption isotherm, is shown in Fig. 6 as a function of outgassing temperature. The A_m values of α-2 and γ-1 decrease with the rise in temperature up to 200 °C and become nearly constant above 400 °C, whereas A_m of β-1 below 200 °C is considerably high but decreases abruptly in the temperature range 200—300 °C. Above 400 °C, where transformation into α-Fe_2O_3 occurs, the A_m value of β-1 becomes equal to that of α-2 and γ-1. The large A_m of β-FeOOH seems to be

8) G. Okamoto, R. Furuichi, and N. Sato, *Electrochim. Acta*, **12**, 1287 (1967).

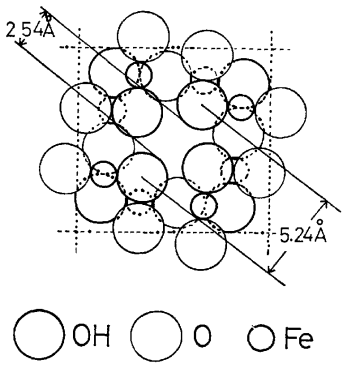

Fig. 7. Projection of the crystal structure of β-FeOOH on (001). β-FeOOH has a tetragonal lattice with the following unit cell dimensions: $a=b=10.48$ Å, $c=3.02$ Å.

due to the formation of micropores in crystals with the release of molecular water by outgassing. The crystal structure of β-FeOOH proposed by Mackay[9] has micropores parallel to c-axis as shown in Fig. 7. The diameter of these micropores is estimated to be 2.54 Å from the effective diameter of the hydroxyl group (1.35 Å) and the distance between hydroxyl groups (5.24 Å). On the other hand, the diameter of N_2 molecule and H_2O molecule is 3.5 and 2.5 Å, respectively. H_2O molecule has a strong dipole moment, whereas N_2 molecule has only a quadrupole moment. Thus, it is plausible that the micropores are more accessible to H_2O molecules than to N_2 molecules. According to X-ray diffraction results (Fig. 3) in which the β-FeOOH crystal turns into an amorphous state in the temperature range 200—300 °C, the decrease in A_m of β-FeOOH in the course of outgassing below 300 °C seems to be due to the destruction of β-FeOOH structure having the micropores.

The decrease in A_m of α-FeOOH or γ-FeOOH below 200 °C might be attributed mainly to the removal of surface hydroxyl groups. The heat of immersion (ΔH_I) per unit surface area of α-FeOOH is shown in Fig. 8 against outgassing temperature. The decrease in ΔH_I below 150 °C is considered to be due to the removal of the hydroxyl groups acting as hydrophilic sites on the ferric oxyhydroxide surface. In contrast

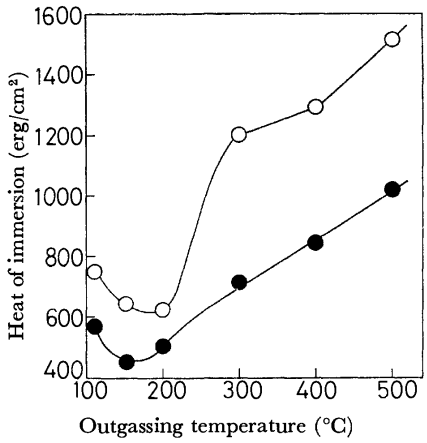

Fig. 8. Effect of outgassing temperature on the heat of immersion of α-FeOOH: ○, α-1; ●, α-2.

9) A. L. Mackay, *Miner. Mag.*, **32**, 545 (1960).

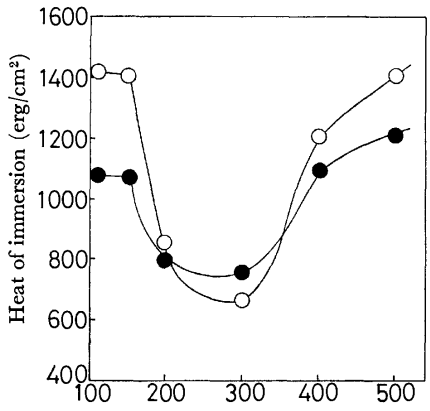

Fig. 9. Effect of outgassing temperature on the heat of immersion of β-FeOOH; ○, β-1, ●, β-2.

to this, the increase in ΔH_I above 200 °C seems to be caused by rehydration of the α-Fe_2O_3 surface, the dehydrated surface being readily rehydrated to be covered again with hydroxyl groups during the immersion process in water.[5] γ-FeOOH shows the same tendency as α-FeOOH. As illustrated in Fig. 9, β-FeOOH shows a larger ΔH_I than that of other ferric oxyhydroxides below 150 °C, the ΔH_I value falling sharply in the temperature range 150—200 °C. Above 300 °C, ΔH_I increases with temperature probably by surface rehydration as with other ferric oxyhydroxides.

It is apparent that α-Fe_2O_3 samples obtained by outgassing α-2, β-1, and γ-1 at 400 and 500 °C were almost completely dehydrated, since they show a constant weight loss above 400 °C as shown in Fig. 5. The heat of immersion (ΔH_I) for these samples therefore includes the heat evolved with the rehydration of dehydrated α-Fe_2O_3 surface. The heat of rehydration depends upon the stability of the oxygen bridge such as $-Fe\langle\overset{O}{O}\rangle Fe-$ which is formed on dehydration. The stability of the oxygen bridge is considered to be related to the crystallinity of α-Fe_2O_3. The crystallite size as a measure of crystallinity was calculated by the Scherrer equation for the α-Fe_2O_3 (104) pattern at 2θ of 41.9° in X-ray diffraction diagrams. ΔH_I was plotted against crystallite size (Fig. 10) to show that it increases with increase in crystallite size. This could be explained by assuming that the oxygen bridge of less crystalline α-Fe_2O_3 is so unstable as to be rehydrated with evolution of less heat than that of more crystalline α-Fe_2O_3.

The large ΔH_I of β-FeOOH below 150 °C (Fig. 9)

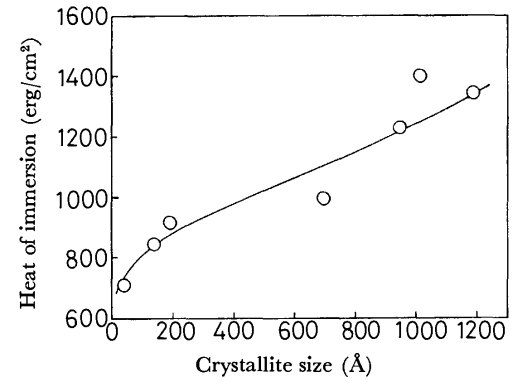

Fig. 10. Relation between crystallite size and the heat of immersion.

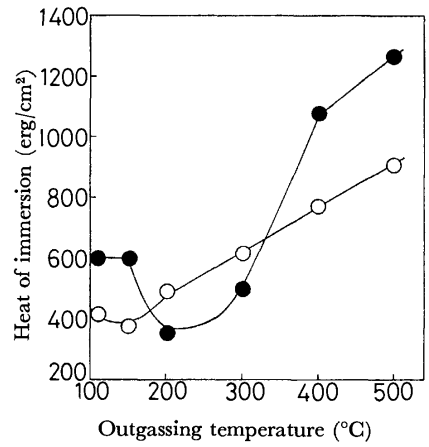

Fig. 11. The heat of immersion per unit H_2O surface area: ○, α-2; ●, β-1.

seems to be associated with the microporous structure of β-FeOOH. The depression of ΔH_I in the temperature range 150—200 °C is caused by the destruction of the microporous structure of β-FeOOH. The heat of immersion in water, per unit surface area obtained by N_2 adsorption, shows a large value caused by the existence of the micropores into which H_2O molecules are adsorbed more easily than N_2 molecules. To exclude the micropore effect on the heat of immersion, calculation based on the surface area estimated from H_2O adsorption, using 10.6 Å for the sectional area of an adsorbed water molecule, was attempted. However, β-FeOOH still showed a higher heat of immersion than other ferric oxyhydroxides up to 150 °C (Fig. 11). It is concluded, therefore, that β-FeOOH is more reactive to H_2O as compared with other ferric oxyhydroxides.

The Crystal Structure of Cinchomeronic Acid

Fusao TAKUSAGAWA, Ken HIROTSU, and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received March 2, 1973)

The crystal structure of cinchomeronic acid (3,4-pyridinedicarboxylic acid) has been determined by the method of X-ray diffraction. The crystals are orthorhombic, with a space group of $P2_12_12_1$, and with cell dimensions of $a=11.211$, $b=11.206$, and $c=5.285$ Å. The structure was determined by the method of symbolic addition. The final R value was 5.90% for 828 observed reflections. The molecule takes the form of a zwitter ion in the crystal. The pyridine ring has, approximately, the C_{2v} symmetry. One carboxyl group consists of C=O and C–O(H) groups, while the other consists of two C···O groups. These carboxyl groups twist out of the plane of a pyridine ring by 39.6° and 73.0° respectively. The hydrogen bonds are in the forms of two spirals around the two-fold screw axes parallel to the c axis, thus linking the molecules three-dimensionally. There are four molecules per turn of the spiral along the c axis. The carbonyl oxygen atom O(2) is free from the hydrogen bond, while the nitrogen atom N(1) in the pyridine ring participates in it. The relations between the C–N–C bond angle of the pyridine ring and the N···H distance, and also between the net charge on the nitrogen atom calculated by the "complete neglect of differential overlap" (CNDO) method and the O···N distance for a hydrogen bond are discussed in connection with five pyridine-carboxylic acids.

This work is a part of series of O–H···N hydrogen bonding studies by means of X-ray crystal structure analyses of some carboxylic acids based on a pyridine ring. In the course of this study, some interesting features have been revealed in connection with the form of a molecule as well as with the type of hydrogen-bond formation. Thus, the nicotinic acid[1] and dipicolinic acid[2] molecules took a neutral form, while the quinolinic acid[3] molecule took the form of a zwitter ion. The dinicotinic acid[4] molecule was intermediate between the above two forms. Such a problem does not occur in carboxylic acids based on a benzene ring, since they do not involve a nitrogen atom, which can also take part in a hydrogen bond. Moreover, the relation among the molecular forms (neutral or intermediate or zwitter ion), the positions of the substituted carboxyl groups and the hydrogen-bonding system has not been established in the crystal structures studied hitherto. In this sense, it seemed that it would be of interest to elucidate the effect of a nitrogen atom in a pyridine ring on the hydrogen-bond formation in solids. The cinchomeronic acid molecule in the present study can take three forms—neutral, intermediate and zwitter ions, and it has the same framework and isoelectronic structure as phthalic acid[5] and quinolinic acid. It is also of interest to study the intramolecular hydrogen bond between adjacent carboxyl groups, because it has already been found in the crystals of quinolinic acid, but not in those of phthalic acid.

Experimental

The crystals were obtained in the form of colorless prisms by recrystallization from an aqueous solution. Weissenberg photographs showed the crystal to be orthorhombic, with the space group $P2_12_12_1$. The unit cell dimensions were measured from zero-layer Weissenberg photographs, which were calibrated with superimposed Al powder lines. The crystal data are given in Table 1. Using a spherically shaped crystal with an average diameter of 0.4 mm, the intensity data were collected for the 0—5 layers around the c axis and for the 0—2 layers around the b axis by the use of a multiple-film equi-inclination integrating Weissenberg technique, with Cu$K\alpha$ radiation. The intensities were estimated visually by comparison with an intensity standard. Of the possible 922 reflections within the Cu$K\alpha$ sphere, 848 independent reflections were measured; 20 were too weak to be observed. No absorption and extinction corrections were applied.

TABLE 1. CRYSTAL DATA FOR CINCHOMERONIC ACID

Molecular formula	$C_7H_5NO_4$
Molecular weight	167.12
Crystal size	~0.4×0.4×0.4 mm
Crystal system	Orthorhombic
Space group	$P2_12_12_1$
Cell dimensions;	
a	11.211±0.006 Å
b	11.206±0.004

Structure Determination and Refinement

The crystal structure was solved easily by the symbolic addition method. The first postulated structure gave an R value of 41%; this decreased to 17% after three cycles of least-squares refinements with individual isotropic thermal parameters.

Anisotropic thermal parameters were then introduced, and the block-diagonal least-squares refinement was

Table 2. The observed and calculated structure factors

F_o, F_c and DF have been multiplied by 10.
The unobserved reflection is indicated by an asterisk. The reflection with
$|F_o - F_c| / |F_o|$ larger than 0.3 is indicated by a plus sign.

TABLE 3. THE FINAL PARAMETERS AND THEIR ESTIMATED STANDARD DEVIATIONS (in parentheses).

The coordinates of the non-hydrogen atoms have been multiplied by 10^4; those of the hydrogen atoms, by 10^3. The anisotropic thermal parameters of non-hydrogen atoms are of the form $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$, and have been multiplied by 10^4. For the hydrogen atoms, the values listed are isotropic thermal parameters B(Å^2).

continued to reduce the R value to 8.1%. At this stage of refinement, a difference Fourier map was computed, from which the positions of the five hydrogen atoms were located (Fig. 1). There was no significant peak on this map except those due to hydrogen atoms. With anisotropic thermal parameters for non-hydrogen atoms and isotropic thermal parameters for hydrogen atoms, the final R value was 5.90%, excluding un-

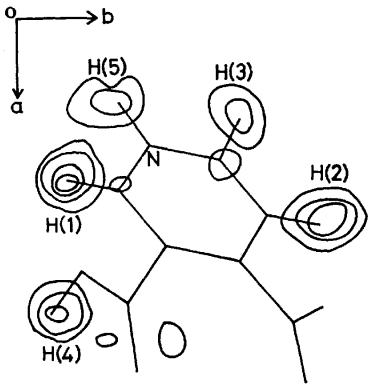

Fig. 1. A composite drawing of the electron density associated with the hydrogen atoms. The contours at intervals of 0.1 e·Å^{-3}, beginning with 0.2 e·Å^{-3} contour.

observed reflections. The $\sum w(F_o-F_c)^2$ function was minimized, where:

$$w = 0.5 \text{ for } |F_o| \leqq 0.5,$$
$$w = 1.0 \text{ for } 0.5 < |F_o| < 6.0 \text{ and}$$
$$w = 6.0/|F_o| \text{ for } 6.0 \leqq |F_o|.$$

The atomic scattering factors used were those listed in the International Table for X-ray Crystallography for C, N, and O atoms and the spherical scattering factors proposed by Stewart, Davidson, and Simpson[6] for H atom. The observed and calculated structure factors are listed in Table 2. The fractional coordinates and thermal parameters are listed, along with their estimated standard deviations, in Table 3.

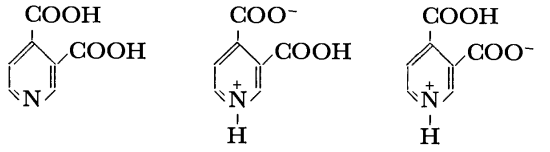
Results and Discussion

Molecular Structure. The bond lengths and angles are listed, along with their estimated standard deviations, in Table 4; they are shown in Fig. 2. Figure 3 shows the anisotropic thermal ellipsoids of the non-hydrogen atoms and the isotropic thermal ellipsoids of the hydrogen atoms. The ellipsoids are scaled to include a 74% probability.

The cinchomeronic acid molecule can take the three forms shown below and two intermediate forms between the neutral molecule (A) and the zwitter ions ((B) or (C)).



(A) Neutral molecule (B) Zwitter ion (C) Zwitter ion

The present study has revealed that the molecule takes the form of the zwitter ion (B) in the crystal. This is

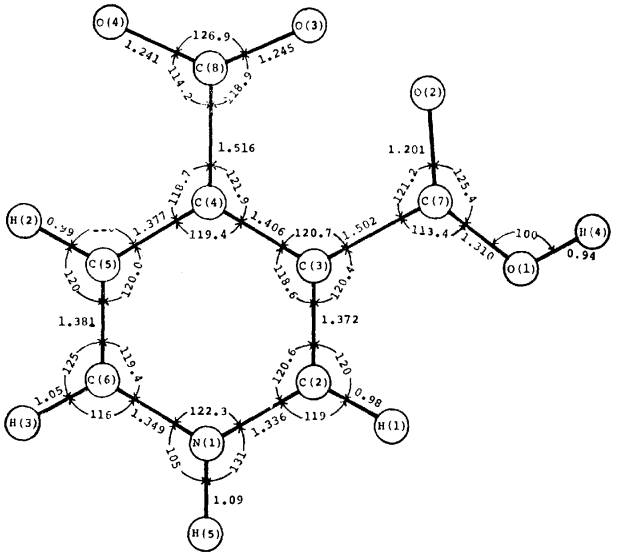


Fig. 2. Dimensions of cinchomeronic acid molecule.

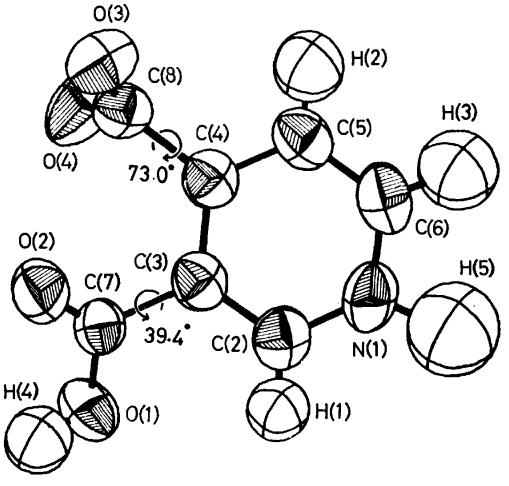

Fig. 3. The anisotropic thermal ellipsoids of non-hydrogen atoms and the isotropic thermal ellipsoids of hydrogen atoms. Ellipsoids are scaled to include a 74% probability.

evident from the position of the hydrogen atom in the difference Fourier map. It is also confirmed by the C(2)–N(1)–C(6) bond angle, 122.3(3)°, and the C(8)–O(3) and C(8)–O(4) bond lengths, 1.245(4) and 1.241(5) Å respectively (the values in parentheses denote the e.s.d.'s in the last digits).

The pyridine ring is essentially planar. The equation of the least-squares plane through six non-hydrogen atoms of the pyridine ring is:

$$0.6248X - 0.3913Y - 0.6756Z = -1.5159,$$

where X, Y, and Z are coordinates in Å along the a, b, and c axes respectively. The maximum deviation of the ring atom from this plane is 0.013 Å. The displacements of all the atoms from the plane are listed in Table 5.

Table 5. The distances from the least-squares plane defined by the six non-hydrogen atoms of the pyridine ring

Atom	Deviation(Å)	Atom	Deviation(Å)
N(1)	0.002	O(1)	−0.450
C(2)	−0.013	O(2)	0.946
C(3)	0.012	O(3)	0.965
C(4)	0.001	O(4)	−1.153
C(5)	−0.013	H(1)	0.01
C(6)	0.013	H(2)	−0.02
C(7)	0.215	H(3)	−0.02
C(8)	−0.047	H(4)	0.05
		H(5)	0.16

The differences in the corresponding bond lengths and angles of a pyridine ring, the N(1)–C(2) and N(1)–C(6), the C(2)–C(3) and C(6)–C(5), the C(3)–C(4) and C(5)–C(4) bond lengths, the N(1)–C(2)–C(3) and N(1)–C(6)–C(5), and the C(2)–C(3)–C(4) and C(6)–C(5)–C(4) bond angles, are −0.013(5), −0.009(5), 0.019(5) Å, 1.2(4)° and −1.4(3)°. These values show that the pyridine ring has, approximately, the C_{2v} symmetry in the molecule. The slight deviations from C_{2v} symmetry may be due to the substitution of a carboxyl group in the β-position.

In the carboxyl group (C(7)O(1)O(2)H(4)), each C–O bond length is clearly different from the others. Hence, this group consists of C=O and C–O(H) groups. On the other hand, the C(8)–O(3) and C(8)–O(4) bond lengths in another carboxyl group, 1.245(4) and 1.241(5) Å, are equal within the limits of experimental error. This fact suggests that the hydrogen atom moves from the oxygen atom O(4) to the nitrogen atom N(1) of a pyridine ring. The C(7)–O(2) bond length is the shortest of the four C–O bond lengths. This can be explained by the fact that only the O(2) atom does not participate in a hydrogen bond. Similar situations have been observed in dinicotinic acid and quinolinic acid. The difference between the C(3)–C(7) and C(4)–C(8) bond lengths, 0.014(5) Å, lies on the borderline of significance in relation to their estimated standard deviations. A similar tendency has been observed in quinolinic acid. These differences may be caused by the formation of a zwitter ion.

There is no intramolecular hydrogen bond between the adjacent carboxyl groups. The carboxyl groups twist by 39.6° (C(7)O(1)O(2)) and 73.0° (C(8)O(3)-O(4)) out of the plane of the pyridine ring, as is shown in Fig. 3, so that the repulsion between the oxygen atoms is reduced by the twists of the C–C bonds.

Molecular Arrangement and Hydrogen-bond System. The crystal structure is shown in Figs. 4 and 5. The distances and angles of hydrogen bonds are listed in Table 6. The hydrogen bonding system is shown in Fig. 6. In Figs. 4, 5, and 6, the same numbers designate the same molecules. The symmetry codes corresponding to these molecules are shown in Table 6.

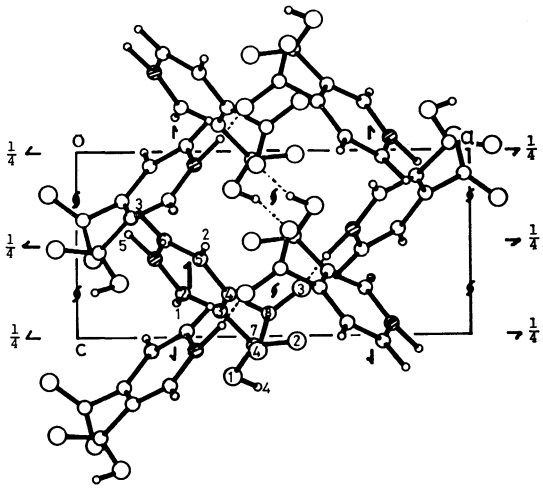

Fig. 4. A view of the crystal structure down the b axis. The hydrogen bonds are shown by broken lines.

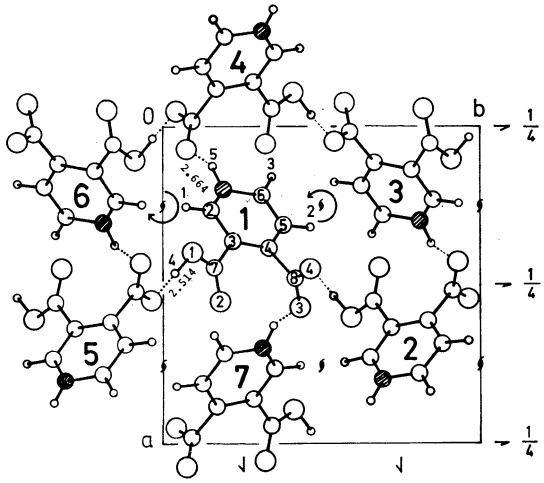

Fig. 5. A view of the crystal structure down the c axis. The hydrogen bonds are shown by broken lines. The ↻ signs around two-fold screw axes indicate the directions of spirals.

The hydrogen bonds are found in two spiral forms around the two-fold screw axes parallel to the c axis, thus linking the molecules three-dimensionally. There are four molecules per turn of spiral along the c axis. The carbonyl oxygen atom O(2) is free from the hydrogen bond, while the nitrogen atom N(1) in a pyridine ring participates in it. This is a remarkable feature of the crystal structures of carboxylic acids with a pyridine ring. This situation has been found in all crystal structures of pyridinecarboxylic acids deter-

Table 6. Hydrogen bond distances (Å) and angles (degree)

mined by the X-ray method except for that of one hydrate.

Figure 7 shows the relation between the C–N–C bond angle of a pyridine ring and the N···H distance for a hydrogen bond about four pyridine-dicarboxylic acids. There is a clear correlation between them. This result is an example of the change in electronic

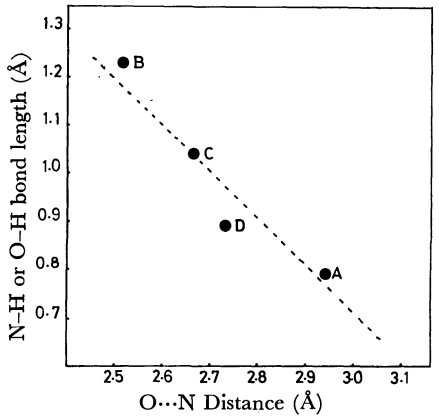

Fig. 8. The variation of the bond length in proton donor group with the O···N distance for hydrogen bond. A, B, C, and D are the same compounds as listed in Fig. 7.

structure in a nitrogen atom corresponding to the variation in interaction between the nitrogen and hydrogen atoms in the hydrogen bond. When the N···H distance is long, as in dipicolinic acid, the nitrogen atom acts as a proton acceptor and gives a C–N–C bond angle similar to that of pyridine[7] itself. On the other hand, the protonated nitrogen atom can be regarded as a proton donor in the case of a short N–H distance, as in quinolinic acid and cinchomeronic acid; it gives a larger C–N–C bond angle than that of pyridine itself in relation to the change in the electronic structure in a nitrogen atom. The situation lies between these two cases in dinicotinic acid. Figure 8 gives the variation in the bond length in a proton donor group with the O···N distance for a hydrogen bond. It may be seen that the stronger interaction occurs between the hydrogen and proton acceptor atoms in the case of the shorter hydrogen bond. Hence, the hydrogen bonds between the nitrogen and oxygen atoms in pyridine-dicarboxylic acids may be classified in terms of the O···N distance in to the following three forms:

(1) O–H···N: long hydrogen bond (longer than 2.75 Å)
(2) $\bar{O}$···H–$\overset{+}{N}$: middle hydrogen bond (2.60—2.75 Å)

7) B. Bak, L. H. Nygaard, and J. R. Andersen, *J. Mol. Spectrosc.*, **2**, 361 (1958).

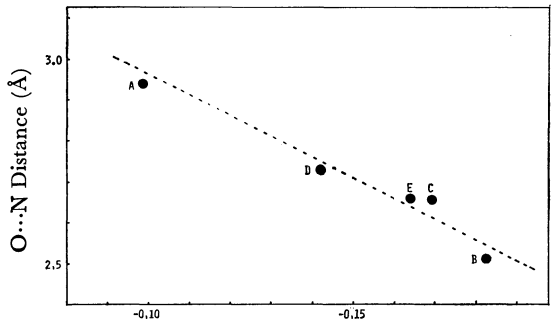

Fig. 9. The relation between the net charge on nitrogen atom calculated by the CNDO method and the O···N distance for hydrogen bond. A, B, C, and D are the same compounds listed in Fig. 7.
E: Nicotinic acid (Ref. 1)

(3) O–H–N: short hydrogen bond (shorter than 2.60 Å)

Using the neutral structures of several pyridinecarboxylic acids, the net charges on the nitrogen atoms were calculated by the use of the "complete neglect of differential overlap" (CNDO) method. They are plotted against the O···N distances in Fig. 9. There is a good linear relation between the calculated net charges on the nitrogen atoms and the observed O···N distances for hydrogen bonds. If this relation can be applied to the O···N hydrogen bonds of other pyridinecarboxylic acids, the O···N distances can be easily predicted by the calculation of the net charges on nitrogen atoms. In conclusion, the strength of the hydrogen bond increases with an increase in the net charge on a nitrogen atom. Moreover, the molecular form may depend on the change in the net charge on a nitrogen atom corresponding to the positions of substituted carboxyl groups.

Computer Programs. All the calculations were performed on a FACOM 270-30 computer at the Computer Center of Osaka City University by the use of the following programs—RSLC-3 (cell constant),[8] RSSFR-3 (Fourier synthesis),[9] HBLS-IV (block-diagonal least-squares refinement),[10] DAPH (bond length, bond angle and least-squares plane),[11] SCALE (film factor, Lp and layer scaling,)[12] TE-I (thermal ellipsoid),[13] CNINDO (CNDO and INDO calculations),[14] and PHASE-I, II, III (symbolic addition).[15]

The authors wish to express their thanks to Dr. Kichisuke Nishimoto of this faculty for his useful advice in the CNDO calculation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2675—2683 (1973)

X-Ray Analysis of the Domain Structure of the 1:1 Complex of Carbazole–TCNQ

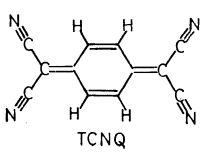
Hayao KOBAYASHI

Department of Chemistry, Faculty of Science, Toho University, Narashino, Chiba 275

(Received March 22, 1973)

The crystal structure of the 1:1 complex of carbazole–TCNQ was investigated by X-ray diffraction. Analysis of sharp spots and diffuse streaks in the diffraction patterns revealed that the crystal is composed of an ordered domain and a disordered one. The ordered domain is made up from two types of ordered molecular arrangements, whereas the disordered one consists of a one-dimensionally disordered structure. The structures of the two ordered domains are closely related with each other. They both contain mixed stack columns of alternating carbazole and TCNQ usually observed in charge transfer (CT) complexes. The existence of various types of domain structures as shown by diffraction patterns of many crystals grown from acetone, acetonitrile and tetrahydrofuran solutions can be interpreted in terms of the combinations of ordered and disordered domains. No CT band appears in the visible absorption spectra of the acetone solution of carbazole–TCNQ, whereas the spectra of the powdered crystals show a CT band at about 18000 cm^{-1}. The calculation of SCF-MO-CI of the system of the carbazole–TCNQ pair indicates a weak CT interaction.

Charge transfer (CT) complexes containing carbazole, a weak electron donor, do not seem to have been investigated much, no structural study ever having been reported. The crystal structure of the 1:1 complex of carbazole and 7,7,8,8-tetracyanoquinodimethane (TCNQ) has been determined. The domain structure



of carbazole–TCNQ, the analysis of diffuse streaks and the spectroscopic study are reported in this paper.

Experimental

The crystals of carbazole–TCNQ were grown by a diffusion method, acetone solution of both compoments being used. The crystal is hardly soluble and black, needle-like crystals could be easily obtained after a few days. Elemental analysis shows that the crystal is the 1:1 complex of carbazole–TCNQ. Found: C, 77.9; N, 18.9; H, 3.3%. Calcd for carbazole–TCNQ (1:1): C, 77.6; N, 18.9; H, 3.5%.

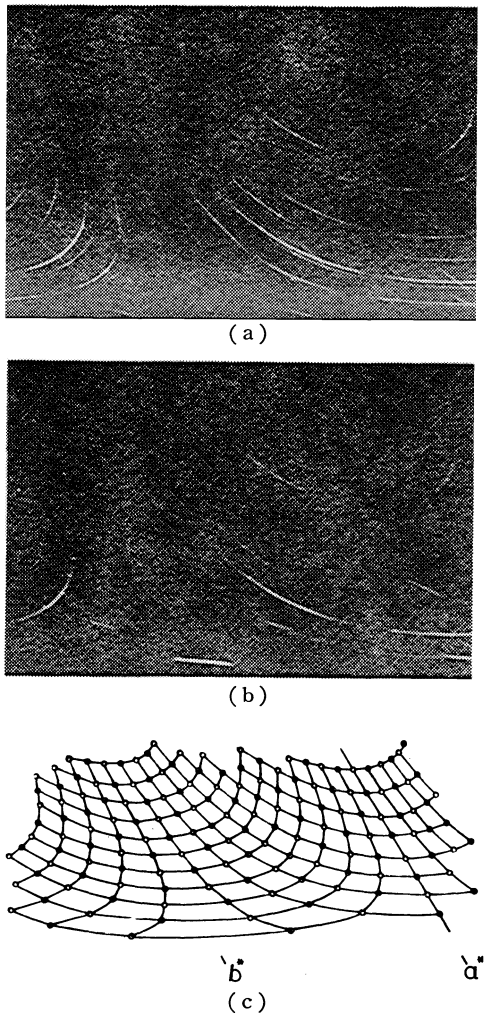


Fig. 1. Weissenberg photographs.
(a) (ξ, η, 1/2), (b) (ξ, η, 3/2), (c) Distribution of sharp spots observed in the photographs (a) and (b). The open circles and filled circles represent the two different groups IIIa and IIIb in Table 2.

Weissenberg photographs are shown in Fig. 1. Oscillation photographs of axes c and a show sharp layer lines and intermediate layer lines with diffuse streaks. Disregarding the layer lines accompanying diffuse streaks, all the spots can be indexed with respect to the orthorhombic unit cell with dimensions listed in Table 1. The diffuse streaks occur parallel to b^*. Distributions of the diffuse streaks are summarized in Table 2. In the half-integral layer lines, the sharp spots appear along the diffuse streaks at intervals of b^*. Closer examination revealed that these spots deviate slightly up and below alternately with respect to the streaks.

TABLE 1. CRYSTALLOGRAPHIC DATA OF THE AVERAGE STRUCTURE OF CARBAZOLE–TCNQ

Carbazole–TCNQ	Formula $C_{12}H_9N \cdot C_{12}H_4N_4$
Orthorhombic	Space group Immm
$a=10.751\pm0.010$ Å	F.W.$=371.4$ g/cm^3
$b=12.944\pm0.020$	d_m $=1.340$ g/cm^3 (flotation method)
$c=3.339\pm0.015$	d_x $=1.328$ g/cm^3
$U=464.6$ Å^3	Z $=1$

TABLE 2. SUMMARY OF REFLECTIONS
The Miller indices refer to the unit cell listed in Table 1. h, k, l, n and m indicate integral number; η may take non-integral values.

	a^*	b^*	c^*		
I	h	k	l	$h+k+l=2n$	sharp spots
II	$h/2$	η	l	$h=2n+1$, $l=2m+1$	streaks
IIIa	$h'/2$	k	$l'^*/2$	$h'=2n'+1$, $(h'+l')/2+k=2m'$, $l'=2n''+1$	sharp spots
IIIb	$h'/2$	k	$l'/2$	$h'=2n'+1$, $(h'+l')/2+k=2m'+1$, $l'=2n''+1$	sharp spots

a) h', l', n', n'', and m' indicate that they differ slightly from integer, *viz.*, the spots of groups IIIa and IIIb deviate slightly from the center of the streaks (group II).

The intensity data were collected with multiple-film equi-inclination Weissenberg photographs with Cu$K\alpha$ radiation. The intensities were estimated visually with a standard film strip and converted into $|F(hkl)|$ by applying the Lorentz-polarization and shape corrections.

Results and Discussion

Determination of the Average Structure. If the half-integral layer lines with diffuse streaks are neglected, the unit cell (Table 1) is of the average structure of a disordered crystal. In view of the planar structures of the component molecules, the space group Immm was assumed. The body centered lattice containing only one formula unit indicates that each lattice point is occupied by carbazole and TCNQ with equal prob-

ability. The average structure thus deduced was refined with the block-diagonal least-squares method. The final R-value was 0.15. The weighting scheme adopted was: $w=1$, for $|F_o|\geq 3.0$ and $w=0.2$ for $|F_o|<3.0$, for all the 179 observed reflections belonging to group I of the reflection (Table 2). The positional and thermal parameters are given in Table 3. The observed and calculated structure factors are compared in Table 4.

The structure within one unit cell as viewed along axis c is shown in Fig. 2. Each lattice point is occupied by carbazole and TCNQ with equal probability. The site symmetry of the lattice point is mmm(D_{2h}), the apparent molecular structures of each component molecules thus being D_{2h}. The orientation of carbazole should be disordered since it has no such high symmetry. The molecule is assumed to take one of two alternative orientations with equal probability (Fig. 2). The bond lengths and angles are shown in Fig. 3. The mean bond lengths are: C–C (TCNQ), 1.37; C–N, 1.16; C–C (carbazole), 1.37; C–N, 1.43 Å. The standard deviations of each bond length and angle are about 0.05 Å and 4°, respectively.

Interpretation of Diffuse Streaks. Consider a lattice

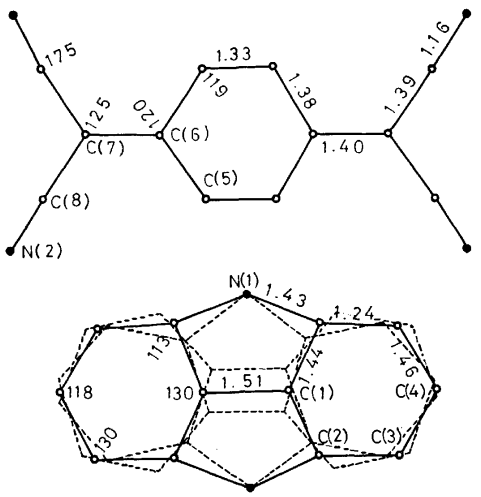

Fig. 3. Bond lengths (Å) and angles (°).
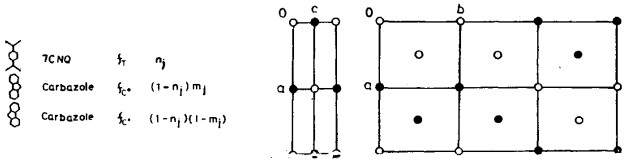
The broken line indicates the two alternative structure of carbazole.

having the same lattice constants as the average structure. Each lattice point can be occupied by TCNQ or carbazole, carbazole having two alternative orientations. Let us introduce $n_j(1-n_j)m_j$ and $(1-n_j)(1-m_j)$ to represent the probability that j-th lattice point is occupied by T, C^+, and C^- respectively, where T denotes TCNQ and C^+ and C^- are the carbazole with the polar axis parallel to the $\boldsymbol{b}$ direction and $-\boldsymbol{b}$ direction, respectively (Fig. 4a).



4a 4b(i) 4b(ii)

Fig. 4. (a) The occupancy probabilities of the lattice points. (b) Schematic drawing of the arrangement of TCNQ and carbazole. (i) indicates that the molecular arrangement is ordered in the a—c layer and (ii) shows an example of the stacking disorder along the b-direction.
The open circles and filled circles represent carbazole and TCNQ molecules, respectively.

The structure factor of this lattice is given by

$$F(\boldsymbol{k}) = \sum_j (n_j f_T + (1-n_j)m_j f_{C^+} + (1-n_j)(1-m_j)f_{C^-}) \exp(i\boldsymbol{k}\cdot\boldsymbol{R}_j), \quad (1)$$

where f is the molecular structure factor, $\boldsymbol{R}_j$ is the lattice vector of j-th lattice point and $\boldsymbol{k}$ is the scattering vector. The corresponding intensity is given by

$$I(\boldsymbol{k}) = |\langle F(\boldsymbol{k})\rangle|^2$$

Neglecting the correlation between n_j and $m_{j'}$ (the correlation between the position of TCNQ and the orientation of carbazole), we have

$$I(\boldsymbol{k}) = |\sum_j (\langle n\rangle f_T + (1-\langle n\rangle)\langle m\rangle f_{C^+} + (1-\langle n\rangle)(1-\langle m\rangle)f_{C^-}) \times e^{i\boldsymbol{k}\cdot\boldsymbol{R}_j}|^2 + |(f_T - \langle m\rangle f_{C^+} - (1-\langle m\rangle)f_{C^-}|^2 \sum_{jj'} \chi^T(j,j') \times e^{i\boldsymbol{k}\cdot(\boldsymbol{R}_j-\boldsymbol{R}_{j'})} + |f_{C^+} - f_{C^-}|^2 \sum_{jj'} \langle (1-n_j)(1-n_{j'})\rangle \times \chi^C(j,j') e^{i\boldsymbol{k}\cdot(\boldsymbol{R}_j-\boldsymbol{R}_{j'})}, \quad (2)$$

where $\langle\ \rangle$ indicates the statistical average and $\chi^T(j,j')$ and $\chi^C(j,j')$ are correlation functions expressed as

$$\chi^T(j,j') = \langle (n_j - \langle n\rangle)(n_{j'} - \langle n\rangle)\rangle$$

and

$$\chi^C(j,j') = \langle (m_j - \langle m\rangle)(m_{j'} - \langle m\rangle)\rangle \quad (3)$$

The intensity formula is composed of the following terms:

$$I = I_B + I_D^1 + I_D^2$$

where

$$I_B = |\sum_j (\langle n\rangle f_T + (1-\langle n\rangle)\langle m\rangle f_{C^+} + (1-\langle n\rangle)(1-\langle m\rangle)f_{C^-}) e^{i\boldsymbol{k}\cdot\boldsymbol{R}_j}|^2$$

$$I_D^1 = |(f_T - \langle m\rangle f_{C^+} - (1-\langle m\rangle)f_{C^-}|^2 \sum_{jj'} \chi^T(j,j') e^{i\boldsymbol{k}\cdot(\boldsymbol{R}_j-\boldsymbol{R}_{j'})}$$

and

$$I_D^2 = |(f_{C^+} - f_{C^-})|^2 \sum_{jj'} \langle (1-n_j)(1-n_{j'})\rangle \chi^C(j,j') e^{i\boldsymbol{k}\cdot(\boldsymbol{R}_j-\boldsymbol{R}_{j'})} \quad (4)$$

(1) I_B can be interpreted as the intensity of X-ray diffraction by the crystal with average structure. When $\langle n\rangle = 1/2$, $\langle m\rangle = 1/2$ (TCNQ and carbazole occupy each lattice point with equal probability, the orientation of carbazole being disordered), I_B gives the intensities of sharp spots in the integral layer lines (group I in Table 2) and can be written as

$$I_B = |\sum_j (f_T + (f_{C^+} + f_{C^-})/2)/2 \times e^{i\boldsymbol{k}\cdot\boldsymbol{R}_j}|^2$$

This intensity equation is the same as that used for the analysis of average structure.

(2) The second term I_D^1 involves the correlation function of TCNQ. Here, we take the average structure (Fig. 4b) in which the following assumptions were made.

1) The molecular arrangement of TCNQ and carbazole is ordered in each a-c layer.

2) The adjacent layers have no correlation irrespective of the molecular arrangement in the first a-c layer. Every lattice point in the second layer is occupied by TCNQ and carbazole with equal probability.

The correlation function $\chi^T(j,j')$ has non-zero value $(\pm 1/4)$ when the positions of the two lattice points j and j' are in the same a-c layer, and zero when they are not:

$$\chi^T(j,j') = \begin{cases} 1/4 \cdots n_1 + n_3 = 2m, & n_2 = 0 \\ -1/4 \cdots n_1 + n_3 = 2m+1, & n_2 = 0 \\ 0 \cdots n_2 \neq 0 \end{cases}$$

This means that the molecular arrangements in the a-c layer is ordered and no correlation exists between different layers. The adjacent layers are related with each other by the translational vector $(\boldsymbol{a}+\boldsymbol{b}+\boldsymbol{c})/2$. Thus we have $\boldsymbol{R}_j - \boldsymbol{R}_{j'} = n_1\boldsymbol{a} + n_2\boldsymbol{b}' + n_3\boldsymbol{c}$, where $\boldsymbol{b}' = (\boldsymbol{a}+\boldsymbol{b}+\boldsymbol{c})/2$. Judging from the molecular arrangement in the body centered lattice of the average structure, this type of stacking disorder is very liekly to occur in this crystal. With the use of Eq. (4) and the above values of $\chi^T(j,j')$, I_D^1 is written as follows.

$$I_D^1(\xi\boldsymbol{a}^*, \eta\boldsymbol{b}^*, \zeta\boldsymbol{c}^*) = \begin{cases} N^2|f_T - (f_{C^+} + f_{C^-})/2|^2/4 & \\ \quad \cdots \xi = n + 1/2,\ \zeta = m + 1/2 & (5) \\ 0 \quad \cdots \xi \neq n + 1/2 \text{ or } \zeta \neq m + 1/2 & \end{cases}$$

where N is the number of lattice points in the layer.

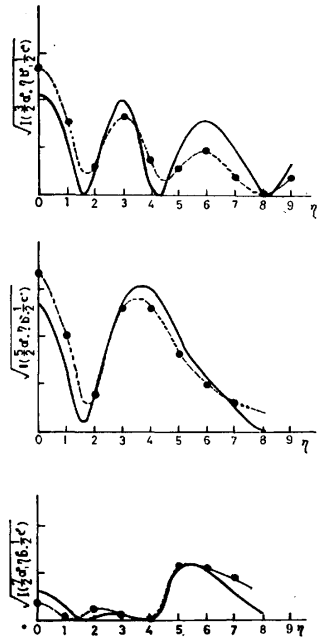


Fig. 5. The observed (solid lines) and calculated (broken lines) intensities of the streaks.

Equation (5) shows that the diffuse streaks appear in the diffraction patterns at the same positions as observed experimentally. The intensity along these streaks varies slowly according to the value of $|f^{T}-(f_{C^+}+f_{C^-})/2|^2$, some of which are shown in Fig. 5. The calculated value of $I_D{}^1$ agrees well with the visually estimated intensity of streaks.

(3) The third term $I_D{}^2$ depends on the correlation function involving the orientation of carbazole. The orientation of carbazole may be random in this disordered structure. Thus the correlation function $\chi^C(j,j')$ can be written as

$$\chi^C(j,j') = \delta_{jj'}/4 \qquad (6)$$

We obtain the equation for $I_D{}^2$ as follows:

$$I_D{}^2 = N|f_{C^+}-f_{C^-}|^2/8 \qquad (7)$$

From Eq. (7), we easily see that $I_D{}^2$ is not important because it indicates the faint scattering widely spread around the origin of the reciprocal lattice.

From the analysis of I_B, $I_D{}^1$, and $I_D{}^2$, we may say that the model of one-dimensionally disordered structure gives a fairly good explanation of the observed X-ray patterns.

Figures 2 and 4b show that the mixed stacks of carbazole and TCNQ exist along axis *c* like many other structures of CT complexes. The intermolecular distance between donor and acceptor molecules is 3.34 Å. The mode of overlapping can be considered to be the ring-external type observed in other CT complexes and radical salts of TCNQ.[1]

Interpretation of Sharp Reflections along the Streaks.
The diffuse streaks appear along the b^* direction, which indicate the stacking disorder along axis *b*.

a) Reflections correspond to those diffracted from structures Ia, Ib, and Ic.

Moreover, associated sharp spots do not lie exactly on the diffuse streaks but deviate slightly alternately from them. Thus the crystal seems to be not nuiform but composed of ordered and disordered domains.

Possible ordered structures are shown in Fig. 6. Six kinds of structures denoted by Ia, Ib, Ic, IIa, IIb, and IIc exist. The lattice spacings are twice those of average structure along directions *a* and *c*. Owing to the characteristic arrangement of molecules, additional and specific absence appears in X-ray diffraction patterns. They are summarized in Table 5 in terms of the basis vectors *a*, *b*, and *c* of average structure. The reflections from structure groups I and II correspond to those of groups IIIa and IIIb, respectively (Tables 2 and 5 and Fig. 1c). Specific features of these structures are as follows:

(1) Structures Ia and IIa are mirror images of each other, as likewise are Ib and IIb, and Ic and IIc.

(2) Ia, Ib, IIa, and IIb are polar due to the ordered orientation of carbazole molecules, while the lattices Ic and IIc are nonpolar due to disordered orientation.

(3) There are twofold axes along b. The lattices therefore might be monoclinic.

If the structures shown in Fig. 6 have rectangular unit cells, the sharp spots would be on the diffuse streaks. In order to explain the observed deviations, the structures should have monoclinic symmetry. It may be quite natural to assume that if the angles β of the unit cells of groups I and II (Fig. 6) are a little less or more than 90° the change in angles β of structures I and II would be equal in magnitude but opposite in sign, since the two structures are related to each other by the mirror planes perpendicular to axis a. If the structures of groups I and II are twinned submicroscopically by the mirror planes parallel to the b-c plane, the sharp spots may satisfy the specific extinction rules (Table 5), deviating alternately from the streaks.

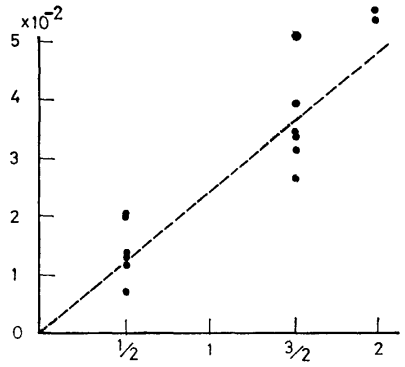

Fig. 7. The magnitude of the deviation of the spots from the streaks.
The numbers on the *abscissa* indicate the layer lines around axis c and those on the *ordinate* are $2|\Delta d|/d$, where d is the distance between two neighboring spots measured along axis a^*.

As shown in Fig. 7, the spots deviate more largely from the streaks in higher layer lines. Some elongated spots in the Weissenberg film of the upper layer around axis c split into two spots. A similar situation was observed for axis a. The magnitude of the change of β is about 0.2°. The crystal symmetry is reduced from Immm to C2 (or C2/m). The relationship between these cells is shown in Fig. 8. The lattice constants of

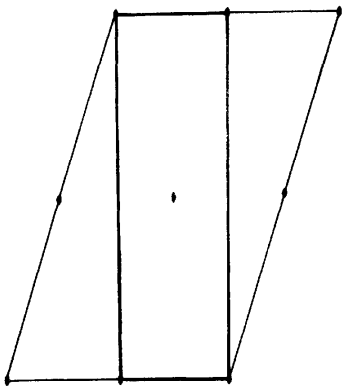

Fig. 8. The relationship between the cells of Immm and C2. The small change of β is neglected in this figure.

monoclinic cell are: $a=11.27$, $b=12.94$, $c=6.78$ Å, $\beta=107.4°$ and $Z=2$.

Using atomic parameters of the average structure and the models of ordered structures shown in Fig. 5, a comparison of the calculated and observed structure factors was made only for strong reflections ($h/2$, k, $1/2$) (Table 2) owing to difficulty in the visual estimation of the intensity of the spots in the streaks. R-value is about 0.19 (Table 6). The difference between models (Ia and IIc) is comparatively small. Thus no refinement was performed.

Description of the Domain Structure. The crystal of carbazole–TCNQ is hardly soluble in acetone, acetonitrile or tetrahydrofuran. The black needles precipitate when the acetone solutions of the components are mixed. From the fact that most non-ionic CT complexes of TCNQ are very soluble and the CT spectrum appears in the visible region, precipitation of black crystals seems to indicate that carbazole–TCNQ is a complex of ionic type, where the CT interaction between donor and acceptor is very strong. However, this is not cosistent with the fact that the CT interaction is very weak, since the visible spectrum of the acetone solution of carbazole–TCNQ closely resembles that of TCNQ (only one strong absorption maximum appears at 4000 Å) with no CT absorption. This fact indicates that the crystal structure of carbazole–TCNQ has somewhat unusual features.

The ordered domain composed of structures Ia, IIa,

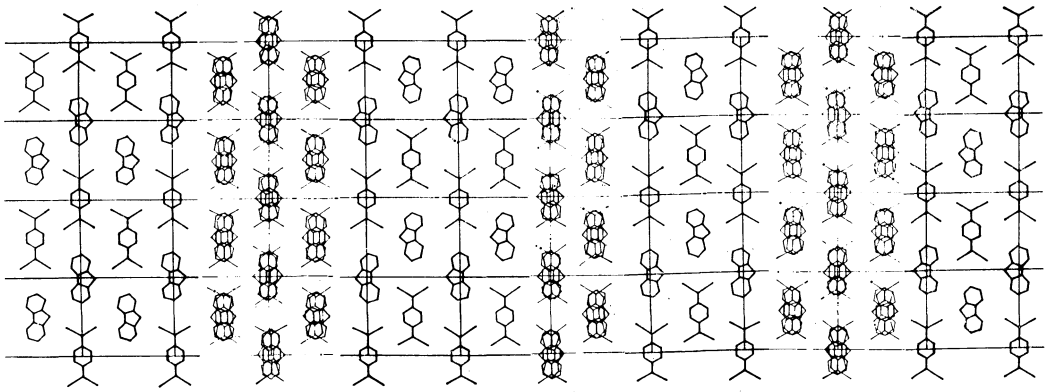

Fig. 9. Schematic drawing of the domain structure.

Ib and IIb has dipole moment along the b and $-b$ directions, respectively. On the other hand, the one-dimensionally disordered structure is non-polar. Thus, an adequate combination of these structures might interpret the appearance of the domain structure. Such a model seems to be stable because it resembles the well-known domain structures of ferromagnetic or ferroelectric substances. The most plausible structure may be that shown in Fig. 9. This structure indicates the strong interaction between domains with positive polarity and those with negative polarity, the domains with opposite polarities tending to gather together.

The crystal should contain an equal amount of positive and negative domains. However, it is difficult to estimate the ratios Ia/Ib and IIa/IIb. The thickness of random domain seems to be larger than that found in ferroelectrics or ferromagnetics, the intensity of the streaks being fairly strong. The space group of the ordered domain is C2.

The domain structure consisting of non-polar structures Ic and IIc can also explain the features of X-ray diffraction patterns. In this case, the ordered domain closely resembles the crystal structure of *N*-methylphenothiazine–TCNQ.[2] The orientation of an *N*-methylphenothiazine molecule is disordered like the carbazole molecule. Both structures contain mixed stacking columns of donors and acceptors. In spite of the assumed similarity of molecular arrangements, the properties of both complexes differ, *viz.*, *N*-methylphenothiazine–TCNQ is very soluble and the solution is strongly colored. This indicates that the non-polar domain dose not seem to be possible. The structure of polar domain structure seems to be confirmed by the appearance of various types of domain structures.

Absorption Spectra of the Crystal of Carbazole–TCNQ. The visible absorption spectrum of the solution of carbazole–TCNQ is similar to that of TCNQ. It is of interest that the CT band appears in the spectrum of a powdered sample (Fig. 10). The SCF-MO's of carbazole–TCNQ complex was calculated by assuming a complex as a single π-conjugated system using the semiempirical parameters.

The two center resonance integral is estimated by using the equation

	Assignment		Character of transitions				
		$\bar{\nu}$(kK)	$(DD)_m$	$(AA)_m$	$(DA)_m$	$(AD)_m$	f
(1)	19.70	CT(D→A)	0.026	0.016	0.950	0.000	0.005

Fig. 10. Absorption spectra of the powdered samples of carbazole–TCNQ and calculated results of SCF-MO-CI.

$$\beta_{\mu\nu} = -\kappa S_{\mu\nu}(I_\mu + I_\nu)/2$$

where $S_{\mu\nu}$ is overlap integral calculated by use of the Slater atomic orbitals, I_μ (I_ν) is ionization potential of the μ-th (ν-th) atom and κ is assumed to be 0.85 when μ and ν belong to the same molecule and 2.0 when they belong to different molecules. The two-center repulsion integral $\gamma_{\mu\nu}$ is evaluated according to the Nishimoto-Mataga method. Semiempirical constants I_μ and $\gamma_{\mu\nu}$ are the same as those given in Ref. 3 ($I_p(C^+)=11.16$, $I_p(N^+)=14.12$, $I_p(N^{++})=26.70$, $\gamma_{C^+C^+}=11.13$, $\gamma_{N^+N^+}=12.34$, $\gamma_{N^{++}N^{++}}=17.44$ eV). The relative arrangement of the constituent molecules is taken as shown in Fig. 2. After five cycles of SCF-MO calculation, the CI calculation was carried out with the lowest 25 singly-excited configulations. Characterization of transition was made according to the method described in Ref. 3.

The results are summarized in Fig. 10. Agreement between the calculated transitions and observed spectra is not satisfactory. The broad peak at about 18 kK, which cannot be observed in the spectra of component molecules, may be regarded as the CT absorption.

2) H. Kobayashi, This Bulletin, to be published.

3) T. Ohta, H. Kuroda, and T. L. Kunii, *Theor. Chim. Acta*, **19**, 167 (1970).

The strong peak at 22.5 kK can be assigned to the local excitation of TCNQ. The amount of charge transferred from carbazole to TCNQ is calculated to be 0.05 e. The small value seems to correspond to the weak interaction.

Various Types of Domain Structure. Since the crystal is made up from a combination of ordered

(g)

Fig. 11. Various types of diffraction patterns and the corresponding domain structures.

and disordered structures, various types of crystals may appear according to the mode of combination. We examined the X-ray diffraction patterns of crystals grown from solvents such as acetone, acetonitrile and tetrahydrofuran, and found many types of patterns, but no solvent effect.

As judged from the X-ray diffraction patterns, the domain structure seems to be formed according to the following conditions:

From the necessity to cancel the polarity of the crystal, there should be equal amounts of positive and negative structures. The thickness of the domain wall will differ to some extent with the sample, since the non-polar structure seems to be less important in view of the stability of the crystalline state.

Type I: The structure composed of Ia, Ib, IIa, IIb and random structure (Fig. 9) gives the X-ray diffraction patterns shown in Fig. 1. The same patterns can also be observed from structures Ia, IIb and random structure (Fig. 11a) or of Ib, IIa and random structure (Fig. 11b). Thus we can not decide from the diffraction patterns which structure is realized in the crystal. All of the three structures might coexist.

Type II: The structure composed of Ia, Ib and random structure (Fig. 11c) gives the X-ray pattern shown in Fig. 11c′, that consisting of IIa, IIb and random structure (Fig. 11d) gives the X-ray pattern shown in Fig. 11d′. The order component of both structures bear twin relationship with each other and patterns are closely related. It may be interesting that the synthesis of Figs. 11c′ and 11d′ gives the same pattern as that of Fig. 1a. Concerning the ordered domain, both structures are made up of the half components of the structure shown in Fig. 9. This is the reason why the number of spots in Figs. 11c′ and 11d′ is a half of those in Fig. 1a.

Type III: Some crystals give diffraction patterns with very faint streaks as shown in Fig. 11e′. The corresponding crystal will be constructed from the regions of Ia and Ib, small amount of IIa and IIb and a very little of random domain (Fig. 11e).

Type IV: There seems to be a domain wall of one-dimensionally disordered structure, in which some inter-layer correlation exists, since in some films the apparent diffuse maxima are observed between sharp spots as shown in Fig. 11f. This type of diffuse maxima has been extensively discussed.[4]

Type V: It may be easily recognized that the sharp spots appear at the positions of the diffuse maxima described in type IV, if the inter-layer correlation becomes complete. Figure 11g shows that the above situation is realized in some crystals. In this case there exist some domain walls whose lattice constant b is twice as large as that of the average structure.

Similar types of X-ray diffraction patterns were reported for the crystals of *o*-chlorobenzamide.[5]

An attempt was made to prepare crystals with a completely polarized structure, which might have similar physical properties to the so-called electret. Silver-paste was coated on both sides of the wall of a 10 mm diam. glass tube, a voltage of 500 V being applied between them. Crystals were prepared by the diffusion method in this tube, but the experiment was not successful, the crystals precipitated appearing to be similar to those obtained before. The results seems to indicate that the stability due to interaction between the polar domains overcomes the stability due to the effect of an external electric field.

The author would like to express his sincere thanks to Prof. Yoshihiko Saito for his keen interest and encouragement. He is also grateful to Prof. Takaaki Danno for his encouragement and to Dr. Ichimin Shirotani for the experiment of visible absorption spectra.

Solubilization Behavior of the Surfactant–Polyethylene Glycol Complex in Relation to the Degree of Polymerization

Fumikatsu TOKIWA and Kaoru TSUJII

Research Laboratories, Kao Soap Company, 2-1-3 Bunka, Sumida-ku, Tokyo 131

(Received March 22, 1973)

The solubilization behavior of the complexes composed of a surfactant and polyethylene glycol (PEG) toward an oil-soluble dye, Yellow OB, has been studied in relation to the degree of polymerization, *n*, of PEG. The solubilizing powers of the anionic surfactants, sodium dodecyl sulfate and sodium *p*-octylbenzene sulfonate, become greater on the addition of PEG, the extent depending on *n*. They increase as *n* increases. It is proposed that there are at least two different types of complexes, *i.e.*, "oligomeric" and "polymeric" PEG–surfactant complexes. The boundary between the oligomeric and polymeric PEG's is estimated to be around an *n* value of 10—15. With an oligomeric PEG–surfactant complex, the solubilization of Yellow OB would occur mainly in the hydrocarbon part of the surfactant micelle. With a polymeric PEG–surfactant complex, on the other hand, the solubilization would take place in the region of a complex rich in PEG. Electrical-conductivity and absorption-spectral data on the complexes are also included in this paper.

When a surfactant is mixed with a polymer in an aqueous solution, a kind of complex is formed by the binding of the surfactant molecules onto the polymer molecule.[1-9] The physicochemical properties of the respective components are, in general, changed by the formation of this complex. For example, the solubilizing power of the surfactant becomes greater on the addition of the polymer.[1,2,8,9] However, the mechanism of the increase in the solubilizing power by the polymer–surfactnat complex formation has not yet been elucidated. The dependence of this complex formation on the degree of polymerization of the polymer is also not well understood.

In the present work, the solubilization behavior of polymer–surfactant complexes toward an oil-soluble dye, Yellow OB, has been studied in relation to the degree of polymerization of the polymer, using two anionic surfactants and polyethylene glycols with different degrees of polymerization. Discussion has also been made of the mechanism of the solubilization of Yellow OB by the complexes composed of the surfactant and polyethylene glycol.

Experimental

Materials. The samples of sodium dodecyl sulfate (abbreviated to $NaC_{12}S$) and sodium *p*-octylbenzene sulfonate (abbreviated to $NaC_8\phi S$) were the same as those used in previous experiments.[10,11] The polyethylene glycols (abbreviated to PEG) were of a reagent grade and had been purified by ion-exchange with Amberite IR-120 and IRA-410.[12] The average degrees of polymerization, *n*, of these PEG samples were 2, 3, 5, 9, 14, 20, 35, 91, and 136; these figures were determined from their hydroxyl values. The Yellow OB used as a solubilizate was of a reagent grade; it had been obtained from Wako Pure Chemicals Co. and recrystallized twice from an ethanol–water mixture (80/20).

Solubilization. The stock solution of a surfactant containing 1.0% PEG was prepared. A sample solution of the desired concentration was made up volumetrically by the dilution of the stock solution with the 1.0% PEG solution. The solubilization of Yellow OB was carried out in a water bath at 30 ± 0.1 °C for 65 hours to attain equilibrium, a method described elsewhere[10] being employed. The amount of the solubilized dye was determined by optical-density measurements at a wavelength of 445 mμ with a Shimadzu Model AQV-50 spectrophotometer.

Electrical Conductivity. A sample solution was prepared by the procedure described above. The conductivity measurements were made with a Toa Electronics Model CM-1DB conductometer at 25 ± 0.01 °C. The observed values were checked by measuring the conductivities of standard solutions of potassium chloride.

Absorption Spectra. The spectral measurements were performed with the above spectrophotometer at room temperature (about 25 °C).

Results and Discussion

In Fig. 1, the amounts of solubilized Yellow OB, *A*, in the presence of PEG with different *n* values are plotted against the concentration, *C*, of $NaC_8\phi S$, the concentration of PEG being kept constant at 1.0%. The *A vs. C* curves similar to those shown in Fig. 1 were obtained for the $NaC_{12}S$–PEG complex. As may be seen in this figure, there is a linear relation between *A* and *C*. The solubilizing power of the PEG–$NaC_8\phi S$ complex, which corresponds to the slope of each *A vs. C* curve, increases as the degree of polymerization of PEG, *n*, increases. Further, the concentration of $NaC_8\phi S$ at which the solubilization sets in shifts to a lower concentration with an increase in the *n*.

Mechanism of the Solubilization of Yellow OB by the Polymer–Surfactant Complex. When a polymer is mixed with a surfactant in an aqueous solution, a

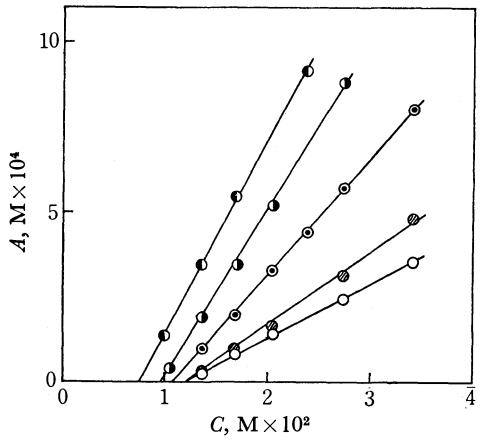

Fig. 1. The curves of the amount of solubilized Yellow OB *vs.* the concentration of $NaC_8\phi S$ in the presence of PEG: ○, $NaC_8\phi S$ alone; ◍, PEG-5; ⊙, PEG-14; ◑, PEG-35; ◐, PEG-136. The curves in the presence of PEG-2,3,9,20, or 91 are not shown here. The number written after PEG expresses the average degree of polymerization.

polymer–surfactant complex is formed by binding the surfactant molecules onto the long chain of the polymer molecule.[1-9] Further, it has been imagined that the binding of the surfactant molecules is not uniform along the polymer chain, but discrete, forming clusters or aggregates on it in such a manner as in micelle formation.[1,2,7-9] If this is the case, Yellow OB should be solubilized in these clusters. Such a solubilization mechanism in the complex is apparently analogous to that in the micelle of the surfactant alone. However, this mechanism itself can not account for such high solubilizing powers of the PEG–$NaC_8\phi S$ complex, as may be seen in Fig. 1.

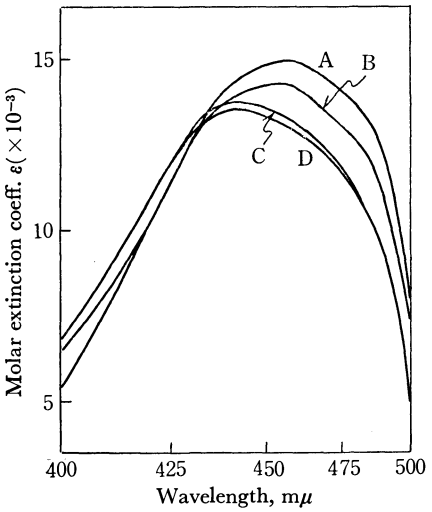

Fig. 2. The absorption spectra of Yellow OB in PEG alone (curve A), and in the aqueous solution of $NaC_8\phi S$ (curve D), $NaC_8\phi S$–PEG-5 (curve C) or $NaC_8\phi S$–PEG-136 (curve B) at 1.0% $NaC_8\phi S$ and PEG concentration.

Figure 2 shows the absorption spectra of Yellow OB in PEG alone as well as in aqueous solutions of $NaC_8\phi S$, $NaC_8\phi S$–PEG-5, and $NaC_8\phi S$–PEG-136. The spectra with $NaC_{12}S$ and $NaC_{12}S$–PEG are almost the same as those shown in Fig. 2, though not specifically shown. With the $NaC_8\phi S$–PEG-136 complex, the shape of the Yellow OB spectrum and its absorption maximum, λ_m, are very similar to those observed with PEG alone. With the $NaC_8\phi S$–PEG-5 complex, on the other hand, the spectrum closely resembles the spectrum in the $NaC_8\phi S$ solution. These results indicate that the solubilization behavior of $NaC_8\phi S$–PEG-136 toward Yellow OB is different from that of $NaC_8\phi S$–PEG-5. In the former case, the solubilization seems to occur in the PEG atmosphere of the complex, while in the latter case, it occurs mainly in the hydrocarbon part of the $NaC_8\phi S$ micelle. The results also suggest that there are at least two different types of complexes, that is, the "polymeric" PEG–$NaC_8\phi S$ complex and the "oligomeric" PEG–$NaC_8\phi S$ complex.

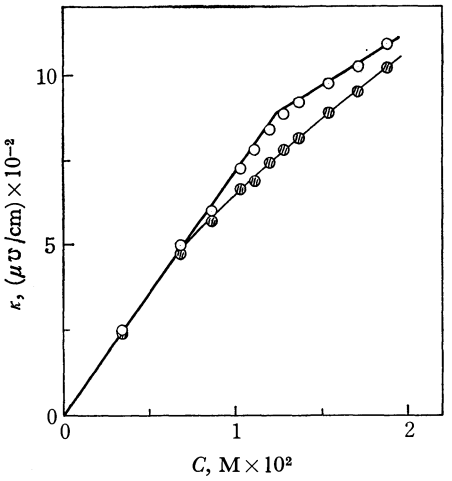

Fig. 3. The electrical conductivity *vs.* concentration curves for $NaC_8\phi S$ in the absence and presence of PEG: ○, $NaC_8\phi S$–PEG-5; ◍, $NaC_8\phi S$–PEG-136. The bold line indicates the curve for $NaC_8\phi S$ alone.

Figure 3 shows the conductivity *vs.* concentration curves for $NaC_8\phi S$ in the absence and in the presence of PEG. There is no difference between the curves for $NaC_8\phi S$ alone (bold line) and $NaC_8\phi S$–PEG-5 (open circle), while the curve for $NaC_8\phi S$–PEG-136 is different from that for $NaC_8\phi S$–PEG-5. This gives another piece of evidence for the existence of the two types of complexes.

To explain the solubilizing power of the complex being much greater than that of the surfactant micelle alone, we here propose new models of the polymer–surfactant complex, different from the model hitherto accepted,[1,2,7-9] based on the above spectral and conductivity data. The following models seem to be plausible for this explanation. The PEG polymer in the form of a random coil would be bound by the surfactant molecules with the hydrophilic group orientating to the aqueous phase; this model is analogous to the structure of polysoaps or proteins in an aqueous solution.[13,14] Probably, the solubilization of Yellow OB may take place in the region of a complex rich in PEG. The PEG itself is a very good solvent for this

13) T. Nakagawa and H. Inoue, *Kolloid-Z. Z. Polymere*, **195**, 93 (1964).
14) C. C. Bigelow, *J. Theoret. Biol.*, **16**, 187 (1967).

dye. An increase in solubilization on the addition of PEG can thus be explained by this mechanism. On the other hand, the PEG oligomer is gathered on the surface of the surfactant micelle in such a manner that polar substances, such as glycerol and dimethylphthalate, are adsorbed on the surface of the micelle.[15,16]

Boundary between Oligomer and Polymer in Complex Formation. The radius of a randam-coil polymer in solution, *i.e.*, the radius of gyration, is proportional to $n^{1/2}$ when the excluded volume effect of the polymer is negligible[17] and where n is the degree of polymerization of the polymer. This condition may be satisfied in the present case.[18] Thus, the average volume of the polymer coil will be proportional to $n^{3/2}$.

It seems reasonable to assume that the solubilization capacity of the polymeric PEG–surfactant complex is proportional to the volume of the polymer coil, provided that the solubilization of Yellow OB occurs in the region of this polymer coil, as has been already described. Thus, the solubilizing power of the complex is expected to be proportional to $n^{1/2}$, since the number of the polymer molecules is inversely proportional to n at a constant weight concentration.

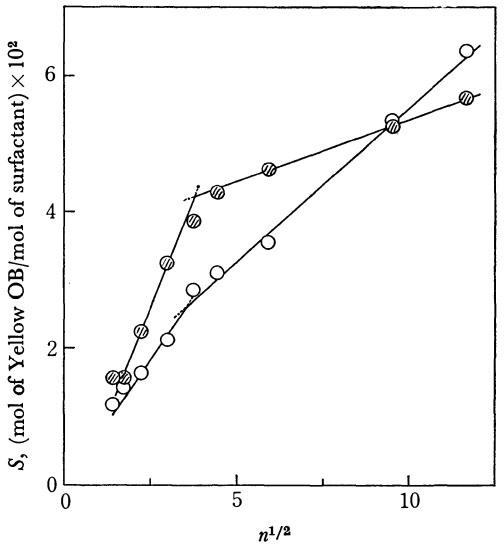

Fig. 4. The solubilizing power of surfactant–PEG-n complex plotted against $n^{1/2}$; ○, $NaC_{12}S$–PEG-n; ◍, $NaC_8\phi S$–PEG-n.

In Fig. 4, the solubilizing power, S, of the $NaC_8\phi S$–PEG complex, obtained from the slope of the straight line shown in Fig. 1, is plotted against $n^{1/2}$. This figure also includes the S *vs.* $n^{1/2}$ plot for the $NaC_{12}S$–PEG complex. In both cases, it should be noted that there is an inflection point around $n=10$—15. This point or region may be interpreted as a boundary between the two different types of polymer–surfactant complexes, or as a transition from oligomeric to polymeric PEG.

According to the thermodynamics of micelle formation, the following equation may be written:[19]

$$\mu_M^\circ = \mu_m^\circ + RT \ln C_O \qquad (1)$$

where μ_M° and μ_m° are the standard chemical potentials of a surfactant in the micelle phase and in the monomer phase respectively, and where C_O is the critical micelle concentration of the surfactant. Analogously to Eq. (1), we may write this equation:

$$\mu_c^\circ = \mu_m^\circ + RT \ln C_C \qquad (2)$$

for the formation of the polymer-surfactant complex. Here, μ_c° refers to the standard chemical potential of the surfactant in the complex phase, and C_C is the surfactant concentration of complex formation at which the solubilization begins. Eliminating μ_m° from Eqs. (1) and (2), we obtain:

$$\mu_c^\circ - \mu_M^\circ = RT \ln (C_C/C_O) \qquad (3)$$

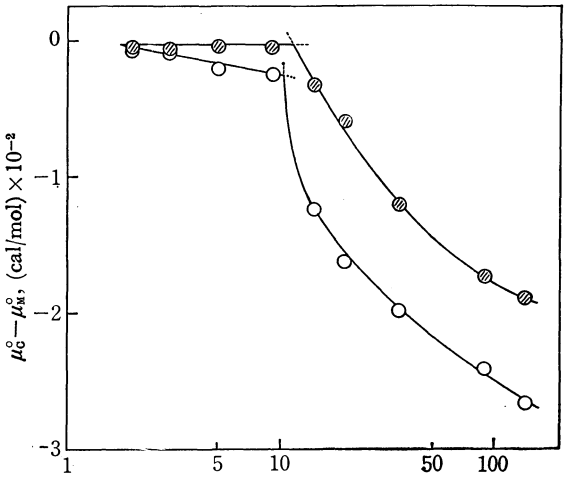

Fig. 5. The value of $(\mu_c^\circ - \mu_M^\circ)$ plotted against n: ○, $NaC_{12}S$–PEG-n: ◍, $NaC_8\phi S$–PEG-n.

The value of $(\mu_c^\circ - \mu_M^\circ)$ calculated from C_C and C_O by means of Eq. (3) is plotted against n in Fig. 5. The curves of $(\mu_c^\circ - \mu_M^\circ)$ *vs.* n for both the $NaC_8\phi S$–PEG and $NaC_{12}S$–PEG complexes have an inflection at $n=10$—15. In the oligomeric region, the value of $(\mu_c^\circ - \mu_M^\circ)$ is nearly independent of n and μ_c° is equal to μ_M°, which suggests that the complex formation takes place simultaneously with, or just after, the micelle formation. In the polymeric region, on the other hand, the value of $(\mu_c^\circ - \mu_M^\circ)$ decreases with the increase in n. This implies that the complex becomes more stable as n increases. Probably, these results could be explained as showing that the surfactant molecules are bound more easily onto the PEG polymer with a larger n because of the lower electrical repulsion of their ionic heads on the complex surface.

The Contact-term Contributions to Lanthanide-induced ^{13}C Paramagnetic Shifts in Acridine, Quinoline, and Isoquinoline

Masatoshi HIRAYAMA and Yoshiaki HANYU*

Department of Chemistry, Faculty of Science, Ibaraki University, Bunkyo, Mito 310

(Received March 23, 1973)

^1H and ^{13}C paramagnetic shifts induced by $Eu(DPM)_3$ and $Pr(DPM)_3$ in acridine, quinoline, and isoquinoline in CCl_4 are observed. It has been found that, while the ^1H shifts can be interpreted solely in terms of a pseudo-contact interaction, there is a much larger contact-term contribution to ^{13}C shifts induced by $Eu(DPM)_3$ than by $Pr(DPM)_3$ in these compounds; this contribution to the ^{13}C shifts cannot be explained by a simple combination of σ- and π-contact terms.

Since the discovery by Hinckley[1] that the dipyridine adduct of europium(III) tris(dipivalomethanate), Eu(DPM)$_3$, produces large and stereo-specific chemical shifts in the NMR spectrum of cholesterol, numerous communications reporting work with lanthanide-shift reagents of this type have appeared. While the action of these shift reagents is generally attributed to a through-space dipolar interaction,[2,3] it has recently been reported that abnormal shift values are observed for atoms (^{14}N) co-ordinated to the lanthanide ion[4] and for ^{13}C and ^1H nuclei close to the co-ordinating atom in some aliphatic compounds.[5] Johnson *et al.* have reported that abnormal relative ^1H shift patterns are observed for substituted pyridine *N*-oxides and anilines with some lanthanide complexes, and that the shift patterns for these substrates with $Eu(FOD)_3$ are characteristic of a contact interaction attributed to the π-spin density.[6] For pyridine derivatives, several workers have observed ^1H shifts induced by $Ln(DPM)_3$ and $Ln(FOD)_3$ (Ln=lanthanide ion).[3,7-9] These shifts were interpreted approximately in terms of a pseudo-contact interaction by all these authors[3,7,8] except for Mackie *et al.*,[9] who showed that a contact mechanism made the major contribution to the observed shifts induced by $Eu(DPM)_3$ in γ-picoline. The large ^1H isotropic shifts observed in the complexes of Pr^{3+} and Nd^{3+} (nitrates and perchlorates) with some pyridine derivatives were interpreted as originating from both contact and pseudo-contact terms of nearly equal magnitudes, but of opposite signs.[10] Also for quinoline, the observed ^1H shifts induced by some lanthanide chelates, $Ln(DPM)_3$, could be explained approximately by a pseudo-contact term.[7,11] Huber *et al.* tentatively took account of the contact-term contribution through π-bonding by using the Hückel spin distribution of the quinoline anion radical; they obtained better predicted values, but the agreement was not good.[11]

On the other hand, we have previously reported that the observed ^{13}C paramagnetic shifts induced by two lanthanide chelates, $Ln(DPM)_3$ and $Ln(FOD)_3$, in pyridine and β-picoline include a large contact term which does not arise through π-bonding.[8] Thus, further data on the ^{13}C shifts are required for the interpretation of a spin-delocalization mechanism in such a system. We wish to report here on the ^{13}C shifts induced by $Eu(DPM)_3$ and $Pr(DPM)_3$ in acridine, quinoline, and isoquinoline, discussing the contact-shift patterns in these ligand compounds.

Experimental

Quinoline and isoquinoline were purified by vacuum distillation, and acridine, by recrystallization from ethanol. CCl_4 was used as the solvent. $Eu(DPM)_3$ and $Pr(DPM)_3$ were obtained from Dojindo Co., Ltd., Research Laboratories, and were dried before use. Particular care was taken for all the substrates used to ensure anhydrous conditions, since the observed shifts are very sensitive to traces of moisture. The solutions were *ca.* 1.1 M in acridine and *ca.* 1.4 M in quinoline and isoquinoline for ^{13}C, and *ca.* 0.6 M for ^1H. The amount of the lanthanide complex was continuously varied up to a complex-substrate molar ratio of 0.2.

The ^{13}C spectra were recorded at 22.63 MHz with a Hitachi R-22 spectrometer with an R-228 proton wide-band decoupler and an A-1600A signal-averaging analyzer at a probe temperature of 35 °C, and the ^1H spectra, with a Hitachi R-20A spectrometer at 60 MHz at a probe temperature of 34 °C, both spectrometers operating in the frequency-swept mode.

Results and Discussion

The observed ^1H and ^{13}C shifts for these compounds

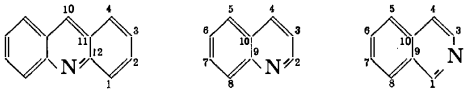
a) S is the lanthanide-induced shift in ppm obtained by linear extrapolation to a complex-substrate ratio of 1.0. Negative signs designate shifts to lower field.
b) The large errors may be involved in these values, owing to the weak intensities of spectral lines.
c) The pseudo-contact contributions.



are listed in Table 1.[12] The spectral assignments made by Pugmire *et al.*[13] were used here, those for ^1H being quite consistent with those made from the observed splitting patterns. On the assumption that

12) In the course of this work, ^{13}C lanthanide-induced shift data for quinoline have been reported, which are quite similar to our data. See, A. A. Chalmers and K. G. R. Pachler, *Tetrahedron Lett.*, **1972**, 4033.

13) R. J. Pugmire, D. M. Grant, M. J. Robins, and R. K. Robins, *J. Amer. Chem. Soc.*, **91**, 6381 (1969).

the geometries of the adducts of $Eu(DPM)_3$ and $Pr(DPM)_3$ are identical, the $S_{obsd}(Eu)/S_{obsd}(Pr)$ ratio should be constant over all the positions in a ligand substrate if both $S_{obsd}(Eu)$ and $S_{obsd}(Pr)$ arise only from a pseudo-contact interaction. Table 1 shows that while the ratios for ^1H are approximately constant, those for ^{13}C are quite variable, and, furthermore, that the shifts of ^{13}C in the β-position to nitrogen (β-^{13}C) induced by $Eu(DPM)_3$ are positive in all three substrates (they are negative, but very small in the 3 position of quinoline). Thus, it is apparent from the present data that the contact-term contributions to the ^1H shifts by both $Eu(DPM)_3$ and $Pr(DPM)_3$ are very small, while those to the ^{13}C shifts are much larger when affected by $Eu(DPM)_3$ than by $Pr(DPM)_3$; this is consistent with the result for pyridine[8] with respect to the dependence of the contact-term contribution on a lanthanide chelate.

It has been recently found that this kind of lanthanide chelate adduct is not axially symmetric;[14] consequently, information is not obtainable concerning the location of its principal magnetic axis.[15] Therefore, the use of the so-called geometric factor $(3\cos^2\theta-1)/r^3$ in the calculation of pseudo-contact shifts, as is commonly done, is essentially inappropriate.[16] However, in the present estimation of a relative pseudo-contact term, this approximation is adopted, because such an approximation of an axial symmetry has successfully been used for a number of systems by many workers. Calculations done while changing the N–Eu(Pr) distance led to a good agreement of the relative geometric factors (R) with the relative observed ^1H shifts obtained with both $Pr(DPM)_3$ and $Eu(DPM)_3$ at 4.5 Å[17] for acridine, at 3.6 Å for quinoline, and at 3.0 Å for isoquinoline.[18] For ^{13}C, the agreement is, however, not good, particularly with $Eu(DPM)_3$. These results substantiate the above expectation that ^1H shifts can be approximately explained only with a pseudo-contact interaction.[19] Therefore, a proportionality constant (A) fitting $S_{pcs}(^1H)=A\times R$ to $S_{obsd}(^1H)$, was calculated by the least-squares technique. On the reasonable assumption that $S_{obsd}=S_{pcs}+S_{cs}$, the S_{cs} values for ^1H and ^{13}C were estimated as the differences in the S_{obsd} values and the S_{pcs} values calculated by using the A values. Hence, the S_{cs} values for ^1H should be small. The calculated results are listed in Table 2 only for $Eu(DPM)_3$ for a reason to be given below.

Since the S_{cs} values of ^{13}C induced by $Pr(DPM)_3$ are relatively small, these magnitudes are extremely sensitive to even small variations in A and to the molecular geometry of the ligand substrate; consequently,

17) For $Eu(DPM)_3$, a further better agreement was obtained with 3.8 Å.
18) This Ln–N distance for quinoline is approximately equal to those by Reuben *et al.* and Huber *et al.*, and that for isoquinoline is also quite similar to that by Huber *et al.*
19) Such a lack of the contact contribution in ^1H shifts is consistent with the results due to Reuben *et al.*[7] and Huber *et al.*,[11] but is inconsistent with the consideration on the γ-picoline–$Eu(DPM)_3$ system due to Mackie *et al.*[9] This may be attributed to that they have not taken account of the difference of a pseudo-contact shift contribution between γ-picoline and 2,4,6-trimethylpyridine arising from the difference of N–Eu distances based on steric hindrance. Relatively large contact shifts observed by Birnbaum *et al.* for some lanthanide complexes may be ascribed to a very short Ln–N distance.[10]

the intrinsic pattern of ^{13}C contact shifts was difficult to identify for the three ligand compounds. However, those induced by $Eu(DPM)_3$ are not greatly dependent on these parameters; hence, a pattern mode with marked features was commonly found for the three ligands; the patterns are downfield for α- and γ-^{13}C, and for the ^{13}C nearest to the Eu ion in the adjacent ring, and upfield for β-^{13}C, the contact-term contributions being comparatively small in the other positions. The spin-density distributions obtained from these contact shift patterns are shown in Fig. 1. It can thus

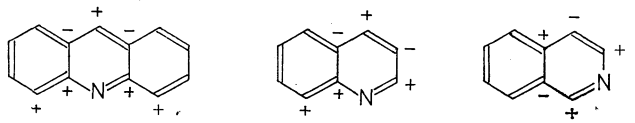

Fig. 1. The spin-density distributions induced by $Eu(DPM)_3$.

be assumed from the sign alternation in the pyridine ring that a negative spin induced by the Eu ion onto the nitrogen atom is transmitted through σ-bonds by means of a spin-polarization mechanism. Although this assumption is consistent with the observed large upfield shift of the ^{14}N resonance line induced by $Eu(DPM)_3$,[20] the sign alternation is opposite to that observed for the quinoline- and isoquinoline-$Ni(AcAc)_2$ systems, where the σ-contact shift term has already been shown to be the main contributor to the paramagnetic shifts.[21] Furthermore, the large positive spin density at C-1 in acridine and C-8 in quinoline cannot yet be reasonably explained.

Then, assuming that the contact shift term arises only through π-bonds (S_π), the relative π-contact terms (R_π) were tentatively estimated. First, the hyperfine splitting constants, a^C and a^H, were calculated from McLachlan's spin distribution[22] in the anion radicals of these compounds by using the approximation that the bonding orbital formed between an f-orbital on Eu containing an unpaired electron and a π^*-MO of a ligand substrate may be regarded as the π^*-MO itself. The following values for σ-π interaction parameters in the McConnell and the Karplus-Fraenkel equations[23] were used:

$Q^H_{CH}=-23.0$ G in the equation, $a^H=Q^H_{CH}\rho^\pi_C$;

$Q^C_{CN}=4.0$ G, $Q^C_{NC}=-20.5$ G,[24] and the generally-used values for S^C, $Q^C_{CC'}$, $Q^C_{C'C}$, and Q^C_{CH} in the equation,

$$a^C=(S^C+\sum_i Q^C_{CX_i})\rho^\pi+\sum_i Q^C_{X_iC}\rho^\pi_i.$$

Secondly, the R_π values were estimated from the contact-shift equation and the relation $\gamma_H/\gamma_C=ca.\ 4$. The calculated results are listed in Table 2. An attempt was also made to estimate the ^{13}C shifts from the spin-density distribution of the cation radical (Table 2). It is apparent from Table 2 that the ^{13}C contact shifts can be explained neither by a π-contact interaction nor by a suitable combination of σ- and π-contact terms. Although the spin-transfer mechanism is still under investigation, together with the diamagnetic induction effect, we assume that a positive spin induced directly by the Eu ion to α-^{13}C and the ^{13}C nearest to the Eu ion contributes to the ^{13}C paramagentic shift induced by $Eu(DPM)_3$.

The Microwave Spectrum and Quadrupole Coupling Constant Tensor of Bromomethylsilane

Michiro HAYASHI and Kazunori KUWADA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received March 26, 1973)

The microwave spectra of four isotopic species of bromomethylsilane have been measured, *viz.*, the ^{79}Br and ^{81}Br species of $BrCH_2SiH_3$ and $BrCH_2SiD_3$. The observed rotational constants have been well explained by a model of which the structural parameters have been transferred from the corresponding parameters determined for ethylbromide and chloromethylsilane. The principal quadrupole coupling constants have been determined through the analysis of the first- and second-order effects of quadrupole coupling on the hyperfine structure of the observed spectra. It was concluded, within the experimental error, that the quadrupole coupling constants tensor of this molecule has the cylindrical symmetry around the largest principal axis, the direction of which coincides approximately with the C–Br internuclear line.

The microwave spectra of ethyl chloride and chloromethylsilane had been investigated by Schwendeman and Jacobs.[1,2] Their works were concerned with the r_s structure, the quadrupole coupling constants and the barrier to the internal rotation of these molecules. Wagner, Dailey, and Solimene[3] had investigated the microwave spectrum of ethyl bromide in relation to the diagonal components of the quadrupole coupling constant tensor referred to the principal inertial axes of the molecule.

Flanagan and Pierce[4] had reinvestigated the microwave spectrum of ethylbromide in order to determine the r_s structure, the barrier to the internal rotation and the quadrupole coupling constant tensor. They had found that in the limit of the first-order quadrupole coupling theory certain transitions show anomalous hyperfine splittings which are removed when the second-order quadrupole coupling effects are considered.

The present work is concerned with the investigation of the microwave spectrum of the ^{79}Br and ^{81}Br species of $BeCH_2SiH_3$ and $BrCH_2SiD_3$.

The approximate molecular structure had been estimated from the observed rotational constants and the quadrupole coupling tensor has been determined from the hyperfine splittings of the spectra. One of our interests on bromomethylsilane was on the barrier height of the internal rotation. Lowe and Parr[5] had estimated the barrier of this molecule to be roughly equal to that for chloromethylsilane (2550 cal/mol) by their semi-empirical theory. However, our preliminary calculations had indicated that the splittings of the spectra due to the internal rotation in the ground and first excited torsional states may be much smaller ($<$0.3 MHz) than the resolving power of our instrument for the transitions with $J<15$ if the barrier is higher than about 2000 cal/mol. As no spectra had actually been observed with the splitting due to the internal rotation, the barrier height cannot be determined at present.

Experimental

The samples of bromomethylsilane and its deuterated species were prepared by the reaction of $SiBr_4$ and diazomethane in ethylether and by the reduction of the resultant $BrCH_2SiBr_3$ with $LiAlH_4$ or $LiAlD_4$ in *n*-butylether.[6]

The microwave spectra of the samples were measured in the region from 8500 to 36000 MHz with conventional sinusoidal and square wave Stark modulation spectrometers at the temperature of dry ice.

Spectra and Analysis

Bromomethylsilane is a slightly asymmetric prolate top molecule with a plane of symmetry perpendicular to the largest moment of inertia. Both "a" and "b" type transitions have been observed. Both ^{79}Br and ^{81}Br have nuclear spin of 3/2, so that for each transition of every species, there are four comparatively intense hyperfine components except for the low J transitions, under the rule of $\Delta F=\Delta J$.

