Dependence of the Catalytic Rate on [As(V)]. The dependence of R_c on [As(V)](0.066—0.15 M) has been studied at 30 °C, pH 7.78; [As(III)]=6.2×10^{-4} M, and I=0.43 M (Fig. 4). Corrections were applied to the observed rates for the small differences in pH (<0.1). The plots of log R_c against log [As(V)] fall on a straight line with a slope of 1.10 ± 0.07. The catalytic process is approximately first-order with respect to [As(V)].

The rate law of the catalytic process may be written as:

$$R_c = k[H^+][As(III)][As(V)]. \quad (1)$$

Mechanism of the Catalytic Process. Wilson and Dickinson[3] have shown that the exchange of radioactive arsenic does not occur between arsenite and arsenate ions in dilute acid(0.1 M HCl) and alkaline(*ca* 1 M NaOH) solutions. This indicates that the direct transfer of oxygen atoms does not occur between these ions. Thus, a mechanism of the catalysis of the oxygen exchange which involves a rapid interchange of oxygen between arsenious acid and water, followed by a transfer of oxygen from the arsenate to the arsenious acid, may be excluded.

Another possibility is the general acid catalysis of the exchange reaction between arsenate ions and water by arsenious acid. In this case, it is natural to interpret the bimolecular rate term of the arsenate-water exchange,[1] $k_4[H_2AsO_4^-]^2$, also in terms of the general acid catalysis by $H_2AsO_4^-$. However, since $H_2AsO_4^-$ is a stronger acid than H_3AsO_3, the mechanism involving the general acid catalysis is inconsistent with the fact that the arsenate-water exchange is catalyzed by arsenious acid.

The catalytic process may be considered to be the reversible condensation of arsenate ions with arse-

2) [As(III)] is the total concentration of the arsenious acid; [As(III)]=[H_3AsO_3]+[$H_2AsO_3^-$].

3) J. N. Wilson and R. G. Dickinson, *J. Amer. Chem. Soc.*, **59**, 1358 (1937).

nious acid or arsenite ion to form arsenitoarsenate ions:

$$H_2AsO_4^- + H_3AsO_3 \rightleftharpoons H_3As_2O_6^- + H_2O, \text{ etc.}$$

The rate law of the catalytic process may now be written as:

$$R_c = k_1[H_2AsO_4^-][H_3AsO_3] + k_2[HAsO_4^{2-}][H_3AsO_3] + k_3[H_2AsO_4^-][H_2AsO_3^-] + k_4[HAsO_4^{2-}][H_2AsO_3^-]. \quad (2)$$

Since $R_c \approx 0$ at pH$\approx$10, the contribution of the k_4-term may be ignored. The rate law (2) becomes:

$$\frac{R_c}{[H_2AsO_4^-][H_3AsO_3]} = k_1 + \frac{K_2}{[H^+]}\left\{k_2 + k_3\frac{K_1'}{K_2}\right\}, \quad (3)$$

where K_2 and K_1' are the dissociation constants of $H_2AsO_4^-$ and H_3AsO_3 respectively.

In Fig. 5, the data in Fig. 1 are replotted according to the above equation. From the intercepts of the lines drawn through the plots, the values of k_1 are determined to be $k_1(30\,°C) = 6.8\ M^{-1}\,s^{-1}$ and $k_1(14.5\,°C) = 2.2\ M^{-1}\,s^{-1}$. The activation parameters of the k_1-path are $E_a = 52.3$ kJ mol^{-1} and $\Delta S^{\neq} = -38$ J K^{-1} mol^{-1}.

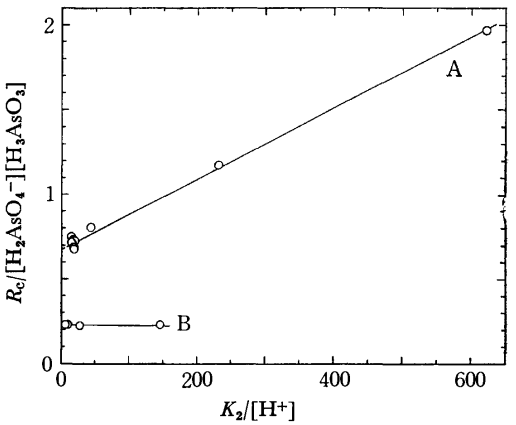

Fig. 5. $R_c/[H_2AsO_4^-][H_3AsO_3]$ as a function of $K_2/[H^+]$: A; 30 °C, B; 14.5 °C.

Table 2. Rates and activation parameters of several reactions of $H_2AsO_4^-$.

	Rate const. ($M^{-1}\,s^{-1}$), 30°C	Act. energy (kJ mol^{-1})	$\Delta S^{\neq}$ (J K^{-1} mol^{-1})
$H_2AsO_4^- + H_2O$,[a]	1.1×10^{-4}	$\approx$92	≈ -46
$H_2AsO_4^- + H_2AsO_4^-$,[a]	7.4×10^{-2}	$<$54	< -71
$H_2AsO_4^- + H_3AsO_3$,[b]	6.8	52	-38

a) $I = 0.55$ M, b) $I = 0.2$ M.

From the slope of the line A (Fig. 5), the value of $\{k_2 + k_3(K_1'/K_2)\}$ at 30 °C is evaluated as 0.02 $M^{-1}\,s^{-1}$. Since k_2 may reasonably be assumed to be larger than k_3 and since $K_1'/K_2 = 2.8\times10^{-3}$ at 30 °C, the value of k_2 may be put equal to 0.02 $M^{-1}\,s^{-1}$. This path plays a dominant role above pH 9. To estimate the value of k_2 at 14.5 °C is beyond the scope of the present work.

The reactivities of several nucleophiles towards $H_2AsO_4^-$ obtained in the present and the previous[1] works are listed in Table 2. The higher reactivity of arsenious acid as compared with $H_2AsO_4^-$ may be attributable to the entropy factor.

The authors wish to thank Professor Shinichi Kawaguchi of Osaka City University for his helpful discussions.

The Intensity in the Resonance Raman Effect. I. The Diatomic Molecule in the Harmonic Potential Approximation

Shunsuke KOBINATA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received April 14, 1973)

The formulas for the Raman intensities of fundamental and n-th overtones were investigated theoretically, starting from the Kramers-Heisenberg dispersion formula and referring to a diatomic molecule in a harmonic potential approximation. The derived formulas were then applied to fifteen overtone bands of iodine, which have been observed in gas, and to the exciting frequency dependence of the fundamental and the first overtone intensities of iodine in a $CHCl_3$ solution. It was shown that the formulas quantitatively explain the trend of the observed data well.

With the advent of various laser light sources, the resonance Raman effect has come to be investigated extensively in recent years. It has been observed that higher overtones appear in a spectrum with considerable intensities as the exciting light frequency approaches an electronic absorption band. For example, the fifteen overtones of iodine have been obtained in gas using the argon ion laser at 4880 Å by Holzer *et al.*[1]

The origin of the resonance Raman effect has been investigated theoretically by several authors. Peticolas *et al.*[2,3] have derived the formula of the n-th overtone Raman intensity using the technique of the time-ordered diagram and have then applied this equation to the experimental data on iodine in gas. The quantitative agreement with the observed data has been poor for higher overtones. Verlan[4] has investigated the formula of the resonance Raman intensity based on the generalized perturbation theory of Heitler,[5] and has formulated a rather complicated expression.

We obtained a simple expression of the Raman intensity starting from the Kramers-Heisenberg dispersion equation and using the idea of the effective transition frequency.[6] The vibrational frequency difference between the ground and the excited electronic states was taken into account. The formulas were then applied to the observed data on iodine; reasonable results were obtained.

Method

The intensity of the Raman scattering associated with the $m \rightarrow n$ vibrational transition in the electronic ground state, $|g\rangle$, is given,[7] after averaging the overall orientation of the molecule, by:

$$I_{mn} = (2^7\pi^5/(3^2c^4))I_0(\nu_0+\nu_{mn})^4 \sum_{\rho,\sigma} (\alpha_{\rho\sigma})^2_{mn} \quad (1)$$

where ν_0 and I_0 are the frequency and the intensity of the incident light. The ρ,σ (=x, y, z) component of the scattering associated with the transition is expressed by:

$$(\alpha_{\rho\sigma})_{mn} = (1/h) \sum_{e,v} (M_\rho)_{ev,gn}(M_\sigma)_{gm,ev}/(\nu_{ev,gn}-\nu_0+i\gamma_e) + (M_\rho)_{gm,ev}(M_\sigma)_{ev,gn}/(\nu_{ev,gn}+\nu_0+i\gamma_e) \quad (2)$$

in accordance with the Kramers-Heisenberg dispersion theory. Verlan has shown that Eq. (2) is applicable in the case of the resonance Raman effect. The summation is taken over all the electronic excited states, $|e\rangle$, and the vibrational states, $|v\rangle$, accompanying them. The γ is the damping constant of the electronic state $|e\rangle$.[4,7]

The vibronic transition moment, $(M_\rho)_{ev,gn}$, can be expanded in the nuclear coordinate, Q, of a diatomic molecule assuming adiabatic approximation by:

$$(M_\rho)_{ev,gn} = (M_\rho)^0_{ge}\langle ev|gn\rangle + (M_\rho)'_{ge}\langle ev|Q|gn\rangle \quad (3)$$

where $(M_\rho)_{ge}{}^0$ is the component of the pure electronic transition moment at the equilibrium configuration in the $|g\rangle$ state. $(M_\rho)_{ge}{}'$ is the derivative of the electronic transition moment with respect to the nuclear coordinate, Q, $(M_\rho)_{ge}{}'=\{\partial(M_\rho)_{ge}/\partial Q\}_0$. The $\langle ev|gn\rangle$ and $\langle ev|Q|gn\rangle$ give integrals in the nuclear coordinate between the vibrational-state functions of $|e\rangle$ and $|g\rangle$ states.

Following Albrecht,[7,9] Eq. (2) is given by the representation:

$$(\alpha_{\rho\sigma})_{mn} = A_{mn} + B_{mn} + B'_{mn} \quad (4)$$

$$A_{mn} = (1/h) \sum_{e,v} (M_\rho)^0_{ge}M_\sigma)^0_{ge}\langle gm|ev\rangle\langle ev|gn\rangle \times\{(\nu_{ev,gm}-\nu_0+i\gamma_e)^{-1} + (\nu_{ev,gn}+\nu_0+i\gamma_e)^{-1}\} \quad (4a)$$

$$B_{mn} = (1/h) \sum_{e,v} (\nu_{ev,gm}-\nu_0+i\gamma_e)^{-1} \times\{(M_\rho)^0_{ge}(M_\sigma)'_{ge}\langle gm|Q|ev\rangle\langle ev|gn\rangle + (M_\rho)'_{ge}(M_\sigma)^0_{ge}\langle gm|ev\rangle\langle ev|Q|gn\rangle\} \quad (4b)$$

$$B'_{mn} = (1/h) \sum_{e,v} (\nu_{ev,gn}+\nu_0+i\gamma_e)^{-1} \times\{(M_\rho)^0_{ge}(M_\sigma)'_{ge}\langle gm|ev\rangle\langle ev|Q|gn\rangle + (M_\rho)'_{ge}(M_\sigma)^0_{ge}\langle gm|Q|ev\rangle\langle ev|gn\rangle\} \quad (4c)$$

The A_{mn} term, which does not depend on the vibronic interaction, $(M_\rho)'_{ge}$, contributes to the Raman intensity

only when the electronic ground and excited states have the potential curves displaced or distorted in relation to each other.[10] The B_{mn} and B'_{mn} terms depend on the vibronic interaction, $(M_\rho)'_{ge}$, and have been extensively investigated by Albrecht in the case of the ordinary Raman effect. For practical use, we must further simplify these expressions of the scattering tensor.

A_{mn} Term. First, let us investigate the A_{mn} term. For the sake of simplicity, we will consider the vibration of a diatomic molecule assuming a harmonic oscillator. The vibrational ground state, $|g0\rangle$, is taken as the initial state, $|gm\rangle$. Then, the frequency corresponding to the vibronic transitions concerned may be expressed as:

$$\nu_{ev,g0} = \nu_{e0,g0} + v\nu_e \tag{5}$$

where $\nu_{e0,g0}$ is the 0–0 transition frequency between $|g\rangle$ and $|e\rangle$ electronic states, and where ν_e is the vibrational frequency in the $|e\rangle$ state. The substitution of the above expression into Eq. (4a) leads to:

$$A_{0n} = \sum_e \{(M_\rho)^0_{ge}(M_\sigma)^0_{ge}/(h\nu_e)\} \sum_v \langle g0|ev\rangle\langle ev|gn\rangle \times \{(c_1+v)^{-1}+(c_2+v)\}^{-1} \tag{6}$$

where:

$$c_1 = (\nu_{e0,g0}-\nu_0+i\gamma_e)/\nu_e$$
$$c_2 = (\nu_{e0,gn}+\nu_0+i\gamma_e)/\nu_e. \tag{6a}$$

It is generally difficult to carry out the summation over v because the $|e\rangle$ state gives a different equilibrium internuclear distance, r_e^0, and different fundamental vibrational frequency, ν_e, from the corresponding quantities in the ground state, r_g^0 and ν_g. Therefore we will first consider a somewhat specialized case where $\nu_e=\nu_g$ but where $r_e^0=r_g^0$.

Now using the expression of the Franck-Condon overlap integrals given by Hutchinson,[11,12] we obtain for $\nu_e=\nu_g$:

$$\langle gm|ev\rangle = \exp(-\delta_e^2/4)/\sqrt{(m!v!)/(2^{m+v})}\,\delta_e^m \times \sum_{k=0}((-1)^{m-k}2^k\delta_e^{v-2k})/(k!(m-k)!(v-k)!) \tag{7}$$

and, consequently:

$$\sum_v \langle g0|ev\rangle\langle ev|gn\rangle/(c+v) = \sqrt{n!/2^n}(-\delta_e)^n\exp(-\delta_e^2/2) \times \sum_{k=0}(-1)^k/(k!(n-k)!)\sum_v(\delta_e^2/2)^{v-k}/(c+v)(v-k)! \tag{8}$$

where:

$$\delta_e = \alpha_e(r_g^0-r_e^0) \tag{9}$$
$$\alpha_e = 4\pi^2\mu\nu_e/h;\ \mu;\ \text{reduced mass} \tag{9a}$$

The dimensionless quantity, δ_e, is the difference in the equilibrium internuclear distance between the $|g\rangle$ and $|e\rangle$ states in the unit of the classical vibrational amplitude, $1/\alpha_e$, of the vibrational ground state.

The summation over v on the right-hand side of Eq. (8) can be approximately written as:

$$\sum_v(\delta_e^2/2)^{v-k}/((c+v)(v-k)!) \doteqdot \exp(\delta_e^2/2)/(c+\delta_e^2/2+k) \tag{10}$$

It can easily be seen that the above relation applies fairly well for $c=1$ for all values of δ_e and when $\delta_e<1$ for a wide range of c.

Then, using the formula:

$$\sum_{k=0}^{n}(-1)^k n!/((c+k)(n-k)!k!) = n!/\{c(c+1)\cdots\cdots(c+n)\} \tag{11}$$

Equation 8 can be written as:

$$\sum_v \langle g0|ev\rangle\langle ev|gn\rangle/(c+v) = \sqrt{n!/2^n}(-\delta_e)^n/\{c^*(c^*+1)\cdots\cdots(c^*+n)\} \tag{12}$$

where, according to Eq. (10):

$$c^* = c + \delta_e^2/2. \tag{12a}$$

Thus, we have:

$$A_{0n} = (1/h)Q_n\sum_e(M_\rho)^0_{ge}(M_\sigma)^0_{ge}(-\delta_e\nu_e)^n \times\{\prod_{p=0}^{n}(\nu_{eg}-\nu_0+i\gamma_e+p\nu_e)^{-1} + \prod_{p=0}^{n}(\nu_{eg}+\nu_0+i\gamma+p\nu_e)^{-1}\} \tag{13}$$

where:

$$Q_n = \langle g0|Q^n|gn\rangle = \sqrt{n!/2^n} \tag{13a}$$
$$Q = \alpha_g(r-r_g^0) \tag{14}$$

ν_{eg} is the effective transition frequency from $|g\rangle$ to $|e\rangle$ and may be represented approximately, according to Eq. (12a), by:

$$\nu_{eg} \doteqdot \nu_{e0,g0} + \nu_e\delta_e^2/2 \tag{15}$$

which equals the vertical transition frequency from the $|g\rangle$ to the $|e\rangle$ state. Equation (15) indicates that the maximum Raman scattering would occur at the position of the absorption maximum. However, this statement should be modified slightly when applied to the real system, because we neglected the effect of the anharmonicity of the potential curves and the effect of the other virtual states. Therefore, there may occur the case in which the position of the maximum Raman scattering differs to some extent from that of the absorption maximum.

Next, let us deal with another specialized case where $r_g^0=r_e^0$ but where $\nu_e \fallingdotseq \nu_g$. The Franck-Condon overlap integrals in Eq. (4a) are calculated by a method similar to that used before. Then, the scattering tensor may be represented as:

$$A_{0,2n} = (1/h)\,Q_{2n}\sum_e(M_\rho)^0_{ge}(M_\sigma)^0_{ge}(-\nu_e\Delta_e)^n \times\{\prod_{p=0}^{n}(\nu_{eg}-\nu_0+i\gamma_e+p\nu_e)^{-1} + \prod_{p=0}^{n}(\nu_{eg}+\nu_0+i\gamma_e+p\nu_e)^{-1}\} \tag{16}$$

where

$$\Delta_e = (\nu_e-\nu_g)/(\nu_e+\nu_g) \tag{17}$$

retaining only the term which has the lowest order of Δ_e.[12]

The general case of $r_e^0 \fallingdotseq r_g^0$ and $\nu_e=\nu_g$ may be

10) W. Siebrand, *ibid.*, **46**, 440 (1967).
11) E. Hutchinson, *Phys. Rev.*, **36**, 410 (1930).
12) C. Ting, *Spectrochim. Acta*, **24A**, 1177 (1968).

treated by introducing explicitly ν_e and ν_g into Eq. (12), in which $\nu_e=\nu_g$ has been assumed, and by then combining this with Eq. (16). This leads to the following expression of $A_{0,n}$:

$$A_{0n} = \langle g0|A_- + A_+|gn\rangle \tag{18}$$

where:

$$A_\mp = (1/h)\sum_e \{(M_\rho)^0_{ge}(M_\sigma)^0_{ge}/(\nu_{eg}\mp\nu_0+i\gamma_e) \times (1+\nu_e\delta_e Q/\langle\nu_{eg}\mp\nu_0+i\gamma_e\rangle)^{-1} \times (1+\nu_e\Delta_e Q^2/\langle\nu_{eg}\mp\nu_0+i\gamma_e\rangle)^{-1} \tag{18a}$$

The bracket notation is used for the sake of simplicity. It indicates that, in expanding the above equation, $\langle\nu_{eg}\mp\nu_0+i\gamma_e\rangle^q$ must be replaced by $\prod_{p=1}^{q}(\nu_{eg}\mp\nu_0+i\gamma_e+p\nu_e)$. The contribution of Eq. (16) to the scattering tensor must be considerably smaller than that of Eq. (12), because usually $\Delta_e \ll 1$.

Supposing the A term is dominant in Eq. (4), and neglecting the contribution of Eq. (16), the intensity of the n-th overtone, I_{0n}, is expressed as:

$$I_{0n} = K(\nu_0-n\nu_g)^4 n!(\nu_0^2\delta_e^2/2)^n \times \prod_{p=0}^{n}\{(\nu_0-\nu_{eg}+p\nu_e)^2+\gamma_e^2\}^{-1} \tag{19}$$

when ν_0 approaches ν_{eg}.

Equation (19) has a form similar to Eq. (2) of Peticolas *et al*,[2] apart from the hot-band summation, which is neglected in our treatment. The main differences between our Eq. (19) and Eq. (2) of Peticolas *et al.* are, in the energy denominator, the presence of the effective transition frequency, ν_{eg}, and the vibrational frequency, ν_e, of the electronic excited state, instead of the 0-0 transition frequency and the vibrational frequency, ν_g, of the electronic ground state. In order to take into account of the effect of $\nu_e \neq \nu_g$ on the Raman intensity by means of the formulation of Peticolas *et al.* it is necessary to carry out a higher-order perturbation expansion. The physical meaning of the appearance of ν_e instead of ν_g is apparent, because the resonance should occur at the incident light frequency, $\nu_0=\nu_{eg}+p\nu_e$. When the vibrational frequencies, ν_g and ν_e, are quite different as in the case of iodine and bromine, the presence of ν_e instead of ν_g has a significant effect upon the resonance Raman intensity. The necessity of introducing the effective transition frequency, ν_{eg}, has clearly been shown experimentally by Yu and Shen using a tunable dye laser.[13] They have shown that the resonance Raman scattering cross-section of InSb as a function of the incident-light frequency has a maximum at an appreciably higher position than that of the reflectivity spectra.

The B_{mn} and B_{mn}' Vibronic Terms. In order to estimate the contribution of the B_{0n} and B_{0n} vibronic terms of Eqs. (4b) and (4c), it is necessary to carry out the following types of summation:

$$\sum_v \langle g0|ev\rangle\langle ev|Q|gn\rangle/(c+v) \quad \text{and} \quad \sum_v \langle g0|Q|ev\rangle\langle ev|gn\rangle/(c+v) \tag{20}$$

Using the relations applicable to a harmonic oscillator;

$$2Q|gn\rangle = \sqrt{n}\,|g,n-1\rangle + \sqrt{(n+1)}\,|g,n+1\rangle$$
$$Q|g0\rangle = |g,1\rangle$$

we can transform the above summation into the following form:

$$\sum_v \langle g0|ev\rangle\langle ev|g,\ n\pm1\rangle/(c+v) \tag{21a}$$

$$\sum_v \langle g1|ev\rangle\langle ev|gm\rangle/(c+v) \tag{21b}$$

Eq. (21a) is the same type of summation as appears in the calculation of the A-term (Eq. (8)); Eq. (21b) is generally difficult to estimate. When there is an ordinary Raman effect, $|c|\gg 0$, however, this summation may be written as:

$$\sum_v \langle g1|ev\rangle\langle ev|gm\rangle/(c+v) = \sqrt{n!/2^{n-1}}\,(-\delta_e)^{n-1}\prod_{p=1}^{n}(c+p)^{-1} \tag{22}$$

We assume that this equation holds approximately in the case of the resonance and preresonance Raman effect if we replace the c of Eq. (22) with the c^* of Eq. (11a), *i.e.*, if we introduce the effective transition frequency, ν_{eg}, and the damping constant, γ_e. Thus, the vibronic terms may be represented as:

$$B_{0n} = (1/h)Q_n\sum_e(-\nu_e\delta_e)^{n-1} \times\{(M_\rho)^0_{ge}(M_\sigma)'_{ge}+(M_\rho)'_{ge}(M_\sigma)^0_{ge}\} \times\prod_{p=1}^{n-1}\{(\nu_0-\nu_{eg}+i\gamma_e)+p\nu_e\}^{-1} \tag{23}$$

$$B'_{0n} = (1/h)Q_n\sum_e(-\nu_e\delta_e)^{n-1} \times\{(M_\rho)^0_{ge}(M_\sigma)'_{ge}+(M_\rho)'_{ge}(M_\sigma)^0_{ge}\} \times\prod_{p=1}^{n-1}\{(\nu_0+\nu_{eg}+i\gamma_e)+p\nu_e\}^{-1}. \tag{24}$$

Equations (23) and (24) indicate that, for the appearance of overtones by the vibronic mechanism, it is necessary, along with $M_{ge}'\neq 0$, that a molecule has a different geometry in the excited state from that of ground state, as in the A-term (Eq. 13).

As a summary of the above discussions of the A-term and the vibronic terms, the scattering tensor may be represented, using the same bracket notation as in Eq. (18b), by:

$$(\alpha_{\rho\sigma})_{0n} = \langle g0|S_- + S_+|gn\rangle$$
$$S_\mp = (1/h)\sum_e\{(M_\rho(Q))_{ge}(M_\sigma(Q))_{ge}/(\nu_{eg}\mp\nu+i\gamma_e)\} \times(1+\nu_e\delta_eQ/\langle\nu_{eg}\mp\nu_0+i\gamma_e\rangle)^{-1} \times(1+\nu_e\Delta_eQ^2/\langle\nu_{eg}\mp\nu_0+i\gamma_e\rangle)^{-1} \tag{25}$$

where $(M_\rho(Q))_{ge}=(M_\rho)_{ge}{}^0+(M_\rho)_{ge}{}'Q+\cdots$.
It may easily be seen that, under the appropriate conditions of the pre-resonant case, Eq. (25) gives the Shorygins semiclassical equation for the fundamental $n=1$,[6] using the relation:

$$\nu'_{eg} = (\partial\nu_{eg}/\partial Q)_0 = \nu_e\delta_e \tag{26}$$

13) P. Y. Yu and Y. R. Shen, *Phys. Rev. Lett.*, **29**, 468 (1972).

Comparison with Experiments

Holzer *et al.* observed the resonance Raman effect of iodine in a gas state up to the 15-th overtone using 4880 Å line of the argon ion laser as the exciting light.[1,3] Peticolas *et al.* have carried out a quantitative calculation of the relative intensities of these overtones with respect to the fundamental. The agreement with the observed data has been poor for the higher overtones.

Although several authors have emphasized the role of the continuous upper electronic state in the resonance Raman effect, we assume tentatively that the equations derived above are applicable to the case of the resonance Raman effect of iodine.[14-16]

Supposing that the contributions of the vibronic terms and Eq. (17) are negligible in the resonance Raman region, we re-calculated the relative intensities of the overtones of iodine with respect to the fundamental intensity: $R_n=I_{0n}/I_{01}$. R_n is represented, following Eq. (19), by:

$$R_n = (\nu_0-n\nu_g)^4/(\nu_0-\nu_g)^4(\nu_e^2\delta_e^2/2)^{n-1}n! \times \prod_{p=2}^{n}\{(\nu_{eg}-\nu_0+p\nu_e)^2+\gamma_e^2\}^{-1} \quad (28)$$

The δ_e, ν_{eg}, and γ_e values were determined so as to fit with the observed R_n, *i.e.*, so as to minimize $\sum_n |R_n^{calc}-R_n^{obs}|$, ($n$=2,3,·····,15). The ν_g and ν_e values were taken to be 215 cm^{-1} and 128 cm^{-1} respectively.[17] The results are shown in Table 1, along with the experimental data (Calc. 1 and Calc. 2). Although the results differ to some extent depending on the initial choice of the values of δ_e, ν_{eg} and γ_e, in any event the agreement between the calculated and the observed relative intensities are fairly good through the 15 overtones. The value, $|r_g^0-r_e^0|$=0.368~0.408 Å, calculated from δ_e using Eq. (9) coincides reasonably well with the observed value, 0.346 Å (Table 2). As to the effective transition frequency, a value of ν_{eg}= 20890~21200 cm^{-1} is obtained. This value is near to the frequency of the absorption maximum of iodine in gas (~20000 cm^{-1}). The ν_{eg} value calculated from Eq. (5), 17800~18200 cm^{-1}, is a little smaller than these. This difference probably arises from the neglect of the effect of anharmonicity and from the effect of the other virtual states in Eq. (5). It should be noted that the calculated value of the damping constant, γ =200~600 cm^{-1}, corresponds to the rate of the vibrational relaxation and the internal conversion, and is considerably larger than those of the fluorescence and the phosphorescence.[16] The calculations show that the introduction of the effective transition frequency, ν_{eg}, and the vibrational frequency, ν_e, of the electronic excited state in the energy denominator is important in obtaining agreement with the observed R_n.

Table 1. Intensities of overtones of iodine in gas relative to the fundamental

	Observed[1,2]	Calcd 1	Calcd 2	Calcd 3
R_2	0.71	0.672	0.675	0.708
R_3	0.55	0.531	0.550	0.538
R_4	0.45	0.450	0.486	0.450
R_5	0.36(±0.02)	0.391	0.442	0.388
R_6	0.25(±0.02)	0.340	0.402	0.339
R_7	0.22(±0.02)	0.293	0.359	0.296
R_8	0.22(±0.02)	0.248	0.312	0.257
R_9	0.194(±0.02)	0.204	0.263	0.219
R_{10}	0.194(±0.02)	0.163	0.213	0.183
R_{11}	0.167(±0.02)	0.127	0.167	0.151
R_{12}	0.139(±0.02)	0.096	0.126	0.121
R_{13}	0.111(±0.02)	0.070	0.091	0.096
R_{14}	0.084(±0.02)	0.050	0.063	0.074
R_{15}	0.084(±0.02)	0.034	0.042	0.056
δ_e		−6.34	−5.71	−6.37
$\nu_{eg}-\nu_0$ (cm^{-1})		691	397	737
γ_e (cm^{-1})		206	578	212
$\lvert r_g^0-r_e^0\rvert$ (Å)		−0.408	−0.368	−0.410
Δ_e		0	0	−0.36

To see the effect of Δ_e, we have calculated R_n on the basis of Eq. (18), considering Δ_e to be an adjustable parameter along with δ_e, ν_{eg} and γ_e. The results are shown in Table 1 (Calc. 3). As may be seen from Table 1, the introduction of Δ_e improves the agreement between the calculated and the observed relative intensities to some extent, but not very much. The calculated value of Δ_e=−0.36 is reasonable compared with the observed value, −0.254 (Table 2).

Strictly speaking, the equations derived above are applicable only to an isolated molecule. It is interesting, however, to apply these equations to a molecule in solution and to compare the results with that of gas obtained above. The intensity variation in the fundamental and the first overtone of iodine as a function of the exciting light frequency have been obtained by Mortensen in a chloroform solution.[18]

The relative intensities of the fundamental and the first overtone at the exciting light frequency, ν, relative to that of ν_0, $R_1(\nu,\nu_0)$ and $R_2(\nu,\nu_0)$, are given, following Eq. (19), by:

$$R_1(\nu,\nu_0) = \{(\nu-\nu_g)^4/(\nu_0-\nu_g)^4\} \times \prod_{p=0}^{1}\{(\nu_{eg}-\nu_0+p\nu_e)^2+\gamma_e^2\} \Big/ \prod_{p=0}^{1}\{(\nu_{eg}-\nu+p\nu_e)^2+\gamma_e^2\} \quad (29)$$

$$R_2(\nu,\nu_0) = \{(\nu-2\nu_g)^4/(\nu_0-2\nu_g)^4\} \times \prod_{p=0}^{2}\{(\nu_{eg}-\nu_0+p\nu_e)^2+\gamma_e^2\} \Big/ \prod_{p=0}^{2}\{(\nu_{eg}-\nu_0+p\nu_e)^2+\gamma_e^2\} \quad (30)$$

4880 Å	0.77	0.72	0.60	0.60	0.56	0.59
4765 Å	0.52	0.55	0.37	0.36	0.50	0.51
ν_{eg}	19220 cm^{-1}		19240		18600	
γ_e	2160 cm^{-1}		2140		2990	
$\|r_g^0 - r_e^0\|$					0.329 Å	

a) The observed data are taken from Ref. 18.

Applying these equations to the observed data, we can estimate γ_e and ν_{eg} so as to fit the observed data. The results are shown in Table 3. The agreement between the calculated and the observed values is fairly good. Furthermore, the values of $\gamma_e = 2160$ cm^{-1} and $\nu_{eg} = 19220$ cm^{-1} obtained from $R_1(\nu,\nu_0)$ coincide well with those of $\gamma_e = 2140$ cm^{-1} and $\nu_{eg} = 19240$ cm^{-1} obtained from $R_2(\nu,\nu_0)$. We have also determined ν_{eg}, γ_e, and δ_e from the exciting-light-frequency dependence of the first overtone with respect to the fundamental intensity, using the $R_2(\nu)$ of Eq. (28).

In the above calculations, we have neglected the effect of the hot-band summation. This effect is important in the higher overtones. The values of γ_e and δ_e derived from the R_n value of iodine gas would be increased and decreased respectively to some extent by taking into account the effect of the hot-band summation. This point will be investigated in a subsequent paper.

Finally, then, we can estimate $\gamma_e = 2000$—3000 cm^{-1} for iodine in a chloroform solution. This value is quite large compared with that of $\gamma_e = 200$—600 cm^{-1} of iodine in gas. This indicates that the damping constant is sensitively influenced by molecular interactions. The trend $\gamma_e(\text{soln}) \gg \gamma_e(\text{gas})$ seems reasonable because, in a solution, the molecular interactions are larger in gas, therefore, the excited state of a molecule usually has a smaller life-time.[19]

As a summary of the above discussions, we can say that the trend of the observed Raman intensities of iodine is explained well quantitatively by Eq. (19) in the resonance region. This would indicate that A-term of Eq. (4a) *i.e.*, the effect of the deformation of the molecular geometry and the vibrational frequency change in the excited state compared with that of the ground state, is a dominant factor in determining the resonance Raman intensities of iodine. Therefore, an analysis of the resonance Raman effect offers a means of estimating the molecular geometry and vibrational frequencies in the electronic excited state. The idea of the effective transition frequency and the introduction of the vibrational frequency, ν_e, of the electronic excited state in the energy denominator is necessary to obtain the simpler expressions and also to obtain an agreement with the observed data.

The author wishes to express his thanks to Professor Shiro Maeda of this Institute for his kind advice and discussions.

An Investigation of the Gas-Solid Interface Reaction

Masayuki KATSUMOTO, Kazuo FUEKI, and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 2, 1973)

The isotopic exchange between H_2S and D_2 on molybdenum disulfide and manganese sulfide has been studied kinetically between 420° and 500 °C. The reaction proceeded *via* these steps:

$$H_2S + D_2 = D_2S + H_2$$

$$H_2 + D_2 = 2\,HD$$

From the analysis of the kinetic data, the rate constant of the sulfurization of both metal sulfides by "hydrogen sulfide,"[1] k_1, and that of their reduction by "hydrogen,"[1] k_1', were calculated. The dependence of these rate constants on the sulfur activity was determined. A possible mechanism of the reaction at the surface of the sulfides is discussed in this paper.

Kobayashi and Wagner first determined the rate of the gas-solid interface reaction, not only as a function of the partial pressure of the reactant gases, but also as a function of the activity of chemical species in a solid, in their study of the reduction of Ag_2S by "hydrogen". They proposed a mechanism in which e^-, S, S^-, and S^{2-} in Ag_2S act as reactant species.[2]

The isotopic exchange method, one of those by which the rate of gas-solid interface reaction can be determined as a function of the activity of chemical species in a solid, has been applied to oxide and sulfide systems.[3-5] As to sulfide systems, Cu_2S (p-type semiconductor) and β-$Fe_{1-x}S$ (metallic conductor) were studied by present authors and their collaborators.[4,5] The experimental results for β-$Fe_{1-x}S$ could not be explained by the mechanism proposed by Kobayashi and Wagner.[2]

The present work aims to examine whether or not the gas-solid interface reaction on MoS_2 (an intrisic semiconductor)[6] and MnS (a p-type semiconductor)[7] can be explained on the basis of the Kobayashi-Wagner mechanism, by using the isotopic exchange method.

Experimental

Isotopic Exchange Study. The apparatus, the method of the purification of gases, and the experimental procedure were essentially the same as in previous works.[4,5]

The sulfide samples were prepared as follows:

(a) *MoS_2 sample*: A single crystal of molybdenite was cloven into thin films, which were then minced into small pieces. The surface area was 2.19×10^3 cm^2 g^{-1}. Spectroscopic analysis revealed that the sample was of a high purity.

(b) *MnS sample*: Hydrogen sulfide of a 99.9% purity was introduced into an aqueous solution of high-purity manganese acetate in order to precipitate manganous sulfide. After filtration, the precipitate was treated *in vacuo* at 300 °C for 1 hr and then in a "hydrogen sulfide"-"hydrogen" mixture at 900 °C for 5 hr. The surface area was 1.87×10^3 cm^2 g^{-1}.

The isotopic exchange was carried out after chemical equilibrium had been reached between the sulfide sample and the "hydrogen sulfide"-"hydrogen" gas mixture. Therefore, a_s, the sulfur activity of the solid, defined as the pressure ratio of "hydrogen sulfide" to "hydrogen", was kept constant throughout the isotopic exchange run, irrespective of the change in the concentration of the isotopic species.

Results and Discussion

Isotopic Exchange Reaction. Figures 1 and 2 show the change in x_{H_2}, x_{HD}, and x_{D_2}, the mole fractions of H_2, HD, and D_2 respectively, at different sulfur activities in the presence of MoS_2.

As was mentioned in a previous paper,[5] the following two mechanisms are possible for the formation of H_2 and HD. In the first mechanism, H_2 and HD formed by these steps:

$$H_2S \rightleftharpoons HS(ad) + H(ad) \quad (1a)$$

$$D_2 \rightleftharpoons 2\,D(ad) \quad (1b)$$

$$D(ad) + H(ad) \rightleftharpoons HD \quad (1c)$$

$$H(ad) + H(ad) \rightleftharpoons H_2 \quad (1d)$$

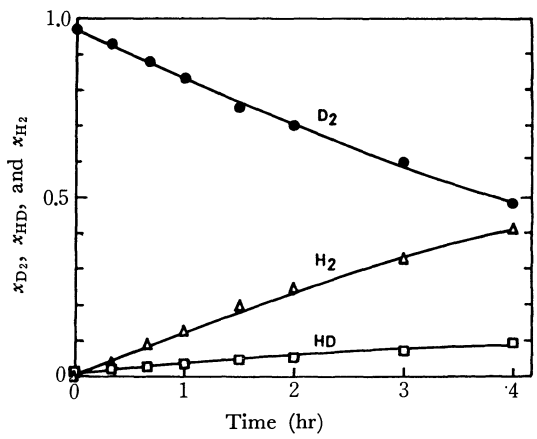

Fig. 1. Change in x_{D_2}, x_{HD}, and x_{H_2} with time.
(MoS_2, 480 °C, $P_{H_2S}°=179.9$ mmHg, $P_{D_2}°=30.0$ mmHg, $a_s=6$)

1) Terms such as "hydrogen" and "hydrogen sulfide" are used in a generic sense, irrespective of the isotopic species. The chemical symbols "H_2S" and "H_2" are employed for the chemical species of "hydrogen sulfide" and "hydrogen" respectively.

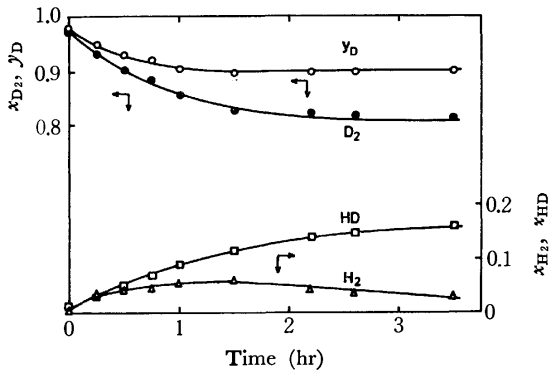

Fig. 2. Change in x_{D_2}, x_{HD}, x_{H_2}, and y_D with time.
(MoS_2, 480 °C, $P_{H_2S}^{\circ}=10.3$ mmHg $P_{D_2}^{\circ}=102.7$ mmHg, $a_s=1/10$)

where H(ad), D(ad), and HS(ad) represent the H, D, and HS adsorbed on the surface of sulfide.

In the second mechanism, H_2S is directly converted to H_2:

$$H_2S \rightleftharpoons H_2+S(ad) \qquad (2a)$$

and then H_2 reacts with D_2 to form HD:

$$H_2 + D_2 = 2\,HD \qquad (2b)$$

where S(ad) represents the S adsorbed on the surface of sulfide. Reaction (2a) is characterized as a redox reaction.

At the higher range of a_s, the HD formation is not remarkable (Fig. 1). Thus, it may be concluded that the exchange reaction proceeds *via* Step (2a). At $a_s=1/10$, HD formation is remarkable. After increasing in the initial period, x_{H_2} reaches its maximum value, and then decreases. We can estimate the contribution of the (2a) mechanism to the transfer of chemical species between "H_2S"[1] and "H_2"[1] at $a_s=1/10$ as follows.

Les us express the rate of the formation of H_2 in the manner proposed by Boreskov[8] and Novakova[9]:

$$\frac{1}{A}\frac{dn_{H_2}}{dt} = R_1(x_{H_2S}-x_{H_2}) + R_2[\alpha(1-y_D')^2 + (1-\alpha)(1-y_D')(1-y_D)-x_{H_2}] + R_3[(1-y_D)^2-x_{H_2}] \qquad (3)$$

where, n_{H_2} is the number of moles of H_2, x_{H_2S} is the mole fraction of H_2S, $y_D=x_{D_2}+1/2x_{HD}$, $y_D'=x_{D_2S}+1/2x_{HDS}$, and A is the surface area. R_1 and R_2 are the rates of the transfer of chemical species between "H_2S" and "H_2" by Mechanisms (2a) and (1a)—(1d) respectively. R_3 is the rate of isotopic exchange by Reaction (2b). α is a parameter related to the surface concentration of "HS" and "H"[1] and ranges from zero to unity.

As is shown in Fig. 2, y_D decreases in the initial period, reaches a constant value at the time corresponding to the maximum of x_{H_2}, and then remains unchanged. At $a_s=1/10$, the ratio of y_D is 1/10 and $y_D^e=y_D'^e=0.909$. Therefore, the observed constant value of y_D is equal to y_D^e within the limits of experimental error. This means that the isotopic equilibrium between "H_2S" and "H_2" is attained at the time corresponding to the maximum of x_{H_2}. Putting $dn_{H_2}/dt=0$ and replacing y_D and y_D' by y_D^e, we obtain:

$$R_1(x_{H_2S}-x_{H_2}) + (R_2+R_3)[(1-y_D^e)^2-x_{H_2}] = 0 \qquad (4)$$

i. e.:

$$\frac{R_1}{R_2+R_3} = \frac{x_{H_2}-(1-y_D^e)^2}{x_{H_2S}-x_{H_2}} \qquad (5)$$

Since $x_{H_2S}+1/2x_{HDS}=1-y_D'^e=1-y_D^e$, $x_{H_2S}<1-y_D^e$. Therefore,

$$\frac{x_{H_2}-(1-y_D^e)^2}{x_{H_2S}-x_{H_2}} > \frac{x_{H_2}-(1-y_D^e)^2}{(1-y_D^e)-x_{H_2}} \qquad (6)$$

By inserting $y_D^e=0.909$ and $\{(x_{H_2})_{max}\}_{obsd}=0.06$ we obtain 1.7 as the numerical value of the right-hand of side Eq. (6). Since $R_1/(R_2+R_3)>1.7$, one can conclude that the most predominant mechanism of isotopic exchange between "H_2S" and "H_2" is (2a), even at $a_s=1/10$.

x_{H_2}, x_{HD}, x_{D_2}, and y_D in the presence of MnS change with time in a way similar to that seen in the case of

9) J. Novakova, *Catal. Rev.*, **4**, 77 (1971).

MoS_2. Therefore, one can determine k_1 and k_1', the rate constants of the sulfurization and reduction of Reaction (2a) respectively, by means of the method proposed in the previous paper.[5]

Figures 3 and 4 give the plots of log k_1 and log k_1' against log a_s. The plots for MoS_2 (Fig. 3) are linear, and the slopes for k_1 and k_1' are −0.98 and 0.02 respectively. The plots for MnS are curved (Fig. 4). The solid line in Fig. 4 is evaluated theoretically, as will be described later. The Arrhenius plots of k_1 at $a_s=1$ for both sulfides are given in Fig. 5. The activation energies are determined as 24.6 kcal mol^{-1} for MoS_2 and 26.1 kcal mol^{-1} for MnS.

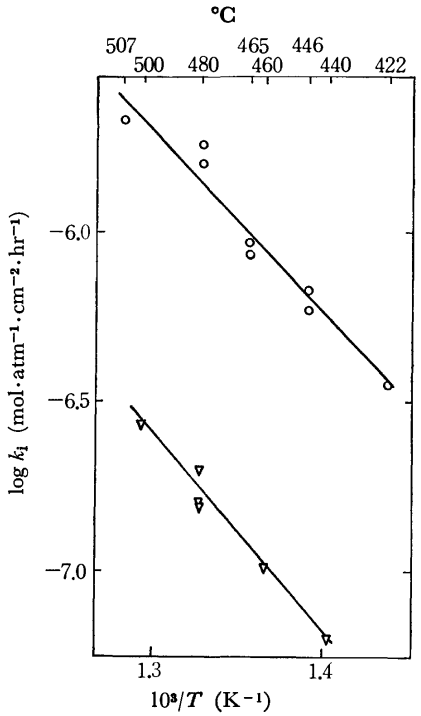

Fig. 5. Arrhenius plots for k_1 at $a_s=1$.
○: MoS_2, ▽: MnS

Table 1 summarizes the results of the present study, together with those obtained in the previous studies. It is noteworthy that the activation energies, $(\partial \log k_1/\partial \log a_s)$ and $(\partial \log k_1'/\partial \log a_s)$, for all sulfides are nearly the same.

Mechanism of the Surface Reaction. In order to explain the a_s dependence of the rate constants of the redox reaction (2a) on the surface of Ag_2S, Kobayashi and Wagner proposed the following mechanisms:

$$\text{"}H_2S\text{"}^{1)} \rightleftharpoons \text{"}H_2\text{"}^{1)} + S(ad) \quad (7A)$$

$$\text{"}H_2S\text{"} + e^- \rightleftharpoons \text{"}H_2\text{"} + S^-(ad) \quad (7B)$$

$$\text{"}H_2S\text{"} + 2e^- \rightleftharpoons \text{"}H_2\text{"} + S^{2-}(ad) \quad (7C)$$

where S(ad), S^-(ad), and S^{2-}(ad) are the sulfur atom and the mono- and di-valent sulfur ions adsorbed on Ag_2S and where e^- is an electron. The rate equation for Reactions (7A) to (7C) can be expressed in a generallized formula:

$$v = k_1 P_{\text{"}H_2S\text{"}} a_e^m - k_1' P_{\text{"}H_2\text{"}} a_s^{m-} \quad (8)$$

where m is the integer characteristic of the reaction mechanism, namely:

$m = 0$ for Mechanism (7A)
$m = 1$ for Mechanism (7B)
$m = 2$ for Mechanism (7C)

Let us first discuss the mechanism of the redox reaction on the surface in terms of the Kobayashi-Wagner mechanism.

According to the results of Nakata's conductivity measurement,[6] MoS_2 seems to be an intrinsic semiconductor above 440 °C. In the intrinsic region, one can expect the conductivity to be independent of a_s. This relationship was confirmed experimentally in the temperature range of 420° and 550 °C and in the a_s range of 1/10 to 10. Therefore, it is considered that the activity of electrons, a_e, in MoS_2 is not influenced by a_s. Assuming the following equilibria:

$$S^- \rightleftharpoons S + e^- \quad (9a)$$

$$S^{2-} \rightleftharpoons S + 2e^- \quad (9b)$$

we obtain:

$$a_{s^-} \propto a_s \quad (10a)$$

$$a_{s^{2-}} \propto a_s \quad (10b)$$

The insertion of Relations (10a) and (10b) into Eq. (8) yields:

$$v = k_2 P_{\text{"}H_2S\text{"}} - k_2' P_{\text{"}H_2\text{"}} a_s \quad (11)$$

The activity of electrons in MnS is proportional to $a_s^{-1/3}$.[7] The combination of this dependence with the equilibrium conditions for (9a) and (9b) gives:

$$a_{s^-} \propto a_s^{2/3} \quad (12a)$$

$$a_{s^{2-}} \propto a_s^{1/3} \quad (12b)$$

By inserting Relations (12a) and (12b) into Eq. (8), we obtain:

$$v = k_3 P_{\text{"}H_2S\text{"}} a_s^{-m/3} - k_3' P_{\text{"}H_2\text{"}} a_s^{1-2m/3} \quad (13)$$

Table 1.

Solid	Cu_2S[4]	β-$Fe_{1-x}S$[5]	MoS_2	MnS
Type of conductor	p-type semiconductor	metallic conductor	intrinsic semiconductor	p-type semiconductor
$\frac{\partial \log k_1}{\partial \log a_s}$ [a]	−1.07	−0.97	−0.98	−0.95—−0.6[b]
$\frac{\partial \log k_1'}{\partial \log a_s}$ [a]	−0.07	0.03	0.02	0.05—0.4[b]
Activation energy (kcal mol^{-1})	27.8	26.8	24.7	26.1

a) at 480 °C. b) As seen in Fig. 4 the plots are curved.

The a_s dependence of the reaction rate expressed by Eqs. (11) and (13) does not interpret the results observed in this study.

As has been mentioned above, the activation energies, $(\partial \log k_1/\partial \log a_s)$ and $(\partial \log k_1'/\partial \log a_s)$, for Reaction (2a) are almost the same for all the sulfides studied. This fact suggests that the mechanism of Reaction (2a) is the same, irrespective of the kind of sulfides.

According to the results of an adsorption experiment[10] in which the adsorption of sulfur on metals was studied in "H_2"-"H_2S" gas mixtures at higher temperatures, the coverage increases rapidly from zero to a saturation value within a narrow region of log a_s as log a_s increases. A similar adsorption curve was observed in the case of the adsorption of oxygen atoms on copper at high temperatures.[11]

In a case where the interaction between adsorbed sulfur atoms can be neglected, θ, the fraction of surface adsorption sites occupied by adsorbed sulfur atoms, S(ad), can be expressed by the Langmuir equation:

$$\theta = \frac{K(P_{\text{"}H_2S\text{"}}/P_{\text{"}H_2\text{"}})}{1+K(P_{\text{"}H_2S\text{"}}/P_{\text{"}H_2\text{"}})} = \frac{a_s/a_s^0}{1+(a_s/a_s^0)} \qquad (14)$$

where K is a constant and where a_s^0 is the sulfur activity at which $\theta=0.5$ is attained.

If the exchange of sulfur atoms between "H_2S"-"H_2" gas mixtures and a solid occurs by means of the mechanism:

$$\text{"}H_2S\text{"} + \square\,(\text{vacant sites}) \rightleftharpoons \text{"}H_2\text{"} + \text{S(ad)} \qquad (15)$$

and if Eq. (15) is the rate-determining step of the redox reaction, the rate equation can be expressed as:

$$v = k(1-\theta)P_{\text{"}H_2S\text{"}} - k'\theta P_{\text{"}H_2\text{"}} \qquad (16)$$

Eq. (16) indicates that k_1 and k_1' are proportional to $(1-\theta)$ and θ respectively.

When Eq. (14) holds for the adsorption, the plots of θ, log $(1-\theta)$, and log θ against $\log(a_s/a_s^0)$ are as is shown in Fig. 6. In a range of a_s/a_s^0 much lower than unity, the slope of the plot of $\log(1-\theta)$ *vs.* $\log(a_s/a_s^0)$ is 0. However, this slope gradually changes in the vicinity of $a_s/a_s^0=1$, and in a range of a_s/a_s^0 much higher than unity the value of the slope becomes -1. The slope of the plot of log θ *vs.* $\log(a_s/a_s^0)$ changes with $\log(a_s/a_s^0)$ in the manner the inverse of that of log $(1-\theta)$ *vs.* $\log(a_s/a_s^0)$.

From a comparison of Figs. 3 and 4 with Fig. 6, it may be concluded that Reaction (15) is the rate-determining step of the redox reaction and that the surface sites of MoS_2 are almost covered with sulfur atoms during the reaction, while those of MnS are only partially covered.

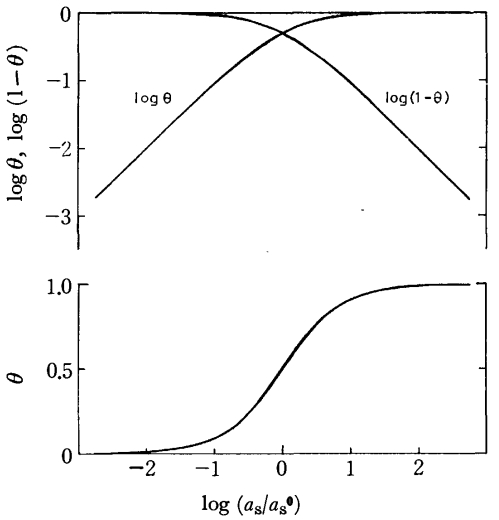

Fig. 6. Schematic representation of θ, log θ and log $(1-\theta)$ against log (a_s/a_s^0) when θ is represented by the Langmuir equation.

Summary

1) The isotopic exchange between H_2S and D_2 on MoS_2 and MnS were investigated as a function of the temperature and the sulfur activity of the sulfides.

2) It was found that the isotopic exchange reaction proceeds *via* these steps:

$$H_2S + D_2 = D_2S + H_2$$
$$H_2 + D_2 = 2\,HD$$

3) The rate constant of the sulfurization of the sulfides, k_1, and that of the reduction k_1', were calculated, and the dependence of these rate constants on the sulfur activity was determined. The activation energies were 24.6 kcal mol^{-1} for MoS_2 and 26.1 kcal mol^{-1} for MnS.

4) The a_s dependence of the rate constants of the redox reaction on the surfaces of sulfides could not be explained by the Kobayashi-Wagner theory. It could, however, be explained by assuming that Reaction (15) is rate-controlling.

The authors wish to express their thanks to Dr. Ju Kumanotani of the Faculty of Engineering, University of Tokyo, for his help in carrying out the Mass spectroscopic analysis.

Polarized Absorption Spectra of Single Crystals of Ion Radical Salts. III. Temperature Dependence of the Crystal Spectra of Potassium-Chloranil

Shoji HIROMA and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received May 4, 1973)

The polarized absorption spectra in the 10000—37000 cm^{-1} region were observed on the single crystal of the water-free modification of the potassium-chloranil salt, $K^+ \cdot (chloranil)^-$, by using a microspectrophotomer, and the variation of the spectra with temperature was examined. The crystal gives a near-infrared absorption band associated with the charge transfer between chloranil radical anions, the maximum of which is located at 11.5×10^3 cm^{-1}. The absorption bands in the 20000—37000 cm^{-1} region were assigned to the local-excitation bands associated with the transitions in the chloranil anion. The intensity of the charge-transfer band gradually increases on lowering the temperature. An abrupt increase of intensity occurrs in the charge-transfer band at the phase-transition point. There is a close correlation between this change and the temperature dependence of the paramagnetic susceptibility of the salt.

The potassium-chloranil anion radical salt, $K^+ \cdot (chloranil)^-$, has been reported to exhibit a phase transition at about 210 K, where the salt changes from the "low susceptibility" to the "high susceptibility" form.[1-3] It was found by Andre and Weill[3] that the latter form is stabilized when the powder of K·(chloranil) is dispersed in KBr matrix, whereas the former form is stabilized when dispersed in LiF matrix, and a strong near-infrared band appears in the optical absorption spectrum of the powder dispersed in LiF pellet, but not in the spectrum of the powder dispersed in KBr pellet. They also examined the polarizations of the absorption bands of a single crystal by means of an optical system composed of a polarizing microscope and an interference filter, and confirmed that the near-infrared absorption band mentioned above is polarized in the direction of the molecular columns of chloranil anion, hence is a charge-transfer band. But, the details of the single crystal spectrum has not been reported.

The room-temperature absorption spectrum of K·(chloranil) powder has been also given by Iida[4] and by Sakai *et al.*[5]

Although these previous authors have not described the effect of water, we noticed that the K·(chloranil) salt has a tendency to take water molecules into the crystal lattice, particularly, when it is kept in the form of a crystalline powder, and there is an appreciable difference in the single-crystal spectrum between the water-free and water-containing modifications.

Recently, the crystal structure of the water-free modification at the room temperature was determined by Konno *et al.*[6] Thus, in the present study, we have investigated the polarized absorption spectrum of the single crystal of the water-free modification of K·(chloranil) and examined its temperature dependence.

Experimental

The polarized absorption spectra were measured by means of a microspectrophotometer equipped with a small cryostat at the specimen stage to keep the crystals at low temperature.[7,8] The measurement was done over the temperature range from the room temperature to 160 K.

The K·(chloranil) salt was synthesized according to the method reported by Torrey and Hunter.[9] The single crystals of microscopic size[10] for the measurement of absorption spectrum were prepared by the recrystallization either from acetone solution or from acetonitrile solution. In this case, the solvent and/or water molecules are included in the crystal to give the solvent-containing modification, but they can be easily taken out from the crystal by evacuation. In the present study, the specimen was placed in the cryostat and evacuated for a period sufficient to convert the crystals to the solvent-free state prior to the measurements of spectra, and the spectrum was observed without breaking the vacuum.

According to Konno *et al.*,[6] there are two solvent-free modifications of the K·(chloranil) salt at the room temperature, which are called the α- and β-form respectively. We examined the X-ray diffraction pattern of the evacuated powder. Although most diffraction lines were identified as those of the α-form, there were weak lines which were due to the β-form: the amount ratio of the α-form to the β-form was estimated as about 10 : 1. In carrying out the measurement with the microspectrophotometer, it was not possible to differentiate the β-form crystals from the α-form ones. We observed the spectra on several different crystals but obtained identical results. Therefore, we shall tentatively assume that the spectra discussed in the present paper are those of the α-form crystal.

Results and Discussion

Room Temperature Spectra and Assignment of Absorption Bands. According to Konno *et al.*, the α-form crystal is orthorhombic, space group $P2_12_12_1$ with unit cell dimension: $a=13.49$, $b=17.02$, $c=4.03$ Å.[6] The

8) The cryostat was designed and constructed by Mr. K.Kaneko in our laboratory.
9) H. A. Torrey and W. Hunter, *J. Amer. Chem. Soc.*, **34**, 702 (1912).
10) The crystals used here were thin plates elongated along c-axis, (20—30 μ in length), the width in the b-axis direction being about 5 μ.

unit cell contains four formula units of K·(chloranil), and the chloranil anions are stacked face-to-face on each other to form molecular columns parallel to the c-axis.

The polarized absorption spectra were measured on the (100) face of a single crystal for the polarizations parallel to the b- and c-axes respectively. The spectra obtained at the room temperature are shown in Fig. 1. The wave number and the relative intensity of each observed peak are listed in Table 1.

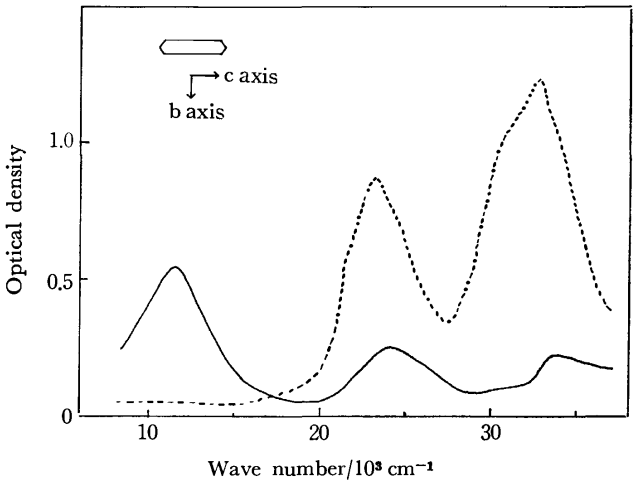

Fig. 1. Room-temperature spectra of the potassium-chloranil crystal.

(—— c-axis spectrum, ····· b-axis spectrum)

Table 1. Wave numbers and relative intensities of absorption peaks

(Intensities are given in parentheses)

	c-axis spectrum $\bar{\nu}$ [10^3 cm^{-1}]		b-axis spectrum $\bar{\nu}$ [10^3 cm^{-1}]	
CT-band	11.5	(0.62)		
($^2B_{1u}\leftarrow{}^2B_{2g}$)			23.1	(1.00)
($^2A_u\leftarrow{}^2B_{2g}$)	24.0	(0.28)		
($^2B_{1u}\leftarrow{}^2B_{2g}$)			30.7 32.7	(1.66)
	33.4	(0.3)		

The 11.5×10^3 cm^{-1} band is strongly polarized in the c-axis direction which is the direction of the column of the chloranil anion. In this region, we can expect no local-excitation band associated with the transition in the chloranil anion. Thus we can safely assign this band to the charge-transfer band due to the interaction between chloranil anions. Although Andre and Weill[3] reported that the charge-transfer band disappears in the "high susceptibility" form, this band is observed still with a considerable intensity in the c-axis spectrum at the room temperature.

In order to find out the interpretation for the spectra in the region above 20000 cm^{-1}, we carried out the SCF-MO-CI calculations on the transition in the free chloranil anion. We used here the method of Longuet-Higgins and Pople for the open-shell π-conjugated system.[11] The semiemprical parameters were determined by using the Nishimoto-Mataga's formula for the two-center repulsion integrals,[12] and the Nishimoto-Forster's formula[13] for the two-center resonance integrals.[14] We assumed the D_{2h} geometry for the chloranil ion, and took the bond lengths and bond angles estimated from the crystal structure data of the chloranil salt of Würster's blue.[15] In Fig. 2, the results of calculation are compared with the transitions observed in the solution spectrum of the chloranil anion. There are two types of transition, namely, $^2B_{1u}\leftarrow{}^2B_{2g}$ and $^2A_u\leftarrow{}^2B_{2g}$, the transition moments of which are respectively parallel and perpendicular to the molecular axis connecting the two oxygen atoms. Although there are some discrepancies between the calculation and observation, we can assign the absorption bands observed in the solution spectrum at 22.2×10^3 cm^{-1} (2.75 eV) and 31.1×10^3 cm^{-1} (3.86 eV) respectively to the first and second $^2B_{1u}\leftarrow{}^2B_{2g}$ transitions, and the one observed at 27.5×10^3 cm^{-1} (3.14 eV) to the first $^2A_u\leftarrow{}^2B_{2g}$ transition. On the basis of such interpretation of the solution spectrum of the chloranil anion, we examined the crystal spectrum. If we assume the oriented-gas model and estimate the dichroic ratio, I_b/I_c, of absorption band for the α-form crystal of the potassium-chloranil, we obtain 3000 for the $^2B_{1u}\leftarrow{}^2B_{2g}$ transition and 0.32 for the $^2A_u\leftarrow{}^2B_{2g}$ transition of the chloranil anion. Thus an absorption band due to a $^2B_{1u}\leftarrow{}^2B_{2g}$ transition should be almost completely polarized in the b-axis direction when the crystal spectrum is observed on the (100) face, while the one due to a $^2A_u\leftarrow{}^2B_{2g}$ transition should be stronger in the c-axis spectrum than in the b-axis spectrum.

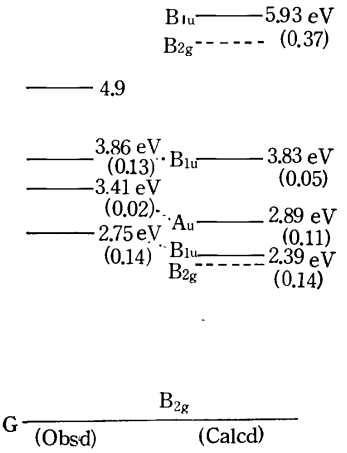

Fig. 2. Observed and calculated energy levels of the chloranil anion, (—— allowed, ····· forbidden). The oscillator strengths are given in parentheses.

12) K. Nishimoto and M. Mataga; *Z. Phys. Chem.* (Frankfurt), **12**, 335 (1957).

13) K. Nishimoto and L. S. Forster, *Theor. Chim. Acta*, **3**, 407 (1965); **4**, 155 (1966).

14) The parameters used for chlorine atom are as follows: $-W_\mu=23.3$ eV, $\gamma_{\mu\mu}=10.79$ eV, $\beta_{C\text{-}Cl}=2.99\ r-6.00$ eV, where r is the interatomic distance.

15) J. L. de Boer and A. Vos, *Acta Crystallogr.*, **B24**, 720 (1968).

Thus the 32.7×10^3 cm^{-1} band observed in the b-axis spectrum can be assigned to the local-excitation band associated with the 31.1×10^3 cm^{-1} ($^2B_{1u}\leftarrow{}^2B_{2g}$) transition of the chloranil anion, although a weak absorption peak is observable at 33.4×10^3 cm^{-1} in the c-axis spectrum. Seemingly, the first strong absorption band in the b-axis spectrum observed at 23.1×10^3 cm^{-1} is associated with the 22.2×10^3 cm^{-1} ($^2B_{1u}\leftarrow{}^2B_{2g}$) transition of the chloranil anion. However, the dichroic ratio in this region is evidently too small. It should be noted that, in the 20000—30000 cm^{-1} region, we can expect another absorption band associated with the 27.5×10^3 cm^{-1}($^2A_u\leftarrow{}^2B_{2g}$) transition of the chloranil anion. Thus, it is likely that the 24.0×10^3 cm^{-1} band in the c-axis spectrum is not the c-axis component corresponding to the 23.1×10^3 cm^{-1} band of the b-axis spectrum, but is the one mainly due to the $^2A_u\leftarrow{}^2B_{2g}$ transition.

Temperature Dependence of the Spectra. The crystal spectra observed at several different temperatures are shown in Fig. 3. We found that a significant change appeared mainly in the region of the charge-transfer band. Only a small change was detected in the region of local-excitation bands. Above the phase-transition point, the intensity of the charge-transfer band gradually increased on lowering the temperature. An abrupt rise of intensity occurred near the phase-transition point with a decrease in the band width.

In Fig. 4, the intensity change of the charge-transfer band is compared with the change in the magnetic susceptibility.[16] Clearly there is a close correlation between them. The behavior found here is quite analogous to the one reported for the Würster's blue perchlorate. The latter has been explained with the model that the interaction between neighboring Würster's blue cation radicals gives a singlet state and a triplet state, in which the former is a little stabilized in respect to the latter, and the intensity of the charge-transfer band is governed by the singlet population in the crystal while the paramagnetism is governed by the triplet population.[17] A similar model seems to be applicable also for the K·(chloranil) salt.

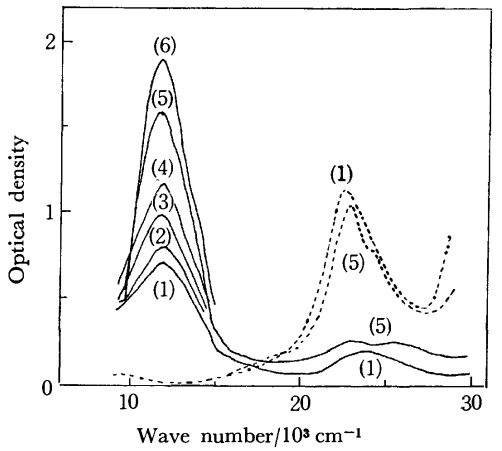

Fig. 3. Temperature dependence of the crystal spectra of the potassium-chloranil. (1): 297 K, (2): 280 K, (3): 240 K, (4): 218 K, (5): 209 K, and (6): 163 K.
(—— c-axis spectrum, ····· b-axis spectrum)

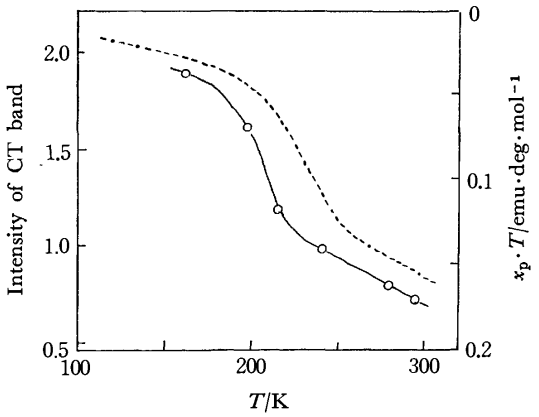

Fig. 4. Variation of the intensity of the charge-transfer band (——) and the magnetic susceptibility (·····)

In the room-temperature phase of the K·(chloranil), the chloranil anions are equally spaced in the column to give a crystal structure of monomeric form, the intermolecular spacing being 3.47 Å. The abrupt intensity increase of the charge-transfer band at the transition point would suggest that the low-temperature phase has a crystal structure of a dimeric arrangement of the chloranil anion, as in the case of monomeric-dimeric transition of the Würster's blue perchlorate. In this connection, it is interesting to see that, in the b-axis spectrum observed at a low temperature, a shoulder appeared at about 25×10^3 cm^{-1}. The chloranil anion dimer formed in solution has been reported to give a charge-transfer band at 14.9×10^3 cm^{-1} and a local excitation band at 26.3×10^3 cm^{-1}.[5] It is possible that the 25×10^3 cm^{-1} shoulder is the one corresponding to the 26.3×10^3 cm^{-1} band of the dimer. It would be of particular interest to examine if this shoulder grows up at a lower temperature. Unfortunately, however, we were not able to confirm this because of the limitation of our experimental set-up.

The authors wish to thank Professor Y. Saito and Miss M. Konno of the Institute for Solid State Physics of the University of Tokyo for allowing us to use the data of the crystal structure of the potassium-chloranil salt prior to the publication. Thanks are also due to Dr. T. Ohta for his help in the calculations of the electronic states of the chloranil anion.

16) The magnetic susceptibility data used here are those measured by Mr. T. Mizoguchi in our laboratory by means of a Faraday-type magnetic balance.

Studies on Fragment Ion Distribution and Reaction with a Charge Spectrometer. V. Applicability of the MO Theory to the Fragmentation of Alkanes by Charge Exchange

Shigeru IKUTA, Kenji YOSHIHARA, and Takanobu SHIOKAWA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Sendai 980

(Received May 31, 1973)

The relation between the fragment ion distribution and recombination energy of the incident positive ions was studied by means of charge exchange reactions. The energy range which is consistent with the molecular orbital (MO) theory proposed by Hirota to account for the mass spectra by electron impact was also investigated, and the usefulness of the theory was discussed. The energy range to which the MO theory is applicable is very limited, the fragment ions produced at the high recombination energy to which it is apparently applicable, being the C_2, C_3 and C_1 ion groups. It is probable that these species are not produced directly from the parent but by degradation mechanisms *via* intermediate steps, thus causing disagreement with the MO theory. Its applicability to alkanes is open to question. The dissociation schemes on *n*-alkanes are presented from the expreimental results.

Mass spectra obtained by electron impact are utilized for the identification of organic compounds. Although mass spectroscopic analysis is widely used, only empirical or semi-empirical rules have been used to explain the experimental results.[1] The theory of mass spectra by electron impact is important for studying the initial processes of radiation actions on various substances since the interaction of radiation with materials is attributed almost substantially to excitation and/or ionization by radiation-induced electrons.

In 1952 Rosenstock *et al.*[2] proposed a quasi-equilibrium theory to account for the mass spectra of relatively simple organic substances by electron impact, the underlying assumptions of the theory being as follows:

(1) The electronically excited molecular ion produced by interaction of the molecule with an electron changes swiftly into the electronically ground but vibrationally excited molecular ion.

(2) The fragment ions are formed by unimolecular decomposition of the vibrationally excited molecular ion involving competing and successive processes.

(3) The rate constants of the elementary processes are determined by the use of the absolute rate theory.

They estimated the breakdown curve of the *n*-propane molecular ion, in qualitative accordance with the experimental results, but quantitative agreement was not so good.

Efforts were made to improve the agreement of the theory with experimental results.[3] Vestal *et al.*[4] developed a method of enumerating the states and succeeded in evaluating the mass spectra quantitatively. In this improved quasi-equilibrium theory, however, there have still been difficulties as regards its application to cases involving fragmentation processes from electronically excited states and those from super-excited states.[5]

For explanation of the fragment ionization process, Fueki and Hirota[6] proposed a theory based on the assumption that the probability of fragmentation is proportional to the electron density on the highest occupied molecular orbital in the molecule. The theory was applied to many organic compounds and fairly good accordance was observed with the experiments using electron impact of normal or cycloalkanes.[7] However, experimental evidence of the energy range fit to the theory seems to be lacking.

We have studied the relation between the distribution of fragment ions and the recombination energy of the incident ions by means of pure charge exchange reactions involving no transfer of momentum. The energy range consistent with the molecular orbital (MO) theory was also investigated, and the usefulness of the theory was discussed.

Experimental

The charge exchange reactions of various molecules were carried out with a double mass spectrometer.[8] The primary ions, produced with a bombarding electron beam (100 eV), were accelerated to 800 V and led into the reaction chamber whose repeller potential was below 10 V. The ions produced by the charge exchange reactions were drawn into the second analyzer system at 3.5 KV, and detected with an electron multiplier of 16 stages.

The pressure of the reaction chamber was 8×10^{-6} mmHg. *n*-C_4H_{10}, *n*-C_5H_{12}, *n*-C_7H_{16}, *n*-$C_{10}H_{22}$, cyclo-C_5H_{10}, cyclo-C_6H_{12}, cyclo-C_7H_{14} and cyclo-C_8H_{16} were reagent grade(Tokyo Kasei Co.) and *n*-C_8H_{18} was spectroscopically pure. *n*-C_6H_{14} was purified from starting material of reagent grade (Tokyo Kasei Co.) by means of gas chromatography.

8) T. Shiokawa, K. Yoshihara, M. Yagi, T. Omori, H. Kaji, T. Nagatani, and Y. Takita, *Shitsuryo Bunseki*, **18**, 1230 (1970).

CH_3^+, CH_2^+, $C_2H_2^+$, H_2O^+, Xe^+, Cl^+, H^+, Kr^+, N_2^+, Ar^+, Xe^{++}, Ar^{++}, and He^+ were used as the source of primary ions. CH_3^+ and CH_2^+ were obtained from methane, Cl^+ was the fragment ion of trichlorofluoromethane, H^+ the fragment ion of hydrogen, and $C_2H_2^+$, H_2O^+ and N_2^+ were obtained from C_2H_2, H_2O and N_2 respectively. All the other ions were produced from the corresponding rare gases.

Prior to experiments of charge exchange reactions, a re-examination of the recombination energy of the incident primary ions should be necessary because of the comparatively large velocity. However, with the use of the double mass spectrometer, Nagatani *et al.*[9] observed that the recombination energy of the comparatively fast primary ions was in good agreement with Lindholm's value of slow ones.[10] We therefore used the following Lindholm's values as the recombination energies of primary incident ions:

CH_3^+	a range around 9.8 eV
CH_2^+	10.4 eV and lower
$C_2H_2^+$	11.4 eV
H_2O^+	12.4 eV
Xe^+	12.1—13.4 eV
Cl^+	12.9—14.4 eV
H^+	13.6 eV
Kr^+	14·0—14.7 eV
N_2^+	15.3 eV
Ar^+	15.8 eV
Xe^{++}	18.0—20.0 eV
Kr^{++}	21.0 eV
Ar^{++}	24.0 eV
He^+	24.6 eV

Results and Discussion

The charge exchange reaction is generally considered as follows.

$$A + M^+ \rightarrow A^+ + M \quad (3)$$

where the energy E_c for producing the process $A \rightarrow A^+$ is dependent on the recombination energy of M^+, the ionization potential of A, and the kinetic energies of A and M^+. For the pure charge exchange reaction not involving the transfer of kinetic energy, the following equation can be applied:

$$A + M^+ \rightarrow A^+ + M + (R.E.)_M - (I.P.)_A \quad (4)$$

where $(R.E.)_M$ is the recombination energy of M and $(I.P.)_A$ the ionization potential of A. If M=A in Eq. (4), the resonance process for which $E_c=(R.E.)_M-(I.P.)_A=0$ occurs. For the case of $M \neq A$ one can excite the molecular ion A^+ by the energy $E_c=(R.E.)_M-(I.P.)_A$.

Thus the fragmentation processes from the particular excited state of the molecular ion by the charge exchange reactions can be observed with the use of a double mass spectrometer. The produced fragment ions are normalized to the sum of the total ion intensity, and the relation between the fragment ion distribution and the recombination energy of the incident ions can be illustrated as the breakdown curve of the molecular ion.

It is considered that the breakdown curve obtained by the charge exchange reactions is closely related to the mass spectra by electron impact. Mass spectra by electron impact are expressed as the sum of the mass spectra over internally excited states of various energies of the molecular ion, and calculated by the use of the breakdown curve and the internally energy distribution of the molecular ion.[11]

As an example the breakdwon curve for n-C_7H_{16} is shown in Fig. 1. The abscissa indicate recombination energy of the incident positive ions and the ordinate indicates the intensity of the ions. The plotted data were obtained in this work, and the curve in the low energy region (<14 eV) was obtained by Steiner *et al.*[12] using the photon impact. From this breakdown

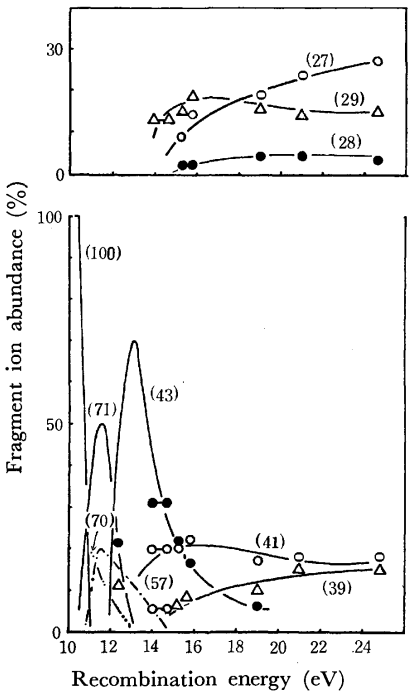

Fig. 1. Breakdown curve of n-C_7H_{16}.

and the internal energy distribution function the composite fragment ion distribution can be calculated.[9] The result is compared with the observed values by electron impact (electron energy: 70 eV) in Table 1. The agreement is quite satisfactory. This means that the fragment ionization processes after the charge exchange reactions are almost consistent with ones by electron impact for the same energy imparted.

In contrast to the quasi-equilibrium theory, the MO theory proposed by Hatada and Hirota and others[7] to account for the mass spectra by electron impact contains three assumptions.

(1) The lifetime of the excited molecular ion is very short ($<10^{-13}$ s), the excited molecular ion being in a super-excited state, and the fragmentation occurring in the stabilization process.

(2) The scission probability of the skeletal bonds of bombarded molecule is proportional to the positive charge distribution at the corresponding bond of the molecular ion, or proportional to the electron density of the highest occupied molecular orbital at the corresponding bond of the bombarded molecule.

(3) The theory is applicable only to the primary scission, and the secondary and other scissions are explained by the quasi-equilibrium theory.

Hirota[13] pointed out that the electronically excited molecular ion is produced in a super-excited state, several eV above the ground state. The minimum energy for producing the super-excited molecular ions can be estimated by the following equation:

$$V(\min) = \text{I.P.} + nRT + D(\text{c-c}) \qquad (5)$$

where I.P. is the ionization potential of the starting molecule, n the number of the degree of freedom, D the dissociation energy for the carbon bonds, T absolute temperature (K) and R the gas constant. 20 eV was obtained for the molecule having 50 degrees of freedom.

In order to examine this theory it is important to study the energy dependence of the fragment ion distribution especially in the recombination energy region of about 20 eV. From the breakdown curve (Fig. 1), it is necessary to study the energy region which is consistent with the MO theory (or to check the fragment ion distribution predicted by the theory).

In the MO theory, Fueki and Hirota[6] could not determine which of the ruptured fragment groups was in the positive state *i.e.* which one lost an electron on the rupture event. C_i+C_{n-i} was therefore used to represent the scission probability for the i-th bond from the end. The summation C_i+C_{n-i} was normalized to be 100 except for the parent ion group. Thus we first obtain the breakdown curve of the molecular ion by the charge exchange reaction and next the abundance of the C_i group. Finally the relation between C_i+C_{n-i} and the recombination energy of the incident ion can be obtained, and the energy in which the MO theory holds can be determined. The relation of C_i+C_{n-i} versus energy in n-C_7H_{16} is shown in Fig. 2 with the data in Fig. 1. The predicted values on n-C_7H_{16} by the MO theory are as follows: $C_3+C_4=54$ (%), $C_2+C_5=35$ (%), $C_1+C_6=11$ (%).

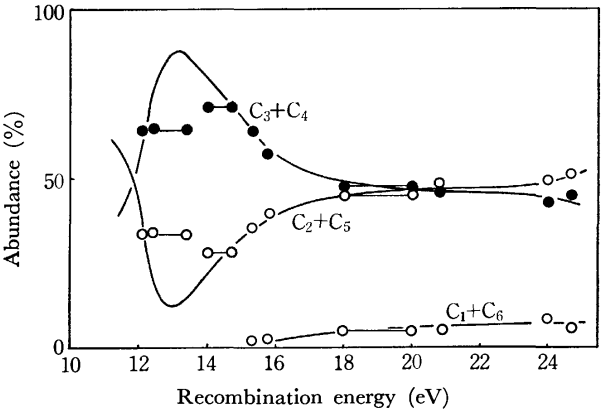

Fig. 2. Relation between C_i+C_{n-i} and recombination energy of incident positive ions on n-C_7H_{16}.

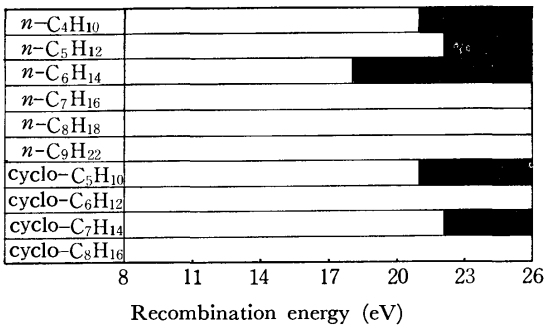

Fig. 3. Energy range of fragmentation consistent with the MO theory.

The energy range to which the MO theory is applicable is thus determined for n-alkanes and cycloalkanes. In Fig. 3, the black portion shows the energy range apparently consistent with Hirota's MO theory. We see that the energy range to which the MO theory is applicable is very limited. There are no energy regions to fit the MO theory in n-C_7H_{16}, n-C_8H_{18}, n-$C_{10}H_{22}$, cyclo-C_6H_{12} and cyclo-C_8H_{16}. The results for n-C_7H_{16} and n-C_8H_{18} were re-estimated more rigorously than in the previous communication.[14]

The mass spectra by electron impact can be calculated by the breakdown curve and the internal energy distribution function. It is assumed, however, that the maximum of the internal energy distribution func-

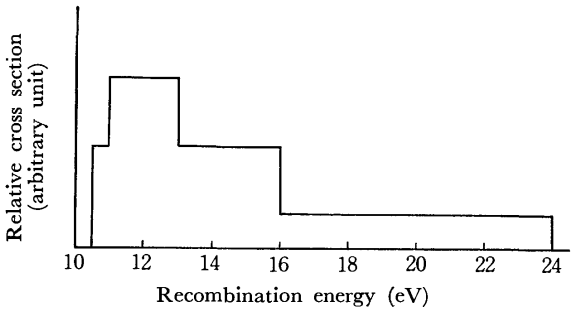

Fig. 4. Internal energy distribution of n-C_7-H_{16} molecular ion.

13) K. Hirota, *Shitsuryo Bunseki*, **20**, 101 (1972).

14) S. Ikuta, K. Yoshihara, and T. Shiokawa, *Chem. Lett.*, **1972**, 685.

tion is about 1 eV plus the ionization potential. Figure 4 shows the internal energy distribution on n-C_7H_{16} molecular ion which was used to calculate the mass spectra. The breakdown phenomenon in the high recombination energy range seems to contribute very little to the whole mass spectra. This means that the mass spectra in the energy range which are consistent with the MO calculation (Fig. 3) contribute little to the whole mass spectra by electron impact.

Although Hirota *et al.* could not quantitatively predict which of the fragment C_n and C_m ($m=N-n$; where N is the total number of carbon atoms) was to be in the positive charge, they qualitatively proposed that the abundance of the C_n ion group was larger than that of the C_m ion group in case of $n>m$, since the charge density of the C_n ion group was larger than that of the C_m ion group. It seems that there is a comparatively large ion group ($>C_{N/2}$: C_N is the parent ion group) in the energy range to which the MO theory is applicable.

Figure 5 shows the breakdown curve of the n-hexane parent ion obtained by the charge exchange reactions. It is evident that the fragment ions produced at the high recombination energy, to which the MO theory is applicable are the C_2, C_3 and C_1 ion groups. These C_2, C_3 and C_1 groups are predominant in the mass spectra at the high recombination energy on all alkanes. These results do not agree with the MO theory.

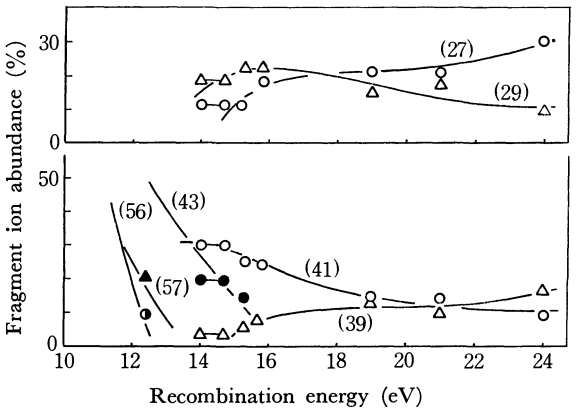

Fig. 5. Breakdown curve of n-C_6H_{14}.

From the above results, there arise some doubts about the applicability of the MO theory to alkanes. It is probable that the agreement between the observed values by electron impact and the predicted values by the MO theory happens to be given by integration of the breakdown curve along the internal energy distribution by chance. The argument seems to hold in the case of cycloalkanes in which double scissions are necessary to give the fragment ion distribution in the present study. We cannot exclude a possibility that there is a discrepancy in the mechanism between electron impact and charge exchange resulting in fragmentations. The possibility that the mechanism involving the pre-ionization from the super-excited state should also be considered but we do not believe this will alter the discussion given above.

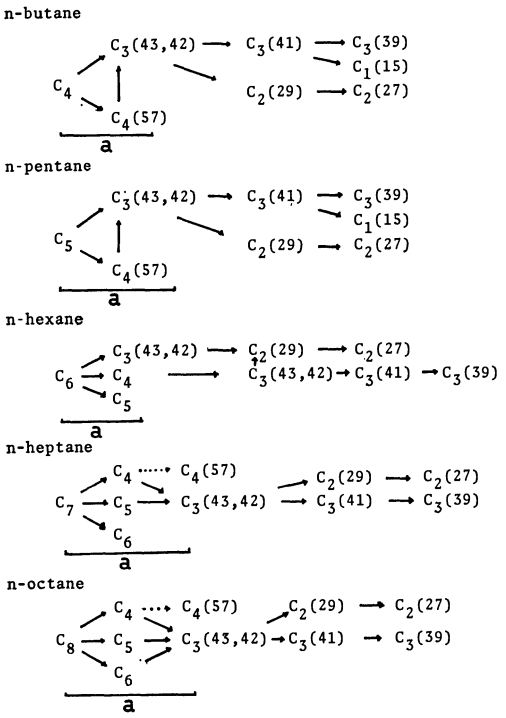

Fig. 6. Dissociation schemes of n-alkanes.

It seems that application of the MO theory to the fragmentation of the alkanes ($>C_4$) as a whole is difficult.

The dissociation scheme on alkanes is given in Fig. 6. At the high recombination energy (>17 eV) fragment ions were always C_2, C_3 and C_1 ion groups. Figure 6 [a] shows comparatively swift fragmentation processes. It is assumed that the molecular ions produced change swiftly to the C_3 or C_2 ion groups, and thereafter the C_3 or C_2 ion groups comparatively slowly change to the C_3', C_2' and C_1 ion groups experimentally observed. In the swift process one can imagine that availability of the molecular orbital consideration may be possible, although it is far from proven in the results of this study.

The authors wish to thank Prof. K. Hirota for his discussion and Mr. M. Hiraga for his assistance in the course of this study.

Polarographic Studies of Some Porphyrins and Metalloporphyrins in *N,N*-Dimethylformamide

Tadaaki KAKUTANI, Shoji TOTSUKA, and Mitsugi SENDA

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Kyoto 606

(Received June 15, 1973)

Electrochemical behavior of protoporphyrin IX dimethylester (PPDM), mesoporphyrin IX dimethylester-(MPDM), Fe(III)Cl-protoporphyrin, Ni(II)-, Cu(II)-, Co(II)-, Zn(II)- and Mn(III)Cl·H_2O–PPDM was investigated in dimethylformamide by use of AC polarography, cyclic voltammetry and DC polarography. These porphyrins and divalent metal complexes of PPDM gave, for the most part, three reduction waves. The first and second waves were reversible one-electron steps in each case, but the third step was an irreversible one. Mn(III)-complex gave four reduction waves and one oxidation wave. The first three reduction waves were one-electron steps and the oxidation wave was identified as that due to chloride anion. Fe(III)-complex gave five reduction waves and one oxidation wave. The first two reduction waves were one-electron steps. All these compounds showed specific adsorption at the potential more positive than −1.1 V *vs.* SCE. Assignment of the reduction steps of the metalloporphyrins is described. The observed order of increasing negative half-wave potentials is discussed in terms of Zerner and Gouterman's molecular orbital calculation.

Nonaqueous electrochemistry of porphyrins and metalloporphyrins has been studied by several authors. Electrochemical measurements have been accompanied by ESR and absorption spectral data, and the correlation of half-wave potentials with molecular structures has been discussed.[1-6] The electrode processes have also been studied in detail.[7,8]

In this study, the polarographic reduction of some porphyrins and metalloporphyrins in aprotic solvent, *N,N*-dimethylformamide(DMF), was examined in detail by use of DC polarography, cyclic voltammetry and AC polarography.

Experimental

Materials. Hemine(Fe(III)Cl-PP), protoporphyrin IX dimethylester (PPDM) and mesoporphyrin IX dimethylester (MPDM) were prepared from cow blood by established methods[9-11] and purified by repeated column chromatography on neutral alumina with 200 : 1 chloroform–methanol and by recrystallization from chloroform–methanol mixture. Ni(II)-, Cu(II)-, Co(II)- and Zn(II)-PPDM were prepared from the free base by standard procedures[11] and separated from unreacted ligand by repeated column chromatography on neutral alumina with benzene. The solids were recrystallized from chloroform–methanol (or petroleum ether) and dried under vacuum. The absence of metal-free and altered porphyrin impurities in the metalloporphyrins was confirmed by thin layer chromatography on silica gel and absorption spectrophotometry. Mn(III)Cl·H_2O-PPDM was prepared by Boucher's procedures.[12]

DMF(reagent grade) was shaken with potassium hydroxide (about 30 g/l of solvent) for a few hours, decanted, and after bubbling nitrogen gas for thirty minutes, shaken with phosphorus pentoxide (about 40 g/l of solvent) for a few hours. After decanting, the solvent was distilled under reduced pressure (at 45—55 °C) with nitrogen passing through a Widmer's fractional distillation column. The central 60% fraction was collected and stored under dried nitrogen gas. Tetraethylammonium perchlorate(TEAP) was prepared and purified by the methods previously described.[13] Nitrogen gas was dried by passing through a washing bottle containing concd. sulfuric acid and a U-tube containing calcium chloride.

Electrochemical Measurements. DC polarograms and cyclic voltammograms were measured with a potentiostat, Yanaco PE-21-TB2S, equipped with a function generator, YHP 3310 B. AC polarograms were measured with the aid of a lock-in amplifier, NF LI-572B. A polarographic H-cell was used with dropping mercury electrode and platinum wire electrode coiled around the tip of the DME in the same arm. The other arm of the cell was filled with a supporting electrolyte solution(DMF containing 0.1 M TEAP) and connected with a nonaqueous salt bridge(DMF-methylcellulose-0.5 M TEAP) to an aqueous saturated calomel electrode(SCE). The liquid junction was by-passed for alternating current by a "pool" capacitor[16] of 2000 μF between the coiled platinum wire electrode and SCE. The cell was immersed in a water thermostat controlled at 25± 0.1 °C. Measurements were carried out under dried nitrogen atmosphere.

The capillary characteristics were $m=1.07_8$ mg/sec and $t=5.8$ s at $h=70$ cmHg in DMF containing 0.1 M TEAP at −0.5 V *vs.* SCE. Cyclic voltammograms were recorded with a very slowly dropping mercury electrode[14] (usually at $t=90$ or 120 s), whose capillary characeristics were $m=4.56\times10^{-2}$ mg/s and $t=345.1$ s at $h=50$ cmHg in DMF containing 0.1 M TEAP at −0.5 V *vs.* SCE.

The porphyrins and their metal complexes were generally sparingly soluble in DMF, and usually their saturated solutions (for the most part, approximately 4×10^{-4} M) were used.

Results

Reduction of PPDM, MPDM, Cu(II)-PPDM and Zn(II)-PPDM. These compounds in DMF gave three well-defined polarographic waves, as shown in Fig. 1. In this figure dotted lines indicate the base currents. By addition of the depolarizer a lowering of the residual current was observed at the potential more positive than about −0.7 V. This can be ascribed to the adsorption[15] of depolarizer on the electrode surface, a fact which was confirmed also by AC polarography and electrocapillary studies, as described below. All three waves gave limiting currents which are proportional to the concentration of depolarizer over the range from 5×10^{-5} to 4×10^{-4} M. Upon variation of the mercury column height, h, from 40 to 80 cm, all limiting currents of these three steps were proportional to $h^{1/2}$. The half-wave potentials of the first two steps were found to be independent of the concentration of depolarizer and of the mercury column over the range studied. The temperature coefficient of the limiting current was, for example, 0.7% at 25 °C for the first two steps of PPDM. These results are typical of a diffusion-controlled electrode process at the d.m.e.. When corrected for drop time, the three waves were in the ratio of 1 : 1 : 1.8 for PPDM and MPDM, and 1 : 1 : 1.5 for Cu(II)-PPDM and Zn(II)-PPDM. The polarographic data and analysis for these compounds are summarized in Table 1. Analysis of the rising portion of the waves indicated that the first two steps were reversible one-electron reduction process. The third step appeared irreversible.

Concentration: about 4×10^{-4} M (but Cu-complex, about 2×10^{-4} M). Dotted lines indicate the base currents.

The DC polarographic results were confirmed by cyclic voltammetry. A typical cyclic voltammogram of PPDM is shown in Fig. 2. The first two steps showed cathodic and anodic peak separation of about 60 mV indicative of a reversible one-electron step. Peak currents of the first two steps were proportional to the concentration of depolarizer (less than 4×10^{-4} M) and

square root of the scan rate(0.1 to 1 V/s). The cathodic and anodic peak potentials for the first two steps were found to be independent of the concentration and of the scan rate over the range studies. These results again indicate that the first two steps are reversible one-electron processes. The third step appeared irreversible, showing no corresponding anodic peak. In the case of Cu(II)-PPDM and Ni(II)-PPDM, however, an additional anodic peak was observed at the potential about 0.1 V more positive than that of the first anodic peak, as shown in Fig. 3. In the case of Zn(II)-PPDM, one more anodic peak was observed between the first and second anodic peaks. These anodic peaks were not observed until the cathodic scan limit was extended to the third step. It is clear that these additional peaks are associated with the oxidation of the products produced at the third reduction step.

In AC polarography, these compounds gave four peaks. Fig. 4 shows a typical AC polarogram of PPDM. A small peak observed at the most positive

15) M. Senda and I. Tachi, *Rev. Polarogr.* (Kuoto), **10**, 79 (1962).

potential is considered to be due to a trace of iodide anion remaining in supporting electrolyte because it was observed also with the base solution. Three AC peaks observed at −1.24, −1.61 and −2.4 V will be denoted by Peaks 1, 2 and 3, respectively. These three peaks correspond respectively to the three reduction steps in DC polarography. The summit potentials of Peaks 1 and 2, being independent of concentration, agreed with the corresponding DC half-wave potentials within experimental error. The half-width of these peaks were about 90 mV. The summit currents were proportional to the concentration over the range studied(see Fig. 5). The apparent lower height of Peak 2 in comparison with Peak 1 is in large part due to the decreasing of drop time. The lower height of Peak 3 is due to its irreversibility. These AC results are in good agreement with the results in DC polarography and cyclic voltammetry.

The AC peak observed at around −0.95 V, being denoted by Peak A, had no counter part in DC polarography. Figure 5 shows the dependence of the summit potentials and summit current of the AC peaks 1, 2, and A on the concentration of PPDM. The behavior of 1 and 2 is that of the reversible process. In contrast, with increasing concentration of the depolrizer the summite current of Peak A increased nonlinearly and approached a limiting value and the summit potential shifted to more negative potential. With a rise in temperature the summit current decreased and the summit potential was shifted to more positive potential, as shown in Fig. 6. Further, the rising potential of Peak A approximately agreed with the potential where the depression of the DC residual current was restored. These results indicate that Peak A is a tensammetric desorption wave.[15,16] This assignment was clonfirmed also by electrocapillary measurements. Fig. 7 shows the electrocapillary curves(drop time–potential curves). The addition of depolarizer to the base solution caused a significant depression of drop time at the potential

more positive than about −1.0 V, and the magnitude of the depression increased with increasing concentration of depolarizer. However, at the potential more negative than −1.1 V the depression was no more observed. These observations are consistent with the AC and DC polarographic results described above and indicate that the adsorption effects on the electrode process are practically negligible at the potential more negative than −1.1 V.

Reduction of Ni(II)-PPDM. A polarogram of this compound is shown in Fig. 1. The DC and AC

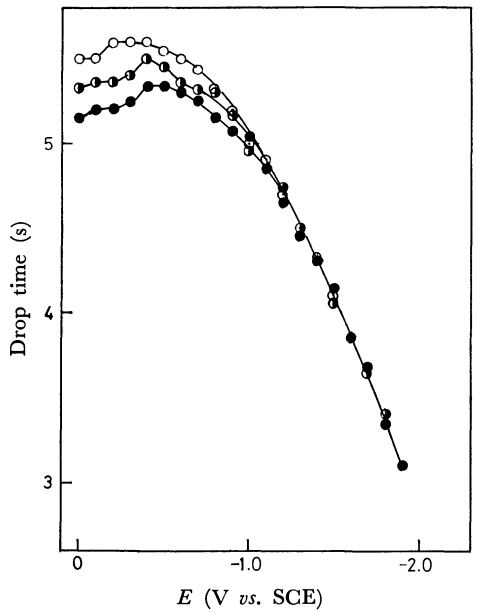

Fig. 7. Electrocapillary curves of a DMF solution containing 0.1 M TEAP(○), and in the presence of 1/8 (◑) and 1/1(●)× *ca.* 4×10^{-4} M MPDM in the base solution at 25 °C.

polarographic properties of the first two steps were essentially the same as those of the other metalloporphyrins described above. The first step in DC polarography was a one-electron reversible step, but the height of the second step was slightly larger than that of the first one. This slight increase of the current would be attributed to electroreduction of products that were produced in chemical reactions, including protonation, following the second electrochemical step. The third and fourth DC steps were poorly defined, irreversible waves.

Reduction of Co(II)-PPDM. Co(II)-PPDM in DMF gave two well-defined polarographic waves at −0.96 and −2.06 V, and an ill-defined wave at −2.35 V, as shown in Fig. 8. A small maximum was also observed at about −1.1 V on the first step. The limiting currents of the first two steps were proportional to square root of the mercury column height, indicating that these were controlled by diffusion. When corrected for drop time, the two wave heights were in the ratio of 1 : 0.9. The wave slopes for the first and second steps were 70 and 60 mV, respectively.

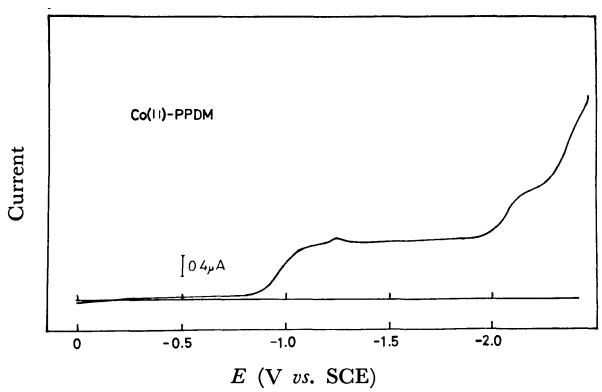

Fig. 8. DC polarogram of Co(II)-PPDM in DMF, 0.1 M TEAP at 25 °C.
Concentration: about 4×10^{-4} M.

A cyclic voltammogram of Co(II)-PPDM is shown in Fig. 9. The first wave, corresponding to the first DC step, has a complicated shape, which may be ascribed to the adsorption of metalloporphyrin molecules on the electrode surface. In contrast, the second peak, appearing at the potential of the second DC step, has the normal shape with a corresponding anodic peak, indicating that the second step is a simple one-electron reversible reduction.

In AC polarography, this compound gave four peaks, as shown in Fig. 10. Three AC peaks observed at −0.96, −1.14 and −2.05 V will be denoted by Peaks 1, A and 2, respectively. The summit potential of Peaks 1 and 2 agreed with the half-wave potentials of the first and second steps, respectively. Figure 11 shows the dependence of the summit current and summit potentials on the bulk concentration of depolarizer. The summit current of Peak 2 was proportional to the concentration and its summit potential was nearly independent of the concentration. Moreover, the waveform of Peak 2 was practically symmetrical with respect to the summit potential with a half-width of about 100 mV. On the other hand, with increasing concentration of the depolarizer the summit current

of Peak A increased nonlinearly and approached a limiting value and its summit potential shifted to more negative potential. The summit current of Peak 1 increased linearly with the concentration, but the linear regression line intersected with the current axis at a negative value. The summit potential of Peak 1 was practically independent of the concentration. Effect of temperature on the summit currents and summit potentials is shown in Fg. 12. The sumit currents of Peaks 1 and 2 inclined to increase with a rise in temperature and the apparent shift of their summit potentials are negligibly small. The temperature coefficients of these summit currents were in the order of that of AC reversible peak.[17] On the contrary, the summit current of Peak A decreased and its summit potential shifted to more positive potential with a rise in temperature. Namely, the behavior of Peak A was characteristic of the tensammetric desorption wave.

In conclusion it may be stated that the first DC wave is a reversible one-electron reduction wave overlapped with an adsorption post wave,[18] though the latter is poorly separated from the main wave. The AC polarographic behavior of peaks 1 and A reasonably supports this interpretation.[19] The adsorption effect is negligible at the potential more negative than −1.2 V. The second DC wave is a simple reversible one-electron reduction wave.

Reduction of Mn(III)Cl·H_2O-PPDM and Fe(III)Cl-PP. In DC polarography, the Mn(III)-complex gave four reduction steps and an oxidation double wave, as shown in Fig. 13. Polarographic reduction of Mn(II)-porphyrin derivatives in aprotic media has been studied by Boucher and Garber.[4] The results in the present study were, for the most part, in good agreement with those reported by them. The oxidation double wave was identified as an oxidation wave due to chloride anion. This suggests that an axial ligand such as chloride anion is displaced by a solvent molecule in such a strongly coordinating solvent as DMF, which is consistent with spectral observation by Boucher.[12] In AC polarography, was observed a peak of asymmetric shape at the potential of the first redox waves as well as four AC peaks corresponding to the tensammetric desorption (Peak A) and the second, third and fourth reduction steps (Peaks 1, 2 and 3, see Fig. 4).

Fe(III)Cl-PP	0.28	0.07	1.20	0.06	1.64[d]
Mn(III)Cl·H_2O-PPDM	0.37	0.08	1.49	0.06	1.97[e]

a) Volts *vs.* aq. SCE. b) $\Delta E=E_{1/4}-_{3/4}$ (in V). c) One more wave at −2.7 V. d) Two more waves at −1.84 and −2.4 V. e) One more wave at −2.4 V.

DC polarogram of Fe(III)Cl-PP is shown in Fig. 13. The first and second reduction steps were one-electron diffusion-controlled steps. Three more reduction waves were observed. An oxidation wave was also observed. In AC polarography, five peaks were observed, but a peak corresponding to the DC third step was not observed.

Discussion

The half-wave potentials of the porphyrins and metalloporphyrins measured in this study are summarized in Table 1. Polarographic reduction of tetraphenylporphin (TPP) and its metal complexes in dimethylsulfoxide has been studed by Felton and Linschitz.[2] On comparing the half-wave potentials of PPDM complexes with those of TPP complexes, we may find that the difference between the corresponding steps was nearly constant; for the first step, 0.19 V (TPP–PPDM), 0.16 V (Ni-TPP—Ni-PPDM), 0.17 V (Cu-TPP—Cu-PPDM), 0.18 V (Zn-TPP—Zn-PPDM), 0.14 V (Co-TPP—Co-PPDM), and for the second step, 0.14 V (TPP–PPDM), 0.14 V (Ni-PPT—Ni-PPDM), 0.14 V (Cu-TPP—Cu-PPDM), 0.12 V (Zn-TPP—Zn-PPDM), 0.19 V (Co-TPP—Co-PPDM). This result suggests that the polarographic reduction of these metal-PPDM complexes proceeds in a similar manner as that of metal-TPP complexes. Accordingly, the first two reduction steps of Ni(II)-PPDM, Cu(II)-PPDM and Zn(II)-PPDM will be assigned to successive addition of one electron to orbitals belonging mainly to the porphyrin ring, and the first step of Co(II)–PPDM to addition of one electron to a metal-centered orbital.[2]

The first DC waves of Fe(III)Cl-PP and Mn(III)-Cl·H_2O-PPDM should reasonably be assigned to the reduction of a trivalent metal complex to a divalent metal complex. The half-wave potential of the first step of Fe(III)-complex is 0.09 V more positive than that of Mn(III)-complex. Correspondingly, the difference in reduction potentials between hematoporphyrin complexes of Fe(III) and Mn(III) in aqueous solution is reported to be 0.05 to 0.08 V.[2),21] The subsequent reduction steps of the trivalent metalloporphyrins should be assigned to the reduction of the divalent metalloporphyrins.

The observed order of increasing negative half-wave potential of the first step of the divalent metalloporphyrins or the second step of the trivalent metalloporphyrins is $Co \ll Fe < Ni \lesssim Cu \ll Zn \simeq Mn$. On the other hand, the calculated order[22] of increasing negative charge on the porphyrin moiety is $Mn \ll Fe < Cu \lesssim Ni < Co < Zn$. The observed order $Fe < Ni \lesssim Cu \ll Zn$ should be considered as practically agreed with the calculated order of increasing negative charge in the porphyrin moiety. This is in harmony with the charge in the porphyrin moiety. This is in harmony with the stated conclusion that the addition of electron to these metalloporphyrins, except Fe(II)-complex, takes place in porphyrin moiety. For Fe(II)-complex the possibility of the electron addition to metal-centered orbital may not be excluded. It is also noted that the half-wave potential of Fe(II)-complex (second step of Fe(III)Cl-PP) is more positive than that of the free base, PPDM (Table 1). The half-wave potential of Mn(II)-PPDM is much more negative than predicted from the molecular orbital calculation, in which a planar configuration is assumed. This discrepancy may be interpreted by assuming that in Mn(II)-porphyrins the metal atom is out of the plane of the porphyrin, so that the porphyrin ring retains a high negative charge in this configuration because of the poor sigma donation of the porphyrin to the metal. The assumed structure is consistent with the ease of demetallation of Mn(II)-porphyrin derivatives[20] and the lack of strong mixing of metal $d\pi$ orbitals with ring π orbitals, as suggested by the spectral data.[4,23]

The half-wave potential of Co(II)-PPDM is remarkably more positive than predicted by the calculation. This result may be understood by the reason that in this complex the electron is added to the metal-centered orbital, exceptionally among the divalent metalloporphyrins studied.