As is shown in Tables 1 and 6, these quartets exhibit more or less asymmetry of the splittings. Since the first-order perturbation theory predicts that for the transitions having $J>3$ the four hyperfine components will appear as two doublets with the equal splitting, the observed asymmetry of the splittings suggests that the perturbation treatment should be extended at least up to the second-order in the analysis of the quadrupole coupling effect.

For the quadrupole coupling tensor in the principal inertial axes system, χ_{ab} is alone the non-zero off-diagonal element from the molecular symmetry. The second-order effects on the hyperfine structure of the spectra, therefore, depend mainly on $|\chi_{ab}|$ when at least one of the energy levels of the transitions is in near degeneracy with the other levels. Since $|\chi_{ab}|$ is estimated to be relatively large, the rotational states within about 30000 MHz can affect with each other beyond the experimental error. Since the second-order perturbation sums relating to χ_{ab} contain the matrix element of $\Phi_{za}\Phi_{zb}$, the sums vanish unless the direct

a) The frequencies of the hyperfine components of the transitions are shown in the order of $F'\leftarrow F=(J'+3/2\leftarrow J+3/2)$, $(J'+1/2\leftarrow J+1/2)$, $(J'-1/2\leftarrow J-1/2)$, $(J'-3/2\leftarrow J-3/2)$ where J' and J indicate the rotational quantum number of the higher and lower energy levels of the transition, respectively. The dash indicates that the component of the quartet is actually either completely obscured by the other spectra or defectively resolved from the other spectra.

b) The frequency difference of the hyperfine component (ν) and the hypothetical unsplit frequency (ν_0) of the transition.

c) The contribution to $\nu-\nu_0$ from the first-order theory.

d) The contribution to $\nu-\nu_0$ from the second-order theory.

Table 2. Hypothetical unsplit frequencies (ν_0) of bromomethylsilane in MHz

a) The definition of the asymmetry of the splittings is in Eq. (1) in the text.
b) The contribution of $\delta\nu$ from a pair of levels in near degeneracy using the formula given in Eq. (2) in the text.
c) For these transitions, since one of the components of the quartets is obscured by the other spectra, the calculated frequency is used instead of the observed one for this component.

product of the representation of the two rotational states is equal to that of $\Phi_{za}\Phi_{zb}$. Then, the direct product of the representations of the states which are able to couple with each other should be belonging to the B_c species of the four group. Therefore, the number of the rotational states having the second-order quadrupole effects is much restricted.

Since the molecule is too close to the symmetric top, the transitions having $K_{-1}>1$ become to be weak and furthermore, the K degeneracy makes the hyperfine structure analysis of the observed spectra too complicated. Therefore, the measurements were not extended to these transitions. From the observed quartets, the analysis was performed by the following procedures.

First, rough values of the rotational constants were determined by fitting the averaged frequencies of the components for each quartet to the rigid rotor expression.

Second, the asymmetry of the splitting was defined for each quartet as:

$$\delta\nu = \nu(J'+1/2\leftarrow J+1/2) + \nu(J'-3/2\leftarrow J-3/2) - \nu(J'+3/2\leftarrow J+3/2) - \nu(J'-1/2\leftarrow J-1/2) \quad (1)$$
$$= a\chi_{ab}^2 + b\chi_{aa}^2 + c\eta\chi_{aa}^2 + d\eta^2\chi_{aa}^2$$

where $\nu(J'+1/2\leftarrow J+1/2)$ indicates a component of a quartet having $F'=J'+1/2$ and $F=J+1/2$ for the higher and lower levels of the transition, respectively, and so on, and a, b, c, and d are the constants depending on the structure and the type of the transition.

Then, χ_{ab} was obtained taking average of the χ_{ab} values derived from the observed $\delta\nu$ for each quartet.

Third, the observed quartets were corrected by subtracting the contributions of the χ_{ab} terms and the hypothetical quartet patterns due to the first-order quadrupole coupling effects were obtained from which the values of χ_{aa} and $\eta(=(\chi_{bb}-\chi_{cc})/\chi_{aa})$ were determined by the least-squares technique.

Fourth, the unperturbed frequencies for the transitions were calculated by fitting the calculated frequencies of the components of the quartets including both the first- and second-order contributions with the observed.

Fifth, by the least-squares technique the rotational constants were recalculated by fitting the obtained unperturbed frequencies to the rigid rotor expression modified by the term of $-D_J[J(J+1)]^2$ of the centrifugal distortion.

The procedures were repeated until the self-consistent results were obtained. For some of the transitions small χ_{aa}^2, $\eta\chi_{aa}^2$, and $\eta^2\chi_{aa}^2$ contributions were also included in the second-order perturbation corrections. The results are shown in Tables 1, 2, 3, and 5.

Discussion

Structure. Since the observed rotational constants of a sufficient number of the isotopic species are not available, the r_s structure of the molecule cannot be obtained at present. However, when the structural parameters for this molecule are assumed to be equal to those of chloromethylsilane except r(C–Br) which is taken to be equal to that of ethylbromide, the calculated moments of inertia reproduce the observed ones within the deviation of 0.6%.

As is shown in Table 4, the structural parameters of the skeleton of ethyl chloride and bromide are found to be essentially identical except r(C–Br), while r(C–Cl) is found to be identical for ethyl chloride and chloromethylsilane. Then, it is not surprising that the above set of the structural parameters for bromomethylsilane gives an excellent agreement between the calculated and the observed moments of inertia. Therefore, this structure may be proposed as the best structure of bromomethylsilane at present.

Quadrupole Coupling Tensor. As both diagonal and off-diagonal elements of the χ tensor in the inertial principal axis system are obtained, the own principal values and the own principal axis system of the χ tensor can easily be evaluated by diagonalization. As is shown in Table 5 the asymmetry parameter η_{bond} $(=(\chi_{xx}-\chi_{yy})/\chi_{zz})$ around the axis of the largest principal value χ_{zz} is close to zero so that the charge distribution is approximately axially symmetric about the z axis within the limit of the experimental error for all of the isotopic species. The angle θ_{za} which is the angle between the z axis and the "a" inertial principal axis, is also shown and compared with the angle θ which is the angle between the C–Br internuclear line and the "a" axis calculated from the structure mentioned above. The discrepancies between θ_{za} and θ are within about 30′ and the two angles can be regarded as essentially identical.

Then, it can be concluded that the C–Br bond in this molecule seems not to be bent within the limit of the experimental error.

The magnitude of the largest principal quadrupole coupling constant χ_{zz} can be related to the ionic character of the bond.

If the d and the double-bond characters of the bond orbital are neglected, the ionic character i is found by the equation:

$$i = (1-s^2) - (\chi_{zz}/\chi_{at})$$

where s is the s character of the bond orbital and may be taken to be $s^2=0.15$. $\chi_{at}=eQq_{at}$ is the quadrupole coupling constant of the atom and is taken to be $+769.76$ MHz[7] for ^{79}Br. Then, the ionicity of the C–Br bond in bromomethylsilane is calculated to be 10%, while that for ethyl bromide is calculated to be 14%.

The ratio of the quadrupole moments between ^{79}Br and ^{81}Br are found to be 1.1965 and 1.2014 for $BrCH_2SiH_3$ and $BrCH_2SiD_3$, respectively, which give an excellent agreement with the reported value (1.19707).[8]

Asymmetry of the Splittings. As already was mentioned, the asymmetry of the splittings has been removed when the second-order quadrupole coupling effects are considered. Since bromomethylsilane is so nearly a symmetric top, the calculation of the second-order quadrupole effects can be much simplified. Furthermore, near degeneracy of the energy levels occurs usually only in a pair of the levels having relatively low J and $K_{-1}=0$ or 1, that is, the levels $J_{1,J-1}$ and J_{0J} are in near degeneracy with $(J+1)_{0,J+1}$ and $(J-1)_{1,J-2}$, respectively.

Therefore, the asymmetry of the splittings $\delta\nu$ defined in Eq. (1) for these low transitions can be approximately expressed as the following formula without a serious error in comparison with the experimental error.

$$\begin{aligned}
\delta\nu &= [\delta\nu_1(J)-\delta\nu_2(J)]\chi_{ab}^2 && \text{for } J_{1,J-1}\leftarrow J_{0J}\\
\delta\nu &= [\delta\nu_2(J)-\delta\nu_2(J-1)]\chi_{ab}^2 && \text{for } J_{0J}\leftarrow(J-1)_{0,J-1}\\
\delta\nu &= 0 && \text{for } J_{1J}\leftarrow(J-1)_{1,J-1}\\
\delta\nu &= [\delta\nu_1(J)-\delta\nu_1(J-1)]\chi_{ab}^2 && \text{for } J_{1,J-1}\leftarrow(J-1)_{1,J-2}\\
\delta\nu &= [\delta\nu_2(J)]\chi_{ab}^2 && \text{for } J_{0J}\leftarrow(J-1)_{1,J-1}
\end{aligned} \quad (2)$$

where

$$\delta\nu_1(J) = \left[\frac{12(J+2)-J^2(2J+1)(2J+5)-(J+2)^2(2J-1)(2J+3)}{24J(J+1)(2J+1)(2J+3)\Delta E_1(J)}\right] \quad (3)$$

$$\Delta E_1(J) = \left[A-\frac{1}{2}(B+C)\right]\left[1+\frac{J(J+1)}{2}b_p\right] - 2(J+1)\left(\frac{B+C}{2}\right) \quad (4)$$

7) T. M. Sugden and C. N. Kenney, "Microwave Spectroscopy of Gases," Van Nostrand Co., London (1965), p. 121.

8) C. H. Townes and A. L. Schawlow, "Microwave Spectroscopy," McGraw-Hill Book Co., New York (1955), p. 645.

and $\delta\nu_2$ can be obtained by replacing J with $J-1$ and $\Delta E_2(J)=-\Delta E_1(J-1)$. As is shown in Table 6, the calculated $\delta\nu$ by the formula (2) which is labeled as "one level", gives a large portion of the total $\delta\nu$ of the transitions with $J<6$ for every isotopic species so that we may neglect the other contributions. However, the contribution becomes smaller as J increases except $J_{0J}\leftarrow(J-1)_{1,J-1}$ where this is still large even for the transitions with $J>6$.

Since the dependence on the molecular asymmetry is completely neglected for the matrix elements of $\Phi_{za}\Phi_{zb}$ on the derivation of Eq. (2), the above formula will be invalid if the molecular asymmetry increases. However, we believe, these will be useful for the molecules having Ray's asymmetry parameter $|\kappa|>0.90$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2698—2701 (1973)

Charge Transfer Interaction between the Cation Radicals of Some Aromatic Diamines and Triethylamine

Tadayoshi SAKATA, Toshihiro OKAI,* Hiroaki SUGIMOTO,** and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received March 27, 1973)

Electronic spectra of the cation radicals of some aromatic diamines in triethylamine were found to differ remarkably from those in other solvents such as ether or alcohol as regards (1) swelling of the absorption at around 25000 cm^{-1}, (2) broadening of the first band system and (3) red shift of the same system. It was concluded that these phenomena are due to the charge transfer interaction between cation radicals and triethylamine.

Dimerization of organic ion radicals in solutions has been extensively studied.[1-6] An anion radical (A^-) or a cation radical (D^+) dimerizes easily in the solution and a new absorption band due to the charge transfer (CT) between the two half-occupied orbitals of component radicals appears in the long wavelength region. The local excitation bands of the component radicals are also influenced largely by dimerization.

Recently the existence of a complex formed between an organic molecule (D) and its cation radical (D^+) has been found and studied extensively by γ radiolysis.[7-10] In this case also, a new absorption band due to charge resonance interaction appears in the visible or near infrared region.

From this $D^+\cdots D$ type complex a $D^+\cdots D'$ type one would be expected, D' being a different molecule from D. However, no report seems to have been made so far. Since such a complex would be of importance as an intermediate in reactions of cation radicals, we have attempted to find it.

Experimental

Preparation of Materials. Commercial *p*-phenylenediamine(PPD) was recrystallized in benzene and sublimed *in vacuo*. Commercial *N,N*-dimethyl-*p*-phenylenediamine (DMPD) and *N,N*-diethyl-*p*-phenylenediamine(DEPD) were purified by use of the vacuum line technique.

An aqueous solution of commercial *N,N,N',N'*-tetramethyl-*p*-phenylenediamine(TMPD) dihydrochloride was treated with 28% ammonia. The precipitate obtained was dried and sublimed several times *in vacuo*. Triethylamine(TEA), tri-*n*-propylamine(TNPA) and tri-*n*-butylamine(TNBA) were dried over pellets of potassium hydroxide for a day and fractionally distilled in a stream of nitrogen under reduced pressure.

Procedure. Solutions of the aromatic diamines in aliphatic amines, ethanol and EPA were degassed in 15 mm diam. quartz cells by the freeze-pump-thaw technique and sealed. These solutions were cooled in a quartz Dewar with liquid nitrogen and irradiated with a 250 W high pressure mercury lamp through a Toshiba glass filter UV D2, passing 300—400 nm light, to produce the cation radicals of the aromatic diamines. These UV-irradiated samples were then illuminated in the visible and near infrared region, longer than 500 nm, through a Toshiba glass filter V-052 or V-G54 in order to remove absorption due to the solvated electron.[11,12]

The electronic absorption spectra were recorded with a Shimadzu Multipurpose Recording Spectrophotometer MPS-50L.

Results

Electronic absorption spectra of the cation radicals formed by UV-irradiation of PPD and its derivatives in the rigid glasses of TEA and EPA at 77 K are shown in Figs. 1—4. Curves a and b show the absorption of the irradiated solutions in EPA and TEA, respectively, and curves c give their differences.[13] Change of spectra from EPA solutions to TEA solutions can be characterized as follows.

1. Swelling of the absorption at around 25000 cm^{-1}, attributable to a new band as shown by curve c.
2. Broadening of the first longest wavelength band system of the cation.
3. Red shift of the same system.

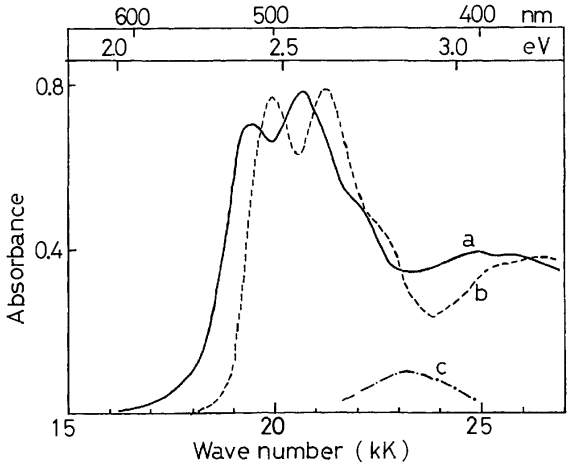

Fig. 1. The visible absorption spectra of the cation radical of *p*-phenylenediamine: a, in TEA; b, in EPA; c, a−b, the difference between a and b.

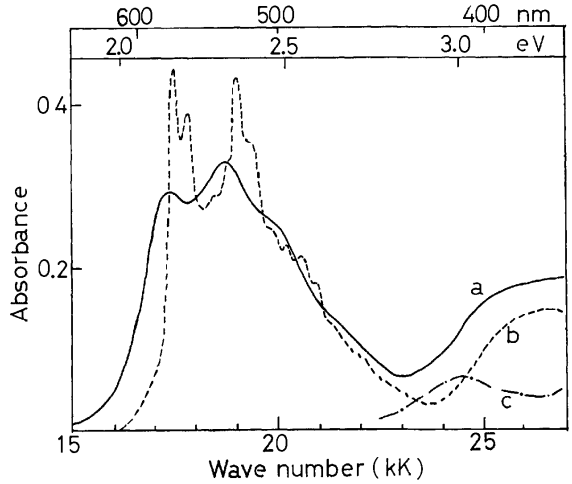

Fig. 2. The visible absorption spectra of the cation radical of *N,N*-dimethyl-*p*-phenylenediamine: a, in TEA; b, in EPA; c, a−b.

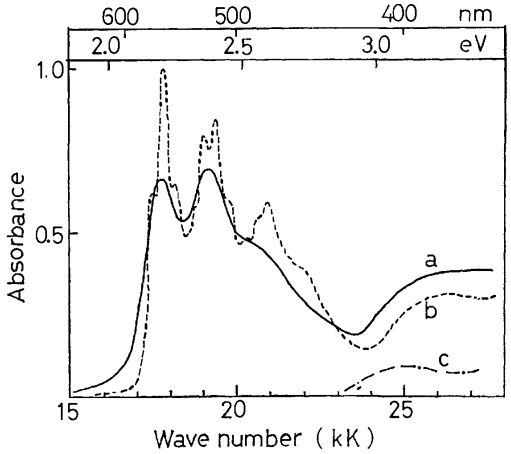

Fig. 3. The visible absorption spectra of the cation radical of *N,N*-diethyl-*p*-phenylenediamine: a, in TEA; b, in EPA; c, a−b.

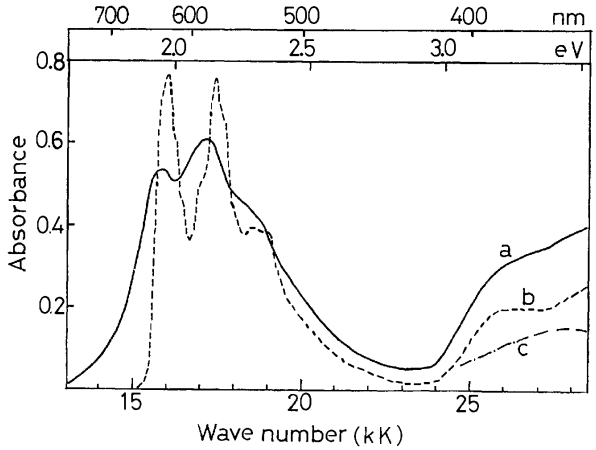

Fig. 4. The visible absorption spectra of the cation radical of *N,N,N',N'*-tetramethyl-*p*-phenylenediamine: a, in TEA; b, in EPA; c, a−b.

relating them with the nature of the solvent. The maximum wavelengths of the observed new absorption (curves c, Figs. 1—4) are summarized in Table 2.

Discussion

We see from Table 1 that the first band system of the cation radical in EA, EPA, and EP shows a tendency to become sharper and shift slightly to shorter wavelength with decreasing polarity of solvents. Since aliphatic amines are less polar than EPA, a sharpening of the band shape along with the blue shift is expected in amine solutions. The results are contrary to this expectation (Table 1 and Figs. 1—4), and it seems most likely that they can only be explained by taking the CT interaction between the cation radical and the aliphatic amine into account. In connection with this, the new absorption bands as shown by curves c, in Figs. 1—4 are most probably assigned to the CT bands, with the cation radical as acceptor and triethylamine as donor. These assignments are quantitatively verified as shown below.

By assuming weak CT interactions, the vertical CT energy ($E_{CT}{}^{v}$) from an aliphatic amine (D′) as an electron donor to a cation radical (D^+) as an electron acceptor can be expressed by

$$E_{CT}{}^{v} = I_p{}^{v}(D') - E_A{}^{v}(D^+) + P(D\cdots D'^+) - P(D^+\cdots D') \quad (1)$$

where $I_p{}^{v}$ and $E_A{}^{v}$ are vertical ionization potential and vertical electron affinity, respectively. $P(D^+\cdots D')$ represents the static polarization energy in the ground state of the complex, and $P(D\cdots D'^+)$ the electronic polarization energy in the excited CT state. The polarization energy can be estimated approximately using Born's equation $P=-(1-1/\varepsilon)e^2/2r_0$, where r_0 is the effective radius of an ion and ε the dielectric constant of the medium. The static dielectric constant of triethylamine at 77 K can be estimated to be $\varepsilon_{77K}=3.6$.[14] The dielectric constant in the visible region is calculated to be $\varepsilon_{op}=1.96$ using the refractive index $n^{20°C}=1.40$ at the sodium D-line.[16] When the effective radii for triethylamine and the cation radicals of the aromatic diamines are assumed to be both 3.3 Å, the polarization energy in Eq. (1) is calculated to be

$$P(D\cdots D'^+) - P(D^+\cdots D') = (1/\varepsilon_{op}-1/\varepsilon)e^2/2r_0 = 0.7 \text{ eV}.$$

The relation between the ionization potential of a neutral molecule and the electron affinity of its cation radical is schematically given in Fig. 5. As a rough approximation, we assume that

$$I_p{}^{v}(D) - I_p{}^{a}(D) \cong I_p{}^{a}(D) - E_A{}^{v}(D^+) \quad (2)$$

Superscripts v and a are abbreviations of "vertical" and "adiabatic", respectively. The $I_p{}^{v}$'s and $I_p{}^{a}$'s of DMPD

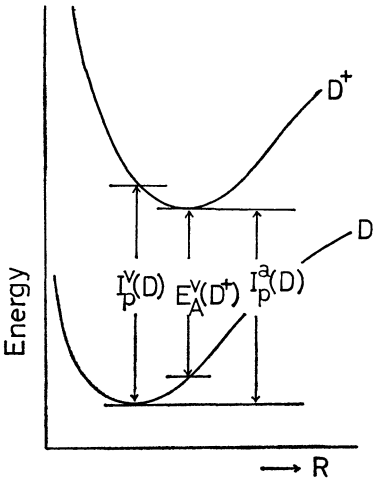

Fig. 5. Schematic energy curves for D and the cation D^+ against a generalized coordinate R for the molecular structure.

and TMPD were measured by Nakato *et al.*[17] The ionization potentials of PPD and DEPD can be estimated from the peak positions of the CT bands of the CT complexes formed between these aromatic diamines and 1,3,5-trinitrobenzene.[18] The results are shown in Table 3.

The theoretically expected values of E_{CT}, using 7.84 eV as the $I_p{}^{v}$ for triethylamine[19] are shown in

Table 3. Ionization potentials of aromatic diamines and electron affinities of their cation radicals

D	$I_p{}^{v}$ (D), eV	$I_p{}^{a}$ (D), eV	$E_A{}^{v}$ (D^+), eV
PPD	7.27	6.74[a]	6.21
DMPD	6.97	6.46	5.95
DEPD	6.81	6.28[a]	5.75
TMPD	6.75	6.20	5.65

a) Estimated by subtracting 0.53 eV from $I_p{}^{v}$. 0.53 eV is the avarage value of $I_p{}^{v}-I_p{}^{a}$ for DMPD and TMPD.

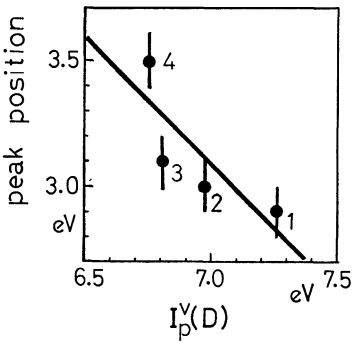

Fig. 6. Plot of the transition energies for the new bands of the cation radicals of: (1) *p*-phenylenediamine; (2) *N,N*-dimethyl-*p*-phenylenediamine; (3) *N,N*-diethyl-*p*-phenylenediamine; (4) *N,N,N′,N′*-tetramethyl-*p*-phenylenediamine, in the rigid glass of triethylamine at 77 K against their ionization potentials.

14) Assuming an approximate equation $\varepsilon_T{}'=\varepsilon_T-\alpha(T'-T)$ with $\alpha=5.2\times10^{-3}$ deg^{-1} and $\varepsilon_{298\,K}=2.42$, we obtain 3.6 as $\varepsilon_{77\,K}$[15]. Here, the value of α for triethylamine is taken to be equal to that for trimethylamine, since the former is not known.[15]

The behavior of the new band for $TMPD^+$ in some aliphatic amines was examined, the result being given in Table 4. The energy at the maximum of the new band was found to become lower, the lower the ionization potential of the aliphatic amines, as expected theoretically from Eq. (1). The magnitude of the shift seems reasonable, although the exact data of ionization potential of these aliphatic amines are not available. These results strongly support our assertion that the new bands originate from charge transfer from triethylamine to the cation radicals.

The remarkable broadening of the first band system of the cation in TEA compared with that in EPA may be explained as follows. The minimum charge transfer energy, that is, the adiabatic charge transfer energy E_{CT}^a, can be obtained by substituting $I_p^a(D')$ and $E_A^a(D^+)$ for $I_p^v(D')$ and $E_A^v(D^+)$, respectively, in Eq. (1). The result is shown in Table 2. Here 7.50 eV was used as the value of I_p^v for TEA.[20] As is seen in this table, E_{CT}^a is smaller than E_{CT}^v by 6000—7000 cm^{-1}. Accordingly, it is most probable that the first band system of the cation radicals lies entirely in the region of the lower vibronic part of the CT state. These lower vibronic CT states may be considered to be pseudocontinuous and optically forbidden. They interact with the vibronic states of the first system of D^+ to broaden their band shape.[21,22] Similarly the red shift of the absorption peak of the first system of the cation radicals might be explained by the interaction with the CT states.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2701—2708 (1973)

An Experimental Study of Gibbs-Donnan Membrane Equilibria Across Permselective Membranes Which Involve the Ions of Strong Inorganic Electrolytes*

Reita TAMAMUSHI

National Institute of Arthritis, Metabolism, and Digestive Diseases, National Institutes of Health, Bethesda, Md. 20014, U.S.A.

*The Institute of Physical and Chemical Research, Wako-shi, Saitama, Japan***

(Received March 29, 1973)

The Donnan membrane equilibria arising across permselective collodion matrix membranes were studied both by a static and a flow method in systems which contain only simple strong electrolytes at relatively high concentrations, up to 0.4 equiv/l. Experimental details of the flow method and its advantage in studying the ion activity behavior are presented. From the measurements of equilibrium concentrations and Donnan membrane potentials the ratios of ion activity coefficients were calculated for the following pairs of electrolytes in mixed solutions: sodium chloride–sodium nitrate, sodium sulfate–ammonium sulfate, potassium oxalate–ammonium sulfate, and potassium oxalate–ammonium oxalate. The experiments prove the feasibility of determining the ratios of ion activity coefficients in mixed solutions at concentrations where other methods lose their usefulness.

After the theory of the Gibbs-Donnan equilibrium was developed by Donnan in 1911[1] extensive studies were carried out experimentally to test this theory.[2] These studies, however, were for a long time restricted

* The experimental work reported in this paper was carried out in 1952—1953, while the author worked at the National Institute of Arthritis, Metabolism, and Digestive Diseases, supported by a travel grant under the Fulbright Act.

to systems containing colloidal, semicolloidal or relatively large ions like the ferrocyanide ion as the non-diffusible species. Donnan stated quite early, in 1924,[3] that "an accurate experimental study of the equilibria produced by ionically semipermeable membranes may prove to be of value in the investigation of ionic activity coefficients" of strong inorganic electrolytes. For several decades, however, studies of this type remained impossible until "permselective" membranes of extreme ionic selectivity were developed by Sollner and collaborators[4-7] by means of which Gregor and Sollner in 1945[6,7] demonstrated the feasibility of studying membrane equilibria in systems with solutions containing only the ions of the simple strong inorganic electrolytes. Shortly thereafter Sollner[8] showed explicitly how to investigate the activity behavior of individual ions in mixed solutions by the use of permselective membranes. In later years the properties of the permselective collodion matrix membranes have been greatly improved,[9-11] and more precise measurements of membrane equilibria at higher concentrations thus became feasible. It hardly needs to be mentioned that one may use for such studies, more or less conveniently, any of the various types of permselective ion exchanger membranes which have been described by numerous investigators during the last twenty years[12,13] provided their ionic selectivity is sufficiently high. Recently the Donnan membrane equilibrium across commercial permselective membranes was used by Wallace[14] for the determination of dissociation (or stability) constants of some inorganic electrolytes in aqueous solutions.

The results to be presented below show that the method suggested by Sollner[8] is very promising when applied to the experimental determination of activity coefficients in mixed solutions at concentrations where current theories cannot be tested by other methods. This general approach to the study of membrane equilibria and membrane potentials has assumed increasing interest in recent years in view of the advent of the liquid ion exchanger membranes[15-22] and the observation reported by Shean and Sollner[17] that such membranes, if properly constituted, show virtually zero leakage of the nominally impermeable ion even in systems with electrolyte solutions up to several molar. This latter observation and the possibilities it opens up have prompted the author to publish the present paper at this time.

Theoretical

Though the Donnan equilibrium is discussed to some extent in many textbooks of physical chemistry, it is necessary to recapitulate here some of its essential features which must be clearly understood in the present context.

Let us consider a system, System I, of two solutions 1 and 2 which are separated by an ideally cation-permeable membrane, $|\leftarrow\oplus\rightarrow|$. For the sake of simplicity, solutions 1 and 2 are assumed to contain uni-univalent strong electrolytes A^+X^- and B^+X^-, respectively, at different concentrations c_1 and c_2. The two solutions are at the same temperature, but not necessarily at the same pressure. The initial state of the system is represented by the scheme:

$$\begin{array}{l|c|l} [A^+] = c_1 & & [B^+] = c_2 \\ [X^-] = c_1 & \leftarrow\oplus\rightarrow & [X^-] = c_2 \\ \text{Solution 1} & & \text{Solution 2} \end{array} \qquad \text{(System I, initial state)}$$

The ionic exchanges of permeable cations A^+ and B^+ across the membrane must proceed in such a way that the electrical neutrality is satisfied in the bulk of both solutions 1 and 2. The semi-permeable nature of the membrane results in an unequal ionic distribution and an electric potential difference between the two solutions at the equilibrium state:

$$\begin{array}{l|c|l} [A^+] = c_1 - x & & [A^+] = x \\ [B^+] = x & \leftarrow\oplus\rightarrow & [B^+] = c_2 - x \\ [X^-] = c_1 & & [X^-] = c_2 \\ \text{Solution 1} & & \text{Solution 2} \end{array} \qquad \text{(System I, equilibrium state)}$$

Membranes commonly available are more or less permeable to water, and the equilibrium regarding water between the two solution phases should be considered as well as the equilibrium with respect to the permeable ions. Thus the conditions for membrane

equilibrium of system I are given by a following set of equations:[23,24]
for permeable cations A^+ and B^+,

$$\mu_{A^+}^{\circ(1)} + RT\ln a_{A^+}^{(1)} + F\phi^{(1)} = \mu_{A^+}^{\circ(2)} + RT\ln a_{A^+}^{(2)} + F\phi^{(2)} \quad (1a)$$

$$\mu_{B^+}^{\circ(1)} + RT\ln a_{B^+}^{(1)} + F\phi^{(1)} = \mu_{B^+}^{\circ(2)} + RT\ln a_{B^+}^{(2)} + F\phi^{(2)} \quad (1b)$$

for water,

$$\mu_{H_2O}^{\circ(1)} + RT\ln a_{H_2O}^{(1)} = \mu_{H_2O}^{\circ(2)} + RT\ln a_{H_2O}^{(2)} \quad (2)$$

The equalities between the chemical potentials between the two solutions do not hold for the anions X^-, that is

$$\mu_{X^-}^{\circ(1)} + RT\ln a_{X^-}^{(1)} - F\phi^{(1)} \neq \mu_{X^-}^{\circ(2)} + RT\ln a_{X^-}^{(2)} - F\phi^{(2)} \quad (3)$$

where μ_i° and a_i are the standard chemical potential and the activity, respectively, of the species i in the solutions specified by superscripts (1) and (2), $\phi^{(1)}$ and $\phi^{(2)}$ are the electric potentials of solutions 1 and 2, and the other symbols have their usual meaning.

The Donnan membrane potential is determined by the condition that, at the equilibrium, the work associated with the transfer of permeable cations should be counterbalanced by the electrical energy due to the potential difference between the two solutions. From Eqs. (1a) and (1b) we obtain,

$$E = \phi^{(2)} - \phi^{(1)} = \frac{RT}{F}\ln\frac{a_{A^+}^{(1)}}{a_{A^+}^{(2)}} + \frac{1}{F}(\mu_{A^+}^{\circ(1)} - \mu_{A^+}^{\circ(2)}) = \frac{RT}{F}\ln\frac{a_{B^+}^{(1)}}{a_{B^+}^{(2)}} + \frac{1}{F}(\mu_{B^+}^{\circ(1)} - \mu_{B^+}^{\circ(2)}) \quad (4)$$

for the Donnan membrane potential E, and

$$\frac{a_{A^+}^{(1)}}{a_{A^+}^{(2)}}\exp\left\{\frac{1}{RT}(\mu_{A^+}^{\circ(1)} - \mu_{A^+}^{\circ(2)})\right\} = \frac{a_{B^+}^{(1)}}{a_{B^+}^{(2)}}\exp\left\{\frac{1}{RT}(\mu_{B^+}^{\circ(1)} - \mu_{B^+}^{\circ(2)})\right\} \quad (5)$$

for the activity ratios of the permeable cations at the equilibrium.

The equilibrium condition for water, Eq. (2), will generally reslut in a pressure difference between the two solutions, which is called the osmotic pressure difference. Under the presence of the osmotic pressure difference, the standard chemical potential of the permeable cation in solution 1 is not equal to that in solution 2, *i.e.* $\mu_{A^+}^{\circ(1)} \neq \mu_{A^+}^{\circ(2)}$ and $\mu_{B^+}^{\circ(1)} \neq \mu_{B^+}^{\circ(2)}$. Such a difference in the standard chemical potentials due to the osmotic pressure difference, however, has been proved both theoretically and experimentally to be very small, and can be neglected in many cases, provided that the solutions are not too concentrated.[25] Experimentally, the osmotic pressure difference can be eliminated by adding a proper amount of impermeable neutral species to the solution of a lower concentration.[7]

Under such conditions the following relations can be used in place of Eqs. (4) and (5) for the membrane equilibrium with a sufficiently high accuracy: for the Donnan membrane potential,

$$E = \frac{RT}{F}\ln\frac{a_{A^+}^{(1)}}{a_{A^+}^{(2)}} = \frac{RT}{F}\ln\frac{a_{B^+}^{(1)}}{a_{B^+}^{(2)}} \quad (6)$$

and for the Donnan activity ratio,

$$\frac{a_{A^+}^{(1)}}{a_{A^+}^{(2)}} = \frac{a_{B^+}^{(1)}}{a_{B^+}^{(2)}} \text{ or } \frac{c_{A^+}^{(1)}}{c_{A^+}^{(2)}}\frac{\gamma_{A^+}^{(1)}}{\gamma_{A^+}^{(2)}} = \frac{c_{B^+}^{(1)}}{c_{B^+}^{(2)}}\frac{\gamma_{B^+}^{(1)}}{\gamma_{B^+}^{(2)}} \quad (7)$$

where c is the equilibrium concentration and γ the activity coefficient. In a particular case when the ratios of activity coefficients, $\gamma^{(1)}/\gamma^{(2)}$, are the same for A^+ and B^+ in the pairs of solutions 1 and 2, Eq. (7) and the condition of electrical neutrality give the simplified original formula of Donnan,[1,2c]

$$\frac{c_{A^+}^{(1)}}{c_{A^+}^{(2)}} = \frac{c_{B^+}^{(1)}}{c_{B^+}^{(2)}} = \frac{c_{X^-}^{(1)}}{c_{X^-}^{(2)}} \quad (8)$$

which refers to analytical concentrations rather than activities.

All the equations mentioned above have been derived by assuming the ideal permselectivity of membranes against cations and anions. Actual membranes, however, are not strictly ideal in their ionic selectivity, and show some leakage of nominally impermeable ions although this leakage is extremely small in the case of good permselective membranes. Such a small leak will not affect the equilibrium conditions for permeable ions seriously, and Eqs. (6) and (7) can be satisfied with a reasonably high accuracy, provided that the exchange rate of nominally impermeable ions across the membrane is very much lower than that of permeable ions.

These theoretical considerations lead to a useful conclusion as follows:[8]
(i) Measurements of equilibrium concentrations of permeable ions in the two solutions give the information on the ratios of their activity coefficients in mixed electrolyte solutions: *i.e.* from Eq. (7) we obtain,

$$\frac{\gamma_{A^+}^{(1)}}{\gamma_{A^+}^{(2)}}\frac{\gamma_{B^+}^{(2)}}{\gamma_{B^+}^{(1)}} = \frac{c_{B^+}^{(1)}}{c_{B^+}^{(2)}}\frac{c_{A^+}^{(2)}}{c_{A^+}^{(1)}} \quad (9)$$

The left-hand side of Eq. (9) is directly calculated from the analytical concentrations of permeable ions at the equilibrium without introducing any further assumptions, and therefore its accuracy is determined only by the accuracy of the concentration determination. If one of the two solutions, say solution 2, is sufficiently dilute so that ionic activity coefficients or their ratios are known by some theoretical means, the ratio of activity coefficients of the permeable cations in the other solution, solution 1, can be calculated.
(ii) Concomitant measurements of equilibrium concentrations and the Donnan membrane potential enable us to calculate the ratios of activity coefficients of permeable ions in solutions 1 and 2: *i.e.* from Eqs. (6) and (7) we obtain,

$$\frac{\gamma_{A^+}^{(1)}}{\gamma_{A^+}^{(2)}} = \frac{c_{A^+}^{(2)}}{c_{A^+}^{(1)}}\exp\left(\frac{EF}{RT}\right), \quad \frac{\gamma_{B^+}^{(1)}}{\gamma_{B^+}^{(2)}} = \frac{c_{B^+}^{(2)}}{c_{B^+}^{(1)}}\exp\left(\frac{EF}{RT}\right) \quad (10)$$

The activity coefficients of each permeable ion in one of the two solutions can be determined provided that the ionic activity coefficients in the other solution are available.

The Donnan membrane potential is usually measured

with a cell, saturated calomel electrode/saturated KCl bridge/solution 1/membrane/solution 2/saturated KCl bridge/saturated calomel electrode. The electromotive force of such a cell involves the liquid junction potentials at the junctions between the KCl bridges and the solutions. Therefore, the accuracy of the ionic activity coefficients determined by Eq. (10) is affected by the accuracy of correcting the measured electromotive force for the liquid junction potentials.

This method of determining ionic activity coefficients in mixed solutions is not exclusively restricted to such a simple system as mentioned above, but can be equally applied to membrane equilibria which may involve any desired combination of uni-univalent and uni-multivalent electrolytes, if the membranes are properly selected.

Experimental

In studying Donnan membrane equilibria with simple electrolytes it is important to use membranes with the following properties: (i) a very high degree of ionic selectivity towards cations over anions or *vice versa*, (ii) sufficiently high rates of exchange of permeable ions across the membrane so that the system can reach the equilibrium state within a reasonable period of time, and (iii) low water permeability. The requirement for membranes to fulfill the last two conditions is somewhat antagonistic. The ohmic resistance of membranes is an indication of the rates of ion exchange and water movement across the membranes; membranes of lower resistance which allow higher rates of ion exchange, tend to show higher water permeability.

By far the most suitable porous membranes for the experimental study of Donnan membrane equilibria with simple electrolytes are the permselective collodion matrix membranes developed by Sollner and collaborators, particularly the exclusively cation-permeable sulfonated polystyrene collodion membranes and the exclusively anion-permeable protamine collodion membranes,[26] which show excellent ionic selectivities.[4,5,9-11] Moreover their ion exchange capacity per cm^2 is very low, a decided advantage in many experimental situations. The information available on these permselective membranes with respect to their ionic selectivity, the rate of exchange of permeable ions across them, the water permeability, *etc.* makes it possible to select membranes with a suitable combination of the properties mentioned earlier.

Permselective sulfonated polystyrene collodion membranes were prepared by the dissolution method described by Neihof,[9] and permselective protamine collodion membranes by the adsorption method.[5] The membranes were test-tube-shaped (25×100 mm) and mounted on glass collars. They were tested for (a) their ohmic resistance in 0.1 M KCl, (b) their ionic selectivity, and (c) their water permeability. Membranes with resistances of several tens ohm cm^2 were considered to be most suitable. The membrane concentration potential of a concentration cell, such as 0.4 M KCl/membrane/0.2 M KCl, is a good measure of the ionic selectivity. We selected the membranes which showed the membrane concentration potential in agreement with the theoretical maximum value within 0.5 mV.

In studying Donnan membrane equilibria the most important experimental consideration is that the rate of exchange of permeable ions across the membrane should be very much faster than the rate of leakage of nominally impermeable ions. Typical results given in Table 1, which is reproduced from a paper by Sollner,[11c] clearly show that the leak of anions, particularly that of bivalent anions, is practically negligible with membranes of the type used here.

The water permeability of membranes was measured by a method similar to that used by Neihof.[27] The test-tube-shaped membrane was tied to a glass collar which was fitted with a rubber stopper carrying a micro-measuring-pipette. The membrane was filled with 30 ml of 0.1 M KCl and immersed in a beaker containing 60 ml of distilled water. The increase in the volume of the inside solution was read by the micro-measuring-pipette at given intervals. The average rate of water movement under these conditions amounted only to 0.03—0.04 ml per 100 cm^2 of membrane area per hour.

Protamine collodion membranes have properties similar but slightly inferior to those of sulfonated polystyrene collodion membranes.

TABLE 1. RATES OF CATION EXCHANGE AND ANION LEAK ACROSS TWO CATION-PERMEABLE SULFONATED POLYSTYRENE COLLODION MEMBRANES USED IN THE STUDY OF DONNAN MEMBRANE EQUILIBRIA[a]

Resistance of membrane in 0.1 M KCl	Original solutions		Cation exchange after 1 hr	Anion leak after 1 hr	Cation exchange after 4 hr	Anion leak after 4 hr
	Solution 1 (inside)	Solution 2 (outside)				
Ohm cm^2	equiv/l	equiv/l	per cent of possible exchange	per cent of actual cation exchange	per cent of possible exchange	per cent of actual cation exchange
60	0.1 NH_4Cl	0.1 $LiNO_3$	35.0	not detectable	83.0	<0.5
90	0.1 NH_4Cl	0.1 $LiNO_3$	29.0	not detectable	68.5	<0.5
60	0.1 $(NH_4)_2C_2O_4$	0.1 Li_2SO_4	35.0	not detectable	79.5	<0.05
90	0.1 $(NH_4)_2C_2O_4$	0.1 Li_2SO_4	29.5	not detectable	73.0	<0.05

a) The data were reproduced from Table 5 in Ref. 11c.

26) After completion of this work new anion-permeable membranes of better properties than old protamine collodion membranes were developed by Sollner and collaborators (see Ref. 10).

27) Ref. 9. See also K. Sollner and I. Abrams, *J. Gen. Physiol.* **24**, 1 (1940).

The ion distribution between two solutions separated by a membrane at the equilibrium was determined by the following two methods, one being called "static", and the other, "flow" or "dynamic" method. The latter is expected to be more suitable than the former for the systems of greater concentration ratios of impermeable ions and for the study of the activity behavior.

In the static method, the inside of a test-tube-shaped membrane was filled with 30 ml of one electrolyte (solution 1), and the membrane was immersed in a larger test tube containing 60 ml of the other electrolyte (solution 2). The membrane was equilibrated with the solutions to be examined prior to each experiment. Both solutions were stirred by passing purified nitrogen or air through the solution. After the membrane equilibrium had been attained, the solutions were analyzed for every ion involved.

Before each experimental run, a preliminary kinetic study was made to determine the time required to establish the equilibrium. Figure 1 shows an example of the kinetic study with a cation-permeable sulfonated polystyrene collodion membrane for the systems of potassium oxalate–ammonium oxalate and potassium oxalate–ammonium sulfate. In all our present systems the equilibrium was reached well within 15 hr.

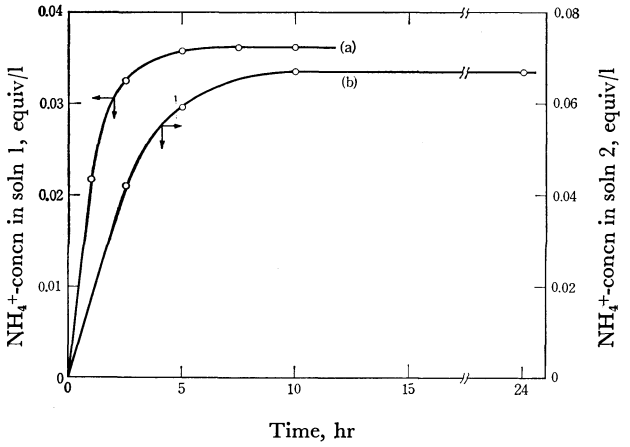

Fig. 1. Exchange of ammonium ions across a permselective cation-permeable sulfonated polystyrene collodion membrane in the course of approach to the membrane equilibrium by the static method. Initial state: (a), 0.200 M $K_2C_2O_4$ (soln 1) |←⊕→| 0.0100 M $(NH_4)_2C_2O_4$ (soln 2); (b), 0.100 M $(NH_4)_2SO_4$ (soln 1) |←⊕→| 0.100 M $K_2C_2O_4$ (soln 2). Volume of solution: soln 1/soln 2=30 ml/60 ml.

In studying the activity of ions by means of Donnan membrane equilibria, it is desirable to keep the composition of one of the two solutions practically unchanged during equilibration with the other solution. Theoretically this can be done by making the volume of the reference solution infinitely larger than that of the test solution.[8] The above-mentioned requirement is effectively satisfied by the *flow method*, that is, by running a large quantity of the reference solution (usually the more dilute solution) at a given constant rate by the outside of a test-tube-shaped membrane which contains the solution to be examined. By this method it is not necessary to determine analytically the equilibrium concentrations of ions in the reference solution; also, it makes it possible to use a very dilute reference solution and to study Donnan equilibria at large concentration ratios of impermeable ions. Furthermore, the flow method has the advantage that the approach to equilibrium can be checked by withdrawing a small amount of inside solution for analyses at given intervals; the change in the volume of the inside solution does not affect the equilibrium since the composition of the outside solution remains at the original, nominal level throughout.

In the present study, the initial volume of the inside solution (solution 1) was 25 ml, and about 60 l of the reference solution (solution 2) was run continuously by the outside of the membrane within about one week. The osmotic water movement across the membrane was compensated by adding a proper amount of impermeable neutral species, sucrose or glucose, to solution 2.[28] Both solutions were stirred by the gentle stream of purified nitrogen or air. A known quantity (1 ml) of the inside solution was pipetted out at given intervals, and analysed for the permeable ions in order to follow the kinetics of the ion exchange and to determine the equilibrium concentrations. The equilibrium was checked by running parallel the same experiments starting from both sides of the equilibrium with a common reference solution. Figure 2 shows a typical example of the kinetic approach to the equilibrium by the flow method, where the method was applied to the system containing potassium and ammonium oxalates. When the concentration ratio of impermeable ion was greater than 20, at least four days were required for the system to attain the equilibrium state.

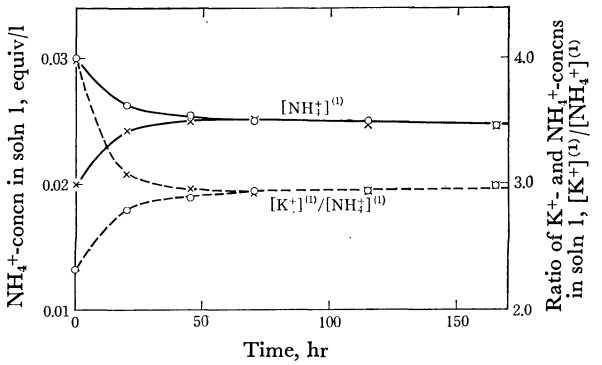

Fig. 2. Exchange of permeable ions, NH_4^+ and K^+, across permselective cation-permeable sulfonated polystyrene collodion membranes in the course of approach to the membrane equilibrium by the flow method. Initial state: solution 1, 0.0350 M $K_2C_2O_4$+0.0150 M $(NH_4)_2C_2O_4$ (-○-) and 0.0400 M $K_2C_2O_4$+0.0100 M $(NH_4)_2C_2O_4$ (-×-); common reference solution 2, 0.000750 M $K_2C_2O_4$+0.000250 M $(NH_4)_2C_2O_4$+0.120 M glucose. Solid lines represent the change in the NH_4^+-concentration in solution 1, and broken lines the change in the concentration ratio $[K^+]^{(1)}/[NH_4^+]^{(1)}$.

The membrane potential at the equilibrium was measured at 25.00±0.05 °C by constructing a conventional electrical cell with two saturated calomel electrodes.[5c] The contribution of liquid junction potentials was estimated by using Henderson's equation and ionic mobility data. The accuracy of the membrane potential thus obtained is considered to be ±0.5 mV in most cases.

28) The addition of impermeable neutral species to the less concentrated solution is a convenient and effective method of eliminating the osmotic water movement across the membrane. This method, however, has a drawback that the activity coefficients of the ions to be studied may or may not be influenced by the presence of some foreign materials. In the study of activity coefficients it will be better to use another method of compensating the effect of the osmotic water movement by blowing appropriately dried air at the proper rate through the more concentrated solution to keep its volume constant. Refer to R. Neihof and K. Sollner, *J. Phys. Chem.*, **61**, 159 (1957).

The concentrations of sodium and potassium ions were determined gravimetrically by the following method. A known volume of the sample solution was evaporated to dryness in order to remove ammonium salts present in the solution. Then the sodium or potassium salts were changed to the sulfate form by a conventional method using a proper amount of sulfuric acid. The sodium or potassium concentrations of the original solution were computed from the weight of the sulfate salts. Ammonium ions were determined by the micro-Kjeldahl method, chloride ions by the Volhard method, and oxalate ions were titrated with a standard potassium permanganate solution in acidic media. The accuracy of these analyses was better than ±0.5% except for concentrations below 0.05 equiv/l.

Results and Discussion

The results of seven typical experiments on Donnan membrane equilibria across permselective membranes, five obtained by the static method and two by the flow method, are given in the self-explanatory Tables 2, 3, and 4. Table 5 summarizes the ratios of activity coefficients of the permeable ions in mixed electrolyte solutions as calculated from the Donnan membrane equilibrium data (Tables 2—4) according to Eqs. (9) and (10).

From these results the following information is obtained with respect to the activity coefficients of the

c) Calculated by Eq. (9).

permeable ions:
(i) In the sodium chloride–sodium nitrate systems with anion-permeable membranes (Experiments I and II), the constancy of the equilibrium concentration ratios as given by the original Donnan equation (8) is satisfied within the limit of experimental errors, which proves the almost identical behavior of the activity coefficients for chloride and nitrate ions in the solutions examined.
(ii) Experiment III shows that Eq. (8) is satisfied and the equilibrium concentration ratio is practically equal to the Donnan activity ratio in the ammonium sulfate–potassium oxalate system of the same anion concentration. This result shows that the activity coefficients of potassium and ammonium ions are not much affected by the change of anions from sulfate to oxalate.
(iii) In the potassium oxalate–ammonium oxalate system (Experiment VII), Eq. (8) is also satisfied with a reasonable accuracy, but the equilibrium concentration ratio is appreciably larger than the Donnan activity ratio. This means that the activity coefficients of potassium and ammonium ions in oxalate solutions decrease in a similar manner with increasing oxalate concentration from 0.002 to 0.1 equiv/l.
(iv) In Experiments IV—VI the constancy of the equilibrium concentration ratios is not fulfilled. The results given in Table 5 suggest that the activity coefficients of ammonium ion are slightly smaller than those of potassium and sodium ions in oxalate or sulfate solutions of concentrations higher than about 0.2 equiv/l.

The present study clearly demonstrates that the method proposed by Sollner[8] is quite feasible to the investigation of ionic activity coefficients in mixed electrolyte solutions on the basis of the Donnan membrane equilibrium. It was verified that the flow method has the following advantages over the static method when used in the study of the Donnan membrane equilibria: (i) a solution of a fixed composition can be used as the reference in a series of experiment, because the composition of the reference solution can be kept unchanged throughout the course to the equilibrium; and (ii) very dilute reference solutions can be employed in the determination of ionic activity coefficients in more concentrated solutions; this is of practical importance because with very dilute reference solutions the influence of any leakage of the membrane is minimized.

In principle, the Donnan membrane equilibrium is not restricted to the systems containing only strong electrolytes, but can equally be applied to any system involving partially dissociated electrolytes and neutral substances as well. With further developments of membranes of various types, porous or liquid, with ever increasing ionic selectivity and specificity, a large area will be opened up for the experimental study of ionic activity behavior in solutions of any desired composition and concentration. The studies along this line should be of interest not only in physical chemistry but also in colloid and biological chemistry.

This study was suggested by Dr. K. Sollner, Chief of the Section on Electrochemistry and Colloid Physics, National Institute of Arthritis, Metabolism, and Digestive Diseases, and carried out under his guidance. The author wishes to express his heartfelt thanks to Dr. Sollner for his valuable advice, critical discussions, and continual encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2708—2711 (1973)

Conformation of Poly(*S*-benzyl-L-cysteine) in Solution

Hiroshi MAEDA, Takashi INOUE, Masa-aki TSUNODA, and Shoichi IKEDA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received April 3, 1973)

Conformation of poly(*S*-benzyl-L-cysteine) was investigated by measurements of optical rotatory dispersion, infrared absorption and viscosity in dichloroacetic acid (DCA)–chloroform mixtures. Transition from random coil to the β-structure was confirmed to occur when DCA content of the solvent was reduced below 40% (v/v). Both dispersion parameters a_0 and b_0 increased as the polymers were transformed into the β-structure. Viscosity of the polymer solution changed only slightly with accompanying the transition. This was interpreted in terms of the formation of intramolecular β-structure. In the region where the β-structure was dominant both optical rotatory parameters and viscosity were independent of solvent composition. Such behavior has been rarely observed in the β-coil transition of other polypeptides. The β-structure of poly(*S*-benzyl-L-cysteine) was shown to be more stable than that of poly(*O*-benzyl-L-serine) as referred to respective random coil conformations.

Early studies on the β-structure in solution were mostly carried out in organic solvent systems for the purpose of detecting the β-structure in solution for the polypeptides which had been confirmed to be in this conformation in solid state. Short chain poly(γ-benzyl-L-glutamate)[1-5] and polymers of the derivatives of

serine,[6-8] cysteine,[9-12] and threonine[13] have been shown experimentally to assume the β-structure in solution under suitable conditions (solvent composition, polymer concentration, temperature, *etc.*).

Those studies were also aimed at deducing experimentally the optical rotatory properties of the β-structure. It was commonly found that the increase in dextrorotation due to the formation of the β-structure as compared with the random coil conformation.[1-3,5-13] However, different results have been obtained about the Moffitt-Yang parameter b_0.[14,15] The parameter increased in many cases,[3,6-8,10-13] but it remained constant in others.[9,12] The extent of increase in b_0 was not unique, being fairly large in some cases[3,7] and small in others.[6,8,10-12] The different behavior of the change in b_0 has not been clarified so far.

With recent development in the preparation of protolytic polypeptides capable of forming the β-structure,[16-18] it has become possible to make various approaches to a study of the β-structure in solution. Nevertheless, the importance of its study in organic media is by no means reduced, since the β-structure in both organic solvents and aqueous media can not be assumed *a priori* to be identical. This is partly supported by the significant role assigned to the hydrophobic interaction in the β-structure in aqueous media.[19]

In the present study, the β-random coil transition of poly(*S*-benzyl-L-cysteine) was investigated in a mixed solvent system of dichloroacetic acid (DCA)–chloroform. The polymer was chosen because it has a less polar side chain than that of other polypeptides forming the β-structure,[1-13] and also because a comparison of the β-structures of serine and cysteine derivatives will be best attained, when polymers of their benzyl esters are compared.

The conformation of the present polypeptide in solid state was previously shown to be of β-structure.[20,21]

Experimental

Materials. *S*-Benzyl-L-cysteine was prepared according to the literatures.[22,22] *S*-Benzyl-*N*-carboxy-L-cysteine anhydride was synthesized as usual. Mp 109—110 °C. Polymerization was carried out in dichloromethane using sodium methoxide as an initiator. Polymer solutions were prepared by dissolving a weighed amount of the polymer into a mixed solvent prepared in advance.

Optical Rotatory Dispersion (ORD). The rotatory dispersion was measured on a JASCO ORD/UV 5 spectropolarimeter using a 1 cm cell at 25 °C. The wavelength region examined was 300 to 550 nm. Polymer concentration c was about 0.5 g/dl unless otherwise stated. The results were analyzed in terms of the Moffitt-Yang equation,[14,15]

$$[m'] = [3/(n^2+2)][\alpha](M_0/100)$$
$$= a_0\lambda_0^2/(\lambda^2-\lambda_0^2) + b_0\lambda_0^4/(\lambda^2-\lambda_0^2)^2$$

Additivity of the term $[3/(n^2+2)]$ was assumed for different solvent compositions.

Viscosity. Viscosity was measured at 25.0 °C using Ubbelohde type viscometers. Flow times of the solvents were larger than 100 s. Reduced viscosity was measured in the concentration range below 1 g/dl and plotted against c. Intrinsic viscosity $[\eta]$ and Huggins' constant k' were obtained from the intercept and slope of the plot, where k' was defined as $(1/[\eta]^2)\mathrm{d}(\eta_{sp}/c)/\mathrm{d}c$.

Infrared Spectra. Infrared spectra were recorded on a JASCO DS 402-G spectrophotometer at 25 °C. For determination of the spectra in solution, a cell with potassium bromide windows was used.

Results and Discussion

Solubility and Its Change with Time. Solubility of the sample D1119 in both DCA and chloroform was very low (less than 0.5 g/dl at 25 °C), but a mixture of the two liquids was found to serve as a solvent. Solutions with polymer concentration of about 0.5 g/dl were obtained when the DCA content was 4—80% (v/v). However, the solubility was found to change considerably after storage of the sample for about a year in a desiccator over P_2O_5. The range of DCA content giving solutions of the aged sample to the same concentration was reduced to 15—80%. Various measurements were then made on the aged sample. Almost the same results were obtained but quantitative agreement was not attained for some properties. The aged sample was designated D1119A and treated as a different sample.

Low solubility in DCA has been reported on the β-structure of polypeptides with nonpolar side chains, such as polyglycine I, poly-L-alanine, and poly-L-valine.[24] Thus similar behavior found in the present polymer might be attributed to the relatively nonpolar side chains involved.

Conformation of the Polymer in Solid State. Infrared spectra of the polymer in solid films cast from DCA–chloroform solutions showed amide I band at 1629 and 1694 cm^{-1} and amide II band at 1520 cm^{-1}. Thus the β-structure with antiparallel arrangement of adjacent chains can be assigned to the conformation of the polymer in solid state, which is consistent with previous results.[20,21]

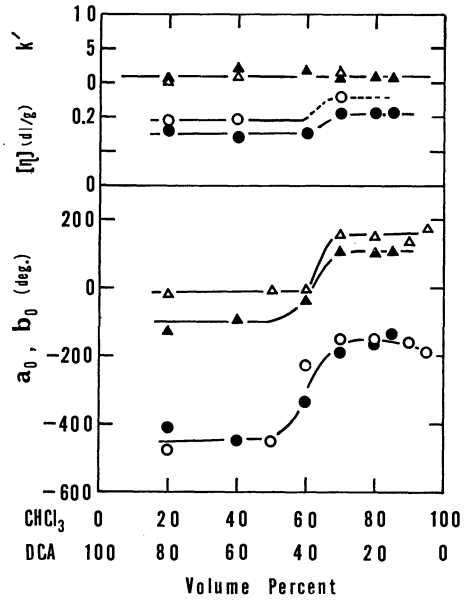

Fig. 1. Solution properties as a function of solvent composition. Polymer concentration: 0.5 g/dl. 25 °C. Circles: a_0 and intrinsic viscosity [η]. Triangles: b_0 and Huggins' constant k'. Open marks refer to D1119 and filled ones to D1119A.

Conformation of the Polymer in DCA–Chloroform Mixtures. The optical rotations of all polymer solutions were levorotatory everywhere in the wavelength region examined. The values of a_0 and b_0 are plotted in Fig. 1 against solvent composition. In the solvents of high DCA content (greater than about 50%) the dispersion is characterized by constant values of b_0 which are about zero for D1119 and −100° for D1119A. On further reduction of DCA content, b_0 begins to increase up to about 150 and 100°, respectively, indicating a conformational transition. The transition seems to be complete when DCA content reaches 30% or less, since no further change in b_0 is observed. Another parameter a_0 is also shown to increase around this region (DCA 30—50%) and to reach an almost constant value. A difference in the two samples is not detectable in the case of a_0.

Infrared spectra of the sample D1119 in solutions of low DCA content are given in Fig. 2. The difference spectra were obtained by subtracting the spectra of solvent from those of the solution. The amide I band splits into two peaks, one at 1630 cm^{-1} and the other at 1695 cm^{-1}. The results demonstrate that the conformation of the polymer in the solution is the β-structure with antiparallel arrangement of adjacent chains. Thus we can reasonably interpret the rotatory behavior in terms of the transition between random coil and β-structure.

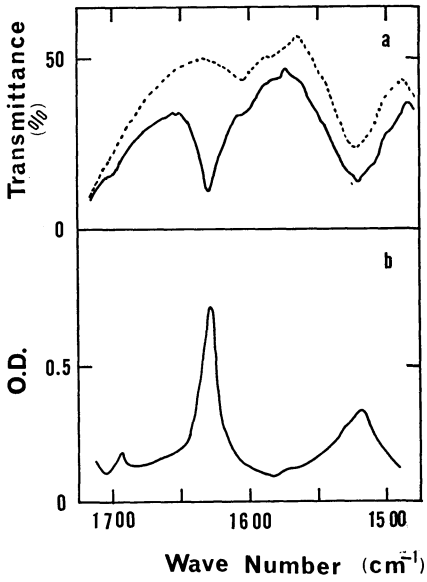

Fig. 2. Infrared spectra of the polymer solution. Sample: D1119. Solvent composition: DCA 5%–$CHCl_3$ 95% (v/v). Polymer concentration: 1 g/dl. Cell length: 200 μ.
(a) Spectra of the solution (solid line). Spectra of the solvent (broken line).
(b) Difference spectra of the polymer in solution.

Values of both intrinsic viscosity and Huggins' constant are also shown in Fig. 1. In the composition range where rotatory property changes sharply (DCA 30—40%), a slight but definite change in intrinsic viscosity occurs. Since the conformational transition from random coil to β-structure is confirmed to occur in this solvent composition range, the observed change in viscosity can be regarded to correspond to the transition. Contrary to the drastic changes in rotatory property, which is considered to reflect both the conformational change and the effect of polarity of the environment of chromophores, viscosity shows no such large change accompanying the transition. Since viscosity represents over-all shape and dimension of polymer chains and the effect of association as well, the results obtained strongly suggests that the β-structure of the present polymer is formed intramolecularly and that the association of polymers does not play a significant role in the formation of the β-structure. Huggins' constant also shows no appreciable change accompanying the transition, which has been known to be a measure of interparticle hydrodynamic interaction. It should be noted that changes in both intrinsic viscosity and Huggins' constant are many times larger than those obtained in the present study if association of polymers is essential for the formation of the β-structure.[10]

We can obtain the change in b_0 accompanying the transition to be about 150° (from 0 to +150°) or 200° (from −100 to +100°). This large change in b_0 is similar to that of poly(*O*-benzyl-L-serine),[7] these polypeptides differing from others in this respect. On the other hand, the increase in a_0 accompanying the transition is about 300° (from −450 to −150°), which is smaller than any other reported values for the coil to β transition. Generally, two contributions to a_0

should be taken into account, one from conformation-dependent optical activity and the other from environmental effect for chromophores. Since more peptide groups are considered to be solvated with DCA in the intramolecular β-structure than in the intermolecular one, the observed small increase in a_0 may be a support for the intramolecular β-structure of the present polymer.

Effect of Polymer Concentration. Effect of polymer concentration was examined using the sample E1119 at three values of c, 0.490, 0.802, and 1.173 g/dl, in the solvent of DCA content 5%. The values of b_0 were found to be constant (180—190°) and those of a_0 to slightly decrease with concentration. That rotatory properties are independent of polymer concentration also supports the assignment of the intramolecular β-structure.

Stability of the β-Structure. Comparison of the stability of the β-structure of the present polymer with that of poly(*O*-benzyl-L-serine)[7] becomes possible since temperature and solvent system (DCA–chloroform) are identical. If we assume that the β-structures of both polypeptides are molecularly dispersed, we can compare the stability in a quantitative manner, following the reasoning by Auer and Doty.[25] The composition where the midpoint of transition is located is about 10% DCA in the case of poly(*O*-benzyl-L-serine). This is considerably smaller than the value of about 35% DCA in the present polymer. Hence the difference in stability amounts to 2.303 RT log (35/10).[25] This demonstrates that the relative stability of the β-structure as referred to the random coil is larger by about 760 cal per mole of residue than that of the corresponding serine polymer. Since the chain length (as judged from intrinsic viscosity in DCA) and concentration of the two polymers were almost the same in the two experiments, the observed difference would be explained in terms of the difference between sulfur atom and oxygen atom involved in the respective side chains. It should be noted that association of polymers was not necessarily ruled out in the formation of the β-structure of poly(*O*-benzyl-L-serine), because viscosity was not measured.[7] Thus, if association was significant for the β-structure of poly(*O*-benzyl-L-serine), the estimated figure for the difference in stability becomes meaningless.

It should be emphasized that in the present system both optical rotatory parameters and viscosity were independent of solvent composition when the β-structure became dominant. Such behavior has been rarely reported for the β-coil transition.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2711—2715 (1973)

Counterion Effect on the Titration Behavior of Poly(maleic acid)

Nobuhiko MUTO, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received April 10, 1973)

The potentiometric titration of poly(maleic acid) (PMaA) in aqueous solutions containing alkali metal salts and a tetramethylammonium salt was carried out at 25 °C, and the effect of the counterions on the titration behavior of PMaA was examined in detail. The acidity of the primary carboxylic groups of PMaA increases in the order of $(CH_3)_4N^+ < Li^+ < Na^+ < K^+$, whereas that of the secondary carboxylic groups increases with the decrease in the crystallographical radius of the counterions, in agreement with the results for ordinary polycarboxylic acids. The order of $K^+ > Na^+ > Li^+$ for the binding strength to the primary carboxylate groups of PMaA is interpreted in terms of the radius of the hydrated cations; it can be attributed to the stable ring structure of the monoanion of the maleic acid residue, resulting from the hydrogen bonding between two adjacent carboxylate groups.

It is well known that the titration behavior of weak polyelectrolytes is remarkably affected by the nature of the counterions. This can be ascribed to the polyion-counterion interaction caused by the high electrostatic potential around the macroions. Gregor *et al.*[1,2] investigated the effect of alkali metal ions and tetraalkylammonium ions on the titration behavior of poly(acrylic acid) and poly(methacrylic acid), and demonstrated that the acidity of those polymonocarboxylic acids decreases with the increase in the counterion size; that is, the alkali metal ions are bound to the polyanions in the order of $Li^+ > Na^+ > K^+$. Similar phenomena have been observed in connection with the viscosity,[3] the conductivity,[3,4] and the counterion activity[5] in such polyelectrolyte systems.

As for polydicarboxylic acids, several studies have been performed on counterion binding with maleic

acid copolymers,[6-9] though few papers have described the effect of alkali metal ions in detail. Recently, homopolymers of maleic anhydride have been prepared by the use of γ-irradiation[10] and radical initiators,[10-12] and the titration behavior of their hydrolysis products in added salt-free solutions has been briefly reported.[10,13] The counterion effect on the behavior, however, has still not been adequately examined.

The present authors have synthesized a homopolymer of maleic anhydride by radical polymerization in acetic anhydride and have carried out the potentiometric titrations of the hydrolysis product, namely, poly(maleic acid) (PMaA), in aqueous solutions containing added salts. The present study will deal with the effects of alkali metal ions (Li^+, Na^+, and K^+) and the tetramethylammonium ion on the titration behavior of PMaA. Especially, the binding of the alkali metal ions to the primary carboxylate groups of PMaA will be discussed.

Experimental

The PMaA sample was prepared by reference to the procedure of Lang *et al.*[10] as follows. Maleic anhydride was polymerized in an acetic anhydride solution containing 50 wt% monomer and 3 wt% α,α'-azobisisobutyronitrile at 80 °C for 48 hr. The reaction mixture thus became a deep purple color.[10] From the reaction solution diluted with methyl ethyl ketone, the polymer was separated by precipitation in toluene. The poly(maleic anhydride) was purified by reprecipitation and dried *in vacuo* at 60 °C. The product retained a slight purple tint.[10,12] Found: C, 47.03; H, 3.67; N, 1.23%. Calcd for $(C_4H_2O_3)_n$: C, 48.92; H, 2.20%. The molecular weight of the poly(maleic anhydride) was determined by means of vapor-pressure osmometry to be 2500. The intrinsic viscosity, $[\eta]$, in acetophenone was 0.082 dl/g at 25.0 °C. The anhydride polymer was hydrolyzed in water at 80—90 °C for 6 hr. The PMaA solution was standardized potentiometrically and stored in a polyethylene container at 5 °C.

The titrants, NaOH and $Ba(OH)_2$ solutions, were prepared so as to be carbonate-free. As added neutral salts, the nitrates of lithium, sodium, and potassium, and tetramethylammonium chloride were used. All the chemicals used were of a guaranteed reagent grade. The maleic and acetic anhydrides were purified by distillation. All the aqueous solutions were prepared by the use of deionized water.

The pH values were measured by the aid of a Yokogawa KPH-51A pH meter, with Toa Denpa HG-4005 glass and HC-205 calomel electrodes separated by a saturated KCl-agar salt bridge. The titrations were performed in a special titration vessel maintained at 25.0 °C under a nitrogen atmosphere. It was found that the acid-base equilibrium was not immediately attained in the region around and beyond the half-neutralization point of PMaA. Similar phenomena have been observed in the cases of other polyacids.[14,15] In this region, the solutions were stirred for 15 min—1 hr after each addition of a certain amount of the base, until the pH readings were ascertained to be constant; then the titrations were resumed. The repeated-titration curves were reproducible to within ± 0.01 pH unit.

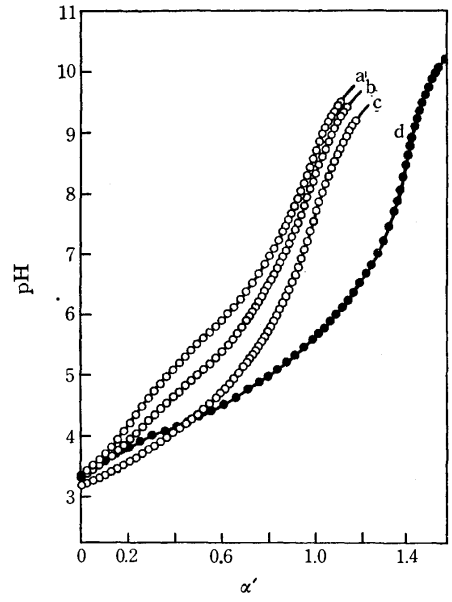

Fig. 1. The pH titration curves of 3.88×10^{-3} N PMaA (in the primary carboxylic groups) with NaOH in water (a), in 0.01 mol/l $NaNO_3$ (b), in 0.1 mol/l $NaNO_3$ (c), and with $Ba(OH)_2$ in water (d).

Results and Discussion

Figure 1 shows the pH titration curves of PMaA with NaOH and $Ba(OH)_2$ in water or in the presence of $NaNO_3$, where α' is the degree of the neutralization of the primary carboxylic groups of PMaA. Each titration curve with NaOH (open circles) has an inflection point at the same degree of neutralization ($\alpha'=1.0$), which corresponds to the equivalent point of the primary carboxylic groups, regardless of the ionic strength. It has been found that the carboxylic groups of PMaA as well as those of the ethylene–maleic acid copolymer[6] dissociate in two distinct steps.[10,13] The titration curve with $Ba(OH)_2$ (solid circles) had the end point for the total (primary and secondary) carboxylic groups at $\alpha'=1.4$. This indicates that, in the present PMaA sample, part of the secondary carboxylic groups (60%) are lost or are turned into some nonionic forms by side reactions in the course of the polymerization; as a result, there are many single carboxylic groups besides vicinal ones derived from the anhydride units. This finding is similar to that of Braun *et al.*,[12] who carried out the radical homopolymerization of maleic anhydride in organic solvents.

Figure 2 illustrates the titration curves of PMaA with

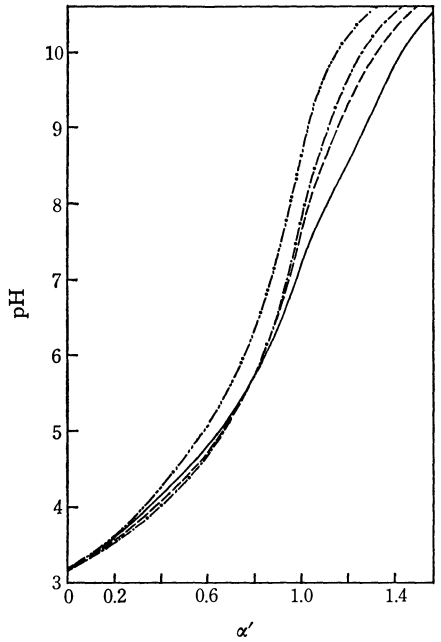

Fig. 2. The pH titration curves of 3.88×10^{-3} N PMaA with NaOH in 0.1 mol/l $LiNO_3$ (——), $NaNO_3$ (------), KNO_3 (-·-·-), and $(CH_3)_4NCl$ (·····).

NaOH in 0.1 mol/l solutions of four kinds of 1-1 salts. The first equivalent point is independent of the sort of added salt as well. Since, in these titrations, the added salt concentration (0.1 mol/l) is much higher than that of polyacid (*ca.* 10^{-3} N primary carboxylic groups), the dissociation behavior of PMaA must be substantially influenced by the cations of added salts, in spite of the use of NaOH as a titrant in all cases.

The effect of the four kinds of cations in the first dissociation step seems to differ from that in the second one. In the second dissociation step ($\alpha'\geq1.0$), the pH values at a given α' decrease in the order of $(CH_3)_4N^+>K^+>Na^+>Li^+$, in agreement with the cases of ordinary polycarboxylic acids.[1] On the other hand, in the first dissociation step a peculiar effect of the alkali metal ions is observed; that is, the pH values at a given α' decrease in the order of: $(CH_3)_4N^+>Li^+>Na^+>K^+$ in the region of $\alpha'\leq0.8$. It has been found that, in the titrations of the ethylene–maleic acid copolymer with KOH and $(CH_3)_4NOH$,[6] the pH values decrease in the order of: $(CH_3)_4N^+>K^+$ over the whole range of α'. This fact indicates that the potassium ion is bound to the polymer in a certain way.[6] Lang *et al.*[10] carried out similar titrations of PMaA with LiOH, NaOH, KOH, and $(CH_3)_4NOH$, but they made no reference to the specific effect of the alkali metal ions in the first dissociation step.

In order to characterize this counterion effect, the apparent acid-dissociation constants (K) were calculated from the titration curves according to this equation:

$$pK = pH + \log\frac{1-\alpha}{\alpha} \qquad (1)$$

where α is the degree of dissociation of the primary carboxylic groups of PMaA. The α values were determined from the electroneutrality condition in acidic solutions;

$$\alpha = \frac{[NaOH]+[H^+]}{[A_t]} = \alpha' + \frac{[H^+]}{[A_t]} \qquad (2)$$

where $[A_t]$ represents the total concentration of the primary carboxylic groups; the $[H^+]$ values were calculated from the measured pH values, with a correction for the activity coefficient ($\gamma_{H^+}=0.83$ at the ionic strength of 0.1[16]). It is well known that the apparent dissociation constant for weak polyacids continuously decreases with the increase in α. This effect is connected with the increasing difficulty in the removal of

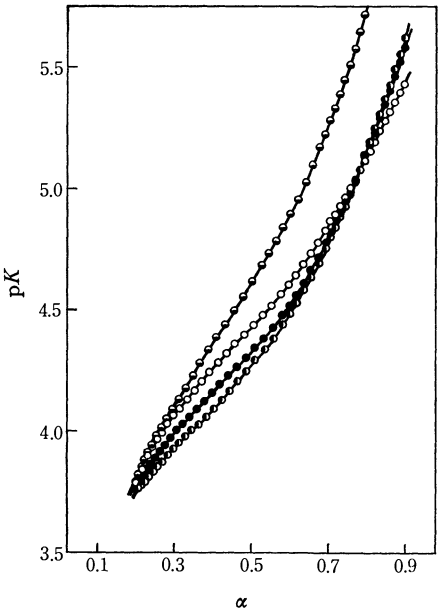

Fig. 3. The dependence of pK on α, calculated from the curves in Fig. 2. ○: $LiNO_3$, ●: $NaNO_3$, ◐: KNO_3, and ◒: $(CH_3)_4NCl$.

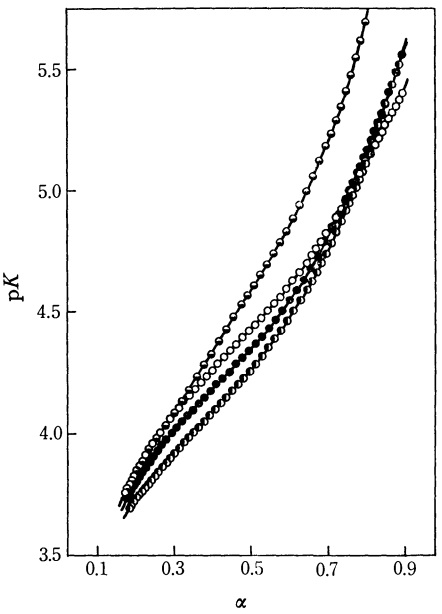

Fig. 4. The pK *vs.* α curves of 5.82×10^{-3} N PMaA with NaOH in 0.1 mol/l $LiNO_3$ (○), $NaNO_3$ (●), KNO_3 (◐), and $(CH_3)_4NCl$ (◒).

16) J. Kielland, *J. Amer. Chem. Soc.*, **59**, 1675 (1937).

protons from polyions with the increase in the charge on a polymer chain.[17]

Figures 3 and 4 show the pK *vs.* α curves. The latter was obtained at a polyacid concentration higher by 50% than the former. The curves with the same added salt are virtually superposed on each other, irrespective of the polymer concentration. In the case of poly(acrylic acid),[18] it has been found that the pK_{av} (pK at α=0.5) values at the same ionic strength are, in fact, constant over the concentration range of 10^{-3}—10^{-1} N polyacid.

Table 1. The pK_{av} values of the primary carboxylic groups of PMaA in 0.1 mol/l added salts

Counterion	Polyacid concentration[a]	
	3.88 mN	5.82 mN
$(CH_3)_4N^+$	4.61	4.59
Li^+	4.43	4.43
Na^+	4.33	4.35
K^+	4.27	4.27

a) In the primary carboxylic groups.

It is noticeable that, in the region of $\alpha \leq 0.8$, the pK values at a given α decrease in the order of: $(CH_3)_4N^+ > Li^+ > Na^+ > K^+$, and that the p$K$ curves in the presence of the alkali metal ions deviate most from each other in the region of $0.4 \leq \alpha \leq 0.5$. Table 1 summarizes the pK_{av} values of the primary carboxylic groups determined in Figs. 3 and 4. The differences in pK_{av} with the alkali metal ions (0.06—0.10 pK unit) are sufficiently larger than the estimated uncertainty on pK (0.02), not to mention the differences in the effect between the $(CH_3)_4N^+$ ion and the others. In such a case, the extent of the lowering in the pK or the increment in acidity gives a measure of the interaction between carboxylic groups and counterions.

On the basis of the assumption that no $(CH_3)_4N^+$ ions are bound to carboxylate groups in the PMaA–$(CH_3)_4NCl$ system, the degree of binding (θ) of the alkali metal ions (M^+) with the primary carboxylate groups (A^-) was calculated from the titration curves. The θ is defined by the equation:

$$\theta = \frac{[MA]}{[A_t]} = \frac{[A_t]-[HA]-[A^-]}{[A_t]} \qquad (3)$$

where [HA] and [A^-] are the concentrations of the undissociated and dissociated primary carboxylic groups respectively, and where [MA] is that of the primary carboxylate groups bound to the alkali metal ions. In Eq. (3), [HA] is found to be:

$$\begin{aligned}[HA] &= [A_t] - [NaOH] - [H^+] \\ &= [A_t](1-\alpha') - [H^+] \end{aligned} \qquad (4)$$

from the conservation and electroneutrality conditions. The [A^-] values in the 0.1 mol/l MNO_3 solutions are determined by the use of the reference curve for the 0.1 mol/l $(CH_3)_4NCl$ solution (Fig. 5). After the determination of the (pH+log[HA]) values for the 0.1 mol/l MNO_3 solutions at the same concentration of PMaA, the appropriate [A^-] concentrations in the MNO_3 solutions can be found in the reference graph. The scheme with the reference curve has been devised by Mandel *et al.*;[19] their method of calculation for the formation curves of metal-polyacid complexes from the titration curves is a modification of the method proposed by Gregor *et al.*[14]

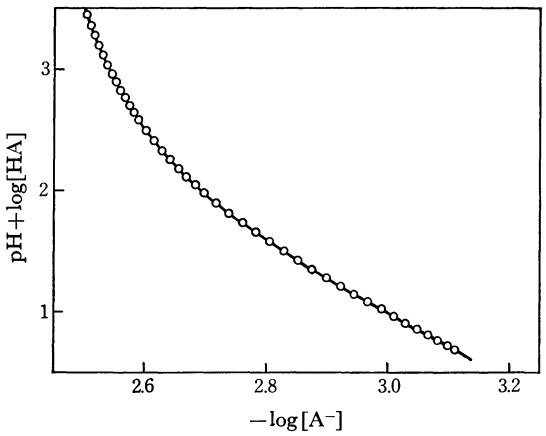

Fig. 5. The reference plot of 3.88×10^{-3} N PMaA in 0.1 mol/l $(CH_3)_4NCl$, for calculation of θ.

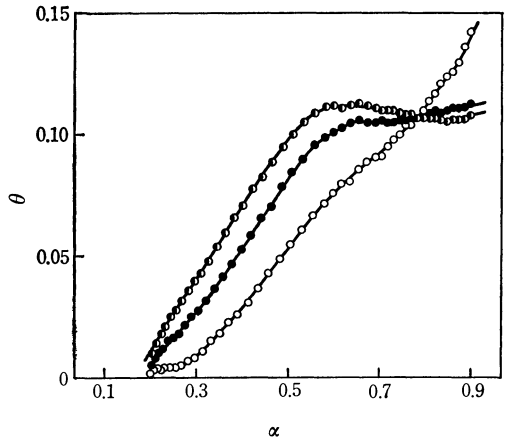

Fig. 6. The dependence of θ on α, calculated from the curves in Fig. 2. ○: Li^+, ●: Na^+, and ◐: K^+.

The dependence of θ on α is shown in Fig. 6. In the region of $\alpha \leq 0.8$, the binding strength was in the order of $K^+ > Na^+ > Li^+$, whereas in the region of $\alpha \geq 0.8$ the order was reversed. With the increase in α, the θ values in the cases of the K^+ and Na^+ ions were saturated so as to be practically constant (0.10—0.11) in the region of $\alpha \geq 0.5$. On the other hand, the θ values for Li^+ ions monotonously increased with α and grew much higher than those for other ions beyond α=0.8. Since, in the present PMaA sample, the equivalent point of the total carboxylic groups was found at α'=1.4, roughly half of the total carboxylic groups are dissociated at the above-mentioned point of α=0.8. That is to say, the dissociation behavior in the region of

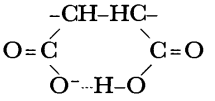
17) J. Th. G. Overbeek, *Bull. Soc. Chim. Belges*, **57**, 252 (1948).
18) J. V. McLaren, J. D. Watts, and A. Gilbert, *J. Polymer Sci., Ser. C*, **16**, 1903 (1967).
19) M. Mandel and J. C. Leyte, *ibid., Ser. A*, **2**, 2883 (1964).

$\alpha \leq 0.8$ may be influenced predominantly by the typical primary carboxylic groups in the maleic acid residues, and then in the region of the larger α values the single and the secondary carboxylic groups may dissociate. Thus, the present results indicate that the mode of the binding of the alkali metal ions to the primary carboxylate groups of PMaA differs from that to the secondary and the single carboxylate groups.

The binding order of $Li^+ > Na^+ > K^+$ with the secondary carboxylate groups of PMaA (Fig. 2) agrees with the results for ordinary polymonocarboxylates[1,3,4] and for the secondary carboxylate groups of maleic acid copolymers.[8] The latter were obtained in connection with dilatometric studies of the binding of Li^+ and K^+ ions to the carboxylate groups in 0.2 mol/l $(CH_3)_4NCl$ solutions.[8] The results can be explained in terms of the crystallographical ionic radius of alkali metals;[2] that is, the smallest Li^+ ion is bound to the largest extent.

It is noteworthy that the binding strength of the alkali metal ions to the primary carboxylate groups is in the order of: $K^+ > Na^+ > Li^+$. In general, the binding strength of ion pairs increases with the decrease in a certain ionic-size parameter as far as the same valence type is concerned. The order of the binding strength with the primary carboxylate groups can, therefore, be interpreted in terms of the radii of the *hydrated* alkali metal ions, which increase in the order of: $K^+ < Na^+ < Li^+$. In other words, in the first dissociation step of PMaA the so-called solvent-separated ion pairs between hydrated cations and carboxylate groups are predominant, not the so-called contact ion pairs interpreted in terms of the crystallographical ionic radii of the counterions.[2]

It can be presumed that the specific counterion binding to the primary carboxylate groups results from the peculiar structure of the maleic acid polymers, in which the local density of ionizable groups on the main polymer chain is much higher than that in ordinary polycarboxylic acids; hence, the interaction between neighboring groups must be considerable. Recently, Strauss *et al.* measured by dilatometry the volume changes associated with the binding of the hydrogen ion to the anions of maleic acid copolymers in 0.2 mol/l $(CH_3)_4NCl$ solutions,[8] and pointed out that the monoanion of the maleic acid residue has the following structure:



involving cooperative hydrogen bonding by two adjacent carboxylate groups.[8,20] Felber *et al.*,[7] who measured the heats of the protonation of the ethylene–maleic acid copolymer, have proposed the same structure in the first ionization process, too. In a monomeric maleic acid molecule, the intramolecular hydrogen bond of the hydrogen maleate anion has been confirmed.[21,22]

It is considered that, in the first dissociation step of PMaA, the monoanion of the maleic acid residue probably has a stable ring structure resulting from the hydrogen bond, in which a single electronic charge is distributed by resonance over a wide range. Therefore, the primary carboxylate groups, which would be bound to the alkali metal ions by nature, are more tightly bound to the protons of the secondary carboxylic groups. The present findings that hydrated alkali metal ions are more loosely bound to the primary carboxylate groups can be attributed to such a chelation of a proton with two adjacent carboxylate groups. In the second dissociation step, the intramolecular hydrogen bond almost disappears; hence, the contact ion pairs between alkali metal ions and carboxylate groups become predominant.

Finally, the potentiometric titration method has been found to be very useful in detecting such subtle differences in the modes of short-range interaction as the binding of counterions to polyelectrolytes. Similar studies will be performed on the titration behavior of other dicarboxylic acid polymers.

The authors wish to thank Professor Mitsuru Nagasawa of Nagoya University for generously supplying valuable unpublished data on PMaA and Associate Professor Seiichi Tokura of their own department for affording the facilities for the use of a vapor-pressure osmometer. The present work has been supported in part by a Grant for Scientific Research from the Ministry of Education.

Solvent Effect in Electron Spin Resonance Spectra and Electrochemical Reaction of Substituted Nitrobenzene Anion Radicals

Taitiro FUJINAGA, Yasuo DEGUCHI, and Kisaburo UMEMOTO*

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 5, 1972)

In order to examine the effect of solvents on the hyperfine splittings of anion radical the electron spin resonance spectra of substituted nitrobenzene anion radicals were studied. The effect of hydroxylic solvent is enhanced when the nitro group is forced out of the plane of the benzene ring due to the steric influence of the bulky functional group at the *ortho* position. The effect is reduced when the nitro group forms intramolecular hydrogen bond with the hydroxyl group at the *ortho* position. A model for the solvent effect considering the hindered rotation of the nitro group in the radical molecule caused by the formation of intermolecular hydrogen bond with solvent is found to be reasonable from a molecular orbital calculation, taking account of changes in molecular orbital parameters resulting from hydroxylic solvation. The shifts in polarographic half wave potentials with the solvent system as well as the dehalogenation reaction in the course of electrochemical reduction of halonitrobenzenes is interpreted by means of the model.

Several investigators have studied the solvent effect in electron spin resonance (ESR) spectra of organic anion radicals.[1-12] It is well-known that the hyperfine splittings in ESR spectra are influenced by the solvent characteristics as well as the species which interact with the radical in solution. The nitrogen coupling constant of di-*para*-anisyl nitric oxide increases with the increase of the dielectric constant of the solvent, the effect being remarkably enhanced in hydroxylic solvents such as water and alcohols.[2] The solvent effects of substituted nitrobenzene anion radicals were studied extensively by Adams and his co-workers[3-5] and summarized by Kitagawa;[6] the nitrogen coupling constant a^N of nitrobenzene anion radical produced electrochemically in aprotic solvents increases rapidly with the addition of a small amount of water. The effect is remarkable when the nitro group is sterically hindered. The presence of alkali metal cations also increases the a^N of *p*-chloronitrobenzene anion radical.[7] Theoretical studies of the dependency of the hyperfine splittings in ESR spectra on the solvent characteristics were undertaken by Reiger and Fraenkel[8] and Gendell *et al.*[9] on the assumption that the charge in the functional group is affected by the presence of localized complexes between the solvent and the functional group of the radical. Since then MO calculations have been recognized to be useful for the interpretation of the complicated phenomena observed in ESR spectra.[10-12] We have examined the solvent effect in ESR spectra as well as the electrochemical reduction of substituted nitrobenzene by MO calculation in order to clarify the nature of the solvent effect.

Experimental

All the nitro compounds, such as nitrobenzene, nitrophenol, 2-nitroresorcinol, nitrotoluene, nitroanisole, and halonitrobenzenes, were of G. R. grade and purified by recrystallization from benzene when necessary. Tetra-*n*-propyl ammonium perchlorate was prepared by adding perchloric acid to tetra-*n*-propyl ammonium hydroxide and purified by recrystallization from hot acetonitrile-water mixture. *N,N'*-Dimethylformamide (DMF) was dried over anhydrous potassium carbonate for a few days and then distilled twice taking the fraction boiling at 151—153 °C. Acetonitrile (ACN) was dried over anhydrous phosphorus pentoxide and the fraction distilled at 80—81 °C was used. The anion radicals were prepared by electrolytic reduction in DMF-water or ACN-water mixture containing 2×10^{-3} M nitro compound and 0.1 M tetra-*n*-propyl ammonium perchlorate. The cell and technique are described in detail elsewhere.[13-15] The coupling constants were calibrated with the splittings of nitrosodisulphonate anion.

Results and Discussion

Solvent Effect in ESR Spectra. The coupling constants of fluoronitrobenzene anion radicals in DMF-water mixture are given in Table 1. Assignments of the coupling constants to specific nuclei were made in accordance with Hückel MO calculation and INDO

a) Assignments of the coupling constants to specific nuclei were made in accord with our Hückel MO calculation for *o*, *p*-isomers and with the INDO MO calculation[16] of Pople *et al.* for *m*-isomer.

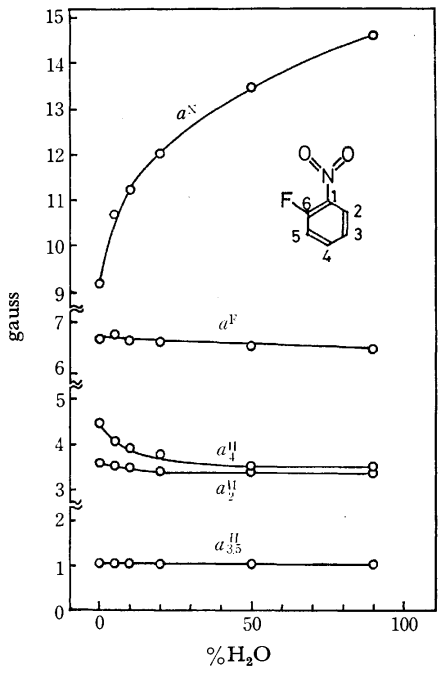

Fig. 1. Hyperfine coupling constants of *o*-fluoronitrobenzene anion radical shown as a function of water content in DMF–water mixture.

MO methods.[16] The graphical shifts in coupling constants of nitrogen, proton, and fluorine nuclei of *o*-fluoronitrobenzene anion radical are shown in Fig. 1 as a function of water content. Similar shifts in a^N of some other substituted nitrobenzene anion radicals are summarized in Figs. 2a and 2b. We see that a^N increases with the increase of water content, the splittings of nuclei at *meta* and *ortho* positions showing little change. The figures present an excellent comparison. In the case of fluoronitrobenzene, nitroanisole, and nitrotoluene (Fig. 2a), the shifts in a^N of *ortho* isomers are greater than those of *meta* or *para* isomers, and the shift in a^N of a radical with a bulkier substituent at the *ortho* position is remarkably enhanced with the increase of the water content. In the case of *o*-nitrophenol anion radical which forms an intramolecular hydrogen bond[13] (Fig. 2b), the shift in a^N is smaller than in the case of *para* and *meta* isomers. The shift in a^N of 2-nitroresorsinol anion radical which forms two intramolecular hydrogen bonds[4] is much smaller. These observations are in good accord with the following general aspects of the solvent effect of substituted nitrobenzene anion radicals:[4] i) When the nitro group forms intramolecular hydrogen bonds the solvent effect is impeded as the nitro group is rendered to be a weaker proton acceptor. ii) When the nitro group forms a localized complex with solvent molecules and is sterically hindered by the substituent at the *ortho* position in such a way as to be twisted out of plane of the benzene ring, the solvent effect is much more effective than in the unhindered cases. The second model is based on the fact that a substituted nitrobenzene anion radical having a sterically hindered nitro group has a larger nitrogen splitting and smaller ring proton splittings than unhindered substituted nitrobenzene anion radicals.[17] In general, the nitro group of *ortho* substituted nitrobenzene is known to be sensitive to the steric influence of the substituent at the *ortho* position and the twisting effect is operative in some cases, *e.g.*, in the case of *o*-nitrotoluene the twisted angle of the nitro group has been

estimated to be 34°.[18] The chlorine atom is suggested to be about as effective as a methyl group with regard to its steric influence on an adjacent nitro group.[4] The fluorine atom is certainly less effective than chlorine atom. Nonetheless, if hydrogen bond complex is formed the nitro group should be dislocated to accommodate the added bulky group. This situation should be reflected in the observed extra sensitivity of the splittings (Table 1).[19]

In order to verify the applicability of the model of solvent effect, the Hückel MO calculation was performed for *o*-fluoronitrobenzene anion radical by taking account of the following two factors[8,12,20] i) The oxygen Coulomb integral α_0 of the nitro group increases as a result of hydroxylic solvation since the oxygen atom in the nitro group becomes more electronegative by forming intermolecular hydrogen bonds with solvents, ii) the resonance integral β_{CN} between the nitro group and the benzene ring decreases when the conjugation between the nitro group and the benzene ring is reduced by twisting of the nitro group. The calculated distribution of the unpaired electron spin densities of *o*-fluoronitrobenzene anion radical is summarized in Table 2. By using these densities the calculated hyperfine coupling constants were obtained from the relations

$$a^N = A\rho^N - B\rho^O \quad (1)$$

$$a_i^H = Q\rho_i^C \quad (2)$$

where ρ^N and ρ^O denote the electron spin densities on nitrogen and oxygen atoms, respectively, and ρ_i^C denotes the spin density on the i-th carbon atom to which the i-th hydrogen atom is bonded. A, B, and Q are constants. Equation (1) was given by Rieger and Fraenkel. They gave $A=99$ and $B=71$ gausses as values which fit their experimental nitrogen splittings.[8] Equation (2) was given by McConnel,[21] Q being estimated to be -30 gauss for hydrocarbon anion radicals.[22] The values of a^N and a_i^H obtained from Eqs. (1) and (2) by using our spin densities did not agree with the experimental results. However, the calculated results may still be used for studying the relative magnitude of the observed shift in splittings. The calculated shifts in a^N, a_2^H, and a_4^H with the increase of the Coulomb integral of the oxygen atom α_0 are graphically shown in Fig. 3a and those with the decrease of the resonance integral β_{CN} in Fig. 3b. The origin of the curves were so chosen that the calculated results might coincide with the experimental results. The calculated shifts in a^N and a_4^H with the increase of α_0 qualitatively correlates with the experimental results, namely a^N increases and a_4^H decreases (Figs. 1 and 3a). However, the change in the observed a_4^H was not reproduced by calculation, a more evident contradiction being shown for a_2^H which was found to show a slight increase by calculation and a slight decrease by experiment. On the other hand, the calculated shift in a^N, a_2^H, and a_4^H with the decrease of β_{CN} is qualitatively correlated with the experimental results; a^N increases and both a_2^H and a_4^H decrease. However, the relative magnitudes of the changes in a_2^H and a_4^H were calculated to be comparable. The experiment indicated that the magnitude of the change in a_4^H is greater than that in a_2^H. Hence, neither the increase of α_0 nor the decrease of β_{CN} reflects precisely the nature of the solvent effect by itself. However, the

19) The out-of-plane bending of the nitro group, the other possibility of steric effect, seems to be less probable, since the ring nuclei splittings were observed to be affected by the solvent system (*cf.* Refs. 4 and 17).

experimental results can be reproduced by combining both effects: A larger shift in a_4^H than a_2^H is expected by combining the two results (Figs. 3a and 3b). The expectation agrees very well with the experimental results. Thus, for the solvent effect the following model seems to be reasonable; the nitro group of the *o*-fluoronitrobenzene anion radical is strongly solvated with water, the solvated nitro group being simultaneously twisted out of the plane of the benzene ring. The model of solvent effect was first suggested by Ludwig *et al.*[4] as the most likely for *ortho* substituted nitrobenzene anion radicals based on the results of MO calculation for nitrobenzene anion radical given by Rieger and Fraenkel. The reason why the model of the solvent effect given by Ludwig *et al.* is acceptable, although their model was not derived from a precise MO calculation for *ortho* substituted nitrobenzene anion radical itself but for the unsubstituted nitrobenzene anion radical, can be understood as follows. For the shift in splittings, the MO calculation made by Rieger and Fraenkel and by us for both nitrobenzene and *o*-fluoronitrobenzene give similar results. Both a^N and a_2^H increase with the increase of α_O, while a^N increases and a_2^H as well as a_4^H decrease with the decrease of β_{CN}, indicating that the tendency of the shift in splittings with the variation of α_O and β_{CN} is insensitive to the species of the substituent as well as the position of the substitution. It is also expected that the results (Figs. 3a and 3b) can be applied to *meta* or *para* mono substituted nitrobenzene anion radicals. Thus, the experimental results where the relative magnitudes of the shift in splittings of mono substituted nitrobenzene anion radicals are in the order *ortho*>*meta*>*para* isomers, can be attributed to the steric influence of the substituent on the nitro group.

Solvent Effect in Polarographic Half-Wave Potentials. It is known that a correlation exists between polarographic half-wave potential $E_{1/2}$ and the energy of the lowest vacant orbital m such as[23]

$$-E_{1/2} = -bm + c \qquad (3)$$

where m is the energy in unit of β, b and c are both constants. The values $b=3.0$ and $c=1.0$ were obtained as values which fit our experimental results. Half-wave potentials calculated from Eq. (3) as well as the experimental results are given in Table 3. Comparison of the calculated values with the experimental values indicates that there are three characteristic cases. Firstly, for fluoronitrobenzene, in which little steric effect is expected, the calculated values correlate very

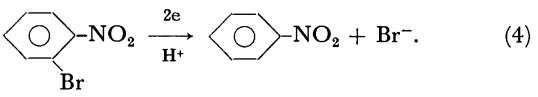
well with the experimental results *viz.*, the order of the half-wave potential is *meta*>*ortho*>*para* isomers. Secondly, for chloronitrobenzene and nitrotoluene, in which steric hindrance of the nitro group is expected for *ortho* isomers, experimental results show that the order of the half-wave potential is *meta*>*para*>*ortho* isomers, while calculation shows it to be *meta*>*ortho*>*para* isomers. Thirdly, for nitrophenol, in which intramolecular hydrogen bond is expected for *ortho* isomers, experimental results show the order to be *ortho*>*meta*>*para* isomers, and calculation *meta*>*ortho*>*para* isomers. As is evident from the calculated values of m (Table 2), the energy level of the lowest vacant orbital falls with the increase of α_0 while it is enhanced with the decrease of β_{CN}. Thus, when hindered rotation of the nitro group is expected to be operative the half-wave potential will shift to more negative, resulting in a potential series of *meta*>*para*>*ortho* isomers. On the other hand, when intramolecular hydrogen bond is expected the half-wave potential will shift to less negative, resulting in a potential series of *ortho*>*meta*>*para* isomers. The expectation agrees very well with the experimental results of nitrotoluene, chloronitrobenzene and nitrophenol.

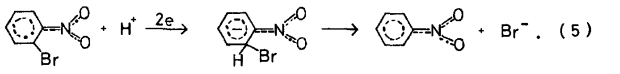
The half-wave potentials of halonitrobenzenes were reported to shift to less negative with increasing the concentration of water in DMF.[24] The shift in half-wave potentials of *ortho*, *meta*, and *para* isomers, at 20 per cent water content, were found to be 0.17 V, 0.17 V, 0.18 V, respectively, for fluoronitrobenzene and 0.17 V, 0.17 V, 0.19 V, respectively, for chloronitrobenzene and 0.14 V, 0.16 V, 0.18 V, respectively, for bromonitrobenzene and 0.14 V, 0.14 V, 0.17 V, respectively, for iodonitrobenzene, indicating that the relative magnitude of the shift in half-wave potential is generally in the order *ortho*<*meta*<*para* isomers. It is now evident that the hindered rotation of the nitro group resulting from the hydroxylic solvation will make the half-wave potential shift to more negative, while the hydroxylic solvation alone will make it shift to less negative. Thus, the slightest shift in half-wave potentials of *ortho* isomers and the most pronounced shift for *para* isomers with the increase of water concentration would be understood.

Solvent Effect in Electrochemical Reduction of Halonitrobenzene. The electrochemical reduction of mono substituted halonitrobenzene has been studied by ESR spectroscopy as well as by voltammetry, attention being paid to the elimination of the halogen atom. The chlorine atom of *o*-chloronitrobenzene and the bromine atom of *o*-bromonitrobenzene were eliminated by electrolytic reduction at mercury pool cathode and the ESR spectrum of nitrobenzene anion radical was observed.[14,24-26] When phenol or water was added as proton donors the elimination of the halogen atom was impeded. A survey of the proposed reaction mechanism for the elimination of the halogen atom of halonitrobenzene indicates that two electrons should be involved in this reaction.[24] Thus, the dehalogenation reaction at the electrode is shown schematically as follows by taking *o*-bromonitrobenzene as an example



(4)

The process is considered to be a kind of electrophilic aromatic substitution reaction. The following transition state is acceptable in view of the fact that the aromatic substitution reaction under consideration proceeds following the electrochemical reduction



(I) (II) (III) (5)

The reactivity of the aromatic substitution reaction was studied by Fukui and his co-workers, and an index called the frontier electron density or superdelocalizability correlated with the stability of the transition state similar to the state (II) has been proved to be useful for elucidating the reactivity of the aromatic substitution.[27] The frontier electron density of the reaction under consideration is the electron density of the lowest vacant orbital of halonitrobenzene. It is formulated as $f_r^N=2(C_r^{lv})^2$. This index is reduced in magnitude (Table 2) with the reduction of the conjugation between the nitro group and the benzene ring. Thus, the dehalogenation reaction should be expected to be impeded as increasing the strong hydro-

xylic solvation.[28] The expectation is well correlated with experimental observation. A similar decrease of reactivity of the halogen atom of halonitrobenzene due to the hindered rotation of the nitro group has been summarized by Hammond and Hawthone;[29] the reactivity against piperidine decreases when the nitro group is sterically hindered. In conclusion, this model will constitute a major physical picture of solvent effect although it may not be conclusive, in so far as rigorous synthetic investigations by various experimental methods are still insufficient.

The authors express their thanks to Profs. Kenichi Fukui and Teijiro Yonezawa and laboratory members for their suggestions and cooperation in carrying out the molecular robital calculation. Thanks are also due to Prof. Toshio Arai for his discussion on the dehalogenation reaction.

28) The frontier electron density as well as the superdelocalizability indicate that the most reactive position of *ortho* substituted nitrovenzene anion radical is not *ortho* but *para* position. No sample reactions are known to verify this. Our present interest is to know how the reactivity of the ring substitution reaction changes with the value of β_{CN}, irrespective of the reaction position.

Studies on Fragment Ion Distribution and Reactions with the Use of a Charge Spectrometer. IV. Dependence of Cross Sections of Some Ion-Molecule Reactions on the Kinetic Energy of Ions

Toshio NAGATANI, Kenji YOSHIHARA, and Takanobu SHIOKAWA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received January 9, 1973)

Cross sections of methylamine and methanol for ion-molecule reactions with various rare gases have been studied by means of a charge spectrometer used as a double mass spectrometer. The results differed from those predicted by the Gioumousis-Stevenson theory. The difference was most pronounced for helium ion, the lightest ion.

It was reported by Field, Franklin, and Lampe[1] and also by Gioumousis and Stevenson[2] that the cross section of the ion-molecule reaction was inversely proportional to the square root of the kinetic energy of ions. Their argument was based on the theory of ion-induced dipole interaction. However, interpretation of the results by such a model is not always simple. The reaction cross section is predominantly determined by the collision cross section in gas kinetics when the energy of ions increases.[3]

The present report deals with the specific features of the reaction cross sections of methylamine and of methanol for various ions of rare gases.

Expreimental

Details of the charge spectrometer which also served as a double mass spectrometer of a perpendicular type were reported elsewhere.[4,5] The procedure was modified by applying a different electric field gradient. The primary ions of 10^{-13}—10^{-12} A were introduced into the source volume filled with target gases. The maximum pressure of the gases was 1.0×10^{-5} Torr. The reaction products in the source volume were abstracted into the analyzer system by the action of the installed lenses and measured with an electron multiplier of 16 stages.

An example of the mass spectrum of methylamine bombarded with Xe^+ with energy of 8.0 eV is shown in Fig. 1. We see that there are two series of product ions: one with mass-charge ratio of an integer produced through collision complex formation (open bars); the other with non-integer

4) T. Shiokawa, K. Yoshihara, M. Yagi, T. Omori, H. Kaji, M. Hiraga, T. Nagatani, and Y. Takita, *Shitsuryo Bunseki*, **18**, 1230 (1970).

5) T. Nagatani, K. Yoshihara, and T. Shiokawa, *ibid.*, **20**, 97 (1972).

values of mass-charge ratio produced by pure charge exchange (closed bars). Since kinetic energy is transferred to the product in the complex formation, the apparent m/e ratio of the same fragment ion appears in the higher position as compared with that derived from pure charge exchange. Thus, the ions of the m/e ratio (30.5), (29.5), and (28.5) are considered to be the products by pure exchange whose net m/e ratios are (31), (30), and (29), respectively. The intensity of the ions caused by the charge exchange is 28.5% for the total ionization (Fig. 1). The same treatment is applicable to the other gases.

Results and Discussion

The ions abstracted into the analyzer system are classified as follows.

1) Primary ions,

a) having unchanged kinetic energy without interaction with target gases.

b) having altered kinetic energy by interaction with target gas molecules, *i.e.* inelastic scattering.

2) Stripping reaction products,

$$A^+ + B_1B_2 \longrightarrow AB_1^+ + B_2$$

where A^+ is the primary ion, B_1B_2 denotes the target molecule composed of parts B_1 and B_2, and AB_1^+ is the stripping reaction product.

3) Product ions formed through complex formation,

$$A^+ + B_1B_2 \longrightarrow [A-B_1B_2]^+ \longrightarrow B_1^+ + B_2 + A$$
$$\text{or } B_1 + B_2^+ + A \text{ etc.}$$

4) Product ions formed by charge exchange,

$$A^+ + B_1B_2 \longrightarrow A + B_1B_2^+$$

This is often accompanied by dissociation reactions.

$$A^+ + B_1B_2 \longrightarrow A + B_1B_2^+$$
$$B_1B_2^+ \longrightarrow B_1^+ + B_2$$
$$\text{or } B_1 + B_2^+$$

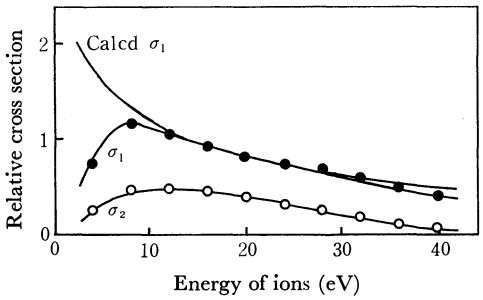

Fig. 2. Two kinds of cross sections of methylamine bombarded with Xe^+.

We defined the reaction cross section σ_1 according to complex formation and σ_2 according to charge exchange. The intensity of the stripping reaction products is very small and can be neglected. The relations of σ_1 and σ_2 with energy are shown in Fig. 2 which corresponds to the experiment of methylamine bombarded with Xe^+. The error of each experimental point does not exceed 20%. The calculated values are obtained by application of the Gioumousis-Stevenson's theory of inverse-square-root dependence of kinetic energy. Experimental values of σ_1 fit the calculated values in the range 12.0—32.0 eV. The charge exchange cross section σ_2 shows a somewhat different inclination from that of σ_1. Increase of σ_1 in the very low energy region implies that fragmentation increases as translational energy carried into the methylamine molecule from the xenon ion increases and the activated complex highly excited in its vibrational states increases.

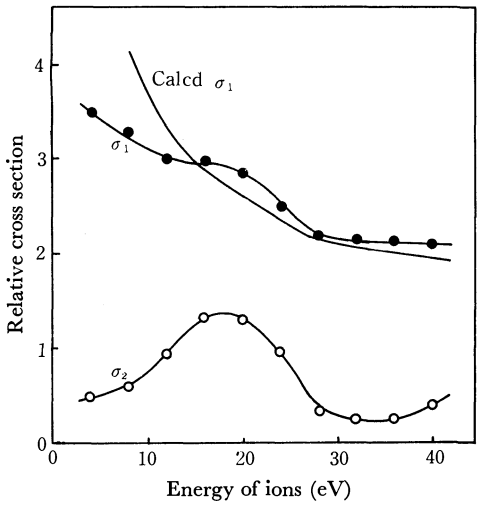

Fig. 3. Two kinds of cross sections of methanol bombarded with Xe^+.

The results for methanol are plotted in Fig. 3. The calculated values for σ_1 according to the Gioumousis-Stevenson's theory can nearly account for the experimental values in the range 16.0—36.0 eV. It seems that the inverse-square-root dependence of the cross section on ion energy fits the energy range below 40 eV irrespective of ions. The trend of σ_2 for methanol differs from that of σ_1. It has a maximum at 16.0—20.0 eV. For both systems the fragment ions which contribute to σ_2 include the same ionic species of the approximately same relative intensity.[6,7] This shows that the separation of σ_2 from σ_1 is quite good.

However, when Ar^+ is introduced into the source volume as the primary ion, there is a large difference

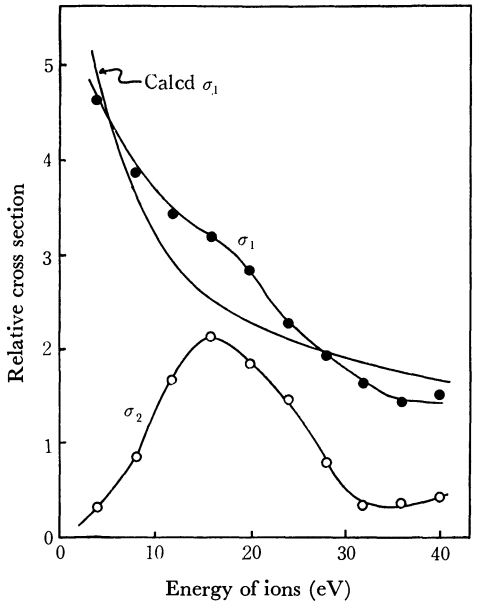

Fig. 5. Ionization cross sections of methanol bombarded with Ar^+.

between the systems of methylamine and methanol (Figs. 4 and 5). For the primary ion whose recombination energy is about 15 eV, the ratio σ_2/σ_1 is very small in methylamine. When translational energies of primary ions increase to 100—200 eV, σ_2 becomes 10% for σ_1, and negligible for the ions of 2 keV. The trend of σ_1 in 30—40 eV fits the calculated value.

σ_1 in the methanol system is in good accordance with the calculated value (Fig. 5). However, σ_2 has a maximum at about 16 eV. At this energy σ_2 contributes 40.1% of the total ionization cross section.

σ_2 is small for the primary ions of He^+. It is negligibly small in methylamine (Fig. 6). Similar results for methanol are shown in Fig. 7. The calculated values of σ_1 for methylamine and for methanol using the Gioumousis-Stevenson's theory largely differ from the experimental ones. Replacement of inverse-square-root dependence by inversely proportional dependence does not essentially change the situation. These discrepancies suggest some factors other than induced dipole interaction. In this connection recent reports by Koski and his co-workers are of interest.[8-11] Their

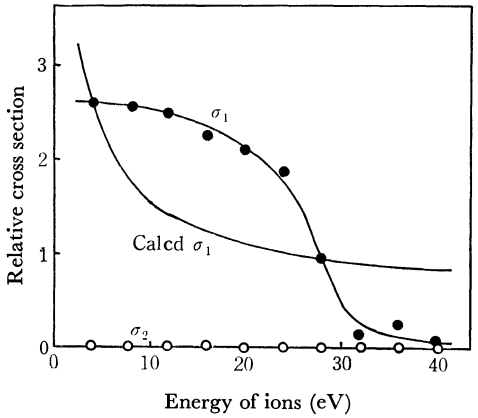

Fig. 6. Ionization cross sections of methylamine bombarded with He^+.

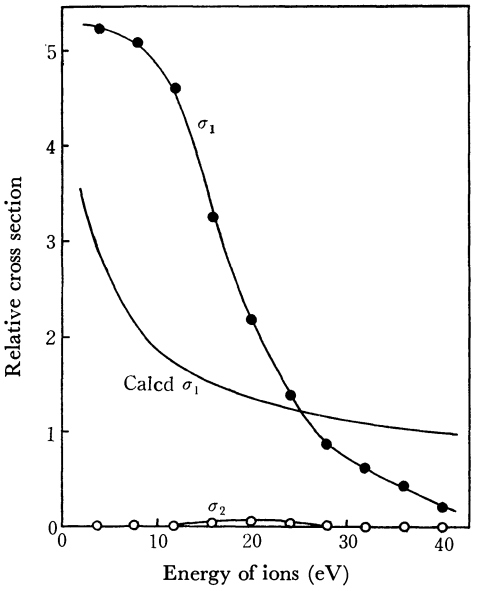

Fig. 7. Ionization cross sections of methanol bombarded with He^+.

results show that complicated factors are included in determining the formation of ionic species in the reaction of C^+ with hydrocarbons. However, it is not easy to understand why in the case of the lightest rare gas ion the deviation from the Gioumousis-Stevenson's theory is most pronounced. It is possible that the energy carried into the activated complex through the collision is not kept in vibronic states or that the contributed energy is limited through the collision which resembles an elastic one.

The authors thank Mr. Hiraga for his kind help in the operation of the double mass spectrometer.

The Magnetic Properties of Manganese(II) Phthalocyanine

Hirokazu MIYOSHI, Hiroaki OHYA-NISHIGUCHI, and Yasuo DEGUCHI*

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

**College of Liberal Arts and Science, Kyoto University, Kyoto 606*

(Received January 11, 1973)

The magnetic transition from the ferro- to the para-magnetic state of manganese(II) phthalocyanine ($C_{32}H_{16}N_8Mn$) has been observed by measurements of the magnetic susceptibility, the magnetization and the proton magnetic resonance in the low-temperature range. The positive Weiss constants were obtained from the static susceptibility measurements and the proton magnetic measurements. Moreover, the magnetic-field dependences of the experimental results were found in the low-temperature range. All of those findings confirm the ferromagnetic behavior of this substance in the lower-temperature region. From the measurements of the frequency shift in the resonant circuit of the proton magnetic resonance apparatus, the transition temperature was determined to be 8.6 K. A possible mechanism of long-range ordering was also discussed on the basis of the crystal structure of this substance.

The phthalocyanines are interesting organo-metallic compounds which have been extensively studied for their semiconductive and photoconductive properties. Moreover, most of the transition-metal phthalocyanines are known to be paramagnetic; some of them have been studied in terms of their electronic structures by the electron spin resonance[1-4] or magnetostatic methods.[5]

The magnetic behaviors[6] of transition-metal phthalocyanines have been investigated in the temperature range above 77 K; the results obey the Curie-Weiss law, with mostly negative Weiss constants, thus implying the existence of large zero-field splittings or of antiferromagnetic exchange interactions among molecules. So far we know, most reports of the magnetic properties have been concentrated upon an investigation of the electronic structures of the molecule. However, the investigations of the magnetic properties themselves, especially from a viewpoint of the magnetic-phase transition, are still not well-established.

The magnetic properties of manganese (II) phthalocyanine (hereafter abbreviated as PcMn) are of considerable interest. This substance obeys the Curie-Weiss law in the high-temperature range, and its Weiss constant has a positive sign, unlike those of the other metal-phthalocyanines. The magnetic susceptibilities of PcMn have been measured by Lever,[6] who found the positive Weiss constant to be 6 K. Recently, Mitra and his co-workers[7] measured the magnetic susceptibilities and anisotropies of PcMn over quite a wide temperature range (1.7—300 K) and reported the existence of the ferromagnetic interaction among molecules; they added some speculations about the spin state of the molecule that a divalent-manganese ion might have at $s=3/2$. However no detailed discussion of the occurrence of the magnetic ordering has been made so far.

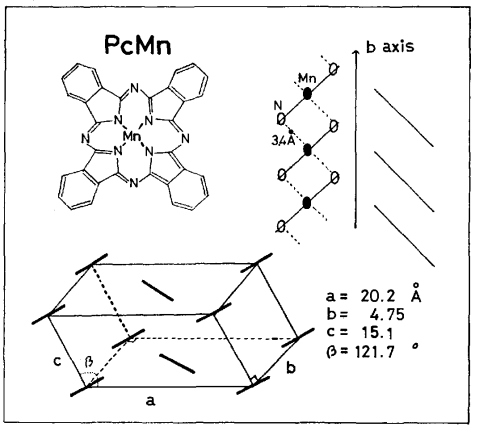

Fig. 1. Molecular and schematic crystal structures of manganese(II) phthalocyanine ($C_{32}H_{16}N_8Mn$). The molecular plane is approximately normal to the ab-plane.

We have studied the magnetic properties of PcMn in more detail and obtained affirmative evidence for the occurrence of the magnetic-phase transition of PcMn.

Experimental

PcMn was prepared by the method of Linstead *et al.*[8] The product was extracted with α-chloronaphthalene and then sublimed in an atmosphere of pure nitrogen at the temperature of 550 °C. The single crystals grown by sublimation were ground and powdered. Found: C, 67.54; H, 2.76; N, 19.19%. Calcd: C, 67.7; H, 2.8; N, 19.7%.

All the measurements were carried out in the microcrystalline state. The measurements of the static (dc) susceptibility and the temperature dependence of the magnetization were performed on powder samples of about 10—50 mg between 1.8 and 77 K in the magnetic fields of 0.82, 1.12, 1.88, 7.0, 8.3, and 10.2 KOe, by means of a magnetic torsion balance described elsewhere.[9] The temperatures of the samples were measured with a carbon resister

and an AuCo–Cu thermocouple calibrated by measuring not only the magnetic susceptibility of Mn-Tutton salt, but also the vapor pressures of liquid helium, liquid hydrogen, and liquid nitrogen. Moreover, the susceptibility measurements were made by means of a Hartshorn bridge between 13.8 and 20.2 K in the temperature region attainable by the pumping out of liquid hydrogen. The temperature was determined from the known susceptibility of the standard sample, $Cr(NH_3)_6Cl_3$, and from the vapor pressures of liquid hydrogen.

The proton NMR absorption spectra were observed between 10.8 and 20 K using the usual Pound-Watkins-type oscillator with a 80 Hz field modulation and a field sweep. The oscillator coil with a sample tube was directly immersed in liquid hydrogen. The temperatures were measured with a calibrated carbon resister and by means of the vapor pressure of liquid hydrogen. The proton NMR absorption of liquid hydrogen was used as a standard for the estimation of the absorption line-shift. The magnetic field was calibrated by means of the proton absorption of H_2O.

Results

Magnetic Suscetibility. The diamagnetic correction was within the range of experimental error at low temperatures.[10] The results of the dc susceptibility measurements in the field of 10.2 KOe obey the Curie-Weiss law between 30 and 77 K; thus, a positive Weiss constant, 18.4 K, was obtained, one which agrees almost entirely with those reported by Mitra *et al.* From the slope of the $1/\chi_M$ *vs.* T plots, we obtained a g-value of 2.25, assuming that $s=3/2$ (the effective moment, $\mu_{eff}=4.36\ \mu_B$). At temperatures below about 20 K, the molar susceptibility deviates from the Curie-Weiss law and reaches a constant maximum value below 7 K; this behavior is dependent on the magnetic-field strength.

Avoiding the effect of an extensive magnetic field, as will be discussed later, the ac susceptibilities were also measured in the temperature range between 13.7 and 20.2 K.

The results precisely obey the Curie-Weiss law for $s=3/2$ and $g=2.93$ in this temperature range, in contrast with the results of the dc susceptibilities, and they show a positive Weiss constant of 9.0 K.

Magnetization. The field dependence of the magnetization was measured at the temperatures of 4.2, 11.1, and 20.3 K, as is shown in Fig. 2. At 20.3 K, the magnetizations are linearly dependent on the magnetic field as the usual paramagnetic substance, but at 11.1 K they deviate from a linear dependence and at 4.2 K they become larger. We have rewritten the data in relation with σ^2 to H/σ in Fig. 3. It is also worth-while to notice that, in Fig. 2, the value of the saturation magnetization extrapolated from the value at 4.2 K is much smaller than the value calculated using $s=3/2$ and $g=2$. The temperature dependence of the magnetization at several constant fields between 0.84 KOe and 10.2 KOe is shown in Fig. 4. The dependence of the magnetization on the magnetic-field strength is then found, as in the usual ferro-magnetic substances.

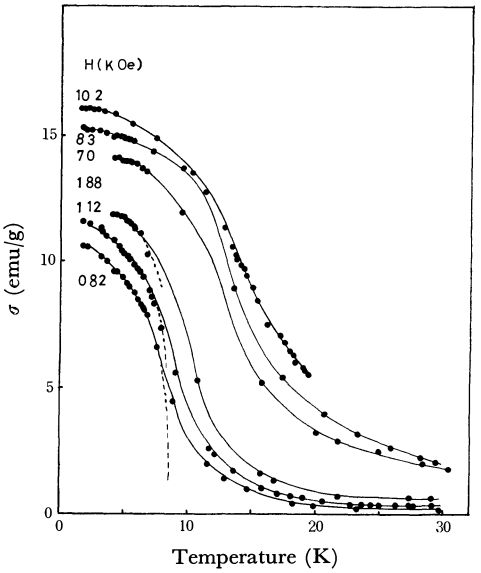

Fig. 4. Temperature dependences of the magnetization at the field of 0.82, 1.12, 1.88, 7.0, 8.3, and 10.2 KOe.

Proton Magnetic Resonance. The proton magnetic resonance (PMR) measurements were carried out at the frequencies of 18 and 12 MHz. In the first, when measured at the frequency of 18 MHz and the tem-

10) C. G. Barraclough, R. L. Martin, and S. Mitra, *J. Chem. Phys.*, **55**, 1426 (1971).

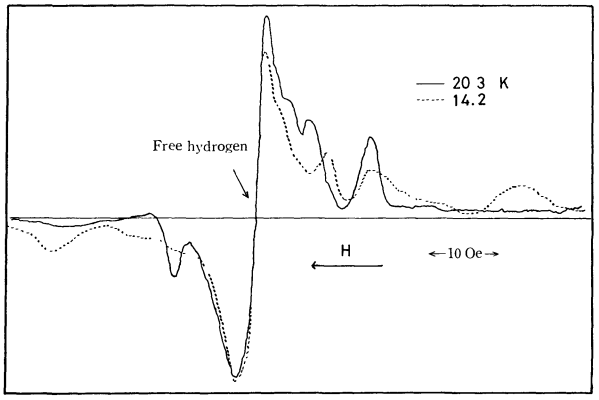

Fig. 5. PMR spectra of the polycrystalline sample at 20.3 and 14.2 K at 12 MHz. In the figure, *free hydrogen* means a free proton absorption of the coolant.

perature of liquid helium (4.2 K), no signals could be observed by sweeping the magnetic field between 500 Oe and 12 KOe. In the second, when measured between 10.8 and 20 K, a temperature range attainable by the pumping out of liquid hydrogen, several absorption lines were observed, as is shown in Fig. 5, where the absorption of the hydrogen molecule used as a coolant is superimposed upon them. We could confirm at least four lines, three in the lower field and one in the higher field. These signals can not be interpreted by the model of the two different proton sites in the molecule, but they may be attributed to the different local fields caused by the magnetic short-range ordering effect at the individual proton sites. We are now engaged in clarifying this point further. The shifts of the higher- and lower-field absorptions were measured from the position of that of the hydrogen molecule; the reciprocals of the shifts are plotted as a function of the temperature in Fig. 6. At 12 MHz, the results are linearly proportional to the temperature between 14 and 20.2 K. The straight line intersects the abscissa displaying the temperature of 9.6 K. Similarly, at 18 MHz, the reciprocal shifts are linear to the temperature between 15 and 20.2 K and intersect the abscissa at the same point, 9.6 K. However, the deviation from the linearity appears at a higher tem-

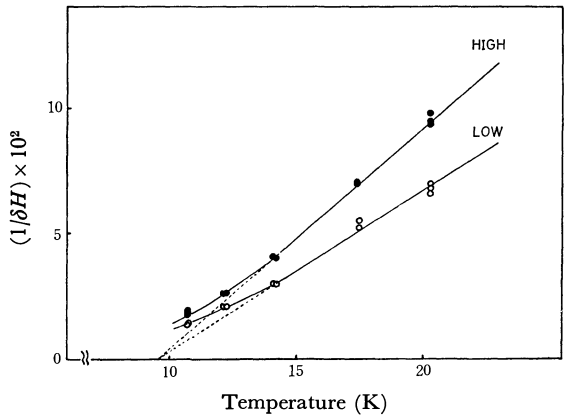

Fig. 6. Reciprocals of the PMR line shifts ($1/\delta H$) as a function of temperature at 12 MHz. HIGH and LOW mean higher and lower portions of the spectrum, as shown in Fig. 5, respectively.

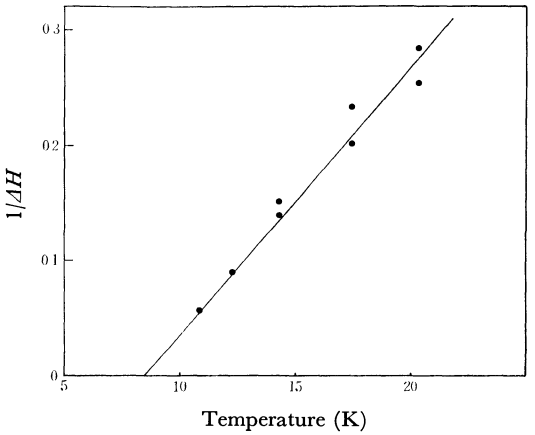

Fig. 7. Reciprocal PMR line-width ($1/\Delta H$) of the lower portion in Fig. 5 as a function of temperature.

perature, 15 K, and is much larger than that at 12 MHz.

The reciprocal line-width of the lower portion at 12 MHz is also shown as a function of the temperature in Fig. 7. The reciprocal PMR line-widths are linearly proportional to the temperature between 10.8 and 20.2 K.

To determine the transition temperature more accurately,[11] a powdered sample was placed in the coil of an oscillator used for PMR, and the relative ac susceptibilities (detected as a frequency shift in the resonant circuit) in a zero field and at 8 KOe were measured as a function of the temperature from 4.2 to 30 K. A typical measurement is shown in Fig. 8. The frequency shift in the zero field reaches a maximum around 9.2 K, but the point of intersection of the two gradients on the upper and the lower sides of the maximum is 8.6 K; this is regarded as the magnetic transition temperature. The shift at about 8 KOe also shows a broad maximum, but the transition point is obscured by the influence of the magnetic field.

Ferromagnetic Resonance. In order to investigate the magnetic-ordered state of PcMn, ferromagnetic resonance measurements using an X-band ESR spectrometer were carried out in both powder and needle-like

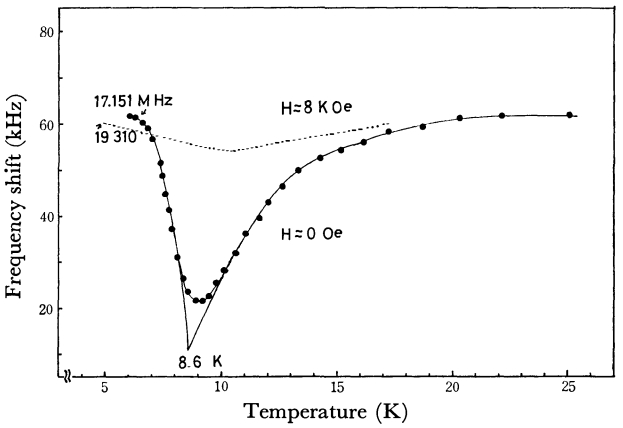

Fig. 8. Frequency shift (relative ac susceptibility) as a function of temperature.

11) H. H. Wickman, A. M. Trozzolo, H. J. Williams, G. W. Hull, and F. R. Merritt, *Phys. Rev.*, **155**, 563 (1967).

single crystal samples at 4.2 and 77 K with fields up to 25 KOe. Assuming the obtained needle-like crystal to be an infinitely elongated cylinder in order to calculate its demagnetization factor, and estimating the saturation magnetization (M_0) as 1.7β/ion (*cf.* Fig. 2), we calculated the resonance frequency (ω) of PcMn based upon Kittel's resonance conditions[12] and concluded that the deviation from the usual resonant field should be much smaller than 10^3 Oe ($\omega/\gamma = H + 2\pi M_0$, $2\pi M_0 \ll 10^3$ Oe). However, we observed only one weak absorption with $g \approx 2.0$, the line-width ≈ 6 Oe; they seemed to be a free-radical resonance characteristic of most of the phthalocyanine compounds reported by Assour and Harrison.[13]

Discussion

The Weiss constant derived from ac susceptibility measurements in the temperature range between 13.7 and 20.4 K has a positive value, 10 K; this suggests the existence of ferromagnetic interaction between molecules. As is well known,[14] when there is an applied magnetic field the ferromagnetic substance retains its magnetization in the vicinity of the Curie temperature. Thus, near the Curie temperature, the various magnetic properties of the ferromagnetic substance will be influenced by the applied magnetic field and, hence, the Curie temperature will be obscured. As is shown in Fig. 4, the dc susceptibility and the magnetization in the low-temperature range are dependent on the magnetic-field strength; the higher the magnetic field, the more gradually the magnetzation decreases when the temperature is raised, as is characteristic of the usual ferromagnetic substances (that is, as has been stated above, the influence of the magnetic field obscures the transition temperature from the para-magnetic state to the ferro-magnetic state). From the microscopic point of view, the results of PMR measurements between 10.8 and 20.2 K support the existence of a positive Weiss constant as well as the influence of the magnetic field, as will be shown below. The paramagnetic shift is proportional to the mean value, $\langle S_z \rangle$, of the electron-spin component and, consequently, to the bulk magnetic susceptibility of the sample. The Weiss constants obtained from the temperature variations of the paramagnetic shifts at 12 MHz and at 18 MHz are both 9.6 K; this is consistent with the results of the bulk ac susceptibility. The deviation from the Curie-Weiss law is larger at 18 MHz than at 12 MHz, indicating the influence of the magnetic field on the shifts. The positive Weiss constants obtained from the microscopic PMR measurements as well as from the bulk dc and ac susceptibility measurements, and the magnetic-field dependences of experimental results, all confirm the ferromagnetic behavior of this substance in the lower-temperature region.

Now, let us turn to the determination of the Curie temperature (T_c) of PcMn, in which spontaneous magnetization occurs. In Fig. 3, H/σ is plotted against σ^2. From the thermodynamic description[14] of the magnetization of a ferro-magnetic material, $H/\sigma = A + B\sigma^2$, where the coefficients, A and B, are the functions of the temperature. The Curie temperature (T_c) can be determined from the temperature at which the coefficient $A=0$. Taking this relation into account, it is evident that T_c exists between 4.2 and 11.1 K. As is shown in Fig. 2, the saturation magnetization (σ_s) extrapolated from the data at 4.2 K is 17.0 G cm^3/g, much smaller than the theoretically-estimated value, (29.5 G cm^3/g calculated from $s=3/2$ and $g=2.0$). Using the relation that $\sigma_s M = Ng\langle\mu\rangle$ on the assumption of $g=2.0$, the obtained average moment, $\langle\mu\rangle$, is 1.7 Bohr magneton. This value is about half the total spin value (3 Bohr magneton) expected from $s=3/2$. The temperature dependence of the magnetization in the magnetic field of 0.82 KOe suggests that the Curie temperature exists between 8 and 10 K, as is shown in Fig. 4.

The transition temperature was determined more accurately by relative ac susceptibility measurements using a PMR oscillator. In Fig. 8, the transition temperature is identified as 8.6 K on the basis of these data; this is consistent with the Weiss constants obtained by different methods of measurements. Similarly, as has already been mentioned, a remarkable magnetic-field dependence can be noticed, so that the transition temperature is obscured in the high magnetic field of 8 KOe. This is another piece of evidences for the ferromagnetic behavior of PcMn.

The reciprocal PMR line-width tends to broaden rapidly as the temperature is decreased, and it seems to diverge at T'_c (8.5 K), as may be extrapolated from Fig. 7. This temperature (T'_c) is surprisingly in agreement with the Curie temperature obtained above. So far we do not have a sufficient theoretical elucidation of the linewidth variation of PMR. However, provided that the divergence of the linewidth may be attributed to the onset of the long-range ordering of electron spins, we can recognize the coincidence of T'_c with T_c, because the rapid broadening of the line-width is the result of the critical fluctuation of spins in the neighborhood of the transition temperature.

From the experimental facts presented above, one may conclude that PcMn is the first example of a ferromagnet among the organo-metallic compounds and that its Curie temperature is 8.6 K.

A Possible Mechanism of Long-range Ordering. The above discussion has concentrated upon the magnetic properties. Now, let us briefly discuss the possible mechanism of long-range ordering. The crystal structure of PcMn is isomorphous with nickel(II) phthalocyanine,[15] whose structure is well known. As is shown in Fig. 1, the molecules are square planar ones stacked along the short monoclinic b axis of the crystal and the distance between these nearest molecules is 3.4 Å, which provides a possible pathway for magnetic ex-

change interaction between electron spins. The unit cell contains two nonequivalent molecules with parameters of (0, 0, 0) and (1/2, 1/2, 0). The axes of symmetry of a couple of molecules in the unit cell are almost at right angles, and both of them are equally inclined to the ac plane by an approximate angle of 45°.

Therefore, PcMn may form a magnetic chain different from the three-dimensionally-interacting spin system, and the exchange coupling between the next-nearest-neighbor spins in different chains (that is, between the different sites) is much weaker than that between nearest-neighbor spins in the same chain (between the equivalent ions along the b-axis). Possible pathways for superexchange between nearest-neighbor spins in the same chain were considered by S. Mitra *et al.*[7] It is well known theoretically[16] that the isolated magnetic linear chains do not have any magnetic-phase transition, but, in the presence of a small interaction between chains, there occurs a magnetic transition to the long-range ordered state in the lower-temperature region. Considering the discussion of PcCu based on ESR measurements,[4] there is a possibility for PcMn to go into a long-range ordered state, since the interaction between chains cannot be neglected. On the other hand, a reported speculation[7] on the electronic structure has suggested the existence of the zero-field splitting of the ground state, which may dominate the spin structure of the ordered state. Perhaps, the small value of saturation magnetization in Fig. 2 and the absence of any absorption signals of ESR and PMR measurements at 4.2 K suggests the canted ferromagnetism of PcMn. At any rate, for the discussion of the finer mechanism of the ferromagnetic interaction and the spin structure of the ordered state, it would be necessary to know which interaction is more dominant and what type of exchange is involved. Study along this line is now under way.

The authors wish to acknowledge their helpful discussions with Professor Mamoru Mekata, Dr. Yoshitami Ajiro and their other collaborators in the laboratory. They are also grateful to Professor Ikuji Tsujikawa and Dr. Hanako Kobayashi for offering them a chance to use the Hartshorn bridge apparatus. They also wish to thank Professor Natsu Ueda and Dr. Takashi Kobayashi for their helpful advice on the preparation of the manganese(II) phthalocyanine.

(Received February 7, 1973)

The static magnetic susceptibility and the ESR spectra from 1.6 to 300 K have been measured on a powder sample of the titled free radical. The broad maximum in the susceptibility which indicates an antiferromagnetic interaction has been observed at 6.9 K. The broadening of the ESR absorption line and the shift of the *g*-value have been found in the temperature region below T_{max}, in which the susceptibility reached its round maximum. There appeared anomalies in the slope of the susceptibility, the linewidth, and the *g*-value *versus* temperature curves in the vicinity of 1.7 K. These anomalies may imply a magnetic-phase transition from the short-range ordered state to the long-range ordered state at about 1.7 K. The existence of a ferromagnetic interaction between the magnetic chains in the triphenylverdazyl radical solid is discussed on the basis of the susceptibility, the spin distribution, and the crystal structure. It is understood qualitatively that the radical with a negative spin density has a latent ferromagnetic interaction in or between the magnetic chains, and that the obsrevation of this interaction greatly depends upon the molecular and crystal structure.

At a low temperature a number of free radical solids exhibit broad maxima in their susceptibilities which indicate an antiferromagnetic interaction between unpaired electrons in the radicals. In the case of neutral organic radicals, the magnetic behavior has been explained on the basis of magnetic linear chain models, where the linear Heisenberg and the one-dimensional Ising models have been commonly employed. On the other hand, all the organic free radicals show practically isotropic *g*-values very close to the free electron value. This implies a small spin-orbit interaction due to the quenching of the orbital angular momentum; as a result, one may take into account an isotropic exchange inter-

1) Part I: K. Mukai, N. Azuma, and K. Ishizu, This Bulletin, **43**, 3618 (1970).

action and a smaller magnetic dipolar one in order to interpret the magnetic data. Therefore, the appropriate model for discussing the magnetic behavior of free radicals may not be of the Ising-type with extremely anisotropic spins, but the Heisenberg model, with the isotropic exchange interaction; this model is employed in the present case. The one-dimensionality of the magnetic structure in the free radical solids may be acceptable, firstly, because the low symmetry of the crystal structure,[2-5] which, in turn, results in the small coordination number, z, of the unpaired electrons, where the linear chain $z=2$, and secondly, because of the uniaxial angular dependence of the $p_z\pi$-orbitals occupied by the unpaired electrons. In fact, we have found neither two- nor three-dimensional magnetic lattice in any organic radical solid, although Duffy *et al.*[6] proposed a magnetic quadratic-layered structure for di-*p*-anisyl nitroxide (DANO) in accordance with the crystal quadratic layer sub-lattice, which consists of molecular centers,[3] but with no regard for the angular dependence of the orbitals.[7]

It is well known theoretically[8] that the isolated magnetic linear chains do not show any sharp magnetic phase transition, but, a rather broad maximum susceptibility, and that, in the presence of a small interaction between the chains, the phase transition from a short-range ordered state to a long-range ordered state may occur. This magnetic phase transition has thus far been considered to be found in the complex of 1,3-bisdiphenylene-2-phenylallyl with benzene (BDPA-*Bz*)[7,9,10] and in 1,3-bisdiphenylene-2-*p*-chlorophenylallyl (*p*-Cl-BDPA).[7,11] The present paper will deal with 1,3,5-triphenylverdazyl (TPV), the magnetic measurements of which show the possible existence of the long-range ordering and whose crystal structure has been determined recently.[2]

If the crystal structure is known, one can carry out more detailed experiments to study minutely the magnetism of the radical solid. Unfortunately, the crystal structure of neither BDPA-*Bz* nor *p*-Cl-BDPA has been solved. It is also of much interest to relate the magnetic properties of radicals to their crystal structures and to examine the exchange interaction mechanism. In this paper we would like to describe the magnetic behavior of the titled radical and discuss the magnetism of TPV from the standpoints of exchange interaction, spin density, and the crystal structure. In the last section of discussion, the magnetism of the galvinoxyl radical will be discussed from the present point of view.

Experimental

The sample was prepared by the method of Kuhn and Trischmann and was purified a few times through recrystallization from a mixture of acetone and methanol.[12] The melting point, which ranged from 142.0 to 142.5 °C, was found to agree well with the value in the literature. The results of the elementary analysis for carbon, hydrogen, and nitrogen were in good accord with the calculated values (Found: C, 76.43; H, 5.52; N, 17.94%.) The ESR spectrum in 2-methyltetrahydrofuran (2-MeTHF) *in vacuo* appeared in nine lines, with a line separation of 5.8 Gauss which can be assigned as the hyperfine coupling constant of four nearly equivalent nitrogen nuclei, and which is close to the value measured in a benzene solution and reported in the literature.

The magnetic susceptibilities from 1.6 to 300 K were measured on powder samples prepared independently in a heterogeneous magnetic field up to 8.8 kOe by means of a magnetic torsion balance described elsewhere.[13] The temperatures were determined using a calibrated AuCo-Cu thermocouple and a carbon resister. Manganese Tutton salt was used for the calibration of the thermometers as well as the product of the magnitude times the gradient of the magnetic field.

The ESR absorption spectra were observed on powder samples from 1.7 to 4.2 K and at the temperature of liquid nitrogen and at room temperature using a JES-ME-type spectrometer with an 80 Hz-field modulation. The temperatures were determined by means of the vapor pressures of liquid helium. An aqueous solution of peroxylamine disulfonate was used as the standard for the estimation of the g-value at room temperature. Mn^{2+} in MgO was taken as the second standard for the g-value measurement at lower temperatures and as a field-calibrating material.

Results

Susceptibility. The data have been corrected for the diamagnetic contribution using Pascal's constants.[14] The absolute molar susceptibility, χ_M, corrected for diamagnetism, complies with Curie-Weiss law with a negative Weiss constant, $\theta=-8$ K, in the higher-temperature region. The susceptibility, however, deviates from the Curie-Weiss law at lower temperatures, and it shows a broad maximum with a value of $\chi_{max}=203\times10^{-4}$ emu/mol at a temperature of $T_{max}=6.9$ K. When the temperature is lowered further, the susceptibility decreases comparatively slowly towards a minimum and then, as is shown in Fig. 1, unexpectedly increases again just after passing through the minimum point at $T_n=1.7$ K, where a discontinuity in the slope of the susceptibility is observed. The finite susceptibility at 0 K is roughly estimated as to be equal to $\chi_{T=0}=170\times10^{-4}$ emu/mol by the extrapolation of the χ_M *versus* T curve between the T_{max} and T_n temperatures. The radical concentration, as determined from the susceptibility in the temperature region above

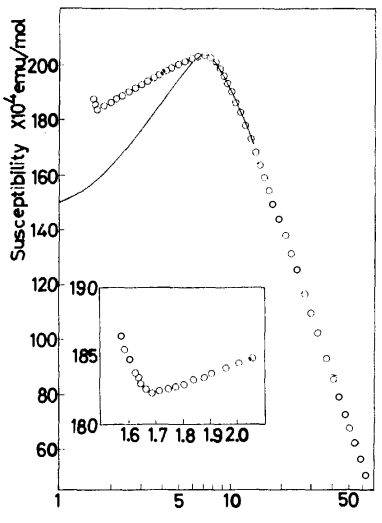

Fig. 1. Magnetic molar susceptibility of TPV.
Solid line represents the theoretical susceptibility calculated by the linear Heisenberg model. The inset shows the susceptibility at temperatures below 2 K.

77 K, was found to be 100% within the limit of experimental error. The reproducibility of the data was confirmed by comparing them with the data of samples prepared independently.

ESR. The ESR absorption spectrum shows a single line with an exchange-narrowed Lorentzian shape. In the higher-temperature region above T_{max}, the g-value was found to be practically isotropic, close to the free electron value and independent of the temperature. However, the g-value rapidly increases because of the anisotropic contribution in the lower-temperature region below T_{max}. The estimated g-value *versus* temperature curve is shown in Fig. 2. The temperature-dependent g-value of the another verdazyl radical, which exhibits a broad maximum susceptibility at *circa* 12 K but which is subjected to no long-range ordering in the available temperature range, is shown in the same figure for the sake of comparison.[15] The linewidth, which was taken to be the peak-to-peak linewidth (ΔH_p) of the first derivative of the resonance spectrum, probably starts to increase rapidly as the temperature is decreased below about T_{max}. The increase becomes more rapid as the temperatures approach

$T_n = 1.7$ K, which may be closely related to the increase in the g-value. The temperature dependences of the linewidths of TPV and the aforementioned radical are compared in Fig. 3.

Discussion

Susceptibility. One of the features of the susceptibility is, as may be seen in Fig. 1, that a finite susceptibility at 0 K seems to be left; this suggests a Heisenberg-type linear exchange interaction between unpaired electrons. This agrees well with the isotropic character of the g-factor. Therefore, the suceptibility may be described with neither Ising models[16,17] nor an exchange-coupled model.[18]

Therefore, we considered the linear Heisenberg model with isotropic exchange interaction, following the numerical calculation made by Bonner and Fisher.[19] The procedure of estimating the susceptibility has been described elsewhere.[7] The susceptibility gives an excellent fit to the value observed using $J/k = -5.4$ K, without any extra parameter such as a purity factor, in the temperature region above 6 K. However, the observed susceptibility deviates upwards from the theoretical value as the temperature is decreased below T_{max}. The value of $\chi_{max}/\chi_{T=0}$, being independent of the J parameter, is actually 1.2, while the theory predicts 1.45. On the other hand, the Weiss constant of -8 K, which agrees well with the value measured preliminarily in the temperature range above 77 K,[20] is larger in its absolute value than the theoretical one of 0.78 T_{max}, in contrast with the case of the product of T_{max} times χ_{max} 0.141 and 0.140 emu K/mol for the theoretical and observed values respectively. These two relationships are also independent of the J parameter.

Two coexistent interactions may make possible an interpretation of this feature. One of them rules predominantly and antiferromagnetically over the magnetism in the higher-temperature region and behaves one-dimensionally; the other is weaker than the former and is negligible in the higher-temperature region, but its latent ferromagnetic nature to tie up chain with chain is significant at temperatures below T_{max}. When the ferromagnetic contribution is adequately subtracted from the observed susceptibility, T_{max} may be shifted towards a higher temperature; the value of $|\theta|/T_{max}$ may then decrease to the theoretical value. One might suspect that the low-temperature discrepancy could be attributed to radical impurities, such as a defect in the crystal structure or a terminal spin contribution in the magnetic chain. However, the sample with a lower radical concentration (92%) shows a susceptibility quite similar to that of the pure sample except for the slight decrease in T_{max} (6.6 K), while a pure sample prepared independently gives an excellent agreement with the data of the other pure sample. Thus, the impurity contribution can not explain the discrepancy. Even if a two-dimensional antiferromagnetic model is taken into account, this low-temperature residual susceptibility may also be almost unchanged, although for the two-dimensional Heisenberg antiferromagnet neither an exact nor appropriate solution reliable at tempreatures below $|J|/k$ is yet known.

The presence of the interchain magnetic interaction accounts for the magnetic-phase transition from the short-range ordered state to the long-range ordered state, a transition which is inferred from the discontinuity in the slope of the susceptibility and the anomalies in the linewidth and g-value curves in the vicinity of 1.7 K.

ESR. Recently, Nagata *et al.* reported the short-range-order effects on the g-values in the Heisenberg linear chain antiferromagnets containing Mn^{2+} ion ($S=5/2$).[21] By introducing a small magnetic dipolar interaction and single-ion D-term, both of a uniaxial symmetry referred to the linear-chain direction, they classically estimated the simple relations between the anisotropies of the g-value and the susceptibility. The relationships were as follows:

$$\Delta g_{//}/g = (\chi_{//}-\chi_{\perp})/\chi_{//}, \quad (1)$$

$$\Delta g_{\perp}/g = (\chi_{\perp}-\chi_{//})/(2\chi_{\perp}). \quad (2)$$

When we assume the following relation for the powder sample:

$$\Delta g_{iso} = (\Delta g_{//}+2\Delta g_{\perp})/3, \quad (3)$$

then Eqs. (1) and (2) give this expression:

$$(1/g)\Delta g_{iso} = -(\chi_{//}-\chi_{\perp})^2/(3\chi_{//}\chi_{\perp}). \quad (4)$$

Eq. (4) indicates that, under their conditions, the g-value observed on the powder sample decreases with a decrease in the temperature if the anisotropic susceptibility is produced. We would like, however, to suggest that the essential part of Eqs. (1)—(4) lies in neither the sign nor the exact amplitude of the g-value shift, but in their suggestion that the anisotropic g-value reflects the anisotropy in susceptibility. Therefore, in comparison with the two curves shown in Fig. 2, the low-temperature g-value shift of TPV can be attributed to the susceptibility anisotropy in its solid. The striking shift in the temperature region below 2 K may imply the evolution of a severe change in the spin system in the vicinity of that temperature and may provide additional evidence of the phase transition at any temperature below 2 K. The sign of the g-value shift of TPV has to be subjected to an intense examination, together with the anisotropy in the susceptibility.

Although no appropriate theory for the linewidth of free radicals has been established, one of the present authors has previously reported the temperature dependence of the ESR absorption linewidth on a number of free radicals.[7] He found that the short-range ordering, remarkably developed near T_{max}, can be observed on the increase in the ESR linewidth, because the line broadening corresponds to an increase in the correlation time of the exchange motion due to the magnetic short-range ordering. In the present case, the line broadening probably starts to increase significantly at a higher temperature than what would be expected from T_{max} in view of the other data published.[7] This may be attributed to the precocious short-range ordering and may provide another support for the interchain ferromagnetic interaction derived from the susceptibility measurements. The broadening-out of the resonance line in the temperature region below 2 K may also be associated with the onset of the magnetic-phase transition in the neighborhood of that temperature, since, as the phase-transition temperature is approached, the increased spin-spin correlation results in the decreased exchange-narrowing of the linewidth.

Spin Distribution in the Molecule. The magnetic properties of free radicals with a delocalized unpaired electron may be greatly affected by the spin distribution. The proton NMR spectrum of TPV in a solution has exhibited well-resolved absorption lines.[22] Using the simple form of the McConnell relationship:[23]

$$a_i = -Q\rho_i, \quad Q = 23.7 \text{ Gauss},[24]$$

where a_i is the isotropic hyperfine splitting of the ith proton and where ρ_i is the spin density on the adjacent carbon atom, the spin densities on the carbon atoms were estimated, they are listed in Table 1. The McLachlan spin densities have been calculated and give a good agreement with the observed nitrogen hyperfine splitting of TPV.[23] Only the spin densities on the atoms with no adjacent hydrogen atom are also listed in the same table, because the McLachlan spin densities on aromatic rings do not always reproduce the proton splittings. The spin distribution in the table, together with the crystal structure to be considered in the next paragraph, will be discussed in connection with the magnetic structure of TPV.

a) Numbering system is shown in Fig. 4.
b) The spin density is omitted in view of its small value for the sake of simplicity.

Williams prior to publication,[2] the molecule of TPV has no symmetry element in its crystalline state, although those of the other two symmetrical verdazyls possess a mirror plane.[25] The small twist angles about the bonds connecting the *sym*-tetrazyl ring with the aromatic rings attached to the nitrogens are observed in all three of the verdazyls, while the respective *C*-phenyl ring is almost coplanar with the plane defined by the four nitrogens. The atomic deviation of all the aromatic ring carbons from the plane of the nitrogens is comparatively small for all the radicals. There is no essential difference among the molecular geometries of the three radicals, so that the molecules of the symmetrical verdazyls seem to be subjected mainly to intramolecular requirements or to steric and electronic effects. Therefore, it may be acceptable to assume that the electronic configuration as well as the molecular structure of TPV in its solid state are similar to those in solution, except for the effect of the largest exchange force in the crystal. The molecular structure and the numbering system of TPV are shown in Fig. 4.

The crystals of TPV belong to the orthorhombic system, with the space group of $P2_12_12_1$ and with these lattice parameters; $a=18.467$, $b=9.854$, and $c=8.965$ Å. Figure 5 shows the mutual arrangement of the molecules; the numbers are used to show the molecular positions. The number of the intermolecular approaches less than 4.0 Å from the **1** molecule to those at the other positions is 58, 39 vectors of which direct to the molecules at the **1′**, **2**, and **2′** positions. The other 19 approaches are randomly distributed on the other five molecules and include neither N···N nor C···N contact. The 39 intermolecular approaches are listed in Table 2. For each molecule four planes are defined—three phenyl-ring planes and the plane of the four nitrogens. C6 is assumed to be positioned on the nitrogen plane. The dihedral angle between the planes including the two atoms being examined into the interatomic distance is shown in the third column of the same table. The angle defined by an interatomic vector and the corresponding plane in the **1** molecule is listed in the fourth column of the table.

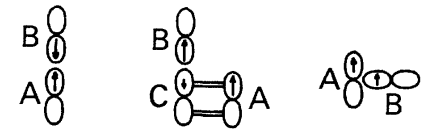
Exchange Interaction and Spin Densities. It is also important to discuss the relation between the signs of the apparent exchange integral and the spin density, because a problem may occur in certain solids of free radicals with a delocalized unpaired electron. Let us consider the following p-orbital exchange scheme:



Case I corresponds to the general situation; that is, two p-orbitals on different molecules overlap with each other in the *z*-direction. In this case the favorable spin orientation is antiparallel or J_{AB} is negative, because of the evolution of a small covalent bond. Case II illustrates the arrangement of the orbitals in the solid, which was referred to as a certain solid. The A and C orbitals belong to one molecule, and B, to the neighboring molecule. When the down-spin on the C orbital is polarized by the up-spin on the A orbital, the former spin can be related to the negative spin density. The overlap integral of the B and C orbitals results in a negative exchange integral, J_{BC}, so that a positive J_{AB} may be observed. This mechanism is one way to explain the totally parallel spin

25) unpublished data.

orientation or the ferromagnetic interaction between unpaired electrons. Case III shows another variation of the orbital arrangement. The exchange integral in this case is positive but very small, because of the mutual orthogonality of the orbitals.[26,27] The magnitude of the apparent exchange interaction of these scheme may be proportional to the triple product of the spin densities on the two atoms concerned with the overalp and the corresponding exchange integral. This relation of the signs of the exchange integral and the spin densities is summarized and extended to a many-center problem by the following Hamiltonian:[26]

$$H^{AB} = -\mathbf{S}^{A}\mathbf{S}^{B}\sum_{ij} J_{ij}^{AB}\rho_i^{A}\rho_j^{B}, \qquad (6)$$

where $\mathbf{S}^{A}$ and $\mathbf{S}^{B}$ are the total spins on Molecules A and B and where ρ_i^{A} and ρ_j^{B} are the π-spin densities on the i and j atoms of Molecules A and B. When the sum in Eq. (6) is positive, the apparent exchange interaction is ferromagnetic. The negative sign of the sum corresponds to an antiferromagnetic exchange interaction between unpaired electrons.

$$H^{AB} = -J_{AB}\mathbf{S}^{A}\mathbf{S}^{B} \qquad (7)$$

When Eq. (6) is compared with Eq. (7), which corresponds to the Hamiltonian for the ordinary two-spin problem, then the sum in Eq. (6) can be named as the apparent exchange integral for a many-center problem.

Possible Magnetic Structure. The intermolecular distances less than 6.0 Å and the aforementioned angles were calculated in order to picture the magnetic structure of the TPV radical solid. Assuming that J_{ij}^{AB} is simply proportional to the inverse of the interatomic distance (d) alone and that the negative unity for d=1 Å, Eq. (6) was applied to the data of the interatomic distance less than 4.0 Å and the corresponding spin densities listed in Table 1. The results are shown in Table 2, where the values in the fifth and sixth columns have been multiplied by 10^5.

The molecules in the possible magnetic chain are related with each other by a twofold screw axis parallel to the c-axis. In this chain, the numbers of the intermolecular distances less than 4.0 Å from the atoms in the asymmetric unit molecule (Position **1**) to atoms in the nearest-neighboring (Position **2**) and the next nearest-neighboring (Position **1'**) molecules are 15 and 14 respectively; this is an interesting situation. The sum in Eq. (6) is negative for the nearest-neighboring molecule, while that for the next nearest-neighbor is positive, within the limits of the aforementioned broad assumption. The negative sign of the former sum indicates an antiferromagnetic interaction between the unpaired electrons, while the positive sign of the latter sum suggests a ferromagnetic interaction. However, these results may not indicate a competitive intrachain exchange interaction, but, rather, a cooperative totally antiferromagnetic interaction in the magnetic linear chain. It is suspected that the sum for the nearest-neighbor is estimated more highly than the sum for the next nearest-neighbor, taking account of the angular dependence of the exchange integral, J_{ij}^{AB}. The angle between the two orbitals may be inferred from the angles in the third and fourth columns of Table 2. We thus presume that the cooperative mechanism or the contribution of the second nearest-neighbor is too significant to neglect in this radical solid.

The number of the intermolecular approaches less than 4.0 Å associated with the nearest-neighboring molecule in the adjacent magnetic chain is 10, and the sum of these data gives a positive sign, which indicates

a ferromagnetic interchain interaction. Thus, the intrachain antiferromagnetic and interchain ferromagnetic interactions inferred from the susceptibility measurement are qualitatively confirmed on the basis of the spin distribution and the crystal structure.

Galvinoxyl Radical. In order to confirm our proposal regarding the ferromagnetic interaction, let us consider the galvinoxyl radical solid, the susceptibility of which follows the Curie-Weiss law with a positive Weiss constant of 11 K above 83 K.[28] The crystal system of the radical solid is monoclinic, with a space group of C2/c, and with the cell dimensions of $a=23.78$, $b=10.87$, $c=10.69$ Å, and $\beta=106.6$ degrees.[4] Figure 6 shows the molecular packing, where the a-axis is drawn up to the half way mark. The molecule has a diad axis through the C–H bond in the methine group; this molecular twofold axis coincides with the crystallographic diad axis. The dihedral angel between the planes of the radical halves is 17 degrees. In Fig. 6, two methine carbons on the a-plane are positioned at (0.0, 0.03668, 0.25) and (0.0, −0.03668, 0.75); the other two methine carbons have the coordinates (0.5, 0.53668, 0.25) and (0.5, 0.46332, 0.75) respectively. Therefore, it can be said that this radical solid has a typical linear-chain magnetic structure along the c-axis, without any significant interchain interaction; therfore the above-mentioned susceptibility data may give information about its intrachain interaction alone. Within the chain, the intermolecular vectors which make angles from 70 to 90° (taken as an acute angle) with the phenyl plane and shorter than 5.0 Å were collected; the number of the vectors was 24. The spin densities were taken from Refs. 29 and 30. A procedure similar to that in the last section gives a positive sign for the sum in Eq. (6). Therefore, the comparatively large positive Weiss constant of 11 K may correspond to the ferromagnetic interaction caused by the overlap of a positive-spin-density-radical part with the negative-spin-density one in the neighboring molecule. It is interesting to notice that the qualitative magnetic behavior of two radical solids can be explained using Eq. (6).

Summary

The experimental results may be summarized as follows:
1) The susceptibility of TPV is well described by the linear Heisenberg model in the temperature region above 6 K, but deviates upwards from the theoretical one with a decrease in the temperature below 6 K and then exhibits a discontinuity in its slope at 1.7 K. The parameters derived from the susceptibility are $\theta=-8$ K, $T_{max}=6.9$ K, $\chi_{max}=203\times10^{-4}$ emu/mol, and $J/k=-5.4$ K. 2) The ESR absorption linewidth, which is associated with the correlation time of the exchange motion, increases in the vicinity of T_{max} and broadens rapidly with a decrease in the temperature below 2 K. The temperature dependence of the g-value, which reflects the anisotropy in the susceptibility, is similar to that of the linewidth.

To summarize our interpretation of the results:
1) This radical solid may belong to the linear antiferromagnetic Heisenberg magnet, with a considerable ferromagnetic interaction between the chains. The discontinuing susceptibility at 1.7 K may imply a magnetic long-range ordering caused by the interchain ferromagnetic coupling. The pronounced increases in both the linewidth and the g-value below 2 K may be attributed to the critical fluctuation of electron spins in the neighborhood of the transition temperature. 2) The magnetic structure has been discussed on the basis of the spin distribution on the single molecule and the crystal structure. The possible linear chain is parallel to the c-axis, which is the shortest of the three orthorhombic axes. In this chain, the contribution of the second nearest-neighbor is significant and this is a ferromagnetic interaction which is cooperative with the antiferromagnetic one between the adjacent spins. The interchain interaction derived by our calculating procedure is ferromagnetic. 3) This magnetic structure can account for the qualitative experimental results of TPV. The method employed in the case of TPV was applied to the galvinoxyl radical solid and its positive Weiss constant of 11 K was attributed to the intrachain ferromagnetic interaction.

The authors would like to acknowledge the continuing guidance and encouragement of Professors Hideo Takaki and Mamoru Mekata of Kyoto University and Professor Kazuhiko Ishizu of Ehime University. They are also deeply indebted to Professor Yoshihiko Saito of the University of Tokyo for his helpful advice and for the use of considerable facilities in the determination of the crystal structures of the verdazyl radicals under consideration. They also thank Professor D. E. Williams of Louisville University, who supplied a preprint about the crystal structure of TPV and allowed them to reproduce the crystallographic figures of TPV and galvinoxyl radicals.

Interaction of Bovine Serum Albumin with Detergent Cations

(Received February 19, 1973)

The binding isotherms of bovine serum albumin (BSA) with cationic detergents, decyltrimethylammonium bromide, dodecyltrimethylammonium bromide, and tetradecyltrimethylammonium bromide have been determined at temperatures 8 and 25 °C for pH 6.8. The isotherms have also been determined at pH 3.0 and 25 °C. The effect of KBr on the binding of dodecyltrimethylammonium bromide to BSA has been examined at 25 °C for pH 6.8. The results obtained are as follows. (a) The average number of detergent cations bound, $\bar{\nu}$, increased with the increase in the length of hydrocarbon chain, (b) the standard free energy changes $-\Delta G°$, calculated from the intrinsic association constants K, were comparable with the cohesive energy change when one methylene group is transferred from the aqueous phase to the hydrocarbon environment on micellization, (c) values of $\bar{\nu}$ at pH 3.0 differ only slightly from those at pH 6.8 in a wider range of detergent concentration, and (d) the presence of the salt shifted the binding isotherms to the lower detergent concentrations. These results are discussed as regards the nature of micellization of detergents.

Various studies have been made[1-5] on the interaction of serum albumin with anionic detergents but only a few[3,6-8] on cationic detergents.[9] So far it is known that the initial binding of anionic detergents to bovine serum albumin (BSA) involves 11 equivalent sites which do not interact, and that at higher levels of binding, at neutral pH, three stoichiometric complexes can be distinguished having the respective compositions AD_m, AD_n, and AD_{2n} (A: BSA, D: detergent anion, $m=11$, and $n=38$). Examination of the binding of different charged, cationic detergents to BSA will contribute significantly to elucidate whether the binding is attributed to the hydrophobic interaction or the electrostatic interaction. We have studied the effects of hydrocarbon chain length, pH, and added salt on the binding of cationic detergents to BSA by the method of equilibrium dialysis to elucidate the mechanism of interaction. The results obtained are compared with those of the binding of anionic detergents. The cationic detergents used are decyltrimethylammonium bromide (DeTAB), dodecyltrimethylammonium bromide (DTAB), and tetradecyltrimethylammonium bromide (TTAB).

Experimental

Materials. DeTAB, DTAB, and TTAB, prepared by the reaction of the corresponding alkylbromides with trimethylamine,[10] were purified by recrystallization from acetone. Alkylbromides used for the preparation of the cationic detergents were gas chromatographically pure. All the detergents prepared gave correct elemental analyses.

A solution of BSA (Armour, Lot. CK5010 and PK4471), after storage at 2—5 °C and pH 2 for 2 days was centrifuged and filtered to remove lipid contaminants.[4] The solution was dialyzed against distilled water and finally against the buffer solution of desired pH.

Equilibrium Dialysis. Detergent binding measurements were carried out by the method of equilibrium dialysis at 8(±0.01) and 25(±0.01) °C in phosphate buffer of ionic strength 0.1 and pH 6.8 and also at 25 °C in citrate buffer of ionic strength 0.1 and pH 3.0. Visking tubing for dialysis was heated for 3 hr in the saturated solution of $NaHCO_3$ near boiling point and rinsed thoroughly with distilled water to remove impurities. The tubing treated was then stored in distilled water at 2—5 °C. Bags were filled with 5 ml of *ca.* 1% protein solution in buffer and suspended in 10 ml of the same buffer for 3 days (at 25 °C) or 4 days (at 8 °C) with occasional shaking. The detergent was placed outside the dialysis bag. The amount bound to BSA was calculated by determining concentrations of detergent in the outside solution before and after the dialysis. A blank correction was made for the adsorption of detergent to the bag when no protein was present. The concentration of cationic detergent was determined by a spectrophotometric dye method.[11] The complex of orange II-detergent cation was extracted by chloroform and the optical density of the chloroform solution was determined at 485 mμ using a Hitachi 101 spectrophotometer. The protein concentration was determined from optical density measurements at 279 mμ; $E_{1\%}^{1cm}$ was assumed to be 6.67 for BSA at this wavelength.[4]

Critical Micelle Concentration (CMC). The CMC's of cationic detergents were determined by the surface tension method using the stalagmometer at 25(±0.01) °C. The values of CMC in aqueous solution of DeTAB, DTAB, and TTAB were 64.45, 15.54, and 4.01 mmol/kg-H_2O, respectively.

Results and Discussion

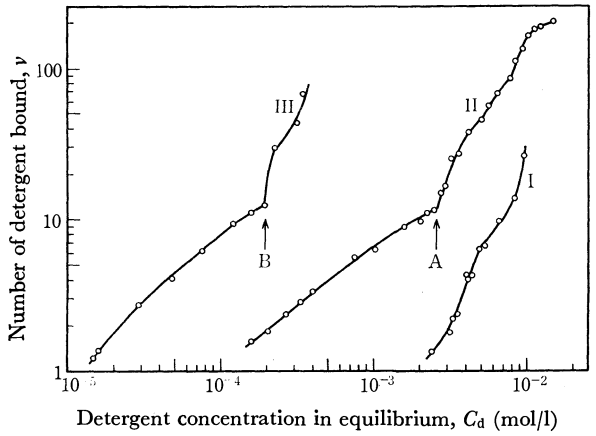

Fig. 1. Binding isotherms for cationic detergents and BSA at 25 °C and pH 6.8 (ionic strength 0.1). I: DeTAB, II: DTAB, and III: TTAB.

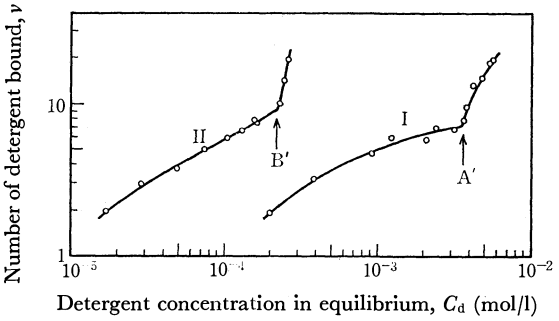

Fig. 2. Binding isotherms for cationic detergents and BSA at 8 °C and pH 6.8 (ionic strength 0.1). I: DTAB and II: TTAB.

pH 6.8 and 25 °C for three detergents are shown in Fig. 1. The shape of isotherm for DeTAB differs from that for others. The binding isotherms at 8 °C and pH 6.8 for DTAB and TTAB are shown in Fig. 2. At each temperature, the longer the hydrocarbon chain of detergents, the lower the concentration of free detergent in equilibrium. The slope of binding isotherm for DTAB and TTAB changes at 25 °C at points A and B (in Fig. 1) at which the number of bound detergent $\bar{\nu}$ is 12 and 13 for DTAB and TTAB, respectively. The slope of isotherm changes at 8 °C also at A′ and B′ (in Fig. 2) at which $\bar{\nu}=8$ and $\bar{\nu}=10$ for DTAB and TTAB, respectively. The concentration at A is the same as that at which several zones appear suddenly in the pattern of acrylamide-gel electrophoresis for this system.[12]

It is known that a cationic detergent, dodecylpyridinium bromide, as well as anionic detergents, forms the AD_m type complex with horse serum albumin.[3] It is seen in Figs. 1 and 2 that such a complex is formed at points A, B, A′, and B′, and that changes in conformation of the protein occurs in the region where $\bar{\nu}$ is larger than that at A or B, and the steepening of the isotherm begins. It was observed by using acrylamide-gel electrophoresis that the complex AD_{11} of sodium dodecylsulfate (SDS) prevented heat denaturation but the complex formed at point A did not prevent denaturation but rather promoted it.[13] Markus *et al.*[14] stated that the protective effect by SDS against urea denaturation of BSA is due to cross-links formed by the detergent anions between groups of nonpolar residues (presumably located in crevices formed by the folding of the peptide chain) and positively charged lysine residues. The mechanism of binding by Markus *et al.* is not applicable to the present system since no protection against denaturation occurs.[13] Thus, it is expected that the site on BSA for DTAB binding differs from that for SDS binding.

Thermodynamic Parameters. If the binding sites on protein are equivalent and non-interacting, the binding of detergents to protein is known to follow the equation[15]

$$\frac{1}{\bar{\nu}} = \frac{1}{Kn}\frac{1}{C_d} + \frac{1}{n} \qquad (1)$$

where $\bar{\nu}$ is the average number of moles of detergent cation bound per mole of protein, K the intrinsic association constant of each site for the detergent, n the total number of sites having an association constant K, and C_d the free detergent concentration in equilibrium. Plots of $1/\bar{\nu}$ *vs.* $1/C_d$ lie on a straight line for DTAB and TTAB in the region $\bar{\nu}<ca.$ 10. The intercept and slope of these lines for DTAB and TTAB give $1/n$ and $1/Kn$, respectively. The reciprocal plot for DeTAB, however, is not satisfactorily linear. The values of n and K thus obtained for DTAB and TTAB are given in Table 1 together with the standard free energy change calculated by the relation $\Delta G^\circ = -RT \ln K$. The values for anionic detergents by other workers are also included in Table 1 for comparison. The association constant K for cationic detergents increases with the increase in length of hydrocarbon tail and is lower than that for the corresponding alkylsulfates. The value of n increases with the increase in length of hydrocarbon tail at a constant temperature.

TABLE 1. ASSOCIATION CONSTANTS K, AFFINITIES $-\Delta G^\circ$, AND NUMBERS OF BINDING SITES FOR DETERGENTS ON BSAn

Detergent	K	$-\Delta G^\circ$ (kcal/mol)	n	Temp. °C	Ref.
$C_{12}H_{25}N(CH_3)_3Br$	1.6×10^3	4.1	8	8	
	4.5×10^2	3.6	22	25	
$C_{14}H_{29}N(CH_3)_3Br$	1.2×10^4	5.3	10	8	
	3.1×10^3	4.8	33	25	
$C_8H_{17}SO_4Na$	0.6×10^6	7.3	4—5	2	5
$C_{10}H_{21}SO_4Na$	1.4×10^6	7.8	5—6	2	5

The n value at 8 °C is in fair agreement with the number of detergents bound at points A′ and B′ in Fig. 2. The value of n at 25 °C, however, is far larger than $\bar{\nu}$ at A and B in Fig. 1.

The difference in values of $-\Delta G°$ for DTAB and TTAB can be attributed to the difference in the length of hydrocarbon tail. The difference in the standard free energy change thus calculated gives 1.0 kT per methylene group at two temperatures. The values for alkylsulfate, calculated from the data by Karush and Sonenberg,[2] was found to be 0.96 kT. These values are comparable with the cohesive energy change 1.0—1.2 kT[16] when one methylene group is transferred from the aqueous medium to the hydrocarbon environment on micellization of various detergents.

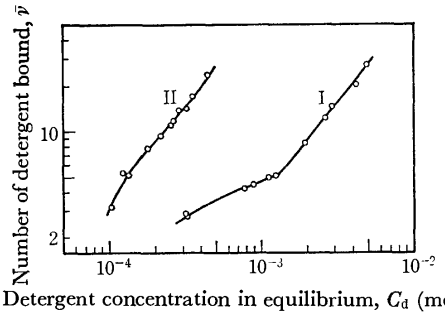

Fig. 3. Binding isotherms for cationic detergents and BSA at 25 °C and pH 3.0 (ionic strength 0.1). I: DTAB and II: TTAB.

Effect of pH. Equilibrium dialysis was carried out at more alkaline pH than the isoelectric point of BSA. If the pH of solution turns more acidic than that of isoelectric point, the net charge of BSA changes from negative to positive. Thus, if the binding is assumed to be electrostatic, the number of detergent cations bound should decrease remarkably at the acid pH. Isotherms of BSA with DTAB and TTAB at pH 3.0 are shown in Fig. 3. Comparing Fig. 3 with Fig. 1, we see that the difference in $\bar{\nu}$ between isotherms at pH 6.8 and 3.0 is not remarkable. The reversible expansion of BSA which occurs at below pH 3.5[17] would expose both sites for electrostatic binding and hydrophobic binding. However, the number of bound detergent cations did not change remarkably with pH. Thus, the interaction of BSA with detergent cations appears to be hydrophobic rather than electrostatic.

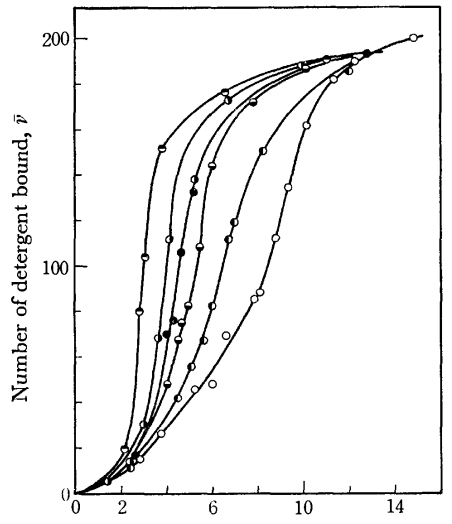

Fig. 4. Effect of KBr on the binding of DTAB to BSA at 25 °C and pH 6.8 (ionic strength 0.1). Concentrations of KBr; 0 (○), 0.02 (◐), 0.04 (◒), 0.06 (●), 0.10 (◑), and 0.15 (◓) mol/l.

Table 2. Effect of KBr on the CMC of DTAB in phosphate buffer (ionic strength 0.1, pH 6.8) at 25 °C

Concn of KBr (mol/l)	CMC $\times 10^3$ (mol/l)
0	12.2
0.02	8.6
0.04	6.6
0.06	5.3
0.10	4.0
0.15	3.2

Effect of Added Salt. The interaction of BSA with detergents at higher concentration is as follows. The binding isotherms of BSA with DTAB, obtained at various concentrations of added KBr, are shown in Fig. 4. In the range 0.02—0.15 mol/l, the increase in concentration of KBr shifts the isotherm toward the lower concentration of DTAB in equilibrium, *viz.*, the concentration of detergent at which a particular number of bound detergent cations lowers as the concentration of salt increases. This tendency is in line with the fact

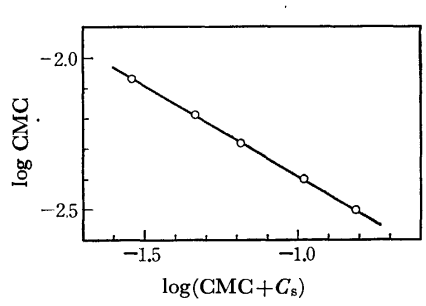

Fig. 5. Effect of KBr concentration on the CMC of DTAB in phosphate buffer (pH 6.8, ionic strength 0.1) at 25 °C.

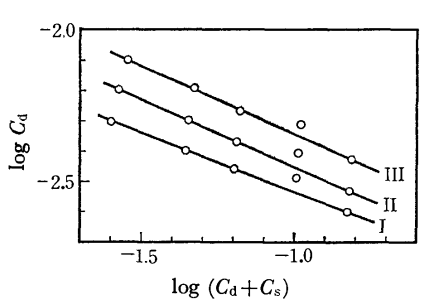

Fig. 6. Plots of log C_d *vs.* log (C_d+C_s) at constant $\bar{\nu}$. I: $\bar{\nu}$ = 50, II: $\bar{\nu}$ = 100, and III: $\bar{\nu}$ = 150.

17) C. Tanford, *Proc. Iowa Acad. Sci.*, **59**, 206 (1952). G. Scatchard, *Am. Scientist*, **40**, 61 (1952).

that the added salt lowers the CMC of detergents. The effect of added KBr on the CMC of DTAB in the phosphate buffer solution is presented in Table 2. The CMC of detergent is related to the concentration of added salt C_s by the relation[18]

$$\log \mathrm{CMC} = a - b \log (\mathrm{CMC} + C_s) \qquad (2)$$

where a and b are constants. Data in Table 2 satisfy Eq. (2) as is shown in Fig. 5. If we assume that the binding of DTAB to BSA is governed by the same force as in the micelle formation, CMC in Eq. (2) can be replaced by the concentration of detergent in equilibrium C_d at a constant $\bar{\nu}$. The plot of log C_d *vs.* log (C_d+C_s) at a constant $\bar{\nu}$, for example $\bar{\nu}=50$, 100, and 150, falls on a straight line (Fig. 6).

In conclusion, the nature of the binding of alkyltrimethylammonium bromides with BSA is very similar to that of micelle formation of detergent. In the micelle formation of ionic detergent, hydrophobic interaction plays a predominant role. From the analogy to micelle formation, the cationic detergent-BSA interaction is hydrophobic in nature in the ranges of $\bar{\nu}$ and concentration of detergent in this experiment.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2738—2741 (1973)

Ultrasonic and Thermodynamic Studies on the Aqueous Solutions of Tetramethylurea

Katsutaka SASAKI and Kiyoshi ARAKAWA

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received February 27, 1973)

Ultrasonic absorption and sound velocity were measured for aqueous solutions of tetramethylurea at temperatures 10—30 °C. Excess compressibility and partial molar volume were obtained. The curves for the concentration dependence of density, viscosity, and absorption show a maximum at about 60 vol% (20 mol%). The excess compressibility curve shows a minimum at the same concentration. It is concluded that a molecular complex of the molar ratio 4: 1 (water: tetramethylurea) linked with hydrogen-bonds is formed at 20 mol%. In a dilute solution (below 4 mol%), the magnitude of ultrasonic absorption of tetramethylurea solutions is equal to that of 1,3-dimethylurea solutions, but is less than that of 1,3-diethylurea solutions. The tetramethylurea–water interaction is of a similar nature to that between 1,3-dimethylurea and water in a dilute solution.

From the results of our ultrasonic studies on the effects of guanidine hydrochloride, urea and its alkyl derivatives upon the structure of water, it was concluded that guanidine hydrochloride and urea molecules behave as a structure breaker for liquid water.[1-3]

Recently, Subramanian *et al.*[4] have shown from NMR and specific heat capacity data on aqueous solutions of urea and its derivatives that the relative decreasing order of structure making propensities (in water) is tetramethylurea>1,3-dimethylurea>urea, and they stated to have reached the same conclusion as ours. However, they have misinterpreted our study, for we made no mention of the aqueous solutions of tetramethylurea in our report.[2] Finer *et al.*[5] pointed out that the results of proton chemical shift studies on aqueous solutions of urea strongly disagree with that by Subramanian *et al.*[4] Therefore, the conclusion on the order of structure making propensities given by Subramanian *et al.* is doubtful.