The Primary Photochemical Process of Isoquinoline *N*-Oxide in Hydroxylic Solvents

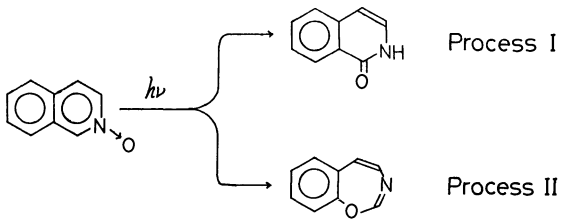
Isao ONO and Norisuke HATA

Department of Chemistry, Faculty of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received March 7, 1973)

In order to deduce the nature of the reactive state of the photochemical isomerization of isoquinoline *N*-oxide in methanol or water, investigations by means of steady-light irradiation and flash spectroscopy were carried out under various conditions. Transient absorptions were observed in the spectral region between 360 nm and 600 nm; they were identified as being due to a T–T transition of isoquinoline *N*-oxide. Experiments on both the measurements of the quantum yields and the decay kinetics of the transient species under different conditions revealed that the excited singlet state of isoquinoline *N*-oxide was responsible for the isomerization. The photochemical behavior in aqueous solutions at various pH values was also examined; consequently, the photochemical isomerization was found to be independent of the hydrogen ions, although it did not occur in a strongly acidic solution (pH<3.0) because of the formation of the protonated *N*-oxide. The biacetyl-photosensitization for isoquinoline *N*-oxide led to the dissociation of the N–O bond instead of to isomerization.

It is well known that the azanaphthalene *N*-oxides undergo interesting but complex photochemical reactions in solution.[1] For example, the ultraviolet irradiation of quinoline *N*-oxide or isoquinoline *N*-oxide results in the formation of lactams and/or oxazepines, depending on the nature of the reaction medium or the substituent group. Hereafter, the photochemical change leading to the formation of a lactam will be referred to as Process I, while the photochemical conversion to an oxazepine will be termed Process II.



In hydroxylic solvents, such as methanol and water, the quinoline- or isoquinoline-*N*-oxide is predominantly transformed into its lactam (carbostyril or isocarbostyril) as a result of the ultraviolet irradiation, whereas in non-hydroxylic solvents, such as acetone and carbon tetrachloride, Process II generally becomes much more important than Process I. Mechanistic studies, including the identification of the reactive excited state, of the photochemical isomerizations of heterocyclic *N*-oxides have been extensively performed in recent years.[1-3] In order to account for such photochemical isomerizations, the oxaziridine has been customarily postulated to be a photochemical intermediate common to both Processes I and II. Very recently, however, Lohse has suggested that it is not valid to assume an oxaziridine as a photochemical intermediate common to both Processes.[2b] As an aid in the mechanistic elucidation of the photochemical reactions of azanaphthalene *N*-oxides, therefore, the present authors carried out studies by means of both steady-light and flash illumination for the isoquinoline *N*-oxide in methanol or water (Process I).

Experimental

Materials. The isoquinoline *N*-oxide used in this experiment was synthesized by Ochiai's method,[4] and the product was purified by vacuum distillation, followed by silica gel chromatography (using diethyl ether–ethanol as the eluant). In the irradiation experiments, reagent-grade methanol of Wako Pure Chemical Industries was used without further purification; a 1 M sodium hydroxide solution, 20% hydrochloric acid, and a standard buffer solution (pH 6.86) were also used. The 1,3-cyclohexadiene, piperylene, isoprene (Tokyo Kasei Kogyo Co.), and biacetyl (Wako Pure Chemical Ind.) used as triplet quenchers or sensitizers were purified by distillation.

Steady-light Experiment. Small-scale photolyses for the determination of the quantum yield were performed in a quartz cylindrical cell 5 cm in diameter and 1 cm in length. The UV light source was a 250 W high-pressure mercury lamp (Ushio-250). For the 313-nm irradiation, a filter combination of a nickel sulfate solution with UV-29 and UVD-25 Toshiba filters was used. The light intensity was determined by means of a potassium ferrioxalate actinometer. The disappearance of isoquinoline *N*-oxide was followed quantitatively at 298 nm with a Hitachi recording spectrophotometer, EPS-3T. The amounts of isocarbostyril produced were measured by means of a chromatographic separation (silica gel, chloroform–ethanol) combined with a spectrophotometric determination; for this purpose, a UV spectrometer, UVICON-540 (Tokyo Kagaku Sangyo Co.), and a recorder, EPR-2TP (Toa Dempa Kogyo Co.), were used. Large-scale photolyses were performed at concentrations of approximately 5.0×10^{-3} M (70 ml) in a Pyrex vessel using a 100 W high-pressure immersion mercury lamp (Riko Kagaku Sangyo Co.) under the bubbling in of nitrogen; the photoproducts were then separated by silica gel chromatography. In the case of the biacetyl-sensitization experiment, a methanol solution containing 6.0×10^{-3} M of isoquinoline *N*-oxide and 3.0×10^{-2} M of biacetyl in a quartz cylindrical reaction vessel (5 cm in diameter and 1 cm in

length) was irradiated with a 250 W high-pressure mercury lamp (Ushio-250) equipped with a Toshiba V-Y 43 filter for 10 hrs under a nitrogen atmosphere. The phosphorescence spectra were taken with a Hitachi fluorescence spectrophotometer MPF-2A, with a phosphorescence accessory attached.

Flash Spectroscopic Experiment. The flash-photolysis apparatus used in this experiment was the same as that described elsewhere.[5] An energy of 120J was dissipated by discharging a bank of condenders of 2 μF charged to 11 kV; the duration of the flash was about 10 μs.

Results and Discussion

The isoquinoline *N*-oxide in methanol or ethanol isomerizes upon irradiation by ultraviolet light to give isocarbostyril in *ca.* 70% yield.[6] This photochemical isomerization (Process I) also proceeded in an aqueous solution to give a good yield (*ca.* 75%), irrespective of the atmosphere, nitrogen or oxygen. Figure 1 shows the progressive spectral change in isoquinoline *N*-oxide on 313-nm irradiation in methanol; it was observed that the absorption of isoquinoline *N*-oxide decreased in intensity, and a new absorption band due to isocarbostyril appeared with isosbestic points, as the irradiation time increased.

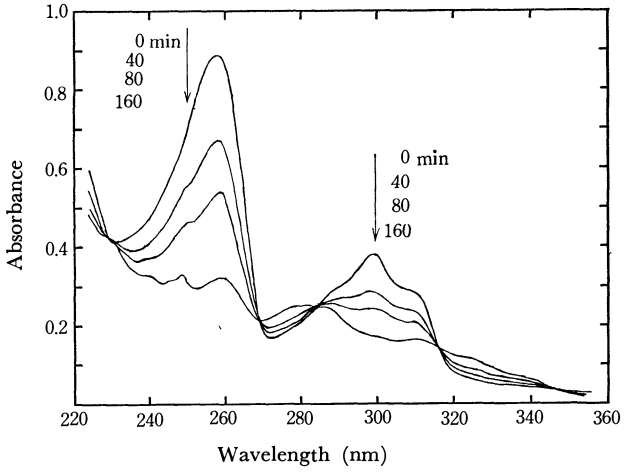

Fig. 1. The progressive spectral change of isoquinoline *N*-oxide (3.5×10^{-5} M) on 313 nm irradiation in methanol. Numbers refer to the irradiation time.

Phosphorescence Spectra. Curve (a) in Fig. 2 shows the phosphorescence spectrum from EPA glass containing 5.0×10^{-5} M of isoquinoline *N*-oxide at 77 K. As is shown in the figure, the phosphorescence lifetime was quite dependent on the emission wavelength; that is, it was *ca.* 1.0 s at the shorter wavelengths (400—500 nm), while it was *ca.* 60 ms at the longer wavelengths (500—600 nm). Ziolkowsky and Dörr[7] have obtained the same results; they have assigned the shorter wavelength band to the phosphorescence of isoquinoline *N*-oxide. However, the

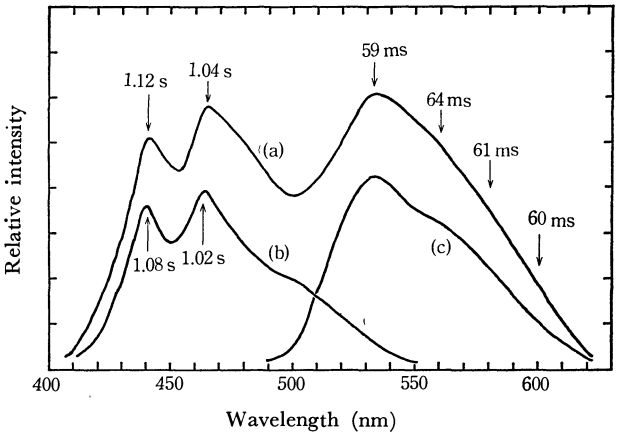

Fig. 2. Phosphorescence spectra of (a) isoquinoline *N*-oxide (5.0×10^{-5} M), (b) isocarbostyril (1.0×10^{-4} M), and (c) highly fresh solution of isoquinoline *N*-oxide (5.0×10^{-5} M) in EPA glass at 77 K.

experimental results to be presented below definitely show that the longer wavelength band can better be ascribed to the phosphorescence of isoquinoline *N*-oxide, whereas the shorter wavelength one should be ascribed to the phosphorescence of the isocarbostyril resulting photochemically from isoquinoline *N*-oxide.

(i) The shorter wavelength band was quite similar to the phosphorescence spectrum of isocarbostyril (Curve (b) in Fig. 2); the decay time (1.08 s) was also in good agreement with the phosphorescence lifetime of isocarbostyril (1.05 s). (ii) The very fresh solution (5.0×10^{-5} M), immediately after preparation, gave only the longer-wavelength emission (Curve (c) in Fig. 2). When the solution was allowed to stand for a while in the light, however, the shorter-wavelength emission appeared also. (iii) The longer-wavelength emission band was in a mirror-image relation with the S–T absorption band of isoquinoline *N*-oxide determined by Kubota et al.[8] (Fig. 3).

From the maximum of the phosphorescence spectrum of isoquinoline *N*-oxide (532 nm), the excitation energy of the lowest triplet state was estimated to be about 53.7 kcal·mol^{-1}. Consequently, the addition of 1,3-cyclohexadiene (E_T=52.5 kcal·mol^{-1}) to a methanol solution of isoquinoline *N*-oxide in amounts much greater than the molar equivalence led to the complete disappearance of the phosphorescence (Fig. 3). On the other hand, the addition of piperylene (E_T= 56.9 kcal·mol^{-1}) or isoprene (E_T=60.1 kcal·mol^{-1}) did not quench the phosphorescence of isoquinoline *N*-oxide, but it did quench the phosphorescence of isocarbostyril. Interestingly, in a concentrated solution (4.0×10^{-4} M) of isoquinoline *N*-oxide, only its phosphorescence spectrum was observed. This is probably because the phosphorescence of isocarbostyril can be quenched by an unexcited *N*-oxide, since the T–T energy transfer between them is energetically possible.

Steady-light Irradiation. The quantum yields of both the disappearance of isoquinoline *N*-oxide (Φ_d) and the formation of isocarbostyril (Φ_f) were examined in a deaerated methanol at room temperature. Figure 4(a) shows the effect of the irradiation time on the quantum yield in a 1.0×10^{-4} M solution; the results indicate that the quantum yield was independent of the irradiation time. The quantum yields were also determined as a function of the initial concentration of isoquinoline *N*-oxide. As is shown in Fig. 4 (b), a long-lived excited species susceptible to a collisional deactivation by an unexcited *N*-oxide is not involved in the photochemical reaction. In order to clarify whether or not the triplet species are responsible for this isomerization, therefore, the triplet quenching or sensitization experiments for the photochemical reaction of isoquinoline *N*-oxide were undertaken by using a 1,3-cyclohexadiene (triplet quencher) or a biacetyl (triplet sensitizer) in a deaerated methanol. As can be seen from Fig. 4(c), the quantum yield of the *N*-oxide disappearance was unaffected by the addition of 1,3-cyclohexadiene. Furthermore, the biacetyl-sensitization for the isoquinoline *N*-oxide in deaerated methanol did not lead to the isomerization of *N*-oxide, but instead resulted in the dissociation of the N–O bond, thus giving rise to the isoquinoline in a 30% yield. Similar results were also obtained in the case of a deaerated chloroform or benzene solution. These results suggest that the lowest triplet state of isoquinoline *N*-oxide is responsible for the deoxygenation, but not for the isomerization.

Flash Spectroscopy. In order to get information on the photochemical intermediate which may be formed during the reaction, the flash-spectroscopic examinations were carried out in EPA glass at 77 K or in a deaerated methanol at room temperature. As is shown by Curve (a) in Fig. 5, the transient absorption was observed around 400 nm (strong) and 480 nm (weak) in EPA glass at 77 K. Figure 6 shows the results when the first-order rate law was applied to the decay of transients at 77 K at various wavelengths. The decay time was evaluated from the slope of the straight-line to be 57 ms, a value which agreed closely with the phosphorescence lifetime (60 ms). When the deaerated methanol solution of isoquinoline *N*-oxide was flash-illuminated at room temperature, a distinct maximum was observed only around 400 nm, since the absorption

intensity was lowered considerably at room temperature compared to that at 77 K (Fig. 5). The decay time estimated from the first-order rate plot was *ca.* 30 μs.

Next, the effect of the triplet quencher on the transient absorption was investigated in a deaerated methanol at room temperature. As can be seen from Fig. 7, the decay rate of the transient increased linearly with an increase in the concentration of 1,3-cyclohexadiene, although the piperylene or isoprene had no effect on the decay rate. The quenching rate constant evaluated from the slope of the straight-line was 8.1×10^{8} l·mol^{-1}·s^{-1}. The possibility that the transient absorption could be due to a T–T transition of the photoproduct (isocarbostyril) was definitely excluded by the flash-spectroscopic examinations for isocarbostyril itself. That is, as is shown in Figs. 5 and 7, the T–T

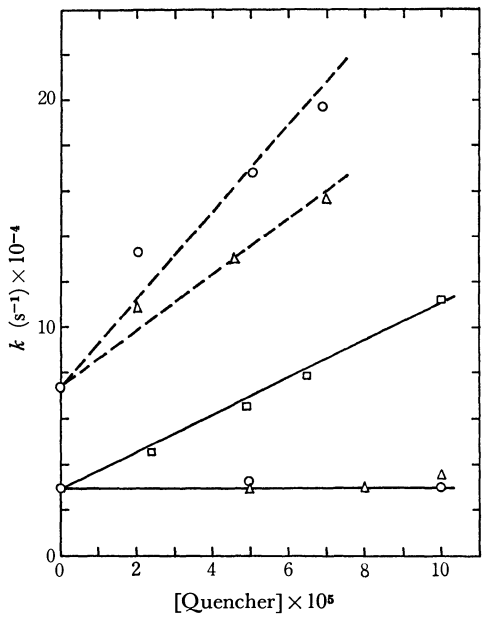

Fig. 7. Effect of the triplet quencher (-○-: isoprene, -△-: piperylene, -□-: 1,3-cyclohexadiene) on the transient species of isoquinoline *N*-oxide and isocarbostyril in deaerated methanol at room temperature. ——: for isoquinoline *N*-oxide (5.0×10^{-5} M), ----: for isocarbostyril (1.0×10^{-4} M).

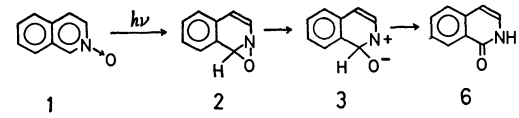
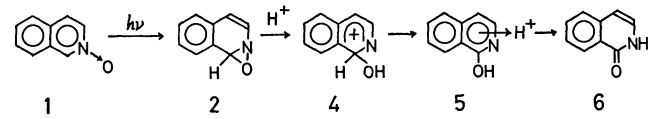
absorption of isocarbostyril in a deaerated methanol at room temperature was completely different from that of isoquinoline *N*-oxide in maximum wavelength and in decay rate. In addition, the decay rate was observed to increase linearly with an increase in the concentration of the piperylene or isoprene (Fig. 7). Therefore, the transient absorption (Curve (a) in Fig. 5) was definitely identified as being due to a T–T transition of isoquinoline *N*-oxide. Although the triplet species was effectively quenched by 1,3-cyclohexadiene, the quantum yield of the photochemical isomerization was unaffected, as has been described before (Fig. 4). This also supports the idea that the lowest triplet state of isoquinoline *N*-oxide is not involved in the photoisomerization, but that the isocarbostyril results from an excited singlet state.

Effect of pH *on the Photochemical Isomerization.* In order to account for Processes I and II of the azanaphthalene *N*-oxides, Buchardt and Kaneko have independently proposed the idea that an oxaziridine may be initially formed as a photochemical intermediate common to both Processes.[1,3] On the basis of this assumption, Process I has been explained as follows. According to Buchardt,[1] the zwitter ion, **3**, resulting from a heterolytic cleavage of the oxaziridine **2** may be supposed to rearrange by a 1,2 shift (Scheme 1). Since a protonation of the $-O^-$ group may take place during the rearrangement, the photochemical isomerization in an aqueous solution is inferred to be affected by a variation in the pH values. Kaneko[3] has assumed a heterolytic cleavage of the oxaziridine **2**, followed by the formation of a carbonium ion, **4**, which can then rearrange to the lactam (Scheme 2); thus, the photoisomerization is considered to be facilitated by the presence of hydrogen ions. In either case, the photochemical isomerization in an aqueous solution is expected to be influenced to some extent by a lowering of the pH values.



Scheme 1



Scheme 2

Therefore, in order to clarify the effect of hydrogen ions on the isomerization process, photochemical examinations of isoquinoline *N*-oxide were performed on aqueous solutions at different pH values. Curve (a) in Fig. 8 shows the quantum yields of the disappearance of isoquinoline *N*-oxide plotted against the pH; that is, the independence of the quantum yield (*ca.* 0.07) of the pH in the 13.0—3.0 range was observed,[9] al-

9) The similar result has been also obtained in the case of quinoline *N*-oxide by Favaro.[2a]

though there was a steep increase at lower pH values (<3.0). In addition, the chemical yield of the isocarbostyril produced (Curve (b) in Fig. 8) was also found to be independent of the pH values except for the case of a strongly acidic solution (pH<3.0). These facts probably mean that Process I does not proceed ionically through the oxaziridine intermediate, as is shown in Schemes 1 and 2. For this reason, it seems to be difficult to assume that Procesess I and II involve a common intermediate such as an oxaziridine. This view seems to support the conclusion of Lohse.[1b]

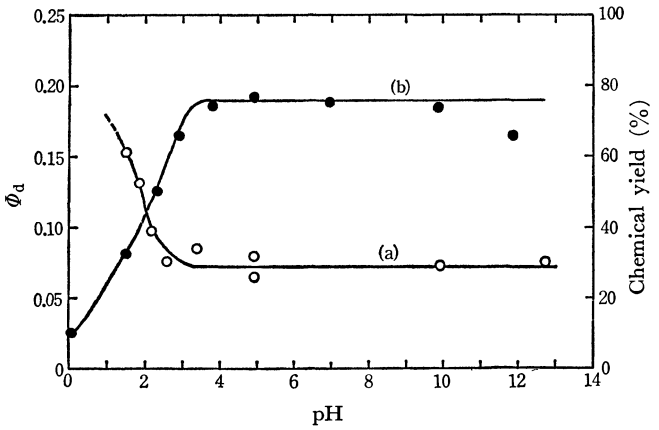


Fig. 8. Effect of pH on the quantum yield of isoquinoline *N*-oxide disappearance (-○-) and the chemical yield(%) of isocarbostyril (-●-) in aqueous solutions at room temperature.

Meanwhile, the p*K*a values of isoquinoline *N*-oxide in the ground and lowest-excited singlet states have been reported by Kubota[10a] to be 1.05 (or 1.01[10b]) and 0.81 respectively. Therefore, the remarkable change in both the quantum and chemical yields in strongly acidic solutions could be interpreted in terms of an acid-base equilibrium in the ground or lowest excited singlet state; that is, the photochemical isomerization of isoquinoline *N*-oxide proceeds from the excited non-protonated *N*-oxide, while the excited protonated molecule undergoes decomposition instead of isomerization.

The authors wish to thank Professor Shiro Matsumoto of this university for his permission to use the flash-photolysis apparatus.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3662—3665 (1973)

The Photo-Erasable Memory Switching Effect of Ag Photo-Doped Chalcogenide Glasses

Isamu SHIMIZU, Hiroshi KOKADO, and Eiichi INOUE

Imaging Science and Engineering Laboratory, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received May 1, 1973)

The electric conductivity of the chalcogenide glass increased with an increase in the amount of Ag which had been photo-doped. By applying the electric field to the electrodes which were set on the surface of the Ag photo-doped chalcogenide glass film, a conductive path was grown from the cathode to the anode. As a result of the connection of the electrodes with the path, the electric resistance of the cell abruptly decreased (ON state). The path was made of the metal silver reduced by electrolysis and was diminished by irradiation with light. As the path was erased, the cell was turned into the resistant state (OFF state). The cycles were repeatable many times. There was a delay time (t_d) in turning the cell from the OFF to the ON state by applying the electric field (E). It was empirically described by the following equation for the Ag photo-doped chalcogenide glasses:

$$t_d = a \exp(-b \cdot E)$$

When a binary layer of metal and chalcogenide glass was exposed to light with the fundamental absorption band of the glass, the metal was doped into the glass layer. The term "photo-doping"[1] was given to the phenomenon on analogy with the doping of the foreign materials into the semiconductors.

As the electric fleld was applied to a pair of electrodes set on the surface of the Ag photo-doped chalcognide glass film, a conductive path was grown from the cathode to the anode. When the electrodes were connected with the path, the electric conductivity of the cell abruptly increased (ON state). The path remained stable even if the field was removed, while it could be erased at will by irradiation with light. As the path was erased, the cell returned to the resistant OFF state. These cycles were repeatable many times and were similar to the memory-switching effect[2] in the chalcogenide glass film. This phenomenon, however, was characteristic because of the following facts. In an ordinary case, the transition between the OFF and the ON state caused by applying a field is due to the phase transition between the vitreous and crystalline states. On the contrary, in this case

1) H. Sakuma, I. Shimizu, H. Kokado, and E. Inoue, Proc. 3rd Conf. Solid States Devices, Japan, *Supplement to Oyo Butsuri*, **41**, 76 (1972).

2) E. J. Evance, J. H. Helbers, and S. R. Ovsihnsky, *J. Non-crystalline Solids*, **2**, 334 (1970).

a migration of the silver ion in the glasses by applying the field takes place and the silver ions are reduced to the metal at the cathode, thus forming the conductive path. Moreover, the path can be erased by illumination at will.

The delay time (t_d) for the conductivity change from the OFF to the ON state under the field (E) was measured for the Ag photo-doped chalcogenide glasses. An empirical relation was obtained between t_d and E.

$$t_d = a \exp(-b E) \quad (1)$$

Here, a and b are constant.

Experimental

The chalcogenide glasses were prepared by the methods described in a previous paper.[3] The binary layers of Ag-chalcogenide glass were made on a substratum (slide glass) by successive vacuum evaporation (10^{-5} Torr). The silver layer on the chalcogenide glass was completely doped by irradiation with light. A high-pressure mercury lamp (Ushio-USH 250 W) fitted with an IR cut filter was used as the source. When the silver layer was completely photo-doped, the optical absorption of the metal silver at the wavelength longer than the absorption edge of the chalcogenide glass disappeared. The completion of the photo-doping of the silver layer was confirmed by the above measurement.

Two types of electric cells were used for the electric measurement (see Fig. 1). In the type (a) cell, a pair of the Au electrodes was formed on the surface of the photo-doped glass by vacuum evaporation. In the type (b) cell, an Au electrode was used as the anode and a tungsten pin electrode, as the cathode. An electric resistor of 500 KΩ was connected with the sample in series to prevent the cell from breaking because of the excessive current in the conductive ON state. A regulated power supply (Showa Electronics R-700) was used as the electric source. The electric current of the specimen was measured by means of a micro-ammeter (Takeda Riken TR-8651). To measure a t_d value of less than 1 s., a square wave pulse was used as the source and the change in the current flowing through the cell was traced with a synchroscope as the voltage drop through the series resistance.

Results and Discussion

As a result of the photo-doping of Ag into the chalcogenide glasses, the electric conductivity of the surface of the glass films increased with an increase in the photo-doped silver. When the electric field was applied to the cell (type (a)) on an Ag photo-doped chalcogenide glass film, the conductive path was grown from the cathode to the anode, as is shown in Fig. 2. As a result of tracing with an EMX(electron probe X-ray micro-analyser), it was confirmed that the path was made of silver dendrite. On the basis of these facts, we may suppose that the photo-doped silver was

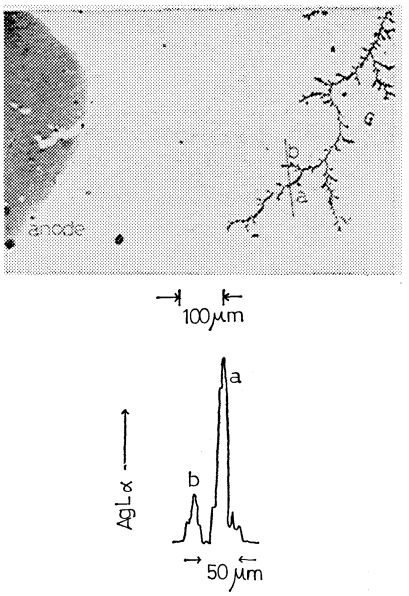

Fig. 2. Micrograph of conductive path grown from cathode to anode and EMX profile traced along a-b.

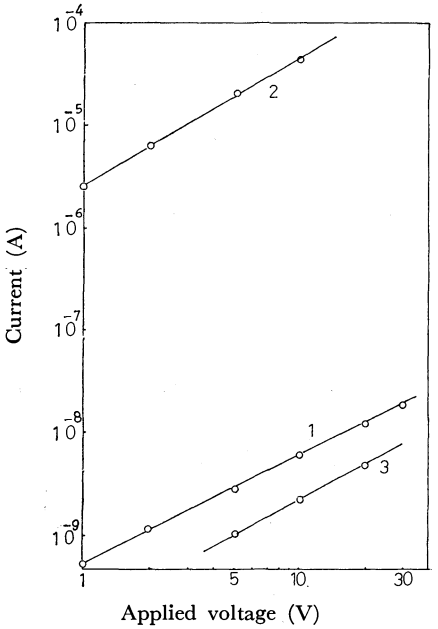

Fig. 3. Typical I-V characteristic curves of Ag (1000A) photodoped chalcogenide glass ($As_{16}S_{80}Te$) showing the photoerasable memory effect.
Type (a) cell was used. 1: OFF state, 2: ON state, 3; after irradiation of (2) with light

moved through the chalcogenide glass as the silver ion by applying the electric field and that the metal silver was reduced as a result of electrolysis at the cathode. The presence of the Ag ion has been supposed from studies of the electric properties of the chalcogenide glasses containing silver.[4] The electric conductivity of the specimen changed a very little before the path reached the anode. As the electrodes were shorted with the path, however, the conductivity of the cell absuptly increased. Figure 3 shows the current-voltage characteristic of the Ag(1000 A in thickness) photo-doped chalcogenide glass ($As_{16}S_{80}Te_4$) film in the OFF and ON states. The path was diminished by irradiation with light. When the path was erased, the cell returned to the OFF state, as is shown by Curve 3 in Fig. 3. These cycles were repeated many times unless the specimen was damaged by the passege of an excessive current through the cell in the ON state.

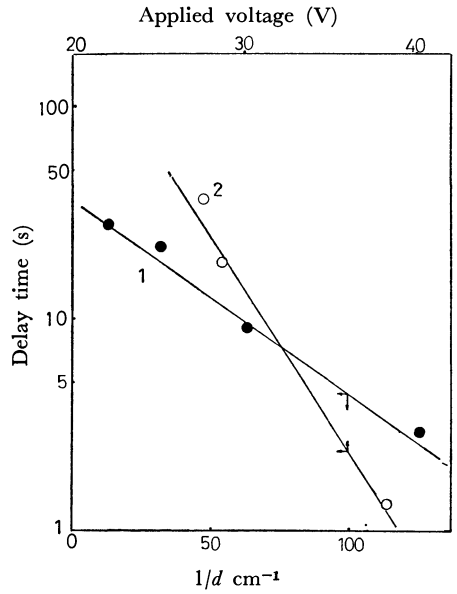

Fig. 4. Delay time plotted against applied field.
1: t_d *versus* V at constant d (1.3×10^{-2} cm), 2: t_d *versus* $1/d$ at constant V (30 volt) for Ag(500A) photo-doped $As_{30}S_{50}Se_{20}$

To regulate the position at which the path was generated, the type (b) cell was used and the delay time (t_d) was measured by changing the applied voltage (V) and the electrode distance (d). When the tungsten pin electrode was used as the cathode, the growth of the path was difficult because of its high contact resistance. Figure 4 shows the curve of the log t_d plotted against the applied voltage at the constant electrode distance ($d=1.3\times10^{-2}$ cm), and also the curve of the log t_d against the reciprocal of the electrode distance at a constant applied voltage (V=30 volt) for the Ag (500 A in thickness) photo-doped glass ($As_{30}S_{50}Se_{20}$) 0.5 μm thick. From these results, the relation between t_d and the electric field ($E=V/d$ V/cm) was described as follows:

$$\log t_d = \log A - B\cdot E. \qquad (2)$$

400	580	3.1×10^{-3}
600		3.7×10^{-3}
500[a]	4.8	1.5×10^{-3}

a) The values A and B presented in the bottom were the ones obtained in high electric field.

Here, A and B are constants. The A and B values for the Ag photo-doped chalcogenide glasses are summarized in Table 1.

The conductive path was easily grown under the lower electric field when iodine was included in the Ag photo-doped chalcogenide glass. Under a constant electric field, the t_d value decreased with an increase in the amount of photo-doped silver. The values for A and B obtained from the results are shown in Table 2. In this case, the decrease in t_d corresponded closely to the increase in the B value for the heavier doped glass. Under a high electric field, we obtained a linear relation different from that obtained under a low field for the same specimen, as is shown in Table 2. In this case, both A and B values were smaller than that obtained under the low electric field. The growth of the conductive path from the cathode to the anode proceeded rapidly under the low electric field, while it became slow in the vicinity to the anode. The change in the growth rate must be due to a scarcity of the silver ions in the vicinity of the anode. No change in the growth rate was, however, observed in the high electric field, because the path arrived at the anode before the depletion zone at the anode was formed. The fact that the conductive path was easily grown in the Ag photo-doped (As_2S_3)–I system may be explained as follows:

(1) A greater amount of silver was ionized in the glass by forming the ionic bond with the iodine.

(2) The migration of the silver ion in the glass easily took place in the same way as that of the silver ion through the ionic crystals, such as α-Ag_2S or AgI.[5]

5) C. M. Perrott, *J. Phys. Chem. Solids*, **31**, 2709 (1970).

Though the Ag photo-doped glasses in this work were confirmed by X-ray diffraction patterns to be retained in the vitreous state, micro-crystallization could occur locally in the glass.

The conductive path was retained for a long time after the electric field was removed, and the cell could be memorized in the ON state. When the cell was exposed to light, the conductive path disappeared and the cell returned to the OFF state. Figure 5 shows the relation between t_d and the exposure time needed to turn the cell into the OFF state for the Ag photo-dopes $(As_2S_3)\cdot I$ system. The experimental conditions are shown in Fig. 1. The OFF state formed by a short illumination was turned into the ON state with a short t_d. In this case, the conductive path is partially diminished. The t_d was recovered to the value for the virgin sample when the specimen was exposed to light for enough time. This implied that the path could be erased completely.

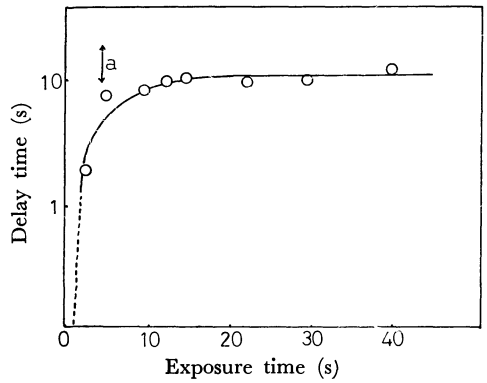

Fig. 5. Delay time plotted against exposure time for Ag-(400A) photo-doped $(As_2S_3)\cdot I$.
Applied field (7.7×10^2 v/cm); (a) shows the t_d for the virgin sample.

Conclusion

An electric memory-switching effect was found in the Ag photo-doped chalcogenide glass. It is different from the memory-switching effect observed in the chalcogenide glass films, such as the As–Ge–Te system, in which the effect is due to the phase transition between the vitreous and crystalline states. The properties of this memory-switching effect were as follows:

(1) In the Ag photo-doped chalcogenide glass, the silver ion was moved by the applied electric field, and the metal silver was reduced by electrolysis at the cathode and formed the conductive path.

(2) The ON state could be reverted to the OFF state at will by exposure to light.

Kinetics of Hydrogen Electrode Reaction on Mercury. I. Theoretical Part. Non-steady State Analysis for the Electrochemical Mechanism

Akiko KATAYAMA and Hideaki KITA
Research Institute for Catalysis, Hokkaido University, Sapporo 060

(Received July 2, 1973)

Potentiostatic and potentiodynamic transients are theoretically analysed on the basis of the electrochemical mechanism for the hydrogen electrode reaction. The interface was assumed to consist of the metal surface, the plane on which the adsorbed intermediate of $H_2^+(a)$ stays, and the diffuse double layer. The repulsive force between the intermediates was introduced by proportional approximation. From the results the depolarization observed in Tafel plots is understood as a non-steady state phenomenon, and observation by the potential-sweep method offers information on both the features of the adsorbed intermediate and the kinetics of the step preceding the rate-determining step.

In 1936 Horiuti and Okamoto found[1] that experimental values on the separation factor of the hydrogen evolution reaction serve to classify electrode metals into two groups. A dual mechanism was proposed[2,3] for the hydrogen electrode reaction (H.E.R.) on these groups of metals, *i.e.*, catalytic mechanism on Pt (at high overvoltages), Ni, Au, Cu, and Pb (in alkaline solution), and electrochemical mechanism on Hg, Pb (in acidic solution), Sn, and Pt (at low overvoltages). One of the present authors (H.K.)[4] surveyed data of H.E.R. on various metals reported for the last two decades and examined the relationship between the catalytic activity of electrodes and the heat of adsorption of hydrogen or the work function. A grouping of metals similar to Horiuti's was found, transition metals including IB metal (Cu, Ag, Au) being denoted by "d-metal" and those after IIB in the periodic table by "sp-metals". He showed that the difference between d- and sp-metals can be explained by the dual mechanism, *i.e.*, the catalytic mechanism on d-metals and the electrochemical mechanism on sp-metals.

The electrochemical mechanism consists of the following consecutive steps:

$$2H^+ + e^- \rightleftarrows H_2^+(a) \quad \text{(I)}$$

$$H_2^+(a) + e^- \rightarrow H_2, \quad \text{(II)}$$

where (II) is the rate-determining step and $H_2^+(a)$ is a hydrogen-molecule ion adsorbed on the electrode. However, the mechanism most frequently quoted, especially for Hg,[5] is the slow discharge mechanism, in which the rate-determining step is the formation of an adsorbed hydrogen atom, H(a); $H^+ + e^- \rightarrow H(a)$. This mechanism seems to be widely accepted because it provides the simplest way for an explanation of the kinetics observed. However, for Hg many experimental results which cannot be explained easily by means of the slow discharge mechanism have been obtained, *e.g.*, prolonged evolution of hydrogen gas after cessation of a cathodic polarization,[6,7] abnormal shift of a half-wave potential $E_{1/2}$ under various conditions,[6,8] and large transfer coefficient (>0.5) observed by the faradaic rectification method.[9] The prolonged evolution of hydrogen gas indicates that the rate-determining step is preceded by a fast step which produces an intermediate. According to the simple discharge mechanism, $E_{1/2}$ is not expected to shift with the pH of the solution, but this is not the case.[8] The effect of the column height of dropping mercury electrode on $E_{1/2}$ differs from that expected from the slow discharge mechanism. The symmetrical polarogram predicted from the slow discharge mechanism was not also observed under various conditions.[6] Barker found a larger value for a transfer coefficient by the sophisticated method of the faradaic rectification and attributed it to H_2^+ formation.[9]

Horiuti *et al.* who proposed the electrochemical mechanism, predicted the change in the Tafel slope from 40 to 120 mV on Hg with increase of a cathodic polarization. Experimental results, however, show the depolarization at low overvoltages; the observed current density is much higher than that extrapolated from the linear part of Tafel plots observed at high overvoltages. A possible explanation for the depolarization is to consider it a non-steady state phenomenon. As seen from an extremely small exchange current density of $10^{-12} \sim 10^{-13}$ A/cm^2 on Hg,[4] it may take a considerably long time for H.E.R. to attain a steady state, especially at low overvoltages. The reaction will then appear to be in a steady state on the time scale of usual observation though in fact it is not.

In the present work we attempt to interpret H.E.R. on Hg in a non-steady state and its transient process to attainment of steady state, assuming the electrochemical mechanism. A theoretical analysis is described.

Formulation

In the case of the electrochemical mechanism, the non-steady state is expressed by

$$Q\mathrm{d}\theta/\mathrm{d}t = i_1 - i_2 \mp 0, \tag{1}$$

where Q represents a monolayer quantity of $H_2^+(a)$ in electricity, θ the coverage of $H_2^+(a)$, and i_1 and i_2 net currents of steps (I) and (II), respectively. Non-steady state analysis is to solve the above equation for i_1 and i_2, and hence for the total current i,

$$i = i_1 + i_2, \tag{2}$$

as a function of time.

Rate expression. We first treat the rate expressions for i_1 and i_2. Horiuti developed a generalized theory for a reaction rate,[10,11] which gives precise rate formulae even for the heterogeneous reaction. On the basis of a crystal lattice plane model, forward and backward velocities of an elementary step are expressed in current densities by

$$i_+ = F(kT/h)N^{\mp}\theta^{\mp}(0)\exp\{-(\varepsilon^{\mp}-\mu^{\mathrm{I}})/RT\} \tag{3}$$

and

$$i_- = F(kT/h)N^{\mp}\theta^{\mp}(0)\exp\{-(\varepsilon^{\mathrm{I}}-\mu^{\mathrm{F}})/RT\}, \tag{4}$$

where the number of electrons concerned is put to unity. In Eqs. (3) and (4), $\mp$ is a critical system, $N^{\mp}$ the total number of sites for $\mp(\sigma^{\mp})$ per unit area, $\varepsilon^{\mp}$ reversible work required for a critical system to be brought from a standard state to a vacant $\sigma^{\mp}$, $\theta^{\mp}(0)$ the probability of $\sigma^{\mp}$ being vacant, μ^{I} and μ^{F} chemical potentials of the initial and final systems of a step, respectively. F, k, T, and h have their usual meanings.

In order to develop the rate expressions further, we introduce the following four relations.

(a). When the adsorption site of a critical system is the same as that of $H_2^+(a)$, we have

$$\theta^{\mp}(0) = 1 - \theta, \tag{5}$$

where θ represents the coverage of $H_2^+(a)$.

(b). Another fundamental relation is used:[10]

$$\theta/(1-\theta) = \exp\{[\mu(H_2^+) - \varepsilon(H_2^+)]/RT\}, \tag{6}$$

where $\varepsilon(H_2^+)$ is defined as reversible work required for $H_2^+(a)$ to be brought from a standard state to a vacant $\sigma^{\mp}$ (for the sake of simplicity abbreviated to ε). The functions μ^{I}, μ^{F}, and $\varepsilon^{\mp}$ for steps (I) and (II) are summarized in Table 1, where $\mu(H^+)$, $\mu(e^-)$, and $\mu(H_2)$ are chemical potentials of proton, metal electron, and hydrogen gas, respectively.

Table 1. μ^{I} and μ^{F} for steps (I) and (II)

	Step (I)		Step (II)	
μ^{I}	$2\mu(H^+)+\mu(e^-)$	(7.I)	$\mu(H_2^+)+\mu(e^-)$	(7.II)
μ^{F}	$\mu(H_2^+)$	(8.I)	$\mu(H_2)$	(8.II)

(c). In order to find a relation between $\varepsilon^{\mp}$ and the reversible work required for the initial system to be brought from a standard state to a vacant site, ε^{I}, we introduce the Horiuti-Polanyi relation,[12]

$$\Delta\varepsilon^{\mp} = \alpha\Delta\varepsilon^{\mathrm{I}} = \alpha(\Delta\varepsilon + F\Delta\eta), \tag{9}$$

where α is a positive proper fraction. This equation is referred to step (I) or (II) where the initial system is $2H^+ + e^-$ or $H_2^+(a) + e^-$. $\Delta\varepsilon$ in the third term of the equation represents the change in ε by experi-

mental conditions such as the kind of electrode. $F\Delta\eta$ represents the change in free energy of metal electron by polarization. Overvoltage, η, is taken positive for a cathodic polarization. Integration of Eq. (9) gives for steps (I) and (II),

$$\varepsilon_1^{\neq} = \alpha_1(\varepsilon+F\eta) + K_1 \quad (10.\text{I})$$

$$\varepsilon_2^{\neq} = \alpha_2(\varepsilon+F\eta) + K_2, \quad (10.\text{II})$$

where the sufficies 1 and 2 refer to steps (I) and (II) respectively, and K_1 and K_2 are integral constants. (d). $\mu(H^+)$, $\mu(e^-)$, and $\mu(H_2)$ are given as follows in reference to a standard state of the normal hydrogen electrode;

$$\mu(H^+) = RT \ln a_{H^+} \quad (11)$$

$$\mu(e^-) = F(-E_e+\eta) \quad (12)$$

and

$$\mu(H_2) = RT \ln P_{H_2}, \quad (13)$$

where a_{H^+} is an activity of H^+, E_e an equilibrium potential, and P_{H_2} a hydrogen pressure. E_e is given by

$$E_e = (RT/2F) \ln \{a_{H^+}^2/P_{H_2}\}. \quad (14)$$

i_1 and i_2. The forward current density of step (I), i_{+1}, is obtained from Eqs. (3), (5), (7.I), (10.I), and (11)$\sim$(13) as

$$i_{+1} = k_1 F a_{H^+} P_{H_2}^{1/2}(1-\theta) \exp\{[-\alpha_1\varepsilon+(1-\alpha_1)F\eta]/RT\}, \quad (15)$$

where $k_1 \equiv (kT/h)N^{\neq} \exp(-K_1/RT)$. Similarly, the backward current density of step (I), i_{-1}, is obtained from Eqs. (4), (5), (8.I), (10.I), and (11)$\sim$(13) as

$$i_{-1} = k_1 F\theta \exp\{[(1-\alpha_1)\varepsilon-\alpha_1 F\eta]/RT\}. \quad (16)$$

The net current density of step (I), i_1, is then

$$i_1 = k_1 F[a_{H^+} P_{H_2}^{1/2}(1-\theta) \exp\{[-\alpha_1\varepsilon+(1-\alpha_1)F\eta]/RT\} - \theta \exp\{[(1-\alpha_1)\varepsilon-\alpha_1 F\eta]/RT\}]. \quad (17)$$

The net current density of step (II), i_2, is obtained from Eqs. (3), (4), (6), (7.II), (8.II), (10.II), and (11)$\sim$(13) as

$$i_2 = k_2 F[a_{H^+}^{-1} P_{H_2}^{1/2}\theta \exp\{(1-\alpha_2)(\varepsilon+F\eta)/RT\} - P_{H_2}(1-\theta) \exp\{-(\alpha_2\varepsilon+\alpha_2\eta)/RT\}], \quad (18)$$

where $k_2 \equiv (kT/h)N^{\neq} \exp(-K_2/RT)$.

Equation (1) is now subjected to calculation by introducing Eqs. (17) and (18) for i_1 and i_2.

Calculation

Equations (17) and (18) show that i_1 and i_2 are as follows at given a_{H^+}, P_{H_2}, and α's;

$$i_1 \text{ or } i_2 = f(\theta, \eta, \varepsilon, k_1 \text{ or } k_2),$$

where k_1 and k_2 are parameters. In solving i_1 and i_2 as a function of θ, we need a relation between θ, ε, and η.

ε for $H_2^+(a)$. The adsorption energy of H_2^+(a), ε, will be given approximately by[13]

$$\varepsilon = \varepsilon_{00} + FE_p + R_e\theta, \quad (19)$$

where ε_{00} is the adsorption energy in the absence of potential difference from that of solution and at $\theta=0$, the second term an electrostatic potential energy at the plane where H_2^+(a) is located, and the third term a repulsive interaction energy between H_2^+(a)'s. In the present work, the repulsive energy is expressed to be proportional to the concentration of surrounding neighbours, *i.e.*, to θ.[14] R_e is the repulsive interaction energy at $\theta=1$. As the intermediate is a charged one, E_p and θ are interrelated in principle by the Poisson equation.

The Poisson Equation. To find the relation between E_p and θ, we employ Horiuti's model[13] (Fig. 1). P represents the plane on which H_2^+(a)'s are located. No charge is present between P and electrode surface, C. Beyond P, a diffuse double layer is present. The distance between C and P is x_p, and the dielectric constant is denoted by D_p in C–P and D_B beyond P. These dielectric constants are assumed to be potential-independent.

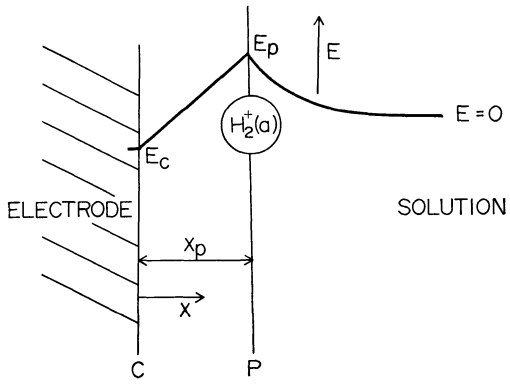

Fig. 1. A model for the double layer at interface.

Horiuti[13] analysed in detail the relation between E_p and θ as follows. One dimensional Poisson equation is given by

$$(D/4\pi)d^2E/dx^2 = -\rho, \quad (20)$$

where E is an electrostatic potential, and ρ is space charge density. Integration of Eq. (20) with respect to x gives at $x=x_p$,

$$-\frac{1}{4\pi}\lim_{t\to0}\left(D\frac{dE}{dx}\right)_{x_p-t} + \frac{1}{4\pi}\lim_{t\to0}\left(D\frac{dE}{dx}\right)_{x_p+t} = -\lim_{t\to0}\int_{x_p-t}^{x_p+t}\rho dx. \quad (21)$$

As there is no charge between C and P, the first term of the left hand side of Eq. (21) becomes $-D_p(E_p-E_c)/4\pi x_p$ where E_c is an electrostatic potential at C. The right hand side represents the charge on P, *i.e.*, $Q\theta$. Thus Eq. (21) becomes

$$-(D_p/4\pi x_p)(E_p-E_c) + (D_B/4\pi)\lim_{t\to0}(dE/dx)_{x_p+t} = -Q\theta. \quad (22)$$

The charge distribution beyond P is given for n mol/ml of 1–1 electrolyte solution by

$$\rho = Fn(e^{-FE/RT} - e^{FE/RT}). \quad (23)$$

13) J. Horiuti, *J. Res. Inst. Catal. Hokkaido Univ.*, **3**, 52 (1954).

14) The validity of proportional approximation is discussed by J. Horiuti and T. Toya, *Solid State Surface Science*, **1**, 1 (1969).

Since we have the relation $2d^2E/dx^2=d(dE/dx)^2/dE$, Eqs. (20) and (23) give

$$\lim_{t\to 0}\left(\frac{dE}{dx}\right)_{x_p+t} = \pm\left[-\frac{8\pi}{D_B}Fn\int_{E_p}^{0}(e^{-FE/RT}-e^{FE/RT})dE\right]^{1/2} \quad (24)$$

where $E=0$ and $dE/dx=0$ at $x\to\infty$.

We obtain from Eqs. (22) and (24)

$$C_{dl}(E_p-E_c)-(2D_BRTn/\pi)^{1/2}\sinh(FE_p/2RT) = Q\theta, \quad (25)$$

where $C_{dl}\equiv D_p/4\pi x_p$. Since the potential in bulk solution is zero, positive sign in Eq. (24) is chosen. Equation (25) becomes identical with the equation derived by Breiter *et al.*[15] when $\theta=0$.

In order to relate potential E with a measurable quantity, we take E_c as an electrostatic potential difference from the potential of point of zero charge E_z, *i.e.*, a rational potential, and assume that the work function of the electrode is constant over all overvoltage region. Thus E_c is given by

$$E_c = -\eta - E_z + (RT/2F)\ln(a_{H^+}^2/P_{H_2}). \quad (26)$$

The last term is due to the present choice of a standard state at normal hydrogen electrode (NHE). Thus, Eqs. (19), (25), and (26) give a relation for ε as a function of θ and η.

Two conditions for η. We selected the two following conditions so as to bring a transient behavior which can be easily tested by experiments.

(A) Constant Polarization: Variation of current i with time t was calculated at a constant polarization of the electrode to a certain η. The electrode can be initially in various conditions. In the present calculation, the initial condition of $\eta=0$ was chosen. Hence, θ at $t=0$ is an equilibrium value at $\eta=0$, $\theta_e°$. $\theta_e°$ was determined from Eqs. (1), (25), and (26) at $d\theta/dt=0$ and $\eta=0$. Since the polarization is a step function of t, E_p at $t=0$, $E_p°$ was determined from Eqs. (25) and (26) at $\eta=\eta$ and $\theta=\theta_e°$ (The Regula Falsi method was used).

(B) Potential Sweep: Current was calculated as a function of t (or η) when η was proportional to t. Initial condition was again chosen as $\eta=0$.

Calculations. The change of θ with t is given by Eq. (1) together with Eqs. (17) and (18). The relationship between θ and E_p is given by Eq. (25). The current at a certain time can be obtained from the solution of Eqs. (1) and (25). However, direct computation of these equations is so cumbersome that the derivative of Eq. (25) with respect to t is used for calculation; $d\theta/dt$ in the derivative is given by Eq. (1), $d\eta/dt$ being zero at condition (A) or equal to a sweep rate at condition (B). The Runge-Kutta-Gill method was used for calculations.

Parameters. Constants k_1 and k_2 are expected to have the relation $k_1\gg k_2$ since step (II) is slower than step (I). In the first calculation, k_2F was equated to the observed exchange current density, *i.e.*, $k_2=10^{-17}$ s^{-1} cm^{-2}. k_1 was chosen to be 10^5 times larger than k_2. We can evaluate ε_{00} by following the method of Horiuti *et al.*[13] However, the circumstances of the electrode seem to be more complicated than those treated by them, and hence $\varepsilon_{00}=-0.5$ eV was arbitrarily chosen. R_e was evaluated to be $26.7/D_p$ eV from coulombic repulsive force between H_2^+(a)'s on Hg whose atomic radius is 1.57 Å.[16] Each H_2^+(a) can be surrounded by six H_2^+(a)'s at full coverage. In the calculation, R_e was first taken to be 26.7 eV. The other parameters were, if not stated, $C_{dl}=18$ μF/cm², $E_z=-0.2$ V *vs.* NHE, $\alpha_1=\alpha_2=0.5$, and $a_{H^+}=P_{H_2}=1$.

Values of k_1, k_2, ε_{00}, R_e, C_{dl}, a_{H^+}, and E_z were further changed and their effects were examined.

The calculation was performed at Hokkaido University Computing Center with a FACOM 230—60 computer. Subroutine programs of Runge-Kutta-Gill and Regula Falsi methods furnished in FACOM were used.

Results

Condition (A). Figure 2 shows the relationship of logarithm of currents i_1, i_2, and i with time t at $\eta=0.2$ V. The relationships between log i and t are illustrated at various overvoltages in Fig. 3 where the result at $\eta=0.1$ V with $R_e=26.7/2$ eV is also shown. We see that the smaller R_e and overvoltage, the longer the time to attain a steady state. Coverage θ is plotted against t in Fig. 4. Comparison of Figs. 3 and 4 shows that the time to attain a steady value of θ is shorter than that of i at $\eta<0.3$ V. We denote steady values of i, θ, and E_p by i_s, θ_s, and E_{ps}, respectively.

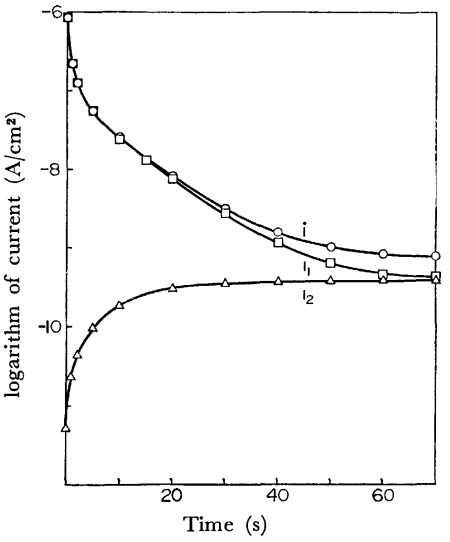

Fig. 2. Logarithm of currents i_1, i_2, and i *vs.* time curves at $\eta=0.2$ V (Condition (A)).

In Fig. 5, θ_s and E_{ps} in 1 M acidic solution are plotted as a function of η by the use of different set of values for the double layer capacity and the potential of the point of zero charge, *i.e.*, 18 μF/cm² and −0.2 V, 40 μF/cm² and −0.2 V, and 18 μF/cm² and −0.6 V (NHE), respectively. It is seen that θ_s first increases with η but becomes almost independent at

○, $R_e = 26.7$ eV; ●, 26.7/2 eV. Time scale is indicated for each curve. $k = 10^{-12}\ s^{-1}\ cm^{-2}$, $k_2 = 10^{-17}\ s^{-1}\ cm^{-2}$, $\varepsilon_{oo} = -0.5$ eV, $C_{dl} = 18\ \mu F/cm^2$, $E_z = -0.2$ V *vs.* NHE, and $a_{H^+} = P_{H_2} = 1$.

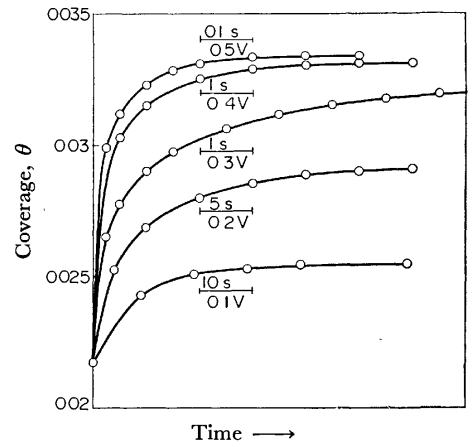

Fig. 4. Coverage *vs.* time curves at various overvoltages in Condition (A).
Time scale is indicated for each curve.

$\eta > 0.3$ V. E_{ps}, on the other hand, monotonously decreases with η. Tafel plots (the logarithm of i_s *vs.* η) for the above three sets of values give curve 2 in Fig. 6. Values of C_{dl} and E_z do not affect i_s to an appreciable extent at every overvoltage. We find that Tafel plots consist of two straight lines whose breakpoint coincides with that of the curve, θ_s *vs.* η in Fig. 5. The effect of the concentration of H^+ on the steady relation appears in the lower overvoltage region as shown by curves 1∼3 in Fig. 6. The current density at a given overvoltage is larger for the smaller H^+ concentration. However, the dependence is reversed when η is replaed with the potential referred to NHE.

When only k_1 is decreased by an order of 10^2, the time to attain the steady state becomes considerably longer and θ_s becomes smaller than those in Figs. 3 and 5.

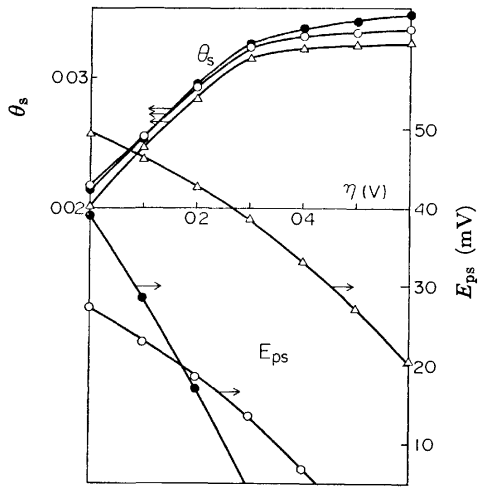

Fig. 5. θ_s and E_{ps} *vs.* η curves.
○, $C_{dl} = 18\ \mu F/cm^2$ and $E_z = -0.2$ V *vs.* NHE; ●, $C_{dl} = 40\ \mu F/cm^2$ and $E_z = -0.2$ V *vs.* NHE; △, $C_{dl} = 18\ \mu F/cm^2$ and $E_z = -0.6$ V *vs.* NHE.
E_{ps} is referred to the potential in the bulk of solution.

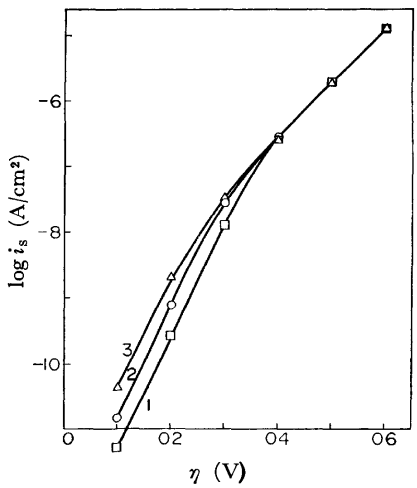

Fig. 6. Tafel plots at various H^+ concentration.
Curve 1(□), 10 N H^+; 2 (○), 1.0 N H^+; and 3 (△), 0.1 N H^+.

The variation of R_e causes a large change on $\log i$ *vs.* t (Fig. 3). On the other hand, our separate calculation shows that the change of ε_{00} does not appreciably affect $\log i$ *vs.* t and Tafel plots, except for θ and E_p. Thus, the changes of θ_s and E_{ps} are associated. The changes of double layer capacity and/or E_z affect θ_s and E_{ps} but neither $\log i$ *vs.* t nor Tafel plots.

Condition (B). With the same initial condition and parameters as in Fig. 3, a current was calculated up to $\eta = 0.5$ V for various sweep rates. The results are given in Fig. 7. It is interesting to see that the current plateau apprears on $\log i$ *vs.* η curve. The value of the current at the plateau is almost proportional to the sweep rate. In the overvoltage region lower than the plateau, $\log i$ *vs.* η represents the relationship of $\log i_1$ *vs.* η at $t \to 0$. In that higher than the plateau, the relation corresponds to Tafel plots ($\log i_s$ *vs.* η). The value of a current at the plateau i_p is computed for various values of parameters as in Condition (A)

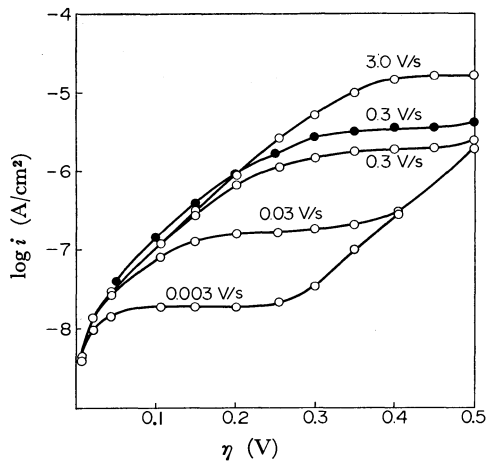

Fig. 7. $\log i$ *vs.* η curves at various potential-sweep rates in Condition (B).
○, $R_e=26.7$ eV; ●, $R_e=26.7/2$ eV.

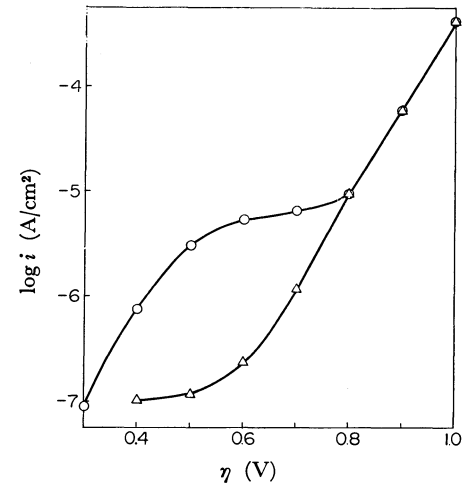

Fig. 8. $\log i$ *vs.* η curves in Condition (A).
$R_e=26.7/2$ eV, $k_1=10^{-14}$ s^{-1} cm^{-2}, and $k_2=10^{-19}$ s^{-1} cm^{-2} are used. ○, at a time of 90 ms after overvoltages are applied; △, at 5 s.

and found to be almost independent of them, except for R_e. i_p is nearly proportional to the reciprocal of R_e as seen from the curves for 0.3 V/s (solid and open circles in Fig. 7). The plateau has a tendency to lose its flat portion with increase of the sweep rate and to become shorter when the velocities of steps (I) and (II) become closer. Such a tendency makes it difficult to decide the value of i_p. In the case of $k_1/k_2=10^3$, i_s is one tenth smaller than that for $k_1/k_2=10^5$, where k_2 is kept at 10^{-17} s^{-1} cm^{-2} in both cases.

Discussion

In the above calculation, the value of k_2F was equated to the exchange current density determined by extrapolation of the linear part of Tafel plots at high overvoltages.[4] However, the calculated Tafel plots at high overvoltages show an appreciably larger current than the observed one. The discrepancy is due to the conventional linear extrapolation of Tafel plots observed at high overvoltages to $\eta=0$, whereas the present calculation reveals a break in the Tafel plots, giving the other linear portion with smaller Tafel slope at lower overvoltages. Such a break has been proposed by Horiuti *et al.*[17] When k_2 value is reduced to 10^{-19} s^{-1} cm^{-2} with $k_1/k_2=10^5$, Tafel plots reproduce the experimental data at high overvoltages. In this case, i_{+2} at $\eta=0$ becomes one hundredth of the extrapolated exchange current density.

Condition (A). The present calculation gives an interpretation for the depolarization at low overvoltages. The calculated $\log i$ *vs.* η at $t=5$ s and 90 ms is shown in Fig. 8, where $k_2=10^{-19}$ s^{-1} cm^{-2}, $k_1=10^{-14}$ s^{-1} cm^{-2}, and $R_e=26.7/2$ eV. The plots at $t=90$ ms show a typical S-type depolarization curve. Tza and Iofa,[18] and Iofa *et al.*[19] observed an S-type depolarization, which was markedly enhanced in the presence of specifically adsorbable anions. Former authors' interpretation, revised by Frumkin,[5] was based on the steady state treatment and successful only for the initial deviation from the linear part but not over all region. The present non-steady treatment has satisfactorily reproduced the whole S-type depolarization.

The depolarization contradicts Horiuti's prediction as commented by Frumkin.[5] Horiuti predicted that Tafel plots consist of the two linear parts with Tafel constants of 1.5 at low overvoltages and 0.5 at high overvoltages. The present work reproduces Horiuti's prediction in a steady state as seen in Fig. 6. Hence, the discrepancy will be due to a slow attainment of the steady state. The coverage in the steady state increases with the increase of overvoltage but becomes almost constant in the overvoltage region of Tafel constant of 0.5. It is interesting to see that θ itself is very small and approaches a limiting value by its increase in a very small amount; these results are attributed to the repulsive interaction between H_2^+(a)'s.

Coverage θ_e° is determined by the condition, $i_1=i_2=i=0$; Eqs. (17) and (18) show that ε_{00} and R_e are primarily important factors in a determination of θ_e°. ε_{00} is a parameter in the present calculation, and can not be estimated experimentally, although R_e is estimated from the experiments carried out with Condition (B). Tafel plots are also largely dependent on i_1 of step (I); the larger the α_1, the larger the Tafel slope.

At high overvoltages, Tafel plots at various H^+ concentrations give a single straight line. This is consistent with the observation, reviewed by Frumkin,[5] although he interpreted it on basis of the slow discharge mechanism. pH effect in a steady state can not manifest the principal mechanism.

Condition (B). The linear potential-sweep method has been employed for the study of dielectric relaxations, electrode processes, *etc.*

Let us suppose that adsorption process is expressed

by a series combination of the adsorption capacity c_{ads}, and the adsorption resistance r_{ads}. When the linear potential-sweep (sweep rate, v) is applied to such a circuit, the current of adsorption i_{ads} is given as $i_{ads}=v\ c_{ads}[1-\exp(-t/c_{ads}r_{ads})]$, where c_{ads} and r_{ads} are assumed to be constant. Hence, i_{ads} reaches finally a constant value of $v\ c_{ads}$. Appearance of the current plateau thus indicates the existence of adsorption process. If the pseudocapacity of H_2^+(a) c_p is given from a current plateau i_p and a sweep rate v by $i_p=v\ c_p$, we obtain 6 μF/cm^2 for R_e=26.7 eV and 12 μF/cm^2 for R_e=26.7/2 eV from Fig. 7. Such a simple calculation shows that c_p is strongly dependent on R_e.

However, r_{ads} in the present work is not constant as seen from the relation between i and η given by Eqs. (2), (17), and (18). This potential-dependent nature of r_{ads} is one reason for the shift of the current plateau to a more cathodic region with increase of the sweep rate. At lower overvoltages than the plateau region, log i *vs.* η is approximately equal to log i_1 *vs.* η so that we can estimate the velocity of the step preceding the rate-determining step. At higher overvoltages, log i *vs.* η represents its steady state, *i. e.*, Tafel plots, which agree with steady values calculated for Condition (A). Consequently, the potential-sweep method reveals information on the amount of pseudo-capacity, the velocity of the step preceding the rate-determining step, and the repulsive force energy constant of the proportional approximation.

Since a large value of the repulsive force between H_2^+(a)'s is expected from its Coulombic nature, the pseudo-capacity c_p may be quite small as calculated. The large value of R_e employed for the calculation, *i. e.*, 26.7 eV and 26.7/2 eV, does not necessarily mean that we insist on a value of D_p of unity or two. The present value of R_e is tentative and used only to give probable features.

In conclusion, potentiostatic and potentiodynamic transients have been calculated on the basis of the electrochemical mechanism of the hydrogen electrode reaction. The present double layer model and the repulsive force between adsorbates are somewhat simplified but the calculated results explain the depolarization observed at low overvoltages and give many predictions. Calculated features for the non-steady and steady states will be subjected to experimental tests and discussed in Part II.

The authors would like to express their appreciation to Professor T. Nakamura, Research Institute for Catalysis, Hokkaido University, for valuable discussion.

Kinetics of Hydrogen Electrode Reaction on Mercury. II. Experimental Part. Elucidation of Non-steady State by Constant Potential and Linear Potential-sweep Methods

Akiko KATAYAMA and Hideaki KITA

Research Institute for Catalysis, Hokkaido University, Sapporo 060

(Received July 2, 1973)

Potentiostatic and potentiodynamic experiments on Hg in 1 M HCl, HBr, and HI solutions were carried out to elucidate transient phenomena of the electrochemical mechanism of the hydrogen electrode reaction. The results obtained by both methods agree with the analysis of the non-steady state based on the electrochemical mechanism. The large effect of anions on the transient phenomena is satisfactorily interpreted by the change of repulsive force energy between H_2^+(a)'s on electrode, which is caused by the presence of specifically adsorbed anions in various degrees. The potential-sweep method reveals features of the step preceding the rate-determining step and gives the value of the repulsive force energy between H_2^+(a)'s as expected by the analysis.

We have theoretically discussed transient phenomena of the hydrogen electrode reaction(HER) on mercury on the basis of the electrochemical mechanism.[1] It was found that in relaxation methods the steady state condition can not be fulfilled at low overvoltages and that the linear potential-sweep will reveal Tafel plots with the current plateau characteristic of adsorption process.

A tendency to the current plateau, known as "depolarization", has been reported on a hanging electrode in H_2SO_4 solution by the galvanostatic method[2] and on DME in acidic KI solutions.[3] Tza and Iofa[3] interpreted the tendency by tacitly assuming a steady state of the reaction. However, the steady state assumption cannot predict either S-type Tafel plots or the dependence of the current plateau on the sweep rate.

The present work has been carried out to test experimentally these predictions and verify our fundamental assumption of the non-steady state of the reaction. A few analyses on the non-steady state have been reported; Horiuti and Okamoto[4] discussed HER

on Ni and Gerischer and Mehl[5] on Hg, Ag, and Cu. However, both works were restricted to a qualitative discussion. The latter authors applied only a constant overvoltage of 1.0 V to Hg electrode in 1/2 M H_2SO_4 solution and hence, though they did not observe the time-dependent current, their work is not sufficient to deduce the nature of the non-steady state.

We have applied the pulses of various constant overvoltages and of linear potential-sweep with different sweep rates to Hg electrode in acidic solutions. The resulting current-time or current-potential curves were compared with the predictions from the non-steady state analysis.

Experimental

Cell. An H-type cell of Pyrex was used; DME served as a test electrode.[6] The cell was kept in a water-bath whose temperature was controlled at 30±0.01 °C. The resistance of mercury column of DME was 58 ohms.

Solutions, Gas, and Mercury. 1 M solutions of HCl, HBr, HI, KCl, KBr, and KI were used. They were prepared from reagents of special grade and the water was purified as follows. The water from a Cu still was again distilled over alkaline $KMnO_4$ in a Pyrex flask furnished on top with a glass tube full of glass beads heated at 100 °C. The water vapor thus fractionally distilled was passed through a quartz tube heated at 450 °C for the protection of the creeping of water film along the wall. Commercial H_2 gas was purified through a permeation-type purifier of Japan Pure Hydrogen Co. The purified H_2 was introduced through a liquid N_2 trap and a bubbler of the distilled water into both compartments of the cell in order to deaerate and saturate the solution with H_2. Bubbling in the compartment of DME was stopped during measurements. Mercury flow rate of DME was 1.23 mg/s.

Electrical circuits. Pulse of constant potential or linear potential-sweep was applied to a growing Hg drop through a potentiostat. The τ_1, the time when the pulse was imposed and τ_2, a drop life time were controlled respectively at 3.6 and 4.0 s by Tektronix 160 series Generators with a device of mechanical knocking. Figure 1 shows a basic circuit of the potentiostat with a current transducer of operational amplifier, OP-C. The power supply for the potentiostat was made by Teledyne 825 Du Voltage Regulators.

DME was initially kept at an overvoltage η_1 by Takasago DC power Supply GPO-2 through the potentiostat. After DME was kept at η_1 for τ_1 s, pulses of constant or sweeping potential from Hewlett Packard Function Generator 3300A with Plug-in Unit of 3302A were applied through the potentiostat. The width of the pulse Δt was limited by $\Delta t < \tau_2-\tau_1$. Since the area of DME, A is proportional to $(mt)^{2/3}$ at a constant flow rate of mercury m, the increase of drop area ΔA during Δt is given by

$$\frac{\Delta A}{A}=\frac{\{m(\tau_1+\Delta t)\}^{2/3}-(m\tau_1)^{2/3}}{(m\tau_1)^{2/3}}\simeq\frac{2\Delta t}{3\tau_1} \quad (1)$$

The last member of Eq. (1) holds when $\Delta t \ll \tau_1$.

Measurements. Δt was always less than 0.1 ms. Therefore, $\Delta A/A$ was less than 2%. Overvoltage of DME was η_1 at $\tau=0\sim\tau_1$ and then $\eta(>\eta_1)$ at τ_1, where η's were defined at the negative of the electrode potential referred to reversible hydrogen electrode. All measurements with HI and KI solutions were performed in the dark.

Results

(A) Constant Potential Method. Current *vs.* time ($I-t$) curves are observed for various η in 1 M HCl (Fig. 2, $\eta_1=0$), 1 M HBr (Fig. 3, $\eta_1=0$), and 1 M HI

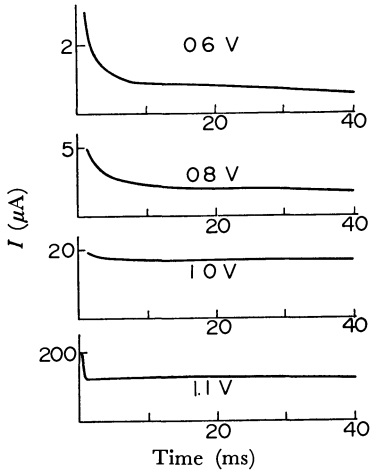

Fig. 2. Current *vs.* time curves for various overvoltages in 1 M HCl solution when $\eta_1=0$ V.

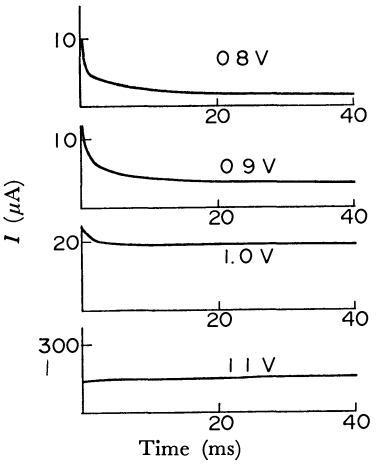

Fig. 3. Current *vs.* time curves for various overvoltages in 1 M HBr solution when $\eta_1=0.2$ V.

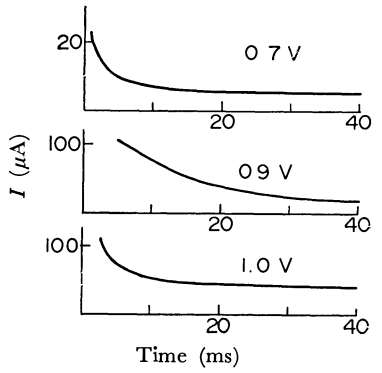

Fig. 4. Current *vs.* time curves for various overvoltages in 1 M HI solution when $\eta_1=0.2$ V.

(Fig. 4, $\eta_1=0.2$ V) where t is counted from τ_1. As these figures have a common time scale, we can easily find effects of the overvoltage and electrolyte on $I-t$ curve. Each figure shows a similar overvoltage effect; a decay of I with t is weakened with the increase of η and at sufficiently high overvoltages I seems to be time-independent. This decay can not be attributed to an effect of the charging of double layer, since the time constant of the charging is less than 0.05 ms. As regards the electrolyte effect, the decay of I is enhanced in the order HI>HBr>HCl. $I-t$ curves observed on the electrode initially polarized with various η_1 are compared in Fig. 5. Current tends to reach earlier a constant common value when η_1 is increased. This is in line with the theoretical analysis; the coverage of H_2^+(a), θ, at high η_1 is estimated to be close to a limiting value, so that the current will more rapidly reach a steady value.

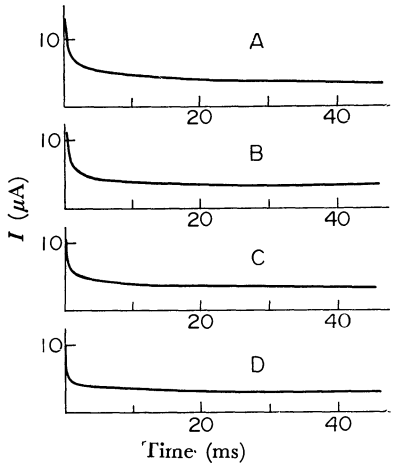

Fig. 5. Current *vs.* time curves at $\eta=0.9$ V in 1 M HBr solution, when (A) $\eta_1=0$, (B) 0.2 V, (C) 0.3 V, and (D) 0.4 V.

Logarithms of the current density at $t=40$ ms (the longest time) are plotted against η in Fig. 6. At high overvoltages log i *vs.* η curves for various acidic solutions converge into one straight line with a slope of *ca.* 120 mV. However, at lower overvoltages, deviation from the straight line appears first in 1 M HI solution, then 1 M HBr and 1 M HCl solutions. This deviation is known as depolarization. It should be

○, 1 M HCl; △, 1 M HBr; □, 1 M HI.

emphasized that the curves reveal an S-type behavior with a current plateau, though the latter is somewhat gradated.

Close examination of Fig. 6 in comparison with Figs. 2~4 shows that the S-region of log i *vs.* t curves has a different feature in $I-t$ curves of Figs. 2—4 from those in the region of a straight line. In the S-region, I continues to decrease with t, but in the other, I remains constant from the begining. Thus, the appearance of the S-type behavior will prove that the reaction is in a non-steady state. In the region of a straight line, the reaction has already attained a steady state. The upward deviation from the straight line, *i.e.*, the depolarization, is simply due to the fact that the current in a non-steady state is always larger than that in a steady state. The results of Figs. 2—5 satisfy the predictions in Part I.

The degree of depolarization is found to be the largest in HI and the least in HCl solution. This is interpreted by the theoretical analysis[1] as follows. The halide ions are known to be specifically adsorbed on the electrode surface in the order $I^->Br^->Cl^-$. Since the charge of these ions is opposite to that of the intermediate H_2^+(a), adsorbed halide ions will reduce a coulombic repulsive force between H_2^+(a)'s in conformity with the degree of specific adsorption of these anions. Thus, H_2^+(a)'s in iodide solution have the least repulsive force. Our non-steady state analysis has predicted that the smaller the repulsive force between H_2^+(a)'s, the longer the time is required for a steady state to be attained. Consequently, the largest degree of depolarization is expected in iodide solution. The effect of halide ions on the depolarization is thus explained by the change of repulsive force between H_2^+(a)'s owing to their specific adsorption.

(B) Linear Potential-sweep Method. *(1) Neutral Solutions*: In neutral solutions, mercury electrode holds its ideally polarized state down to *ca.* −1.5 V

vs. NHE.[7] When the pulse of a linear potential-sweep is applied to the ideally polarizable electrode, the current observed consists of only the charging current of the double layer at an interface, I_{dl}, and satisfies the following relation with the sweep rate, v,

$$I = I_{dl} = C_{dl}v, \qquad (2)$$

where C_{dl} is double layer capacity.

Figures 7～9 show the double layer capacity calculated by the use of Eq. (2) for various v's in solutions of 1 M KCl, KBr, and KI, respectively. The values of C_{dl} are almost independent of v, except in 1 M KBr (Fig. 8) where at high overvoltages they deviate somewhat in a systematic way. It can be stated that this deviation is not caused by the desorption process of Br^-, since Lorenz[8] has shown that its desorption occurs at more positive potentials in a reversible way. Hence, it must be ascribed to some other processes. Nevertheless, the deviation does not give any serious effect on the following treatment. Figures 7～9 give a double layer capacity almost identical to that measured by AC bridge.[3,7] The double layer is known to be dependent on the kind of anion but independent of a cation (H^+ or K^+). Such a dependence, however, vanishes at sufficiently negative potentials (Figs. 7～9). Specifically adsorbed anions are considered to be absent at those negative potentials.

Thus, the currents observed in neutral solutions were used for the purpose of excluding I_{dl} from the observed one in the respective hydrogen halide solutions in which HER takes place.

(2) Acidic Solutions: Figure 10 shows typical i *vs.* potential E curves obtained at the same sweep rate in 1 M HCl and KCl solutions, where i represents the current density in A/cm². Those in 1 M HBr and HI solutions were described elsewhere.[6] The reaction current density i_r is equated by $(i-i_{dl})$, where i_{dl} is given by the current with the same sweep rate in neutral solution having the common anion. It is plausible that the double layer capacity does not undergo a change by the change of the solution from 1 M KCl to 1 M HCl, since Frumkin *et al.*[9] obtained the same double layer capacities by AC bridge method both in HCl and LiCl solutions, even though HER takes place in HCl solutions.

i_r thus obtained does not show a monotonous increase with η, but a plateau on the way of η increase. We shall call it a current plateau and denote its value at a flat portion by i_p. Values of i_p in HCl, HBr, HI solutions are found to be in the order i_p (HCl)$\lesssim i_p$(HBr)$\ll i_p$(HI). i_p(HCl) and i_p(HBr) are relatively

small compared with i_{d1}, but i_p(HI) is much larger than i_{d1}.

Figures 11~13 show $\log i_r$ *vs.* η plots for various sweep rates in 1 M HCl, HBr, and HI solutions. It is to be noted that the current at a flat portion i_p is almost independent of the sweep rate in 1 M HCl, but increases in 1 M HI solution. In the latter case, i_p at sweep rates of 11.6 V/s and 23.2 V/s is proportional to the sweep rate. The proportionality is what was predicted[1] by non-steady state analysis. Potential drop through a Hg column of DME is corrected at high current density in 1 M HI solution. Figure 14 shows the dependence of i_p of 1 M HI on the sweep rate in logarithmic scale, where we find a depression in its dependence from the proportional one when the sweep rate is large.

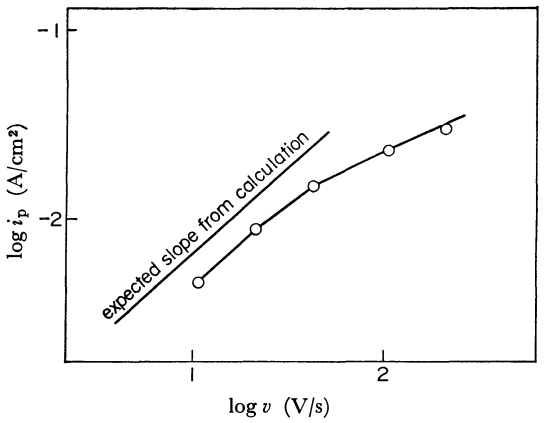

Fig. 14. Logarithm of plateau current *vs.* logarithm of sweep rate curve in 1 M HI.

This dependence of i_p on the kind of anion and on the sweep rate can be interpreted as follows.

i) Dependence of i_p on the kind of anion: Values of i_p in the respective solutions are in the same order as the degree of the specific adsorption of these anions. The current plateaus appear around overvoltages of 0.8 and 1.0 V in 1 M HCl and HI solutions (Figs. 11 and 13) and the double layer capacities at the corresponding potentials are 18 and 22 μF/cm² (Figs. 7 and 9), respectively. The value 18 μF/cm² is the same as that of the ideally polarized electrode, indicating the absence of the specifically adsorbed Cl^-. On the contrary, the latter value of C_{d1} in HI solution indicates the presence of specifically adsorbed I^- at potentials where i_p is observed.[6] Enhancement in i_p by the change of anion from Cl^- to I^- is clearly due to the specific adsorption of I^-.

The adsorbed anion is expected to reduce the effective charge of H_2^+(a)'s and hence to increase the coverage H_2^+(a). The relation $i_p(I^-) \gg i_p(Br^-) \gtrsim i_p(Cl^-)$ is thus explained by the change of repulsive force between H_2^+(a)'s. We can estimate the repulsive energy con-

stant R_e from i_p[1]; at a sweep rate of 11.6 V/s, R_e= 14 eV for 1 M HCl and HBr solutions and R_e=0.28 for 1 M HI solution where pseudocapacities are obtained as 12 μF/cm^2 and 600 μF/cm^2, respectively.

ii) Dependence of i_p on the sweep rate: i_p is expected to be proportional to the sweep rate, in which we have assumed that the repulsive force between H_2^+(a)'s is invariable irrespective of applied potentials. However, since the specific adsorption of anions varies with applied potentials, the repulsive force between H_2^+(a)'s should change with the change of the applied potential.

The current plateau appears at a more negative potential when the sweep rate is increased (Fig. 13). At more negative potentials, the repulsive force between H_2^+(a)'s increases because of the desorption of anions which act to reduce the H_2^+(a)'s repulsive force. As a consequence, i_p does not increase as expected from the proportional relationship with the sweep rate. In HCl and HBr solutions, i_p is smaller than i_{dl} and the subtraction of i_{dl} from i brings a relatively large error in i_p. We consider that this uncertainty in i_p is one reason for i_p in HCl and HBr appearing not to have a clear dependence on v.

Log i_r *vs.* η curves at more negative potentials than those in the region of the current plateau are independent of the sweep rate and become a single straight line, which agrees with the straight line mentioned in (A). We therefore infer that this portion represents the relation at a steady state.

Discussion

Employing the expression for the velocity of HER on Hg[1] and the repulsive energy constants in the previous section, (B)-(2)-(i), we simulated the values of rate constants so that the experimental Tafel plots at high overvoltages were reproduced. The rate of the step preceding the rate-determining one was found to be faster than the latter by three orders of magnitude in the case of *e.g.*, Fig. 13. The fitting rate constants are $k_2=10^{-18}$ s^{-1} cm^{-2} and $k_1=10^{-15}$ s^{-1} cm^{-2}. From values of the repulsive energy constant and the rate constants, we can estimate the time required for the steady state to be attained when a constant potential is applied. The results are shown in Table 1, where the other parameters not listed are identical to those given previously.[1] Thus, the time required strongly depends on the repulsive energy constant between H_2^+(a)'s.

The explanation for depolarization by Tza and Iofa[3] is based on the steady state assumption and only successful in the relatively negative potential regions where depolarization is small. The S-type Tafel plots can be explained only as a transient phenomena where the reaction stays in non-steady state, as demonstrated by the present two methods. Our observation at an overvoltage of 1.0 V in 1 M HCl is very analogous to that in 0.5 M H_2SO_4 by Gerischer and Mehl,[5] although their conclusion is contradictory to ours since their observation was limited only to a value of 1.0 V.

Table 1. THE TIME REQUIRED FOR A STEADY STATE TO BE ATTAINED

η	Time (s)		
	R_e=13.35 eV	2.67 eV	0.534 eV
0.1 V	1.7×10^4		
0.2	1.2×10^4	2.5×10^4	$>6\times10^4$
0.3	4.9×10^3		
0.4	6.5×10^2	$>1.2\times10^3$	
0.5	90		
0.6	20	$>1.8\times10^2$	
0.7	2		

$k_1=10^{-15}$ s^{-1} cm^{-2}, $k_2=10^{-18}$ s^{-1} cm^{-2}.

No pH dependence of double layer capacity observed by 1 kHz AC bridge could be taken as an evidence for the exclusion of the electrochemical mechanism,[9] since the presence of the reversible step of $2H^+ + e^- \rightleftarrows H_2^+$(a) should rise to the additional pseudocapacity which is pH dependent. However, we have found that the rate of this step is so small in its absolute magnitude that it can not follow the rapid variation of voltages such as 1 kHz AC. Moreover, the repulsive force between H_2^+(a)'s is so large that θ reaches a limiting value by the very small increase. The change of coverage in HCl and HBr solutions is at maximum $\Delta\theta=2\times10^{-3}$, which was obtained from observed i_p's and theoretical analysis. Such a small $\Delta\theta$ can not be detected by AC bridge. Thus, the observation with 1 kHz AC provides only information on the intrinsic double layer capacity as seen in (B)—(l) in the previous section. However, in HI solution, i_p is markedly large in comparison with that in HCl and HBr solutions; $\Delta\theta$ amounts to 0.65 at maximum.

A striking effect of the specific adsorption of anion on transient phenomena of HER is the strong evidence for the assumption that the intermediate possesses a charge; namely the fact that the adsorbed anion reduces the repulsive force among intermediates, strongly suggests positively charged intermediate such as H_2^+(a) in the electrochemical mechanism.

The Cadmium-photosensitized Decomposition of Acetaldehyde, Propionaldehyde, and *n*-Butyraldehyde

Koji YAMAMOTO, Shigeru TSUNASHIMA, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 9, 1973)

The reactions of acetaldehyde, propionaldehyde, and *n*-butyraldehyde photosensitized by cadmium ($^3P_1$) have been investigated at 270 °C. The pressure dependence of the main products, CO, RH (R=CH_3, C_2H_5, and *n*-C_3H_7) and R_2, was well explained by the following reaction mechanism; Cd*+RCHO→R+CHO+Cd or RH+CO+Cd. R+RCHO→RH+RCO, RCO→R+CO, CHO→H+CO, H+RCHO→H_2+RCO, R+R→R_2 or RH+Olefin. Carbon dioxide was found to be a rather good quencher for triplet cadmium atoms, and was used for estimating the relative quenching efficiencies of the three aldehydes and acetone. The values obtained were 0.16, 1.0, 1.3, 1.2, and 1.4, respectively for carbon dioxide, acetone, acetaldehyde, propionaldehyde, and *n*-butyraldehyde, when the efficiency of *cis*-2-butene was assumed to be unity.

Since the available energy is only 87.7 kcal/mol in the cadmium($^3P_1$)-photosensitization, an appreciable bond scission cannot be observed in the reactions of hydrocarbons photosensitized by cadmium($^3P_1$).[1] When acetone[2] and cyclopentanone[3] were used, however, the decompositions could be observed and their quantum yields were estimated to be about 0.3 for both compounds.

The photolyses of the aldehydes including the mercury- and the acetone-photosensitizations, have long been studied by many investigators and their reaction mechanisms have almost completely been established.[4] However, no studies have been reported on the reactions of the aldehydes photosensitized by cadmium. In a previous paper,[1] were compared the quenching efficiencies of several hydrocarbons for Hg($^3P_1$), Cd($^3P_1$) and triplet benzene, and found that, although the energy transferred in the reaction with Cd($^3P_1$) is closer to that from triplet benzene ($^3B_{1u}$; 84.4 kcal/mol) than that from Hg($^3P_1$), the quenching efficiencies for Cd($^3P_1$) have more similar tendencies with those for Hg($^3P_1$) than those for triplet benzene.

The present authors hoped to ascertain whether the reaction mechanism previously proposed for the photolysis of the aldehydes can be applied also for the cadmium-photosensitization and, if possible, to find out the detailed mechanism of the energy transfer from Cd($^3P_1$) to the carbonyl compounds.

Experimental

The commercially available acetaldehyde (Wako Pure Chemical), and *n*-butyraldehyde (Koso Chemical) were used without purification. The gas chromatographic analysis showed that the impurity content was less than 0.5%. Since the propionaldehyde (Tokyo Kasei) contained a large amount of impurity, this reagent was purified by gas chromatography. All aldehydes were kept in traps at the temperature of liquid nitrogen after bulb-to-bulb distillations.

The *cis*-2-butene, carbon dioxide, ethane, ethylene, propane, and *n*-butane were purchased from the Takachiho Chemical Co. Metallic cadmium (5-nine) was the product of the Osaka Asahi Metal Co.

The experimental procedure was almost the same as described previously.[3] All runs were made at 270±1 °C, using two home-made resonance lamps. Since a combination of a Toshiba UV-25 filter and a Pyrex glass plate was used as a filter, the irradiating light mainly consisted of a 326.1 nm resonance line. The light intensities from the two resonance lamps were 0.21 and 0.34μ Einstein/min which were measured by using the *cis-trans* isomerization of *cis*-2-butene photosensitized by cadmium, the quantum yield being assumed to be 0.5.[5] The relative intensity of the light through the reaction vessel was also measured by the combination of a slit, a Toshiba M.S. 9SY photomultiplier and a micro-ammeter.

The columns used for the gas chromatographic analyses were 5m-polypropylene glycol for oxygenated compounds, 30m-dimethylsulfolane, and 5m-activated alumina for hydrocarbons.

Results

Before starting photochemical studies, the thermal decomposition of aldehydes was checked in the dark. Very small amounts of products were observed in the case of acetaldehyde. The amount was less than 10^{-3} times that of the photolysis. The results were not reproducible, probably because the reactions were not homogeneous.

The results of the cadmium-photosensitized reactions are summarized in Table 1. In order to obtain the accurate quantum yield of ethane in the case of acetaldehyde, another series of experiments were carried out. The result is shown in Fig. 1. In the cadmium-photosensitization, the direct light absorption by al-

dehydes might play a role in the formation of the products. To estimate this contribution, we measured the relative intensity of the light which passed through the reaction vessel. As Fig. 2 shows, the relative light intensity in the presence of the cadmium vapor was independent of the pressure of propionaldehyde. This result suggests that the direct photolysis in this system is negligibly small compared with the decomposition induced by the $Cd(^3P_1)$.

In order to obtain the quenching efficiencies of the aldehydes for $Cd(^3P_1)$, a mixture of *cis*-2-butene and acetaldehyde was irradiated; however, the data obtained were much complicated by the reactions of the produced radicals. After several trials, carbon dioxide was found to be a rather good quencher for $Cd(^3P_1)$ without any products. Figure 3 shows the

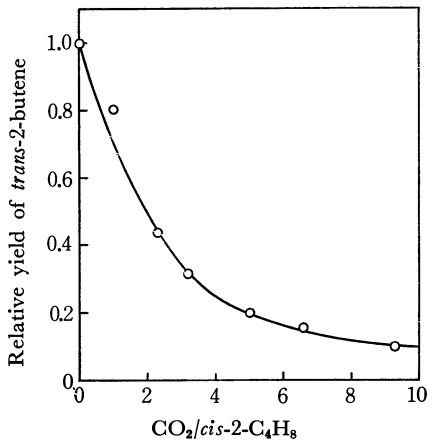

Fig. 3. The effect of carbon dioxide on the *cis-trans* isomerization of *cis*-2-butene photosensitized by cadmium.

effect of carbon dioxide on the relative rate of the formation of *trans*-2-butene from *cis*-2-butene photosensitized by $Cd(^3P_1)$. A simple kinetic analysis showed that the relative quenching efficiency of carbon dioxide for $Cd(^3P_1)$ is 0.16 ± 0.01, when the efficiency of *cis*-2-butene is assumed to be unity. The kinetic treatment will be shown later.

The similar experiments were carried out with the mixture of acetone and CO_2. The reciprocal of the relative rate of the formation of carbon monoxide was plotted in Fig. 4 as a function of the pressure ratio of CO_2 to acetone. The relative quenching efficiency of acetone was calculated to be 1.0 ± 0.1. Table 2

summarizes the results of the cadmium-photosensitized decomposition of the three aldehydes in the presence of CO_2.

In order to check the insensitivity of CO_2 to the radical reactions, the effect of CO_2 on the direct photolysis of propionaldehyde was also investigated. No effect was observed within the experimental error.

Discussion

As has been shown in the Results section, all of the aldehydes studied decomposed in chain mechanism, and the main products were CO, RH (R=CH_3, C_2H_5, and n-C_3H_7, respectively, for acetaldehyde, propionaldehyde, and n-butyraldehyde), and R_2. To explain the results of the cadmium-photosensitized reactions, we considered the following reaction scheme,

$$\begin{aligned}
Cd + h\nu &\longrightarrow Cd^* && I\\
Cd^* + RCHO &\longrightarrow CdH + RCO && \alpha \\
&\longrightarrow R + CHO + Cd && \beta \\
&\longrightarrow RH + CO + Cd && \gamma \quad \Big\} \; k_q\\
R + RCHO &\longrightarrow RH + RCO && k_1\\
RCO &\longrightarrow R + CO && k_2\\
R + R &\longrightarrow R_2 && k_3(1-\eta)\\
&\longrightarrow RH + Olefin && k_3\,\eta\\
CHO &\longrightarrow H + CO && k_4\\
CdH &\longrightarrow Cd + H && k_5\\
H + RCHO &\longrightarrow H_2 + RCO && k_6
\end{aligned}$$

Because of high temperature, the RCO, CHO, and CdH radicals were assumed to decompose unimolecularly.[4]

The steady state treatment gives the equations,

$$\phi_{CO} = (2\alpha+2\beta+\gamma) + \{(\alpha+\beta)/Ik_3\}^{1/2}k_1[RCHO] \quad (1)$$

$$\phi_{RH} = (\alpha+\beta) + \gamma + \{(\alpha+\beta)/Ik_3\}^{1/2}k_1[RCHO] \quad (2)$$

$$\phi_{R_2} = (1-\eta)(\alpha+\beta) \quad (3)$$

Here, ϕ_{CO}, ϕ_{RH} and ϕ_{R_2} denote the quantum yields of CO, RH and R_2. Figure 5 shows the predicted linear relationship between ϕ_{CO} and [RCHO], from which we can estimate the values of $(\alpha+\beta)$, γ and $k_1/k_3^{1/2}$ by assuming the η values. The quantum yield of ethane from the reaction of acetaldehyde has already been shown in Fig. 1. Since $\eta=0$ in this case,

$$\phi_{C_2H_6} = \alpha + \beta = 0.18 \pm 0.01$$

This value may be more accurate than that estimated using Eq. (1) or (2). In the case of n-butylaldehyde,

$$\phi_{C_3H_6} = \eta(\alpha+\beta) \quad (4)$$

By taking $\eta=0.16$,[6] we can calculate that $\alpha+\beta=0.14\pm 0.04$. Also in the reaction of n-butyraldehyde, the formation of ethylene was observed. This compound may be formed in the following initial process,

$$CH_3CH_2CH_2CHO + Cd^* \rightarrow CH_3CHO + C_2H_4 + Cd \quad \delta$$

The δ value is about 0.06. Table 3 summarizes all of the estimated values.

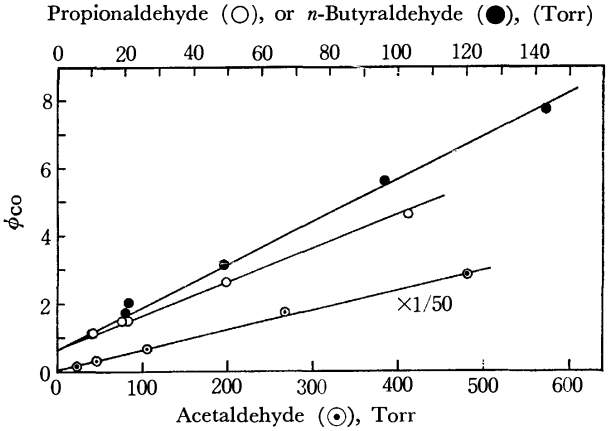

Fig. 5. The quantum yields of carbon monoxide in the cadmium-photosensitized decomposition of three aldehydes as functions of their pressures.

TABLE 3. THE QUANTUM YIELDS OF THE INITIAL PROCESSES, $\alpha + \beta$, γ AND δ

	$\alpha+\beta$	γ	δ
Acetaldehyde	0.18	0.1	—
Propionaldehyde	0.14[a)]	0.4[a)]	—
n-Butyraldehyde	0.14[a)]	0.5[b)]	0.06

a) Experimental error is ±20%. b) ±50%.

It is known that, in the direct photolysis at the wavelengths longer than 300 nm, the β process is the most prominent among the three initial processes, α, β and γ.[4] However, Table 3 suggests that, in the cadmium photosensitization, the γ process is one of the important processes, although the experimental errors preclude the quantitative estimation. Since the γ process contradicts the spin-conservation rule, the above result is not self-evident. Our reasoning for this is that, since CO is a good quencher for $Cd(^3P_1)$,[7] the intermediate complex between Cd* and CO may be formed in the course of the γ process,

$$RCHO + Cd^* \rightarrow \left(\begin{matrix} R \\ H \end{matrix}\!\!>\!C\!-\!\!-\!O \atop \vdots \\ Cd\end{matrix}\right)^* \rightarrow RH + (CO\cdots Cd)^*$$

and then this complex decomposes into CO and Cd after crossing over the potential barrier between the triplet and the singlet states. This reasoning is obviously based on the assumption that the energy transfer from $Cd(^3P_1)$ to an aldehyde occurs through the interaction of $Cd(^3P_1)$ with a π electron in the C=O bond of the aldehyde. On the basis of this reasoning and of the smallness of the quenching efficiency of any alkanes to the $Cd(^3P_1)$ atom,[1] it may safely be said that the contribution of the α process to the decomposition of aldehydes is negligibly small compared with the β process.

The Competition between CO_2 and Other Molecules in Quenching $Cd(^3P_1)$ Atoms. When CO_2 is added into the system of the Cd-photosensitized isomerization of 2-butene, CO_2 compete with 2-butene in quenching $Cd(^3P_1)$. The reaction scheme may be described as follows:

$Cd + h\nu \longrightarrow Cd^*$	I
$Cd^* \longrightarrow Cd + h\nu$	k_0
$Cd^* + CO_2 \longrightarrow Cd + CO_2$	k_C
$Cd^* + cis \longrightarrow Cd + {}^3B$	k_{cis}
$Cd^* + trans \longrightarrow Cd + {}^3B$	k_{trans}
${}^3B + M \longrightarrow 1/2\,cis + 1/2\,trans + M$	

Here, *cis*, *trans* and ^3B denote *cis*- and *trans*-2-butene and the triplet state, respectively. The steady state treatment on the assumption that $k_{cis}=k_{trans}=k_B$ and that $k_0 \ll k_B$[butene] at butene pressures higher than 1 Torr,[1] gives the relation:

$$\frac{I\,t}{[\text{butene}]\,\log\left(\frac{C-T}{C_0-T_0}\right)} = 1 + \frac{k_C[CO_2]}{k_B[\text{butene}]} \qquad (5)$$

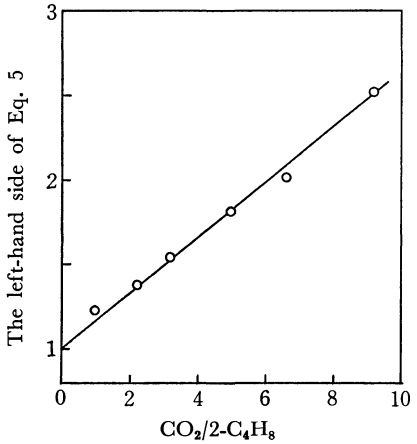

Fig. 6. The effect of carbon dioxide on the reaction of *cis*-2-butene.

Here, t is the reaction time, and C_0, C, T_0 and T are the initial and final concentrations of *cis*- and *trans*-2-butene. The predicted linear relationship between the left-hand side of Eq. (5) and the $[CO_2]$/[butene] ratio is shown in Fig. 6, from which we can calculate the quenching ratio of k_C/k_B to be 0.16±0.01 as has already been stated in the Results section.

The relative quenching efficiency of acetone was obtained by measuring the quantum yield of CO produced in the reaction of acetone in the presence of CO_2.

$$Cd^* + CH_3COOCH_3 \rightarrow 2\,CH_3 + CO \qquad k_A$$

The steady state treatment predicts the relationship:

$$\frac{\phi^0_{CO}}{\phi_{CO}} = 1 + \frac{k_A[\text{acetone}]}{k_C[CO_2]} \qquad (6)$$

The result has already been shown in Fig. 4.

In the case of three aldehydes, the kinetic treatment is not so simple, because these three compounds decompose in chain mechanism. Although it is a little complicated, a straight forward steady state treatment gives the relationship:

$$\phi_{CO} = \frac{2\alpha+2\beta+\gamma}{1+mx} + \sqrt{\frac{\alpha+\beta}{Ik_3(1+mx)}}k_1[RCHO] \qquad (7)$$

Here, $m=k_C/k_q$ and $x=[CO_2]/[RCHO]$. Then, using the notations:

$$y = \phi^0_{CO}/\phi_{CO}$$

and

$$c = \frac{1}{2\alpha+2\beta+\gamma}\sqrt{\frac{\alpha+\beta}{Ik_3}}k_1[RCHO]$$

which corresponds to the ratio between the ϕ_{CO} observed and the intercept obtained in Fig. 5, we can obtain

$$y = \frac{(1+c)(1+mx)}{1+c(1+mx)^{1/2}} \qquad (8)$$

This equation may be rewritten as follows:

$$1 + mx = \frac{y}{1+c} + \frac{1}{2}\left(\frac{cy}{1+c}\right)^2 + \left(\frac{cy}{1+c}\right)^2\left(\frac{1+c}{c^2y}+\frac{1}{4}\right)^{1/2} = z \qquad (9)$$

Since the right-hand side of Eq. (9), which is denoted

7) S. Tsunashima, T. Toyono, and S. Sato, This Bulletin, **46**, 2654 (1973).

by z, can be calculated from the observed values, the quenching ratio, m, can also be estimated from the plots of z as a function of x. In the case of acetaldehyde, the c value is much larger than unity, as has been shown in Fig. 5. Equation (8), therefore, may be simplified in the form:

$$1 + mx = y^2 \qquad (10)$$

Figures 7 and 8 show the plots for Eqs. (9) and (10). The relative quenching efficiencies thus obtained are listed in Table 4, together with those of other compounds previously obtained.

Molecular-symmetry Reduction in C_mH_{m-2} Cata-condensed Nonalternant Hydrocarbons

Azumao TOYOTA* and Takeshi NAKAJIMA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai 980

(Received July 10, 1973)

On the basis of the second-order Jahn-Teller effect and the semiempirical SCF MO method, we examined the energetically most favorable molecular-symmetry groups and geometrical structures with respect to C–C bond lengths of the C_mH_{m-2} cata-condensed nonalternant hydrocarbons. In the $4n$ π-electron systems the first excitation energies in the fully-symmetrical nuclear arrangements were predicted to be significantly smaller than a certain critical value, and a molecular-symmetry reduction accompanied by a marked double-bond fixation in the peripheral carbon skeleton to occur. On the other hand, in the $4n+2$ π-electron systems, such energies were found to be considerably large for small members and to decrease rapidly with the number of carbon atoms, resulting in the molecular-symmetry reduction for members larger than a certain critical size. The electronic spectra were calculated using the most stable geometrical structures obtained by the SCF MO method.

For predicting the energetically most favorable molecular shapes with respect to C–C bond lengths of conjugated hydrocarbons, we developed a symmetry rule based on the second-order Jahn-Teller theorem.[1-5] The pseudo, or the second-order Jahn-Teller effect is the stabilization which occurs when a certain bond distortion mixes two electronic states nearly degenerate in the fully-symmetrical nuclear arrangement.[6] On the basis of this theory, we examined the second-order Jahn-Teller effects on bond lengths and stability of

a number of nonalternant hydrocarbons.[1,7-9]

In this paper we apply the symmetry rule to the prediction of the stable geometrical structures of the cata-condensed nonalternant hydrocarbons, whose general formula is C_mH_{m-2} (Fig. 1). Of these systems, pentalene ($m=8$), azulene ($m=10$), and heptalene ($m=12$) have been investigated by several authors.[10-14] They found that the stable ground-state equilibrium configurations of pentalene and heptalene, both having $4n$ π-electrons, should belong to the reduced molecular-symmetry group C_{2h}, exhibiting a marked double-bond fixation in the peripheral carbon skeleton. On the other hand, it was predicted that in azulene belonging to the $4n+2$ π-electron system, no molecular-symmetry reduction occurs. The prediction is in good agreement with available experimental results. We were interested in why azulene does not reduce its molecular-symmetry group from C_{2v} to C_s. The purpose of this paper is to examine systematically the possibility of a relationship between the number of carbon atoms(m) and the molecular-symmetry reduction in the C_mH_{m-2} cata-condensed nonalternant hydrocarbons considered as formed by the introduction of a cross-link between the two carbon atoms of a like parity of the C_mH_m cyclic polyenes.

Theoretical

First we assume a fully-symmetrical nuclear arrangement as the unperturbed nuclear configuration for a conjugated molecule. We further assume that in the unperturbed nuclear çonfiguration all the symmetrical bond distortions take place until the first-order energy equilibrium is reached. The unperturbed electronic wavefunctions $\psi_0, \psi_1, \cdots, \psi_n, \cdots$ and the corresponding eigenvalues $E_0, E_1, \cdots, E_n, \cdots$ are assumed to be known. We now distort the nuclei from the symmetrical first-order nuclear arrangement by means of the ith normal coordinate of nuclear motion Q_i. On the basis of the same approximation as used previously,[1] the energy of the ground state after deformation may be written as

$$E(Q_i) = E_0 + \frac{1}{2}\left\{k - 2\sum_n{}' \frac{|\langle\psi_n|(\partial H_\pi/\partial Q_i)_0|\psi_0\rangle|^2}{(E_n - E_0)}\right\}Q_i^2$$

where k and H_π represent the force constant for an sp^2 hybridized C–C σ-bond and the Hamiltonian for π-electrons, respectively.