In the present paper we report on ultrasonic studies on aqueous solutions of tetramethylurea with an intention to investigate alkyl group–water interactions, and compare it with the results for 1,3-dimethylurea and 1,3-diethylurea solutions. Despite the usefulness of the material as a good solvent for many organic substances, physicochemical studies on tetramethylurea solutions are very few.[6] Tetramethylurea is one of the few urea derivatives which is liquid at room temperatures and acts only as a hydrogen bond acceptor without an ability as a proton donor. We discuss in this paper the solute-solvent interactions in tetramethylurea solutions.

Experimental

Measurements of sound velocity and absorption coefficient were carried out by an ultrasonic pulse technique. The apparatus and procedure of measurements were already described.[7] The absorption coefficient was determined in the frequency range 15—45 MHz. Temperature range was 10—30 °C, the accuracy being within ±0.1 °C. The sound

velocity was measured at 5 MHz.

Tetramethylurea (Aldlich Co. Ltd., USA) was used after being refluxed with calcium hydride under nitrogen atmosphere and distilled at 10 mmHg. Density of aqueous solutions was measured with an Ostwald type pycnometer at 20 °C, and partial molar volume was calculated. Viscosity coefficients for the solutions were measured with an Ostwald type viscometer (flow time for pure water, 270 s at 20 °C).

Results

Sound Velocity and Compressibility. The accuracy of sound velocity was within ±1 m/s. The values obtained are plotted against concentration (vol%) in Fig. 1. The density data at 20 °C are shown in Fig. 2. Excess compressibility $(V\kappa_s)_{\text{excess}}$ is defined by

$$(V\kappa_s)_{\text{excess}} = (V\kappa_s) - (x_1V_1\kappa_{s,1} + x_2V_2\kappa_{s,2}) \quad (8)^{8)}$$

where V, V_1, and V_2 are molar volume of solution, solvent, and solute, respectively, κ_s, $\kappa_{s,1}$, and $\kappa_{s,2}$, adiabatic compressibility of solution, solvent, and solute, respectively, and x_1 and x_2, mole fraction of solvent and solute, respectively. The results are plotted against concentration (mol%) in Fig. 3. We see that the excess compressibility curve has a minimum at about

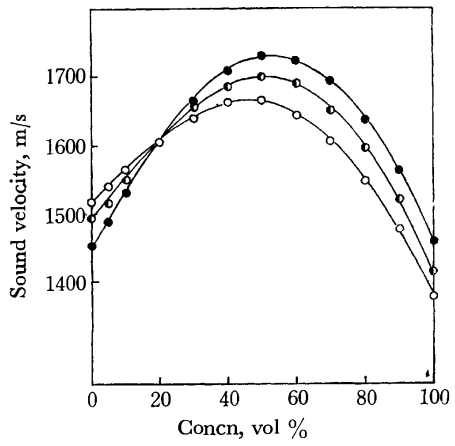

Fig. 1. Sound velocity for tetramethylurea solutions.

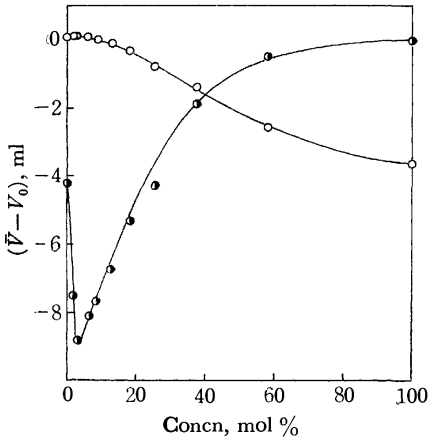

Fig. 4. Partial molar volume for tetramethylurea solutions at 20 °C.
○: water, ◑: tetramethylurea

20 mol%. The partial molar volume obtained from density data is given in Fig. 4. The partial molar volume of solute rapidly decreases up to about 4 mol% (20 vol%) while that of solvent water increases only slightly. Sound velocity *vs.* concentration curves at various temperatures intersect at about 20 vol% (4 mol%) (Fig. 1).

Ultrasonic Absorption and Viscosity. The data of ultrasonic absorption are reproducible within ±2%. The α/f^2 *vs.* concentration curves (α, absorption coefficient and f, frequency) are given in Fig. 5. The magnitude of absorption increases slowly up to about 20 vol% (4 mol%), and rapidly from 20 to about 60 vol%.

Viscosity coefficients were measured in order to obtain classical absorption. The results are given in Fig. 6. The classical absorption is given by

$$(\alpha/f^2)_{\text{class.}} = \frac{8\pi^2\eta}{3\rho V^3} \quad (2)$$

where ρ is density, V sound velocity and η viscosity coefficient. The structural absorption is given by

$$(\alpha/f^2)_{\text{struct.}} = (\alpha/f^2)_{\text{obsd.}} - (\alpha/f^2)_{\text{class.}} \quad (3)$$

The results at 20 °C as compared with the data of observed and classical absorption are given in Fig. 7. The increase of observed absorption is primarily at-

tributed to the structural absorption. The magnitude of absorption on the solutions of low concentration is compared with that of 1,3-dimethylurea and 1,3-diethylurea solutions (Fig. 8). The absorption is equal in magnitude to that of 1,3-dimethylurea solutions in the same region of concentration.

Discussion

Alkyl Group–Water Interaction. All curves intersect nearly at a point at about 20 vol% (4 mol%) (Fig. 1). An intersection point in a family of sound velocity *vs.* concentration curves at different temperatures appears in various aqueous systems.[9,10] The concentration at the crossing point (Fig. 1) corresponds to that of the sharp minimum of partial molar volume curve of solute (Fig. 4). The partial molar volume of solvent increases only slightly up to about this concentration. Below the concentration of 20 vol% (4 mol%), solute molecules might enter the cavities of water structure causing no conceivable rearrangement of the structure of water. This is due to the cooperative nature of structure formation in liquid water.[3] Since the magnitude of α/f^2 for pure tetramethylurea dose not differ much from that of pure water (Fig. 5), substitution of tetramethylurea molecules for solvent molecules in aqueous solutions causes no appreciable change in α/f^2 for solutions in a dilute region.

From a comparison of the magnitude of α/f^2 for tetramethylurea, 1,3-dimethylurea and 1,3-diethylurea solutions (Fig. 8), we can discuss alkyl group–water interactions. It is seen that the magnitude of absorption for tetramethylurea solutions is equal to that of 1,3-dimethylurea solutions, while the magnitude of α/f^2 for 1,3-diethylurea solutions is fairly larger. 1,3-Diethylurea molecules behave as a structure former on the structure of water.[2] The rapid increase of α/f^2 with concentration for 1,3-diethylurea solutions is ascribed to the structure formation around ethyl groups of solute molecules in water. In tetramethylurea and 1,3-dimethylurea solutions the situation is different.

Barone *et al.*[11] pointed out that from a spectroscopic study the structure forming ability of tetramethylurea in liquid water was stronger than that of 1,3-dimethlyurea and 1,3-diethylurea. However, the low "structure

9) R. Parshad, *J. Acoust. Soc. Amer.*, **20**, 66 (1948).
10) G. W. Willard, *ibid.*, **12**, 438 (1940).
11) G. Barone, E. Rizzo, and V. Vitagliano, *J. Phys. Chem.*, **74**, 2230 (1970).

temperature" [12,13] of tetramethylurea they gave should be ascribed to some other source, since their measurements were carried out in a higher concentration region. Study on iceberg formation should be made in a relatively dilute concentration region in order to avoid the effect from other factors of solute–solvent interactions.

The difference in α/f^2 *vs.* concentration curves (Fig. 8) is thus attributed to the difference between the behavior of the methyl group and ethyl group in water. The van der Waals radius of methyl group given by Pauling is about 2.0 Å.[14] The value is not much larger than that of water molecule,[14,15] and the methyl group seems to rotate nearly free from the absence of steric hindrance in water. Thus, the tetramethylurea-water interaction is found to be essentially similar to that of 1,3-dimethylurea solutions in low concentrations. This is in agreement with the result of viscosity increment (coefficient B) for solutions of tetramethylurea, 1,3-dimethylurea and 1,3-diethylurea by Herskovits *et al.*[16] The present result seems to be in line with that of the gas solubility study by Wetlaufer *et al.*[17]

Formation of Tetramethylurea Hydrate. The concentration of maximum density is found at about 60 vol% (18.5 mol%) (Fig. 2). The excess compressibility curve has a minimum at about 20 mol% (Fig. 3). It is thus expected that a tetramethylurea hydrate is formed. A maximum of α/f^2 was found at 63 vol% (20.4 mol%) at each temperature (Fig. 5) and a maximum of viscosity coefficient at 64 vol% (21.1 mol%) (Fig. 6).

Lüttringhause and Dirksen[6] proposed from density measurements that a molecular complex is formed with the molar ratio 6: 1 (water: tetramethylurea). However, we see a maximum or a minimum at a concentration of about 20 mol% in each curve for density, compressibility, ultrasonic absorption and viscosity coefficient. This corresponds to the molar ratio 4: 1 (solvent: solute). Tetramethylurea acts only as a hydrogen-bond acceptor, since all hydrogens of amide nitrogen are substituted by the CH_3 groups. Thus, it is tentatively assumed that tetramethylurea tetrahydrates are formed in aqueous solutions by hydrogen bonding. From the temperature dependence of maximum values of absorption, the apparent activation energy was calculated to be 6.9 kcal/mol. This value seems to be adequate for the tetrahydrate formation. The increase of observed absorption is mainly due to the increase of structural absorption (Fig. 7). Thus, we can conclude that the maximum value of ultrasonic absorption at 60 vol% is ascribed to the presence of tetrahydrate.

The authors wish to thank Mr. Nobuo Takenaka for his cooperation in this study.

Kinetic Studies of Photosensitized Oxidation through Semioxidized Eosine in an Aqueous Solution

Yoshiharu USUI and Haru ENOKIDO*

Department of Chemistry, Ibaraki University, Mito 310

(Received April 5, 1973)

The rate constant for an electron transfer reaction between triplet eosine and potassium tris(oxalato)cobaltate-(III) was estimated. The experimental results from flash photolysis indicate that a transient semioxidized eosine exists in a free state. When a substrate was added to the deaerated eosine and complex solution at an optimum concentration, the original dye was restored by electron transfer from a substrate to the semioxidized eosine, sensitized oxidation occurring efficiently. Choosing indole and its derivatives as a substrate, we have obtained the elementary rate constants of the eosine recovery process.

In a previous paper it was reported that semioxidized eosine (E^+) produced by electron transfer from triplet eosine to potassium tris(oxalato)cobaltate(III) ($K_3[Co(C_2O_4)_3]$) might exist as a free radical in a degassed aqueous solution and the reactivity of E^+ for leucofluorescein was discussed on the basis of a comparison with its transient complex forms such as $E^+\cdots O_2^-$ and $E^+\cdots E^-$.[1)]

This paper shows kinetically the occurrence of eosine sensitized oxidation with a high efficiency in this deaerated solution, where original eosine could be reproduced through a semioxidized form *via* an electron transfer with a substrate. Since the sensitization cycles

are not disturbed by the unreactive species of cobaltous and oxalate ions aquated from unstable potassium tris-(oxalato)cobaltate(II) in a neutral solution, the mechanism is expected to be determined as the simple scheme by the retarding effect of a substrate on the eosine bleaching rate.

Including the case of a coupled formation of E^+ and E^- by D–D mechanism,[2] this sensitized oxidation pattern through the path of the semioxidized form may be significant as compared with the classical photodynamic action in which oxygen needs to take the major role of substrate oxidation.[3]

Experimental

Purification of materials except substrates and most of the experimental procedures were similar to those described previously. All substrate reagents (Tokyo Kasei G.R.); indole, 3-methylindole, and L-tryptophan *etc.* were used without further purification. All the reactions were carried out at 25.0 °C.

Results and Discussion

Reaction Mechanism of Photooxidation of Eosine by Potassium Tris(oxalato)cobaltate(III). In flash photolysis of the deaerated eosine and complex aqueous solution, three main maxima of a transient species appeared at 408 nm (semireduced form, E^-), 460 nm (semioxidized form, E^+) and 580 nm (eosine triplet, E^T). E^- was slightly accompanied by D–D mechanism.[2] The lifetime of E^+ is considerably longer (~1 ms) than that in a plain aqueous solution, where the decay is expressed as the recombination of E^+ and E^- to restore original eosine.[4] When cobalt complex (C) is added in order of magnitude greater than 10^{-4} M, E^+ could be produced by the reaction of $E^T+C \longrightarrow E^+ + C^-$, a destructive bleaching of eosine occurring with high quantum yield.

A competitive effect of the complex concentration on the decay of E^T is shown in Fig. 1. Putting $k_s = k_d^{\circ} + k_D^s[D]$, the pseudo-first order rate constant (k) is written as

$$k = k_d^{\circ} + k_D^s[D] + k_c^s[C] = k_s + k_c^s[C]$$

where k_d°, k_D^s, and k_c^s ($=k_c^r + k_c^d$) are the rate constants on triplet eosine for a unimolecular decay, D–D interaction and a reaction with the complex, respectively. From the slope in Fig. 1, we get the k_c^s value as 9.2×10^6 M^{-1} sec^{-1}.

To clarify the genuine rate of an electron transfer from E^T to C by a steady-light illumination experiment, the quantum yield (Φ) of eosine bleaching was determined from the slope of a plot $\ln(e^E-1)$ *vs.* time (E is optical density). A linear relationship in the reciprocal plots ($1/\Phi$ *vs.* $1/[C]_0$) holds in the dilute concentration region of the complex lower than 1×10^{-3} M (Fig. 2). A deviation at higher concentration seems to be related with the effect of ionic strength and/or the reaction in an excited singlet state of eosine with the complex. Thus, the reaction scheme can be written as follows.

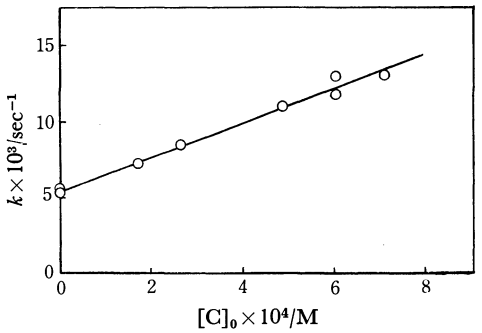

Fig. 1. Dependence of triplet eosine decay constant on $K_3[Co(C_2O_4)_3]$ concentration. ($[E]=1.0\times10^{-5}$M)

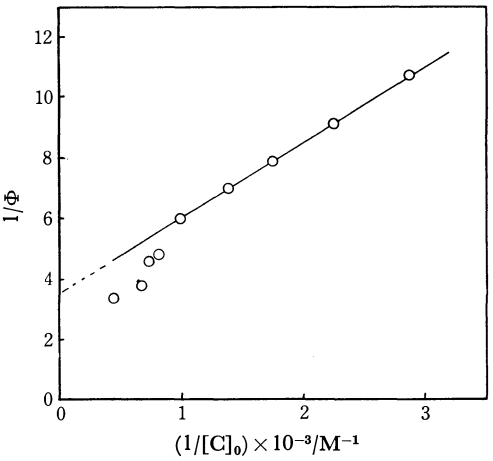

Fig. 2. Plots of $1/\Phi$ against $[K_3(Co(C_2O_4)_3)]_0^{-1}$. pH=7.0, $[E]=1.0\times10^{-5}$M.

3) L. I. Grossweiner, *Photochem. and Photobiol.*, **10**, 183 (1969).

$$\begin{aligned}
&(1)\quad E \xrightarrow{h\nu} E^* \longrightarrow E^T && \phi_{st}I_{ab}\\
&(2)\quad E^T \longrightarrow E && k_d^{\circ}\\
&(3)\quad E^T + E \longrightarrow 2E \text{ (and } E^+ + E^-) && k_D^{s}\\
&(4)\quad E^T + C \longrightarrow E^+ + C^- && k_c^{r}\\
&\qquad\quad \longrightarrow E + C && k_c^{d} \Big\} k_c^{s}\\
&(5)\quad E^+ \longrightarrow \text{Decomposition} && k_+
\end{aligned}$$

$$\Phi = \frac{\phi_{st}k_c^{r}[C]}{k_s + k_c^{s}[C]} \qquad (I)$$

ϕ_{st} and k_s are known to be 0.64 and 4.5×10^3 sec^{-1} ($[E]_0=1.0\times10^{-5}$ M), respectively.[4,5] From an intercept and slope of the line in Fig. 2, the values of $\phi_{st}k_c^{r}/k_c^{s}$ and k_s/k_c^{s} were evaluated respectively as 0.2 and 0.71×10^{-3} M, in which the latter value coincides with the value 0.60×10^{-3} M obtained independently from the slope and interception in Fig. 1. Substituting ϕ_{st} and k_c^{s} values into $\phi_{st}k_c^{r}/k_c^{s}$, we get the genuine rate constant k_c^{r} to be 3.2×10^9 M^{-1} sec^{-1}. Thus the efficiency of an electron transfer between eosine triplet and the complex is roughly estimated to be one third.

Photosensitized Oxidation of Added Substrates. It was confirmed by flash photolysis that the rate constant for the reaction $E^+ + FH_2 \longrightarrow E + FH + H^+$ was of the order of magnitude of 10^9 M^{-1} sec^{-1} (FH_2, leucofluorescein)[1], and the reformation behavior of eosine was observed on the transient spectral change when phenanthroline and indole *etc.* were added.

Keeping the concentration of substrates and the complex as 50 μM and 1.0 mM, respectively (the competitive reaction of substrates with triplet eosine is neglected), we carried out semiquantitative survey for the retarding effect on quantum yield of eosine bleaching. Quite a large effect was obtained in the case of hydroquinone and indole-type substrates (Table 1).

It is noticeable that in the flash experiment of direct photoionization of a tryptophan alkaline solution,[6] the formation quantum yield (0.12) for a tryptophane radical cation was roughly of the same magnitude as its value listed in Table 1. By comparing the light energy (102 kcal) of maximum absorption wavelength which yields the same quantity of a tryptophan radical cation, its gain in energy is about two times higher in the eosine sensitization (55 kcal) than in the case of direct photoionization. From the viewpoint of a photoinactivation of aqueous lysozyme in which electron ejection from the essential tryptophan residues could inactivate the enzyme,[6] indole and its derivatives are taken as substrates for a kinetic treatment in the sensitized oxidation.

Kinetic Treatment of Photosensitized Oxidation of Several Substrates (S). From the above results, we see that the phenomenon could be interpreted by introducing following eosine recovery process in addition to the scheme (1) to (5);

$$\begin{aligned}
&(6)\quad E^+ + S \longrightarrow E + S^+ && k_+^{s}\\
&(7)\quad S^+ \longrightarrow \text{Decomposition}
\end{aligned}$$

Table 1. Relative recovery effect to bleaching eosine on the quantum yield (Φ°)[a]

Substrate	Φ°	$(\Phi_n^\circ-\Phi^\circ)/\Phi_n^\circ$
Leucofluorescein	0	1.00
Hydroquinone	0	1.00
L-Tryptophan	0.003	0.99

Allylthiourea	0.067	0.49
EDTA	0.070	0.47
Histidine	0.031	0.82
Imidazole	~0.17	~0
Adenine	~0.14	~0
none	0.13 (Φ_n°)	—

a) [Eosine]=10 μM, [Substrate]=50 μM, $[Co(OX)_3^{3-}]$=1.0 mM 25.0 °C, pH=7.0

Table 2. Rate constants for reaction (6)

Substrate	k_+^{s} M^{-1} sec^{-1}
L-Tryptophan	6.4×10^{8} [a]
3-Methylindole	1.9×10^{8}
Indole	7.3×10^{7}
Allylthiourea	2.0×10^{7}

a) pH=6.27

The eosine bleaching reaction was found to occur with a good linear relationship between $\ln(e^E-1)$ and time at the initial stage of a constant substrate concentration. Thus under conditions when reaction (4) predominates greatly over the reaction between E^T and S, the concentration dependence of the quantum yield of eosine bleaching in an initial stage (Φ^0) on a substrate is expressed as follows.

$$\Phi^\circ = \phi_{st}\frac{k_c^{r}[C]_o}{k_s+k_c^{s}[C]_o}\frac{k_+}{k_++k_+^{s}[S]_o} \qquad (II)$$

Figure 3 shows a linear relationship between the reciprocals of Φ° and initial substrate concentration $[S]_0$ as is expected from Eq. (II). Putting $[C]_0$= 1.0 mM, $k_s=4.5\times10^3$ sec^{-1} and $\phi_{st}=0.64$, we obtain

$$\frac{1}{\Phi^\circ} = 7.5\left(1+\frac{k_+^{s}}{k_+}[S]_o\right) \qquad (III)$$

From a flash experiment, we get k_+ as 1×10^3 sec^{-1} by analysing the decay of free semioxidized eosine as a first order.[1] Thus the rate constant k_+^{s} of reaction (6) for several substrates could be obtained from Eq. (III) and Fig. 3. The results are listed in Table 2. The k_+^{s} value for L-tryptophan is in good agreement with the value obtained in the flash photolysis experiment by Kepka and Grossweiner.[7] It seems that E^+ (and E^-) produced *via* D–D mechanism may exist freely during millisecond after flash irradiation.

7) A. G. Kepka and L. I. Grossweiner, *ibid.*, **14**, 621 (1971).

Although it could be noted that all the compounds sensitized by eosine have lower ionization potential than that of eosine, investigations on k_+^s value should be extended to other combinations of sensitizer and substrate.

The authors wish to express their hearty thanks to Professor Masao Koizumi, Tohoku University, for his helpful discussion and encouragement, and to Miss Michiko Ohsawa who carried out a part of the experimental work. This work was supported in part by a grant (Y.U) from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2744—2747 (1973)

Studies of Photochemical Reactions Using Organic Photosensitizers. III. Direct Photolysis and Biacetyl-photosensitized Decomposition of Azopropanes

Shigeru YAMASHITA, Kuniyasu OKUMURA, and Teruo HAYAKAWA

Department of Chemistry, Faculty of Liberal Arts and Sciences, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received April 16, 1973)

The direct photolyses in the two wavelength regions and the biacetyl-photosensitized decomposition have been studied for 1,1′-azo-*n*-propane and 2,2′-azo-isopropane. The value of k_d/k_c, the ratio of the disproportionation rate to the combination rate of free radicals, has been found to be slighlty dependent on the exciting wavelength as for *n*-propyl and isopropyl radicals. The higher the exciting energies, the larger the ratio k_d/k_c. From the quenching study of biacetyl phosphorescence, it was found that the energy of the excited biacetyl molecule was transferred to the azopropane molecule at every collision.

The disproportionation and combination of alkyl radicals have been the object of many investigations. In the preceding work on the photodecomposition of vinyl iodide in the gas phase,[1] we found the slight energy dependence of k_d/k_c, the ratio of the rate of disproportionation to that of combination reactions of vinyl radicals as in the case of CH_3S radicals.[2]

In the present work, we have carried out the direct photolyses in the two wavelength regions and the biacetyl-photosensitized decomposition of 1,1′-azo-*n*-propane and 2,2′-azo-isopropane in order to study the energy dependence of the *n*-propyl and isopropyl radicals produced. The effect of the excess energy of *n*-propyl and isopropyl radicals on the ratio of k_d/k_c has been examined.

The photosensitizer, biacetyl, has been used for exciting azopropane to an excited state lower than the excited states caused by direct absorption in the UV-range or by mercury-photosensitization.

In the preceding papers of this series[3,4] we reported the benzene-photosensitized photolysis of nitrous oxide and the biacetyl-photosensitized photolysis of dimethylnitrosoamine, where the reactants were excited to the triplet states lying in the lower level comparing with the excited singlet states produced by direct absorption.

Since the lowest triplet level of biacetyl has been known to be 56 kcal/mol,[5] the *n*-propyl and isopropyl radicals produced by the biacetyl-sensitized photolyses of the corresponding azopropanes should have much less excess energy compared with the case of direct photolyses.

The phosphorescence of biacetyl was found to be quenched effectively[6] by azoalkanes indicating high efficiency of energy transfer from the biacetyl molecule in the triplet state to azoalkane molecules.

Experimental

Azo-*n*-propane and azo-isopropane were obtained from Merck Sharp and Dohme of Canada Ltd. and were purified by vacuum distillation and stored at low temperature in the dark. The absorption spectra of azo-*n*-propane and azo-isopropane in the vapor phase are shown in Fig. 1.

The apparatus was similar to that of the previous work[1] and a high intensity light source, USH-500D high pressure mercury lamp manufactured by Ushio Electric Co., was used for the sake of the predominance of radical-radical reactions with high concentration of the free radicals excluding radical-molecule reactions.[1,7]

For the direct photolysis, Toshiba UV-35 and UV-29 filters were used. When UV-35 was used, 366 nm line of the mercury lamp was almost exclusively effective for the photolyses of both azo-*n*-propane and azo-isopropane. By use of UV-29 filter, about ten percent contribution from 334 nm line was estimated for the excitation of azo-*n*-propane

and about thirty percent contribution from 302, 313, and 334 nm lines for the excitation of azo-isopropane. Highly monochromatic light was not available to excite the reactants because high intensity of the light source was necessary for high concentration of free radicals. All of the runs were carried out at room temperature in the dark room. Before the analysis of the reaction products, unreacted azopropanes were condensed by a cold trap cooled at −20 °C. The separated products were analyzed by a gas chromatograph using a column packed with dimethylsulfolane on alumina, and by a Hitachi RMU-5 mass spectrometer when necessary. The emission measurements for quenching were carried out in the dark room. The exciting light was 436 nm line of a mercury lamp and the phosphorescence emitted by biacetyl in the absence and presence of azopropanes was measured by a grating monochromator and 1P28 photomultiplier with TR-8651 electrometer of Takeda Riken Ind. Co. Ltd.

Results and Discussion

The reaction products obtained were N_2, C_3H_8, C_3H_6, and C_6H_{14} in the direct photolysis and biacetyl-sensitized photolysis of both azopropanes. The product hexane was *n*-hexane in the photolysis of 1,1′-azo-*n*-propane and 2,3-dimethylbutane from 2,2′-azo-isopropane, respectively. In all of the runs, the amounts of C_3H_8 and C_3H_6 were found to be equimolar.

Under high light intensity conditions of this work, the reaction scheme may be rather simplified as following because radical-molecule reactions can be neglected due to the high concentration of the free radicals.

For the direct photolysis, the reaction scheme may be proposed as follows:

$$C_3H_7N_2C_3H_7 + h\nu \longrightarrow C_3H_7N_2C_3H_7^* \quad (1)$$

$$C_3H_7N_2C_3H_7^* \longrightarrow N_2 + C_3H_7\cdot + C_3H_7\cdot \quad (2)$$

$$C_3H_7\cdot + C_3H_7\cdot \xrightarrow{k_d} C_3H_8 + C_3H_6 \quad (3)$$

$$C_3H_7\cdot + C_3H_7\cdot \xrightarrow{k_c} C_6H_{14} \quad (4)$$

For the biacetyl-sensitized photolysis, the following processes seem to produce propyl radicals:

$$B + h\nu' \longrightarrow B^* \longrightarrow B^{**} \quad (5)$$

$$B^{**} + C_3H_7N_2C_3H_7 \longrightarrow B + C_3H_7N_2C_3H_7^{**} \quad (6)$$

$$C_3H_7N_2C_3H_7^{**} \longrightarrow C_3H_7\cdot + C_3H_7\cdot + N_2 \quad (7)$$

here, B means biacetyl and the symbols *, ** denote excited singlet and triplet states, respectively. According to the reaction scheme shown above, equimolar amounts of C_3H_8 and C_3H_6 should be produced, which is supported by the experimental results obtained.

The amount of CO and C_2H_6 were found to be negligible in the biacetyl-photosensitized reaction, meaning that the side reactions of the biacetyl photodecomposition could be left out of account probably because of the extremely large quenching cross section for biacetyl by azopropanes as described later.

Since the greaseless system was not available in the present work, complete separation of hexane has not been achieved. The corrected value of the rate of hexane formation was estimated by the difference $[N_2]-[C_3H_8]$ assuming a material balance between the products as described in the photolysis of 2,2′-azo-isobutane.[8] This procedure for the estimation of hexanes was found reasonable by a blank test and by the fact that the ratio between the direct photolysis products was in good agreement with the results of the greaseless system work reported by Terry and Futrell[7] when the wavelength range for excitation was arranged similar to their conditions.

Table 1. Photolysis of azo-isopropane
Illumination time: 2∼10 min

Filter	Pressure (Torr)	Products (micromole)				k_d/k_c
		N_2	C_3H_8	C_3H_6	C_6H_{14}	
UV-29	20.15	54.50	22.16	21.92	32.34	0.685
	20.18	43.62	18.13	18.30	26.49	0.712

	19.62	21.09	8.22	8.63	12.87	0.639

Table 1 shows the results of the direct photolysis of azo-isopropane using UV-29 and UV-35 filters. The value of k_d/k_c was obtained by taking the ratio $[C_3H_8]/\{[N_2]-[C_3H_8]\}$ equal to $[C_3H_8]/[C_6H_{14}]$ assuming a material balance as described above. Table 2 shows the results of the direct photolysis of azo-*n*-propane.

The amounts of the photolysis products were found to be proportional to the illumination time, which

means that all the reaction products were produced in the primary process, not in the secondary process.

Tables 3 and 4 show the results of the biacetyl-photosensitized decomposition of azo-isopropane and azo-*n*-propane, respectively. The quantum yields of N_2 formation were obtained for the direct photolysis by UV-35 and for biacetyl-photosensitization, as shown in Table 5. The quantum yields by biacetyl-photosensitization are about one tenth smaller than that by the direct photolysis.

Figure 2 shows the phosphorescence spectrum of biacetyl vapor in the absence and presence of quenchers. Ausloos and Rebbert reported much higher

TABLE 5. QUANTUMM YIELDS OF N_2 FORMATION OBTAINED BY DIFFERENT EXCITATIONS

Reactants	Direct photolysis with UV-35 (366 nm)	Biacetyl-photosensitization
Azo-isopropane	0.66±0.04	0.08±0.02
Azo-*n*-propane	0.98±0.14	0.06±0.01

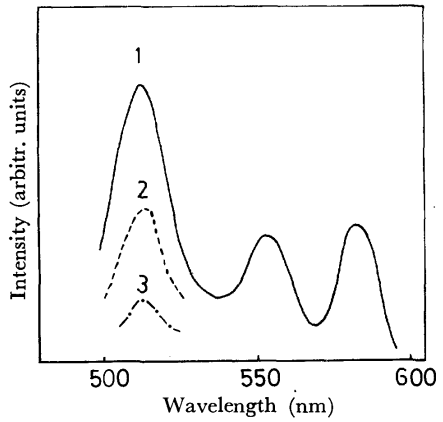

Fig. 2. Phosphorescence of biacetyl vapor (20 Torr, 20 °C). Curve 1: pure biacetyl, Curve 2: with 0.038 Torr O_2, Curve 3: with 3.7×10^{-4} Torr azo-isopropane.

cross sections of azomethane and azoethane than that of oxygen for quenching the phosphorescence of biacetyl.[6] In the present work azo-isopropane was found to have higher cross section than azomethane for quenching the phosphorescence of biacetyl. From the Stern-Volmer plot of the quenching experiments, the quenching rate constant k_q was found to be 3×10^{11} l mol^{-1} s^{-1}, equivalent to the value of the effective collisional cross section σ_Q^2 of 45×10^{-16} cm^2 taking the lifetime of the excited triplet biacetyl molecule to be 10^{-3} s.[9] The value of the quenching rate constant k_q suggests that the excited biacetyl molecule is quenched at every collision with azopropane molecule meaning high efficiency of energy transfer from excited biacetyl to reactant azopropane.

Rather low quantum yield of the azopropane decomposition in the case of the biacetyl-sensitized photolysis, in spite of the high efficiency of energy transfer from excited biacetyl to reactant azopropane, shows that excited azopropane produced by biacetyl-photosensitization is more easily deactivated than by the direct photolysis.

TABLE 6. DEPENDENCE OF THE RATIO k_d/k_c ON THE EXCITATION ENERGIES FOR THE PRODUCTION OF PROPYL RADICALS

Reactant	Excitation condition	Excitation energy (kcal/mol)	k_d/k_c
Azo-isopropane	Direct photolysis (UV-29 filter)	78~95	0.69
	Direct photolysis (UV-35 filter)	78	0.63
	Biacetyl-photosensitization	56	0.27
Azo-*n*-propane	Direct photolysis (UV-29 filter)	78~95	0.15
	Direct photolysis (UV-35 filter)	78	0.12
	Biacetyl-photosensitization	56	0.05

Table 6 summarizes the k_d/k_c values obtained with different excitation energies. The ratio k_d/k_c increases with increasing excitation energies for both azo-isopropane and azo-*n*-propane, which means that k_d/k_c increases with the increment of the excess energies carried by propyl radicals produced by photolysis. This tendency agrees with the results obtained in the case of CH_2=CH·[1] and CH_3S·[2] radicals produced by the photolyses.

The processes (2) and (7) forming two propyl radicals and one nitrogen molecule may be composed of two successive one-bond fission steps:

$$C_3H_7N_2C_3H_7^* \text{ (or } C_3H_7N_2C_3H_7^{**}) \longrightarrow C_3H_7N_2 + C_3H_7 \quad (8)$$

and succeedingly

$$C_3H_7N_2 \longrightarrow C_3H_7 + N_2 \quad (9)$$

Such two-step mechanism was previously confirmed

9) H. L. J. Backström and K. Sandros, *Acta Chem. Scand.*, **14**, 48 (1960).

in the case of the direct photolysis of azo-*n*-propane by illumination of the molecular flow of the reactant in the ion source of a mass spectrometer.[10]

The excess energies carried by propyl radicals were estimated in the case of azo-isopropane since the dissociation energy of the C–N bond of azo-isopropane has been found to be about 33 kcal/mol.[11] From the value of the C–N bond dissociation energy of azo-isopropane and other thermochemical data, the upper limit of the excess energy of the isopropyl radical may be estimated to be 28 kcal/mol for the direct photolysis with UV-35 and 14 kcal/mol for biacetyl-photosensitization. Table 6 shows, anyway, the higher the excitation energies, the larger the excess energies carried by propyl radicals resulting in the increment of k_d/k_c values. The considerably small k_d/k_c values obtained in the biacetyl-photosensitization might suggest the effect of the spin-multiplicity difference besides the energy dependence of k_d/k_c.

Since the effect of the addition of *n*-butane as third body to the reaction system was found almost insignificant, it was inferred that the hot propyl radicals produced by the highly intense illumination reacted each other before thermalization in accord with the suggestion given by Thynne.[12]

It may be said that the disproportionation reaction of free radicals is a kind of inter-radical hydrogen-atom abstraction in the transition state.[13,14] From this viewpoint the increment of the k_d/k_c values with increasing excitation energies seems to be understandable since the feasibility of hydrogen-atom abstraction by the free radicals increases with the increment of the excitation energies used for photochemical free radical formation.[15,16]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2747—2751 (1973)

Crystal Structure and Absolute Configuration of (−)-2,2′-Bisbromomethyl-1,1′-binaphthyl

Kazuaki HARATA and Jiro TANAKA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 25, 1973)

Crystals of (−)-2,2′-bisbromomethyl-1,1′-binaphthyl have been subjected to crystal structure analysis in order to determine the absolute configuration of optically active 1,1′-binaphthyl derivatives. The crystals are orthorhombic, space group $P2_12_12_1$ with $Z=4$ and the lattice constants are; $a=10.360$, $b=13.052$, $c=13.178$ Å. The structure was solved by the heavy atom method and the final R index was 0.064. The absolute configuration was determined as (*S*)-configuration by utilizing the anomalous dispersion effect of bromine atom.

The absolute configuration of optically active substituted 1,1′-binaphthyl molecules is of great interest since the molecule has a C_2 symmetry and the rotational strength is very large in spite of simple chromophore structure. The chemical investigations revealed that the rotation around the 1,1′-single bond is restricted when the 2,2′-positions are substituted by the bulky groups.[1,2] Correlation of the absolute configuration with the optical activity of substituted binaphthyls will be important in developing the theory of the optical activity of coupled chromophore systems. The present investigation was undertaken to find the absolute configuration of one of the simplest hindered binaphthyls. The molecular structure and the absolute configuration will be discussed with a reference to the results of binaphthyl[3] and (+)-2,2′-dihydroxy-1,1′-bisnaphthalene-3,3′-dicarboxylic acid dimethyl ester.[4]

Experimental

Optically active (−)-1,1′-bisnaphthalene-2,2′-dicarboxylic acid was prepared according to the method of Hall and Turner[1] and the resolution was performed by successive recrystallization of diastereoisomer with quinine until the value of optical rotation gave an agreement with the reported one. The acid groups were reduced to hydroxymethyl groups and then transformed into bromomethyl groups. The configurations were retained throughout these reactions and it was confirmed by the CD spectral measurement.

The crystals used for crystallographic study were colorless thick plates or transparent prisms obtained from methylethylketone solution. The density was measured by the flotation method. The lattice constants were refined by a least-squares method using twelve reflections on Hilger-Watt four circle diffractometer with Cu$K\alpha$ radiation ($\lambda=1.5418$ Å).

Crystal Data

(*S*)-(−)-2,2′-bisbromomethyl-1,1′-binaphthyl, $C_{22}H_{16}Br_2$, Mol. Wt. 440.2, orthorhombic,

$a=10.360\pm0.002$, $b=13.052\pm0.001$, $c=13.187\pm0.001$ Å

$D_m=1.625$, $D_c=1.639\ g\cdot cm^{-3}$, $Z=4$;

Absent spectra, $h00$, $0k0$, and $00l$ when h, k, or l is odd. Space group, $P2_12_12_1$. The intensity data were collected on the diffractometer using Cu–$K\alpha$ radiation and 2083 independent non-zero reflections were obtained.

Determination of the Structure

From the Patterson map the positions of bromine atom were determined and all of 22 carbon atoms were revealed from an electron density map calculated by the heavy atom method. Positional and thermal parameters were refined by the block-diagonal least-squares method. In the calculation of the structure factors, the anomalous dispersion effect was taken into account. The final R index was 0.064 for 1607 observed reflections with $|F_o|>3\sigma$. The atomic parameters with standard deviations are listed in Table 1, and observed and calculated structure factors are given in Table 2. Least-squares planes of naphthyl groups and the deviations of atoms from these planes are shown in Table 4. Atomic scattering factors were taken from the International Tables for X-ray Crystallography.[5]

Absolute Configuration

The absolute configuration of (−)-2,2′-bisbromomethyl-1,1′-binaphthyl was determined by the Bijvoet method using the values of $\Delta f' = -0.9$ and $\Delta f'' = 1.5$ for bromine atom.[5] A comparison of calculated and observed intensity ratios for hkl and $\bar{h}\bar{k}\bar{l}$ reflections is shown in Table 3 and the coordinates given in Table 1 are shown to be the correct ones in the right-handed coordinate system. Thus the absolute configuration can be designated as (S). All figures are drawn with the correct absolute configuration.

Results and Discussion

The present analysis showed that the absolute configuration of (−)-2,2′-bisbromomethyl-1,1′-binaphthyl is (S)-configuration. The chemical studies on (−)-2,2′-dihydroxymethyl-1,1′-binaphthyl and (−)-1,1′-bisnaphthalene-2,2′-dicarboxylic acid showed that the configurations were retained, so that all these related molecules have (S)-configuration. This result is in good agreement with the chemical correlation studies on substituted binaphthyls[2,6] and the X-ray study of Akimoto and Iitaka[4] on (+)-2,2′-dihydroxy-1,1′-bis-

Table 4. Least-squares planes and the deviation of atoms from the planes

The planes are of the form $AX+BX+CZ+P=0$, where X,Y,Z are coordinates measured along three cell edges in Å unit.

Table 5. Comparison of bond lengths and angles

Molecule	Bond length between C(1) and C(1′)	Twist angle between two planes
1,1′-Binaphthyl[3]	1.475Å	68°
(+)-2,2′-Dihydroxy-1,1′-bisnaphthalene-3,3′-dicarboxylic acid dimethyl ester[4]	1.49Å	76.6°
(−)-2,2′-Bisbromomethyl-1,1′-binaphthyl	1.50Å	91.6°

naphthalene-3,3′-dicarboxylic acid dimethyl ester, which was shown as (*R*)-configuration.

The naphthyl groups are nearly planar (Table 4). One naphthyl group is twisted against the other one with an angle of 91.6°. The values for other related molecules are listed in Table 5. It is interesting that the present molecule exhibits the largest twist angle, which may be related to the steric repulsion of bulky substituents such as bromomethyl group.

The bond lengths and angles are shown in Figs. 1 and 2. The bond length between C(1) and C(1′) is close to the normal single bond like those in other related molecules, and the resonance effect may not be significant. The projection of molecules onto the crystallographic planes are illustrated in Figs. 3 and 4 with interatomic distances.

The absolute configuration determined as (*S*)-configuration will be used for the chiro-optical study of (−)-binaphthyl derivatives.

Infrared Absorption Intensities of Torsion-Rotation Transitions of Molecules with Symmetric Internal Rotor

Hiromu SUGETA and Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received June 5, 1973)

The infrared absorption intensities of torsion-rotation transitions were theoretically derived on the basis of torsion-rotation interactions of molecules with symmetric internal rotor. The theoretical intensities depend upon molecular structure parameters and molecular dipole moment. Implications of the present theory are discussed on absolute intensities, orientations of dipole transition moment, band types (A, B, or C), and deuteration effects on absorption intensities of methyl torsional transitions. For propylene oxide and propylene sulfide, the far infrared spectra of the gaseous state were measured, and the experimental absorption intensities of methyl torsional vibrations were compared with theoretical intensities.

A number of investigations on internal-rotation barriers of symmetric internal rotors ($-CH_3$, $-SiH_3$, $-CF_3$ *etc.*) have been carried out by the microwave spectroscopy[1] and far-infrared spectroscopy.[2] Far infrared bands due to torsional vibrations often exhibit complicated contours due to torsion-rotation interactions.[2] For detailed analyses of torsional bands, it is necessary to elucidate the effects of torsion-rotation interactions not only on energy levels but also on absorption intensities of torsion-rotation transitions. The effects of these interactions on energy levels have been extensively studied for analysing microwave spectra of molecules with symmetric internal rotors.[3] In the present study, the infrared absorption intensities of torsion-rotation transitions have been worked out, taking account of torsion-rotation interactions.

Torsion-Rotation Wave Functions

The model used in the present study consists of a rigid frame and a symmetric internal rotor that performs torsional motion with respect to the frame. With the principal-axis-method, the Hamiltonian (H) for this model is given by[3]

$$H = H_r + H_t + H_{tr} \tag{1}$$

where H_r and H_t are the rotational and torsional Hamiltonian, respectively, and H_{tr} is the Hamiltonian for the torsion-rotation interactions. These Hamiltonians may be written as,

$$H_r = AP_a^2 + BP_b^2 + CP_c^2 + F\mathscr{P}^2 \tag{2}$$

$$H_t = Fp_\alpha^2 + V(\alpha) \tag{3}$$

$$H_{tr} = -F(p_\alpha\mathscr{P} + \mathscr{P}p_\alpha) = -2Fp_\alpha\mathscr{P} \tag{4}$$

and

$$A = \hbar^2/2I_a \text{ etc} \tag{5}$$

$$F = \hbar^2/2rI_\alpha \tag{6}$$

$$r = 1 - \sum\lambda_g^2 I_\alpha/I_g \quad (g=a, b, \text{ or } c) \tag{7}$$

where I_g is the principal moment of inertia of the entire molecule, I_α is the moment of inertia of the internal rotor about its symmetry axis, λ_g is the direction cosine between the principal axis (g) and the internal-rotation axis. P_g is the component of the total angular momentum (in unit of $\hbar$) along the principal axis g,

$$\tilde{P} = [P_a\ P_b\ P_c] \tag{8}$$

p_α is the angular momentum of the internal rotor along its symmetry axis and $V(\alpha)$ is the potential energy for the internal-rotation. The angular momentum $\mathscr{P}$ in Eqs. (2) and (4) is given as

$$\mathscr{P} = \sum_g(\lambda_g I_\alpha/I_g)P_g = \boldsymbol{\rho}\cdot\boldsymbol{P} \tag{9}$$

where

$$\tilde{\boldsymbol{\rho}} = [\lambda_a I_\alpha/I_a\ \lambda_b I_\alpha/I_b\ \lambda_c I_\alpha/I_c] \tag{10}$$

In the present study, the torsion-rotation interaction H_{tr} [Eq. (4)] is treated as the perturbation term. The eigenvalues and wave functions of the rotational Hamiltonian H_r [Eq. (2)] are denoted as E_r and $|r\rangle$, respectively. The eigenvalues and wave functions of the torsional Hamiltonian H_t [Eq. (3)] are denoted as $E_{v\sigma}$ and $|v\sigma\rangle$, respectively, where v is the torsional quantum number and σ is the symmetry index ($\sigma=0$ for A and $\sigma=\pm1$ for E species). The unperturbed wave function is constructed as the product of the torsional and rotational parts, $|v\sigma\rangle|r\rangle$ and the matrix elements of the perturbation H_{tr} is given by

$$\begin{aligned}\langle r_2|\langle v_2\sigma_2|H_{tr}|v_1\sigma_1\rangle|r_1\rangle &= -2F\langle r_2|\langle v_2\sigma_2|p_\alpha\mathscr{P}|v_1\sigma_1\rangle|r_1\rangle \\ &= -2F\delta_{\sigma_1\sigma_1}\langle v_2\sigma_2|p_\alpha|v_1\sigma_1\rangle\langle r_2|\mathscr{P}|r_1\rangle\end{aligned} \tag{11}$$

Accordingly, with the first-order perturbation theory, the perturbed wave functions $|v\sigma,r\rangle$ are given by

$$|v\sigma, r\rangle = |v\sigma\rangle|r\rangle - 2F\sum_{v'}{}'\sum_{r'}\frac{\langle v'\sigma|p_\alpha|v\sigma\rangle\langle r'|\mathscr{P}|r\rangle}{(E_{v\sigma}+E_r)-(E_{v'\sigma}+E_{r'})}|v'\sigma\rangle|r'\rangle \tag{12}$$

Neglecting the rotational energy differences ($E_r - E_{r'}$) as compared with the torsional energy differences ($E_{v\sigma} - E_{v'\sigma}$), Eq. (12) may be rewritten as

$$|v\sigma, r\rangle = |v\sigma\rangle|r\rangle - 2F\left[\sum_{v'}{}'\frac{\langle v'\sigma|p_\alpha|v\sigma\rangle}{E_{v\sigma}-E_{v'\sigma}}|v'\sigma\rangle\right][\sum_{r'}\langle r'|\mathscr{P}|r\rangle|r'\rangle] \tag{13}$$

Line Strength of Torsion-Rotation Transition

The absorption intensity (I) for the transition between states A and B is given by[4]

$$I = \frac{n}{z}\frac{8\pi^3\nu_{AB}}{3hc}[\exp(-E_A/kT)-\exp(-E_B/kT)]S_{AB} \quad (14)$$

where n is the number of molecules per unit volume, z is the partition function, E_A and E_B are the energy of the states A and B, respectively. ν_{AB} is the transition frequency

$$\nu_{AB} = (E_B-E_A)/h \quad (15)$$

and S_{AB} is the line strength given by

$$S_{AB} = \sum_a\sum_b|\langle b|\bar{\mu}|a\rangle|^2 = 3\sum_a\sum_b|\langle b|\bar{\mu}_F|a\rangle|^2 \quad (16)$$

where a and b denote individual degenerate substates of A and B, respectively, $\bar{\mu}$ is the electric dipole moment operator in the space-fixed coordinate system, and $\bar{\mu}_F$ is the F component. The component $\bar{\mu}_F$ is related to the molecule-fixed dipole moment operator μ_g by the direction cosine Φ_{Fg} between the space-fixed F axis and molecule-fixed g axis,

$$\bar{\mu}_F = \Phi_F\cdot\boldsymbol{\mu} = \sum_g\Phi_{Fg}\mu_g \quad (17)$$

$$\tilde{\Phi}_F = [\Phi_{Fa}\ \Phi_{Fb}\ \Phi_{Fc}] \quad (18)$$

$$\tilde{\mu} = [\mu_a\ \mu_b\ \mu_c] \quad (19)$$

In general, the molecule-fixed dipole moment μ_g depends only upon vibrational coordinates whereas the direction cosines Φ_{Fg} depend only upon rotational coordinates. For a molecule with a rigid frame and a symmetric internal rotor, then, the transition moment for the unperturbed wave functions $|v\sigma\rangle|r\rangle$ may be written as

$$\begin{aligned}\langle r_2|\langle v_2\sigma_2|\bar{\mu}_F|v_1\sigma_1\rangle|r_1\rangle &= \langle v_2\sigma_2|\boldsymbol{\mu}|v_1\sigma_1\rangle\cdot\langle r_2|\Phi_F|r_1\rangle \\ &= \sum_g\langle v_2\sigma_2|\mu_g|v_1\sigma_1\rangle\langle r_2|\Phi_{Fg}|r_1\rangle \quad (20)\end{aligned}$$

Furthermore, with the present model, the molecule-fixed dipole moment $\boldsymbol{\mu}$ in Eq. (20) is independent of the internal rotation and is equal to the permanent dipole moment $\boldsymbol{\mu}^\circ$.

$$\tilde{\mu} = \tilde{\mu}^\circ = [\mu_a^\circ\ \mu_b^\circ\ \mu_c^\circ] \quad (21)$$

Accordingly, for unperturbed wave functions,

$$\langle v_2\sigma_2|\mu_g|v_1\sigma_1\rangle = \mu_g^\circ\langle v_2\sigma_2|v_1\sigma_1\rangle = \mu_g^\circ\delta_{v_1v_1}\delta_{\sigma_1\sigma_1} \quad (22)$$

and Eq. (20) may be rewritten as,

$$\begin{aligned}\langle r_2|\langle v_2\sigma_2|\bar{\mu}_F|v_1\sigma_1\rangle|r_1\rangle &= \langle r_2|\langle v_2\sigma_2|\boldsymbol{\mu}^\circ\cdot\Phi_F|v_1\sigma_1\rangle|r_1\rangle \\ &= \delta_{v_1v_1}\delta_{\sigma_1\sigma_1}\boldsymbol{\mu}^\circ\cdot\langle r_2|\Phi_F|r_1\rangle \\ &= \delta_{v_1v_1}\delta_{\sigma_1\sigma_1}\langle r_2|\bar{\mu}_F|r_1\rangle \quad (23)\end{aligned}$$

The matrix element of the transition moment for $|v_2\sigma_2,r_2\rangle\leftarrow|v_1\sigma_1,r_1\rangle$ is now derived from the perturbed wave function $|v\sigma,r\rangle$ [Eq. (13)] and the transition moment for unperturbed wave functions $|v\sigma\rangle|r\rangle$ [Eq. 23)].

$$\begin{aligned}\langle v_2\sigma_2, r_2|\bar{\mu}_F|v_1\sigma_1, r_1\rangle &= \langle r_2|\langle v_2\sigma_2|\bar{\mu}_F|v_1\sigma_1\rangle|r_1\rangle \\ &\quad -2F\sum_v{}'\sum_r\frac{\langle v_2\sigma_2|p_\alpha|v\sigma_2\rangle}{E_{v_1\sigma_1}-E_{v\sigma_1}}\langle r_2|\mathscr{P}|r\rangle\langle r|\langle v\sigma_2|\bar{\mu}_F|v_1\sigma_1\rangle|r_1\rangle \\ &\quad -2F\sum_v{}'\sum_r\langle r_2|\langle v_2\sigma_2|\bar{\mu}_F|v\sigma_1\rangle|r\rangle\langle r|\mathscr{P}|r_1\rangle\frac{\langle v\sigma_1|p_\alpha|v_1\sigma_1\rangle}{E_{v_1\sigma_1}-E_{v\sigma_1}} \\ &= \delta_{v_1v_1}\delta_{\sigma_1\sigma_1}\langle r_2|\bar{\mu}_F|r_1\rangle \\ &\quad -2F\sum_v{}'\sum_r\frac{\langle v_2\sigma_2|p_\alpha|v\sigma_2\rangle}{E_{v_1\sigma_1}-E_{v\sigma_1}}\langle r_2|\mathscr{P}|r\rangle\delta_{vv_1}\delta_{\sigma_1\sigma_1}\langle r|\bar{\mu}_F|r_1\rangle \\ &\quad -2F\sum_v{}'\sum_r\delta_{v_1v}\delta_{\sigma_1\sigma_1}\langle r_2|\bar{\mu}_F|r\rangle\langle r|\mathscr{P}|r_1\rangle\frac{\langle v\sigma_1|p_\alpha|v_1\sigma_1\rangle}{E_{v_1\sigma_1}-E_{v\sigma_1}} \quad (24)\end{aligned}$$

Here only for $\sigma_1=\sigma_2(=\sigma)$, the transition moments are nonvanishing. Furthermore, for torsion-rotation transitions ($v_1\neq v_2$), Eq. (24) may be rewritten as,

$$\begin{aligned}\langle v_2\sigma, r_2|\bar{\mu}_F|v_1\sigma, r_1\rangle &= -2F\sum_r\left[\frac{\langle v_2\sigma|p_\alpha|v_1\sigma\rangle}{E_{v_1\sigma}-E_{v_1\sigma}}\langle r_2|\mathscr{P}|r\rangle\langle r|\bar{\mu}_F|r_1\rangle\right. \\ &\quad \left.+\langle r_2|\bar{\mu}_F|r\rangle\langle r|\mathscr{P}|r_1\rangle\frac{\langle v_2\sigma|p_\alpha|v_1\sigma\rangle}{E_{v_1\sigma}-E_{v_1\sigma}}\right] \\ &= 2F\frac{\langle v_2\sigma|p_\alpha|v_1\sigma\rangle}{E_{v_1\sigma}-E_{v_1\sigma}}\langle r_2|\bar{\mu}_F\mathscr{P}-\mathscr{P}\bar{\mu}_F|r_1\rangle \\ &= 2F\frac{\langle v_2\sigma|p_\alpha|v_1\sigma\rangle}{E_{v_1\sigma}-E_{v_1\sigma}}\langle r_2|[\bar{\mu}_F,\mathscr{P}]|r_1\rangle \quad (25)\end{aligned}$$

The commutation $[\bar{\mu}_F,\mathscr{P}]$ in Eq. (25) may be derived from the commutation relations between the angular momentum P_g (g=x, y, or z) and the direction cosines Φ_{Fg},[5]

$$[\Phi_{Fx}, P_x] = \Phi_{Fx}P_x - P_x\Phi_{Fx} = 0 \quad (26)$$

$$[\Phi_{Fx}, P_y] = [P_x, \Phi_{Fy}] = -i\Phi_{Fz}\ \textit{etc.} \quad (27)$$

From Eqs. (9), (17), and (21),

$$\begin{aligned}[\bar{\mu}_F, \mathscr{P}] &= [(\boldsymbol{\mu}^\circ\cdot\boldsymbol{\Phi}_F), (\boldsymbol{\rho}\cdot\boldsymbol{P})] \\ &= [(\mu_x^\circ\Phi_{Fx}+\mu_y^\circ\Phi_{Fy}+\mu_z^\circ\Phi_{Fz}), (\rho_xP_x+\rho_yP_y+\rho_zP_z)] \\ &= -i\{(\mu_y^\circ\rho_z-\mu_z^\circ\rho_y)\Phi_{Fx}+(\mu_z^\circ\rho_x-\mu_x^\circ\rho_z)\Phi_{Fy} \\ &\quad +(\mu_x^\circ\rho_y-\mu_y^\circ\rho_x)\Phi_{Fz}\} \\ &= -i(\boldsymbol{\mu}^\circ\times\boldsymbol{\rho})\cdot\boldsymbol{\Phi}_F \quad (28)\end{aligned}$$

Substituting Eq. (28) into Eq. (25), the transition moment is finally expressed as the product of the vibrational part and rotational part.

$$\begin{aligned}\langle v_2\sigma, r_2|\bar{\mu}_F|v_1\sigma, r_1\rangle &= \left\{-2iF\frac{\langle v_2\sigma|p_\alpha|v_1\sigma\rangle}{E_{v_1\sigma}-E_{v_1\sigma}}(\boldsymbol{\mu}^\circ\times\boldsymbol{\rho})\right\}\cdot\{\langle r_2|\Phi_F|r_1\rangle\} \quad (29) \\ &\qquad\text{[vibration]} \qquad\qquad \text{[rotation]}\end{aligned}$$

Absorption Intensity of Torsional Band

The vibrational part of the transition moment may be used for deriving the integrated absorption intensity of the torsional band. Thus, the molar absorption intensity of the torsional transitions $|v+1,\sigma\rangle\leftarrow|v,\sigma\rangle$ is given by

$$I_{v,\sigma;\,v+1,\sigma} = \frac{N}{z}\frac{8\pi^3}{3h^2c}[\exp(-E_{v,\sigma}/kT)-\exp(-E_{v+1,\sigma}/kT)] \times 4F^2|\boldsymbol{\mu}^\circ\times\boldsymbol{\rho}|^2\frac{|\langle v_2\sigma|p_\alpha|v_1\sigma\rangle|^2}{E_{v+1,\sigma}-E_{v,\sigma}} \quad (30)$$

4) B. L. Crawford, Jr. and H. L. Dinsmore, *J. Chem. Phys.*, **18**, 983 (1950).

5) P. C. Cross, R. M. Hainer, and G. W. King, *ibid.*, **12**, 210 (1944).

where N is the Avogadro number. The integrated absorption intensity of the torsional fundamental band is given by

$$\int_{\text{band}} \alpha(\nu)\mathrm{d}\nu = \sum_{v,\sigma} I_{v+1,\sigma;\, v,\sigma} \tag{31}$$

where $\alpha(\nu)$ is the molar absorption coefficient for the absorption frequency ν.

For a high barrier case (see Appendix I), the energy levels $E_{v\sigma}$ and the integrals $\langle v+1,\sigma|p_a|v,\sigma\rangle$ are almost independent of the symmetry index σ, and from Eqs. (A3), (A7), and (A8),

$$|\langle v+1|p_a|v\rangle|^2 = (N/2)^2[(v+1)s^{1/2}/2][1-(v+1)/2s^{1/2}] \tag{32}$$

$$E_{v+1}-E_v = (N/2)^2F[2s^{1/2}][1-(v+1)/2s^{1/2}] \tag{33}$$

so that

$$\frac{|\langle v+1|p_a|v\rangle|^2}{E_{v+1}-E_v} = (v+1)/4F \tag{34}$$

Substituting Eq. (34) into Eq. (30),

$$I_{v,v+1} = \frac{N}{z}\frac{8\pi^3}{3h^2c}[\exp(-E_v/kT)-\exp(-E_{v+1}/kT)] \times|\boldsymbol{\mu}^\circ\times\boldsymbol{\rho}|^2F(v+1) \tag{35}$$

Finally, with the harmonic oscillator approximation for energy levels, the integrated absorption intensity of the torsional band is obtained by substituting Eq. (35) into Eq. (31),

$$\int_{\text{band}} \alpha(\nu)\mathrm{d}\nu \cong (8\pi^3N/3h^2c)F|\boldsymbol{\mu}^\circ\times\boldsymbol{\rho}|^2 \tag{36}$$

Discussion

Absolute Absorption Intensity. By the use of Eq. (30) [or (35)] and (31) [or (36)], the integrated intensity of the torsional band may be calculated from molecular structure parameters and molecular dipole moment. The theoretical intensity value is also useful for estimating the path length and sample pressure required for absorption measurements.

The absorption intensity is proportional to $F|\boldsymbol{\mu}^\circ\times\boldsymbol{\rho}|^2$ as shown in Eq. (30). Accordingly, the fundamental transition is forbidden for molecules in which the dipole moment $\boldsymbol{\mu}^\circ$ and the $\boldsymbol{\rho}$ vector are parallel to each other, for examples for CH_3–CX_3, CH_3–NO_2 *etc.* On the other hand, if the dipole moment $\boldsymbol{\mu}^\circ$ is nearly perpendicular to the $\boldsymbol{\rho}$ vector, the absorption intensity is strong. For a simple example, if the dipole moment is parallel to the a axis ($\mu^\circ=\mu^\circ_a$, $\mu^\circ_b=\mu^\circ_c=0$) and the symmetry axis of the internal rotor is parallel to the b axis ($\lambda_a=\lambda_c=0$, $\rho_a=\rho_c=0$, $\lambda_b=1$, $\rho_b=I_a/I_b$), the absolute intensity of the torsional band is given by

$$\int_{\text{band}} \alpha(\nu)\mathrm{d}\nu = \frac{8\pi^3N}{3h^2c}\frac{h^2I_b}{8\pi^2I_a(I_b-I_a)}\left(\mu^\circ\frac{I_a}{I_b}\right)^2 = (N\pi/3c)(\mu^\circ)^2I_a/I_b(I_b-I_a) \tag{37}$$

Thus, for this simple case, the absorption intensity is nearly proportional to the inversed square of the moment of inertia (I_b) of the entire molecule. In general, the absorption intensity of torsional vibrations is expected to be weaker for a molecule with a larger (heavier) frame than for a molecule with a smaller (lighter) frame.

As an experimental proof of the present intensity theory, the far infrared bands due to methyl torsional vibrations were studied. The far infrared spectra of propylene oxide CH_3–$\underset{\backslash O /}{CH}$–$CH_2$ and propylene sulfide CH_3–$\underset{\backslash S /}{CH}$–$CH_2$ have been reported previously by Fateley and Miller.[6] In the present study, however, the absorption intensities of the torsional bands of these molecules were remeasured with a Hitachi FIS-3 Far Infrared Spectrophotometer. It is experimentally difficult to determine the absolute values of the absorption intensities in the far infrared region. Therefore, the absorption intensities of these two molecules were measured with the same spectral conditions and were found to be 0.9_7 and 0.2_0 $cm^{-2}\cdot atm^{-1}$ for propylene oxide and sulfide, respectively, at 300 K. On the other hand, the theoretical intensity was treated with Eqs. (30) and (31) and the intensity values were calculated as 1.76 and 0.45 $cm^{-2}\cdot atm^{-1}$ for propylene oxide and sulfide, respectively, at 300 K, from the structure parameters and dipole moments as determined by the analyses of microwave spectra.[7,8] The experimental ratio of the absorption intensities of propylene oxide and sulfide is $4._9$: 1, in good agreement with the theoretical intensity ratio of 3.9: 1.

The theoretical intensity of propylene oxide and sulfide was also treated with the harmonic oscillator approximation [Eq. (36)]. Although the barriers were not extremely high ($s=\sim69$ for oxide and ~89 for sulfide), the calculated intensity values of 2.03 and 0.47 agreed fairly well (especially for sulfide) with the intensity values calculated with Eqs. (30) and (31).

Orientation of Transition Moment. The band envelopes of absorption bands depend upon the direction of the transition dipole moment. The direction of the transition moment for the torsional vibration of the present model is given by the vector product of $\boldsymbol{\mu}^\circ\times\boldsymbol{\rho}$. This vector product is useful for predicting the type of the torsional bands of asymmetric-top molecules, since otherwise the direction of the transition dipole moment may not be determined from the molecular symmetry.

The molecules of propylene oxide and sulfide belong to the point group C_1 and the direction of the transition moment can not be determined from their molecular symmetry. However, from the present theory, the intensity ratio of the A, B, and C type transitions is calculated as 3: 18: 100 for propylene oxide and as 1: 16: 100 for propylene sulfide and accordingly both molecules are expected to exhibit prominent C-type band envelopes with sharp Q branches. In fact, as shown in Fig. 1, the far infrared spectra of propylene oxide and propylene sulfide exhibit Q-branch series primarily due to the C-type transitions.

Deuteration Effect of Methyl Group. The deuteration of a methyl group reduces the F value to about one half but approximately doubles the $\boldsymbol{\rho}$ vector.

6) W. G. Fateley and F. A. Miller, *Spectrochim. Acta*, **19**, 611 (1963).

7) J. D. Swalen and D. R. Herschbach, *J. Chem. Phys.*, **27**, 100 (1957).

8) S. S. Butcher, *ibid.*, **38**, 2310 (1963).

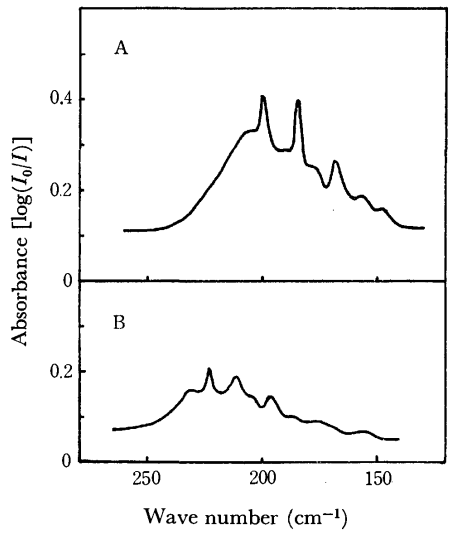

Fig. 1. Far infrared spectra of propylene oxide (path length of 4.9 m and sample pressure of 50 Torr) [A] and propylene sulfide (path length of 4.9 m and sample pressure of 96 Torr) [B].

Accordingly, the value of $F|\boldsymbol{\mu}^\circ \times \boldsymbol{\rho}|^2$ is increased nearly twice by the deuteration of the methyl group. For the simple example of Eq. (37), the absolute intensity of the torsional band is nearly proportional to I_α, the moment of inertia of the internal rotor, so that the intensity is nearly doubled on the deuteration of the methyl group. It is interesting to remark that the absorption intensities of the torsional vibration of the methyl group is expected to increase whereas the absorption intensities of the C–H stretching vibrations are decreased on deuteration of the methyl group. In fact, for ethyl fluoride, the absorption intensity of the torsional vibration of the methyl group was found to increase on deuteration of the methyl group.[9]

Appendix I High Barrier Approximation

The Hamiltonian and the wave equation for the internal rotation with the N-fold symmetry may be written as

$$H = Fp_\alpha^2 + V_N(1-\cos N\alpha)/2 \quad [p_\alpha = -i(\mathrm{d}/\mathrm{d}\alpha)] \tag{A1}$$

$$H\Psi_{v\sigma}(\alpha) = E_{v\sigma}\Psi_{v\sigma}(\alpha) \tag{A2}$$

where $E_{v\sigma}$ and $\Psi_{v\sigma}(\alpha)$ are the energy and wave function of the $v\sigma$ state (v: torsional quantum number, σ: symmetry index). Equations (A1) and (A2) may be transformed into a reduced form by the following transformations,

$$H = (N/2)^2 F\eta$$

$$p_\alpha = (N/2)p_x \quad [p_x = -i(\mathrm{d}/\mathrm{d}x)]$$

$$V_N = (N/2)^2 Fs$$

$$N\alpha = 2x$$

$$\Psi_{v\sigma}(\alpha) = \Phi_{v\sigma}(x)$$

$$E_{v\sigma} = (N/2)^2 F b_{v\sigma} \tag{A3}$$

$$\eta = p_x^2 + s(1-\cos 2x)/2 \tag{A4}$$

$$\eta\Phi_{v\sigma}(x) = b_{v\sigma}\Phi_{v\sigma}(x) \tag{A5}$$

For a high barrier case ($s \gg 1$), Eq. (A4) may be expanded in the power series of x.

$$\eta = p_x^2 + sx^2 - (1/3)sx^4 + (2/45)sx^6 - \cdots \tag{A6}$$

Equation (A6) may be treated as a perturbed harmonic oscillator Hamiltonian. The eigenvalues b_v for $b_v \ll s$ are derived by the second-order perturbation theory.

$$b_v = s^{1/2}(2v+1) - (1/2^3)[(2v+1)^2+1] - (1/2^6)s^{-1/2}(2v+1)[(2v+1)^2+3] \tag{A7}$$

The matrix elements of p_x, p_x^2, x, and x^2 are given, through first-order, as follows.

$$\langle v+1|p_x|v\rangle = is^{1/4}[(v+1)/2]^{1/2}[1-(1/4)s^{-1/2}(v+1)]$$

$$\langle v+3|p_x|v\rangle = -i(1/8)s^{-1/4}[(v+1)(v+2)(v+3)/2]^{1/2}$$

$$\langle v|p_x|v'\rangle = -\langle v'|p_x|v\rangle \tag{A8}$$

$$\langle v|p_x^2|v\rangle = (1/2)s^{1/2}(2v+1) - (1/8)[(2v+1)^2+1]$$

$$\langle v+2|p_x^2|v\rangle = -(1/2)s^{1/2}[(v+1)(v+2)]^{1/2} \times [1-(1/8)s^{-1/2}(2v+3)]$$

$$\langle v+4|p_x^2|v\rangle = (1/8)[(v+1)(v+2)(v+3)(v+4)]^{1/2}$$

$$\langle v|p_x^2|v'\rangle = \langle v'|p_x^2|v\rangle \tag{A9}$$

$$\langle v+1|x|v\rangle = s^{-1/4}[(v+1)/2]^{1/2}[1+(1/4)s^{-1/2}(v+1)]$$

$$\langle v+3|x|v\rangle = -(1/24)s^{-3/4}[(v+1)(v+2)(v+3)/2]^{1/2}$$

$$\langle v|x|v'\rangle = \langle v'|x|v\rangle \tag{A10}$$

$$\langle v|x^2|v\rangle = (1/2)s^{-1/2}(2v+1) + (1/8s)[(2v+1)^2+1]$$

$$\langle v+2|x^2|v\rangle = (1/2)s^{-1/2}[(v+1)(v+2)]^{1/2} \times [1+(5/24)s^{-1/2}(2v+3)]$$

$$\langle v+4|x^2|v\rangle = -(1/24s)[(v+1)(v+2)(v+3)(v+4)]^{1/2}$$

$$\langle v|x^2|v'\rangle = \langle v'|x^2|v\rangle \tag{A11}$$

Studies on the Interactions of 1-Substituted 2,4-Dinitrobenzenes with Hydroxide Ion in Aqueous Dimethyl Sulfoxide by Means of the Rapid Scan Spectrophototometer

Yoshinori HASEGAWA and Takehiro ABE

College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received April 20, 1973)

The initial interactions of *m*-dinitrobenzene, 2,4-dinitroanisole, 2,4-dinitrofluorobenzene, and 2,4-dinitrochlorobenzene with hydroxide ion in aqueous dimethyl sulfoxide were studied with a rapid scan spectrophotometer. In all the cases, the first transient colored-species assigned to 1-hydroxy-3-substituted-2,6-dinitrocyclohexadienates were observed at initial stages before the formations of the second colored-species having the π-electronic structures of 1,3-dinitropentadienyl anion were complete.

In the interactions of aromatic polynitro compounds with nucleophiles, many transient colored-species have been detected by NMR and visible spectroscopies before the appearances of the thermodynamically stable colored-species.[1] No example has been reported of the initial transient colored-species formed from 1-X-2,4-dinitrobenzenes (X=H, CH_3O, halogeno) and bases.

An attempt has, therefore, been made to pursue the changes of the visible absorption spectra of the dimethyl sulfoxide (DMSO) solutions of *m*-dinitrobenzene, 2,4-dinitroanisole, 2,4-dinitrofluorobenzene, and 2,4-dinitrochlorobenzene in the presence of hydroxide ion.[2]

Experimental

All the dinitrobenzenes used were available commercially and were purified by recrystallization or by distillation. DMSO was dried with calcium hydride and fractionated under reduced pressure.

Electronic absorption spectra at various stages of a reaction path in solution were measured with a Hitachi rapid scan spectrophotometer RSP-2. The apparatus was equipped with an automatically controlled mixing cell, and could operate for the use of the continuous flow method. The mixing cell having the path length of 1.0 cm was roughly controlled at 25 °C by means of a thermocirculator. In the wavelength range from 220 to 700 nm it took 150 msec to record a spectrum on a memoriscope. The possible error in determining absorption positions with the spectrophotometer was estimated to be within 5 nm from the comparison between the spectra of the same solution, the one being recorded by the rapid scan spectrophotometer and the other being measured by a Hitachi recording spectrophotometer EPS-3.

The DMSO solutions subjected to the spectral measurements contained 2 or 10% (by volume) water. The DMSO solutions containing the corresponding amounts of water in the absence of both the dinitrobenzenes and sodium hydroxide were used as references.

Results

The spectral changes observed are shown in Figs. 1—4. In all the cases, the first colored-species having

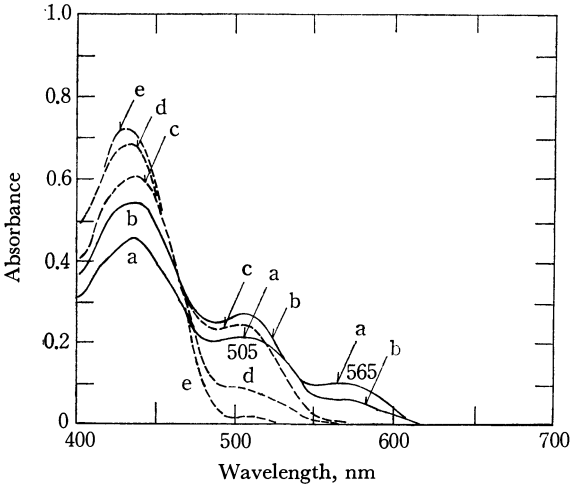

Fig. 3. Spectra observed with the DMSO solution containing 2,4-dinitrofluorobenzene (4.8×10^{-5}mol/l), sodium hydroxide (2.3×10^{-3}mol/l), and water (2% by volume). Times measured after the mixing: a, *ca.* 1/3 sec; b, 5 sec; c, 30 sec; d, 5 min; e, 12 min.

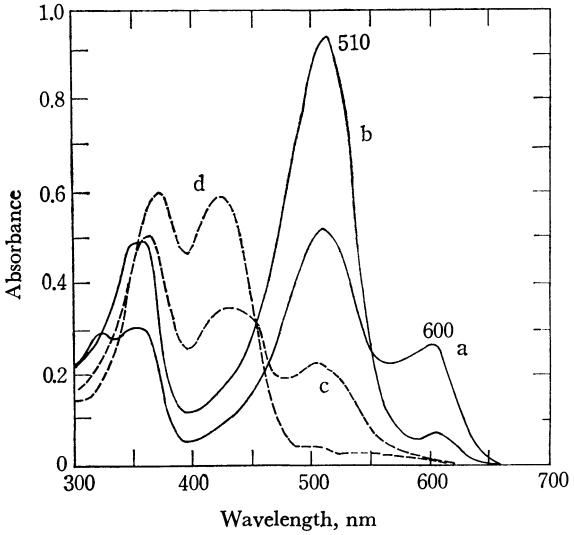

Fig. 4. Spectra observed with the DMSO solution containing 2,4-dinitrochlorobenzene (4.9×10^{-5}mol/l), sodium hydroxide (1.7×10^{-2}mol/l), and water (10% by volume). Times measured after the mixing: a, *ca.* 1/3 sec; b, 10 sec; c, 2 min; d, 8 min.

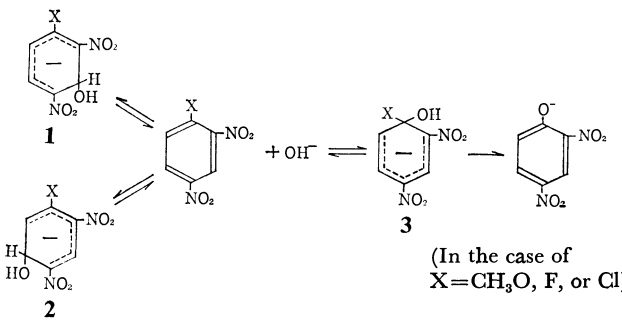
absorption bands in the range of 550—650 nm appeared at the initial stages and disappeared within several seconds after mixings. After the complete disappearances of the first colored-species, the second colored-species having bands at around 500 nm remained and gradually disappeared. As the peaks of the second colored-species decreased in intensity, the intensities of bands at 375 and 430 nm increased except the case of *m*-dinitrobenzene. The bands at 375 and 430 nm are due to 2,4-dinitrophenoxide ion, because the same alkaline solution of 2,4-dinitrophenol in DMSO containing 2% (by volume) water showed bands at 375 and 430 nm. The reaction product of 2,4-dinitrophenoxide ion agreed with the results of Bowden and Cook.[3] The peak intensity at 535 nm in Fig. 1 decreased very slowly after thermal equilibrium had been reached.

Discussion

From the analogy with the interactions of 2,4-dinitro-6-Y-anisoles (Y=F, Cl, CF_3, CN) with methoxide ion,[1e,4-6] the possible structures of the colored species are restricted to the following types **1**—**3**. This is supported by the theoretical calculations leading to the prediction that the stablization energies of 1,3- and 1,5-dinitropentadienyl anions (1.736 and 1.111 eV, respectively) are considerably great compared with that (0.004 eV) of 2,4-dinitropentadienyl anion.[7] The colored-species of the types **2** and **3** are expected to show absorption bands at the same range, because they have the similar π-electronic systems of 1,3-dinitropentadienyl anion.



It has been known from visible and NMR spectroscopies that the methoxide complexes having the π-electronic structures of 1,3- and 1,5-dinitropentadienyl anions in media rich in DMSO show longer-wavelength bands at the ranges of *ca.* 505 nm and of 585—640 nm, respectively.[1,4-6] Accordingly, the first and second colored-species may be assigned, respectively, to the structure of the type **1** and to what has the same π-electronic structure with 1,3-dinitropentadienyl anion. According to Crampton,[8] the first colored-species should be the kinetically controlled products and the second colored-species should be thermodynamically more stable.

It is known from Figs. 1—4 that the substituents such as CH_3O, F, and Cl shift the band of the first colored-species of 1-hydroxy-2,6-dinitrocyclohexadienate (X=H in **1**) to the blue.

From the comparison with the band (λ_{max}=505 nm) of the methoxide complex of 2,4-dinitroanisole, having the established structure of 1,1-dimethoxy-2,4-dinitrocyclohexadienate,[1a] the band of the second colored-species formed from 2,4-dinitroanisole may be due to the similar structure **3** (X=CH_3O).

According to Crampton *et al.*,[1g] the second colored-species formed from 2,4-dinitro-fluorobenzene and

-chlorobenzene should be ascribed to the structures of the type **2** (X=F, Cl), since they have reported that the additions of bases occur not at the carbons carrying chlorines but at the 3-positions in picryl chloride and in 2,6-dinitrochlorobenzene derivatives.

Recently, from ESR studies Bellobono *et al.*[9] reported that the stable colored-species formed from *m*-dinitrobenzene and methoxide ion in DMSO containing 2% (by volume) methanol was the anion-radical of *m*-dinitrobenzene. However, the second colored-species formed from *m*-dinitrobenzene may be assigned to the structure **3** (X=H), because the band shape of the second colored-species in Fig. 1 does not resemble that of the 530-nm band of the *m*-dinitrobenzene anion-radical with a distinct vibrational structure.[10] Moreover, the anion-radical shows bands at 385 and 415 nm.[10] As mentioned by Crampton,[8] the anion-radical is probably a minor product.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2758—2761 (1973)

A Study of Complex Formation by the Cation Exchange Method. Bivalent Metal Complexes with Univalent Anions

Emiko OHYOSHI*

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received November 13, 1972)

An attempt was made to estimate the amount of the cationic complex MA^+ adsorbed on a cation exchanger. This method is based on the fact that the ratio of the distribution coefficients of M^{2+} and MA^+ should vary with the ionic strength of the medium. The Ni(II) acetate system studied by Fronaeus has been reexamined. The results show that the distribution coefficient of $NiAc^+$ (Ac=acetate) is negligible compared with that of Ni^{2+} upon the variation of the ionic strength from 0.2 to 1.0. It was found that Fronaeus overestimated the distribution coefficient of $NiAc^+$ and that this caused the value of β_2 to be much greater. In conclusion, the two functions, φ_1 and f, introduced by Fronaeus could not be determined with high accuracy; for the stability constants obtained by Fronaeus's method, they must be confirmed by conducting the experiment at a different ionic strength.

The cation exchange resin has been widely used for the study of complex formation. In cases where the reaction $M^{2+}+A^-=MA^+$ or $M^{3+}+A^-=MA^{2+}$ occurs, it is difficult to estimate the amounts of them adsorbed on the resion. Fronaeus proposed a method to analyze the data under such conditions and used it to study the acetate complexes of Ni(II)[1] and Ce(III)[2] and the thiocyanate complexes of Ni(II).[3] In these investigations, he estimated an appreciable amount of the cationic complex to be adsorbed on the resin. On the other hand, it has been demonstrated, by means of acetate labelled with tritium and with ^{14}C, that the cationic species of Co(II) and Mn(II) acetate complexes are not taken up by the cation exchanger.[4] If Fronaeus overestimated the distribution coefficient of the cationic complex of Ni(II) acetate, the evaluation of the stability constants would also be higher.

In this study, we attempted to ascertain the extent of the adsorption of a cationic complex, MA^+, experimentally. Although M^{2+} and MA^+ were both adsorbed on the resin, the change in the ionic strength of the medium should have different effects on their distribution coefficients depending on the different ionic charges. From this, we can conclude whether the extent of the adsorption of MA^+ is appreciable or negligible. This method was applied to study the Ni(II) acetate system, and the results were compared with those obtained by Fronaeus's method.

Estimation of the Amount of MA^+ Adsorbed on a Cation Exchanger. When a cation exchange resin, NaR, is added to a solution involving a free metal ion, M^{2+}, and the complexes MA^+, MA_2, $\cdots$, MA_n^{2-n}, the following exchange equilibria are established:

$$M^{2+} + 2NaR = MR_2 + 2Na^+ \quad (1)$$

$$MA^+ + NaR = MAR + Na^+ \quad (2)$$

The distribution coefficients of M^{2+} and MA^+, l_0 and l_1, can be expressed as:

$$l_0 = [MR_2]/[M^{2+}] = k_0[NaR]^2/[Na^+]^2$$

$$l_1 = [MAR]/[MA^+] = k_1[NaR]/[Na^+]$$

where k_0 and k_1 are the equilibrium quotients of Reactions (1) and (2). The distribution of the metal, M(II), between resin and solution is given as:

$$\varphi = \frac{l_0(1+l_1'[A^-])}{1+\sum\beta_j[A^-]^j} \quad (3)$$

where $l_1'=l_1\beta_1/l_0$ and $\beta_j=[MA_j^{2-j}]/([M^{2+}][A^-]^j)$. For the determination of β_j under such conditions, Fronaeus[1] introduced two functions, φ_1 and f:

$$\varphi_1 = (l_0/\varphi - 1)/[A^-] \quad (4)$$

$$\varphi_1^0 = \lim_{[A^-]=0} \varphi_1 = \beta_1 - l_1'$$

$$f = [(l_0/\varphi)\{(\beta_1 - l_1')[A^-] - 1\} + 1]/[A^-]^2$$

$$= \beta_1\varphi_1 - \sum_{j=2}^{n} \beta_j [A^-]^{j-2} \quad (5)$$

At relatively small values of $[A^-]$, the following relation between the differences can be given:

$$\Delta f = \beta_1 \Delta\varphi_1 - \beta_3 \Delta[A^-] \quad (6)$$

β_1 can be obtained graphically from Eq. (6); β_2, $\beta_3 \cdots \beta_n$ can also be obtained from Eq. (5).

This method has been widely used in the study of complex formation containing cationic species. However, the evaluation of l_1/l_0 seems to be generally large, considering the differences in the ionic charge and in the size of M^{2+} and MA^+, *e.g.*, $l_1/l_0=0.78$ for the Mn(II) chloride system at $\mu=0.69$.[5] In this case, the value of k_1 is estimated to be greater than that of k_0. If l_1/l_0 is overestimated, all of the formation constants of complexes β_1, β_2, $\cdots$, β_n would also be overestimated. As may be seen from Eq. (4), the function φ_1 comes to involve a large error as $[A^-]$ approaches 0 where $l_0/\varphi \simeq 1$. The value of $\beta_1 - l_1'$ obtained from the extrapolation of φ_1 to $[A^-]=0$ must also be uncertain. Since this value affects the function f, reliable values for β_1, β_2, $\cdots$, β_n can not be expected by means of the functions φ_1 and f.

The use of the function $1/\varphi$, whose accuracy is much greater than that of φ_1 at small values of $[A^-]$, may be more feasible for the analysis of the data.

$$\frac{1}{\varphi} = \frac{1}{l_0} \frac{1 + \sum \beta_j [A^-]^j}{1 + l_1'[A^-]} \quad (7)$$

Differentiating $1/\varphi$ and assuming that the terms greater than $[A^-]^2$ can be neglected at small values of $[A^-]$, we obtain:

$$\frac{d(1/\varphi)}{d[A^-]} \simeq \frac{1}{l_0} \frac{(\beta_1 - l_1') + 2\beta_2[A^-]}{1 + 2l_1'[A^-]} \quad (8)$$

This equation shows that when l_1' can not be neglected, a plot of $1/\varphi$ *vs.* $[A^-]$ at small values of $[A^-]$ gives a curve the slope of which decreases ($\beta_2/l_1' < \beta_1 - l_1'$) or increases ($\beta_2/l_1' > \beta_1 - l_1'$) with an increase in $[A^-]$. On the other hand, if the plot gives a straight line and if the intercept agrees with the value of $1/l_0$ obtained experimentally, it can generally be concluded that l_1' can be neglected and that the slope corresponds to β_1/l_0. Though it is rare, an apparent linear relation between $1/\varphi$ and $[A^-]$ will be given when $\beta_2/l_1' \simeq \beta_1 - l_1'$. In this case, the slope corresponds to $(\beta_1 - l_1')/l_0$. However, we can readily distinguish between the two cases. The linear relation can be settled at any concentration of Na^+ in the former case, while it can not be expected in the latter since the value of β_2/l_1' becomes smaller of greater than that of $\beta_1 - l_1'$ at a different Na^+ concentration.

The term $\beta_1 - l_1'$, which can be obtained from the slope of the $1/\varphi$ plot *vs.* $[A^-]$ at $[A^-]=0$ (see Eq. (8)), is expressed by:

$$\beta_1 - l_1' = \beta_1\{(1 - k_1[Na^+]/(k_0[NaR])\} \quad (9)$$

When $[Na^+] \gg [M^{2+}]$ and $[NaR] \gg [MR]$, we obtain:

$$\beta_1 - l_1' = \beta_1(1 - K[Na^+]) \quad (10)$$

where K is nearly constant. The β_1 varying with the ionic strength can be estimated by the change in the activity coefficient of M^{2+}, γ. The relation expressed by:

$$\beta_1 = \gamma\beta_{1(a)}/\gamma_{(a)} \quad (11)$$

where $\beta_{1(a)}$ and $\gamma_{(a)}$ are β_1 and γ at a fixed ionic strength of a. By substituting this equation to Eq. (10), we obtain:

$$\gamma_{(a)}(\beta_1 - l_1')/\gamma = \beta_{1(a)}(1 - K[Na^+]) \quad (12)$$

When the values of $(\beta_1 - l_1')\gamma_{(a)}/\gamma$ decrease with an increase in $[Na^+]$, a linear relation can be obtained in a range where K is practically constant. From the slope, the magnitude of $K[Na^+]$, that is, l_1/l_0, can be estimated. On the other hand, the values remain essentially constant; in other words, the decrease in $\beta_1 - l_1'$ with an increase in the ionic strength is the same as that caused by the decrease in the activity of M^{2+}, the ratio l_1/l_0 is very small in comparison with unity, and l_1' can practically be neglected.

Experimental

Materials. A stock solution of Ni(II) was prepared by dissolving $NiCl_2 \cdot 6H_2O$ in 1.0 M $NaClO_4$ to obtain the concentration of 0.01 M. The solution involving 1.0 M CH_3COONa and 1.0 M CH_3COOH was diluted with 1.0 M $NaClO_4$ to produce various acetate concentrations at $\mu=1.0$. In a similar manner, acetate soltuions at other ionic strengths (0.2—0.5) were prepared. All the chemicals used were of a G.R. grade. For the cation exchanger, Dowex 50W-X8 (100—200 mesh) in the sodium form was used.

Procedures. The ion-exchange experiments were carried out as follows. The solutions (10 ml) made up from the stock solution of Ni(II) (1.0 ml) and the solutions in varying acetate concentrations (9.0 ml) were shaken with portions of dry resin (0.2—0.5 g) in 20 ml glass vials with stoppers for 8 hr at 25 °C. Then the amount of Ni(II) in each supernatant was determined by EDTA titration, using murexide as the indicator. The distribution coefficient, φ, was calculated as follows:

$$\varphi = \frac{\text{mmol of Ni(II) in the resin/mass of dry resin (g)}}{\text{mmol of Ni(II) in the soln./vol. of soln. (ml)}}$$

Results and Discussion

Measurements of l_0. Fronaeus reported that the distribution coefficient of Ni(II) is dependent on the concentration of NiR_2, though it is kept very small in comparison with the exchange capacity. He concluded that Ni^{2+} ions are not as free as Na^+ ions in the resin phase, but are partly coordinated to groups fixed at the exchanger. Thus, he corrected the φ values to that at a constant value of [NiR], 10^{-2} mmol/g, for the calculation of the formation constants of Ni(II) acetate complexes. It is important to know whether or not the exchange reaction between the Ni^{2+} ion and NaR is reversible. In the case of a reversible reaction involving a minute amount of M^{2+} compared with $[Na^+]$ and [NaR], the value of l_0 should remain

Table 1. Effect of variation in the mass of resin on l_0 of Ni(II), pH=4.5, μ=1.0, volume of soln.=10.0 ml

Mass of resin (g)	l_0
0.200	15.6
0.300	16.5
0.400	16.0
0.500	15.8

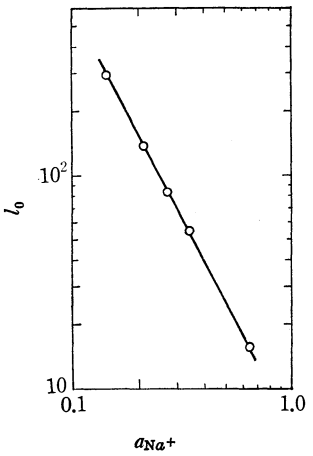

Fig. 1. Relationship between l_0 of Ni(II) and the activity of Na^+ ion.

unchanged with a varying mass of resin, and a linear relation whose slope is 2 should be obtained between log l_0 and the log of the activity of Na^+. To examine the reversivility, we measured l_0 as a function of the mass of the resin and the concentration of Na^+ in the solution. As is shown in Table 1 and Fig. 1, the value of l_0 remains practically constant with the variation in the mass of resin from 0.2 to 0.5 g, and the plot of log l_0 *vs.* the log of the activity of Na^+ yields a straight line with the slope of 2. From these results, the reversible exchange reaction between the Ni^{2+} ion and the exchanger, NaR, could be confirmed.