According to the above equation, the force constant for the normal vibration Q_i can be identified with the term in the braces and can be negative if a given matrix element $\langle\psi_n|(\partial H_\pi/\partial Q_i)_0|\psi_0\rangle$ is nonvanishing and the associated energy gap $E_n - E_0$ is sufficiently small. If the force constant is negative, the energy should be lowered by the nuclear deformation Q_i, and a pseudo-Jahn-Teller distortion from the symmetrical nuclear arrangement would occur spontaneously.

The symmetry rules[1] for predicting the stable molecular shapes in the ground state are as follows: the symmetry of the normal displacement with the smallest force constant is identical with that of the lowest excited state, ψ_1. If the energy gap $E_1 - E_0$ is smaller than the critical value, *ca.* 1.2 eV, the molecule would be distorted into a less symmetrical nuclear configuration. The most favorable type of bond distortion is predicted by examining the distribution of the transition density ρ_{01} over the molecular skeleton. When the lowest excited state is represented by a one-electron transition between molecular orbitals ϕ_i and ϕ_j, the transition density ρ_{01} between the ground and the lowest exicted states is given by $\sqrt{2}\,\phi_i\phi_j$.[6]

Since it is based on the second-order perturbation theory, the symmetry rule gives only the type of the most favorable bond distortion. In order to obtain information on the actual magnitude of distortion or the equilibrium bond lengths at which the nuclei of the real molecule will settle, we use the variable bond-length SCF MO method.[15]

Results and Discussion

cal nuclear arrangements of the cata-condensed nonalternant hydrocarbons are listed in Table 1. The two-center components of the transition densities for the some selected molecules are shown in Fig. 2. The correlation of the first excitation energies for the fully-symmetrical nuclear arrangement with the number of carbon atoms of the C_mH_{m-2} systems is shown in Fig. 3, in which the excitation energies for pentalene, azulene, and heptalene, which are the isomers of the molecules III, IV, and V, respectively, are also included. The dashed line represents the critical value for the molecular-symmetry reduction. In the hatched area the molecule should distort into a less symmetrical nuclear configuration.

From Table 1 and Fig. 3, it is seen that in molecules with $4n$ π-electrons the energy gaps E_1-E_0 are all considerably smaller than the critical value, *ca.* 1.2 eV. In the $4n+2$ π-electron systems, the energy gaps decrease with the number of carbon atoms rapidly as compared with the case of the $4n$ π-electron

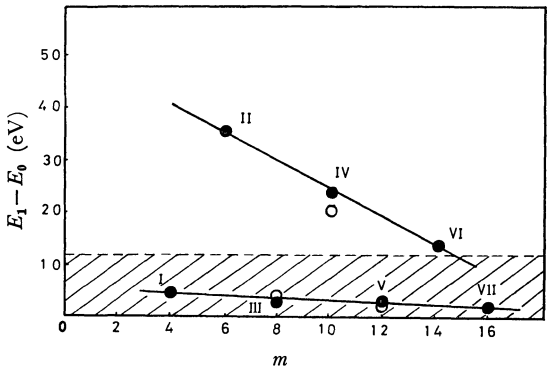

Fig. 3. Correlation of E_1-E_0 with the number of carbon atoms of C_mH_{m-2}. Open circles mean values for pentalene ($m=8$), azulene ($m=10$) and heptalene ($m=12$).

systems. The origin of the smallness of the energy gaps E_1-E_0 in these $4n$ π-electron systems (that is, the near degeneracy of the ground state with the lowest excited state) may be explained as follows. In the C_mH_m cyclic polyenes with $4n$ π-electrons, the ground-state is degenerate with the lowest excited states in the Hückel MO approximation, since the highest occupied molecular orbitals are doubly degenerate and there are four ways of assigning two electrons to the degenerate orbitals. The cata-condensed nonalternant hydrocarbons are considered to be formed by the introduction of a cross-link between the two carbon atoms of a like parity of the C_mH_m cyclic polyenes. The highest occupied molecular orbitals which are doubly degenerate in the unperturbed cyclic polyenes are split only a slight degree by the introduction of such a cross-link. The energy separation between these split orbitals is small and the lowest excited state for the perturbed system is represented by a one-electron transition between these molecular orbitals, so that the energy gap between the lowest excited and the ground states, E_1-E_0, is very small.

On the basis of the symmetry rule, we can predict that molecules I and VII should reduce their ground-state molecular-symmetry groups to C_{2h} from D_{2h} by the interaction with the lowest excited state through the b_{3g} nuclear displacement. Molecules III and V may also lower their ground-state molecular-symmetry groups from C_{2v} to C_s by the interaction with the lowest excited state through the b_2 nuclear displacement. The shapes of the stable molecular structures are predicted from the distribution of transition densities ρ_{01}.

On the other hand, in II and IV, molecules with $4n+2$ π-electrons, the energy gaps are definitely large as compared with the critical value for the molecular-symmetry reduction in the ground state. In molecule VI, the energy gap is comparable with the critical value for the molecular-symmetry reduction.

In order to obtain the equilibrium C–C bond lengths we performed the variable bond-length SCF MO calculation, taking into account all the possible distorted structures as the starting geometry.[16] The molecular-symmetry groups and bond lengths corresponding to the most stable nuclear arrangements for the cata-

16) T. Nakajima and A. Toyota, *Chem. Phys. Lett.*, **3**, 272 (1969).

condensed nonalternant hydrocarbons are shown in Fig. 1.

From the result of SCF MO calculation it turns out that, as predicted from the symmetry rule, molecules I, III, V, and VII reduce their ground-state molecular-symmetry groups to C_{2h}, C_s, C_s, and C_{2h}, respectively.

In II and IV, the molecular-symmetry reduction does not occur. However, VI reduces its molecular-symmetry group to C_s from C_{2v}. It should be noted that the molecular-symmetry reduction in the $4n+2$ π-electron systems will be realized if the molecule becomes larger than a certain critical size ($n\sim3$).

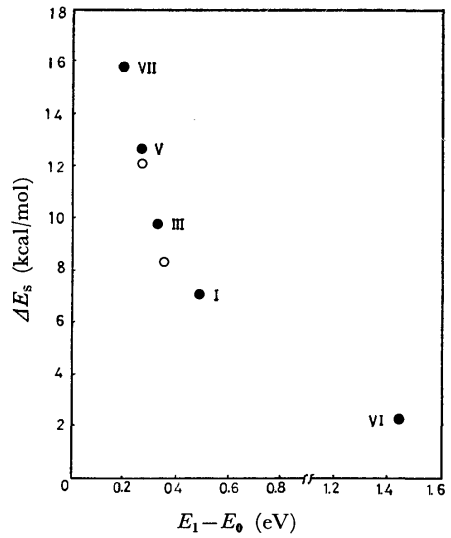

Fig. 4. Correlation of ΔE_s with E_1-E_0. Open circles mean values for pentalene (0.35 eV) and heptalene (0.26 eV).

In Fig. 4 is shown the correlation of the stabilization energies for the molecular-symmetry reduction with the excitation energies E_1-E_0, as calculated by assuming the fully-symmetrical nuclear arrangements. We define the stabilization energy as the difference in total energy between the fully-symmetrical and the reduced molecular geometries. The total energy is assumed to be the sum of π-bond and σ-bond energies, the latter being calculated using the harmonic oscillator model with the force constant equal to 714 kcal mol^{-1} Å^{-2}.[17] We see that there is a good correlation between the stabilization energy ΔE_s and E_1-E_0; the smaller the latter, the larger the former. The stabilization energies for pentalene and heptalene are also included (open circles).

From the viewpoint of the largeness of stabilization energy, we may say that the second-order Jahn-Teller effect becomes strong with the number of carbon atoms in the $4n$ π-electron systems.

As for the C–C bond-length distribution in the stable nuclear arrangements (Fig. 1), it may be said that the double-bond fixation, *i.e.*, bond-length alternation, is the common phenomenon in the reduced molecular geometries, as is expected from the distribution of transition densities ρ_{01}.

Excited-state Molecular-symmetry Groups. It is of interest to note the molecular shape of the lowest excited state. The criterion for the molecular-symmetry reduction in the excited state is that the energy gap E_2-E_1 is less than the critical value, *ca.* 0.6 eV.[1] From this criterion and Table 1 we may predict that all the molecules examined do not reduce their molecular-symmetry groups in the first singlet excited states. That is, the stable molecular shapes in the excited states belong to their fully-symmetrical nuclear arrangements.

Electronic Spectra. In calculating electronic spectra, we used the bond lengths for the energetically stable nuclear arrangements. The method of calculation employed is the Pariser-Parr-Pople MO method, and the configuration mixing of all the singly excited states is included (Table 2).

Table 2. Transition energies and intensities

Molecule (Point group)	Transition symmetry	ΔE (eV)	f (c.g.s)
I (C_{2h})	^1A_g	2.26	Forb.
	^1B_u	5.57	0.632
	^1B_u	10.14	0.912
II (C_{2v})	$^1B_2$	3.57	0.046
	$^1A_1$	5.89	0.137
	$^1B_2$	6.82	0.008
	$^1A_1$	6.85	1.160
III (C_s)	$^1A'$	1.65	0.004
	$^1A'$	4.06	0.327
	$^1A'$	5.07	0.054
	$^1A'$	5.75	0.272
IV (C_{2v})	$^1B_2$	2.36	0.072
	$^1A_1$	3.77	0.032
	$^1B_2$	4.44	0.068
	$^1A_1$	4.96	2.014
V (C_s)	$^1A'$	1.61	0.001
	$^1A'$	3.12	0.273
	$^1A'$	4.01	0.117
	$^1A'$	4.76	0.690
VI (C_s)	$^1A'$	1.81	0.046
	$^1A'$	2.69	0.000
	$^1A'$	3.46	0.313
	$^1A'$	3.93	1.930
VII (C_{2h})	^1A_g	1.67	Forb.
	^1B_u	2.67	0.361
	^1B_u	3.41	0.234
	^1A_g	4.37	Forb.

It should be noted that the excitation energies, particularly the lowest ones, calculated assuming the reduced molecular-symmetry groups for molecules I, III, V, VI, and VII, are predicted to be considerably higher than those calculated using the fully-symmetrical nuclear configurations (compare Table 1 with Table 2).

However, so far there is no experimental data for a comparision with theoretical values, except for pentalene (1-methyl-pentalene), azulene, and heptalene.[18–20]

Conclusion

The problem of molecular-symmetry reductions in the cata-condensed nonalternant hydrocarbons C_mH_{m-2} has been systematically examined on the basis of the second-order Jahn-Teller theorem. It was assumed that only the lowest excited state plays a dominant role in determining the most favorable nuclear displacement which reduces the molecular-symmetry group to a less symmetrical nuclear configuration. In spite of this very crude approximation, the predicted types of the energetically most favorable bond distortions, determined by examining the two-center components of transition densities, are in good agreement with the results of variable bond-length SCF MO calculations. The success of this approximation for predicting the stable molecular shapes might be ascribed to the fact that in the fully-symmetrical nuclear arrangements of the $4n$ π-electron systems the ground state is nearly degenerate with the lowest excited state, and that the second excited state is well separated from the lowest excited state.

Finally we may say that the pseudo, or the second-order Jahn-Teller effect becomes strong with increasing the number of carbon atoms in the C_mH_{m-2} cata-condensed nonalternant hydrocarbons.

The numerical calculation was carried out at Tohoku University with a NEAC 2000—500 electronic computer.

Raman Spectra and Internal Rotation of Ethyl Methyl Ether

Teizo KITAGAWA, Kazuo KUSAKI, and Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received July 16, 1973)

The Raman spectra of ethyl methyl ether in the liquid state were measured at various temperatures from 298 K to 195 K. The energy difference between the *gauche* and *trans* isomers in the liquid state was found to be 1.1 kcal/mol. This value is appreciably higher than the value 0.77 kcal/mol for *n*-butane. The tendency of assuming the *trans* form is higher for the CH_2–O bond than for the CH_2–CH_2 bond. The infrared intensity of the band at 465 cm^{-1} (gas) is largely due to the *gauche* isomer but the Raman intensity of the line at 471 cm^{-1} (liquid) is largely due to the *trans* isomer.

The infrared and Raman spectra of ethyl methyl ether in the gaseous, liquid, and crystalline states have been analyzed[1-8] and it has been established that the *trans* and *gauche* isomers coexist in the gaseous and liquid states while only the *trans* isomer remains in the crystalline state. Vibrational assignments of low frequency vibrations have been established, including internal-rotation vibrations of the methyl groups and the threefold potential barriers of the methyl groups of the *trans* isomer have been studied.[7,8]

Energy-difference data of rotational isomers about CH_2–O bonds are important for studying internal-rotation of polyethers including polyethylene glycol. The energy difference between the *gauche* and *trans* isomers of ethyl methyl ether in the gaseous state has been obtained as $\Delta H(H_g - H_t) = 1.5 \pm 0.2$ kcal/mol[4] from the temperature dependence of the relative intensity of the infrared bands at 375 cm^{-1} (*gauche*) and at 280 cm^{-1} (*trans*). On the other hand, the energy difference in the dilute carbon-disulfide solution has been determined as 1.35 kcal/mol[7] from the relative intensity of the infrared bands at 980 cm^{-1} (*gauche*) and at 1015 cm^{-1} (*trans*).

For measuring infrared intensities in the low-frequency region, it is required to take due care of natural emission from the sample and/or the attenuator of a double-beam spectrophotometer. Thus, corrections were made[4] for natural emission from the gas cell at elevated temperatures and relative intensities of the infrared bands of rotational isomers were measured. On the other hand, in measuring absorption intensities of the sample in a low-temperature cell, the natural emission from the optical attenuator causes a systematic error. Apparent transmittance of infrared bands is shifted lower than actual transmittance, unless the double-chopping method is used.[8]

Intensity measurements of Raman lines are not disturbed by these systematic errors, and more reliable values of energy differences may be obtained. In the present study, the Raman spectra of ethyl methyl ether in the liquid state at low temperatures were measured in order to determine the energy difference in the liquid state.

Experimental

The sample of ethyl methyl ether (b.p. 279 K) as prepared in the preceeding study[8] was transferred through a vacuum

line and was sealed into a liquid cell. The liquid cell was then held in a low-temperature apparatus. Raman spectra were excited with an argon-ion laser (488.0 nm) and were measured with a JEOL Raman spectrometer (Model JRS-02AS).

Results

Relative intensities of Raman lines of ethyl methyl ether in the liquid state were found to vary markedly with temperature. Typical examples of the Raman spectra at 298 K and 200 K are shown in Fig. 1. Thus, the relative intensities of the Raman lines at 381, 978, and 1069 cm^{-1} were found to be stronger at higher temperature than at lower temperature. These Raman lines correspond to the infrared bands at 376 cm^{-1} (in CCl_4 solution[4]), 979 and 1068 cm^{-1} (in CS_2 solution[6]) which are not observed in the crystalline state

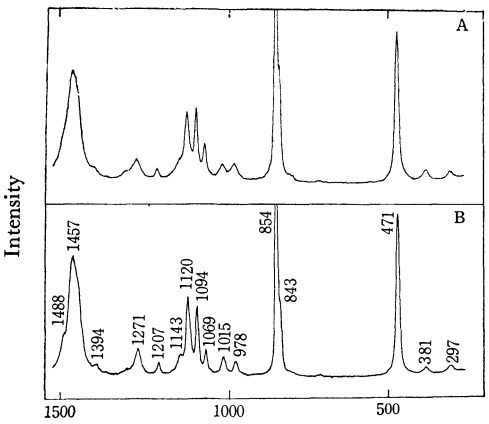

Fig. 1. Raman spectra of ethyl methyl ether in the liquid state, (A) at 298 K and (B) at 200 K, excited with an argon-ion laser (488.0 nm).

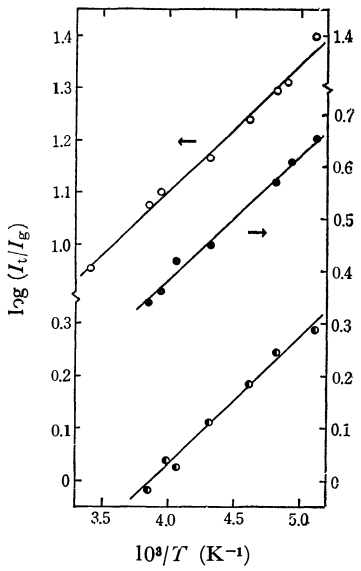

Fig. 2. Temperature dependence of the intensity ratios of the Raman lines of the *trans* isomer (I_t) and the *gauche* isomer (I_g), ○: 471 cm^{-1}/381 cm^{-1}, ◐: 1015 cm^{-1}/978 cm^{-1}, ●: 1120 cm^{-1}/1069 cm^{-1}.

and accordingly are assigned to the *gauche* isomer. The Raman lines due to the *trans* isomers are observed at 471, 1015, and 1120 cm^{-1}.

The ratios of area intensities of the Raman lines of the *gauche* (I_g) and *trans* isomers (I_t) were measured at temperatures from 298 K to 195 K (Fig. 2). The energy difference [$\Delta H(H_g-H_t)$] between the *gauche* and *trans* isomers was found to be 1.1±0.1, 1.1±0.2, and 1.1±0.1 kcal/mol from the pairs (*trans*/*gauche*) of Raman lines [471 cm^{-1}/381 cm^{-1}], [1015 cm^{-1}/978 cm^{-1}], and [1120 cm^{-1}/1069 cm^{-1}], respectively. Thus the values of ΔH obtained from the three pairs agreed closely with one another.

For the pair of the Raman lines at 1094 cm^{-1}/1069 cm^{-1}, the apparent energy difference was obtained as 0.9±0.1 kcal/mol. This value is slightly smaller than the value of $\Delta H(H_g-H_t)=1.1$ kcal/mol, so that the Raman intensity at 1094 cm^{-1} is largely due to the *trans* isomer but also partly due to the *gauche* isomer.

Discussion

The energy difference $\Delta H=1.1$ kcal/mol in the liquid state is smaller than the value $\Delta H=1.35$ kcal/mol in CS_2 solution[7] or the value $\Delta H=1.5$ kcal/mole in the gaseous state.[8] The small difference between the values in the liquid state and in the gaseous state is due to the small difference between the dipole moments of the *trans* and *gauche* isomers.

The energy difference $\Delta H=1.1$ kcal/mol for ethyl methyl ether [CH_3–CH_2–O–CH_3] in the liquid state is appreciably higher than the value $\Delta H=0.77$ kcal/mol for *n*-butane [CH_3–CH_2–CH_2–CH_3].[9] This indicates that the tendency of assuming the *trans* form is higher for the CH_2–O bond than for the CH_2–CH_2 bond. Similarly, the energy difference [$\Delta H=1.1$ kcal/mol[10] or 1.37 kcal/mol[11]] between the *trans-gauche* and *trans-trans* isomers of diethyl ether [CH_3–CH_2–O–CH_2–CH_3] is appreciably higher than the value $\Delta H=0.60$ kcal/mol[12] for *n*-pentane [CH_3–CH_2–CH_2–CH_2–CH_3].

The relative intensity of the infrared bands of the gaseous state at 375 cm^{-1} (*gauche*) and 465 cm^{-1} was previously[8] found to be independent of temperature indicating that the bands of the *trans* and *gauche* isomers overlap at 465 cm^{-1} and the intensity of the composite band is largely due to the *gauche* isomer. However, in the Raman scattering, the relative intensity of the Raman lines at 1120 cm^{-1} (*trans*) and 471 cm^{-1} (in the liquid state) is independent of temperature so that the Raman scattering intensity at 471 cm^{-1} is almost exclusively due to the *trans* isomer. For the *trans* isomer of ethyl methyl ether, the Raman line at 471 cm^{-1} corresponds to the Raman line of liquid *n*-butane at 425 cm^{-1} and is assigned to the accordion vibration. On the other hand, the antisymmetric C–C–C–C deforma-

tion frequency of the *gauche* isomer of *n*-butane is calculated very close to the accordion frequency of the *trans* isomer[13] but has not been observed separately in the Raman scattering. Similarly, the Raman intensity of the 'antisymmetric' C–C–O–C deformation vibration of the *gauche* isomer of ethyl methyl ether may well be negligible as compared with the Raman intensity of the accordion vibration of the *trans* isomer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3687—3689 (1973)

On the Decomposition of $C_6H_5CO^+$ Ions Produced from Several Alkyl Phenyl Ketones by Electron Impact

Susumu TAJIMA, Nobuhide WASADA and Toshikazu TSUCHIYA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received August 13, 1973)

The decomposition of $C_6H_5CO^+$ ions produced by electron impact from seven alkyl phenyl ketones, C_6H_5-COR (R=H, CH_3, C_2H_5, *n*-C_3H_7, *iso*-C_3H_7, *n*-C_4H_9, *n*-C_5H_{11}), has been studied. By determining the heats of formation, the $C_6H_5CO^+$ ions produced from the different precursors in the vicinity of the threshold are shown to have the same structure, and it is also shown that there is a linear relationship between the heat of formation of the activated complex for the reaction $C_6H_5CO^+ \rightarrow C_6H_5^+ + CO$ and the vibrational degrees of freedom of the neutral fragment, R.

Many authors have studied[1-7] the decomposition of a common intermediate ion produced from various precursors, in order to study how the difference of the precursors reflects on the decomposition of the common intermediate ions assuming quasi-equilibrium theory (QET) of mass spectra[8] to be valid.

The present paper describes the decomposition of the benzoyl ions, $C_6H_5CO^+$, produced from seven alkyl phenyl ketones, benzaldehyde, acetophenone, ethyl phenyl ketone, *n*-propyl phenyl ketone, isopropyl phenyl ketone, *n*-butyl phenyl ketone, and *n*-amyl phenyl ketone, on the basis of the following assumption: As is usually assumed in QET,[8,9] when a molecular ion with internal energy E decomposes into a neutral and an ionic fragments, the energy, E_M, in excess of the activation energy, is partitioned in proportion to the number of vibrational degrees of freedom in the neutral and the ionic fragments.

Experimental

The appearance potentials (AP) of the various ions were measured with a CEC 21—103 C mass spectrometer. The temperatures of the ion source and the sample manifold were about 250 °C and 100 °C, respectively. The electron-trap current was 10 μA. The electron accelerating voltage was supplied by a battery, and set with a 20-turn potentiometer (Sakae Tsushin Kogyo Co., Ltd.).

AP values were obtained by the energy distribution difference (EDD) technique[10] after the ionization efficiency curves were smoothed by the least-squares method. The constant, b, used in the EDD calculation was 0.67. The details have already been given.[11] Krypton (IP=14.00 eV) was used as calibrating gas for the electron energy scale.

All the samples studied were of research grade, and were obtained from Tokyo Kasei Co., Ltd., and were used without further purification.

Results and Discussion

Calculation of the Heat of Formation. The heat of formation of the $C_6H_5CO^+$ ion and that of the state which can be taken to be the activated complex for the reaction (1), $\Delta H_f(C_6H_5CO^+)$ and $\Delta H_f(C_6H_5^+ \cdots CO)$, are calculated by the Eqs. (2) and (3).

$$C_6H_5CO^+ \longrightarrow C_6H_5^+ + CO \quad (1)$$

$$\Delta H_f(C_6H_5CO^+) = AP(C_6H_5CO^+) + \Delta H_f(M) - \Delta H_f(R) - E_1 \quad (2)$$

$$\Delta H_f(C_6H_5^+ \cdots CO) = AP(C_6H_5^+) + \Delta H_f(M) - \Delta H_f(R) - E_2 \quad (3)$$

where $AP(X^+)$ is the appearance potential of the ion X^+, $\Delta H_f(M)$ and $\Delta H_f(R)$ are the heats of formation

of the neutral molecule, M, and radical, R, respectively, and E_n is the excess energy of the fragments at the threshold.

The AP values of the $C_6H_5CO^+$ ions and the $C_6H_5^+$ ions from seven alkyl phenyl ketones measured in this experiment are given in Table 1. Each value represents an average taken from at least three measurements, and the given experimental errors are maximum deviations.

The values of the heat of formation used for the neutral molecules and free radicals, ΔH_f(M) and ΔH_f(R), are given in Table 2. These values are taken from the literature.[12] Some ΔH_f(M) values which are not given in the literature were calculated by approximation methods used by Franklin.[13]

Using the AP values in Table 1 and the values of heat of formation shown in Table 2, the heat of formation of the $C_6H_5CO^+$ ions and that of the activated complexes for the reaction (1) were calculated by Eqs. (2) and (3), respectively. The results are shown in Fig. 1. The values in Fig. 1 are obtained by taking E_n as zero.

$C_6H_5CO^+$ Ions. As seen in Fig. 1, the values for heat of formation of the $C_6H_5CO^+$ ions from seven alkyl phenyl ketones studied here are the same within the experimental error. Therefore, these $C_6H_5CO^+$ ions produced in the vicinity of the threshold are considered to have the same structure.[14,15] Consequently,

TABLE 1. APPEARANCE POTENTIALS (eV) OF THE $C_6H_5CO^+$ IONS AND THE $C_6H_5^+$ IONS FROM ALKYL PHENYL KETONES

C_6H_5COR	AP($C_6H_5CO^+$)	AP($C_6H_5^+$)

n-Propyl phenyl ketone	−29.6[a]	22.1
Isopropyl phenyl ketone	−30.9[a]	16.8
n-Butyl phenyl ketone	−34.5[a]	18.5
n-Amyl phenyl ketone	−39.4[a]	9.1

a) These values were calculated by approximation methods used by Franklin.[9]

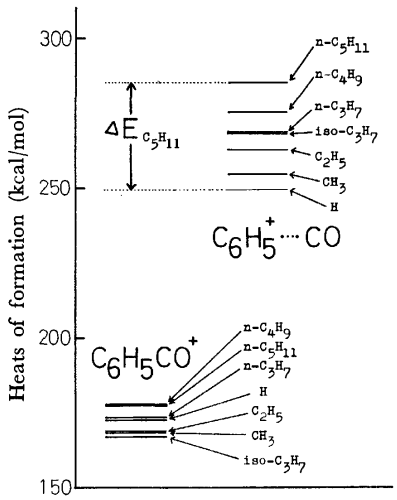

Fig. 1. The heats of formation (kcal/mol) of the $C_6H_5CO^+$ ions and the activated complexes for the reaction (1), $\Delta H_f(C_6H_5CO^+)$ and $\Delta H_f(C_6H_5^+\cdots CO)$.

the decomposing $C_6H_5CO^+$ ions of reaction (1), produced from various precursors, will also have the same structure, that is, the values for heat of formation of the activated complexes for the reaction (1) will be the same.[14,16]

The Activated Complexes for the Reaction (1). As seen in Fig. 1, the heats of formation of the activated complexes for the Reaction (1) show some scatter, compared with that of $C_6H_5CO^+$ ions, and furthermore, the values increase systematically as the number of atoms in R is large. In this study, we have investigated the source of the difference in the values, on the basis of the above assumption.

A few authors have reported[17,18] that during the dissociation of a molecular ion, the energy, E_M, in excess of the activation energy, is partitioned to the neutral and the ionic fragments, R and $C_6H_5CO^+$ in this study, respectively, and consequently, that the appearance potentials for the secondary ions, $C_6H_5^+$ in the present study, will be somewhat higher than the "true" values. In this experiment, the number of vibrational degrees of freedom of the R differs from compound to compound, and a part of the energy E_M will be carried away by the R. Therefore, as a consequence of the assumption, the extent of the effect on the AP($C_6H_5^+$) will also vary, and each AP($C_6H_5^+$) will be high according to the number of the vibrational degree of freedom of the R.

In this study, benzaldehyde was taken as the standard, since the number of the vibrational degree of freedom of the R in the compound is zero. ΔE_R is defined as the difference between the heat of formation of the activated complex for the reaction (1) of a compound, C_6H_5COR, and that of benzaldehyde. In Fig. 1, the $\Delta E_{C_5H_{11}}$ for $C_6H_5COC_5H_{11}$ is shown as an example. ΔE_R is considered to be the energy which

is partitioned to the radical R during the decomposition of the molecular ion. From the assumption, it is reasonable to expect that the following equation holds:

$$\Delta E_R/\alpha = f_R/f_{\phi-CO}$$

Therefore, $$\Delta E_R = (\alpha/f_{\phi-CO}) \times f_R \quad (4)$$

where α is the energy which is partitioned to the $C_6H_5CO^+$ ion during the decomposition of the molecular ion; f_R and $f_{\phi-CO}$ are the numbers for vibrational degree of freedom of the radical R and the $C_6H_5CO^+$ ion, respectively.

The plot of ΔE_R *vs.* f_R is given in Fig. 2. As expected from Eq. (4), the plot gives a straight line which passes through the origin. The experimental formula shown in Fig. 2 is obtained by the least-squares method. From the slope of the line, the value α=27.4 kcal/mol was obtained taking $f_{\phi-CO}$=33. By definition, α=27.4 kcal/mol is the energy which is partitioned to the $C_6H_5CO^+$ ion during the decomposition of the $C_6H_5COR^+$ ion, while the difference between the heat of formation of the activated complex and that of the $C_6H_5CO^+$ ion for benzaldehyde is about 75 kcal/mol (refer to Fig. 1). For benzaldehyde, the value $\Delta H_f(C_6H_5^+)$=275.6 kcal/mol was obtained taking $\Delta H_f(CO)$ =−26.4 kcal/mol,[12] this value is comparable to the value $\Delta H_f(C_6H_5^+)$=284 kcal/mol which was obtained from phenyl radical by Lossing *et al.*[19] Therefore, it can be seen that these $C_6H_5^+$ ions in this study are produced in the vicinity of the ground state of the $C_6H_5^+$ ion. It is reasonable that the excess energy of H-atom in this case is taken as zero, because if there is any energy partition to the H-atom, values for heat of formation of the $C_6H_5^+$ ion from benzaldehyde will be higher than that of the $C_6H_5^+$ ion from phenyl radical.

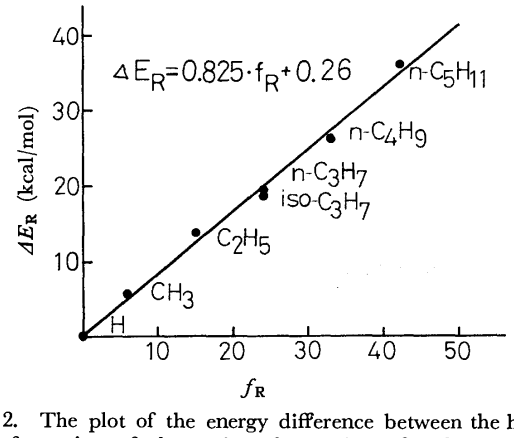

Fig. 2. The plot of the energy difference between the heats of formation of the activated complexes for the reaction (1), ΔE_R, *vs.* the number of vibrational degree of freedom of the radical R, f_R.

As a consequence of the above consideration, if the assumption is valid, the experimental results lead us to conclude that CO loss occurs from the $C_6H_5CO^+$ ion after the $C_6H_5CO^+$ ion, produced from the decomposition of the molecular ion in an excited electronic state, is transferred to a vibrationally excited state of its ground electronic state. An alternative explanation is that the assumption is not valid. Each decomposition reaction occurs from a vibrationally excited state of the ground electronic state of each ion, and only a part of the excess energy E_M is partitioned in proportion to the number of the vibrational degrees of freedom in radical R and the ion $C_6H_5CO^+$, and all of the remaining energy of E_M is partitioned to the $C_6H_5CO^+$ ion.

Conclusions

1) By using the data concerning the heat of formation, the decomposition of the $C_6H_5CO^+$ ions produced from seven alkyl phenyl ketones, are studied, on the basis of an assumption. The $C_6H_5CO^+$ ions produced in the vicinity of the threshold can be considered to have the same structure.

2) It was found that there is a linear relationship between the number of the vibrational degree of freedom, f_R, of the alkyl radical R and the difference of the values for heat of formation, ΔE_R, of the activated complex for the reaction (1). Two different conclusions on the mechanism of the decomposition of the $C_6H_5CO^+$ ions are derived, depending upon whether the assumption is valid or not.

Far Infrared and Raman Spectra of $K_3[Co(CN)_6]$ and $[Co(NH_3)_6][Co(CN)_6]$

Ichiro NAKAGAWA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
and
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received September 12, 1973)

Far infrared spectra of $K_3[Co(CN)_6]$ and $[Co(NH_3)_6][Co(CN)_6]$ and a single crystal Raman spectrum of $K_3[Co(CN)_6]$ have been measured. Calculations of optically active crystal vibration frequencies have been made, on the basis of the crystal structure determined precisely. For these two types of established crystal structures (C_{2h}^5 for $K_3[Co(CN)_6]$ and C_{3i}^2 for $[Co(NH_3)_6]$) $[Co(CN)_6]$ of hexacyano-complex salts, lattice frequencies have been determined. For $[Co(NH_3)_6][Co(CN)_6]$ the mean amplitudes of two kinds of cobalt atoms have been calculated and compared with those obtained by Iwata and Saito assuming that both complex ions behave as a rigid body.

Many investigations have been done on the vibrational spectra of hexacyano-complex salts of transition metals and on the nature of the bonding in this complex ion.[1-11] Among them Jones *et al.* and we ourselves have made a thorough study on the basis of infrared and Raman spectra and a normal coordinate treatment including lattice modes. We have investigated far infrared spectra and lattice vibrations of $K_3[Fe(CN)_6]$, $K_3[Cr(CN)_6]$ and $Cs_3[Cr(CN)_6]$ which have the monoclinic structure with the space group C_{2h}^5.[7] Swanson and Jones have investigated infrared and single-crystal Raman spectra and lattice vibrations of $Cs_2LiCo(CN)_6]$ which has the cubic structure and for which the Bravais primitive cell is composed of one formula unit.[10]

In the present study a measurement has been made for the far infrared and single-crystal Raman spectra of $K_3[Co(CN)_6]$ which is isomorphous with $K_3[Fe(CN)_6]$ and takes a monoclinic structure C_{2h}^5. A far infrared spectrum of $[Co(NH_3)_6][Co(CN)_6]$ has also been measured, since Iwata and Saito have recently performed a very detailed X-ray analysis for the crystal structure of this complex salt, according to which the space group of this crystal is C_{3i}^2 ($R\bar{3}$).[12] Optically active lattice frequencies of the crystal have been calculated for these two complex salts. For $[Co(NH_3)_6][Co(CN)_6]$, the mean amplitudes of the displacements for the two Cobalt atoms have been calculated, which may be compared with the data obtained by Iwata and Saito.[12]

Experimental

Infrared measurement: Samples dispersed homogeneously in polyethylene or Nujol mull were used for the measurement

of far infrared spectrum. A Hitachi EPI-L double beam spectrometer flushed by dry air (700—300 cm^{-1}) and a Hitachi FIS-1 vacuum double beam far infrared spectrometer (500—60 cm^{-1}) were used. The observed spectra are reproduced in Figs. 1~3.

Raman measurement: Raman spectra of a single-crystal sample of $K_3[Co(CN)_6]$ were observed using a JEOL JRS-U1 Raman spectrometer equipped with an Ar ion laser and a Spex 1401 double monochromator equipped with a He–Ne laser. The observed spectrum is reproduced in Fig. 4. Polarization measurements for this monoclinic crystal do not supply sufficient data to determine the a_g and b_g species vibrations.

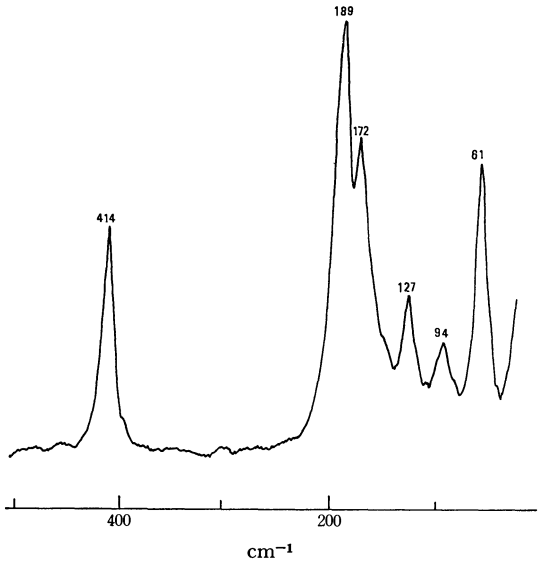

Fig. 4. Single crystal Raman spectrum of $K_3[Co(CN)_6]$.

Observed Results and Analysis

$K_3[Co(CN)_6]$. The crystal structure is monoclinic with the space group C_{2h}^5. The Bravais primitive cell contains two formula units and the factor group analysis shows that the 21 a_g and 21 b_g vibrations are Raman active and the 26 a_u and 25 b_u vibrations are infrared active. The 21 modes in each of the a_g and b_g species are composed of 15 inner modes and 3 rotational and 3 translational lattice modes. The 26 a_u modes are composed of 18 inner and 8 translational lattice modes, while the 25 b_u modes of 18 inner and 7 translational lattice modes. A vibrational analysis and a normal coordinate treatment of optically active crystal vibrations are made just in the same way as in the case of $K_3[Fe(CN)_6]$ described in the previous paper.[7] The detailed structure of $K_3[Co(CN)_6]$ was determined by neutron diffraction study.[13] Potential constants (intramolecular and interionic force constants) used in this calculation are taken the same values as those in $K_3[Fe(CN)_6]$ except for the Co–C and C≡N stretching force constants, K(Co–C) and K(C≡N) (see Table 3 of Ref. 7). The values of K(Co–C) and K(C≡N) are taken 2.6 mdyn/Å and 16.5 mdyn/Å, respectively. The results of the calculations are listed

in Table 1, together with the observed frequencies. The calculated frequencies, for which the interionic force constants were neglected (as an isolated complex ion), are also included in this table.

In Table 1 the observed infrared bands as a whole correspond well with the calculated frequencies as in the case of isomorphous $K_3[Fe(CN)_6]$. Furthermore it is noted that the Raman frequencies are also in good agreement with the calculated values using the same values of potential constants without any modification. Now that the vibrational analysis of this type of complex salts, $K_3[M(CN)_6]$, with the monoclinic structure C_{2h}^5, has been established rather fully, some discussions will be given below. The lattice frequencies due to the interaction between the complex ions and outer cations may be classified into two groups for both infrared and Raman spectra. One is located above 150 cm^{-1} and the other below 100 cm^{-1}. In the former the displacements of the K^+ ions are predominant while in the latter those of the complex ions are appreciable. The rotaional lattice frequencies in the a_g and b_g vibrations correspond with the lower group of vibrations and some of them may not be observed. Adams and Hooper argued that the high frequencies of the lattice modes in contrast with those of complex halides K_2MCl_6 indicate a higher degree of covalent bonding between anions and cations than in complex halides.[11] In fact the nearest distance between K^+ ion and N atom is about 2.5 Å. Anyhow the lattice dynamical treatment of optically active crystal vibrations, where the interionic potential constants for the atom pairs with distances shorter than 4.0 Å are taken into account and they are vaired according to the distances, is a plausible analysis to interpret both the lattice vibrations and the inner vibrations for the complex salts. The calculated frequencies as an isolated complex ion show that the outer ion affects very little upon the metal-ligand stretching frequencies in both the gerade and ungerade species though the low-frequency CCoC deformation modes are more or less coupled with the lattice modes.

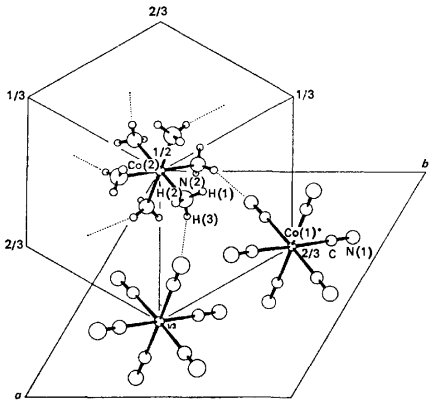

Fig. 5. Crystal structure of $[Co(NH_3)_6][Co(CN)_6]$. (Reproduced from Fig. 1 of Ref. 12 with the courtesy of Prof. Saito).

$[Co(NH_3)_6][Co(CN)_6]$. Figure 5 (the reproduction of the figure (Fig. 1) in Ref. 12) shows the crystal structure determined by Iwata and Saito.[12] This crystal is trigonal with the space group C_{3i}^2 ($R\bar{3}$) and as shown in Fig. 5 the Bravais primitive cell contains one formula unit, in other words, one $[Co(NH_3)_6]^{3+}$ ion and one $[Co(CN)_6]^{3-}$ ion (38 atoms). It can be shown from the factor group analysis that the 19 a_u and 19 e_u vibrations are infrared active, of which only 1 a_u and 1 e_u vibrations correspond to the interionic lattice modes. The 18 a_g and 18 e_g vibartions are Raman active. However, the displacements of cobalt atoms occur only for the infrared active ungerade modes.

A normal coordinate analysis of optically active crystal vibrations has been done based on the geometry[14] determined by X-ray analysis,[12] using the potential constants listed in Table 2. The values of the intramolecular force constants were at first obtained from our previous study on ammine complexes[15] and $K_3[Co(CN)_6]$ described above and then modified slightly so that the calculated frequencies may ex-

a) Calculated value where interaction potential constants were neglected.

plain the observed frequencies as a whole. The value of NH_3 torsional force constant is somewhat arbitrary, since a definite observed frequency is not determined for this mode. As for the interaction potential constants, several kinds of the bent type hydrogen bonding N–H···N and N–H···C should be taken into account. From the crystal structure shown in Fig. 5, there are 3 kinds of N···H atom-pairs whose distances are about 2.17 Å, 2.50 Å and 2.52 Å, respectively, and 2 kinds of C···H atom-pairs of about 2.68 Å and 2.75 Å. The interatomic force constants are taken for these atom pairs. The values of f(C···H) were determined according to Harada-Shimanouchi's potential,[16] while those of f(N···H) were determined on referring to the data of the hydrogen-bonded dimers such as adenine and uracil crystals studied by Harada and Lord.[17] The results of the calculations are listed in Table 3, together with the infrared observed frequencies. The frequencies are well interpreted based on the trigonal structure determined by X-ray analysis.

Then mean amplitudes of displacements of two kinds of cobalt atoms in $[Co(NH_3)_6][Co(CN)_6]$ were calculated, using the value of potential constants in Table 2. The Cartesian displacement of i-th atom is expressed as:

$$\Delta x_i = \sum_a (L_X)^a_{x_i} Q_a$$

where Q_a denotes a-th normal coordinate. Therefore one obtains

$$\langle \Delta x_i^2 \rangle = \sum_a [(L_X)^a_{x_i}]^2 \langle Q_a^2 \rangle$$

$$\langle \Delta x_i \Delta y_i \rangle = \sum_a [(L_X)^a_{x_i}(L_X)^a_{y_i}] \langle Q_a^2 \rangle$$

where $\langle\ \rangle$ denotes mean values. $\langle Q_a{}^2 \rangle$ is expressed as

$$\langle Q_a^2 \rangle = (h/8\pi^2 c\nu_a) \coth (hc\nu_a/2kT)$$

16) I. Harada and T. Shimanouchi, *J. Chem. Phys.*, **46**, 2708 (1967).
17) I. Harada and R. C. Lord, *Spectrochim. Acta*, **26A**, 2305 (1970).

TABLE 4. MEAN AMPLITUDES OF DISPLACEMENTS OF Co ATOMS IN $[Co(NH_3)_6][Co(CN)_6]$

	Co (in $[Co(NH_3)_6]^{3+}$)	Co (in $[Co(CN)_6]^{3-}$)
$2\sqrt{\langle \Delta z_i^2 \rangle}$	0.151 Å	0.131 Å
$2\sqrt{\langle \Delta x_i^2 \rangle}$ ($2\sqrt{\langle \Delta y_i^2 \rangle}$)	0.133 Å	0.122 Å

Taking the principal axes as x, y and z axes, $\langle \Delta x_i \Delta y_i \rangle$ naturally disappears. Mean amplitudes of displacements of cobalt atoms were calculated at 300 K, the vibrations of the ungerade species being only taken into consideration for the displacements of cobalt atoms. The result is shown in Table 4. Iwata and Saito[12] made the calculations of thermal parameters assuming that both complex ions behave as a rigid body. They obtained tensors to describe the translational vibration and libration of the rigid body and showed that rigid-body motions are similar in both complex ions and are strikingly isotropic (the mean amplitude of translational motion is 0.12~0.13 Å). It should be noted that the result in Table 4 is in good agreement with that by Iwata and Saito.

In conclusion both $K_3[Co(CN)_6]$ and $[Co(NH_3)_6]$-$[Co(CN)_6]$ are well-established typical cyano-complex salts from the crystal-structural point of view. Vibrational spectra are interpreted satisfactorily on the basis of the crystal structure determined by neutron and X-ray analyses. Mean amplitudes calculated using the potential constants based on the spectroscopic data may supply thermal parameters in the X-ray analysis.

Most parts of this work were made in Department of Chemistry, The University of Tokyo. The author wishes to express his sincere thanks to Prof. Takehiko Shimanouchi for his encouragement throughout this study. Thanks are also due to Prof. Yoshihiko Saito, Institute for Solid State Physics, The University of Tokyo, for his valuable discussions.

The Electronic Absorption Spectra of Würster's Cation Radicals and Their Dimerization in Solution*

Shigeki NAKAYAMA** and Keisuke SUZUKI

Faculty of Science, Kwansei Gakuin University, Nishinomiya 662

(Received May 4, 1973)

The visible and ultraviolet absorption spectra of the *p*-phenylenediamine cation (PD^+), the *N,N*-dimethyl-*p*-phenylenediamine cation ($DMPD^+$), and the *N,N,N',N'*-tetramethyl-*p*-phenylenediamine cation ($TMPD^+$) in the presence and in the absence of an excess counter anion ($X^-=Br^-$, Cl^-, and ClO_4^-) are studied at low temperatures. Analyses of the data show that these cation radicals are in an equilibrium represented by $2R^+ + X^- \rightleftarrows R^{++}{}_2X^-$ (or, more exactly, $2R^+ + 0.7X^- \rightleftarrows R^{++}{}_2(X^-)_{0.7}$). It is found that the absorption maxima of the dimer and the value of the heat of dimerization are independent of the kind of counter anion. It is concluded that PD^+ and $DMPD^+$ form strong dimers (heat of dimerization, $\Delta H=-8.0$ and -8.2 kcal/mol respectively) and that $TMPD^+$ forms a relatively weak one ($\Delta H=-5.6$ kcal/mol). The features of the dimer spectra reflect the strength of the interaction of the radical in the dimer. In a strong dimer, the spectrum in the low-frequency region consists of a strong intermolecular charge-transfer band (C band) and a weak local excitation band (R' band), and the frequency shifts of the local excitation bands in the dimer (R' and Y' bands) from corresponding bands in the monomer (R and Y) are large. On the other hand, the spectrum in the weak dimer consists of relatively weak C and strong R' bands, and the shifts of the R' and Y' bands are small. A model of the dimer is proposed in which the two cations are arranged in a parallel manner and are surrounded by the ionic atmosphere of the counter anions.

The half-oxidation products of *p*-phenylenediamine and its *N*-methyl substituted derivatives, which are called Würster's cation radicals, are known as stable organic cation radicals. Michaelis and Granick[1] first suggested that Würster's cation radicals, except for the *N,N,N',N'*-tetramethyl-*p*-phenylenediamine cation ($TMPD^+$ or Würster's blue), are polymerized in crystalline states and in concentrated or cooled solutions. Hausser[2] found that, with lowering of the temperature, a Würster's blue perchlorate solution shows an intense new absorption band in the near-infrared region of the spectrum, a band which appears to increase in intensity as the paramagnetism of the solution decreases. Hausser and Murrell[3] suggested the formation of a radical dimer (π-complex) and assigned the new band to an intermolecular charge-transfer band in the dimer. In the previous preliminary papers,[4] the present authors experimentally confirmed the suggested solution dimerization by an analysis of the temperature-dependent absorption spectra of several Würster's cation radicals at low temperatures. A similar line of investigation has also been performed by Kimura, Yamada, and Tsubomura.[5]

In these previous works, however, the role of the counter anion in the dimerization was not considered. In the present investigation, spectrophotometric measurements of the solutions of cation radicals of *p*-phenylenediamine (PD^+), *N,N*-dimethyl-*p*-phenylenediamine ($DMPD^+$), and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine ($TMPD^+$) were carried out at low temperatures and at various concentrations by using newly-constructed, accurate temperature-control equipment. In order to study the possible contribution of the counter anion to the dimerization, an excess amount of a salt containing a counter anion (ammonium bromide, chloride, or perchlorate) was added to the radical solution and the observed spectrophotometric changes were analyzed on the basis of several monomer-dimer equilibrium models including the counter anion. The nature of dimer interaction was then discussed by using the monomer and the dimer spectra of PD^+, $DMPD^+$, and $TMPD^+$ together with the results of other analyses.

Experimental

p-Phenylenediamine bromide (PDBr), *N,N*-dimethyl-*p*-phenylenediamine perchlorate ($DMPDClO_4$) and *N,N,N',N'*-tetramethy-*p*-phenylenediamine perchlorate ($TMPDClO_4$) were used for this study. These radical salts were prepared according to the method described in the literature.[1] For the spectrophotometric solvents, an ethanol–ethyl ether mixture (volume ratio of 2 : 1) was used for $DMPD^+$ and $TMPD^+$, while *n*-propanol was used for PD^+, because of the slower decomposition rates of the radicals in the solutions. Each solvent was purified by distillation after desiccation over sodium wire (for ether) or calcium oxide (for alcohols).

The absorption spectra of the radical solutions at low temperatures were obtained in quartz absorption cells with optical path lengths of 0.1, 0.3, 1.0, and 3.0 cm. The cell was cooled by cold nitrogen gas in a quartz Dewar vessel with optical windows. The cold nitrogen gas was supplied from a liquid nitrogen tank equipped with an electric heater immersed in the liquid nitrogen.

The temperature of the solution in the cell was measured by means of a copper-constantan thermocouple with a standard DC voltage source, a DC amplifier, and an electronic recording millivoltameter with lower and upper limit switches, as is shown in Fig. 1. The rate of the flow of the cold nitrogen gas was controlled automatically by regulating an applied voltage drop across the heater by the use of the switches.

Thus, the temperature of the cell was kept constant within 0.1 K.

The thermal expansion of the solution was calibrated in each measurement. A Cary recording spectrophotometer, model 14, was used for all the spectrophotometric measurements.

Results and Discussion

Electronic Absorption Spectra of PD⁺, DMPD⁺, and TMPD⁺ Solutions and Their Temperature Dependence. The spectra of PD⁺, DMPD⁺, and TMPD⁺ in dilute solutions at room temperature, *i. e.*, the spectra of radical monomers, all show similar structures, as Figs. 2—4 show. Each spectrum is characterized by an R band with fine vibrational structure in the visible region and by weak X and strong Y bands in the near-ultraviolet region.

At low temperatures, the spectra of these three radicals were significantly changed, as is also indicated in Figs. 2—4: the spectra at low temperatures showed new absorption bands C, R′, and Y′. As the temperature was lowered, it was found that the optical densities of the C, R′, and Y′ bands increased at the expense of those of the R and Y bands. In addition, a similar decrease in the optical density of the X band and the appearance of a new band (X′ band) can be

expected. However, quantitative measurements in these frequency regions were difficult because of stronger overlapping Y and Y′ bands.

By comparing the temperature dependence of various solutions at different concentrations, we are able to determine that the R and the Y bands can be attributed to the radical monomer, and the C, R′, and Y′ bands, to the radical dimer, as will be shown in the next section.[6]

The frequencies of the absorption maxima (ν_{max}) and oscillator strengths (f) of these bands are given in Table 1. The frequency shift of the R′ band from the R band and that of the Y′ band from the Y band are also given in the table. They will be discussed in the last section by comparing them with the heats of dimerization. These spectral properties will be theoretically treated in the next paper.[7]

Analyses of the Temperature-dependent Spectra. Up to the present, several investigators have interpreted or analyzed their experimental results[4-6] by assuming a simple dimerization equilibrium:

$$2R^+ \rightleftharpoons (R^+)_2 \qquad (1)$$

or a simple polymerization equilibrium:

$$nR^+ \rightleftharpoons (R^+)_n \qquad (2)$$

6) By analogy with the interpretation of spectra of certain dye solutions (see : E. Rabinowitch and L. F. Epstein, *J. Amer. Chem. Soc.*, **63**, 69 (1941)). R′ and Y′ bands may be assigned to the perturbed excitations in the dimer corresponding to R and Y bands, respectively.

7) To be published elsewhere.

a) Calculated as a monomer.

Electrostatic repulsion between the positive charges may retard the process of dimerization (or polymerization) in these models. The electrostatic repulsion energy between two point charges which, are separated by 3.1 Å (obtained from the interplanar separation between the parallel benzene rings in the DMPDBr crystals[8]) amounts to several eV. The energy may be reduced to about a half of the original one if the point charge is distributed over eight atoms of each radical according to the mobile π-electron densities. The dielectric constant of the medium may also reduce the energy. However, the energy would still be sufficient to retard the dimerization. Thus, a generalized formula is assumed in the present paper.

$$nR^+ + mX^- \rightleftharpoons (R^+)_n(X^-)_m \qquad (3)$$

where R^+ is a radical cation, and X^-, a counter anion (Cl^-, Br^-, or ClO_4^-). In this model, the contribution of the counter anion may reduce the electrostatic repulsion between the R^+'s. The equilibrium constant is given by;

$$K_{nm} = [(R^+)_n(X^-)_m]/([R^+]^n[X^-]^m) \qquad (4)$$

To justify the above assumption, a spectrum of a radical solution was compared with that of another solution containing the same amount of the radical and, in addition, an excess amount of an anion. If the anion plays some role in the polymerization, as is shown in Eq. (3), the concentration of the dimer must be increased by the addition of the excess amount of the anion, thus, the spectrum of the latter solution must show larger dimer bands (C, R', and Y') and smaller monomer bands (R and Y). In fact, such spectral changes were observed experimentally. For example, the optical density of a solution containing 2.3×10^{-4} mol/l PDBr at 176 K and 6050 Å (the absorption maximum of the C band) was 0.79, whereas that of a solution containing approximately the same amount of PDBr and 6.2×10^{-3} mol/l ammonium bromide was 1.00 at the same temperature and wavelength. At the same time, the R' and the Y' bands increased, and the R and the Y bands decreased. Similar spectral changes were also observed upon the addition of excess chloride or perchlorate anion. The assumption is thus justified.

Next, the numerical values of m, n, and K_{nm} were determined.

a) Determination of n: The value of n was determined from a series of temperature-dependent spectrophotometries of a solution containing a very large excess of X^-. Under the condition of ($[X^-]\gg[R^+]$), the value of the relative equilibrium constant, K_n is given by;

$$K_n = kK_{nm}[X^-] = I_P/(I_M)^n \qquad k: \text{const.} \qquad (5)$$

where I_p and I_M are the values of the optical densities of a polymer band (C, R', or Y') and a monomer band (R and Y) respectively. Eq. (5) is obtained by assuming that the extinction coefficients of the polymer and the monomer bands do not depend upon the temperature over the temperature region measured. Plots of log K_n against $1/T$ should be linear if the assumed n value is adequate. A series of measurements of a PD^+ solution for the cases of $n=1$, 2, 3, and 4 are given in Fig. 5. The linear dependence of log K_n *versus* $1/T$ is obtained if we take $n=2$. The dimerization of the radicals was confirmed from several such series of measurements.

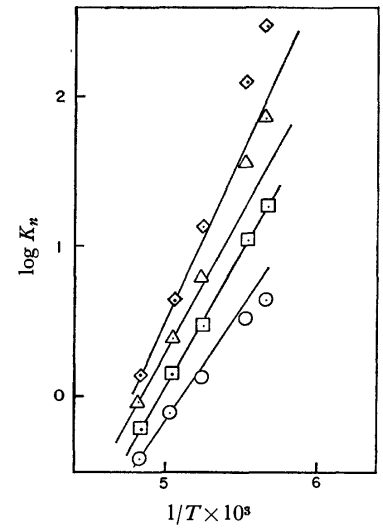

Fig. 5. Plots of log K_n against $1/T$ for a PD^+ solution.
○: $n=1$, □: $n=2$, △: $n=3$, ◇: $n=4$.
Stoichiometric concentrations of the radical and the bromide anion are 9.5×10^{-5} and 5.7×10^{-3} mol/l, respectively.

b) Determination of m: Two types of absorption spectra were obtained under the conditions of $[X^-]=[R^+]$[9] and of $[X^-]\neq[R^+]$,[10] and the spectrophotometric data were analyzed as follows. It was assumed that the data were accounted for by one of the following three equilibria:

$$2R^+ \rightleftharpoons R_2^{++} \qquad (6)$$

8) J. Tanaka and N. Sakabe, *Acta Crystallogr.*, **B24**, 1345 (1968).

9) A solution containing only a radical salt was used.

10) A mixed solution of a radical salt and an ammonium salt was used.

$$2R^+ + X^- \rightleftharpoons R_2X^+ \quad (7)$$

and

$$2R^+ + 2X^- \rightleftharpoons R_2X_2 \quad (8)$$

The corresponding equilibrium constants are given by:

$$K_{20} = \alpha/\{2c_R(1-\alpha)^2\} \quad (9)$$

$$K_{21} = K_{20}/\{c_X - (\alpha/2)c_R\} \quad (10)$$

and

$$K_{22} = K_{20}/(c_X - \alpha c_R)^2 \quad (11)$$

respectively, where α is the degree of dimerization, and where c_R and c_X are the stoichiometric concentrations of the cation radical and the counter anion respectively. α is estimated from the spectrophotometric data.

The most accurate value of α was obtained from $\alpha = I_C/I_C^0$, where I_C is optical density of the C band at the observed temperature and where I_C^0 is that at the lower temperature, where the monomer bands disappear. The values of log K_{nm} of PD^+ are plotted against $1/T$ in Fig. 6. The results show that none of the three models (6), (7), and (8) is able to fit the experimental data satisfactorily; *i. e.*, the R_2 model fails to explain the increase in the degree of dimerization upon the addition of the excess anion, and the R_2X and the R_2X_2 models overestimate the effect of the added salt. These models, the R_2X model is most likely, but it is still not entirely satisfactory. The best fit with the experimental data is obtained if we assume a non-integral m value, $m=0.7$.

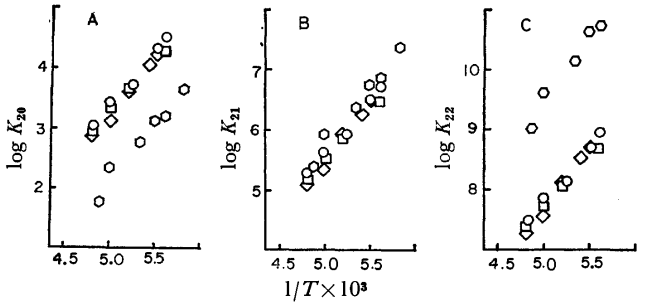

Fig. 6. Plots of log K_{nm} against $1/T$ for PD^+ solutions.
(A): $m=0$, (B): $m=1$, (C): $m=2$.
Stoichiometric concentrations of the radical and the anion of each series are:
○: $R^+=9.53\times10^{-5}$ mol/l, $Br^-=5.7\times10^{-3}$ mol/l,
□: $R^+=9.87\times10^{-5}$ mol/l, $Cl^-=5.65\times10^{-3}$ mol/l,
◇: $R^+=9.67\times10^{-5}$ mol/l, $ClO_4^-=5.68\times10^{-3}$ mol/l,
⬡: $R^+=Br^-=2.36\times10^{-4}$ mol/l.

The concentration-dependent optical densities of the C bands of PD^+, $DMPD^+$, and $TMPD^+$ without an excess anion were analyzed by the use of Eqs. (9)—(11). The results lead to the conclusion that the R_2 model underestimates the concentration dependence, while the R_2X and the R_2X_2 models overestimate it.

The spectrophotometric data of the other bands were also analyzed in similar manners. The results lead to the same conclusion as the above one within the limits of experimental error.

The heat of dimerization derived from the slopes of the log K_{21} *versus* $1/T$ plots are $\Delta H=-8.0$, -8.2, and -5.6 kcal/mol for the PD^+, $DMPD^+$, and $TMPD^+$ dimers respectively. The ΔH values are found to be independent of the kind of counter anion added.

Finally, we must add our important observations that the values of ν_{max}'s are also found to be independent of either the kind or amount of anion added. The only change observed upon the addition is in the degree of dimerization of the radical.

Structure of the Dimer. The structure of the R_2X dimer (or, more exactly, $R_2X_{0.7}$) suggested by the above results is one in which the dimer is surrounded by an ionic atmosphere of the counter anions, X^-'s. The ionic atmosphere may reduce the electrostatic repulsions between the R^+'s. The non-integral m value ($m=0.7$), which is best accounts for the experimental data, is perhaps due to averaged effective contribution of the various ionic atmospheres. The model is supported by the independence of the values of ν_{max}'s and ΔH's of the kind of anion added, X^-.

Another model, a sandwich-type model, in which an anion, X^-, is sandwiched by the two cation radicals, may also explain the fact that $m=1$. However, this model asserts a strong dependence of ν_{max}'s and ΔH's on the kind of anion; this conflicts with the experimental results.

The origin of the attractive force between the cation radicals in the present dimer model is the direct (partly covalent and partly ionic) interaction of the π-electron systems of the R^+'s, while that between the cation radical and the anion in the ionic atmosphere is mainly electrostatic.

The proposed model is supported by the crystal structures of Würster's radical salts. In Würster's blue ($TMPD^+$) perchlorate crystal,[11] the radical monomer are packed in a parallel manner, forming a column of radicals which is surrounded by perchlorate anions. In Würster's red ($DMPD^+$) bromide crystal,[8] a radical dimer is formed by placing two radicals in a parallel manner, and the dimers are packed together, forming a column of dimers. The column is surrounded by bromide anions.

The present model for the solution dimer is considered to be a fragment of the column of cation radicals in the crystal. The interaction between the two cation radicals and that between the cation and the anion in the model are, in principle, the same as those in the crystals. It is reasonable that the crystal and the solution dimer have similar structures and similar interactions.

The Strong Dimer and the Weak Dimer, and Their Spectral Features. The heat of dimerization obtained in the present work is a measure of the strength of the π-electronic interaction in the dimer. Therefore, it may reasonably be concluded that the interactions in the PD^+ and the $DMPD^+$ dimers are stronger than that in the $TMPD^+$ dimer. The weaker interaction in the $TMPD^+$ dimer may be accounted for by the increased steric repulsions between the crowded methyl groups in the two $TMPD^+$ radicals.

11) J. D. Turner and A. C. Albrecht, unpublished data, see : *J. Chem. Phys.*, **39**, 2321 (1964).

These two types of dimers show different spectral features. The strong dimer have strong C and the weak R′ bands, whereas the weak dimer has weak C and strong R′ bands, as Table 1 shows. The shifts of the ν_{max}'s of the local excitation bands by the dimerization ($\Delta\nu_R$, and $\Delta\nu_Y$, in the table) also show different trends; *i. e.*, they are larger for the strong dimer and smaller for the weak one. These interesting properties will be theoretically treated in the next paper.[7]

The authors should like to express their thanks to Professor Ooshika (Osaka Institute of Technology) for his kind discussions throughout the work; they also wish to express their thanks to Mr. Osamu Uemura and Miss Yukiko Seo for the measurements of the absorption spectra of $DMPD^+$.

Circular Dichroism and Optical Rotatory Dispersion Spectra of Poly[γ-(1-naphthylmethyl)-L-glutamate] and Its Charge-transfer Complex

Masahiro HATANO, Takamichi ENOMOTO, Ichi ITO, and Michio YONEYAMA*

Chemical Research Institute of Non-aqueous Solutions, Tohoku University, Sendai 980

(Received May 26, 1973)

Poly-γ-(1-naphthylmethyl)-L-glutamate was synthesized and its structure analyzed by the measurements of circular dichroism and absorption spectra. When the circular dichroism band at 219 nm in the circular dichroism spectrum of the polymer can be assigned to the band due to n–π* transition in the peptide main chain of the polymer, the calculated content of the right hand helix in the polymer is about 54% in ethylene chlorohydrin solution. It was also found that the polypeptide can form a charge-transfer complex with an organic electron acceptor in ethylene chlorohydrin solution. In the charge-transfer complex, a circular dichroism band could be observed at the wavelength corresponding to that of the charge-transfer band in the absorption spectrum of the complex. From the results, it was confirmed that the charge-transfer complex contains α-helix structure of this polypeptide. The temperature dependence of the charge-transfer complex formation was discussed in terms of the formation constant and thermodynamic parameters. The polypeptides having various portions of the 1-naphthylmethyl-D-glutamate residue were synthesized from poly-γ-methyl-D-glutamate by a polymer reaction using *p*-toluenesulfonic acid. The values of b_0 for the polypeptides derived from poly-γ-methyl-D-glutamate were estimated by means of Moffitt-Yang's equation, and the correlation between the b_0 values and the contents of 1-naphthylmethyl residue in the polypeptides was discussed.

In 1952, Mulliken[1] suggested that charge-transfer complexes may play an important role in biological systems. Some possible implications have been discussed by Szent-Gyorgyi,[2] his major concern being with the proposal that charge-transfer complexes are involved in biochemical reactions. There are two procedures in studying the possibility firstly to show the existence of charge-transfer complex formation in the biological systems, and secondly to demonstrate that it is essential in biological reaction. In some cases, the existence of charge-transfer complex formation between components in a given biochemical system has been proposed on the most tenuous evidence. The mere production of a colour, when two biochemical (or other) reagents are mixed, has often been given as the sole evidence for the charge-transfer complex formation. Obviously, such an observation alone is insufficient to justify the conclusion. Recent discussion has mainly centred around particular groups of compounds, including model compounds containing what are thought to be essential structural features. In aqueous solution, where most biological reactions occur, the dissociation of the complex may be so high that any charge-transfer absorption can be detected only with difficulty. Quite apart from the experimental difficulties of detecting a possible charge-transfer absorption band, there remains the fact that for most charge-transfer complexes, charge-transfer forces are not the major factor contributing to the stability of the complex in the ground state. Consequently, correlation between electron-donating ability of one component (or electron-accepting ability of the second component) and the association constant, free energy, or enthalpy of formation, cannot in general be assumed to be a necessary feature of a group of charge-transfer complexes. This is especially important when large component molecules are involved; steric effects and other features of the molecule may completely overwhelm any trend in thermodynamic quantities resulting from charge-transfer forces. Thus, it is important to clarify the steric factors for the charge-transfer complex formation in biological systems. In view of this, we examined the formation of charge-transfer complexes of polypeptides having aromatic residues, which behave as electron donors, in order to clarify the correlation between the α-helix content in the polypeptide and formation of their complexes.

The polymer effect on the formation constant of the charge-transfer complex of poly-*N*-vinylcarbazole,

* Present address; Department of High-polymer Science, Faculty of Science, Hokkaido University, Sapporo.

1) R. S. Mulliken, *J. Amer. Chem. Soc.*, **74**, 811 (1952).

2) A. Szent-Gyorgyi, "Introduction to a Submolecular Biology," Academic Press, New York and London (1960).

which has a helical structure, with organic electron acceptors was recently studied.[3] The results indicate the polymer to be tactic in solution because of the steric hindrance resulting from interactions between the neighbouring carbazole units. Accordingly, the extraordinarily high photoconductivity of the charge-transfer complex of poly-*N*-vinylcarbazole with an organic electron acceptor may depend on the helical structure of poly-*N*-vinylcarbazole.

It is interesting to study various factors of the conformational stability of polypeptides in biological systems. The stability of the α-helix structure which is influenced by the sequence of the amino acid residues, solvents and side chain groups is of particular interest. Conformational analyses of various synthetic poly-α-amino acids have been carried out,[4] especially the effects of the side chain groups near the main chain on the conformational stability.[5,6] Fraser[7] studied the conformational stability attributed to van der Waals forces between the aromatic side chains in the polypeptides including poly-γ-(1-naphthylmethyl)-L-glutamate. We have synthesized poly-γ-(1-naphthylmethyl)-L-glutamate and analyzed the structures of its charge-transfer complex in ethylene chlorohydrin or tetrachloroethane solution by various spectral measurements.

Experimental

Preparation of the Polymers. *1-Naphthylmethyl-L-glutamate (I)*: 1-Hydroxymethyl-naphthalene (11.1 g; 0.07 mol) and L-glutamic acid (9.5 g; 0.065 mol) were dissolved in dioxane of 80 ml, and then *p*-toluenesulfonic acid (13.3 g) was added to the reaction mixture. The esterification reaction was carried out for 24 hrs. at 55 °C. After the reaction, the solution was neutralized with sodium bicarbonate, and the reaction product was separated as a white precipitate. The product was filtered on a glass filter, washed with 95% aqueous ethanol solution, and finally recrystallized from the mixture of acetic acid and acetone. Yield 33%. mp. 173—175 °C. Elemental analyses are as follows; Found: C, 65,93; H, 5.77; N, 4.88%. Calcd for $C_{16}H_{17}NO_4$, C, 64.65; H, 5.72; N, 4.71%. $[\alpha]_D^{22}=15.4°$ (in CH_3COOH).

The IR spectrum shows an ester band 1735 cm^{-1}.

1-Naphthylmethyl-L-glutamate NCA(II): Ester(I) (4.5 g, 0.016 mol) was suspended in anhydrous dioxane, and to this system was passed dry phosgene for about 30 min. At the end of the reaction, the suspended NCA(II) was dissolved in dioxane. NCA(II) obtained was recrystallized from ethyl acetate-cyclohexane system. mp. 72—73 °C. Elemental analyses:

Found: C, 63.81; H, 5.11; N, 5.84%. Calcd for $C_{17}H_{15}NO_5$, C, 64.15; H, 4.78; N, 4.47%.

The IR spectrum of NCA(II) shows two bands at 1850 and 1785 cm^{-1}, due to carboxyanhydride group, and an ester band at 1735 cm^{-1}.

Poly-γ-(1-naphthylmethyl)-L-glutamate(III): 1-Naphthylmethyl-L-glutamate NCA(II) was dissolved in 100 ml of anhydrous dioxane and the initiator (*n*-hexylamine) was added. Polymerization conditions and the intrinsic viscosities of the polymer are summarized in Table 1. The IR spectrum of (III) shows an ester band at 1735 cm^{-1} and an amide band at 1655 cm^{-1}. Elemental analyses:

Found: C, 70.74; H, 6.02; N, 5.20%. Calcd for $C_{16}H_{15}NO_3$, C, 71.37; H, 5.58; N, 5.20%.

In the measurements of various spectra, the polymer denoted by No. 1290—2 was used.

Ester Exchange Reaction of Poly-γ-methyl-D-glutamate with 1-Hydroxymethylnaphthalene: Poly-γ-methyl-D-glutamate, prepared by the conventional NCA method (Ajinomoto Co. Ltd.), was used. It has a 1.4 intrinsic viscosity in dichloroethane solution at 30 °C. The ester exchange reactions were carried out as follows. 0.5 g of *p*-toluenesulfonic acid and 2.0 g of 1-hydroxymethylnaphthalene were added to a solution (3% by weight) of poly-γ-methyl-D-glutamate in dichloroethane, and the reaction mixture was then stirred at 60 °C. The molar ratio of poly-γ-methyl-D-glutamate (based on the glutamyl residue) to 1-hydroxymethylnaphthalene in reaction system was varied as shown in Table 2. After the reaction, the reaction product was precipitated with methyl alcohol, and washed several times with methyl alcohol, and finally dried *in vacuo*. The extent of the ester exchange reactions was estimated by means of the nitrogen contents of the reaction products. The conditions and extent of reactions are given in Table 2. From viscosity measurements, it was confirmed that no or less decrease of the degree of the polymerization of the polymer was observed.

Spectral Measurements. Optical rotatory dispersion (ORD) and circular dichroism (CD) measurements were

carried out with JASCO ORD/UV-5 and J-20A polarimeters, respectively. Absorption (AB) spectrum was measured with a Hitachi EPS-3T spectrophotometer. In these measurements, spectral grade ethylene chlorohydrin and 1,1,2,2-tetrachloroethane were used as solvents. Ethylene chlorohydrin was dried with CaH_2, distilled over CaH_2 under reduced pressure, and stored with exclusion from moisture in air. Purified ethylene chlorohydrin has a cut-off near 205 nm and high solubility for this polymer and is the best solvent for its CD measurement. From the observed ORD curves, the so-called Moffitt-Yang plots were made by means of the equation

$$[m']\frac{\lambda^2-\lambda_0^2}{\lambda_0^2} = a_0 + b_0\frac{\lambda_0^2}{\lambda^2-\lambda_0^2} \quad (1)$$

where λ_0 was taken to be 212 nm, and the mean residue optical rotation, [m'], was estimated, assuming the refractive index of 1,1,2,2-tetrachroethane to be 1.49 and neglecting the wavelength dependence of the refractive index. Furthermore, the CD and AB spectra of the charge-transfer complex of this polymer with 2,4,7-trinitro-9-fluorenone or 2,4,5,7-tetranitro-9-fluorenone were observed.

Results and Discussion

Absorption Spectrum of Poly-γ-(1-naphthylmethyl)-L-glutamate. Hypochromism is a familiar phenomenon in nucleic acids. A similar situation prevails in α-helical polypeptides and proteins. The hypochromic effect with the α-helix formation was treated theoretically by Tinoco,[8] and can be qualitatively accounted for in terms of the interaction of the transition moment for the absorption band in question in one residue, with transition moments of other transitions of adjoining residues. When the chromophores are aligned side by side, lower energy transition will be hypochromic. Since this polymer includes an α-helical structure and the naphthyl residues in the amino acid units of the polymer may be aligned side by side to form a type of a stacking structure, it is expected that the absorption intensities of the transitions in naphthyl residue decrease appreciably.

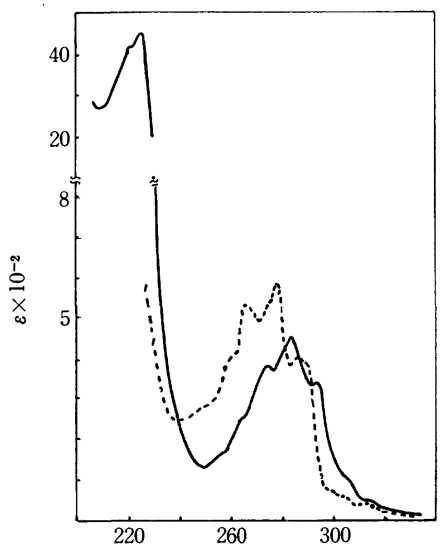

Fig. 1. Absorption spectra of naphthalene and poly-γ-(1-naphthylmethyl)-L-glutamate; dotted line, naphthalene; solid line, poly-γ-(1-naphthylmethyl)-L-glutamate.
Solvent: Ethylene chlorohydrin.

Figure 1 shows absorption spectra of both naphthalene and poly-γ-(1-naphthylmethyl)-L-glutamate in ethylene chlorohydrin. The ^1L_a(p) band including vibration modes of naphthyl residue in the polymer shifts to longer wavelength region than in the case of naphthalene. In this polymer, an appreciable hypochromicity can also be seen in the spectral region.

Circular dichroism spectrum of poly-γ-(1-naphthylmethyl)-L-glutamate. The CD spectrum in visible region of poly-γ-(1-naphthylmethyl)-L-glutamate in 1,1,2,2-tetrachoroethane is shown in Fig. 2. A very weak positive CD band is seen at 400 nm (25.0×10^3 cm^{-1}), and a weak band at 365 nm(27.4×10^3 cm^{-1}), which corresponds to the AB band at 365 nm in the AB spectrum of the polymer. The CD and AB bands at 365 nm may be assigned to an electronic transition, assumed to be as $^1L_b(\alpha)$, in naphthyl residue of the polymer. On the other hand, no CD band can be observed in the ^1L_a(p) band region. The CD spectra of poly-γ-methyl-L-glutamate and poly-γ-(1-naphthylmethyl)-L-glutamate in the spectral region near 222 nm are also shown in Fig. 2. The former exhibits a large negative CD band at 222 nm, and the latter a large negative CD band at 219 nm and a negative CD band at 230 nm. The CD band at 230 nm is assigned to $^1B_b(\beta)$ band in naphthyl residue of the latter polymer (Fig. 1).

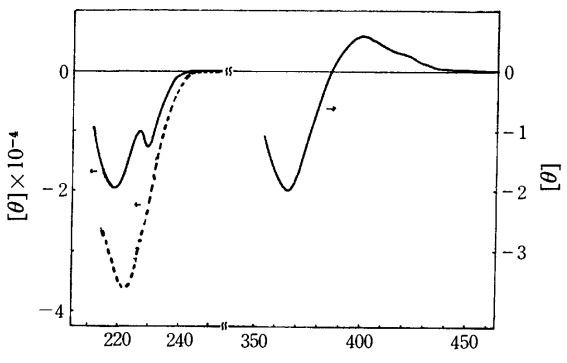

Fig. 2. Circular dichroism spectra of poly-γ-methyl-L-glutamate and poly-γ-(1-naphthylmethyl)-L-glutamate; dotted line, poly-γ-methyl-L-glutamate; solid line, poly-γ-(1-naphthylmethyl)-L-glutamate.
Solvent: Tetrachloroethane (in visible region).
Ethylene chlorohydrin (in ultraviolet region).

If the CD band at 219 nm in the CD spectrum of poly-γ-(1-naphthylmethyl)-L-glutamate can be assigned to the band due to n-π* transition in the peptide main chain of the polymer, the calculated content of the right-hand helix in the polymer is about 54% ethylene chlorohydrin solution. The reason for the CD band due to the n-π* transition shifting from 222 nm to 219 nm can be clarified theoretically.

Spectral-Analyses of Charge-transfer Phenomena between Poly-γ-(1-naphthylmethyl)-L-glutamate and an organic Elec-

tron Acceptor. Figure 3 shows the spectral variation of the system of the peptide and 2,4,5,7-tetranitro-9-fluorenone when the molar ratio of the glutamyl redidue to the acceptor was varied in the ethylene chlorohydrin solution. A broad CD band can be observed at 483 nm in the CD spectra of the polymer-acceptor systems, increasing gradually with the increase of the molar ratio of acceptor to donor (Fig. 4). The wavelength of the charge-transfer band, as a shoulder, in the AB spectra is uncertain, but that of the CD trough at 483 nm can be determined exactly. Appearance of the CD band in the vicinity of the charge-transfer band, confirmed by the Benesi-Hildebrand plots for the absorbances at 483 nm in the AB spectra, indicates that the electric transition moments of the charge-transfer transition in the complex may orientate circularly around the polypeptide helix axis. This assumption can be easily elucidated by a simple

exciton theory.[9] This is the first example for the origin of the optical activity to be discussed on the basis of the charge-transfer phenomena including polypeptide with electron acceptor.

The Benesi-Hildebrand plots could be obtained in a conventional way from the variation of the absorbances at 483 nm in the AB spectra of the polypeptide-acceptor systems. The extinction coefficients and the equilibrium constants in the charge-transfer complex systems were then estimated from the plots, and several thermodynamic parameters in the charge-transfer complex formation were calculated. The calculated values are summarized in Table 3 together with those for the complex formation from naphthalene, which is a model compound for the polymer, and 2,4,5,7-tetranitro-9-fluorenone. The equilibrium constants in the complex formation between poly-γ-(1-naphthylmethyl)-L-glutamate and 2,4,5,7-tetranitro-9-fluorenone are appreciably smaller than those in the complex formation between naphthalene and the same acceptor. The decrease of the equilibrium constants in the polymer-acceptor system may result from a smaller enthalpy change. The results are in contrast to those for the complex formation from poly-*N*-vinylcarbazole and TCNQ, where the difficulty of complex formation was elucidated in terms of entropy change.[3]

Appreciable enhancement of helix stability in poly-γ-(1-naphthylmethyl)-L-glutamate by charge-transfer interaction with 2,4,5,7-tetranitro-9-fluorenone. In order to clarify the correlation between the helix content in the polypeptide and formation of the type of charge-transfer complex, the extent of helix in the polypeptide-acceptor complex was estimated at various ratios of the glutamyl residue to the acceptor. Figure 5 shows this variation of the CD spectra, particularly in the region of the n-π^* transition. We see that the formation of the charge-transfer complex stabilizes the helix structure in the polypeptide, and that some excess addition of the acceptor disturbs the formation of a helix structure in the polypeptide. At an equal molar ratio of the glutamyl residue to the acceptor, the complex exhibits the highest content of helix, which reaches about 100%. Thus, Szent-Gyorgyi's expectation could be confirmed experimentally. Although the enhancement of helix stability by the charge-

transfer interaction between the side chain groups of the polypeptide and the added acceptor molecules in ethylene chlorohydrin solution can not be directly correlated with most biological phenomena, it can be expected that some extent of looseness in the local motion of polypeptide main chains in enzymes are restricted by the charge-transfer interactions between the donor portions in enzymes and the added small acceptor molecules.

Correlation between Moffitt b_0 values and the contents of 1-naphthylmethyl residue in the polypeptides. Poly-γ-(1-naphthylmethyl)-L-glutamate has 54% helix content in ethylene chlorohydrin solution. This suggests that 1-naphthylmethyl groups in side chains of the polypeptide may disturb the formation of a helical structure in the polypeptide. The correlation between the Moffitt b_0 values and the contents of 1-naphthylmethyl residues in the polypeptides, synthesized by the ester exchange reaction between poly-γ-methyl-D-glutamate and 1-hydroxymethylnaphthalene with *p*-toluenesulfonic acid, is given in Table 2. The optical rotatory dispersion spectra were measured for the 1,1,2,2-tetrachloroethane solutions of the polypeptides. The observed value of b_0 for the polypeptide, in which the ester exchange reaction proceeded almost completely (polymer 5), was 230. This means that the polypeptide has 37% of helix content, assuming that b_0 is 630 in the completely helical polypeptide.[6] We see that the helix content of the polypeptides decreases gradually with the increase of 1-naphthylmethyl residues in the polypeptides. Thus, 1-naphthylmethyl groups in side chains of the polypeptides disturb the sterical formation of a helix structure in the polypeptide. However, the interference of 1-naphthylmethyl residue in the course of helix formation of the peptide may be so small that the interference can be removed by weak interactions such as charge-transfer interaction.

Side chain effect on the helix stability in the polypeptides. Introduction of nitro-group to the benzyl side chain in poly-γ-benzyl-L-glutamate or poly-β-benzyl-L-aspartate results in the lowering of helix content, and the polypeptides including nitroaromatic groups as side chains exhibit some CD bands which can be assigned to the transitions due to the nitroaromatic groups. This led us to assume that the nitroaromatic group in the polyglutamate or polyaspartate is an asymmetric environment forming a relatively rigid side chain helix of its own when the polypeptides are dissolved in helix solvents in a lower concentration.

Steric hindrance and/or electric dipole repulsion between the side chain groups may constrain the side chain groups to form a relatively rigid side chain helix around the axis of the main chain helix, and to disturb the helix formation of the polypeptide main chain. Steric considerations for poly-γ-(1-naphthylmethyl)-L-glutamate are similar, since the polypeptide exhibits some CD bands which can be assigned to the transitions due to the naphthyl residue in the side chain and has relatively low content of helix.

In the ethylene chlorohydrin solution of this polypeptide, the CD magnitude at 219 nm increased appreciably and the CD trough shifted to 222 nm, when the concentration of the polypeptide was increased to 0.1 M. This suggests that the interaction between the naphthyl groups in the side chains is too weak to increase the rigidity of the polypeptide main chain in a higher concentration.

Thus, an appreciable enhancement of helix stability by the charge-transfer interaction between the side chain group and the added acceptor molecule is possible, although the energetics in the helix formation should be analyzed in more detail in the correlation with other charge-transfer systems.

The authors express their sincere thanks to Professor S. Nagakura, The University of Tokyo, for his valuable discussion. They are grateful to Dr. S. Mori, the Central Research Laboratories, Ajinomoto Co., Inc. for supplying poly-γ-methyl-D-glutamate. Acknowledgement is made for a Scientific Research Grant-in-aid from the Ministry of Education.

Effects of Inorganic Salts on the Dissociation of a Complex of β-Cyclodextrin with an Azo Dye in an Aqueous Solution

Kazuo MOCHIDA, Akio KAGITA, Yoshihisa MATSUI, and Yoshio DATE

Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue 690

(Received June 11, 1973)

The apparent dissociation constant (K_{app}) of a complex between β-cyclodextrin and an azo dye, sodium *p*-(4-hydroxy-1-naphthylazo)benzenesulfonate, was determined by spectrophotometry in a phosphate buffer solution (pH 5.91) in the absence and in the presence of various inorganic salts at 25 °C. The cyclodextrin and the azo dye formed a 1 : 1 complex with the K_{app} value of 2.44×10^{-3} M in a 0.1 M phosphate buffer. K_{app} decreased with an increase in the concentration of the phosphate buffer and with the addition of some inorganic salts, such as Li_2SO_4, Na_2SO_4, K_2SO_4, $LiIO_3$, $NaIO_3$, KIO_3, and KF. These results were explained mainly in terms of the decrease in the activity of water, which takes part in the dissociation reaction of the inclusion complex, with an increase in the concentration of the inorganic salts. On the other hand, K_{app} increased with the addition of such salts as KCl, KBr, KI, KNO_3, KSCN, and $KClO_4$. These results were attributed mainly to the formation of the inclusion complexes of the cyclodextrin with the anions of these salts, competing with the azo dye for the cyclodextrin-binding site.

Cyclodextrins form inclusion compounds with various organic compounds. The equilibrium constants of the inclusion compounds have often been determined in aqueous solutions by spectrophotometric,[1,2] kinetic,[3-6] and solubility[7-9] measurements. In most of these measurements, inorganic salts have been added to the solution in order to control the pH and the ionic strength. However, the effect of the salts on the apparent equilibrium constants had generally been neglected until Schlenk and Sand[7] showed that some inorganic salts prevent the association of organic acids with α-cyclodextrin. Cramer *et al.*[2] clearly indicated that inorganic salts affect the equilibrium constant in two ways: (1) Inorganic salts change the structure of water, which has an influence on the hydrophobic interaction between cyclodextrins and guest organic molecules. (2) The anions of some inorganic salts compete with guest organic molecules for the binding sites of cyclodextrins. Cramer *et al.* showed that the perchlorate, nitrate, and iodide ions are trapped within the void space of α-cyclodextrin molecules, preventing *p*-nitrophenol from forming inclusion complexes with the cyclodextrin, and that the sulfate and phosphate ions have no influence on the cyclodextrin-*p*-nitrophenol complex formation. However, the salts examined were somewhat limited.

In the present study, we attempted to examine in detail the effects of various inorganic salts on the apparent dissociation constant (K_{cpp}) of the inclusion compound of β-cyclodextrin (β-CD) with an azo dye. As the azo dye, sodium *p*-(4-hydroxy-1-naphthylazo)-benzenesulfonate (Na^+HNB^-) was used because in it the difference in molar absorption coefficient between the free and the complexed HNB^- ions is largest among the dyes examined so far in our laboratory; therefore, it is possible to determine K_{app} by spectrophotometry with a high accuracy.

Results and Discussion

phate buffer (pH 5.91) at 25 °C. Although the wavelength of the absorption maximum (475 nm) was virtually unchanged, the absorbance of HNB^- at the maximum decreased with an increase in the concentration of β-CD. There were two isosbestic points, at 431 and 576 nm, indicating the formation of a 1 : 1 complex between β-CD and HNB^-. According to Cramer *et al.*,[2] the decrease in the absorbance (ΔE) of an HNB^- solution on the addition of β-CD is related to the total concentration ($c_\beta°$) of β-CD by the following equation:

$$c_a°c_\beta°/\Delta E = K_{app}/\Delta\varepsilon + c_\beta°/\Delta\varepsilon \quad (1)$$

where $c_a°$ is the total concentration of HNB^-, and $\Delta\varepsilon$, the difference in the molar absorption coefficient between the free and the complexed HNB^- ions. In fact, the plot of $c_a°c_\beta°/\Delta E$ *vs.* $c_\beta°$ for the present case gave a straight line (Fig. 2), where each ΔE was measured at 475 nm. The values of $\Delta\varepsilon$ and K_{app} were determined from the slope and the intercept of the line to be $9.59\times10^3\ M^{-1}\,cm^{-1}$ and 2.44×10^{-3} M respectively.

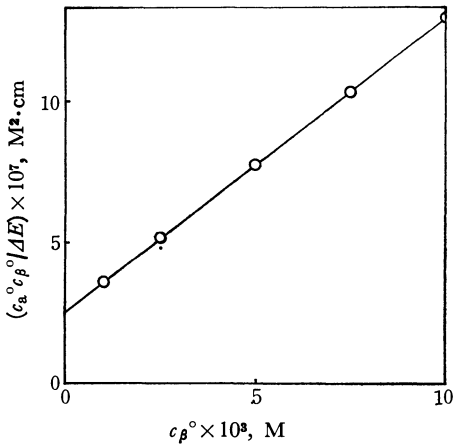

Fig. 2. Plot of $c_a°c_\beta°/\Delta E$ *vs.* $c_\beta°$.

$KClO_4$	3.84	—

a) c_s : Concentration of a salt added to 0.1 M phosphate buffer. b) Determined at c_s=0.125 M.

The K_{app} values were similarly determined at various concentrations of the phosphates (Table 1) or in the presence of potassium sulfate (Table 2) and the other potassium salts (Table 3), where the pH of each solution was adjusted to 5.91 by the use of a phosphate buffer. The $\Delta\varepsilon$ value was virtually constant at $9.59\times10^3\ M^{-1}\,cm^{-1}$ through all these measurements.

K_{app} decreased with increases in the concentrations of the phosphate, sulfate, iodate, and fluoride. On the other hand, K_{app} increased upon the addition of the chloride, bromide, iodide, nitrate, thiocyanate, and perchlorate. One can consider that the inorganic salts affect K_{app} in three different ways: (1) They change the activities of the free and the complexed HNB^- ions. Although the activity of β-CD may also somewhat vary upon the addition of the salts, the extent may be negligibly small because β-CD is a neutral molecule. (2) They change the activity of water, which probably takes part in the dissociation reaction of the inclusion complex. (3) Some of the salts are included in β-CD, competing with HNB^- for the binding site of β-CD. Among these effects, the first one was approximately estimated as follows.

Correction of K_{app} on the Change in the Activities of the Free and the Complexed HNB^- Ions. In order to estimate the activities of the free and the complexed HNB^- ions at various concentrations of inorganic salts, the activity coefficients (f's) of them at an ionic strength, I, were calculated by the use of the Debye-Hückel equation:[10a,11]

$$\log f = -AZ^2I^{1/2}/(1+BaI^{1/2}) \quad (2)$$

where A and B are constants equal to $0.5115\ M^{-1/2}$

10) R. A. Robinson and R. H. Stokes, "Electrolyte Solutions," Butterworths, London (1970), a) p. 229; b) p. 468; c) p. 477; d) p. 465.

11) It is known that Eq. (2) holds up to ionic strength of about 0.1, but at higher ionic strengths the following equation is more adequate to estimate the f value:

$$\log f = -AZ^2I^{1/2}/(1+BaI^{1/2}) + bI$$

where b is a parameter relating to the dielectric constant of an electrolyte solution. However, it may be recognized that the f_t/f_c in Eq. (3) calculated by the use of this equation is virtually equal to that calculated by Eq. (2), provided that the b value for the free HNB^- is approximately equal to that for the complexed HNB^-.

and 0.3291×10^8 $M^{-1/2}$ cm^{-1} respectively at 25 °C;[10b] Z is the ionic valence, and a, the effective diameter of the hydrated ion. The a values for the free and the complexed HNB^- ions were conductometrically estimated to be about 6×10^{-8} and 12.5×10^{-8} cm, as will be described in the Experimental section.

The corrected apparent dissociation constant (K_{corr}) was evaluated by the introduction of the activity coefficients thus calculated for the free and the complexed HNB^- ions (f_f and f_c, respectively) to Eq. (3):

$$K_{corr} = K_{app} \times (f_f/f_c) \quad (3)$$

Figure 3 shows the plot of K_{corr} *vs.* I, together with the plot of K_{app} *vs.* I, drawn on the basis of the data determined in the presence of the phosphate, sulfate, fluoride, and iodate. It is obvious that K_{corr} decreases more rapidly than K_{app} with an increase in I. This is caused by the fact that the size of the free HNB^- is smaller than that of the complexed HNB^-; therefore, the activity of the former decreases more rapidly than that of the latter with an increase in I. On the other hand, K_{corr} increases with increasing concentrations of the chloride, bromide, iodide, nitrate, and thiocyanate (Table 4), similarly to the case of K_{app}. These results show that the change in K_{app} with increasing concentrations of inorganic salts can hardly be explained only in terms of the change in the activities of the free and complexed HNB^- ions. Therefore, we examined the second effect of inorganic salts described above.

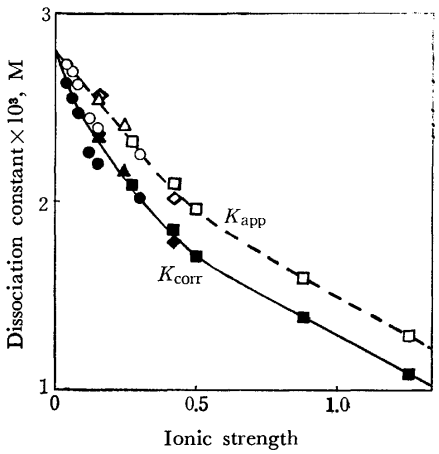

Fig. 3. Plots of K_{app} and K_{corr} *vs.* ionic strength.

a) c_s : Concentration of a salt added to 0.10 M phosphate buffer.

Effect of the Change in the Activity of Water on K_{corr}. In the preceding section we did not take into account the role of water in the dissociation of the β-CD-HNB^- complex. However, it is very probable that a large number of water molecules take part in the reaction, as was suggested by Cramer *et al.*,[2] for the water structure must be broken down around the complex during the dissociation reaction, and after that it must be reconstructed around β-CD and HNB^-. If the role of water is considered, the dissociation reaction can be expressed by the following equation:

$$\beta\text{-CD-HNB}^-(H_2O)_m + nH_2O \rightleftharpoons \beta\text{-CD}(H_2O)_p + \text{HNB}^-(H_2O)_{m+n-p} \quad (4)$$

The dissociation constant (K_d) for this reaction is given by:

$$K_d = K_{corr}/a_w{}^n \quad (5)$$

where a_w is the activity of water. The addition of inorganic salts may result in a decrease in a_w, causing a decrease in K_{corr} if K_d remains constant. Thus, we can qualitatively explain the effect on the K_{corr} of such inorganic salts as the phosphate, sulfate, iodate, and fluoride described above.

The a_w value changes not only with the salt concentration, but also with the kind of salt added. For example, the a_w of a potassium salt solution is generally larger than that of a sodium salt solution, which is in turn larger than that of a lithium salt solution, when these salts have the same anion and are in the same concentration. This is due to the fact that the extent of the hydration of these metallic cations increases in the order of K^+, Na^+, and Li^+. Table 5 shows K_{corr} values in solutions containing different metallic cations at the same pH and the same ionic strength. It is obvious that K_{corr} decreases in the order of K^+, Na^+, and Li^+ salts in the cases of both sulfate and iodate, as had been expected. This also indicates that the role of the water activity is important in the dissociation equilibrium of the β-CD-HNB^- complex.

TABLE 5. THE K_{corr} VALUES IN PHOSPHATE BUFFER (pH 5.91) CONTAINING DIFFERENT METALLIC CATIONS AT 25 °C

Cation	$K_{corr} \times 10^3$, M	
	Sulfate[a]	Iodate[b]
Li^+	2.08	2.04
Na^+	2.20	2.16
K^+	2.22	2.33

a) Phosphate : 0.050 M, Sulfate : 0.030 M.
b) Phosphate : 0.100 M, Iodate : 0.030 M.

We have no data about the values of a_w at various concentrations of these salts, and the value of n is also unknown. Therefore, the K_d value can not be estimated directly from K_{corr}. In order to estimate the approximate n and K_d values, we tried, for convenience, to use the a_w values for H_2SO_4 solutions available in the literature[10c] as substitutes for those of the potassium sulfate solutions. The a_w values used

had been estimated by measurements of the depression in the vapor pressure. From Eq. (5), we obtain:

$$\log K_{corr} = \log K_d + n \log a_w \quad (6)$$

Figure 4 shows the plot of $\log K_{corr}$ in the sulfate solutions *vs.* $\log a_w$. For the sake of simplifying the calculation, we set a_w in the reference state as equal to its mole fraction. The plot was virtually linear. From the slope and the intercept at $\log a_w = 0$, the values of n and K_d were obtained as 50 and 2.66×10^{-3} M respectively. It seems that the value of n is somewhat larger than would be expected from the sizes of β-CD and HNB^-. This may mainly be due to the inadequacy of the a_w values used. However, the results suggest that a considerably large number of water molecules participate in the dissociation of the inclusion complex.

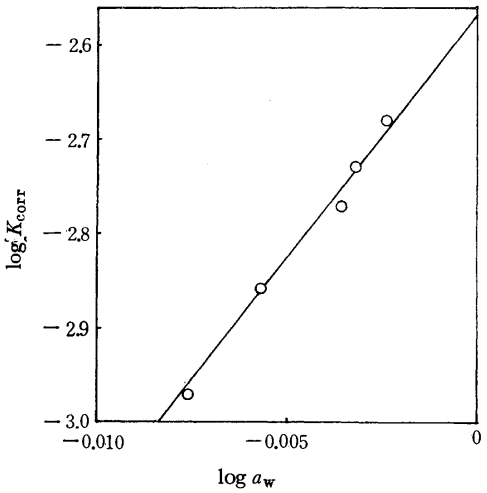

Fig. 4. Plot of $\log K_{corr}$ *vs.* $\log a_w$ for sulfate solutions.

In the above calculation, it was assumed that there is no appreciable interaction between β-CD and the inorganic salts. If these salts interact in some extent with β-CD, thus forming inclusion complexes, K_{corr} must increase with an increase in the concentrations of the salts, as will be described later in the case of such salts as the iodide, nitrate, and thiocyanate. In practice, however, the reverse was found here. Accordingly, it may be presumed that the interaction between them is negligibly small even if it does exist.

Inclusion of Inorganic Anions in β-CD. As has been shown in Table 4, K_{corr}'s in solutions containing KCl, KBr, KI, KNO_3, KSCN, or $KClO_4$ increased with increases in the concentrations of these salts. These results can not be explained in terms of the decrease in water activity, because the correction for water activity results in a further increase in K_{corr} with an increase in the concentration of the salts. One can explain the results only in terms of the inclusion of the anions of these salts in β-CD. If the anions form adducts with β-CD in aqueous solutions, they compete with HNB^- for the binding site of β-CD, resulting in the increase in K_{app} or K_{corr} with the increase in the concentrations of the anions.

The dissociation constant (K_s) for an β-CD-anion complex can be calculated by the use of Eq. (7) below, which one can easily derive on the assumption that the concentration of the inorganic salt is much higher than those of β-CD and HNB^-:

$$K_s = c_s^\circ K_{corr}^\circ / (K_{corr} - K_{corr}^\circ) \quad (7)$$

where K_{corr}° is the value of K_{corr} at the same ionic strength in a solution containing a salt which forms no adduct with β-CD, and where c_s° is the total concentration of the salt. The values of K_s thus calculated at $I=0.15$ and 0.42 are given in Table 6. In these calculations, the K_{corr}° values at $I=0.15$ and 0.42 were taken as 2.20×10^{-3} and 1.82×10^{-3} M respectively; these are the mean values of K_{corr}° determined in solutions containing the phosphate, sulfate, iodate, and fluoride at the respective ionic strengths.

Table 6. The K_s values for several anions in 0.10 M phosphate buffer (pH 5.91) at 25 °C

Anion	K_s, M	
	c_s[a] = 0.030 M (I = 0.15)	c_s = 0.300 M (I = 0.42)
Cl^-	0.8	0.8
Br^-	0.6	0.6
I^-	0.16	0.14
NO_3^-	0.3	0.4
SCN^-	0.09	0.11
ClO_4^-	0.05	—

a) c_s : Concentration of an anion added to 0.10 M phosphate buffer.

The K_s value for each salt was virtually invariable, regardless of the concentration. This indicates that the change in K_s with the decrease in water activity is small compared with the experimental error. The K_s values decreased in the order of Cl^-, Br^-, NO_3^-, I^-, SCN^-, ClO_4^-. This sequence is in agreement with that reported by Schlenk and Sand,[7] who showed that the degree of the association of halide ions with α-cyclodextrin increases in the order of Cl^-, Br^-, I^-. Cramer *et al.*[2] have also shown that ClO_4^- froms a fairly stable adduct with α-cyclodextrin.

One can consider that these anions are bound to β-CD by van der Waals force, hydrophobic interaction, and/or hydrogen bonding. In connection with this point, it was noticed that the hydrated anions forming no complex with β-CD have effective diameters of not less than 3.5 Å,[16] *i.e.*, 4—4.5 Å for $H_2PO_4^-$ and IO_3^-, 4 Å for HPO_4^{2-} and SO_4^{2-}, and 3.5 Å for F^-, whereas those forming complexes with β-CD have effective diameters of not more than 3.5 Å, *i.e.*, 3 Å for Cl^-, Br^-, I^-, and NO_3^-, and 3.5 Å for SCN^- and ClO_4^-. From this fact, it might be considered that the former anions are too large to be included within the void space of β-CD, whereas the latter anions are small enough to fit within it. However, the internal diameter of the β-CD ring is about 7.5 Å, which is larger than the effective diameters of the hydrated ions. Furthermore, it has been reported that α-cyclodextrin, whose internal diameter is about 6.0 Å, includes ClO_4^- to form a complex with K_{app} of 0.034 M,[2] which is comparable with that of the complex between the ion and β-CD. These facts indicate that the role of the van der Waals

force is not very important in the formation of the inclusion complexes between inorganic anions and β-CD. The role of hydrophobic interaction and hydrogen bonding is not yet clear. It may be necessary to study fur ther the physicochemical properties of β-CD and hydrated anions.

Experimental

Materials. The β-CD was isolated from a mixture of α, β, and γ-cyclodextrins given us by the Matsutani Kagaku Co. and was purified according to the directions of Cramer and Henglein.[12] $[\alpha]_D = +168°$ (lit.,[13] $+162.5°$). It was confirmed by paper chromatography with the two solvent systems (*s*-BuOH–pyridine–water (1 : 1 : 1)[14] and *n*-BuOH–DMF–water (2 : 1 : 1)[15]) that the β-CD contained no appreciable amounts of α- or γ-cyclodextrins. The Na^+HNB^-, obtained commercially, was dissolved in hot distilled water and salted out by the addition of NaOAc. After this procedure had been repeated twice, the precipitate was recrystallized twice from water, washed with hot alcohol, and then recrystallized three times from alcohol. The KH_2PO_4, Na_2HPO_4, and KNO_3 were recrystallized from water. The Li_2SO_4, Na_2SO_4, K_2SO_4, $NaIO_3$, KIO_3, KF, KCl, KBr, KI, and KSCN were obtained commercially and were used without further purification. The $LiIO_3$ was prepared from LiOH and HIO_3 and was recrystallized from water. The water used for the preparation of buffer solutions and for the conductivity measurements was obtained by the distillation of city water with a Kokura distillatory apparatus, Model 8000; its specific conductance was *ca.* $2\times10^{-6}\ \Omega^{-1}\ cm^{-1}$ at 25 °C. A 0.10 M phosphate buffer solution was made by mixing 10 ml of 0.10 M Na_2HPO_4 and 90 ml of 0.10 M KH_2PO_4.[16]

Apparatus. For the determination of the K_{app} of the β-CD-HNB^- complex, absorption spectra were recorded by the use of a Hitachi Model 124 spectrophotometer. The cell (1.0 cm) was maintained at 25±0.1 °C with a jacket through which water was circulated from a constant-temperature bath. The pH of each aqueous solution was measured by means of a Hitachi-Horiba pH meter, model M-4. For the conductivity measurements, a Yanagimoto conductivity outfit, model MY-7, was used. A conductivity cell was fitted with circular, blacked Pt electrodes separated by 10 mm. The cell constant was 0.4829. The viscosity of the aqueous solutions was determined by the use of an Ostwald viscometer. All the measurements were made at 25±0.1 °C.

Determination of the a Values for the Hydrated Free and Complexed HNB^- Ions. The *a* values for the free and the complexed HNB^- ions were estimated by conductometry.[17] Figure 5 shows the relations between the molar conductivity (Λ) and the square root of the concentration for the free and the complexed Na^+HNB^- salts in distilled water at 25 °C. Each Λ value for the complexed Na^+HNB^- (Λ_c) was determined as follows: (1) The conductivity (κ_t) of an aqueous solution containing 10.0 mM β-CD and a certain concentration of Na^+HNB^- was measured and multiplied by 1.020, a figure which corresponds to the relative viscosity of the solution against distilled water, in order to correct for the effect of the increase in the viscosity of the medium upon the addition of β-CD on the basis of Walden's rule. (2) The concentrations of the free and the complexed Na^+HNB^- salts (c_f and c_c, respectively) were calculated from the K_{app} value of 2.47×10^{-3} M, determined in distilled water at 25 °C by the same spectrophotometric method as has been described above. (3) The conductivity (κ_f) of the free Na^+HNB^- salt at the calculated concentration was graphically estimated from the curve plotting the κ_f *vs.* the concentration of Na^+HNB^- measured in distilled water. (4) The conductivity (κ_c) of the complexed Na^+HNB^- salt was calculated by subtracting the κ_f value from $1.020\times\kappa_t$. The Λ_c value was obtained by dividing κ_c by c_c.

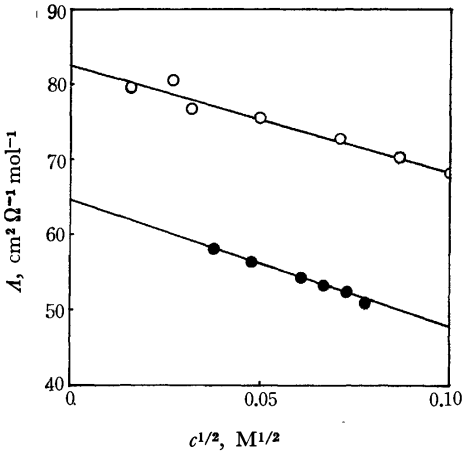

Fig. 5. Plots of the molar conductivity *vs.* the square root of concentration for the free (○) and the complexed (●) Na^+HNB^- salts in distilled water at 25 °C.

By the extrapolation of the plots in Figure 5 to the intercept, the molar conductivities at an infinite dilution of the free and the complexed Na^+HNB^- salts ($\Lambda_f°$ and $\Lambda_c°$) were evaluated to be 82.5 and 64.6 $cm^2\ \Omega^{-1}\ mol^{-1}$ respectively. Then, the molar conductivities of the free and the complexed HNB^- ions ($\lambda_f°$ and $\lambda_c°$, respectively) were estimated to be 32.4 and 14.5 $cm^2\ \Omega^{-1}\ mol^{-1}$ respectively by subtracting $\lambda°(Na^+) = 50.1\ cm^2\ \Omega^{-1}\ mol^{-1}$ [10d] from the $\Lambda_f°$ (the $\Lambda°$ value for the free Na^+HNB^- salt) and $\Lambda_c°$. By the use of this equation:[17] $a = k|Z|/\lambda°$, where $k = 182\times10^{-8}\ cm^3\ \Omega^{-1}\ mol^{-1}$ and where Z is the ionic valence, the *a* values for the free and the complexed HNB^- were calculated to be about 6×10^{-8} and 12.5×10^{-8} cm respectively.

Electron-diffraction Investigation of the Molecular Structure of Tetramethyltin

Makoto NAGASHIMA, Hideji FUJII*, and Masao KIMURA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 15, 1973)

The structure parameters of tetramethyltin have been determined by gas-phase electron diffraction to be as follows: r_g(Sn–C)$=2.143_6\pm0.003_0$ Å, r_g(Sn···H)$=2.764_2\pm0.012_5$ Å, r_g(C–H)$=1.117_9\pm0.009_0$ Å, l(Sn–C)$=0.049_6\pm0.009_8$ Å, and l(Sn···H)$=0.153_2\pm0.013_2$ Å. The experimental molecular intensity has been well reproduced by the molecular model in which the methyl groups are rotating freely, or nearly freely. The scattering factors, based upon the relativistic Hartree-Fock-Slater or the Hartree-Fock atomic potential, have given a theoretical background in better agreement with the experimental one and have led to a more reasonable Sn–C mean amplitude than did the scattering factors based upon the Thomas-Fermi-Dirac or the Thomas-Fermi atomic potential.

The molecular structures of alkyltin-hydrides,[1] and chlorides[2] in the gas state have recently been investigated by the sector-microphotometer method of electron diffraction. Though tetramethyltin is one of this series, its molecular structure has, however, thus far been determined only by the visual method.[3] The main purpose of the present report is to present a structure determined more accurately by the sector-microphotometer method of electron diffraction and to complete the structural data for organotin compounds.[4]

The second purpose of the present study is concerned with the scattering factors. In a previous study,[5] the small angle scattering of electrons from molecules containing heavy atoms, including $Sn(CH_3)_4$, was observed by a counting technique and the results compared with theory, calculated from a set of the elastic scattering factors based upon the relativistic Hartree-Fock-Slater atomic potentials[6] and the inelastic scattering factors based upon the Hartree-Fock atomic potentials[7] (RHFS, HF), and from a set of the elastic and inelastic scattering factors based upon Thomas-Fermi-Dirac[8] and Thomas-Fermi atomic potentials[9] (TFD, TF) respectively. The (RHFS, HF) scattering factors reproduced the experimental intensities better at small scattering angles, particularly in the range below $s=6$, than did the (TFD,TF) scattering factors. This fitting was in line with the results of the diffraction studies of dimethylmercury[10] and mercury(II) chlorides,[11] where the experimental background agreed better with the (RHFS, HF)-based theoretical background than with the (TFD, TF)-based one. In view of the better agreement of the experimental and theoretical backgrounds, as well as the theoretical sophistication of the atomic potentials, we adopted the (RHFS, HF) scattering factors in the previous structure determinations. The scattering intensities from tetramethyltin, as measured by a photographic method, are expected to provide information on the scattering factors at larger scattering angles, which the counting technique does not cover efficiently. Thus, the present study has been performed under the best possible experimental conditions, particularly with a minimum of extraneous scattering.

Experimental

The diffraction unit used in the present study has been described elsewhere.[12] Photographs were taken with an r^3-sector under the following experimental conditions: accelerating voltage, about 42 kV; camera length; 24.43 cm; sample pressure, 10—25 Torr; exposure time, 40—60 s; beam current, 0.09 μA; and room temperature, 17 °C. The scale factor was determined with reference to the diffraction patterns of carbon disulfide taken in the same sequence. The photographs of carbon disulfide were also used for judging if

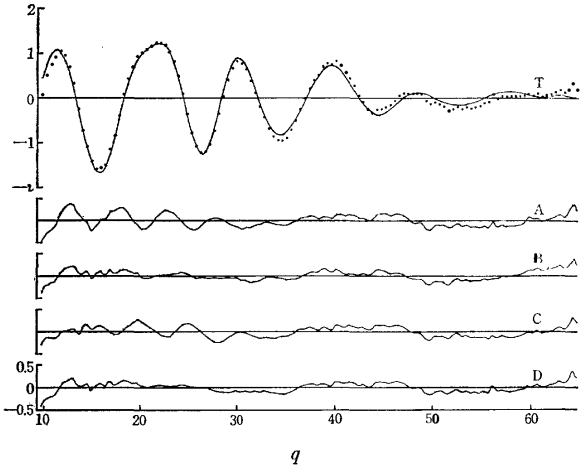

Fig. 1. Experimental molecular intensities (dotts), the best-fit theoretical intensity curve (T), and the difference correspond to the models with rotational angles of the methyl groups, 0° (eclipsed), 30° (intermediate), 60° (staggered) and the free-rotation model, respectively.

the apparatus was in sufficiently good condition. Thus it was confirmed that no significant extraneous scattering was involved in the present experiment.[13] Four plates for the sample and four for the reference were selected and used for the structure analysis. The molecular intensities, $qM(q)$, were reduced following our conventional procedure.[2a] In this and the succeeding procedures for structure determination, the (RHFS,HF) scattering factors were employed. A comparison between the two sets of the scattering factors will be presented later. The molecular intensities obtained from one of the four plates are plotted in Fig. 1. The data covered the range of $10 \leqq q \leqq 60$.[14]

Structure Analysis

Least-squares Refinement. The molecular structure was determined by the least-squares method applied to the molecular intensity.[15] The SnC_4 frame and the methyl group were assumed to have the T_d symmetry and the C_{3v} symmetry respectively. With this frame symmetry, four molecular models were taken into account: three hindered-rotation models, staggered (rotational angle 60°), eclipsed (0°), and intermediate (30°) with regard to the relative positions of the methyl groups to the opposite SnC_3 frame, and a free-rotation model. The free-rotation model was approximated by mixing the three hindered-rotation models weighted equally. The independent parameters for each model were chosen to be r_a(Sn–C), r_a(Sn···H), r_a(C–H), l(Sn-C), and l(Sn···H). The other non-bonded distances were constrained in the r_a distances. The l(C–H) was assumed to be 0.08 Å, and the other non-bonded C···H and the H···H mean amplitudes were transferred from those of propane.[16] The parallel and perpendicular mean amplitudes of the SnC_4 system were estimated by solving a five-body problem in which the methyl groups were regarded as mass points. In this calculation, the Urey-Bradley force field was used with the assumption that $F' = -F/10$. The results of the vibrational analysis for the SnC_4 system are shown in Table 1, along with the mean amplitudes determined in the present study. The asymmetry parameters, κ, were estimated by a diatomic approximation[18] to be 9.0×10^{-6} Å^3 for Sn–C and 10.0×10^{-6} Å^3 for C–H; they were assumed to be zero for all the other non-bonded distances.

Table 1. Vibrational data for $Sn(CH_3)_4$

	Frequency (in cm^{-1})		Force constant (in md/Å)	
	Obsd[a]	Calcd		
A_1	507	507	K	2.10
E	145	145	H	0.049
F_2	532	532	F	0.044
	160	160		

	Mean-amplitudes (in Å) parallel	perpendicular	Stretchings (in Å) $r_a - r_\alpha$
Sn-Me	0.0529	0.0209	0.0036
Me-Me	0.1370	0.0144	−0.0033

a) Raman data. Ref. 17.

The results are listed in Columns (A), (B), (C), and (D) of Table 2, while the differences between the theoretical and observed molecular intensities are shown by Curves (A), (B), (C), and (D) in Fig. 1. As may be seen in Table 2, the r_a(Sn–C) distance converges to a constant value, irrespective of the selected models. As for the other parameters, on the other hand, the results for the hindered-rotation models are slightly different from one model to another, although they agree within their standard deviations. The results for the free-rotation model coincide with those for the intermediate model. The differences between the theoretical and observed molecular intensities all seem within the range of estimated experimental uncertainties in the intensity measurements. On a closer examination, however, the difference curves for the staggered and eclipsed models are seen to oscillate in the $10 < q < 30$ range. This oscillation in the difference curves appears consistently in all the data with phases approximately opposite to each other for the staggered and eclipsed models. The contributors to this oscillation are confirmed to be the non-bonded C···H distances, not the Sn···H distances, which also depend slightly on the selected models. Such oscillations disappear in the difference curves for the intermediate and free-

rotation models, where the non-bonded C···H distances are intermediate between (or are composed of) those for the eclipsed and staggered models. The standard deviations are also much smaller for the intermediate and free-rotation models. The free-rotation model adopted in the present study is not a rigorous one, but, in the light of the finding mentioned above, the nearly free rotation of the methyl groups is acceptable and the diffraction pattern can be interpreted satisfactorily by a nearly free rotation. No further investigation was made of the rotational states of the methyl groups, for the contribution from the C···H and H···H non-bonded distances to the total intensities was not sufficiently large to distinguish more precisely various conformations, or the rotational states of the methyl groups. The intermediate conformation cannot be rejected on the basis of the electron-diffraction data alone, although it is unlikely for a reason to be described later. The possibility of the eclipsed or the staggered conformation as a stable one can, however, be ruled out.

Molecular Structure. The final parameter values were determined from the results yielded for the free-rotation model. Table 3 shows the r_g distances and the mean-amplitudes obtained from four plates, along with the limits of error, which include 2.58 times the standard deviations and the error in the scale factor.

TABLE 3. MOLECULAR STRUCTURE OF $Sn(CH_3)_4$[a] (IN Å UNITS)

φ_g (Sn-C-H)	112.0±1.6°	

a) The uncertainties represent estimated limits of error.

Scattering Factors

The (RHFS, HF) and (TFD, TF) scattering factors differ from each other in their absolute values and phase factors. Figures 2 and 3 show the ratio of the backgrounds calculated from the two sets of scattering factors, and the leveled intensity curves, respectively. As

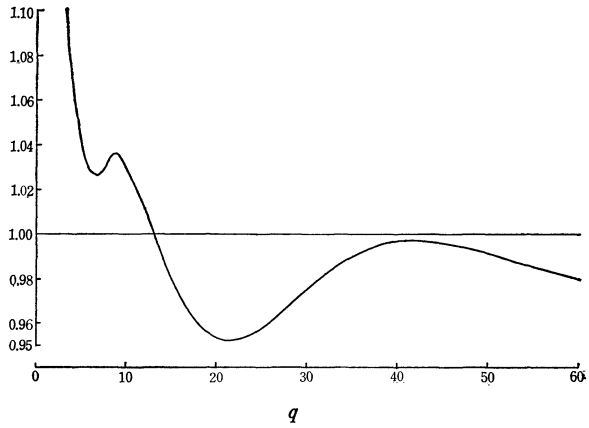

Fig. 2. Comparison of the theoretical backgrounds for $Sn(CH_3)_4$, ($I_B^{TF,DTF}/I_B^{RHFS,HF}$) *vs.* q.

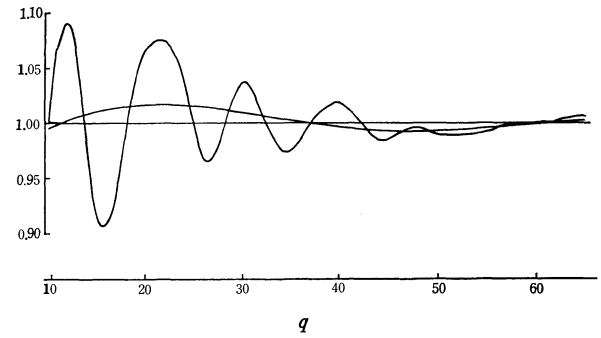

Fig. 3. The total intensity and the experimental background leveled by the use of the theoretical background calculated from the (RHFS, HF) potentials.

may be seen in Fig. 2, the two backgrounds are greatly different around $q=20$, making a strong undulation in the ratio curve. The leveled intensity based upon the (TFD, TF) is higher and deviates farther from the baseline around $q=20$ than that based upon the (RHFS, HF). This indicates that the (RHFS, HF)-based background reproduces the experimental one better, in conformity with the conclusion drawn from the small-angle scattering experiment, where stress was laid on relatively small scattering angles, $q<15$.[4]

In order to investigate the influence of the scattering factors chosen for structure determination, the whole analytical process was repeated using the (TFD, TF) scattering factors, and the results were compared with those obtained by the (RHFS, HF)-based analysis. The Sn–C distances agreed within the standard deviations, while the Sn–C mean amplitude was increased to about 0.07 Å. This value is much larger than the experimental value obtained by the (RHFS, HF)-based analysis. Two origins for such a large mean amplitude may be considered. The first is that the cut-off in the TFD scattering factors is at a larger angle. Since the cut-off points for the Sn–C are at $q=63$ and 60 in the TFD and RHFS scattering factors respectively, the use of the (TFD, TF) scattering factors gives a larger Sn–C mean amplitude. In order to observe this effect, the structure parameters were refined by using the (RHFS, HF)-based molecular intensities employed for the present structure determination and the (TFD, TF) scattering factors. Only the l(Sn–C) amplitude was thus changed, to 0.063 Å, a value which is 0.013 Å larger than the value determined in the last section. The second, less definite but still probable, origin is the peculiar background in the (TFD, TF)-based leveled intensity described in the preceding paragraph. An initial background curve is generally drawn flat, whereas the (TFD, TF)-based leveled intensity has a strong swelling near $q=20$. As a result, the molecular intensity in the smaller q region might have been amplified falsely, leading to an apparently large mean-amplitude.

In the light of the facts mentioned above, together with those derived from the studies of $Hg(CH_3)_2$[10] and $HgCl_2$[11] and from the small-angle scattering from molecules containing heavy atoms,[5] it may be concluded that the (RHFS, HF) scattering factors are the best of all the available scattering factors for structure

analysis. Recently, Beagley and McAloon[19] discussed the scattering factors for Sn in conjunction with the electron diffraction studies of organotin hydrides. They stated that the Cox and Bonham scattering factors[20] for Sn resulted in anomalously small mean amplitudes for the Sn-C and Sn-H distances, while the scattering factors calculated independently by them and by one of the present authors (M.K.) and his co-workers on the basis of the TFD potential led to a definite improvement in the mean amplitudes, *i.e.*, $l(\text{Sn-C})=0.071\pm0.009$ Å in $(CH_3)_3SnH$ and $l(\text{Sn-H})=0.098\pm0.015$ Å in $(CH_3)_2SnH_2$. It is probable that the $l(\text{Sn-C})$ value proposed by Beagley and McAloon becomes rather small and approaches a theoretical estimate of about 0.05 Å if the (RHFS, HF) scattering factors are used.

Methyl Torsion and Sn-C Distance

The present analysis has ruled out a hindered rotation about the staggered or the eclipsed position with C···H mean amplitudes similar to those in propane. According to NMR[21] and spectroscopic studies,[22] the barriers to hindered rotation in solid $Sn(CH_3)_4$ are 0.46 and 0.8 kcal/mol respectively. There is no available experimental value on the barrier hindering methyl torsion in gaseous $Sn(CH_3)_4$. However, in the discussion of the thermodynamic properties of tetramethyl compounds of the Group IV elements, Staveley *et al.*[23] concluded that the observed rise in the entropy of fusion with an increase in the size of the central atom was due to the release from molecular interlocking when the crystal melted and, consequently, the gain of a greater degree of rotational freedom by the methyl group in the bulky molecule than in the more compact molecules. This suggests that the hindering barrier in gaseous $Sn(CH_3)_4$ is probably lower than the values found in the solid state. Thus, the methyl groups in $Sn(CH_3)_4$ are considered to undergo oscillation with a very low hindering barrier, or a nearly free rotation.

The Sn–C distance determined in the present study, 2.144 ± 0.003 Å, is nearly the same as those observed in alkyltin hydrides, *e.g.*, 2.150 ± 0.003 Å for $Sn(CH_3)_2H_2$ and 2.147 ± 0.003 Å for $Sn(CH_3)_3H$. The Sn–C distances in the $Sn(CH_3)_nH_{4-n}$ molecules ($n=1$—3) are equal to each other. They are, however, longer than the corresponding distances in the $Sn(CH_3)_nCl_{4-n}$ molecules ($n=1$—3), 2.104—2.108 Å,[2] and become shorter in the solid state.[24] These experimental facts pose an interesting problem for the future.

We wish to thank Professor Takao Iijima and Dr. Shigehiro Konaka for their helpful suggestions and discussions throughout this work. The calculations were performed on a FACOM 230—60 of the Computing Center of Hokkaido University and also on a FACOM 270—20 electronic computer in the laboratory of Professor Kimio Ohno, to whom our thanks are also due.

Self-diffusion of a Cation through Cation Exchange Membrane and Membrane Permeability

Kozue KAIBARA, Keiji SAITO,* and Hideo KIMIZUKA

Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812

(Received July 28, 1972)

The self-diffusion coefficient of an ion and the membrane permeability were studied with a system consisting of two identical electrolyte solutions separated by a cation exchange membrane. The membrane permeability to cation was estimated from the membrane conductance data. The result indicated that the membrane permeability increased with a decrease in electrolyte concentration. The self-diffusion coefficients and the concentrations of Na^+, Cs^+, and Ca^{2+} in the membrane were also measured by the radiotracer method. At concentrations less than 0.1 M, the self-diffusion coefficients more or less increased with increasing concentrations, while the concentrations within membrane remained almost constant. The membrane permeability to ion estimated from the conductance data was in excellent agreement with that calculated by the relation in which the membrane permeability is given as the self-diffusion coefficient times the partition coefficient divided by the membrane thickness.

A number of studies, theoretical and experimental, have been carried out on ion transport through membrane. A theory of ion transport across membrane was presented,[1,2] in which an ion flux was shown to be proportional to the difference in electrochemical activities or total activities of the ion in exterior phases. The proportionality coefficient was defined as the membrane permeability to the ion. Equations for the membrane current, conductance and potential could easily be derived from the flux equation and were found to be suitable for an explanation of the electrochemical data of the living cell membranes.[1,2]

The membrane permeability to an ion in equilibrium was expressed as the diffusion coefficient times the partition coefficient divided by the membrane thickness.[3] The present work is aimed at providing an experimental verification for this physical picture of membrane permeability and discussing related phenomena.

Experimental

Materials. A "CK-1, 1.0 t" cation exchange membrane (Asahi Chemical Industry Co., Ltd.) was used. It was conditioned by the ordinary method before use. The membrane consists of homogeneous sulfonated styrene-divinylbenzene copolymer with an ion exchange capacity of 2.8 meq/g dried membrane and water content of 38 percent. The thickness of the membrane was 1.09 mm after equilibration with 1.0 M sodium chloride solution, and remained almost unaltered even when the electrolyte concentration was changed. Radioactive sodium-22, cesium-137, and calcium-45 in chloride form (Japan Radioisotope Association) were used. Inorganic salts of extra pure grade were used without purification.

Measurement of Tracer Flux. The flux measuring cell consists of two compartments I and II of an equal 3 ml volume, separated by a preconditioned membrane with diffusion area 1 cm^2. For the measurement, the compartments were filled with the electrolyte solutions of the same concentration, the non-radioactive solution being introduced into compartment I and the radioactive solution, into compartment II. The radioactivities of the solutions were measured after a given time interval with either an Aloka ND-151D γ-ray scintillation counter or a Beckman LS-100 liquid scintillation counter. Compartments I and II were replaced several times with the radioactive and non-radioactive solutions, respectively, until a stationary tracer flux was attained. This could be observed within several hours.

J_M^*, the stationary tracer flux per unit area of membrane, is related to the self-diffusion coefficient, D_M, and the concentration of the tracer in compartment II, C_M^*, as follows[4]

$$J_M^* = D_M \frac{C_M^m}{C_M^s} \frac{C_M^*}{\delta} \quad (1)$$

where the subscript M refers to the ion M, δ denotes the membrane thickness, and C_M^m and C_M^s are the concentrations of the ion M in the membrane and the two electrolyte solutions, respectively. When the diffusion process is membrane-controlled, D_M should be replaced by[5]

$$D_M = D_M^m \Big/ \left(\frac{C_M^m}{C_M^s} + 1\right) \quad (2)$$

where D_M^m is the true self-diffusion coefficient of the ion M through membrane. Combining Eqs. (1) and (2), we obtain

$$D_M^m = \left(\frac{C_M^s}{C_M^m} + 1\right) \frac{\delta J_M^*}{C_M^*}. \quad (3)$$

Let S be the radioactivity per unit volume of the solution in compartment I with V ml in volume, t the time for permeation, A the membrane area, and S_0 the radioactivity per unit volume of the solution in compartment II. We then have

$$J_M^* / C_M^* = VS/AtS_0. \quad (4)$$

According to Eq. (4), J_M^* / C_M^* can be estimated by measuring S_0 and S/t since V and A are known. Hence D_M^m can be evaluated according to Eq. (3) provided the concentration of the ion M within membrane C_M^m is known.

Measurement of Concentration within Membrane. The membrane with 1 cm square was preconditioned by equilibration with a metal chloride solution of a given concentration and immersed in the 500 ml of the radioactive solution having the same concentration as the preconditioning solution. The membrane was taken out at a given time interval, the

adhering solution being removed with filter paper, and the radioactivity entering the membrane was measured. The sample membrane was then brought back into the radioactive solution. Radioactivity measurements were carried out until an attainment of equilibrium which was within several hours.

The ratio C_M^m/C_M^s at equilibrium can be evaluated according to the following relation

$$\frac{C_M^m}{C_M^s} = \frac{S_0^s - S_\infty^s}{S_\infty^s} \cdot \frac{V^s}{V^m} = \frac{r^s S_\infty^m}{r^m S_\infty^s} \cdot \frac{V^s}{V^m} \qquad (5)$$

where superscripts m and s refer to the membrane phase and the solution phase, respectively, S_0 and S_∞ denote the radioactivity per unit volume at the initial and final states, respectively, V denotes volume, and r specific activity.

Membrane Conductance Measurement. The cell is illustrated in Fig. 1. The membrane conductance was measured with a 4255 A universal bridge and a 4440 B decade capacitor (Yokogawa-Hewlett-Packard, Ltd.). Before the measurement, slow streams of salt solutions were introduced from the solution reservoirs, running through and overflowing the two solution chambers of the cell. Equilibrium was attained within several hours. Mercury was then introduced from the reservoirs so that the salt solutions were pushed out and the solution chambers were filled up with mercury. The bridge was connected to the platinum plugs of the cell and the membrane conductance was measured. The temperature was kept at 20±1 °C.

Results and Discussion

The C_M^m values are plotted against C_M^s in Fig. 2. The concentrations of Na^+ were almost the same as those of Cs^+ within experimental error. The values of C_M^m at external salt concentrations less than 0.2 M were found to be almost constant at 1.7±0.2 M, which is close to the fixed charge density of membrane. Since the external salt concentrations for the measurements of the membrane conductance and the tracer flux were less than 0.1 M, we may regard C_M^m as a constant. The C_M^m increased at higher salt concentrations due to the Donnan effect.

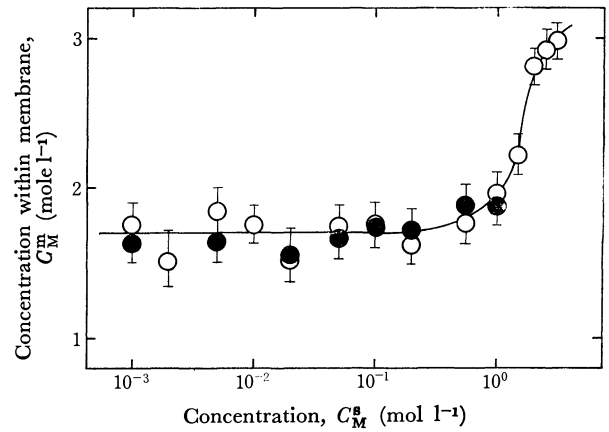

Fig. 2. Cationic concentration within membrane *vs.* external electrolyte concentration curve. The symbols ● and ○ denote C_{Na}^m and C_{Cs}^m, respectively.

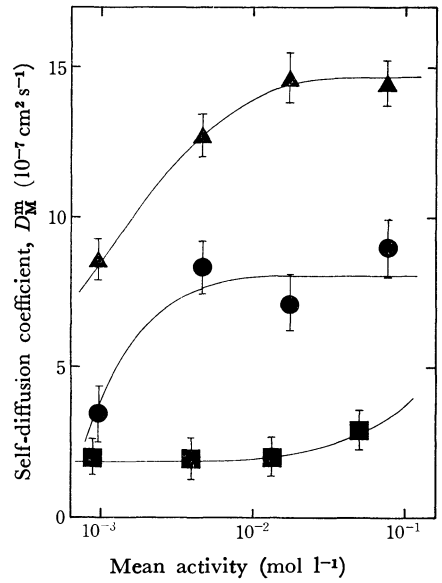

Fig. 3. Self-diffusion coefficient of cation through membrane *vs.* mean activity of salt in the external solution. The symbols ●, ▲, and ■ indicate D_{Na}^m, D_{Cs}^m, and D_{Ca}^m, respectively.

Fig. 3 shows the self-diffusion coefficients of metal ions through the membrane which are less than those in aqueous solution by a factor of the order of 1 or 2. It is seen that D_{Na}^m and D_{Cs}^m are almost constant at higher concentrations of external solutions and decrease at lower concentrations, while D_{Ca}^m is almost constant at lower concentrations and increases at higher concentrations.

The membrane permeability to the ion M, P_M, in equilibrium is related to D_M^m and C_M^m as follows[3]

$$P_M = \frac{D_M^m}{\delta} \frac{C_M^m}{a_M} \qquad (6)$$

where a_M denotes the activity of the ion M in the external solution. Since the quantities on the right-hand side are known, P_M can be calculated.

The results of the membrane conductance measurements are shown in Fig. 4. This figure indicates that

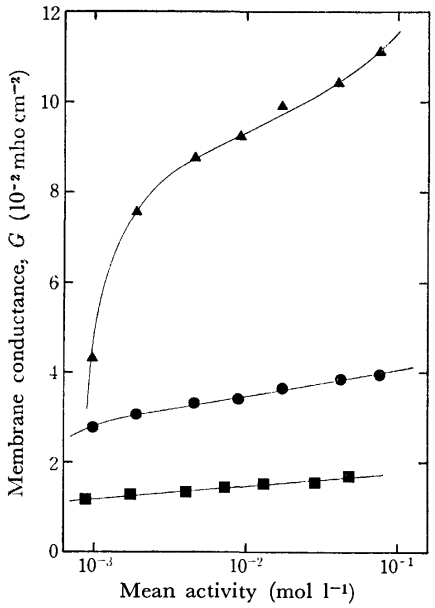

Fig. 4. Membrane conductance *vs.* mean activity of external salt solution. The symbols ●, ▲, and ■ indicate the membrane conductances in the NaCl, CsCl, and $CaCl_2$ system, respectively.

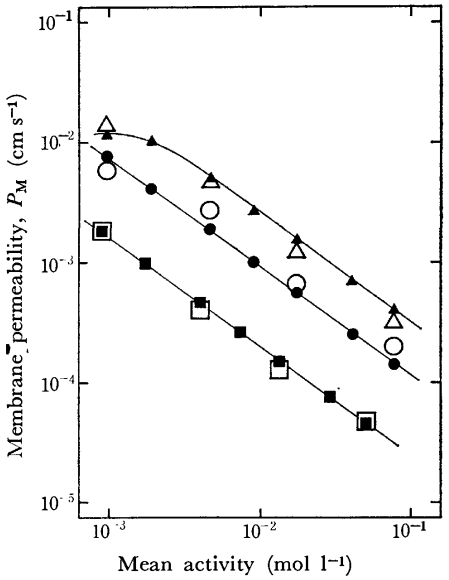

Fig. 5. Memrane permeability *vs.* mean activity of external salt solution diagramms. The symbols ●, ▲, and ■ denote electrochemically estimated P_{Na}, P_{Cs}, and P_{Ca}, respectively, and ○, △, and □, those estmated by tracer method, respectively.

the membrane conductances increase more or less with the increase in the concentration of the external solution. The membrane permeability to cation M can be estimated by the relation[1]

$$G = \frac{Z_M F^2}{RT} P_M a_M \qquad (7)$$

where G denotes the membrane conductance per unit area, Z_M the charge, and F, R, and T have their usual meanings. In Eq. (7), the contribution of an anion to the membrane conductance is ignored since the sample membranes can be regarded as ideally selective for cation permeation.

The values of P_M calculated from the self-diffusion coefficients and the ion concentrations in membrane are compared with those calculated from the conductance data (Fig. 5). The agreement is satisfactory.

Combining Eq. (6) with Eq. (7) we have

$$\delta G = \frac{Z_M F^2}{RT} D_M^m C_M^m = \kappa \qquad (8)$$

where κ denotes the specific membrane conductance. The diffusion coefficients estimated from the conductance data by using Eq. (8) were always greater than those estimated from the tracer diffusion by using Eq. (1).[6] Mackay and Meares[7] attributed this to the contribution due to the electro-osmosis.

From our result it is pointed out that the disagreement was caused by neglecting the correction term indicated by Eq. (2).

Transport Properties of Multi-component Polar Gas Mixtures Containing Mono-, Di-, and Trimethylamines*

P. NASER

Department of Chemistry, Jundi-Shapur University, Ahwaz, Iran

(Received November 11, 1972)

The viscosity and thermal conductivity coefficients of monomethylamine (MMA), dimethylamine (DMA), and trimethylamine (TMA), and their binary mixtures have been measured in the temperature range 25—250 °C. In addition, determinations of thermal conductivity of ternary mixtures at 33 and 88 °C and of several quaternary mixtures (with ammonia) at 33 °C have been made. The results are discussed in the light of modern kinetic theory of gases. Finally, the coefficients of self-diffusion and mutual diffusion in binary mixtures of these gases are estimated from the experimental viscosity results.

In two previous studies[1,2] measurements of the viscosities and thermal conductivities of ammonia-monomethylamine mixtures have been reported. In the present paper, we extend these measurements to di- and trimethylamine and to binary mixtures of these gases with each other and with monomethylamine. In addition, we have made thermal conductivity measurements of some ternary mixtures of the methylamines and of some quaternary ones of these gases with ammonia. No previous studies of the transport properties of di- and trimethylamine or any of the mixtures mentioned have been reported. Furthermore, no previous work seems to have been done on the thermal conductivities of polar gas mixtures containing more than two polar gases except that of Maczek and Gray[3] on mixtures of methyl chloride, sulfur dioxide, and dimethyl ether.

Theoretical Considerations

The interaction between a pair of polar molecules may be expressed by the Stockmayer potential model: $\phi(r)=4\varepsilon[(\sigma/r)^{12}-(\sigma/r)^6+\delta(\sigma/r)^3]$, where $\delta=(\mu^2/4\varepsilon\sigma^3)-\zeta$; μ is the dipole moment, ε and σ are the potential parameters representing the depth of the potential well and the molecular separation at zero interaction distance, respectively; and ζ is a function of the relative orientation of the colliding pair of dipoles. Monchick and Mason[4] have published the collision integrals (averaged over all relative orientations) for this potentail model and have outlined a procedure for obtaining the potential parameters (ε, σ, and $\delta_{max}=\mu^2/2\varepsilon\sigma^3$) from the experimental viscosity data. The Stockmayer model has been extended to polar gas mixtures by Mason and Monchick.[5] Simple standard combining rules, namely, $\sigma_{12}=(\sigma_1+\sigma_2)/2$, $\varepsilon_{12}=(\varepsilon_1\varepsilon_2)^{1/2}$, $\delta_{12}=(\delta_1\ \delta_2)^{1/2}$ are found to be adequate in applying this method to the gas mixtures considered here.

The viscosity of the binary gas mixtures is given by Eq. (8.2—22) of the treaties of Hirschfelder *et al.*[6] The mutual diffusion coefficients and the collision integral ratio $\langle A^*_{12}\rangle$ which appear in this equation were calculated from the tabulated collision integrals in conjunction with the above combining rules. The viscosity and the self-diffusion coefficients can be obtained from the rigorous kinetic theory expressions.[6] The self-diffusion coefficients of a pure gas can also be obtained from the relation[7,8]

$$D_{11} = (6/5)(RT/p)(\eta/M)\langle A^*_{11}\rangle, \qquad (1)$$

where R is the gas constant, T is the absolute temperature, p is the pressure, η is the viscosity coefficient, and M is the molecular weight. The values of the collision integral ratio $\langle A^*_{11}\rangle$ are very insensitive to the particular potential model chosen and to the temperature; thus Eq. (1) is essentially dependent on the gas viscosities.

Apart from the empirical or the semi-empirical methods, the mutual diffusion coefficients can be calculated from the rigorous kinetic theory expression,[6] or can be obtained from the experimental viscosities of the binary gas mixtures according to the relation due to Weissman and Mason.[7,8] This relation is analogous to Eq. (1), but involves solution of a quadratic equation in pD_{12} whose coefficients involve functions of mole fractions, molecular weights of pure gases, viscosity of the gas mixture, and collision integral ratio $\langle A^*_{12}\rangle$.

For the pure gases it is customary to express the thermal conductivity in terms of the dimensionless Eucken factor $f=\lambda M/\eta C_v$, where λ is the thermal conductivity coefficient, M is the molecular weight, η is the viscosity coefficient, and C_v is the constant volume molar heat capacity. Rigorous theory and the experiment both show that f has a value close to 2.5 for the structureless gases.[9] For polyatomic gases, however, f is less than 2.5. Eucken[10] thus proposed

a simple correction: $f_E=1+(9/4)(R/C_v)$. Later, a modified Eucken formula was suggested which was based on a diffusion mechanism theory:[11] $f_{ME}=(\rho D_{11}/\eta)+(3/2)[(5/2)-(\rho D_{11}/\eta)]\ (R/C_v)$, where ρ is the density of the gas and other symbols have been previously defined. Finally, Mason and Monchick[12] have suggested a second approximation which is based on the formal kinetic theory of gases: $f_{MM}=f_{ME}-(2/\pi C_v)-[(5/2)-(\rho D_{int}/\eta)]^2\ (C_{int}/Z_{int})$, where D_{int} is the diffusion coefficient for the diffusion of the internal energy, C_{int} is the internal contribution to C_v, and Z_{int} is the collision number for relaxation of the internal modes of energy. Essentially, the only internal mode of energy for small gaseous molecules at ordinary temperatures is the rotational mode, since the vibration excitation is very small. Therefore, C_{int} may be taken as $(3/2)R$ for non-linear molecules. Z_{int}, which by the same token would be taken as Z_{rot}, can be best treated as an adjustable parameter in correlating this theory with the experimental data. D_{int}, finally, is the ordinary self-diffusion coefficient corrected for the resonant exchange of the rotational quanta of energy.

For the thermal conductivity of multi-component gas mixtures the Hirschfelder-Eucken equation may be used: $\lambda_{mix}=(\lambda_{mix})_{tr}+(\lambda_{mix})_{int}$. $(\lambda_{mix})_{tr}$ is the first approximation of the thermal conductivity of a gas mixture containing several monatomic components and is expressed by a ratio of two determinants, which is given by Eq. (8.2-43) of Ref. 6. The complication of the evaluation of this equation, however, is twofold. In fact not only must one solve a $(2n+1)\times(2n+1)$ and a $(2n)\times(2n)$ determinant for an n-component mixture, but also each of the elements of these determinants is very complicated. Mason[13] and Muckenfuss and Curtiss[14] have derived simpler formulas with the same degree of rigor as the original one. In this study we have considered Mason's, *i.e.*,

$$(\lambda_{mix})_{tr}=4\begin{bmatrix} L_{11} & \cdots & L_{1n} & x_1 \\ \vdots & & \vdots & \vdots \\ L_{n1} & \cdots & L_{nn} & x_n \\ x_1 & \cdots & x_n & 0 \end{bmatrix}\begin{bmatrix} L_{11} & \cdots & L_{1n} \\ \vdots & & \vdots \\ L_{n1} & \cdots & L_{nn} \end{bmatrix}^{-1} \quad (2)$$

where,

$$L_{ii}=\frac{-4x_i^2}{[\lambda_i]_1}-\frac{16T}{25p}\times\sum_{\substack{k=1\\k\neq i}}\frac{x_ix_k[(15/2)M_i^2+(5/2)M_k^2+4M_iM_kA_{ik}^*]}{(M_i+M_k)^2[D_{ik}]_1}, \quad (3)$$

and,

$$L_{\substack{ij\\(i\neq j)}}=\left(\frac{16T}{25p}\right)\frac{x_ix_jM_iM_j(10-4A_{ij}^*)}{(M_i+M_j)^2[D_{ij}]_1}, \quad (4)$$

where $[\lambda_i]_1$ and $[D_{ij}]_1$ are the first approximations to the thermal conductivity and the mutual diffusion coefficients, respectively, and M_i and X_i are the molecular weight and the mole fraction of the component i, and other terms have their ordinary meanings. $(\lambda_{mix})_{int}$ in the Hirschfelder-Eucken expression is the contribution of the internal modes to the thermal conductivity coefficient and is given by:[15]

$$(\lambda_{mix})_{int}=\sum_i\lambda_{int\,i}\left[1+\sum_{i\neq j}\frac{D_{ii,int}x_j}{D_{ij,int}x_i}\right]^{-1}, \quad (5)$$

where $\lambda_{int,i}=\lambda_{expt,i}-[\lambda_i]_1$, and $D_{ii,int}$ is the self-diffusion coefficient of internal energy which has been equated to the ordinary diffusion coefficient by Hirschfelder.[15] $D_{ij,int}$ corresponds, accordingly, to the mutual diffusion coefficient of internal energy.

Among the several empirical formulas which have been put forward for the thermal conductivity of the mixtures, we have considered the better-know Wassiljewa equation:[16]

$$\lambda_{mix}=\sum_i\lambda_i\sum_{i\neq j}\left[1+A_{ij}\frac{x_j}{x_i}\right]^{-1}. \quad (6)$$

In the above equation λ_i is the experimental thermal conductivity coefficient of the component i. The Wassiljewa coefficients, A_{ij}'s, can be calculated from the Lindsay-Bromley approximation:[17]

$$A_{ij}=\frac{1}{4}\left[1+\left\{\frac{\eta_i}{\eta_j}\left(\frac{M_i}{M_j}\right)^{3/4}\frac{T+S_i}{T+S_j}\right\}^{1/2}\right]^2\left(\frac{T+S_{ij}}{T+S_j}\right), \quad (7)$$

where S_i is the Sutherland's coefficient (Ref. 6, p. 550) and $S_{ij}=(S_iS_j)^{1/2}$, and other symbols have their usual meanings. It will be discussed later that the use of Eqs. (2) and (5) is justified by the theoretical studies of Monchick *et al.*,[18] and by the previous experimental studies.[2,19]

Experimental

The apparatus used in the viscosity and in the thermal conductivity measurements have been described previously by Chang *et al.*[19] The viscometer was a constant volume type employing the capillary transpiration method. The thermal conductivities were measured with a "potential leads" hot wire type cell. In both cases the apparatus were placed in an oil bath and in a furnace for the measurements below and above 150 °C, respectively. The temperature could be controlled to within 0.2 °C in the lower temperature ranges and to within 0.5 °C in the higher ones. The gases were supplied by the Matheson Company (minimum purities: NH_3, 99.9%; CH_3NH_2, 98.0%; $(CH_3)_2NH$, 99.0%; $(CH_3)_3N$, 99.0%). The gas mixtures were prepared in the usual way.[1,2,19] Heat capacity data were obtained from Kobe and Harrison.[20] The computations were carried out at the Yalem Computer Center of St. Louis University using a CDC 3300 computer.

Temp (°C)	DMA		TMA	
	λ (exptl)	λ (calc)	η (exptl)	η (calc)
37.0	3.57	4.68	3.44	4.28
88.0	5.30	6.00	4.96	5.46
133.0	6.85	7.12	6.40	6.58
188.0	8.70	8.85	8.12	8.01
237.0	10.66	10.37	9.80	9.36

are presented. Table 2 contains the corresponding thermal conductivities. In both cases the experimental data have been corrected appropriately for "slip" (in the case of viscosity) and "temperature jump" (in the case of thermal conductivity).

The Stockmayer potential parameters were found to be:

(i) for $(CH_3)_2NH$: $\sigma=5.09$ Å, $\varepsilon/k=191$ K, and $\delta_{max}=0.14$

(ii) for $(CH_3)_3N$: $\sigma=6.25$ Å, $\varepsilon/k=85$ K, and $\delta_{max}=0.065$.

The quoted values of λ_{MM} were found, as mentioned before, by treating Z_{rot} as an adjustable parameter, and then using their averaged values in the expression of f_{MM}. The averaged values were found to be 1.99 and 0.67 for dimethylamine and trimethylamine, respectively. We could have arrived at better agreement between λ_{exp} and λ_{MM} if we were using different values of Z_{rot} at each temperature. However, the extreme sensitivity of Z_{rot} to f_{exp} would make such a treatment rather unreliable. To account for the resonant exchange of rotational energy, we have employed the values of the moments of inertia[21] with other necessary constants in the appropriate formulas.[12] We have treated dimethylamine as a "prolate top" and trimethylamine as an "almost spherical top". We have found that the correction is indeed negligibly small for both gases (less than 0.01 per cent).

The self-diffusion coefficients were predicted by using the kinetic theory expression and the Eq. (1), as mentioned previously. No experimental self-diffusion data are available for comparison purposes. However, these predictions are generally quite reliable.[8] In the case of gaseous ammonia, the earlier predictions of the self-diffusion coefficient by Burch and Raw[1] were found later to be in excellent agreement with the experimental results of Baker.[22] The predicted values of the self-diffusion coefficients of di- and trimethylamines are presented in Table 3.

other, and this difference was in order of the experimental uncertainties of the viscosity measurements (1%). The mutual diffusion coefficients of ammonia–dimethylamine and ammonia–trimethylamine mixtures, at 33 °C, were found to be 0.129 cm^2 s^{-1} and 0.111 cm^2 s^{-1}, respectively, according to the kinetic theory. The corresponding value for ammonia–monomethylamine mixture was extrapolated from the results of Burch and Raw.[1] These values were used in the Hirschfelder-Eucken formula for the theoretical calculations of the thermal conductivities of the quaternary mixtures. The agreement between the experimental and the predicted values of viscosities, as well as the predicted values of diffusion coefficients by the kinetic theory and the Mason-Weissman expressions, confirms the adequacy of the Stockmayer potential parameters and the simple combining rules. The thermal conductivities of the multi-component mixtures were estimated by the Hirschfelder-Eucken expression. As indicated before, $[\lambda_{tr}]_{mix}$'s were found according to the expression suggested by Mason. In all cases the self diffusion coefficients, D_{ii}, and the mutual diffusion coefficients, D_{ij}, were taken as the internal diffusion coefficients. $D_{ii,int}$ and $D_{ij,int}$, respectively. Although well-established corrections are available for the self-diffusion coefficients, no such corrections has been suggested for $D_{ij,int}$. Writing this correction as δ_{ii}, according to the notation used by Mason and Monchick,[12] then the assignment of $\delta_{ij}=(\delta_{ii}+\delta_{jj})/2$ is as good an empirical guess as any. Nevertheless, these corrections would be negligibly small for the present investigation. The corrections for inelastic collisions applied to the Hirschfelder-Eucken formula come with the use of the experimental thermal conductivities of the pure gases. By using such values, account would be taken of the inelastic as well as the resonant collisions. These considerations are justified by the theoretical studies of Monchick *et al.*,[18] and by the previous experimental measurements.[2,19]

The thermal conductivity coefficients of the binary and the ternary mixtures are also estimated by the Wassiljewa equation. The Wassiljewa coefficients, as obtained from the Lindsay-Bromely relation, are presented in Table 6. As may be seen from this table,

for a given pair of gas molecules i and j, $A_{ij}>A_{ji}$. It has been shown[23] that for a given pair of gas molecules, A_{ij} depends on the ratio $(\sigma_i/\sigma_j)^2$ and on a power less than unity of the mass ratio. For all the cases studied in this work, as may be noted, $\sigma_i>\sigma_j$ and $M_i>M_j$.

The thermal conductivity coefficients of the multi-component mixtures are presented in Tables 7, 8, and 9. As may be seen, the agreement between the theories and the experiment is generally quite good and is

within the range of the experimental uncertainties of the measurements (2%). At the higher temperatures, however, the Hirschfelder-Eucken method seems to be the superior one.

It may be mentioned, finally, that we could have arrived at a much better agreement between the experiment and the Wassiljewa extimations by treating the Wassiljewa coefficients as adjustable parameters. This may be done by employing the experimental quantities in the Wassiljewa expression and then carrying out a full computer search to find the "best" pairs of A_{ij}'s. However, more experimental data on the thermal conductivities of the gas mixtures would be needed in order to make a thorough evaluation of such a treatment.

The author would like to express his deep gratitude to Professor C.J.G. Raw of the Chemistry Department of St. Louis University for continual encouragement of this work and for invaluable suggestions and criticism. He is indebted to the Graduate School of St. Louis University for financial support during his graduate study. He is also grateful to Miss Lucia Plese for her assistance in independent measurements of some of the gas viscosities reported in Tables 1 and 5.

Determination of Electrochemical Kinetic Parameters of Porphyrins and Metalloporphyrins in *N,N'*-Dimethylformamide by Radio Frequency Polarographic Method

Tadaaki KAKUTANI and Mitsugi SENDA

Department of Agricultural Chemistry, Faculty of Agriculture, Kyoto University, Kyoto 606

(Received June 22, 1973)

Electrochemical kinetic parameters were determined for the first two reduction steps of some porphyrins and divalent metalloporphyrins in DMF containing 0.5 M TEAP at 25 °C by use of radio frequency polarographic method. The results were discussed in view of their molecular structures and the diffuse double layer effect on the kinetic parameters.

It has been found [1-4] that in aprotic solvent such as dimethylformamide(DMF) porphyrins and their divalent metal complexes give three or four well-defined reduction waves, of which the first two are in general reversible one-electron reduction steps with negligible complications by specific adsorption. The products produced at the first two steps have been found to be reasonably stable. These findings have made it possible to study the electrode kinetics of these compounds in quantitative way.

In this study the kinetic parameters for the first two reduction steps of some porphyrins and divalent metal complexes in DMF were determined by use of the radio frequency polarographic method.[5-8] The results were discussed in view of their molecular structures and the diffuse double layer effect on the kinetic parameters.

Experimental

Materials: Protoporphyrin IX dimethylester (PPDM), mesoporphyrin IX dimethylester(MPDM), Cu(II)-PPDM, Ni(II)-PPDM, Co(II)-PPDM, Zn(II)-PPDM and Mn(III)-Cl·H_2O-PPDM were prepared and purified by previously described methods.[4] The supporting electrolyte, tetraethylammonium perchlorate(TEAP), was prepared and purified as described elsewhere.[9] The solvent, DMF, was purified as described previously.[4]

Electrochemical Measurements. Conventional DC polarograms and square wave polarograms were measured with a Yanagimoto polarograph PF-500 and auxiliary potentiometer. The Faradaic rectification current at the DME or the radio frequency polarographic current was measured also with a Yanagimoto polarograph PF-500 equipped with a laboratory-made RF (0.05 to 2 MHz) generator and appropriate low-pass filter circuits, using the square wave amplitude modulation technique developed by Barker.[5] Differential capacity was measured with a Grahame's AC bridge at 1 kHz.[10]

The polarographic cell was described elsewhere.[4] All potential measurements were made with respect to an aqueous saturated calomel electrode (SCE). The capillary characteristics were $m=1.07_8$ mg/s and $t=5.8$ s at $h=70$ cmHg in DMF containing 0.1 M TEAP at -0.5 v *vs.* SCE.

When the RF and SW polarographic currents were measured, the drop time was controlled by an electro-mechanical synchronizer and the RF current pulse or SW voltage pulse was applied to the DME at the last stage of a drop life, usually from $t=2.0$ to 3.0 s. Measurements were carried out, under dried nitrogen atmosphere, usually with nearly saturated solution(approx. 4×10^{-4} M, but for Cu(II)-complex approx. 2×10^{-4} M) of porphyrins or metalloporphyrins in DMF containing 0.5 M TEAP at 25 ± 0.1 °C. Under the conditions total cell resistance varied from 200 to 300Ω depending on drop area.

Results

As described in the previous work,[4] the first two reduction steps of PPDM, MPDM, Cu(II)-PPDM, Ni(II)-PPDM, and Zn(II)-PPDM and the second reduction step of Co(II)-PPDM and Mn(III)Cl-H_2O-PPDM are characterized by simple one-electron transfer reaction. Furthermore, for these steps the specific adsorption seems to have no or little effect on the electrode processes. Accordingly we applied the Faradaic rectification method to determine the kinetic parameters of the electrode charge transfer reactions of these reduction steps.

Determination of Kinetic Parameters. Computation of the kinetic parameters, *i.e.*, the (measured) rate constant of charge transfer at the standard redox potential, k_{sm}, and the (measured) transfer coefficient, α_m, was based on analysis of the rectification voltage, $\Delta\bar{E}_\infty$, or $\psi(=4RT\Delta\bar{E}_\infty/nFV_A^2)$ against applied DC potential, E_{DC}, curves,[7,8] where n is the number of electrons involved per reacting molecule or ion, F the Faraday, R the gas constant and T the absolute temperature. The rectification voltage was evaluated by the comparison method, *i.e.*, by comparison of RF

polarographic current at a given E_{DC} with SW polarographic current at the same E_{DC}, with the same and one electrolysis solution. V_A is the amplitude of RF voltage applied to the electrode interface and was caluclated from the differential double layer capacity which was measured with DMF solution containing only a supporting electrolyte and the amplitude of RF current pulse applied to the electrode interface. ψ *vs.* E_{DC} curves were obtained at several frequencies, *i.e.*, 0.05, 0.1, 0.25, 0.5 and 1.0 MHz. The diffusion coefficient of PPDM was estimated by Ilković equation to be 3.7×10^{-6} cm^2/s, and this value was employed for all porphyrin compounds studied here. It was also assumed that the neutral molecule, the monoanion radical, and the dianion possesed equal diffusion coefficient.

Figure 1 shows the first two steps of MPDM as observed by DC, SW, and RF polarography, and Figs. 2 and 3 show ψ–E_{DC} curves of the first and second steps, respectively.

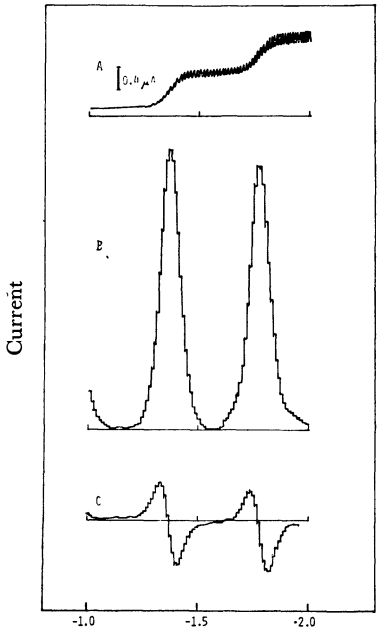
According to the theory,[7] the rectification voltage for a simple charge transfer reaction (O+ne=R) may be represented by

$$\psi = \frac{4RT}{nFV_A^2}\Delta\bar{E}_\infty = (2\alpha_m-1) + \left[(1-2\alpha_m) + \frac{P-1}{P+1}\right]F(\xi) \quad (1)$$

where

$$F(\xi) = \frac{2\xi^2+\xi}{2\xi^2+2\xi+1}, \quad (2)$$

$$\xi = \frac{k_{sm}}{\sqrt{2\omega D}}(1+P)P^{-\alpha_m}, \quad (3)$$



E_{DC} (V *vs.* SCE)

Fig. 3. ψ–E_{DC} curves of the second step of MPDM in DMF containing 0.5 M TEAP at 25 °C. Radio frequency: ⊙: 0.1 MHz; ◑: 0.5 MHz; ●: 1.0 MHz.

$$P = \exp\left[\frac{nF}{RT}(E_{DC}-E_{1/2})\right], \quad (4)$$

$\omega=2\pi f$, f is the frequency of the applied RF voltage, and $D=(D_R)^{\alpha_m}(D_O)^{1-\alpha_m}$, D_R and D_O are the diffusion coefficients of R and O, respectively. When the rectification voltages were measured at several frequencies, all ψ–E_{DC} curves intersect at a single point having the ordinate and abscissa given by

$$\psi = (2\alpha_m - 1), \quad (5)$$

and

$$\tanh\left[\frac{nF}{2RT}(E_{DC}-E_{1/2})\right]=(2\alpha_m-1)\,. \qquad (6)$$

respectively. Thus we can calculate the parameter α_m in two ways from the coordinates of the intersection point. As predicted from the theory, the experimental curves in Fig. 2 and Fig. 3 exhibit single intersection point in each case. From their coordinates one calculates $\alpha_m=0.5$(abscissa) and $\alpha_m=0.5$(ordinate) for the first step, and $\alpha_m=0.38$(abscissa) and $\alpha_m=0.37$(ordinate) for the second step. Two values of α_m calculated from the coordinates agreed to within ±0.02 for all compounds studied here.

After α was determined in this way, k_{sm} was calculated by either one of the following two methods: 1) when α_m is between 0.4, and 0.6, k_{sm} was estimated from the $\psi_{0.1}/\psi_{1.0}$ ratios at several E_{DC}'s, where $\psi_{0.1}$ and $\psi_{1.0}$ are the ψ values measured at 0.1 and 1.0 MHz, respectively, or 2) when α is larger than 0.6 or smaller than 0.4, k_{sm} was calculated from the values of E_{DC} at $\psi=0$ for each frequency. Such calculations will give several values of k_{sm} for each charge transfer step and these values are expected to be constant if such a simple theory is applicable to the analysis of the present results. Thus we obtained, for example, for the first step of MPDM, $k_{sm}=3.8$(calculated from $\psi_{0.1}/\psi_{1.0}$ at $p=4$), 3.9 ($p=2$), 3.6($p=1/2$), or 3.7 cm/s ($P=1/4$), and for the second step, $k_{sm}=1.14$(calculated from E_{DC} at $\psi=0$ ofr 0.1 MHz), 1.45 (0.5 MHz) or 1.44 cm/s (1 MHz). Namely, the values of k_{sm} were reasonably constant for each step (within $\pm10\%$). The variance of k_{sm}'s for other compounds studied here was also of the same order of magnitude as that of MPDM. The polarographic results and the kinetic parameters of porphyrins and metalloporphyrins examined in this study are summarized in Table 1.

Discussion

As described previously,[4] the first and second steps of Ni(II)-PPDM, Cu(II)-PPDM and Zn(II)-PPDM as well as PPDM and MPDM are believed to be successive additions of one electron to the porphyrin ring of the complexes. The second step of Mn(III)Cl-H_2O-PPDM is supposed also to be an addition of one electron to the porphyrin ring of Mn(II)-complex. The third wave of Mn(III)-complex is not sufficiently reproducible to give reliable kinetic data. The first step of Co(II)-complex, being assigned[4] to one-electron addition to metal-centered orbital, was complicated by specific adsorption, so that significant kinetic data were not observed.

The kinetic data are characterized as follows. For all compounds studied, the measured rate constants of the first reduction step ($R+e=R^{-}$), $k_{sm}(1)$, are larger than that of the second reduction step($R^{-}+e=R^{2-}$), $k_{sm}(2)$. The measured transfer coefficients of the first step, $\alpha_m(1)$, are close to 0.5, and those of the second step, $\alpha_m(2)$, are between 0.3 and 0.4.

For the series of compounds, a decreasing tendency of k_{sm}'s with negative shift of half-wave potentials was found, with a few exceptions. The kinetic parameters given in Table 1 are apparent values uncorrected for double layer effects, but calculation showed that this tendency was significant after the double layer correction(see Table 2). As stated in previous paper,[4] the negative shift of the reduction potentials in the series may be correlated with the order of increasing negative charge in the porphyrin ring,[11] that is, with an increase in the non-uniformity of charge distribution in the depolarizer molecule. Similar correlation of the rate constants with molecular structures was first found for a series of nitro-compounds by Peover and Powell,[12] who attributed this phenomenon to the non-uniform distribution of charge in the anion radicals derived from the nitro-compounds. Similar experimental results for substituted nitrobenzenes were confirmed also by the present authors.[13] Therefore, it is likely that the change of rate constants for the series of porphyrin compounds would again be interpreted in terms of Marcus-Hush's theory, *i.e.*, by the difference in the electrostatic solvent reorganization energy, as proposed by Peover and Powell. It is noted, however, that the decreasing of the rate constants with the negative shift of half-wave potentials is less pronounced in the case of the porphyrin compounds than the nitro-compounds. This would be due to the difference in electrostatic solvation energy, which arises from the difference in molecular size between the porphyrin compounds and

the nitro-compound.

Results in Table 1 show that the measured rate constants of the negative ion reductions are about an order of magnitude smaller than those of the neutral molecule reductions. The measured rate constant, k_{sm}, is related to the true rate constant, k_s, by[14]

$$k_s = k_{sm} \exp\left[-(\alpha_m n - z)\frac{F}{RT}\phi\right],$$

where ϕ is the potential at the pre-electrode site relative to the solution and z is the charge on the oxidized from. Table 2 shows the potential values of the outer Helmholtz plane at the half-wave optentials of the first and second steps, $\phi_0(1)$ nad $\phi_0(2)$, being calculated from Gouy-Chapman theory on the assumption that no specific adsorption of the supporting electrolyte ions occurs. Also shown are some calculated values of Frumkin correction factor, $f[\phi]=\exp[-(\alpha_m n-z)F\phi/RT]$; $f[\phi_0(1)]$ and $f[\phi_0(2)]$ are calculated on the assumption that the pre-electrode site is the outer Helmholtz plane, whereas $f[\phi_0'(1)]$ and $f[\phi_0'(2)]$ are calculated on the assumption that it is located 2 Å out of the outer Helmholtz plane, where the ϕ_0' potentials are about 50 per cent of ϕ_0. It will be reasonable to suppose that the pre-electrode sites are much the same for the anion reduction at the neutral molecule reduction. Accordingly, if we admit the prediction[15] of about the same true rate constants for anion reduction as the neutral molecule reduction, we may conclude that the pre-electrode site is likely located about 2 Å or further out of the outer Helmholtz plane. Similar results have also been obtained for aromatic compounds by Peover.[15] However, the measured transfer coefficients of the anion reductions are significantly different from those of the neutral molecule reductions, suggesting that the charge transfer mechanisms are very different for these two reductions. It is noted that the presence of homogeneous chemical reaction following the charge transfer predicts an increase of the measured transfer coefficient.[8] Stronger repulsive effect (Levich correction)[8] for the form also predicts an increase in the measured transfer coefficient. These arguments lead to another supposition that the true rate constants are not necessarily the same for the anion reduction as the neutral molecule reduction. Theories of Marcus[16] and Hush[17] seem to predict that the electrostatic solvent reoganization energy may depend upon the transfer coefficient. As to the location of pre-electrode site, closer approach to the electrode surface may be understandable by imagining the reacting depolarizers at the size with their porphyrin ring planes parallel to the electrode surface. Conclusive interpretation can not be given at present. Further study is in progress.

This work was partly supported by a grant from the Ministry of Education, to which the authors' thanks are due.

A Study on Spontaneous Resolution of Cobalt(III) Complex Salts

Kazuaki YAMANARI, Jinsai HIDAKA, and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 22, 1973)

Solubility of the racemic and optically active isomers of $[Co(ox)en_2]X$, $[CoCO_3en_2]X$, *cis*-$[Co(NO_2)_2en_2]X$ and $M[Co(edta)]$ in water was determined at 5—60 °C (X=Cl, Br, and I; M=NH_4 and K). The correlation between solubility of the spontaneously resolved racemic complex and of the corresponding optically active isomer is discussed. Spontaneous resolutions were observed for $[Co(ox)en_2]X$ (X=Cl, Cl·H_2O, and Br·H_2O), *cis*-$[Co(NO_2)_2en_2]X$ (X=Cl and Br) and $M[Co(edta)]\cdot 2H_2O$ (M=NH_4 and K).

It is believed that so-called spontaneous resolution can be observed in limited cases. Only some dozen metal complexes have been reported to be spontaneously resolved.[1-8] It is evident that solubility plays an extremely important role in spontaneous resolution and related phenomena such as optical resolution by the formation of diastereomer or so-called configurational activity.[9-11] Systematic investigation of solubility of metal complexes is necessary for an explanation of these phenomena; nevertheless, only a few reports have been published so far. The present paper deals with the solubility and spontaneous resolution of (1 : 1) electrolyte salts containing configurationally chiral cobalt(III) complexes.

Experimental

Preparation and Resolution. *(1) Bis(ethylenediamine)-oxalatocobalt(III) Complex, $[Co(ox)en_2]X$, (X=Cl^-, Br^-, and I^-)*: The chloride salt was prepared and resolved by the method of Dwyer *et al.*[12] The racemic and optically active bromides or iodides were obtained by adding a calculated amount of NH_4Br or NH_4I to an aqueous solution of the corresponding chloride. The spontaneous resolution of monohydrated bromide salt was observed for the rhombic crystals prepared as follows: about 0.7 g of the racemic bromide monohydrate was dissolved in 50 ml of water at 50 °C and the solution was kept standing in refrigerator (at about 5 °C) for several days for crystallization.

(2) cis-*Bis(ethylenediamine)dinitrocobalt(III) Complex, cis-$[Co(NO_2)_2en_2]X$, (X=Cl^-, Br^-, and I^-)*: The nitrite salt *cis*-$[Co(NO_2)_2en_2]NO_2$ was prepared by the reaction of *trans*-$[CoCl_2en_2]Cl$ (20 g) and KNO_2 (20 g) in 100 ml of water at 50 °C and optically resolved by the method of Dwyer and Garvan.[13] The chloride and iodide salts were derived from the bromide by treating with AgCl and AgI, respectively. Crystallization was carried out as follows: 1.5 g of the racemic chloride (0.5 and 0.2 g of the bromide and iodide, respectively) was dissolved in 20 ml of water at 40 °C and the solution was kept standing in a refrigerator (at about 5 °C) for several days.

(3) Carbonatobis(ethylenediamine)cobalt(III) Complex, $[Co-CO_3en_2]X$, (X=Cl^-, Br^-, and I^-): Racemic chloride salt was prepared by Werner's method[14] and racemic bromide or iodide salt was obtained by adding an appropriate amount of NH_4Br or KI to an aqueous solution of the chloride. Optically active chloride and bromide salts were derived from the active iodide, which was resolved by the method of Dwyer *et al.*,[15] by treating with the corresponding silver halides.

(4) Ethylenediaminetetraacetatocobaltate(III) Complex, M-[Co(edta)], (M=K^+ and NH_4^+): The potassium salt dihydrate was prepared and resolved by the method of Dwyer and Garvan.[16] The ammonium salt was similarly obtained by using ammonium acetate instead of potassium acetate. The desired crystals of potassium and ammonium salts were gradually crystallized from the solution containing 6 g of potassium salt (5 g for ammonium salt) in 10 ml of warm water (50 °C) by being kept standing at room temperature.

Measurements. Solubility measurements were carried out spectrophotometrically with a Beckman DU spectrophotometer at 5—60 °C. Saturation equilibrium of solutions was attained in an Erlenmeyer flask, which was maintained in a thermostat regulated within ±0.1°C. An aqueous solution containing an excess of solid complex salt in the flask was stirred mechanically at the desired temperature and the resulting saturated solution was sampled by sucking up with a pipet through a filter. The sample solution was weighed exactly, diluted to an appropriate volume and its optical density was measured at the maximum wavelength of the first absorption band of the complex. To detect the occurrence of spontaneous resolution, the crystal of racemic complex was arbitrarily chosen and dissolved in a small amount of water, and the optical rotatory dispersion (RD) curve was measured with a Yanagimoto recording spectropolarimeter model-187.

General Consideration

The correlation between solubility of the racemic compound and of the corresponding optically active isomers has not been discussed by means of an explicit formula except for some qualitative treatment using phase

diagrams.[17,18] Racemic complexes are classified into two groups on the basis of the mode of crystallization. In the first group, a racemic complex forms racemic crystals, the unit cell of which contains an equal number of the Δ and Λ enantiomeric complexes. In the second group, a racemic complex forms a racemic mixture, which is a mixture of the pure Δ and Λ crystals. The latter case has been named the spontaneous resolution.

The solubility product (K_{SP}) for an optically active (Δ, for example) complex salt of the $[M]^+X^-$ type[19] at t °C is given by

$$K_{SP}^{\Delta} = \{[M]^+\}_{\Delta} \cdot \{X^-\} = S_{\Delta} f_{[M]}^{\Delta} \cdot S_{\Delta} f_X^{\Delta} = (S_{\Delta})^2 \cdot f_{[M]}^{\Delta} f_X^{\Delta} \quad (1)$$

where $\{[M]^+\}$ and $\{X^-\}$ denote the activities of the complex cation and the counter simple anion, respectively, S_{Δ} the molar solubility of the optically active Δ salt, and $f_{[M]}^{\Delta}$ and f_X^{Δ} the activity coefficients of the complex cation and the counter anion, respectively. If the spontaneous resolution occurs for the corresponding racemic complex salt, the solubility product for the Δ isomer in the racemic mixture, $K_{SP}^{\Delta(\Delta\Lambda)}$, is represented as follows, since the Δ isomer in the racemic mixture behaves independently of the Λ isomer.

$$K_{SP}^{\Delta(\Delta\Lambda)} = K_{SP}^{\Lambda(\Delta\Lambda)} = \{[M]^+\}_{\Delta \text{ or } \Lambda} \cdot \{X^-\} = \frac{1}{2} S_{\Delta\Lambda} f_{[M]}^{\Delta\Lambda} \cdot S_{\Delta\Lambda} f_X^{\Delta\Lambda} = \frac{1}{2} (S_{\Delta\Lambda})^2 \cdot f_{[M]}^{\Delta\Lambda} f_X^{\Delta\Lambda} \quad (2)$$

where $f_{[M]}^{\Delta\Lambda}$ and $f_X^{\Delta\Lambda}$ denote the activity coefficients of the complex cation and the counter anion in the racemic solution, respectively. Since the relation $K_{SP}^{\Delta} = K_{SP}^{\Delta(\Delta\Lambda)}$ should hold, we have

$$S_{\Delta\Lambda} = \sqrt{2}\, S_{\Delta} (f_{[M]}^{\Delta} \cdot f_X^{\Delta})^{1/2} / (f_{[M]}^{\Delta\Lambda} \cdot f_X^{\Delta\Lambda})^{1/2} \quad (3)$$

Thus, if we assume an ideal solution, the solubility of a spontaneously resolved racemic complex salt of the $[M]^+X^-$ type must be $\sqrt{2}$ times larger than that of the corresponding optically active complex salt. Activity coefficients decrease in most cases with increasing ionic strength in the concentration range 10^{-3}—10^{-1} mol/l. Since the spontaneously resolved racemic complex salt is more soluble than the active isomers, we have $f_{[M]}^{\Delta\Lambda} < f_{[M]}^{\Delta}$ and $f_X^{\Delta\Lambda} < f_X^{\Delta}$. Therefore, Eq. (3) shows that *the solublity of the spontaneously resolved racemic salt of the $[M]^+X^-$ type is $\sqrt{2}$ or more times larger than that of the corresponding optically active salt.*

The treatment can be extended to other types of complex electrolytes and to the complex molecule also. For the $[M]^{n+}(X^-)_n$ type we obtain

$$S_{\Delta\Lambda} = \sqrt[n+1]{2}\, S_{\Delta} (f_{[M]}^{\Delta} \cdot f_X^{\Delta})^{1/(n+1)} / (f_{[M]}^{\Delta\Lambda} \cdot f_X^{\Delta\Lambda})^{1/(n+1)} \quad (4)$$

and for the complex molecule

$$S_{\Delta\Lambda} = 2 S_{\Delta} (f_{[M]}^{\Delta} / f_{[M]}^{\Delta\Lambda}) \quad (5)$$

In the case of true racemic crystal, $[M]^+{}_{\Delta}[M]^+{}_{\Lambda}(X^-)_2$, which contains an equal number of the Δ and Λ complexes in its unit cell, the solubility product is given by

$$K_{SP}^{\Delta\Lambda} = \{[M]^+\}_{\Delta} \cdot \{[M]^+\}_{\Lambda} \cdot \{X^-\}^2 = \frac{1}{2} S_{\Delta\Lambda} f_{[M]}^{\Delta\Lambda} \cdot \frac{1}{2} S_{\Delta\Lambda} f_{[M]}^{\Delta\Lambda} \cdot (S_{\Delta\Lambda} f_X^{\Delta\Lambda})^2 = \frac{1}{4} (S_{\Delta\Lambda})^4 \cdot (f_{[M]}^{\Delta\Lambda} f_X^{\Delta\Lambda})^2 \quad (6)$$

In this case the solubility $S_{\Delta\Lambda}$ is independent of that of the corresponding pure Δ or Λ enantiomer, not exceeding $\sqrt{2}S_{\Delta}$ or $\sqrt{2}S_{\Lambda}$ in an ideal solution. The general conclusion is summarized in Table 1.

Results and Discussion

The solubility data are summarized in Table 2.

(1) Bis(ethylenediamine)oxalatocobalt(III) Complexes: Solubility curves of the complex halides are shown in Fig. 1—3. Of these halides the chloride salt has been reported to show the so-called spontaneous re-

3) Values in parentheses for the optically active carbonato complexes are invalid because of partial racemization.

solution.[5,8)] The solubility of racemic chloride salt is larger than $\sqrt{2}$ times that of its optically active isomer in the range 5—60 °C (Fig. 1). The solubility curves show an inflection at about 36 °C, where the solid phase changes from monohydrate (below 36 °C) to anhydrous (above 36 °C). The bromide salts show a quite similar relationship in solubility curves to those of the chlorides except that the former shows no inflection (Fig. 2). Therefore, spontaneous resolution is expected for the racemic salt. In fact, the crystal which was arbitrarily chosen showed the same RD curve as that of the resolved isomer. No hemihedral facets, however, were observed for the crystals. Contrary to the bromide salt, no optical activity was observed for the iodide crystals. This agrees with the solubility curve relation $S_\Lambda > S_{\Lambda\Lambda}$ of the iodide salts (Fig. 3).

(2) Carbonatobis(ethylenediamine)cobalt(III) Complexes: The solubility curves of three optically active isomers deviate from the usual pattern at about 35 °C or above.

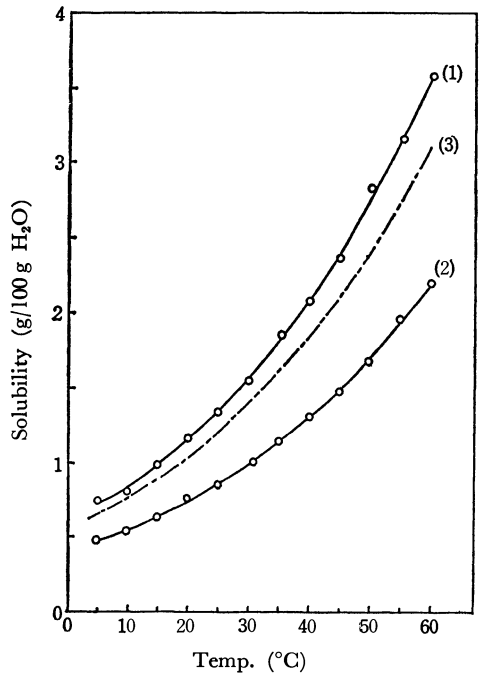

Fig. 2. Solubility curves of $[Co(ox)en_2]Br \cdot H_2O$: (1) racemic form, (2) *Λ* form and (3) calculated curve: $(2) \times \sqrt{2}$.

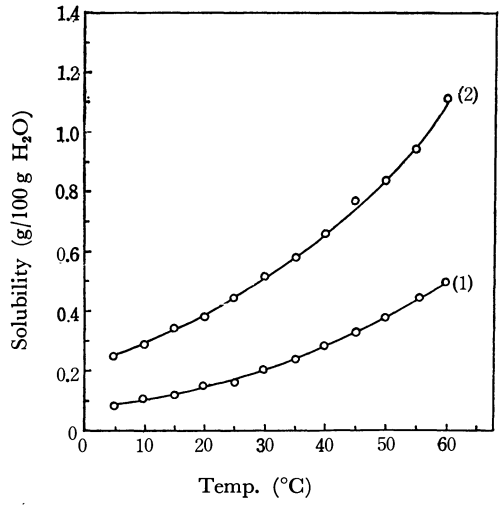

Fig. 3. Solubility curves of $[Co(ox)en_2]I$: (1) racemic form, (2) *Λ* form.

It was confirmed by the absorption and optical rotation measurements that these deviations arose from racemization. An inflection appears at 16 °C for the racemic bromide salt (Fig. 4) and at 17 °C for the racemic iodide one. These are the transition points from the dihydrates (below 16 °C or 17 °C) to the anhydrous (above 16 °C or 17 °C). The solubility curve of the racemic bromide (16—30 °C) shown by the dotted line is attributable to the metastable state of the dihydrate (Fig. 4). Both the chloride and iodide salts show $S_{\Lambda} > S_{\Lambda\Lambda}$ type. The bromide shows $S_{\Lambda} < S_{\Lambda\Lambda}$, but the curve of racemic salt is lower than the calculated $\sqrt{2}$ times curve of the active salt. Spontaneous resolution was not observed.

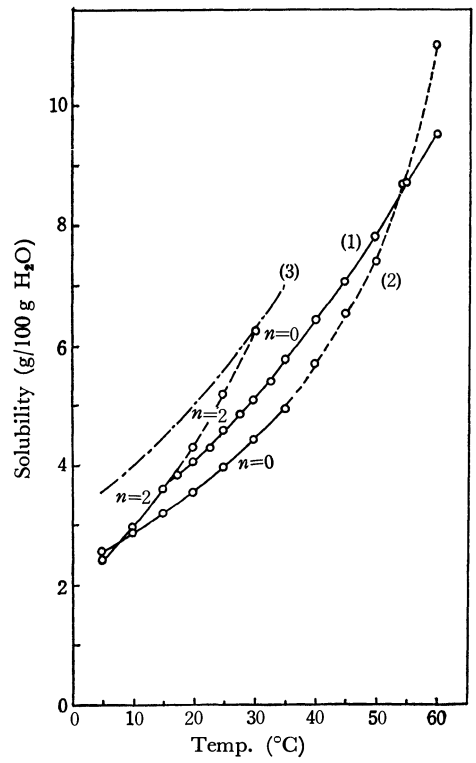

Fig. 4. Solubility curves of $[CoCO_3en_2]Br \cdot nH_2O$: (1) racemic form, (2) *Λ* form and (3) calculated curve: $(2) \times \sqrt{2}$.

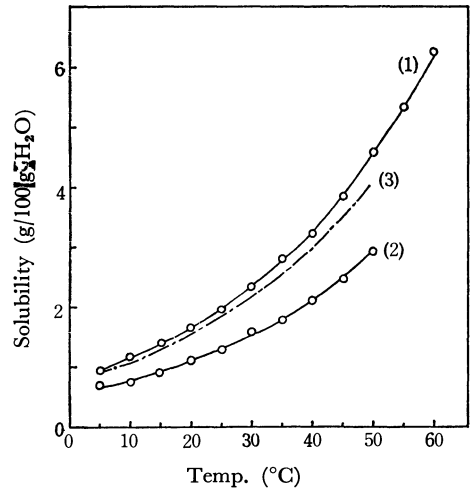

Fig. 5. Solubility curves of *cis*-$[Co(NO_2)_2en_2]Br$: (1) racemic form, (2) *Λ* form and (3) calculated curve: $(2) \times \sqrt{2}$.

(3) cis-*Bis(ethylenediamine)dinitrocobalt(III) Complexes*: Spontaneous resolution is expected for the chloride and bromide salts, since both salts show a solubility $S_{\Lambda\Lambda}$ larger than the calculated $\sqrt{2}$ times curve of the active salt (Table 2 and Fig. 5). The crystals from the racemic mixture show a similar RD curve to that of the resolved isomer. However, the crystals did not show any hemihedral facets. In contrast to the chloride and bromide salts, no optical rotation was observed for the crystals from the racemic iodide salt in spite of the $S_{\Lambda\Lambda} > S_{\Lambda}$ type (Fig. 6). This is acceptable in view of the relationship $S_{\Lambda\Lambda} < \sqrt{2} S_{\Lambda}$.

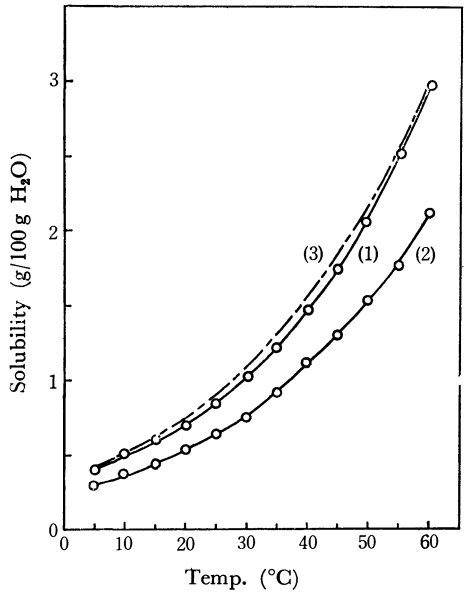

Fig. 6. Solubility curves of *cis*[Co$(NO_2)_2en_2$]I: (1) racemic form, (2) *Δ* form and (3) calculated curve: (2)$\times\sqrt{2}$.

(4) Ethylenediaminetetraacetatocobaltate(III) Complexes: Spontaneous resolution has been reported for NH_4[Co(edta)]·$2H_2O$ and Rb[Co(edta)]·$2H_2O$, both of which belong to the space group $P2_12_12_1$. The solubility type of NH_4[Co(edta)]·$2H_2O$ is $S_{\Delta\Delta} > \sqrt{2}S_{\Delta}$ in agreement with the above information. The curves of K[Co(edta)]·$2H_2O$ are quite similar to those of ammonium salts and suggest the possibility of spontaneous resolution. In fact, the crystal from the racemic mixture shows a quite similar RD curve to that of the resolved isomer. No distinguishable hemihedral facet could be observed.

The results confirm the view that spontaneous resolution is predictable from the relation between the solubility of racemic and optically active salts. The method we proposed is fairly useful for the investigation of spontaneous resolution, since distinguishable hemihedral facets are not always observable. The result suggests that the spontaneously resolvable salts are unexpectedly distributed in the cobalt(III) complexes of (1 : 1) electrolyte type.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3728—3733 (1973)

Copper(II) Complexes with Some Aliphatic Diaminealcohols

Yasuo ISHIMURA, Yasuomi NONAKA, Yuzo NISHIDA, and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka 812

(Received August 26, 1972)

Copper(II) complexes were prepared with a series of tridentate ligands, $NH_2(CH_2)_mCHRNH(CH_2)_nOH$ (R=H or CH_3; m=1 or 2; n=2 or 3). Compounds obtained can be classified into three groups: (1) $CuLCl_2$, (2) $CuL(ClO_4)$ and (3) CuL_2X_2, (L and L′ represent the neutral and the anionic ligands, respectively, and X denotes Cl or ClO_4). (1) and (3) were found to be mononuclear in which L functions as a bidentate ligand donating with the two nitrogen atoms. (2), except for the complex with L′=$NH_2(CH_2)_3NH(CH_2)_2O^-$, have the binuclear structure with alkoxo bridges. The absorption bands at about 350 nm are characteristic of the binuclear structure with alkoxo or hydroxo bridges.

Since it was found that the band at 370 nm in copper(II) alkanoates is diagnostic of the binuclear structure,[1-4] a number of spectral studies of copper(II) alkanoates have been reported.[5-10] However, the origin of the band has been a subject of controversy.[8,9] It seems desirable to see whether binuclear copper(II) complexes of other types show similar bands to those copper(II) alkanoates. Recently Yamada and Ojima[11] observed the bands at about 355 nm in a series of the binuclear copper(II) complexes such as bis(μ-*N*-oxo-propyl-*N*′-methylglycinamido)dicopper(II), and assumed the bands to be characteristic of the μ-dioxo structure of the complexes. However, further evidences seem to be necessary for establishing general relationship between the binuclear structure and the appearance of the band at about 350—360 nm in copper(II) complexes. In most dimeric copper(II) complexes so far reported, the ultraviolet region is masked by absorptions resulting from ligands. We therefore, attempted to prepare a series of ligands such as $NH_2(CH_2)_mCHRNH(CH_2)_nOH$ (R=H or CH_3, m=1 or 2, and n=2 or 3), which are capable of forming five- and/or six-membered chelate rings and, under some conditions, of forming binuclear complexes. They are new compounds except for the one with R=H, m=1 and n=2. Since these ligands have no double

bond, and consequently no absorption in visible and near-ultraviolet region, their complexes were considered to be suitable for the present investigation.

The relationship of the structure of a tridentate chelate ring system to the stability and magnetic properties of the binuclear copper(II) complexes was discussed by Ueda *et al.*,[12] but the ligands studied were limited to the condensed Schiff bases. Thus, in addition to the spectral study, we have investigated the effects of size and structure of chelate rings on the stability and magnetic properties of the binuclear copper(II) complexes, using the series of tridentate ligands of saturated chains.

Experimental

Preparation of Ligands. N-*(β-hydroxyethyl)ethylenediamine*, $NH_2(CH_2)_2NH(CH_2)_2OH$=*en-etol*: This compound was prepared by the method of Knorr and Brownsden.[13]

N-*(γ-hydroxypropyl)ethylenediamine*, $NH_2(CH_2)_2NH(CH_2)_3OH$ =*en-prol*: This compound was prepared by the method of Keller and Edwards,[14] except for the use of trimethylene chlorohydrin instead of trimethylene bromohydrin.

N-*(β-hydroxyethyl)trimethylenediamine*, $NH_2(CH_2)_3NH(CH_2)_2$-OH=*tn-etol*: Gaseous ethylene oxide produced by dropwise addition of 24 g (0.3 mol) ethylene chlorohydrin to 32 g (0.6 mol) potassium hydroxide was introduced with stirring into a solution of 74 g (1.0 mol) trimethylenediamine. The unreacted trimethylenediamine was distilled off, and the remaining mixture was distilled under reduced pressure. Bp. 133—134 °C/7 mmHg.

N-*(γ-hydroxypropyl)trimethylenediamine*, $H_2N(CH_2)_3NH(CH_2)_3$ OH=*tn-prol*: To a well-stirred solution of 74 g (1.0 mol) trimethylenediamine in 80 ml of isopropyl alcohol was added 28.4 g (0.3 mol) of trimethylene chlorohydrin, the reaction mixture being maintained at about 50 °C. The mixture was refluxed for 3 hr. 8 g (0.2 mol) of sodium hydroxide was added to the solution, yielding white precipitates which were filtered off. The filtrate was evaporated to remove isopropyl alcohol and the unreacted trimethylenediamine, and then, distilled under reduced pressure. Fractionation of the distillate yielded 11.5 g (43.5% yield based on the trimethylene chlorohydrin) of the final product. Bp. 130—131 °C/3 mmHg.

N-*(γ-hydroxypropyl)-(−)-1,2-propanediamine*, $NH_2CH(CH_3)$-$CH_2NH(CH_2)_3OH$ = *pn-prol*: This compound was prepared in a similar way to that for $H_2N(CH_2)_3NH(CH_2)_3OH$, except for the use of (−)-1,2-propanediamine instead of trimethylenediamine.

Table 1. Abbreviation of ligands

en-etol	$NH_2CH_2CH_2NHCH_2CH_2OH$
en-prol	$NH_2CH_2CH_2NHCH_2CH_2CH_2OH$
tn-etol	$NH_2CH_2CH_2CH_2NHCH_2CH_2OH$
tn-prol	$NH_2CH_2CH_2CH_2NHCH_2CH_2CH_2OH$
pn-prol	$NH_2CH_2CH(CH_3)NHCH_2CH_2CH_2OH$

The primed abbreviation, such as en-prol′ *etc.*, denotes the anion of the ligand, such as $NH_2CH_2CH_2NHCH_2CH_2CH_2O^-$ *etc.*

Preparation of the Complexes. *Cu en-etol Cl_2 (A)* (For abbreviation of ligands, see Table 1): A solution of 1.1 g of en-etol (0.01 mol) in 40 ml of ethanol was added dropwise to a solution of 1.7 g of copper(II) chloride dihydrate (0.01 mol) in 40 ml of ethanol with stirring. The blue powder immediately formed was filtered off, washed with cold ethanol and dried over phosphoric anhydride.

Cu en-prol Cl_2 (B), Cu tn-etol Cl_2 (C) and Cu pn-prol Cl_2 (D) were prepared in a similar way to that for A.

Cu en-prol′ ClO_4 (E): Six tenth grams of potassium hydroxide (0.01 mol) and 1.2 g of en-prol (0.01 mol) were dissolved in 50 ml of methanol. To this was added dropwise a solution of 3.7 g of copper(II) perchlorate hexahydrate (0.01 mol) in 30 ml of methanol. The mixture was stirred for two hours at room temperature. The white precipitate ($KClO_4$) formed was removed by filtration. The filtrate was kept in a refrigerator for a few hours to complete the precipitation of potassium perchlorate, which was removed by centrifugation. The bluish violet solution was evaporated and a dark blue oily substance was obtained. This was dissolved in a small amount of hot ethanol and kept in a refrigerator overnight. Dark blue-violet crystals were obtained. These were recrystallized from ethanol. The compound obtained was hygroscopic in the atmosphere, and was found by elemental analysis to contain one molecule of ethanol for one copper ion. The ethanol was removed by keeping the crystals *in vacuo* at 100 °C for 1 hr.

Cu tn-prol′ClO_4 (F), Cu tn-prol′NO_3 (G), Cu pn-prol′ClO_4 (H), Cu tn-etol′$ClO_4 \cdot H_2O$ (I) and Cu tn-etol′Cl-H_2O (J) were prepared in a similar way to that for E. The crystals of F and H obtained from the ethanol solution were found to contain a certain amount of ethanol (1.0 mol for F and 0.7—0.8 mol for H) which was easily removed as in the case of E.

Compounds F, G, I, and J can also be prepared by mixing copper(II) salt and the ligand with the 1 : 2 mol-ratio in hot ethanol.

$Cu(en\text{-}etol)_2Cl_2$, (K): A hot solution of 1.7 g of copper(II) chloride dihydrate (0.01 mol) in 30 ml methanol was added dropwise to a well-stirred solution of 2.2 g of en-etol (0.02 mol) dissolved in 40 ml methanol. The solution was kept overnight in a refrigerator. The violet crystals separated were filtered off, washed with cold ethanol and dried over phosphoric anhydride.

$Cu(tn\text{-}etol)_2Cl_2$ (L) was prepared in a similar way to that for K.

$Cu(en\text{-}etol)_2(ClO_4)_2$ (M) and $Cu(en\text{-}prol)_2(ClO_4)_2$ (N) were prepared in a similar way to that for the chloride analogues except for the use of copper(II) perchlorate hexahydrate instead of copper(II) chloride dihydrate.

Measurements. Electronic spectra were measured with a Hitachi EPS-3T recording spectrophotometer equipped with a reflectance attachment.

Magnetic susceptibility was determined by the Gouy method at room temperature, diamagnetic corrections being made with Pascal's constants.

ESR spectra were measured using X-band with a JES-ME-3 ESR spectrometer.

Results and Discussion

The analytical, magnetic and spectral data of the fourteen copper(II) complexes obtained are summarized in Tables 2 and 3.

The complexes are classified into three types with the general formulas $CuLCl_2$, $CuL'ClO_4$ and CuL_2X_2, where X=Cl or ClO_4 and L and L′ denote the ligands

Table 2. Elemental analyses

a) met and et denote "in methanol" and "in ethanol", respectively.

$NH_2(CH_2)_mCHRNH(CH_2)_nOH$ and $NH_2(CH_2)_mCHRNH(CH_2)_nO^-$, respectively.

(1) Cu L Cl_2: Compounds A, B, C, and D (where L=en-etol, en-prol, tn-etol and pn-prol; *cf.* Table 3) belong to this group. The tn-prol complex of this type could not be isolated in spite of repeated attempts.

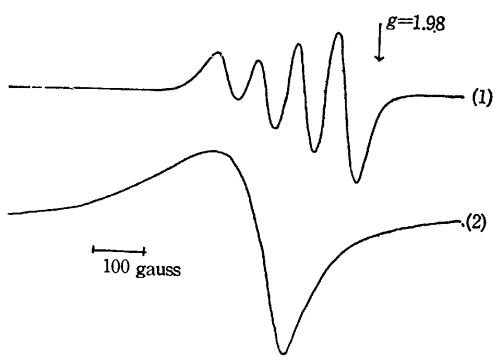

Fig. 1. ESR spectra of Cu en-prol Cl_2
(a) methanol solution at room temperature.
(b) powder at 150 °C (gain 1×1).

The compounds show normal magnetic moments for ordinary mononuclear copper (II) complexes (Table 3). ESR measurements in methanol solution and in powder provide further evidences for the mononuclear structure (Fig. 1).

Their reflectance spectra are similar to that of [Cu-en Cl_2] (en=ethylenediamine), known as a dichloro complex.[15] Thus, the structure of this group is essentially square planar, a copper ion being coordinated with two chloride ions and two amine nitrogen atoms. The alcoholic hydroxyl group is not likely to form a distinct bond with the metal ion, as judged from the visible spectrum (Table 3).

(2) CuL'ClO_4: Compounds E, F, H, and I (where L'=en-prol', tn-prol', pn-prol' and tn-etol'; *cf.* Table 3) belong to this group. Compounds G(=Cu tn-prol'NO_3) and J (=Cu tn-etol'$Cl \cdot H_2O$) appear to be similar to the above compounds and will be discussed here. All attempts to prepare the homologue with en-etol were unsuccessful. The compounds show

subnormal magnetic moments, except for I and J (Table 2). Powder ESR measurements at room temperature show that the spectral patterns of these complexes differ a great deal from those of the ordinary monomeric copper(II) complexes (Figs. 2 and 3). The broad signals observed in the range 1000—8000 Gauss may be due to a triplet state, indicating a considerable magnetic interaction between the two copper ions. Therefore, we may conclude that E, F, G, and H have a binuclear structure bridged with alcoholate oxygen (Fig. 5).

On the other hand, both I and J show a normal magnetic moment, 1.79 BM, at room temperature. However, their ESR spectra, which are very similar to each other, differ entirely from those of ordinary mononuclear copper(II) complexes, especially at low temperature (Fig. 4, and also Fig. 1). It should be noted that the intensities of the ESR signals remarkably increase with the lowering of temperature (Fig. 4), whereas in the other complexes E, F, G, and H, the spectra except for the band at about 3000 Gauss do not increase in intensity but gradually decline with the lowering of temperature (Figs. 2 and 3).

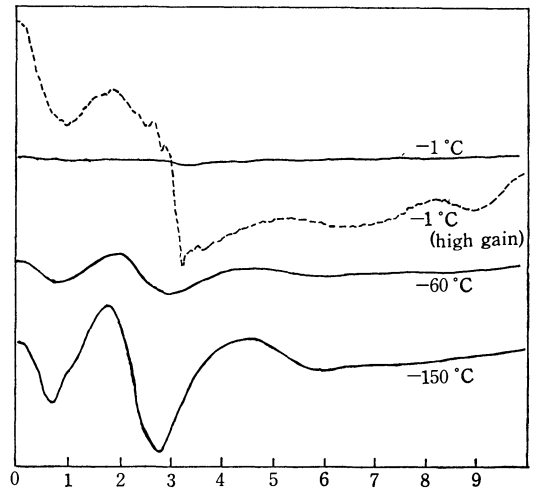

Fig. 4. Powder ESR spectra of Cu tn-etol' $ClO_4 \cdot H_2O$ (gain 1×10 for solid line, 3.2×100 for broken line).

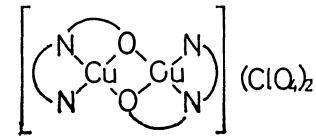

Fig. 5. The structure of $CuL'ClO_4$.

This suggests that ferromagnetic interaction takes place in I and J, where the ground state is triplet (or multiplet) and an upper singlet state is thermally populated at room temperature. As is well-kown in magnetically dilute solid, an ESR signal generally increases in intensity with lowering of temperature due to an increase of the difference of thermal population between the split Zeeman levels.[16] In addition to this effect, in the case of compounds I and J, the ground triplet or multiplet state becomes more populated with the lowering of temperature to increase the ESR intensity. On the other hand, in the antiferromagnetic compounds where the ground state is singlet such as E, F, G, and H, the near-lying upper triplet state becomes less populated with lowering of temperature. The effect acts on ESR to reduce its intensity at low temperature. Thus, the observed ESR intensities of these compounds are nearly counterbalanced by the two opposite temperature effects in a certain temperature range (Figs. 2 and 3). In contrast to this, the signal at about 3000 gauss, which is attributable to a trace of mononuclear impurity, remarkably increases in intensity with the lowering of temperature.

The structures of compounds I and J are likely to be similar to those of Cu aca-etol'[17] and Cu sal-etol'[18] (where aca-etol' and sal-etol' denote $^-OC(CH_3)=CHC(CH_3)=NCH_2CH_2O^-$ and $o\text{-}O^-(C_6H_4)CH=NCH_2CH_2O^-$, respectively), since tn-etol is similar to these

ligands in forming 5- and 6-membered chelate rings upon coordination, and in their magnetic behavior, *i.e.* ferromagnetic interaction takes place though they all show normal magnetic moments at room temperature. The X-ray analysis[17] shows that Cu aca-etol' is tetrameric (Fig. 6), where alcoholate oxygens coordinate to three copper ions and, consequently, are tetrahedrally bonded.

Since no stable binuclear complexes were obtained by using en-etol, pn-etol and tn-etol, we may conclude that for the formation of the binuclear complex the favorable member of the chelate ring involving bridging oxygen is six. The 5- and 6-membered chelate ring system such as Cu tn-prol'ClO_4 seems to be slightly more favorable for the formation of the binuclear complex than the 5- and 6-membered chelate ring system such as Cu en-prol'ClO_4, judging from the easier formation of the former than the latter.

Compounds E, F, G, and H show similar electronic spectra to each other in both solid and ethanolic solutions, giving two bands in the 10—33 kK region (Fig. 7). The numerical data are summarized in Table 3. The bands around 600 nm are undoubtedly assigned to d–d transitions, and the more intense bands around 350 nm can be attributed to charge-transfer transitions from ligands to a metal ion. The latter bands seem to be characteristic of the binuclear structure in which two copper ions are bridged by oxo anions. This assumption well coincides with Yamada and Ojima's observation[11] on some binuclear copper(II) complexes bridged with two alcoholate oxygens. In order to confirm this assumption we have measured powder reflectance spectrum of the binuclear complex, $\left[\mathrm{A\ Cu}\begin{matrix}\diagup\mathrm{OH}\diagdown\\ \diagdown\mathrm{OH}\diagup\end{matrix}\mathrm{Cu\ A}\right](ClO_4)_2$ (where A=*N*,*N*,*N'*,*N'*-tetramethylethylenediamine or *N*,*N*,*N'*,*N'*-tetraethylethylenediamine), and have observed similar bands at about 360 nm (Fig. 10). Their aqueous solutions show shoulders at the same position at pH 8 where the binuclear species dominates in the equilibrium.[19]

(2) A=*N,N,N',N'*-tetramethylethylenediamine.

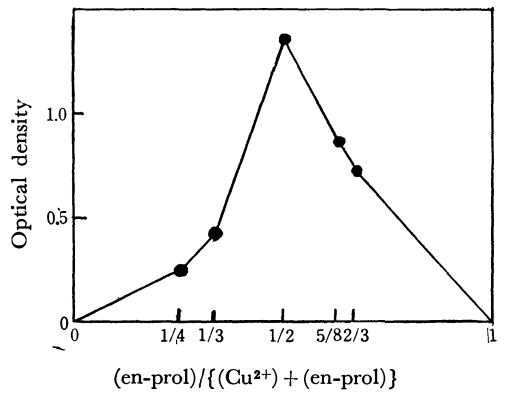

Fig. 11. The continuous variation method at 354 nm applied to the system Cu^{2+}/en-prol in basic solution.
The total concentration of Cu^{2+} and en-etol was 2×10^{-3} mol/l in each solution containing *t*-butylamine with the same molar concentration as that of en-etol.

However, in the low (<6) and the high (>9) pH regions, where the concentration of the binuclear species is negligible, neither a peak nor a shoulder was observed around 360 nm. We also investigated the powder reflectance spectrum of [Cu eta eta']ClO_4[20] (where eta and eta' denote $NH_2CH_2CH_2OH$ and $NH_2CH_2CH_2O^-$, respectively), in order to see whether the band around 360 nm is brought about by coordination of an alkoxo or a hydroxo group to copper(II) ion regardless of bridged or simple coordination. Neither peak nor shoulder has been found in the near-ultraviolet region, indicating that coordination of the alkoxo group to copper(II) ion itself does not cause the characteristic band in the near-ultraviolet region.

20) S. Kida, *Nippon Kagaku Zasshi*, **85**, 428 (1964).

In conclusion, all experimental results so far obtained support the rule that the binuclear copper(II) complex bridged by alkoxo or hydroxo groups always show the characteristic band in the near-ultraviolet region (<29 kK), unless there are other intense absorptions to mask the region.

Compounds I and J show no characteristic band in the near-ultraviolet region in the powder reflectance spectrum (Fig. 9). This is undoubtedly due to the tetrameric structure, where bridging alcoholate oxygens are tetrahedrally bonded, and accordingly have no π-electrons to cause the absorption around 360 nm. In an aqueous or methanolic solution, however, the band was observed at 350 nm, though its intensity is very low as compared to that of the binuclear complexes in this group. Thus, a binuclear complex similar to E, F, G, and H might be partially formed in the solutions of I and J.

(3) CuL_2X_2: Compounds K, L (where L=en-etol, and en-prol; X=Cl), M and N (where L=en-etol and en-prol; X=ClO_4), belong to this group. It should be noted that the same preparative procedure as for the above compounds, *viz.*, mixing the copper(II) salt and the ligand in a 1 : 2 mole-ratio in methanolic solution, did not give rise to the formation of Cu(tn-etol)$_2$(ClO_4)$_2$ and Cu(tn-prol)$_2$(ClO_4)$_2$, but gave Cu tn-etol'$ClO_4\cdot H_2O$ and Cu tn-prol'ClO_4.

The compounds show normal magnetic moments at room temperature, and d–d bands at 560—600 nm (Table 3). The solution and the powder ESR spectra are very close to those of the compounds of group (1), showing characteristic patterns of a mononuclear copper(II) complex. We can thus conclude that complexes of this group are similar to [Cu en$_2$]X_2 in various properties, and that they are of essentially square-planar structure coordinated with four amine nitrogens. The red shift in 10—50 nm relative to [Cu en$_2$](ClO_4)$_2$ implies that there is some perturbation along the tetragonal axis, but not strong enough to be called a coordination bond.

It is remarkable that the solution spectra in the near-ultraviolet region differ from the powder spectra (Fig. 8). The bands observed at about 360 nm are similar in contour and in position to those of the oxo-bridged complexes. Therefore, $[Cu\ L_2]^{2+}$ is very likely to dissociate partially in solution to form a binuclear species similar to compounds E, F, G, and H, giving rise to the equilibrium

$$2[CuL_2]^{2+} \rightleftarrows [Cu_2L'_2]^{2+} + 2LH^+. \qquad (a)$$

In fact, the intensities of the bands are much lower than those of the binuclear complexes of group (2), and the spectra do not follow Beer's law in the near-ultraviolet region. The formation of a 1 : 1 complex was verified spectrophotometrically by the use of a continuous variation method (Fig. 11). It should be noted that the addition of some proton acceptor such as trimethylamine to the methanolic solution of a complex of this group gives rise to a distinct promotion of the intensity of the band at about 360 nm. This also supports assumption based on equilibrium (a).

Ion-selective Electrode Membranes Responsive to Maleic and Phthalic Acids

Akinori Jyo, Morihisa Yonemitsu, and Nobuhiko Ishibashi*

Department of Applied Analytical Chemistry, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received May 28, 1973)

Ion-selective electrodes responsive to maleic and phthalic acids were prepared. The organic solvent solution of the ion-pair of the objective monovalent acid anion with a Crystal Violet or a tris(bathophenanthroline)-iron(II) ion was used as the electrode membrane. The responses of both electrodes were linear down to 10^{-4}—$10^{-4.5}$ M, with an ideal Nernstian slope of 57—58 mV per activity decade at 20 °C. Together with the potential slope, the pH dependence of the potential showed that the electrode responded to the monovalent anion of maleic or phthalic acid. The interferences of acetate, benzoate, and chloride were extremely low, whereas iodide and perchlorate interfered greatly. The maleic acid electrode works well without the interference of fumaric aicd. The phthalic acid electrode also functions without any interferences by isophthalic or terephthalic acid.

Various methods of analyzing maleic and phthalic acids have been reported.[1-6] However, no report has been presented on an electrode responsive to maleic or phthalic acid.

Maleic acid is easily extracted into an organic solvent containing a large cation, such as a crystal violet or a tris(bathophenanthroline)iron(II) ion, and forms an ion-pair with the cation, whereas fumaric acid, the *trans*-isomer of maleic acid, is not extracted. A similar phenomenon is observed among the isomers of the benzenedicarboxylic acids, and phthalic acid is preferentially extracted into the above-mentioned organic solvent from an aqueous solution of a mixture of the isomers.

In a previous communication, we have briefly reported on the performances of maleic acid- and phthalic acid-sensitive electrodes prepared by utilizing the extractability differences among the isomers.[7] This paper will describe further details of the preparations and performances of the electrodes. By using the electrodes, it became possible to determine the concentrations of the acids more rapidly and simply than by the conventional methods.

Experimental

Reagents. All the chemicals used were of reagent-grade quality. The aqueous solution of the monosodium salt of maleic or phthalic acid was prepared by mixing the aqueous solution of the acid and the sodium hydroxide solution in an appropriate ratio. The pH of the sample solution was adjusted with an aqueous solution of sulfuric acid, potassium dihydrogenphosphate, or sodium hydroxide.

Sensitive Liquid Membrane. An organic solvent solution of the Crystal Violet salt or the tris(bathophenanthroline)iron(II) salt of the objective monovalent acid anion was used as the liquid membrane. The concentration of the salt was 10^{-4} M. Nitrobenzene (NB), 1,2-dichloroethane (DCE), and chloroform (CF) were used as the solvents of the membrane.

The membrane solution containing the crystal violet salt was prepared by the following solvent extraction method. Equal volume portions of the organic solvent, a 10^{-2} M aqueous solution of the acid, and a 10^{-3} M aqueous solution of Crystal Violet were poured into a separating funnel, after which the funnel was shaken with a mechanical shaker for 30 min. After the separation of layers, the organic phase was shaken again with a 10^{-3} M aqueous solution of the acid in order to purify it. In the extraction process, the pH of the aqueous phase was maintained at 4 in order to extract the acid as a monovalent anion. The organic phase was separated and diluted with the organic solvent saturated with water. The organic solution thus obtained was used as the sensitive membrane. The membrane solution which contained the tris(bathophenanthroline)iron(II) salt was prepared by a similar procedure.

Potential Measurement. The potential of the following electrochemical cell was measured by using a Takeda Riken Electrometer TR 8651.

+SCE|Reference Solution|Liquid Membrane|Sample Solution|SCE−

The cell assembly has been illustrated in detail elsewhere.[8] The lower part of a glass U-tube was filled with 10 ml of the membrane solution, the reference and sample solutions, 10 ml of each, were thus separated. An agar salt bridge saturated with potassium chloride or ammonium chloride was used to connect the respective saturated calomel electrode (SCE) with the reference and sample solutions. The reference solution was a 10^{-2} M aqueous solution of the objective organic acid, its acidity has been adjusted to pH 4.

Results and Discussion

Potential Response of the Electrode. In the potentiometric determination of the concentration of maleic or phthalic acid, an electrode responsive to a monovalent anion, *i.e.*, a hydrogenmaleate or hydrogenphthalate ion, is preferable to a divalent maleate ion- or phthalate ion-responsive electrode from an analytical viewpoint, because the slope of the calibration curve of the former electrode can be expected to be twice that of the latter electrode.

Since the first and second dissociation constants are $10^{-1.92}$ and $10^{-6.22}$ for maleic acid, and $10^{-2.95}$ and $10^{-5.41}$ for phthalic acid, respectively, the main component species of the acids are the monovalent anions around pH 4. Accordingly, the response of the electrode was examined on the sample solution at pH 4

Maleic acid electrode (○)
Membrane: 10^{-4} M nitrobenzene solution of crystal violet salt of corresponding monovalent acid anion.

in order to detect the acid as monovalent anion species.

Figure 1 shows the potential response of the electrode. The membrane consisted of a 10^{-4} M nitrobenzene solution of the crystal violet salt of the monovalent acid anion. The response of the phthalic acid electrode could be examined on the sample solution below 10^{-2} M because of the small solubility of phthalic acid at pH 4. The activity coefficient of the objective anion was calculated from the Debye-Hückel equation, in which the ion-size parameter was assumed to be equal to those of salicylate and vinylacetate.[9] The responses of both electrodes were linear over the activity ranges from 10^{-1} to 10^{-4} M and from 10^{-2} to $10^{-4.5}$ M for the maleic and phthalic acid sample solutions respectively. An ideal Nernstian slope of 58 mV per activity decade at 20 °C was observed for each electrode. Equilibrium potentials were achieved within a few sec, and potential values were reproducible to ±0.2 mV.

The responses of the electrodes with different ion-exchange sites and different membrane solvent species are summarized in Table 1. Irrespective of the site and the membrane solvent species, the properties of the electrode membranes, such as the potential slope, the response time, and the stability of the potential, were almost the same as those of the nitrobenzene membranes described above. The slope of 57—58 mV indicated that the electrodes responded to the monovalent anion species of maleic and phthalic acids.

Influence of pH on the Electrode Potential. The potential can be effected to vary with the pH of the sample solution, since the relative concentration of the monovalent anion depends on the acidity of the solution. Figure 2 shows the potentials of the electrodes for 10^{-3} M sample solutions with different pH values. The theoretical value of 56 mV was observed in the pH ranges from 3 to 5 and from 3.8 to 4.2 for the solutions of the maleic and phthalic acids respectively. In the higher and lower pH regions, the remarkable change in the potential was in accordance with the concentration decrease in the monovalent anion species of the acid. This suggests that the electrodes

do not respond to the undissociated acids and the divalent anions of the acids, and supports the view that the acids are extracted into an organic solvent as monovalent anions and not as divalent anions.[6] In the practical use of the electrode, care must be taken in the adjustment of the pH of the sample solution.

Selectivity of the Electrode. The potential, E, for the sample solution containing the primary ion, i, and any other ion, j, is given by the empirical Eq. (1):

$$E = 2.303\,RT/F\log(a_i'/(a_i''+K a_j'')) \quad (1)$$

where a_i and a_j are the activities of the monovalent anions, i and j, and where K is a selectivity coefficient. The activities of the reference and sample solutions are designated by prime and double prime respectively.