The Ni(II) Acetate System. The Ni(II) acetate complexes were studied by the cation exchange method. Figure 2 shows the realtion between $1/\varphi$ and [Ac^-] at the same ionic strength as that used by Fronaeus (μ=1.0). At the values of [Ac^-] examined, a linear relation is obtained and the intercept of the line agrees well with the value of $1/l_0$ obtained experimentally. This indicates either that l_1' is negligible or that β_1-l_1' is nearly equal to β_2/l_1. To know the magnitude of l_1', the experiments were carried out at the Na^+ concentrations of 0.2, 0.3, 0.4, and 0.5. The results are shown in Fig. 3, where $1/\varphi$ is plotted *vs.* [Ac^-]. All of the plots yield a good linearity, and the intercept of each line agrees well with the values of $1/l_0$ obtained at the corresponding concentration of Na^+. From this, we can conclude that l_1' is negligible at an ionic strength of less than 1, since it is unreasonable to say that the relation $\beta_1-l_1'\simeq\beta_2/l_1'$ is settled at any concentration of Na^+. The values for β_1-l_1' are given as 6.5, 5.9, 5.6, and 5.5 from the slopes of the straight lines at μ=0.2, 0.3, 0.4, and 0.5. In Eq. (12), when we take the fixed ionic strength as 0.2, the values of $\gamma_{(0.2)}$ $(\beta_1-l_1')/\gamma$ at μ=0.2, 0.3, 0.4, 0.5, and 1.0 were calculated to be 6.5, 6.7, 6.7, 6.8, and 6.0 by the estimation of the activity coefficient of Ni^{2+} from the formula of Davies:[6] $\log\gamma_i=-0.5Z_i^2\sqrt{\mu}/(1+\sqrt{\mu})+0.1Z_i^2\mu$, where Z_i=2. These values seem to be essentially the same, considering that the γ values were calculated from an approxinate formula. That is, the extent of the decrease in β_1-l_1' with an increase in the ionic strength is nearly equal to that caused by the decrease in the activity of Ni^{2+}. The acetate complex of Ni(II), $NiAc^+$, like those of Co(II) and Mn(II),[4] is not taken up by the cation exchanger to any appreciable extent. Thus, the values of β_1 at μ=0.2, 0.3, 0.4, 0.5, and 1.0 were obtained as 6.5, 5.9, 5.6, 5.5, and 5.2. The values for β_2 could not be determined exactly in the range of low concentrations of Ac^- studied. Fronaeus reported that β_1=4.7 and β_2=18 at μ=1.0. Although the value of β_1 is in fair agreement with our results, the value of β_2 appears to be too large. If such a high value is given for β_2, the slope of the lines in Fig. 3 must be increased with an increase of [Ac^-], even at small values of [Ac^-]. This large value of β_2 is caused by the estimation of l_1' as 1.9.

The value of 6.5 at μ=0.2 obtained for β_1 in this study is larger than that of 2.6 determined by polaro-

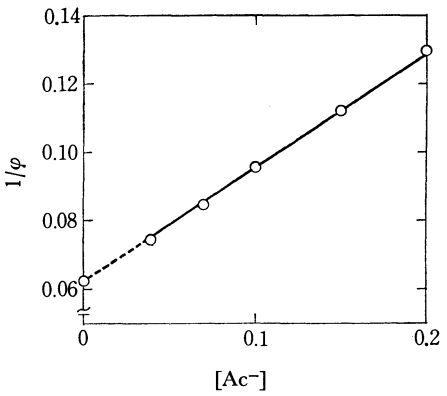

Fig. 2. A plot of $1/\varphi$ *vs.* [Ac^-] for Ni(II) acetate system at μ=1.0.

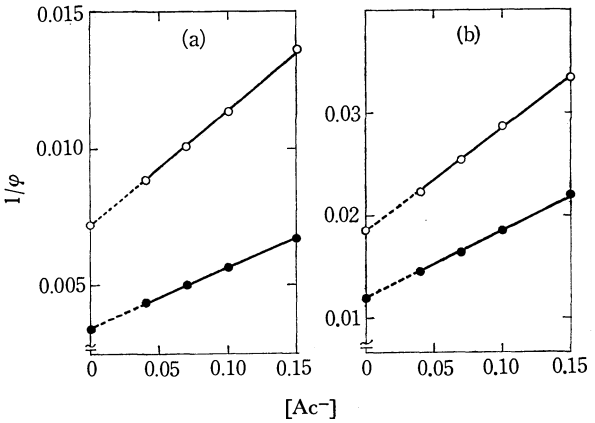

Fig. 3. Plots of $1/\varphi$ *vs.* [Ac^-] for Ni(II) acetate system at various ionic strengths; (a) μ=0.2 —●—, μ=0.3 —○—, (b) μ=0.4 —●—, μ=0.5 —○—.

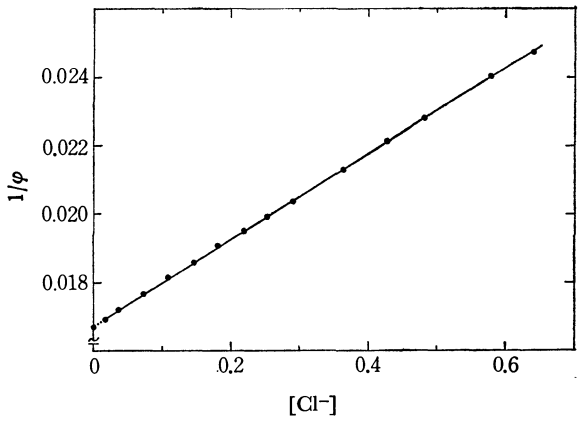

Fig. 4. A plot of $1/\varphi$ *vs.* [Cl⁻] for Mn(II) chloride system.[5]

graphy[7] at the same ionic strength. However, this value of 2.6 seems to be rather small in comparison with the value of 10 determined at $\mu=0.1$ by potentiometry.[8]

Mn(II) Chloride System. The study of Mn(II) chloride complexes by Fronaeus's method[5] appears to be a similar example of overestimating l_1'. Morris and Short estimated l_1' to be 2.98 and determined the formation constants, β_1, β_2, and β_3, to be 3.85, 1.80, and 0.44 at $\mu=0.691$. These values are comparable to those of the Fe(III) chloride complexes.[9] For the calculation of the function, φ_1, from which the value of β_1-l_1' was obtained, they used the value of l_0 obtained experimentally. As is shown in Fig. 4, when we try to plot the function $1/\varphi$ against [Cl⁻], a good linearity is yielded over the range of [Cl⁻] investigated and the intercept of the line agrees with the value of $1/l_0$ within the limits of experimental error ($\pm 0.5\%$). Assuming that $l_1'\simeq 0$, β_1 is obtained as 0.75. This value is close to that of 1.1 obtained by polarography.[10] It is noted that the evaluation of β_1-l_1' by Fronaeus's method is much affected by the value of l_0 adopted; that is, β_1-l_1' is greatly varied with a minute change in l_0.

In conclusion, when l_1' is estimated by Fronaeus's method to be appreciable, it is necessary to confirm the results by an experiment at a different ionic strength.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2761—2765 (1973)

Distribution of Alkali Metal Picrates between Water and Methyl Isobutyl Ketone

Tadashi IWACHIDO

College of Liberal Arts, Okayama University, Tsushima, Okayama 700

(Received December 8, 1972)

As regards the distribution of alkali metal picrates between water and methyl isobutyl ketone, distribution ratios of alkali metals and acid species were determined in the pH range 1.5—8.5. The extraction curves are almost the same for each alkali metal. Association constants of the picrates and the dissociation constant of picric acid in the organic phase were determined conductometrically. The association constants of picrates in the aqueous phase were determined with distribution coefficients by means of a solvent extraction method. The results obtained show that the picrates exist mainly in a dissociated form in both phases, whereas picric acid exists in a weakly dissociated form in the organic phase. The extractability of picrates is discussed on the basis of the extraction parameter proposed and compared with that of the nitrobenzene system.

The results obtained from the previous study on the distribution of alkali metal picrates between aqueous and nitrobenzene phases[1] can be summarized as follows. The extractability of alkali metal picrates can be represented in terms of the extraction parameter $D^{MR}K_a^{MR}/K_o^{MR}$, where K_a^{MR} and K_o^{MR} denote the association constants of the picrates in the aqueous and the organic phases, respectively, and D^{MR} denotes the distribution coefficient. The parameter can also be a good measure of the solvent. Since picrates are strong electrolytes, the ratio D^{MR}/K_o^{MR} is expected to increase with the ionizing power of solvent, giving rise to enhanced extractability.

Acetone and methyl ethyl ketone are known to be ionizing solvents for picrates stronger than nitrobenzene.[2,3] However, they are not suitable for extraction because of their high miscibility with water. Methyl isobutyl ketone (MIBK) was chosen, since it is a dipolar aprotic solvent with high ionizing power yet immiscible with water.

Association constants show that MIBK functions as an ionizing solvent with levelling property, in contrast to the differentiating property of nitrobenzene. The

2) M. B. Reynolds and C. A. Kraus, *J. Amer. Chem. Soc.*, **70**, 1709 (1948).

3) C. W. Davies, "Ion Association", Butterworths, London (1962) p. 96.

levelling property, commonly observed in acetone and methyl ethyl ketone, becomes conspicuous with the addition of water, which reflects on the extractability of alkali metals. Discussion is made on the basis of equilibrium constants.

Experimental

Reagents. Alkali metal picrates were recrystallized from water except for lithium salt (from an alcohol-water mixture). Sodium and lithium picrates were determined to be monohydrate by measuring the weight loss on heating under reduced pressure. The solvent was purified in the usual way: MIBK previously treated with potassium permanganate was washed with an aqueous solution of sodium carbonate and distilled. The distillate was dried over anhydrous sodium sulfate for two days and distilled again.

Citric acid-citrate buffers (0.01 M) and phosphoric acid-phosphate buffers (0.01 M) were used to adjust the pH of the solutions to pH 2.5—5.5 and pH 6—8, respectively. Strongly acidic solutions (pH below 2.5) were prepared with hydrochloric acid. A series of buffer solutions were prepared with five kinds of alkali metals. All the aqueous solutions were previously saturated with MIBK and all the MIBK solutions with water, in order to avoid volume change on mixing.

Extraction. Dependence of distribution ratios of alkali metals and the acid species on pH was investigated as follows: 10 ml of a 0.01 M buffer solution and 10 ml of a 1×10^{-4} M aqueous alkali metal picrate solution were transferred to a 50 ml centrifuge tube equipped with a stopper. 20 ml of MIBK was then added. The resulting mixture was shaken for two hours at 25 °C. The distribution coefficients and association constants (in the aqueous phase) were determined by modifying the above procedures: 10 ml of an aqueous solution of alkali metal picrate (1×10^{-4} M) was mixed with 10 ml of a buffer solution containing an alkali metal of the same kind to various concentrations (up to 10^{-2} M). The resulting solution was then treated as before.

Determination of Alkali Metals and the Acid Species. After equilibration the alkali metals in the organic phase were determined with an atomic absorption spectrophotometer (Nippon Jarrell Ash, Type AA-1). The acid species in the aqueous phase was determined spectrophotometrically (Hitachi Ltd., Type 124) by using matched 50 mm cells at 355 nm, at which the absorption of dissolved MIBK is negligible.

The pH of an aqueous solution saturated with MIBK was measured with a pH meter in the usual way. The MIBK dissolved increased the pH value less than 0.02 unit in each case.

Conductance Measurements in the Organic Phase. Conductances of alkali metal picrates in dry and wet (water-saturated) MIBK solutions were measured with a conductometer (Ando Electric Co. Ltd., Universal Bridge, LCR-10). The solution was kept at 25±0.005 °C by circulating thermostated water around the vessel equipped with platinized platinum electrodes and a copper-constantan thermocouple. Specific conductances of the dry and wet solvents were 0.2 and 1.0 $\mu\Omega^{-1}$ cm^{-1}, respectively. Conductivities of the solutions of 0.5×10^{-4}—7×10^{-4} M were measured by a dilution method with a weighing buret.

Theoretical

The equilibria for the picric acid and alkali metal picrates, denoted by HR and MR, respectively, can be written as follows:

1) Dissociation of Picric Acid:

$$HR \rightleftarrows H^+ + R^- \qquad K_a^{HR} = \frac{[H^+]_a[R^-]_a}{[HR]_a} \tag{1}$$

$$K_o^{HR} = \frac{[H^+]_o[R^-]_o}{[HR]_o} \tag{2}$$

2) Association of Alkali Metal Picrates:

$$M^+ + R^- \rightleftarrows MR \qquad K_a^{MR} = \frac{[MR]_a}{[M^+]_a[R^-]_a} \tag{3}$$

$$K_o^{MR} = \frac{[MR]_o}{[M^+]_o[R^-]_o} \tag{4}$$

3) Distribution of the Acid and the Picrates:

$$D^{HR} = \frac{[HR]_o}{[HR]_a} \tag{5}$$

$$D^{MR} = \frac{[MR]_o}{[MR]_a} \tag{6}$$

Subscripts a and o refer to aqueous and organic phases, respectively; molar concentrations are given in brackets.

i) Association Constants in the Organic Phase K_o^{MR}. Association constants of the picrates in MIBK solutions were determined by the method of Shedlovsky.[4] Conductance Λ is related to the concentration of electrolyte C by the equation

$$\frac{1}{\Lambda S} = \frac{1}{\Lambda_\infty} + \frac{K_o^{MR}C\Lambda S f_o^2}{\Lambda_\infty^2} \qquad S \equiv \left[\frac{Z}{2}+\sqrt{1+\left(\frac{Z}{2}\right)^2}\right]^2$$

$$Z = \frac{\alpha\sqrt{C\Lambda}}{\Lambda_\infty^{3/2}} \tag{7}$$

where Λ_∞ refers to the limiting conductance; f to the mean activity coefficient, and α to the Onsager coefficient.

ii) Association Constants in the Aqueous Phase K_a^{MR} and Distribution Coefficients D^{MR}. The distribution ratio of the acid species in a sufficiently alkaline solution can be written as

$$q^R = \frac{[MR]_o+[R^-]_o}{[MR]_a+[R^-]_a} \tag{8}$$

Combination of Eqs. (3), (4), (6), and (8) leads to the following equation:

$$\frac{Y}{q^R} = \frac{1}{D^{MR}} + \frac{1}{D^{MR}K_a^{MR}f_a^2[M^+]_a} \tag{9}$$

$$Y = \frac{\sqrt{0.25+C_oK_o^{MR}f_o^2}+0.5}{C_oK_o^{MR}f_o^2} + 1$$

The values of the mean activity coefficient in both aqueous and MIBK solutions were approximated by the Debye-Hückel limiting law

$$-\log f^2 = \frac{3.6494\times10^6\sqrt{I}}{(\varepsilon T)^{3/2}} \tag{10}$$

where I denotes the ionic strength.

iii) Distribution of Acid Species. At equilibrium the distribution ratio of the acid species between the two phases can generally be written as

$$q^R = \frac{[HR]_o+[MR]_o+[R^-]_o}{[HR]_a+[MR]_a+[R^-]_a} \tag{11}$$

4) T. Shedlovsky, *J. Franklin Inst.*, **225**, 739 (1938).

Substitution of the equilibrium constants defined by Eqs. (1)—(6) into Eq. (11) gives

$$q^{R} = D^{HR}\frac{1+\left\{\left(1+\frac{1}{K_o^{MR}[M^+]_o}\right)D^{MR}K_a^{MR}[M^+]_a\right\}\frac{K_a^{HR}}{D^{HR}[H^+]_a}}{1+(1+K_a^{MR}[M^+]_a)\frac{K_a^{HR}}{[H^+]_a}} \quad (12)$$

iv) Distribution of Alkali Metals. The distribution of alkali metals can also be written as

$$q^{M} = \frac{[MR]_o+[M^+]_o}{[MR]_a+[M^+]_a} \quad (13)$$

Total concentrations of the acid species C^R and alkali metals C^M are represented as

$$C^R = [HR]_a + [HR]_o + [MR]_a + [MR]_o + [R^-]_a + [R^-]_o \quad (14)$$

$$C^M = [MR]_a + [MR]_o + [M^+]_a + [M^+]_o \quad (15)$$

The electroneutrality condition in the organic phase is expressed by

$$[R^-]_o = [M^+]_o + [H^+]_o \quad (16)$$

Combining Eqs. (14), (15), and (16) and solving for $[R^-]_a$ gives

$$\frac{1}{[R^-]_a} = \frac{1+\frac{(1+D^{HR})}{K_a^{HR}}[H^+]_a}{C^R-C^M+[M^+]_a-[H^+]_o} \quad (17)$$

On the other hand, rearrangement of Eq. (13) gives

$$q^{M} = \frac{[MR]_o\left(1+\frac{1}{K_o^{MR}[R^-]_o}\right)}{[MR]_a\left(1+\frac{1}{K_a^{MR}[R^-]_a}\right)} \quad (18)$$

Substitution of Eq. (17) into Eq. (18) gives the useful expression

$$q^{M} = D^{MR}\frac{\left\{1+\frac{1}{K_o^{MR}([M^+]_o+[H^+]_o)}\right\}}{\left\{1+\frac{1+(1+D^{HR})[H^+]_a/K_a^{HR}}{K_a^{MR}(C^R-C^M+[M^+]_a-[H^+]_o)}\right\}} \quad (19)$$

It should be noted that all the experiments were carried out under conditions where the value of C^M is about 100 times that of C^R.

Results and Discussion

Equilibria Involved in the Extraction System. Fundamental equilibria are shown by Eqs. (1)—(6). MIBK is a solvating solvent like water, but little is known about the solvates of the picrates both in wet MIBK solution and MIBK-saturated aqueous solution. The solvates in both phases are represented by the simplest symbols. The equilibrium constants obtained should be distinguished from those defined in a pure medium.

Interactions between alkali metal cations and the citrate anions added as buffers should be considered. The values of the ion-pair formation constants of the alkali metal citrates obtained by Rechnitz and Zamochnick[5] are 6.8, 5.0, 3.9, 3.1, and 2.1, in going from lithium to cesium at constant initial metal and citric acid concentration of 0.1 M and pH 8.3. The values are about a quarter of those of respective picrates. Under the present experimental conditions, however, the influence of the citrate ions are negligible below pH 5.5, when the acid dissociation constant of citric acid ($pK_3=6.396$)[6] is taken into account.

The dissociation constant of picric acid in the wet MIBK solution is determined conductometrically to be 3.00×10^{-5}. This indicates that the dissociation of the acid can no longer be neglected as compared with other equilibria. This is quite different from the case of the nitrobenzene system. Introduction of the acid dissociation complicates theoretical treatments, but without this the extraction curve especially the acidic parts can not be explained.

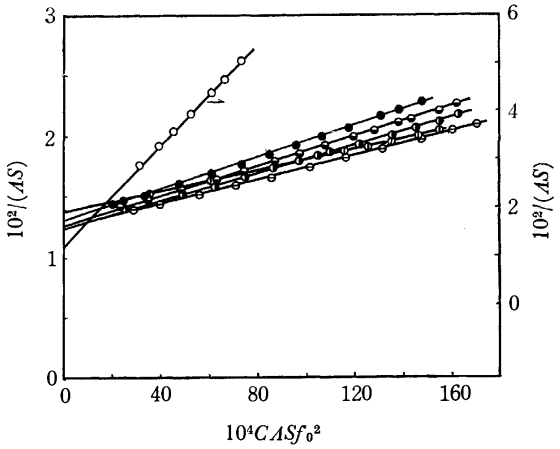

Fig. 1. Shedlovsky plot of the alkali metal picrates in wet MIBK ○: H-Pic, ◐: Li-Pic, ●: Na-Pic, ◒: K-Pic, ◑: Rb-Pic, ⊖: Cs-Pic.

Association Constants K_0^{MR}. Conductance measurements were carried out with dry and wet MIBK solutions. A plot of Λ *vs.* $C^{1/2}$ gives a curve characteristic of a weak electrolyte. The value of Λ_∞ evaluated graphically is used for the first Shedlovsky plot. The data required for the plot are given in Table 1. The reciprocal of the intercept on $1/(\Lambda S)$-axis gives the second approximation for Λ_∞. The Shedlovsky plot is repeated until Λ_∞ gives a constant value. The final plots are shown in Fig. 1, the values of Λ_∞ and K_0^{MR} being determined simultaneously (Table 2).

The levelling property of MIBK is reflected on the limiting conductances and all the equilibrium constants as seen from Table 2. The water added emphasizes the property. The strong levelling power of water has

also been observed in the nitrobenzene system (Table 3). Association of the picrates in dry MIBK solutions is only a case that shows a definite correlation with the sizes of the cations concerned, though not so conspicuous as in the nitrobenzene system.

With dry ketones (acetone, methyl ethyl ketone, and MIBK), the $1/\varepsilon$ law is verified. The distance of closest approach is calculated to be about 4 Å on the basis of the theory by Denison and Ramsey.[7)] This suggests that the main factor in determining the extent of the ion association is an electrostatic force.

Distribution Coefficients D^{MR} and Association Constants K_a^{MR}. Measurements of these constants were carried out under conditions in which aqueous solutions were sufficiently alkaline (pH about 7.5) not to allow the presence of HR. A plot of Y/q^R *vs.* $1/(f_a^2[M^+]_a)$ shows a straight line in accordance with theoretical requirements (Fig. 2). The values of the intercept on the ordinate are so close to zero that the values of K_a^{MR} and D^{MR} are less accurate than those obtained with the nitrobenzene system.

For sodium picrate the value of K_a^{MR} is also determined potentiometrically to be about 20 by using a sodium-sensitive glass electrode. The value is in fair agreement with that given in Table 3, indicating the validity of the present method.

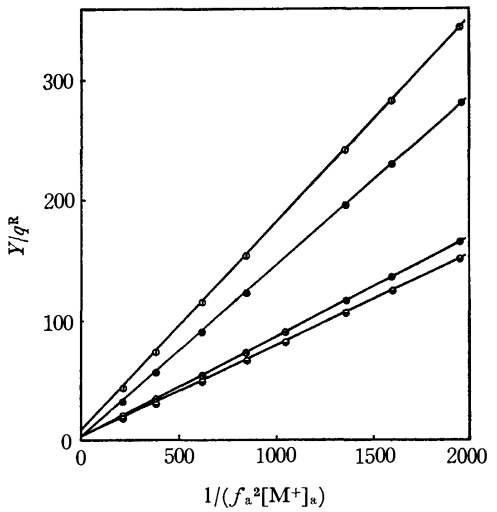

Fig. 2. The plot of Y/q^R *vs.* $1/(f_a^2[M^+]_a)$
The symbols used are the same as those in Fig. 1.

The D^{MR} values obtained show that MIBK dissolves larger quantities of the picrates than nitrobenzene. It is also shown that MIBK acts as a levelling solvent for the distribution and association of the picrates.

The value of D^{HR} is evaluated in such a way that the q^M and q^R curves calculated for five kinds of picrates

7) J. T. Denison and J. B. Ramsey, *J. Amer. Chem. Soc.*, **77**, 2615 (1955).

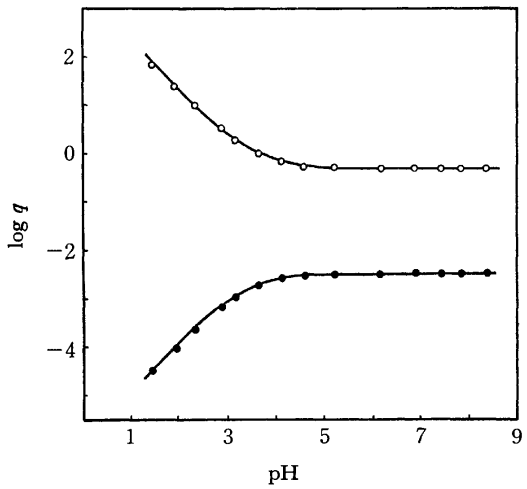

Fig. 3. The distribution of sodium picrate
○: q^R, ●: q^M

fit the observed ones. The best fit (Fig. 3, solid lines) is attained by choosing the value of 500, which is comparable to that obtained with the nitrobenzene system.

A value of 0.381[9] obtained in pure water is chosen for K_a^{HR} by neglecting a possible effect of the MIBK dissolved.

Distribution of Alkali Metals q^M. A typical plot of log q^M *vs.* pH for sodium picrate is shown in Fig. 3 by solid circles. The curves for the other picrates are not shown, since they were almost the same. The q^M and q^R values in Table 2 can serve as a measure of the slight differences in the curves among the picrates.

Appearance of a horizontal line can be explained by means of Eq. (19) as follows: When the aqueous solution is kept sufficiently alkaline, Eq. (19) can be rearranged into the following by neglecting $[H^+]_o$ and the terms containing $[H^+]_a$

$$q^M = D^{MR}\frac{\left([M^+]_o+\frac{1}{K_o^{MR}}\right)}{\left\{[M^+]_a+\frac{1}{K_a^{MR}}\left(1+\frac{D^{HR}}{K_a^{HR}}[H^+]_a+A\right)\right\}}\frac{[M^+]_a}{[M^+]_o}\left(1+\frac{A}{[M^+]_a}\right) \qquad (20)$$

$$C^R - C^M = A$$

This is further simplified to

$$(q^M)^2 = \frac{D^{MR}K_a^{MR}}{K_o^{MR}}\left(1+\frac{A}{[M^+]_a}\right) \qquad (21)$$

where $[M^+]_a/[M^+]_o$ is approximated by $1/q^M$. The concentrations of alkali metals remain practically constant over the whole pH range studied, since the concentrations of the picrates are much smaller than those of the alkali metals added as buffers. The values of q^M, therefore, become constant.

In the acidic region, on the other hand, circumstances are not so simple as in the alkaline region, since the term $[H^+]_o$ can not be neglected. Since no direct method for determining the $[H^+]_o$ values is known, the values are calculated from the pH:

$$[H^+]_o = \frac{K_o^{HR}K_o^{MR}D^{HR}[M^+]_o}{K_a^{HR}K_a^{MR}D^{MR}[M^+]_a}[H^+]_a \qquad (22)$$

Introduction of this term makes it difficult to estimate a simple relationship between the values of log q^M and pH, as has been shown in the nitrobenzene system.

Distribution of the Acid Species q^R. The dependence of the distribution ratio upon pH is calculated from Eq. (12). This equation can be simplified under sufficiently alkaline conditions as

$$q^R = \frac{D^{MR}K_a^{MR}}{K_o^{MR}}\left(K_o^{MR}[M^+]_a+\frac{1}{q^M}\right) \qquad (23)$$

This is further simplified to

$$q^R = \frac{D^{MR}K_a^{MR}}{K_o^{MR}}\cdot\frac{1}{q^M} \qquad (24)$$

showing that q^R values are independent of pH. The equation also shows that the q^M values are smaller than the q^R values by a factor of $(1+A/[M^+]_a)$. When the initial concentrations of C^M and C^R are equal ($A=0$), the values of q^M and q^R become the same, as in the nitrobenzene system.

In the acidic region, on the other hand, the q^R values vary almost linearly with pH, though the slope is slightly smaller than -1.

It has been comfirmed that the distribution of the picrates can be explained by means of six kinds of equilibria. The validity of such treatments may be proved indirectly by the fact that the K_a^{MR} value obtained with sodium picrate agrees well with that determined potentiometrically. No successful application to the mutual separation of alkali metals can be expected for the MIBK system because of its high levelling property.

The author wishes to express his gratitude to Professor Kyoji Tôei for his guidance throughout the course of this work. The work was supported in part by a grant from the Ministry of Education.

ESR of Copper(II) Complexes in Magnetically Non-dilute Crystals. I. Single Crystals of Bis(L-alaninato)copper(II)

Hiroshi YOKOI and Shigeru OHSAWA*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received January 11, 1973)

Single-crystal ESR studies have been carried out on bis(L-alaninato)copper(II). Only one symmetric absorption peak has been obtained in any direction of the magnetic field, regardless of the fact that there are two molecules per unit cell. The principal values and the directions of the principal axes of the g tensor have been determined, and a correlation between those components of the g tensor and the crystal structure has been confirmed on the basis of the effect of the spin-exchange interaction between the dissimilar copper(II) ions. The absorption linewidths have been examined in order to estimate the spin-exchange energy.

In general, it is not easy to determine the g values reflecting the local copper(II)-ion environment for the magnetically non-dilute crystals or polycrystals of copper(II) complexes with polymolecular unit cells if there is an appreciable spin-exchange interaction between the dissimilar copper(II) ions.[1-5] However, the estimation of the molecular g values from the crystal g values for the crystals of chemically-complicated chelate complexes with polymolecular unit cells is occasionally desired.[6] Single crystals of bis(L-alaninato)copper(II), which have two molecules per unit cell, showed only one symmetric ESR absorption line in any direction of the magnetic field. The purpose of this paper is to present the ESR findings on undiluted single crystals in connection with the crystal structure and spin-exchange interaction between dissimilar copper(II) ions.

Experimental

Single crystals of bis(L-alaninato)copper(II) were obtained from an aqueous solution by slow evaporation. The crystals

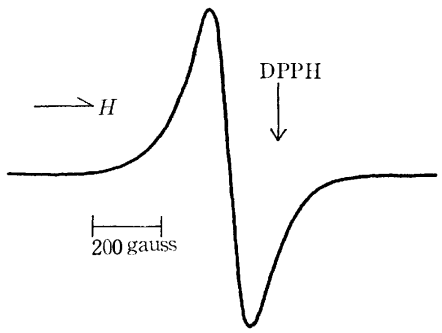

Fig. 2. The single crystal ESR spectrum of bis(L-alaninato)-copper(II) at $\theta=0°$ and $\varphi=0°$(X-band, at room temperature).

were optically identified by the use of a Stoe two-circle goniometer by measuring their interfacial angles. The crystals used in the ESR measurements were mounted on the end of a glass rod in various orientations by means of the goniometer. The ESR spectra were obtained at room temperature about each of three mutually perpendicular axes by rotation at 10 ° intervals, using a Hitachi X-band ESR spectrometer, Model-4001, equipped with a 100 kHz field modulation unit. The field was calibrated with an NMR probe and then with a benzene solution of vanadyl acetylacetonate.

Results

Crystals of bis(L-alaninato)copper(II) are monoclinic, with a bimolecular unit with these dimensions: $a=9.24\pm0.04$, $b=5.05\pm0.02$, $c=9.59\pm0.04$ Å, and $\beta=95.2\pm0.3°$. The space group is $P2_1(C_2^2)$.[7] A right-hand system is chosen in the crystals, as is shown in Fig. 1. Only one symmetric ESR absorption peak was observed in any direction of the magnetic field. One of the observed ESR spectra is shown in Fig. 2. All the rotation data of ESR measurements are shown in Figs. 3 and 4. The rotation data concerning the g values were fitted by the least-squares method to expressions of the type given by Schonland,[8] diagonalization then giving the eigenvalues and vectors for the g tensor.

The calculated direction angles for several molecular axes are given in Table 1. The principal values for the g tensor are also given in the table, together with the direction angles for the principal axes. The prin-

cipal g values obtained in this work agree with those determined from the powder K-band ESR spectrum by the use of the approximation of Kneubühl.[9,10]

Discussion

When there are two types of copper(II) ions with different g values, g_a and g_b respectively ($\Delta g=|g_a-g_b|$), the observed ESR line shape will depend on whether the spin-exchange energy, $2J$, is greater or smaller than $\Delta g\beta H$. If $2J>\Delta g\beta H$, only one absorption peak is to be expected, because of the unifying effect of the exchange interaction.[1-4,6] Let us now consider the case of a unit cell containing only two sets of crystallographically-non-equivalent axial molecules ($g_{//}$ and $g_\perp$). Let the two principal axes of the molecules be inclined at the 2γ angle. In the case of $2J>(g_{//}-g_\perp)\beta H$, the following three principal g values ($g_1\leq g_2\leq g_3$) are given as the crystal g values:[4]

$$g_1 = g_\perp \quad (1)$$

$$g_2 = \sqrt{g_\perp^2+(g_{//}^2-g_\perp^2)\sin^2\gamma} \quad (2)$$

$$g_3 = \sqrt{g_\perp^2+(g_{//}^2-g_\perp^2)\cos^2\gamma} \quad (3)$$

where the axes of g_2 and g_3 are directed to the external and internal bisectors respectively of the axes normal to two sets of crystallographically-non-equivalent molecular planes, and where the g_1 axis is perpendicular to both the g_2 and g_3 axes.

It is characteristic of the crystals of bis(L-alaninato)-copper(II) that the direction angles of the g_3 axis are in close agreement with those of the above-mentioned internal bisector, whereas those of the g_2 axis coincide with those of the external bisector, as is shown in Table 1. These experimental facts can be clearly understood from Eqs. (1)—(3). On the assumption of an axial symmetry in the molecular g values for this complex in crystals, we can determine a $g_{//}$ value which minimizes the equation of $(g_2^{ob}-g_2^{calc})^2+(g_3^{ob}-g_3^{calc})^2$, where g^{ob} represents the observed g value, and g^{calc}, the g value calculated from Eqs. (2) and (3). This $g_{//}$ value was determined to be 2.247_0 using $g_\perp=2.049_0$ and $\gamma=28°29'$, where the γ value is half the angle between the two above-mentioned molecular planes. Then, the calculated g values were found to be as follows:

$$g_2^{calc} = 2.095_7 \text{ and } g_3^{calc} = 2.203_5$$

These calculated crystal g values agree with those listed in Table 1 within the limits of experimental error. The assumption of an axial symmetry in the molecular g values for this complex in crystals contradicts a suggestion previously reported.[9] From the point of view of chemical constitution, it had been considered that the local copper(II)-ion environment of bis(amino acidato)copper(II) complexes is rhombically distorted. However, a nearly axial symmetry in the molecular g values for this complex in crystals seems to be highly probable, since there is a satisfactory agreement between the calculated and experimentally-

9) H. Yokoi, M. Sai, T. Isobe, and S. Ohsawa, This Bulletin, **45**, 2189 (1972).
10) F. K. Kneubühl, *J. Chem. Phys.*, **33**, 1074 (1960).

determined g values, as has been mentioned above, since various bis(amino acidato)copper(II) complexes in magnetically-diluted crystals have been reported to be of an axial symmetry in the g values[11] and since it is considered that the alanine complex in crystals is not largely different from that in an aqueous solution in either the g values or the visible absorption energy; $g_{//}=2.264$, $g_{\perp}=2.056$, and $\lambda_{max}=617$ (nm) in aqueous-methanolic solutions, whereas the above-assumed molecular g values and $\lambda_{max}=590$ (nm) in crystals.[9]

The approximate spin-exchange energy can be estimated from the observed linewidth and the calculated dipolar width using the following equations:[12]

$$\Delta H = \frac{6.67(\Delta H^{d})^{2}}{H_{ex}} \tag{4}$$

$$H_{ex} = \sqrt{2.83}\frac{J}{g\beta}\sqrt{S(S+1)} \tag{5}$$

where ΔH and ΔH^{d} are the observed half-width and the dipolar half-width respectively, and where H_{ex} is the exchange energy between the copper(II) ions expressed in the units of the magnetic field. It is assumed in Eqs. (4) and (5) that J is the value of the isotropic exchange interaction. ΔH^{d} can be calculated from the second moment, $\langle \Delta H^{2} \rangle$, assuming that the line shape is of Gaussian form:

$$\Delta H^{d} = 2.35\sqrt{\langle \Delta H^{2} \rangle} = 2.35\left[\frac{3}{4}\mu^{2}\sum_{i,j}\frac{(3\cos\theta_{ij}-1)^{2}}{r_{ij}^{6}}\right]^{1/2} \tag{6}$$

Table 2. Estimation of the J value

Direction of H	g	ΔH_{msl} (gauss)	ΔH^{d}_{msl} (gauss)	J (cm^{-1})
$a' // H$	2.143	164	344	0.33
$b // H$	2.096	108	364	0.55
$c // H$	2.110	92	293	0.42

where μ is the magnetic moment, where r_{ij} is the distance between the copper ions i and j, and where θ_{ij} is the angle between r_{ij} and the static magnetic field. Instead of ΔH, the separation between the points of the maximum and minimum slopes, ΔH_{msl}, was used for all the calculations, with an appropriate correction. The results are summarized in Table 2. The estimated J values in the table slightly differ with different directions of H. The reason for this may be that Eqs. (4) and (5) are approximate equations for the present case, since they are valid only when the g tensor is isotropic,[1,12] and that the effect of hyperfine coupling on the linewidth is neglected in these equations.[12] It is expected that the actual J value in the crystals of bis(L-alaninato)copper(II) is slightly larger than those listed in Table 2 because of the broadening effect of the hyperfine structure, and that this effect becomes more profound with g in the indicated directions of H in the table. In conclusion, J is of the order of 0.5 cm^{-1} for this complex in crystals.

The authors are grateful to Professor Taro Isobe for his encouragement throughout this work; they also wish to thank Mr. Makoto Chikira for his helpful advice.

The Electrochemical Behavior of the Low-valent Transition Metal Complexes. II. Iron(0)-2,2′-Bipyridine Complexes

Akira MISONO, Yasuzo UCHIDA, Masanobu HIDAI, Takamichi YAMAGISHI, and Hironori KAGEYAMA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 7, 1973)

The electroreduction reaction of the zero-valent iron-2,2′-bipyridine complexes ($Fe(bipy)_2$ and $Fe(bipy)_3$) was studied in a hexamethylphosphoric triamide solution by polarography and ESR measurements. In the polarography, $Fe(bipy)_2$ was first reduced at a very less negative potential ($E_{1/2} = -0.76$ V *vs.* Hg pool) than the first wave potential of free bipyridine (-2.37 V *vs.* Hg pool). In the presence of excess bipyridine, $Fe(bipy)_2$ was first reduced at -1.10 V *vs.* Hg pool corresponding to the second reduction step of the solution of $Fe(bipy)_2$. The visible spectra of the solution of $Fe(bipy)_2$ in the presence of excess bipyridine was different from that of the solution of $Fe(bipy)_2$ only. The signal with hyperfine structure attributable to the anion radical of bipyridine was observed by means of ESR analysis of the solution electrolyzed at the potential corresponding to the second reduction step. From these results, it was concluded that $[Fe(bipy)(HMPT)_m]$ was reduced at the first step, and $[Fe(bipy)_2(HMPT)]$ was reduced at the second.

Although many electrochemical studies on high-valent transition metal complexes have been reported,[1,2] only a few studies on the electrochemical behavior of low-valent transition metal complexes have been carried out. It seemed that it would be interesting to perform a study of the electrochemical behavior of low-valent transition metal complexes in relation to evaluation of the charge distribution and the stability of the reduced complexes.

In a previous paper,[3] we reported a study on the electrochemical behavior of the low-valent nickel-2,2′-bipyridine complexes. In this paper, the electrochemical study on the zero-valent iron-2,2′-bipyridine complexes will be described.

Experimental

Materials. Hexamethylphosphoric triamide (HMPT) used as solvent was refluxed over calcium hydride for several hours and was then fractionally distilled under a reduced nitrogen pressure. Tetra-*n*-butylammonium perchlorate (TBAP) was prepared by the published method.[3] 2,2′-Bipyridine was used as purchased, mp 69.5—70.0 °C.

The examined complexes were bis(2,2′-bipyridine)iron(0) ($Fe(bipy)_2$), and tris(2,2′-bipyridine)iron(0) ($Fe(bipy)_3$). $Fe(bipy)_2$ was obtained by heating a benzene solution of diethylbis(2,2′-bipyridine)iron(II) ($Et_2Fe(bipy)_2$) at 50 °C for several hours.[4] $Fe(bipy)_3$ was obtained by decomposing $Et_2Fe(bipy)_2$ in the presence of excess bipyridine at 50 °C for several hours.[4] Tris(2,2′-bipyridine)iron(II) perchlorate ($[Fe(bipy)_3](ClO_4)_2$) was prepared according to the method of Nyholm *et al.*[5]

Apparatus and Procedure. The polarographic analysis was performed using an H-type cell. The cathode and the anode were a dropping mercury and a mercury pool, respectively. The concentration of the complexes was generally 5.0×10^{-3} mol/l, while that of TBAP was 2.0×10^{-1} mol/l. The polarograph used was a Yanagimoto Model PB-105. For the ESR analysis, an electrolytic cell as shown in the previous paper[3] was used. The ESR spectra were recorded on a JEOL Model JS-3BS-X Spectrometer. The visible spectra of the complex solution were measured using a Shimadzu Model MPS-50L Spectrophotometer. All operations were handled under nitrogen purified by activated copper.

Results and Discussion

Polarographic Results on the Complexes. The complex $Fe(bipy)_2$ is stable in non-polar solvents such as benzene and tetrahydrofuran, but it is unstable in polar solvents such as 1,2-dimethoxyethane, acetonitrile, and HMPT. The color of the HMPT solution of $Fe(bipy)_2$ changed from brown to violet, and lastly a yellow precipitate was produced under nitrogen at room temperature within a few hours. Therefore the polarographic measurement of the complexes was performed quickly. The polarographic results on the complexes are shown in Table 1.

Table 1. Polarographic results on the complexes

Complex	$E_{1/2}(1)$[b]	$E_{1/2}(2)$[b]	$E_{1/2}(3)$[b]	Wave height ratio
$Fe(bipy)_2$	−0.76	−1.08	−1.40	1.0 : 0.9 : 1.0
$Fe(bipy)_2$ + bipy[a]	−1.10	−1.41		1.0 : 0.9
$Fe(bipy)_3$	−1.89			
$[Fe(bipy)_3](ClO_4)_2$	−1.29	−1.53	−1.85	1.0 : 1.0 : 1.0
	(−1.34)[c]	(−1.55)[c]	(−1.89)[c]	
Free bipyridine	−2.37	−2.80		1.0 : 0.7

Conditions: cathode, a dropping mercury electrode; anode, a mercury electrode; solvent, hexamethylphosphoric triamide; concentration of the complex, 5.0×10^{-3} mol/l; supporting electrolyte, $(n\text{-}C_4H_9)_4N^+ClO_4^-$ (TBAP); concentration of TBAP, 2.0×10^{-1} mol/l.
a) $Fe(bipy)_2$: bipy=1.0: 10 (molar ratio) b) Potential *versus* Hg pool c) Ref. 2.

The first half-wave potential ($E_{1/2}(1)$) of $Fe(bipy)_2$ appeared at a far less negative potential (−0.76 V *vs.* Hg pool) than $E_1/_2(1)$ of free bipyridine. The reduction step of the complex was less reversible, but the electron to be transferred was supposed to be one from the slope of the reduction wave. The ratio of the heights of the first and the second waves was 1.0: 0.9, and the slope of the second wave indicates a one-electron transfer in the second as well as in the first.

When a 10-fold molar amount of bipyridine was added to the complex solution, the decomposition of the complex was suppressed, and the first wave appeared at −1.10 V *vs.* Hg pool corresponding to the second reduction step of the solution of $Fe(bipy)_2$ as shown in Fig. 1. The second wave appeared at −1.41 V *vs.* Hg pool corresponding to the third reduction step of the solution of $Fe(bipy)_2$. The addition of bipyridine increased the height of the second and the third waves of the solution of $Fe(bipy)_2$ only. Furthermore these waves became reversible as their height was increased by the addition of bipyridine as shown in Table 2. The change in the height and reversibility of the second and the third waves suggests that added bipyridine takes part in these reduction steps.

Table 2. Effect of addition of bipyridine on the second reduction wave of $Fe(bipy)_2$ in HMPT

Molar ratio		Relative wave height[a]	Slope (mV)[b]
bipy/$Fe(bipy)_2$	0	—	91.2
bipy/$Fe(bipy)_2$	10	2.2	73.4
bipy/$Fe(bipy)_2$	100	4.0	65.0

Conditions: cathode, a dropping mercury; anode, a mercury pool; concentration of the complex, 5.0×10^{-3} mol/l; concentration of TBAP, 2.0×10^{-1} mol/l.
a) The ratio of the height of the first wave in the presence of excess bipyridine to the height of the second wave in the absence of bipyridine b) Value in the log-plot analysis

The reduction waves of the solution of $Fe(bipy)_2$ at a considerably negative potential could not be successfully observed because of the disturbance in the wave shapes. The reduction wave of free bipyridine was observed after the wave in which the complex was considered to take part. After a prolonged reduction of the complex solution at about −2.0 V *vs.* Hg pool, the color of the solution faded and the resulting polarogram showed only the reduction waves of free bipyridine. These results may be attributable to the instability of the reduced species in spite of the presence of a large amount of bipyridine.

The Visible Spectra of the Complex Solutions. The complex $Fe(bipy)_2$ is very slightly soluble in benzene, to give a blue-violet colored solution. This intense color is considered to be due to the charge transfer between the central metal atom and the ligand molecule.[6] However $Fe(bipy)_2$ was readily soluble in HMPT, to give a brown colored solution, and then decomposed into a yellow precipitate within a few hours under nitrogen at room temperature.

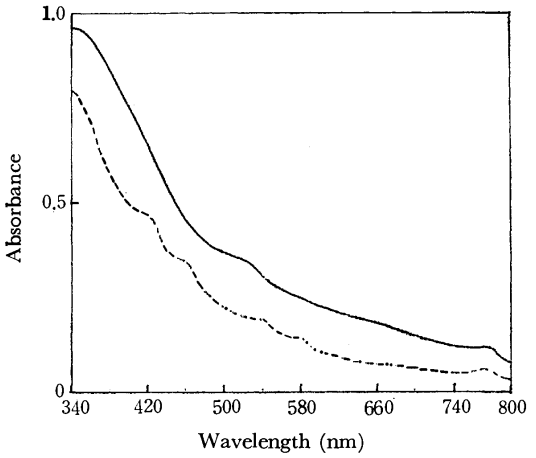

Fig. 2. The visible spectra of $Fe(bipy)_2$–HMPT solution.
——: $Fe(bipy)_2$ in HMPT
-----: $Fe(bipy)_2$+10-fold molar amount of bipyridine in HMPT.

When excess bipyridine was added to the complex solution, the visible spectrum of the solution is different from that of the solution of $Fe(bipy)_2$ in the absence of bipyridine. These spectra are shown in Fig. 2.

When $Et_2Fe(bipy)_2$, $Fe(bipy)_2$, and $Fe(bipy)_3$ were used as the catalysts for the oligomerization of butadiene(BD), the reaction intermediate is considered to be $[Fe(bipy)(BD)_2]$.[4] HMPT with a donor- and an acceptor-level can also coordinate to a low-valent transition metals. It is therefore reasonable to consider that the coordinated bipyridine is replaced by HMPT, and $[Fe(bipy)(HMPT)_m]$ (m=1, 2, or 3) is produced in an HMPT solution.

$Fe(bipy)_3$ is very slightly soluble and stable in ben-

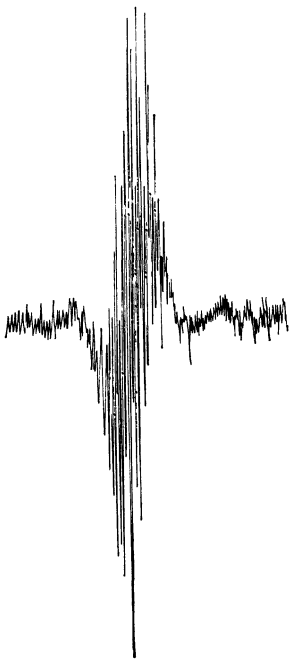

Fig. 3. ESR signal in the electrolysis of $Fe(bipy)_2$ at -1.30 V *vs.* Ag wire (*g*-value, 2.002_5).

zene and HMPT, to give a dark brown colored solution. The visible spectrum of the solution of $Fe(bipy)_3$ did not change by the addition of bipyridine.

ESR Measurements. In the electrolysis of $Fe(bipy)_2$ in HMPT at the potential sufficiently negative to cause the first reduction step, no ESR signal was observed. However in the electrolysis at the potential corresponding to the second reduction step, the ESR signal with hyperfine structure attributable to the anion radical of 2,2′-bipyridine[7] was observed. This signal was stable in HMPT and was observed to be overlapped with another signal with an ill-defined structure. The observed signal is shown in Fig. 3. The similar signal was observed in the electrolysis of the nickel(0)-2,2′-bipyridine complexes in HMPT at the potential corresponding to the second reduction step.[3]

Taking into account the polarographic results at the second reduction step, it was concluded that the anion radical of bipyridine was formed by the dissociation of the species produced at the second reduction step.

Reaction Mechanism in the Electrolysis of $Fe(bipy)_2$. Taking into account the polarographic results and the visible spectra of the solution of $Fe(bipy)_2$, the following equilibrium in HMPT is proposed.

$$[Fe(bipy)_2(HMPT)] \overset{HMPT}{\rightleftharpoons} [Fe(bipy)(HMPT)_m] + bipy$$

As a mechnism of the electro-reduction of $Fe(bipy)_2$ in HMPT, the following mechanism is proposed.

$$\begin{array}{ccc}
[Fe(bipy)_2(HMPT)] & \overset{-bipy}{\underset{+bipy}{\rightleftharpoons}} & [Fe(bipy)(HMPT)_m] \\
-e^- \uparrow\downarrow +e^- \text{ 2nd step} & \swarrow\ -[bipy]^- & -e^- \uparrow\downarrow +e^- \text{ 1st step} \\
[Fe(bipy)_2(HMPT)]^- & \overset{-bipy}{\underset{+bipy}{\rightleftharpoons}} & [Fe(bipy)(HMPT)_m]^- \\
-e^- \uparrow\downarrow +e^- \text{ 3rd step} & & -e^- \uparrow\downarrow +e^- \\
[Fe(bipy)_2(HMPT)]^{2-} & \overset{-bipy}{\underset{+bipy}{\rightleftharpoons}} & [Fe(bipy)(HMPT)_m]^{2-}
\end{array}$$

The complex $Fe(bipy)_2$ is unstable and gave a disturbed polarogram, from which no clear-cut information was obtained, but it showed more reduction waves at a potential more negative than the third reduction step, so a reduction state more than the third reduction state may be expected. Tris(2,2′-bipyridine)chromium(0) has previously been reported to be reduced to the hexa-anion stage, $Ca_3[Cr(bipy)_3]\cdot 7NH_3$.[8]

The Electroreduction Reaction of $Fe(bipy)_3$ in HMPT. Tanaka *et al.*[2,9] reported that in the electroreduction of $[Fe(bipy)_3](ClO_4)_2$ in acetonitrile, the following mechanism has been proposed.

$$[Fe(bipy)_3]^{2+} + e^- \rightleftharpoons [Fe(bipy)_3]^+ \qquad E_{1/2} = -1.34 \text{ V } vs. \text{ SCE}$$

$$[Fe(bipy)_3]^+ + e^- \rightleftharpoons [Fe(bipy)_3]^0 \qquad E_{1/2} = -1.55 \text{ V } vs. \text{ SCE}$$

$$[Fe(bipy)_3]^0 + e^- \rightleftharpoons [Fe(bipy)_3]^- \qquad E_{1/2} = -1.89 \text{ V } vs. \text{ SCE}$$

The first wave potential of $Fe(bipy)_3$ in HMPT appeared at -1.89 V *vs.* Hg pool. The visible spectrum of the solution of $Fe(bipy)_3$ is similar to that in benzene, and it did not change by the addition of free bipyridine. From the above results, the analogous reaction mechanism was proposed in the electrolysis of $Fe(bipy)_3$ in HMPT.

$$Fe(bipy)_3 + e^- \rightleftharpoons [Fe(bipy)_3]^-$$

Ion-selective Electrodes Sensitive to Some Organic Compounds Used as Drugs

Kenyu KINA, Nobuko MAEKAWA, and Nobuhiko ISHIBASHI

Department of Applied Analytical Chemistry, Faculty of Engineering, Kyushu University Higashi-ku, Hakozaki, Fukuoka 812

(Received February 23, 1973)

Drug ion-selective electrodes with a liquid membrane have been developed which are sensitive to methacholine, neostigmine, *N*-1-methyl nicotinamide, diphenhydramine, vitamin B_1, vitamin B_6, *p*-aminosalicylic acid (PAS), and salicylic acid. Crystal violet or ferroin-compound cations and dipicrylamine or tetraphenylborate anions were used as the ion-exchange sites in the liquid membrane. Each liquid membrane was prepared by using the solvent-extraction method and exhibited an appropriate Nernstian response to the respective ion down to 10^{-4} or to 10^{-5} M. The electrode performances, including the selectivity coefficients, are summarized in Table 1.

In a previous paper vitamin-sensitive electrodes based on the solvent extraction of the protonated vitamin cation have been reported on.[1] Among other drugs, we found many ionic and water-soluble organic compounds. For example, methacholine chloride, neostigmine bromide, and *N*-1-methyl nicotinamide chloride are water-soluble salts of quarternary ammonium or pyridinum cations. Diphenhydramine, vitamin B_1, and B_6 are present as protonated cations in an acidic aqueous solution from pH 3 to 5. From the acid-dissociation constants of *p*-aminosalicylic acid and salicylic acid, it can easily be understood that they are present as singly-charged anions in the pH range from 6 to 11. These organic ions can be extracted with the ionic extractant into an organic solvent such as 1,2-dichloroethane or nitrobenzene; the resulting organic solution is useful as a "liquid membrane" for the corresponding ion-selective electrode.

This paper will describe the performance of the electrodes sensitive to some organic compounds used as drugs.

Experimental

Chemicals and Liquid-membrane Solutions. The crystal violet (CV) and the dipicrylamine (Hexyl) were obtained from the Kishida Kagaku Co. The sodium tetraphenylborate (TPB), *o*-phenanthroline (Phen), and bathophenanthroline (Bphen) were obtained from the Dojindo Co., Ltd. The objective drugs were obtained from the Kishida Kagaku Co. or the Tokyo Kasei Co.

The liquid membranes of the electrodes were prepared by using the ion-association extraction method.[1]

As the extractant of a drug cation, sodium tetraphenylborate or dipicrylamine was used, whereas the crystal violet cation or the ferroin compound (the iron chelate of *o*-phenanthroline or bathophenanthroline) was used as the extractant of the drug anion. Nitrobenzene (NB) or 1,2-dichloroethane (DCE) was used as the membrane solvent; the concentration of the liquid membrane was 1×10^{-4} M.

Evaluation of the Electrode Performance. Either a U-shaped glass tube or an Orion liquid-membrane barrel was used for the drug ion-sensitive electrode.

The selectivity and sensitivity of the drug ion-selective electrode were estimated by measuring the electromotive force of the following concentration cell:

+SCE/Reference solution (′)/Organic liquid membrane/Sample solution (″)/SCE−

The reference solution and sample solution were separated by means of the liquid membrane in the lower part of a U-shaped glass tube. The details of the cell assembly have been described in earlier papers.[2]

An Orion liquid-membrane barrel equipped with a Milliporefilter solvinert membrane (Pore size 0.25 micron) was used for the dynamic response and potentiometric titration studies. The outer chamber of the barrel was filled with the "liquid membrane." The internal reference chamber was filled with a corresponding drug-ion solution.

The measurements of the membrane potential were made by means of a Takeda Riken electrometer, TR-8651. The dynamic response of the electrode was recorded with a National Pen Recorder (Model VP-653A).

Results and Discussion

Response of the Electrode. The electrode potential in the presence of an interfering ion is empirically given by:

$$E = \text{Constant} + (2.303RT/nF)\log(A_i'' + K_j(A_j'')^{n/z}) \quad (1)$$

where n and z are the charges of the i and j-ions respectively and where K_j is the selectivity coefficient of the j-ion for the i-ion-sensitive electrode. As the reference solution we used a 1×10^{-3} M solution of the objective drug ion. The A_i'' and A_j'' activities in Equation (1) were approximated by the use of the molar concentration, because the dilute solution was used. The selectivity coefficient was determined by using the separate-solution method.[3] The observed electrode performance is summarized in Table 1. Methacholine and neostigmine electrodes are most sensitive, having useful response ranges up to 1×10^{-6} M. This suggests that methacholine and neostigmine cations are well extractable into the organic solvent, because the electrode of the higher extractable ion is usually more sensitive.[4]

The sequence of selectivity coefficients is consistent with the order of the extractability of the ion into the

a) C denotes the molar concentration of drug ion. b) TEA denotes tetraethylammonium ion.

organic solvent.[5] Among the coexisting competitive ions, the easily extractable ion produces a large interference. Salicylic acid interferes remarkably with the performance of the *p*-aminosalicylic acid-sensitive electrode. This reflects a decreased extractability of *p*-aminosalicylic acid resulting from its hydrophilic amino group.

According to Eisenman's theoretical prediction of the liquid membrane potential,[6] the selectivity of the electrode depends entirely on the membrane solvent rather than on the particular exchange-site species in the limiting case of the complete dissociation in a liquid membrane. The ion-pair complex in the nitrobenzene membrane may be completely dissociated, because nitrobenzene has a relatively high dielectric constant and because the concentration of the ion pair is sufficiently dilute.[4]

As can be seen in the cases of the neostigmine-, *p*-aminosalicylic acid-, and salicylic acid-sensitive electrodes in Table 1, no difference in either the selectivity or the sensitivity was found among different exchange sites when nitrobenzene was used as the membrane solvent. The 1,2-dichloroethane membrane gives a selectivity quite different from that of the nitrobenzene membrane. Hence, the observed selectivity coefficients qualitatively support Eisenman's expectation.

Dynamic Response and Potentiometric Titration. The dynamic response was evaluated on the methacholine ion-sensitive electrode by exposing the electrode to a rapid change of methacholine-ion concentration from 10^{-5} to 10^{-3} M. The solution was agitated with a magnetic stirrer.

The electrode potential changed rapidly, and the resulting constant potential was obtained within one second, although the response time depends on the efficiency of the solution mixing. Such a rapid response is, in practice, sufficiently useful for performing the potentiometric titration. The methacholine ion-selective electrode was used in the potentiometric titration of methacholine chloride by using the sodium tetraphenylborate solution as a titrant. The end point of the potentiometric titration agreed well with that of the argentimetric titration of the chloride ion. As has been mentioned above, the several drug ion-selective electrodes have comparatively good analytical responses from the view points of sensitivity and selectivity.

These drug ion-selective electrodes, therefore, could be used in the analyses of mixed pharmaceutical preparations.

Kinetics and Mechanisms of the Reactions of Ce(IV) and Co(III) with Variamine Blue, [*N*-(*p*-Methoxyphenyl)phenylenediamine], in Aqueous Perchlorate Media

Taira IMAMURA and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received March 31, 1973)

The kinetics of the non-complementary reactions of Ce(IV) and Co(III) with Variamine Blue perchlorate were studied under nitrogen atmosphere in aqueous perchlorate media of ionic strength $\mu=2.0$ M. The iminoquinone form of Variamine Blue was spectrophotometrically followed at 550 nm by stopped-flow technique. The rate constants of the stepwise reaction, $M^{n+}+(V.B.)\underset{k_r}{\overset{k_\alpha}{\rightleftharpoons}}M^{(n-1)+}+(V.B.)_{sox}$, $M^{n+}+(V.B.)_{sox}\xrightarrow{k_\beta}M^{(n-1)+}+(V.B.)_{ox}+2H^+$ were evaluated at 25 °C to be $k_\alpha=1.7\times10^5$ and $k_\beta=2.4\times10^5$ M^{-1} sec^{-1} for Ce^{4+} and $k_\alpha=1.35\times10^4$ and $k_\beta=1.53\times10^4$ M^{-1} sec^{-1} at [H]=1.0 M for Co^{3+}. The rates of Ce^{4+} were not affected by [H]. The [H]-dependence of k_α and k_β for Co^{3+} gives the mechanism $Co^{3+}_{aq}+B\underset{k_1}{\rightleftharpoons}$product, $CoOH^{2+}_{aq}+B\xrightarrow{k_2}$product, $Co^{3+}_{aq}\overset{K_h}{\rightleftharpoons}CoOH^{2+}_{aq}+H^+$, with $k_2\simeq10^7$ M^{-1} sec^{-1}, suggesting an outer-sphere mechanism for the electron transfer with $CoOH^{2+}$.

In preceding reports we discussed the reactions of Variamine Blue (abbr. V.B.) with iron(III) and thallium(III), in which the formation of the iminoquinone form of V.B. was treated as a two-setp reaction for iron(III)[1] and as a one-step reaction for thallium-(III).[2]

The question has been raised whether the two-step scheme is essential in the non-complementary reaction of V.B. with other metal ions in high oxidation states such as cerium(IV) and cobalt(III). The redox reaction rates of cobalt(III) are generally slower than those predicted from its high redox potential.[3] In the present paper the reactions of V.B. with aquo ions, cerium(IV) and cobalt(III) are reported.

Experimental

Materials. Deionized water was distilled with an all-joint Pyrex apparatus. Purified sodium perchlorate[4] was used to maintain the ionic strength at 2.0 M.

Cerium(IV) and cobalt(III) perchlorates were prepared by electrolytic oxidation from cerium(III) and cobalt(II) perchlorates, respectively. The current was kept constant at *ca.* 100 mA. The concentration of cerium(IV) was estimated by indirect spectrophotometric measurements of iron-(III) formed in the reaction with iron(II) perchlorate, with [$\varepsilon^{Fe(III)}_{260\,nm}=(2.88\pm0.33)\times10^3$].[5] Cobalt(III) was also determined similarly at 260 nm or directly at 605 nm with [$\varepsilon^{Co(III)}_{605\,nm}=35.5\pm1$].[6] The concentrations of cobalt(III) determined by the two spectrophotometric measurements agreed with each other within experimental error.

Cerium(III) perchlorate was prepared from cerium(III) carbonate and perchloric acid. Cobalt(II) perchlorate was prepared by heating cobalt(II) chloride with a slight excess of perchloric acid and made free from chloride by repeated recrystallization.

Commercial Variamine Blue hydrochloride often becomes a faint blue-color by air-oxidation or photochemical reaction. Dilute solution of Variamine Blue, for example, *ca.* 10^{-3} M, was colorless for 1—2 days but gradually turned bluish accompanied by precipitate formation.

Variamine Blue perchlorate was prepared from commercial V.B. hydrochloride.[7] 0.1 g V.B. and 0.04 g sodium dithionite were dissolved in hot water. The solution was shaken with 0.15 g active carbon and filtered. The filtrate was mixed with 5 ml saturated sodium perchlorate solution and cooled for *ca.* 1 hr in a refrigerator. The silky crystalline precipitate was filtered and washed with cold water and dried *in vacuo*. The elemental analyses of a commercial Variamine Blue hydrochloride and the prepared Variamine Blue perchlorate are given in Table 1.

Table 1. Elemental analyses of variamine blue specimens

Specimen		C(%)	H(%)	N(%)	Cl(%)
Commercial V.B. hydrochloride	Found	60.4	5.80	10.93	15.71
	Calcd for $C_{13}H_{15}ON_2Cl$	62.2	6.03	11.17	14.14
Prepared V.B. perchlorate	Found	49.35	4.56	8.70	
	Calcd for $C_{13}H_{15}O_5N_2Cl$	49.61	4.80	8.90	

Kinetics. Yanagimoto SPS-1 stopped-flow apparatus with a 4-jet mixing chamber and a 10 mm optical cell was used for kinetic measurements. The reservoirs of the stopped-flow apparatus were thermostated by circulating water from a thermostat. Purified nitrogen gas was passed through the reservoirs of the solutions in the course of measurements. The changes in absorbance were followed on the storage-screen of an oscilloscope.

The reactions of V.B. with cerium(IV) and cobalt(III) were studied in the hydrogen-ion concentration range 0.2—2.0 M since these ions are very unstable in low acid region. The reactions were followed at 550 nm, the absorption maximum of $(V.B.)_{ox}$, the iminoquinone form of V.B., in the presence of a large excess of metal ions.

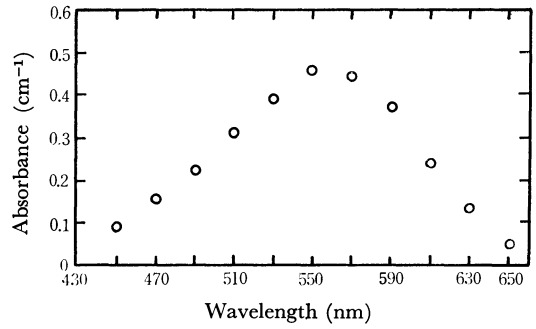

Fig. 1. Absorbance-wavelength plots at equilibrium of the initial fast reaction of V.B. with cobalt(III) measured by stopped-flow technique.
$[Co(III)]_0=2.6\times10^{-3}$M, $[V.B.]_0=2.5\times10^{-5}$M, [H]=0.5M, μ=2.0 and 25 °C.

Results

The rapid initial increase in absorbance at 550 nm was followed by a comparatively slow decrease.[8] Figure 1 shows the absorbance-wavelength plots at the end of the initial increase in absorbance measured by stopped-flow technique. No shift of absorption maximum at 550 nm was observed. The rates of increase in absorbances observed at any wavelengths in the visible range did not differ from each other.

Chloride ions did not affect the rate of increase in absorbance at 550 nm.

As shown in Figs. 2 and 3, the absorbances at 550 nm increase linearly with the initial concentrations of V.B., the half-life of reaction being independent of $[V.B.]_0$ under the experimental conditions. The rate also does not obey the pseudo-first-order rate law even in the presence of a large excess of metal ions as observed in the reaction of V.B. with iron(III).

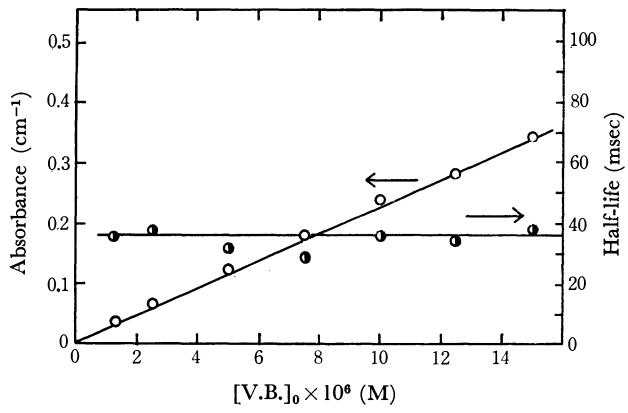

Fig. 2. Absorbance (550 nm) and half-life *vs.* initial concentration of V.B. plots in the reaction with cerium(IV).
$[Ce(IV)]=2.14\times10^{-4}$M, [H]=0.5M, μ=2.0 and 25 °C.

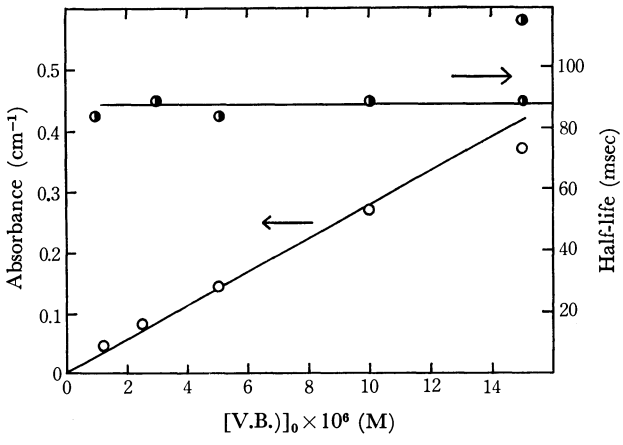

Fig. 3. Absorbance (550 nm) and half-life *vs.* initial concentration of V.B. plots in the reaction with cobalt(III).
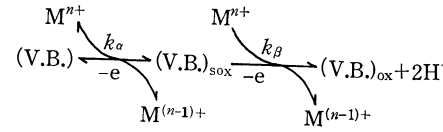
$[Co(III)]=1.33\times10^{-3}$M, [H]=1.0M, μ=2.0 and 25 °C.

8) The slow decrease in absorbance suggests a subsequent redox reaction of the iminoquinone form of Variamine Blue with the oxidants, color fading being accelerated by the metal ions.

Discussion

The reactions of V.B. with Ce^{4+} and Co^{3+} are interpreted as a two-step mechanism:



(1)

The values of rate constants for Ce^{4+} are evaluated by the equation in the preceding paper[1] to be $k_\alpha=1.7\times10^5$ and $k_\beta=2.4\times10^5$ $M^{-1}sec^{-1}$ at 25 °C and μ=2.0. The rates were not affected by hydrogen-ion concentrations. This suggests that the reaction proceeds *via* inner-sphere mechanism.

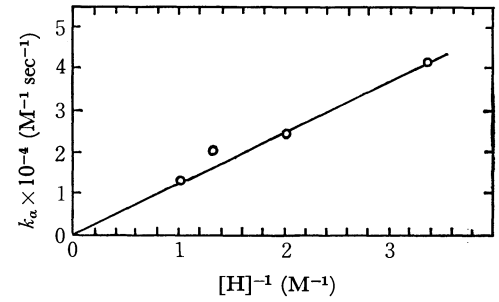


Fig. 4. Rate constant k_α *vs.* $[H]^{-1}$ plots in the reaction of V.B. with cobalt(III).

For the reaction of V.B. with Co^{3+}, the values of k_α and k_β are calculated to be 1.35×10^4 and 1.53×10^4 $M^{-1}sec^{-1}$, respectively, at 25 °C, μ=2.0 and [H]=1.0. The rate constants k_α and k_β are inversely proportional to hydrogen-ion concentration (Fig. 4). The observed second-order rate constants at each step suggest the expression to be

$$k_{obs} = k_1 + k_2K_h/[H], \quad (2)$$

corresponding to the reactions[9]

$$Co_{aq}^{3+} + B \overset{k_1}{\rightleftharpoons} \text{product} \quad (3)$$

9) The reactions can proceed *via* either path of the two indistinguishable reactions;

$CoOH^{2+}$ + protonated V.B. → product (6)

or

Co^{3+} + unprotonated V.B. → product. (7)

However, in the high acidity range the protonated form of Variamine Blue seems to be predominant.

$$CoOH_{aq}^{2+} + B \overset{k_2}{\rightleftharpoons} \text{product} \quad (4)$$

$$Co_{aq}^{3+} \overset{K_h}{\rightleftharpoons} CoOH_{aq}^{2+} + H^+ \quad (5)$$

where B is the species of Variamine Blue in the reaction. The type of rate law is common to many reactions of Co^{3+}. It should be noted that (2) is a special case of the general rate law

$$k_{obs} = (k_1 + k_2K_h/[H])/(1 + K_h/[H]) \quad (8)$$

for $K_h \ll [H]$ as fulfilled under experimental conditions. From the slope of k_α *vs.* $[H]^{-1}$-plot in Fig. 4, the value of k_2 was estimated to be in the order of magnitude of $10^7\ M^{-1}\,sec^{-1}$ using the value $K_h = (2 \pm 1) \times 10^{-3}$ M.[10] The rapid reaction of cobalt(III) with V.B. is most likely to be of an outer-sphere mechanism as in the reactions of Co^{3+} with hydroquinone or iodide.[6] The concentrations of $(V.B.)_{ox}$ calculated from the values of k_α and k_β are plotted as a function of time in Figs. 5 and 6. The concentrations agree with the ones observed in the course of reaction.

Increase in absorbance at 550 nm in the reactions

with cerium(IV) and cobalt(III) was about 15—20% larger than that measured in the reaction of commercial Variamine Blue with iron(III). The difference in absorbance exceeds the experimental error ±10%.

The fact that the absorbance at 600—650 nm increases in the reaction of V.B. with iron(III)[11] in low concentrations suggests the possibility of the presence of some polymeric species of V.B.[12] which is rather stable against iron(III). The extra increase in absorbance at 550 nm observed in the reaction with cerium(IV) and cobalt(III) would be ascribed to a further reaction of these polymeric forms or to some subreactions of V.B. with the metal ions owing to their very high redox potentials.

The present work was supported in part by a grant-in-aid for Scientific Research from the Ministry of Education.

Isotopic Exchange Kinetics between Dibenzoylmethane-^{14}C and Its Tris-type Complex with Aluminium(III) in Tetrahydrofuran

Kazuyo MATSUZAWA (née MASUDA) and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received May 2, 1973)

Isotopic exchange kinetics between [Al(dbm)$_3$] and Hdbm-^{14}C (dbm$^-$, anion of dibenzoylmethane in enol form) has been studied in tetrahydrofuran (THF) at 30 to 55 °C. During several half lives the McKay plot gives straight lines, the AB spectrum remaining unchanged. The rate is very small in the absence of catalysts, and accelerated by water and trichloroacetic acid, but not by weak acids and pyridine. The rate is expressed by

$$R = [\text{complex}](k_2[H_2O] + k_3'[\text{acid}] + k_3[\text{acid}][H_2O])$$

The Arrhenius plots of k_2, k_3', and k_3 give an equal $\Delta H^{\neq}$ value 25.6 kcal/mol. It appears one of the ligands is present as unidentate in the intermediate state, and the break of the remaining bond is the rate-determining step.

As an extension of our previous kinetic studies of isotopic exchange between acetylacetone-^{14}C (Hacac) and trisacetylacetonatoaluminium(III) ([Al(acac)$_3$]),[1] we have examined the isotopic exchange kinetics between the corresponding dibenzoylmethane (Hdbm) complex, in order to find the influence of a more basic ligand upon the kinetic formula and rate. Because of the smaller solubility of [Al(dbm)$_3$] in various organic solvents, the rate was precisely studied only in tetrahydrofuran (THF).

Experimental

Materials. *The Labelled Ligand*: Acetic acid-^{14}C imported from Radiochemical Centre, Ammersham, England, was converted into acetophenone in benzene by the Friedel-Crafts reaction, and treated with ethyl benzoate (Claisen condensation) to give Hdbm. The product with a specific activity *ca.* 10 μCi per mg was diluted with commercial Hdbm before use to obtain samples with a specific activity *ca.* 0.5 μCi per mg.

The Complex: Dibenzoylmethane (5 g) in ethanol (25 ml) was treated with aluminium chloride hexahydrate (1.5 g) in water (5 ml) and sodium acetate (3 g) in water (5 ml) to give crude [Al(dbm)$_3$] (4 g). The product was dissolved in THF (50 ml) and precipitated with a large amount of petroleum ether. The purity of these products were confirmed by elemental analysis and UV spectroscopy. Trichloroacetic acid and THF were purified as mentioned before.[1]

Kinetic Runs. The complex in THF (0.01 to 0.1 M) was mixed with Hdbm in THF (0.01 to 0.3 M) in a thermostat (total volume 10 to 15 ml) and portions (1 to 2 ml) were withdrawn into chilled petroleum ether (*ca.* 15 ml) at appropriate intervals. The complex was precipitated instantaneously in fine crystals, which were filtered off with a piece of filter paper and dried at 80 °C. A known amount of the precipitate (3 to 10 mg) was dissolved in anisole containing *p*-terphenyl and POPOP as wave length shifters and submitted to scintillation counting. The results were calculated by McKay's formula to obtain R values under various conditions.

Measurements. The counting rate was measured with an automatic apparatus from Nuclear Chicago. The AB spectra were recorded with a Hitachi 124 Double Beam Spectrometer. Karl Fischer titration was employed for the determination of water.

1) K. Saito and K. Masuda, This Bulletin, **43**, 119 (1970).

Results

The influence of the complex concentration upon R was examined as in Ref. 1, and a similar diagram to Fig. 1 of Ref. 1 was obtained. The influence of water content is shown in Fig. 1 at 30, 40, and 50 °C. The straight lines pass the origin, so that the k_0 values are expressed by

$$R = k_0[\text{complex}] = k_2[\text{complex}][H_2O] \quad (1)$$

Trichloroacetic acid catalyses the exchange reaction. The extent depends on the concentration of water at a given concentration of acid. Figure 2 shows that the lines have intercepts. When the concentration of trichloroacetic acid was increased at a given concentration of water, the k_0 values increase linearly in a low acid concentration range and then the gradient decreases as the acid concentration increases. (Fig. 3) Hence the overall formula is written for low acid concentration region as Eq. (2).

$$R = [\text{complex}](k_2[H_2O] + k_3'[\text{acid}] + k_3[\text{acid}][H_2O]) \quad (2)$$

The k_3 and the k_3' values are known from the gradients

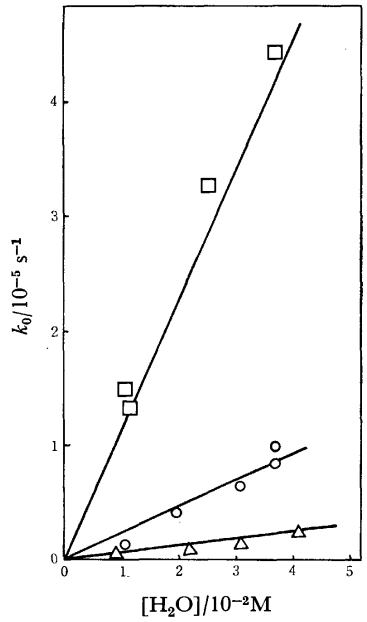

Fig. 1. Influence of water concentration at various temperatures.
(—△— 30 °C, —○— 40 °C, —□— 50 °C, [Hdbm] = 0.050 M)

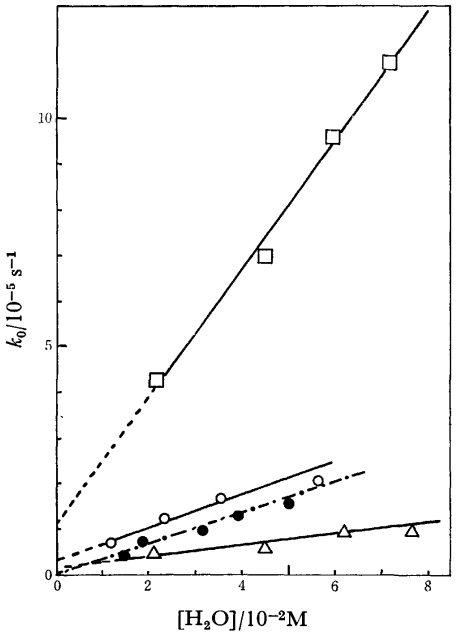

Fig. 2. Influence of water concentration in the presence of trichloroacetic acid at various temperatures.
(—△— 30 °C, —○— and —●— 40 °C, —□— 50 °C; open marks [acid]=0.0286 M, full marks [acid]=0.0021 M; [Hdbm]=0.050 M)

(—△— 30 °C, [H$_2$O]=0.046 M; —○— 40 °C, [H$_2$O]=0.035 M; [Hdbm]=0.050 M)

and the intercepts of Fig. 2, respectively. Weaker acids such as *m*-toluic do not give acid catalysis. Pyridine has no influence on the exchange rate.

There is a very slight influence of the concentration of Hdbm upon the rate at given water concentrations, as shown in Fig. 4, in which $k_0/[H_2O]$ is plotted against [Hdbm]. The change in $k_0/[H_2O]$ is very small unless a large amount of Hdbm is added. The values of k's in Table 1 are those at [Hdbm]=0.05 M, and are very near to the intercepts of diagrams in Fig. 4.

Arrhenius plots of k_2, k_3', and k_3 at 30, 40, 50, and 55 °C gave parallel lines and the activation enthalpies were known to be 25.6±0.2 kcal/mol for all the terms. The k_0 values were converted into those at 25 °C and

the k's tabulated in Table 1 together with those for the exchange reaction between [Al(acac)$_3$] and Hacac-^{14}C.[1]

Discussion

Since the absorption spectrum does not change during kinetic runs and McKay plots give straight lines, it is clear that the isotopic exchange takes place without involving net chemical change. It is remarkable that the exchange is very slow in the absence of water and acid. Except this the rate formula is very similar to that for [Al(acac)$_3$], although the figures are smaller by *ca.* one order than those for [Al(acac)$_3$]. Another marked feature for the present case is that the $\Delta H^{\neq}$ values are the same for all the reaction paths within experimental error. This fact is again very similar to that for [Al(acac)$_3$], although the value itself is bigger than that for [Al(dbm)$_3$].

We consider that the rate-determining step for the three reaction paths are equal. Fig. 5 gives the plausible reaction mechanism. Although the observed k values for each-term in Eq. (2) consist of more than one constant as seen in Fig. 5, the biggest and the most remarkable contribution should come from the k's at the rate-determining step. The equality of observed $\Delta H^{\neq}$ values can be ascribed to the equality of activation enthalpies for the k's. The capital K's indicate equilibrium constants for the given stages, and small k's rate constants at the rate-determining steps. The complex must be in rapid equilibrium with an intermediate

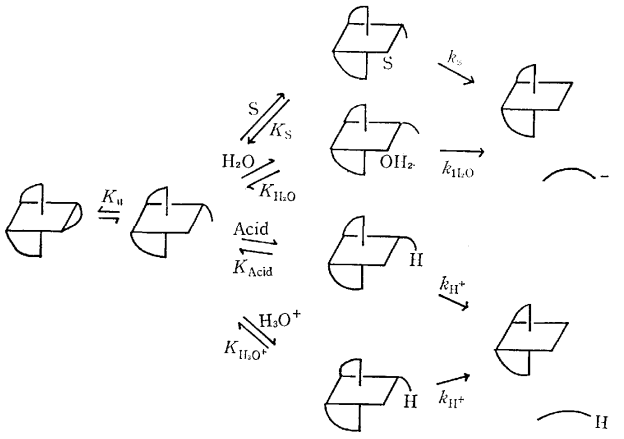

Fig. 5. Probable reaction mechanism.
(arc-like curves represent dbm$^-$; S, solvent molecule)

form, which has one of the ligands as unidentate. The break of its remaining bond is reckoned as the rate-determining step.

The catalytic action of water will be accounted for by considering that it occupies the vacant coordination site to retard the recombination of the free end of unidentate ligand. Hence k_2 is written as Eq. (3).

$$k_2 = k_{H_2O}K_uK_{H_2O} \quad (3)$$

The k_3' and the k_3 path seem to represent acid catalysis with different proton carriers. In the k_3' path, the acid itself will act as proton carrier and the following equation holds.

$$k_3' = k_{H^+}K_uK_{acid} \quad (4)$$

Addition of proton on the free end of unidentate ligand will make its recombination more difficult and increase the probability of break of the remaining bond. In the k_3 path, proton will be transferred to water according to Eq. (5) and k_3 is expressed by Eq. (6).

$$Cl_3CCOOH + H_2O \overset{K_{hdx}}{\rightleftharpoons} H_3O^+ + Cl_3CCOO^- \quad (5)$$

$$k_3 = k_{H^+}K_uK_{H_3O^+}[H_3O^+] \quad (6)$$

A characteristic feature in the present study is that the influence of acid concentration tends to show saturation. (Fig. 3) This trend is interpreted in two ways. If Eq. (5) reaches saturation in the given concentration range, further increase in acid concentration will not increase the $[H_3O^+]$. On the other hand, if all the free end of unidentate ligand were protonated, *i.e.* equilibrium $K_{H_3O^+}$ reaches saturation, further increase in $[H_3O^+]$ would not affect the rate.

Whenever HX is a weak acid, the H_3O^+ concentration is expressed by $(K_{hdx}[acid][H_2O])^{1/2}$ from Eq. (5). If so, square root of the acid concentration should have to be plotted on the abcissa in Fig. 2. Although K_{hdx} of trichloroacetic acid is not known in THF, it is a strong acid in water with a pK_a value 0.635 at 25 °C. When the acid is extremely strong, $[H_3O^+]$ is equal to acid concentration in the presence of excess of water, and equal to water concentration in the presence of excessive acid. Figure 3 gives straight lines when the acid concentration is small as compared with water concentration, and the curves approach saturated values with increase in acid concentration. Such a saturation is observed, however, before the acid concentration overwhelms the water concentration, and fails to be seen in Fig. 2. Thus we tend to consider that the saturation may be due to saturation of $K_{H_3O^+}$. Trisacetylacetonatoaluminium(III) did not exhibit such a saturation presumably owing to the smaller $K_{H_3O^+}$ value. The fact that ordinary organic acids fail to give acid catalysis is presumably because their K_{acid} and K_{hdx} values are not big enough to bring about effective protonation upon the free end.

As seen in Eqs. (3), (4), and (6), k_2, k_3', and k_3 involve various factors. The pK_a values of Hacac and Hdbm are not known in THF, but they are *ca.* 11 and 13 respectively at 25 °C in water. The smaller k's for $[Al(dbm)_3]$ than for $[Al(acac)_3]$ are understood by considering that the stronger Lewis base dbm$^-$ gives much smaller k_{H_2O} and k_{H^+} values than acac$^-$ does, and the bigger K_{acid} and $K_{H_3O^+}$ values are overwhelmed. The greater ΔH^* of $[Al(dbm)_3]$ than $[Al(acac)_3]$ is also thus accounted for. Absence of k_1 path for $[Al(dbm)_3]$ is similarly interpreted, too. Further, the effective charge of aluminium ions in $[Al(dbm)_3]$ will be smaller owing to the coordination of more basic dbm$^-$ and the equilibrium constant K_S (coordination of solvent molecule on the vacant site) would be smaller.

Another characteristics in the present kinetic study is that increase in the concentration of ligand increases the exchange rate, although the extent is very small. Such an influence was also seen in the exchange between $[Co(acac)_3]$ and Hacac-^{14}C in toluene and anisole.[2] If Hdbm attacks the vacant coordination site of the intermediate as rate-determining step, increase in Hdbm concentration will increase the rate of exchange. However, the gradients of lines in Fig. 4 are very small, and the contribution of ligand concentration is appreciable only at a high concentration range. The k_2 values at the ligand concentration 0.05 M are very near to that at null ligand concentration, and was not included in the main kinetic formula. If Hdbm behaved as an acid and gave proton to the free end of the unidentate ligand in the intermediate, a similar kinetic result would be obtained. This is not probable, however, because a stronger acid, *m*-toluic acid, does not exhibit acid catalysis. Further, $[Al(acac)_3]$ failed to show such a tendency. If acid catalysis were operating, a stronger acid, Hacac, should give a bigger influence on a more labile $[Al(acac)_3]$. Hence the effect in Fig. 4 should be due to the nucleophilic attack of Hdbm upon the complex, probably in the intermediate state. The basicity of Hdbm must be bigger than Hacac even in the protonated state.

Thus all the differences in kinetics between $[Al(dbm)_3]$ and $[Al(acac)_3]$ are understood by taking the difference in basicity of the ligands into account. Our present results seem to support and reinforce the reaction mechanism postulated in Ref. 1, that the complex is in rapid equilibrium with an intermediate with one of the ligands as unidentate and break of the remaining Al–O bond is the rate-determining step.

We thank Nishina Memorial Foundation for financial support.

Catalysis of Manganese Salts in the Autoxidation of Cyclohexanone

Yoshio KAMIYA and Masayoshi KOTAKE

Department of Reaction Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo 113

(Received May 25, 1973)

The rate of oxidation of cyclohexanone catalyzed by manganese salt increases remarkably in the presence of acetic acid, and is about one hundred times as high as the limiting rate of oxidation $k_p^2(RH)^2/2k_t$. However, manganese concentration does not affect the rate of oxidation much in a wide range. The oxidation of cyclohexanone by manganic ion should be the rate determining step, since the rate of oxidation, which is of first order in cyclohexanone but independent of manganous ion, corresponds to the rate of oxygen absorption of cyclohexanone with the same manganese concentration. The oxidation of cyclohexanone by manganic ion seems to proceed through enol intermediates, since the rate of oxidation increases in the presence of alkali acetates. The rate equation including enolization step and the subsequent oxidation of enol intermediate with manganic ion agrees with the experimental results. A remarkable synergistic effect of metal salts was observed in a mixture of manganese and cobalt. The oxidation products were also analyzed and discussed.

Although the autoxidation of cyclohexanone is an important process for the production of adipic acid and has been studied by many workers,[1] the role of metal catalysts in the autoxidation reaction is still not clear. The oxidation of cyclohexanone by metal ions was studied by Rocek and Riehl,[2] Best *et al.*[3] and Littler.[4,5] It was found that oxidation by V(V), Co(III), Ce(IV), and Mn(III) proceeds through direct oxidation, but that by Hg(II), Mn(VII), Tl(III), and Br_2 through enol intermediate.

The metal-catalyzed autoxidation of cyclohexanone shows a complicated behavior. (1) The rate of oxidation in an acidic solvent is much higher than that in a neutral one. (2) Although manganese salt is not so effective catalyst in acetic acid solution as cobalt salt, it shows the highest catalytic activity in the oxidation of cyclohexanone. (3) When a metal catalyst is used as a decomposer of hydroperoxide, the rate of oxidation of hydrocarbons does not exceed the limiting rate $k_p^2(RH)^2/2k_t$,[6] but that of cyclohexanone catalyzed by cobalt and manganese in acetic acid far exceeds the value of $k_p^2(RH)^2/2k_t$, where k_p and k_t represent the propagation and termination rate constants, respectively.

In a previous paper,[7] it was shown that the rate-determining step of the cobalt-catalyzed autoxidation of cyclohexanone in acetic acid is the oxidation of cyclohexanone by cobaltic ion. We have studied the effect of manganese catalyst on the autoxidation of cyclohexanone, since catalysis by manganese salt greatly differs from that by cobalt salt.

Experimental

Cyclohexanone was fractionally distilled and kept in a brown glass bottle and in nitrogen atmosphere. Acetic acid was distilled in the presence of potassium permanganate and acetic anhydride.

Manganic Acetate.[8] A mixture of manganous acetate (303 g) and glacial acetic acid (4.4 kg) was boiled under reflux for 2 hr. Potassium permanganate (68.2 g) was then added, the mixture being stirred under reflux for 45 min and then allowed to cool while water (750 ml) was added dropwise. The crude $Mn(OAc)_3 \cdot 2H_2O$ was recrystallized from a mixture of glacial acetic acid and water.

Oxidation of Cyclohexanone by Manganic Acetate in Nitrogen Atmosphere. The reaction vessel, a *ca.* 60 ml flask with two necks, one at the top and the other at the side of the flask, was connected through a tygon tube to a vacuum line and a nitrogen reservoir. The solution was frozen with a dry ice-acetone solution and degassed repeatedly in the usual way, and the vessel was filled with nitrogen. After thermal equilibrium had been obtained, samples were withdrawn through the side neck at appropriate intervals under current of nitrogen. The volume of each sample was 5 ml. Determination of manganic acetate was carried out by potentiometric titration using ceric sulfate after adding an excess amount of ferrous ammonium sulfate.