The interfering effects of the isomer ions were examined on the basis of the mixed solution method.[10] In this method, the potential was measured on a series of sample solutions, each solution containing a fixed amount of an interferant, j, and a varying amount of the primary ion, i. The influences of the isomer ions are summarized in Table 2. At the lowest limit of linear response, the sample solution contained 100 times more fumaric acid than maleic acid, and about 20 times more isophthalic acid than phthalic acid.

10) G. J. Moody and J. D. R. Thomas, "Selective Ion Sensitive Electrodes," Merrow Pub. Co. Watford, England, (1972).

However, no interfering effect of fumaric or isophthalic acid was observed. The response of the phthalic acid electrode was not affected by the presence of the terephthalic acid, even in the saturated solution of the latter acid. These results indicate that the electrodes are capable of determining the concentrations of maleic and phthalic acids without any interference by the isomer acids.

The interfering effects of other organic and inorganic anions were examined by using the separate-solution method.[10] In this method, the potential was measured on the sample solution containing an interferant alone. The pH of the sample solution was maintained within the region where the interferant existed as a monovalent anion. In Table 3, the selectivity coefficients of the maleic acid electrode are listed. The interferences of acetate, benzoate, and chloride were extremely low, but the salicylate and iodide interfered greatly. The perchlorate ion showed the highest interference. The selectivity of the phthalic acid electrode is also summarized in Table 4. The selectivity of the phthalic acid electrode was better than that of the maleic acid electrode. The chloroform membrane electrode had slightly higher selectivity values than the nitrobenzene and 1,2-dichloroethane membrane electrodes. The selectivity coefficients were approximately independent of the site species if the electrode membrane was prepared by using the same solvent with a relatively high dielectric constant. These results agree with the view proposed by Eisenman of the selectivity of the ion-sensitive electrode with a liquid ion-exchanger membrane of the complete-dissociation type.[11]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3737—3744 (1973)

Derivatographic Studies on Transition Metal Complexes. XII.[1] Thermal Olation of Hydroxoaquo Cobalt(III) and Chromium(III) Complexes Containing Amino Acids in Solid Phase[2]

Ryokichi Tsuchiya, Akira Uehara, and Eishin Kyuno

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received May 29, 1973)

The thermal olation of the following four types of complexes in a solid phase was investigated by means of derivatography: 1) cationic complexes, $[Co(OH)(n_3\text{-}o)(H_2O)]X$, 2) anionic complexes, $M[Co(OH)(n\text{-}o_3)(H_2O)]$, 3) double complexes, $[Co(OH)(n_3\text{-}o)(H_2O)][Co \text{ or } Cr(OH)(n\text{-}o_3)(H_2O)]$ and 4) neutral complexes, $[Co(OH)(n\text{-}o)_2(H_2O)]$, where n_3-o, n-o_3 and $(n\text{-}o)_2$ denote gly-en (glycinate ion and ethylenediamine) or dtma (diethylenetriaminemonoacetate ion), the analogues of nta (nitrilotriacetate ion) and α-amino acid ions, respectively. The thermal data such as initiation temperature, enthalpy change and activation energy of the olation were estimated from the respective derivatograms. From the results the effect of various ligands or counter ions (outer-sphere ions) on the olation was discussed.

Olation in a solid phase was first observed by Werner[3] in the $[Co(OH)(H_2O)(NH_3)_4]X_2$ type complexes. Recently, Wendlandt and Fisher reported that the olation of complexes of this type takes place endothermically and that the heats of olation are 3.3, 6.1, 4.2 and 2.4 kcal/mol for $X=Cl^-$, Br^-, NO_3^- and SO_4^{2-}, respectively.[4] It is of interest that the values are considerably smaller than those expected for the liberation of coordinated water alone. However, these values are understandable if the olation is considered to involve both dissociation of coordinated water and formation of olated compound simultaneously; the former step might be an endothermic, and the latter step an exothermic reaction.

In part IV of this series, we reported on the olation of the anionic complexes having the general formula $K[Co(OH)(n\text{–}o_3)(H_2O)]$,[5] where the ligand $(n\text{–}o_3)$ refers to nta, nipda, α-abda, vda, lda, pgda and pada.[6] The values of enthalpy change estimted from the DTA curves showed that the olation of all the anionic complexes proceeds exothermically. From an inspection of the numerical values of initiation temperature and activation energy, we concluded that the olation takes place more readily according to the sequence: nta→nipda→α-abda→vda→lda→pgda→pada-complexes.

The present study was undertaken to obtain information on the olation of various types of complexes and to systematically examine the effect of various ligands

5) R. Tsuchiya, A. Uehara, and E. Kyuno, This Bulletin, **44**, 701 (1971).

6) The full names are as follows : nta : nitrilotriacetate ion, nipda : nitriloisopropionicdiacetate ion, α-abda : *d,l*-α-amino-*n*-butyric-*N,N*-diacetate ion, vda : *l*-valine-*N,N*-diacetate ion, lda : *l*-leucine-*N,N*-diacetate ion, pgda : *d*-α-phenylglycine-*N,N*-diacetate ion and pada : *d,l*-α-phenylalanine-*N,N*-diacetate ion.

and counter ions (outer-sphere ions) on the olation. The thermal olation of cationic, anionic, double and neutral complexes was investigated by means of derivatography; it can be formulated as follows:

1) $2[Co(OH)(n_3\text{-}o)(H_2O)]X \rightarrow [(n_3\text{-}o)Co(OH)_2Co(n_3\text{-}o)]X_2 + 2H_2O$

2) a) $2K[Co(OH)(n\text{-}o_3)(H_2O)] \rightarrow K_2[(n\text{-}o_3)Co(OH)_2Co(n\text{-}o_3)] + 2H_2O$

b) $2M(I)$ *or* $M(II)_{1/2}[Co(OH)nipda(H_2O)] \rightarrow M(I)_2$ *or* $M(II)[(nipda)Co(OH)_2Co(nipda)] + 2H_2O$

3) $[Co(OH)(n_3\text{-}o)(H_2O)][Co$ *or* $Cr(OH)(n\text{-}o_3)(H_2O)] \rightarrow [(n_3\text{-}o)Co(OH)_2Co$ *or* $Cr(n\text{-}o_3)] + 2H_2O$

4) $2[Co(OH)(n\text{-}o)_2(H_2O)] \rightarrow [(n\text{-}o)_2Co(OH)_2Co(n\text{-}o)_2] + 2H_2O$

where n_3-o, n-o and n-o_3 denote gly-en (glycinate ion and ethylenediamine) or dtma (diethylenetriaminemonoacetate ion), α-amino acid ion and the analogues of nta ion, respectively, and M(I) and M(II) refer to any one of the alkali metal and the alkaline earth metal ions, respectively.

The hydroxoaquo-type complexes used as the starting materials are listed in Table 1 (The numerals refer to the index numbers of the respective complexes).

As cationic complexes, $[Co(OH)gly(H_2O)en]X$ and $[Co(OH)dtma(H_2O)]X$ were used, where X represents a univalent anion such as Cl^-, NO_3^-, Br^- and I^-.

Table 1. List of hydroxoaquo-type complexes used in the present study

	Type		General formula	Complex[a]	Index No.
1.	Cationic complexes	1.	$[Co(OH)gly(H_2O)en]X$	[Co (gly en)]Cl·aq	1.1.1
				[Co (gly en)]NO_3·aq	1.1.2
				[Co (gly en)]Br	1.1.3
		2.	$[Co(OH)dtma(H_2O)]X$	[Co (dtma)]NO_3	1.2.1
				[Co (dtma)]Br·aq	1.2.2
				[Co (dtma)]I	1.2.3
2.	Anionic complexes	1.	$K[Co(OH)(n\text{-}o_3)(H_2O)]$	K[Co nta]·aq	2.1.1
				K[Co nipda]·2aq	2.1.2
				K[Co α-abda]·2aq	2.1.3
				K[Co vda]·1.5aq	2.1.4
				K[Co lda]·aq	2.1.5
				K[Co pada]·5aq	2.1.6
		2.	$M(I)[Co(OH)nipda(H_2O)]$	Li[Co nipda]·aq	2.2.1
				Na[Co nipda]·aq	2.2.2
				Rb[Co nipda]·aq	2.2.3
				Cs[Co nipda]	2.2.4
		3.	$M(II)_{1/2}[Co(OH)nipda(H_2O)]$	Mg[Co nipda]$_2$·2aq	2.3.1
				Ca[Co nipda]$_2$·2aq	2.3.2
				Sr[Co nipda]$_2$·2aq	2.3.3
				Ba[Co nipda]$_2$·4aq	2.3.4
3.	Double complexes	1.	$[Co(OH)gly(H_2O)en][Co(OH)(n\text{-}o_3)(H_2O)]$	[Co (gly en)][Co nta]·2aq	3.1.1
				[Co (gly en)][Co nipda]·2aq	3.1.2
				[Co (gly en)][Co α-abda]·2aq	3.1.3
				[Co (gly en)][Co vda]·2aq	3.1.4
				[Co (gly en)][Co lda]·2aq	3.1.5
				[Co (gly en)][Co pada]·2aq	3.1.6
			$[Co(OH)gly(H_2O)en][Cr(OH)(n\text{-}o_3)(H_2O)]$	[Co (gly en)][Cr nta]·2aq	3.1.7
				[Co (gly en)][Cr nipda]·2aq	3.1.8
				[Co (gly en)][Cr α-abda]·2aq	3.1.9
				[Co (gly en)][Cr vda]	3.1.10
				[Co (gly en)][Cr lda]·2aq	3.1.11
				[Co (gly en)][Cr pada]·2aq	3.1.12
		2.	$[Co(OH)dtma(H_2O)][Co(OH)(n\text{-}o_3)(H_2O)]$	[Co (dtma)][Co nta]·2aq	3.2.1
				[Co (dtma)][Co nipda]·2aq	3.2.2
				[Co (dtma)][Co α-abda]·2aq	3.2.3
				[Co (dtma)][Co vda]·2aq	3.2.4
				[Co (dtma)][Co lda]·2aq	3.2.5
				[Co (dtma)][Co pada]·2aq	3.2.6
			$[Co(OH)dtma(H_2O)][Cr(OH)(n\text{-}o_3)(H_2O)]$	[Co (dtma)][Cr nta]·4aq	3.2.7
				[Co (dtma)][Cr nipda]·4aq	3.2.8
				[Co (dtma)][Cr α-abda]·2aq	3.2.9
				[Co (dtma)][Cr vda]·2aq	3.2.10
				[Co (dtma)][Cr lda]·4aq	3.2.11
				[Co (dtma)][Cr pada]·2aq	3.2.12
4.	Neutral complexes		$[Co(OH)(n\text{-}o)_2(H_2O)]$	[Co $(gly)_2$]·2aq	4.1
				[Co $(ala)_2$]·aq	4.2

n-o_3 and n-o denote the analogues of nta ion and α-amino acid ions, respectively.

a) OH and H_2O are omitted in all the formulas.

For the anionic complexes, all the ligands (n-o_3) used can form (5,5,5)-membered chelate rings and their structures become more bulky according to the order: nta→nipda→α-abda→vda→lda→pgda→pada.

Two kinds of double complexes were obtained, one containing cobalts as the central metal both in cationic and anionic species (designated as [Co][Co]), and the other containing cobalt in cationic and chromium in anionic species (designated as [Co][Cr]). The double complexes are especially interesting for carrying out studies from the viewpoint of 1) whether the olation takes place between two identically charged complex ions or between two counter charged complex ions, and 2) the difference in olation to be found between [Co][Co] and [Co][Cr].

Neutral complexes are advantageous for observing the net olation because of the lack of counter ions.

Experimental

Preparation of Materials. *1) Cationic Complexes. Hydroxoglycinatoaquoethylenediaminecobalt(III) Perchlorate, [Co(OH)gly(H_2O)en]ClO_4 (reddish violet).* Eight grams of the chloroaquo complex ([CoCl(gly)(H_2O)en]Cl[7]) was dissolved in 25 ml of aqueous solution containing 1.5 g of sodium hydroxide. The solution was mildly heated at 50 °C on a water-bath until the violet solution turned dark red. Special care should be taken to prevent the temperature of the solution from exceeding 50 °C, otherwise an undesirable diaquo complex is frequently generated. Twenty-five milliliters of water containing 14 g of sodium perchlorate was added to the dark red solution. Gentle heating was continued until the color turned bright reddish violet. As soon as reddish violet crystals began to appear, the solution was cooled in a refrigerator. A pH value of 10—11 was suitable for obtaining the desired complex. The crystals were recrystallized from water. Yield 2 g

The corresponding chloride, nitrate and bromide were prepared by the same procedure except that sodium chloride, sodium nitrate and sodium bromide were used, respectively, in place of sodium perchlorate.

Found: C, 14.11; H, 4.37; N, 12.91%. Calcd for [Co(OH)gly(H_2O)en]ClO_4: C, 14.67; H, 4.61; N, 12.83%.

Hydroxodiethylenetriaminemonoacetatoaquocobalt(III) Perchlorate, [Co(OH)dtma(H_2O)]ClO_4 (reddish violet). The complex was prepared by a method similar to that for [Co(OH)gly(H_2O)en]ClO_4 except that the dichloro complex ([$CoCl_2$dtma][8,9]) was used as the starting material in place of [CoCl(gly)(H_2O)en]Cl. Twenty-nine grams of the dichloro complex was dissolved in 200 ml of aqueous solution containing 6 g of sodium hydroxide. The solution was gently heated at 50 °C on a water-bath until the violet solution turned dark red. To this solution was added 14 g of sodium perchlorate. The solution was again concentrated by gentle heating (50 °C) until reddish violet crystals were separated out. Another crop of crystals was obtained by cooling the solution. The product was recrystallized from water. Yield 5 g.

The corresponding nitrate, bromide and iodide were prepared by the same procedure except that sodium nitrate, sodium bromide and sodium iodide were used, respectively, instead of sodium pechlorate.

Found: C, 21.36; H, 4.74; N, 11.69%. Calcd for [Co(OH)dtma(H_2O)]ClO_4: C, 20.92; H, 5.11; N, 11.83%.

2) Anionic Complexes. K[Co(OH)nta(H_2O)]·H_2O,[10] K[Co(OH)nipda(H_2O)]·$2H_2O$,[11] K[Co(OH)α-abda(H_2O)]·$2H_2O$,[12] K[Co(OH)vda(H_2O)]·$1.5H_2O$,[12] K[Co(OH)lda(H_2O)]·H_2O,[13] K[Co(OH)pada(H_2O)]·$5H_2O$,[14] K[Cr(OH)nta(H_2O)]·$2H_2O$,[15] K[Cr(OH)nipda(H_2O)]·$2H_2O$,[16] K[Cr(OH)α-abda(H_2O)]·$2H_2O$,[17] K[Cr(OH)vda(H_2O)]·$2H_2O$,[17] K[Cr(OH)lda(H_2O)]·$3H_2O$[13] and K[Cr(OH)pada(H_2O)]·$5H_2O$[14] were prepared by the procedures described in the respective references.

Li, Na, Rb and Cs salts of the M(I)[Co(OH)nipda(H_2O)] type and Mg, Ca, Sr and Ba salts of the M(II)[Co(OH)nipda(H_2O)]$_2$ type were synthesized by similar way to that for K[Co(OH)nipda(H_2O)]·$2H_2O$[11] except that lithium carbonate, sodium bicarbonate, rubidium carbonate, cesium carbonate, magnesium carbonate, calcium carbonate, strontium carbonate and barium carbonate were used, respectively, in place of potassium bicarbonate.

3) Double Complexes. The procedure is a simple one. After 0.1 mmol of the hydroxoaquo cationic and anionic complexes were dissolved separately in 100 ml of hot aqueous solution, the two solutions were mixed together. On cooling, the double complexes were immediately separated out as violet crystals.

Although double complexes, in general, have low solubility, they can be recrystallized from a large amount of hot water. These complexes were obtained almost stoichiometrically.

4) Neutral Complexes. Hydroxobis(glycinato)aquocobalt(III) Dihydrate, [Co(OH)gly$_2$(H_2O)]·$2H_2O$ (violet). Twenty three grams of cobalt(II) chloride hexahydrate was dissolved in 100 ml of water. Fifteen grams of glycine was neutralized with 100 ml of water containing 8 g of sodium hydroxide. The two solutions were mixed and 10 ml of 28% hydrogen peroxide solution of was then added in order to oxidize the cobalt(II) ion. The solution was gently heated on a water-bath. Violet crystals gradually separated out during the heating. A pH value of 9—10 was suitable for obtaining the desired compound. The compound could not be recrystallized since it was sparingly soluble in ordinary solvents. However, chemical analysis showed that it is highly pure.

Found: C, 17.59; H, 5.14; N, 10.20%. Calcd for [Co(OH)gly$_2$(H_2O)]·$2H_2O$: C, 17.27; H, 5.43; N, 10.07%.

Hydroxobis(α-alaninato)aquocobalt(III) Monohydrate, [Co(OH)ala$_2$(H_2O)]·H_2O (violet). The complex was prepared by a procedure similar to that for [Co(OH)gly$_2$(H_2O)]·$2H_2O$ except that 18 g of α-alanine was used in place of glycine. It was also violet and insoluble in any solvent. Thus, recrystallization could not be carried out.

Found: C, 24.78; H, 5.69; N, 9.52%. Calcd for [Co(OH)ala$_2$(H_2O)]·H_2O: C, 25.01; H, 5.95; N, 9.72%.

Fig. 3. Geometrically possible isomers of $[Co(OH)(n\text{-}o)_2(H_2O)]$.

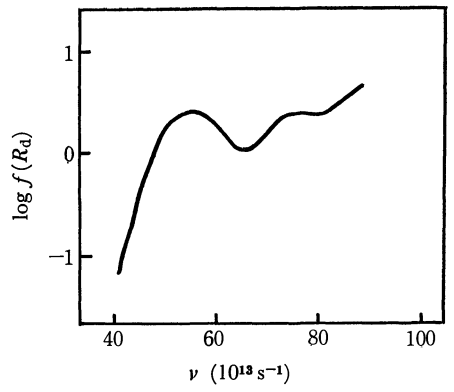

Fig. 4. Electronic spectrum of $[Co(OH)gly_2(H_2O)]\cdot 2H_2O$ (4.1).

The derivatograms for $[Co(OH)gly(H_2O)en]Cl\cdot H_2O$ (1.1.1), $[Co(OH)dtma(H_2O)]Br\cdot H_2O$ (1.2.2) and $K[Co(OH)lda(H_2O)]\cdot H_2O$ (2.1.5) as the representatives of the cationic and anionic complexes are shown in Fig. 5. As seen in the TG curve of $K[Co(OH)lda(H_2O)]\cdot H_2O$ (2.1.5), the mass losses corresponding to one mole of water are detected at *ca.* 60 and 175 °C. The former step corresponds to the liberation of crystalline water, the latter to the olation due to the removal of coordinated water. The color turned pink from bluish violet in the latter step, where an exothermic

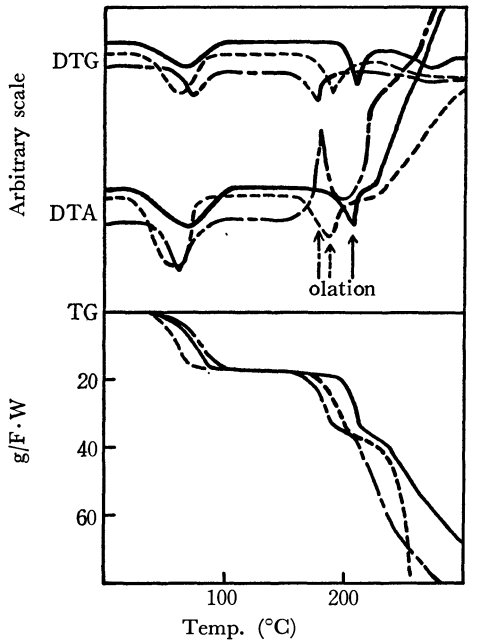

Fig. 5. Derivatograms for $[Co(OH)gly(H_2O)en]Cl\cdot H_2O$ (1.1.1)(——), $[Co(OH)dtma(H_2O)]Br\cdot H_2O$ (1.2.2)(——), and $K[Co(OH)lda(H_2O)]$(2.1.5)(– – –).

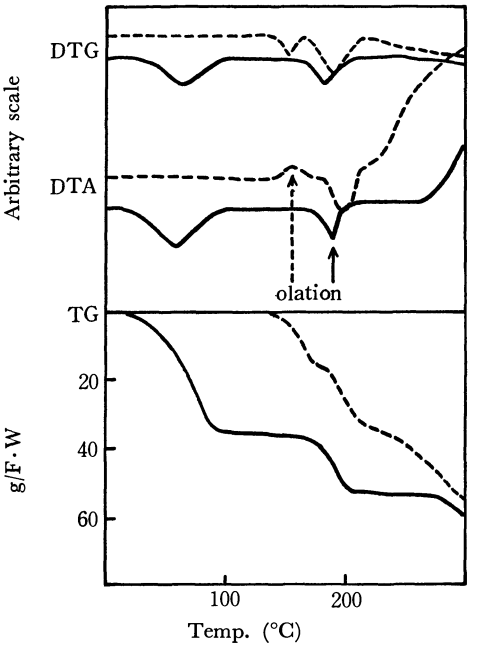

Fig. 6. Derivatograms for $K[Co(OH)nta(H_2O)]\cdot H_2O$ (2.1.1) (——) and $[Co(OH)gly_2(H_2O)]\cdot 2H_2O$(4.1)(——).

DTA peak appears. Such a change was observed in all the anionic complexes. However, the case is different with K[Co(OH)nta(H_2O)]·H_2O (2.1.1), the derivatogram of which is shown in Fig. 6 together with that of the neutral complex, [Co(OH)gly_2(H_2O)]·$2H_2O$ (4.1). In the case of K[Co(OH)nta(H_2O)]·H_2O (2.1.1), although the two steps of mass losses corresponding to one mole of water were separately observed at *ca.* 150 and 175 °C, the color change was found in the former step, with an exothermic DTA peak. The former step is thus thought to correspond to the olation and the latter to the liberation of crystalline water.

The cationic complex [Co(OH)gly(H_2O)en]Cl·H_2O (1.1.1) lost one mole of water at both 37 and 166 °C. The original reddish violet color turned pink in the latter step. Olation seems to take place in this step as a consequence of the liberation of the coordinated water. The thermal decomposition process of [Co(OH)dtma(H_2O)]Br·H_2O (1.2.2) was essentially similar to that of [Co(OH)gly(H_2O)en]Cl·H_2O (1.1.1). The olation in both cationic complexes was endothermic in contrast to that of the anionic complexes as seen in DTA curves, Fig. 5.

As for the olation of the neutral complexes, an endothermic peak was detected as in the DTA curve of [Co(OH)gly_2(H_2O)]·$2H_2O$ (4.1).

Since there is a striking contrast between the DTA curves of the cationic and anionic complexes, it is of interest to observe the olation of the double complexes. The derivatograms for [Co(OH)gly(H_2O)en][Co(OH)pada(H_2O)]·$2H_2O$ (3.1.6), [Co(OH)gly(H_2O)en][Cr(OH)pada(H_2O)]·$2H_2O$ (3.1.12) and [Co(OH)dtma(H_2O)][Co(OH)pada(H_2O)]·$2H_2O$ (3.2.6) are shown in Fig. 7. All three complexes lose each two moles of water in two separate steps. In the latter step, the color of [Co(OH)gly(H_2O)en]-[Co(OH)pada(H_2O)]·$2H_2O$ (3.1.6) and [Co(OH)-dtma(H_2O)][Co(OH)pada(H_2O)]·$2H_2O$ (3.2.6) turned pink from violet while that of [Co(OH)gly(H_2O)en]-[Cr(OH)pada(H_2O)]·$2H_2O$ (3.1.12) brownish pink from violet. The color change is probably due to the consequent olation.

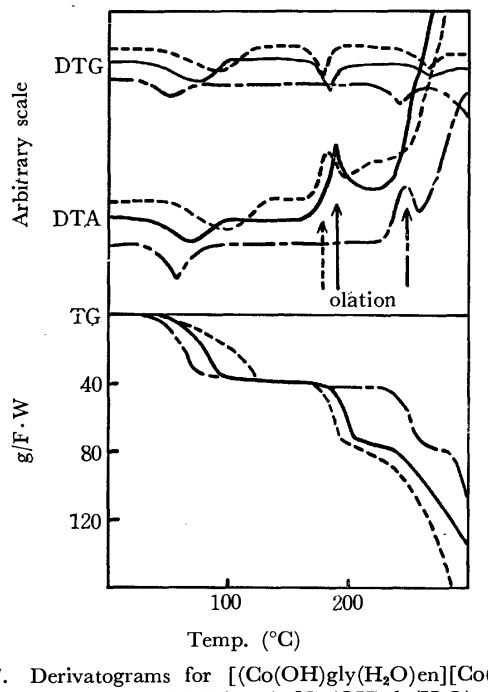

Fig. 7. Derivatograms for [(Co(OH)gly(H_2O)en][Co(OH)-pada(H_2O)]·$2H_2O$ (3.1.6)(----), [Co(OH)gly(H_2O)en][Cr-(OH)pada(H_2O)]·$2H_2O$ (3.1.12)(———) and [Co(OH)-dtma(H_2O)][Co(OH)pada(H_2O)]·$2H_2O$ (3.2.6)(——).

Electronic Spectra. It is well-known that cobalt(III) complexes containing "ol" groups show a specific band due to the bridged OH groups at about 100×10^{13} s^{-1}, the second band being frequently concealed by the strong specific band.[19]

The specific band could not be directly detected for all the complexes after heating since it was experimentally impossible to measure the electronic spectra beyond 90×10^{13} s^{-1} in a solid state. However, the obscurity of the second band of all the complexes after heating indicates that the specific band due to the bridged OH groups probably remains in the region of about 100×10^{13} s^{-1}.

Far-Infrared Spectra. In general, the hydroxoaquo complexes give bands at 640, 570 and 535 cm^{-1} in the region 700—500 cm^{-1}, and the diol complexes at 630, 545 and 505 cm^{-1}. All the hydroxoaquo complexes after heating at the above temperatures give spectra similar to those of the diol complexes. Thus, the results suggest the conversion of the hydroxoaquo complexes into the corresponding diol complexes upon heating.

From a study on the far-infrared spectrum of [$(NH_3)_4$-$Co(OH)_2Co(NH_3)_4$]$(SO_4)_2$·$2H_2O$ in the CsBr region, it is presumed that the strong band at 530—540 cm^{-1} is due to the presence of the four-membered cobalt-oxygen ring (–$Co(OH)_2Co$–).[20] The band of the diolcomplexes which appears at 545 cm^{-1} might be a characteristic band due to the skeletal vibration of –$Co(OH)_2Co$–.

Magnetic Moments. In order to examine the valency state of the central metal ions, the effective magnetic moments (μ_{eff}) were calculated from the magnetic susceptibilities measured at an ambient temperature by the Gouy method.

As for K[Co(OH)(n-o_3)(H_2O)], M(I) or $M(II)_{1/2}$-[Co(OH)(nipda)(H_2O)], [Co(OH)(n_3-o)(H_2O)]X and [Co(OH)(n_3-o)(H_2O)][Co(OH)(n-o_3)(H_2O)] type complexes, all the complexes were diamagnetic both before and after heating. On the other hand, the magnetic moments of [Co(OH)(n_3-o)(H_2O)][Cr(OH)(n-o_3)-(H_2O)] type complexes were 3.8—3.9 B.M., which is very close to the spin-only value of tervalent chromium ion. The actual change in magnetic moments could not be detected after heating.

The results indicate that both chromium and cobalt ions in all the complexes are tervalent, no actual electron transfer taking place upon heating. However, it is not clear whether or not such an electron transfer is generated in a step of the overall heating processes.

Thermochemical Data. The enthalpy changes (ΔH) of the olation of all the complexes were estimated from the DTA peak area.[18] The Arrhenius activation

energies (E_A) of the reaction were calculated from the slope of the Arrhenius plots derived by the analysis of DTA or DTG curve.[18] The detailed analysis of DTA or DTG curve confirmed that the olation of all the complexes proceeds in a first-order. The numerical values of the thermochemical data are summarized in Table 2. For the sake of simplification, some of the data obtained are diagramatically plotted as in Figs. 8 (A) through (F). In the abscissa, the outer sphere ions or the ligands (n-o_3) are taken at regular intervals in the order of the increase of radius or volume, while the initiation temperatures (T), the enthalpy changes (ΔH) and the Arrhenius activation energies (E_A) are plotted in the ordinate.

1) Cationic Complexes. We see from Fig. 8 (A) that the initiation temperature rises with the size of the outer sphere ions (for example, in the case of [Co(OH)gly(H_2O)en]X, $Cl^- < NO_3^- < Br^-$), and the same tendency is also observed in the activation energies. This means that the increase in the anion size reduces the ease of olation. The enthalpy changes for the nitrate salts [Co(OH)gly(H_2O)en]$NO_3 \cdot H_2O$ (1.1.2) and [Co(OH)dtma(H_2O)]NO_3 (1.2.1) are significantly smaller as compared with those for the other complexes. This may be due to the fact that the nitrate salts are decomposed just after the olation takes place and the heat of olation overlaps that of the subsequent decomposition. A comparison of [Co(OH)gly(H_2O)-en]X with [Co(OH)dtma(H_2O)]X reveals that both the initiation temperatures and the activation energies of the latter type complexes are somewhat higher than those of the former except for the initiation temperature of the bromide salts. This suggests that olation takes place more readily with [Co(OH)gly(H_2O)en]X than with [Co(OH)dtma(H_2O)]X.

2) Anionic Complexes. Figure 8 (B) illustrates the diagramatical relation of the thermochemical data when the ligands (n-o_3) are varied against the fixed cation (K). Fig. 8 (C) and (D) show the corresponding data when the cations are varied against the fixed ligand (nipda).

As seen from Fig. 8 (B), the exothermic heat of olation shows an increasing trend with the structural complexity of the ligands (n-o_3). On the other hand, a decreasing trend is found in the values of E_A except for that of K[Co(OH)nta(H_2O)]$\cdot H_2O$ (2.1.1). Accordingly, it is conceivable that the olation easily takes place in the order: nipda→pada-complexes and the nta-complex can be most easily olated.

Since the M(II)[Co(OH)nipda(H_2O)]$_2$ type complexes decomposed just after the olation took place and their fine derivatograms could not be obtained, the ΔH and E_A could not be estimated. Thus the initiation temperatures alone are given in Table 2 and Fig. 8 (D). From a comparison of the data for the M(I) *or* M(II)$_{1/2}$[Co(OH)nipda(H_2O)], K[Co(OH)(n-o_3)(H_2O)] and [Co(OH)(n_3-o)(H_2O)]X type complexes, it follows that the thermochemical data found when cations (M(I) and M(II)) are varied are not so greatly affected as those obtained when the ligands (n-o_3 and n_3-o) or the anions are varied. This suggests that the effect of cations on the olation is smaller than that of anions or ligands. The initiation temperatures of the M(II)$_{1/2}$[Co(OH)nipda(H_2O)] type complexes are considerably higher than those of the M(I)[Co(OH)nipda(H_2O)] type complexes. The reason might be attributed to the difference of the crystal structures.

3) Neutral Complexes. The data for [Co(OH)-gly$_2$(H_2O)]$\cdot 2H_2O$ (4.1) and [Co(OH)ala$_2$(H_2O)]$\cdot H_2O$ (4.2) indicate a tendency for the latter to give rise to olation more easily than the former.

4) Double Complexes. In the case of the [Co]-[Co] type complexes, as shown in Fig. 8 (E), the initiation temperatures and the activation energies decrease in the order of the complexity in the structure of the n-o_3 ligands: nta-→pada-complexes. The tendency is compatible with that found in the case of the anionic complexes.

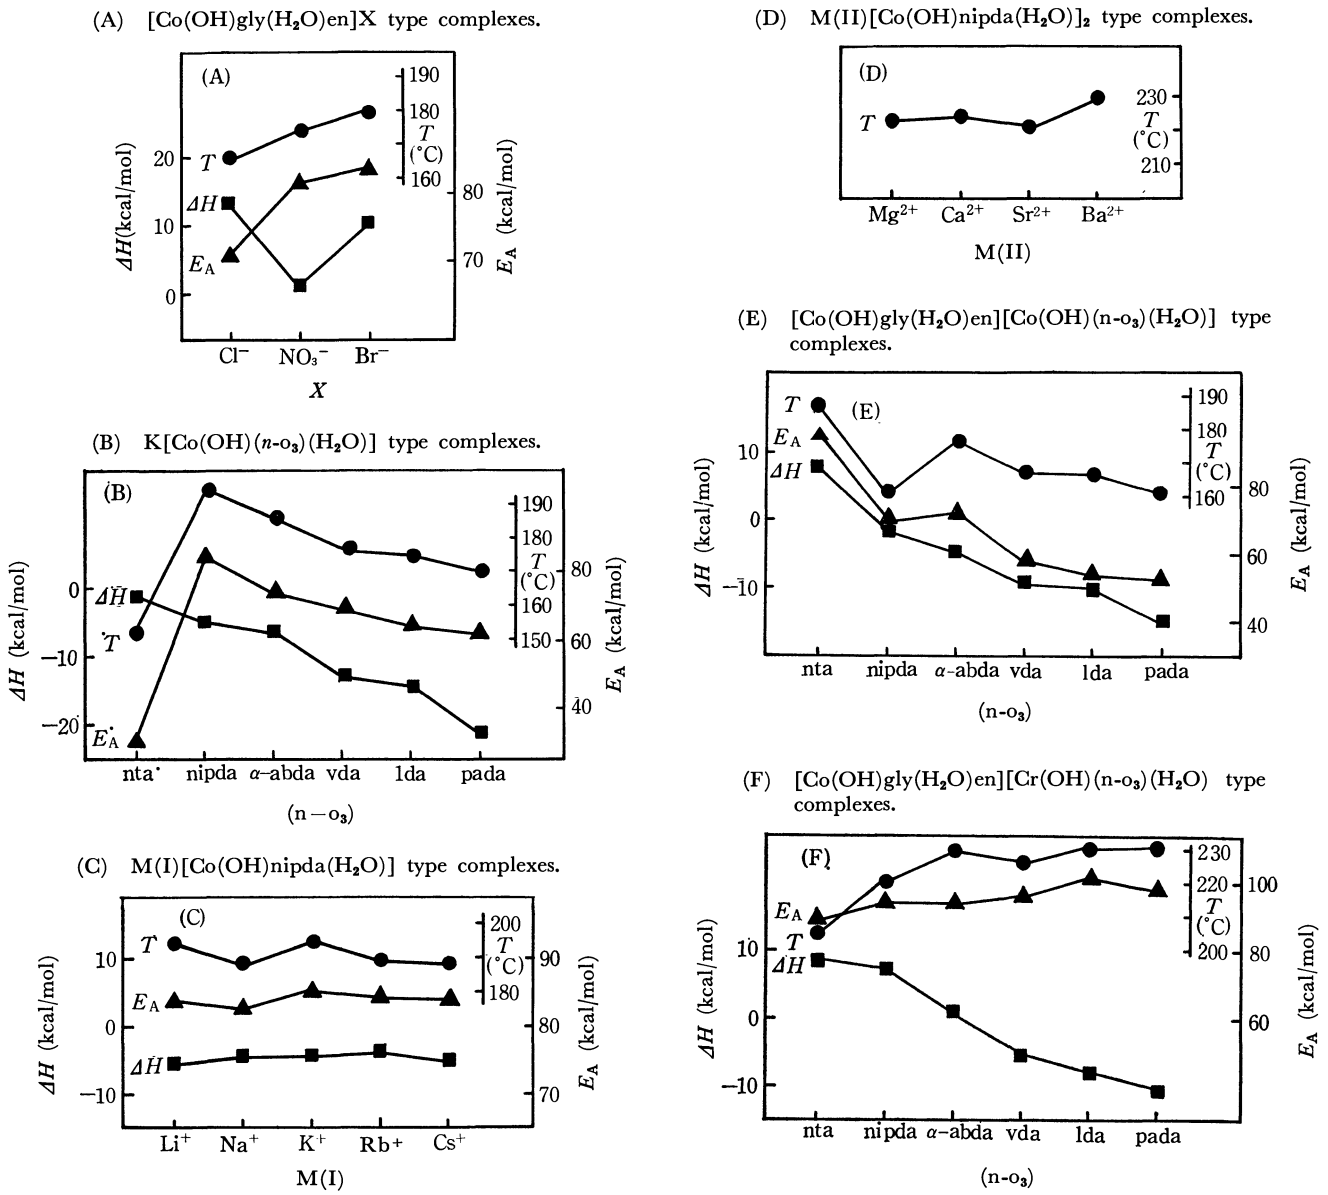

Fig. 8. Diagrammatical relation of thermochemical data.

In contrast, in the case of the [Co][Cr] type complexes a distinct tendency is not observed, but we see that the values of the initiation temperatures and the activation energies become to some extent higher in the order: nta-→pada-complexes. This indicates that the olation readily takes place in the order: pada-→nta-complexes, differing from the case of the [Co][Co] complexes.

The enthalpy changes for the olation of the anionic complexes show a decreasing trend with the complexity in the structures of the n-o_3 ligands: nta-→pada-complexes. On the other hand, the enthalpy changes accompanied by the olation of the double complexes are uniformly larger than those of the respective anionic complexes. Thus, it might be concluded that the values of ΔH for the olation of the double complexes are approximately proportional to the sum of the values for the cationic and anionic complexes; *i.e.*, ΔH_d (for double complex)$=\Delta H_c$ (for cationic complex)$+\Delta H_a$ (for anionic complex).

An Optical Absorption Study of the Reaction of Bis(*O,O'*-diethyldithiophosphato)oxovanadium(IV) with Pyridine

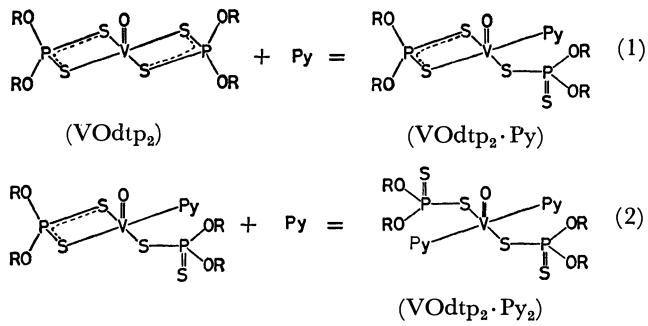
Mitsuo SATO and Takao KWAN

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received June 16, 1973)

The interaction of bis(*O,O'*-diethyldithiophosphato)oxovanadium(IV), $VOdtp_2$, with pyridine has been studied in toluene by means of the optical absorptions. It has been found that the visible absorption band characteristic of $VOdtp_2$ was shifted toward longer wavelengths upon the formation of the complex species identified as $VOdtp_2 \cdot Py$ and $VOdtp_2 \cdot Py_2$. The equilibrium constants and enthalpy and entropy changes for the formation of $VOdtp_2 \cdot Py$ were determined from the spectral characteristics, measured as a function of the solvent composition and the temperature. The results obtained were then discussed in comparison with those for the base addition of other oxovanadium complexes.

In the foregoing paper,[1] ESR evidence was presented that bis(*O,O'*-diethyldithiophosphato)oxovanadium(IV), $VOdtp_2$, reacts with pyridine to form both mono- and dipyridine complexes. Pyridine bases were found to coordinate the vanadium nucleus, as is shown by the following scheme:



Since such a coordination scheme affords a marked contrast to that generally accepted for the base addition of oxovanadium(IV) complexes,[2] it seems worthwhile to investigate Reactions (1) and (2) in more detail. In the present work, an optical absorption method was used to investigate the equilibria involved and to obtain their thermodynamic data; the results will be reported here.

Experimental

Materials. Bis(*O,O'*-diethyldithiophosphato)oxovanadium(IV), $VOdtp_2$, was prepared as has been described previously.[1] The pyridine and toluene were obtained from Wako Junyaku Kogyo Co. and were used after distillation from calcium hydride and potassium hydroxide respectively.

Measurements. Since the complex species in solutions were unstable to air, all the measurements were carried out on sample solutions carefully prepared in an atmosphere of nitrogen or *in vacuo*. The optical absorption spectra were measured with a Hitachi spectrophotometer (Model EPS-3T), using 10-mm quartz cells fitted with vacuum stopcocks or a nitrogen-bubbling device. The spectrophotometer was equipped with a temperature-regulated cell holder, and a constant temperature was maintained by circulating water through the cell holder. The temperatures were regulated by circulating through the cell holder water that had been cooled or warmed to the desired temperature. The temperatures were measured by means of a copper-constantan thermocouple directly inserted into the toluene placed in the reference cell. The ESR spectra were recorded with a JEOL spectrometer (Model P-10), as has been described previously.[1]

Results

Visible Absorption Spectra of Complex Species in Solutions. The optical absorption spectra of toluene solutions containing $VOdtp_2$ and pyridine in various mole ratios, as well as those of toluene and pyridine solutions of $VOdtp_2$, were measured at 18 °C. Some typical visible absorption spectra thus obtained are illustrated in Fig. 1. It is apparent from Fig. 1 that the spectrum A, obtainable without pyridine bases, shifts to B and C successively upon an increase in the pyridine content, thus affording three types of visible spectra.

In light of the ESR spectra of these solutions,[3] the visible spectra mentioned above can readily be

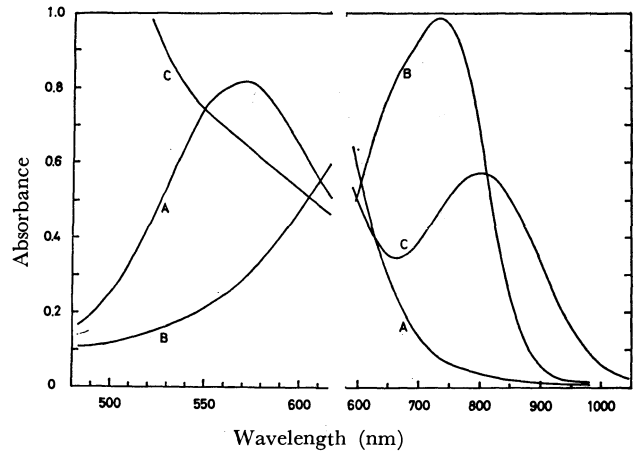


Fig. 1. Visible absorption spectra of toluene-pyridine solutions of $VOdtp_2$ at 18°C.
(A) $VOdtp_2$ in toluene, $[VOdtp_2]_0 = 0.015$ M;
(B) $VOdtp_2$-pyridine in toluene, $[VOdtp_2]_0 = 0.015$ M, $[Py]_0 = 0.091$ M;
(C) $VOdtp_2$ in pyridine, $[VOdtp_2]_0 = 0.012$ M.

1) M. Sato, Y. Fujita, and T. Kwan, This Bulletin, **46**, 3007 (1973).

2) J. Selbin, *Chem. Rev.*, **65**, 153 (1965).

3) Corresponding to the three types of visible absorption spectra, ESR spectra characterized with 24, 16, and 8 resonance lines were observed. The interpretation of these ESR spectra has already been reported in the foregoing paper, together with the proposed structures of the complex species.

interpreted as due to the complex species, $VOdtp_2$, $VOdtp_2 \cdot Py$, and $VOdtp_2 \cdot Py_2$, in the respective solutions. The absorption maxima and molar extinction coefficients determined for these complex species were given by:

(A) $VOdtp_2$; λ_{max} 570 nm, $\varepsilon_{A(max)}$ 53 $M^{-1}cm^{-1}$.

(B) $VOdtp_2 \cdot Py$; λ_{max} 735 nm, $\varepsilon_{B(max)}$ 71 $M^{-1}cm^{-1}$.

(C) $VOdtp_2 \cdot Py_2$; λ_{max} 800 nm, $\varepsilon_{C(max)}$ 47 $M^{-1}cm^{-1}$.

where the values of $\varepsilon_{A(max)}$ and $\varepsilon_{C(max)}$ were derived directly from Fig. 1, while that of $\varepsilon_{B(max)}$ was obtained by the procedure to be described below.

The band at 570 nm observed for $VOdtp_2$ seems to originate from a d-d transition;[4] this band is considered to shift to lower energies to produce a new band at 735 nm or 800 nm when one or two of the equatorial sulfur ligands are displaced by pyridine bases.

The Equilibrium Constant of Reaction (1). Job's method of continuous variations and the mole-ratio method[5] were applied to the $VOdtp_2$-pyridine system at 18 °C, first to confirm the stoichiometry of Reactions (1) and (2) and then to evaluate their equilibrium constants. It was found, however, that Reaction (2) did not proceed at all under the conditions employed in these experiments.

As can be seen from the results of the continuous variation method (Fig. 2), the absorbance at 735 nm reached its maximum at 50 mole% pyridine, indicating that one mole of $VOdtp_2$ reacts with one mole of pyridine, consistent with the stoichiometry of Reaction (1). On the other hand, the mole-ratio method showed

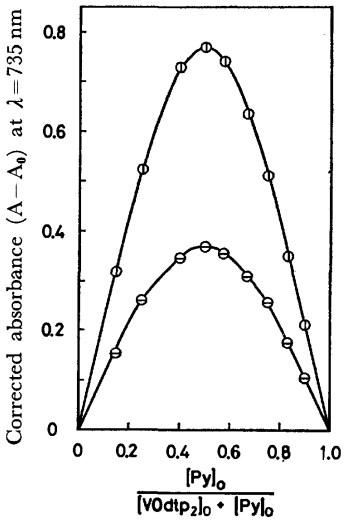

Fig. 2. Continuous variation method as applied to the $VOdtp_2$-pyridine system by visible absorption measurements at 18 °C.

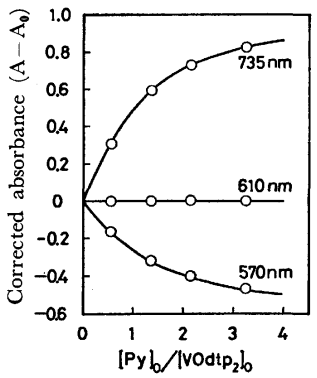

Fig. 3. Mole-ratio method as applied to the $VOdtp_2$-pyridine system by visible absorption measurements at 18 °C.
$[VOdtp_2]_0=0.015$ M (const.).

the presence of two absorbing species, $VOdtp_2$ and $VOdtp_2 \cdot Py$, in solutions, as can be seen from Fig. 3, where an isosbestic point at 610 nm is shown with the increasing and decreasing absorbances at 735 and 570 nm. These results are in accordance with the previous ESR information[1] that $VOdtp_2 \cdot Py$ is rather stable in toluene and is present in equilibrium with $VOdtp_2$ and pyridine over a wide concentration range, while $VOdtp_2 \cdot Py_2$ is formed only when $VOdtp_2 \cdot Py$ interacts with a large excess of pyridine bases.

The equilibrium constant, $K=[VOdtp_2 \cdot Py]/[VOdtp_2][Py]$, of Reaction (1) was then evaluated from the data shown in Figs. 2 and 3 after the procedure by Lang.[5,6] On the basis of the presence of two absorbing species, $VOdtp_2$ and $VOdtp_2 \cdot Py$, in solutions, the measured absorbance, A, at the chosen wavelength is given by:

$$A = \varepsilon_A[VOdtp_2] + \varepsilon_B[VOdtp_2 \cdot Py]$$
$$= \varepsilon_A[VOdtp_2]_0 + (\varepsilon_B - \varepsilon_A)[VOdtp_2 \cdot Py] \quad (3)$$

We then obtain the following expression for the equilibrium constant:

$$K = \frac{[VOdtp_2 \cdot Py]}{([VOdtp_2]_0 - [VOdtp_2 \cdot Py])([Py]_0 - [VOdtp_2 \cdot Py])}$$
$$= \frac{\dfrac{A-A_0}{\varepsilon_B-\varepsilon_A}}{\left([VOdtp_2]_0 - \dfrac{A-A_0}{\varepsilon_B-\varepsilon_A}\right)\left([Py]_0 - \dfrac{A-A_0}{\varepsilon_B-\varepsilon_A}\right)} \quad (4)$$

where ε_A and ε_B are the molar extinction coefficients at the chosen wavelength for $VOtdp_2$ and $VOdtp_2 \cdot Py$ respectively, where A_0 is the absorbance of $VOdtp_2$ at the wavelength in the absence of pyridine ($A_0=\varepsilon_A[VOdtp_2]_0$), and where $[VOdtp_2]_0$ and $[Py]_0$ are the initial concentrations of the two species.

To estimate the two unknowns, K and ε_B, the equation was rewritten as:

$$\frac{[VOdtp_2]_0[Py]_0}{A-A_0} = \left\{[VOdtp_2]_0 + [Py]_0 - \frac{A-A_0}{\varepsilon_B-\varepsilon_A}\right\} \cdot \frac{1}{\varepsilon_B-\varepsilon_A} + \frac{1}{K} \cdot \frac{1}{\varepsilon_B-\varepsilon_A} \quad (5)$$

6) R. P. Lang, *J. Amer. Chem. Soc.*, **84**, 1185 (1962).

$[VOdtp_2]_0[Py]_0/(A-A_0)$ was plotted against $\{[VOdtp_2]_0+[Py]_0-(A-A_0)/(\varepsilon_B-\varepsilon_A)\}$ by using a tentative value[7] of ε_B and also by employing the absorbance data at $\lambda=735$ nm shown in Figs. 2 and 3. The plot yielded a straight line with a slope of $1/(\varepsilon_B-\varepsilon_A)$ and an intercept of $1/K(\varepsilon_B-\varepsilon_A)$, from which a new value of ε_B was determined along with that of K. This procedure was repeated until a consistent set of values for both ε_B and K was obtained from two successive plots. The final plot is presented in Fig. 4, with the following consistent values: $K_{(18°C)}=1.2\times10^2\ M^{-1}$, $\varepsilon_{B(\lambda=735nm)}=71\ M^{-1}\,cm^{-1}$. The uncertainties in the values estimated from the deviations in the linearity of the plots are about $\pm0.3\times10^2\ M^{-1}$ and $\pm5\ M^{-1}\,cm^{-1}$ for K and ε_B respectively.

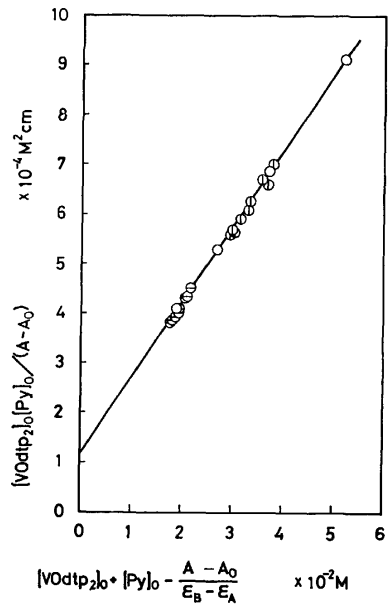

Fig. 4. Lang's plots of the $VOdtp_2$-pyridine system ($\lambda=735$ nm).

○: Absorbance data from Fig. 3.

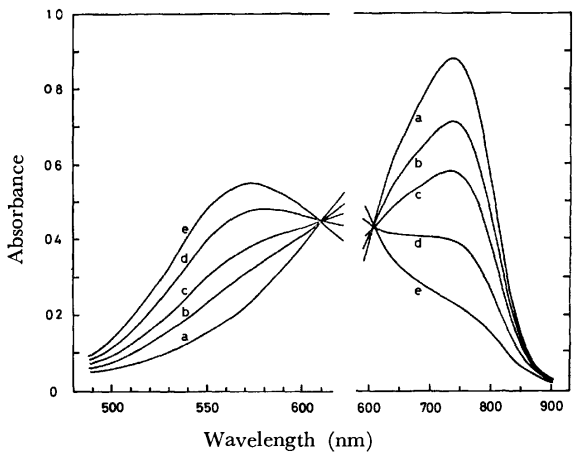

Fig. 5. Effect of temperature on visible absorption spectra.
$[VOdtp_2]_0=0.015$ M, $[Py]_0=0.035$ M.
a) 10 °C, b) 24 °C, c) 34 °C, d) 51 °C, e) 73 °C.

7) A tentative value of ε_B was advantageously determined by using data from two solutions and by solving Eq. (5) simultaneously for ε_B and K.

Temperature Dependence of the Equilibrium Constant. Figure 5 shows a typical set of visible spectra observed at different temperatures. It can be seen that the spectra show a sharp isosbestic point at 610 nm, with two absorption peaks at 570 and 735 nm. The presence of the isosbestic point again indicates that the equilibrium relation (1) is valid even at higher temperatures without any side reaction. Such an equilibrium relation between $VOdtp_2$ and $VOdtp_2\cdot Py$ was clearly evidenced also by the ESR spectra observed at different temperatures, as is shown in Fig. 6.

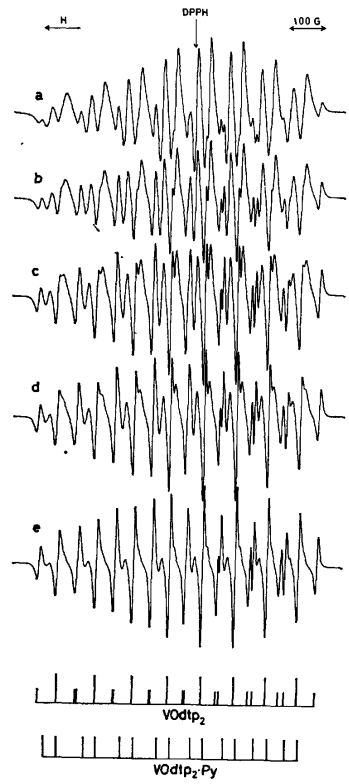

Fig. 6. Effect of temperature on ESR spectra.
$[VOdtp_2]_0=0.015$ M, $[Py]_0=0.035$ M.
a) 18 °C, b) 31 °C, c) 45 °C, d) 56 °C, e) 84 °C.
(The stick diagrams at the bottom of Figure indicate the 24 and 16 resonance lines expected from the complex species, $VOdtp_2$ and $VOdtp_2\cdot Py$.)

The equilibrium constant at each temperature was calculated using Eq. (4) on the assumption that molar extinction coefficients of $VOdtp_2$ and $VOdtp_2\cdot Py$ were constant over the entire temperature range. The resulting K values were found to be:

K = 160 (10 °C), 65 (24 °C), 35 (34 °C), 15 (51 °C), 5.5 M^{-1} (73 °C).

A plot of $\ln K$ *vs.* $1/T$ yielded a good straight line, and the following standard enthalpy and entropy changes for Reaction (1) were derived from the slope and intercept:

$$\Delta H° = -10.5\ \text{kcal/mol},$$
$$\Delta S° = -27.0\ \text{e.u.}$$

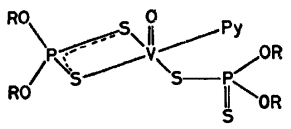
These values may be compared to those ($\Delta H°=-12$ kcal/mol, $\Delta S°=-30$ e.u.) obtained from an

analysis of the ESR spectra shown in Fig. 6. In view of the uncertainties in the values from the ESR spectra, both results seem to be compatible within the limit of experimental errors.

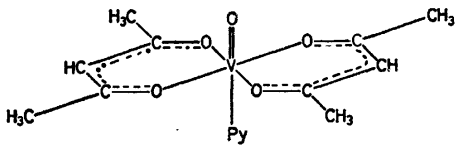
Discussion

It has generally been accepted[2] that square pyramidal oxovanadium(IV) complexes have a tendency to add a sixth ligand to the open coordination site *trans* to the apical oxygen atom when they are allowed to react with a variety of bases in solutions. For example, the formation of base adducts of bis(acetylacetonato)oxovanadium(IV), $VO(acac)_2$, has long been studied extensively by many workers,[8] and the thermodynamical data for the equilibria of the base addition to the sixth coordination site have already been repoted.[9,10]

However, our ESR and optical absorption studies have shown that the base addition reaction of $VOdtp_2$ is not a simple process in which the pyridine base adds to the open coordination site. The reaction has been found to be a rather complicated process involving the displacement of the equatorial sulfur ligand and leading to the formation of the complex species, $VOdtp_2 \cdot Py$, depicted as:



This type of base addition affords a marked contrast to the corresponding base adduct of $VO(acac)_2 \cdot Py$:



It is, however, not completely clear why there exists such a structural difference between $VOdtp_2 \cdot Py$ and $VO(acac)_2 \cdot Py$. For the moment, we can only say that the difference seems to result in part from the different natures of the equatorial ligands.

From this point of view, it is interesting to compare the thermodynamical data determined for the equilibrium of the $VOdtp_2$-pyridine system with those reported previously for the $VO(acac)_2$–pyridine system ($K_{(25°C)}=58\ M^{-1}$, $\Delta H°=-7.4$ kcal/mol, $\Delta S°=-16.6$ e.u.).[10] A close similarity in the K values at 25 °C is noticeable, although there are some differences in the $\Delta S°$ and $\Delta H°$ values. The difference in the $\Delta S°$ values may be taken to reflect the different steric and solvation effects between the two systems. The $\Delta H°$ values may indicate that the vanadium-nitrogen coordination in $VOdtp_2 \cdot Py$ is much stronger than that in $VO(acac)_2 \cdot Py$, since the $\Delta H°$ for the $VOdtp_2$-pyridine system is attributable mainly to the differences in the bond energies of the vanadium-sulfur bond broken and the vanadium-nitrogen bond formed, while the $\Delta H°$ for the $VO(acac)_2$–pyridine system results mainly from the bond energy of the vanadium nitrogen bond formed. Such a notion is in accordance with the view that oxovanadium complexes coordinate a sixth axial ligand much more weakly than the equatorial ligands.

Since, in properties and structure, $VOdtp_2$ closely resembles bis(dithiocarbamato)oxovanadium(IV), $VOdtc_2$, rather than $VO(acac)_2$, it is important for us to note the recent spectroscopic studies of the interaction of $VOdtc_2$ with pyridine. McCormick[11] found that visible absorption bands associated with the d–d transitions of $VOdtc_2$ were shifted about 5000 cm^{-1} to lower energies when $VOdtc_2$ was dissolved in pyridine. He interpreted this red shift in terms of the addition of pyridine to the open coordination site and was able to isolate $VOdtc_2 \cdot Py$ as a solid.

However, the magnitude of the red shift observed for $VOdtc_2 \cdot Py$ is much closer to that (about 4000 cm^{-1}) for $VOdt_2p \cdot Py$ than to that (about 2000 cm^{-1}) for $VO(acac)_2 \cdot Py$.[10,11] Moreover, the ESR spectra of the $VOdtc_2$-pyridine system have provided no conclusive information about the structure of the complex species formed.[13]

From these points of view, we consider that at least two possibilities should be discussed equally for the base addition of $VOdtc_2$. The first possibility is, of course, that $VOdtc_2$ reacts with pyridine similarly to $VO(acac)_2$, while the second is that it reacts similarly to $VOdtp_2$. In order to distinguish these two possibilities, we have also made an ESR examination of the $VOdtc_2$-pyridine system. However, our ESR results have again provided no conclusive information as to which of the two possibilities is more probable. For the moment, it can only be said that further work, such as structural analysis by X-ray, will be required to confirm the structure of $VOdtc_2 \cdot Py$ and to decide between the above possibilities.

This work was supported in part by a grant of the Ministry of Education, to which the authors' grateful acknowledgements are made.

Stability of Fused Rings in Metal Chelates. XI. Stability of Dipeptide Amide-Copper(II) Complexes

Osamu YAMAUCHI, Yasuo NAKAO, and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received August 7, 1973)

The structure-stability relationship between the copper(II) complexes of several dipeptide amides consisting of glycine and/or β-alanine has been investigated by potentiometric titration. The amides of glycylglycine, glycyl-β-alanine, and β-alanylglycine (abbreviated as H_2L) have been found to form complexes of the type $Cu(H_2L)^{2+}$ with log K_1 values 4.80—5.22. The $-\log K_{c_1}$ values for deprotonation of the peptide group are 5.05—5.42 and comparable to those of tripeptides, whereas the $-\log K_{c_2}$ values for the terminal amide group are 7.96 for glycylglycine amide and 8.99 for glycyl-β-alanine amide. This indicates that, at neutral pH, the $-CONH_2$ group coordinates to copper(II) mainly through the carbonyl oxygen. β-Alanyl-β-alanine amide-copper(II) system gave precipitates at an early stage of titration. The structures and relative stability of the complexes of types $Cu(H_2L)^{2+}$, $Cu(HL)^{+}$, and CuL have been discussed from comparative studies of their stability constants.

Amide groups in amino acid amides and peptides exhibit interesting reactivity toward copper(II) ions. Their modes of reaction reflect the influence of the environment. The reactivity, expressed in terms of the dissociation constant for the amide group in the presence of copper(II), appears to depend on whether the group is in a simple amino acid amide or in a peptide chain and how it can have access to the central metal ion.[1,2]

With this in mind, we have investigated the structure-stability relationship between the copper(II) complexes of several dipeptide amides, in order to get information on the factors affecting the complexing abilities of the amide groups and the probable structures of the resulting complexes in aqueous solution.

For closer comparison with the reported peptide-copper(II) systems,[2,3] the solution equilibria of the copper(II) complexes of glycylglycine amide (abbreviated as Gly·Gly·NH_2), glycyl-β-alanine amide (Gly·β-Ala·NH_2), β-alanylglycine amide (β-Ala·Gly·NH_2), and β-alanyl-β-alanine amide (β-Ala·β-Ala·NH_2) have been studied by potentiometric titration, the results of which are given in the following.

Experimental

All the melting points are uncorrected.

Preparation of Dipeptide Amides and Related Compounds

The ethyl ester hydrochlorides of glycine, β-alanine, glycylglycine, and glycyl-β-alanine were prepared according to the ordinary method.[4]

Carbobenzoxyglycylglycine Ethyl Ester. To a solution of 10 g of glycylglycine ethyl ester hydrochloride in 40 ml of water were gradually added 12 g of potassium bicarbonate and then 90 ml of chloroform. Into the resulting mixture was added 8.5 ml of carbobenzoxy chloride over a period of 15—20 min under constant stirring. After it had been stirred at room temperature for 1—2 hr, unreacted carbobenzoxy chloride was treated with pyridine. The organic fraction was washed successively with 2—3% aqueous sodium bicarbonate, dilute hydrochloric acid, and water, and then dried over anhydrous magnesium sulfate. The filtrate was concentrated *in vacuo* to give a crystalline product, which was recrystallized from ethyl acetate–petroleum benzin.

Carbobenzoxyglycyl-β-alanine Ethyl Ester. This was prepared by a similar procedure to that for the carbobenzoxyglycylglycine ethyl ester.

The two materials described above were identified by comparing their melting points with those in the literature.[5,6]

Carbobenzoxy-β-alanylglycine Ethyl Ester. This was prepared in the same manner as reported by Winitz *et al.*[7] To a mixture of 15.6 g of carbobenzoxy-β-alanine[8] prepared from β-alanine and carbobenzoxy chloride, 9.8 g of glycine ethyl ester hydrochloride, and 9.8 ml of triethylamine in 160 ml of chloroform was added 14.5 g of *N,N'*-dicyclohexylcarbodiimide, and the reaction mixture was stirred at room temperature overnight. After removal of *N,N'*-dicyclohexylurea, the filtrate was washed successively with water, dilute hydrochloric acid, saturated aqueous sodium bicarbonate and water, dried over anhydrous magnesium sulfate and evaporated to dryness *in vacuo*. The product was identified by its melting point.[6]

Carbobenzoxy-β-alanyl-β-alanine Ethyl Ester. This was prepared from carbobenzoxy-β-alanine and β-alanine ethyl ester hydrochloride in the same way as for carbobenzoxy-β-alanylglycine ethyl ester.

Carbobenzoxy Derivatives of Glycylglycine-, Glycyl-β-alanine-, β-Alanylglycine-, and β-Alanyl-β-alanine-amide. These compounds were prepared according to the known method.[6] The first three compounds were confirmed by their melting points,[6,9] and elemental analysis. Carbobenzoxy-β-alanyl-β-alanine amide recrystallized from methanol–ether melted at 192—195 °C. Found: C, 57.49; H, 6.49; N, 14.24%. Calcd for $C_{14}H_{19}N_3O_4$: C, 57.32; H, 6.54; N, 14.33%.

Hydrochlorides of Glycylglycine-, Glycyl-β-alanine-, β-Alanylglycine-, and β-Alanyl-β-alanine-amide. These were obtained by the catalytic reduction of the corresponding amide

derivatives of the carbobenzoxy peptides by using palladium black as a catalyst. In all cases, methanol was used as solvent with a small amount of hydrochloric acid. Glycylglycine amide hydrochloride and glycyl-β-alanine amide hydrochloride were recrystallized from methanol-ethyl acetate, whereas β-alanylglycine amide hydrochloride and β-alanyl-β-alanine amide hydrochloride were recrystallized from methanol-ether.

Glycylglycine Amide Hydrochloride: Mp 192—193 °C. Found: C, 28.53; H, 6.27; N, 25.46%. Calcd for $C_4H_{10}N_3O_2Cl$: C, 28.66; H, 6.03; N, 25.07%.

Glycyl-β-alanine Amide Hydrochloride: Mp 166—168 °C. Found: C, 33.05; H, 6.53; N, 23.25%. Calcd for $C_5H_{12}N_3O_2Cl$: C, 33.06; H, 6.67; N, 23.14%.

β-Alanylglycine Amide Hydrochloride: Mp 182—183 °C. Found: C, 32.98; H, 6.59; N, 23.58%. Calcd for $C_5H_{12}N_3O_2Cl$: C, 33.06; H, 6.67; N, 23.14%.

β-Alanyl-β-alanine Amide Hydrochloride: Mp 135—137 °C. Found: C, 36.93; H, 7.05; N, 21.48%. Calcd for $C_6H_{14}N_3O_2Cl$: C, 36.83; H, 7.23; N, 21.48%.

Glycylglycine Amide Acetate: This was prepared according to the method of Fruton and Bergmann.[9]

Preparation of the Neutral Copper(II) Complex of Glycylglycine Amide To a solution of 0.75 g of glycylglycine amide acetate in 10 ml of water was added freshly precipitated copper(II) hydroxide obtained from 1.5 g of copper(II) sulfate pentahydrate. The mixture was stirred at room temperature for about 30 min, and, after removal of excessive copper(II) hydroxide, added into ethanol-ether (2 : 1 by volume) under vigorous stirring. The complex was obtained as violet crystals. Found: C, 22.35; H, 4.53; N, 18.67%. Calcd for $[Cu(C_4H_7N_3O_2)(OH_2)]\cdot 1/2H_2O$: C, 21.87; H, 4.60; N, 19.13%.

pH Titration. Aqueous solutions (4.0×10^{-3} M; μ= 0.1 (KNO_3)) of the dipeptide amides were titrated in the absence and the presence of an equimolar amount of copper(II) nitrate.

The apparatus and the procedure were the same as reported previously.[2]

Results and Discussion

Titration Curves and Equilibrium Constants. The pH titration curves of the dipeptide amides in the absence and the presence of copper(II) nitrate are shown in Fig. 1. The amides with the β-alanyl group at the NH_2-terminus gave precipitates during the titration in the presence of copper(II). Since the structures of the dipeptide amides are closely related to those of the reported di- and tri-peptides[2,3] and the behavior of the terminal amide group is considered to be very similar to that of simple amino acid amides,[1] it is reasonable to assume from the titration curves the following reaction sequences and the species involved therein:

$$Cu^{2+} + H_2L \overset{K_1}{\rightleftharpoons} Cu(H_2L)^{2+} \quad (1)$$

$$Cu(H_2L)^{2+} \overset{K_{c_1}}{\rightleftharpoons} Cu(HL)^{+} + H^{+} \quad (2)$$

$$Cu(HL)^{+} \overset{K_{c_2}}{\rightleftharpoons} CuL + H^{+} \quad (3)$$

where H_2L refers to free dipeptide amide, and $Cu(HL)^+$ and CuL to the complexes formed upon removal of one and two protons, respectively, from the peptide linkages in the dipositive complex $Cu(H_2L)^{2+}$. The

relevant equilibrium constants are defined by the following equations.

$$K_1 = \frac{[Cu(H_2L)^{2+}]}{[Cu^{2+}][H_2L]} \quad (4)$$

$$K_{c_1} = \frac{[Cu(HL)^{+}][H^{+}]}{[Cu(H_2L)^{2+}]} \quad (5)$$

$$K_{c_2} = \frac{[CuL][H^{+}]}{[Cu(HL)^{+}]} \quad (6)$$

The curve for Gly·Gly·NH_2–copper(II) indicates the dissociation of the third proton from the water molecule in the complex at high pH to give a hydroxy complex $CuL(OH)^-$ according to the equation:

$$CuL \overset{K_{OH}}{\rightleftharpoons} CuL(OH)^{-} + H^{+} \quad (7)$$

where

$$K_{OH} = \frac{[CuL(OH)^{-}][H^{+}]}{[CuL]} \quad (8)$$

Calculation of the equilibrium constants K_1, K_{c_1}, K_{c_2} and K_{OH} was carried out by the method of non-linear least-squares with the use of a NEAC 2200/500 computer. Derivation of the equations for the least-squares treatment and the computer program were essentially the same as those reported for the tripeptide-copper(II) systems.[2] Because of precipitation, the K_{c_2} value for β-Ala·Gly·NH_2 and all the constants for β-Ala·β-Ala·NH_2 could not be calculated.

The calculated equilibrium constants are shown in Table 1 together with the corresponding constants for the amino acid amide-,[1] dipeptide-,[3] and tripeptide-copper(II)[2] systems included for comparison. The reliability of the calculated constants was confirmed by duplicate or triplicate titration and by comparing the theoretical curves with the experimental ones, the deviations expressed in titer being negligibly small

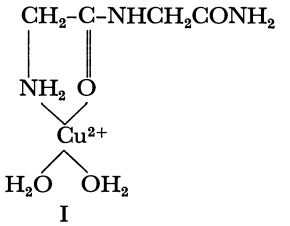
(less than 0.03 ml for the titers of 0—3.0 ml) for all the systems in the pH ranges studied.

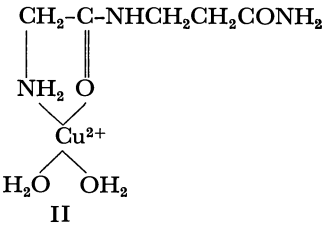
The log K_1 values are 4.80—5.22 and close to those for the tripeptide-copper(II) systems. A possible reason for the low value for Gly·Gly·NH_2 might be that this ligand has the lowest pK_a value. This system has been reported recently by Sigel *et al.*[10] who obtained the value of 5.05 for log K_1.

Dissociation of the peptide hydrogens in the complexed species are measured by means of pK_{c_1} (−log K_{c_1}) and pK_{c_2} (−log K_{c_2}), which can be compared with the corresponding values for the dipeptides and the tripeptides. The pK_{c_1} values are essentially the same for the three amides and seem to be independent of the nature of the *N*-terminal amino acid, whereas the pK_{c_2} values reflect the steric requirements around copper(II) and are much higher than those for the tripeptides. The reported values[10] of pK_{c_2} (7.29) and estimated pK_{OH} (−log K_{OH}) (~8.3) for Gly·Gly·NH_2 differ considerably from the present values, this being ascribable to precipitation which was not observed in our experiment.

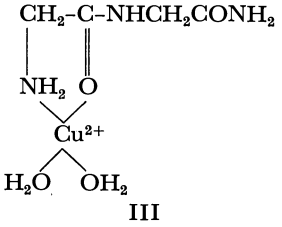
Structure-Stability Relationship. The dipeptide amides in acid solution are most probably bidentate ligands like glycinamide and tripeptides, coordinating through the amino and the peptide carbonyl group as shown by the following structures I—III.[1,2,11,12]



I



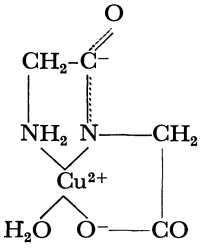
II



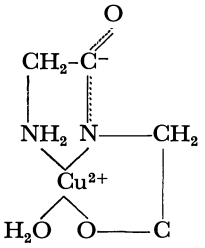
III

That the log K_1 value for β-Ala·Gly·NH_2 is close to that for Gly·β-Ala·NH_2 in spite of the higher pK_a may reasonably be explained by the less stable six-membered ring (III) as compared with the five-membered rings in I and II. These structures for $Cu(H_2L)^{2+}$ may be accepted, because the pK_a and log K_1 values are in excellent agreement with the corresponding values[1] for glycinamide and β-alaninamide both of which are known to form chelates in acid solution through the amino nitrogen and the amide oxygen.[1,12]

Deprotonation from the peptide linkage leads to $Cu(HL)^+$, where the pK_{c_1} values are comparable to those of tripeptides, but about 1 log unit higher than those of dipeptides. This may be interpreted in terms of the more effective coordination by the carboxyl group in dipeptides (IV) than the amide carbonyl group in dipeptide amides (V) and tripeptides.



IV



V

The degrees of formation of $Cu(HL)^+$ at a fixed pH can be expressed by the log $K_1K_{c_1}$ values, which are found to be around −0.2 as compared with 0—0.25 and 1—1.4 for the structurally related tripeptide-copper(II) and the dipeptide-copper(II) systems, respetively. As far as these peptide-copper(II) complexes are concerned, the 5-6-membered fused-ring systems are as stable as the 5-5-membered when compared on the basis of log $K_1K_{c_1}$. It is interesting to note in this connection that Weatherburn *et al.*[13] reported a similar stability relationship between the nickel(II)

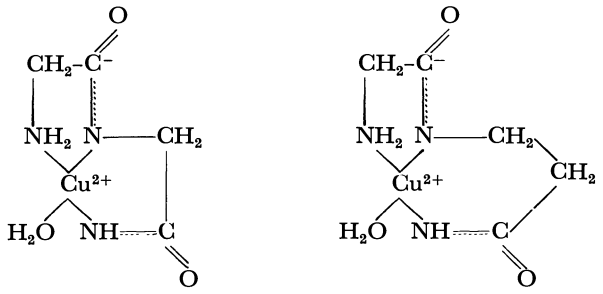
complexes of diethylenetriamine (5-5-membered) and *N*-(2-aminoethyl)-1,3-propanediamine (5-6-membered).

In dilute aqueous solution, the complexes of type CuL formed upon dissociation of the second proton from $Cu(HL)^+$ may be described by rigid fused-ring structures like VI and VII, whose relative stability is inferred from the log $K_1K_{c_1}K_{c_2}$ values.

$\log K_1K_{c_1}K_{c_2}$

−8.21 −9.19



VI VII

The stability-determining factor is definitely the pK_{c_2} value, which is low for Gly·Gly·NH_2 (7.96) and high for Gly·β-Ala·NH_2 (8.99). Thus, Gly·Gly·NH_2-Cu(II) (VI) is estimated to be more stable than Gly·β-Ala·NH_2-Cu(II) (VII), and the stability order is the reverse of that found for the Schiff base-copper(II) complexes[14] and reminds us of that between glycylglycine- and glycyl-β-alanine-copper(II), although the stability difference is much smaller. The complexes of β-Ala·Gly·NH_2 and β-Ala·NH_2 are supposed to be less stable because they were hydrolyzed to form precipitates at pH below 6.4.

When compared with the tripeptides, the dipeptide amides lose a proton from the terminal amide group at higher pH. A reasonable explanation for this may be that deprotonation from the peptide group nearest the COOH-terminus of tripeptides results in the formation of an additional chelate ring which is considered to increase the chelate stability by the "chelate effect," whereas the deprotonation from the dipeptide amides does not affect the stability in the same way.

The abundance of the coordinated species in the Gly·Gly·NH_2- and Gly·β-Ala·NH_2-copper(II) systems is shown in Figs. 2 and 3, respectively. One important feature of the curves is that the most abundant species at neutral pH is $Cu(HL)^+$ as described by V where the amide NH_2 group remains intact. This suggests that, at physiological pH, $-CONH_2$ groups from the asparagine or the glutamine residue in peptide chains coordinate to copper(II), if at all, through their carbonyl oxygen and not through the nitrogen as is usually the case with oligopeptides.

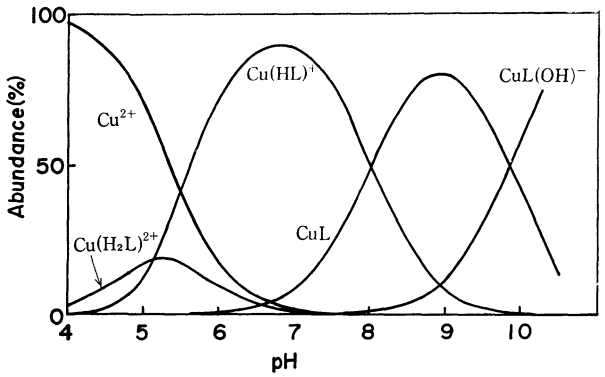


Fig. 2. Calculated abundances of the coordinated species in the 1 : 1 Gly·Gly·NH_2-Cu(II) system.

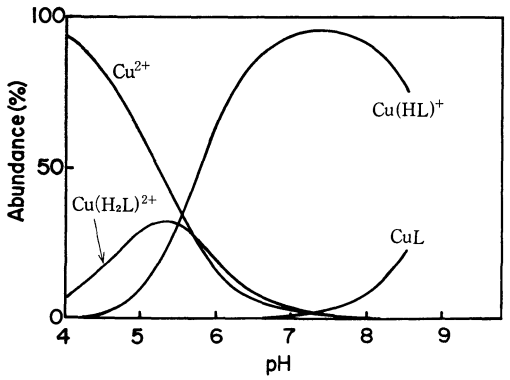

Fig. 3. Calculated abundances of the coordinated species in the 1 : 1 Gly·β-Ala·NH_2-Cu(II) system.

Ionic Equilibria in Mixed Solvents. X. Hydrolysis of Nickel(II) Ion in Dioxane-Water Mixtures

Takayoshi KAWAI, Haruko OTSUKA*, and Hitoshi OHTAKI

Department of Electrochemistry, Faculty of Engineering, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

**Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464*

(Received September 3, 1973)

The hydrolytic reactions of nickel(II) ion were studied at 25 °C in water and dioxane-water mixtures containing 3 M (Li)ClO_4 as an ionic medium. Emf measurements were carried out in the range of the total nickel(II) ion concentration of 0.02469—0.7891 M in water, 0.02488—0.7996 M in a 0.1 mole fraction (35.21% w/w) dioxane-water mixture and 0.05170—0.9016 M in a 0.2 mole fraction (55.01% w/w) dioxane-water mixture, respectively. Some supplementary measurements were performed in a 0.5 mole fraction (83.02% w/w) dioxane-water mixture. Only the $Ni_4(OH)_4^{4+}$ complex was found in all solvent systems and its formation constant in log $*\beta_{44}$ was -27.32 ± 0.08 (in water), -27.11 ± 0.08 (in a 0.1 mole fraction dioxane-water mixture), and -27.04 ± 0.05 (in a 0.2 mole fraction dioxane-water mixture). In order to test the relative change of the formation consatnt of the $Ni_4(OH)_4^{4+}$ complex over the whole solvent composition examined, the variation of the formation constant was measured with the continual change of solvent composition at constant Z. Approximate values of the solubility products of $Ni(OH)_2$ and $NiOHClO_4$ precipitates were estimated from maximum values of Z.

A number of authors studied the hydrolysis of nickel(II) ion in water and the results are summarized in "Stability Constants" and its supplement.[1] Among them, Burkov, Lilič and Sillén,[2] Ohtaki and Biedermann,[3] and Kennedy[4] reported that the $Ni_4(OH)_4^{4+}$ complex is the main product. Although Ohtaki and Biedermann[3] and Kennedy[4] proposed some minor species such an $NiOH^+$, Ni_2OH^{3+} [3] and $Ni_2(OH)_2^{2+}$,[4] information for minor species has not clearly been established yet.

In general, the hydrolytic reaction of nickel(II) ion is written by the following equation.

$$qNi^{2+} + pH_2O = Ni_q(OH)_p^{(2q-p)+} + pH^+ \quad (1)$$

The concentration of hydrogen ion set free on hydrolysis is given as follows,

$$BZ = \sum_p \sum_q p*\beta_{pq} b^q h^{-p} \quad (2)$$

$$= h - H + K_w h^{-1} \quad (3)$$

where K_w is the autoprotolysis constant of the solvent. The formation constant ($*\beta_{pq}$) of a species is defined by Eq. (4).

$$*\beta_{pq} = [Ni_q(OH)_p^{(2q-p)+}][H^+]^p/[Ni^{2+}]^q \quad (4)$$

Symbols

- h Hydrogen ion concentration at equilibrium
- H Analytical excess of hydrogen ions $=[ClO_4^-]-[Li^+]-2B$

Experimental

The measurements were carried out at 25.00 ± 0.02 °C in a liquid paraffin bath set in a room thermostated at 25 ± 1 °C. Lithium perchlorate was used as an ionic medium to keep the perchlorate concentration at 3 M. The total concentration of nickel ion studied ranged from 0.02469 to 0.7891 M in water, 0.02488 to 0.7996 M in a 0.1 mole fraction (35.20% w/w) dioxane-water mixture, and 0.05170 to 0.9016 M in a 0.2 mole fraction (55.01% w/w) dioxane-water mixture. Some supplementary measurements were carried out in a 0.5 mole fraction (83.02% w/w) dioxane-water mixture and results obtained were compared with those in other solvent systems.

A slightly acid nickel(II) perchlorate solution in water or a mixed solvent was bubbled with nitrogen gas to remove carbon dioxide and then was mixed with a lithium hydroxide solution, which had been prepared by electrolysis, to form a small amount of precipitates. The turbid solution was stirred by bubbling with nitrogen gas for several days and filtered through G3 and G4 glass filters on which fine platinum powder was placed. A clear solution thus obtained was used as a test solution. The total concentration of nickel ion in a test solution was determined gravimetrically as its dimethylglyoximate.

The electric circuit for emf measurements was as follows.

G. E.	Solution	3M $LiClO_4$ mixture		
	3M $LiClO_4$ aq. soln	0.01M $AgClO_4$ 2.99M $LiClO_4$ aq. soln	AgCl-Ag	

Hydrogen ions were added coulometrically into the test solution during titrations. The circuit for coulometry was the same as that used in the preceding paper.[5] The emf reached a constant value within 15 minutes after coulometric generation of hydrogen ions and remained unchanged within ±0.2 mV for more than several hours. The emf at equilibrium is written by the following equation.

$$E = E^{0*} + 59.15 \log h + 59.15 \log f_H + E_j(h, B) \quad (5)$$

1) L. G. Sillén and A. E. Martell, "Stability Constants," Chem. Soc., London(1964), Supplement No. 1 (1971).

2) K. A. Burkov, L. S. Lilič, and L. G. Sillén, *Acta Chem. Scand.*, **19**, 14 (1965).

4) B. Kennedy, S. C., Ph. D. Georgetown University, 1969.

5) H. Ohtaki and T. Kawai, This Bulletin, **45**, 1735 (1972).

This equation is reasonably rewritten as Eq. (6) when only a small part of nickel ions hydrolyzes at a constant total concentration of nickel and the hydrogen ion concentration is $10^{-2}>h>10^{-12}$ M.

$$E = E^\circ + 59.15 \log h \quad (6)$$

where E° is a constant. Eq. (6) was used for determination of the concentration of hydrogen ion at equilibrium from emf data.

Apparatus. *Glass Electrodes*: Beckman (No. 40498) glass electrodes were used in combination with a Radiometer PHM-4d pH meter (Copenhagen).

Silver-Silver Chloride Electrodes set in the "Wilhelm" type of the half cell[6] were prepared according to Brown.[7]

A Coulometric Analyzer (Leeds & Northrup Co., Philadelphia, Pa.) was used as a current source for generation of hydrogen ions in a solution during titration.

Reagents. *Nickel(II) Perchlorate*: Reagent grade nickel(II) nitrate was recrystallized twice from water and the crystals were heated under an infrared lamp and then in an electric oven at about 500 °C for several hours to decompose into nickel oxide. Nickel oxide thus prepared was dissolved in a little excess of about 30% hot perchloric acid solution and the solution was filtered through a G4 glass filter. Nickel(II) perchlorate was recrystallized twice from water. The crystals were dissolved into distilled water and a small amount of perchloric acid was added to keep pH of the solution at about 3 in order to prevent hydrolysis of the nickel ions. The concentration of nickel ion in the stock solution was determined by electrogravimetry, and that of hydrogen ion by potentiometry in combination with coulometry. The end point was detected according to Gran plot.[8]

Lithium Perchlorate and Lithium Hydroxide were prepared by the same procedures as described in the previous paper.[5]

Dioxane purified by an ordinary method[5] was stored in a refrigerator and melted just before preparation of a test solution.

The concentration of protolytic impurities in a 3 M lithium perchlorate solution was estimated from the deviation of a Gran plot at the end point of neutralization of perchloric acid in the solution in the absence of nickel ions. The total concentration of protolytic impurities was 75 ± 10 μeq./l independent of solvent composition. Thus, it is very reasonable to conclude that most impurities had been contained in lithium perchlorate.

Results and Discussion

The results obtained are summarized in Figs. 1—3 as Z *vs.* $-\log h$ plots. These data have been corrected for the protolytic impurities on an assumption of the complete dissociation of the impurities[9] at pH where nickel(II) ions hydrolyze.

On the basis of the data shown in Figs. 1—3, $\log BZ$ was plotted against $-\log h$. The plots gave a set of straight lines with slope 4 in each solvent system. These results indicated that only homoligandic hydrolyzed species containing four hydroxyl groups were formed. A plot of $(\log BZ+4\log h)$ against $\log B$ yielded a straight line with a slope of 4. Therefore, it was concluded that the hydrolyezd species is $Ni_4(OH)_4^{4+}$ in dioxane–water mixed solvents at least to 0.2 mole fraction dioxane (55.01% w/w), as several investigators concluded so far in water.[2,3,4] Minor components such as $NiOH^+$ and Ni_2OH^{3+} upon which some authors reported were not detected with reasonable

certainties in this study. Solid lines in Figs. 1—3 indicate calculated values of Z with formation constants given in each solvent system listed in Table 1.

Results obtained in a 0.5 mole fraction dioxane-water mixture were not sufficiently reliable because of low solubility of nickel(II) hydroxo complexes. The concentration of protolytic imputiries was almost comparable with that of nickel(II) hydroxo complexes present in the solution. However, the results were reasonably interpreted by the assumption of formation of the $Ni_4(OH)_4^{4+}$ complex with the formation constant of about $10^{-28\pm1}$.

Results are tabulated in Table 1 in the form of log $*\beta_{44}$. These values were obtained after refinement by electronic computer calculations by means of a generalyzed least-squares method.

The composition of the complex formed remained unchanged with solvent composition over the wide range of the dioxane content, the same phenomenon having been found in the case of beryllium ion.[10] In the hydrolytic reaction of copper(II) ion[5] higher polymers gradually disappear with solvent composition, although formation constants of the complexes are not appreciably affected with solvent composition.

Solvent Effects on the Formation Constants of Complexes. The authors previously found that the solvent effect of dioxane on the formation constants of hydrolysis of metal ions is much smaller than that expected in usual acid dissociation reactions.[11,12]

In order to test the relative change of formation constants with solvent composition, the following experiment was carried out. The method was first employed by Ohtaki and Kato[13] in their study of the solvent effect on hydrolysis of beryllium ion. We measured the change of emf on mixing two hydrolyzed solutions which had been prepared to have the same total concentration of nickel(II) ion and Z value and the different solvent composition. The change of the liquid junction potential, E_j in Eq. (5), with dioxane content was found to be negligible by using two reference cells. A salt bridge of one of the reference cells was composed of 3 M $LiClO_4$ aqueous solution and the other by 3 M $LiClO_4$ solution of a 0.2 mole fraction dioxane–water mixture. Negligible volume change was also found from the density measurements of 3 M $LiClO_4$ solution of dioxane–water mixtures. Then the following equation is reduced from Eq. (6).

$$\Delta \log h = (\Delta E - \Delta E^\circ)/59.15 \quad (7)$$

The change of E°, ΔE°, was determined by similar measurements without nickel ions.[14]

If there is an appreciable amount of $Ni_4(OH)_4^{4+}$ in the solution, the following relations hold. From Eq. (2),

$$BZ = 4*\beta_{44}b^4h^{-4} \quad (8)$$

and

$$B = b + 4*\beta_{44}b^4h^{-4} = b + BZ$$

and therefore,

$$b = B(1-Z) \quad (9)$$

Insertion of Eq. (9) into Eq. (8) leads to

$$BZ = 4*\beta_{44}B^4(1-Z)^4h^{-4} \quad (10)$$

Rearrangement of Eq. (10) gives rise to Eq. (11)

$$Z(1-Z)^{-4} = 4*\beta_{44}B^3h^{-4}$$

or

$$\log Z - 4\log(1-Z) = \log 4 + \log^*\beta_{44} + 3\log B - 4\log h \quad (11)$$

From the differeniation of Eq. (11) at constant Z and B, Eq. (12) is obtained.

$$\partial \log^* \beta_{44} = 4\partial \log h \quad (12)$$

The change of the formation constant was determined from emf data with Eqs. (7) and (12), and results are given in Fig. 4. The formation constant first increases with dioxane concentration and then reaches a plateau.

On the Solubility of Nickel(II) Hydroxo Complexes. Approximate values of the solubility product of nickel(II) hydroxide precipitates were estimated from maximum values of Z in various solvent systems.

The maximum value of Z, Z_{max}, increases with B to reach a maximum and then decreases. This suggests that besides the nickel hydroxide the basic nickel perchlorate also precipitates as have been pointed out in the study of hydrolysis of nickel ion in the chloride system.[3]

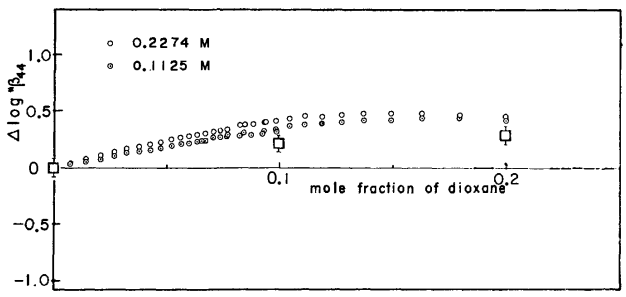

Fig. 4. $\Delta \log *\beta_{44}$ from the value in aqueous solution for $Ni_4(OH)_4^{4+}$ complex in dioxane-water mixtures. Circles; points of continuous measurements, squares; points of individual determination with experimental uncertainties.

14) H. Ohtaki, Abstract of the Informal Meeting of the 10th ICCC (1967), Nikko, p. 43.

If the following equilibrium is assumed,

$$Ni(OH)_{2-x}(ClO_4)_x(s) + xH_2O = k_{sx}Ni(OH)_2(s) + xClO_4^- + xH^+$$

$$k_{sx} = \frac{[Ni(OH)_2(s)][ClO_4^-]^x[H^+]^x}{[Ni(OH)_{2-x}(ClO_4)_x(s)]} = \frac{m(C_0h)^x}{1-m} \quad (13)$$

where (s) represents the solid phase and C_0 denotes the perchlorate ion concentration assumed to be constant (3M) and m the mole fraction of $Ni(OH)_2$ in the solid phase with an assumption of unit activity coefficient, the mole fraction m is obtained as follows:

$$m = \frac{k_{sx}}{k_{sx}+(C_0h)^x} \quad (14)$$

Solubility products of nickel hydroxide, $*K_{s1}$, and basic nickel perchlorate, $*K_{s2}$, respectively, are defined as follows.

$$*K_{s1} = \frac{[Ni^{2+}][H^+]^{-2}}{[Ni(OH)_2(s)]} = \frac{bh^{-2}}{m} \quad (15)$$

$$*K_{s2} = \frac{[Ni^{2+}][H^+]^{-(2-x)}[ClO_4^-]^x}{[Ni(OH)_{2-x}(ClO_4)_x(s)]} = \frac{b(C_0h)^xh^{-2}}{1-m} \quad (16)$$

Therefore,

$$k_{sx} = *K_{s2}/*K_{s1} \quad (17)$$

$$b = *K_{s1}mh^2 = *K_{s1}h^2\frac{k_{sx}}{k_{sx}+(C_0h)^x} \quad (18)$$

Thus BZ_{max} is represented as follows.

$$BZ_{max} = 4*\beta_{44}b^4h_{max}^{-4} = \frac{4*\beta_{44}*K_{s1}^4k_{sx}^4h_{max}^4}{\{k_{sx}+(C_0h_{max})^x\}^4} \quad (19)$$

If we put $C_0h/k_{sx}^{1/x}=\omega$, we can compare Eq. (19) with Eq. (20)

$$y = \left[\frac{a\omega}{(1+\omega^x)}\right]^4;\ a=\{4*\beta_{44}\}^{1/4}*K_{s1}k_{sx}^{1/x}/C_0 \quad (20)$$

or

$$Y = \log\frac{\omega}{(1+\omega^x)} \quad (21)$$

Curve fitting of $(\log BZ_{max})/4$ *vs.* $\log h$ with Y *vs.* $\log \omega$ at various x gives the values of x about 1.0—1.3 in all solvent systems. A typical example is shown in Fig. 5. If we assume a stoichiometric composition of the basic nickel perchlorate taking into account the experimental uncertainties of BZ_{max} values and a simple assumption of ideal solid solution of the $Ni(OH)_{2-x}(ClO_4)_x$ mixture, the composition of the basic nickel perchlorate may be described as $NiOHClO_4$ ($x=1$). Under these assumptions the value of log with the known value of $*\beta_{44}$. Results are given in k_{sx} can be obtained from the abscissa and log $*K_{s1}$, and thus log $*K_{s2}$, from the ordinate Table 1. Solubility products of both hydroxide and basic perchlorate are fairly insensitive to the dioxane content as has been found in the case of copper(II) hydroxide.[5]

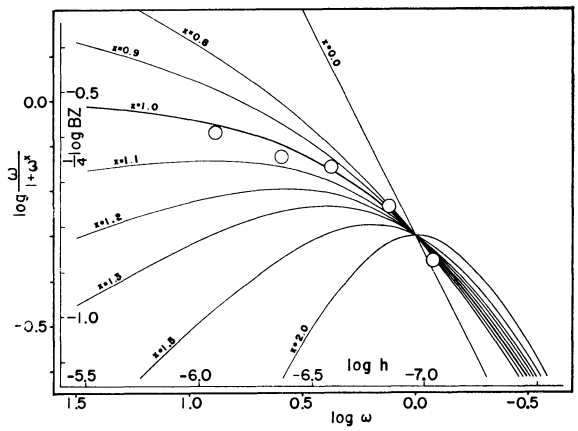

Fig. 5. A family of normalized curves of $Y=\log\frac{\omega}{(1+\omega^x)}$ *vs.* $\log\omega$ at various x. Circles show values of $(\log BZ_{max})/4$ obtained in a 0.2 mole fraction dioxane-water mixture.

The logarithmic values of solubility product of nickel hydroxide have been reported to be -13.8—-17.2 in aqueous solutions,[1] which correspond to $14._2$—10.8 in the log $*K_{s1}$ scale. The value of log $*K_{s1}=13.3$ in aqueous solution found in the present work can reasonably be compared with these literature values. No value has been found in literature for the solubility product of basic nickel salt.

It should be noted that the value of k_{sx} was kept constant at $10^{-6.4}$—$10^{-6.6}$ independent of solvent composition, although the reaction is not isoelectric.

A part of the present study has been carried out in the laboratory of Analytical Chemistry in Nagoya University. This work was financially supported by the Ministry of Education.

Pressure Effect Determined with Use of the Nondispersive Infrared Gas Analyser

Eiji NIKI and Tsutomu YONEZAWA

Department of Industrial Chemistry, Faculty of Engineering, Tokyo University, Hongo, Tokyo 113

(Received June 16, 1972)

The pressure effect of nitrous oxide and nitric oxide due to nitrogen gas was investigated with use of a nondispersive infrared gas analyser. The results are in line with the theoretical curves derived from the Elsasser theory. The calculated expression is partly improved and the error of calculations is estimated in regard to carbon dioxide.

With a nondispersive infrared gas analyser, it is easily observed that the absorption increases with increasing pressure of nitrogen gas at constant pressure of infrared absorbing gases such as carbon dioxide or carbon monoxide. This effect is known as the pressure broadening. In a previous paper[1] the mean absorption was calculated on the Elsasser theory as a function of the partial pressure of absorber, the total pressure and the length of the sample cell. The result was proved to interpret fairly well the experimental results for carbon dioxide and carbon monoxide. In this paper, the influence of the Bessel function of order zero approximated by unit is evaluated in regard to carbon dioxide. Experiments were carried out on nitrous oxide and nitric oxide concerning the self broadening of the absorbing gas and the foreign gas broadening due to nitrogen gas in order to see whether the result of calculation can be applied to other infrared absorbing gases.

Apparatus

The apparatus consists of a nondispersive infrared gas analyser of the zero method positive filter type with a condenser microphone detector.[2] The windows consist of LiF. A schematic diagram is given in Fig. 1.

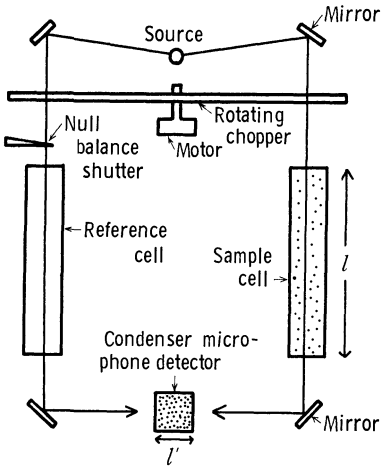

Fig. 1. The schematic diagram of the nondispersive infrared gas analyser. The temperature of the infrared source is about 600 °C. $l'=5$ cm.

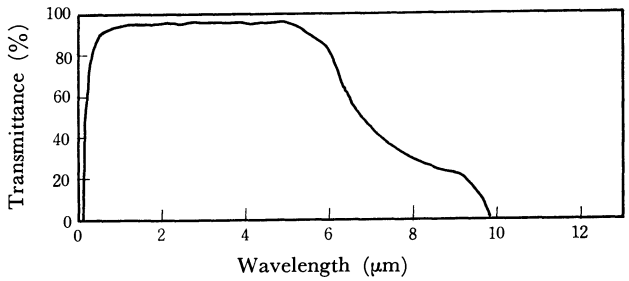

Fig. 2. The spectral transmission of LiF.

The sample gas is prepared in the mixing vessel and its pressure is measured by a mercury manometer. Figure 2 shows the spectral transmission of lithium fluoride.[3] Its absorption edge is about 1030 cm^{-1}.

Theoretical

For the sake of simplicity let us consider the expression

$$y = \frac{\int_0^\infty \{1-\exp(-\sum_{m=1}^{n} k_m l)\}d\nu}{nd} \tag{1}$$

which gives the mean absorption of the band spectrum in the infrared region, where k_m is the absorption coefficient of each vibrational rotational line, m the number added to each line, n the total number of lines, d the line spacing and l the thickness of the layer. The absorption coefficient k_m, in general, can be expressed by means of the Lorentz curve

$$k_m = \frac{(\alpha_m/\pi)\delta}{(\nu-\nu_m)^2+\delta^2} \tag{2}$$

ν_m being the frequency at the center of the mth line. α_m is equivalent to $\int_0^\infty k_m d\nu$ and assumed to be proportional to the partial pressure of absorber p_a,

$$\alpha_m = \alpha_{0m} p_a \tag{3}$$

α_{0m} being the proportional constant. δ is the damping constant and is known to be common to all the lines. From kinetic theory of the gas, δ is given by[4]

$$\delta = \frac{1}{4\pi}\sum_i N_i (D_{a,i})^2 \left[2\pi kT\left(\frac{1}{m_a}+\frac{1}{m_i}\right)\right]^{1/2} \tag{4}$$

where N_i is the number of molecules of the ith type gas per unit volume, $D_{a,i}$ the sum of the optical col-

lision diameters of the absorbing molecule and a molecule of the ith type, m_a the mass of the absorbing molecule and m_i the mass of the ith type of molecule. Replacing the number of molecules N_i by the corresponding partial pressure p_i in Eq. (4), we have

$$\delta = \frac{1}{4\pi}\left(\frac{2\pi}{kT}\right)^{1/2} \sum_i C_{a,i} p_i \tag{5}$$

where $C_{a,i}$ is a constant involving the masses and optical collision diameters of the absorbing and ith gas, respectively. If Eq. (5) is restricted to the binary mixtures, then

$$\delta = \frac{1}{4\pi}\left(\frac{2\pi}{kT}\right)^{1/2} (C_{a,a}p_a + C_{a,b}p_b) \tag{6}$$

where a refers to the absorbing molecule and b the foreign molecule. From Eq. (6) we get

$$\delta = \frac{1}{4\pi}\left(\frac{2\pi}{kT}\right)^{1/2} C_{a,a}\{p_a + (C_{a,b}/C_{a,a})p_b\}. \tag{7}$$

The expression in parentheses gives the effective pressure P_e of the gas mixture. If we denote coefficient $1/4\pi(2\pi/kT)^{1/2}C_{a,a}$ by a δ_0, then δ is given by

$$\delta = \delta_0 P_e. \tag{8}$$

For binary mixtures, we have $P_e = p_a + (1/B)p_b$ where $B = C_{a,a}/C_{a,b}$ which is called the self-broadening coefficient[5] of the absorbing gas which represents the ratio of the self-broadening ability of the absorbing gas to the broadening ability of the broadening gas. p_b is the partial pressure of the broadening gas.

If each of the n vibrational rotational lines is supposed to be completely isolated from the neighboring lines, Eq. (1) reduces to

$$y = \frac{\sum_{m=1}^{n}\int_u^v \{1-\exp(-k_m l)\}\mathrm{d}\nu}{nd} \tag{9}$$

u, v being $\nu_m - d/2$ and $\nu_m + d/2$. Introducing the following mean fractional transmission of mth line T_m defined by Elsasser[6]

$$T_m = \frac{1}{d}\int_u^v \exp\left\{-\frac{(\alpha_m/\pi)\delta}{(\nu-\nu_m)^2+\delta^2} l\right\}\mathrm{d}\nu, \tag{10}$$

Eq. (9) becomes

$$y = 1 - \langle T_m \rangle_{av} \tag{11}$$

where $\langle\ \rangle_{av}$ indicates the average of T_m over m, *viz.*, $\langle T_m\rangle_{av} = 1/n\sum_{m=1}^{n} T_m$. T_m was evaluated by Elsasser in regard to the limits of small and large δ. If δ is small compared with the line spacing d, then

$$T_m = 1 - \phi\{(\pi\alpha_m\delta l)^{1/2}/d\} \tag{12}$$

where ϕ is probability integral. Here ϕ is supposed to be approximated by

$$\phi\{(\pi\alpha_m\delta l)^{1/2}/d\} = 2(\alpha_m\delta l)^{1/2}/d. \tag{13}$$

Thus we have

$$y = 2\langle(\alpha_m\delta l)^{1/2}/d\rangle_{av}. \tag{14}$$

By means of Eqs. (3) and (8), the equation becomes

$$y = 2\left\langle \frac{\alpha_{0m}{}^{1/2}\delta_0{}^{1/2}}{d}\right\rangle_{av} p_a{}^{1/2}P_e{}^{1/2}l^{1/2}. \tag{15}$$

If δ is large compared with the line spacing, then

$$T_m = \exp\{-(\alpha_m l/d)\tanh 2\beta\} \times J_0\{i(\alpha_m l/d)\tanh 2\beta/\cosh 2\beta\} \tag{16}$$

where $\beta \equiv \pi\delta/d$ and J_0 is the Bessel function of order zero and imaginary argument. By replacing $\tanh 2\beta$ with 2β and J_0 with the unit in Eq. (16), we get

$$T_m = \exp(-2\pi\alpha_m\delta l/d^2). \tag{17}$$

Substituting Eq. (17) into Eq. (11) and using Eqs. (3) and (8), we have

$$\begin{aligned} y &= 1 - \langle\exp\{-2\pi(\alpha_{0m}\delta_0/d^2)p_aP_el\}\rangle_{av} \\ &= 1 - \langle\exp\{-2\pi(\alpha_{0m}\delta_0/d^2)P_ew\}\rangle_{av} \end{aligned} \tag{18}$$

where the optical thickness $w = p_a l$ is used. Employing the cumulant expansion theorem in the calculation of $\langle\ \rangle_{av}$ in Eq. (18), we get

$$\begin{aligned} y = 1 - \exp\Bigg\{ & -2\pi\left\langle\frac{\alpha_{0m}\delta_0}{d^2}\right\rangle_{av} P_ew \\ & + \frac{(2\pi)^2}{2!}\left(\left\langle\left(\frac{\alpha_{0m}\delta_0}{d^2}\right)^2\right\rangle_{av} - \left\langle\frac{\alpha_{0m}\delta_0}{d^2}\right\rangle_{av}^2\right)(P_ew)^2 \\ & - \frac{(2\pi)^3}{3!}\left(\left\langle\left(\frac{\alpha_{0m}\delta_0}{d^2}\right)^3\right\rangle_{av} - 3\left\langle\left(\frac{\alpha_{0m}\delta_0}{d^2}\right)^2\right\rangle_{av}\left\langle\frac{\alpha_{0m}\delta_0}{d^2}\right\rangle_{av} \right. \\ & \left. + 2\left\langle\frac{\alpha_{0m}\delta_0}{d^2}\right\rangle_{av}^3\right)(P_ew)^3 \\ & + \cdots\cdots\cdots\Bigg\}. \end{aligned} \tag{19}$$

Here $\alpha_{0m}\delta_0/d^2$ can be approximately evaluated if the minimum transmittance $T_m{}^{dis}$ is observed correctly. The observable minimum transmittance $T_m{}^{dis}$ is given by

$$T_m{}^{dis} = \int_0^\infty \exp\left[-\frac{(\alpha_m/\pi)\delta l}{(\nu-\nu_m)^2+\delta^2}\right] f(|\nu-\nu_m|, a)\mathrm{d}\nu \Big/ \int_0^\infty f(|\nu-\nu_m|, a)\mathrm{d}\nu \tag{20}$$

where $f(|\nu-\nu_m|, a)$ is the slit function, a being the slit width of apparatus. When the triangular form is used for the slit function, we have approximately[7]

$$T_m{}^{dis} = 1 - 2(\alpha_m\delta l)^{1/2}/a + \cdots\cdots\cdots. \tag{21}$$

Thus

$$E_m = -\ln T_m{}^{dis} = 2(\alpha_m\delta l)^{1/2}/a \tag{22}$$

for the maximum extinction E_m. If k_{0m} is defined by the relation

$$k_{0m} = E_m{}^2 \Big/ \left\{4\cdot\left(\frac{d}{a}\right)^2 p_a{}^2 l\right\}, \tag{23}$$

then the following relation is obtained by substituting Eqs. (22), (3) and (8) into Eq. (23)

$$\alpha_{0m}\delta_0/d^2 = k_{0m} \tag{24}$$

provided that P_e of Eq. (3) is put equal to p_a. When the Gaussian form is used for the slit function, for example, the maximum extinction is

$$E_m = 1.879(\alpha_m\delta l)^{1/2}/a. \tag{25}$$

Thus if we assume that when the true slit function, not known beforehand, is used, the maximum extinction

5) D. E. Burch, E. B. Singleton, and D. Williams, *Appl. Opt.* **1**, (1962).

6) W. M. Elsasser, *Phys. Rev.*, **54**, 126 (1939).