Determination of Reaction Products. Cyclohexanone was oxidized under vigorous agitation in a three necked flask with oxygen inlet and outlet, and the oxidation products were analyzed by gas chromatography with a 3 m column of diethyleneglycol adipate after esterification with diazomethane. After cooling of outlet gas, carbon dioxide was absorbed by passing through an aqueous solution of sodium hydroxide and titrated.

The oxygen absorption apparatus has been described elsewhere.[6]

Results and Discussion

Rate of Oxidation of Cyclohexanone. The steady rate of oxidation of neat cyclohexanone catalyzed by manganese decanoate as a function of catalyst concentration is given in Fig. 1. The rate of oxidation is of the order 0.7—0.8 with respect to manganese concentration and exceeds a little the limiting rate of

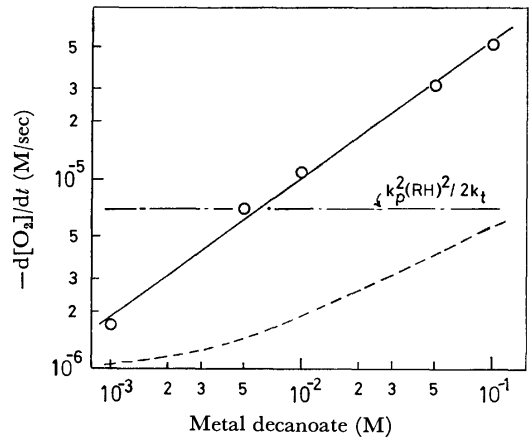

Fig. 1. The rate of oxidation of cyclohexanone as a function of manganese decanoate concentration at 60 °C. A broken line represents the rate of oxidation with cobalt decanoate

oxidation $k_p^2(RH)^2/2k_t$ 7×10^{-6} M/sec calculated from azobisisobutyronitrile initiated autoxidation of cyclohexanone. This shows that manganese decanoate is more effective than cobalt decanoate as an oxidation catalyst of neat cyclohexanone.

When manganese acetate was used as a catalyst in acetic acid solution, the rate of oxidation of cyclohexanone became extremely high. For example, it was 4×10^{-4} M/sec at manganese concentration of 0.02 M and 60 °C, and almost independent of catalyst concentration in contrast to the half order relation of cobalt acetate[7] (Fig. 2). A sudden decrease in the rate at manganese concentrations below 5×10^{-4} M suggests a change of the rate determining step and also a slow regeneration of manganic ion by the oxidation of manganous ion due to the peroxidic intermediates as peracids.

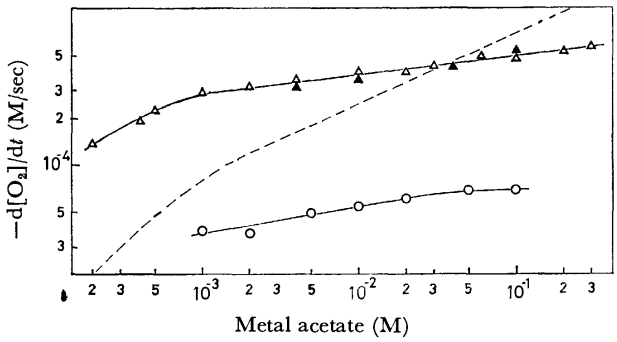

Fig. 2. The rate of oxidation of a 1: 1 mixture by volume of cyclohexanone and acetic acid as a function of metal acetate concentration.
△: manganous acetate at 60 °C, ▲: manganic acetate at 60 °C, ○: manganous acetate at 40 °C.
A broken line represents the rate of oxidation with cobalt acetate.

The rate of oxidation reached a steady state within a few minutes, the solution turning dark brown due to manganic ion. A portion of the solution in the steady state of oxidation was taken out and titrated potentiometrically to determine the concentration of manganic ion. Approximately 90% of the manganese ions was found to be manganic in the manganese concentration range 0.01—0.05 M.

The rate of oxidation catalyzed by pure manganic acetate is also shown in Fig. 2. There seems to be no difference between the catalysis by manganous and manganic acetates. This indicates that manganese ions rapidly reach a steady concentration in course of oxidation at manganese concentrations above 0.005 M.

The decomposition rate of hydroperoxide by manganese salt[6c] in acetic acid is usually slow as compared with that by cobalt. This corresponds to the fact that the rate of oxidation of tetralin,[5c] ethylbenzene,[9] and cumene[10] catalyzed by manganese acetate in acetic acid is much smaller than that catalyzed by cobalt acetate. In contrast, the decomposition of hydroperoxide by manganese salt does not seem to affect the rate of oxidation of cyclohexanone, since the actual rate of oxidation by manganese salt represents a similar value to that by cobalt salt, far exceeding the limiting rate.

The fact that the rate of oxidation exceeds the limiting rate of oxidation $k_p^2(RH)^2/2k_t$ by a factor of 100 indicates that the ordinary hydrogen abstraction step by peroxy radical plays only a minor role as explained by Walling,[11] since the chain length is nearly unity under the limiting rate conditions. If the rate of autoxidation $k_p(RH)(RO_2\cdot)$ increases one hundred times as fast as the limiting rate, the termination reaction should increase by a factor of ten thousands, and the oxidation should stop undoubtedly.

The important step of manganese-catalyzed autoxidation of cyclohexanone should be the oxidation of cyclohexanone due to manganic ion as in the case of cobalt acetate. However, the reaction mechanism by manganese catalyst seems to differ greatly from that by cobalt salt, since the rate of oxidation is almost independent of manganese concentration in a wide range of concentration above 0.001 M.

The rate of oxidation of cyclohexanone with manganese acetate was enhanced from 4.1×10^{-4} M/sec to 1.15×10^{-3}, 9.9×10^{-4}, and 8.2×10^{-4} M/sec in the presence of 0.5 M of lithium acetate, sodium acetate and potassium acetate, respectively. This effect seems to result from the enhancement of enolization rate of cyclohexanone. Lienhard and Wang[12] reported that sodium acetate and sodium pivalate increased the rate of enolization of cyclohexanone as acid and base. The effect of alkali acetate strongly supports the view that enol intermediate is involved in the rate-determining step of the oxidation of cyclohexanone catalyzed by manganese.

Oxidation of Cyclohexanone by Manganic Acetate in Nitrogen Atmosphere. Since the manganese ion in acetic acid solution during the course of oxidation is mostly manganic and radical formation by the manganese-catalyzed decomposition of hydroperoxide is not considered to be of significance, the oxidation of cyclohexanone by manganic ion seems to play an important role. The rate of Mn(III) reduction with Mn(III) of

9×10^{-3} M and cyclohexanone of 4.83 M in acetic acid at 40 °C in the absence of oxygen was 5.2×10^{-5} M/sec, which agrees with the value of 5.4×10^{-5} M/sec, the rate of oxygen absorption of cyclohexanone with manganese acetate 0.01 M at 40 °C. Agreement of the two rates strongly support the view that the rate-determining step is the oxidation of cyclohexanone by Mn(III), since the molar ratio of oxygen molecule absorbed by oxidized cyclohexanone should be 1.0—1.5 according to oxidation products.

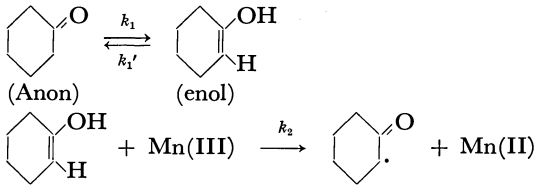
Oxidation of cyclohexanone with manganic acetate under nitrogen atmosphere was studied under various conditions (Figs. 3, 4, and 5). The rate of reduction of Mn(III) was of first order with respect to cyclohexanone (Fig. 3) and independent of manganous ion (Fig. 4) in contrast to the case of cobalt salt.[7] The reduction of Mn(III) increased slowly with the increase of its concentration (Fig. 5).

There are several reasons for the rate determining step in the manganese-catalyzed autoxidation of cyclohexanone being the enolization of cyclohexanone and not the electron transfer step.

Den Hartog and Kooyman[13] confirmed that the enolization step of acetophenone was rate determining in the manganese-catalyzed autoxidation of acetophenone. There was no significant difference between the rates of oxidation of cyclohexanone by cobaltic and manganic acetates at 0.01 M, although the rate of oxidation of toluene by cobaltic acetate[14] was much higher than the rate by manganic acetate.[8] The rate of oxidation of cyclohexanone by manganic acetate was independent of manganous ion concentration and increased in the presence of alkali acetates.

When the oxidation of cyclohexanone by Mn(III) proceeds through enol intermediates, the reaction scheme and the rate of equation can be expressed as follows.



$$-d[Mn(III)]/dt = k_1k_2[Mn(III)][Anon]/(k_1' + k_2[Mn(III)]) \quad (5)$$

$$[Anon]/(-d[Mn(III)]/dt) = (1/k_1) + k_1'/k_1k_2[Mn(III)] \quad (6)$$

A plot of $[Anon]/(-d[Mn(III)]/dt)$ against $1/[Mn(III)]$ should give a straight line with an intercept equal to $1/k_1$ and a slope of k_1'/k_1k_2. The results

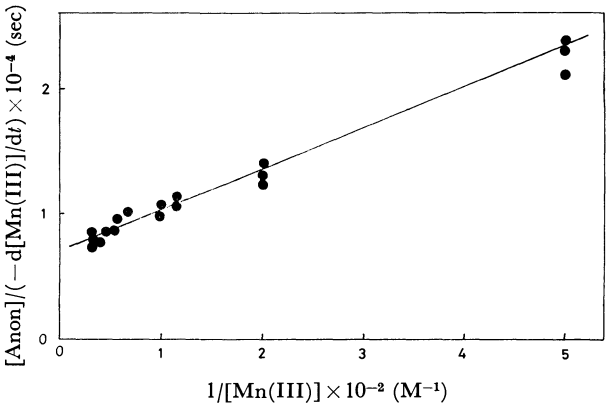


Fig. 6. [Anon]/(−d[Mn(III)]/dt) versus 1/[Mn(III)].

13) H. J. Den Hartog, E. C. Kooyman, *J. Catal.* **6**, 347 (1966).
14) K.Sakota, Y. Kamiya, and N. Ohta, *Can. J. Chem.*, **47**, 387 (1969).

obtained in several cyclohexanone-acetic acid mixtures are plotted in this manner in Fig. 6. A straight line through the experimental points is consistent with an intercept of 7×10^4 sec as required for the value of $1/k_1$. Scattering of points might be mainly due to experimental error, with possible effects of other reactions.

The satisfactory linear correlation in Fig. 6 supports the enolization mechanism.

Comparison of the Rate of Oxygen Absorption and the Rate of Reduction of Mn(III). From the value of k_1 (1.43×10^{-5} sec^{-1}), the limiting rate of Mn(III) reduction at 4.83 M cyclohexanone and 40 °C was calculated to be 6.9×10^{-5} M/sec.

The measured rate of oxygen absorption at 40 °C did not exceed the value of 6.8×10^{-5} M/sec (Fig. 2). Thus, the maximum rate of oxygen absorption can be predicted by Eq. (5). There is no significant difference between the rate of reduction of Mn(III) and that of oxygen absorption at manganese concentrations above 5×10^{-3} M, provided that the ratio of manganic to total manganese ions is kept 0.9 and the molar ratio of absorbed oxygen to reacted cyclohexanone 1—1.5.

The ratio of the rate of oxygen absorption to the rate of reduction of Mn(III) increases with decreasing manganese concentration and reaches 1.8 at 10^{-3} M manganese. This may be partly due to the participation of acylperoxy radical in the propagation step and also to a trace of oxygen remaining in the solution, since the regeneration of Mn(III) from the reaction of Mn(II) and peroxidic compounds would be affected even in the presence of 10^{-4} M of oxygen at manganese concentrations as low as 10^{-3} M.

Synergistic Effect of Metal Acetates. For the case in which one component is manganese acetate and the other a transition metal such as cobalt, the rate of oxidation was studied as a function of composition. A remarkable synergistic effect was observed in the mixture of manganese and cobalt as shown in Fig. 7. When the metal concentration is as low as 10^{-5} M, the synergistic effect was found to be more remarkable, since the rate of autoxidation by single component falls to values less than 10^{-5} M/sec.

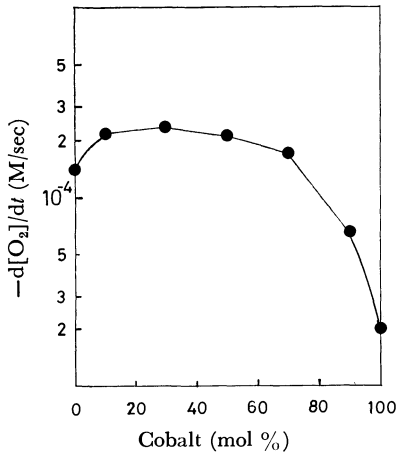

Fig. 7. The mixing effect of manganese with cobalt acetate at total concentration of 2×10^{-4}M on the oxidation of a 1:1 mixture by volume of cyclohexanone and acetic acid at 60 °C.

In the case of cobalt acetate, the rate of oxidation of cyclohexanone can be expressed as k[Co(III)]^2[Anon]/[Co(II)] and the rate of oxygen absorption catalyzed by cobalt acetate in acetic acid is of about half order in total cobalt concentration. On the other hand, the manganese-catalyzed autoxidation showed a small dependence on catalyst concentration. The marked decrease in the rate of oxidation at low manganese concentration can be attributed mostly to the slow regeneration of Mn(III) by the oxidation of Mn(II) with peracids, since the rate of decomposition of peracids with manganese acetate in acetic acid is much smaller than that with cobalt acetate.

Thus, if cobalt is mixed with manganese at low catalyst concentrations, cobalt would take over the role of peroxide decomposition and the resulting cobaltic ion would oxidize manganous ion to manganic. As a result, the rate of oxidation catalyzed by a mixture of cobalt and manganese would assume the theoretical value represented by Eq. (5).

A similar synergistic effect was observed in the mixture of nickel and manganese acetates. This can also be explained in the same manner.

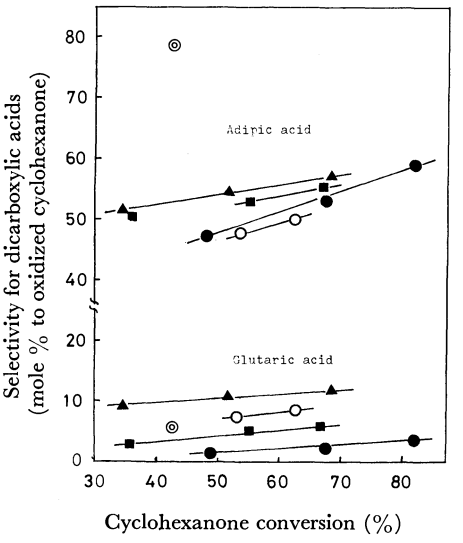

Fig. 8. The selectivities for adipic and glutaric acids in the oxidation of a 1:1 mixture by volume of cyclohexanone and acetic acid as a function of cyclohexanone conversion with 10^{-3}M metal acetates.
▲: Cobalt, ●: Manganese, ○: Cobalt/Manganese=1/1, ■: Manganese/Nickel 1/1, ◎: Manganese/Copper=1/1.

Oxidation Products. Selectivity to adipic and glutaric acids *versus* the conversion of cyclohexanone is given in Fig. 8. The selectivity for adipic acid increased gradually as the conversion increased and the highest value of 79% was obtained for all catalysts tested in the 1:1 mixture of manganese and copper. The reason why the yield of adipic acid by Mn–Cu catalyst is considerably high can be attributed to the retardation effect of Cu(II) on the coupling reaction of alkyl radicals, since Cu(II) is known to oxidize alkyl radicals[15] and the rate of oxidation of cyclo-

15) J. K. Kochi, A. Bemis, and C. L. Jenkins, *J. Amer. Chem. Soc.*, **90**, 4616 (1968).

hexanone catalyzed by 6.4×10^{-4} M Mn decreased from 9.2×10^{-5} to 5.2×10^{-5} M/sec after 50% of Mn was replaced by Cu.

Cobalt showed a higher yield of glutaric acid than the other catalysts. This may be due to its activity[16] in the decarboxylation reaction of adipic acid. The ratio of carbon dioxide to glutaric acid was 1—1.5, and almost independent of cyclohexanone conversion at conversion 40—70%. The selectivity for adipaldehyde was 6—8% in the case of manganese catalyst but only 1—2% in the presence of cobalt acetate. It seems reasonable that cobalt is more effective in the oxidation of intermediate aldehydes than manganese.

The oxidation products described above can not explain the carbon distribution satisfactorily except for the products obtained by Mn–Cu. The balance may be mostly polymerized products such as 2-cyclohexan-1-yl cyclohexanone[2] and other intermediate products[1d,2] such as dione and oxycyclohexanone.

Photochemical Reactions of Uranyl Ions with Organic Compounds. V. Effects of Temperature and Solvent on the Photooxidation of Alcohols

Shukichi SAKURABA, Soichi MIMURA, and Ryoka MATSUSHIMA*

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received July 19, 1972)

A comparative study of the photokinetic behaviors of aliphatic alcohols and related substrates was made for the photooxidation with uranyl ions. Ethylene glycol, glucose, sucrose and some other substrates showed abnormal results compared to a series of simple aliphatic alcohols: the photoredox quantum yields ϕ for the former substrates decreased with substrate concentration (at their higher concentrations) and temperature rise, in contrast to simple aliphatic alcohols. In aqueous acetone solution ϕ increased with the increase in acetone content, the reaction constant ρ^* being more negative than in aqueous solution. In 40% aqueous acetone solution the ϕ values for simple aliphatic alcohols varied in a complicated way with temperature. The abnormal results were interpreted in terms of the relative importance of physical quenching competing with the primary chemical process.

As regards the mechanism of the photooxidation of some aliphatic alcohols by uranyl ions, the initial stage was assumed to be the α-hydrogen abstraction (one-equivalent redox) *via* bimolecular collision of the excited uranyl ion with the substrates, followed by the two disproportionation reactions of the primary intermediates.[1,2]

However, in the course of the photokinetic investigations, we observed that some alcohols, such as glucose and benzyl alcohol, exhibited abnormal behaviors.

In the present paper the effects of temperature, substrate concentration and solvent on the photokinetics are discussed.

Experimental

Guaranteed reagents were used without purification. 0.02 M uranyl nitrate solution was prepared from a 0.1 M stock solution. The solutions (pH=1) were deaerated by the passage of oxygen-free nitrogen for 20—30 min per 5—15 ml, kept air-tight with liquid paraffin and then exposed to irradiation (mostly 405 and 436 nm) using a suitable combination of glass filters or an interference filter from a 100 or 500 W high pressure mercury lamp. The temperature was controlled with a thermostat.

Methods for actinometry and determination of the photoproducts were the same as those previously described.[1] Since the molar ratio of the products, aldehyde or ketone/uranium(IV), was unity regardless of the conditions,[1] only the formation of the uranium(IV) species was followed for the estimation of the photoredox quantum yield ϕ.

Results and Discussion

Effects of Temperature and Substrate Concentration. The plot of the reciprocal of the photoredox quantum yield $1/\phi$ as a function of the reciprocal of alcohol concentration gave a straight line for the photooxidation of simple aliphatic alcohols by uranyl ions in aqueous acidic media, in agreement with the empirical equation: $1/\phi=\alpha+\beta/[\text{alcohol}]$, where $\alpha=2$ at pH$\geqq$1[1] (Fig. 1). The relation seems to hold under some different conditions (temperature and solvent) for *n*-propyl alcohol (Fig. 1). The photoredox reaction of ethyl and three butyl alcohols with uranyl ions has been explained by a mechanism which involves one-equivalent redox reaction between the excited uranyl ions and the substrates *via* bimolecular collision, followed by thermal disproportionation reactions of the primary redox intermediates.[1] The fact that the photoredox quantum

yield increases with temperature (Fig. 2) might support the bimolecular collision mechanism.

In contrast, the plot $1/\phi$ *vs.* 1/[substrate] for ethylene glycol, glucose, and sucrose gave no straight line (Fig. 3). This implies that some depression of the photoredox reaction becomes significant with the increase in substrate concentration at higher concentrations (>0.1 M). The photoredox quantum yield decreases with temperature rise for thse substrates, whereas the reverse is the case for simple aliphatic alcohols (Fig. 2). Plots of log ϕ *vs.* $1/T$ for simple aliphatic alcohols are given in Fig. 4. Ethyl, isopropyl, *n*-butyl and isobutyl alcohols gave similar results. Plots for glucose and benzyl alcohol are given in Fig. 5. Qualitatively, the positive apparent activation energies for simple aliphatic

alcohols, 2—5 kcal/mol, might support a bimolecular collision mechanism, but not negative apparent activation energies for glucose and benzyl alcohol, −1.5 kcal/mol.

Solvent Effects. Change in the photoredox quantum yield with acetone content is given in Table 1. The increase in ϕ with the acetone content is partly attributable to the increase in the mean lifetime of uranyl fluorescence. The Stern-Volmer plots gave straight lines for most aliphatic alcohols in 40% aqueous acetone as well as in aqueous medium.

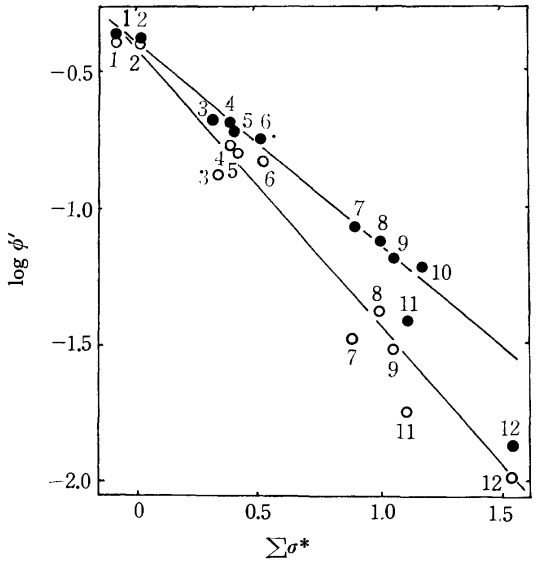

Fig. 6. Plot of log ϕ' *vs.* $\sum\sigma^*$ at pH 1, 20 °C. $\sum\sigma^*=\sigma(R_1)+\sigma^*(R_2)$; $\sigma^*(R_1)$ and $\sigma^*(R_2)$ are Taft σ^*-values of the substituents R_1 and R_2 in R_1R_2CHOH. ϕ' is the photoredox quantum yield divided by the number of the α-hydrogen atoms of each alcohol. 1: *sec*-butyl, 2: isopropyl, 3: isobutyl, 4: *n*-butyl, 5: *n*-propyl, 6: ethyl, 7: 3-chloro-*n*-propyl, 8: methyl, 9: 2-hydroxyethyl, 10: 2-propenyl, 11: benzyl, 12: 2-chloroethyl alcohols; 0.1 M in each alcohol.
○: 40% aqueous acetone, ●: aqueous medium.

Figure 6 shows the polar substituent effect of alcohols on the photoredox quantum yield in 40% aqueous acetone as compared with that in aqueous medium. The ρ*-values under some different conditions are in the range $-1.4<\rho^*<-0.6$, an indication of a free radical reaction.[3)] The ρ*-value remains unchanged with the changes in temperature and alcohol concentration, but it changes with the change in the medium

Table 2. Effects of temperature, solvent and alcohol concentration on the ρ*-value

Temperature/°C	Solvent	[Alcohol]/M[a)]	−ρ*
4	water	0.04	0.80
20	water	0.10	0.80
35	water	0.04	0.80
20	40 % acetone	0.06	0.95

a) Alcohols are the same as in Fig. 6.

(Table 2). This might be attributed to the effect of solvent polarity.

The Stern-Volmer formula, the linearity of the plot of log ϕ' *vs.* $\sum\sigma^*$, and the range of the ρ*-value, indicate that the primary process in 40% aqueous acetone is similar to that in aqueous medium, *i.e.*, α-hydrogen abstraction.[1,2)]

On the other hand, plot 4 in Fig. 2 shows a straight line with the intercept of 2 in 40% aqueous acetone medium. The intercept of 2 suggests that the secondary process in this medium is similar to that in aqueous medium, *i.e.*, disproportionation reactions of the primary redox intermediates.[1)]

Thus, it is very likely that the photoredox reaction in aqueous acetone proceeds through a similar mechanism to that in aqueous medium with different efficiency.

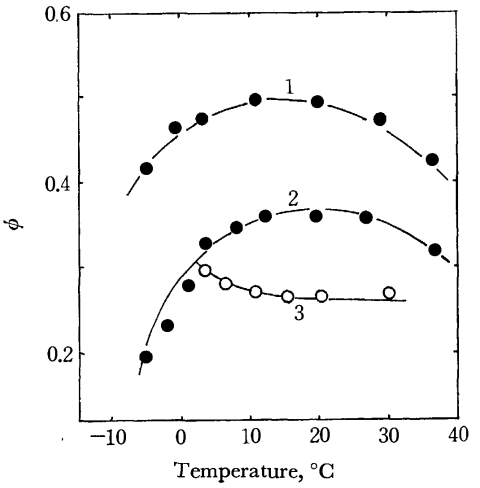

Fig. 7. Temperature dependence of ϕ in 40% aqueous acetone at pH 1. 1: *n*-butyl alcohol, 2: ethyl alcohol, 3: glucose, 0.1 M in each.

The temperature dependence of the photoredox quantum yield in 40% aqueous acetone is shown in Fig. 7. Ethyl and butyl alcohols show abnormal temperature effect in this medium compared to aqueous medium (Fig. 4). Glucose shows a different dependence.

Discussion on the Abnormal Results. Some authors[4,5)] have postulated a ground state complex as the photosensitive species for the photooxidation of sugars and alcohols by uranyl ions. Multidentate alcohols (ethylene glycol, glucose, and sucrose) would have stronger coor-

dination power than unidentate alcohols.[6] The negative apparent activation energies for the multidentate alcohols (Figs. 3 and 5) might be interpreted in terms of the formation of a ground state complex as the photosensitive species in contrast to the positive ones for the unidentate alcohols (Figs. 2 and 4).

If complex formation takes place between the substrates and the uranyl ions, changes in the absorption and/or the fluorescence spectra of the solutions might be expected. The Stern-Volmer plots for the quenching of the uranyl fluorescence by these substrates should give lines concave upward (as is the case for lactic acid, Fig. 8), since the quenching efficiency should increase because of the additional static (intracomplex) quenching process, which is more efficient than a bimolecular collision process.[7] However, the absorption spectra (visible region) and shapes of the fluorescence spectra of uranyl ions in aqueous solution at pH 1 were entirely unchanged by the addition of these substrates in the range of uranyl concentration 0.001—0.1 M. This is in contrast to the fact that even weak complexes with many carboxylic acids show significant spectral changes,[8] though the lack of spectral changes does not always exclude complex formation. The Stern-Volmer plot for glucose gave a line concave downward (the reverse of expectation) as shown in Fig. 8. It seems difficult to explain the decrease in ϕ at higher substrate concentrations (Fig. 3) in terms of complex formation, since increase in substrate concentration should accelerate the formation. Thus, the formation of a ground state complex as the photosensitive species is unlikely and negligible at most.

The relative importance of physical quenching which competes with the primary chemical process might be a possible interpretation of our results. It should be noted that the quenching constants for the multidentate alcohols and phenyl-substituted alcohols are large compared to their photoredox quantum yields.[9] This implies the important role of physical quenching for these substrates, while for simple aliphatic alcohols (physical quenching is small), temperature rise is qualitatively equivalent to the increase in substrate concentration in the sense that the number of effective collisions for the primary chemical act is roughly proportional to substrate concentration and absolute temperature. However, this is not the case for substrates with significant physical quenching efficiencies or for even simple aliphatic alcohols at higher temperature in more complicated media where solute-solvent interaction becomes more sensitive to temperature change. The abnormal temperature dependence of ethyl and butyl alcohols in 40% aqueous acetone (Fig. 7) may be assumed to be the latter case.

For complicated substrates or those for which physical quenching is dominant, effective collision for the chemical process will be restricted, hence the greater part of the primary interaction is apt to fall into physical quenching, giving rise to large quenching constants compared to their photoredox quantum yields. For these substrates the increase in temperature will decrease the viscosity of solutions so as to increase the number of collisions between the reactants, but it will depress the efficient abstraction of α-hydrogen because of the increased steric hindrance (thermal rotations of the bulky groups) of the substrate molecules. It is probable that the increment of the primary chemical act (α-hydrogen abstraction) due to the decreased viscosity (or increased number of collisions) is small compared to its decrement due to the increased physical quenching (steric hindrance). The observed negative activation energies for these substrates may be interpreted as the superposition of these effects.

The decrease in ϕ and the deviation of the Stern-Volmer plot at higher concentrations of the multidentate alcohols (Figs. 3 and 8) may be partly due to the increase in the viscosity which depresses the bimolecular collision between the reactants. However, some other significant effects must be operative, since the decrease in ϕ and the deviation of the Stern-Volmer plot at higher concentrations of the multidentate alcohols are far beyond the effect of increased viscosity.

The stronger affinities of the multidentate alcohols to uranyl ions will accelerate the reverse recombination reactions of the primary redox intermediates, and the higher viscosity of these solutions will depress the secondary bimolecular process (the disproportionation processes of the primary intermediates): both lead to additional increase in the physical quenching constants.

The authors wish to thank Miss S. Yamamura for her assistance.

Kinetics of the Oxidation of Ascorbic Acid by the Copper(II) Ion in an Acetate Buffer Solution

Katumitu HAYAKAWA, Shoko MINAMI, and Sumio NAKAMURA

Department of Chemistry, Faculty of Science, Kagoshima University, Kamoike-cho, Kagoshima 890

(Received October 7, 1972)

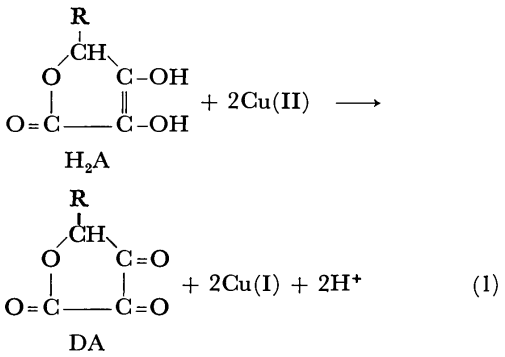
The kinetics of the oxidation of ascorbic acid by the copper(II) ion has been studied spectrophotometrically by a stopped-flow technique. At pH 4—6, the initial rate of the decrease in the monohydroascorbate anion is of the second-order with respect to the total concentration of the copper(II) ion and of the first-order with respect to the concentrations of the monovalent and divalent ions of ascorbic acid:

$$-(\mathrm{d}[HA^-]/\mathrm{d}t)_{t=0} = k_1[Cu(II)]_T^2[HA^-] + k_2[Cu(II)]_T^2[A^{2-}]$$

where HA^- and A^{2-} are the monovalent and divalent ions of ascorbic acid respectively. k_1, k_2, and the activation parameters are obtained as follows: $k_1 = 3.1 \times 10^4$, $k_2 = 6.1 \times 10^{10}$ M^{-2} s^{-1}, $\Delta H^{\neq} = 17$ kcal/mol, $\Delta S^{\neq} = 8.3$ cal/deg mol, and $\Delta G^{\neq} = 15$ kcal/mol. The EPR signal from the ascorbate radical is not observed in the kinetic run by either a flow technique or a quenching technique. Some discussions of the mechanism of the reaction are given.

It is known that the oxidation of ascorbic acid, H_2A, to dehydroascorbic acid, DA, by molecular oxygen is catalyzed with a remarkable activity by the copper(II) ion. Many kinetic studies of the reaction have been made.[1-7] However, the rate of the reaction depends complicatedly on the pH, the catalyst, the oxygen pressure, the buffer, *etc.* and so the rate equation has not been determined.

The present study was undertaken to obtain some information on the kinetics of the reaction between ascorbic acid and the copper(II) ion in the absence of oxygen as a fundamental study of the copper(II) ion-catalyzed autoxidation of ascorbic acid. The electron paramagnetic resonance (EPR) spectra were measured in order to obtain some information on the mechanism of the reaction. The rates were measured in an acetate buffer solution. The stoichiometry of the reaction is as follows:



(1)

Experimental

Reagents. The ascorbic acid, copper(II) sulfate, copper(II) acetate, acetic acid, and sodium acetate were obtained commercially (all GR). The copper(II) sulfate and copper(II) acetate were purified by recrystallization. The other materials were used without further purification. The water used was distilled and bubbled by nitrogen gas for 30 min before the preparation of the reactant solutions. The acetate buffer solution, which had been prepared from 0.1 M acetic acid and 0.1 M sodium acetate, was used between pH 4—6. The ascorbic acid solution was freshly prepared for every kinetic run.

Kinetic Measurements. The absorbance maximum of ascorbic acid is 265 nm in a neutral solution and 245 nm in an acidic solution for the monohydroascorbate anion, HA^-, and ascorbic acid, H_2A, respectively. At pH 4—6, the monohydroascorbate anion is the predominant species present in solution. In the rate study, the decrease in the absorbance was followed at 265 nm by a stopped-flow apparatus constructed in our laboratory, using a Shimadzu SV 50 spectrophotometer and a 5 mm quartz cell. The acetate buffer and the 1 mM $CuSO_4$ solution do not interfere with the absorbance at 265 nm. The initial rate method was used for the analysis of the rate in order to neglect the complexity resulting from the decrease in the reactants and the increase of products during a kinetic run. Nitrogen gas was bubbled through the reactant solutions for 30 min before each kinetic run and during each kinetic run in order to exclude the oxygen. The pH was measured using a Hitachi-Horiba F-5 pH meter. The formation of precipitates by the hydrolysis of the copper(II) ion and copper(I) oxide produced interfered with the kinetic measurements above pH 6.

EPR Measurements. To obtain the EPR signal from the kinetic run, the continuous-flow technique was used with various flow rates.[8] Also, to obtain the EPR signals from the solid phase solutions containing 0.05 M $CuSO_4$ and 0.13 M ascorbic acid in 0.1 M NaOH aqueous solutions (pH *ca.* 5) were rapidly injected into liquid nitrogen and the mixing solutions were quickly quenched after the mixing.[9] The EPR spectra were measured for the solid sample at the temperature of liquid nitrogen. The EPR spectra were recorded using an X-band spectrometer with a 455 kHz field modulation constructed by the Professor Kuwata's Laboratory in Osaka University.

Results and Discussion

The plot of the absorbance at 265 nm, D_{265}, *versus* the concentration of HA^-, which was calculated using the equilibrium constant ($pK_1=4.12$) for $H_2A \rightleftarrows HA^- + H^+$, is given in Fig. 1 in the absence of copper(II). As a straight line passing through the original point is obtained, it may be concluded that the absorbance at 265 nm is based on HA^- under the present experimental conditions; this is consistent with the report by Ogata *et al.*[10] The molar extinction coefficient of HA^- obtained at 265 nm, ε_{HA}, is $(1.62\pm0.02)\times10^4$ $M^{-1}cm^{-1}$ at 20 °C. The spectra of 0.2 mM $CuSO_4$ and the buffer solution and a kinetic run at pH *ca.* 5 are given in Fig. 2. It is found that the absorbance of $CuSO_4$ and the buffer solution do not interfere with the absorbances of HA^- at 265 nm. The absorption bands of the copper(I) compound and dehydroascorbic acid produced by the reaction are absent between 240 to 350 nm. At pH 6.5, the formation of the precipitate of copper (I) oxide[11] interfere with the measurement of the spectra. The copper(II) ion is present as the acetatocopper(II) complex ion in this buffer solution.

In the presence of the copper(II) ion, the formation

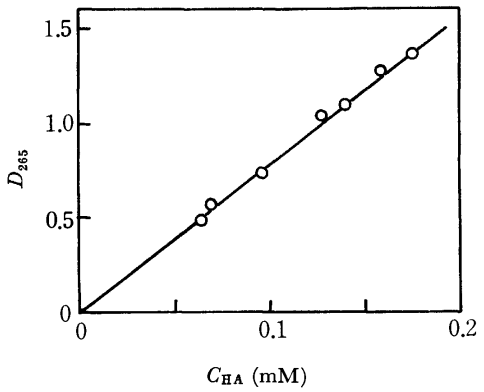

Fig. 1. The plot of the absorbance at 265 nm *versus* the concentration of monohydroascorbate ion; the total concentration of ascorbic acid: 0.08—0.2 mM.

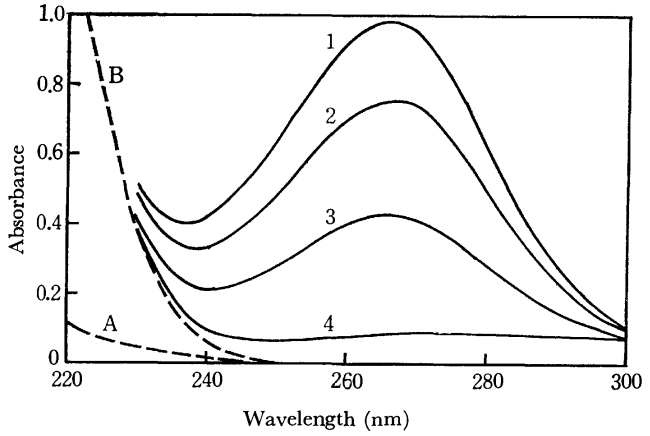

Fig. 2. The absorption spectra of 0.2 mM $CuSO_4$ aqueous solution (broken line A), 0.1 M acetate buffer (broken line B) and kinetic run at pH *ca.* 5 (solid lines; time 1<2<3<4)

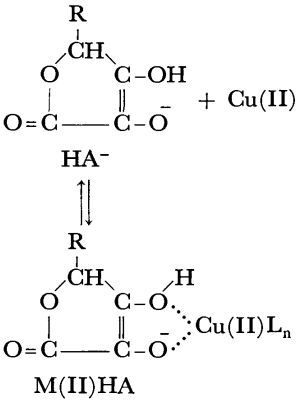
of the monohydroascorbatocopper(II) complex ion, M(II)HA, has been reported by studies of the copper-(II) ion-catalyzed autoxidation of ascorbic acid[1,12] and by spectroscopic studies.[10]



(2)

where L is the other ligand. The λ_{max} of the complex is reported to shift to a shorter wavelength than that of HA^-,[10] but the molar extinction coefficient of the complex at 265 nm is not given. The fact that the absorbance, D_{265}, after a mixing of the reactants is equal to a half of the absorbance before mixing suggests that the concentration of the complex, C_{MHA}, is small compared with that of HA^- and/or that the molar extinction coeffieient of M(II)HA is nearly equal to that of HA^-. From Equilibrium (2), $C_{MHA}=K_{MHA}C_MC_{HA}$, where K_{MHA} is the formation constant of the complex. As C_M is *ca.* 0.1 mM and K_{MHA} is *ca.* 40 M^{-1},[12] it is found that C_{MHA} is very small compared with C_{HA} under the present experimental conditions. Therefore, the decrease in D_{265} corresponds to that of HA^-.

Table 1. Apparent first-order rate constant k'
Temperature 30 °C, $[H_2A]_0$ $(0.73-2.53)\times10^{-4}$ M

$CuSO_4$ ($\times10^4$M)	k' (sec^{-1}) pH=4.80	pH=4.96	pH=5.25	pH=5.50
4.81	170±2	204±2	345±4	457±5
4.01	128±2	161±5	262±3	335±5
3.21	95±1	102±1	185±3	241±2
2.40	59±3	65±4	147±1	168±3
1.60	47±2	46±2	96±7	113±4

The initial rate, $V_0(=-(dD/dt)_{t=0})$, is directly proportional to the initial concentration of ascorbic acid, C_A^0. It is found that this reaction is a first-order reaction with respect to C_A^0. The apparent first-order rate constants, k', are given in Table 1. The apparent first-order rate constant is directly proportional to the square of the initial concentration of the copper(II) ion, C_M^0. It is found that the reaction is a second-order reaction with respect to C_M^0. Therefore, the rate equation is as follows:

$$V_0 = C_A^0(k''C_M^{0^2}+a) \quad (3)$$

where it is considered that the second term is a term resulting from the effect of a very small quantity of oxygen dissolved in the solution. k'' and a are given in Table 2.

TABLE 2. RATE CONSTANT k'' AND a IN EQUATION (3) AT 30 °C

pH	k'' ($\times 10^{-8}$ $sec^{-1}M^{-2}$)	a (sec^{-1})
4.80	61±1	29±4
4.96	81±3	23±4
5.25	119±3	69±4
5.50	166±1	71±1

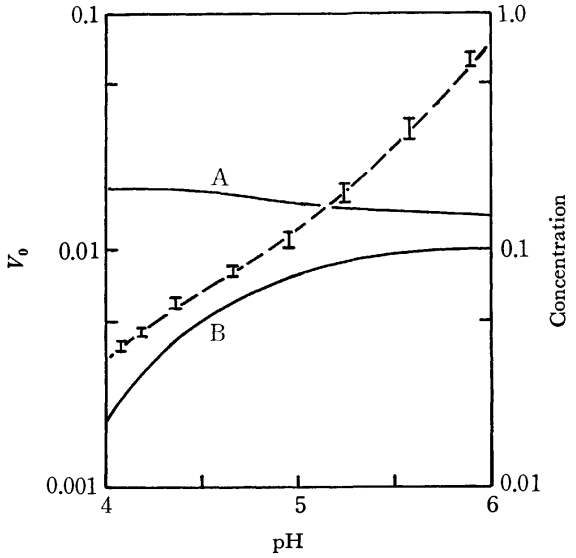

Fig. 3. Dependence of the initial rate at 0.37 mM Cu(II) ion and 0.11 mM ascorbic acid on pH (I) and the dependences of the concentrations of mono- and bis-acetatocopper(II) complex ion on pH (solid line A and B respectively). The broken line is calculated from the next equation:
$V_0=7.5\times10^{-3}/(1+1.3\times10^4C_H)+6.8\times10^{-8}/C_H(1+1.3\times10^4C_H)$.

The logarithm plot of V_0 *versus* the concentration of the hydrogen ion, C_H, is given in Fig. 3 at 0.11 mM H_2A and 0.25 mM Cu(II). It is considered that the dependence of the rate on pH is primarily due to the difference in reactivity between the undissociated form and the dissociated forms of ascorbic acid and, secondary, to the difference in reactivity between the copper(II) ion and the acetatocopper(II) complex ion. According to Weissberger *et al.*, the apparent first-order rate constants of the copper(II)-catalyzed autoxidation of ascorbic acid obtained in phosphate, acetate, and carbonate buffer solutions depend on the pH with a smooth curve.[2] This suggests that the second effect is small. Figure 3 shows that the dependence of the rate on the pH is not consistent with the dependence of the concentrations of the acetatocopper(II) complex ions (solid line), which are calculated using the formation constants of the mono- and bis-acetatocopper(II) complex ions ($K_1=251$ M^{-1} and $K_2=7.94$ M^{-1} respectively[13]). From the plot of $1/V_0$ *versus* C_H in Fig. 4, the next relations are obtained:

$$V_0 = k_1''/(1+bC_H) \quad (pH\leq5) \quad (4a)$$

$$V_0 = k_2''/C_H \quad (pH>5) \quad (4b)$$

13) L. G. Sillén and A. E. Martell, "Stability Constants of Metal-ion Complexes," Chemical Society, London (1964), p. 365.

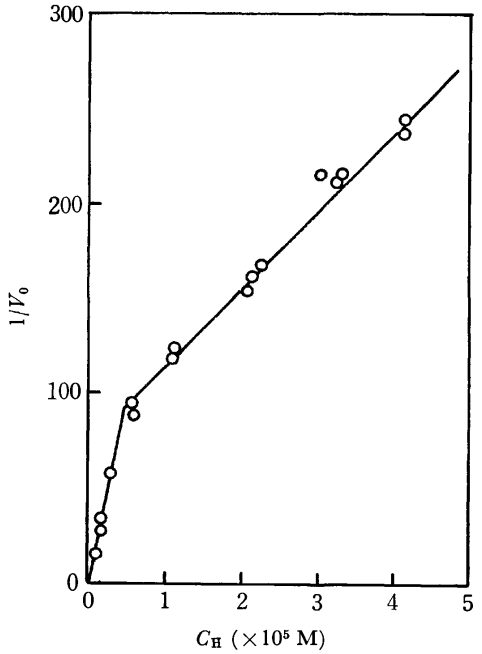

Fig. 4. Dependence of the reciprocal of the initial rate on the concentration of hydrogen ion.

In analogy with the autoxidation of ascorbic acid,[14] it is considered that both the monovalent and divalent ions of ascorbic acid are able to participate in the present reaction. From the dissociation constants of ascorbic acid ($pK_1=4.04$ for $H_2A\rightleftarrows H^+ + HA^-$ and $pK_2=11.34$ for $HA^-\rightleftarrows H^+ + A^{2-}$ at 25 °C), $C_{HA}=C_A^0/(1+K_{-1}C_H)$ and $C_A=C_A^0/K_{-2}C_H(1+K_{-1}C_H)$ at pH 4—6, where $K_{-1}=1/K_1$, $K_{-2}=1/K_2$ and C_{HA} and C_A are the concentrations of HA^- and A^{2-} respectively. Therefore,

$$V_0 = k_1'C_A^0/(1+K_{-1}C_H) + k_2'C_A^0/K_{-2}C_H(1+K_{-1}C_H) \quad (5)$$

Substituting the values of $k_1'C_A^0$, $k_2'C_A^0/K_{-2}$, and K_{-1} (7.5×10^{-3}, 6.8×10^{-8}, and 1.3×10^4 respectively, which are obtained using a curve-fitting method[15]) in Eq. (5), the broken line in Fig. 3 is obtained. The curve is very consistent with the experimental data. Therefore, the experimental rate equation is as follows:

$$V_0/\varepsilon_{HA} = k_1C_M{}^{0^2}C_A^0/(1+bC_H) + k_2C_M{}^{0^2}C_A^0/C_H(1+bC_H) \quad (6)$$

where $k_1=3.1\times10^4$ M^{-2} s^{-1}, $k_2=0.28$ M^{-1} s^{-1}, and $b=1.3\times10^4$ M^{-1}.

In the oxidation of H_2A by the peroxidase and in the autoxidation of H_2A at pH 6.6—9.6, the free radical from H_2A was detected by EPR measurements.[8,16,17] The EPR spectra of kinetic runs containing 0.05 M $CuSO_4$ and 0.13 M H_2A in a 0.1 M NaOH aqueous solution (pH *ca.* 5) were measured using a continuous-flow technique and the quenching technique. The blue solution became brown quickly after mixing. The EPR signal from the copper(II) ion is observed, but that from the ascorbate radical is not observed under

14) A. Weissberger, J. E. LuValle and D. S. Thomas, Jr., *J. Amer. Chem. Soc.*, **65**, 1934 (1943).

15) L. G. Sillén, *Acta Chem. Scand.*, **10**, 186 (1956); D. Dyrssen and L. G. Sillén, *ibid.*, **7**, 663 (1953).

16) I. Yamazaki and L. Piette, *Biochim. Biophys. Acta*, **50**, 62 (1961).

17) C. Lagercrantz, *Acta Chem. Scand.*, **18**, 562 (1964).

the condition of a varying flow rate. It is found by the stopped-flow technique that the EPR signal of the copper (II) ion from the brown solution decreases with the time because of the formation of the copper(I) compound, but the EPR signal from the ascorbate radical is not observed.

The above facts and discussions suggest the following mechanism for the oxidation of ascorbic acid by the copper(II) ion at pH 4—6, C_A^0 *ca.* 0.1 mM, C_M^0 *ca.* 0.1 mM, and 30 °C:

$$H_2A \overset{K_1}{\rightleftharpoons} H^+ + HA^- \quad (7)$$

$$HA^- \overset{K_2}{\rightleftharpoons} H^+ + A^{2-} \quad (8)$$

$$HA^- + Cu(II) \overset{K_9}{\rightleftharpoons} Cu(II)HA \quad (9)$$

$$A^{2-} + Cu(II) \overset{K_{10}}{\rightleftharpoons} Cu(II)A \quad (10)$$

$$Cu(II)HA + Cu(II) \xrightarrow{k_{11}} DA + 2Cu(I) + H^+ \quad (11)$$

$$Cu(II)A + Cu(II) \xrightarrow{k_{12}} DA + 2Cu(I) \quad (12)$$

Assuming that Reactions (11) and (12) are the rate-determining steps and applying the preliminary equilibrium treatment to Reactions (7), (8), (9) and (10), the following expression is obtained:

$$V_0/\varepsilon_{HA} = k_{11}K_9C_M{}^{0^2}C_A{}^0/(1+K_{-1}C_H) + k_{12}K_{10}C_M{}^{0^2}C_A{}^0/K_{-2}C_H(1+K_{-1}C_H) \quad (13)$$

where the next approximations are used: $C_M \gg C_{MHA}$, $C_M \gg C_{MA}$, $C_A \ll C_{HA}$, and $C_A \ll C_A{}^0$. $k_{11}K_9 = 3.1 \times 10^4$ $M^{-2}\,s^{-1}$, $k_{12}K_{10} = 6.1 \times 10^{10}\,M^{-2}\,s^{-1}$ (when $K_{-2} = 2.2 \times 10^{11}\,M^{-1}$ [12]) and $K_{-1} = 1.3 \times 10^4\,M^{-1}$ are also obtained. According to Khan *et al.*, $K_{-1} = 1.1 \times 10^4\,M^{-1}$ at 25 °C.[12] Before the rate-determining steps, the Cu(II)HA⇄Cu(I)HA· and Cu(II)A⇄Cu(I)A· equilibria are considered, but no evidence of the presence of a radical was obtained.

Table 3. Effect of temperature and activation parameters

pH 4.95, $[CuSO_4]_0$ 3.01×10^{-4} M, $[H_2A]_0$ $(0.6—2.5) \times 10^{-4}$ M

Temperature (°C)	k' (sec^{-1})
24.5	70±3
32	137±3
38	281±4
42	360±6

$\Delta H^* = 17$ kcal, $\Delta S^* = 8.3$ cal/deg, $\Delta G^* = 15$ kcal

The dependence of k' on the temperature is given in Table 3. From the Arrhenius plot based on the theory of the transition state, the activation parameters of the present reaction were obtained as follows: $\Delta H^* = 17$ kcal/mol, $\Delta S^* = 8.3$ cal deg^{-1} mol^{-1} and $\Delta G^* = 15$ kcal/mol. These values are comparable with those in the copper(II)-catalyzed autoxidation of H_2A ($\Delta H^* = 15.5$ kcal/mol, $\Delta S^* = 14$ cal deg^{-1} mol^{-1} and $\Delta G^* = 11.3$ kcal/mol[12]).

The authors wish to thank Professor Keiji Kuwata, Department of Chemistry, Osaka University, for kindly putting EPR spectrometer at his disposal and for his valuable advice.

Catalytic Function of Metal Chelates in the Hydration of 2-Pyridinecarbonitrile

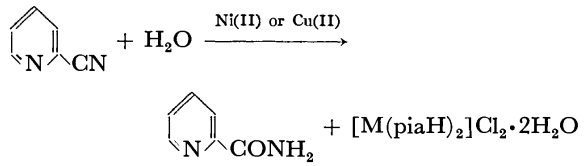
Ken-ichi WATANABE, Shigeo KOMIYA, and Shinnichiro SUZUKI*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received November 1, 1972)

The catalytic effects of various transition metal complexes on the hydration of 2-pyridinecarbonitrile have been investigated. In these homogeneous catalytic reactions, free 2-pyridinecarboxamide was obtained as the sole reaction product. The transition metal species of the complexes used were Cu(II), Ni(II), Co(II), Co(III), and Pt(IV), while the ligands were ethylenediamine, bipyridine, glycine ion, and 2-pyridinecarboxamide. The complexes of Cu(II), Ni(II), and Co(II) were all catalytically active for the hydration, but those of Co(III) and Pt(IV) were inactive. No reaction occurred with 3- and 4-pyridinecarbonitriles under the same reaction conditions. The effect of the pH was remarkable. The active complex catalysts were classified into three types.

It has been reported[1,2] that 2-pyridinecarbonitrile is hydrated to afford the metal chelate of 2-pyridinecarboxamide by the catalytic action of transition metal ions such as Ni(II) or Cu(II). No hydration occurred with 2-pyridinecarbonitrile in a neutral solution without the metal ions. In this catalytic reaction, however, when an excess of 2-pyridinecarbonitrile was employed, free 2-pyridinecarboxamide was obtained together with its metal chelate, and the yield of the free amide increased with the reaction time.



M: Metal ion
piaH: 2-pyridinecarboxamide

It has been proved[1] that the Ni(II) or Cu(II) chelate of 2-pyridinecarboxamide also shows catalytic activity for the hydration of 2-pyridinecarbonitrile.

With this view, we have taken up an idea that metal chelates other than Ni(II) and Cu(II) chelates of 2-pyridinecarboxamide may also act as catalysts for this hydration; we have found that some chelates have enough catalytic activities. A brief note has been already reported.[3]

In this paper, we will report in detail on our studies of the catalytic hydration of 2-pyridinecarbonitrile with various kinds of metal chelates. The relation between the nature and the catalytic activity of the complex catalysts will be discussed.

The meal species of the complexes used were Cu(II), Ni(II), Co(II), Co(III), and Pt(IV), and the ligands were ethylenediamine(en), 2,2′-bipyridine(bipy), glycine ion(gly), and 2-pyridinecarboxamide(piaH). These metal complex catalysts are summarized in Table 1. To make a comparison, aquo metal ions were also used as catalysts. It is characteristic that no hydrolysis occurred; that is, no ammonia was generated in these chelate-catalyzed reactions. The only product was 2-pyridinecarboxamide, and the complex catalysts were recovered without any change in all except a few cases.

TABLE 1. HYDRATION OF 2-PYRIDINECARBONITRILE WITH METAL CHELATES

Results and Discussion

Generally, an aqueous solution of 2-pyridinecarbonitrile containing a complex catalyst was kept at 60 °C, and a definite quantity of the reaction mixture was sampled every hour. The samples were submitted to an ion-exchange column (Dowex 50×2, H-form) and developed with water. The eluate was a solution of unreacted pure 2-pyridinecarbonitrile, which was separated completely from the reaction mixture. The decrease in the amount of the starting material was followed spectrophotometrically at 272 nm, and the yield of the reaction product, 2-pyridinecarboxamide, was calculated.

In other experiments, aqueous reaction mixture con-

taining 2-pyridinecarbonitrile and catalyst were refluxed and then concentrated to small amounts in order to be extracted with ether. From the ethereal solution, only 2-pyridinecarboxamide was obtained in a high yield. The metal complex catalyst was recovered from the water layer.

The labile complexes of Cu(II), Ni(II), and Co(II) were catalytically active. On the other hand, the inert Co(III) and Pt(IV) complexes were inactive.

The Effect of pH on the Hydration of 2-Pyridinecarbonitrile. The effect of hydroxide ions on the hydration was preliminarily examined without catalysts. The reactions were caused to proceed at 60 °C for 5 hr in the pH range of 2—11, and the reactivity of 2-pyridinecarbonitrile was examined spectrophotometrically as has been described above. No reaction occurred in the 2.5—9 pH range, but it proceeded rapidly above pH 10.

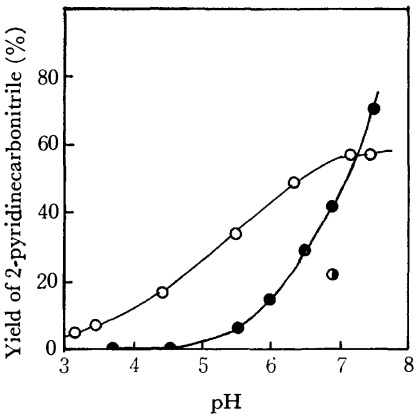

Fig. 1. Effect of pH on the hydration of 2-pyridinecarbonitrile with catalysts.
2-pyridinecarbonitrile: 0.0475 M, metal chelate: 0.00578 M, temp. 60 °C, time 5 hr.
○ $[Cu(piaH)_2]Cl_2 \cdot 2H_2O$, ● $[Ni(piaH)_2]Cl_2 \cdot 2H_2O$,
◑ $[Co(piaH)_2]Cl_2 \cdot 2H_2O$.
In our previous paper,[3] pH 6.0 of $[Ni(piaH)_2]Cl_2 \cdot 2H_2O$ (Fig. 1.) should be corrected to pH 6.5.

All the reactions with the complex catalysts proceeded in the 6—8 pH range. The pH dependence of these chelate-catalyzed reactions are remarkable; *e.g.*, the reactivity of 2-pyridinecarbonitrile was very low in the 9—10 pH range without catalysts, but the reaction with $[Ni(en)_3]Cl_2 \cdot 2H_2O$ was extremely fast in this pH range and the yield of 2-pyridinecarboxamide was about 75% after a 5 hr reaction. On the other hand, the yield decreased to 14% at pH 8 in the same reaction (Table 1). In order to investigate the effect of the pH in detail, solutions of 2-pyridinecarbonitrile and $[Ni(piaH)_2]Cl_2 \cdot 2H_2O$ or $[Cu(piaH)_2]Cl_2 \cdot 2H_2O$ were kept at 60 °C for 5 hr in the 3—7.5 pH range and the reactivities were examined. As is shown in Fig. 1, the reactivity becomes higher with a rise in the pH. Especially, for the nickel(II) complex, no reaction occurred below pH 4.5. The nickel(II) ion showed no catalytic activity at pH 3.9. 2-Pyridinecarbonitrile may not coordinate to the Ni(II) ion below pH 4.5. A solution of 2-pyridinecarbonitrile and nickel(II) chloride (1 : 1 mol) gave the same absorption spectrum as that of nickel(II) chloride at pH 3.8 and at room temperature.

Coordination of 2-Pyridinecarbonitrile. It is conceivable that the labile complexes exchange their ligands with the 2-pyridinecarbonitrile, and that, therefore, the hydration of the nitrile group occurs. The coordination of 2-pyridinecarbonitrile may be due to that of the nitrogen atom of the pyridine ring rather than that of the nitrile group. It is expected that 3- or 4-pyridinecarbonitrile also coordinates with the nitrogen atom of the pyridine ring. The catalytic hydration of the three kinds of pyridinecarbonitrile isomers was examined with $[Ni(en)(H_2O)_4]SO_4 \cdot H_2O$ and $Cu(gly)_2 \cdot H_2O$, but no reaction occurred with the 3- and 4-isomers. Thus, the effect of the coordination of 2-pyridinecarbonitrile is specific. It has been pointed out by Breslow[4] that the nitrile group of 1,10-phenanthroline-2-carbonitrile, although poorly placed for coordination, still has an interaction with the metal ion–Cu(II) or Ni(II)– and undergoes hydration.

Hydration of 2-Pyridinecarbonitrile. The results of the hydration of 2-pyridinecarbonitrile with various metal chelates are given in Table 1. The features of the reactions are not simple. In general, these homogeneous catalytic reactions proceed more rapidly at elevated temperatures. For example, the yield of amide was 22% in Exp. No. 9 (at 60 °C), but it became almost 100% when the reaction mixture was refluxed for three hours. However, no reaction occurred with the inert complex —Exp. Nos. 11—12— even when it was refluxed.

In the case of a metal ion-catalyzed reaction, 2-pyridinecarbonitrile first formed a complex with the metal ion, and then gradually underwent hydration along with a change in the color of the reaction mixture. However, when the initial pH value was about 7 or higher, metal ions afforded precipitates of thier hydroxides in the reaction systems. For this reason, the pH value of the reaction mixture was maintained in the acid region in Exp. No. 13. On the other hand, no hydroxides formed in the reaction with metal complexes, even in a basic solution. Further, metal complexes show different catalytic activities according to the kinds of thier ligands, as is shown in Table 1.

Function of Complex Catalysts. The catalytic functions of the complexes were classified into three types (Type I—III). Free 2-pyridinecarboxamide was obtained with the Type I and Type II complexes. The Type III complex afforded only the mixed complex.

Type I Complexes: The complexes used in Exp. Nos. 1, 2, 5, 7, 8, and 9 (Table 1) belong to Type I. They are recovered without any change after the reactions. Therefore, the complexes of Type I work as ideal catalysts.

Type II Complexes: The complexes used in Exp. Nos. 3, 4, and 6 belong to Type II. A part of their ligands is unidentate, NO_3 or H_2O. With these complexes, the hydration of 2-pyridinecarbonitrile proceeded, but the complexes were changed in composition after the reaction. For example, in the reaction with

4) R. Breslow, R. Fairwether, and J. Keana, *J. Amer. Chem. Soc.*, **89**, 2135 (1967).

$[Ni(en)(H_2O)_4]SO_4 \cdot H_2O$, the color of the reaction mixture changed from light blue to violet blue. The complex recovered was a mixture of tris(ethylenediamine)nickel(II) and bis(2-pyridinecarboxamide)nickel-(II).

Type III Complex: In Exp. No. 10 (Table 1), the catalytic behavior of *cis*-$[CoCl_2(en)_2]Cl$ was different from that of the labile complexes. The amount of reacted 2-pyridinecarbonitrile was 16% after 5 hr, but it was 18% even after a 15 hr reaction. After the reaction, an orange complex was obtained as the main product, and it had almost no catalytic activity.

Experimental

Materials. The 2- and 4-pyridinecarbonitriles (Tokyo Kasei Co., Ltd, Tokyo) were recrystallized from ether (mp 28.5—29.5 °C and 78—79 °C respectively). The 3-pyridinecarbonitrile (Aldrich Chemical Co., Inc.) was used without further purification (mp 49—50 °C). The $CuCl_2 \cdot 2H_2O$ and $NiCl_2 \cdot 6H_2O$ were extra-pure chemicals (Wako Junyaku, Tokyo). $[Cu(piaH)_2]Cl_2 \cdot 2H_2O$,[5] $[Ni(piaH)_2]Cl_2 \cdot 2H_2O$,[5] $[Co(piaH)_2]Cl_2 \cdot 2H_2O$,[5] $Cu(gly)_2 \cdot H_2O$, $[Cu(en)_2]Cl_2 \cdot 2H_2O$, $[Ni(en)(H_2O)_4]SO_4 \cdot H_2O$, $[Ni(en)_3]Cl_2 \cdot 2H_2O$, $[Co(en)_3]Cl_3$, *cis*-$[CoCl_2(en)_2]Cl$, $[Pt(en)_3]Cl_4$, $[Cu(NO_3)_2(bipy)]3H_2O$, and $[Ni(bipy)(H_2O)_4]SO_4 \cdot 2H_2O$ were all prepared and recrystallized several times (piaH: 2-pyridinecarboxamide, en: ethylenediamine, bipy: 2,2′-bipyridine, gly: glycine ion).

Blank Test. In a 25 ml volumetric flask, were placed 10 ml of a 2-pyridinecarbonitrile solution (0.119 M) and 10 ml of a buffer (pH 1—4: 0.1 M gly—0.1 M NaCl—0.1 M HCl, pH 4—7: 0.2 N CH_3COOH—0.2 N CH_3COONa, pH 7—12: 0.1 M gly—0.1 M NaCl—0.1 M NaOH): the content was then made up to 25 ml with distilled water. Ten ml of the solution was placed in a sealed glass tube and kept at 60 °C for 5 hr. The content was charged on a column of ion-exchange resin (Dowex 50×2, H-form) and developed with water. By this elution, only the unreacted 2-pyridinecarbonitrile was obtained. This solution was then diluted to a definite quantity and analyzed spectrophotometrically (λ_{max}=272 nm).

The VIS-UV absorption spectra were obtained with a Hitachi Recording Spectrophotometer EPS-3T.

Hydration of 2-Pyridinecarbonitrile with Metal Chelates or Ions. In a sealed glass tube, were placed 10 ml of a solution containing 2-pyridinecarbonitrile (0.0475 M) and the metal chelate or ion (0.0058 M). The mixture was adjusted to the pH range of 6.0—8.0 with small amounts of 0.1 N HCl or 0.1 N KOH solution, and was then kept at 60 °C for 5hr. After the reaction, an aliquot quantity of the reaction mixture was charged on a column of the cation exchange resin (column: diameter 1 cm, length 3 cm) and developed with water. Thus, unreacted 2-pyridinecarbonitrile was separated completely from the reaction mixture. The decrease in the amount of the starting material was followed spectrophotometrically at 272 nm, and the yield of the reaction product, 2-pyridinecarboxamide, was calculated. The only reaction product was 2-pyridinecarboxamide. Yield (%)=100−unreacted 2-pyridinecarbonitrile (%).

Hydration of 2-Pyridinecarbonitrile with Chelates under Reflux. Thirty ml of a solution containing 2-pyridinecarbonitrile (0.160 M) and chelate (0.02 M) was refluxed for 5 hr. Then, the reaction mixture was concentrated and extracted with ether several times. From the ethereal solution, the reaction product, pure 2-pyridinecarboxamide (white crystals) were obtained in the free form (about a 100% yield; mp 105 °C). No other reaction products were found. From the mother liquor, only the chelate was obtained.

Hydration of 3- and 4-Pyridinecarbonitriles with Metal Chelates. The reaction conditions were the same as in the case with 2-pyridinecarbonitrile. After the reaction, the content was charged on a column of ion-exchange resin (Dowex 50×2, H-form) and developed with a 5.5% ammonia solution. Then, the eluate was analyzed spectrophotometrically; no change of absorbance was observed (3-isomer, 265 nm; 4-isomer, 276 nm). Therefore, it was concluded that no reaction occurred with the two isomers.

In the other reaction, 60 ml of a solution containing 4-pyridinecarbonitrile (0.158 M) and $[Cu(en)_2]Cl \cdot 2H_2O$ (or $Cu(gly)_2 \cdot H_2O$) (0.019 M) was kept at 65 °C for 6 hr. After the reaction mixture has been extracted with ether several times, only the starting material was obtained from the ethereal solution. No 4-pyridinecarboxamide was found at all.

The authors wish to offer their hearty thanks to Professor Masayoshi Nakahara, Rikkyo University, for his valuable advice.

H^+ Ion Equilibria in Solutions of Copolypeptides of L-Lysine and L-Aspartic Acid and of L-Lysine and L-Glutamic Acid

M. Atreyi and R. C. Gupta
Department of Chemistry, University of Delhi, Delhi, India
(Received July 10, 1972)

pH and conductometric titration curves of copolypeptides containing L-lysine and either L-glutamic acid or L-aspartic acid residues have provided necessary evidence to believe that in the copolypeptides the zwitterion formation is complete at the isoionic point. The amounts of acid/alkali used up at the final inflexion/break in the titration curves agreed with the analytically determined quantity of basic/acid groups in the copolypeptides. Besides, the titration curves showed additional inflexions/breaks which distinguished between the various kinds of acid/basic groups present.

Polyamino acids, in particular, copolypeptides, serve as good model systems for understanding the behaviour of proteins. Investigations of the H^+ ion equilibria of copolypeptides in aqueous solutions had been shown[1-4] to be useful in studying conformational changes that occur on reaction with an acid or base. The role of vicinal charged sites on the titrations of polyacids, polybases, and polyampholytes, in general, had been worked out by Katchalsky *et al.*[5,6] but this aspect has received a rather limited attention in the study of polypeptide titrations. The abnormal behaviour of some proteins, however, had been explained[7-10] as arising out of such effects. Using non-peptidic ampholytes, the authors[11,12] had shown that a clear differentiation could be made, studying the titration behaviour of non-equimolar polyampholytes, between groups that take part and those that do not, in the formation of a zwitterion. Further, it had also been demonstrated that conductometric titrations, carried out for the first time on such systems, proved extremely useful in the identification and estimation of different kinds of prototropic groups. The present study is an application of the same kind of approach to the amphoteric polypeptides made up of L-lysine and L-aspartic acid/L-glutamic acid.

Experimental

N-Carboxy anhydrides (NCA) required for the polymerization were prepared starting from the corresponding amino acids, suitably protected, by using either directly phosgene or Leuch's method. The amino acids were modified as follows: L-glutamic acid to γ-benzyl L-glutamate,[13] L-aspartic acid to β-benzyl L-aspartate,[14] and L-lysine to α,ε,N-dicarbobenzoxy L-lysine.[15] Copolymerization was effected in dioxane (4%) with sodium methoxide (A/I=100) as initiator. After polymerization the protecting groups were removed simultaneously by treatment with HBr in acetic acid. The hydrobromide was converted to the free base by passing through a column of Amberlite IRA-400 in its hydroxy form. The isoionic form was obtained by passing through a mixed bed column of Amberlite IRA-120 and IRA-400.

Number-average molecular weights were determined following Sela and Berger.[16] Their amino acid composition was obtained following the method of Giri *et al.*[17]

The isoionic copolypeptide (10—15 mg) was dissolved in 20 ml of water in a titration vessel in which nitrogen could be swept continuously and was titrated with HCl/KOH (0.07—0.1N). pH/specific conductivity was measured after equilibration (2—5 min) after each addition of acid or alkali. A Leeds-Northrup conductivity (drum-type) bridge was used in conjunction with certified Sullivan resistances and a Muirhead Audio frequency oscillator. pH was measured with a Beckman Zeromatic pH meter. All adequate precautions such as using carbonate free alkali and maintaining an inert atmosphere were taken. Titrations were performed at room temperature (25—27°C).

Results and Discussion

Table 1 gives the amino acid composition of the copolypeptides, obtained as stated above, as also the amounts of acidic COOH groups and basic (NH_2) groups expected to be present. It can be seen that while A and C are acidic, B and D are basic. Considering these polypeptides as zwitterions, it follows that whereas the polypeptides under consideration have the acidic or the basic monomer in excess, at the isoionic point, there would be available in the molecule "free" carboxyl or amino groups which have not taken part in zwitterion. In other words, copolypeptides A and C would have the following prototropic groups available: i) COO^- anions, ii) COOH groups, and iii)

Table 1. Amino acids analysis

Copolypeptide	Ratio of lys. to asp. acid residues	Ratio of lys. to glu. acid residues	mequiv. basic groups/100 g of copolypeptide	mequiv. acid groups/100 g of copolypeptide	Mol. wt.
A	1.00/1.59		322	516	21500
B	2.65/1.00		573	220	10700
C		1.00/1.27	342	436	15200
D		2.54/1.00	557	219	10700

NH_3^+ as the titratable groups. IR spectra fully support this in that B and D do not show any characteristic absorption for COOH group (1400 cm^{-1}).[18] Consequently, the copolypeptides A and C have only one kind of basic group, *viz.*, COO^-, to react with an acid, while B and D would have two kinds, COO^- and NH_2. In other words, copolypeptides having an excess of basic groups would be expected to have a two-stage reaction with acid and those with excess of acidic groups a two step reaction with alkali.

Figures 1 and 2 give the representative titration curves of the copolypeptides A and B with HCl and KOH, respectively. It can be seen that the conductometric titration curves marked (2) and (4), show fairly sharp breaks indicating the culmination of one type of reaction. The pH curves have corresponding inflexions, *i.e.*, changes in curvature, which are however less prominent. (In arriving at the position of the inflexions care was taken to scan the regions as carefully as possible with very small additions of acid or alkali and also checking with repetitive experiments. Also refer to modified plots.) Titration curves for the

18) E. R. Blout and M. Idelson, *J. Amer. Chem. Soc.*, **80**, 4909 (1958).

copolypeptides C and D are not given as they are very similar in nature to those of A and B. However, Table 2 summarizes the amounts of acid/base which had to be added to reach the various inflexions/breaks for all the copolypeptides.

In the first place it can be seen that the total amounts of acidic/basic groups which titrate with alkali/acid between the final inflexion/break in the titration curves are in fair agreement with the amount obtained from amino acid analysis. As to the fine features, it is interesting to note in what follows that as anticipated from the zwitterion structure the titration with alkali of A and C did show a two-stage reaction as against the one step reaction in copolypeptides B and D.

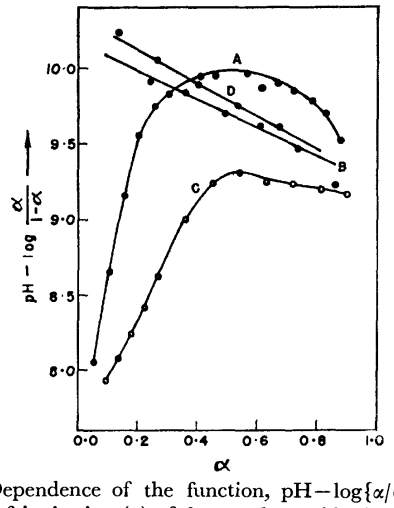

Fig. 3. Dependence of the function, pH−log{α/(1−α)} on degree of ionisation (α) of the copolypeptides in the alkaline region.

The first inflexion/break in the titration of A with KOH (Fig. 1, Curves 1, 2) corresponds to an addition of 195 milliequivalents (mequiv.)/100 g of A. The modified plot, α *versus* pH−log {α/(1−α)}, Fig. 3, shows a sharp change in curvature about the same region (α~0.35). Being an acidic polypeptide this should have two kinds of groups reacting with alkali and the first to react would be the COOH groups, not involved in zwitterion formation, followed by NH_3^+ cations. Amino acid analysis indicates (Table 1) that there would be 194 mequiv. (516—322) of COOH groups and 322 mequiv. of NH_3^+. The titration data leads to values of 195 and 322 mequiv./100 g which is in very good agreement with the expected values. In Fig. 3 can also be seen the modified plot of the acidic copolypeptide C, which is very similar to that of A and showing the expected behaviour of a two-stage neutralization phenomenon (Table 2).

Figure 1 (Curves 3, 4) gives the titration curve of copolypeptide A with HCl and the corresponding modified plots, β *versus* pH+log {β/(1−β)}, are presented in Fig. 4, which bring out the similarity between A and C more clearly. There is a two-stage neutralization against the one stage anticipated. It can be seen from Fig. 1 that it is the second inflexion/break at 322 mequiv./100 g of A that corresponds with the total anticipated COO^- anions of 330 mequiv./100 g (Table 2). The modified plots in Fig. 4 make it clear that in

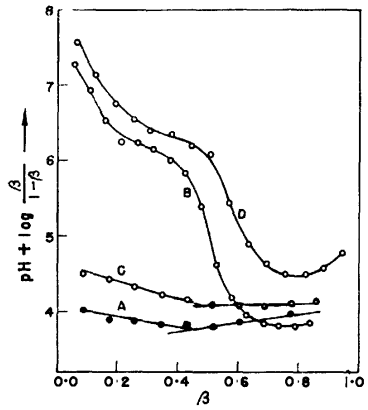

Fig. 4. Dependence of the function, pH+log {β/(1−β)} on the degree of ionisation (β) of the copolypeptides in the acidic region.

both A and C about half of the COO^- groups are stronger (the two segments in the modified plots cannot extrapolate to same pK) indicating the different energies of protonation for the carboxylate anions. This difference perhaps arises out of specific interactions such as hydrogen bond formation[19] and/or interactions between vicinally situated similar charges.[5]

Copolypeptides B and D, as suggested earlier, would be expected to have the ammonium cations as the only kind of acidic group to react with KOH. The modified plots, α *versus* pH−log {α/(1−α)} (Fig.3), show a linear behaviour and the representative titration curves of B (Fig. 2, Curves 1 and 2) show a single inflexion/break at the expected value (Table 2).

Titrations with the acid (HCl), as in the case of those with A and C, seem to deviate from the expected behaviour in having three instead of the two-stage reaction (see Table 2). Figure 3, showing the modified plots, also suggests the same and here again it appears that the protonation of NH_2 groups takes place in two stages followed by a single stage reaction of COO^- anions. This behaviour is again similar to that found in the case of polyvinylamine by Katchalsky *et al.*[5] where the vicinally situated prototropic groups were having a marked influence on their reactivity with acid.

To summarize, the amounts of COO^-, NH_2, and NH_3^+ groups found in the copolypeptides on titration are what one would expect on the basis of the assumption that zwitterion formation is complete at the isoionic point, and consistent with their chemical composition. The sequence in which the groups titrate follows the order $COO^- < NH_2 < NH_3^+$ of their pKs. The difference in the lengths of the side chains of L-aspartic acid and L-glutamic acid residues does not appear to influence the titration pattern of the copolypeptides, though this difference has been found to influence their conformation.[20]

The authors wish to thank Prof. R. P. Mitra for the fruitful discussions. Facilities provided by the Director, Shri Ram Institute for Industrial Research, Delhi (India) for the preparation of amino acid anhydrides are gratefully acknowledged.

The Reaction of Nitriles under High Pressure. II. The Catalytic Effects of Amines and Water on the Formation of Trisubstituted 1,3,5-Triazines from Nitriles[1]

Masahiko YASUMOTO, Koshin YANAGIYA, and Masahiro KURABAYASHI

6th Division, National Chemical Laboratory for Industry[2] (Tokyo Kogyo Shikensho), Mita, Meguro-ku, Tokyo 153

(Received December 1, 1972)

When a mixture of benzonitrile and methanol is kept under a high pressure of a few thousand atoms at an elevated temperature, methyl benziminoether is produced and trimerized to triphenyl-1,3,5-triazine.[1] In the present study it was confirmed that the addition of ammonium salts or some nucleophiles with an active hydrogen atom such as water, amines, and ammonia at several per cents in the molar fraction increases the rate of the formation of this triazine by several times. It was found that the nucleophilic benzamidines produced by the reaction of benziminoether with amines attacked the second molecule of the iminoether and successively took the third iminoether molecule to form a triazine ring. The addition of water to the nitrile-methanol mixture produced amidine, methyl ester, amide, and amidinium carboxylate, of which the carboxylate exhibited the highest promotive effect. Some benzamidines were obtained in fairly good yields from amines and benzonitrile under similar high-pressure conditions. It is thought that this could be useful for synthesizing amidines.

It was found in a previous study[1] that triphenyl-1,3,5-triazine (TPT) is formed under high pressures by the cyclotrimerization of the benziminoether produced from benzonitrile and alcohol and that the triazine formation proceeds through the following reactions:

$$C_6H_5CN + ROH \longrightarrow C_6H_5C(=NH)OR \quad (1)$$

$$2\,C_6H_5C(=NH)OR \xrightarrow[\text{slow}]{-ROH} [C_6H_5C(OR)=NC(=NH)C_6H_5]$$

$$\xrightarrow{+C_6H_5C(=NH)OR} \text{TPT} + 2\,ROH \quad (2)$$

The formation was promoted by the addition of a dipolar aprotic substance such as dimethylformamide.[1] In the present investigation, the influence of protic substances other than alcohol on this reaction was examined under high pressures up to 10000 kg/cm^2.

It was revealed that the cyclotrimerization was intensely promoted by amidines or their salts, which were produced by the reaction of iminoether with substances such as water, ammonia, ammonium salts, and primary or secondary amines. These substances were added in catalytic amounts. The catalytic effects of these nucleophiles and salts were compared with the results obtained by Cairns, Larchar, and McKusick with ammonium acetate and concentrated aqueous ammonia as catalyzers[3] and with the results obtained by Kume and Moriyoshi with water.[4]

Results and Discussion

Influence of Amines. In contrast to the limited effect of tertiary amines with no active hydrogen atoms, ammonia, and primary or secondary amines showed a marked promotive effect on the production of TPT from benzonitrile in the presence of methanol, as is shown in Table 1. Methyl benziminoether (MBI),

TABLE 1. EFFECT OF VARIOUS AMINES ON THE FORMATION OF TPT IN THE MIXTURE OF BENZONITRILE AND METHANOL[a]

a) Reaction conditions were the same as those in Table 1.

which was found to be an intermediate[1)] in the above scheme of Eq. (1), was detected again in every run of the present experiment. Benzamidines were formed when benzonitrile, methanol, and one of the following substances ammonia and primary and secondary amine, were employed. These experimental results, as well as the fact that amidines are synthesized from amines and iminoethers under atmospheric pressure,[5)] indicate that the benzamidines were produced by the reaction of amines with the intermediate, MBI:

$$C_6H_5C(=NH)OCH_3 + RR'NH \quad (3)$$
MBI
$$\longrightarrow C_6H_5C(=NH)NRR' + CH_3OH$$
R, R': H or alkyl group

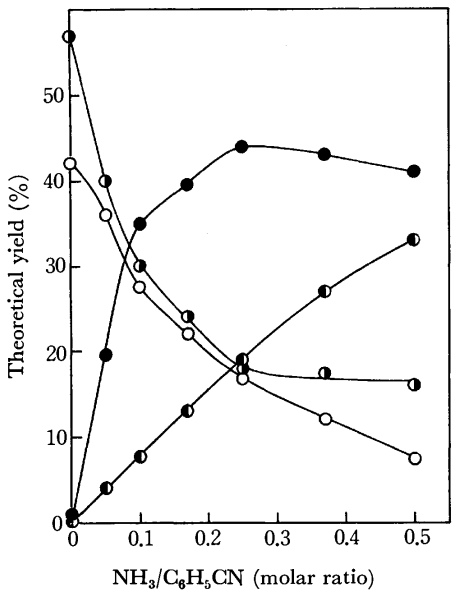

Fig. 1. Dependence of the yields of the reaction products on the amount of ammonia added to the mixture C_6H_5CN: CH_3OH = 1 : 3.2 in mol, at 6800 kg/cm² and 100 °C for 10 hr.
●: TPT, ◑: C_6H_5CN, ○: MBI, ◐: $C_6H_5C(=NH)NH_2$.

Figure 1 shows the relationship between the amount of ammonia added to the benzonitrile–methanol mixture and the amounts of the reaction products. The yield of benzamidine increased with the increase in the amount of ammonia added. The yield of TPT increased to a maximum when the amount of ammonia increased to 25 per cent in the molar fraction; above this fraction the yield decreased gradually, probably because of a decrease in [MBI] × [Benzamidine]. This may be evident from the mechanism described later. The increase in the rate of TPT formation by the addition of ammonia or amines may be assumed to be due to the catalytic effect of amidines derived from these additives. The assumption is supported by the experimental results listed in Table 2, which indicates that, in Exp. 8, the addition of benzamidine only 5 per cent of benzonitrile in the molar fraction yielded a large amount of TPT in the benzonitrile–methanol mixture in contrast to the small yield obtained without any additives in Exp. 1. On the other hand in Exp. 2 the addition of ammonia, the same molar fraction as the added benzamidine in Exp. 8, gave a fairly good yield of TPT amounting to 3/5 of that in Exp. 8 and yielded benzamidine in an amount nearly stoichiometrical to the added ammonia.[6)]

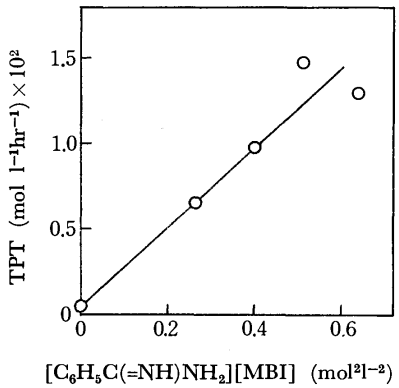

Fig. 2. Relation between the mean rate* of the formation of TPT and the concentrations of bemzamidine and MBI in the mixture C_6H_5CN: CH_3OH: NH_3 = 1 : 3.2 : 0—0.5 in mole, at 4500 kg/cm² and 100 °C for 10 hr.
* The mean rate of the formation of TPT (in mol $l^{-1}hr^{-1}$) is the value of the concentration of TPT divided by the reaction time. The volume of the reaction medium is assumed to be the sum of each volume of the initial material in the atmospheric pressure.

An approximately linear relationship was found between the rate of TPT formation and [MBI] × [Benzamidine] in Fig. 2. This suggests that TPT is produced *via* a rate-determining reaction in which an intermediate, *N*-benzimidoylbenzamidine(I), is formed by an attack of nucleophilic benzamidine on the carbon atom of MBI. This step is expected to proceed more favorably than the rate-determining reaction, Eq. (2), without a catalyzer. This is because benzamidine is a stronger nucleophile (base) than MBI. This step may be followed by the cyclic addition of another molecule

5) R. L. Schriner and F. W. Neumann, *Chem. Rev.*, **35**, 351 (1944); E. S. Hand and W. P. Tencks, *J. Amer. Chem. Soc.*, **84**, 3505 (1962); F. C. Schaefer and G. A. Peters, *J. Org. Chem.*, **26**, 412 (1961).

6) The existence of a benzamidine-rich equilibrium among methyl benziminoether, ammonia, benzamidine, and methanol under high pressures has been confirmed.

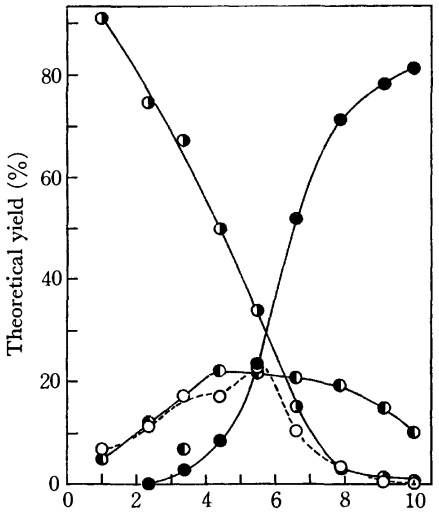

Fig. 3. Dependence of the yields of the reaction products in the mixture C_6H_5CN: CH_3OH: NH_3=1: 3.2: 0.25 in mole on the reaction pressure, at 110 °C for 10 hr.
●: TPT, ◑: C_6H_5CN, ○: MBI, ◐: $C_6H_5C(=NH)NH_2$.

of MBI to form TPT. This mechanism may be expressed as follows:

$$C_6H_5-C(=NH)-NH_2 + C_6H_5-C(=NH)-OR \xrightarrow{-ROH} \left[C_6H_5-C(NH_2)=N-C(=NH)-C_6H_5 \right] (I) \xrightarrow{+C_6H_5C(=NH)OR} TPT + NH_3 + ROH \quad (4)$$

Figure 3 shows that the effect of the pressure on the formation of TPT in the presence of ammonia is as remarkable as in the absence of ammonia.[1)]

Influence of Water. As is shown in Table 3 and Figs. 4 and 5, one of the remarkable effects of the water added to the benzonitrile–methanol mixture is the intense promotion of the TPT formation; another is the formation of benzamide, methyl benzoate, benzamidine, and benzamidinium benzoate. Some experiments were carried out in order to clarify the mechanism of the catalytic effect of water.

The same molar fractions of the by-products described above and some compounds related to the by-products were added to the benzonitrile–methanol mixture. The results of these experiments are listed in Table 4. Of these additives, benzamidinium benzoate and ammonium acetate promoted the TPT formation most. It is certain that the ammonium acetate added to the

a) Reaction conditions were the same as those in Table 1.
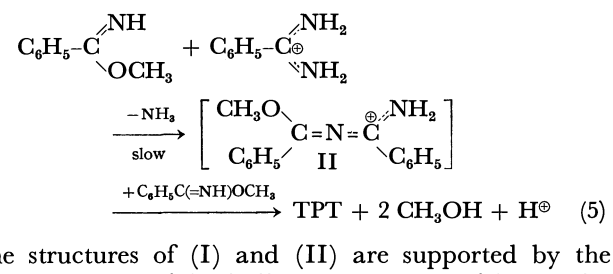
b) Remainder of the substruction of the amount of the added benzamide from that of the observed benzamide in the reaction mixture.

benzonitrile–methanol mixture was converted to benzamidinium acetate, because several amidine salts are synthesized from iminoether salts and ammonia under atmospheric pressure. The fact that sodium acetate had no influence means that the formation of TPT is not influenced by a usual electrolyte. Therefore, the catalytic effects of those salts may be attributed merely to the benzamidinium cation. Figure 4 shows the noticeable yield of benzamidinium benzoate in the reaction with added water. Considering the strong effect of the amidinium cation as a catalyzer, it is likely that the greater part of the promotive effect of water is caused by the benzamidine benzoate derived from water. The rate-determining reaction is inferred to be the attack of the imino-nitrogen of MBI on the strongly positive carbon atom of the benzamidinium cation, which gives *N*-methoxybenzylidenebenzamidinium cation (II) as an intermediate. The whole reaction course is proposed to be as follows:



The structures of (I) and (II) are supported by the literature, in which similar compounds with a polyperhalogenomethylene group have been reported.[7)]

The route of the formation of methyl benzoate may be assumed to be Eq. (6), since the rapid hydrolysis of iminoether into the ester and ammonia under atmospheric pressure is well known:

$$C_6H_5C(=NH)OCH_3 + H_2O \longrightarrow C_6H_5COOCH_3 + NH_3 \quad (6)$$

The ammonia thus liberated will attack MBI to give benzamidine by means of Eq. (3). The nearly equimolar yields of the ester and amidine in the low pressure range shown in Fig. 5 support this reaction scheme.

The experiments shown in Table 5 were carried out to determine the route of benzamide formation in the benzonitrile–methanol mixture. The results of Exp. 15 shows that benzamide is produced more or less by the direct hydration of benzonitrile:

$$C_6H_5CN + H_2O \longrightarrow C_6H_5CONH_2 \quad (7)$$

However, when Exp. 15 is compared with Exp. 16, it appears that there is another route yielding benzamide with the aid of methanol. The hydrolysis of benzamidine is most likely, since this hydrolysis is known to take place smoothly under atmospheric conditions:

$$C_6H_5C(=NH)NH_2 + H_2O \longrightarrow C_6H_5CONH_2 + NH_3 \quad (8)$$

The hydrolysis of MBI to benzamide has not been reported. The ammonolysis of methyl benzoate is unlikely, since the reverse reaction, the methanololysis of benzamide to methyl benzoate, proceeds (see Exp. 17):

$$C_6H_5CONH_2 + CH_3OH \longrightarrow C_6H_5COOCH_3 + NH_3 \quad (9)$$

Benzamide promotes the TPT formation, as may be seen in Exp. 11 in Table 4. The promotion mechanism may be partially explained by Eq. (9).