7) J. R. Nielsen, V. Thorton, and, E. B. Dale, *Rev. Mod. Phys.*, **16**, 308 (1944).

is given by

$$E_m = t(\alpha_m \delta l)^{1/2}/a\,, \tag{26}$$

then

$$\alpha_{0m}\delta_0/d^2 = (2/t)^2 \cdot k_{0m} \tag{27}$$

where t is the constant which is determined if the true slit function is known.

Quantity x, which is measured as the absorption ratio due to the sample gas at the nondispersive infrared gas analyser, is obtained from the following relation

$$(1-x)\int_0^\infty I_\nu\{1-\exp(-\sum_{m=1}^{n} k'_m l')\}\mathrm{d}\nu = \int_0^\infty I_\nu \exp(-\sum_{m=1}^{n} k_m l)\{1-\exp(-\sum_{m=1}^{n} k'_m l')\}\mathrm{d}\nu \tag{28}$$

where I_ν is the energy distribution of the infrared source, k_m and l the absorption coefficient and the cell length of the sample, and k'_m and l' of the condenser microphone detector. k'_m is given by

$$k'_m = \frac{(\alpha'_m/\pi)\delta'}{(\nu-\nu_m)^2+\delta'^2}\,.$$

The same gas as in the absorber is sealed up within the detector in atmospheric pressure. Equation (28) shows that the left-hand gives the energy absorbed in the detector of the infrared ray screened by the null balance shutter and the right-hand the energy absorbed in the detector of the infrared ray passing through the sample cell. Thus we have from Eq. (28)

$$x = \frac{\int_0^\infty I_\nu\{1-\exp(-\sum_{m=1}^{n} k_m l)\}\{1-\exp(-\sum_{m=1}^{n} k'_m l')\}\mathrm{d}\nu}{\int_0^\infty I_\nu\{1-\exp(-\sum_{m=1}^{n} k'_m l')\}\mathrm{d}\nu}\,. \tag{29}$$

For the calculation of Eq. (29) the following two assumptions are made; (i) I_ν=const. over the absorption region of the sample gas, and (ii) the shape of $\{1-\exp(-\sum_{m=1}^{n} k_m' l')\}$ is approximated by the n equivalent rectangles with unit height and the width of d' which varies with l' or the conditions under which the absorbing gas is sealed within the detector. Thus, x is given by

$$x = \sum_{m=1}^{n}\int_{u'}^{v'}\{1-\exp(-k_m l)\}\mathrm{d}\nu/nd'. \tag{30}$$

It is assumed herewith that each of the n vibrational rotational lines are completely isolated from the neighboring lines. u' and v' are $\nu_m-d'/2$ and $\nu_m+d'/2$. Eq. (30) corresponds to replacing d in Eq. (9) with d'. Thus from Eqs. (15) and (19), the expressions for x at low and high pressure are obtained by replacing d in each eq. with d'. From Eq. (15) we get

$$x = 2\left\langle\frac{\alpha_{0m}^{1/2}\delta_0^{1/2}}{d'}\right\rangle_{\mathrm{av}} p_a^{1/2}P_e^{1/2}l^{1/2} \tag{31}$$

and from Eq. (19)

$$x = 1-\exp\left\{-2\pi\left\langle\frac{\alpha_{0m}\delta_0}{d'^2}\right\rangle_{\mathrm{av}} P_e w + \frac{(2\pi)^2}{2!}\left(\left\langle\left(\frac{\alpha_{0m}\delta_0}{d'^2}\right)^2\right\rangle - \left\langle\frac{\alpha_{0m}\delta_0}{d'^2}\right\rangle_{\mathrm{av}}^2\right)(P_e w)^2 - \frac{(2\pi)^3}{3!}\left(\left\langle\left(\frac{\alpha_{0m}\delta_0}{d'^2}\right)^3\right\rangle_{\mathrm{av}} - 3\left\langle\left(\frac{\alpha_{0m}\delta_0}{d'^2}\right)^2\right\rangle_{\mathrm{av}}\left\langle\frac{\alpha_{0m}\delta_0}{d'^2}\right\rangle_{\mathrm{av}} + 2\left\langle\frac{\alpha_{0m}\delta_0}{d'^2}\right\rangle_{\mathrm{av}}^3\right)(P_e w)^3 + \cdots\cdots\right\}. \tag{32}$$

From Eq. (27) we get

$$\alpha_{0m}\delta_0/d'^2 = (2/t)^2\cdot(d/d')^2\cdot k_{0m} \tag{33}$$

Replacing $(2/t)\cdot(d/d')$ with $1/D$, we get

$$\alpha_{0m}\delta_0/d'^2 = k_{0m}/D^2. \tag{34}$$

Rewriting Eqs. (31) and (32) by means of this relation, we get

$$x = 2(\langle k_{0m}^{1/2}\rangle_{\mathrm{av}}/D)p_a^{1/2}P_e^{1/2}l^{1/2} \tag{35}$$

and

$$x = 1-\exp\left\{-(2\pi/D^2)\langle k_{0m}\rangle_{\mathrm{av}}\cdot P_e w + \frac{(2\pi/D^2)^2}{2!}(\langle k_{0m}^2\rangle_{\mathrm{av}} - \langle k_{0m}\rangle_{\mathrm{av}}^2)\cdot(P_e w)^2 - \frac{(2\pi/D^2)^3}{3!}(\langle k_{0m}^3\rangle_{\mathrm{av}} - 3\langle k_{0m}^2\rangle_{\mathrm{av}}\cdot\langle k_{0m}\rangle_{\mathrm{av}} + 2\langle k_{0m}\rangle_{\mathrm{av}}^3)\cdot(P_e w)^3 + \cdots\cdots\right\}. \tag{36}$$

From Eq. (36), we get

$$\ln\frac{1}{1-x} = \sum_{n=1}^{\infty}(-1)^{n-1}\kappa_n(P_e w)^n \tag{37}$$

where

$$\kappa_n = (2\pi/D^2)^n\lambda_n/n\,!$$

λ_n being the cumulant coefficient.

If there exists another weak band, for example a combination band, r, the ratio of the intensity of the infrared source of the fundamental region to that of the combination, should be introduced. Thus, assuming that the shape of the absorption line of the detector is approximated by the $n+n'$ equivalent rectangles with unit height and the average width d'' over both band, we obtain the following relation from Eq. (29):

$$x = \frac{\sum_{m=1}^{n}\int_{u'}^{v'} I_f\{1-\exp(-k_m l)\}\mathrm{d}\nu + \sum_{m'=1}^{n'}\int_{u''}^{v''} I_c\{1-\exp(-k_{m'} l)\}d\nu}{(I_f\cdot n + I_c\cdot n')d''} = \frac{\sum_{m=1}^{n}\int_{u'}^{v'}\{1-\exp(-k_m l)\}\mathrm{d}\nu + r\sum_{m'=1}^{n'}\int_{u''}^{v''}\{1-\exp(-k_{m'} l)\}\mathrm{d}\nu}{(n+rn')d''} \tag{38}$$

where m' is the number added to the lines in the combination band, u' and v' represent $\nu_m-d''/2$ and $\nu_m+d''/2$, u'' and v'' are $\nu_{m'}-d''/2$ and $\nu_{m'}+d''/2$, the constant quantities I_f and I_c are the intensities of the infrared source over the fundamental region and the combination, r is the ratio I_c/I_f, and n' is the total number of lines of the combination band. If we put $n'=n$ in Eq. (38), then

$$x=\frac{\sum_{m=1}^{n}\int_{u'}^{v'}\{1-\exp(-k_m l)\}\mathrm{d}\nu+r\sum_{m'=1}^{n}\int_{u''}^{v''}\{1-\exp(-k_m\, l)\}\mathrm{d}\nu}{(1+r)nd''}. \tag{39}$$

From this relation we get the following expression of x for low pressures

$$x=2\left(\frac{\langle k_{0m}^{1/2}\rangle_{\mathrm{av}}+r\langle k_{0m'}^{1/2}\rangle_{\mathrm{av}}}{(1+r)D}\right)p_{\mathrm{a}}^{1/2}P_{\mathrm{e}}^{1/2}l^{1/2} \tag{40}$$

and that of x for high pressures

$$\begin{aligned}x=1-\exp\Bigg[&-(2\pi/D^2)\cdot\left(\frac{\langle k_{0m}\rangle_{\mathrm{av}}+r\langle k_{0m'}\rangle_{\mathrm{av}}}{1+r}\right)P_{\mathrm{e}}w\\&+\frac{(2\pi/D^2)^2}{2\,!}\left(\frac{\langle k_{0m}^2\rangle_{\mathrm{av}}+r\langle k_{0m'}^2\rangle_{\mathrm{av}}}{1+r}-\frac{\langle k_{0m}\rangle_{\mathrm{av}}^2+r\langle k_{0m'}\rangle_{\mathrm{av}}^2}{1+r}\right)\cdot\\&(P_{\mathrm{e}}w)^2-\frac{(2\pi/D^2)^3}{3\,!}\left\{\frac{\langle k_{0m}^3\rangle_{\mathrm{av}}+r\langle k_{0m'}^3\rangle_{\mathrm{av}}}{1+r}\right.\\&-3\left(\frac{\langle k_{0m}^2\rangle_{\mathrm{av}}+r\langle k_{0m'}^2\rangle_{\mathrm{av}}}{1+r}\right)\cdot\left(\frac{\langle k_{0m}\rangle_{\mathrm{av}}+r\langle k_{0m'}\rangle_{\mathrm{a}}}{1+r}\right)\\&\left.+2\left(\frac{\langle k_{0m}\rangle_{\mathrm{av}}^3+r\langle k_{0m'}\rangle_{\mathrm{av}}^3}{1+r}\right)\right\}\cdot(P_{\mathrm{e}}w)^3\\&+\cdots\cdots\Bigg]\end{aligned} \tag{41}$$

where $1/D=(2/t)(d/d'')$.

In the case of CO_2 the following result is obtained by assuming that I_ν is expressed by Planck's law for temperature radiation and the temperature of the infrared source is 900 K,

$$r=0.524 \tag{42}$$

since the combination band is observed in 3700 cm^{-1} region. The numerical values for CO_2 are as follows.

$$\begin{aligned}&\langle k_{0m}^{1/2}\rangle_{\mathrm{av}}=5.85\times10^{-3}\ \mathrm{cm^{-1/2}\cdot cmHg^{-1}}\\&\langle k_{0m'}^{1/2}\rangle_{\mathrm{av}}=1.05\times10^{-3}\ \mathrm{cm^{-1/2}\cdot cmHg^{-1}}\\&\frac{\langle k_{0m}^{1/2}\rangle_{\mathrm{av}}+r\langle k_{0m'}^{1/2}\rangle_{\mathrm{av}}}{1+r}=4.19\times10^{-3}\ \mathrm{cm^{-1/2}\cdot cmHg^{-1}}\\&\frac{\langle k_{0m}\rangle_{\mathrm{av}}+r\langle k_{0m}\rangle_{\mathrm{av}}}{1+r}=3.77\times10^{-5}\ \mathrm{cm^{-1}\cdot cmHg^{-2}}\\&\frac{\langle k_{0m}^2\rangle_{\mathrm{av}}+r\langle k_{0m'}^2\rangle_{\mathrm{av}}}{1+r}=4.48\times10^{-9}\ \mathrm{cm^{-2}\cdot cmHg^{-4}}\\&\frac{\langle k_{0m}^3\rangle_{\mathrm{av}}+r\langle k_{0m'}^3\rangle_{\mathrm{av}}}{1+r}=6.50\times10^{-12}\ \mathrm{cm^{-3}\cdot cmHg^{-6}}\end{aligned} \tag{43}$$

where 1.59 cm^{-1} is used as the values of the line spacing d.

Experimental

NO System. Figure 3 shows the relations between x and p_{a} of pure NO at low pressures. ○, △, □ represent the values corresponding to various cell lengths. As expected from Eq. (35), a linear relation is obtained between x and p_{a} in the case of pure NO where P_{e} can be put equal to p_{a}:

$$x=2(\langle k_{0m}^{1/2}\rangle_{\mathrm{av}}/D)p_{\mathrm{a}}l^{1/2}. \tag{44}$$

The relations between x/p_{a} and $l^{1/2}$ are plotted by means of the relation in Fig. 3 (Fig. 4). From Eq. (44) we see that x/p^a is proportional to $l^{1/2}$. From the slope of this line, the proportionality constant $\langle k_{0m}^{1/2}\rangle_{\mathrm{av}}/D$ is found to be $3.00\times10^{-3}\ \mathrm{cm^{-1/2}\cdot cmHg^{-1}}$. $k_{0\mathrm{m}}$ can be evaluated by the analysis of the infrared spectrum whose lines are adequately separated. The values of D is the factor that corrects the deviation between $\langle k_{0m}^{1/2}\rangle_{\mathrm{av}}$ and the value obtained above. The results for the binary mixture NO+N_2 are shown in Fig. 5, where the total pressure is kept constant. Broken lines represent the theoretical curves derived from Eq. (35). The self-broadening coefficient B is expreimentally given as 1.47. $\ln 1/(1-x)$ is plotted against the optical thickness w at the total pressure of 70 cmHg (Fig. 6). The solid line may be approximated by Eq. (35).

N_2O System. The infrared absorption spectra of N_2O are given in Fig. 7(a) and (b). The vibrational rotational lines around 2200 cm^{-1} region are imperfectly separated and those around 3400 cm^{-1} are no longer separated. When the separation of the lines is not enough, the analytical values of k_{0m} do not represent the values characteristic of the individual lines, because of the influence of the wings of the neighboring lines. Since the assumption that each line is separated is not valid, Eqs. (40) and (41) are not applied to N_2O. However, it is proved that these equations can

be utilized for the quantitative interpretation of in the clination of the experimental curves of N_2O (Fig. 8).

Discussion

Degree of Separation of Absorption lines. The degree of separation of the absorption lines is determined from the line spacing and the collision width. The line spacing is inversely proportional to the moment of inertia which is geater for CO_2 than for CO. The collision width 2δ is given by Eq. (4). Putting $i=a$ in Eq. (4), δ is found to be proportional to $(D_{a,a})^2\text{-}(kT/m_a)^{1/2}N_a$. With the numerical data[8] $D_{a,a}/D_{a,i}=1.29$ where $a=CO_2$ and $i=CO$, we obtain

$$(D_{i,i}/D_{a,a})^2 = 0.30\,.$$

Since $(m_a/m_i)^{1/2}=1.24$, we get $\delta_i/\delta_a=0.37$. Thus the degree of separation is better for CO than for CO_2 (Fig. 9 (a)$\sim$(d)). The degree of separation influences the degree of accuracy of k_{0m}.

Influence of the Bessel Function of Order Zero. Considering the influence of the Bessel function of order zero, we have from Eq. (16):

$$\langle T_m\rangle_{av} = \langle \exp\{-(\alpha_m l/d')\tanh 2\beta'\} \times J_0\{i(\alpha_m l/d')\tanh 2\beta'/\cosh 2\beta'\}\rangle_{av} \quad (45)$$

where the line spacing d of Eq. (16) is replaced by the distance d', $\beta'=\pi\delta/d'$. Using the modified Bessel function of order zero, Eq. (45) is written as

$$\langle T_m\rangle_{av} = \langle \exp(-a_m) I_0(a_m/\cosh 2\beta')\rangle_{av} \quad (46)$$

where I_0 is the modified Bessel function of order zero, and

$$\begin{aligned} a_m &= (\alpha_m l/d')\tanh 2\beta' = (\alpha_m l/d')\cdot 2\beta'\varepsilon \\ &= 2\pi\varepsilon(\alpha_m \delta l/d'^2) = 2\pi\varepsilon(\alpha_{0m}\delta_0/d'^2)p_a P_e l \\ &= 2\pi\varepsilon(k_{0m}/D^2)P_e w\,, \end{aligned} \quad (47)$$

ε being $\varepsilon=(\tanh 2\beta')/2\beta'$, $I_0(a_m/\cosh 2\beta')$ is given by

$$I_0(a_m/\cosh 2\beta') = \sum_{n=0}^{\infty} \frac{1}{(n\,!)^2}\left(\frac{1}{2\cosh 2\beta'}\right)^{2n} {a_m}^{2n} \quad (48)$$

and hence

$$\begin{aligned} \langle T_m\rangle_{av} &= \left\langle \sum_{n=0}^{\infty} \frac{1}{(n\,!)^2}\cdot\frac{1}{(2\cosh 2\beta')^{2n}}\cdot {a_m}^{2n}\exp(-a_m)\right\rangle_{av} \\ &= \sum_{n=0}^{\infty} \frac{1}{(n\,!)^2}\cdot\frac{1}{(2\cosh 2\beta')^{2n}}\cdot\langle {a_m}^{2n}\exp(-a_m)\rangle_{av}\,. \end{aligned} \quad (49)$$

If $f(a_m, \xi)$ is defined by

$$f(a_m,\xi) \equiv \exp(-a_m\xi), \quad (50)$$

then ${a_m}^{2n}\exp(-a_m)$ is given by

$${a_m}^{2n}\exp(-a_m) = \frac{d^{2n}}{d\xi^{2n}} f(a_m,\xi)\Big|_{\xi=1} \quad (51)$$

and we obtain

$$\langle {a_m}^{2n}\exp(-a_m)\rangle_{av} = \frac{d^{2n}}{d\xi^{2n}}\langle f(a_m,\xi)\rangle_{av}\Big|_{\xi=1}\,. \quad (52)$$

Consequently $\langle T_m\rangle_{av}$ becomes

$$\langle T_m\rangle_{av} = \sum_{n=0}^{\infty}\frac{1}{(n\,!)^2}\cdot\frac{1}{(2\cosh 2\beta')^{2n}}\cdot\frac{d^{2n}}{d\xi^{2n}}\langle f(a_m,\xi)\rangle_{av}\Big|_{\xi=1}\,. \quad (53)$$

8) N. D. Coggeshall and E. L. Saiber, *J. Chem. Phys.*, **15**, 65 (1947).

By use of the cumulant expansion theorem in $\langle f(a_m, \xi)\rangle_{av}$, we obtain

$$\langle f(a_m,\xi)\rangle_{av} = \exp\{h(\xi)\} \quad (54)$$

where

$$h(\xi) = -\langle a_m\rangle_c\xi + \frac{1}{2\,!}\langle {a_m}^2\rangle_c\xi^2 - \frac{1}{3\,!}\langle {a_m}^3\rangle_c\xi^3\,. \quad (55)$$

The higher terms than the third are ignored, $\langle {a_m}^n\rangle_c$ being the cumulant average of a_m of nth order. The derivatives of $\exp\{h(\xi)\}$ with respect to ξ are as follows.

$$\frac{d}{d\xi}\langle f(a_m,\xi)\rangle_{av} = h'(\xi)\exp\{h(\xi)\} \quad (56)$$

$$\frac{d^2}{d\xi^2}\langle f(a_m,\xi)\rangle_{av} = [h''(\xi)+\{h'(\xi)\}^2]\exp\{h(\xi)\} \quad (57)$$

$$\frac{d^3}{d\xi^3}\langle f(a_m,\xi)\rangle_{av} = [h'''(\xi)+3h''(\xi)\cdot h'(\xi) + \{h'(\xi)\}^3]\exp\{h(\xi)\} \quad (58)$$

$$\frac{d^4}{d\xi^4}\langle f(a_m,\xi)\rangle_{av} = [h''''(\xi)+4h'''(\xi)\cdot h'(\xi)+3\{h''(\xi)\}^2 + 6\{h'(\xi)\}^2\cdot h''(\xi)+\{h'(\xi)\}^4]\exp\{h(\xi)\}\,. \quad (59)$$

By substituting Eqs. (57) and (59) into Eq. (53), the following expression is obtained

$$\begin{aligned} \langle T_m\rangle_{av} = \Bigg[& 1+\frac{1}{(2\cosh 2\beta')^2}\cdot\{(\langle {a_m}^2\rangle_c-\langle {a_m}^3\rangle_c) \\ & +(\langle a_m\rangle_c-\langle {a_m}^2\rangle_c+\langle {a_m}^3\rangle_c/2)^2\} \\ & +\frac{1}{4}\cdot\frac{1}{(2\cosh 2\beta')^4}\cdot\{4\langle {a_m}^3\rangle_c\cdot(\langle a_m\rangle_c-\langle {a_m}^2\rangle_c \\ & +\langle {a_m}^3\rangle_c/2)+3(\langle {a_m}^2\rangle_c-\langle {a_m}^3\rangle_c)^2 \\ & +6(\langle a_m\rangle_c-\langle {a_m}^2\rangle_c+\langle {a_m}^3\rangle_c/2)^2\cdot(\langle {a_m}^2\rangle_c-\langle {a_m}^3\rangle_c) \\ & +(\langle a_m\rangle_c-\langle {a_m}^2\rangle_c+\langle {a_m}^3\rangle_c/2)^4\} \\ & +\text{higher terms}\Bigg]\cdot\exp\{h(1)\}\,. \end{aligned} \quad (60)$$

[ ] represents the influence of the Bessel function of order zero. Equation (60) becomes Eq. (36) or (41) if [ ] is approximated by unit. The calculated results of $\langle {a_m}^n\rangle_c$ for the case of CO_2 and the influence of the Bessel function of order zero are given in Table 1.

Table 1. The values of $\langle {a_m}^n\rangle_c$ and the influence of the Bessel function in regard to CO_2
($\varepsilon\approx 1$. $\cosh 2\beta'\approx 1$. $P_e\approx P/B$. $P=70$ cmHg. $D=0.52$)

$\langle {a_m}^n\rangle_c$	$w=5$	$w=10$
$\langle a_m\rangle_c$	0.231	0.462
$\langle {a_m}^2\rangle_c$	0.054	0.232
$\langle {a_m}^3\rangle_c$	0.024	0.159
Influence of the Bessel function	1.020	1.035

$\langle {a_m}^n\rangle_c$ is given by

$$\langle a_m\rangle_c = (2\pi\varepsilon/D^2)\cdot\left(\frac{\langle k_{0m}\rangle_{av}+\langle k_{0m'}\rangle_{av}}{1+r}\right)\cdot P_e w$$

$$\langle {a_m}^2\rangle_c = (2\pi\varepsilon/D^2)^2\cdot\left(\frac{\langle k_{0m}^2\rangle_{av}+r\langle k_{0m'}^2\rangle_{av}}{1+r} - \frac{\langle k_{0m}\rangle_{av}^2+r\langle k_{0m'}\rangle_{av}^2}{1+r}\right)\cdot(P_e w)^2$$

$$\langle a_m{}^3\rangle_c = (2\pi\varepsilon/D^2)^3 \cdot \left\{ \frac{\langle k_{0m}^3\rangle_{av} + r\langle k_{0m'}^3\rangle_{av}}{1+r} - 3\left(\frac{\langle k_{0m}^2\rangle_{av} + r\langle k_{0m'}^2\rangle_{av}}{1+r}\right)\cdot\left(\frac{\langle k_{0m}\rangle_{av} + r\langle k_{0m'}\rangle_{av}}{1+r}\right) + 2\left(\frac{\langle k_{0m}\rangle_{av}^3 + r\langle k_{0m'}\rangle_{av}^3}{1+r}\right)\right\} \cdot (P_e w)^3 . \quad (61)$$

0.52 is used for the value of D by means of Eqs. (40), (43) and the experimental data[1]

$$\frac{\langle k_{0m}^{1/2}\rangle_{av} + r\langle k_{0m'}^{1/2}\rangle_{av}}{(1+r)D} = 8.0\times10^{-3}\ \mathrm{cm}^{-1/2}\cdot\mathrm{cmHg}^{-1}.$$

The influence of the Bessel function is thus proved to be within error. The experimental values are compared with the theoretical ones (Fig. 10). The dotted line shows the experimental curve and the solid line the theoretical curve given by

$$\ln\frac{1}{1-x} = 8.60\times10^{-4}(P_e w) - 8.00\times10^{-7}(P_e w)^2 + 1.01\times10^{-9}(P_e w)^3. \quad (62)$$

This is derived by substituting the values of (43) into Eq. (41) and using 0.52 for D. In order to attain a better agreement between theoretical and experimental values under high pressure, the value of 0.36 should be used as the correction factor D instead of 0.52. In case of CO,[9] similarly to CO_2, the value of 0.16 should be replaced with 0.07. These discrepancies seem to result from several assumptions, especially the roughness of the rectangular approximation concerning the shape of the absorption lines of the detector, and the conditions under which experiments correspond to the intermediate case of δ.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3764—3767 (1973)

The Separation of Silver, Bismuth, Cadmium, and Zinc as Their Trioctylamine Complexes by Extraction Chromatography

Takaharu HONJO, Shigeru USHIJIMA, and Toshiyasu KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi, Kanazawa, Ishikawa 920

(Received June 1, 1973)

The behavior of milligram amounts of silver, bismuth, cadmium, and zinc in liquid-liquid extraction has been studied with 20% trioctylamine (TOA) in carbon tetrachloride. The results have also been applied to the separation of the four metals as their TOA complexes by extraction chromatography. After passing a sample solution of 2 M HCl through a column (ϕ 1 cm×1 30 cm) consisting of a stationary phase of TOA-CCl_4 on Kel-F, the metal ions were retained and then eluted with 5.5 M HCl at the rate of 0.5—1 ml/min at 20±1 °C. Silver was found in 90—180 ml of the effluent; Bi was flowed down in 200—500 ml of the same effluent. The cadmium and Zn were held so firmly on the column that they could not be removed under the above conditions. Therefore, water was passed through to release these metals. Zinc was first flowed down with 0—50 ml, and then Cd, with 200—500 ml of water. When 5 M HNO_3 was used as the eluting solution instead of water, the Cd was immediately removed from the column. The percentage recovery of these metals in the extraction chromatography was estimated as 101% (Ag), 99% (Bi), 97% (Cd), and 94% (Zn) respectively. The distribution ratios of these metals, as obtained by the extraction chromatography of the TOA-carbon tetrachloride (Kel-F)-HCl system, were in quite good agreement with those obtained by the batch extraction.

For the past few years, the group separation of nineteen common cations (Fe, Hg, Sn, Ag, Bi, Zn, Cd, Sb, Cr, Al, Cu, Co, Ni, Pb, Mn, Mg, Ca, Sr, and Ba) has been attempted in the authors' laboratory by extraction chromatography with six different columns (TBP-(1), TOA, TBP-(2), AcAc, TTA-(1), TTA-(2)).[1] One of these columns consists of the 20% TOA–CCl_4–(Kel-F)–2 M HCl system; four metal ions, silver, bismuth, cadmium, and zinc, could be selectively held on this column. The present authors aimed to separate these retained metal ions from each other by passing a suitable eluting solution through the column. The TOA(trioctylamine) has been used as a powerful extractant of metals;[2] recently, however, this liquid ion-exchanger has been found also to be

1) I. Akaza, T. Tajima, and T. Kiba, This Bulletin, **46**, 1199, (1973).

2) T. Sato, *Kagaku to Kogyo*, **20**, 52 (1967).

suitable for the chromatographic separation of metals.[3] Cerrai and Testa have also achieved the mutual separation of Ni-Co-Fe by using a reversed-phase column of cellulose impregnated with TOA, with hydrochloric acid as the eluent.[4] The process of the extraction chromatography are closely related to the ordinary liquid-liquid extraction in batch, as has already been described by the present authors with regard to the Zn Hg, and Co–STTA–cyclohexane (Kel-F) system;[5] therefore, some basic investigations should be made into the behavior of milligram amounts of Ag, Bi, Cd, and Zn in solvent extraction with trioctylamine in carbon tetrachloride. The optimum conditions for the mutual separation of these metals by extraction chromatography could be predicted from the above results. The separation could be achieved successfully; the relation between the extraction chromatography and the liquid-liquid extraction was also considered.

Experimental

Apparatus. A chromatographic glass tube of ϕ 10× 1 300 mm equipped with a fritted glass filter; a Toyo fraction collector, Type E-E, SF 200 A; a KM-type shaking machine, Type V-S, KK IWAKI, 280 stroke/min, a well-type scintillation counter, Kobe Kogyo Corp, Ten scaler SA-250; a 200-channel pulse-height analyser; an Expandmatic Beckman pH meter; a Hitachi Horiba M 5 pH meter.

Materials. The radioisotopes, Ag-110 m, Bi-207, Cd-115m, and Zn-65, were imported from the New England Nuclear Corp and The Radio Chemical Centre, and were used as the tracers. The tracer of Cd contained some radioactive impurities; therefore, it was purified by extraction with 20% TOA-CCl_4 from a 2 M HCl solution and by back-extraction with 5 M HNO_3. The purity of each tracer was checked by means of the 200-channel pulse-height analyser at every use. Each of the metal salts, such as $AgNO_3$, $Bi(NO_3)_3$-$5H_2O$, $Cd(NO_3)_24H_2O$, and $Zn(NO_3)_26H_2O$, was dissolved in a slightly acidic solution (pH 0.3—4.5) to 0.5 mg/ml. TOA (trioctylamine) of the GR grade was purchased from the Tokyo Kasei Co. Kel-F 300 moulding powder, the trade name of polytrifluorochloroethylene, was obtained from the Daikin Kogyo Co. The other reagents were reagent-grade materials.

Extraction and Back-extraction. Into a 50-ml centrifuge tube, 20% TOA in carbon tetrachloride (10 ml) and an aqueous solution (10 ml) containing 0.5 mg of a metal and trace amounts of its radioactive tracer were put together; the contents were then agitated with a shaking machine for 2—30 min at 20±1 °C. After centrifugation, a 3-ml portion was taken out of each phase into a test tube, the radioactivity was counted with the scintillation counter, and the distribution ratio of the metal was calculated. The back-extraction behavior of the metal was also examined by shaking the organic phase with an aqueous solution adjusted to a suitable acidity with HCl. Since the extraction equilibria involve the extraction of HCl along with the metal chloride,[6] the aqueous phase and organic phases were pre-equilibrated with each other to prevent any change in the acidity or in the concentration of the reagent during the extraction.

Preparation of the Column and the Extraction Chromatographic Procedure. The Kel-F was crushed by means of a grinding mixer, and particles of 42—80 mesh was collected by sieving through a screen. A 5.5-g portion of Kel-F and a 10-ml portion of 20% TOA in carbon tetrachloride, which had been pre-equilibrated with 2 M HCl, were put into an Erlenmyer flask fitted with a stopper; the contents were then shaken by hand so as to become homogeneous and subsequently allowed to stand overnight in a dark place. The product was then slurried with an eluting solution: the slurry was then packed, little by little, into a glass tube, which had previously been then filled with an eluting solution as has been described in the preceding paper.[5] The chromatographic column of a 20×2 cm bed was thus prepared simply, and the excess TOA solution was washed down from the column by passing through enough volume of 2 M HCl. In this case, the upper surface of the column should be covered with 2 M HCl to a depth of 1—2 cm. The eluting solution should have been previously saturated with the organic solution of the stationary phase; also, the sample solution should have the same acidity as the eluting solution. Each 1-ml portion of the stock solution, containing 0.5 mg of metal, was mixed with a 49-ml portion of 2 M HCl to prepare the test solution. To investigate the chromatographic behavior of the metals, a minute amount of the radioactive tracer was added to the stock solution; however, the total amount of the metal present in the solution might be taken as unvaried from 0.5 mg. From a separation funnel fitted to the top of the column, a 50-ml portion of the sample solution was flowed down through the column at the rate of 0.5—1 ml/min. After washing the column three times with 5—10 ml of 2 M HCl, 500—1000 ml of the eluting solution, adjusted to an adequate acidity of HCl, was put into a 1000-ml separation funnel and passed through the column at the rate of 0.5—1 ml/min. The eluate was subsequently divided into 5-ml fractions by means of a fraction collector. A 3-ml portion of the eluate was pipetted out of each 5-ml fraction into a test tube, and the radioactivity was counted by means of a NaI(Tl) well-type scintillation counter. All the experimental procedures were carried out in the thermostatic room at 20±1 °C. The Kel-F in the degraded column was taken out into a 200-ml beaker and washed two or three times with ethanol, water, 6 M HCl, acetone, and ether successively. Then the materials were air-dried, and the particles of a 42—80 mesh were collected by sieving them through a screen and were then used for further experiments.

Results and Discussion

Liquid-liquid Extraction of Silver, Bismuth, Cadmium, and Zinc. The extraction of milligram amounts of silver, bismuth, cadmium, and zinc with 20% TOA in carbon tetrachloride was investigated for aqueous solutions with varying concentrations of HCl. The back-extraction behavior of these metals was also investigated with 2—12 M HCl. As is shown in Fig. 1, about a 100% quantitative extraction of metals was achieved in 2—3 M HCl (Ag), 2—5 M HCl (Bi), 2—9 M HCl (Zn), and 2—10 M HCl (Cd). The back-extraction curves of Ag and Bi show shapes almost the reverse of those of the extraction, but Cd and Zn could not be back-extracted with 2—12 M HCl. It seemed strange that zinc has a relatively lower extractability in the acid region of 0—0.6 M, but can

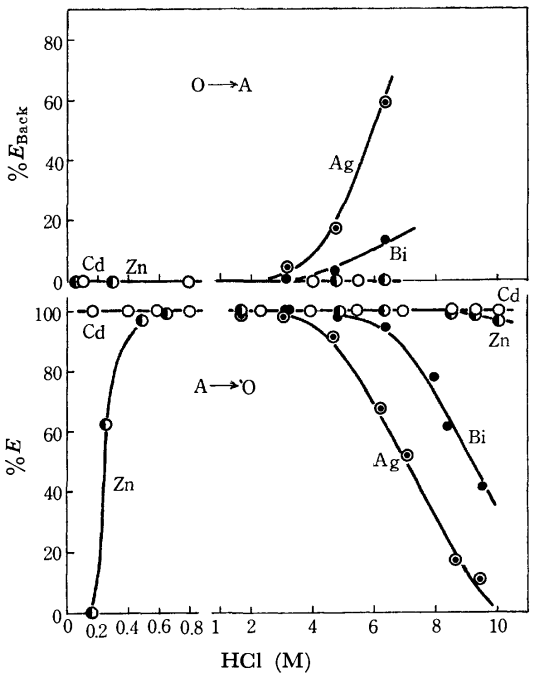

Fig. 1. The extraction and the back-extraction curves of Ag, Bi, Cd, and Zn with 20% TOA in carbon tetrachloride as a function of the acidity of HCl.
Metal: 0.5 mg/ml, Shaking time: 2—30 min, O→A: Back-extraction, A→O: Extraction.

not be back-extracted from the organic phase by shaking the organic phase with an aqueous solution in the same acid region. However, the volume ratio of the aqueous phase to the organic phase was increased; the Zn could be back-extracted 9% (4 : 1), 20% (8 : 1), and 84%(20 : 1) with 0.06 M HCl under shaking for 30 min, but when the volume of the aqueous phase was increased, the organic phase was remarkably in the emulsification state. The aqueous phase in a larger volume might promote the dissociation of the TOA–HCl complexes present in the organic phase as well as the stripping of HCl into the aqueous phase, resulting in a higher acidity of the aqueous solution. In a similar manner, the elution process may take place in the extraction column, where the mobile aqueous phase is always renewed and never again comes into contact with the same place in the stationary phases. On the other hand, as can be seen in Fig. 1, the extraction of Cd was near 100% from 0—2 M HCl; the back-extraction was also impossible under the same acidity. The difference in the behavior of Cd and Zn may be due to the difference in the stability constants of their chloro complexes,[7] the former being more stable than the latter. Nevertheless, in the case of cadmium the metal could be released from the TOA–CCl_4 column by passing it through plenty of water. As has been described above, the equilibria of the TOA–CCl_4 extraction system are affected by the acid concentration of the aqueous phase; therefore, the organic phase and the aqueous phase should be pre-equilibrated with each other in respect to hydrochloric acid. The time needed for the extraction equilibrium to be reached was ascertained to be within 2 min in the metal–20% TOA–CCl_4–HCl system.

The Volume of the Stationary Phase. In the preparation of the column, a simple previously-described method was used: a definite volume of a TOA–CCl_4 solution was held on Kel-F to make a slurry, and the slurry was put into the glass tube; then, the excess portion of the TOA-CCl_4 was washed down by passing 2 M HCl through the column. The difference between the volume of TOA–CCl_4 taken initially and that of the effluent seems to be the volume of the stationary phase in the column. The mean value after five determinations was 8.5 ml.

The Volume of the Mobile Phase. The volume of the mobile phase was determined by means of two methods. 1) The column bed was prepared as has been described above, and much 0.1 M sodium chloride solution saturated with TOA–CCl_4 was allowed to flow down until the effluent showed the same concentration of sodium chloride. After carefully washing the inside of the tube below the fritted glass filter with water, the 0.1 M sodium chloride solution occupying the pores of the column was flowed down by thoroughly washing the column with water pre-equilibrated with TOA–CCl_4. The sodium chloride in the washing liquid was determined by titrating it with a 0.1 M silver nitrate solution as usual. The value was estimated to be 5.45 ml. 2) One drop of a ^{60}Co tracer was put into the top of the column bed, and water pre-equilibrated with TOA–CCl_4 solution was passed through the column. The elution curve was obtained by taking 0.22-ml portions of the effluent and counting the radioactivity of each fraction. The volume of the effluent required to reach the maximum peak of the elution curve was the mobile phase. The value obtained by this method was 5.11 ml.

Mutual Separation of Silver, Bismuth, Cadmium, and Zinc from the Mixed Solution. The optimum acidity of the eluting solution was predicted from the liquid-liquid extraction behavior of the metals. As is shown in

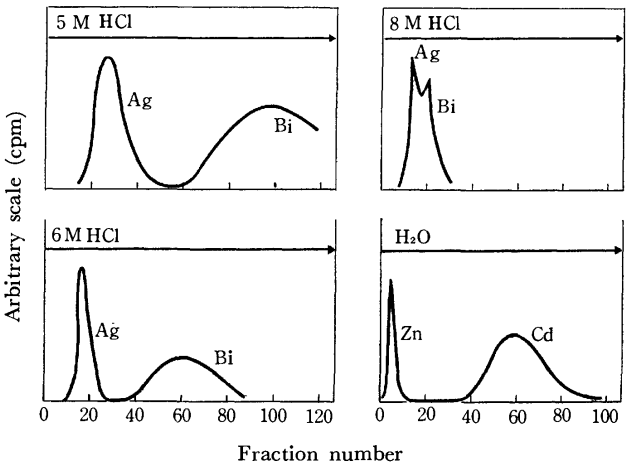

Fig. 2. The elution curves of Ag, Bi, Cd, and Zn retained on the column of 20% TOA-carbon tetrachloride-(Kel-F)-2 M HCl system.
Metal: 0.5 mg/ml, Flow rate: 0.5—1 ml/min, 1 fraction: 5 ml.

7) J. Bjerrum, G. Schwarzenbach, and L. G. Sillen, "Stability Constants," Spec. Publ. No. 7, Chemical Society, London (1958).

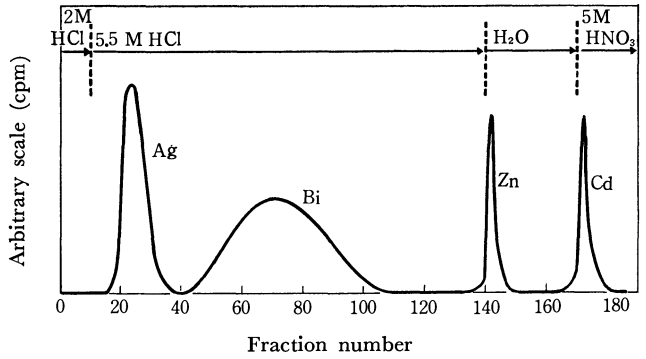

Fig. 3. The mutual separation of Ag, Bi, Cd, and Zn retained on the column of 20% TOA-carbon tetrachloride-(Kel-F)-2 M HCl system from a mixed solution.
Metal: 0.5 mg/ml, Flow rate: 1 ml/min, 1 fraction: 5 ml.

Fig. 2, silver was eluted with 100—225 ml of 5 M HCl, 50—100 ml of 8 M HCl, and 60—125 ml of of 6.5 M HCl at the flow rate of 0.5—1 ml/min. Bismuth was eluted with 325 ml of 5 M HCl, 50—150 ml of 8 M HCl, and 150 ml of 6.5 M HCl. The mutual separation of Ag and Bi could be expected using 5 M or 6 M HCl as an eluting solution, but Cd and Zn could not removed, not even with 2—12 M HCl, as had been predicted from the results of the batch extraction. However, Zn could be eluted with 50—100 ml of water after the elution of Ag and Bi with 5—6 M HCl and that of Cd with 5 M nitric acid. In conclusion, an optimum mutual separation diagram of Ag, Bi, Cd, and Zn in the 20% TOA–CCl_4–HCl system was established, as is given in Fig. 3. Silver and Bi were eluted with 90—180 ml and 200—500 ml of 5.5 M HCl successively. Then Zn was flowed down with 50—100 ml of water. In this case, the pH of the water effluent was found as low as 2. To shorten the eluting time, 5 M HNO_3 was passed through the column after separating Zn; thus, Cd was immediately eluted. The recovery of the metals was 101% (Ag), 99% (Bi), 94% (Zn), and 97% (Cd) respectively for each 0.5-ml portion of the metals.

The Relation of the Extraction Chromatography to the Liquid-liquid Extraction. The extraction and the back-extraction are repeated in the column many times in the process of the extraction chromatography. Therefore, the distribution ratios of the metals obtained by the batch extraction and by the extraction chromatography should be closely related with each other. If the extraction equilibrium is ideal and is attained rapidly at any interval under certain extraction conditions, the net distribution ratio of the metals in the extraction, D, that in the back-extraction, D^*, and the distribution of metals in the column extraction, D^{**}, will be related to the following equation:[1,2]

$$D = \frac{(\text{Total metals})_0}{(\text{Total metals})} = \frac{1}{D^*} = D^{**} = \frac{V_m - V^*}{V_0^*}$$

where ( ) and $(\ )_0$ designate the concentrations of chemical species in the aqueous and in the organic phase respectively, where V_m is the volume of the effluent in relation to the maximum of the eluted metal concentration, where V^* is the volume of the mobile phase, and where V_0^* is that of the stationary phase.

Table 1. Distribution ratio of metal ions with 20% TOA in carbon tetrachloride

	HCl (M)	By solvent extraction	By extraction chromatography
Ag	5	8.0 (6.6)	8.0
	5.5	3.3 (1.9)	3.5
	6	2.1 (1.1)	4.1
	8	0.5 (0.1)	1.7
Bi	5	18 (16)	55
	5.5	32 (12)	29
	6	24 (7.6)	28
	8	3.5 (1.9)	5.0
Zn	0.01	2.5	2.0
Cd	0.01	100	30

The values in the bracket were determined by analysing the back-extraction curves. Metal : 0.5 mg/ml

The values of the distribution ratio of the metals obtained by the batch extraction and the extraction chromatography are summarized in Table 1. The two values are in quite good agreement. The discrepancy may be caused by the differences in the contact times of the two phases and/or by the time-lag in the complex formation in the extraction and the back-extraction.

The authors wish to thank Dr. Ikuko Akaza for her helpful advice and discussion.

The Analytical Application of Sulfur Analogues of β-Diketones. III. The Separation of Cobalt(II), Nickel(II), Copper(II), Zinc(II), Mercury(II), Lead(II), and Cadmium(II) as Their STTA (1,1,1-Trifluoro-4-(2-thienyl)-4-mercapto-3-buten-2-one) Complexes by Thin-layer Chromatography on Silica Gel

(Received June 1, 1973)

Cobalt(II), nickel(II), copper(II), zinc(II), mercury(II), lead(II), and cadmium(II) were extracted with STTA (1,1,1-trifluoro-4-(2-thienyl)-4-mercapto-3-buten-2-one) in cyclohexane, and their colored complexes were chromatographed on a thin-layer of silica gel with various organic solvents. The developing solvents used were 18 kinds of pure solvents and 10 different binary solvent mixtures of 1 : 1, v/v. An excellent separation could be achieved after development with carbon tetrachloride, carbon disulfide, ethyl acetate, and cyclohexane–chloroform, chloroform–carbon disulfide, and carbon tetrachloride–carbon disulfide mixtures. The R_f value generally increased in the following orders: Cd(II), Zn(II), Pb(II), (STTA)<Hg(II)<Co(II, III)<Cu(II)<Ni(II) (with carbon tetrachloride); Cd(II), Zn(II), Pb(II), (STTA)<Co(III)<Hg(II)<Cu(II)<Ni(II) (with carbon disulfide); Cd(II), (STTA)<Zn(II)<Pb(II)<Hg(II), Co(III), Cu(II), Ni(II) (with ethyl acetate); and Cd(II), Zn(II), Pb(II), (STTA)<Hg(II)<Co(III)<Cu(II)<Ni(II) (with the cyclohexane–chloroform, chloroform–carbon disulfide, and carbon tetrachloride–carbon disulfide mixtures). A few μg $Ni(STTA)_2$ chelates on the plate could be determined quantitatively by measuring the spot area from the curve drawn on a millimeter-graph sheet after driving a densitometer across the spot. Some aspects of the behavior of the STTA chelates on the thin-layer of silica gel have also been discussed.

Thin-layer chromatography (tlc) has recently become popular in the separation of a wide variety of organic and inorganic substances, using the standardized procedures of Stahl and others.[1] Taking advantage of this technique, the separation of the metals as their chelates has been performed with several extracting reagents, such as acetylacetone,[2–4] α-nitroso-β-naphthol,[5] 8-hydroxyquinoline,[6] dithizone,[7–12] and diethyldithiocarbamic acid.[13–17] A new chelating reagent, 1,1,1-trifluoro-4-(2-thienyl)-4-mercapto-3-buten-2-one (abbreviated as STTA), has been found to form stable and extractable chelates with a specific color,[18] and it has been used for several analytical purposes, *e.g.*, the spectrophotometric determination of cobalt(II),[19] and the separation of Hg, Co, and Zn by extraction chromatography.[20] However, the STTA chelates have not yet been submitted to thin-layer chromatography. In the present investigations, the metal ions were extracted in cyclohexane containing STTA, and the STTA chelates thus formed were chromatographed on the thin-layer of silica gel using various organic solvents. The possibility of the quantitative determination and the mutual separation of these metal complexes has been investigated; some aspects of the chromatographic behavior of the STTA chelate have also been discussed.

Experimental

Apparatus. The thin-layer chromatograph: TLC "Sandwich" developing apparatus, model TL-IS, of Yamato Scientific Instruments. Densitometer: Atago self-recording densitometer designed for paper electrophoretic patterns.

Materials. Metal ions: Metal salts, $CoCl_26H_2O$, $NiCl_26H_2O$, $CuSO_45H_2O$, $ZnCl_2$, $HgCl_2$, $Pb(NO_3)_2$, and $CdCl_2$, were dissolved in distilled water or in a slightly acidic solution to make a 10^{-1} M aqueous solution of each metal ion.

STTA: STTA was prepared by a modification of the method of Berg and Reed.[19]

Adsorbent: Silica gel for the thin-layer chromatography, WAKOGEL B-5 (binder, $CaSO_41/2H_2O$, 5%).

Developing solvents: Methanol, ethanol, cyclohexanol, acetone, methyl ethyl ketone, ethyl acetate, ethyl ether, carbon tetrachloride, chloroform, ethylene chloride, carbon disulfide, *n*-hexane, cyclohexane, benzene, xylene (bp 138.5—141.5 °C), nitrobenzene, *o*-dichlorobenzene, and benzonitrile were all of reagent-grade materials and were purified by the ordinary method, if necessary.

Solvent Extraction. The experimental procedure for the solvent extraction of trace amounts of metals was almost

the same as has previously been described.[19,21] The sample solutions for the thin-layer chromatography were metal-STTA chelates in cyclohexane, which were prepared as follows: a 10^{-2} M salt solution was acidified with 0.1 M acetic acid to pH 6.0—6.5 and then this solution was shaken with 10^{-3} M STTA in cyclohexane for 1.5 hr. After the extraction, some deposit in a membrane substance at the interface of the phases was found in the cases of Co, Cu, and Hg. Zinc and Ni gave no precipitate, while Pb and Cd gave insoluble chelates in cyclohexane, but soluble ones in ethyl acetate.

Thin-layer Chromatography A homogeneous paste was prepared by thoroughly mixing 30 g of the silica gel with 60 ml of distilled water in a mortar using a pestle. Then, the paste was spread on a 20×20 cm glass plate at a thickness of 0.25 mm using a commercial applicator. The plates were air-dried for 20—30 min at room temperature; then they were activated at 110 °C for 60 min and cooled overnight in a desiccator containing silica gel. By means of an micropipet, a 3-μl portion of a sample solution was placed as a spot on thin-layer at definite intervals within about 1.5 cm from the bottom of the plates. The spots were then air-dried at room temperature. Both sides of the chromatoplates were covered with glass plates to form a kind of sandwich; the plates were firmly held with clips. This "sandwich" was placed in a chromatographic chamber containing an organic solvent or some mixed solvents and was dipped into the solvent up to 1 cm below the sample spots. The organic solvent was allowed to proceed up to about 10 cm of the sample spot, and then the plates were taken out of the chambers and exposed to air. No spraying was necessary for the detection, since most of the chelates show different, characteristic colors. Development on a chromatoplate coated with silica gel was carried out at room temperature (22—26 °C).

The R_f value of the substances, the relative migration rates of the solutes, is one of the most convenient expressions of the position of the compounds on the chromatoplate, where:

$$R_f = \frac{\text{distance traveled by the substance}}{\text{distance traveled by the solvent}}$$

Moreover, the R_f value is a measure of the interaction among solute, solvent, and adsorbent, and is reproducible and characteristic for each solute in a given solvent-adsorbent system under specified conditions.

Results and Discussion

Extraction. The metal ions were extracted in trace amounts with 10^{-3} M STTA in cyclohexane; their extraction curves are presented in Fig. 1. It was found that the quantitative extractions of the STTA chelates of Co(II), Ni(II), Cu(II), Zn(II), Hg(II), Pb(II), and Cd(II) were almost achieved in the pH region below 7. The extraction of cobalt seemed to be accompanied by the transformation of $Co(STTA)_2$ to $Co(STTA)_3$.[19-21]

Absorption Spectra. The absorption spectra of STTA and its metal chelate in cyclohexane are shown in Fig. 2. Each chelate showed its own specific color, had an absorption maxima, and was stable for at least 7 days. These results are summarized in Table 1. The compounds could be identified only by observing the individual specific color on the chromatoplates.

$Cd(STTA)_2$	Yellow	375[a]

a) Diluted with ethyl acetate.

Pure Solvents. Some representative results of the development of STTA and its metal STTA chelate with individual solvents on a thin-layer of silica gel by the ascending method are given in Table 2. The chelates may be classified into four groups by chromatographic behavior: 1) Chelates which do not migrate from the sample spot (with cyclohexane and *n*-hexane). 2) Chelates which can be developed to a moderate distance over a comparatively wide range (with methanol, carbon tetrachloride, and carbon disulfide). 3) Chelates which move up to the solvent front (with ethanol, acetone, methyl ethyl ketone, ethyl acetate, chloroform, ethylene chloride, benzene, xylene, nitrobenzene, *o*-dichlorobenzene, and benzonitrile).

a) The spots disappeared during the development. The average deviation of R_f values was 0.01.

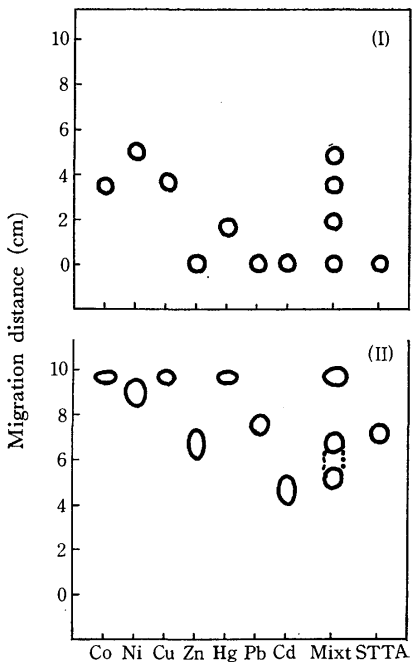

Fig. 3. Chromatogram of STTA and its metal chelates with single component solvent.
STTA, Chelate: *ca.* 5×10^{-4} M (3 μl); Developing solvent: (I) carbon tetrachloride, (II) ethyl acetate

4) Chelates which dissolve in the solvent and the spots of which disappear during development (with cyclohexanol and diethyl ether). The times required for about a 10 cm(8.7—12.4 cm) development were all about 15—90 min. The R_f values of the STTA chelates generally increased in the order of: Cd(II)<Zn(II)<Pb(II), (STTA)<Hg(II)<Co(II, III)<Cu(II)<Ni-(II). With such developing solvents as carbon tetrachloride, carbon disulfide, and ethyl acetate, the mutual separation of various metal chelates was achieved successfully. Some representative chromatograms of STTA and its metal chelates with carbon tetrachloride and ethyl acetate are shown in Fig. 3. It was observed that the cobalt-STTA chelate extracted in high concentrations as 30 μl of a 4×10^{-5} M chelate solution gives two spots; one may possibly correspond to Co(STTA)$_2$ (R_f=0.29), and the other, to Co(STTA)$_3$ (R_f=0.35), using carbon tetrachloride. The elution power of a solvent is generally related to its dielectric constant or its dipole-dipole moment. The greater the polarity of the solvent, the greater the distance of the development on the chromatographic plate. The eluotropic series of solvents proposed by Trappe[22] and by Strain[23] may be valid also with regard to the thin-layer chromatographic behavior of the STTA chelates.

Development and Separation of the STTA Chelates with a Binary Solvent Mixture. By using a binary mixture of solvents in a 1 : 1 volume ratio, STTA and its metal STTA chelates were developed; some representative results are shown in Table 3. All the mix ed solvents could develop the STTA chelates to a moderate distance. Among these mixed solvents, the pairs of cyclohexane–chloroform, chloroform–carbon disulfide, and carbon tetrachloride–carbon disulfide were most suitable for the mutual separation of the STTA chelates. Some representative chromatograms of STTA and its metal chelates with carbon tetrachloride, carbon disulfide, and cyclohexane–chloroform mixtures are shown

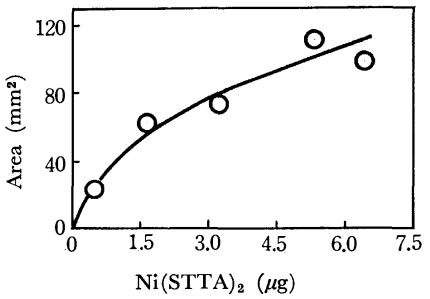

Fig. 5. Calibration curve of a thin layer chromatogram of $Ni(STTA)_2$ chelate obtained by photodensitometry.
Developing solvent: carbon tetrachloride

in Fig. 4. The R_f values of all the STTA chelates with the binary solvent mixtures had the same tendency to increase in the order of Zn(II)<Hg(II)<Co(III)<Cu(II)<Ni(II) as in the case of the single solvents. In the case of the mixed solvents, some demixing may occur, accompanied by some changes in the solvent ratio, because of the difference in the adsorbability of each solvent on the silica gel; therefore, the developed spots are believed to give suitable R_f values, separated from each other.

Quantitative Evaluation of the Thin-layer Chromatograms of the Ni(STTA)$_2$ Chelate. The possibility of the direct quantitative determination of the $Ni(STTA)_2$ chelate, which gives the largest R_f value and a clear spot on its plate, has been investigated by measuring the intensity of its color with the photodensitometer. The spot area was determined from the curve drawn on a millimetergraph sheet after driving the densitometer across the spot. The quantitative extractions of nickel from trace amounts up to 10^{-4} M were achieved with 10^{-3} M STTA in cyclohexane in the pH region above 4.5. The calibration curve in Fig. 5 shows the relation of the areas of the spot of the $Ni(STTA)_2$ chelate developed with carbon tetrachloride *vs.* the amount initially taken. Satisfactory results could be obtained by placing, by means of a microsyringe, a sample organic solution of the STTA chelate in a definite volume of a solvent. This graphical method may be suitable for the successive determination of a few μg each of the other chelates in a developed spot.

Some Aspects of the Behavior of the STTA Chelates on the Thin-layer of Silica Gel. The R_f values of the STTA chelates with various solvents generally increase in the following order: Cd(II)<Zn(II)<Pb(II), (STTA) < Hg(II) < Co (II, III) < Cu(II) < Ni(II). This sequence differs from the acetylacetonates[2-4] the α-nitroso-β-naphtholate[5] series (Zn(II)<Co(II)<Ni(II)<Cu(II)<Co(III)), the 8-hydroxyquinolinate series[6] (Zn(II)<Cd(II)) the dithizonates series[7-12] (Cd(II)< Pb(II)< Co(II)< Zn(II)< Ni(II)< Cu(II)< Hg(II)), or the diethyldithiocarbamates series[13-17] (Co(II)<Ni(II)<Cu(II)). Acetylacetone chelates easily form their hydrate or polymerized compounds less soluble in non-polar solvents, while the STTA chelates do not form such compounds. The tailing

which usually appears in an acetylacetonate system was not observed in the STTA chelate system. It is of interest that the STTA compounds of Co(II), Ni(II), Cu(II), and Hg(II) travel a moderate distance even with such non-polar organic solvents as carbon tetrachloride and carbon disulfide. This behavior was not observed in the other chelate systems described above. It has recently been observed[24] that the replacement of oxygen by sulfur in the bis-chelate complexes of cobalt(II) and nickel(II) has two important structural consequences, the depolymerization and the stabilization of the planar form. Therefore, the depolymerization or the stabilization of the chelates, which is related to the covalency of the bond caused by the $d\pi$-$d\pi$ interaction, may become one of the important factors in these abnormal R_f trends.

(Received June 1, 1973)

The solvent extraction of trace amounts of various metal ions with STTA (1,1,1-trifluoro-4-(2-thienyl)-4-mercapto-3-buten-2-one) in the presence or in the absence of TOPO (tri-*n*-octylphosphine oxide) has been investigated. The results are as follows: (a) The apparent extraction constant of each metal–STTA chelate in cyclohexane, log K, increases, and their $pH_{1/2}$ values decrease, in the order of: Cd(II)-In(III)-Zn(II)-Fe(III)-Ni(II)-Ag(I)-Bi(III)-Co(II)-Pb(II)-Cu(II)-Hg(II). This order was found to hold also in the back-extraction, except for cobalt, which was not back-extracted even with 1—12 M HCl. The other metals, Au(III), and Pd(II), could also be extracted as their STTA chelates. (b) The kind of the solvent has an effect to the lowest pH value where the metal STTA chelates begin to be extracted; the lowest pH is shifted to a higher value in the order of: C_6H_{12}, CCl_4, MIBK, C_6H_6, and $CHCl_3$. (c) The distribution coefficient, P_r, and the enol dissociation constant, K_a, of STTA were log $P_r=2.99$ (10^{-3} M STTA in cyclohexane–0.1 M $NaClO_4$–pH 1.0) and log $K_a=-4.38$ (10^{-4} M STTA in 0.12 M HCl, 0.1 M CH_3COOH (pH 4.5) and 0.1 M NaOH-C_2H_5OH (1/5, v/v) solution) at 20 °C. (d) The extraction equilibrium of Zn seemed to be rapid, that of Ni showed its rate-determining step to be the formation of $Ni(STTA)^+$, and that of Co seemed to be accompanied by a transformation of $Co(STTA)_2$ to $Co(STTA)_3$. (e) In the metal–STTA(0.001 M)–TOPO(0.01 M)–cyclohexane system, the $|\Delta pH_{1/2}|$ was found to be 0.45 for Ni, 1.95 for Zn, and 0.25 for Co. The Co–STTA–TOPO chelate could be back-extracted to some degree with 1 M HCl. The extracted species were ascertained to be $Zn(STTA)_2$, $Zn(STTA)_2TOPO$, $Ni(STTA)_2$, $Co(STTA)_2$, $Co(STTA)_3$, and $Co(STTA)_2TOPO$. The stability constant of $Zn(STTA)_2$ TOPO was found to be 6.05.

A new chelating reagent, STTA (1,1,1-trifluoro-4-(2-thienyl)-4-mercapto-3-buten-2-one), was first prepared by Chaston *et al.*[1] and by Berg and Reed;[2] it has since been used for chelating and for the extractive photometric determination of metals.[3] The present authors have aimed to develop further analytical usages of STTA, and several reports have been published: on the spectrophotometric determination of cobalt(II),[4] the separation of Hg(II), Co(II), and Zn(II) by extraction chromatography,[5] the separation of Co(II), Ni(II), Cu(II), Zn(II), Hg(II), Pb(II), and Cd(II) by thin-layer chromatography,[6] and the separation of Ni(II) and Co(II) by a back-extraction process.[7] In the present work, a number of factors affecting the liquid-liquid extraction of trace amounts of various metal ions with STTA in the presence or in the absence of TOPO (tri-*n*-octylphosphine oxide) have been studied. The application of the solvent extraction techniques to the study of the kinetics of metal-chelate formations in Zn, Ni, and the Co–STTA–TOPO–cyclohexane system has also been examined.

Experimental

Materials. The STTA was synthesized by the reaction of hydrogen sulfide with TTA in absolute ethanol in the presence of hydrogen chloride.[4] The guaranteed-grade reagents of TTA (thenoyltrifluoroacetone) and TOPO-(tri-*n*-octylphosphine oxide) were obtained from Dojindo Co., Ltd. The chlorides or the nitrates of the radioisotopes, ^{110m}Ag, ^{207}Bi, ^{144}Ce, ^{115m}Cd, ^{60}Co, $^{152,154}Eu$, ^{59}Fe, ^{203}Hg, ^{114m}In, ^{54}Mn, ^{63}Ni, ^{210}Pb, ^{46}Sc, ^{124}Sb, and ^{65}Zn, were purchased from the Radiochemical Centre (England), the New England Nuclear Corporation (U.S.A.), and the Union

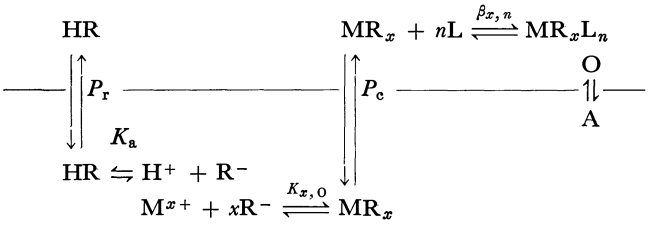
Carbide Corporation (U.S.A.). The non-radioactive metal salts of Al, Au, Be, Cu, Pd, Pt, Ru, Sn, Te, Tl, UO_2, and VO_2, and the other reagents were all reagent-grade materials.

Extraction. The experimental procedures were almost the same as have previously been described.[4-7] The extractions were performed between 5 or 10 ml of an aqueous solution containing individual metal ions and the same volume of an organic solution containing STTA or STTA and TOPO. The aqueous solution was made up to 0.1 M acetic acid (in the acidic region) or 0.1 M boric acid (in the basic region), and its pH was adjusted to a desired value with 0.1—1 M NaOH or 0.1—1 M HCl. The concentration of the STTA in the organic phase was 0.001 M, and various amounts of TOPO were added. After the two phases had been shaken for from 5 min to 2 hr at 20 °C, the distribution of the metal in question was determined radiometrically or spectrophotometrically. The pH of the aqueous phase was checked again after the extraction.

Back-extraction. After the extraction, the back-extraction of the metals from the organic phase was performed with an aqueous solution with a pH value appropriate to the desired condition. The distribution of the metals was determined as in the case of the extraction.

Theoretical

When a metal ion M^{x+}, reacts with STTA (abbreviated as HR) and is extracted as the neutral chelate, MR_x, and forms the adduct compounds, MR_xL_n, with an organic base, L, such as TOPO, the overall extraction processes can be written as in the following scheme:



The equilibrium relations can be expressed by the following equations, in which $K_{x,0}$ means the extraction constant; D, the distribution ratio of the metal; $pH_{1/2}$, the pH of the half-extraction and % E, the percentage of extraction in each extraction or back-extraction, ( ) and ( )$_0$ designate the aqueous and the organic phases respectively.

Extraction (A→O) aqueous to organic

$$M^{x+} + xHR(org) \rightleftharpoons MR_x(org) + xH^+ \quad (1)$$

$$K_{x,0} = (MR_x)_0(H^+)^x/(M^{x+})(HR)_0{}^x \quad (2)$$

$$pH_{1/2} = -1/x \log K_{x,0} - \log(HR)_0 \quad (3)$$

$$D = (MR_x)_0/(M^{x+}) = K_{x,0}(HR)_0{}^x/(H^+)^x \quad (4)$$

$$\% E = 100D/((V/V_0) + D) \quad (5)$$

Back-extraction (O→A) organic to aqueous

The inverse of Eq. (1):

$$D_B = 1/D \quad (6)$$

$$\% \text{ Back } E = 100 - \% E \quad (7)$$

Synergism

$$M^{x+} + xHR(org) + nL \rightleftharpoons MR_xL_n(org) + xH^+ \quad (8)$$

$$K_{x,n} = (MR_xL_n)_0(H^+)^x/(M^{x+})(HR)_0{}^x(L)_0{}^n \quad (9)$$

$$^*pH_{1/2} = -1/x \log K_{x,n} - \log(HR)_0 - n/x \log(L)_0 \quad (10)$$

$$D^* = ((MR_x)_0 + (MR_xL_n)_0)/(M^{x+}) = K_{x,n}(HR)_0{}^x(L)_0{}^n/(H^+)^x \quad (11)$$

$$D^*/D = 1 + \sum_1^n \beta_{x,n}(L)_0{}^n \quad (12)$$

where $\Delta pH_{1/2}$ is the shift of $pH_{1/2}$ from the extraction without the organic base.

$$\Delta pH_{1/2} = {}^*pH_{1/2} - pH_{1/2} = -1/x \log \beta_{x,n}(L)_0{}^n \quad (13)$$

If these three assumptions are fulfilled, all the above equations are valid: 1) the metal concentration is negligibly small compared to the total concentration of STTA; 2) the distribution coefficient of STTA is fairly high, but the acid dissociation is considerably low in the pH region investigated, and 3) the formation of hydroxo complexes can be ignored in the same pH region.

Results and Discussion

In all the figures, A→O means the transfer of the metals from the aqueous phase to the organic phase, and O→A, the so-called back-extraction from the organic phase to the aqueous phase.

Distribution and Dissociation of STTA. The apparent distribution coefficients between water and cyclohexane, and the enol dissociation constant of STTA, were determined spectrophotometrically using the method of Uhlemann and Muller.[8] The following values were obtained: $\log P_r = 2.99$ (10^{-3} M STTA in cyclohexane–0.1 M $NaClO_4$–pH 1.0) and $\log K_a = -4.31$ (10^{-4} M STTA in 0.12 M HCl, 0.1 M CH_3COOH (pH 4.5) and 0.1 M NaOH–C_2H_5OH (1/5, v/v)solution) at 20 °C. The $\log K_a$(−8.64) of TTA[9] in 74.5 vol.% dioxane at 30 °C is smaller than that (−7.05) of STTA under the same conditions.[10] The apparent distribution coefficient of TTA between *n*-hexane and an aqueous solution at the ionic strength of 0.1 M ($HClO_4$+$NaClO_4$) at 25 °C has been described as 0.68.[11] Therefore, the extraction of metals with STTA may be expected to occur n a lower pH region than that with TTA, and only a very small excess of the reagent over the stoichiometrical quantity is needed. Hence, a number of metals can be extracted without any interference by hydrolysis.

Extraction and Back-extraction. The pH dependence of the extractability of metals with 0.001 M STTA in cyclohexane was examined; the extraction curves and the back-extraction curves are compared in Fig. 1 for the first-transition elements, such as Fe, Co, Ni, and Cu. The range of the back-extraction of Fe, Ni, and Cu shifts to a somewhat lower pH than that of the extraction; that is, in the regular extraction its equilibrium seems to be unattainable within only 30 min. The back-extraction of the cobalt-STTA chelate was impossible. The pH-dependence of the

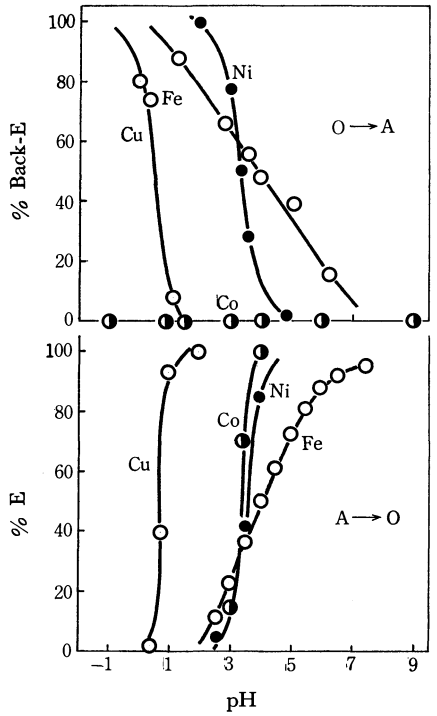

Fig. 1. The effect of pH on the extraction and the back-extraction of trace amounts of Fe(III), Co(II), Ni(II), and Cu(II)–0.001 M STTA–cyclohexane system.

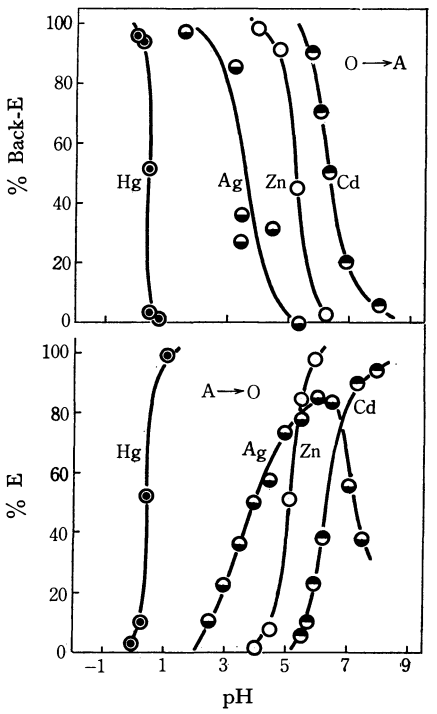

Fig. 2. The effect of pH on the extraction and the back-extraction of trace amounts of Zn(II), Cd(II), Hg(II), and Ag(I)–0.001 M STTA–cyclohexane system.

extractions of Ag and Zn family elements involving Zn, Cd, and Hg with 0.001 M STTA–cyclohexane is shown in Fig. 2. The extraction curves and the back-extraction curves are exactly symmetrical with regard to each other. The pH range of the back-extraction of Ag is somewhat lower than that of the extraction.

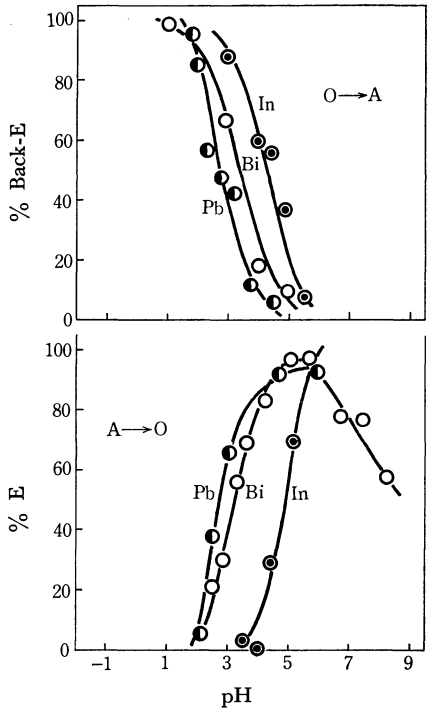

Fig. 3. The effect of pH on the extraction and the back-extraction of trace amounts of In(III), Pb(II), and Bi(III)–0.001 M STTA–cyclohexane system.

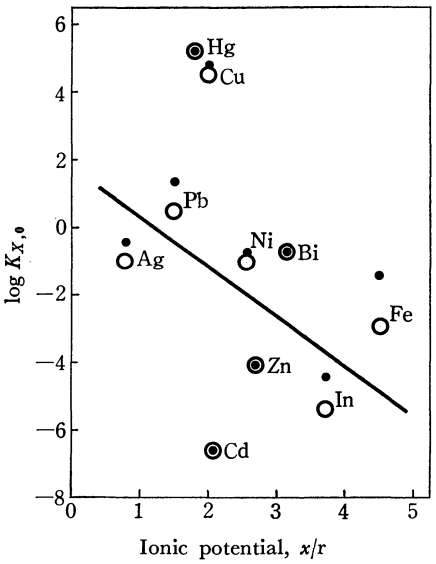

Fig. 4. The apparent extraction constant, log $K_{x,0}$, in the metal–STTA–cyclohexane systems as a function of the ionic potential. The values of the apparent extraction constants, log $K_{x,0}$ was as follows:

	Ag	Bi	Cd	Co	Cu	Fe
A→O (○)	−1.0	−0.75	−6.6	−0.6	4.5	−3.0
O→A (●)	−0.5	−0.75	−6.6	—	4.8	−1.5

	Hg	In	Ni	Pb	Zn
A→O (○)	5.2	−5.4	−1.0	0.50	−4.1
O→A (●)	5.2	−4.5	−0.8	0.80	−4.1

The extraction curves of In, Pb, and Bi are shown in Fig. 3; the pH range of the extraction for Bi is almost the same as that of the back-extraction curve, but in In and Pb the extraction and the back-extraction are somewhat different. The free energy of the formation

of a complex between a metal ion and an organic reagent may be expressed as:

$-\Delta G=RT \log K=\text{const.}\times pH_{1/2}=\text{const.}\times x/r$,[12]

where x is the charge and r is the crystal radius of the metal ion. In Fig. 4, the extraction constants, $K_{x.0}$, of the extractable chelates are plotted as a function of the ionic potentials. The results show that the apparent extraction constants for the STTA chelates tend to decrease with an increase in the ionic potential of the metals. Similar results have been obtained in acetylacetone,[13,14] benzoylacetone,[15] and the β-isopropyltropolone chelate system;[16] that is, in all the $pH_{1/2}$ decreases in the ionic radii or the ionic potential. The stability of the complex of the first-transition elements follows Irving and Williams' order of stability,[17] that is, Zn<Cu>Ni, regardless of the nature of the coordination ligand. In the solvent extractions of the STTA chelates of these metals, a similar sequence is observed. Since the STTA is an oxygen-sulfur-donating ligand, it has a marked tendency to form a covalent bond. The contribution of $d\pi-d\pi$ interactions seems to be responsible for this relationship. The discrepancy in the extraction constants between the extraction and the back-extraction indicates that a 30-min contact is insufficient to establish the extraction equilibrium. As the organic solvent plays an important role in the extration of the metal ions with any chelating reagent, various solvents were examined in the present study; cyclohexane was found to extract the cobalt STTA chelate at the lowest pH among the solvents, followed by CCl_4, MIBK, C_6H_6, and $CHCl_3$, in that order.[4] Experiments were also made on the extraction of trace amounts of zinc with 0.001 M STTA in cyclohexane, benzene, and MIBK. The extractability of the zinc chelate at a constant pH was found to be the same by either cyclohexane and benzene, but it was poor by MIBK, as is shown in Fig. 5. In general, the extractability of the cobalt and zinc STTA chelates is remarkable when

using solvents of a small dielectric constant and a lower solubility of water. These facts show that the extracted chelates are stable and have no significant dipole moment. Therefore, the dipole interaction of the chelates with the diluent can scarcely play any appreciable role in the extraction process. Figure 6 shows the relationship between the absorption maximum of STTA in various solvents and the dielectric constants of the solvents. The STTA solution exhibits a typical absorption band, varying with the dielectirc constant and with the hydrogen-bonding ability of the solvents. This change in the absorption band is generally called the blue shift; its intensity becomes stronger with an increase in the dielectric constant of the solvent. This indicates that the interaction between STTA and the more polar solvent, *e.g.*, the hydrogen bonding or the dipole-dipole interaction, takes place in the solution; it may be one of the most important factors in the decrease of the extractability of cobalt and zinc STTA chelates.

Kinetics of Extraction and Back-extraction. The effects of the pH on the extraction and the back-extraction rate of trace amounts of cobalt, nickel, and zinc with 0.001 M STTA in cyclohexane are shown in Fig. 7. The extractions were carried out under vigorous shaking, for the extent of the extraction is independent of the shaking rate. The extraction of Zn seemed to be rapid, but that of Ni seemed to require about 60 min to reach its extraction equilibrium. Cobalt was not back-extracted, not even with 1—12 M HCl. The experimental results show that the extraction rate of the chelate compounds is a function of the pH and that it usually increases with an increase in the pH under the same conditions. If we assume that the slowest stage in the Ni–STTA–cyclohexane extraction system is due to the first-step formation of the chelate compound, the rate of the extraction of nickel, $-d(Ni^{2+})/dt$, can be shown to obey the following equation in view of the general rate expression[18] for formation of metal chelates:

$$-\frac{d(Ni^{2+})}{dt} = k(Ni^{2+})(R^-) \quad (14)$$

$$= k(Ni^{2+})\frac{K_a}{P_r}\frac{(HR)_0}{(H^+)} \quad (15)$$

$$\log(1-\%\,E/100) = -\frac{k}{2.303}\frac{K_a}{P_r}\frac{(HR)_0}{(H^+)}t \quad (16)$$

$$\log(\log 100/(100-\%\,E)) = \mathrm{pH} + \log(HR)_0 + \log t + \mathrm{const.} \quad (17)$$

where:

$$(Ni^{2+})_{initial} = (Ni^{2+}) + (NiR_2)_0$$

$$D = (NiR_2)_0/(Ni^{2+}),\ \%\,E = 100D/(1+D) \quad (18)$$

Then, $(Ni^{2+}) = (Ni^{2+})_{initial},\ (1-\%\,E/100)$ (19)

As is shown in Fig. 8, the $\log(1-\%E/100)$ *vs.* time plot is linear for 30 min at a constant pH. Moreover, the $\log(\log 100/(100-\%E))$ *vs.* pH plot shows a straight line with the slope of unity. These facts indicate that the rate-determining step in the Ni–STTA–cyclohexane extraction system is controlled by the formation

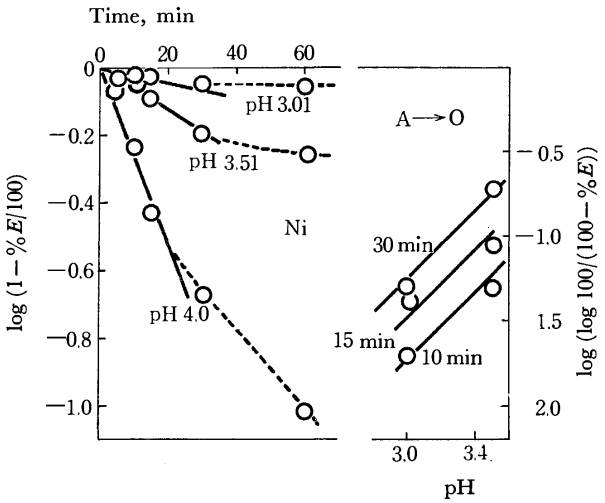

Fig. 8. The kinetics of the extraction of trace amounts of Ni(II) with 0.001 M STTA in cyclohexane at different pH values and time.

of $Ni(STTA)^+$. Similar phenomena have also been observed in Zn, Ni, and the Co–dithizone–chloroform system.[19] The rate of the transfer of the neutral species from the aqueous to the organic phase is a dominant factor in the extraction in Zn-acetylacetone, benzoylacetone, and the dibenzoylmethane–chloroform system.[20] In all cases, the displacement of water molecules coordinated to a metal ion may also play an important role in the chelate-formation rate. In addition, the rate of extraction depends on the nature of the metal ion, the partition coefficient and the dissociation constant of the organic reagent, and the pH. If we postulate that the slowest stage in the Co–STTA–cyclohexane extraction system is due to a transformation of $Co(STTA)_2$ to $Co(STTA)_3$, the rate of the extraction of cobalt, $d(CoR_3)/dt = -d(Co^{2+})/dt$ may be described approximately by the following equation:

$$\frac{d(CoR_3)}{dt} = -\frac{d(Co^{2+})}{dt} = k(CoR_2)(HR)_0 \quad (20)$$

$$= k(Co^{2+})\frac{KP_cK_a}{P_r^3}\frac{(HR)_0^3}{(H^+)^2} \quad (21)$$

$$\log(1-\%\,E/100) = -\frac{k}{2.303}\frac{KP_cK_a^2}{P_r^3}\frac{(HR)_0^3}{(H^+)^2}t \quad (22)$$

$$\log(\log 100/(100-\%\,E)) = 2\,\mathrm{pH} + 3\log(HR)_0 + \log t + \mathrm{const.} \quad (23)$$

As is shown in Fig. 9, the $\log(1-\%E/100)$ *vs.* time plot is linear at a constant pH. Moreover, the plots of $\log(\log 100/(100-\%E))$ *vs.* pH have a slope of 2, and the $\log(\log 100(100/(100-\%E)))$ *vs.* $\log(HR)_0$ plots give a straight line with a slope of 3, as is shown in Fig. 10. These facts indicate that the assumption of the extraction mechanism of cobalt is vaild.

Synergistic and Antagonistic Effect in the Presence of TOPO. In the Ni and Zn–STTA(0.001 M)–TOPO(0.01 M)–cyclohexane systems, $|\Delta pH_{1/2}|$ was found to be 0.45 for Ni and 1.95 for Zn respectively. The logarithm of the distribution ratios of Zn and Ni is linearly related to the pH. The slope of the straight lines becomes 2, indicating that the extracted species can be written as $Zn(STTA)_2$ and $Ni(STTA)_2$ respectively. As is shown in Fig. 11, a straight line with a slope of 1 is obtained when log D^*/D values are plotted against $\log(TOPO)_0$ in the case of the Zn–STTA–TOPO–cyclohexane system. This fact indicates that

one molar TOPO reacts with one molar Zn-STTA chelate to form the Zn(STTA)TOPO adduct in cyclohexane. The stability constant of the adduct was estimated to be log $\beta_{x,1}=6.05$. From the stability constant of the adduct of $Zn(TTA)_2TOPO$, log $\beta_{x,1}=6.47$,[21] under the same conditions, it may be

21) T. Honjo, M. Horiuchi and T. Kiba, This Bulletin, in press.

expected that TOPO forms more stable adducts with the $Zn(TTA)_2$ chelate than with the $Zn(STTA)_2$ chelate. As the extraction constants of $Zn(TTA)_2$ and $Zn(STTA)_2$ are log $K_{x,0}=-8.33$[22] and -3.49 respectively, the general concept that the extraction constant of the chelates increases, while the stability constant of the adducts decreases,[23] is also the case for the metal–TTA and STTA–cyclohexane systems. The donor π-bond formation between the d-electrons of the metal and the sulfur of the STTA, bringing about the stabilization of the chelate, may play an important part. The Ni-STTA chelate ambiguously forms its adduct with TOPO. In the cobalt–STTA(0.001 M)–TOPO(0.001 M)–cyclohexane system, $|\Delta pH_{1/2}|$ was found to be 0.25. The slope in Fig. 12 of the log D against pH plot at a constant STTA(0.001 M) increases steeply up to 2 to 4 as the extraction pH becomes higher. Moreover, the plots of log D *vs.* $\log(STTA)_0$ at a constant pH give straight lines with a slope of 4, as is shown in Fig. 13. However, in the extraction of cobalt in the presence of 0.001 M TOPO, the log D *vs.* pH plots show straight lines with slopes of 2. As is shown in Fig. 12 the log D^*/D *vs.* $\log(TOPO)_0$ plots give concave curves including an antagonistic effect. The effect becomes more remarkable as the extraction is done at a higher pH, and appears most pronouncedly on the extraction of cobalt with STTA in the presence of 0.001 M TOPO. The effects of pH, of the extraction time, and of the TOPO concentration on the extraction and the back-extraction of the metal–STTA–TOPO–cyclohexane system are shown in Fig. 14. The cobalt STTA chelates extracted in the presence of 0.001—0.01 M TOPO could be back-extracted with 1 M HCl to a certain extent. However, when the concentration of TOPO becomes lower than 0.001 M, the cobalt chelate can not be back-extracted even with 1—12 M HCl. As can be seen in Fig. 14, the back-extraction of cobalt

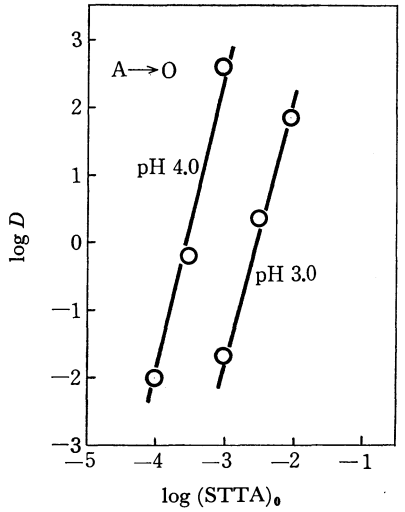

Fig. 13. The variation of the distribution ratio of trace amounts of Co(II) with STTA at definite pH values as a function of STTA concentration.

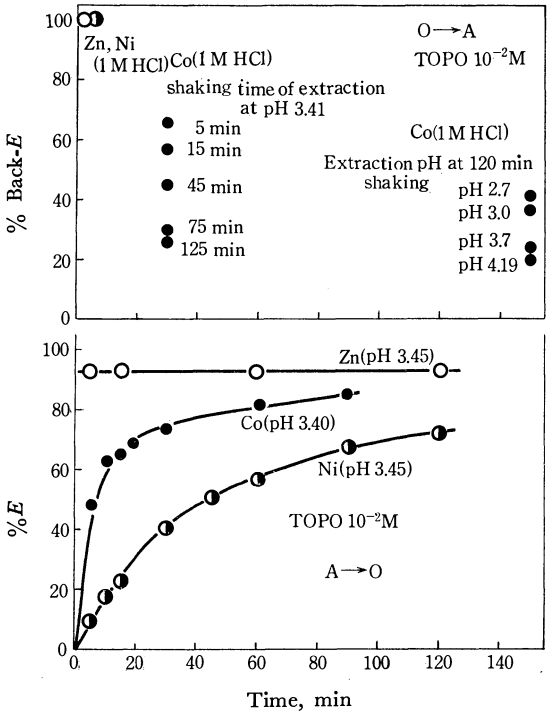

Fig. 14. The rates of the extraction and the back-extraction of trace amounts of Zn(II) and Ni(II)–0.001 M STTA–cyclohexane system in the presence or the absence of TOPO at different pH values or time.

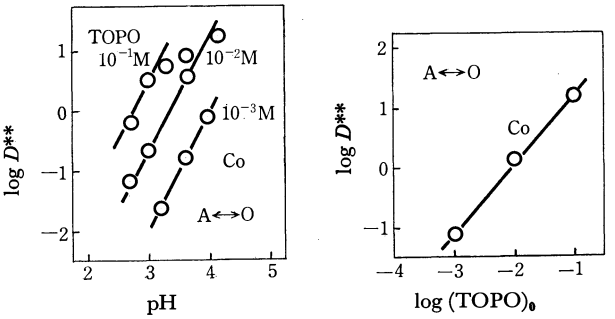

Fig. 15. The variation of the distribution ratio of trace amounts of Co(II)–0.001 M STTA–TOPO–cyclohexane system as a function of pH or TOPO concentration.

is controlled by the shaking time, the pH value, and the TOPO concentration. In the presence of 0.01 M TOPO, the back-extraction of cobalt with 1 M HCl decreases as the shaking time becomes longer and as the pH values increase. In general, the back-extractability of cobalt decreases with a decrease in the TOPO concentration. The Ni and Zn chelates extracted in the presence of TOPO are readily back-extracted with 1 M HCl. In the presence of 0.01 M TOPO, the extraction rate of zinc is rapid, while tha of Ni is somewhat slower than in the absence of TOPO In the extraction of cobalt in the presence of 0.01 M TOPO, the extraction increases greatly for 30 min and then more gradually. In the Co–STTA–TOPO–cyclohexane system, when the dominant species are CoR_2L, (which is back-extractable with 1 M HCl), CoR_3 (which is not back-extracted even with concentrated HCl), and Co^{2+}, the distribution ratio of cobalt in the extraction, D, may be written as follows:

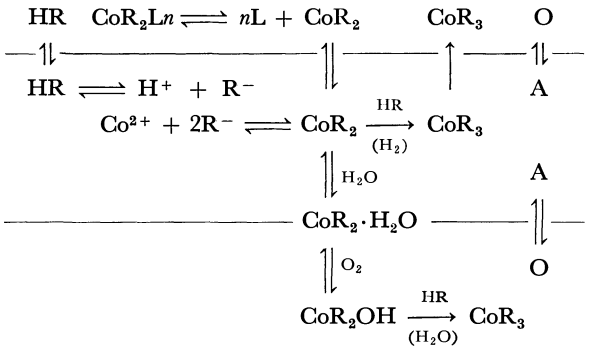
$$D = \frac{(CoR_2L)_0 + (CoR_3)_0}{(Co^{2+})}, \quad D_B = \frac{(CoR_2L)_0}{(CoR_3)_0} \tag{24}$$

$$D^{**} = \frac{(CoR_2L)_0}{(Co^{2+})} = \frac{D}{1+1/D_B} = \frac{K\beta_{x,1}P_cK_a^2}{P_r^2}\frac{(H)_0^2(L)_0}{(H^+)^2} \tag{25}$$

$$\log D^{**} = 2\,pH + 2\log(HR)_0 + \log(L)_0 + \text{const.} \tag{26}$$

Now, when terms such as D_B and D^{**} are used to explain the extraction behevior, the log D^{**} *vs.* pH plot shows a straight line with a slope of 2 at a constant concentration of TOPO, and the log D^{**} *vs.* $\log(TOPO)_0$ plot shows a slope of unity at a constant concentration of STTA as is shown in Fig. 15. These facts suggest that the extracted cobalt compounds are CoR_2L and CoR_3 respectively. From these experimental facts, the extraction mechanism of the cobalt(II)–STTA–TOPO–cyclohexane system may be expressed as follows:



The other evidence of the formation of CoR_2, CoR_2L and CoR_3 is as follows: 1) the existence of the first absorption band near 500 nm in the solution of the cobalt–STTA chelate (CoR_3); 2) the cobalt–STTA chelate crystal prepared by the ordinary extraction was the diamagnetic (CoR_3); 3) the silica gel thin-layer chromatograms of the extracted cobalt–STTA chelates at high concentrations give two spots, one corresponding to CoR_2(R_f=0.29), and the other, to CoR_3 (R_f= 0.35), using carbon tetrachloride as the developing solvent; 4) a part of the cobalt-STTA chelates extracted in the presence of TOPO can be back-extracted with 1—12 M HCl, and the back-extracted cobalt behaves as a divalent ion (CoR_2L). At present time, it should be considered that the irreversible extraction behavior of Co-STTA chelates is due to the inert nature of the trivalent cobalt complexes. The transformation of $Co(STTA)_2$ to $Co(STTA)_3$ may occur both in the aqueous and the organic phases, or at the interface of the two phases, by means of a certain interaction between $Co(STTA)_2$ and STTA in the presence of oxygen and water. However, further investigations of these questions will be necessary before we reach any final conclusion.

Infrared Spectra of Some Transition-metal (Fe, Co, Ru, and Ir) Nitrosyl (^{14}NO and ^{15}NO) Complexes

Eiichi MIKI, Kunihiko MIZUMACHI, Tatsujiro ISHIMORI, and Hisateru OKUNO

Department of Chemistry, College of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received June 4, 1973)

Twelve ^{15}NO-complexes of iron, cobalt, ruthenium, and iridium were prepared. The correlations of the isotopic shifts of their IR spectra with a metal-(NO) bond angle were investigated. For several nitrosyl complexes, the absorption bands due to the skeletal vibrations between the metal and the NO group were clearly assigned. Of the two absorption bands in the region 250—650 cm^{-1}, the absorption band with a smaller isotopic shift could be assigned to the metal-(NO) stretching vibration and that with a larger isotopic shift to the metal-(NO) bending vibration.

Since an infrared study of $Co(NO)(CO)_3$ and its ^{15}N analogue led to definite assignments of the skeletal vibrations between the cobalt and the NO group,[1] the effect of the ^{15}N-substitution on infrared spectra has been measured on several nitrosyl complexes formulated as NO^+ complexes.[2-9] For the nitrosyl complexes of chromium, manganese and ruthenium, distinct assignments of the skeletal vibrations between the metal and the NO group, and determination of the coordinating atom of the NO group to the metal atom have been made from a comparison of the observed isotopic shifts with the calculated ones.[2-4] Recently,

Sabatini[10] and Tosi[11-14] carried out polarized infrared studies on single crystals of some transition-metal nitrosyl compounds to assign the metal-(NO) skeletal vibrations. Their results are consistent with those obtained by the infrared isotopic shift method.

In this paper we describe infrared studies on the nitrosyl complexes of iron, cobalt, ruthenium, and iridium, and their ^{15}NO-complexes.

Experimental

The nitrosyl complexes were prepared according to the methods referred to in Table 1. Their ^{15}NO-complexes were prepared in a vacuum line with the use of ^{15}NO gas (1 mmol) derived from $K^{15}NO_3$ (^{15}N atom% = 95—99). All other reagents were of analytical grade. The infrared spectra and elementary analyses showed that the desired products were obtained.

Infrared spectra were measured in the region 200—4000 cm^{-1} by means of Nujol mull and hexachlorobutadiene mull techniques. JASCO DS-402G (700—4000 cm^{-1}) and JASCO model IR-F (200—700 cm^{-1}) infrared spectrophotometers were used. The wave numbers of the absorption bands were calibrated with 1,2,4-trichlorobenzene, polystyrene film and water vapor.

Results

Assignments of Infrared Spectra. The assignments of the N-O stretching vibrations and the skeletal vibrations between the metal and the NO group were made on the basis of observation of the ^{15}N-isotopic shifts. The ^{15}N-isotopic shifts of the skeletal vibrations observed in the limited region *ca.* 450—650 cm^{-1} were carefully measured[1-17] in order to obtain distinct assignments for the skeletal vibrations. The isotopic shifts observed were compared with those calculated with a three-body model of the metal and the NO group.[3] The assignments of the absorptions due to metal-(NO) skeletal vibrations, and the observed and calculated isotopic shifts are shown in Table 2. A number of absorption bands due to the ligands except for NO group were assigned according to Adams.[18]

trans-$Na_2[Ru(OH)(NO_2)_4(NO)]\cdot 2H_2O$: The skeletal vibrations between the ruthenium and the NO group could not be clearly assigned. The skeletal vibrations, the Ru-OH stretching vibration and the wagging vibration of NO_2 group are observed in the region 550—640 cm^{-1}. These four bands shifted upon ^{15}N-substitution. Deuteration of this complex was carried out for assigning the four bands.

The absorption bands in the region 550—640 cm^{-1} lacked sharpness. This is considered to be due to the overlap with the broad and strong absorption band of

the libration of water of crystallization. The dehydrated salts of the ^{14}NO- and ^{15}NO-complexes were prepared in order to measure the isotopic shifts more exactly. The spectral figure of $Na_2[Ru(OH)(NO_2)_4(NO)]$ is quite similar to that of its dihydrate.

The N–O stretching vibration of $Na_2[Ru(OH)(NO_2)_4(NO)]\cdot 2H_2O$ shifted from 1898 (vs)[19] to 1862 cm^{-1} (vs) upon ^{15}NO-substitution. The 584 cm^{-1} band (m) of $Na_2[Ru(OH)(NO_2)_4(^{14}NO)]$ shifted to 568 cm^{-1} (sh) upon deuterium substitution, but not the bands at 634, 612, and 555 cm^{-1}. Therefore, the band at 584 cm^{-1} (m) could be assigned to the Ru–OH stretching vibration. The 634 (m), 612 (vs), and 555 cm^{-1} (vs) bands of $Na_2[Ru(OH)(NO_2)_4(^{14}NO)]$ shifted downwards by *ca.* 9, 5, and 4 cm^{-1}, respectively, upon ^{15}NO-substitution. From the values of the isotopic shift the 634 cm^{-1} band could be assigned to a skeletal vibration between the ruthenium and the NO group. The 612 and the 555 cm^{-1} bands are considered to be due to another skeletal vibration and the wagging vibration of NO_2 group. The 612 cm^{-1} band may be assigned to the wagging vibration of NO_2 group in view of the following. A neutron diffraction study on $Na_2[Ru(OH)(NO_2)_4(NO)]\cdot 2H_2O$ shows that the $O(H_2O)$–$N(NO_2)$ distances are 2.9—3.3 Å, and the $O(H_2O)$–$O(OH)$ and the $O(H_2O)$–$O(NO)$ distances are 3.5 Å and 3.9 Å, respectively.[20] Thus we see that the water of crystallization affects the wagging vibration of NO_2 groups to a greater extent than the Ru-OH stretching vibration and the skeletal vibrations, and the NO_2 wagging vibration is more influenced by the dehydration of the water of crystallization than the Ru-OH stretching vibration and the skeletal vibrations. The 635 (s), 583 (w), and 557 cm^{-1} (vs) bands hardly shift on the dehydration of water of crystallization, while only the 602 cm^{-1} band (vs, b) shifts to 612 cm^{-1}. The 635 and the 557 cm^{-1} bands of $Na_2[Ru(OH)(NO_2)_4(^{14}NO)]\cdot 2H_2O$ could be assigned to the skeletal vibrations between the ruthenium and the NO group. The 583 and 602 cm^{-1} bands were assigned to the Ru–OH stretching vibration and the wagging vibration of NO_2 group, respectively.

trans-$K_2[Ru(OH)(NO_2)_4(NO)]$: The N–O stretching vibration shifted from 1887 cm^{-1} (vs) to 1848 cm^{-1} (vs) upon ^{15}NO-substitution. In the region 550—640 cm^{-1}, four absorption bands at 623 (vs, b), 580 (s), 573 (s), and 565 cm^{-1} (sh) were also observed as in the case of the sodium salt. Their isotopic shifts upon ^{15}NO- and deuterium substitutions were complicated, making it impossible to assign the four bands unambiguously.

trans-$[Ru(OH)(NH_3)_4(NO)]Cl_2$: The absorption bands at 1841 (vs), 630 (m), and 589 cm^{-1} (m) shifted to 1807, 613, and 585 cm^{-1}, respectively, upon ^{15}NO-substitution. On the other hand, the 564 cm^{-1} band (vs, b) did not shift upon ^{15}NO-substitution and was assigned to the Ru–OH stretching vibration. Ru-NH_3 stretching vibrations were observed at 476 cm^{-1} (m) and 497 cm^{-1} (vw).

trans-$[RuCl(NH_3)_4(NO)]Cl_2$: The 1880 cm^{-1} band (vs) shifted to 1844 cm^{-1}, the 603 cm^{-1} band (s) to 586 cm^{-1}, and the 562 cm^{-1} band (m) to 560 cm^{-1} upon ^{15}NO-substitution. The Ru-NH_3 stretching vibration was observed at 486 cm^{-1} (vs).

$Ru(NO)(S_2CNR_2)_3$ ($R=CH_3$ and C_2H_5) and $Fe(NO)(S_2CN(CH_3)_2)_2$: The absorption bands due to dialkyldithiocarbamate ion[21,22] (the C–S stretching, the C–N–C bending, the metal–S stretching and the ring deformation vibrations) overlapped with the skeletal vibrations between the metal and the NO group. Thus, the isotopic shifts upon the ^{15}NO-substitution could not be measured exactly.

The bands at 1827 (vs), 1808 (vs), and 544 cm^{-1} (sh) for $Ru(NO)(S_2CN(CH_3)_2)_3$ shifted upon ^{15}NO-substitution to 1790, 1771, and 540 cm^{-1} (s), respectively. The bands at 1806 (vs), 572 (s, b), and 554 cm^{-1} (sh) for $Ru(NO)(S_2CN(C_2H_5)_2)_3$ shifted to 1774, 560 (s, b), and 540 cm^{-1} (s), respectively.

The N–O stretching vibration for $Fe(NO)(S_2CN(CH_3)_2)_2$ shifted from 1691 to 1656 cm^{-1}, and the band at 560 cm^{-1} (m) shifted to 556 cm^{-1} (m) upon ^{15}NO-substitution.

$Co(NO)(S_2CN(CH_3)_2)_2$: The N–O stretching vibration shifted from 1624 cm^{-1} (vs) to 1596 cm^{-1} upon ^{15}NO-substitution. Three absorption bands (576 cm^{-1} (w), 555 cm^{-1} (sh) and 551 cm^{-1} (w)) observed in the region where the skeletal vibrations between the metal and the NO group would have been observed did not shift upon ^{15}NO-substitution. These absorption bands could be assigned to the C–S stretching vibration, the Co–S stretching vibration and the ring deformation due to the coordinated dimethyldithiocarbamate.[21,22] On the other hand, the broad bands at 317 cm^{-1} (m) and 259 cm^{-1} (m) shifted by ^{15}NO-substitution to 311 cm^{-1} and 256 cm^{-1}, respectively. These bands observed at rather extraordinarily low frequencies are assigned to the skeletal vibrations between the cobalt and the NO group. An X-ray diffraction study of $Co(NO)(S_2CN(CH_3)_2)_2$ shows that the bond angle of the Co–N–O is 135°, and the oxygen atom of the NO group alternately lies above two of the Co–S bonds of the same dimethyldithiocarbamate ligand.[23] The skeletal vibrations between the cobalt and the NO group are considered to reflect the structure. However, another possibility of overlapping of CoNO skeletal vibrations with the vibrations due to the coordinated dimethyldithiocarbamate ligands can not be excluded.

$[Co(NO)en_2](ClO_4)_2$: The N–O stretching vibration shifted from 1661 (vs) to 1632 cm^{-1} and the bands at 560 (sh) and 490 cm^{-1} (m) shifted to 550 (b, w) and 486 cm^{-1} (m), respectively. These absorption bands seem to be due to the Co–(NO) skeleton.

$Ir(NO)(P(C_6H_5)_3)_3$, $[Ir(NO)_2(P(C_6H_5)_3)_2]ClO_4$, and $Ir(NO)Cl_2(P(C_6H_5)_3)_2$: The N–O stretching vibrations and the skeletal vibrations between the iridium

19) The sign in parentheses presents the abbreviations of the absorption strength and shape; vs=very strong, s=strong, m=medium, w=weak, vw=very weak, sh=shoulder, b=broad.

22) I. Ojima, T. Ohnishi, T. Iwamoto, N. Iwamoto, and K. Tamaru, *Inorg. Nucl. Chem. Letters*, **6**, 65 (1970).

23) Reference (g) in Table 1.

and the NO group overlapped with the absorption bands due to triphenylphosphine. From a comparison of the absorption strength of free triphenylphosphine with that of $Ir(NO)(P(C_6H_5)_3)_3$ and $Ir(NO)Cl_2(P(C_6H_5)_3)_2$, it was considered that the 617 cm^{-1} band assigned to a skeletal vibration might overlap with the band due to triphenylphosphine.

For $Ir(NO)(P(C_6H_5)_3)_3$, the N-O stretching vibrations at 1601 (vs) and 1582 cm^{-1} (m) shifted to 1557 and 1541 cm^{-1}, respectively, upon ^{15}NO-substitution. The bands at 617 (m) and 533 cm^{-1} (w) shifted to 610 (m) and 522 cm^{-1}, respectively.

For $[Ir(NO)_2(P(C_6H_5)_3)_2]ClO_4$, the bands at 1759 (m) and 1707 cm^{-1} (vs) (the N-O stretching vibrations) shifted to 1725 and 1674 cm^{-1}, respectively. Five absorption bands in the region 370—590 cm^{-1} shifted upon ^{15}NO-substitution (from 584 (m), 553 (m), 539 (m), 527 (m), and 381 cm^{-1} (m) to 570 (w), 545 (w), 533 (w), 524 (w), and 373 cm^{-1} (m), respectively). An X-ray diffraction study shows that the O-N-Ir-N-O skeleton belongs to the point group C_{2v}.[24] The seven absorption bands could be attributed to the skeletal vibrations due to the O-N-Ir-N-O group.

For $IrCl_2(NO)(P(C_6H_5)_3)_2$, the bands at 1628 (vs) and 1558 cm^{-1} (vs) shifted to 1599 and 1533 cm^{-1}, respectively, upon ^{15}NO-substitution. The 1558 cm^{-1} band has already been assigned to the N-O stretching vibration.[25] The 1628 cm^{-1} band can also be assigned to it. It is not clear why the splitting of the N-O stretching vibration is extraordinarily large. The skeletal vibrations were observed at 617 (m) and 589 cm^{-1} (w), and shifted to 598 (w) and 576 cm^{-1} (w), respectively.

Calculation of Isotopic Shifts and Definite Assignments of Skeletal Vibrations. In previous reports, the

isotopic shifts observed upon ^{15}NO-substitution were compared with those calculated by the simple three-body model of the metal and the NO group. For the complexes formulated as NO^+ complexes, it has been found that this method is useful for a definite assignment of the skeletal vibrations between the metal and the NO group.[3,6,7]

We have calculated the isotopic shifts for the following six compounds: *trans*-$Na_2[Ru(OH)(NO_2)_4(NO)]\cdot 2H_2O$, $K_2[RuCl_5(NO)]$, *trans*-$[Ru(OH)(NH_3)_4(NO)]Cl_2$, $[Co(NH_3)_5(NO)]Cl_2$, $Ir(NO)(P(C_6H_5)_3)_3$, and $IrCl_2(NO)(P(C_6H_5)_3)_2$.

The isotopic shifts of the N–O stretching vibration and the skeletal vibrations could be measured exactly. When the N–O stretching absorption band splitted into two peaks, the wave number of the stronger peak was used in the calculation.

The isotopic shifts of $K_2[RuCl_5(NO)]$ and $[Co(NH_3)_5(NO)]Cl_2$ were calculated on the assumption that the metal–N–O are linearly arranged.[3] For $K_2[RuCl_5(NO)]$, the bond angle of the Ru–N–O is 171°. The isotopic shifts were therefore recalculated by using the wave numbers already reported and this bond angle. For $[Co(NH_3)_5(NO)]Cl_2$, if the NO group coordinated linearly to the Co atom as revealed by X-ray diffraction studies,[26] a comparison of the observed isotopic shifts with the calculated ones leads to the result that the NO group coordinates to the cobalt atom through the oxygen atom rather than through the nitrogen atom.[3] However, a recent X-ray diffraction study from three-dimensional data has shown that the bond angle of Co–(NO) is 119° (see Table 1). Therefore, the isotopic shifts of the Co–N–O and the Co–O–N arrangements were calculated by using of the wave numbers already reported and this bond angle.

The secular equations for calculating the isotopic shifts were set up in accordance with Wilson's ***GF*** matrix method.[27] The calculations were carried out at the Computation Centre of the University of Tokyo, with a Hitachi 5020E, the programs being set up in the laboratory of Prof. T. Shimanouchi.

Table 2 shows the observed isotopic shifts ($\Delta\nu_{obsd.}$ in cm^{-1}), calculated isotopic shifts ($\Delta\nu_{calcd.}$ in cm^{-1}) and the force constants for the above six compounds. For the compounds which contain a linearly coordinated NO group, the wave numbers, isotopic shifts and force constants were calculated assuming the force constant f_{12} associated with metal–(NO) stretching and N–O stretching vibration to be 0.2 mdyn/Å. For the compounds which contain an angularly coordinated NO group, both f_{12} and f_{13} were presumed to be 0.2 mydn/Å.

Detailed infrared studies on transition-metal cyano complexes have shown that the force constants associated with the C–N stretching and the metal–(CN) stretching vibrations are 0.2—0.4 mdyn/Å.[28,29] The metal–NO bonding state of the nitrosyl complex formulated as NO^+ complex are similar to the metal–CN bonding state. Hence, it is considered to be reasonable as a first approximation that f_{12} and f_{13} are presumed to be 0.2 mydn/Å.

Assignments of the skeletal vibrations between the metal and the NO group were performed by calculating potential energy distribution. The results show that definite assignments of the skeletal vibrations exclusively depend on the extent of the isotopic shifts but not on the relative positions and strength of the absorption bands. Of the two absorption bands in the region 400—650 cm^{-1} where the isotopic shifts are observed, the absorption band which caused a smaller isotopic shift was assigned to the metal-(NO) stretching vibration and another band which caused a larger isotopic shift to the metal–(NO) bending vibration. The same assignments will be also expected for other compounds examined. For *trans*-$[RuCl(NH_3)_4(NO)]Cl_2$, the 603 cm^{-1} band ($\Delta\nu_{obsd.}=17$ cm^{-1}) can be assigned to the Ru–(NO) bending vibration and the 562 cm^{-1} band ($\Delta\nu_{obsd.}=2$ cm^{-1}) to the Ru–(NO) stretching vibration. For $Co(NO)(S_2CN(CH_3)_2)_2$, the 317 cm^{-1} band ($\Delta\nu_{obsd.}=6$ cm^{-1}) may be assigned to the Co–(NO) bending vibration and the 259 cm^{-1} band ($\Delta\nu_{obsd.}=3$ cm^{-1}) to the Co–(NO) stretching vibration. For $[Co(NO)en_2](ClO_4)_2$, the 560 cm^{-1} band ($\Delta\nu_{obsd.}=10$ cm^{-1}) may be assigned to the Co–(NO) bending vibration and the 490 cm^{-1} band ($\Delta\nu_{obsd}=4$ cm^{-1}) to the Co–(NO) stretching vibration. The 544 cm^{-1} band ($\Delta\nu_{obsd}=4$ cm^{-1}) for $Fe(NO)(S_2CN(CH_3)_2)_2$ may be assigned to the Fe–(NO) stretching vibration from the value of the observed isotopic shifts. For $Ru(NO)(S_2CN(C_2H_5)_2)_3$, the isotopic shifts upon the ^{15}NO-substitution were observed but definite as-

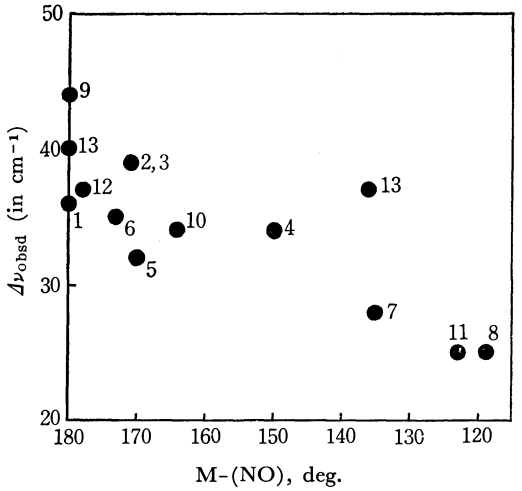

Fig. 1. Correlation of ^{15}N-isotopic shift for N-O stretching vibration with metal-(NO) bond angle.

signments of the skeletal vibrations could not be made from the values of the observed isotopic shifts.

The correlations of the ^{15}N-isotopic shifts observed for the N–O stretching vibrations with a metal–(NO) bond angles are shown in Fig. 1. The isotopic shifts for the N–O stretching vibrations decreased with deviation of metal–(NO) bond angle from linearity.

The force constants calculated from a simple three-body model are also summarized in Table 2. The force constants of the N–O stretching vibrations are 9—15 mdyn/Å, those of the metal–(NO) stretching vibrations 4—6 mdyn/Å and those of the metal–(NO) bending vibrations 0.4—1 mdyn/Å. The force constants (f_{23}) associated with a metal–(NO) stretching and the metal–(NO) bending vibrations are 0.3—1.5 mdyn/Å. The values were found to agree with those already reported.[1,5,30-33]

Discussion

Deviation of the metal-(NO) bond angle from linearity causes a decrease in the isotopic shifts of the N–O stretching vibration. The decrease might be explained as follows; the smaller the metal-(NO) bond angle, the greater the effect on N–O stretching vibration by the skeletal vibrations between the metal and the NO group. Such a phenomenon has been reported on $[RuCl(NO)_2(P(C_6H_5)_3)_2][PF_6]$ on which an X-ray diffraction study has shown that both the linear and the bent nitrosyl groups coordinate to the ruthenium atom, the corresponding bond angles being 179.5° and 136.0°, respectively.[34] The N–O stretching vibrations of the linear and the bent NO groups are observed at 1850 and 1687 cm^{-1}, these bands shifting upon the ^{15}NO-substitution downwards by 40 and 37 cm^{-1}, respectively.[35] This shows that the bond angle significantly influences the value of the isotopic shift.

For $[Co(NH_3)_5(NO)]Cl_2$, a comparison of the observed isotopic shifts with the calculated ones showed that the NO group coordinated to the cobalt atom through the oxygen atom rather than through the nitrogen atom. However, when the bond angle deviates from 180° the criterion based on the isotopic shift becomes less useful; in the case of $[Co(NH_3)_5(NO)]Cl_2$ where Co–(NO) bond angle is 119°, it cannot be concluded whether the coordinated atom is oxygen or nitrogen (Fig. 1).

Calculation of the ^{15}NO-isotopic shifts with the use of the three-body model of the metal and the NO group is useful for assigning distinctly the skeletal vibrations between the metal and the NO group. The isotopic shift of the metal–(NO) stretching vibration is smaller than that of the metal–(NO) bending vibration independent of the metal–(NO) bond angle. This method is considered to be useful for estimating the oxidation state of NO group since the isotopic shifts of the N–O stretching vibrations for the complexes formulated as NO^+ complexes are almost equal to those calculated by assuming a linear arrangement of a metal–N–O, and are larger than those for the NO^- complexes where metal–(NO) bond angle is approximetely 120°. The three-body model can be considered to be a good approximation when the central metal atom and ligands other than the NO group are much heavier than nitrogen and oxygen. Hence, of the complexes examined, the best approximation was given by $K_2[RuCl_5(NO)]$.

The authors are indebted to Professor Ichiro Nakagawa, Tohoku University and Mr. Hiroshi Saito, Rikkyo University, for their valuable suggestions concerning calculations of normal vibrations.

The Chemical Behavior of Low Valence Sulfur Compounds. VIII. The Oxidation of Sodium Thiosulfate with Ozone

Masahiro TAKIZAWA, Akitsugu OKUWAKI, and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki-Aoba, Sendai 980

(Received June 5, 1973)

The oxidation of sodium thiosulfate with ozone in an aqueous solution was investigated as a part of a series of studies on the chemical behavior of such low-valence sulfur compounds as thiosulfate and sulfite. The ozone oxidation was carried out by blowing a mixed gas of ozone and oxygen continuously into a 0.3—0.6 mol/l solution of sodium thiosulfate at 10—80 °C. In a neutral solution, thiosulfate is converted to sulfate, sulfite, tri- and tetrathionates, hydrogen sulfide and sulfur dioxide, and finally to sulfate, tri- and tetrathionates. The yield of the sulfate is only 40% of the total sulfur. In an alkaline solution, however, thiosulfate is oxidized to sulfite as an intermediate, and finally to sulfate.

The oxidation of sodium sulfite, and potassium salts of tri- and tetrathionate with ozone was also studied in order to elucidate its mechanism.

The oxidation of sodium thiosulfate with ozone has been studied only by Yamauchi[1] and Riesenfeld *et al.*[2] in the 1910's.

Yamauchi has reported that sodium thiosulfate oxidized to sulfate, sulfite, and elemental sulfur with ozone in a neutral solution according to Eq. (1):

$$3Na_2S_2O_3 + 2O_3 = 2Na_2SO_4 + Na_2SO_3 + 3S + 2O_2 \quad (1)$$

where the formation of sulfate and sulfite is explained as the conversion of the central sulfur atom of the thiosulfate ion. Riesenfeld has proposed that the oxidation of sodium thiosulfate proceeds according to Eqs. (2) and (3) in a neutral solution, which then becomes acidic.

$$Na_2S_2O_3 + O_3 = Na_2S_2O_6 \quad (2)$$

$$Na_2S_2O_3 + O_3 = Na_2SO_4 + SO_2 \quad (3)$$

The number of oxygen atoms consumed in one ozone molecule is three in a neutral solution, but two in an alkaline solution on the addition of sodium carbonate, although the oxidation products are the same in both neutral and alkaline solutions. Dithionate, however, can not be distinguished from other polythionates by qualitative analysis.

Thus, in the early studies there was much doubt about the identification of products. Recently, though, an investigation of the oxidation of ammonium thiosulfate with ozone in an aqueous ammonia solution by one of the present authors[3] has led to the finding that ammonium thiosulfate is oxidized to sulfate, sulfite, sulfamate, and low polythionates.

In the present study, the oxidation of sodium thiosulfate with ozone was investigated as a part of a series of studies on the chemical behavior of low valence sulfur compounds,[4] furthermore, the ozone oxidations of sulfite, tri- and tetrathionates, which are oxidation products of thiosulfate, were studied in order to elucidate the mechanism.

The results may be usefully applied to the treatment of waste water containing thiosulfate and sulfite.

Experimental

Apparatus and Procedure. The apparatus is depicted schematically in Fig. 1. One liter of 0.3—0.6 mol/l sodium thiosulfate solution was put into three-necked round-bottomed flask kept in a water bath at 10—80 °C. Mixed gas of ozone and oxygen was continuously blown into the solution at atmospheric pressure. Every half hour, 10—20 ml aliquots of the solution were withdrawn for analysis. The flow rate, as determined by the orifice meter, was 1—2.9 (mainly 2.1) N.T.P.l/min. The sodium thiosulfate solution used was neutral or alkaline on the addition of sodium hydroxide, the amount of which was equivalent to or in excess of that of the acid produced by the oxidation reaction. An ozonizer with 6 silent discharge tubes of a special construction devised by Kitahara[5] was used with some modification, the center electrode being covered with glass tube to prevent it from being oxidized by ozone.

Sample. The potassium tri- and tetrathionates were prepared by Martin's method.[6]

Analysis. After dilution to a suitable concentration, the sample solution was analyzed for thiosulfate, sulfite, sulfate, tri-, and tetrathionates as follows:

Thiosulfate: Thiosulfate was titrated with a 0.1 N standard solution of iodine after masking sulfite with an aqueous solution of formaldehyde.

Sulfite: The total amount of thiosulfate and sulfite was determined by iodimetry after the neutralization of the sample solution.

Sulfate: After the oxidation of thiosulfate and sulfite with iodine to tetrathionate and sulfate respectively, the sulfate

was determined to be barium sulfate by gravimetry.

Tri- and Tetrathionates: These polythionates were first identified by paper-chromatography[7,8] and then their quantity was determined by using the sulfide and sulfite methods.[9]

First, the sulfite was removed by the addition of 1 N strontium nitrate, a 4 N aqueous ammonia solution saturated with hydrogen sulfide was then added to the sample solution.

The solution was heated on a water bath for about 10 min, and the thiosulfate released from the following reactions was determined by iodimetry after the removal of the excess hydrogen sulfide with carbon dioxide.

$$S_3O_6^{2-} + S^{2-} = 2S_2O_3^{2-} \quad (4)$$

$$S_4O_6^{2-} + S^{2-} = 2S_2O_3^{2-} + S \quad (5)$$

A buffer solution of pH 9.5 and a 1 N sodium sulfite solution were poured into another sample solution and was kept standing for about 10 min, then, an aqueous solution of formaldehyde was added, and the thiosulfate formed by the following reaction was determined by iodimetry after acidification with 1 N acetic acid.

$$S_4O_6^{2-} + SO_3^{2-} = S_3O_6^{2-} + S_2O_3^{2-} \quad (6)$$

Ozone: A known volume of a mixed gas of ozone and oxygen was passed through a 2% potassium iodide solution. After the acidification of the solution with 6 N sulfuric acid, the iodine liberated was titrated with a 0.1 N standard solution of sodium thiosulfate.

Results and Discussion

Oxidation of Sodium Thiosulfate with Ozone. Different reactions occurred by ozone oxidation depending on the pH of the solutions, whether they were neutral or alkaline. In either solution, however, the ozone supplied was completely consumed throughout the reaction stage except in the terminating period of the reaction.

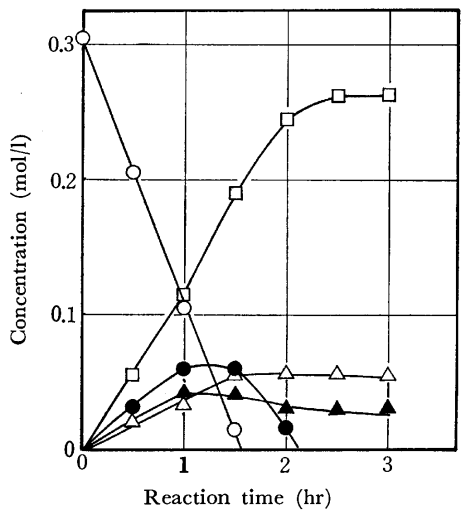

Fig. 2. Oxidation of thiosulfate in neutral solution.
Temp.: 25°C, O_3: 5.16 g/hr, O_3-O_2: 2.1 N.T.P. l/min.
-○-: $S_2O_3^{2-}$, -●-: SO_3^{2-}, -□-: SO_4^{2-},
-▲-: $S_3O_6^{2-}$, -△-: $S_4O_6^{2-}$

In a Neutral Solution. A general view of the reaction at 25 °C is shown in Fig. 2. Thiosulfate was converted into sulfate, sulfite, tri- and tetrathionate, hydrogen sulfide gas, and sulfur dioxide gas. Dithionate was not detected by means of paper-chromatography. Initially, only hydrogen sulfide evolved, and then sulfur dioxide evolved with a lowering of the pH, but their amount as sulfur was less than 5% of the total sulfur. Sulfate and tri- and tetrathionates remained after the complete consumption of the thiosulfate, the amount of sulfate sulfur reached 40% of total sulfur, and the pH of solution decreased to 1—2. The successive oxidation of polythionates proceeded slowly. Although simultaneous and consecutive reactions took place, the amount of thiosulfate decreased linearly, consuming the supplied ozone completely.

The decreasing amount of thiosulfate, R, is proportional to the amount of ozone supplied, R is given as follows:

$$R = kP_{O_3}V_0 \quad \text{(mol/min)} \quad (7)$$

$$r = R/V_0 = kP_{O_3} \quad (8)$$

P_{O_3}: Partial pressure of ozone (atm)
V_0: Flow rate of mixed gas (N.T.P. l/min)
k: Constant (mol/l·atm)

The relation between r and P_{O_3} is shown in Fig. 3.

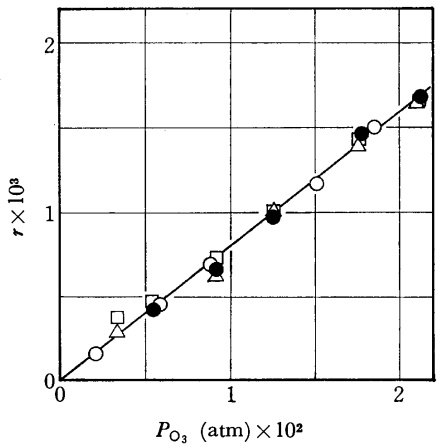

Fig. 3. Plot of r *vs.* P_{O_3}
-●-: 10°C, -○-: 25°C, -△-: 40°C, -□-: 60°C

As is expressed by the straight line which intersects at the point of origin, independently of the reaction temperature, R is shown experimentally as follows:

$$R = 0.080\,P_{O_3}V_0 \quad (10\text{—}60\,^\circ\text{C}) \quad \text{(mol/min)} \quad (9)$$

This equation does not express a stoichiometric relation between thiosulfate and ozone, but it does indicate the relation between the consumed amount of thiosulfate and the supplied amount of ozone. In spite of the perfect consumption of ozone, the reaction was accelerated a little by the addition of 10^{-3}—10^{-4} mol/l of ammonium metavanadate.

In an Alkaline Solution. As is shown in Fig. 4, only sulfite was observed as an intermediate, and thiosulfate was completely oxidized to sulfate. The amount of sulfate formed by the reaction was twice as much as that of the initial thiosulfate. Unlike as a reaction in a neutral solution, the oxidation reaction

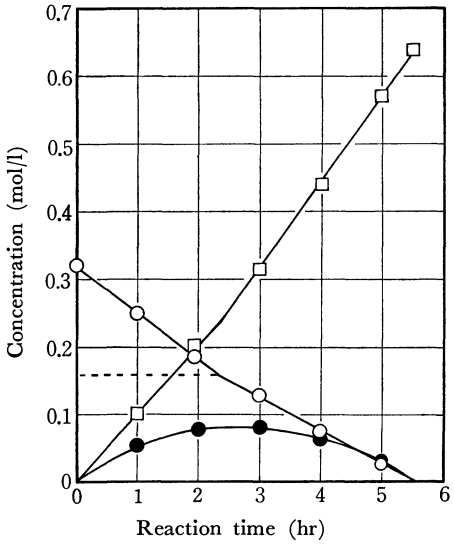

Fig. 4. Oxidation of thiosulfate in alkaline solution.
Temp.: 25°C, O_3: 5.16 g/hr, O_3-O_2: 2.1 N.T.P. l/min.
-○-: $S_2O_3^{2-}$, -●-: SO_3^{2-}, -□-: SO_4^{2-}.

in an alkaline solution was completed as soon as the thiosulfate disappeared. The oxidized amount of thiosulfate, R, decreased gradually with the reaction time, but it may be expressed approximately as follows:

$$C_0 - C_0/2 \quad R = k_1 P_{O_3} V_0 \quad \text{(mol/min)} \tag{10}$$

$$C_0/2 - 0 \quad R = k_2 P_{O_3} V_0 \quad \text{(mol/min)} \tag{11}$$

$$\log k_1 = -170/T - 0.994 \tag{12}$$

$$\log k_2 = -170/T - 1.149 \tag{13}$$

C_0: Initial thiosulfate consentration(mol/l)
T: Reaction temperature (K)
(25—80°C)

These equations are based on the assumption that the relationship between the thiosulfate concentration and the reaction time is expressed by the two straight lines crossing each other at the point indicating one-half of the initial concentration of thiosulfate. The value of R in an alkaline solution is 1/3—1/4 of that in a neutral solution.

Oxidation of Sodium Sulfite with Ozone. The ozone supplied was completely consumed under the present experimental conditions (reaction temperature, 25—60 °C, initial concentration of sodium sulfite, 0.6 mol/l, and flow rate of mixed gas of ozone and oxygen, 2.1 N.T.P-l/min), thus forming sulfate quantitatively. The relation between reaction molar ratio (Na_2SO_3/O_3) and the ozone concentration in the gas phase is shown in Fig. 5. The reaction molar ratio was calculated from Eq. (14):

Na_2SO_3/O_3 = {amount of sulfite oxidized by ozone and oxygen (mol)—amount of sulfite oxidized by oxygen(mol)}/ozone supplied (mol) (14)

The molar ratio was not constant, but gradually increased with a rise in the temperature and with a decrease in the ozone concentration. The molar ratio must be less than 3, judging from Eq. (15), but there were actually cases where it was 3 or more, as is shwon in Fig. 5.

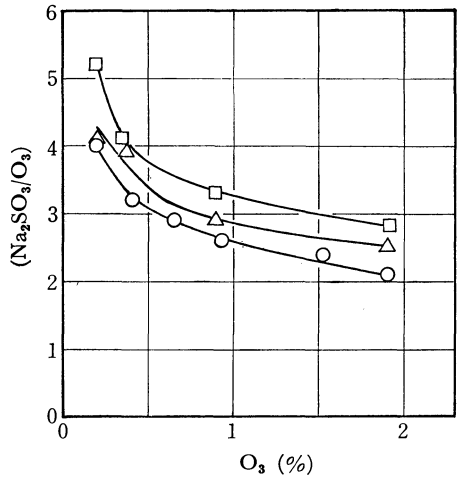

Fig. 5. Plot of (Na_2SO_3/O_3) *vs.* O_3
-○-: 25°C, -△-: 40°C, -□-: 60°C.

$$Na_2SO_3 + 1/3\, O_3 = Na_2SO_4 \tag{15}$$

From the results, it must be considered that the oxidation of sulfite with oxygen is accelerated by the presence of ozone. Under the following conditions:

Reaction temperature:	25—60	(°C)
Partial oxygen pressure P_{O_2}:	0.1—1	(atm)
Partial ozone pressure P_{O_3}:	$(0.1—2) \times 10^{-2}$	(atm)
Flow rate of mixed gas of		
O_3-O_2 or O_3-O_2-N_2	V_0: 1—2.8 (l/min at N.T.P.)	

the amount of oxidized sulfite, R, may be experimentally expressed as follows:

$$R = k P_{O_3}^{0.5} P_{O_2}^{0.5} V_0 \quad \text{(mol/min)} \tag{16}$$

$k_{25} = 0.016$ (mol/l·atm)
$k_{40} = 0.018$ (mol/l·atm)
$k_{60} = 0.020$ (mol/l·atm)

Oxidation of Potassium Tri- and Tetrathionates with Ozone. In the oxidation of these polythionates, only 16% of the trithionate and 4% of the tetrathionate were converted to sulfate after 4 hr in a neutral solution, and no intermediate was detected under the present experimental conditions (reaction temperature, 25 °C; initial tri- and tetrathionate concentration, 0.1 mol/l; ozone flow rate, 4.75 g/hr).

The rate of the reaction was so slow that most of the ozone passed freely through the solution.

The results obtained from an investigation in an alkaline solution are shown in Figs. 6 and 7. It has previously been shown that tri- and tetrathionates decompose by the following reactions in an alkaline solution.[10]

at pH 13: $2S_3O_6^{2-} + 6OH^- = S_2O_3^{2-} + 4SO_3^{2-} + 3H_2O$ (17)

at pH 11.5: $4S_4O_6^{2-} + 6OH^- = 2S_3O_6^{2-} + 5S_2O_3^{2-} + 3H_2O$ (18)

partially $2S_4O_6^{2-} + 6OH^- = 3S_2O_3^{2-} + 2SO_3^{2-} + 3H_2O$ (19)

10) K. Naito, M. Shieh and T. Okabe, This Bulletin, **43**, 1372 (1970).

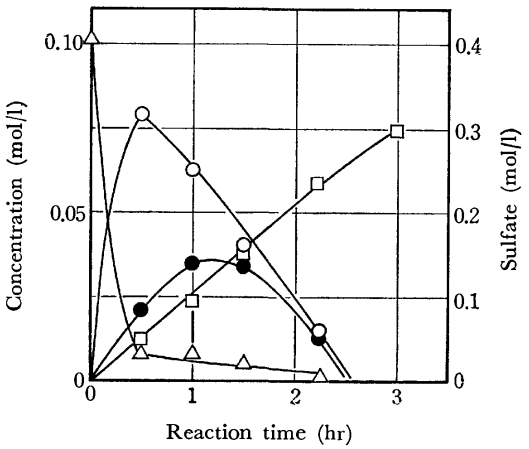

Fig. 7. Oxidation of tetrathionate in alkaline solution.
Temp.: 25°C, O_3: 4.75 g/hr, O_3-O_2: 2.1 N. T. P. l/min.
NaOH: 0.4 mol/l.
-○-: $S_2O_3^{2-}$, -●-: SO_3^{2-}, -□-: SO_4^{2-}, -△-: $S_4O_6^{2-}$.

The changes in degree of the tri- and tetrathionate concentrations in the ozone oxidation were similar to those in their decomposition reaction in an alkaline solution. Therefore, it may be considered that tri- and tetrathionates decompose initially in the manner expressed by Eqs. (17) and (18), and that the thiosulfate and sulfite formed by the decomposition are mainly oxidized by ozone.

The Mechanism of the Oxidation Reaction of Sodium Thiosulfate with Ozone. The reactions expressed by the following equations may be considered to be the oxidation reactions of sodium thiosulfate in a neutral solution.

For the formations of SO_4^{2-} and SO_3^{2-}:

$$S_2O_3^{2-} + O_3 = SO_4^{2-} + SO_2 \quad (3')$$

$$S_4O_6^{2-} + O_3 \rightarrow SO_4^{2-} \quad (20)$$

$$S_3O_6^{2-} + O_3 \rightarrow SO_4^{2-} \quad (21)$$

$$SO_3^{2-} + O_3 \rightarrow SO_4^{2-} \quad (22)$$

$$SO_3^{2-} + 1/2O_2 = SO_4^{2-} \quad (23)$$

For the formation of $S_3O_6^{2-}$:

$$S_4O_6^{2-} + SO_3^{2-} = S_3O_6^{2-} + S_2O_3^{2-} \quad (6)$$

$$S_2O_3^{2-} + SO_3^{2-} + O_3 \rightarrow S_3O_6^{2-} \quad (24)$$

For the formation of $S_4O_6^{2-}$:

$$2S_2O_3^{2-} + 1/3O_3 + H_2O = S_4O_6^{2-} + 2OH^- \quad (25)$$

$$2S_2O_3^{2-} + 1/2O_2 + H_2O \rightarrow S_4O_6^{2-} \quad (26)$$

If it is assumed that Reactions (3'), (6), (25), and (23) proceed mainly in an early stage of the ozone oxidation, the amounts of thiosulfate and ozone used in the reaction can be calculated also from the amounts of products shown in Fig. 2. The calculated values are tabulated as follows, along with values actually used.

Time range (hr)	Thiosulfate (mol)		Ozone (mol)	
	Calcd	Obsd	Calcd	Suppld
0 —0.5	0.108	0.099	0.065	0.054
0.5—1.0	0.215	0.200	0.132	0.108
1.0—1.5	0.293	0.289	0.172	0.162

The calculated values of the thiosulfate consumed are almost equal to the observed values, therefore, the oxidation of thiosulfate with ozone must proceed mainly *via* the route assumed above.

On the other hand, the amount of ozone actually consumed was less by 20% than that calculated. This discrepancy can be accounted for by the consideration that the oxidation of thiosulfate with oxygen, as expressed by Eq. (26), is induced at atmospheric pressure in the presence of ozone, because thiosulfate is oxidized with compressed oxygen to tetrathionate.[10] In view of the results of the oxidation of sulfite, tri- and tetrathionates with ozone, there is no doubt that Reactions (20), (21), and (22) proceed to some extent.

Furthermore, it is probably reasonable to consider that the formation of trithionate takes place, as is

TABLE 1. THE OZONE OXIDATION OF THIOSULFATE IN AN ALKALINE SOLUTION

Time range (hr)	$S_2O_3^{2-}$ (mol)	SO_3^{2-} (mol)	SO_4^{2-}		O_3	
			Obsd (mol)	Calcd (mol)	Calcd (mol)	Suppld (mol)
0—1	0.071	0.023	0.099	—	0.078	0.175
1—2	0.063	0.040	0.104	0.103	0.076	0.175
2—3	0.057	0.054	0.113	0.111	0.075	0.175
3—4	0.053	0.069	0.123	0.122	0.076	0.175
4—5	0.049	0.082	0.132	0.131	0.076	0.175

SO_3^{2-}: Amount of sulfite oxidized by Eq. (23). SO_4^{2-} Calcd: SO_3^{2-} + amount of sulfate formed by Eq. (3).
O_3 Calcd: Amount of ozone being required to oxidize $S_2O_3^{2-}$ to SO_4^{2-} and SO_3^{2-}.

expressed not only by Eq. (6), but also by Eq. (24), by means of the oxidation of a complex which consists of thiosulfate and sulfite, because such a complex is easily formed in an acidic solution.[11]

The evolution of hydrogen sulfide may be considered to be result from the decomposition reaction of thiosufate as follows:

$$S_2O_3^{2-} + H_2O = H_2S + SO_4^{2-} \quad (27)$$

$$2S_2O_3^{2-} + 2H^+ = H_2S + S_3O_6^{2-} \quad (28)$$

11) C. J. Battaglia and W. J. Miller, *Photogr. Sci. Eng.*, **12**, 46 (1968).

The acceleration of ammonium metavanadate may be explained by the fact that Reaction (25) or (26) is promoted by a catalytic action of ammonium metavanadate, for these reactions contribute mostly to the consumption of thiosulfate.

In an alkaline solution, the oxidation of thiosulfate must proceed mainly *via* (3′) and (15), as is shown in Table 1.

Although polythionates could not be detected in the alkaline solution, polythionates are possibly responsible for the formation of sulfite as an unstable intermediate.

Spectrophotometric Study on the Extraction of Magnesium(II)–8-Hydroxyquinoline-5-sulfonic Acid Chelate Anion with Zephiramine

Masao SUGAWARA and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received July 19, 1973)

The ion-pair of magnesium(II)–8-hydroxyquinoline-5-sulfonic acid chelate anion with zephiramine (Z^+Cl^-) was extracted into chloroform. The ternary complex has an absorption maximum at 390 nm in the organic layer. The optimum pH range for the extraction is 10.1—11.4. For the first extract, Beer's law holds for 4.6—20.6 μg of magnesium(II) in 10-ml organic layer, the molar absorptivity being 6.73×10^3 cm^{-1} mol^{-1} l. The composition of the ternary complex is estimated to be $[Mg^{2+}(QS^{2-}Z^+)_2(HQS^-Z^+)]_o$. The extraction equilibrium is given by

$$Mg^{2+} + 3[(HQS^-Z^+)]_o + 2OH^- \rightleftharpoons [Mg^{2+}(QS^{2-}Z^+)_2(HQS^-Z^+)]_o + 2H_2O$$

where QS denotes 8-hydroxyquinoline-5-sulfonic acid and o the organic phase. The equilibrium constant K is given by $\log K = 16.95 \pm 0.13$.

Although magnesium(II) forms with 8-quinolinol a compound $MgOx_2\cdot2H_2O$ slightly soluble in chloroform, Luke and Campbell[1] successfully extracted the compound by using butyl cellosolve as a supplementary solvent to chloroform. Jankowsky and Freiser[2] extracted an ion-pair such as tetra-*n*-butylammonium tris-8-quinolinolatomagnesium, $[(C_4H_9)_4N^+Mg(C_9H_6NO)_3^-]$. Extraction of a similar complex was also reported by Umland and Hoffman.[3] Fukamachi *et al.*[4] reported the extraction of magnesium-Eriochrom Black T complex with zephiramine into 1,2-dichloroethane. Nakaya and Nishimura[5] have reported the extraction of magnesium 8-quinolinolate in the presence of pyridine.

In the present study, magnesium(II)-8-hydroxyquinoline-5-sulfonic acid chelate anion was extracted into chloroform in the presence of zephiramine (tetradecyl-dimethyl-benzyl-ammonium chloride). The composition of the extracted complex as well as fundamental conditions for spectrophotometric determination of magnesium(II) were discussed.

Experimental

Reagent. *Magnesium(II) Standard Solution*: Magnesium sulfate (Wako Chemicals Co.) was dissolved in deionized water. Standardization of the solution was carried out by EDTA-titration using Eriochrom Black T as an indicator. It was found that 228.8 μg of magnesium(II) was contained per milliliter. The solution was diluted as required.

8-Hydroxyquinoline-5-sulfonic Acid Solution (H_2QS): 1.00×10^{-3} M solution was prepared by dissolving H_2QS (Wako Chemicals Co.) in water.

Zephiramine Solution (Z^+Cl^-): 5.00×10^{-3} M solution was prepared by dissolving Dotite zephiramine in water.

Ammonia Buffer Solution, pH 10.0—12.3: 0.1 M stock solutions of ammonium chloride, ammonia and sodium hydroxide were mixed in appropriate proportions.

Borate Buffer Solution, pH 9.2—10.1: Stock solution of 0.05 M borax was suitably mixed with 0.1 M sodium hydroxide.

Chloroform and other reagents were all of analytical reagent. Resin-deionized water was used.

Apparatus. All the measurements were carried out with the same apparatus as that described previously.[6]

Procedure. A definite volume of magnesium(II) standard solution (11.4 μg) was mixed with 15 ml of the H_2QS solution and 5 ml of the zephiramine solution in a 100-ml separatory funnel. pH adjustment was carried out

with 10 ml of the ammonia buffer solution and then filled up to 50 ml with water. The mixture was shaken for 5 min with 10 ml of chloroform and left for 10 min for the phases to separate. The organic phase was drained into a beaker containing anhydrous Na_2SO_4 and subjected to optical measurement. The absorbance of the extract was measured against the reagent blank obtained in the same way.

Results and Discussion

Absorption Spectra. Absorption spectra of the ternary complex in aqueous and organic phases are shown in Figs. 1 and 2, respectively. The ternary complex has an absorption maximum at 400 nm in the aqueous phase and 390 nm in the organic phase. Color of magnesium(II)–H_2QS complex was not developed at the magnesium(II) concentration used.

Effect of pH. The aqueous solution was adjusted to various pH values with the ammonia buffer solution and the extraction was carried out by the above procedure. The optimum pH range for the extraction was found to be 10.1—11.4. The chloroform extract was stable for at least 30 min. At higher pH, the color of the extract changed with a gradual increase in absorbance. Use of borate buffer solution is not desirable since the absorbance of the reagent blank is very high.

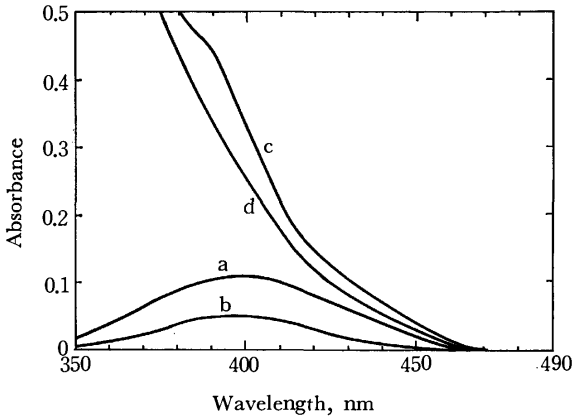

Fig. 1. Absorption spectra of Mg(II)-QS-Z complex in the aqueous solution.
Curve (a): $[Mg(II)]_w = 1.8\times10^{-5}$ M, (b): 0.94×10^{-5} M; $[QS]_w = 3.0\times10^{-4}$ M, $[Z]_w = 5.0\times10^{-4}$ M, pH 10.3,
Curve (a), (b): *vs.* reagent blank, (c): *vs.* water, (d): reagent blank *vs.* water.

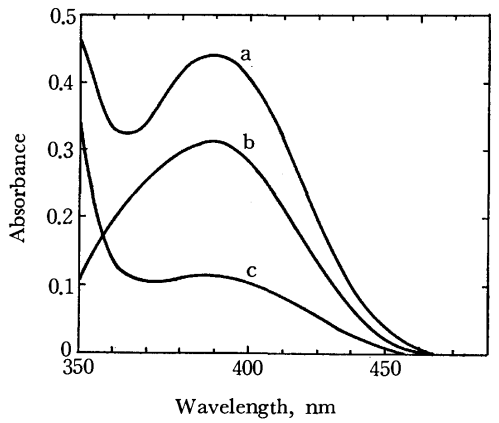

Fig. 2. Absorption spectra of Mg(II)-QS-Z complex in the organic phase after extraction.
Volume of the aqueous phase $V_w = 50$ ml, Volume of the organic phase $V_o = 10$ ml, $[Mg(II)]_w = 0.94\times10^{-5}$ M, $[QS]_w = 3.0\times10^{-4}$ M, $[Z]_w = 5.0\times10^{-4}$ M, pH 10.3,
Curve (a): *vs.* $CHCl_3$, (b): *vs.* reagent blank, (c): reagent blank *vs.* $CHCl_3$.

Effect of H_2QS and Zephiramine Concentration. Varying amounts of reagents were added to the aqueous solution buffered to pH 10.6 and the solution was shaken with chloroform as above. The constant and maximum absorbance of the extract was obtained with a concentration ratio higher than 10-fold of H_2QS and 20-fold of zephiramine to magnesium(II).

Effect of Shaking Time. Shaking time was varied from 2 min to 15 min. The absorbance of the extract was found to decrease when shaking was continued for longer than 10 min. 5 minutes were found to be the desired time for each case.

Extractability and Molar Absorptivity. 25 ml of aqueous solution containing 11.4 μg of magnesium(II) and the reagents of appropriate concentrations was shaken with 10 ml of chloroform. Extraction was repeated with 5 ml of chloroform for the remaining aqueous phase after the separation of the extract. Extractability of magnesium(II) was calculated from absorbances of the extracts. It was found that 98.7% of magnesium(II) was extracted in a single extraction. Molar absorptivity of the ternary complex was 6.73×10^3 cm^{-1} mol^{-1} l, which is higher than the value obtained by Luke and Campbell's method[1] (5600), or that by Nakaya and Nishimura's method(4420),[5] but lower than that by Jankowsky and Freiser's method (7080).[2]

Calibration Curve. Varying amounts of magnesium(II) were extracted. It was found that Beer's law holds for the first extract, 4.6—20.6 μg of magnesium(II), Sandell's sensitivity for the absorbance of 0.001 being 0.0036 $\mu g\ cm^{-2}$.

Interference by Calcium Ion. Various amounts of calcium(II) were added to the aqueous solution containing magnesium(II) and the solution was treated by the above. The results are given in Table 1. When the amount of calcium(II) became about 5-fold of magnesium(II), a larger error was observed.

Composition of the Ternary Complex. The continuous variation method for three-component system[6] was used to determine the composition of the ternary complex. Maximum absorbance of the extract was obtained at the mole ratio of Mg(II) : H_2QS : zephiramine = 1 : 3 : 3 (Fig. 3). The composition of the ternary complex was therefore estimated to be $[Mg^{2+}\text{-}(QS^{2-}Z^+)_2(HQS^-Z^+)]_o$.

Equilibrium Constant. The continuous variation method applied to the system of H_2QS-zephiramine indicates that an ion-pair of $[HQS^-Z^+]_o$ was extracted from the ammonia buffer solution (pH 10.2). Thus extraction equilibrium of magnesium(II) is given by

$$Mg^{2+} + 3\,[(HQS^-Z^+)]_o + 2\,OH^- \rightleftharpoons [Mg^{2+}(QS^{2-}Z^+)_2(HQS^-Z^+)]_o + 2\,H_2O \quad (1)$$

Polarographic Behavior of 9-Nitroanthracene and 9,10-Dinitroanthracene in Dimethylformamide

Toyokichi KITAGAWA and Akio ICHIMURA

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received February 28, 1973)

The polarographic behavior of 9-nitroanthracene and 9,10-dinitroanthracene has been studied in dimethylformamide. 9-Nitroanthracene shows consecutive two one-electron diffusion-controlled reduction waves followed by fast chemical reactions. 9,10-Dinitroanthracene, however, shows only one reversible two-electron diffusion-controlled wave. The effect of the supporting electrolyte cation on these reduction waves was also investigated. In alkali metal or alkaline earth metal perchlorate as a supporting electrolyte, the half-wave potentials shift to the anodic side. The relationship between the half-wave potential and the ionic potential of the cation was discussed.

A number of electrochemical and electron paramagnetic resonance studies of nitro compounds have been reported. The relationship between the structure of substituted nitrobenzene and its electrode kinetic parameter and its nitrogen hyperfine coupling constant was investigated in acetonitrile[1] and in dimethylformamide(DMF).[2,3] It was revealed that the rate constant of anion radical formation increases with the increase in resonance between the nitro groups and the remainder related to the nitrogen hyperfine coupling constant.

Recently, the ion association of radical anion or dianion produced by the reduction of organic compounds with metal cations in aprotic solvent has been investigated electrochemically for nitrobenzenes,[4,5] *p*-chloronitrobenzene,[6] quinones[7] and naphthoquinones.[8] Metal cations interact with anions but tetraalkylammonium ions are free from anions.

In this paper, we report on the reduction process of 9-nitroanthracene and 9,10-dinitroanthracene in DMF containing tetraethylammonium perchlorate (TEAP) as a supporting electrolyte and the effect of the supporting electrolyte cation on these reduction waves in the same solvent.

Experimental

DC and AC polarograms were recorded with a Yanagimoto polarograph P8 with a potentiostat. Cyclic voltammograms were recorded with a Riken Denshi F-32 X-Y recorder at a lower sweep rate and a Matsushita VP-546V oscilloscope with a Kikusui 455 function generator at a higher sweep rate. Capillary characteristics at 0 V *vs.* SCE in DMF containing 0.1 M TEAP were $m=1.52$ mg/s and $t=5.06$ s at $h=45$ cm. The area of the platinum disc electrode was calculated by chronopotentiometry for potassium ferrocyanide in 1.5 M potassium chloride and found to be 0.0665 cm^2. The reference electrode was aqueous SCE with a TEAP-DMF-methylcellulose salt bridge. All polarographic measurements were carried out at 25±0.5 °C in a dry box under a nitrogen atmosphere.

9-Nitroanthracene and 9,10-dinitroanthracene were supplied by Dr. R. Nakashima. DMF was dried over molecular sieve 3A and then distilled under reduced pressure. The content of water in DMF was found to be less than 0.01% by a gas-chromatographic method with a Porapak Q column. TEAP was prepared by neutralizing 10% tetraethylammonium hydroxide solution with 60% perchloric acid. The salt formed was recrystallized several times from water and dried *in vacuo* at 60 °C for 24 hr. Other perchlorates were dried *in vacuo* at 100 °C for 24 hr.

Results and Discussion

Polarographic Behavior of 9-Nitroanthracene and 9,10-Dinitroanthracene. The DC polarogram of 9-nitroanthracene in DMF containing 0.1 M TEAP shows two reduction waves. Its polarographic data are summarized in Table 1. The limiting current of the first wave is proportional to the concentration of 9-nitroanthracene in the range 2×10^{-4}—8×10^{-4} M, but the maximum wave appears at a concentration greater than 8×10^{-4} M. Both reduction waves are considered to be diffusion-controlled from the dependence of their wave height on the mercury column height and the current-time curve during the life of a mercury drop at the potential giving the limiting current. Comparing the diffusion current constant I and the chronoamperometric value $i\cdot t^{1/2}/C^*$, with those of *m*-nitrotoluene which is known to be a diffusion-controlled reversible one-electron process,[3] the reduction process of 9-nitroanthracene is found to be a consecutive two one-electron reduction process. In an AC polarogram under the same conditions, two waves corresponding to the waves in a DC polarogram are observed. The results are summarized in Table 1. We see that the summit potential of these waves is more cathodic than the half-wave potential of the corresponding DC polarographic reduction waves, the height of the more cathodic wave being very small. The irreversibility will be discussed in comparison with the case of 9,10-dinitroanthracene. The cyclic voltammetric behavior at a platinum disc electrode is shown in Fig. 1. Two reduction waves whose peaks correspond to the half-wave potential in the DC polarogram appear. Almost the same voltam-

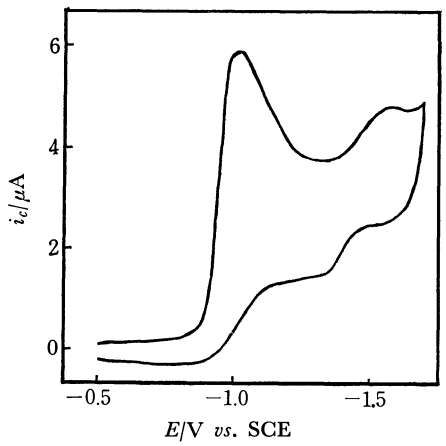

Fig. 1. Cyclic voltammogram of 0.665 mM 9-nitroanthracene at platinum disc electrode in DMF containing 0.1 M TEAP. Sweep rate: 30.3 mV/s.

mogram was obtained at a hanging mercury drop electrode. The potential difference between the cathodic peak potential and its half-peak potential for the first wave at a sweep rate of 30.3 mV/s is 60 mV which is fairly consistent with that for the reversible one-electron process[9] although the second wave shows an ill-defined curve. After reversal of the potential sweep at −1.7 V, no distinct waves corresponding to the re-oxidation of the products of the two cathodic processes appear. The first and second reduction products considered to be an anion radical and a dianion, respectively, might decompose by the following fast chemical reactions.

DC and AC polarographic and chronoamperometric results of 9,10-dinitroanthracene in DMF containing 0.1 M TEAP are also summarized in Table 1. Although most nitro aromatics show the two-step reduction process, only a single reduction wave is obtained for 9,10-dinitroanthracene. The half-wave potential is more anodic than that of the first wave for 9-nitroanthracene presumably because of the increase in coplanarity of nitro group and anthracene plane. The plot of $\log (i/(i_d-i))$ against potential E gives a straight line with a slope of 33 mV, and the diffusion current constant and the chronoamperometric value are 1.3 times as large as that of *m*-nitrotoluene. Hence it appears that the reduction of 9,10-dinitroanthracene is a diffusion-controlled two-electron process, giving a dianion. The AC polarographic summit potential of the reduction wave is slightly more cathodic than the half-wave potential of the corresponding DC polarographic step. The AC wave is very high, its value of $i_s/i_d \cdot \sqrt{t_d} \cdot n$ (where $n=2$) being near that *m*-nitrotoluene which shows a reversible reduction process. In the cyclic voltammogram with a hanging mercury drop electrode at a sweep rate of 30.3 mV/s under the same conditions as above, the peak potential for the reduction is −0.560 V, the difference between the peak potential and the half-peak potential being 34 mV, which is close to the theoretical value for a two-electron transfer process.[9] The relationship between the cathodic peak current and the sweep rate, i_p *vs.* $v^{1/2}$, gives a straight line, the ratio of the cathodic to the anodic peak current being approximately 1.0 in a wide range of the sweep rate. In the case of the platinum disc electrode, the separation of the cathodic peak potential from the anodic peak potential is 147 mV at a sweep rate of 30.3 mV/s. This indicates that the electrode process of 9,10-dinitroanthracene at the platinum disc electrode is less reversible.

The electrode reaction of 9,10-dinitroanthracene is much more reversible than that of 9-nitroanthracene. Investigations of the crystal structure of 9,10-dinitroanthracene and 9-nitroanthracene show that the nitro groups are tilted 64°[10] and 85°,[11] respectively, out of the plane of the anthracene nucleus. The structures cause the decrease in resonance between the nitro groups and the aromatic π-electron. Thus, it can be said that the rate of charge transfer for 9,10-dinitroanthracene is faster than that for 9-nitroanthracene, after those which Peover and Powell developed using the Marcus theory.[3]

Many dinitro compounds have been investigated electrochemically. Most of them show two one-electron reduction process in aprotic solvent with a tetraalkylammonium salt as a supporting electrolyte. A

few dinitro compounds show only a single two-electron reduction process.[1] 9,10-Dinitroanthracene is shown to be the latter example.

Effect of the Supporting Electrolyte on the Reduction Process of 9-Nitroanthracene and 9,10-Dinitroanthracene. DC polarographic waves of 9-nitroanthracene in DMF containing 0.1 M alkali metal perchlorate or 0.05 M magnesium perchlorate are shown in Fig. 2. In 0.1 M potassium or 0.1 M sodium perchlorate, both the half-wave potential and the wave height of the first one-electron reduction process are similar to those in 0.1 M TEAP. The second wave, however, shows an anodic shift of the half-wave potential and an increase in wave height. On the other hand, in 0.1 M lithium or 0.05 M magnesium perchlorate the polarographic behavior differs from that in potassium and sodium salts. The first and the second waves shift to the anodic side, the second wave height increasing particularly in magnesium perchlorate. A new third wave appears in more cathodic potential. The value of $i_s/i_d \cdot \sqrt{t_d} \cdot n$ in 0.1 M perchlorate solution (0.05 M for magnesium perchlorate), showing the reversibility of the charge transfer, decreases in the following order for the cation of the supporting electrolyte: $Et_4N^+ > K^+ > Na^+ > Li^+ > Mg^{2+}$. This coincides with the reverse order for the anodic shift of the half-wave potential.

The effect of metal cation on the polarographic wave of 9,10-dinitroanthracene has also been examined in a similar manner in the case of 9-nitroanthracene. Cyclic voltammograms in various supporting electrolyte are shown in Fig. 3. In 0.1 M potassium, sodium, or lithium perchlorate, the half-wave potential shifts to the anodic but the DC wave height and the reversibility (AC wave height, and peak separation in cyclic voltammetry) remain unchanged in the presence of these metal cations. In 0.05 M magnesium perchlorate, however, the half-wave potential shifts to the more anodic, the AC wave height being about one third of the case of TEAP. The cyclic voltammetric peak current also decreases and the peak separation increases, which indicates the process to be less reversible.

The half-wave potential changes with cations of the supporting electrolytes. The relationship between the half-wave potential of nitroanthracenes and the ionic potential of the cation $\phi(\phi = z/r$, z; charge number, r; crystallographic radius) is plotted in Fig. 4. This gives three straight lines showing that the anodic shift of the half-wave potential increases with

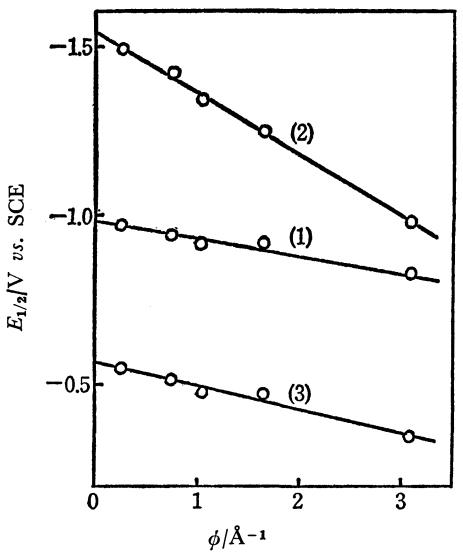

Fig. 4. Relationship between $E_{1/2}$ in 0.1 M perchlorate DMF solution and the ionic potential of the supporting electrolyte cation. From left to right, Et_4N^+, K^+, Na^+, Li^+, Mg^{2+}. 1st (1) and 2nd (2) wave of 9-nitroanthracene and 9, 10-dinitroanthracene (3).

the ionic potential. From the results by Krygowski *et al.*,[12] the relationship can be elucidated from the consideration that the reduction product, which may be radical anion and dianion for 9-nitroanthracene and dianion for 9,10-dinitroanthracene, forms ion pair with the metal cation of supporting electrolyte.

Studies of Nitrogen-Phosphorus Compounds. XXV.[1] The Synthesis of Guanidium Condensed Phosphates

Etsuro KOBAYASHI

National Chemical Laboratory for Industry, Hon-machi, Shibuya-ku, Tokyo 151

(Received April 13, 1973)

In order to develop fireproof materials, an attempt was made to prepare guanidium condensed phosphates ($(H_5CN_3)_n \cdot H_{n+2}P_nO_{3n+1}$, $n=1$—10) by means of a reaction between dicyandiamide ($H_4C_2N_4$) and ammonium dihydrogen phosphate ($NH_4H_2PO_4$) in an autoclave; then the conditions of the synthesis were investigated, and the components of the product were also identified. In the synthesis of gaunidium salt by means of a reaction between dicyandiamide and ammonium salt, generally only ammonium salts of strong acid have been used; also, high yields of guanidium salt could not be obtained with the $(NH_4)_2HPO_4$ used previously. In the present study, a mixture of 1 mol of $H_4C_2N_4$ and 2 mol of $NH_4H_2PO_4$ was heated in an autoclave at 130—300 °C; 70—80% of the dicyandiamide was then converted into guanidium salt under the most suitable conditions. The majority of the product is soluble in water (the insoluble part is less than 3.5% at 150—220 °C), and the solution is almost neutral. The components of the soluble part were 25—26% N and 20—24% P, the mole ratio of N to P being 2.8—2.5; this ratio decreased with an increase in the reaction temperature. On the other hand, the phosphates in the product consist of ortho-, pyro-, tri-, and middlepoly phosphates ($n=4$—10). The guanidium condensed phosphates thus obtained can be utilized as useful flame retarders for paper and wood, as guanidium orthophosphate can be.

Among the derivatives of calcium cyanamide, dicyandiamide, guanylurea, guanidine, and melamine are useful industrial materials. Most of these compounds can readily be obtained from dicyandiamide, as is shown in Fig. 1. The guanidium salts have been formed by reaction fusing a mixture of dicyandiamide and the salt of a strong acid, such as ammonium nitrate or ammonium chloride. An attempt has already been made to prepare guanidium phosphate by means of a reaction between dicyandiamide and diammonium hydrogen phosphate in a sealed tube,[2] with water as the medium, however, a high yield of guanidium phosphate cannot be expected because of the slow reaction rate and the secondary reaction. Therefore, this method has not been employed as an economical process for manufacturing guanidium phosphate. Recently, however, monoguanidium and diguanidium phosphates, which are prepared by the neutralization of guanidium carbonate with phosphoric acid or by a double decomposition between guanidium chloride and sodium phosphate, have been recognized as fireproof materials. As guanidium orthophosphates, a certain derivative of calcium cyanamide and guanidium condensed phosphates may also be used as fireproof materials.

The present author has previously investigated the preparation of ammonium condensed phosphates by the thermal dehydration of $NH_4H_2PO_4$[3] and the

reaction between $NH_4H_2PO_4$, $(NH_2)_2CO$, and H_2O.[4] In the present work, a mixture of 1 mol of dicyandiamide and 2 mols of ammonium dihydrogen phosphate is heated in an autoclave. From the analysis of the resulting products, it is found that most of the orthophosphate is converted into condensed phosphates, and also that 70—80% of the dicyandiamide used is converted into guanidine under the most suitable conditions. In order to ascertain the mechanism of this reaction, the thermal decomposition of monoguanidium phosphate itself is also examined. In this paper, an experimental study of the preparation of guanidium condensed phosphates will also be described.

Experimental

Synthesis. Heat Treatment of Monoguanidium Phosphate: Monoguanidium phosphate was prepared by the neutralization of guanidium carbonate with phosphoric acid. Found: N, 26.7; P, 19.5%. Calcd for $CN_3H_5 \cdot H_3PO_4$: N, 26.7; P, 19.74%. A 20-g portion of this phosphate is placed in a 100-ml test tube; the vessel is then immersed in an oil bath regulated at a proper temperature. The resulting melted products are sampled at proper intervals, and their weight loss on heating and the components are estimated.

Reaction between Dicyandiamide and Ammonium Dihydrogen Phosphate: A mixture of 1 mol of dicyandiamide ($H_4C_2N_4$) and 2 mol of ammonium dihydrogen phosphate ($NH_4H_2PO_4$) was employed as the starting material. A 5-g portion of the mixture was placed in a 100-ml test tube; the vessel was then immersed in an oil bath regulated at a proper temperature for 60 min. After the reaction product had swollen and solidified, it was collected as a powder by raking.

Analysis. A sample solution for analysis was prepared in the following way. A 1.25-g portion of the heating product of $H_5CN_3 \cdot H_3PO_4$ was weighed exactly and dissolved in water, and the volume of the solution was adjusted to 250 ml. A 2.00-g portion of the reaction product between $H_4C_2N_4$ and $NH_4H_2PO_4$ was also weighed exactly, a 50-ml portion of water was added, and the mixture was stirred for 2 hr. The resulting insoluble part was separated from the filtrate, dried for 60 min at 110 °C, and then weighed, while the volume of the filtrate was adjusted to 100 ml.

The phosphorus content was determined gravimetrically as magnesium pyrophosphate. The total nitrogen content was determined by Kjeldahl's method.

In the separation and determination of the condensed phosphates, we used ion-exchange chromatography,[5] the procedures being those of the previously-reported successive elution (see Fig. 5 I, II) and gradient elution (see Fig. 5 III), and paper chromatography using an acid solvent.[6]

In the separation of non-cyclic cyanamide derivatives, we used Takimoto and Koeda's[7] paper chromatography. The non-cyclic cyanamide derivatives were also analysed by Takimoto and Yao's[8] ion-exchange chromatography. The results of the determination of guanidine as the main product accorded with those of Kurabayashi and Yanagiya's[9] method.

The differential thermal analysis (DTA) and thermogravimetric measurements (TGA) were performed simultaneously under a nitrogen atmosphere and at a heating rate of 5 °C/min, using a Rigaku-Denki model DC-Cl-S thermal analyser.

Results and Discussion

Change in Monoguanidium Phosphate upon Heating. It is supposed that guanidium phosphate, which may be formed by the reaction of dicyandiamide and ammonium phosphate, is converted into the condensed phosphates at a high temperature, and that it finally decomposes into condensed phosphoric acids and ammonia. Therefore, the thermal decomposition of guanidium phosphate was examined.

Thermal Analysis. The DTA and TGA curves for diguanidium phosphate and monoguanidium phosphate are shown in Fig. 2. Diguanidium phosphate begins to decompose at about 235 °C, and a remarkable weight loss is observed. From the diagrams, it is supposed that guanidine radicals are decomposed above 300 °C. Monoguanidium phosphate begins to melt at 110 °C; consequently, an endothermic peak appears. A weight loss of 2—5% is observed at 110—250 °C. It is considered that, in this temperature range, the condensation occurs as a result of the thermal dehydration of monoguanidium phosphate,

5—5	20	225	120	26.9	22.7	2.62	5.80	18	18	19	45

and that the guanidine radical does not decompose very much.

Then, the weight changes in monoguanidium phosphate at various temperatures were measured. The results are shown in Fig. 3. Monoguanidium phosphate melts when heated; the rate of dehydration increases with the rise in the temperature, but it does not change very much at 125, 150, and 175 °C. The weight loss is 5.5% for 1 hr and 7.5% for 2 hr at 200 °C. In this case, the rate of thermal dehydration is affected by the considerable viscosity of the salt, so the melting salt was stirred while being heated.

Components of Products. The heating conditions of monoguanidium phosphate and the results of the analysis of the products are summarized in Table 1.

The contents of phosphorus and nitrogen in the product are not very different at 125—250 °C. In this temperature range, the atomic ratio of N to P in the products is roughly analogous to that (3 : 1) in the monoguanidium phosphate used as the starting material. The odor of ammonia is remarkable upon the thermal decomposition of the guanidium radical above 200 °C. It can be supposed that other cyanamide compounds are also formed upon the decomposition of guanidium phosphate. Therefore, a paper chromatogram of the product was compared with those of various cyanamide derivatives used as standard materials; they are shown in Fig. 4.

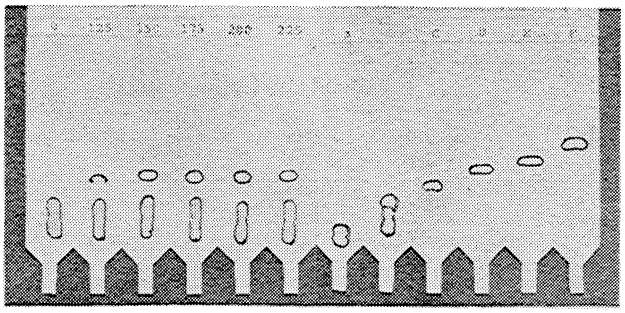

Fig. 4. Paper chromatogram for various cyanamide derivatives and heating products of monoguanidium dihydrogen phosphate.
Numerals in the photograph indicate heating temperatures (°C).
Symbols (A-F) indicate species of cyanamide compound, A: biguanidium sulfate, B: monoguanidium dihydrogen phosphate, C: guanylurea, D: urea, E: biuret, F: dicyandiamide.

In these results, the R_f values of the cyanamide derivatives are as follows: biguanidium sulfate (A), 0.10—0.14; monoguanidium dihydrogen phosphate (B), 0.16—0.27; guanylurea (C), 0.34; urea (D), 0.41; biuret (E), 0.44; and dicyandiamide (F); 0.54. From the values of the spots of the heating product, the existence of a little biguanide and guanylurea in addition to the guanidium salt, which is the main constituent, is recognized. Therefore, the guanidium salt is converted into biguanide by the separation of 1 mol of ammonium from its 2 mol; a part of the biguanide thus formed is also converted into guanylurea by hydration and deammonation. It can be considered that the formation of biguanide described above corresponds to a reverse reaction of the formation of guanidium salt from dicyandiamide and ammonium salt; an equilibrium exists between these reactions. The species of phosphate in the heating product are estimated by paper chromatography and ion-exchange chromatography (see Fig. 5 II); the results are summarized in Table 1,

II: Heating product of $H_5CN_3 \cdot H_3PO_4$ (Table 1, No. 4)
III: Reaction product between $H_4C_2N_4$ and $NH_4H_2PO_4$ (Table 2, No. 7)
Eluent for gradient elution method: 400 ml 0.2 mol/l KCl in mixing bottle, 500 ml 0.35 mol/l KCl in stock bottle.

while an ion-exchange chromatogram is shown in Fig. 5 (II). The orthophosphate used as the starting material is converted partially into pyrophosphate and triphosphate at 125—200 °C; besides, middlepoly phosphates (n=4—8) are formed above 225 °C.

Reaction between $H_4C_2N_4$ and $NH_4H_2PO_4$. Generally, guanidium salts are formed by a reaction between dicyandiamide and ammonium salt such as:

$$H_4C_2N_4 + 2NH_3 \cdot HX \rightleftharpoons 2H_5CN_3 \cdot HX$$

Sugino[2] has already reported the formation of guanidium phosphate by the heating of a mixture consisting of 1 mol of dicyandiamide, 1 mol of diammonium hydrogen phosphate, and about 4.5 mol of water in a sealed tube. The yields of guanidine were 25, 48, and 61% at 140, 160, and 180 °C respectively. His report concluded that the deficiency of NH_4^+ required for the reaction rises from the separation of ammonia from $(NH_4)_2HPO_4$ at high temperatures; simultaneously, the reactant is converted into an alkaline solution, and the dicyandiamide used is immediately decomposed by the alkaline solution. It was also described that the pyrolysis of phosphate occurs in this reaction system. However, the formation of condensed phosphates was not investigated at all. As has already been described, the use of the ammonium salt of a strong acid is suitable for the synthesis of guanidium salt; therefore, $NH_4H_2PO_4$ instead of $(NH_4)_2HPO_4$ was employed initially in this work.

Reaction under Atmospheric Pressure. The reaction between 1 mol of dicyandiamide and 2 mol of ammonium dihydrogen phosphate was examined under atmospheric pressure. Consequently, remarkable weight losses were observed upon heating for 60 min; 6.5% at 150 °C, 22.2% at 185 °C, 23.5% at 200 °C, and 27.0% at 220 °C. Thus, the product decomposes, and its volume expands up to fifty times. Therefore, it has been concluded that the synthesis of guanidium phosphate is difficult under atmospheric pressure. However, the reactant in an autoclave is expanded slightly under the effect of the gas produced by its thermal decomposition.

Components of the Reaction Products. The reaction conditions between dicyandiamide and ammonium dihydrogen phosphate under pressure, and the results of the analysis of the products, are summarized in Table 2. The majority of the products were soluble in water; the insoluble part increases slightly with the rise in the reaction temperature, being within 3.5% at 150—220 °C. The pH of a 1% aqueous solution is 6.3—7.6. The content of nitrogen is about 25% at 150—220 °C; it decreases slightly above 250 °C. The content of phosphorus in the soluble part of a product increases as a result of the large dehydration

with a rise in the reaction temperature, but it decreases with an increase in the insoluble part above 250 °C. The mole ratio of N to P in the mixture of dicyandiamide and ammonium dihydrogen phosphate is theoretically 3 : 1; however, the mole ratios of the products are less than 3 : 1, and the separation of ammonia from the reactant is observed.

Condensed Phosphate in Product. The results of the analysis of the condensed phosphates by means of paper chromatography are summarized in Table 2, while an example of an ion-exchange chromatogram is shown in Fig. 5 (III). The phosphate species from ortho- to decapolyphosphate can be separated by employing gradient elution chromatography,[5] but the ion-exchange chromatogram of the phosphates in a product is separated into eight fractions with tailing because of the effect of the cations connected to the cyanamide derivatives. That is, the reaction products consist of ortho-, pyro-, tri-, and middlepoly phosphates, which have polymerization degrees of about 4—10.

Formation of Cyanamide Derivatives. The paper chromatogram for a mixture of standard materials (S) and the products is shown in Fig. 6. The products do not change at 120 °C and give only the spot of dicyandiamide as the starting material. The proportion of dicyandiamide decreases at 140 °C, and the spots of guanidium salt, a little guanylurea, and biguanide appear. The spot of a little dicyandiamide remains at 150 and 170 °C, but most of the products are converted into guanidium salt; here, the spot of guanidium salt is long and elliptical, and it also possesses the position of the spot for biguanidium salt. As has been described previously, the biguanide is formed upon the heating of monoguanidium phosphate; therefore, although we do not say specifically that biguanidium salt is not formed in this reaction, the existence of its salt is not observed by the chemical analysis. In this case, the long ellipse of the spot seems to be characteristic of guanidium condensed phosphates. The only spot of guanidium condensed phosphates appeared at 185—220 °C. Another spot appeared in the position under the spot of dicyandiamide above 250 °C. Perhaps, this spot indicates the biuret formed

by the thermal decomposition of the products. The paper chromatography can distinguish various cyanamide derivatives in the product, but the color of the spot is not clear and its decolorization is remarkable. Therefore, the ion-exchange chromatography of cyanamide derivatives was also examined; an example of a chromatogram is shown in Fig. 7.

Dicyandiamide and biuret on a cation-exchange resin are easily carried away by water and are received almost quantitatively. On the other hand, guanylurea, guanidine, and biguanide can be separated by using hydrochloric acid in different concentration as eluates, though the yields expected from the description in a previous paper[8] are not obtained because of the decomposition of these compounds by the acid used. Therefore, the ion-exchange chromatography also confirms the existence of cyanamide derivatives in a product; it is employed for the estimation of dicyandiamide and biuret. The results are shown in Table 2.

The main product, guanidine, was estimated by means of the chemical analysis already described for cyanamide derivatives; the results are shown in Table 2. Dicyandiamide is converted into guanidium salt beginning at 140 °C, and the yield of guanidine increases with the increase in the reaction temperature. more than 70% of the dicyandiamide used is converted at 185—220 °C; the maximum is 78.9%. This value is improved remarkably as compared with the yields when diammonium hydrogen phosphate is used as the starting material. Upon a further increase in the reaction temperature, the decomposition of the product occurs, the yield of guanidine decreases, and a little biuret is formed. Guanylmelamine and melamine can be also estimated by chemical analysis; the former can not be detected in any products, while the latter exists in small amounts in the products at 130—140 °C.

The author wishes to thank Dr. Masahiro Kurabayashi for his helpful advice.

Synthesis of Anomeric Methyl 6-*O*-(L-Mycarosyl)-β-D-glucosaminides and 4-*O*-(L-Mycarosyl)-β-D-mycaminosides

Shinkiti KOTO, Kazuo YAGO, Shonosuke ZEN, and Satoshi ŌMURA*

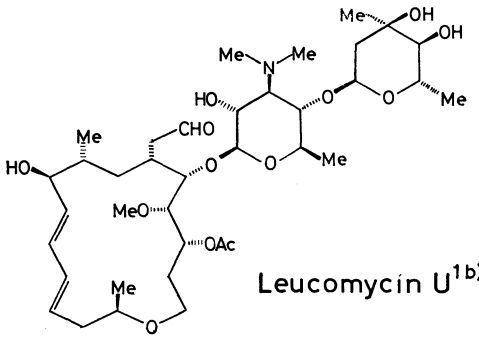
School of Pharmaceutical Sciences, Kitasato University, Shirokane, Minato-ku, Tokyo 108

**The Kitasato Institute, Shirokane, Minato-ku, Tokyo 108*

(Received September 27, 1972)

Condensation of 3,4-*O*-carbonyl-2,6-dideoxy-3-*C*-methyl-L-*ribo*hexopyranosyl chloride (III) with methyl 2-deoxy-2-(2,4-dinitroanilino)-β-D-glucopyranoside and the subsequent removal of blocking groups gave the anomeric isomers of methyl 6-*O*-(2,6-dideoxy-3-*C*-methyl-L-*ribo*hexopyranosyl)-2-amino-2-deoxy-β-D-glucopyranoside (VIIa, VIIb). On the other hand, the condensation of III with methyl 3,6-dideoxy-3-(*N*-methylcarboethoxyamino)-2-*O*-*p*-phenylazobenzoyl-β-D-glucopyranoside (XI) followed by removal of the acyl groups and *N*-methylation afforded the anomeric forms of methyl 4-*O*-(2,6-dideoxy-3-*C*-methyl-L-*ribo*hexopyranosyl)-3,6-dideoxy-3-dimethylamino-β-D-glucopyranoside (XVa, XVb).

Some 16-membered macrolide antibiotics such as magnamycin,[1] leucomycins,[2] spiramycin,[3] B-58945[4] and tylosin[5] have a unique structural feature. They contain a disaccharide moiety in which the neutral branched-chain sugar is linked glycosidically to the 3,6-dideoxy-3-dimethylamino-D-glucopyranose, D-mycaminose. Concerning the structural-activity relationship of macrolide antibiotics,[6] it was surmised that the sugar moiety could be important for antibiotic activity. Attempts to obtain the disaccharide moiety of leucomycins, 4-*O*-(2,6-dideoxy-3-*C*-methyl-α-L-*ribo*hexopyranosyl)-3,6-dideoxy-3-dimethylamino-β-L-glycopyranose, and confirm whether the moiety itself has any activity at all, failed, since 2,6-dideoxy-3-*C*-methyl-L-*ribo*hexopyranose, L-mycarose was preferentially released by acid hydrolysis from the disaccharide, which was expected to be cleaved from the lactone moiety. Thus as a part of chemical studies of macrolide sugar,[7] the syntheses of two model disaccharides have been carried out.[8] This paper deals with the preparation of 3,4-*O*-carbonyl-2,6-dideoxy-3-*C*-methyl-L-*ribo*hexopyranosyl chloride (III) and methyl 4-*O*-(2,6-dideoxy-3-*C*-methyl-L-*ribo*hexopyranosyl)-3,6-dideoxy-3-dimethylamino-β-D-glucopyranoside (XVa, XVb), as well as other related glycosides.



Leucomycin U[1b]

Methyl 3,4-*O*-carbonyl-2,6-dideoxy-3-*C*-methyl-α-L-*ribo*hexopyranosyl[9] (Ia) was hydrolyzed and converted into *p*-nitrobenzoyl derivative (II), which was then subjected to Zorbach's procedure[10] to generate III. The chloride was methanolyzed in the presence of silver oxide to give an anomeric mixture of Ia and Ib; β-anomer was predominant (α : β=2 : 3).

At first, the primary hydroxyl group of methyl 2-deoxy-2-(2,4-dinitroanilino)-β-D-glucopyranoside[11] was condensed with III. Condensation in nitromethane in the presence of mercuric cyanide gave an anomeric mixture (IVa and IVb); α-anomer was predominant (α : β=7 : 3). Condensation products (IVa and IVb) were characterized as the di-*O*-benzoate (Va and Vb). A similar condensation was performed in the presence of 2,6-lutidine,[12] and the predominant formation of the α-anomer was also observed (α : β= 5 : 3). The glycosidation at the C-6 position of 2-amino-2-deoxy-D-glucose was checked by PMR spectra of IVa and IVb in comparison with those of V's: signal of methine protons of C-3 and C-4 of glucosamine moiety shifted toward the lower field by *O*-benzoylation. The preferential glycosidation of the primary hydroxyl group in hexopyranoside has been reported.[13] Removal of the blocking groups of Va and Vb by successive methanolysis and hydrolysis gave methyl

6-*O*-(2,6-dideoxy-3-*C*-methyl-α-L-*ribo*hexopyranosyl)-3,6-dideoxy-3-dimethylamino-β-D-glucopyranoside (VIIa) and its anomer (VIIb).

Finally, the synthesis of methyl 4-*O*-(2,6-dideoxy-3-*C*-methyl-α-L-*ribo*hexopyranosyl)-3,6-dideoxy-3-dimethylamino-β-D-glucopyranoside (XVa) was carried out. 3,6-Dideoxy-3-dimethyl-amino-β-D-glucopyranoside hydrochloride monohydrate[14] was treated with acetyl bromide[15] to give 2,4-di-*O*-acetyl-3,6-dideoxy-3-dimethyl-amino-α-D-glucopyranosyl bromide hydrobromide (VIII), which was methanolyzed, in the presence of silver oxide, to afford methyl 3,6-dideoxy-3-dimethylamino-β-D-glucopyranoside (IX).[16] Compound IX was treated with ethyl chloroformate in the presence of sodium carbonate[17] and ethanolyzed to give methyl 3,6-dideoxy-3-(*N*-methylcarboethoxyamino)-β-D-glucopyranoside (X). Partial acylation of the hydroxyl groups of X with a molar *p*-phenylazobenzoyl chloride in pyridine and subsequent chromatographical separation gave methyl 3,6-dideoxy-3-(*N*-methylcarboethoxyamino)-2-*O*-(*p*-phenylazobenzoyl)-β-D-glucopyranoside (XI) in about 40% yield. The C-2-substitution of compound XI was checked by PMR. Direct partial acylation of IX gave no good results.

Chloride III was condensed with the partialy blocked XI in nitromethane in the presence of mercuric cyanide to afford two products, the α-glycoside XIIa and its β-anomer XIIb; α-glycoside was predominantly formed (α : β=3 : 2). The main product XIIa was converted into *O*-deblocked compound XIIIa which was then hydrolyzed into a free base XIVa. The reductive *N*-methylation with formaldehyde over palladium furnished desired methyl 4-*O*-(2,6-dideoxy-3-*C*-methyl-α-L-*ribo*hexopyranosyl)-3,6-dideoxy-3-dimethylamino-β-D-glucopyranoside (XVa). The minor product XIIb was subjected to the above sequence of reactions to give the β-glycoside XVb.

The anomeric configuration of the synthesized mycarosides VIIa, VIIb, XVa, and XVb was confirmed by the observation of their optical rotation and PMR spectra. PMR data of these compounds indicated that the in mycarosyl moiety had the normal C_4^1 conformation in water (Table 1). In each disaccharide-synthesis, predominant formation of α-glycoside was observed; this is often the case with the glycosidation of the 2-deoxy sugar.[10]

MIC's of the free base, VIIa, VIIb, XVa, and XVb, against *Bacillus subtilis* PCI 219, *Staphylococcus aureus* FDA 209P, *Sarcine Lutea* PCI, 1001, *Escherichia coli* NIHJ, and *Klebsiella pneumoniae* were more than 100 μg/ml.

Experimental

General Procedure. The solvent system used for tlc (Silica Gel No. 7731, Merck) and column chromatography over silica gel (Kanto Kagaku, Co.) was as follows : benzene : 2-butanone=(SA30) 30 : 1, (SA20) 20 : 1, (SA10) 10 : 1, (SA5) 5 : 1; benzene : acetone=(SB3) 3 : 1, (SB2) 2 : 1; acetone : methanol=(SC4) 4 : 1, (SC2) 2 : 1, by volume.

Melting points were determined with a Yanagimoto micro-melting point apparatus; uncorrected values are given. Optical rotations were measured with an Atago Polux apparatus in 1-dm tube and IR spectra with a JASCO IRA-1 spectrometer, absorptions being given in cm^{-1}. PMR spectra were determined with a Varian S-60T spectrometer. Elemental analyses were made with a Perkin-Elmer Model 240 Analyser apparatus.

C=$CDCl_3$/TMS, W=D_2O/TMSS

Methyl 3,4-O-Carbonyl-2,6-dideoxy-3-C-methyl-β-L-ribohexopyranoside (Ib). Cold phosgene solution in toluene (25%; 17 ml) was added to a solution of methyl 2,6-dideoxy-3-*C*-methyl-β-L-*ribo*hexopyranoside[18] (0.69 g) in a mixture of chloroform (30 ml) and pyridine (7 ml). The resulting mixture was stirred at room temperature overnight. Chloroform-extract was chromatographed with the solvent SA10 to give Ib (0.73 g; 92%), bp 110—115 °C/0.003 mmHg, mp 53—54 °C, $[\alpha]_D^{25}$+6.7° (*c* 1.0, $CHCl_3$), ν_{max}^{KBr}: 1795 (carbonate)

Found: C, 53.24; H, 6.99%. Calcd for $C_9H_{14}O_5$: C, 53.46; H, 6.84%.

3,4-O-Carbonyl-2,6-dideoxy-3-C-methyl-1-O-(p-nitrobenzoyl)-β-L-ribohexopyranose (II). Cold concd hydrochloric acid (21 ml) was added to a solution of Ia[9] (0.74 g) in a mixed solvent of dioxane (35 ml) and water (35 ml). The solution was kept standing at room temperature for 3 days, neutralized with sodium bicarbonate to pH 5.5, concentrated and then extracted with chloroform. The extract (0.48 g) treated with *p*-nitrobenzoyl chloride (0.53 g) in pyridine (4.0 ml) gave a crude product (1.2 g), which was crystallized with isopropyl alcohol to give II (0.51 g; 41%); mp 153—154 °C; $[\alpha]_D^{25}$+8° (*c* 2.6, $CHCl_3$); ν_{max}^{KBr}: 1785 (carbonate); 1730, (*p*-nitrobenzoyl); δ_{CDCl3}^{TMS}: 1.45 (3H, doublet; CH_3-5, J=6.0 Hz, 1.65 (3H, singlet; CH_3-3), 2.15 (1H, quartet; H-2a, $J_{1.2a}$=7.5 Hz, $J_{2e,2a}$=15.5 Hz), 2.70 (1H, quartet; H-2e, $J_{1.2e}$=4.0 Hz), 6.30 (1H, quartet; anomeric H).

Found: C, 53.45; H, 4.43; N, 4.16%. Calcd for $C_{15}H_{15}NO_8$: C, 53.42; H, 4.48; N, 4.15%.

3,4-O-Carbonyl-2,6-dideoxy-3-C-methyl-L-ribohexopyranosyl Chloride (III) and Its Methanolysis. II (0.750 g) was dissolved in dichloromethane (40 ml) saturated with hydrogen chloride at 0 °C and the mixture was kept standing at 5 °C for 40 min. *p*-nitrobenzoic acid (0.36 g; 97%) was filtered off, the resulting solution evaporated to dryness and co-evaporated with toluene three times to give III,[19] which was immediately used for the following glycosidation.

Freshly prepared III from II (216 mg) was stirred in methanol (2.0 ml) in the presence of silver oxide (152 mg) at room temperature for one hour in the dark, filtered and chromatographed with the solvent SA20 to give Ia (39 mg; 30%) and Ib (60 mg; 46%), which were identified by means of elemental analyses, mixed melting points and IR spectra (KBr), respectively.

Methyl 6-O-(3,4-O-Carbonyl-2,6-dideoxy-3-C-methyl-α-L-ribohexopyranosyl)-3,4-O-benzoyl-2-deoxy-2-(2,4-dinitroanilino)-β-D-glucopyranoside (Va) and Methyl 6-O-(3,4-O-Carbonyl-2,6-dideoxy-3-C-methyl-β-L-ribohexopyranosyl)-3,4-O-benzoyl-2-deoxy-2-(2,4-dinitroanilino)-β-D-glucopyranoside (Vb). By condensation with mercuric cyanide. III, prepared from II (0.75 g) was stirred with methyl 2-deoxy-2-(2,4-dinitroanilino) β-D-glucopyranoside[11] (1.00 g) in nitromethane (10 ml) in the presence of mercuric cyanide (0.750 g) at room temperature for 20 hr. The mixture was diluted with chloroform, filtered, and then chromatographed with the solvent SB3. After elution of high R_f substances, a compound (IVb) of R_f 0.33 (0.095 g; 8.1% from II) and that (IVa) of R_f 0.25 (0.220 g; 19%) were obtained. IVa (200 mg) was treated with benzoyl chloride (0.2 g) in pyridine (2 ml), chromatographed with the solvent SA20 and crystallized with ethanol to give yellow Va (187 mg; 67%), mp 123—124 °C, $[\alpha]_D^{25}$−13.5° (*c* 0.9, $CHCl_3$), ν_{max}^{KBr}: 1800 (carbonate); 1730 (benzoyl); 1620, 1530, 1345 (dinitrophenyl). Similarly, IVb (90 mg) was benzoylated to give yellow Vb (95 mg; 76%), mp 118—120 °C, $[\alpha]_D^{25}$+16° (*c* 0.9, $CHCl_3$), ν_{max}^{KBr}: 1810 (carbonate); 1733 (benzoyl); 1620, 1525, 1340 (dinitrophenyl). PMR spectra of Va and Vb had multiplets of a couple of methine protons at δ 5.6—6.0, whereas those of IVa and IVb had no signal in this region.

Found: (Va) C, 56.78; H, 4.74; N, 5.96%. (Vb) C, 56.85; H, 4.75; N, 5.46%. Calcd for $C_{35}H_{35}N_3O_{15}$: C, 56.99; H, 4.78; N, 5.70%.

Methanolysis of IVa and IVb with methanolic hydrochloric acid[18] gave Ia and Ib and methyl 2-deoxy-2-(2,4-dinitroanilino)-β-D-glucopyranoside which were detected by tlc.

By condensation with 2,6-lutidine. III, prepared from II (0.78 g) was condensed with the methyl glucosaminide (1.1 g) in nitromethane (10 ml) in the presence of 2,6-lutidine (0.29 ml) for 20 hr at room temperature to yield IVa (0.170 g 14%) and IVb (0.095 g; 7.8%). Each compound was successively benzoylated to give Va and Vb, respectively. These compounds were identified with the above Va and Vb, respectively, by means of elemental analyses and mixed melting points.

Methyl 6-O-(2,6-Dideoxy-3-C-methyl-α-L-ribohexopyranosyl)-2-deoxy-(2,4-dinitroanilino)-β-D-glucopyranoside (VIa). Va (104 mg) was treated with diluted sodium methoxide (0.14 M; 0.7 ml) at room temperature overnight, neutralized with dil. acetic acid (1% in methanol), purified by chromatography with the solvent SB2, and crystallized with benzene to give yellow VIa (51 mg; 72%), mp 116—118 °C, $[\alpha]_D^{25}$ −13° (*c* 1.3, $CHCl_3$). The characteristic bands of carbonate and benzoyl were absent in the IR spectrum (KBr), δ_{CDCl3}^{TMS}: 1.25

18) S. Ōmura, M. Katagiri, H. Ogura, and T. Hata, *Chem. Pharm. Bull.* (Tokyo), **15**, 1529 (1967).

19) Optical rotation could not be observed because of rapid formation of some dark green substance.

singlet; CH_3-3′), 1.31 (3H, doublet; CH_3-5′, J=6.0 Hz), 3.45 (3H, singlet; OCH_3), 4.42 (1H; H-1, $J_{1,2}$=6.5 Hz).

Found: C, 47.87; H, 5.77; N, 8.26%. Calcd for $C_{20}H_{29}N_3O_{12}$: C, 47.71; H, 5.81; N, 8.35%.

Methyl 6-O-(2,6-Dideoxy-3-C-methyl-β-L-ribohexopyranosyl)-2-deoxy-2-(2,4-dinitroanilino)-β-D-glucopyranoside (VIb). Vb (58 mg) was treated with dil. sodium methoxide to give VIb (32 mg; 81%), mp 114—116 °C, $[\alpha]_D^{25}$ −4° (*c* 0.7, $CHCl_3$). $\delta_{CDCl_3}^{TMS}$: 1.31 (3H, singlet; CH_3-3′), 1.33 (3H, doublet; CH_3-5′, J=6.5 Hz), 3.56 (3H, singlet; OCH_3), 4.36 (1H, doublet; H-1, $J_{1,2}$=6.0 Hz).

Found: C, 48.23; H, 6.01; N, 7.76%. Calcd for $C_{20}H_{29}N_3O_{12}$: C, 47.71; H, 5.81; N, 8.35%.

Methyl 6-O-(2,6-Dideoxy-3-C-methyl-α-L-ribohexopyranosyl)-2-amino-2-deoxyl-β-D-glucopyranoside (VIIIa). VIa (50 mg) was treated with Dowex 1X2 (OH) (*ca.* 1 ml) in moist acetone[20] and a crude syrup was chromatographed over the same resin to give a ninhydrin-positive hard syrup of VIIa (27 mg; 81%), which was taken up with a small amounts of methanol and precipitated from isopropyl alcohol, diisopropyl ether, and *n*-hexane to give colorless hygroscopic powder, mp 100 °C; $[\alpha]_D^{25}$ −91° (*c* 1.1, H_2O); $\delta_{D_2O}^{TMSS}$: 1.22 (3H, singlet; CH_3-3′), 1.28 (3H, doublet; CH_3-5′, J=6.5 Hz), 3.54 (3H, singlet; OCH_3), 4.27 (1H; doublet; H-1, $J_{1,2}$=8.5 Hz).

Found: C, 48.38; H, 8.22; N, 3.94%. Calcd for $C_{14}H_{27}NO_8\cdot 1/2H_2O$: C, 48.54; H, 8.14; N, 4.04%.

Methyl 6-O-(2,6-Dideoxy-3-C-methyl-β-L-ribohexopyranosyl)-2-amino-2-deoxy-β-D-glucopyranoside (VIIb). VIb (20 mg) was treated as above to give a hard syrup of VIIb (9.2 mg; 69%); which was treated with *n*-hexane to afford colorless hygroscopic powder, mp 100 °C, $[\alpha]_D^{25}$ −19° (*c* 0.4, H_2O). $\delta_{CDCl_3}^{TMS}$: 1.25 (3H, singlet; CH_3-3′), 1.26 (3H, doublet; CH_3-5′, J=6.0 Hz), 3.55 (3H, singlet; OCH_3), 4.28 (1H, doublet; H-1, J=8.0 Hz).

Found: C, 47.25; H, 8.31; N, 3.78%. Calcd for $C_{14}H_{27}NO_8\cdot H_2O$: C, 47.31; H, 8.22; N, 3.94%.

2,4-Di-O-Acetyl-3,6-dideoxy-3-dimethylamino-α-D-glucopyranosyl Bromide Hydrobromide (VIII). 3,6-Dideoxy-3-dimethylamino-β-D-glucopyranose hydrochloride monohydrate[14] (2.32 g) was added to ice-cooled acetyl bromide (5 ml). The mixture was kept standing in a sealed vessel at room temperature overnight, evaporated and co-evaporated thrice with toluene to give crystalline residue, which was triturated with *n*-hexane to give VIII (3.85 g; 97%), mp 72—76 °C, $[\alpha]_D^{25}$ +100° (*c* 0.7, $CHCl_3$); $\delta_{CDCl_3}^{TMS}$: 1.27 (3H, doublet, CH_3-5), 2.35 (6H, singlet; $OCOCH_3$), 3.03 (6H, broad, $\overset{+}{N}CH_3$), 6.66 (1H, doublet; H-1, $J_{1,2}$=4.0 Hz).

Found: C, 33.51; H, 4.83; N, 3.22%. Calcd for $C_{12}H_{20}NO_5Br\cdot HBr$: C, 34.39; H, 5.05; N, 3.34%.

Methyl 3,6-Dideoxy-3-dimethylamino-β-D-glucopyranoside (IX). VIII (1.91 g) was stirred in methanol (67 ml) in the presence of silver oxide (2.4 g) and anhydrous magnesium sulfate (5 g) at room temperature for 2 hr, filtered, and concentrated to give a residue which was treated with dil. sodium methoxide (0.05 M; 40 ml) for 2 hr at room temperature. The mixture was evaporated below 20 °C and then chromatographed with the solvent SC4 to give IX (0.74 g; 79%), mp 117—119 °C, which was used for the subsequent reaction. Sublimation at 95—100 °C under 0.02 mmHg gave an analytical sample,[21] mp 123—125 °C, $[\alpha]_D^{25}$ −35° (*c* 1.4, H_2O). Lit,[16] mp 126—126.5 °C, $[\alpha]_D^{25}$ −39° (*c* 1, H_2O).

Methyl 3,6-Dideoxy-3-(N-methylcarboethoxyamino)-β-D-glucopyranoside (X). IX (0.44 g) was stirred in ethyl chloroformate (10 ml) in the presence of powdery sodium carbonate (4.2 g) at room temperature for five days, filtered, evaporated, and co-evaporated thrice with toluene at 80 °C to give a syrup which was ethanolyzed with dil. sodium ethoxide (0.1 M, 38 ml) at room temperature overnight. The mixture was neutralized with acetic acid, evaporated and chromatographed with the solvent SB2 to give a homogeneous oil of X (0.47 g; 83%), $[\alpha]_D^{25}$ −1° (*c* 1.5, $CHCl_3$); $\delta_{CDCl_3}^{TMS}$: 1.27 (3H, triplet; $C\underline{H}_3CH_2O$-, J=7.0 Hz), 1.36 (3H, doublet; CH_3-5, J=5.7 Hz), 2.89 (3H, singlet; N-CH_3), 3.55 (3H, singlet; OCH_3), 4.14 (2H, quartet; $CH_3C\underline{H}_2O$-), 4.27 (1H, doublet; anomeric H, $J_{1,2}$=7.3 Hz).

After the elution of X, a small quantity of IX was recovered with the solvent SC4.

Methyl 3,6-Dideoxy-3-(N-methylcarboethoxyamino)-2-O-p-phenylazobenzoyl-β-D-glucopyranoside (XI). A well stirred mixture of *p*-phenylazobenzoyl chloride (2.7 g) in pyridine (60 ml) was added to a solution of X (27 g) in pyridine (40 ml) for 80 min at 2 °C under vigorous agitation and then the temperature was allowed to rise gradually up to 17 °C. The mixture was further stirred for 2 days at the same temperature, treated with a small amount of water, evaporated and then chromatographed with the solvent SA5. The fraction having R_f 0.35 was crystallized with diisopropyl ether to give orange XI (1.8 g; 37%), mp 127—131 °C. Recrystallization form the same solvent gave a single product, mp 134—136 °C. $[\alpha]_D^{25}$ +57° (*c* 1.3, $CHCl_3$); 3410 (OH), 1727 (ester), 1680 (urethane); $\delta_{CDCl_3}^{TMS}$: 0.75 (3H, triplet; $C\underline{H}_3CH_2O$-, J=7.0 Hz), 1.53 (3H, doublet; CH_3-5, J=5.7 Hz), 2.83 (3H, singlet; NCH_3), 3.37 (3H, singlet; OCH_3), 4.72 (1H, doublet; anomeric H, J=7.5 Hz), 4.93 (1H, quasi-triplet; H-3, $J_{2,3}=J_{3,4}$=11.0 Hz), 5.57 (1H, quartet; H-2), Assignments of H-1, H-2, and H-3 were checked by the measurement at 100 MHz (Varian HA-100).

Found: C, 61.27; H, 6.22; N, 8.96%. Calcd for $C_{24}H_{29}N_3O_7$: C, 61.14; H, 6.20; N, 8.91%.

From the mother liquor, a second crop (0.4 g) having a melting point of 100—114 °C was obtained, but this gave no crystals when dissolved in diisopropyl ether. In this PMR spectrum, the quartet at δ 5.57 was entirely deformed by the appearance of new broad signals at δ 5.05—5.20, probably coming form H-4 of a 4-*O*-substituted minor product.

Methyl 4-O-(3,4-O-Carbonyl-2,6-dideoxy-3-C-methyl-α-L-ribohexopyranosyl-3,6-dideoxy-3-(N-methylcarboethoxyamino)-2-O-(p-phenylazobenzoyl)-β-D-glucopyranoside (XIIIa) and Methyl 4-O-3,4-Carbonyl-3,6-dideoxy-3-C-methyl-β-L-ribohexopyranosyl)-3,6-dideoxy-3-(N-methylcarboethoxyamino)-2-O-phenylazobenzoyl-β-D-glucopyranoside (XIIb). Chloride III, prepared from II (0.70 g) was stirred with XI (0.70 g) in nitromethane (5 ml) in the presence of mercuric cyanide (0.70 g) for 2 days at room temperature, diluted with chloroform filtered and evaporated, and then chromatographed with the solvent SA1O to give two crude products; a glass of R_f 0.45 and that of R_f 0.33. The main product R_f 0.33 was refined by preparative tlc with the solvent SA20 with the multiple development technique, and triturated with diisopropyl ether containing *n*-hexane to give orange amorphous XIIa (0.15 g; 11%), mp 97—99 °C, $[\alpha]_D^{25}$ +2° (*c* 1.0, $CHCl_3$); ν_{max}^{KBr}: 1805 (carbonate), 1733 (ester), 1700 (urethane); $\delta_{CDCl_3}^{TMS}$: 1.04 (3H, triplet; $C\underline{H}_3CH_2O$-, J=7.0 Hz), 1.52 (3H, singlet; CH_3-3′), 2.87 (3H, singlet; NCH_3), 3.48 (3H, singlet; OCH_3), 4.55 (1H, doublet; H-1, $J_{1,2}$=8.0 Hz).

The minor product was worked up as above with the solvent SA30 to give orange crystalline XIIb (0.095 g; 7%), 176—178 °C, $[\alpha]_D^{25}$ +105° (*c* 1.0, $CHCl_3$); ν_{max}^{KBr}: 1805 (carbonate), 1720 (ester), 1705 (urethane); $\delta_{CDCl_3}^{TMS}$: 1.12 (3H, triplet; $C\underline{H}_3CH_2O$-, J=7.0 Hz), 1.51 (3H, singlet;

XIIIb (12 mg) was hydrolyzed as above to give a hard syrup of XIVb (8.0 mg; 81%), which was crystallized with diisopropyl ether to give colorless crystals, mp 195—197 °C, $[\alpha]_D^{25}$ +8° (*c* 0.7, CH_3OH).

Found: C, 53.17; H, 8.68; N, 4.12%. Calcd for $C_{15}H_{29}NO_7$: C, 53.72; H, 8.71; N, 4.18%.

Methyl 4-O-(2,6-Dideoxy-3-C-methyl-α-L-ribohexopyranosyl)-3,6-dideoxy-3-dimethylamino-β-D-glucopyranoside (XVa). XIVa (11 mg) was dissolved in ethanol (2 ml) containing formaline (37%; 0.1 ml), hydrogenated over palladium black (10 mg) under hydrogen pressure of 50 lb/in² (initial) for 18 hr at room temperature, filtered, evaporated to dryness and then chromatographed over Dowex 1X2 (OH), irrigated with carbon dioxide-free water to give a homogenous ninhydrin-negative syrup of XVa (11 mg; 96%),[22] which could not be crystallized by any treatment; $[\alpha]_D^{25}$ −93° (*c* 1.1, C_2H_5OH); $\delta_{D_2O}^{TMSS}$: 1.22 (3H, singlet; CH_3-3′), 1.30 6H, doublet; CH_3-5, CH_3-5′, *J*=6.5 Hz), 2.48 (6H, singlet; NCH_3), 3.54 (3H, singlet; OCH_3), 4.24 (1H, doublet; H-1, $J_{1,2}$=8.0 Hz).

Methyl 4-O-(2,6-Dideoxy-3-C-methyl-β-L-ribohexopyranosyl)-3,6-dideoxy-3-dimethylamino-β-D-glucopyranoside (XVb). XIVb 9.0 mg) was *N*-methylated as above to give a ninhydrin-negative glass of XVb (8.5 mg; 91%), $[\alpha]_D^{25}$ +14° (*c* 0.9, C_2H_5OH); $\delta_{D_2O}^{TMSS}$: 1.26 (3H, singlet; CH_3-3′), 2.43 (6H, singlet; NCH_3), 3.53 (3H, singlet; OCH_3), 4.31 (1H, doublet; H-1, $J_{1,2}$=8.0 Hz). Trituration with *n*-hexane turned XVb into powder, mp 134—136 °C (sintered at 125 °C).

Found: C, 53.23; H, 8.72; N, 3.82%. Calcd for $C_{16}H_{31}NO_7 \cdot 1/2H_2O$: C, 53.61; H, 9.00; N, 3.91%.

When a sample of XVa and XVb was methanolyzed with dil. methanolic hydrochloric acid,[18] formation of methyl 2,6-dideoxy-3-*C*-methyl-α- and β-*ribo*hexopyranoside was observed by tlc with the solvent SB2. Hot hydrolysis of XVa and XVb with dil. hydrochloric acid[18] gave 3,6-dideoxy-3-dimethylamino-D-glucopyranose, which was detected by tlc with the solvent SC2.

The authors wish to thank Toyo Jozo Co. for the supply of Leucomycin bulk, and Mr. K. Kushida of Nichiden-Varian for measurement of the 100 MHz PMR spectrum.

22) A sample of methyl 2,6-dideoxy-3-*C*-methyl-α- and β-*ribo*hexopyranoside was subjected to hydrolysis with hot aqueous barium hydroxide and subsequent reductive *N*-methylation. Its perfect stability under this treatment was confirmed by observation of tlc. On the other hand, Compound X gave IX by this treatment, with no by-products.

Photoinduced Reactions. LXVIII. Photochemical Dehydrogenation[1] of Imidazolines to Imidazoles

Teruo MATSUURA, Yoshikatsu ITO, and Isao SAITO

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received March 22, 1973)

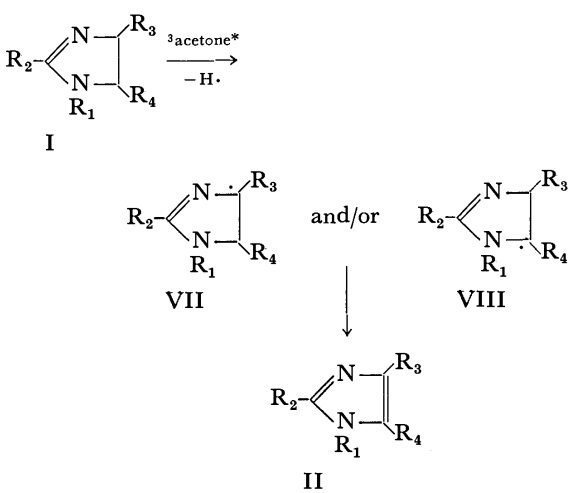
Imidazolines were found to be dehydrogenated to imidazoles by irradiation at 2537 Å or above 2900 Å in acetone. The n,π^* triplet acetone acts as a hydrogen-abstracting agent giving 4- and/or 5-imidazolinyl radicals which in turn are transformed into imidazoles. This scheme is supported by the fact that the AIBN-initiated dehydrogenation of imidazolines gave corresponding imidazoles, that oxygen quenched the photochemical dehydrogenation, and that in some cases coupling products between the imidazolinyl and the acetone ketyl radicals were formed. Various data indicate that the imidazolinyl radical reverts to the parent imidazoline by hydrogen transfer from the acetone ketyl radical during the course of photolysis.

There are several reports on the methods of dehydrogenation of imidazolines leading to the corresponding imidazoles.[2] These methods involve dehydrogenation with catalysts such as nickel, iron, platinum, and palladium or with hydrogen acceptors such as sulfur and selenium. It is well-known that a variety of carbonyl compounds, in their excited states, can abstract hydrogen from various hydrogen-donating substrates.[3] However, examples of the photochemical dehydrogenation of hydroaromatic compounds to aromatic compounds are relatively few,[4] since simple carbonyl compounds often photochemically react with a hydrogen donor to form coupling products.[5] In the present paper we report a simple method for dehydrogenating imidazolines to imidazoles by irradiation in acetone.

Results and Discussion

Irradiation of an acetone solution of imidazolines (I) with a low-pressure mercury lamp (mainly 2537 Å) under nitrogen atmosphere followed by column chromatography of the reaction products gave corresponding imidazoles (II) in reasonable yields. The results are summarized in Table 1. 2-Methylimidazolines (Ia and Ib) gave dehydro-coupling products (III, IV and V) besides the corresponding imidazoles, but 2-hydroxyimidazoline (Ii) only a coupling product VI. It should be noted that both *cis*- (If; amarine) and *trans*- (Ig; isoamarine) 2,4,5-triphenylimidazolines underwent *cis*, *trans*-isomerization being accompanied by dehydrogenation to 2,4,5-triphenylimidazole (IIf; lophine). Acetone pinacol was isolated in low yield only in cases of Ia and Ib but not in all the other cases.

Oxygen was found to quench the formation of an imidazole. Thus, irradiation of 2-methylimidazoline (Ia) under similar conditions except under bubbling oxygen instead of nitrogen gave 2-methylimidazolinium acetate (12%) besides some recovered starting material (27%) but no 2-methylimidazole (IIa). Irradiation of an acetone solution of Ia, which had been degassed by four freeze-thaw cycles at 10^{-4} mm under cooling with liquid nitrogen, gave no effect on the reaction, and the IIa, IIIa, and pinacol were obtained in the same ratio as that under nitrogen. On irradiation in benzene or isopropyl alcohol under nitrogen, these imidazolines (Ib, Ic, Id, and Ie) were recovered unchanged except that *cis*, *trans*-isomerization was observed with amarine (If) and isoamarine (Ig).[6] Thus it is considered that the imidazoles were formed *via* 4-(VII) and/or 5-(VIII) imidazolinyl radicals which were formed from the imidazolines by hydrogen abstraction with the n,π^* triplet state of acetone as shown in Scheme 1.



I VII VIII II

Scheme 1.

In order to confirm this scheme, hydrogen abstraction of 2-methylimidazoline (Ia), amarine (If), and isoamarine (Ig) by the 1-cyano-1-methylethyl radical generated by thermolysis of azobisisobutyronitrile (AIBN) was carried out. The corresponding imidazoles were obtained, their yields being dependent on the

trans-2,4,5-Triphenyl- (Ig)	2.68	8.66	3.24	3.2
	2.73	4.89	1.79	2.0

a) Reaction conditions: 68±1.5°C in acetonitrile under nitrogen. b) Based on the starting imidazoline.

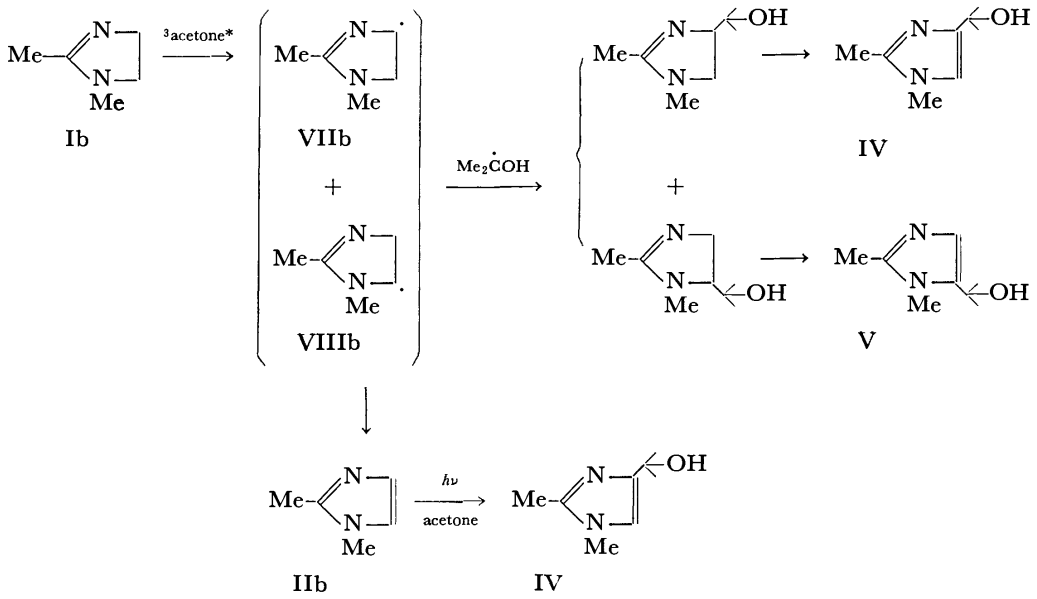
AIBN concentration and also on the structural feature of the imidazolines (Table 2). A difference between the reactivities of Ia and If may be due to the magnitude of the resonance stabilization of the intermediate radicals, VII and/or VIII: *i.e.*, radicals VIIf and VIIIf are obviously more stabilized by a phenyl group at positions 4 and 5, respectively. The slower dehydrogenation rate in Ig compared with If is probably due to a steric repulsion between a phenyl group at position 5 (or 4) and 1-cyano-1-methylethyl radical produced from AIBN in the abstraction of a hydrogen atom at position 4 (or 5).

The mechanism of Scheme 1 involving the imidazolinyl radical (VII or VIII), which is formed from the starting imidazoline by hydrogen abstraction with the n,π^* triplet state of acetone, is supported by the following facts. (1) Imidazoles are also formed by the hydrogen abstraction reaction initiated by AIBN (Table 2). (2) Oxygen, a triplet quencher,[8] inhibits the formation of 2-methylimidazole from 2-methylimidazoline. (3) In some cases coupling products such as III, IV, V, and VI are formed as byproducts, which obviously result from coupling between the acetone ketyl radical and the imidazolinyl radical VII or VIII followed by dehydrogenation of the coupling products in cases of III, IV, and V. Matsuura *et al.* have found that irradiation of 1,2-dimethylimidazole (IIb) in acetone gives exclusively IV, which is formed *via* an unstable oxetane intermediate.[9] Thus the formation of an almost equal amount of IV and V from Ib should result form the coupling between the acetone ketyl radical and the imidazolinyl radicals VIIb and VIIIb, although it is possible that a part of IV formed results from the photochemical addition of acetone to IIb (Scheme 2).

2-Methylimidazoline (Ia) is more susceptible to photochemical dehydrogenation than amarine (If) but less susceptible to the AIBN-initiated one (Tables 1

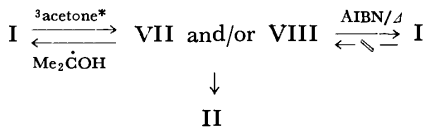
8) W. M. Moore, G. S. Hammond, and R. P. Foss, *J. Amer. Chem. Soc.*, **83**, 2789 (1961).

9) T. Matsuura, A. Banba, and K. Ogura, *Tetrahedron*, **27**, 1211 (1971).



Scheme 2.

and 2). The *cis,trans*-isomerization of amarine (If) and isoamarine (Ig), which is accompanied by dehydrogenation to lophine (IIf), occurs only during irradiation in acetone but not during the AIBN-initiated free radical reaction. This can be interpreted by assuming that, in the case of photoreaction, free radical intermediates VII and/or VIII revert in part to the parent imidazoline by a hydrogen transfer from the acetone ketyl radical[10,11] which is known to act as a hydrogen donor as seen in the photoreduction of benzophenone with isopropyl alcohol,[14] and that, in the absence of such a hydrogen donor (AIBN-initiated reaction), the intermediate radicals VII and/or VIII are transformed to an imidazole II without reverting to the parent imidazoline I (Scheme 3). As regards the overall reaction from I to II, the imidazole-forming step (VII or VIII→II) may be more important in the photoreaction involving a reverse process from VII or VIII to I than in the AIBN-reaction without such a process. In contrast to this, the raidcal-forming step may be more important in the AIBN-reaction than in the photoreaction.[15]



Scheme 3.