The route of the formation of benzamidinium benzoate has not yet been clarified, although the overall reaction may be expressed as follows:

$$C_6H_5C(=NH)NH_2 + C_6H_5COOCH_3 + H_2O \longrightarrow C_6H_5C(=NH)NH_2 \cdot C_6H_5COOH + CH_3OH \quad (10)$$

Figures 4 and 5 show that the total amount of benzamide, methyl benzoate, and benzamidinium benzoate was nearly stoichiometrical to the added water. This indicates the fair stability of these by-products. Of these by-products, benzamide amounted to the largest part when much water was added. The addition of a small amount of water may be effective to obtain TPT in a good yield. The marked positive effect of pressure on the production of TPT as well as on the production of the by-products is shown in Fig. 5.

7) The polymer of perfluorogultaric acid (H. C. Brown, *J. Polymer Sci.*, **44**, 9 (1960)) and $CCl_3C(=NH)NHC(=NH)CCl_3$ (F. C. Schaefer, G. A. Peters, and V. P. Wystrach, *J. Amer. Chem. Soc.*, **81**, 1466 (1959)) correspond to (I). The hydrochloride of the dimer of perfluoroadipo(or glutaro-)iminoether (A. Ya. Yakubovcih, *et al.*, *J. General Chem. USSR*, **36**, 878 (1966)) corresponds to (II).

TABLE 7. PREPARATION OF BENZAMIDINES UNDER HIGH PRESSURE[a)]

Exp. No.	Amine	C_6H_5CN:CH_3OH: Amine (molar ratio)	Yield (%)[b)]			
			C_6H_5CN	MBI	Amidine	TPT
21	NH_3	1 : 3.2 : 0.5	16.3	7.4	33.0 (65.7)	41.1
22	n-$C_4H_9NH_2$	1 : 1.5 : 0.7	16.6	3.2	69.1 (98.7)	4.8
23	$(C_2H_5)_2NH$	1 : 1.5 : 0.7	40.0	7.6	32.0 (44.6)	11.8

a) Reaction conditions were similar to those in Table 1.
b) Theoretical yield based on benzonitrile.
c) Theoretical yield based on the amine.

The reaction products in the mixtures of several combinations of acetonitrile, methanol, water, and acetamide under high pressures are listed in Table 6; the table indicates that the behavior of water in the acetonitrile–methanol mixture is similar to that in the benzonitrile–methanol mixture.

Reaction Conditions for Synthesizing Trisubstituted 1,3,5-Triazines. It is known that noticeable amounts of trisubstituted 1,3,5-triazines are produced in nitrile–alcohol mixtures without a catalyzer under pressures of more than 4000 kg/cm² and at temperatures of more than 100 °C.[1,2)] The rate of the triazine formation increases with an increase in the pressure or with an increase in the equilibrium concentration of iminoether.[1)] This concentration is altered parallel with the pressure and is dependent on the choice of nitrile and alcohol.[1)] The elevation of temperature increases the rate.[1)] However, at temperatures above 140 °C the formation of a by-product, *N*-methylbenzamidine,[8)] was remarkable in the benzonitrile–methanol mixture. The employment of the catalyzers described above may give rise to a rapid progress of the triazine formation, even in somewhat low ranges of the temperature and the pressure.

New Preparative Method of Amidines. Figure 3 shows that the yield of benzamidine increased, until it was nearly stoichiometrical to the added ammonia when the reaction pressure increased to about 5000 kg/cm², above that pressure range it gradually decreased. Those facts suggest the usefulness of this high-pressure reaction for preparing amidines by means of a good selection of reaction conditions. This usefulness is supported by the results listed in Table 7. This procedure is thought to be an excellent method for preparing amidines from nitriles because it does not need any catalyzer. The known one-step methods all require the keeping of nitriles at fairly elevated temperatures with more drastic agents than methanol, such as, ammonium halide, ammonium salts in ammonia,[9)] mixtures of amines and Lewis acids,[10)] and metal amides in benzene or ammonia.[11)]

Experimental

Reaction Apparatus and Procedure. An initial mixture for a reaction was placed in a collapsible lead capsule and was then kept in the desired conditions of pressure and tempera-

8) The route of the formation of the *N*-substituted amide is still unsolved, although one conceivable route is the Chapman rearrangement of the iminoether. The formation of *N*-methyl-2,3,3-tricyanoacrylamide from tetracyanoethylene and methanol at 5000 kg/cm² has been reported (M. Price and J. Horniak, *Chem. Commun.*, **1966**, 455).

9) E. F. Cornell, *J. Amer. Chem. Soc.*, **50**, 3311 (1928).
10) F. C. Schaefer and A. P. Krapcho, *J. Org. Chem.*, **27**, 1255 (1962).
11) P. Oxley, M. W. Partridge, and W. F. Short, *J. Chem. Soc.*, **1947**, 1110.

ture for the desired time, as has been described previously.[1]

Material Supply. The drying and distillation of EP-grade reagents, such as acetonitrile, benzonitrile, methanol, *n*-butylamine, diethylamine, and methyl benzoate, supplied this experiment with the samples of these substances. The water contents of benzonitrile and methanol were less than 0.017 per cent. Ammonia of a chemical grade was evaporated, dried on sodium hydroxide, and absorbed in methanol. The benzamide, ammonium acetate, and potassium acetate were of an EP-grade. The benzamidine was prepared from ethyl benziminoether hydrochloride[1] and ammonia[12] (mp 68.3 °C (80[13])). The melting point of the picrate was 228.5 °C. The benzamidinium benzoate was obtained by mixing an ethereal solution of benzoic acid with a stoichiometric amount of the benzamidine in a benzene solution and by recrystallizing the resulting raw product from water (mp 234.0 °C). Trimethyl-1,3,5-triazine (TMT) was prepared as follows: ethyl acetiminoether hydrochloride was prepared from acetonitrile and ethanol by Pinner's method. The iminoether was liberated by neutralization, fractionated at 87—90.5 °C, mixed with acetic acid (8 mol per cent of the iminoether), and kept at room temperature overnight.[14] The resulting TMT was extracted and distilled. The yield was 50.7 per cent (based on the iminoether) (bp 155 °C (155[14])); C, 58.38 (Calcd 58.52); H, 7.64 (7.37); N, 34.44% (34.12)).

Identification of Reaction Products. MBI and TPT: These substances were identified in a manner described previously.[1]

Amidines: A mixture of benzonitrile, ammonia, and methanol (1: 0.25: 3.2 in mole) was kept at 5500 kg/cm² and 110 °C for 10 hr. The reaction mixture was then separated from a volatile matter *in vacuo* and from TPT by extraction with toluene. A methanolic solution of picric acid was added to this mixture. Benzamidine picrate was precipitated and recrystallized from water to give yellow needles (mp 229 °C (232[15])); C, 44.73 (44.71); H, 3.01 (3.18); N, 20.51% (20.05); Infrared (IR) spectrum, 3400, 3200, 1675, and 1610 cm^{-1} for the amidinium group). The melting point was not decreased by mixing this picrate with the authentic sample described above. *N-n*-butylbenzamidine was collected at 170 °C by the fractionation of the reaction mixture of Exp. 22 by means of preparative gas-liquid phase chromatography (glc) (Reoplex-400, 9×750 mm, 70—200 °C, 4 °C/min, He 150 ml/min) (C, 74.52 (74.96); H, 9.22 (9.15); N, 15.42% (15.89); IR, 3250, 3050, 2930, 1645, 1600, 1570, 1360, 1190, 775, and 690 cm^{-1}). *N,N*-diethylbenzamidine was collected at 146 °C by the fractionation of the reaction mixture of Exp. 23 by the same procedure (C, 74.92 (74.96); H, 9.02 (9.15); N, 15.65% (15.89); IR, 3320, 3050, 2980, 1585, 1570, 1445, 1380, 1225, 1175, 775, and 700 cm^{-1}).

Benzamidinium Benzoate: A mixture of benzonitrile (2.39 g), methanol (2.29 g), and water (0.105 g) (1: 3.2: 0.25 in mol) was kept at 8000 kg/cm² and 110 °C for 10 hr. TPT was removed from the reaction mixture by filtration, and the volatile products were evaporated. The remaining crude benzoate, which amounted to 0.22 g (mp 210 °C; yield, 7.9% based on benzonitrile), was washed with toluene and recrystallized from water (mp 222.8 °C (230[16])); C, 69.53 (69.40); H. 5.91 (5.82); N, 11.65% (11.56); IR, 3200, 3000, 1710, 1610, 1570, 1520, 1490, 1390, 1035, 840, 720, and 690 cm^{-1}). The melting point was not decreased by mixing this crystal with the sample described above. The IR spectrum agreed with that of the sample as well.

Benzamide and N-Methylbenzamide: A mixture of benzonitrile (2.3 g), methanol (2.3 g), and water (0.10 g) (1: 3.2: 0.25 in mol) was kept at 4400 kg/cm² and 170 °C for 10 hr. The reaction mixture was fractionated by preparative glc (Reoplex-400, 9×750 mm, 100—205 °C, 4 °C/min, He 125 ml/min). *N*-Methylbenzamide (0.1 g) (4% based on the benzonitrile) was collected at 190—205 °C (mp 62.5 °C(75[17])); C, 71.33(71.09); H, 6.51(6.71); N, 10.27%(10.36); mol wt (from a parent peak of mass spectroscopy (MS)), 135(135.16); IR, 3350, 3050, 2950, 1640, 1550, 1490, and 1410 cm^{-1}). Benzamide was collected at 250 °C to give (0.8 g) (29% based on the benzonitrile). The melting point, 122 °C (128[13]), and the IR spectrum agreed with those of the authentic sample.

Methyl Benzoate and Acetate: Their presence in the reaction mixtures was assured by the agreement with the authentic samples on glc.

TMT: The reaction mixture of Exp. 19 was fractionated by preparative glc (DNP, 9×750 mm, 100 °C—, 2 °C/min, He 125 ml/min) to give 0.4 g at 121—127 °C (mp 58 °C (59—60[3])); C, 58.21(58.52); H, 7.48(7.37); N, 32.42%(34.12); mol wt (MS), 123 (123.15); IR, 2930, 1560, 1540, 1390, 1020, 925, and 765 cm^{-1}). The melting point, the retention time of glc, and the IR spectrum agreed with those of the authentic sample described above.

Acetamide: The reaction mixture of Exp. 20 gave 0.07 g at 150—174 °C by prepartive glc (Versamide, 9×750 mm, 60 °C—, 6 °C/min, He 125 ml/min) mp 73.5 °C(82.0[13]); C, 40.65(40.67); H, 8.59(8.53); N, 23.31%(23.71). The melting point, the retention time of glc, and the IR spectrum agreed with those of the authentic sample.

Methyl Acetate: This substance was identified from the agreement of the retention time in the glc of the reaction product of Exp. 20 with that of the authentic sample.

Analysis of Reaction Products. The yields of TPT in the reaction products were determined in a manner previously described.[1] The benazmidine was determined as the picrate. The benzamidinium benzoate was determined as a non-volatile and toluene-insoluble matter. The yields of the reaction products other than the above-mentioned substances were determined by two kinds of glc, Reoplex-400, 3×750 mm, 50—200 °C, 4 °C/min, He 25 ml/min and THEED+TEP, 3×2000 mm, 40—110 °C, 2° C/min, He 25 ml/min.

The Reaction of Nitriles under High Pressure. III. The Cyclotrimerization of Aliphatic Nitriles in the Presence of Alcohols and the Rearrangement of the Resulting Trialkyl-1,3,5-triazines to 4-Aminopyrimidines[1]

Koshin YANAGIYA, Masahiko YASUMOTO, and Masahiro KURABAYASHI
6th Division, National Chemical Laboratory for Industry (Tokyo Kogyo Shikensho), Mita, Meguro-ku, Tokyo 153
(Received December 1, 1972)

The examination of the simultaneous formation of symmetrically tri-substituted 1,3,5-triazines, 4-amino-2,5,6-substituted pyrimidines and *N*-pyrimidylamidines in mixtures of lower alcohol and nitrile with more than two hydrogen atoms on the α-position under pressures of a few thousand atm afforded the following information: (1) the triazine is formed by the cyclo-trimerization of the iminoether which is derived from the nitrile and the alcohol; (2) the pyrimidine is formed by the rearrangement of the previously-formed triazine. This rearrangement is caused by an attack of the nucleophilic iminoether on a carbon atom of the triazine ring; and (3) the amidine is assumed to be formed, together with the pyrimidine, by the same attacking mechanism.

In 1952 Cairns, Larchar, and McKusic[2] found that the cyclo-trimerization of acetonitrile to 2,4,6-trimethyl-1,3,5-triazine accompanied the formation of 4-amino-2,6-dimethylpyrimidine and *N*-(2,6-dimethylpyrimidin-4-yl)-acetamidine when acetonitrile was kept under a few thousand atm in the presence of methanol or aqueous ammonia or piperidine at elevated temperatures, and that the triazine was slowly converted to the pyrimidine at 8500 kg/cm² and 150 °C in the presence of methanol. They reported that it was not evident to what extent the triazine may have been an intermediate to the pyrimidine in the trimerization of acetonitrile. This investigation was undertaken in an attempt to determine the mechanism of the conversion of nitriles with more than two hydrogen atoms on their α-carbons into the corresponding 2,4,6-tri-substituted 1,3,5-triazines (I) and the mechanism of the rearrangement of I to the isomeric 4-amino-2,5,6-tri-substituted pyrimidines (II) and to *N*-(2,5,6-substituted pyrimidin-4-yl)-amidine (III), which have the same moieties as the nitriles. Another aim was the elucidation of the above-mentioned unsolved problem proposed by Cairns *et al.*[2]

Results and Discussion

In order to get an overall view of this reaction, acetonitrile was chosen as the nitrile with more than two α-hydrogen atoms and was kept in lower alcohols or other popular solvents at 6600 kg/cm² and 120 °C for 10 hr. The results listed in Table 1 indicate that alcohol is the only promoter of the formation of Ia and that the promotive effect decreases with the increase in the molecular weight of alcohol.[3] The fact that the formation of IIa and IIIa was always accompanied by that of Ia was remarkable in connection with the mechanism of the formation of II and III, (which will be discussed below).

Table 1. Influence of solvents on the formation of Ia, IIa, and IIIa from acetonitrile

Solvent[b]	Reaction conditions			Yields (%)[a]		
	kg/cm²	°C	hr	Ia	IIa	IIIa
CH_3OH	7950	120	10	29.0	5.0	4.0
C_2H_5OH	7950	120	10	5.6	0.1	0.2
H_2O	6650	100	10			
$(C_2H_5)_2O$	6650	100	10			
$(CH_3)_2SO$	6650	100	10			

a) Theoretical yield based on nitrogen atom.
b) The weight of each solvent was the same as that of acetonitrile.

To examine the influence of the moieties of the nitriles, mixtures of ethanol and the same-weight acetonitrile or propionitrile or *n*-butyronitrile were kept under the same reaction conditions. The results are collected in Table 2. The yield of I decreased with the increase in the length of the alkyl chain in the moieties. Similar relations are found between the yield of II or III and the chain length. The fact that three

Table 2. Influence of the moieties of nitriles on the composition of reaction products[a]

R-CH_2CN	Yields (%)				
R	RCH_2CN	$RCH_2C(=NH)OC_2H_5$	I	II	III
H	83.1	1.8_7	11.2	1.5_8	1.5_5

2) T. L. Cairns, A. W. Larchar, and B. C. McKusic, *J. Amer. Chem. Soc.*, **74**, 5633 (1952).
3) This fact was similar to Cairns's data for benzonitrile[2].

Table 3. Influence of iminoether on the reaction products[a)]

CH_3CN (g)	$CH_3C(=NH)OC_2H_5$ (g)	(molar ratio)	C_2H_5OH (g)	Yields (%) Ia	IIa	IIIa
1.93	—	(1: 0)	2.17	16.2	7.1	5.2
1.40	1.50	(2: 1)	1.60	23.7	5.6	4.8
0.67	2.91	(1: 2)	0.68	28.4	7.5	5.5
—	5.03	(0: 1)	—	45.9	6.3	5.8

a) Reaction conditions: 7950 kg/cm², 120 °C, and 24 hr.

kinds of ethyl iminoethers were formed from the respective nitriles gives rise to the assumption that I is formed *via* an iminoether, which is known to be quickly produced from a nitrile and an alcohol under high pressures.[4)] To confirm this assumption, acetonitrile, ethyl acetiminoether, and a mixture of the two were kept in the presence of ethanol under the same pressure. As is shown in Table 3, the greater concentration of the iminoether in the initial mixture resulted the greater yield of Ia. This finding supports the above assumption, which is expressed by Eq. (1):

$$RCH_2CN + R'OH \longrightarrow RCH_2C(=NH)OR' \longrightarrow 1/3\,I + R'OH \quad (1)$$

A similar mechanism has been kinetically proven with an aromatic nitrile by the present authors.[4)]

In Fig. 1, the yields of the products in the acetonitrile–methanol mixture are plotted against the reaction time. In contrast to the gradual increases in the yields of IIa and IIIa with the lapse of the reaction time, the yield of Ia increased to a maximum when the reaction time passed about 50 hr and then decreased gradually with the gradual decrease in the acetonitrile. This fact indicates the conversion of the previously-produced Ia into IIa and IIIa. With the view of determining the mechanism of this conversion, several kinds of amines were added one by one to mixtures consisting of Ia and methanol in the same weight. These mixtures were kept under the same high-pressure conditions. The results are listed in Table 4. The formation of IIa and IIIa was seen

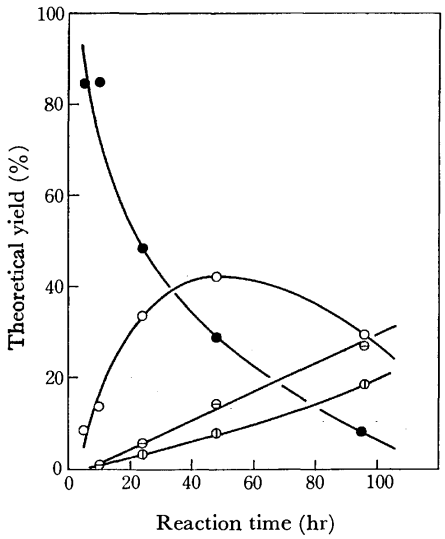

Fig. 1. Time dependence of the composition of the reaction products (theoretical yield based on nitrogen atom) at the starting ratio CH_3CN: CH_3OH=1: 1 (by weight) at 6600 kg/cm² and 100 °C.
●: CH_3CN, ○: Ia, ⊖: IIa, ⓘ: IIIa

only when an amine with less than one active hydrogen atom, such as ammonia, primary amine and secondary amine, was added.[5)] The yield of IIa increased with the increase in the number of the active hydrogen atoms of the additives. Considerable amounts of amines were recovered when ammonia or diethylamine was added, but when *n*-butylamine was added considerable

Table 4. Effect of amines on the rearrangement of I to II and III[a)]

Amines	Yields (%)[c)] CH_3CN[e)]	Ia	IIa	II'a[f)]	IIIa	Amine	Acetamidine[g)]

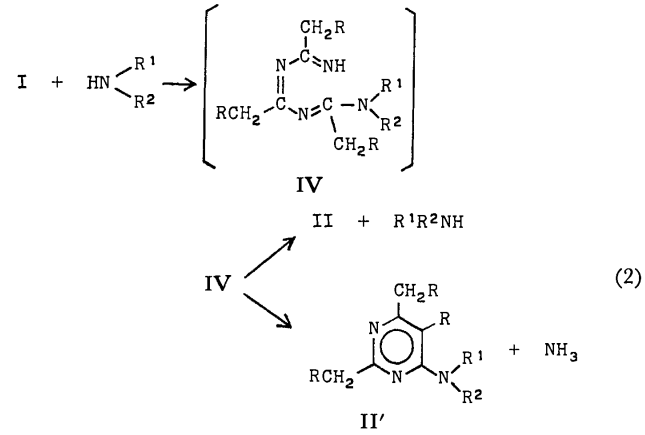
a) Reaction conditions: Ia: Amine: CH_3OH=1: 0.5 (mole); 1 (weight), 8000kg/cm², 100 °C, and 30 hr.
b) In the case without amine, the mixture of same weight of Ia and ethanol was kept at 8000 kg/cm² and 120 °C for 24 hr.
c) Theoretical yield based on nitrogen in the initial Ia.
d) Figures putted in the parenteses are the theoretical yield based on the amines added.
e) Acetonitrile was never detected in the all runs listed in the table.
f) II'a means IIa with the moiety of added amine on its amino-nitrogen.
g) The yields of amidines were determined by use of glc. The details of the identification of them will be mentioned in a later report.
h) Acetamidine was expected to be produced, but its determination was prevented by the coexistence of inseparable Ia.
i) Ammonia yielded in 53% based on the added *n*-butylamine.

4) M. Kurabayashi, K. Yanagiya, and M. Yasumoto, This Bulletin, **44**, 3413 (1971).

5) The promotive effect of ammonia on the rearrangement of Ib to IIb has already been reported.[2)]

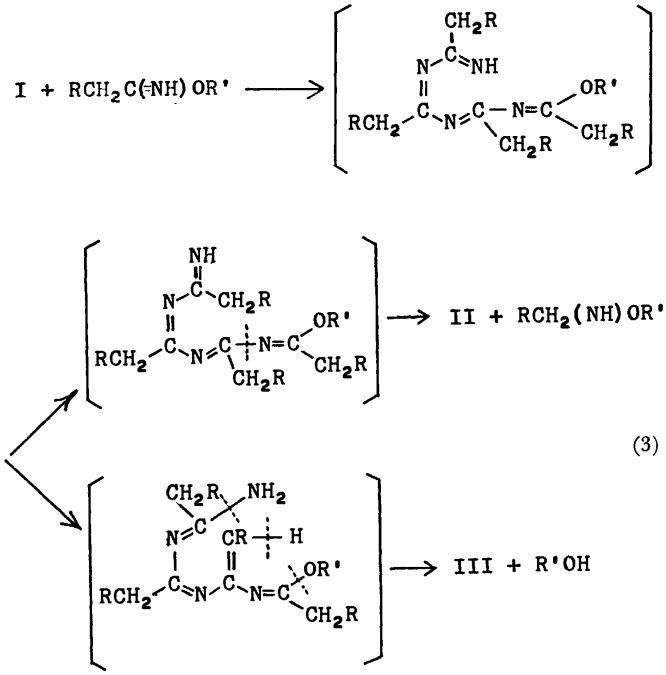
amounts of 2,6-dimethyl-4-*n*-butylaminopyrimidine (II'a) and ammonia were isolated without any recovery of *n*-butylamine. The following rearrangement mechanism is proposed for the conversion of I into II and II' on the basis of these experimental results:



(2)

A triazine ring is attacked on its carbon atom by a neucleophilic nitrogen atom of amine. An open-chain intermediate (IV) is formed by the cleavage of the ring involving the shift of a hydrogen atom of the attacking amine. A ring closing takes place accompanied by a twist of the C–N bond and an elimination of the amine or ammonia. These eliminations both give II and II'.

It may be inferred that, when a reaction is initiated in a nitrile–alcohol mixture, the intermediate iminoether behaves as an amine with an active hydrogen atom and causes I to shift to II and III in the manner shown by Eq. (3):



(3)

This inference is supported by the experimental results listed in Table 5, in which larger yields of IIa and IIIa are seen both in the ethanolic solution of acetonitrile and Ia and in the ethanolic solution of ethyl acetiminoether and Ia than in the ethanolic solution of acetonitrile alone, while no yield of IIa is seen in the ethanolic solution of Ia alone.

It is assumed that the small amounts of acetamidines, which were isolated in the Ia–methanol–amine mixtures (see Table 4), are formed by the partial decomposition of the IVa intermediate to an amidine and acetonitrile:

$$\text{IV} \longrightarrow \text{RCH}_2\text{C(=NH)NR}^1\text{R}^2 + 2\,\text{RCH}_2\text{CN} \qquad (4)$$

It is also assumed that methyl acetiminoether is formed from the acetonitrile thus liberated to satisfy the equilibrium of Eq. (1) and that it attacks Ia to form IIa and IIIa by means of Eq. (3). These assumptions are substantiated by the experimental results that small amounts of IIIa are formed in Ia–methanol–amine mixtures (see Table 4).

It is not speculated that III is formed by an attack of an amino-nitrogen of II on an iminoether under high pressure because of the experimental finding that IIa and ethyl acetiminoether were recovered unreacted from an ethanolic solution of them after a long reflux.

$$\text{CH}_3\text{C}(=\text{NH})\text{OC}_2\text{H}_5 + \text{IIa} \not\longrightarrow \text{IIIa} \qquad (5)$$

On the other hand, we ignored the possibility that, if I is attacked by an amino-nitrogen of II, the resulting IV will give III by means of Eq. (4); we did this in view of the experimental finding that IIIa was not detected in a methanolic or pyrimidine solution of an equimolar mixture of Ia and IIa after 30 hr's standing at 8000 kg/cm² and 120 °C.

$$\text{Ia} + \text{IIa} \not\longrightarrow \left[\text{IVa, R}^1\text{=H; R}^2\text{=}\right.\text{  }\left.\right] \not\longrightarrow \text{IIIa} + 2\,\text{CH}_3\text{CN} \qquad (6)$$

As is shown in Figs. 2 and 3, the elevation of both the reaction pressure and the temperature caused the yields

of Ia, IIa, and IIIa to increase and also caused the yield ratio of IIa to Ia and that of IIIa to Ia to increase. One of the most reasonable interpretations of this experimental fact may be that these elevations promote not only the production of Ia but also the conversion of Ia into IIa and IIIa.[6)]

It is certain that, in a mixture of nitrile and alcohol under high pressures, II and III are produced by the reaction of I with iminoether, although it can not be decided whether this route is the only possible one for the formation of II and III.

Experimental

Reaction Apparatus and Procedure. A mixture of the starting materials was placed in a collapsible lead capsule, was held in a pressure vessel, and was kept under the desired reaction conditions of pressure, temperature, and time by means of a previously-described high-pressure apparatus and procedure.[4)]

Material Supply. The nitriles, alcohols, amines, glacial acetic acid, and solvents were all EP-grade reagents and were dried and distilled. A commercial-grade ammonia was evaporated, dried on sodium hydroxide, and absorbed in methanol.

Ethyl Iminoethers: An iminoether was prepared from a nitrile and ethanol as a hydrochloride by Pinner's method and was liberated by neutralization. $CH_3C(=NH)OC_2H_5$: bp 87—90.5 °C(91[7)]); C, 55.54(55.15 Calcd); H, 10.46(10.41); N, 15.31%(16.08). $C_2H_5C(=NH)OC_2H_5$: 58—59 °C/110 mmHg(110—111[7)]); 59.62(59.37); 11.10(10.96); 13.61% (13.85). n-$C_3H_7C(=NH)OC_2H_5$: 54—55 °C/70 mmHg, 63.03 (62.57); 11.17(11.38); 11.97%(12.16). Methyl acetiminoether was obtained as a mixture containing large amounts of methanol and acetonitrile because of its instability at distillation.

Trialkyl-1,3,5-triazines: These triazines were prepared by the procedure of Schaefer and Peters,[7)] in which an iminoether was cyclotrimerized by the addition of a small amount of acetic acid. Trimethyl-1,3,5-triazine (Ia): yield, 50.7%; bp 155 °C(155[7)]); mp 58.1 °C(59—60[2)]); C, 58.38(58.52); H, 7.64(7.37); N, 34.44%(34.12). Triethyl-1,3,5-triazine (Ib): 74%; 123—125 °C/90 mmHg(128—130/90[7)]); 23 °C(25[7)]); 65.63(65.42); 9.18(9.15); 25.19(25.43). Tri-*n*-proply-1,3,5-triazine (Ic): 36%; 120 °C/13 mmHg(71—72/1[8)]); 69.83 (69.52); 10.01(10.21); 20.16%(20.27).

4-Amino-2,6-dimethylpyrimidine (IIa): The procedure of

6) It will be reported shortly by the present authors that the ring-opening of trialkyl-1,3,5-triazines, similar to that shown by Eq. (3) under high pressures is promoted by the elevation of the pressure or the temperature.

7) F. C. Schaefer and G. A. Peters, *J. Org. Chem.*, **26**, 2778 (1961).

8) A. Ya. Yakubovich, E. L. Zaitseva, G. I. Broz, and V. P. Bazov, *Chem. Abstr.*, **58**, 526 (1963).

Ronzio and Cook as modified by Cairns *et al.*[2] was employed. Acetonitrile was kept in an autoclave with a small amount of sodium methoxide at 150 °C for 12 hr; this yielded the pyrimidine in a 53.8% yield (mp 184.4 °C(182—183[2])); N, 33.63%(34.12)).

4-Chloro-2,6-dimethylpyrimidine: The aminopyrimidine (6.16 g) (0.05 mol) was dissolved in concentrated hydrochloric acid (10 ml) (0.11 mol); the solution was placed in a test tube and then cooled. A concentrated sodium nitrate solution (0.1 mol) was then gently poured into the bottom of the tube. The reaction mixture was neutralized after it had stood overnight and was extracted with ether. The extract was distilled to yield the chloropyrimidine (2.88 g, 46.8%) (bp 82 °C/15 mmHg(182[9])); mp 7.3 °C(7[9])); C, 50.42(50.54); H, 5.09(4.95); N, 18.42(19.65); Cl, 24.11%(24.86).

2,6-Dimethyl-4-n-butylaminopyrimidine (II'a, R^1: H, R^2: n-C_4H_9): A mixture of 4-chloro-2,6-dimethylaminopyrimidine (1.62 g) (0.011 mol) and *n*-butylamine (1.66 g) (0.022 mol) was heated on a water bath. The amount of pyrimidine aimed at in the reaction mixture was determined to be 1.59 g (77.6%) by means of gas-liquid phase chromatography (glc) glc-a (Reoplex-400, 3×750 mm, 50—200 °C, 4 °C/min, He 25 ml/min). When the mixture was fractionated by preparative glc (Carbowax-20 M, 9×750 mm,[10] 220 °C, He 125 ml/min) it gave essentially one fraction (0.5 g) with the retention time of 6—9 min. Found: C, 64.60; H, 9.53; N, 23.10%; infrared (IR), 2960, 2932, 2872, 2862, 1468, 1460, 1384, and 734 cm^{-1} for the *n*-butyl group, 1600, 1505, 1440, and 1360 cm^{-1} for the pyrimidine ring. Calcd for $C_{10}H_{17}N_3$: C, 67.00; H, 9.56; N, 23.44%.

Identification of Reaction Products. *Iminoethers*: Each experiment listed in Table 2 gave one peak of iminoether upon glc-b (Carbowax-1500, 3×1000 mm, 47 °C, He 25 ml/min). These peaks agreed with the corresponding peaks of the authentic samples described above (ethyl acetiminoether: 5.5 min; ethyl propio-: 7.8 min; ethyl *n*-butyro; 16.7 min). Ethyl propioiminoether (0.01 g) was isolated by glc (Carbowax-1500, 67 °C—, 4 °C/min). The IR spectrum of this fraction (3350, 3000, 1655, 1465, 1380, 1345, 1280, 1090, and 835 cm^{-1}) agreed with that of the authentic sample described above.

Trialkyl-1,3,5-triazines: The reactions listed in Table 2 each gave one fraction of triazine in a preparative glc (see Table 6). The retention times of glc-a and the IR spectra of these fractions agreed individually with those of the authentic samples described above.

IIa and IIIa: The mixture of acetonitrile (4.08 g) and methanol (4.08 g) was kept at 145 °C and 8900 kg/cm^2 for 30 hr. The reaction product was then removed from a volatile matter *in vacuo* and co-distilled with kerosene (25 ml) to yield a yellow solid (1.46 g). This solid was extracted with petroleum ether. The residue amounted to 0.79 g. The 0.79 g portion was recrystallized from toluene to yield a white powder (0.62 g) (mp 182—184 °C; C, 58.61 (58.52); H, 7.54 (7.37); N, 33.73% (34.12); λ_{max}^{MeOH} 235 mμ (234, EtOH[2])); log ε, 4.11 (4.02, EtOH[2])); IR, 1594, 1541, 1478, and 1410 cm^{-1} for the pyrimidine ring). These data and the retention time of glc-a agreed with those of the above-described authentic sample of 4-amino-2,6-dimethylpyrimidine. The extract (0.37 g) was recrystallized from petroleum ether to give yellow needles (0.28 g) (mp 148.5 °C (147—148[2])); C, 58.21 (58.52); H, 8.29 (7.37); N, 33.76% (34.12); λ_{max}^{MeOH} 340 mμ (340, EtOH[2])); log ε, 4.51 (4.49, EtOH[2])); IR, 1530 and 1420 cm^{-1} for the pyrimidine ring). This crystal is identical to *N*-(2,6-dimethylpyrimidin-4-yl)-acetamidine.

IIb and IIIb: The reaction products from propionitrile and ethanol listed in Table 2 gave two peaks of glc-a. The former peak, at the retention time of 31 min, is assumed to be that of 4-amino-2,6-diethyl-5-methylpyrimidine. The latter peak, at 35 min, is assumed to be that of *N*-(2,6-diethyl-5-methylpyrimidin-4-yl)-propioamidine.

II'a (R^1: H, R^2: n-C_4H_9): The reaction products from Ia and *n*-butylamine listed in Table 4 were removed from the volatile matter and fractionated by glc (Carbowax-20 M, 312 °C); this gave a fraction (0.2 g) at the retention time of 9 min (C, 66.81; H, 9.49; N, 23.69%; mol wt (from a parent peak of mass spectroscopy), 179 (Calcd 179.25)). These data, the results of glc-a, and the IR spectrum agreed with those of the authentic 2,6-dimethyl-4-*n*-butylaminopyrimidine described above.

Analysis of Reaction Products. The yields of the reaction products were determined mainly by the use of glc-a, but also sometimes by the use of glc (Reoplex-400, 4×2000 mm, 110 °C, He 90 ml/min).

10) The column size and the flow rate of helium for the preparative glcs were always the same in these experiments.

The Reaction of Nitriles under High Pressure. IV. The Replacement of the Substituents of Trialkyl-1,3,5-triazines[1]

Koshin YANAGIYA, Masahiko YASUMOTO, and Masahiro KURABAYASHI

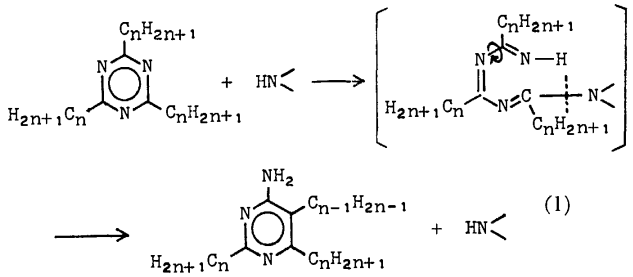
6th Division, National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received December 1, 1972)

It was found that, when some symmetrically 2,4,6-tri-substituted 1,3,5-triazines are kept with an iminoether or an amidine under high pressures and at elevated temperatures, unsymmetrically 2,4,6-tri-substituted 1,3,5-triazines are produced by way of the replacement of one or two $\diagup N \diagdown C \diagup R$ groups of the triazines with the $-N=\overset{|}{C}-R'$ group of the iminoether or that of the amidine. Several mixtures of nitriles and methanol can be used for this replacement reaction in place of iminoethers or amidines at 4000—8000 atm and 100—150 °C. In these mixtures, equilibrium amounts of methyl iminoethers are rapidly formed. Increases in the size of the substituents of the original triazine and in their electron-releasing power inhibit this replacement reaction. Nitriles with an electron-releasing moiety give tri-substituted triazines replaced selectively by one of the original substituents.

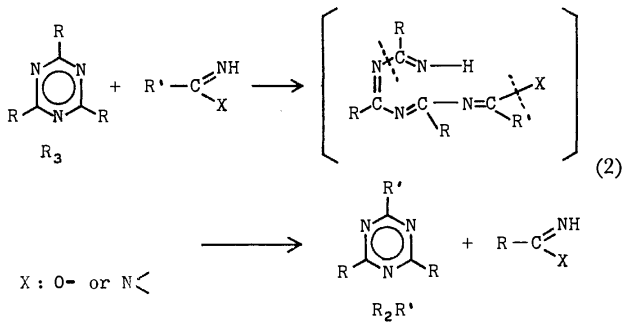
There have been reported no excellent method giving tri-substituted 1,3,5-triazines with two or three different kinds of substituents in a molecule. The stepwise method from cyanuric halide,[2] as one example, requires many synthetic steps and gives a poor yield. The co-trimerization of two kinds of nitriles[3,4] or iminoethers[5] or amidines,[6] and the co-trimerization of an iminoether and an amidine, each of which has a different moiety,[7] as a second example, gives a mixture of four kinds of tri-substituted 1,3,5-triazines, each of which has a different combination of the three substituents. The distribution among the yields of the four triazines was substantially governed by statistical laws, although some cases have been reported in which a triazine with a certain combination of substituents was selectively produced.[4,6,7] The method of substitution on the less available unsubstituted 1,3,5-triazine with iminoethers[8] or amidines,[9] as a third example, gives mono- and di-substituted 1,3,5-triazines, but no tri-substituted one.

It has been made clear[1] that some trialkyl-1,3,5-triazines are rearranged to 4-amino-2,5,6-trialkylpyrimidines by the attack of a nucleophile with an active hydrogen atom, such as primary and secondary amines and ammonia, under a pressure of a few thousand atm in the following manner:



(1)

It was assumed from this rearrangement mechanism that, if a trialkyl-1,3,5-triazine (R_3) is treated with an iminoether ($R'-C\langle^{NH}_{OR''}$) or an amidine ($R'-C\langle^{NH}_{N\langle}$), each of which has a different moiety from the substituents of the triazine, at least one of the three substituents (R) of the triazine may be replaced by the moieties (R') according to the following reaction scheme;



(2)

On the other hand, it is known[10] that an equilibrium amount of iminoether is quickly formed in a mixture of a nitrile and a lower alcohol by means of Eq. (3):

$$R'CN + R''OH \rightleftharpoons R'C\begin{matrix}\diagup NH \\ \diagdown OR''\end{matrix} \qquad (3)$$

Therefore, a mixture of R_3, nitrile R'CN and methanol was kept at 6000—9000 kg/cm² and 100—150 °C. As a result, a mono-replaced triazine (R_2R') was obtained in a good yield. The reaction scheme of Eq. (2) was thus proved actually to take place.

Iminoethers and amidines are known to be synthesized from nitriles under atmospheric pressure. Therefore, many mixtures of nitriles and lower alcohols are thought to be better reagents than iminoethers or amidines for this reaction. This finding may offer a

b) Reaction conditions: mixtures of Me_3, benzonitrile (the same molar amount with Me_3), and methanol (the same weight with Me_3) were kept at 100 °C for 30 hr under the various pressures.
c) Mole fraction based on Me_3.
d) Abbreviations of 4-amino-2,6-dimethylpyrimidine and *N*-2,6-dimethylpyrimidin-4-yl-acetamidine respectively.
e) Methanol was not added.

useful method for the preparation of unsymmetrically tri-substituted 1,3,5-triazines. Some electronic or steric properties of the original substituent and those of the introducing radical, and the relationship between the former and the latter, were shown to have a marked influence on this replacement reaction.

Results and Discussion

The trimethyl-1,3,5-triazine (Me_3), benzonitrile and methanol were kept at 100 °C and 2000—8000 kg/cm² as is shown in Table 1. Methanol was chosen from among the lower alcohols because of the highest equilibrium constant in Eq. (3) among those of the lower alcohols.[10] The reaction scheme proposed by Eq. (2) is supported by the fact that, in contrast to the good yield of Me_2Ph and the fair yields of acetonitrile and methyl benziminoether (MBI) in the presence of methanol at 6000—8000 kg/cm², only an inconsiderable amount of Me_2Ph was yielded without methanol at the same pressure. The progress of the reaction of Eq. (1) was negligibly slow in comparison with that of Eq. (2).

Table 1 shows the marked positive effect of the pressure on this replacement reaction. The ratio of the yield of Me_2Ph at 4000 kg/cm² to that at 2000 kg/cm² was 3.63: 1. This pressure effect is assumed to be due to two factors. One of them is an increase in the equilibrium concentration of iminoether in Eq. (3) with an increase in the pressure, and the other is an increase in the rate constant of Eq. (2) with an increase in the pressure. Here Eq. (2) is supposed to be the rate-determining step. The equilibrium concentrations at the initial point of the reactions at 4000 and 2000 kg/cm² are calculated on the bases of the experimental results reported in a previous paper.[10] These concentrations amount to 0.733 and 0.360 mol l^{-1} respectively.[11] The ratio of the former to the latter amounts to 2.04: 1.[12] This ratio is considerably smaller than the ratio in the yields of Me_2Ph, 3.67: 1 described above. It is clear from these examinations that the pressure effect depends not only upon the increase in the equilibrium constant with an increase in the pressure, but also partially upon the increase in the rate constant of Eq. (2) with that increase. The latter dependence is supported also by the experimental results listed on the first line of Table 2. On the line it is shown that hardly no substituent of Me_3 was replaced by MBI without an increase in the pressure, even at a high concentration of MBI. This high concentration was attained by starting the reaction with a mixture of benzonitrile, MBI, and methanol; it was kept over the equilibrium level throughout the reaction time. It is clear that this replacement reaction does not take place under a pressure of less than a few thousand atm; it starts either with a mixture of R_3 and iminoether or with a mixture of R_3, nitrile, and alcohol.

TABLE 2. REACTION OF METHYL BENZIMINOETHER WITH Me_3 WITHOUT INCREASING PRESSURE[a]

Additive	Yields (%)[b]					
	PhCN	PhC(=NH)OMe	Me_3	Me_2Ph	$MePh_2$	Ph_3
—	3.50	69.1	102.2	2.95		
Et_3N	24.7	47.2	101.8			
EtONa	54.8	7.23	99.1			
AcOH	36.5	6.07	97.5	5.78		13.0

a) Reaction conditions: Me_3: PhC (NH)OMe: MeOH = 1: 1 (in mole): 1 (in weight to Me_3), 100 °C, 30 hr under the saturated pressure of methanol (≈3 kg/cm² gauge.). The lead capsules were filled with the mixtures and placed in an autoclave which was filled with methanol to protect the capsules from rupture.
b) Mole percent based on Me_3.

11) It may be permissible to discuss the results at 100°C on the basis of the data calculated by means of the previously-obtained results at 110°C, because the difference between the pressure dependence of the equilibrium constant at 100°C and that at 110°C is negligible.

12) A smaller value than this can be expected when the calculation is done on the bases of the average concentration in the course of the reaction.

Table 3. Influence of the molar ratio of Me_3 to benzonitrile in the initial mixtures on the yields of the substituent-replaced triazines[a)]

a) Reaction conditions: 6000 kg/cm², 150 °C, 30 hr.
b) Mole percent based on Me_3.

Schaefer and Peters reported that, when 1,3,5-triazine was kept with some iminoethers[8] or amidines,[9] a substitution took place on the 2- or 2- and 4-position of the triazine through a scheme similar to Eq. (2). This difference in reactivity between substituted and unsubstituted 1,3,5-triazines may be caused by the difference in the electron-releasing power between the substituent and the hydrogen atom and by the difference in size between them (see below).

The mixtures of Me_3, MBI, methanol, and a small amount of acids or bases were kept at 100 °C without increasing the pressure with a view to getting a promoter for this replacement reaction. Table 2 shows that this attempt resulted in failure. Acids and bases did not noticeably influence the replacement, but did promote the dissociation of MBI to benzonitrile and methanol.

It is certain that a nitrile eliminated by Eq. (2) is partly re-cyclized to the original triazine, since it is known that nitrile is cyclotrimerized with the help of a lower alcohol under high pressures by means of Eq. (4):[1,10,13]

$$RCN + R''OH \rightleftharpoons R\text{-}C(=NH)OR'' \longrightarrow 1/3\,R_3 + R''OH \qquad (4)$$

Equation (2) is then transformed as Eq. (5) to give the stoichiometrically maximum ratio of R_2R' to R_3:

$$R_3 + 3/2\,R'CN \longrightarrow 3/2\,R_2R' \qquad (5)$$

The results collected in Table 3 indicate that the employment of more than the equimolar amount of benzonitrile to Me_3 was effective in increaseing the yield of Me_2Ph based on Me_3, although nearly quantitative yield by means of Eq. (5) was less possible because of the progress of such side reaction as Eqs. (1), (4), (6), and (7).

The influence of the property of the nitrile moiety on the replacement reaction was examined by keeping equimolar mixtures of Me_3 and various nitriles in methanol under high pressures. The results are shown in Table 4. In the cases of aromatic nitriles, nearly theoretical yields of Me_2R' were obtained. In the case of propionitrile, the only case of an aliphatic nitrile, not only the yield of Me_2R', but also the sum of the yields of Me_2R' and MeR'_2, was far less than the theoretical yields, while the ratio of the yield of MeR'_2 to that of Me_2R' was larger than those in the cases of aromatic nitriles. From these experimental results, the following considerations may be derived. Aromatic iminoether is more basic than aliphatic iminoether[14] probably because of the highly resonating structure of the iminium cation with the aromatic moiety. Therefore, aromatic iminoether may be more active in the replacement reaction, but the resulting mono-replaced triazine may be protected from the next replacement by the increasing density of the π-electron on the carbon atoms of the triazine ring. The increase in the density is caused by the strong electron-releasing power of the newly-introduced aromatic substituent. While aliphatic iminoether is less active in the replacement, the resulting mono-replaced triazine is subject to the next replacement, because the next attack of the iminoether may be less inhibited because of the less electron-releasing property of the newly introduced aliphatic substituent;

$$R_2R' + R'\text{-}C(=NH)X \longrightarrow RR'_2 + R\text{-}C(=NH)X \qquad (6)$$

a) Mole percent based on Me_3.

The influence of the chain length of the original substituents on this replacement reaction is shown in Table 5. The fact that the yields of the mono-replaced triazines decreased with an increase in the length of the original aliphatic substituents suggests that this replacement is hindered by the bulk of the original substituents. The suppressive effect resulting from the electron-releasing power of an aromatic substituent described above is indicated again in this table. The replacement of a substituent of Me_2Ph with a phenyl radical was particularly difficult in comparison with the replacement of a substituent of R_3, such as Me_3, Et_3, and n-Pr_3, by the same radical. These facts suggest that the formation of the small amounts of $MePh_2$ shown in Tables 1, 3, and 4 was due largely to the co-trimerization of the added benzonitrile and the acetonitrile liberated by Eq. (2), and less to the second replacement by Eq. (6).

$$RCN + R'CN \xrightarrow{R''OH} R_3 + R_2R' + RR'_2 + R'_3 \quad (7)$$

In order to demonstrate the excellent applicability of this replacement reaction to the synthesis of unsymmetrically tri-substituted 1,3,5-triazines, R_2R' in particular, the co-trimerization of nitriles under high pressure by means of Eq. (7) was examined as a comparative method. Table 6 indicates that this co-trimerization is not suitable for the selective preparation of a triazine with a desired combination of the three substituents.

Benzamidine, being similar in many cases, to benziminoether in its reacting manner was kept with Me_3 in dioxane at 6000 kg/cm² and 100 °C for 30 hr; this gave the expected triazine, Me_2Ph.

Experimental

Reaction Apparatus and Procedure. The reaction mixtures for these experiments were placed in a collapsible lead capsule and kept under the desired conditions of pressure and temperature for the desired time by means of a high-pressure assembly and procedure described previously.[10]

Materials. The drying and distillation of the reagents (all graded EP) supplied this experiment with benzonitrile, p-tolunitrile, methanol, triethylamine, and glacial acetic acid. The sodium ethylate was prepared in the usual manner in the form of a concentrated ethanolic solution. The β-naphthonitrile (Tokyo Chem. Ind.) and isonicotinonitrile (Koei Chem. Ltd)[10] were used without further purification. The Me_3, Et_3, and n-Pr_3 were the same as have been previously reported.[1] The Me_2Ph was prepared by the reaction of Me_3 with benzonitrile (see below).

Preparation of Authentic Samples, Identification of Reaction Products, and Analysis. Nitriles, Iminoethers, and Benzamidine: The procedures for the preparation, identification, and analysis

of these substances have been described in previous reports.[10,15]

Me_3 and Ph_3: The identification and analysis of these substances were similar in a manner to those previously reported.[15]

Me_2Et, $MeEt_2$, and Et_3: A mixture of equimolar amounts of ethyl acetiminoether and ethyl propioiminoether[1] was added to glacial acetic acid (15 per cent of the total iminoether in the molar fraction), and the resulting mixture was kept at room temperature for 24 hr. The weight ratio of the four triazines produced in the mixture was determined by means of gas-liquid phase chromatography (glc) glc-a[16] to be Me_3: Me_2Et: $MeEt_2$: Et_3=1: 0.9: 0.8: 3.1. The mixture was gradually warmed to 100 °C in 10 hr to complete the co-trimerization. This procedure was carried out with reference to the methods of Schaefer and Peters[17] and Yakubovich *et al.*[5] The reaction mixture was separated from a majority of Me_3 by filtration and was fractionated into the four triazines by glc-A.[18] On the other hand, the reaction product of the mixture of Me_3, propionitrile, and methanol listed in Table 4 was fractionated by glc-A. The first fraction, at 142—148 °C amounted to 0.03 g. Found: bp 175.6 °C; C, 61.96; H, 8.17; N, 29.71%; mol wt (from the parent peak of mass spectroscopy (MS)), 137. Calcd for $C_7H_{11}N_3$: C, 61.29; N, 8.09; N, 30.63%; mol wt, 137.18. The results of the glc-a and infrared (IR) spectrometry of this fraction agreed with those of the 2,4-dimethyl-6-ethyl-1,3,5-triazine described above. The second fraction, at 149—154 °C amounted to 0.02 g. Found: bp 190.8 °C; C, 63.53; H, 8.85; N, 27.48%. Calcd for $C_8H_{13}N_3$: C, 63.55; H, 8.67; N, 27.79%. The data of the glc-a and IR spectrometry agreed with those of the 2,4-diethyl-6-methyl-1,3,5-triazine described above. The third fraction, at 155—160 °C, was a minute amount. The retention time of the glc-a and the IR spectrum (2960, 1540, 1460, 1425, 1390, 1070, 890, 840 cm^{-1}) agreed with those of the authentic sample of triethyl-1,3,5-triazine described above.

Me_2Ph and $MePh_2$: The reaction mixture of the experiment conducted at 7950 kg/cm^2 listed in Table 1, when it was treated by means of preparative glc glc-B,[19] yielded 0.32 g at 190—200 °C (mp 38 °C (34,[7] 35—37[2])); C, 71.16 (71.33 Calcd); H, 5.84 (5.99); N, 23.26% (22.69); mol wt (MS), 185 (185.23); IR, 3070, 2970, 2940, 1540, 1435, 1375, 750, and 690 cm^{-1} for the alkyl, phenyl, and triazinyl groups). It was identified with 2,4-dimethyl-6-phenyl-1,3,5-triazine. The preparative glc gave another fraction (0.11 g) at 230—260 °C (mp 105 °C (110[2])); C, 76.36 (77.71); H, 5.34 (5.30); N, 18.09% (16.99); mol wt (MS), 247 (247.31); IR, 3050, 2950, 1535, 1525, 1425, 1380, 1365, 740, and 680 cm^{-1} for alkyl, phenyl, and triazinyl group). It was determined to be 2,4-diphenyl-6-methyl-1,3,5-triazine.

Et_2Ph and $EtPh_2$: The preparative glc-C[20] of the reaction products in the mixture of Et_3, benzonitrile, and methanol, which are shown in Table 5, gave two fractions. The first amounted to 0.02 g at 196—226 °C. Found: C, 73.48; H, 7.47; N, 19.51%; IR, 3050, 2950, 1590, 1530, 1450, 1420, 1385, 790, and 690 cm^{-1} for the alkyl, phenyl, and triazinyl groups. Calcd for $C_{13}H_{15}N_3$: C, 73.21; H, 7.09; N, 19.71%. This fraction was determined to be 2,4-diethyl-6-phenyl-1,3,5-triazine. The second amounted to 0.005 g at 226—243 °C (IR, 3050, 2950, 1520, 1440, 1380, 740, and 680 cm^{-1}). This fraction is assumed to be 2,4-diphenyl-6-ethyl-1,3,5-triazine.

n-Pr_2Ph: The fractionation by glc-C of the reaction products in the mixture of *n*-Pr_3, benzonitrile, and methanol listed in Table 5, gave a fraction of 0.04 g at 193—217 °C. Found: C, 74.84; H, 7.44; N, 17.39%; IR, 3050, 2950, 1590, 1530, 1450, 1380, 760, and 690 cm^{-1} for the alkyl, phenyl, and triazinyl groups. Calcd for $C_{15}H_{19}N_3$: C, 74.66; H, 7.94; N, 17.42%. This fraction was determined to be 2,4-di-*n*-propyl-6-phenyl-1,3,5-triazine.

Me_2 p-$CH_3C_6H_5$: The reaction products in the mixture of Me_3 and methanol (each 1.66 g) and *p*-tolunitrile (1.58 g) at 8000 kg/cm^2, listed in Table 4, were filtered. The residue was then recrystallized from ethanol to give 0.19 g. Found: mp 78.4 °C; C, 71.68; H, 6.60; N, 21.73%; mol wt (MS), 199; IR, 2920, 1610, 1530, 1430, 1405, 1370, and 790 cm^{-1} for the alkyl, phenyl, and triazinyl groups. Calcd for $C_{12}H_{13}N_3$: C, 72.33; H, 6.57; N, 21.09%; mol wt, 199.25. This crystal was determined to be 2,4-dimethyl-6-*p*-tolyl-1,3,5-triazine.

Me_2 p-ClC_6H_4 and (p-$ClC_6H_4)_3$: The reaction mixture from Me_3 and methanol (each 0.51 g) and *p*-chlorobenzonitrile (0.57 g), listed in Table 4, was separated from the precipitate by filtration, was separated from the volatile matter *in vacuo* and was then recrystallized from ethanol to give 0.55 g. Found: mp 133.1 °C; C, 60.20; H, 4.51; N, 19.24; Cl, 16.43%; mol wt (MS), 219; IR, 3030, 2900, 1570, 1530, 1430, 1400, 1380, 1370, 860, 850, and 790 cm^{-1} for the alkyl, *p*-chlorophenyl, and triazinyl groups. Calcd for $C_{11}H_{10}N_3Cl$: C, 60.14; H, 4.59; N, 19.13; Cl, 16.14%; mol wt, 219.67. It was determined to be 2,4-dimethyl-6-*p*-chlorophenyl-1,3,5-triazine. The precipitate was washed with methanol and amounted to 0.015 g. Found: mp 323 °C; C, 61.34; H, 3.06; N, 10.86; Cl, 24.73%; mol wt (MS), 412; IR, 3050, 1580, 1520, 1400, 1365, 1350, 840, and 800 cm^{-1} for the *p*-chlorophenyl and triazinyl groups. Calcd for $C_{21}H_{12}N_3Cl_3$: C, 61.12; H, 2.93; N, 10.18; Cl, 25.77%; mol wt, 412.71. It was determined to be tris(*p*-chlorophenyl)-1,3,5-triazine.

Me_2 β-Naph: The reaction products from Me_3 and methanol (each 1.55 g) and β-naphthonitrile (1.36 g), listed in Table 4, gave a fraction (0.07 g) at 210—240 °C by glc-C. Found: mp 133.4 °C; C, 75.99; H, 5.43; N, 17.85%; mlo wt (MS), 235; IR, 2950, 1600, 1530, 1470, 1390, 800, 795, and 750 cm^{-1} for the alkyl, naphthyl, and triazinyl groups. Calcd for $C_{15}H_{13}N_3$: C, 76.57; H, 5.57; N, 17.86%; mol wt, 235.27. 2,4-Dimethyl-6-naphth-2-yl-1,3,5-triazine was identical with this fraction.

Me_2 γ-Py, Me γ-Py_2, and γ-Py_3: The reaction products in the mixture of Me_3 and methanol (each 1.73 g) and isonicotinonitrile (1.46 g) listed in Table 4, were separated from the solid product and were then fractionated by glc-C. The fraction at 185—196 °C amounted to 0.48 g. Found: mp 71.8 °C; C, 64.42; H, 5.56; N, 29.93%; mol wt (MS), 186; IR, 3030, 2950, 1600, 1530, 1430, 1390, 1370, 850, 790, and 660 cm^{-1} for the alkyl and heteroaromatic groups. Calcd for $C_{10}H_{10}N_4$: C, 64.50; H, 5.41; N, 30.09%; mol wt, 186.22. This fraction was determined to be 2,4-dimethyl-6-pyrid-4-yl-1,3,5-triazine. The fraction at 228—250 °C amounted to 0.08 g. Found: mp 127.5 °C; C, 66.69; H, 4.76; N, 28.56%; mol wt (MS), 249; IR, 3030, 2950, 1600, 1525, 1430, 1380, 1370, 820, 790, and 670 cm^{-1}. Calcd for $C_{14}H_{11}N_5$: C,

(Received December 4, 1972)

A kinetic study of the fusion reaction and the reaction in dimethyl sulfoxide of 2,6-dichloropurine with 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose was undertaken, and both of them were proved to be of the second order. The activation energy and the activation entropy of the reaction in dimethyl sulfoxide were obtained: $E_a = 38.0$ kcal/mol and $\Delta S^{\neq} = +15.3$ cal/deg·mol. The reaction was thus concluded to be bimolecular involving a considerable unimolecular character. Subsequently, the fusion reactions of 2,6-dichloro- and 2,6,8-trichloropurine with 1,2,3,5-tetra-*O*-acetyl-α- and -β-D-ribofuranose were examined by NMR spectroscopy with respect to the relative content ratios of all the materials and products in each reaction mixture; the results were found to be in good agreement with those obtained by the above kinetic study. On the basis of these results, the mechanism of the fusion reaction was discussed.

In the previous paper,[1] the mechanism of the acid-catalysis and the new activating agents for the reaction of a purine with a fully-acetylated sugar were examined; it was proved that a purine is activated by the interaction with an acidic catalyst to react with an acetylated sugar. Successively, a kinetic study of the reaction of 2,6-dichloropurine (**1**) with 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (**2**) by means of UV absorption spectroscopy, and a study of the process of the reaction of **1** with **2** and 1,2,3,5-tetra-*O*-acetyl-α-D-ribofuranose (**3**) respectively by NMR spectroscopy, were undertaken.

Results and Discussion

*A Kinetic Study of the Reaction of 2,6-Dichloropurine with 1,2,3,5-Tetra-*O*-acetyl-β-D-ribofuranose.* No kinetic study of the synthetic reaction of glycosides by the fusion method has ever been undertaken since the discovery of the fusion reaction for the synthesis of phenyl glycosides. The reasons may be that a remarkable coloration inevitably accompanies the reaction with phenols, although it proceeds under a completely homogeneous state, and that the reaction with purines usually proceeds under a heterogeneous state in addition to a considerable coloration. Fortunately, the reaction of **1** with **2** was found to proceed autocatalytically[2a] under a completely homogeneous state, and it is accompanied by a scarce coloration which may be accepted as showing that the reaction scarcely involves decomposition of the materials or of the resultant 2,6-dichloro-9-(2′,3′,5′-tri-*O*-acetyl-β-D-ribofuranosyl)-purine (**4**). The appearance of the reaction system did not vary much even in the presence of an acidic catalyst provided that the reaction time was not extended much longer.[2b] In view of this, kinetic studies of the fusion reaction and of the reaction in dimethyl sulfoxide of **1** with **2** were undertaken by means of UV-absorption spectroscopy. It was considered possible to follow the reaction by measuring the UV spectra of the reaction mixture at different reaction times, since the spectra of **1** and **4** were found to be completely different from each other in an aqueous ethanolic sodium hydroxide solution (λ_{max} 258 nm[3] and λ_{max} 280 nm respectively). These spectra were confirmed to be unchanged under the present conditions even after 24 hr. An equimolar mixture of **1** and **2**, which were mingled as completely as possible,

2) a) Y. Ishido, T. Matsuba, A. Hosono, K. Fujii, T. Sato, S. Isome, A. Maruyama, and Y. Kikuchi, *ibid.*, **40**, 1007 (1967); b) Y. Ishido, A. Hosono, K. Fujii, Y. Kikuchi, and T. Sato, *Nippon Kagaku Zasshi*, **87**, 752 (1966).

3) The chloro substituent at the 6-position of **4** is known to be susceptible to hydrolysis under alkaline conditions to give 2-chloroinosine[A. Yamazaki, T. Saito, Y. Yamada, and I. Kumashiro, *Chem. Pharm. Bull.* (Tokyo), **17**, 2581 (1969); λ_{max}^{pH13} 258 nm (ε 11400)].

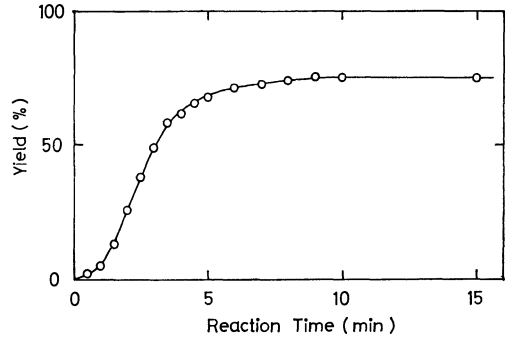

Fig. 1. A plot of the yields of the fusion reaction of **1** with 1,2,3,5-tetra-*O*-acetyl-*β*-D-ribofuranose (**2**).

in a capillary tube was heated at 152—154 °C for a scheduled reaction time in a micro melting-point apparatus. On the basis of the molar extinction coefficients of **1** ($\varepsilon_{280\text{ nm}}$ 8670 and $\varepsilon_{258\text{ nm}}$ 4150) and **4** ($\varepsilon_{280\text{ nm}}$ 2440 and $\varepsilon_{258\text{ nm}}$ 11800) in the same alkaline solvent, the yields of the reaction at each reaction time were calculated by the following simultaneous equations, where A, x, and y stand for the total molar extinctions observed at both of the wavelengths, molar concentration of **1**, and that of **4** after t hr respectively:

$$\begin{cases} A_{258\text{ nm}} = 4150 \cdot x + 11800 \cdot y \\ A_{280\text{ nm}} = 8670 \cdot x + 2440 \cdot y \end{cases}$$

A plot of the yields $[y/(x+y)]$ against the reaction times is shown in Fig. 1; it was thus proved that the equilibrium of the reaction was established at the yield of *ca.* 76%. The reaction can thus be stated to be reversible provided that the reaction is accompanied by no decomposition reaction as has been mentioned above. The reversibility of this reaction was confirmed by a tlc examination and by a UV spectral determination with respect to a mixture which had been obtained by fusing **4** with glacial acetic acid at 150 °C for 15 min. The content ratio of **1** and **4** in this mixture was determined to be 18: 82 on the basis of the total molar extinctions at 258 and 280 nm in the alkaline solvent. Supposing that a stand for the initial concentration of **1**, and that the reaction is of the second order with respect to both reactants and products, the reaction was assumed to conform to the following second-order equation, where k_1 and k_2 stand for the rate constants of the reactants and products respectively:

$$dy/dt = k_1 \cdot (a-y)^2 - k_2 \cdot y^2 \qquad (1)$$

The correlation between k_1 and k_2 can be concluded from the concentrations of **1** and **4** at the equilibrium of this reaction as below:

$$0.24^2 \cdot k_1 = 0.76^2 \cdot k_2 \qquad (2)$$

Supposing the equilibrium constants as K, moreover, Eq. (3) can be obtained:

$$k_2 = \frac{1}{K} \cdot k_1 \qquad (3)$$

When Eq. (3) was substituted into Eq. (1), the resultant equation was integrated to give Eq. (4):

$$t = \frac{2.303 \cdot \sqrt{K}}{2a \cdot k_1} \log \left| \frac{K+\sqrt{K}-(K-1)\cdot y/a}{K-\sqrt{K}-(K-1)\cdot y/a} \right| + \text{Const.} \qquad (4)$$

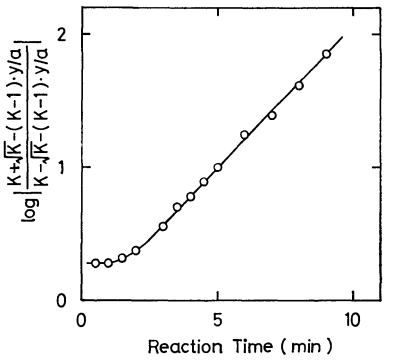

Fig. 2. A plot of $\log|\{K+\sqrt{K}-(K-1)\cdot y/a\}/\{K-\sqrt{K}-(K-1)\cdot y/a\}|$ *vs.* reaction time determined in the fusion reaction of **1** with **2**.

Moreover, y/a corresponds to the yields of the reaction, and K is $76^2/24^2$, which was obtained from Eq. (2). Thus, we can obtain the values of $\log|[K+\sqrt{K}-(K-1)\cdot y/a]/[K-\sqrt{K}-(K-1)\cdot y/a]| = \log|(475-325\cdot y/a)/(247-325\cdot y/a)|$ by measuring the yields at each reaction time. A plot of these values against the reaction time is given in Fig. 2. The deviation of the plots of the initial stage of the reaction from the linearity may be ascribed to the heterogeneity of the reaction mixture because it takes about 2.5 min until the mixture becomes almost homogeneous. According to the figure, it can be concluded that the fusion reaction of **1** with **2** is of the second order with respect to both reactants and products, and that the linear relationship implies that the reaction is reversible and that there is no catalytic effect of the acetic acid co-produced during the reaction.

Subsequently, the rate of the equimolar reaction in dimethyl sulfoxide was measured in the same way, since it was impossible to calculate the precise concentrations of **1**, **2**, and **4** in the fusion state; we thus obtained the activation energy and the activation entropy for the reaction. Supposing that the reaction in dimethyl sulfoxide also conforms to the second-order equation, the following relation can be expected to hold for the reaction:

$$k \cdot t = y/[a \cdot (a-y)] = \frac{y}{x+y} \cdot \frac{1}{a\{1-[y/(x+y)]\}}$$

The values of $y/[a\cdot(a-y)]$ can be determined from the data of UV spectroscopy, which were obtained in the same way as has previously been described; these values were then plotted against the reaction times to give the two linear relationships, which were obtained at 130 and 135 °C as demonstrated in Fig. 3. The rate constants of $k_{130°C}$ and $k_{135°C}$ were calculated as 1.46×10^{-4} l/mol·sec and 2.50×10^{-4} l/mol·sec respectively from the slopes of these linear rate plots. According to the following equations, the activation energy (E_a) and the activation entropy (ΔS^*) of this reaction were calculated as 38.0 kcal/mol and +15.3 cal/deg·mol respectively, where K, h, R, and ΔH^* stand for the Boltzmann constant, the Planck constant, the gas constant, and the activation enthalpy respectively:

$$E_a = \frac{T_1 \cdot T_2}{T_1 - T_2} \cdot R \cdot \ln \frac{k_1}{k_2}$$

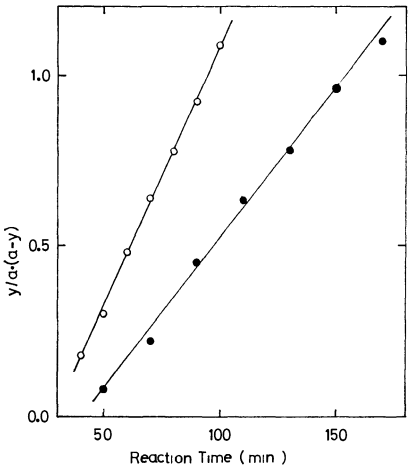

Fig. 3. A plot of $y/a(a-y)$ *vs.* reaction time in the reaction of **1** with **2** in DMSO at 130 °C (—●—) and at 135 °C (—○—).

$$E_a = \Delta H^* + R \cdot T$$

$$k = \frac{K \cdot T}{h} \cdot e^{\Delta S^*/R} \cdot e^{-\Delta H^*/R \cdot T}$$

On the basis of these results, the reaction of **1** with **2** in dimethyl sulfoxide was concluded to be second order, involving a considerable first-order character; *i.e.*, the reaction conceivably proceeds through a bimolecular mechanism involving a considerable unimolecular character. In this case, no catalytic effect of the co-produced acetic acid was also observed. Thus, this fact provides a new concept with respect to the acid-catalysis in the condensation reaction of purines with fully-acetylated sugars, although it has been generally accepted that the reaction may be induced by the interaction of the acidic catalyst with fully-acetylated sugars to give the corresponding *C*-1 carbonium ion—*i.e.*, that the rate-determining step of the reaction may be the step of the carbonium-ion formation.[4] In the autocatalytic reaction of **1** with **2**, the acidic proton of **1** must be concluded to induce the reaction in view of the lack of any catalytic effect of acetic acid. Consequently, it was deduced that the rate-determining step of the reaction must not be the step of the *C*-1 carbonium-ion formation; this was deduced from the facts that the reaction is of a second order and that the more weakly acidic compounds,

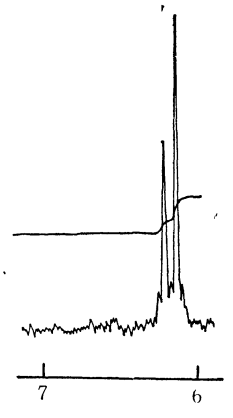
Scheme 1.

such as 6-chloropurine (pK_a=7.68[5]) and 6-cyanopurine (pK_a=6.88[6]) *etc.*, in addition to **1** and in comparison with acetic acid, also gave the corresponding nucleosides in the reaction with **2** in the absence of such acidic catalyst as *p*-toluenesulfonic acid.[2a] Therefore, it is now necessary to postulate another reaction mechanism. On the basis of the above results, the autocatalytic reaction was postulated to proceed *via* the mechanism depicted in Scheme 1, which implies that the rate-determining step of the reaction is the step of the elimination of acetic acid from purines and fully-acetylated sugars. Thus, usual purines may be activated by interaction with acidic catalysts to react with fully-acetylated sugars, and the corresponding nucleosides may be produced accompanied by an electron transfer such as is depicted in the Scheme. The mechanism of the acid-catalysis in the fusion reaction has recently been verified by an investigation of the reaction of 1,2,3,4,6-penta-*O*-acetyl-β-D-glucopyranose with theophylline in competition with *p*-nitrophenol and in the presence of *p*-toluenesulfonic acid;[1] this reaction resulted in the selective formation of 7-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosyl)-theophylline.

*An Examination on the Reaction of 2,6-Dichloropurine with 1,2,3,5-Tetra-*O*-acetyl-α- and -β-*D*-ribofuranose by NMR Spectroscopy.* In order to elucidate the steric course of the fusion reaction, the reactions of **1** with **2** and with



(δ-value)

Fig. 4. The anomeric region (δ 6—7 ppm) of the NMR spectrum ($CDCl_3$, TMS) of the resultant mixture from the fusion reaction of **1** with **2** at 150 °C for 10 min *in vacuo*.

4) a) The fusion reaction was suggested to proceed *via* a $C_{(1)}-C_{(2)}$ orthoester-type carbonium ion on the basis of requirement of 2-*O*-acyl groups in all sugar derivatives thus far examined[T. Shimadate, *Nippon Kagaku Zasshi*, **83**, 214(1962)]; b) The reaction was, on the other hand, considered to proceed *via* the *C*-1 carbonium ion, at least in the case of fully acylated D-ribofuranoses, because of the steric effect of the 3-*O*-acyl group, which may prevent the formation of such a carbonium ion, as has been described by Shimadate[4a] [2b]; The mechanism involving the orthoester-type carbonium ion, which had been proposed by R. U. Lemieux and W. P. Shyluk [*Can. J. Chem.*, **31**, 528 (1953)] in the acid-catalyzed condensation reaction of phenol with 1,2,3,4,6-penta-*O*-acetyl-β-D-glucopyranose, has been reinvestigated by J. I. Bose and T. R. Ingle [*Chem. Ind.*, **1967**, 1451]; they concluded that the reaction proceeded *via* the *C*-1 carbonium ion on the basis of the simultaneous formation of phenyl 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranoside and its β-anomer.

6) A. G. Sorolla, *ibid.*, **80**, 3732 (1958).

3 were examined by NMR spectroscopy. A crude mixture obtained from the fusion reaction of **1** with **2** at 150 °C for 10 min gave an NMR spectrum with the anomeric region shown in Fig. 4. The reaction was thus concluded to give **4** (*H*-1′: δ 6.24 ppm, $J_{1',2'}$= 4.7 Hz) selectively; *i.e.*, it gave a nucleoside with the same anomeric configuration as that of the fully-acetylated sugars used as the starting material. A crude mixture obtained from the same reaction after 60 min gave substantially the same spectrum, as is shown in Fig. 4. No other new anomeric proton signals could be detected, not even by an enhancement of the ratio of signal to noise. Accordingly, it can further be stated that the autocatalytic fusion reaction is not accompanied by any anomerization reaction of the nucleoside once produced in the course of the reaction.

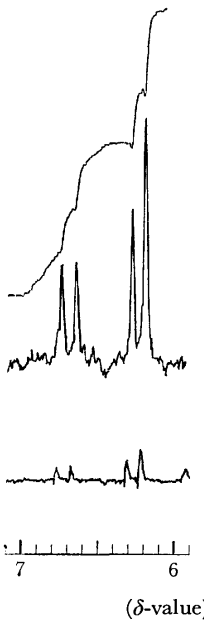

Fig. 5. The anomeric region (δ 6—7 ppm) of the NMR spectrum ($CDCl_3$, TMS) of the resultant mixture from the fusion reaction of **1** with 1,2,3,5-tetra-*O*-acetyl-α-D-ribofuranose (**3**) at 150 °C for 10 min *in vacuo*.

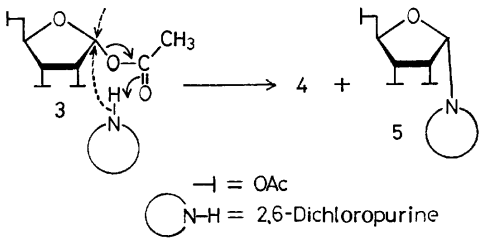
On the other hand, a crude mixture obtained from the reaction of **1** with **3** at 150 °C for 10 min gave a spectrum with the anomeric region shown in Fig. 5; this is in remarkable contrast with that of the reaction with **2**. A new doublet (δ 6.75 ppm, J=5.6 Hz) appeared other than that of **4** in the spectrum. The product, which gave the new doublet, was deduced to be the α-anomer of **4** (**5**) in view of the NMR data reported with respect to the α-D-ribofuranose derivatives.[7] The relative ratio of **4** to **5** in the mixture was calculated to be 59/41 from the integration curve of its spectrum.

The difference in the content ratio of the anomeric nucleosides between the above reaction mixtures were of interest in connection with the reaction mechanism, since no anomerization reaction of the nucleosides is conceivable in the autocatalytic fusion reaction. Incidentally, the fusion reactions of phenol with 2,3,4,6-tetra-*O*-acetyl-1-*O*-trichloroacetyl-β-[8] and -α-D-glucopyranose[9] have been shown to give the corresponding glycosides, with the same anomeric configuration as those of the starting material, in 70 and 20% yields respectively.[10] Thus, the reaction described here can be explained as proceeding through a bimolecular mechanism involving a considerable unimolecular character, *i.e.*, a considerably cationic character, assuming that the conclusion in the kinetic study of the reaction of **1** with **2** in dimethyl sulfoxide is the case for the fusion reaction as well. The results obtained in this section were proved to support the results of the kinetic study strongly. Accordingly, the reaction was deduced



Scheme 2.

to proceed through the mechanism depicted in Schemes 1 and 2. Just after the elimination of acetic acid between **1** and **2** or **3**, accompanied by such electron transfer as is shown in the arrows with ordinary lines, the carbonium ion thus produced may be subjected to the nucleophilic attack of the anion of **1** to afford **4** or **5**. In any case, the reaction conceivably proceeds with a considerably strong interaction between the acidic proton of **1** and the 1-*O*-acetyl group of **2** or **3**. The concomitant formation of **4** and **5** in the fusion reaction with **3** can be explained as being brought about by the steric effect of the 2-*O*-acetyl group of the D-ribofuranosyl ring on the attacking of the resultant anion of **1** on the short-lived *C*-1 carbonium ion.

Subsequently, the acid-catalyzed fusion reaction of **1** with **2** was examined by the same technique in order to elucidate the effect of the acidic catalyst on the relative ratio of the anomeric nucleosides in the resultant reaction mixture. A mixture of **1**, **2**, and sulfamic acid (molar ratio=1 : 1 : 0.02) was heated at 150 °C *in vacuo* for a scheduled period in a small test tube. The resultant mixtures, obtained at the reaction times of 1, 2, 3, 4, 5, 7, and 10 min, were each dissolved in

7) J. D. Stevens and H. G. Fletcher, Jr., *J. Org. Chem.*, **33**, 1709 (1968); where the anomeric proton signals of α- and β-ribazole tri-*O*-acylates were reported to be observed in their NMR spectra ($CDCl_3$, TMS) as follows:

Ribazole	Chemical shift of anomeric protons in δ value($J_{1',2'}$, Hz)	
	Acetate	Benzoate
α-anomer	6.47 (5.0)	6.70 (5.0)
β-anomer	6.08 (5.0)	6.11 (5.0)

8) B. Helferich and B. Gootz, *Ber.*, **62**, 2788 (1929).

9) I. Karasawa and R. Onishi, *Nippon Nogei Kagaku Zasshi*, **33**, 817 (1961).

10) It was elucidated, by an examination with NMR spectroscopy, that these reactions resulted in the predominant formation of the phenyl glycosides with the same anomeric configuration as that of the fully-acylated sugars used for starting materials. The results will be published elsewhere, together with those obtained in the same way with respect to other phenyl glycoside syntheses.

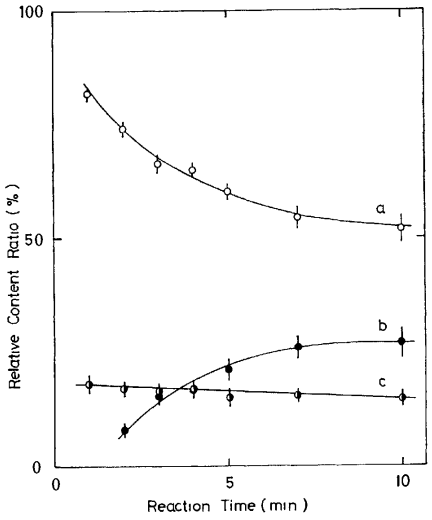


Fig. 6. The outline of the fusion reaction of **1** with **2** in the presence of sulfamic acid as a catalyst at 150 °C *in vacuo*; curves *a*, *b*, and *c* corresponds to the relative content ratio of **4**, the α-anomer of **4**(**5**), and **2** respectively.

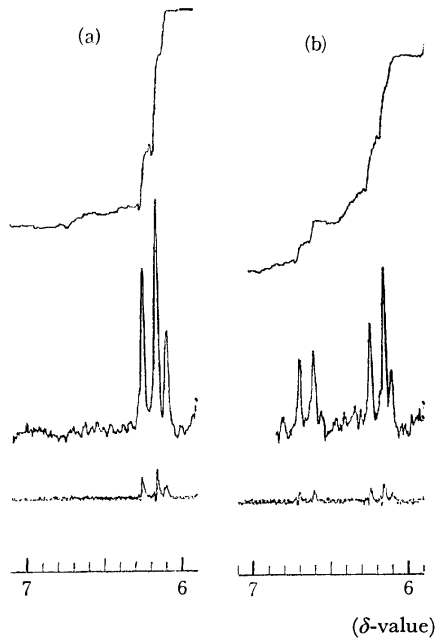

Fig. 7. The observed change in the anomeric region (δ 6—7 ppm) of the NMR spectrum ($CDCl_3$, TMS) in the acid-catalyzed fusion reaction of **1** with **2**; *a* and *b* corresponds respectively to the spectrum of the resultant mixture obtained after 1 and 10 min from the beginning of the reaction.

deuterochloroform, and their NMR spectra were taken. The relative content ratios of **2**, **4**, and **5**, which were calculated from the integration curves corresponding to the anomeric region of each NMR spectrum of the resultant mixtures, were plotted against the reaction times to give an outline of the reaction process such as is shown in Fig. 6. For reference, the spectra of the resultant mixtures obtained after 1 and 10 min are shown in Fig. 7. Judging from Fig. 6, **4** was predominantly produced in the initial stage of the reaction, and its content ratio decreased with the passage of time. Parallel with this decrease, the relative content ratio of **5** gradually increased, although a scarce anomerization of **2** into **3** was observed during the reaction. Incidentally, the anomerization of **4** into **5** was also detected by heating **4** with a catalytic amount of sulfamic acid under the same conditions; this gave the doublet at δ 6.75 ppm corresponding to the anomeric proton of **5**, in addition to that at δ 6.24 ppm corresponding to that of **4**. Consequently, the acid-catalyzed fusion reaction of **1** with **2** was deduced to proceed through this mechanism; *i.e.*, **1** might be activated by the interaction with an acidic catalyst, as was also confirmed recently in a different manner,[1] and the β-nucleoside (**4**) formed by the reaction of activated **1** with **2** might be isomerized into its α-anomer (**5**) by the effect of the acidic catalyst.

An Examination of the Fusion Reaction of 2,6,8-Trichloropurine with 1,2,3,5-Tetra-O-acetyl-D-ribofuranoses by NMR Spectroscopy. An autocatalytic fusion reaction of 2,6,8-trichloropurine (**6**) with **2** at 150 °C was found to give 2,6,8-trichloro-9-(2′,3′,5′-tri-*O*-acetyl-β-D-ribofuranosyl)-purine (**7**) selectively, much as in the reaction of **1** with **2**. The anomeric region of the NMR spectrum of the reaction mixture obtained by heating at the same temperature for 10 min is shown in Fig. 8;

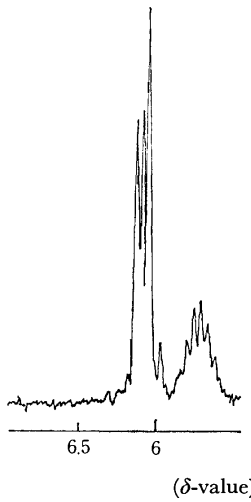

Fig. 8. The anomeric region (δ 6—7 ppm) of the NMR spectrum ($CDCl_3$, TMS) of the resultant mixture from the fusion reaction of 2,6,8-trichloropurine (**6**) with **2** at 150 °C for 10 min *in vacuo*.

the anomeric proton of **7** was observed, together with one of the other ring protons on its D-ribofuranosyl ring, at *ca.* δ 6.1 ppm. Accordingly, the steric course of this reaction can be concluded to be the same as that of the reaction of **1** with **2**. In contrast with the reaction of **1**, an autocatalytic reaction of **6** with **3** and the acid-catalyzed reactions of **6** with **2** and **3** were all found to give **7** predominantly. In the latter two cases, a new doublet (δ 6.60 ppm, J=5.0 Hz) was distinctly observed; this signal may arise from the formation of the α-anomer of **7** (**8**), in view of the data reported with respect to the α-D-ribofuranose derivatives.[7] On the basis of this assumption, the relative content ratios of **7** to **8** were calculated, from the integration curve of each NMR spectrum, as 79/21 and 81/19 respectively. In the reactions of **6**, the

relative content ratio of **8** to **7** was considerably lower than those observed in the reaction of **1** with **2** in the presence of the catalyst and in the autocatalytic and the acid-catalyzed reaction of **1** with **3**. These results can be ascribed to the steric effect of the chloro substituent at the 8-position of **6** in addition to that of the 2-*O*-acetyl group of **2** or **3**. That is, the nucleophilic attack of the anion of **6** from the α-side of the D-ribofuranosyl ring may be largely prevented by those steric effects. A bulky substituent at the 8-position of purine nucleus was also found to affect the relative content ratio of the position isomers of purine nucleosides in a condensation reaction.[11]

These facts, elucidated by the above kinetic and NMR spectroscopic investigation of the reaction of **1** or **6** with **2** or **3**, can be considered to hold for reactions involving other purine derivatives and acetylated sugars.

Experimental

The UV spectra were taken with a Hitachi EPS-3T photoelectronic spectrophotometer. The NMR spectra were taken with a JEOL JNM-C-60 spectrometer in deuterochloroform, with tetramethylsilane as the internal standard.

Rate Determination of the Reaction of 2,6-Dichloropurine with 1,2,3,5-Tetra-O-acetyl-β-D-ribofuranose. a) The Solvent for the Determination of UV Absorption Spectra (0.1 M ethanolic aqueous sodium hydroxide solution): In a measuring flask (500 ml), a 1 M (f=0.887) aqueous sodium hydroxide solution (50 ml) was mixed with ethanol (250 ml), which had then purified by distillation after having been treated with sodium hydroxide under reflux. The mixture was then diluted to the total volume of 500 ml by the addition of distilled water.

b) The UV Spectral Data of 2,6-Dichloropurine (1) and 2,6-Dichloro-9-(2',3',5'-tri-O-acetyl-β-D-ribofuranosyl)-purine (4): The UV spectra of **1** and **4** were determined in the above alkaline solution as follows:

1: $\lambda_{max}^{1M\ NaOH/EtOH\text{-}H_2O}$ 280 nm (ε 8670)

4: $\lambda_{max}^{1M\ NaOH/EtOH\text{-}H_2O}$ 258 nm (ε 11800)

Moreover, the ε_{258nm} of **1** (ε^1_{258nm}) and ε_{280nm} of **4** (ε^4_{280nm}) were determined as follows:

$\varepsilon^1_{258\,nm}$: 4150 $\varepsilon^4_{280\,nm}$: 2440

The data concerned with **4** were used as they were for the calculation of its concentration, because it was convenient to use them for the conversion of its UV spectral data in the calculations, although the data were identical with those reported with respect to 2-chloroinosine.[3]

c) Rate Determination of the Fusion Reaction: Equimolar amounts of **1**[12] (0.0187 g, 0.1 mmol) and 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (**2**)[13] (0.0318 g, 0.1 mmol) were mingled in an agate mortar as completely as possible, and then a suitable amount of the mixture was placed in a capillary tube. The sample in the capillary tube was heated at 152—154 °C for a scheduled period in a Micro Melting Point Apparatus (Yanagimoto Seisakusho Co., Ltd.) and then cooled immediately in an ice-bath after the reaction. The fused mixture was taken out by crushing the capillary tube, and then it was dissolved in the alkaline solvent described in a). The total coefficients of the ε_{258nm} and ε_{280nm} of the resultant solution, which had been properly diluted with the same solvent so as to enable us to determine the UV spectrum, and the yields of the reaction at each reaction time were calculated in the manner described in the text. The $y/(x+y)$[yields] thus obtained were plotted against the reaction times to give an outline such as is shown in Fig. 1.

The reversibility of this reaction was confirmed by heating **4** (300 mg) with glacial acetic acid (0.1 ml) in a small test tube at 150 °C for 15 min in an oil-bath. The tlc examination of the resultant fusion on a plate of Wakogel B5-F (0.25 mm) [the solvent system for the development: benzene–methanol (9: 1 v/v)], in comparison with the authentic **1**, **2**, and **4**, showed the formation of **1** and **2** by the reverse reaction. The spots corresponding to **1**, **2**, and **4** were easily detected by the use of a UV lamp [S. L. Light, Tokyo Machinery Co., Ltd. (2537 and 3650 Å)] or by developing with iodine or with a dilute aqueous sulfuric acid solution, followed by heating. The UV spectral determination of the resultant fusion proved it to be composed of **1** (18) and **4** (82%).

d) Rate Determination of the Reaction of 1 with 2 in Dimethyl Sulfoxide: The reaction rates were determined at 130 °C and at 135 °C. Dimethyl sulfoxide shows no absorption in the vicinity of either 258 or 280 nm under the conditions mentioned above. **1** and **4** were used for the determinations as a 40 mmol/l dimethyl sulfoxide solution. The reaction vessel used for the determinations was a three-necked, 100 ml, round-bottomed flask, fitted with a standard stopcock and an automatic stirrer. The temperature of the reaction bath (Mitamura Riken Kogyo Inc., Type 13—76) was regulated precisely with a thermostat (Jumo Co., Ltd., West Germany) within ±0.2 °C. 20 ml portions of the above freshly-prepared solution of **1** and **2** was pipetted into the reaction vessel, the mixture being constantly stirred at the reaction temperature. After each scheduled reaction time, a small amount of the reaction mixture was taken out with a pipette and diluted properly with the same alkaline solvent so as to enable us to determine the UV spectra. The data thus obtained were treated in the same way as has been described in c).

NMR Examination of the Relative Content Ratios of Anomeric Nucleosides in the Mixtures Obtained by the Fusion Reactions. a) The Sample from the Reaction of 2,6-Dichloropurine (1) with 1,2,3,5-Tetra-O-acetyl-β-D-ribofuranose (2) for NMR Determination: Equimolar amounts of **1** (1.87 g, 10 mmol) and **2** (3.18 g, 10 mmol) were sufficiently mingled in an agate mortar, and then a 200 mg portion of the mixture was put into a small glass test tube. The sample was then heated in the above-described reaction bath at 150 °C *in vacuo* for a scheduled reaction time and subsequently cooled immediately after the reaction in an ice-bath. Each of the resultant mixtures was dissolved in deuterochloroform and then subjected to an NMR determination. The deuterochloroform solution was filtered through a small cotton tampon on precipitation of some crystalline mass. In the case of the acid-catalyzed fusion reaction, a mixture of **1** (10 mmol), **2** (10 mmol), and sulfamic acid (20 mg, 0.02 mmol) was utilized after sufficient mingling in the mortar. The anomeric proton signals of 2,6-dichloro-9-(2',3',5'-tri-*O*-acetyl-β-D-ribofuranosyl)-purine (**4**)[2] and its α-anomer (**5**) were observed at 6.24 ($J_{1',2'}$=4.7 Hz) and 6.75 ($J_{1',2'}$=5.6 Hz) ppm respectively (*cf.* Figs. 4, 6, and 7).

b) The Sample from the Fusion Reaction of 1 with 1,2,3,5-

11) A similar steric effect of 8-halogeno substituents has recently been reported in the condensation reaction of 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide with 8-chloro(or -iodo)adenine, which brought about the preferred formation of the corresponding nucleoside glycosylated at $N_{(3)}$ in the purine nucleus[C. L. Schmidt and L. B. Townsed, *J. Org. Chem.*, **37**, 2300 (1972)].

12) G. B. Elion and G. H. Hitchings, *J. Amer. Chem. Soc.*, **78**, 3508 (1956).

13) H. Zinner, *Chem. Ber.*, **83**, 517 (1950).

Tetra-O-*acetyl*-α-D-*ribofuranose (3)*: The sirup of **3**, which had been prepared according to the method of Zinner,[14] was found to be composed of **2** and **3** in the ratio of 13/87, by a study of the integration curve of its NMR spectrum, in which a quartet (δ 6.80, *H*-1 of **3**) and a singlet (δ 6.28, *H*-1 of **2**) were observed in the anomeric region. An equimolar mixture of **1** and **3** was prepared in the way described in connection with the previous experiment, a). A 200 mg portion of this mixture was put into a small test tube and similarly subjected to a reaction. After the reaction, the resultant mixture was dissolved in deuterochloroform and used for the NMR determination (*cf.* Fig. 5).

c) The Sample from the Fusion Reaction of 2,6,8-Trichloropurine (6) with 2 or 3: The mixture of **6**[15] and **2** or **3** for the autocatalytic or acid-catalyzed fusion reaction was prepared in the way described in a) and then treated similarly. The resultant mixtures were dissolved in deuterochloroform, filtered with a small cotton tampon if needed, and used for the NMR determination. The anomeric proton signals of 2,6,8-trichloro-9-(2′,3′,5′-tri-*O*-acetyl-β-D-ribofuranosyl)-purine (**7**)[2a] and its α-anomer (**8**) were observed at *ca.* δ 6.1 ppm, together with the other one proton on the D-ribofuranosyl ring, and at 6.60 ($J_{1',2'}$=5.0 Hz) ppm respectively (*cf.* Fig. 8).

The authors wish to express their thanks to Professor Juji Yoshimura, Tokyo Institute of Technology, for his valuable discussions throughout this work, and to Mr. Keiji Eguchi, Japan Electric Optics Lab., for his help in carrying out the NMR spectral measurement of the samples. They are also grateful to the Ministry of Education, Japanese Government, for a Scientific Research Grant-in-Aid.

Oxidative Additions of Alkyl Halides to Palladium(0) Carbonyl Complex

Koji KUDO, Michito SATO, Masanobu HIDAI, and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Tokyo 113

(Received February 3, 1973)

Oxidative addition reactions of alkyl halides to $Pd(CO)(PPh_3)_3$ were studied. Vinyl chloride, allyl chloride, allyl bromide, methallyl chloride, benzyl bromide, methyl iodide, and iodobenzene react with $Pd(CO)(PPh_3)_3$ to afford the corresponding acyl complexes of the type *trans*-$PdX(COR)(PPh_3)_2$. The reactions proceed rapidly when the dissociation energy of carbon-halogen bond in the saturated alkyl halides is smaller than about 60 kcal/mol. In the case of the unsaturated alkyl halides the more inert carbon-halogen bond can be activated by initial formation of π complexes.

Oxidative addition reactions to lower valent metal complexes are currently drawing considerable attention in relation to transition metal catalysis. The reactions with alkyl compounds often give products possessing stable metal-carbon σ bonds.

So far the acyl complexes of palladium(II) of the type *trans*-$PdX(COR')(PR_3)_2$ reported have been limited to acetyl or benzoyl complexes such as *trans*-$PdCl(COMe)(PPh_3)_2$ prepared by oxidative addition of acetyl chloride to $Pd(PPh_3)_4$[1] and *trans*-$PdX(COR)(PEt_3)_2$ (R=Me or Ph) prepared by carbonylation of *trans*-$PdX(R)(PEt_3)_2$.[2] We found that oxidative addition of alkyl halides to $Pd(CO)(PPh_3)_3$ gives the acyl complexes of this type.[3] In this paper we wish to report the reactivity of various alkyl halides towords $Pd(CO)(PPh_3)_3$.

Results and Discussion

Reactions were carried out by addition of excess alkyl halides to toluene solutions containing $Pd(CO)(PPh_3)_3$ under carbon monoxide at 1 atm. Immediate reaction took place, the original yellow color of the solutions paled and the solutions were stirred for 1—2 hr at ambient temperature for completion of the reactions. After addition of *n*-hexane to the solutions, the acyl complexes were obtained.

Among the alkyl halides examined, allyl chloride, allyl bromide, methallyl chloride, benzyl bromide, and iodobenzene react with the carbonyl complex rapidly, giving the corresponding acyl complexes of the type *trans*-$PdX(COR)(PPh_3)_2$ in high yields.

$$Pd(CO)(PPh_3)_3 + R\text{-}X \longrightarrow PdX(COR)(PPh_3)_2$$

Methyl iodide gave two isomers of methyl complexes in addition to the expected acetyl complex. Vinyl chloride is less reactive and the oxidative addition product was obtained in a poor yield.[3] Other alkyl halides such as PhBr, $PhCH_2Cl$, MeBr, EtI, EtBr, *n*-PrCl, *n*-PrBr, *i*-PrCl, *i*-PrBr, $CCl_2{=}CCl_2$ or *cis*-CHCl=CHCl did not react, the carbonyl complex being recovered.

The reactivity of alkyl halides decreased in the order iodide>bromide>chloride, and allyl≈methallyl>benzyl>phenyl≈methyl>vinyl>propyl≈ethyl. In a series of alkyl chlorides, allyl, and methallyl chlorides give the acyl complexes in high yields but not benzyl chloride. Benzyl bromide gives the acyl com-

Me-	—	80	X[b]	67	26[a,c]	54
Ph-	—		X[b]	71	95	61

a) Quoted from Ref. 3.
b) No reaction occurred.
c) $PdI(Me)(PPh_3)_2$ (2 isomers) were also obtained(30%).

plex, whereas in the case of methyl and phenyl halides only iodides react with the carbonyl complex. The reaction of vinyl chloride gives the acyl complex in a poor yield. No reaction takes place in the case of propyl and ethyl halides. This is in line with the increase of the dissociation energy (Ed) of the carbon-halogen bond in alkyl halides (Table 1). The reaction of the saturated alkyl halides proceeds rapidly when Ed is smaller than about 60 kcal/mol. Unsaturated compounds which have larger Ed undergo oxidative additions. For example, methallyl chloride undergoes reaction, though Ed is 70 kcal/mol, comparable to that of methyl and phenyl bromides which do not undergo oxidative addition. Even more inert vinyl chloride (Ed=85.5 kcal/mol) gives $PdCl(COCH=CH_2)(PPh_3)_2$, though in a poor yield. This may be explained by the initial coordination of the unsaturated compounds to palladium through a π-bonding, which would cause the activation of the carbon-halogen bond, followed by isomerization to the acyl complexes.

In these oxidative addition reactions to zero-valent palladium complexes, the dissociated species are generally considered to be active species. Since $Pd(CO)(PPh_3)_3$ dissociates to a coordinatively unsaturated species $[Pd(CO)(PPh_3)_2]$ in solution,[3] the reaction probably proceeds according to the following scheme:

$$Pd(CO)(PPh_3)_3 \rightleftharpoons [Pd(CO)(PPh_3)_2] + PPh_3 \xrightarrow{R\text{-}X}$$
$$[PdX(R)(CO)(PPh_3)_2] \longrightarrow PdX(COR)(PPh_3)_2$$

The unsaturated species $[Pd(CO)(PPh_3)_2]$ is susceptible to electrophilic attack by alkyl halides, giving the unstable five-coordinate palladium(II) carbonyl complex $[PdX(R)(CO)(PPh_3)_2]$. An immediate insertion of the carbonyl ligand into the palladium-alkyl bond may occur to produce the acyl complexes $Pd(COR)X(PPh_3)_2$. The alkenyl halides initially react with the coordinatively unsaturated species $[Pd(CO)(PPh_3)_2]$ to form π complexes $[Pd(C=C)(CO)(PPh_3)_2]$, followed by isomerization to the acyl complexes. This is supported by the fact that vinyl chloride reacts with $Pd(PPh_3)_4$ affording an unstable π-complex.[4] The reaction mechanism involving the initial formation of alkyl complexes $PdX(R)(PPh_3)_2$ followed by carbonylation with atmospheric carbon monoxide is reasonably excluded for the following reasons: the acetyl complex could be obtained by a reaction of methyl iodide under nitrogen atmosphere, and Booth and Chatt reported that carbonylation of the aromatic phosphine complexes of palladium-alkyl was unsuccesful.[2]

The acyl complexes obtained here are stable in an inert atmosphere. It is reasonable that they have a *trans*-structure in analogy with $PdCl(COCH_2CH=CH_2)(PPh_3)_2$ which shows ν(Pd–Cl) at 320 cm^{-1} corresponding to a *trans*-square planar. It is known that the *trans*-isomer is more stable in these palladium(II) phosphine complexes than the *cis*, especially in the presence of excess triphenylphosphine.[1]

Table 2. IR data and decomposition points of *trans*-$PdX(COR)L_2$ (L=PPh_3)

Complex	ν(C=O)	ν(C=C) cm^{-1}	°C
$PdCl(COCH=CH_2)L_2$	1665	1620	—
$PdCl(COCH_2CH=CH_2)L_2$	1675	1636	115
$PdBr(COCH_2CH=CH_2)L_2$	1687	1640	—
$PdBr(COCH=CHCH_3)L_2$	1680	1634	—
$PdCl(COCH_2CMe=CH_2)L_2$	1695	1647	70
$PdBr(COCH_2Ph)L_2$	1696	—	105
$PdI(COMe)L_2$	1690	—	141
$PdI(COPh)L_2$	1634	—	107

IR spectra of the acyl complexes show a strong absorption at 1700—1630 cm^{-1}, assignable to C=O stretching (Table 2). The low shift of ν(C=O) for the benzoyl complex may be attributed to the conjugation between the caronyl group and phenyl ring. A slight conjugation between the carbonyl group and the carbon-carbon double bond is observed in the acryloyl complex obtained by the reaction of vinyl chloride. The product from allyl chloride exhibits absorptions at 1675 and 1636 cm^{-1} assignable to ν(C=O) and ν(C=C), respectively. Deformations of terminal vinyl group occur at 990 and 905 cm^{-1}, indicating that the complex is 3-butenoyl complex $PdCl(COCH_2CH=CH_2)(PPh_3)_2$. On the other hand, the product from allyl bromide shows ν(C=O) at 1687 and 1680 cm^{-1} and ν(C=C) at 1640 and 1634 cm^{-1}, respectively, indicating the formation of two isomers, presumably 2- and 3-butenoyl complexes. The absorption bands at 1680 and 1634 cm^{-1} are assignable to 2-butenoyl complex $PdBr(COCH=CHCH_3)(PPh_3)_2$, since the slight conjugation between C=O and C=C groups is expected to shift the bands to lower region. Separation of the two isomers was unsuccessful. The relationship between ν(C=O) and thermal stability of the acyl complexes was not observed. This may be explained by the fact that contribution of back donation from palladium to acyl group to stability is small, though the back donation is expected to strengthen the palladium-acyl bond and be reflected in ν(C=O).

Experimental

IR spectra were recorded as Nujol mulls on a JASCO DS-403 spectrophotometer. Decomposition points were measured in an argon atmosphere and are uncorrected. $Pd(CO)(PPh_3)_3$ was prepared according to Method B in literature.[3]

Reaction of Methallyl Chloride. 0.12 ml of methallyl

4) P. Fitton and J. E. McKeon, *Chem. Commun.*, **1968**, 4.

chloride was added through a syringe to a toluene solution (3 ml) containing 0.12 g of $Pd(CO)(PPh_3)_3$ at $-10°$. The solution immediately turned from orange-yellow to pale yellow. It was stirred for 2 hr at ambient temperature, during which course of time 0.085 g (91%) of *trans*-$PdCl(COCH_2CMe{=}CH_2)(PPh_3)_2$ precipitated. Decomp. 70 °C. Found: C, 65.6; H, 4.8%. Calcd for $C_{41}H_{37}OClP_2Pd$: C, 65.7; H, 5.0%.

Reaction of Allyl Bromide. A mixture of *trans*-$PdBr(COCH_2CH{=}CH_2)(PPh_3)_2$ and *trans*-$PdBr(COCH{=}CHCH_3)(PPh_3)_2$ (0.069 g; 95%) was obtained analogously from 0.086 g of $Pd(CO)(PPh_3)_3$ and 0.08 ml of allyl bromide in 3 ml of toluene. Found: C, 60.2; H, 4.7%. Calcd for $C_{40}H_{35}OBrP_2Pd$: C, 61.6; H, 4.5%.

Reaction of Benzyl Bromide. 0.10 g (81%) of *trans*-$PdBr(COCH_2Ph)(PPh_3)_2$ was obtained from 0.14 g of $Pd(CO)(PPh_3)_3$ and 0.18 ml of benzyl bromide in 3 ml of toluene. Decomp. 105 °C. Found: C, 64.1; H, 5.0%. Calcd for $C_{44}H_{37}OBrP_2Pd$: C, 63.7; H, 4.5%.

Reaction of Iodobenzene. 0.056 g (95%) of *trans*-$PdI(COPh)(PPh_3)_2$ was obtained from 0.063 g of $Pd(CO)(PPh_3)_3$ and 0.08 ml of iodobenzene in 3 ml of toluene. Decomp. 107 °C. Found: C, 59.6; H, 3.9%. Calcd for $C_{43}H_{35}OIP_2Pd$: C, 59.8; H, 4.1%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2822—2827 (1973)

Linear Conjugated Systems Bearing Aromatic Terminal Groups. XII.[1] Syntheses and Electronic Spectra of α,ω-Di-2-pyrenyl- and α,ω-Di-2-fluorenylpolyenes

Yasuhira TAKEUCHI, Akio YASUHARA, Shuzo AKIYAMA, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received December 14, 1972)

The syntheses of α,ω-di-2-pyrenyl- and α,ω-di-2-fluorenylpolyenes I_n and I_n' ($n=1$—6) by means of the Wittig reaction are described. Aldehydes II, II′, propenals IV, IV′, pentadienals V, V′ bearing 2-pyrenyl or 2-fluorenyl terminal group and muconaldehyde VI were used as carbonyl components. Phosphoranes III, III′, VII, VII′, VIII and VIII′ were prepared from methyl-, propenyl-, and pentadienyltriphenylphosphonium bromides substituted with 2-pyrenyl or 2-fluorenyl group by the reaction with phenyllithium. I_n and I_n' were obtained by the reaction of carbonyl components with phosphoranes by proper combination. It was found that the bathochromic shift of the longest-wavelength peaks of I_n and I_n' can be expressed by the following empirical equations:

$$I_n : \lambda = 44.6n^{0.7} + 314 \text{ (nm in tetrahydrofuran)}$$

$$I_n' : \lambda = 29.5n^{0.8} + 353 \text{ (nm in tetrahyhrofuran)}$$

The bathochromic shift of the longest-wavelength absorption maxima (λ) of some α,ω-diarylpolyenes [$Ar(CH=CH)_nAr$] can be expressed by the empirical formula $\lambda = An^x + B$.[2,3] The value of x changes with terminal group and the position of linking of polyene chain. This indicates a marked influence of terminal groups on the electronic excitation of polyene chromophore. The present paper deals with the syntheses and electronic spectral regularity of α,ω-di-2-pyrenyl- and α,ω-di-2-fluorenylpolyenes (I_n and I_n', $n=1$—6) which were carried out for the purpose of getting information on the role of aromatic terminal groups on the spectral regularity of diarylpolyenes.

Syntheses. The syntheses of I_n and I_n' were carried out by the Wittig reaction. The combination of carbonyl component and phosphorane is shown in the Scheme. 2-Formylpyrene[4] (II) and 2-formylfluorene[5] (II′) were prepared by the reported methods. 3-(2-Pyrenyl)-2-propenal (IV) was prepared by the reaction of lithium ethoxyacetylide with II followed by reduction with lithium aluminum hydride and anionotropic rearrangement under acidic conditions. 3-(2-Fluorenyl)-2-propenal (IV′) could be obtained by the Meyer-Schuster rearrangement of 1-(2-fluorenyl)-2-propyn-1-ol derived from II′. The reaction of Grignard derivative of methoxybutenyne with the aldehyde (II or II′) followed by reduction and acid treatment afforded 5-aryl-2,4-pentadienal (V or V′) in a reasonable yield.

Phosphorane (III) was prepared from 2-pyrenylmethyltriphenylphosphonium bromide.[6] 2-Formyl-

1 $\underset{\text{II, II'}}{RCHO} + \underset{\text{III, III'}}{RCH=PPh_3} \longrightarrow \underset{I_1,\ I_1'}{RCH=CHR}$

2 $\underset{\text{IV, IV'}}{RCH=CHCHO} + \underset{\text{III, III'}}{RCH=PPh_3} \longrightarrow \underset{I_2,\ I_2'}{R(CH=CH)_2R}$

Table 1. Physical properties of di-2-pyrenyl- and di-2-fluorenylpolyenes (I_n and I_n')

	Di-2-pyrenylpolyene (I_n)			Di-2-fluorenylpolyene (I')		
n	Color of crystals	Mp (°C)	δ (cm^{-1})	Color of crystals	Mp (°C)	δ (cm^{-1})
1	greenish yellow	>360	951	colorless	304—305	967
2	pale yellow	354—355	974	yellow	301—302	990
3	yellow	329—330	980	yellow	296—297	1000
4	yellow	320	987	yellow	289—291	1005
5	orange	303	990	yellow	277	1005
6	orange	298—299		orange	298—300	1005

5 $R(CH{=}CH)_2CHO$ (V, V′) + $R(CH{=}CH)_2CH{=}PPh_3$ (VII, VII′) ⟶ $R(CH{=}CH)_5R$ (I_5, I_5')

6 $RCH{=}CHCH{=}PPh_3$ (VIII, VIII′) + $OCH(CH{=}CH)_2CHO$ (VI) ⟶ $R(CH{=}CH)_6R$ (I_6, I_6')

fluorene (II′) was reduced to 2-hydroxymethyl derivative by sodium borohydride, which was converted into 2-bromomethylfluorene by the usual method. 2-Fluorenylmethyltriphenylphosphonium bromide prepared by the reaction of triphenylphosphine with 2-bromomethylfluorene was treated with phenyllithium to give phosphorane (III′). Reduction of propenal (IV or IV′) with sodium borohydride afforded the corresponding propenol, which was converted into propenyl bromide and treated with triphenylphosphine to give triphenylphosphonium bromide. The reaction of phenyllithium with the phosphonium bromide gave phosphorane (VIII or VIII′). Similarly, 5-aryl-2,4-pentadienal (V or V′) was converted into phosphorane (VII or VII)′ *via* pentadienol and pentadienyl bromide.

1,2-Di(2-pyrenyl)- and 1,2-di(2-fluorenyl)ethylene (I_1 and I_1') were obtained by the reaction of aldehydes (II and II′) with phosphoranes (III and III′), respectively. The combination of propenal (IV or IV′) with phosphorane (III or III′) afforded 1,4-di(2-pyrenyl)- or 1,4-di(2-fluorenyl)-1,3-butadiene (I_2 or I_2'). 1,6-Di(2-pyrenyl)- and 1,6-di(2-fluorenyl)-1,3,5-hexatrienes (I_3 and I_3') were prepared by the reaction of pentadienals (V and V′) with phosphoranes (III and III′), respectively. The reaction of muconaldehyde (VI) with III or III′ afforded 1,8-di(2-pyrenyl)- or 1,8-di(2-fluorenyl)-1,3,5,7-octatetraene (I_5 or I_5'). The reaction of propenylidenephosphorane (VIII or VIII′) with muconaldehyde (VI) gave 1,12-di(2-pyrenyl)- or 1,12-di(2-fluorenyl)-1,3,5,7,9,11-dodecahexaene (I_6 or I_6').

The color of crystals, melting points and wave number of IR absorption in the region of C–H out-of-plane deformation (δ) of *trans*-double bond are summarized in Table 1. Regular increase in melting point with the increase of n reported for α,ω-diphenylpolyenes[7] could not be observed in the series of I_n and I_n'. The solubility of both series of polyenes

a) Owing to poor solubility, the spectra of I_{4-6} were measured with solutions of unknown concentration employing 10 cm glass cells. b) Shoulder. c) Absorption maxima of L_b species.

7) R. Kuhn and A. Winterstein, *Helv. Chim. Acta*, **11**, 87 (1928).

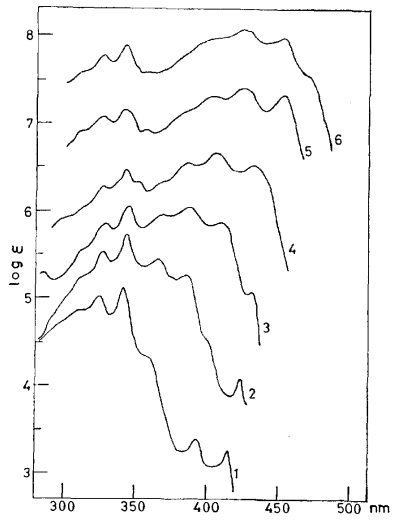

Fig. 1. Absorption curves of di-2-pyrenylpolyenes (I_n) in tetrahydrofuran. The spectra of I_{4-6} were measured with solutions of unknown concentration using 10 cm glass cells. Each curve, except for I_1, has been displaced upward by a 0.5 log ε unit increment from one immediately below it.

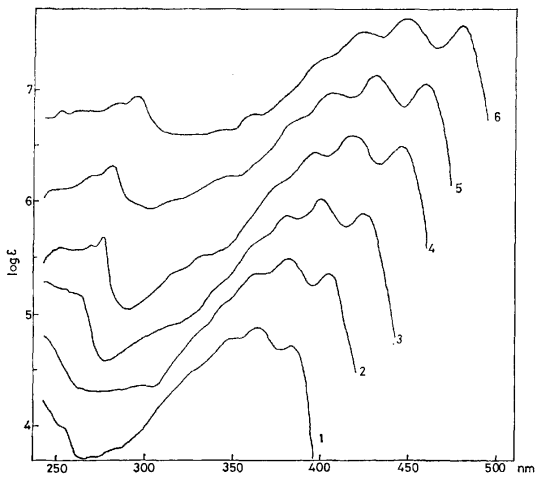

Fig. 2. Absorption curves of di-2-fluorenylpolyenes (I'_n) in tetrahydrofuran. Each curve, except for I_1', has been displaced upward by a 0.5 log ε unit increment from one immediately below it.

decreases markedly with the increase in n. Shift of δ to higher wave number along with the increase of n observed in other series of diarylpolyenes[2,3] was also found in the series of I_n and $I_{n'}$.

Electronic Spectra. Numerical data of the electronic spectra of I_n and $I_{n'}$ are summarized in Table 2. The absorption curves of both series of diarylpolyenes I_n and $I_{n'}$ exhibit well-defined vibrational fine structure (Figs. 1 and 2). The characteristic of electronic spectra of I_n and $I_{n'}$ is similar to that of other series of diarylpolyenes,[2,3] *i.e.*, the intense bands in the long-wavelength region, which seems to arise from an interaction of L_a band of the terminal group with the polyene chromophore, shift to longer wavelength with the increase in n. However, the increase in the length of polyene chain exerts a minor effect on the location of short wavelength bands. The weak absorption maxima at the longest-wavelength region observed in I_1, I_2, and I_3 can be attributed to the L_b band of pyrene nucleus. Discussion is given on the spectral regularity for the longest-wavelength sub-bands (λ) of the intense long-wavelength absorption band. It was found that the plots of λ of I_n and $I_{n'}$ *versus* $n^{0.7}$ and $n^{0.8}$, respectively, gave good straight lines (Figs. 3 and 4). The following empirical equations can well express the linear relationships:

$$\lambda = An^{\pi} + B$$

I_n : $\lambda = 44.6n^{0.7} + 314$ (nm in tetrahydrofuran)

$I_{n'}$: $\lambda = 29.5n^{0.8} + 353$ (nm in tetrahydrofuran)

The linear relationship of acetylenic analogues of I_n and $I_{n'}$, 2,2′-dipyrenylpoly-ynes[4] and 2,2′-difluorenylpoly-ynes[8] can be expressed by $\lambda=12.6\ n^{1.4}+327$ (nm in toluene) and $\lambda=9.0\ n^{1.5}+350$ (nm in tetrahydrofuran). The value of A in polyene series were found to be much larger than those in poly-yne analogues. This indicates that the electronic interaction of aromatic terminal group with polyene chromophore differs from that with poly-yne system, since the value of A can be regarded as a measure of interaction between terminal group and unsaturated function.

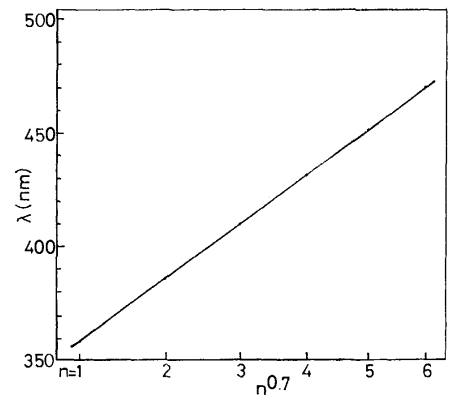

Fig. 3. Plot of λ *vs.* $n^{0.7}$ for di-2-pyrenylpolyenes (I_n).

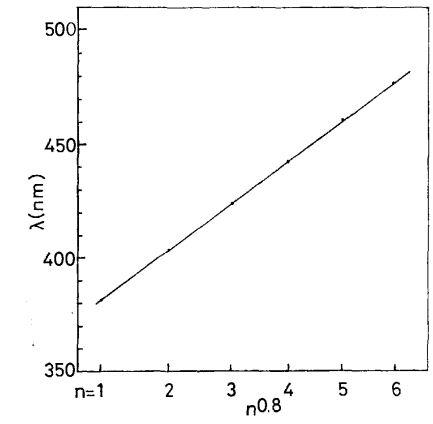

Fig. 4. Plot of λ *vs.* $n^{0.8}$ for di-2-fluorenylpolyenes (I_n').

Experimental

All melting points are not corrected. The electronic spectra were measured with a Hitachi EPS-3T spectrophotometer

8) K. Nakasuji, S. Akiyama, and M. Nakagawa, This Bulletin, **45**, 883 (1972).

using a well-matched pair of 1 cm quartz cells unless otherwise stated. IR spectra were obtained on a Hitachi EPI-2 spectrophotometer by the KBr-disk method. Preparation of phosphoranes was carried out under nitrogen atmosphere using an ethereal solution of phenyllithium as a base. The Wittig reaction was performed under shielding from light.

3-(2-Pyrenyl)-2-propenal (IV). To a solution of lithium ethoxyacetylide prepared from 2-chlorovinyl ethyl ether (7.0 g, 0.066 mol) in tetrahydrofuran (20 ml) and lithium amide (from lithium, 0.8 g, 0.12 g-atom) in liquid ammonia (130 ml) was added a solution of II[4] (3.0 g, 0.013 mol) in tetrahydrofuran (40 ml). After being stirred overnight at the boiling point of ammonia, stirring was continued overnight at 0 °C allowing the ammonia to evaporate. Ammonium chloride (10 g) and water were added to the residue. The organic layer, after washing and drying, was concentrated to give a dark brown liquid which was dissolved in tetrahydrofuran (40 ml). Lithium aluminum hydride (2.2 g, 0.058 mol) in the same solvent (50 ml) was added to the solution and the mixture was stirred for 2 hr at room temperature. Ethyl acetate (10 ml) and 2 M sulfuric acid (100 ml) were added successively, and the mixture was stirred overnight at room temperature. The aqueous layer was extracted with benzene. The combined organic layer and extract, after being washed and dried, were concentrated under reduced pressure. Crystals, 0.26 g, mp 183—194 °C obtained by trituration of the residue with a small amount of ether-tetrahydrofuran were dissolved in benzene and passed through a short column of alumina. Crystals obtained from the filtrate were recrystallized from benzene to yield pure IV, mp 205—206 °C, IR: 1693 (C=O), 973, 963 (=C-H) cm^{-1}.

Found: C, 88.57; H, 4.72%. Calcd for $C_{19}H_{12}O$: C, 89.04; H, 4.72%.

5-(2-Pyrenyl)-2,4-pentadienal (V). A solution of II[4] (4.4 g, 19 mmol) in tetrahydrofuran (50 ml) was added to a solution of Grignard derivative of methoxybutenyne prepared by the reaction of the butenyne (3.2 g, 38.9 mmol) in tetrahydrofuran (12 ml) with ethylmagnesium bromide (from ethyl bromide, 4.3 g and magnesium, 0.70 g in the same solvent, 22 ml). After being stirred overnight at room temperature, ethanol (1.3 ml) and lithium aluminum hydride (1.1 g, 29 mmol) were added and stirred for 1.5 hr. Ethyl acetate (10 ml), water (10 ml) and 2 M sulfuric acid (100 ml) were successively added to the reaction mixture and stirred for 2 hr. The aqueous layer was extracted with tetrahydrofuran, and the extract was combined with the organic layer. Light brown crude crystals, mp 212—217 °C, 3.8 g (64.2%) obtained by evaporation of the combined organic layer, after being washed and dried, were dissolved in benzene and passed through a short column of alumina. Concentration of the filtrate afforded pure V, mp 219 °C, IR: 1673 (C=O), 990 (=C-H) cm^{-1}.

Found: C, 89.17; H, 4.92%. Calcd for $C_{21}H_{14}O$: C, 88.86; H, 5.22%.

3-(2-Pyrenyl)-2-propen-1-ol. To a stirred solution of IV (0.434 g, 1.7 mmol) in a mixture of tetrahydrofuran (50 ml) and methanol (5 ml) was added a solution of sodium borohydride (0.5 g, 13 mmol) in methanol (10 ml). After being stirred for 1 hr at room temperature, dilute hydrochloric acid was added to the reaction mixture, the organic solvent being removed under reduced pressure. The residue was extracted with benzene. The extract, after being washed and dried, was concentrated to give pale yellow crystals, mp 111—118 °C, 0.30 g (quantitative), which were recrystallized from benzene to yield pure propenol, colorless plates, mp 130.5—131.1 °C, IR: 3300—3200 (O-H), 1105 (C-O), 993, 974, 965 (=C-H) cm^{-1}.

Found: C, 87.30; H, 5.99%. Calcd for $C_{19}H_{14}O$: C, 87.15; H, 6.02%.

5-(2-Pyrenyl)-2,4-pentadien-1-ol. A solution of sodium borohydride (1.0 g, 27 mmol) in methanol (40 ml) was added to a stirred solution of V (1.5 g, 5.6 mmol) in tetrahydrofuran (100 ml). After being stirred for 2 hr at room temperature, dilute hydrochloric acid and water were successively added to the reaction mixture. Yellow plates deposited, 1.05 g (69.5%), were recrystallized from benzene to give pure pentadienol, yellow plates, mp 175—176 °C, IR: 3300 (O-H), 987 (=C-H) cm^{-1}.

Found: C, 88.47; H, 5.67%. Calcd for $C_{21}H_{16}O$: C, 88.20; H, 5.92%.

3-(2-Pyrenyl)-2-propenyltriphenylphosphonium Bromide. A solution of phosphorus tribromide (0.85 g, 3.0 mmol) in chloroform (15 ml) was added, under cooling on an ice-salt bath, to a solution of 3-(2-pyrenyl)2-propen-1-ol (0.43 g, 1.66 mmol) in the same solvent containing 5 drops of pyridine. After being stirred for further 1 hr at room temperature, the reaction mixture was poured onto ice-water. The organic layer was successively washed with water, dilute hydrochloric acid, and water, and dried. Pale yellow crystals obtained by evaporating the solvent were mixed with triphenylphosphine (0.65 g, 2.4 mmol) in benzene (20 ml) and the mixture was refluxed overnight to give phosphonium bromide, colorless crystals, mp 240—252 °C, 0.338 g (34.9%).

5-(2-Pyrenyl)-2,4-pentadienyltriphenylphosphonium Bromide. Crude bromide obtained as greenish yellow crystals by the reaction of pyrenylpentadienol (0.80 g, 2.94 mmol) with phosphorus tribromide (1.8 g, 6.75 mmol) by the above procedure were mixed with triphenylphosphine (1.3 g, 5.0 mmol) in benzene (50 ml) and the mixture was refluxed for 15 hr to give phosphonium bromide, pale yellow crystals, mp 239—244 °C, 1.4 g (79.8%).

1,2-Di(2-pyrenyl)ethylene (I_1). To a suspension of 2-pyrenylmethyltriphenylphosphonium bromide[6] (0.67 g, 1.2 mmol) in benzene (20 ml) was added phenyllithium (0.88N, 1.4 ml). After being stirred for 20 min at room temperature, a solution of II[4] (0.23 g, 1.0 mmol) in benzene (20 ml) was added to the resulting orange red solution of III, and the mixture was stirred for 24 hr at room temperature. The solvent was removed under reduced pressure and the residue was extracted with hot benzene. Pale greenish yellow needles, mp>360 °C, 0.110 g (25.7%) obtained by cooling the extract were dissolved in hot benzene and passed through a short column of alumina to give pure I_1, greenish yellow plates, mp>360 °C, IR: 1598, 1440, 951, 865, 833, 807, 700 cm^{-1}.

Found: C, 95.39; H, 4.72%. Calcd for $C_{34}H_{20}$: C, 95.30; H, 4.70%.

1,4-Di(2-pyrenyl)-1,3-butadiene (I_2). A solution of 3-(2-pyrenyl)-2-propenal (0.26 g, 1.0 mmol) in benzene (45 ml) was added to a solution of III prepared from 2-pyrenylmethyltriphenylphosphonium bromide[6] (0.67 g, 1.2 mmol) in benzene (20 ml) and phenyllithium (0.73N, 1.6 ml). After the mixture had been stirred for 24 hr at room temperature, the solvent was removed under reduced pressure, and the residue was extracted with hot toluene. Yellow needles, mp 339—340 °C, 0.024 g (5.3%) obtained by concentrating the extract were dissolved in hot toluene, and the hot solution was percolated through a short column of alumina. Pure I_2, pale yellow needles, mp 354—355 °C, IR: 1600, 1440, 974, 870, 835, 818, 700 cm^{-1} was obtained from the filtrate.

Found: C, 94.62; H, 4.76%. Calcd for $C_{36}H_{22}$: C, 95.12; H, 4.88%.

1,6-Di(2-pyrenyl)-1,3,5-hexatriene (I_3). To a solution of III prepared from phosphonium bromide[6] (0.61 g, 1.1 mmol)

in benzene (20 ml) and phenyllithium (0.89N, 1.2 ml) was added a solution of 5-(2-pyrenyl)-2,4-pentadienal (0.24 g, 0.9 mmol) in benzene (70 ml) and the mixture was stirred for 26 hr at room temperature. Crystalline residue obtained by evaporating the solvent was extracted with hot benzene. Yellow fine needles, mp 308—315 °C, 0.035 g (8.1%), obtained on cooling the extract, were dissolved in hot toluene and passed through a short column of alumina to give pure I_3, yellow plates, mp 329—330 °C, IR: 1597, 1440, 980, 875, 870, 833, 804, 700 cm^{-1}.

Found: C, 95.18; H, 5.07%. Calcd for $C_{38}H_{24}$: C, 94.97; H, 5.03%.

1,8-Di(2-pyrenyl)-1,3,5,7-octatetraene (I_4). 2-Pyrenylmethyltriphenylphosphonium bromide[6] (0.67 g, 1.2 mmol) in benzene (20 ml) was treated with phenyllithium (0.88N, 1.4 ml) to give a solution of III. A solution of muconaldehyde (VI, 0.055 g, 0.5 mmol) in benzene (10 ml) was added to the solution of III and the mixture was stirred for 24 hr at room temperature. The solvent was removed under reduced pressure and the residue was digested with hot toluene. Fine orange yellow needles, mp 269—276 °C, 0.109 g (21.5%) obtained by concentrating the extract were dissolved in hot toluene. Percolation of the hot solution through a thin layer of alumina afforded pure I_4, mp 320 °C, IR: 1595, 1440, 992, 878, 853, 833, 810, 700 cm^{-1}.

Found: C, 93.89; H, 5.23%. Calcd for $C_{40}H_{26}$: C, 94.83; H, 5.17%.

1,10-Di(2-pyrenyl)-1,3,5,7,9-decapentaene (I_5). To a dark red solution of VII prepared from 5-(2-pyrenyl)-2,4-pentadienyltriphenylphosphonium bromide (0.283 g, 0.47 mmol) in benzene (25 ml) and phenyllithium (0.73N, 0.7 ml) was added a solution of 5-(2-pyrenyl)-2,4-pentadienal (0.11 g, 0.40 mmol) in the same solvent (65 ml). After being stirred for 24 hr at room temperature, the solvent was removed under reduced pressure. The residue dissolved in hot toluene was passed through a short column of alumina. Concentration of the filtrate afforded pure I_5, orange needles, mp 303 °C, IR: 1595, 1440, 990, 880, 860, 835, 700 cm^{-1}.

Found: C, 94.49; H, 5.37%. Calcd for $C_{42}H_{28}$: C, 94.70; H, 5.30%.

1,12-Di(2-pyrenyl)-1,3,5,7,9,11-dodecahexaene (I_6). A solution of muconaldehyde (VI, 0.0265 g, 0.25 mmol) in benzene (7 ml) was added to a solution of VIII prepared from 3-(2-pyrenyl)-2-propenyltriphenylphosphonium bromide (0.338 g, 0.58 mmol) in benzene (20 ml) and phenyllithium (0.84N, 0.7 ml). After the mixture had been stirred for 22 hr, the solvent was removed under reduced pressure. The residue dissolved in hot toluene was passed through a thin layer of alumina. Concentration of the filtrate yielded pure I_6, orange needles, mp 298—299 °C, 3 mg.

Found: C, 94.06; H, 5.31%. Calcd or $C_{44}H_{30}$: C, 94.59; H, 5.41%.

3-(2-Fluorenyl)-2-propenal (IV'). A mixture of concentrated sulfuric acid (2.4 ml), water (20 ml), dioxane (118 ml) and 1-(2-fluorenyl)-2-propyn-1-ol[8] (5.9 g, 26.8 mmol) was refluxed for 48 hr. Water was added to the reaction mixture and the aqueous layer was extracted with benzene. The combined organic layer, after being washed and dried, was concentrated to give a dark brown liquid. The liquid was triturated with a small amount of ethyl acetate containing a trace of ether to cause crystallization (yellow crystals, mp 97—107 °C, 3.05 g). The filtrate, after being evaporated, was dissolved in benzene and shaken with a saturated sodium hydrogen sulfite solution for 48 hr. Decomposition of sulfite adduct with a dilute sodium hydroxide afforded an additional amount of yellow crystals, mp 100—105 °C, 0.805 g. The combined crystals (3.85 g, 65.2%) were recrystallized from benzene to yield pure IV', mp 114 °C, colorless crystals, IR: 1675 (C=O), 970 (=C-H) cm^{-1}.

Found: C, 86.91; H, 5.42%. Calcd for $C_{16}H_{12}O$: C, 87.24; H, 5.49%.

5-(2-Fluorenyl)-2,4-pentadienal (V'). Methoxybutenyne (3.2 g, 38.9 mmol) in tetrahydrofuran (12 ml) was converted into the Grignard derivative by the reaction with ethylmagnesium bromide in the same solvent (22 ml) (from ethyl bromide, 4.4 g and magnesium, 0.70 g, 28 mg-atom). A solution of II'[5] (3.7 g, 19 mmol) in the same solvent (12 ml) was added to the Grignard reagent and the mixture was stirred for 15 hr at room temperature. Ethanol (1.3 ml) and lithium aluminum hydride (1.1 g, 29 mmol) were added to the reaction mixture. After being stirred for 1 hr at room temperature, water (6 ml) and 2 M sulfuric acid (100 ml) were successively added under ice-cooling, and worked up by the usual way to yield crude V', orange yellow crystals, mp 137—143 °C, 2.4 g (51.3%) which were recrystallized from ethyl acetate, yielding pure V', yellow plates, mp 158—159 °C, IR: 1665 (C=O), 995 (=C-H) cm^{-1}.

Found: C, 87.55; H, 5.76%. Calcd for $C_{18}H_{14}O$: C, 87.88; H, 5.73%.

3-(2-Fluorenyl)-2-propen-1-ol. Treatment of 3-(2-fluorenyl)-2-propenal (0.110 g, 0.5 mmol) with sodium borohydride according to a procedure similar to that for 2-pyrenyl analogue afforded fluorenylpropenol, colorless crystals, mp 133—143 °C, 1.02 g (92.5%), which were recrystallized from benzene to yield pure material, colorless plates, mp 155—156 °C, IR: 3300—3200 (O-H), 1010 (C-O), 995, 968 (=C-H) cm^{-1}.

Found: C, 86.10; H, 6.28%. Calcd for $C_{16}H_{14}O$: C, 86.45; H, 6.35%.

5-(2-Fluorenyl)-2,4-pentadien-1-ol. According to a similar procedure to that for 2-pyrenyl analogue, 5-(2-fluorenyl)-2,4-pentadienal (1.0 g) was reduced with sodium borohydride, yielding fine yellow crystals, mp 106—113 °C, 0.90 g (78.8%).

3-(2-Fluorenyl)-2-propenyltriphenylphosphonium Bromide. Fluorenylpropenol (1.40 g, 6.3 mmol) in chloroform (50 ml) containing 4 drops of pyridine was treated with phosphorus tribromide (1.2 g, 4.4 mmol) in chloroform (20 ml). The reaction of crude bromide in boiling benzene (25 ml) with triphenylphosphine (1.9 g, 7.3 mmol) afforded fine pale yellow crystals, 1.26 g which were recrystallized from ethanol-benzene to give pure phosphonium bromide, colorless crystals, mp 158—159 °C.

Found: C, 76.67; H, 5.42; Br, 12.66%. Calcd for $C_{34}H_{28}BrP \cdot C_6H_6$: C, 76.79; H, 5.48; Br, 12.77%.

5-(2-Fluorenyl)-2,4-pentadienyltriphenylphosphonium Bromide. Fluorenylpentadienol (0.75 g, 3.0 mmol) was converted into bromide by the reaction of phosphorus tribromide (0.41 g, 1.5 mmol) according to a procedure similar to that for pyrenyl analogue. Crude bromide, fine yellow crystals, was mixed with a solution of triphenylphosphine (0.95 g, 3.6 mmol) in benzene (40 ml) and the mixture was refluxed for 9.5 hr. The reaction mixture was allowed to stand overnight at room temperature to yield phosphonium bromide, fine colorless crystals, mp 243—257 °C, 0.24 g (18.0%).

1,2-Di(2-fluorenyl)ethylene (I_1'). To a suspension of 2-fluorenylmethyltriphenylphosphonium bromide[8] (0.78 g, 1.2 mmol) in benzece (25 ml) was added phenyllithium (0.73N, 1.8 ml) and the mixture was stirred for 30 min at room temperature. To the resulting solution of III' was added II'[9] (0.19 g, 1.0 mmol) in benzene (10 ml). After being stirred for 26 hr at room temperature, the solvent was removed under reduced pressure. Crude crystals, colorless plates, mp 268—300 °C, 0.102 g (29.6%) obtained by extraction of the residue with hot benzene followed by concentration were

dissolved in hot benzene and passed through a short column of alumina. Pure I_1', colorless plates, mp 304—305 °C, IR: 1454, 1428, 1395, 967, 870, 767, 732 cm^{-1} was obtained from the filtrate.

Found: C, 94.34; H, 5.66%. Calcd for $C_{28}H_{20}$: C, 94.45; H, 5.59%.

1,4-Di(2-fluorenyl)-1,3-butadiene (I_2'). To a benzene solution of III′ prepared from 2-fluorenylmethyltriphenylphosphonium bromide (0.73 g, 1.5 mmol) and phenyllithium (0.48N, 3.1 ml) was added a solution of IV′ (0.22 g, 1.0 mmol) in the same solvent (15 ml). After the mixture had been stirred for 40 hr at room temperature, the solvent was removed under reduced pressure and the residue was extracted with hot benzene. Yellow crystals, mp 297—300 °C, 0.124 g (32.4%) obtained by concentrating the extract were dissolved in benzene and percolated through a thin layer of alumina to give pure I_2', yellow plates, mp 301—302 °C, IR: 1453, 1418, 1395, 990, 878, 763, 730 cm^{-1}.

Found: C, 94.41; H, 5.75%. Calcd for $C_{30}H_{22}$: C, 94.20; H, 5.80%.

Concentration of mother liquor of the first crop of crystals afforded the second crop of I_2', yellow plates, mp 267—277 °C, 0.147 g (36%).

1,6-Di(2-fluorenyl)-1,3,5-hexatriene (I_3'). A solution of V′ (0.36 g, 1.5 mmol) in benzene (26 ml) was added to a solution of III′ prepared from phosphonium bromide (0.935 g, 1.8 mmol) and phenyllithium (0.47N, 3.8 ml) and the mixture was stirred for 46 hr. The residue obtained by removing the solvent under reduced pressure was extracted with hot benzene and toluene. The extract was concentrated to give yellow fine crystals, mp 272—286 °C, 0.519 g (84.5%) which were dissolved in hot toluene and percolated through a short column of alumina to give pure I_3', yellow plates, mp 296—297 °C, IR: 1452, 1425, 1395, 1000, 880, 764, 730 cm^{-1}.

Found: C, 93.74; H, 5.93%. Calcd for $C_{32}H_{24}$: C, 94.08; H, 5.92%.

1,8-Di(2-fluorenyl)-1,3,5,7-octatetraene (I_4'). A solution of III′ was prepared from phosphonium bromide (0.625 g, 1.2 mmol) in benzene (20 ml) and phenyllithium (0.50N, 2.4 ml). A solution of VI (0.055 g, 0.5 mmol) in the same solvent (15 ml) was added to the solution of III′. After being stirred for 26 hr at room temperature, the solvent was removed under reduced pressure. Yellow fine crystals, mp 279—287 °C, 0.205 g (94.3%) obtained by extracting the residue with hot toluene followed by concentration were dissolved in hot toluene and passed through a short column of alumina, yielding pure I_4', yellow needles, mp 289—291 °C, IR: 1450, 1395, 1005, 880, 830, 760 cm^{-1}.

Found: C, 93.72; H, 6.03%. Calcd for $C_{34}H_{26}$: C, 93.97; H, 6.03%.

1,10-Di(2-fluorenyl)-1,3,5,7,9-decapentaene (I_5'). A solution of V′ (0.0985 g, 0.40 mmol) in benzene (10 ml) was mixed with a solution of VII′ in the same solvent (15 ml) prepared from 5-(2-fluorenyl)-2,4-pentadienyltriphenylphosphonium bromide (0.240 g, 0.54 mmol) and phenyllithium (0.58N, 0.9 ml). After the mixture had been stirred for 28 hr at room temperature, the solvent was removed under reduced pressure and the residue was extracted with hot toluene. Yellow fine crystals, mp 268—276 °C, 0.0684 g (37.2%) obtained by concentrating the extract were dissolved in hot toluene. Percolation of the hot solution through a thin layer of alumina afforded pure I_5', fine yellow needles, mp 277 °C, IR: 1453, 1395, 1005, 882, 836, 817, 760 cm^{-1}.

Found: C, 93.52; H, 6.03%. Calcd for $C_{36}H_{28}$: C, 93.87; H, 6.13%.

1,12-Di(2-fluorenyl)-1,3,5,7,9,11-dodecahexaene (I_6'). To a solution of VIII′ prepared from 3-(2-fluorenyl)-2-propenyltriphenylphosphonium bromide (0.656 g, 1.2 mmol) in benzene (20 ml) and phenyllithium (1.04N, 1.1 ml) was added a solution of VI (0.055 g, 0.5 mmol) in the same solvent (7 ml) and the mixture was stirred for 20 hr at room temperature. Orange powder obtained by evaporating the solvent under reduced pressure was digested with hot toluene. Concentration of the extract afforded orange fine crystals, mp 267—279 °C, 0.104 g (21.4%) which were dissolved in hot toluene and passed through a short column of alumina. Pure I_6', fine orange crystals, mp 298—300 °C, IR: 1452, 1395, 1005, 882, 760 cm^{-1} was obtained from the filtrate.

Found: C, 93.26; H, 6.20%. Calcd for $C_{38}H_{30}$: C, 93.79; H, 6.21%.

Linear Conjugated Systems Bearing Aromatic Terminal Groups. XIII.[1] Syntheses of α-(*p*-Methoxyphenyl)-ω-(*p*-nitrophenyl)polyenes

Yasuhira TAKEUCHI, Shuzo AKIYAMA, and Masazumi NAKAGAWA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received February 21, 1973)

α-*p*-Methoxyphenyl-ω-*p*-nitrophenylpolyenes (III_n, $n=1$—5) were prepared by the Wittig reaction of *p*-methoxyphenylpolyenals (I, $n=1$—5) with phosphorane derived from *p*-nitrobenzyltriphenylphosphonium bromide (II). The electronic spectra of III_n showed broad and structureless absorption curves. However, the trend of bathochromic shift of long wavelength absorption maxima with increasing length of polyene chain suggests that no alternation in the type of light-absorption of polyene chromophore is caused by the introduction of electron donating and withdrawing substituents in the terminal phenyl groups.

In view of prominent effect of terminal groups of α,ω-diarylpolyenes on the electronic spectral regularity,[2-5] it seemed to be of interest to prepare a series of polyenes bearing electron donating and withdrawing substituents in each of the terminal aromatic rings. The present paper deals with the syntheses of a series of α-*p*-methoxyphenyl-ω-*p*-nitrophenylpolyenes (III_n $n=1$—5).

Syntheses of III_n were performed by the Wittig reaction of ω-*p*-methoxyphenyl polyene aldehydes (I, $n=1$—5)[6] with phosphorane prepared from *p*-nitrobenzyltriphenylphosphonium bromide (II).[7]

The physical properties of III_n are summarized in Table 1. We see that the frequency of C–H out-of-plane deformation (δ_{C-H}) and that of C=C stretching vibration ($\nu_{C=C}$) move to higher and lower wave number, respectively, along with the increase in *n*. The absorption curves of electronic spectra of III_n in tetrahydrofuran at room temperature are illustrated in Fig. 1. Owing to the broad and structureless feature of the absorption curves, estimation of the exact wavelength of maxima of long wavelength bands was difficult and no discussion could be given on the regularity of electronic spectra. However, it was observed that the magnitude of bathochromic shift of long wavelength band between III_{n+1} and III_n ($\Delta\lambda$) decreases with the increase of n (Table 1). This indicates that the introduction of electron donating and withdrawing groups does not alter the type of light-absorption properties of α,ω-diarylpolyene system (convergent type).[8]

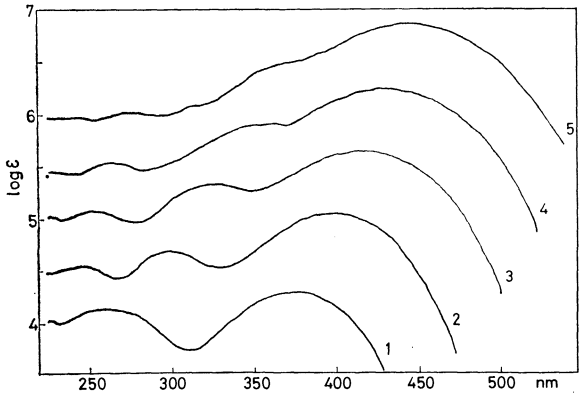

Fig. 1. Absorption curves of α-*p*-methoxyphenyl-ω-*p*-nitrophenylpolyenes (III_n) in tetrahydrofuran. Each curve, except for the lowest one, has been displaced upward by a 0.5 log ε unit increment from one immediately below it.

TABLE 1. PHYSICAL PROPERTIES OF α-*p*-METHOXYPHENYL-ω-*p*-NITROPHENYLPOLYENES (III_n)

n	Color of crystals	Mp (°C)	λ_{max} (log ε) (nm)	$\Delta\lambda$	δ_{C-H} (cm^{-1})	$\nu_{C=C}$ (cm^{-1})
1	yellow	130—131	374 (4.29)		968	1587
				26		
2	yellow	173—175	400 (5.56)		993	1585
				19		
3	orange yellow	178—179	419 (4.65)		1000	1580
				11		
4	orange	204—205	430 (4.75)		1002	1565
				12		
5	reddish brown	229—231	442 (4.85)		1002	1552

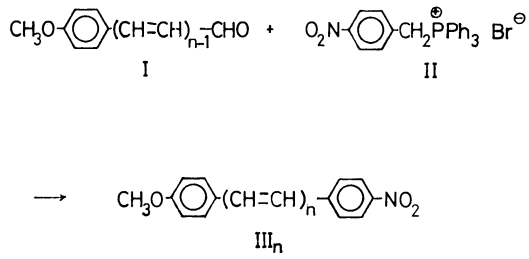
8) $\Delta\lambda$ of diarylpoly-ynes was found to increase with the increase of n ($n=1-6$) [M. Nakagawa, S. Akiyama, K. Nakasuji, and K. Nishimoto, *Tetrahedron*, **1971**, 5401] and $\Delta\lambda$ of charge resonance system such as cyanine dyes has been found to be constant regardless of change of *n* (nonconvergent type).



Experimental

All melting points are not corrected. The electronic spectra in tetrahydrofuran were obtained on a Hitachi EPS-3T spectrophotometer using a well-matched pair of 1 cm quartz cells, the shoulder being denoted by an asterisk. The IR spectra were measured with a Hitachi EPI-2 spectrophotometer by the KBr-disk method. Preparation of phosphorane was performed under nitrogen atmosphere using an ethereal solution of phenyllithium as a base. The Wittig reaction was carried out under shielding from light. Initially deposited crystals in the final recrystallization were used in the measurements of electronic spectra to avoid contamination with an isomer containing *cis*-linkage.

1-p-*Methoxyphenyl-2*-p-*nitrophenylethylene* (III_1). To a suspension of *p*-nitrobenzyltriphenylphosphonium bromide[7] (II, 1.44 g, 3.0 mmol) in benzene (15 ml) was added a solution of phenyllithium (0.24 N, 12.5 ml). After being stirred for 2 hr at room temperature, a solution of *p*-methoxybenzaldehyde (I, n=1, 0.27 g, 2.0 mmol) in benzene (5 ml) was added and the mixture was stirred overnight. The residue obtained by evaporation of the solvent *in vacuo* was extracted with hot benzene. Crude crystals deposited on concentration of the extract were recrystallized from ethanol to give yellow plates, mp 127—128 °C, 0.124 g (24.3%) which were recrystallized from the same solvent to give pure III_1, yellow plates, mp 130—131 °C (lit,[9] mp 131—132.5 °C), UV, λ_{max} (log ε): 258 (4.14), 270*, and 374 (4.29) nm.

1-p-*Methoxyphenyl-4*-p-*nitrophenyl-1,3-butadiene* (III_2). A solution of *p*-methoxycinnamaldehyde (I, n=2, 0.32 g, 2.0 mmol) in benzene (6 ml) was added to a solution of phosphorane prepared from II[7] (1.44 g, 3.0 mmol), benzene (15 ml) and phenyllithium (0.28N, 11.5 ml). After the mixture had been stirred for 21 hr at room temperature, the solvent was removed under reduced pressure. The residue was digested with boiling benzene and the extract was passed through a short column of alumina. Yellow needles, mp 169—178 °C, 0.292 g (42.6%) obtained on concentrating the filtrate were recrystallized from benzene to give pure III_2, yellow needles, mp 173—175 °C, UV, λ_{max} (log ε): 248 (4.06), 295 (4.21), and 400 (4.56) nm.

Found: C, 72.77; H, 5.40%. Calcd for $C_{17}H_{15}NO_3$: C, 72.58; H, 5.37%.

1-p-*Methoxyphenyl-6*-p-*nitrophenyl-1,3,5-hexatriene* (III_3). A solution of phosphorane was prepared from II[7] (1.44 g, 3.0 mmol), benzene (15 ml) and phenyllithium (0.24N, 8.4 ml). A solution of 5-*p*-methoxyphenyl-2,4-pentadienal[6] (I, n=3, 0.38 g, 2.0 mmol) in benzene (6 ml) was added to the solution and the mixture was stirred overnight at room temperature. The residue obtained by evaporating the solvent under reduced pressure was extracted with hot benzene, and the extract was percolated through a short column of alumina. Concentration of the filtrate afforded orange yellow plates, mp 175—180 °C, 0.235 g (38.2%) which were recrystallized from benzene to give pure III_3, orange yellow plates, mp 178—179 °C, UV, λ_{max} (log ε): 254 (4.14), 325 (4.32), 336 (4.32), and 419 (4.06) nm.

Found: C, 74.29; H, 5.56%. Calcd for $C_{19}H_{17}NO_3$: C, 74.25; H, 5.57%.

1-p-*Methoxyphenyl-8*-p-*nitrophenyl-1,3,5,7-octatetraene* (III_4). A solution of 7-*p*-methoxyphenyl-2,4,6-heptatrienal[6] (I, n=4, 0.43 g, 2.0 mmol) in benzene (35 ml) was added to a solution of phosphorane prepared from II[7] (1.44 g, 3.0 mmol), benzene (20 ml) and phenyllithium (0.24N, 12.5 ml), and the mixture was stirred for 21 hr at room temperature. Brown powder deposited was digested with boiling benzene. Concentration of the extract, after being filtered, afforded fine orange crystals, mp 200—202 °C, 0.222 g (33.3%). Recrystallization of this material from benzene afforded pure III_4, orange plates, mp 204—205 °C, UV, λ_{max} (log ε): 265 (4.06), 360 (4.41), 430 (4.75), and 445* nm.

Found: C, 75.81; H, 5.72%. Calcd for $C_{21}H_{19}NO_3$: C 75.65; H, 5.74%.

1-p-*Methoxyphenyl-10*-p-*nitrophenyl-1,3,5,7,9-decapentaene* (III_5). To a solution of phosphorane prepared from II[7] (0.94 g, 1.95 mmol), benzene (15 ml) and phenyllithium (0.24N, 8.2 ml) was added a solution of 9-methoxyphenyl-2,4,6,8-nonatetraenal[6] (I, n=5, 0.32 g, 1.3 mmol) in benzene (60 ml) and tetrahydrofuran (10 ml). After the mixture had been stirred for 21 hr, reddish brown solid deposited was collected by filtration. The soild was extracted with boiling benzene. The extract was filtered and concentrated. Reddish brown crystals, mp 229—230 °C, 0.123 g (26.3%) thus obtained were recrystallized from benzene to give pure III_5, reddish brown rods, mp 229—230 °C, UV, λ_{max} (log ε): 277 (4.01), 370 (4.49), 442 (4.85), and 455* nm.

Found: C, 76.86; H, 5.89%. Calcd for $C_{23}H_{21}NO_3$: C, 77.01; H, 5.83%.

Linear Conjugated Systems Bearing Aromatic Terminal Groups. XIV.[1] On the Electronic Spectral Regularity of α,ω-Diarylpolyenes

Shuzo AKIYAMA, Yasuhira TAKEUCHI, Akio YASUHARA, Masazumi NAKAGAWA,[2] and Kichisuke NISHIMOTO*

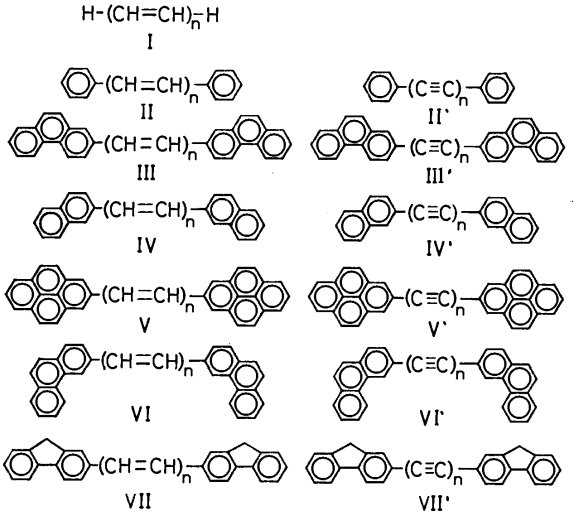
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
**Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka 558*

(Received February 21, 1973)

The bathochromic shift of the longest wavelength absorption maxima (λ) of several series of polyenes along with the increase in number of ethylenic double bond (n) can be expressed excellently by the empirical formula $\lambda=An^x+B$. The value of x varies from 0.5 to 0.8 [$0.5\leq x\leq 0.8$] depending on the nature of terminal groups and the position of linking of polyene chain to terminal aryl nucleus, being $x=0.5$ in the case of parent polyenes (I) and $x=0.8$ for di(3-phenanthryl)- (VI) and di(2-fluorenyl)polyenes (VII). The linear relationship could be reproduced fairly well by the HMO method using the usual bond-alternation approximation ($\beta_{C=C}=1.1\,\beta$; $\beta_{C-C}=0.9\,\beta$; $\beta_{C\equiv C}=\beta$. C≡C denotes aromatic double bond). The calculation based on a modified bond-alternation approximation ($\beta_{C=C}=[1+0.5/(n+4)]\beta$; $\beta_{C-C}=[1-0.5/(n+4)]\beta$; $\beta_{C\equiv C}=\beta$) which is analogous to that successfully applied to diarylpoly-ynes did not reproduce the spectral regularity of diarylpolyenes. This seems to offer further support for the pertinence of assumption of increasing contribution of cumulenic structure in diarylpoly-ynes along with the increase in n.

The bathochromic shift of the longest wavelength absorption maxima (λ) in the electronic spectra of α,ω-diarylpoly-ynes along with the increase in number of acetylenic bond (n) can be expressed well by the empirical formula $\lambda=An^x+B$, indicating a prominent effect of aromatic terminal groups on the electronic spectral regularity.[3,4] The finding prompted the authors to synthesize various α,ω-diarylpolyenes to reveal the influence of the aromatic terminal groups on the electronic excitation of conjugated polyene chain.[5-9] Five series of α,ω-diarylpolyenes (III, IV, V, VI, and VII) exhibited electronic spectra with well-developed vibrational fine structure. The bathochromic shift could be expressed by the same type of empirical formula. The present paper gives the results of a HMO treatment to reproduce the linear relationship between λ and n^x observed in α,ω-diarylpolyenes.

The empirical formulas are summarized in Table 1 together with those for the corresponding acetylenic analogues. The plots of the reported values of the longest wavelength absorption maxima (λ) of polyenes (I)[10] and those of diphenylpolyenes (II)[11] against $n^{0.5}$ and $n^{0.6}$, respectively, gave straight lines. The empirical formulas for (I) and (II) are also included in Table 1.



The values of A, x, and B are dependent on the nature of terminal group and the position of linking of unsaturated chain to terminal aryl system. The fact that the B-values of the polyene series and the poly-yne series are similar is understandable since they formally correspond to the absorption wavelength of hypothetical coplanar biaryls ($n=0$). The trend of variation of A, x, and B was found to be similar in both diarylpoly-ynes[4] and diarylpolyenes. The values of x and B increase with the augmentation of conjugate system in the terminal groups. On the other hand, the values of A decrease along with the increase in x and B. It is to be noted that the increase of x-value with the variation of terminal group accords to the same sequence as that found in diarylpoly-yne series. Diphenylpolyenes (II)[11] exhibit the longest wavelength absorption maxima at longer wavelength (Table 2) as compared with those of corresponding diphenylpoly-ynes (II', $n=1$, 297; $n=2$, 326; $n=3$, 358; $n=4$, 397;

Table 1. Electronic spectral regularity of polyenes and poly-ynes[a)]

R		$R(CH=CH)_nR$	n		$R(C\equiv C)_nR$	n
H-	I	$\lambda=132.3\ n^{0.5}+39$	3—6			
Phenyl-	II	$\lambda=65.2\ n^{0.6}+253$	1—6	II′	$\lambda=33.0\ n^{1.0}+263$	1—6
2-Phenanthryl-	III	$\lambda=57.9\ n^{0.6}+303$	1—6	III′	$\lambda=13.9\ n^{1.3}+333$	1—6
2-Naphthyl-	IV	$\lambda=45.4\ n^{0.7}+302$	1—6	IV′	$\lambda=15.5\ n^{1.3}+319$	1—6
2-Pyrenyl-	V	$\lambda=44.6\ n^{0.7}+314$	1—6	V′	$\lambda=12.6\ n^{1.4}+327$	1—6
3-Phenanthryl-	VI	$\lambda=30.3\ n^{0.8}+348$	1—6	VI′	$\lambda=10.8\ n^{1.4}+347$	1—6
2-Fluorenyl-	VII	$\lambda=29.5\ n^{0.8}+353$	1—6	VII′	$\lambda=9.0\ n^{1.5}+350$	1—6

a) The spectral data in tetrahydrofuran were used except for I, II, and II′ to which the reported values in isooctane, benzene, and ethanol, respectively, were used.

$n=5$, 431, and $n=6$, 460 nm)[12] within a limited length of linearly conjugated system ($n=1$—4). This seems to reflect an enhanced electronic interaction of the ethylenic bond with the phenyl group as compared with the acetylenic bond. The value of A can be regarded as a measure of electronic interaction between terminal group and unsaturated function. Therefore, much larger A-values found in various kinds of polyene series indicate that the interaction of ethylenic bond with aromatic nucleus is stronger than that of the acetylenic bond, regardless of the nature of terminal aromatic system.

One of the authors (K. N.) pointed out that the Hückel molecular orbital (HMO) energy difference between the highest occupied and the lowest vacant orbitals (Δm) (in β-unit) and the absorption wavelength (λ) associated with the ^1L_a band can be correlated by the equation[13]

$$\lambda(^1L_a) = 474(\Delta m)^{-1/2} - 145\ \text{nm} \qquad (1)$$

The electronic spectral regularity of various kinds of α,ω-diarylpoly-ynes could be reproduced satisfactorily by means of the HMO method using Eq. (1). The resonance integrals were assumed as follows [modified bond-alternation approximation, Eq. (2)] considering increasing contribution of dipolar cumulenic structure (VIII) along with the increase of chain length (n):[4,14]

$$\beta_{C\equiv C} = [1+1/(n+4)]\beta;\ \beta_{C-C} = [1-1/(n+4)]\beta;$$
$$\beta_{C=C} = \beta \qquad (2)$$

Experimental support for this assumption has been obtained by comparing the wave number of spacing of vibrational sub-band of the electronic spectra with that of C≡C stretching vibration in the IR spectra.[4]

$$Ar\text{-}(C\equiv C)_n\text{-}Ar \longleftrightarrow {}^+Ar=(C=C)_n=Ar^- \longleftrightarrow {}^-Ar=(C=C)_n=Ar^+ \qquad \text{(VIII)}$$

Since the electronic spectral characteristic of linear polyene system has been explained in terms of bond-alternation,[15,16] we carried out the HMO calculation using the usual bond-alternation model in which the resonance integrals are assumed as follows:

$$\beta_{C=C} = 1.1\beta;\ \beta_{C-C} = 0.9\beta;\ \beta_{C=C} = \beta \qquad (3)$$

(C=C denotes aromatic double bond.)

In the case of di(2-fluorenyl)polyenes (VII), the resonance integral of the central C–C bond linking two benzene rings was assumed to be 0.9β. The observed and calculated values of absorption wavelength are summarized in Table 2. The present calculation reproduced the experimental relationship $\lambda=An^x+B$ except for the constant term B (Fig. 1). In the series of V and VII, calculation gave less satisfactory A-values than those of the other series. However, agreement between experimental and calculated results seems to be rather good in view of the simple treatment based on HMO.

The HMO calculation employing other parameters such as $\beta_{C=C}=1.2\beta$; $\beta_{C-C}=0.8\beta$; and $\beta_{C=C}=\beta$ gave less satisfactory results. The results based on the following modified bond-alternation approximation (Eq.

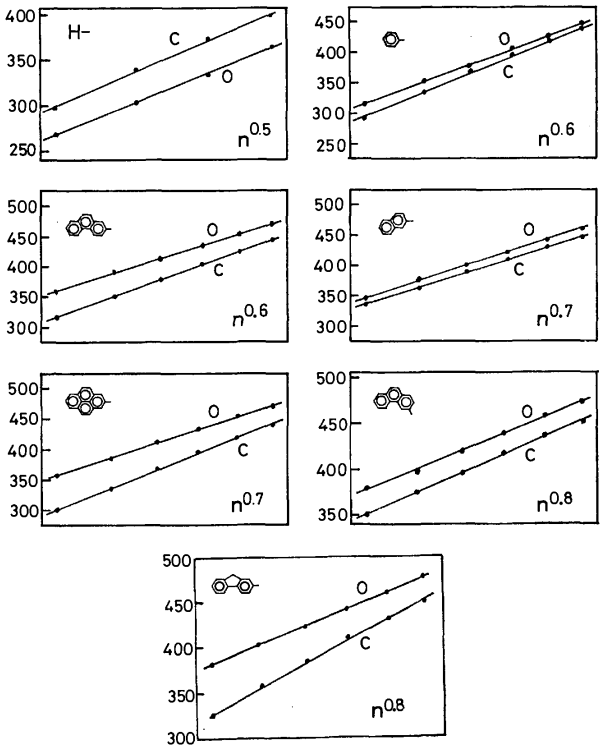

Fig. 1. Plots of λ (nm) *vs.* n^x.

BA = Calculated values by bond-alternation approximation (Eq. (3)).
MBA = Calculated values by modified bond-alternation approximation (Eq. (4)).

(4)) analogous to Eq. (2) are given in Table 2.

$$\beta_{C=C} = [1+0.5/(n+4)]\beta;\ \beta_{C-C} = [1-0.5/(n+4)]\beta;\ \beta_{C=C} = \beta \quad (4)$$

(C=C denotes aromatic double bond.)

The plots of calculated wavelength against corresponding n^x yielded no straight lines. This can be regarded as a further support for the pertinence of assumption of increasing contribution of cumulenic structure (VIII) in diarylpoly-ynes along with the increase in the number of n.

It is accepted that the square of wavelength of the longest wavelength absorption maxima (λ^2) of various kinds of linear polyenes varies linearly with the number of ethylenic bond (n) [*i.e.*, $\lambda = An^{0.5} + B$]. However, the present study demonstrates that the validity of $\lambda = An^{0.5} + B$ relationship is restricted to polyenes (I) and presumably to α,ω-dialkylpolyenes, the power of $n(x)$ varying from 0.5 to 0.8 [$0.5 \leq x \leq 0.8$] depending on the nature of terminal groups and the position of linking of polyene chain to terminal aromatic system.

Stereospecific and Stereoselective Reactions. II.[1] Preparation of Esters of *N*-Phthaloyl-α-amino Acid from Esters of α-Hydroxy Acid

Makoto WADA, Takashi SANO, and Oyo MITSUNOBU*

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received March 20, 1973)

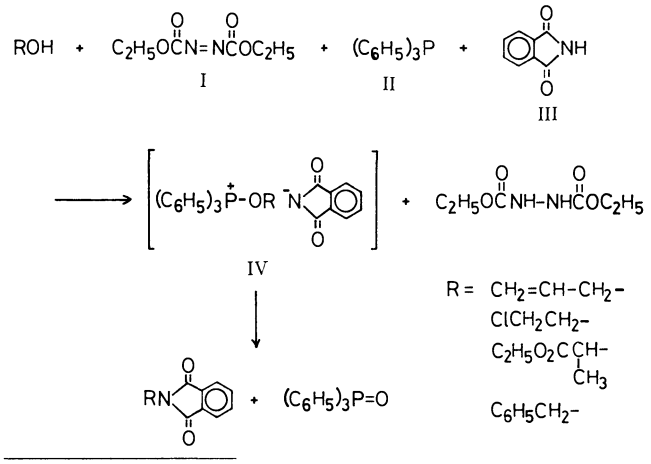
Functional selectivity and stereospecificity of the intermolecular dehydration between alcohols and phthalimide (III) by means of diethyl azodicarboxylate (I) and triphenylphosphine (II) was examined. The reaction of allyl alcohol, 2-chloroethanol or (±)-ethyl lactate with I, II, and III led to the formation of corresponding *N*-alkylphthalimide. The reaction was further applied to the synthesis of esters of *N*-phthaloyl-α-amino acid. (*S*)-(−)-ethyl 2-hydroxy-3-phenylpropionate was converted into (*R*)-(+)-*N*-phthaloylphenylalanine ethyl ester with high stereospecificity.

In previous reports, we described the efficient, stereospecific intermolecular dehydration between alcohols and acidic compounds with $pK_a<13$ by means of diethyl azodicarboxylate (I) and triphenylphosphine (II).[2] The present work was undertaken to examine functional selectivity of the reaction and stereospecific α-amino acid synthesis.

Functional Selectivity. Intermolecular dehydration by means of I and II proceeds under mild neutral conditions. Thus, when alcohols bearing another functional group such as halogen or double bond were used, the hydroxyl group would selectively undergo the reaction giving the corresponding condensation products which can be used in the subsequent displacement or addition reaction.

When allyl alcohol, 2-chloroethanol or (±)-ethyl lactate was allowed to react with I, II and phthalimide (III) at room temperature, *N*-allyl-, *N*-(2-chloroethyl)-phthalimide and (±)-*N*-phthaloylalanine ethyl ester was obtained in 73, 72, and 58% yield, respectively. No affection of functional groups other than the hydroxyl group was observed. It would be reasonable to assume the formation of an alkoxyphosphonium salt (IV) as an intermediate.

The reaction of benzyl alcohol with I and II resulted in the formation of diethyl *N*-benzylhydrazodicarboxylate and triphenylphosphine oxide in good yields.[3] Benzyl-oxygen bond in a benzyloxyphosphonium salt is readily cleaved by the attack of nucleophiles.[4] These facts led us to test the benzylation of III by the present method. When benzyl alcohol was treated with I, II, and III in a similar manner to that described above, *N*-benzylphthalimide was isolated in a 70% yield and no diethyl *N*-benzylhydrazodicarboxylate was obtained.



α-Hydroxy acids are easily dehydrated to afford the corresponding alkenes if carbon-carbon double bonds formed are particularly stabilized by conjugation with carbonyl and phenyl groups. In order to know limitations of the present procedure, the following reactions were attempted. (*S*)-(−)-Ethyl 2-hydroxy-3-phenylpropionate was allowed to react with equimolar amounts of I, II, and III, *N*-phthaloylphenylalanine ethyl ester (V) being isolated in a 46% yield. When the reaction was carried out by the use of 2 molar equivalents each of I and II, the yield of V increased to 66%. The reaction of methyl 2-hydroxy-2-methylpropionate, a tertiary alcohol, with I, II, and III gave only a 15% yield of methyl 2-phthalimido-2-methylpropionate. On the other hand, the reaction of diethyl malate with I, II, and III exclusively gave diethyl fumarate in a 59% yield. Diethyl fumarate was also obtained when the reaction was carried out in the absence of III.

The reaction can be explained by assuming the formation of an alkoxyphosphonium salt (VI). The

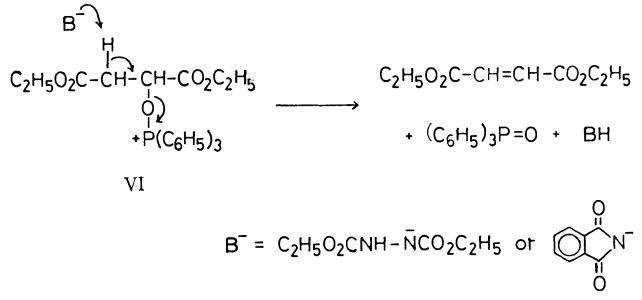
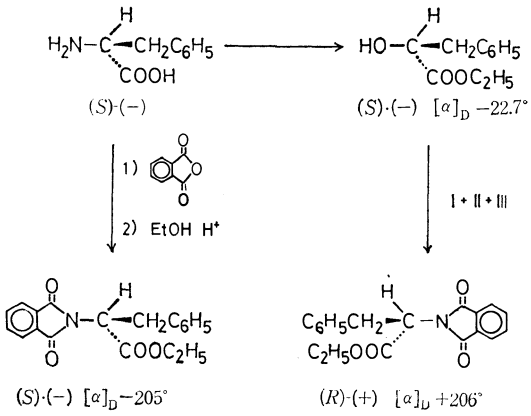
b) Diethyl fumarate was obtained in a 59% yield.

hydrogen atom at α'-carbon of the intermediate was abstracted by the anion of diethyl hydrazodicarboxylate giving diethyl fumarate, diethyl hydrazodicarboxylate and triphenylphosphine oxide. An alternative process in which active hydrogen atom at α'-carbon was abstracted by the anion of phthalimide is conceivable. Such a reaction has also been observed in the anhydrobond formation of uridine.[2b,5] Whether intermolecular dehydration takes place or intramolecular dehydration occurs would depend on relative acidities of active hydrogen of the alkoxyphosphonium salt, diethyl hydrazodicarboxylate and/or phthalimide.



Stereospecificity. Various esters of α-hydroxy acid were converted into the corresponding esters of *N*-phthaloyl-α-amino acid. The results are summarized in Table 1. For the preparation of α-amino acids, it is necessary to determine the steric course. In view of the results so far obtained,[2a,6] the present reaction can be expected to proceed with the inversion of configuration when displacement occurs at an asymmetric carbon.

N-Phthaloylphenylalanine ethyl ester (V) prepared by the reaction of (*S*)-(−)-ethyl 2-hydroxy-3-phenylpropionate with I, II, and III had $[\alpha]_D$ +206±4°. That V possesses *R*-configuration was established by comparison with the reference compound, (*S*)-(−)-*N*-phthaloylphenylalanine ethyl ester ($[\alpha]_D$ −205±1°), prepared from (*S*)-(−)-phenylalanine by stereochemically unambiguous sequences. This result indicates that the complete or almost complete inversion occurred in the intermolecular dehydration reaction.



Experimental

The IR spectra were measured on a Nippon Bunko IR-G spectrophotometer. The NMR spectra were obtained on a Hitachi Perkin-Elmer R-20 high resolution spectrometer at 60 MHz. The chemical shifts (δ) are expressed in ppm from internal tetramethylsilane. The optical rotation was measured with JASCO ORD/UV-5. Thin layer chromatography (tlc) was carried out on Wakogel B-5 or Merck PF_{254}.

N-Allyl- and N-(2-Chloroethyl)-phthalimide. A solution of I (174 mg, 1 mmol) in tetrahydrofuran (THF, 2 ml) was added dropwise to a solution of II (262 mg, 1 mmol), III (147 mg, 1 mmol) and either allyl alcohol (117 mg, 2 mmol) or 2-chloroethanol (161 mg, 2 mmol) in THF (3 ml) with stirring at room temperature. After the solution was kept standing overnight, it was applied to a silica gel plate which was then developed in benzene giving the desired products.

N-Allylphthalimide: 136 mg, 73%, mp 72—73 °C (from *n*-heptane). NMR (CCl_4); 4.2 (2H, $-CH_2-$), 5—6.2 (3H, $-CH=CH_2$), 7.7 (4H, aromatic H).

N-(2-Chloroethyl)phthalimide: 151 mg, 72%, mp 82—84 °C (from *n*-heptane containing a small amount of ether). NMR (CCl_4); 3.5—4.1 (4H, $-CH_2-CH_2-$), 7.75 (4H, aromatic H).

N-Phthaloylalanine Ethyl Ester. (±)-Ethyl lactate (118 mg, 1 mmol) was treated with I (147 mg, 1 mmol), II (262 mg, 1 mmol) and III (147 mg, 1 mmol) in THF (3 ml) in the same manner as above. After 3.5 hr, the solution was concentrated and applied to a silica gel plates, developed in chloroform giving *N*-phthaloylalanine ethyl ester; 144 mg, 58%, mp 60—61 °C (from petroleum ether). Found: C, 63.14; H, 5.30%. Calcd for $C_{13}H_{13}NO_4$: C, 63.15; H, 5.30%.

NMR (CCl_4); 1.25 and 4.2 (3H and 2H, CH_3–CH_2–O–), 1.7 (3H, >CH–C$\underline{H}_3$), 4.85 (1H, >C$\underline{H}$–CH_3), 7.75 (4H, aromatic H). IR (KBr) cm^{-1}; 1780, 1720 (C=O).

N-Benzylphthalimide and Methyl 2-Phthalimido-2-methylpropionate. In the same manner as above, *N*-benzylphthalimide was isolated in a 75% yield by preparative tlc (benzene). When the reaction was carried out in an ice bath, the yield of *N*-benzylphthalimide decreased to 70%; NMR (CCl_4): 4.75 (2H, $-CH_2-$), 7—8 (9H, aromatic H). IR (KBr) cm^{-1}: 1770, 1720 (C=O).

Similarly, methyl 2-hydroxy-2-methylpropionate was converted into methyl 2-phthalimido-2-methylpropionate in a 15% yield. NMR (CCl_4): 1.8 (6H, $(CH_3)_2C$<), 3.7 (3H, CH_3O–), 7.74 (4H, aromatic H). IR (liquid film) cm^{-1}: 1770, 1730 (C=O).

Reaction of Diethyl Malate with I and II in the Presence or Absence of III. Diethyl malate (190 mg, 1 mmol) was allowed to react with equimolar amounts of I, II, and III in THF (4 ml) at room temperature for 3 hr. The reaction mixture was separated by preparative tlc (chloroform) giving diethyl fumarate; 105 mg, 59%. NMR: 1.30 and 4.18 (6H and 4H, CH_3–CH_2–O–), 6.75 (2H, ^{H}>C=C<$_{H}$). IR (liquid film) cm^{-1}: 1715 (C=O), 1640 (>C=C<). When the reaction was carried out in the absence of III, diethyl fumarate was afforded in a 51% yield.

(R)-(+)-N-Phthaloylphenylalanine Ethyl Ester. (*S*)-(−)-Ethyl 2-hydroxy-3-phenylpropionate[7] (194 mg, 1 mmol, $[\alpha]_D$ −22.7° (*c* 4.52 in benzene); lit,[7a] $[\alpha]_D^{24}$ −22.6° (*c* 4.33 in benzene)) was allowed to react with equimolar amounts of I, II, and III at room temperature for 3 hr. The reaction mixture was separated by preparative tlc (benzene) giving (*R*)-(+)-*N*-phthaloylphenylalanine ethyl ester; 148 mg, 46%, mp 65—66 °C. NMR (CCl_4): 1.2 and 4.2 (3H and 2H, CH_3–CH_2–O–), 3.5 (2H, $C_6H_5C\underline{H}_2$–), 5.05 (1H, >C–H), 7.1 and 7.6 (5H and 4H, aromatic H). IR cm^{-1}: 1780, 1720 (C=O). $[\alpha]_D$ +210.6° (*c* 0.470 in benzene) and +201.5° (*c* 0.428 in benzene). Average $[\alpha]_D$ +206±4°.

(S)-(−)-N-Phthaloylphenylalanine Ethyl Ester. Dry hydrogen chloride was passed through a solution of (*S*)-(−)-phthaloylphenylalanine[8] (2.95 g, 10 mmol) in ethanol (9.20 g) for 1 hr and the solution was refluxed for 1 hr. After removal of the solvent, the residue was applied to a silica gel plate which was developed in benzene. The crude (*S*)-(−)-*N*-phthaloylphenylalanine ethyl ester (1.31 g) thus obtained was again purified by tlc, mp 56—57 °C. This product was further recrystallized from petroleum ether; $[\alpha]_D$ −206.2° (*c* 0.456 in benzene) and −204.1° (*c* 0.446 in benzene). Average $[\alpha]_D$ −205±1°.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 2835—2839 (1973)

Synthesis of Pyrimidines and Condensed Pyrimidines

Shigeru KOBAYASHI

Chemical Research Laboratories, Central Research Division, Takeda Chemical Industries, Ltd., Osaka 532

(Received March 31, 1973)

A new one-step synthesis of pyrimidines and condensed pyrimidines by heating carboxamides or cyclic lactams with formamide in the presence of $POCl_3$ in a sealed tube is described.

This paper provides the full version of the new one-step synthesis of pyrimidine and condensed pyrimidine compounds published in a previous communication.[1)]

4-Aminopyrimidine (**1a**) was obtained when a mixture of acetamide and formamide (FA) was heated in the presence of $POCl_3$ at 120 °C in a sealed vessel for 12 hr. The structure was established by comparing its IR spectrum with that of an authentic material.

Several workers have already reported the one-step synthesis of pyrimidines. Davies *et al.*[2a)] reported syntheses of 4-amino-5-arylpyrimidines in yields of 4—54%, by heating arylacetonitriles and FA under nitrogen flow. However, under these conditions, aliphatic nitriles and FA did not react. Tsatsaronis and Kehayoglov[2b)] also obtained 4-amino-5-arylpyrimidines in yields of 7—54% by the reaction of tris(formylamino)methane with substituted acetonitriles, acetamides, and the corresponding esters. But the yield of 4-amino-5-methylpyrimidine was only 1.8%. Bredereck *et al.*[3)] obtained purine in 19% yield by heating aminoacetonitrile and FA. Loader and Timmons[4)] obtained benzo[*f*]quinazoline by heating β-naphthylamine and FA in the presence of $POCl_3$ in a yield of 3.5%. Yamada and Okamoto[5)] also obtained purine by heating FA alone for 28 hr in 20.5% yield.

Experiments designed to maximize the yield of **1a** showed that the best yields were obtained when the reaction was carried out between 120—160 °C (Fig. 1), with the optimum reaction time being 12—20 hr (Fig.

5) H. Yamada, and T. Okamoto, *Chem. Pharm. Bull.* **20**, 632 (1972).

2). Although the yield did not change significantly as the molar ratio of FA to acetamide varied, maximum yield was obtained when this ratio was between 2: 1 and 3: 1 (Fig. 3). The final and most crucial factor varied in this study of reaction conditions was the condensing agent (Table 1). Of the several condensing agents tested, $POCl_3$ and PCl_5 proved to be effective, with $POCl_3$ giving higher yields of **1a**. The best

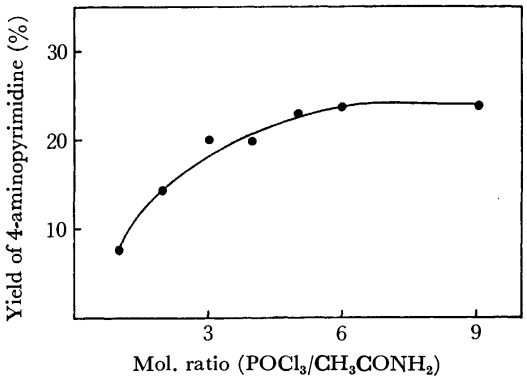

Fig. 4. Effect of mol. ratio ($POCl_3$ to CH_3CONH_2) on the yield of 4-aminopyrimidine (**1a**).
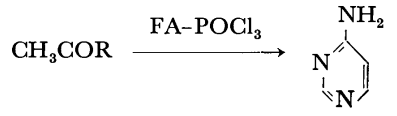
Reaction temp.: 120 °C, Reaction time: 10 hr
Mol. ratio (FA/CH_3CONH_2): 2

$POCl_3$ to acetamide ratio was between 3 and 9 (Fig. 4). The isolated yield of **1a** was 32% when a mixture of acetamide, FA and $POCl_3$ (molar ratio 1: 2: 3) was heated in a sealed tube at 120 °C for 12 hr.

When acetic acid and ethyl acetate were used instead of acetamide, **1a** was also obtained in yields of 13 and 12%, respectively. In these cases, acetamide is thought to be formed in the reaction media *via* acid-amide exchange reaction and then similarly converted to **1a**. Acetic chloride and acetic anhydride also gave **1a** although the yields diminished significantly, as shown in Table 2.

One-Step Synthesis of 4-(Substituted amino)pyrimidines. Although the reaction mechanism of this novel one-step synthesis is far from clear, it is worthwhile to note that

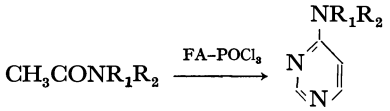
Table 2. Yields of 4-aminopyrimidine (**1a**) from acetic acid derivatives



R	Yield of 4-aminopyrimidine (%)
NH_2	34
OH	13
OCH_2CH_3	12
Cl	4.7
$OCOCH_3$	3.5

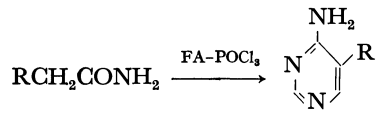
Reaction temp.: 120°.
Reaction time: 12 hr.

two nitrogen atoms on a pyrimidine nucleus originate from FA, as shown in the following examples. *N,N*-Dimethylacetamide, when treated with FA–$POCl_3$, gave 4-(dimethylamino)pyrimidine (**2**). Similarly, acetanilide gave 4-anilinopyrimidine (**3**).



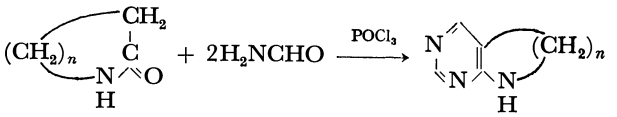
2: $R_1=R_2=CH_3$ (17%)
3: $R_1=H$, $R_2=Ph$ (9%)

One-Step Synthesis of 4-Amino-5-alkylpyrimidines. In other attempts to generalize the one-step synthesis, propionamide and stearamide were treated with FA–$POCl_3$. The product isolated from the propionamide experiment was the anticipated 4-amino-5-methylpyrimidine (**1b**). Similarly, stearamide gave 4-amino-5-hexadecylpyrimidine (**1i**). Other aliphatic carboxamides could be used and the same class of compounds was obtained, as shown in Table 3. Thus, these reactions furnish a convenient one-step synthesis of 4-amino-5-alkylpyrimidines, as illustrated by the general equation:



1

One-Step Synthesis of Condensed Pyrimidines. Cyclic lactams could also be the substrates of this novel one-step synthesis. Thus, α-pyrrolidone (**4**), δ-valerolactam (**5**), and ε-caprolactam (**6**) gave 5,6-dihydro-7*H*-pyrrolo-[2,3-*d*]pyrimidine (**7**), 5,6,7,8-tetrahydropyrido[2,3-*d*]-pyrimidine (**8**) and 5,6,7,8-tetrahydro-9*H*-pyrimido[4,5-*b*]azepine (**9**), respectively.



4: $n=2$
5: $n=3$
6: $n=4$

7: $n=2$ (9%)
8: $n=3$ (15%)
9: $n=4$ (7%)

When adipamide was treated with FA–$POCl_3$, the isolated product was white and crystalline, and its analysis agreed with the formula $C_7H_9N_3$. Its NMR spectrum was consistent with the structure of 4-amino-6,7-dihydro-5*H*-cyclopenta[*d*]pyrimidine (**10**).