For the sake of confirmation, the total π electron energies (E_π) of I, VII, and II were calculated by the HMO method.[16,18] It was assumed from the calculated E_π values for VII and VIII that VII contributes more than VIII to the free radical intermediate. Comparisons of the values of $\Delta E_{\pi 1}=E_\pi(\mathrm{VII})-E_\pi(\mathrm{I})$ and $\Delta E_{\pi 2}=E_\pi(\mathrm{II})-E_\pi(\mathrm{VII})$ with the yields of the imidazoles from the imidazolines I are given in Table 3. The yield of the photochemical conversion to imidazoles decreases in the order Ia>If>Ib>Ic. This is qualitatively correlated with $\Delta E_{\pi 2}$ but not with $\Delta E_{\pi 1}$. A decrease in the yield of the photochemical conversion to imidazoles seems to be general for 1-alkylimidazolines as seen in the case of Ib, Id and Ie (Table 1). The yield of the AIBN-initiated conversion to imidazoles seems to be correlated with $\Delta E_{\pi 1}$ rather than $\Delta E_{\pi 2}$. This led us to conclude that in the photochemical de-

10) In the cases of amarine (If) and isoamarine (Ig), it was shown that intermediate radicals VIIf and/or VIIIf revert only to amarine but not to isoamarine.[7] Formation of isoamarine (Ig) during the course of irradiation of amarine was found to arise from the excited state of amarine itself.[6,7]

11) The bond dissociation energy of the acetone ketyl radical ($Me_2\dot{C}O$–H) appears lower than that of $Me_2C(CN)$–H, since that of $\cdot CH_2O$–H (29 kcal/mol[12]) is much lower than that of H–CH_2CN (*ca.* 86 kcal/mol[13]).

12) M. K. Phibbs and B. deB. Darwent, *J. Chem. Phys.*, **18**, 495 (1950).

14) E. S. Huyser and D. C. Neckers, *J. Amer. Chem. Soc.*, **85**, 3641 (1963).

15) This is similar to the notion of a successive reaction:

$$A \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} B \qquad B \xrightarrow{k_2} C$$

If the process B→A is much faster than the process B→C, the latter should be rate-determining (case 1). If on the contrary B→A is much slower than B→C, the former process should be rate-determining (case 2). The photochemical reaction is similar to case 1 and the AIBN-initiated one to case 2.

16) Parameters were selected from those presented by Streitwieser[17a] except for parameters concerning sulfur bonds.[17b] The use of the E_π value for VIII for the following discussion does not alter the conclusion.

17) a) A. Streitwieser, Jr., "Molecular Orbital Theory," John Wiley & Sons, Inc., New York, N. Y. (1961), p. 117. b) T. Yonezawa, N. Nagata, H. Kato, and A. Imamura, "Ryoshi-Kagaku Nyumon," Kagaku Dojin, Tokyo (1968), p. 56.

18) An attempt to correlate the relative rates of hydrogen abstraction from a series of arylmethanes by the trichloromethyl radical or bromine atom with the change in HMO ΔE_π value has been reported. [J. D. Unruh and G. J. Gleicher, *J. Amer. Chem. Soc.*, **93**, 2008 (1971); R. B. Roark, J. M. Roberts, D. W. Croom, and R. D. Gillion, *J. Org. Chem.*, **37**, 2042 (1972)].

19) When the twisted angle is assumed to be 25°, $\Delta E_{\pi 2}$ value is calculated to be 2.58445β. G. Rasch [*Z. Phys. Chem.*, **219**, 180 (1962)] assumed the twisted angle of phenyl groups of *cis*-stilbene as $26\pm4°$.

TABLE 3. COMPARISON OF THE YIELD OF IMIDAZOLES (II) FROM IMIDAZOLINES (I) WITH $\Delta E_{\pi 1}$ AND $\Delta E_{\pi 2}$ VALUES

Imidazoline	Yield of imidazole (%)			$\Delta E_{\pi 2}(\beta)$[d]	$\Delta E_{\pi 1}(\beta)$[d]
	Photochemical		AIBN-initiated[c]		
	High concn[a]	Low concn[b]			
2-Methyl- (Ia)	60	20.0±0.5	6	2.58100	0.67520
1,2-Dimethyl- (Ib)	22	—	—	2.55070	0.69020
2-Phenyl- (Ic)	15	—	—	2.52744	0.73246
cis-2,4,5-Triphenyl- (If)	35	16.1±1.2	26	2.53995[e]	1.21005

a) Taken from the data of Table 1 (irradiation time, 24 hr). b) A *ca.* 10^{-3} M acetone solution was externally irradiated using a merry-go-round apparatus and the yields of imidazoles formed were determined by UV analysis. c) Taken from the data of Table 2. d) See text. e) Calculation was carried out by assuming that two phenyl groups at positions 4 and 5 are twisted 30° from the plane of the imidazole ring.[19]

TABLE 4. DEUTERIUM INCORPORATION INTO 2-PHENYLIMIDAZOLINE (Ic) DURING PHOTOLYSIS IN THE PRESENCE OF MeOD AND D_2O IN ACETONE

Concn of Ic ($\times 10^{-2}$ M)	Solvent			Irradn. time (hr)	Ic-d_1[a] (%)
	Acetone	MeOD	D_2O		
4.75	5	10	0	41[b]	0.2±0.1
3.63	5	10	5	163[c]	1.9±0.1
3.43	5	10	5	245[c]	1.6±0.2

a) Deuterium analysis was done by mass-spectrometry. c) Externally irradiated with a 100W high-pressure mercury lamp (Pyrex filter). c) Externally irradiated with a 450W high-pressure mercury lamp (Pyrex filter).

hydrogenation the resonance stabilization of the product imidazoles, represented by a higher $\Delta E_{\pi 2}$ value, is more important, and that in the AIBN-initiated dehydrogenation the resonance stabilization of the intermediate free radical VII, represented by a higher $\Delta E_{\pi 1}$ value, is more important. Accordingly, these calculated data are not inconsistent with the mechanism shown in Scheme 3.

For the sake of confirming the back reaction of the imidazolinyl radicals VII or VIII to I by a hydrogen transfer from the acetone ketyl radical (Scheme 3), an acetone solution of 2-phenylimidazoline (Ic) was irradiated in the presence of MeOD and D_2O with different periods. The incorporation of deuterium into the recovered Ic obviously indicates that the back hydrogen transfer to VII or VIII by the acetone ketyl radical occurs in the photochemical reaction (Table 4). The deuterium incorporation into Ic was not so much as expected. This is probably due to a slower exchange reaction between the acetone ketyl radical and MeOD or D_2O than the back-transfer reaction.

Experimental

All the melting points are uncorrected. The NMR spectra were taken on an NEVA T-60 spectrometer using tetramethylsilane as an internal standard. The IR spectra were measured on a JASCO IRS spectrometer. The UV spectra were obtained with a JASCO ORD/UV-5 spectrometer. Vapor phase chromatography (vpc) was carried out with a Shimadzu GC-2C apparatus on Apiezon Grease L using helium as a carrier gas. Thin layer chromatography (tlc) was carried out with Merck "Kieselgel GF 254," "Aluminiumoxid GF 254" or Nagel "Cellulosepulver MN 300 G," using UV light and iodine vapor for compound detection. Column chromatography was carried out with Mallinckrodt silicic acid (100 mesh).

Starting Materials. Commercial 2-Methylimidazoline (Ia) and 2-phenylimidazoline (Ic) were used after recrystallization from acetone. Commercial ethylenethiourea (Ih) and ethyleneurea (Ii) were used without further purification.

1,2-Dimethylimidazoline (Ib) was prepared by the method of King and McMillan.[20] To 5 g of *N*-methylethylenediamine was added 7 g of acetic anhydride at room temperature and the mixture was heated at 170—190 °C for 1 hr. After cooling 3 g of magnesium powder was added. The mixture was heated at about 300 °C for 1 hr, then1, 2-dimethylimidazoline formed was distilled out. It was further refined by vacuum distillation to give pure Ib as a colorless liquid (3 g; 46%) which gave satisfactory spectral and analytical data; bp *ca.* 70 °C/14 mmHg (lit,[21] 60—62 °C/12 mmHg); n_D^{26} 1.4759 (lit,[21] n_D^{20} 1.4766); picrate, mp 137—138.5 °C (lit,[21] 145—147 °C).

1-Methyl-2-phenylimidazoline (Id) was prepared by the method of Hill and Aspinall.[22] 18.4 g of benzoic acid was added to 11.2 g of *N*-methylethylenediamine and the mixture was heated at 150—170 °C for 1.5 hr, then at 200—220 °C for 2 hr. The product was refined by repeated vacuum distillation to give Id as colorless liquid (5 g; 21%); bp *ca.* 95 °C/4 mmHg; IR (neat 2850, 1605, 1270, 1065, 775, and 700cm^{-1}; NMR ($CDCl_3$) τ 2.30—2.69 (m, 5H), 5.88—6.80 (m, 4H), and 7.20 (s, 3H); *m/e* 160 (M^+). Found: C, 75.25; H, 7.79; N, 17.31%. Calcd for $C_{10}H_{12}N_2$: C, 74.96; H, 7.55; N, 17.49%. It gave a picrate, mp 121—123 °C.

1-(β-hydroxyethyl)-2-phenylimidazoline (Ie) was prepared analogously from N-(β-hydroxyethyl)ethylenediamine and benzoic acid, as colorless crystals; mp 103—104.5 °C; IR (Nujol) 3200, 1590, 1570, 1235, 765, and 685 cm^{-1}; NMR ($CDCl_3$) τ 2.33—2.72 (m, 5H), 5.90—7.00 (m, 8H), and 6.17 (s, 1H). Found: C, 69.68; H, 7.13; N, 14.81%. Calcd for $C_{11}H_{14}ON_2$: C, 69.50; H, 7.37; N, 14.71%.

Amarine (If) was prepared by the method of Strain[23] and purified by repeated recrystallization from anhydrous ether. Isoamarine (Ig) was prepared by isomerizing amarine with sodium methoxide at 160—170 °C,[24] and purified by repeated recrystallization from ethanol.

General Procedure for Photodehydrogenation. The following procedure was used for experiments listed in Table 1. A solution of about 2 g of an imidazoline in 220 ml of acetone was irradiated with a 10 W low-pressure mercury lamp (Vycor

housing) under nitrogen at room temperature for 24 hr or more. After irradiation the solvent was removed under reduced pressure and the residue was chromatographed on a silica gel column. The yield of products was obtained by NMR or vpc analysis of the reaction mixture or by product isolation.

Isolation and Identification of Dehydrogenation Products. *2-Methylimidazoline (Ia)*: The residue obtained from 2.10 g of Ia was chromatographed on 70 g of silica gel. Elution with 100 ml of acetone yielded 350 mg of an oil which was again chromatographed to give 150 mg of pinacol (identified by IR and NMR). Further elution with 200 ml of acetone–ethanol (1 : 1) gave 1.18 g of a solid. Recrystallization from chloroform gave 400 mg of 4-(α-hydroxyisopropyl)-2-methylimidazole (III) as colorless crystals which were identical with an authentic sample[9] (IR, NMR, and mixed mp). Crystals obtained from the mother liquor were recrystallized from benzene to give 2-methylimidazole (IIa) as colorless crystals, identical with a commercial authentic sample (IR, NMR and mixed mp). Further elution of the chromatogram yielded 680 mg of a solid which was identified as IIa. The yields of the products were determined by NMR analysis of the product mixture with an internal standard (acenaphthene). The yield of pinacol was 6% assuming that 1 mol of Ia gives 1 mol of pinacol.

1,2-Dimethylimidazoline (Ib). The residue obtained from 1.85 g of Ib was chromatographed on 50 g of silica gel. Elution with 300 ml of chloroform and acetone (1 : 1) yielded 300 mg of an oil which was shown by IR and NMR to contain pinacol. Further elution with 300 ml of acetone yielded 110 mg of a solid which was recrystallized from acetone to give 10 mg of 1,2-dimethyl-5-(α-hydroxyisopropyl)-imidazole (V) as colorless crystals; mp 179—181 °C; IR (Nujol) 3200, 1150, and 810 cm^{-1}; NMR ($CDCl_3$) τ 3.33 (s, 1H), 6.25 (s, 3H), 6.79 (s, 1H), 7.67 (s, 3H), and 8.39 (s, 6H); mass spectrum, *m/e* 154 (M^+). The NMR and mass spectra are very similar to those of IV.[9]

Found: C, 62.67; H, 9.23; N, 17.71%. Calcd for $C_8H_{14}ON_2$: C, 62.30; H, 9.15; N, 18.15%.

The mother liquor was shown by IR and NMR analyses to consist of 1,2-dimethylimidazole (IIb), 1,2-dimethyl-4-(α-hydroxyisopropyl)imidazole (IV) and V. Compound IIb was isolated by vpc and identified by comparison with an authentic sample[9] (IR). Compound IV was dehydrated during vpc to give 1,2-dimethyl-4-isopropenylimidazole,[9] which was identified by comparison with an authentic sample[9] (IR). Further elution of the chromatogram with acetone yielded a mixture of IIb, IV, and V, identified by tlc. The yields of these products were determined by vpc analysis with an internal standard (*p-t*-butylphenol). NMR analysis of the product mixture showed the formation of pinacol (0.3 mol/mol of IIb).

2-Phenylimidazoline (Ic). The residue obtained from 2.60 g of Ic was chromatographed on 60 g of silica gel. Elution with chloroform and ethanol (9 : 1) yield 2-phenylimidazole (IIc), identical with a commercial authentic sample (IR,, NMR and mixed mp). The yield of IIc was determined by vpc analysis with an internal standard (diphenyl).

1-Methyl-2-phenylimidazoline (Id). The residue obtained from 2.03 g of Id was chromatographed on 60 g of silica gel. Elution with chloroform yielded 1-methyl-2-phenylimidazole (IId) as a liquid; bp 140—145 °C (bath temperature)/3 mmHg (lit,[24] bp 175 °C/15 mmHg); IR (neat) 1500, 1480, 1410, 1270, 770, 715, and 700 cm^{-1}; NMR ($CDCl_3$) τ 2.21—2.60 (m, 5H), 2.83 (d, 1H, J=1 Hz), 3.01 (d, 1H, J=1 Hz) and 6.25 (s, 3H). It gave satisfactory elemental analyses. The yield of IId shown in Table 1 is based on the product isolated. The recovered Id was analyzed by vpc.

Amarine (If) and Isoamarine (Ig). The residues obtained from 2.09 g of If and 2.02 g of Ig were chromatographed on 70 g of silica gel, respectively. Elution with chloroform successively gave lophine (IIf), Ig, and If, which were identical with authentic samples (IR and NMR). The yield of IIf was determined by UV analysis in ethanol and the recovered materials by NMR analysis with an internal standard, 2-methylimidazoline (in carbon tetrachloride–dimethylsulfoxide-d_6).

2-Hydroxyimidazoline (Ii). A suspension of Ii (1.63 g) was irradiated. The insoluble solid separated by filtration was found to be mainly the recovered Ii (IR and NMR). The residue from the filtrate was chromatographed on 60 g of silica gel. Elution with acetone yielded VI as colorless crystals; mp 198—201 °C; IR (Nujol) 3300, 1655, and 1175 cm^{-1}; NMR (DMSO-d_6) τ 5.26 (s, 4H), 6.63 (s, 2H), and 8.86 (S, 12H).

Found: C, 53.48; H, 8.94; N, 13.75%. Calcd for $C_9H_{18}N_2O_3$: C, 53.44; H, 8.97; N, 13.85%.

The compound showed a UV maximum at 275 nm in ethanol identical with that of Ii. Further elution yielded additional Ii. The yields given in Table 1 are based on the product isolated.

Photoreaction of 2-Methylimidazoline (Ia) under Oxygen. A solution of 2.08 g of Ia in acetone was irradiated for 24 hr under similar conditions but with oxygen-bubbling instead of nitrogen. After removal of the solvent under reduced pressure, the residue was chromatographed on 60 g of cellulose powder (Whatman CF11). Elution with 1200 ml of benzene–chloroform (1 : 4) yielded 530 mg (27%) of Ia, identified by IR. Further elution with 1000 ml of acetone–ethanol (1 : 1) yielded 1.12 g of an oil. Vacuum distillation of the oil gave 400 mg (12%) of 2-methylimidazolinium acetate, mp 95—96 °C (lit,[26] mp 94.5—95.5 °C), which was identical with an authentic sample (IR and NMR).

Hydrogen Abstraction of Imidazolines Initiated with AIBN. A given amount of each imidazoline was dissolved in 150 ml of acetonitrile. The solution was heated at 68±1.5 °C under nitrogen, a given amount of azobisisobutyronitrile being added. After being left standing at the same temperature for 24 hr, the mixture was worked up in the same manner as in the photoreaction. The results are given in Table 2. 2-Methylimidazole was analyzed by NMR with an internal standard, pinacol, and lophine by UV in ethanol.

Deuterium Incorporation Experiment. A solution of *ca.* 100 mg of 2-phenylimidazoline (Ic) in a mixture of acetone and MeOD and D_2O placed in a Pyrex tube was sealed after bubbling nitrogen and irradiated externally. After evaporation of the mixture under reduced pressure, the residue was dissolved in chloroform and washed three times with 2 ml of water to remove any deuterium bound to nitrogen atom of Ic. The solution was evaporated after being dried with anhydrous sodium sulfate. The recovered Ic in the residue was isolated by preparative tlc (Al_2O_3; acetone–ethanol (3 : 1)) and recrystallized from benzene–petroleum ether. The pure Ic thus obtained was analyzed on a Hitachi VD-10001-A mass spectrometer. The molecular ion region was scanned several times for each sample. Deuterium contents were calculated by comparing peak heights with those of a non-deuterated sample of Ic.

Oxidation by Transition Metal Complexes. VI.[1] Oxidation of Cyclohexenes Catalyzed by Rhodium Complexes

Kiyotomi KANEDA,* Takashi ITOH, Yuzo FUJIWARA, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Osaka 560

(Received March 15, 1973)

Rhodium complexes can cause the catalytic oxidation of cyclohexene to give ketone, alcohol, and epoxide. The product distribution is dissimilar to that of the metal-catalyzed decomposition of cyclohexene hydroperoxide(V). Ketone and alcohol are derived from the decomposition of the intermediate hydroperoxide (V) but epoxide is not formed by the oxygen transfer reaction from V. Oxidation of methylcyclohexenes was also studied and discussed in relation to the effect of methyl substituent.

X-Ray analysis of oxygen complexes indicated that the coordinated oxygen is in an electronically excited state, that is, the anionic species of O_2^-, O_2^{--} formed by charge transfer from the metal.[2] Recently, the application of the coordinated oxygen to oxidation reaction has been studied extensively, particularly using rhodium complexes.[3] It is generally said that rhodium complexes act as the catalyst for hydrogen abstraction from substrates by the coordinated oxygen and as a catalyst inducing the decomposition of hydroperoxide formed by oxygen and olefin (Haber-Weiss mechanism).

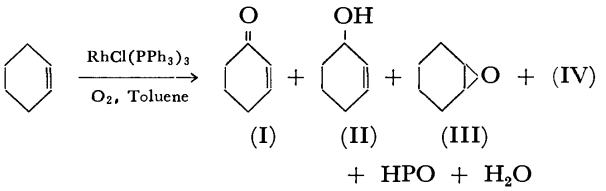
In previous papers, we reported on the oxidation of styrene and its derivatives catalyzed by rhodium complexes and proposed that the oxidation might proceed *via* a four-center intermediate in which both oxygen molecule and olefin are coordinated to the rhodium complex.[1,4]

In connection with this work, we have studied the oxidation of cyclohexene and methylcyclohexene catalyzed by $RhCl(PPh_3)_3$. Although the oxidation of cyclohexene having active hydrogens at the allylic position of olefin has been investigated by many workers,[5] in the cyclohexene oxidation using rhodium complexes, the reaction products have not yet been examined in detail.

In this paper we will discuss the development of the reaction products, *i.e.*, ketones, alcohols, and epoxides.

Results and Discussion

Oxidation of Cyclohexene. Cyclohexene was oxidized under a constant bubbling of oxygen with $RhCl(PPh_3)_3$ catalyst in toluene at 80 °C for 8 hr. It gave 2-cyclohexen-1-one (I, 1530% based on catalyst), 2-cyclohexen-1-ol (II, 852%), cyclohexene oxide (III, 351%), benzaldehyde (IV, 524%), hydroperoxides, and water.



The formation of aldehyde IV is considered to arise from the oxidation of toluene solvent.[6]

The relation between yields of the products and reaction time in the cyclohexene oxidation is given in Fig. 1. The yields of I and II increased with reaction time. I was the main product for 8 hr. The content of hydroperoxides determined by the iodometric method showed a maximum value at 3 hr, suggesting that they could be intermediate species for I and II.[7] The hydroperoxides should be composed of mostly cyclohexene hydroperoxide (V).

The decomposition of V by $RhCl(PPh_3)_3$ under argon atmosphere was then carried out under the same reaction conditions as above. The starting hydroperoxide (V) was perpared by treatment of cyclohexene

6) It is of noteworthy that toluene could not be directly oxidized to IV by $RhCl(PPh_3)_3$ under oxygen atmosphere.

7) In the case of styrene, hydroperoxides were scarcely detected at all and the oxidation was not remarkably affected by a free radical inhibitor. On the other hand, oxidation of cyclohexene was perfectly inhibited by the inhibitor.

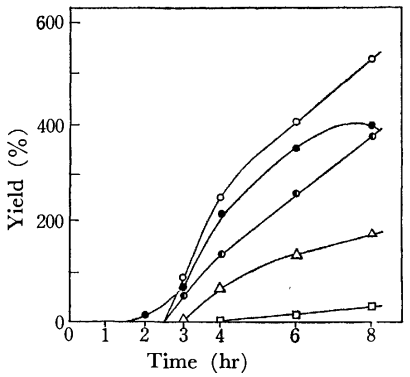

Fig. 2. Oxidation of cyclohexene with $RhCl(PPh_3)_3$ in the presence of pyridine.
Cyclohexene: 50 mmol, $RhCl(PPh_3)_3$: 0.50 mmol, Pyridine: 5 mmol, Toluene: 75 ml.

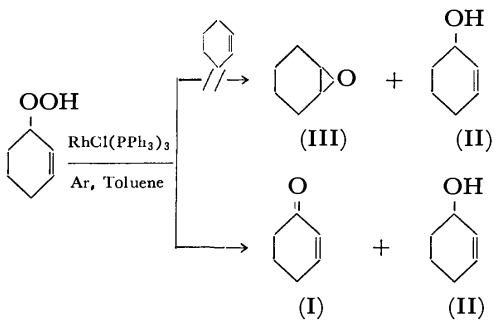
with azobis(2-methylpropionitrile), (ABN) under oxygen atmosphere. It decomposed within 2 hr to give ketone (I, 53% based on V), alcohol (II, 47%), IV (trace), and water, whereas the thermal decomposition of V without $RhCl(PPh_3)_3$ did not occur at 80°C for 8 hr. Thus the formation of ketone (I) and alcohol (II) can be explained by the decomposition of intermediate V according to the Haber-Weiss mechanism.

Addition of pyridine or $O=PPh_3$ to the reaction system depressed the oxidation reaction (Fig. 2). This suggests that the coordination of oxygen to the rhodium complex is prevented by the high coordination ability of these compounds.[8]

It should be noted that the decomposition of V did not result in the formation of epoxide III, while the yield of III increased with reaction time and reached 351% after 8 hr, the oxidation of 1-methylcyclohexene giving 1-methylcyclohexene oxide as the main product (1340%).

Two types of reactions are known in catalytic epoxidation, *i.e.*, double bond reacting with (a) hydroperoxide and (b) organic peracid (cooxidation).

In order to examine the possibility of mechanism (a) in this reaction system, autoxidation of cyclohexene or 1-methylcyclohexene with ABN was carried out in the presence of oxygen. It gave mainly ketones and alcohols accompanied by a small amount of epoxide. The reaction of V and cyclohexene with $RhCl(PPh_3)_3$ under argon atmosphere gave rise to only the decomposition products, I and II. None of III could be detected, the same result being also obtained with *t*-butyl hydroperoxide.

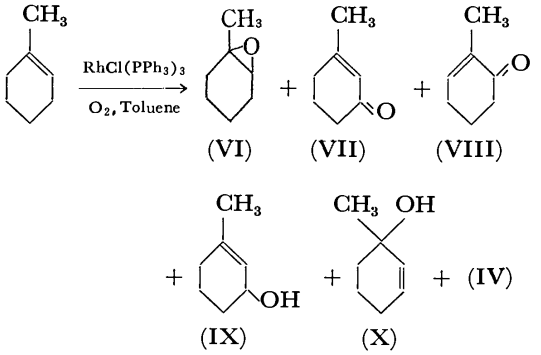


Thus the formation of epoxide (III) might be expected by cooxidation of aldehyde (IV), possibly derived from toluene solvent, and cyclohexene (mechanism b). Oxidation of cyclohexene was then carried out by adding about 5-fold excess of benzaldehyde to the catalyst. However, no remarkable accelerating effect of epoxidation was observed.

Thus the epoxidation could be explained by neither oxygen transfer reaction from V (mechanism a), nor cooxidation with IV (mechanism b). Details of the epoxidation are not clear at present, but it seems that the coordinated oxygen molecule would directly attack the olefin double bond to give epoxides.[10]

Oxidation of Methylcyclohexene. The oxidation of methylcyclohexenes with $RhCl(PPh_3)_3$ was studied in order to determine whether the methyl substituent has any steric factor or directive influence on the site of the oxidation and, hence, the isomer composition.

1-Methylcyclohexene was oxidized under the same conditions as for cyclohexene. The gas chromatogram of the reaction mixture showed eight major compounds, six of which have been isolated by preparative gas chromatography and was identified by NMR and IR in comparison with those of authentic samples. Two unidentified products were obtained in less than 50% yield. The identified products were 1-methylcyclohexene oxide (VI, 1340%), 3-methyl-2-cyclohexen-1-one (VII, 1052%), 2-methyl-2-cyclohexen-1-one (VIII, 366%), 3-methyl-2-cyclohexen-1-ol (IX 90%), 1-methyl-2-cyclohexen-1-ol (X, 83%) and IV (799%).



This indicates that all possible allylic positions except for the methyl group were oxidized in the reaction.

The reaction paths for the formation of ketones and alcohols might be as presented in Scheme I, allylic hydrogen of olefin being abstracted by oxygen. The attack of oxygen at the less hindered site of allyl radical (1) results in the formation of major product VII through hydroperoxide.

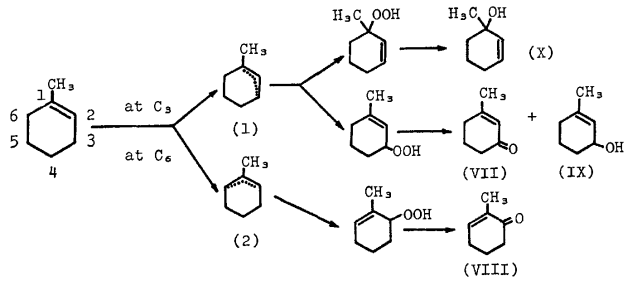
The total sum of yields of VII, IX, and X arising

8) James and Ochiai studied the oxidation of cyclooctene with a rhodium complex by infrared spectroscopy and reported on the mechanism in which both oxygen and olefin coordinated to rhodium.[9]

9) B. R. James and E. Ochiai, *Can. J. Chem.*, **49**, 975 (1971).

10) Recently, Minoun and his coworkers reported that expoxidation with molybdenum peroxy complex might proceed *via* the coordination of olefin to metal complex containing an aprotic 1,3-dipole mechanism.[11]

11) H. Mimoun, I. Seree de Roch, and L. Sajus, *Tetrahedron*, **26**, 37 (1970).

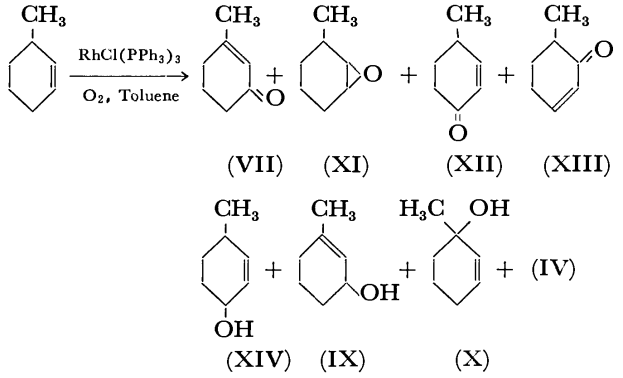


Scheme 1.

from hydrogen abstraction at C-3 was 1225%, whereas the yield of VIII from that at C-6 was 366%. Namely, hydrogen at C-3 is favorably abstracted over that at C-6 by a ratio of 3 : 1. This might be explained by the stabilization energy of the intermediate radical. The same tendency has been reported in the oxidation of methylcyclohexene using chromium trioxide in acetic acid and chromium trioxide–pyridine complex in methylene chloride (10 : 1 and 4 : 1 respectively).[12]

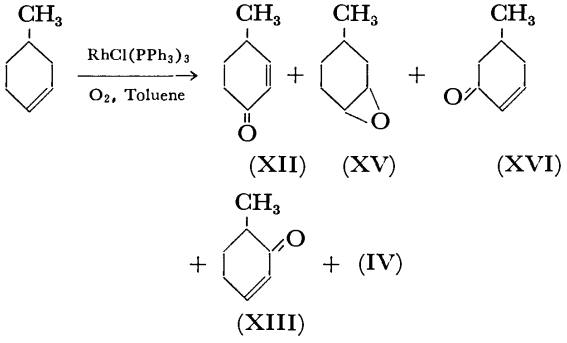
3-Methylcyclohexene and 4-methylcyclohexene were also oxidized with $RhCl(PPh_3)_3$ under the same reaction conditions as above. The product distribution of each reaction could be explained in a similar way to that for 1-methylcyclohexene.

Thus, 3-methylcyclohexene was oxidized to give VII (1372%), 3-methylcyclohexene oxide (XI, 391 %), 4-methyl-2-cyclohexen-1-one (XII, 384%), 6-methyl-2-cyclohexen-1-one (XIII, 232%), 4-methyl-2-cyclohexen-1-ol (XIV, 168%), IX (124%), X (98%), and IV (684%). These products were identified by comparison with authentic samples.

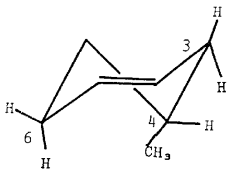


The main product VII could arise by oxygen attack at a less hindered site of the intermediate allyl radical.

Similarly, 4-methylcyclohexene was oxidized to give five products, XII (846%), 4-methylcyclohexene oxide (XV, 360%), 5-methyl-2-cyclohexen-1-one (XVI, 232%), XIII (115%), and IV (660%).



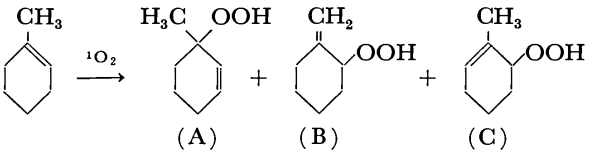
Hydrogen abstraction at C-3 yielding XII and XIII in 961% exceeds that at C-6 yielding XVI in 232% by a ratio of 4 : 1.



In all cases, ketones are formed in higher yields than the corresponding alcohol, though the decomposition of methylcyclohexene hydroperoxide by $RhCl(PPh_3)_3$ gave ketones and alcohols in nearly equivalent yields. Oxidation of alcohol IX did not afford the corresponding ketone XII in a good yield (6% yield based on the alcohol).

The yield of methylcyclohexene oxide increased as follows: 4-methyl < 3-methyl < 1-methylcyclohexene. This is in line with the increase of the electron density on carbon-carbon double bond.

It is known that singlet oxygen reacts with olefins bearing the allylic hydrogen to give hydroperoxides. The oxidation of 1-methylcyclohexene with singlet oxygen has been reported to give the following hydroperoxides.[13]



From the present result of 1-methylcyclohexene catalyzed by a rhodium complex, alcohol X and ketone VIII would be derived from the hydroperoxide of type A and type C, respectively. However, no ketone and alcohol arising from type B hydroperoxide could be observed. The formation of ketone VII, the major product of the present reaction, has not been detected among the products of oxidation reaction using singlet oxygen. This seems to be due to the fact that in cyclohexene oxidation, the oxygen molecule coordinated to a rhodium complex has few of the singlet oxygen character, if any.

Experimental

Materials and Analysis. All temperatures were uncorrected. The IR spectra were recorded on a JASCO IR-E spectrometer. The NMR spectra were measured on a Japan Electron Optics JNM-4H-100 spectrometer. Chemical shifts are given in τ units together with splitting patterns and relative integrated area. Vpc analysis was carried out with a Yanagimoto G-8 gas chromatograph using Chro-

mosorb-W and Carbowax-20M columns. The gas chromatographic method was employed for both qualitative and quantitative determination of the reaction products. Cyclohexene hydroperoxide was decomposed in vpc to give nearly equal quantities of ketones and alcohols but no epoxides. The yields of ketones and alcohols should therefore be corrected according to the decomposition of hydroperoxides. However, no such correction was carried out since the content of hydroperoxide was low after 8 hr. The active oxygen in the reaction mixture was determined by the iodometric method.[14] Cyclohexene was prepared by the dehydration of cyclohexanol with phosphoric acid. Bp 82.7 °C (lit,[15] 82.7 °C). 1-Methylcyclohexene was prepared by treatment of cyclohexanone with methylmagnesium iodide followed by dehydration with anhydrous aluminum sulfate. bp 34.3 °C/38 mmHg (lit,[16] 110 °C/760 mmHg). 3-Methylcyclohexene was prepared by treatment of bromocyclohexene with methyl iodide. Bp 42.0 °C/97 mmHg (lit,[17] 104 °C/760 mmHg). 4-Methylcyclohexene was of commercial grade. All cyclohexenes used were subjected to repeated washing with ferrous sulfate solution containing sulfuric acid to eliminate the peroxides, separation and drying of the organic phase over anhydrous magnesium sulfate and distillation under nitrogen atmosphere before use. Absence of peroxides after the treatment was verified by vpc analysis. Cyclohexene hydroperoxide was prepared by treatment of cyclohexene with ABN under an oxygen atmosphere; bp 53—56 °C/0.6 mm Hg (lit,[18] 42—45 °C/0.5 mmHg). The peroxide content was 85%.

1-Methylcyclohexene 3-hydroperoxide was prepared from 1-methylcyclohexene in a manner similar to that for cyclohexene hydroperoxide; bp 42.5—46.2 °C/0.008 mmHg (lit,[19] 64—67 C°/0.2 mmHg). The peroxide content was 87%. Analysis by NMR indicated a mixture of 1-methylcyclohexene 3-hydroperoxide, 1-methylcyclohexene 6-hydroperoxide, and 3-methylcyclohexene 1-hydropreoxide. *t*-Butyl hydroperoxide was prepared by treatment of *t*-butanol with hydrogen peroxide in sulfuric acid solution; bp 34.5—36.0 °C/17 mmHg (lit,[20] 4.5—5.0 °C/2 mmHg). The peroxide content was 92%. Toluene was purified as mentioned previously.[4] $RhCl(PPh_3)_3$ was prepared by the method of Osborn *et al.*[21]

Oxidation of Cyclohexene. In a flask similar to that described previously[4] was charged a mixture of 0.463 g (0.500 mmol) of $RhCl(PPh_3)_3$ and 4.11 g (50 mmol) of cyclohexene and 75 ml of toluene as solvent under nitrogen atmosphere. The oxidation reaction was carried out at 80 °C with a constant bubbling of oxygen for 8 hr. A portion of the reaction solution was analyzed at an appropriate interval by the iodometric method and vpc. After work-up, brown solids deposited at the bottom of the flask. The resulting mixture was filtered to remove the brown precipitates (120 mg). In a separative experiment, the purified complex was not the active catalyst for oxidation of cyclohexene. The properties of the complex were as follows: mp 260—270 °C (decomp.), IR(nujol): 3360—3280, 1000, 762, 730, and 705 cm^{-1}. Found: C, 45.38; H, 3.95; Cl, 7.67%. Calcd for $RhCl_{0.7}(PPh_3)_{0.7}(H_2O)_{1.5}$: C, 44.66; H, 4.00; Cl, 7.64%. The filtrate was concentrated and the liquid phase was isolated and analyzed by vpc to give 738 mg (1530%) of I, 418 mg (852 %) of II, 173 mg (351%) of III, 277 mg (524%) of IV, and water. These compounds were identified by comparison with authentic samples. Compound I: IR(neat): 2940—2860, 1675—1650, 1458, 1430, 1397, 1243, 1210, 1128, 947, 888, 770, and 740 cm^{-1}; NMR (CCl_4): 3.10 (m, 1H, olefinic), 4.13 (m, 1H, olefinic), and 7.4—8.1 τ (m, 6H methylene). Compound II: IR(neat): 3400—3280, 2940—2860, 1650, 1440, 1275, 1182, 1068, 1048, 1007, 962, and 735 cm^{-1}; NMR(CCl_4): 4.35 (m, olefinic), 5.98 (m, 1H, methine), 8.10 (s, 1H, hydroxyl), and 7.9—8.5 τ (m, 6H, methylene). Compound III: IR (neat): 3000—2870, 1444, 1260, 972, 900, 885, 850, and 790 cm^{-1}; NMR(CCl_4): 7.06 (m, 2H, methine), 8.0—8.3 (m, 4H, methylene), and 8.5—8.9 (m, 4H, methylene). Compound IV: IR (neat): 3040, 1703, 1603, 1313, 1210, 1170, 840, 757, and 700 cm^{-1}; NMR(C_6D_6): −0.02 (s, 1H, formyl) and 2.3—3.1 τ (m, 5H, phenyl) The solid material was chromatographed on a silica gel column (50 g). Elution of ether (300 ml) gave triphenylphosphine oxide (235 mg).

Oxidation of 1-Methylcyclohexene. The same procedure as for cyclohexene was used. A solution of 0.463 g (0.500 mmol) of $RhCl(PPh_3)_3$, 4.81 g (50 mmol) of 1-methylcyclohexene and 75 ml of toluene was heated at 80 °C for 8 hr with a constant bubbling of oxygen. Reaction products were 750 mg (1340%) of VI, 579 mg (1052°₀) of VII, 202 mg (366%) of VIII, 50 mg (90%) of IX, 46 mg (83%) of X, and 413 mg (779%) of IV. These compounds were identified by comparison with authentic samples. Compound VI: IR(neat): 2960—2870, 1440, 1385, 1220, 1188, 1124, 1032, 918, 845, and 770 cm^{-1}; NMR(CCl_4): 7.24 (t, 1H, methine), 8.1—8.4 (m, 4H, methylene), 8.6—8.8 (m, 4H, methylene), and 8.77 τ (s, 3H, methyl). Compound VII: IR(neat): 2940—2880, 1670—1655, 1438, 1250, 1200, 970, 890, and 768 cm^{-1}; NMR(CCl_4): 4.27 (m, 1H, olefinic), 7.6—8.1 (m, 6H, methylene), and 8.02 τ (s, 3H, methyl). Compound VIII: IR(neat): 2940—2880, 1676—1657, 1456, 1364, 1178, 1108, 1020, 904, 885, and 809 cm^{-1}; NMR(CCl_4): 3.37 (m, 1H, olefinic), 7.5—8.1 (m, 6H, methylene), and 8.28 τ (s, 3H, methyl). Compound IX: IR(neat): 3360—3280, 2950—2880, 1677—1653, 1443, 1280, 1171, 1080, 1063, 1039, 964, 911, 827, 784, and 716 cm^{-1}; NMR(CCl_4): 4.58 (m, 1H, olefinic), 6.14 (m, 1H, methine), 8.49 (s, 1H, hydroxyl), 8.1—8.4 (m, 6H, methylene), and 8.28 τ (s, 3H, methyl). Compound X: IR(neat): 3400—3000, 2940—2880, 1702, 1650, 1460, 1180, 1130, 1020, 910, and 740 cm^{-1}; NMR(CCl_4): 4.45 (m, 2H, olefinic), 8.0—8.5 (m, 6H, methylene), 8.83 (s, 3H, methyl), and 8.95 τ (s, 1H, hydroxyl).

Oxidation of 3-Methylcyclohexene. The same procedure as above was used. A solution of 0.463 g (0.500 mmol) of $RhCl(PPh_3)_3$, 4.81 g (50 mmol) of 3-methylcyclohexene and 75 ml of toluene was heated at 80 °C for 8 hr with a constant bubbling of oxygen. Reaction products were 755 mg (1372%) of VII, 220 mg (391%) of XI, 212 mg (384%) of XII, 128 mg (232%) of XIII, 94 mg (168%) of XIV, 70 mg (124%) of IX, 55 mg (98%) of X, and 363 mg (684%) of IV. These compounds were identified by comparison with authentic samples. Compound XI: IR (neat): 3000—2880, 1455, 1386, 1255, 1004, 920, 879, 830, and 771

Compound XIV: IR(neat): 3360—3280, 2940—2880, 1700, 1650, 1457, 1280, 1110, 1060, 1029, 855, and 743 cm^{-1}; NMR (CCl_4): 4.48 (s, 2H, olefinic), 5.93 (m, 1H, methine), 7.27 (s, 1H, hydroxyl), 7.8—8.9 (m, 5H, methine and methylene), and 9.03 τ (d, 3H, methyl).

Oxidation of 4-Methylcyclohexene. The same procedure as above was used. A solution of 0.463 g (0.500 mol) of $RhCl(PPh_3)_3$, 4.81 g (50 mmol) of 4-methylcyclohexene and 75 ml of toluene was heated at 80 °C for 8 hr with a constant bubbling of oxygen. Reaction products were 476 mg (846%) of XII, 202 mg (360%) of XV, 128 mg (232%) of XVI, 64 mg (115%) of XIII, 350 mg (660%) of IV. These compounds were identified by comparison with authentic samples. Compound XV: IR(neat): 2960—2870, 1440, 1259, 1153, 1010, 970, 818, 792, and 770 cm^{-1}; NMR(CCl_4): 7.05 (m, 2H, methine), 7.8—8.9 (m, 7H, methylene and methine), and 9.14 τ (d, 3H, methyl). Compound XVI: IR(neat): 2950—2880, 1684—1652, 1458, 1393, 1273, 1240, 1187, 884, and 742 cm^{-1}; NMR (CCl_4): 3.17 (m, 1H, olefinic), 4.10 (m, 1H, olefinic), 7.6—8.1 (m, 5H, methylene and methine), and 8.91 τ (d, 3H, methyl).

Autoxidation of 1-Methylcyclohexene with ABN as Initiator. A mixture of 4.81 g (50 mmol) of 1-methylcyclohexene, 0.041 g (0.250 mmol) of ABN, and 75 ml of toluene was heated at 80 °C for 8 hr under a constant bubbling of oxygen. The reaction solution was analyzed by vpc to give 263 mg of VII, 129 mg of 2-methyl-2-cyclohexen-1-ol (XVII), 127 mg of IX, 109 mg of VI, 100 mg of VIII, 32 mg of X, and trace of IV. Compound XVII: IR (neat): 3400—3300, 2950—2880, 1660, 1445, 1275, 1160, 1057, 990, 952, 919, 868, and 816 cm^{-1}; NMR(CCl_4): 4.60 (m, 1H, olefinic), 6.15 (m, 1H, methine), 6.80 (m, 1H, hydroxyl), 7.9—8.4 (m, 6H, methylene), and 8.30 τ (s, 3H, methyl).

Oxidation of 3-Methyl-2-cylcohexen-1-ol (IX). A solution of 0.463 g (0.500 mmol) of $RhCl(PPh_3)_3$, 2.80 g (25 mmol) of IX, and 75 ml of toluene was treated in a manner similar to that for cyclohexene oxidation. After 8 hr, the reaction product was 0.174 g (1.58 mmol) of VII.

Decomposition of V catalyzed by $RhCl(PPh_3)_3$. A mixture of 0.463 g (0.500 mmol) of $RhCl(PPh_3)_3$, 1.00 g of V and 75 ml of toluene was heated at 80 °C with a constant bubbling of argon. A portion of the reaction solution was analyzed at an appropriate interval, by the iodometric method. Decomposition of V was complete in 2 hr. After 2 hr, the solution was analyzed by vpc to give 462 mg of I and 399 mg of II. Decomposition of the mixture of three isomers of methylcyclohexene hydroperoxides (1.33 g) was complete in 1 hr to give 269 mg of IX, 214 mg of VII, 186 mg of XV, 140 mg of X, and 138 mg of VIII.

Oxygen Transfer Reaction of Cyclohexene Hydroperoxide and Cyclohexene. A mixture containing 0.463 g (0.500 mmol) of $RhCl(PPh_3)_3$, 1.34 g of V, 0.821 g (10 mmol) of cyclohexene, and 75 ml of toluene was heated at 80 °C with a constant bubbling of argon. A portion of the reaction solution was analyzed at an appropriate interval by the iodometric method. Decomposition of V was complete in 2 hr. After 8 hr, the solution was analyzed by vpc to give 475 mg of I and 504 mg of II. Oxygen transfer reaction of *t*-butyl hydroperoxide and cyclohexene gave only the hydroperoxide decomposition products.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3814—3817 (1973)

Photochemical Rearrangement of 2-Nitrophenyl Phenyl Sulfoxide to 2-Nitrosophenyl Phenyl Sulfone

Rikuhei TANIKAGA and Aritsune KAJI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received May 14, 1973)

Irradiation of 2-nitrophenyl phenyl sulfoxide (I) gave 2-nitrosophenyl phenyl sulfone (II) as the sole product. The rearrangement was not affected by a quencher, but took a different course in the presence of a sensitizer or a halogen-containing solvent. When I with an electron-donating substituent at a 4′-position or electron-withdrawing one at a 4-position was irradiated, the corresponding II was obtained in a lower yield. 2-Nitrophenyl phenyl sulfide was photochemically stable. From the results, it is proposed that in the excited singlet state of I the oxyanion of a nitro group attacks the positive sulfur atom, and oxygen transfer takes place.

Organic nitrogen compounds, with an N→O bond such as $-\underset{|}{N}=N\rightarrow O$, $-CH=\underset{|}{N}\rightarrow O$ or $O=\underset{|}{N}\rightarrow O$, are known to undergo photochemical oxygen transfer reactions. Both rearrangements of azoxybenzene to 2-hydroxyazobenzene and of *N*,α-diphenylnitrone to 2,3-diphenylaziridine are postulated to proceed *via* the excited singlet state.[1,2]

In an aromatic nitro compound, a number of photochemical oxygen transfer reactions are also reported, but the reaction mechanism is not always straightforward.[3] In the rearrangements of 2-nitrobenzaldehyde to 2-nitrosobenzoic acid and of 2-nitrostilbene to 2-phenylisatogen, it is presumed that the reaction starts from an $n\rightarrow\pi^*$ excitation and the oxygen atom of the nitro group in the (n,π^*) triplet state abstracts a hydrogen atom or adds to an unsaturated system like the oxygen of a carbonyl group.

On the other hand, both azoxybenzene and nitrobenzene are known to be stronger bases in the excited

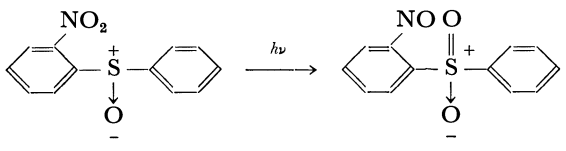
singlet state than in their ground state.[4,5] Thus a nitro compound might undergo an oxygen transfer reaction from the excited singlet state like an azoxy compound. 2-Nitrophenyl phenyl sulfoxide was found to rearrange to 2-nitrosophenyl phenyl sulfone possibly from the excited singlet state.[6]

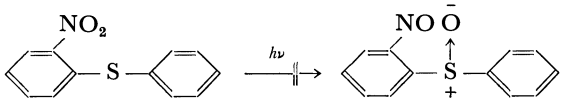
The principal objective of this work is to discuss the effect of a sensitizer, a quencher, a solvent, or a substituent on this new type of reaction, and to propose the mechanism.

Results and Discussion

A solution of 2-nitrophenyl phenyl sulfoxide (I) in benzene was irradiated with a high-pressure mercury lamp. Thin-layer chromatography analysis on silica gel revealed that 2-nitrosophenyl phenyl sulfone (II) was formed as the sole product, but not 2-nitrophenyl phenyl sulfide (III) or 2-nitrophenyl phenyl sulfone. This shows that an intramolecular oxygen transfer reaction took place. Neither thermal nor reverse photochemical rearrangement occurred. III was photochemically stable and gave no 2-nitrosophenyl phenyl sulfoxide. This suggests that the oxygen atom can attack only the positive sulfur atom.



(I) (II)



(III)

Effect of Sensitizer and Quencher. The results of the irradiation of I in benzene using a Pyrex filter are given in Table 1.

Table 1. Irradiation of I (10^{-2} M) for 3 hr

Sensitizer (M)	Quencher (M)	Yield (%) I	II	III
None	Degassed	84	12	0
None	O_2	84	12	0
None	1,3-Pentadiene (10^{-2})	85	11	0
$(C_6H_5)_3N$ (10^{-1})	Degassed	88	3	4
$(C_6H_5)_3N$ (10^{-1})	O_2	92	3	1

The rearrangement of I to II was not affected by oxygen or 1,3-pentadiene. Thus the oxygen transfer may occur directly from the excited singlet state.

Benzophenone, frequently used as a sensitizer, has one weak absorption band (λ_{max}=343 nm, ε_{max}=130) in benzene due to an n→π^* transition in the wavelengths above 310 nm, whereas I has much stronger absorption in the same region (for example, ε_{343nm}=925). Therefore, a large excess of benzophenone should be used for photochemical sensitization, but such a reaction condition does not seem suitable because of the possibility of a chemical sensitization.

On the other hand, triphenylamine has a strong absorption band (λ_{max}=302 nm, ε_{max}=2290) in benzene, and its intersystem crossing efficiency is known to be high. When triphenylamine was used as a sensitizer, two different reactions appear to have occurred at the same time; a direct photorearrangement of I in its excited singlet state to II, and a photosensitized reaction of I to III, that is, the reduction of the S→O bond of I presumably in its excited triplet state. One plausible explanation for the low yield of III is to assume that I in the excited triplet state can not easily be reduced to III.

Effect of Solvent. The results of the photolysis of I in various solvents using a Pyrex filter are given in Table 2. Irradiation was stopped at an early stage of the reaction to prevent the product from absorbing light.

It was not possible to determine what excitation occurred, since no electronic spectrum of I has yet been assigned. Nitrobenzene in heptane has a long-wavelength absorption maximum at 330 nm (ε=165) which has been assigned as an n→π^* band.[7] An ethanol solution of I shows only one absorption band at 235 nm (ε=11000) presumably arising from a π→π^* transition, and other absorptions are completely submerged under this high intensity band. It appears attractive to assume that the reaction of I starts from its π→π^* transition, since the yield of II was higher in quartz tube in spite of a weak radiation of the lamp used at 254 nm. Although there remain some possibilities that the reaction starts from another type of excitation, the possibility of an n→π^* excitation may be excluded, since the absorption of I around 330 nm

Table 2. Irradiation of I (10^{-2} M) for 3 hr

Solvent	Yield (%) I	II	III
n-Hexane	81	14	0
n-Hexane[a]	76	17	0
Benzene	84	12	0
Ethanol	79	10	0
Acetonitrile	85	6	0
1-Chloropropane	86	3	0
1-Bromopropane	88	1	1
1,3-Dibromopropane	87	1	3

a) Quartz was used.

is rather strong ($\varepsilon > 1000$).

The spectra of I in various solvents are very similar. II was obtained in a higher yield in a non-polar solvent.

The irradiation of I in a halogen-containing solvent tended to afford III in place of II. In that solvent I in the excited singlet state is expected to undergo an intersystem crossing as a result of a heavy-atom effect. Thus it seems reasonable that the yield of II *via* the excited singlet state decreased, and that of III *via* the excited triplet state increased. The possibility of excitation of the solvent must be excluded, since the absorption intensity of the solvent is much lower in the wavelengths above 310 nm than that of I in 10^{-2} M concentration. Pyridine *N*-oxide is reported to be reduced to pyridine through the excited triplet state by the photolysis in a halogen-containing solvent.[8]

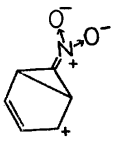
Effect of Substituent. The results of the photolyses of 2-nitrophenyl phenyl sulfoxide with a substituent in benzene using a Pyrex filter are given in Table 3. Irradiation was stopped at an early stage of the reaction to prevent the product from absorbing light.

TABLE 3. IRRADIATION OF I (10^{-2} M) WITH SUBSTITUENT FOR 3 hr

Substituent	Yield (%)	
	I	II
4′-CH_3O	88	8
4′-CH_3	91	6
4′-Cl	85	12
H	84	12
3′-Cl	82	16
4′-CH_3CO	83	14
4′-NO_2	86	11
4-NO_2	100	0

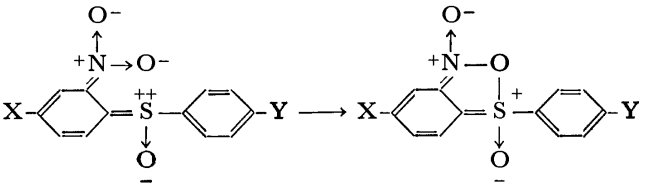
The electronic spectra of these compounds have only one strong absorption band in the wavelengths around 250 nm, and show similar intensities in wavelengths longer than 290 nm (Table 5). Although there will be problems in the discussion of the substituent effect, it is interesting to note that 2-nitrophenyl phenyl sulfoxide with an electron-donating group at a 4′-position tends to give the corresponding sulfone in a lower yield, and I with nitro group at a 4-position does not give any sulfone. These substituent effects are in contrast to those in the case of the oxygen transfer reaction of 2-nitrostilbene,[9] in which an electron-donating group at a 4′-position and an electron-withdrawing group at a 4-position promote the rearrangement.

Reaction Mechanism. In the excited (presumably (π,π^*)) singlet state, an aromatic nitro compound is known to have a higher electron density at the oxygen atom of the nitro group and a lower one at the meta-position of the phenyl ring.[5] This phenomenon can be illustrated by means of the following valence bond picture.[5a]

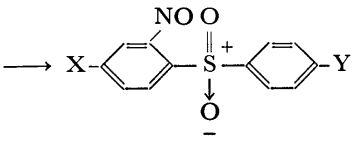


S*(π, π^*)

Thus, the most reasonable mechanism of the photochemical oxygen transfer reaction of I is as follows. In the excited (π,π^*) singlet state the oxyanion of a nitro group attacks the positive sulfur atom, and the oxygen transfer takes place without a spin inversion. This mechanism of the reaction of I is similar to that of azoxybenzene[1] and of *N*,α-diphenylnitrone.[2]



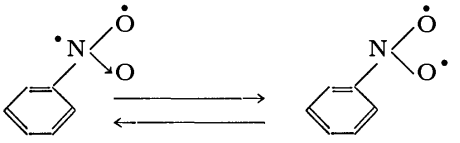
S*(π, π^*)



X: electron-donating group
Y: electron-withdrawing group

The above mechanism, in which the rearrangement occurs directly from the excited singlet state, can be explained by the effects of a sensitizer, a quencher and a halogen-containing solvent. The mechanism, in which an intramolecular nucleophilic attack occurs on the sulfur atom, can also be explained by the effect of a substituent on the rearrangement of I and the photochemical stability of III. The interesting intermolecular nucleophilic substitution on a sulfur atom was reported in the photochemistry of 2,4-dinitrobenzenesulfenyl derivatives.[10] The oxygen-bridged transition state may be supported by the effect of a solvent polarity.

On the other hand, in the excited (presumably (n,π^*)) triplet state a nitro compound is believed to have the following biradical structure.[3]



T*(n, π^*)

Thus, the oxygen atom of the nitro group in the excited state can have two opposite behaviors, a nucleophilic property in the excited (π,π^*) singlet state and an electrophilic one in the excited (n,π^*) triplet state. The former case was observed in the photochemical rearrangement of I to II, and the latter one is reported by de Mayo[11] in the photochemical electrophilic addition of an aromatic nitro compound

to an alkene. A similar biradical property of the nitro group in the excited (n,π^*) triplet state also appears to be observed in the intramolecular electrophilic attack of the nitro group to the double bond in the photochemical reaction of 2-nitrostilbene to 2-phenylisatogen.[9]

In conclusion, the property of an aromatic nitro compound in the excited (π,π^*) singlet state differs a great deal from that in the excited (n,π^*) triplet state.

Experimental

Starting Materials. The sulfides were prepared by the reaction of sodium thiophenolates and aryl halides. The sulfoxides were prepared by controlled oxidation of the corresponding sulfides with hydrogen peroxide. They were purified by column chromatography and recrystallization until their thin-layer chromatography showed only one spot, and were identified by elemental analysis, and NMR and IR spectra. Photolysis of 2-Nitrophenyl Phenyl Sulfoxides to 2-Nitrosophenyl Phenyl Sulfones. A solution of 2 g of 2-nitrophenyl phenyl sulfoxide (I) in 500 ml of benzene was internally irradiated for 3 hr with a 300 W high-pressure mercury lamp using a Pyrex filter. Removal of the solvent gave a dark oil which was chromatographed on preparative thin-layer plates (Merck silica gel G). Development with chloroform three times gave two separated bands, the second band arising from I. The material from the first band was recovered by extraction with chloroform. Slow recrystallization from chloroform and *n*-hexane gave 400 mg of pale crystals Z; mp 145 °C; UV (benzene) λ_{max} 783 nm (nitroso); IR (KBr) 1320, 1150 cm^{-1} (sulfone).

Found: C, 58.58; H, 3.66; N, 5.59; S, 12.85%. Calcd for $C_{12}H_9NO_3S$: C, 58.29; H, 3.67; N, 5.66; S, 12.97%.

Compound Z was positive to the Liebermann test, and yielded 2-nitrophenyl phenyl sulfone by oxidation with hydrogen peroxide. Consequently, Z was assigned to 2-nitrosophenyl phenyl sulfone (II).

Other 2-nitrosophenyl phenyl sulfone derivatives were isolated and identified as described above. (Table 6)

Table 6. 2-Nitrosophenyl phenyl sulfones

Substituent	Mp (°C)	ν_{max}^{KBr} (cm^{-1})
H	145	1320, 1150
4′-CH_3O	152	1320, 1150
4′-CH_3	200	1300, 1150
4′-Cl	169	1330, 1160
3′-Cl	195	1330, 1165
4′-CH_3CO	154	1320, 1150
4′-NO_2	161	1300, 1160

Photolysis of I in the Presence of Sensitizer or Quencher. A Pyrex tube (inner diameter, 0.9 mm) containing a degassed or oxygen-saturated solution (2 ml) of I (10^{-2} M), with or without 1,3-pentadiene (10^{-2} M) or triphenylamine (10^{-1} M), was kept standing in a "merry-go-round" apparatus. The solution was irradiated for 3 hr with a 100 W high-pressure mercury lamp fitted with a water-cooled immersion well, and thermostated at 25 °C. Five ml of chloroform was added after irradiation and 0.5 ml of the resulting solution was developed on the thin-layer plate (silica gel G), and each component was extracted with chloroform. The yield was determined from the intensity of the absorption of the extract in an electronic spectrum, whose extinction coefficient had previously been determined with an authentic sample.

Reproducibility of the data obtained by this method was satisfactory. The results are given in Table 1.

Photolysis of I in Various Solvents. A solution (2 ml) of I (10^{-2} M) in each solvent was irradiated in a Pyrex or quartz tube for 3 hr. The yield of each product was determined as described above. The results are shown in Table 2.

Photolysis of 2-Nitrophenyl Phenyl Sulfoxide with Substituent. A solution (2 ml) of 2-nitrophenyl phenyl sulfoxide, with such substituents as shown in Table 3, in benzene, was irradiated in a Pyrex tube for 3 hr. The yield of each component was determined as described above. The results are shown in Table 3.

Behavior of 2-Pyrazolin-5-ones toward Activated Double Bond Systems: Cyanoethylation of 2-Pyrazolin-5-ones

Mohamed Helmi ELNAGDI and Masaki OHTA

Department of Chemistry, Faculty of Science, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 21, 1973)

3-Methyl-2-pyrazolin-5-one(Ia) reacts with acrylonitrile to yield either 4,4-di(β-cyanoethyl)-5-hydroxy-3-methylpyrazole(IV) or 1,4,4-tri(β-cyanoethyl)-3-methyl-2-pyrazolin-5-one(V) depending on the amount of reagent and the reaction conditions. Ia reacts with ethyl acrylate or crotononitrile to yield the 4-alkylated derivatives VIII and IX respectively. 3-Methyl-1-phenyl-2-pyrazolin-5-one(Ib) reacts with acrylonitrile to yield only 4,4-di(β-cyanoethyl) derivative XII which on hydrolysis affords the corresponding dicarboxylic acid (XIII). 3-Amino-1-phenyl-2-pyrazolin-5-one(Ic) adds to two molecules of ethyl acrylate or acrylonitrile to yield the 4,4-disubstituted derivatives XIV and XV, but only to one molecule of benzalacetophenone to yield the 4-substituted 3-amino-2-pyrazolin-5-one derivative XVIII. The pyrazolopiperidine derivative(XVI) was obtained on treatment of Ic with ethyl crotonate in the presence of sodium ethoxide.

In continuation of previous works,[1-3] the behavior of the 2-pyrazolin-5-one derivatives (Ia-c) toward a variety of reagents containing activated double bonds was investigated. Kost *et al.*[4] showed that, where as 3-methyl-2-pyrazolin-5-one(Ia) and 4-(β-cyano-ethyl)-3-methyl-2-pyrazolin-5-one(IIa) react with acrylonitrile in *t*-butyl alcohol to yield 5-(β-cyanoethoxy)-3-pyrazole-(IIIa) and 5-(β-cyanoethoxy)-4-(β-cyanoethyl)-3-methylpyrazole(IIIb), respectively, 3-methyl-1-phenyl-2-pyrazolin-5-one(Ib) reacts with the same reagent under the same conditions to yield 4-(β-cyano-ethyl)-3-methyl-1-phenyl-2-pyrazolin-5-one(IIb).

It has been found that Ia reacts with acrylonitrile in aqueous pyridine to yield either 4,4-di(β-cyano-ethyl)-5-hydroxy-3-methylpyrazole(IV) or 1,4,4-tri(β-cyanoethyl)-3-methyl-2-pyrazolin-5-one(V) depending on the molar ratio of the reactants and the reaction conditions. Thus, when Ia was treated with acrylonitrile in a molar ratio of 1 : 2, compound IV was formed. On the other hand, when Ia was refluxed with excess acrylonitrile in the presence of catalytic amount of potassium hydroxide, tri(β-cyanoethyl)-3-methyl-2-pyrazolin-5-one(V) was formed. Compound V was also formed by the action of acrylonitrile on 1,4-di(β-cyanoethyl)-3-methyl-2-pyrazolin-5-one(VI).

The structure proposed for compound IV was deduced from analytical data, non-identity with the known IIIb and VI, and its preparation by the action of acrylonitrile on IIa. Hydrolysis of IV with acetic acid–hydrochloric acid mixture affords 4,4-di(β-carboxyethyl)-5-hydroxy-3-methylpyrazole (VII). The IR spectrum of IV shows no ring CO absorption but a band extending over 2400—2700 cm^{-1} for the chelated hydroxyl group. Similar spectra were reported for C-4 alkylated 1-unsubstituted-2-pyrazolin-5-ones.[5] The absence of ring CO absorption in the IR spectrum indicates that IV exists mainly, at least in solid state, in the 5-hydroxypyrazole structure.

Attempts to obtain a mono β-cyanoethyl derivative of Ia in pyridine medium were unsuccessful. Even when limited quantities of acrylonitrile were used under conditions[6,7] favorable for monocyanoethylation, the isolable product was compound IV and unchanged Ia. This is similar to the behavior of many compounds containing activated methylene group, where the isolation of a mono β-cyanoethyl derivative is difficult as has been reported.[6-10]

In contrast to the behavior of Ia toward acrylonitrile, we have found that it adds to only one molecule of either of ethyl acrylate or crotononitrile to yield 4-(β-ethoxycarbonylethyl)-5-hydroxy-3-methylpyrazole (VIII) and 4-(β-cyano-α-methylethyl)-5-hydroxy-3-methylpyrazole (IX or possible tautomers), respectively. Compounds VIII and IX were also obtained by the action of hydrazine hydrate on diethyl α-acetylglutamate(X) and ethyl 1-acetyl-3-cyano-2-methylbutyrate(XI), respectively. That acrylonitrile easily effects dialkylation of Ia, whereas ethyl acrylate and crotononitrile effect only mono alkylation under more severe conditions is in accordance with the sequence of reactivity of these reagents as Micheal acceptors.[11] A similar discrepancy in behavior of many

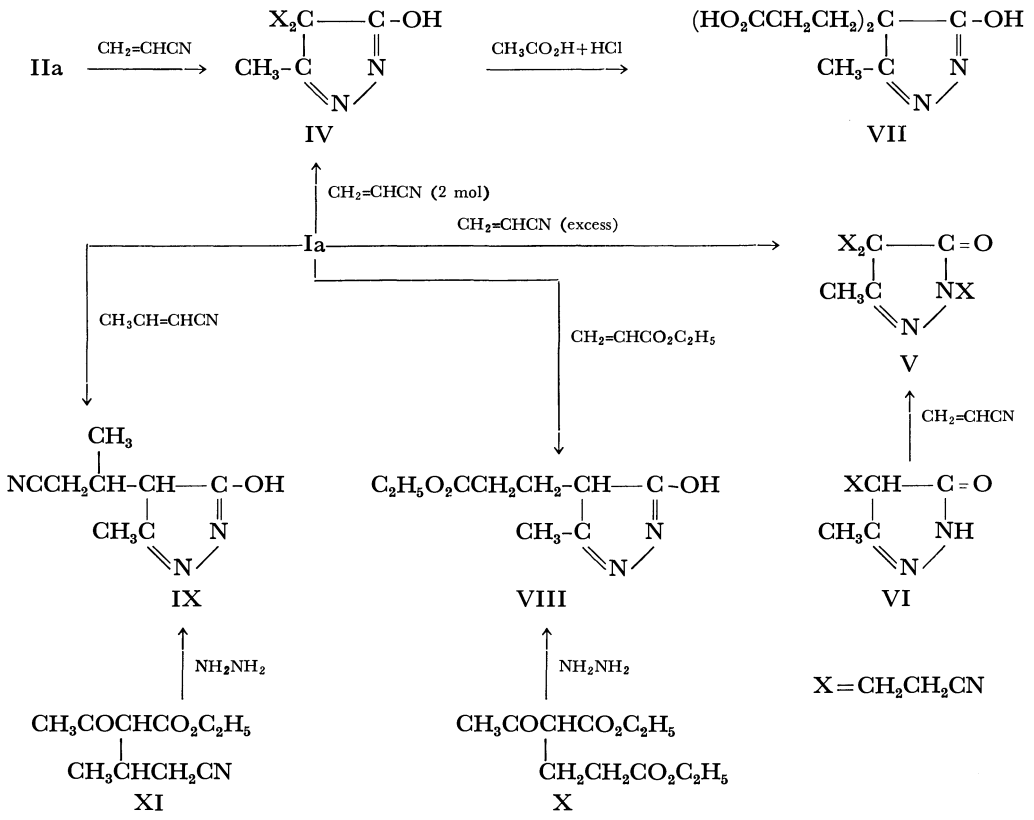

Chart 1

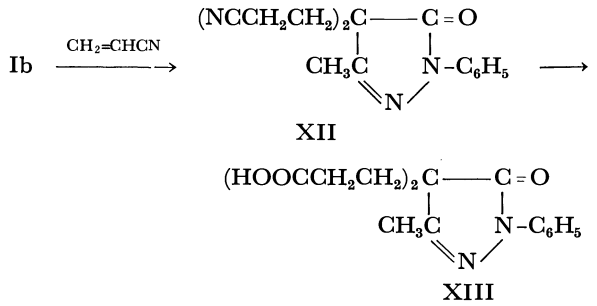
active methylene compounds toward the action of these reagents has been reported.[12-14]

An investigation of the behavior of Ib toward acrylonitrile in aqueous pyridine solution shows that it reacts with two molecules of the reagent yield the 4,4-di(β-cyanoethyl)-1-phenyl-3-methyl-2-pyrazolin-5-one derivative (XII), which on hydrolysis with acetic acid–hydrochloric acid mixture affords the corresponding 4,4-di(β-carboxyethyl) derivative(XIII).



The behavior of 3-amino-1-phenyl-2-pyrazolin-5-one(Ic) toward the action of various reagents containing an activated double bond system was also investigated. Treatment of Ic with ethyl acrylate or acrylonitrile resulted in the formation of products, the analytical data of which indicated that two molecules of either of the reagents had been added and for which structures XIV and XV were proposed. Many isomeric structures for the reaction products of Ic with ethyl acrylate or acrylonitrile are possible. However, the IR spectra of either of the products indicated that the ring CO and the amino group are not involved in the reaction. The 4,4-dialkylated structure (*cf.* XIV and XV) is preferable to the possible 1,4-dialkylated isomer based on analogy to the behavior of Ia, b and the stability of the reaction products toward the action of acetic acid[1,2] and amines.[15] The weak reactivity of possition 2 and the amino group in 3-amino-1-phenyl-2-pyrazolin-5-one has been reported.[1]

We have found that Ic reacts with ethyl crotonate in the presence of sodium ethoxide to yield the pyrazolopiperidine derivative XVI. The structure of XVI was inferred from analytical and spectral data, and its synthesis *via* the action of phenylhydrazine on α-ethoxycarbonyl-β-methylglutamonitrile (XVII). The discrepancy in behavior between Ic and Ia toward the action of ethyl acrylate can be rationalized in terms of increment of reactivity of the methylene group in Ic as compared to that of Ia, induced by the presence of amino group on C-3 which is tautomeric with the imino form.

The compound Ic adds also the benzalacetophenone

to yield compound XVIII. This is similar to the behavior of Ib toward the same reagent.[16]

Experimental

All melting points were determined on a micro hot stage and are uncorrected. The IR spectra were recorded with a Hitachi Grating IR spectrophotometer Model EPI-G3.

4,4-Di(β-cyanoethyl)-5-hydroxy-3-methylpyrazole (IV). *1) From 3-Methyl-2-pyrazolin-5-one (Ia):* To a solution of acrylonitrile(10 ml) in pyridine(150 ml) and water(50 ml) was added 10 g of Ia. The reaction mixture was refluxed for 6 hr and the solvent was evaporated *in vacuo* to leave a residue which was purified by crystallization from water to give 15.5 g of IV. Colorless crystals, mp 159 °C. IR: 2920—2600(chelated OH), 2230 cm^{-1} (CN). Found: C, 58.31; H, 5.84; N, 27.80%. Calcd for $C_{10}H_{12}ON_4$: C, 58.88; H, 5.92; N, 27.44%.

2) From 4-(β-Cyanoethyl)-3-methyl-2-pyrazolin-5-one (IIa). To a solution of acrylonitrile(1.6 ml) in pyridine(50 ml) and water (70 ml) was added 3 g of IIa. The reaction mixture was refluxed for 10 hr and then evaporated *in vacuo*. The residue was collected, recrystallized and identified(mp and mixed mp) as IV. Yield, 2.5 g.

1,4,4-Tri(β-cynoethyl)-3-methyl-2-pyrazolin-5-one (V). *1) From Ia.* To a solution of acrylonitrile(1.0 ml) in pyridine(30 ml) and water(10 ml) was added 2.0 g of Ia and then one drop of concentrated potassium hydroxide. The mixture was refluxed for 10 hr and left to stand overnight at room temperature. The solvent was removed *in vacuo* and the resulting oily residue was dissolved in hot ethanol. The crystals, which separated on standing, were recrystallized from ethanol to yield 1.8 g of V, colorless crystals, mp 89 °C. IR: 2220(CN), 1700(ring CO) cm^{-1}. Found: C, 60.44; H, 5.84; N, 27.19%. Calcd for $C_{13}H_{15}ON_5$: C, 60.68; H 5.88; N, 27.22%.

2) From 1,4-Di(β-cyanoethyl)-3-methyl-2-pyrazolin-5-one(VI). Compound VI was treated with acrylonitrile using the same experimental procedure as above and the product was identified (mp and mixed mp) as V. Yield, 51%.

4,4-Di(β-carboxyethyl)-5-hydroxy-3-methylpyrazole (VII). A solution of 3.0 g of IV in acetic acid (30 ml) was mixed with 10 ml of concentrated hydrochloric acid and refluxed for 3 hr. The solvent was removed *in vacuo* and the resulting solid product was crystallized from water to yield 1.5 g of VII, colorless crystals, mp 230 °C (decomp.). Found: C, 49.49; H, 5.94; N, 11.59%. Calcd for $C_{10}H_{14}O_5N_4$: C, 49.58; H, 5.83; N, 11.57%.

4-(β-Ethoxycarbonylethyl)-5-hydroxy-3-methylpyrazole (VIII). *1) From Ia and Ethyl Acrylate:* To a solution of ethyl acrylate (5.0 ml) in ethanol(100 ml) and water(50 ml) was added 5.0 g of Ia. One drop of concentrated potassium hydroxide was then added and the reaction mixture was refluxed for 6 hr. The solvent was then removed *in vacuo* and the oily residue formed was dissolved in benzene and petroleum ether was added. The crystals separated were collected by filtration and recrystallized from benzene to yield 4.7 g of VIII, colorless crystals, mp 100 °C. IR: 2900—2675(OH), 1740 (ester CO)cm^{-1}. Found: C, 54.74; H, 7.06; N, 14.08%. Calcd for $C_9H_{14}O_3N_2$: C, 54.53; H, 7.12; N, 14.13%.

2) From X and Hydrazine Hydrate. To a solution of X (2.0 g) in ethanol(20 ml) was added hydrazine and the mixture was refluxed for 2 hr. The solvent was removed *in vacuo* and the residue was worked up as described above. The product was identified (mp and mixed mp) as VIII. Yield 1.6 g.

4-(β-Cyano-α-methylethyl)-5-hydroxy-3-methylpyrazole (IX). To a solution of crotononitrile(7.0 ml) in pyridine (150 ml) and water (50 ml) was added 10 g of Ia. One drop of potassium hydroxide solution was added and the reaction mixture was refluxed for 24 hr. The solvent was removed *in vacuo* and the residue was dissolved in a small quantity of water and acidified with 10 ml of acetic acid. The solid product separated on being left to stand was collected and crystallized from water to yield 9.0 g of IX, colorless crystals, mp 193 °C. IR: 2900—2650(OH), 2240(CN), 1690(ring CO)cm^{-1}. Found: C, 58.19; H, 6.54; N, 25.30%. Calcd for $C_8H_{11}ON_3$: C, 58.16; H, 6.71; N, 25.44%.

The same compound(IX) was similarly obtained by the reaction of ethyl 1-acetyl-3-cyano-2-methylbutyrate(XI) and hydrazine hydrate.

4,4-Di(β-cyanoethyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (XII). To a solution of acrylonitrile(10 ml) in pyridine(150 ml) and water(50 ml) was added 9.0 g of Ib. The mixture was refluxed for 10 hr, evaporated *in vacuo* and the residual oily product was dissolved in hot ethanol. The crystals separated on cooling were collected and recrystallized from ethanol to give 10 g of XII, mp 74 °C. IR: 2220(CN), 1700(ring CO)cm^{-1}. Found: C, 68.98; H, 5.45; N, 20.01%. Calcd for $C_{16}H_{14}ON_4$: C, 69.05; H, 5.07; N, 20.13%.

4,4-Di(β-carboxyethyl)-3-methyl-1-phenyl-2-pyrazolin-5-one (XIII). Compound XII was treated with acetic acid

16) A. Mustafa, M. Fleifel, M. Ali, and N. M. Hassan, *Ann. Chem.*, **739**, 75 (1970).

and hydrochloric acid by the same procedure as for the preparation of VII. The solid product obtained upon evaporation of the solvent *in vacuo* was crystallized from water to give colorless crystals of XIII, mp 142 °C, in a yield of 80%. Found; C, 60.27; H, 5.70; N, 8.79%. Calcd for $C_{16}H_{18}O_5N_2$: C, 60.37; H, 5.70; N, 8.80%.

3-Amino-4,4-di(β-ethoxycarbonylethyl)-1-phenyl-2-pyrazolin-5-one (XIV). This compound was obtained by a similar procedure to that for XII. Mp, 84 °C, Yield 12.0 g. IR: 1745, 1725(ester CO), 1710(ring CO), 3450, 3355 (NH_2) cm^{-1}. Found: C, 60.43; H, 6.77; N, 12.11%. Calcd for $C_{25}H_{25}O_5N_3$: C, 60.78; H, 6.71; N, 11.19%.

3-Amino-4,4-di(β-cyanoethyl)-1-phenyl-2-pyrazolin-5-one (XV). To a solution of acrylonitrile(5.0 ml) in ethanol(150 ml) and water(50 ml) was added 5.0 g of Ic and the mixture was worked up as for XIV. The solid product obtained on evaporation of the solvent was crystallized from water to give 6.0 g of XV, mp 164 °C. IR: 3390, 3300, 3190(NH_2), 2220(CN), 1710(ring CO) cm^{-1}. Found: C, 64.32; H, 5.40; N, 25.24%. Calcd for $C_{15}H_{15}ON_5$: C, 64.06; H, 5.47; N, 24.90%.

2,3-Dihydro-4-methyl-2-phenylpyrazolo[3,4-b] piperidine-3,6-dione (XVI). *1) From Ic and Ethyl Crotonate*: To a solution of ethyl crotonate(3 ml) in pyridine(150 ml) and water (50 ml) containing one drop of concentrated potassium hydroxide solution was added 7.0 g of Ic. The mixture was refluxed for 10 hr and then evaporated *in vacuo*. The residual oil was treated with sodium ethoxide solution (perpared from 2.0 g of sodium and 150 ml of ethanol) and the mixture was refluxed for 2 hr and again evaporated *in vacuo*. The oil was dissolved in water(100 ml) and acidified with acetic acid. The precipitates were collected by filtration and crystallized from ethanol to give 4 g of XVI, colorless crystals, mp 233 °C. IR: 3130(NH), 1710—1690, 1645—1630(ring CO), 1590(CN) cm^{-1}. Found: C, 63.97; H, 5.33; N, 17.10%. Calcd for $C_{13}H_{13}O_2N_3$: C, 64.18; H, 5.39; N, 17.28%.

2) From Phenylhydrazine and XVII: To a sodium ethoxide solution (prepared from 5.0 g of sodium and 160 ml of ethanol) was added, 12 g of XVII and 7 ml of phenylhydrazine. The mixture was refluxed for 16 hr and then evaporated *in vacuo*. The residue was treated as above and the product was identified (mp and mixed mp) as XVI. Yield, 2.0 g.

3-Amino-4-(1-phenyl-2-benzoylethyl)-1-phenyl-2-pyrazolin-5-one (XVIII). To a sodium ethoxide solution(prepared from 3.0 g of sodium and 150 ml of ethanol) were added, 8.5 g of Ic and 5.0 g of benzalacetophenone. The reaction mixture was refluxed for 6 hr and then evaporated *in vacuo*. The residue was dissolved in water and acidified with concentrated hydrochloric acid. The precipitates were collected by filtration and crystallized from ethanol to yield 6.6 g of XVIII, colorless crystals, mp 300 °C. Found: C, 75.10; H, 6.10; N, 10.58%. Calcd for $C_{24}H_{21}O_2N_3$: C, 75.15; H, 5.52; N, 10.96%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3821—3824 (1973)

Studies on Reactions of the *N*-Phosphonium Salts of Pyridines. III. A New Method for the Activation of Amines *via* the *N*-Phosphonium Salts by Means of Oxidation of Phosphorous Acid and Its Esters in the Presence of Tertiary Amines

Noboru YAMAZAKI and Fukuji HIGASHI

Department of Polymer Science, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received May 22, 1973)

Amines were treated with the *N*-phosphonium salts of pyridine prepared by the oxidation of the phosphorous acid and its esters with mercuric chloride in pyridine; they yielded the corresponding amides in good yields upon acidolysis with carboxylic acids, together with metallic mercury in a nearly quantitative yield. The reaction was studied using phosphorous acid and its several esters, and was presumed to proceed *via* the activation of amines by the *N*-phosphonium salts of pyridine which were characterized by IR spectroscopy. This process for the activation of amino groups was successfully extended to peptide synthesis in pyridine at low temperature using diphenyl phosphite.

We obtained the *N*-phosphonium salts of pyridines by the oxidation of phosphorous acid and its esters in tertiary amines like pyridine.[1-3] The reactions of the salts with carboxylic acids were elucidated by the replacement of the chlorine atom on the salts by the acid (Eqs. 1 and 2), and the nucleophilic attack of the acid on the phosphorus atom (Eq. (3)).

A similar mechanism was proposed in the reaction of the salts (Ia-d) with amine.[3]

The present paper deals with detailed studies on the reactions of the *N*-phosphonium salts with the amines, and the application to peptide synthesis.

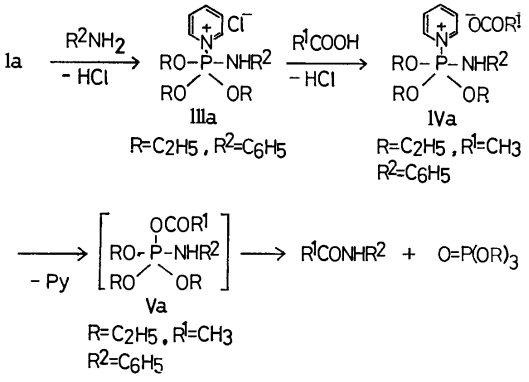
Results and Discussion

The *N*-phosphonium salt of pyridine (I) has been obtained by the oxidation of phosphorous acid and its esters with mercuric chloride in pyridine. When the salt in pyridine was refluxed with aniline for 1 hr and then with acetic acid for 1 hr, acetanilide was obtained in excellent yields. Similarly, several anilides were prepared by using phosphorous acid, its mono-, di- and tri-esters. The results are given in Table 1.

The reaction can be assumed to proceed *via* *N*-phosphonium salt(III) carrying aniline obtained by the reaction of I with aniline. III is converted into IV on treatment with carboxylic acids. IV is unchanged in pyridine at ordinary temperature, but decomposes to the anilide *via* V at higher temperatures (see Scheme 1).

In order to confirm the mechanism, III and IV were separated as syrups containing pyridine hydrochloride.[1] They do not seem to have been purified because of contamination of pyridine hydrochloride and of difficulty in crystallization. Though V could not be isolated, it was considered to take part in the reaction from the result of steric effect of carboxylic acids upon the yield of the anilides.

The structure of Ia ($R=C_2H_5$-) has been discussed previously.[1] The IR spectrum of IIIa ($R=C_2H_5$-), like that of Ia ($R=C_2H_5$-), showed characteristic bands at 1630, 1580 and 1485 cm^{-1} due to $\nu_{C=N^+}$ of the *N*-phosphonium salt of pyridine, and a strong band at 1600 cm^{-1} due to $\nu_{C=C}$ of anilino moiety. From the results and the appearance of the bands due to pyridine hydrochloride after the reaction of Ia ($R=C_2H_5$–) with aniline, IIIa ($R=C_2H_5$–) was assumed to be produced by replacement of a chlorine atom (or ion) on

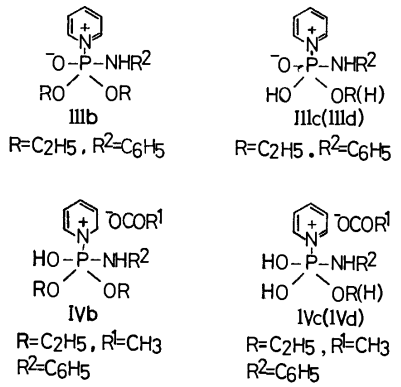


Scheme 1.

Ia ($R=C_2H_5$–) with anilino moiety. The IR spectrum of IVa ($R=C_2H_5$–) also showed bands due to $\nu_{C=N^+}$ of the *N*-phosphonium salt, νC=C of anilino moiety and $\nu_{C=O}$ of acetoxy group.

The reaction with the triester is summarized in Scheme 1.

The reactions with phosphorous acid (Id) and its other esters (Ib and Ic) might proceed in a similar way. The corresponding *N*-phosphonium salts of pyridine were prepared from phosphorous acid (IIId and IVd), its monoester (IIIc and IVc) and its diester (IIIb and IVb), and characterized by IR spectroscopy. These can be envisaged as follows.



The reaction of III with carboxylic acids took place easily and gave better results than that of II with amines. For example, IIId from phosphorous acid gave acetanilide in a nearly quantitative yield (97%) by the reaction with acetic acid for only 1 hr of reflux, whereas in the case of IId more than 2 hr of reflux with aniline was required to obtain the anilide in the same yield.[2]

This would be attributed to the difference in reactivity between IId and IIId toward nucleophiles, since the formation of IId was almost completed under these conditions, the ether extract from the reaction mixture of Id and acetic acid containing no acetic acid.[1]

The facility of acidolysis of III can be explained in terms of the electromeric effect of the anilino group on III. The effect may cause a decrease of electron-density on the phosphorus atom through the migration of the electron of phosphorus-nitrogen (aniline) bond toward the nitrogen atom, resulting in an increase in electrophilicity on the phsophorus atom. Consequently, II can be readily attacked by the carboxylate anions to give the corresponding anilides by way of IV and V.

In the reactions with the monoalkyl esters, the yield of the anilide was unexpectedly low, but that of monophenyl ester was excellent (Table 1). The increase in pK_a of carboxylic acids did not improve the yield (see trifluoroacetanilide), suggesting that the rate-determining step in the reaction with monoalkyl esters is the nucleophilic attack of aniline in the phosphorus atom on Ic. Therefore, the presence of electron-attracting groups such as the phenyl group, increased the electrophilicity on the phosphorus atom, facilitating the attack of aniline on Ic. On the other

hand, the electron-donating nature of alkyl groups retarded the reaction.

A similar effect caused by the electronic nature of alkyl and phenyl groups was also expected in the reactions with the diesters, but no effect was observed. It seems reasonable to assume that the reaction of Ib with aniline is unaffected by the electrophilicity on the phosphorus atom because of an easy replacement reaction of the chlorine atom (or ion) in Ib by the anilino group in a similar manner to Eq. (2).

The yield of the anilides was affected by the steric effect of amines, carboxylic acids and tertiary amines, similarly to those in the reactions of I with carboxylic acids.[1,2]

The steric effect of carboxylic acids upon the yield was reflected in the lower yields of pivalanilide than those of acetanilide (see Table 1). Pivalanilide was obtained in nearly the same amount by acidolysis of III as by aminolysis of II. The results led us to consider that the nucleophilic attack of carboxylate anions on the phosphorus atom is involved in the reaction, by possible destruction of the phosphorus-nitrogen (pyridine) bond to give V.

Another possible route of reaction *via* anilinophosphoramides was excluded by the fact that diethyl anilinophosphoramidate yielded no acetanilide when refluxed with acetic acid in pyridine.

Carboxylic amides were proved to be produced through a similar activation of amines to that of carboxylic acids. They were also obtained in the presence of both amines and carboxylic acids.[3] Consequently, three procedures were available for the preparation of carboxylic amides by means of the *N*-phosphonium salts of pyridines, *viz.*, aminolysis after activation of carboxyl component (method A), acidolysis after that of the amino component (method B) and the activation instantly followed by the coupling reaction in the presence of both components (method C).

The three methods were tested in the reaction of benzyloxycarbonyl-glycine and ethyl glycinate in order to find the most effective one for peptide synthesis. Both activation and coupling reactions were carried out at low temperature (45 °C) to prevent racemization. The activation procedures were achieved by adding the amino and/or carboxyl components to the mixture prepared by the oxidation of diphenyl phosphite with mercuric chloride in pyridine.[3] Methods B and C were preferable to A, indicating that even in the presence of both components the amino component was preferably activated to yield the peptide in a good yield (Table 2).

A variety of phosphorus compounds were examined

Table 1. Preparation of anilides through activation of aniline using various phosphorus compounds and mercuric chloride in tertiary amines

TABLE 3. PREPARATION OF Z-Gly-Gly-OEt USING VARIOUS PHOSPHORUS COMPOUNDS

Phosphorous compounds	Yield, %[a)]
Phosphorous Acid	4
Monophenyl Ester	20
Diisopropyl Ester	18
Diphenyl Ester	95
Triisopropyl Ester	23

a) The reactions were carried out at 45 °C for 12 hr by method C.

in the reaction between benzyloxycarbonyl-glycine and ethyl glycinate by method C (Table 3). Diphenyl phosphite was found to be most effective. This may be due to the increase in electrophilicity of the phosphorous atom caused by the electron-attracting nature of the phenyl groups in the phosphite.

Several other peptides were also synthesized using diphenyl phosphite by methods B and C. The results are given in Table 2. Good yields without detectable racemization were obtained within experimental errors.

It is surprising that the presence of the free side chains of glutamic acid, glutamine and methionine in the carboxyl component, and of tyrosine in the amino component did not cause any difficulty in the reactions. For example, the α-carboxyl rather than the γ-carboxyl group in glutamic acid referred to be activated, producing the α-peptide in a high yield. Similarly, a peptide of glutamine was obtained accompanied by no side reactions such as nitrile formation.

The oxidation mixture involving the *N*-phosphonium salts of pyridine could activate not only carboxyl and amino groups but also hydroxyl groups.[3)] Thus, a competitive activation of the amino and hydroxyl groups was expected in the reaction between ethyl tyrosinate and benzyloxycarbonyl-glycine, giving the corresponding amide and ester. The result shows that the amino group in ethyl tyrosinate was preferably activated to give the amide without yielding any detectable amount of the ester.

Experimental

Preparation of I, III and IV. Preparation of I was described in previous papers.[1,2)] A mixture of equimolar amounts of triethyl phosphite (2.1 g, 12.5 mmol) and mercuric chloride (3.5 g) was refluxed for 1 hr in 20 ml of pyridine, and for 1 hr after addition of aniline (1.2 g, 12.5 mmol). From the mixture, IIIa ($R=C_2H_5-$) was obtained as an ether-insoluble syrup by a similar procedure to that for Ia($R=C_2H_5-$). When IIIa ($R=C_2H_5-$) was treated with acetic acid at room temperature, IVa ($R=C_2H_5-$) was also obtained as a syrup. Similarly, IIIb~IIId and IVb~IVd were obtained.

Preparation of Anilides through the Activation of Aniline. A mixture of equimolar amounts of phosphorous acid and its esters (12.5 mmol) and mercuric chloride was heated at 115 °C for 1 hr in 20 ml of tertiary amines. The resulting mixture was treated with aniline (12.5 mmol) for 1 hr under reflux, and then with equimolar amounts of carboxylic acids for 1 hr. The resulting anilides were isolated and purified according to the previously reported procedures.[3)] The anilides thus obtained had melting points and infrared spectra identical with those of authentic samples.

Preparation of Peptides using Phosphorous Acid and Its Esters in Pyridine. A mixture of equimolar amounts of phosphorous acid and its esters (12.5 mmol) and mercuric chloride was refluxed for 1 hr in 20 ml of pyridine.

Method A: The oxidation mixture was treated with a benzyloxycarbonyl amino acid (12.5 mmol) in 10 ml of pyridine. After 1 hr, an amino acid ester hydrochloride (12.5 mmol) was added to the mixture, and then the solution was kept at 45 °C for 12 hr. The peptide formed was isolated and purified as described previously.[3)]

Method B: The oxidation mixture was treated as in method A with an amino acid ester hydrochloride, a benzyloxycarbonyl amino acid being added after 1 hr, and the mixture kept under the same conditions.

Method C: A mixture of a benzyloxycarbonyl amino acid and an amino acid ester hydrochloride in 20 ml of pyridine was added to the oxidation mixture, and then the solution was kept under the same conditions as for method A.

An Addition Reaction of Diethylamine to Styrene Catalyzed by Lithium Diethylamide

Tadashi NARITA, Teruo YAMAGUCHI, and Teiji TSURUTA

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113

(Received April 25, 1973)

An addition reaction of diethylamine to styrene catalyzed by lithium diethylamide was found to proceed stoichiometrically to produce 1-diethylamino-2-phenylethane. The rate of the reaction was expressed by the equations: $v=k[\text{Styrene}][Et_2NLi]^{1.3}$ and $v=k[\text{Styrene}][Et_2NLi]$, the ratios of $[Et_2NH]_0$ to $[Et_2NLi]_0$ being 3.0 and 10 respectively. On the basis of the kinetic studies, the mechanism of the addition reaction was elucidated. The nucleophilic character of this reaction was clearly demonstrated by the σ-ρ Hammett plot. The second-order rate constant for the addition reaction of styrene was found to be of the same order of magnitude as that of butadiene. The presence of butadiene in the reaction system showed no effect on the reactivity of styrene.

The reactions of some active hydrogen compounds with butadiene initiated by alkyllithium has recently been reported to produce interesting intermediate compounds for organic synthesis.

The reaction of diphenylmethane with butadiene initiated by the system consisting of *n*-butyllithium and a donor compound has been found to produce 5,5-diphenylpentene derivatives.[1] A stereospecific reaction takes place, on the other hand, when diethylamine is reacted with butadiene in the presence of lithium diethylamide at the $[Et_2NH]_0/[Et_2NLi]_0$ ratio of 3.0, the selectivity of the product, 1-diethylamino-*cis*-butene-2, being up to 99%.[2] On the basis of kinetic and spectroscopic studies, the lithium diethylamide—diethylamine (1 : 2) complex has been concluded to play an important role in this reaction.[3]

It is widely accepted that the microstructures of polydienes prepared by alkyllithium are markedly different from one another according to the nature of the solvents or complexing agents used for the polymerization reactions. The predominant formation of 1,4-structure in hydrocarbon solvents is interpreted in terms of a concerted mechanism in which the preliminary coordination of diene molecules to the organolithium species is assumed. Lewis bases used as solvents (or complexing agents) interfere with the coordination of the monomer molecules, resulting in the predominant formation of the 1,2-structure in the polymer chain.

It is also known, in the styrene-diene copolymerization initiated by alkyllithium in hydrocarbon, that the reactivity of styrene is very much enhanced in the presence of Lewis bases.

In the light of these previous results, the stereospecific addition reaction of the lithium diethylamide—diethylamine complex seems to possess some peculiar character, for the 1,4-*cis*-structure is almost exclusively formed in the addition product, even in the presence of the Lewis base. In order to make clear the nature of the lithium amide complex in more detail, the addition reactions to styrene and its derivatives were studied.

Experimental

Most of the experiments were carried out under a purified nitrogen atmosphere in order to exclude oxygen and moisture.

Materials. Commercial cyclohexane, styrene, α-methylstyrene, butadiene, diethylamine, and triethylamine were purified by the usual method. *n*-Butyllithium was prepared from *n*-butyl chloride and lithium metal in purified petroleum ether and was used as a cyclohexane solution. *p*-Methylstyrene[4] and *p*-methoxystyrene[5] were synthesized according to the literature.

Procedures. The methods of the rate study of the addition reactions were described in an earlier publication.[3] The analyses of the addition-reaction product of diethylamine with styrene, 1-diethylamino-2-phenylethane, and of those with *p*-methylstyrene and *p*-methoxystyrene were performed by studying the infrared and proton magnetic resonance spectra.

Results and Discussion

As has been reported previously, the addition reaction of lithium diethylamide with butadiene does not

proceed in the absence of dialkylamine.[2,3] A similar phenomenon was also observed in the reaction of lithium diethylamide with styrene, no addition product, 1-diethylamino-2-phenylethane, being detected until an excess of free diethylamine is present along with the lithium amide in the reaction system.

The dependence of the initial styrene concentration on the reaction rate is shown in Fig. 1. As the curves for the concentrations of the starting materials and of the addition product measured independently by means of the vapor-phase chromatography are clearly symmetrical, any possibilities of side reactions such as telomerization[6] may be ruled out. Since the first-order analyses shown in Fig. 1 stay linear until 50% conversion, the reaction rate is proportional to the first-order of the styrene concentration. The pseudo first-order rate constants are summarized in Table 1.

TABLE 1. PSEUDO FIRST-ORDER RATE CONSTANTS OF THE REACTION OF Et_2NH-Et_2NLi COMPLEX WITH STYRENE[a)]

$[Et_2NH]_0$ mol/l	$[Et_2NLi]_0$ mol/l	$[Styrene]_0$ mol/l	k' hr^{-1}
0.750	0.250	0.125	0.49
0.750	0.250	0.250	0.48
0.750	0.250	0.375	0.49

a) In cyclohexane at 50°C.

In order to determine the dependency of the reaction rate on the concentration of lithium diethylamide, the reaction rate was analyzed under a constant concentration of styrene, with the ratio of $[Et_2NH]_0$ to $[Et_2NLi]_0$ being 3.0. When the reaction rate is expressed as Eq. (1), the pseudo firstorder rate constant, k', can be determined from the slopes of the straight lines in Fig. 2:

$$v = k'[\text{Styrene}] \quad (1)$$

The slopes of the line which are obtained from the plot of log k' *vs.* log$[Et_2NLi]$ should show the dependency on the lithium diethylamide concentration:

$$k' = k_s[Et_2NLi]^x \quad (2)$$

As is shown in Fig. 3 and Table 2, the reaction rate can be expressed as Eq. (3) in the range of $[Et_2NH]_0/[Et_2NLi]_0 \geqq 10$:

$$v = k_s[\text{Styrene}][Et_2NLi] \quad (3)$$

whereas the reaction order shows some fractional power in the cases of $[Et_2NH]_0/[Et_2NLi]_0=3.0$ ($x=1.3$) and 5.0 ($x=1.2$), as is shown in Eq. (4):

$$v = k_s[\text{Styrene}][Et_2NLi]^x \quad (4)$$

This phenomenon may be explained in terms of the "solvent effect", because the increase in the lithium amide concentration is accompanied by an increase in the double mole quantity of diethylamine. The increase in the rate caused by the "solvent effect" may be eliminated by adjusting the total amine concentration with triethylamine. The results of the experiments in which the total amine concentration, $[Et_2NH]_0+[Et_3N]$, was kept constant are shown by a dotted line in Fig. 3. The reaction order obtained from the slope is 1.0_4. The acceleration of the addition reaction rate observed in Fig. 3 may, therefore, be concluded to come from the "solvent effect" of amines.[7]

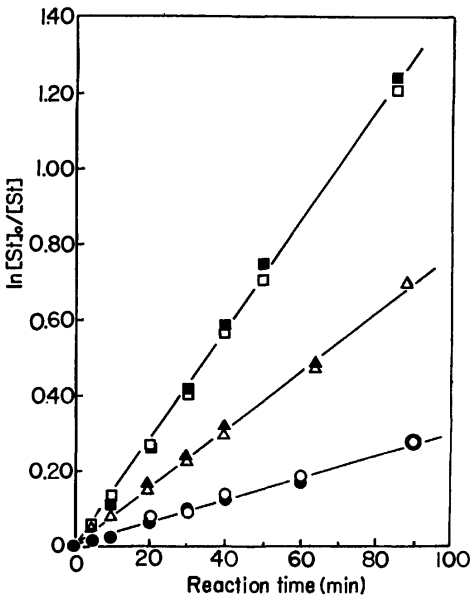

Fig. 2. Reaction of Et_2NH-Et_2NLi complex with styrene: dependence of lithium diethylamide concentration: first-order analyses for styrene concentration.

Dotted line: $[Et_2NH]_0/[Et_2NLi]_0=3.0$, $[Et_2NH]_0+[Et_3N]=0.375$ mol/l (*cf.* Fig. 2).

7) Possibility that the difference may come from the decrease of effective concentration of the active species by the reverse reaction of Eq. (6) might be disproved since ultraviolet spectral measurement of the reaction system showed no peak assignable to $Et_2NCH_2\overset{\ominus}{C}HC_6H_5\overset{\oplus}{Li}$.[8]

Table 2. Reaction kinetics of Et_2NH-Et_2NLi complex with styrene[a)]

$\frac{[Et_2NH]_0}{[Et_2NLi]_0}$	$[Et_2NLi]_0$ mol/l	k' hr^{-1}	Note

	0.375	2.16	
15	0.125	0.83	$v=k_s[\text{Styrene}][Et_2NLi]$
	0.250	1.81	$k_s=2.0\times10^{-3}$ l/mol·s
	0.375	2.61	
28	0.250	2.32	$k_s=2.6\times10^{-3}$ l/mol·s

a) $[\text{Styrene}]_0=0.250$ mol/l, in cyclohexane at 50°C.

The acceleration of the rate by the increased concentrations in the range of higher concentrations may also be seen in Table 2.

These results show that the reactivity of styrene is more sensitive to the change in the polarity of the solvent used than is that of butadiene (*cf.* Table 3).

The overall reaction scheme of the addition reaction of diethylamine with styrene can, therefore, be depicted as follows:

$$Et_2NLi + 2Et_2NH \rightarrow Et_2NLi\cdot 2Et_2NH \quad (5)$$

$$Et_2NLi\cdot 2Et_2NH + C_6H_5CH{=}CH_2 \xrightarrow{k_s} Et_2NCH_2CHC_6H_5Li\cdot 2Et_2NH \quad (6)$$

$$Et_2NCH_2CHC_6H_5Li\cdot 2Et_2NH + Et_2NH \longrightarrow Et_2NCH_2CH_2C_6H_5 + Et_2NLi\cdot 2Et_2NH \quad (7)$$

In order to get a hint about the character of the lithium diethylamide—diethylamine complex, the addition reactions of some substituted styrene with the amide complex at $[Et_2NH]_0/[Et_2NLi]_0=10$ were studied. The first-order analyses and the rate constants are shown in Fig. 4. As is shown in Fig. 5, the resultant ρ value is +5.0, in good agreement with the value reported for the anionic reaction system of polystyrylsodium with substituted styrene in tetrahydrofuran.[9)]

It is well known that, in the styrene–butadiene copolymerization with a lithium alkyl initiator in hydrocarbon media, the presence of a diene monomer pronouncedly suppresses the reactivity of styrene, although the rate of the homopolymerization of styrene is greater than that of butadiene under the same conditions. The microstructure of the butadiene units of the copolymer prepared under the above-mentioned copolymerization system is predominantly the 1,4-structure. On the other hand, when the reactivity of styrene is increased by the addition of some Lewis bases in the copolymerization system, the amount of the 1,2-structure in the butadiene units is also increased. In order

to compare the reactivity of lithium diethylamide with that of lithium alkyl, the reactivity of styrene toward the lithium amide in the presence of butadiene was examined. It may be seen in Table 3 that the presence of butadiene has no effect on the reactivity of styrene in contrast with the reaction with lithium alkyl. Table 3 also shows the two monomers to possess rate constants of almost the same order of magnitude. The isomer

distribution of the 1-diethylaminobutene produced here is not different compared with the results reported previously.[2,3]

The above results suggest that the mechanism of the stereospecific addition reaction of the lithium diethylamide complex to butadiene is different from the usual stereospecific addition reaction of lithium alkyl in hydrocarbon solvents, since the 1,4-*cis*-structure formation in butadiene units is still retained, even under reaction conditions which result in comparable monomer reactivities in the styrene–butadiene copolymerization.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3828—3830 (1973)

Mechanism of Transylidation of Stable Sulfonium Ylids with Alkyl Sulfides in the Presence of Catalytic Disulfides[1)]

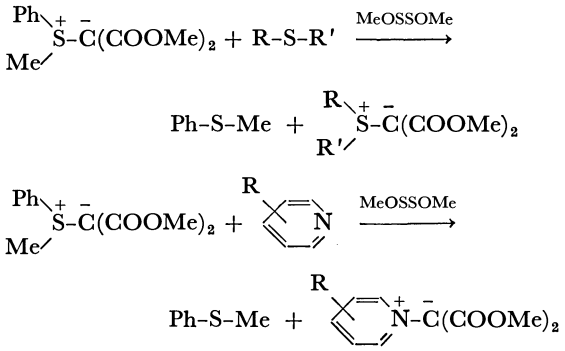
Haruo MATSUYAMA, Hiroshi MINATO, and Michio KOBAYASHI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received May 31, 1973)

In the presence of bis(trifluoromethyl) disulfide, methylphenylsulfonium bis(methoxycarbonyl)methylid is readily attacked by a nucleophile (an alkyl sulfide or a pyridine) and the corresponding new ylid is produced. In the NMR spectrum of a mixture of an ylid, an alkyl sulfide, and a catalytic disulfide, a remarkable broadening in the signals of the α-hydrogen of the sulfide was observed. A mechanism is suggested, which involves a complex from the two reactants and the catalyst.

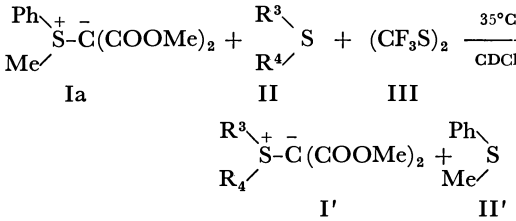
In the presence of a dialkoxy disulfide or thiocyanogen an alkyl sulfide or pyridine attacks the ylid carbon atom of a sulfonium ylid and the corresponding new ylid is formed.[2)]



It has been found that bis(trifluoromethyl) disulfide possesses a similar catalytic activity, and with this catalyst some NMR spectroscopic evidence suggesting the formation of a complex has been obtained.

Results and Discussion

Transylidation of methylphenylsulfonium bis(methoxycarbonyl)methylid (Ia) was carried out with

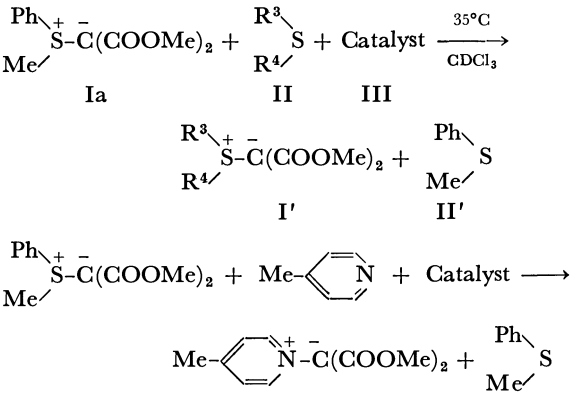


a: $R^3=R^4=Me$, b: $R^3=Me$, $R^4=Et$, c: $R^3, R^4=(CH_2)_4$

1) Organic Sulfur Compounds. Part XLV.
2) H. Matsuyama, H. Minato, and M. Kobayashi, This Bulletin, **46**, 2845 (1973).

several sulfides and 4-methylpyridine in the presence of bis(trifluoromethyl) disulfide (III). In Table 1, the results are compared with those obtained in the presence of dimethoxy disulfide or thiocyanogen. It is clear that when III was used as the catalyst the transylidation proceeds much more slowly than when dimethoxy disulfide or thiocyanogen was used.

TABLE 1. TRANSYLIDATION OF YLID Ia WITH A SULFIDE OR A PYRIDINE IN $CDCl_3$ AT 35°C[a)]



Nucleophile	Catalyst	Time (min)	Products (mol%) Recovered Ia	I'	II'
MeSMe	$(CF_3S)_2$	90	—	93	100
MeSEt	$(CF_3S)_2$	267	—	93	94
$(CH_2)_4S$	$(CF_3S)_2$	30	—	91	98
Me-pyridine	$(CF_3S)_2$	594	64	31	31
MeSMe	$(MeOS)_2$	7	—	100	98
Me-pyridine	$(N{\equiv}CS)_2$	3	—	96	96

a) A mixture consists of Ia (0.5 mmol), a nucleophile (1.0—1.5 mmol) and a catalyst (0.07—0.12 mmol).

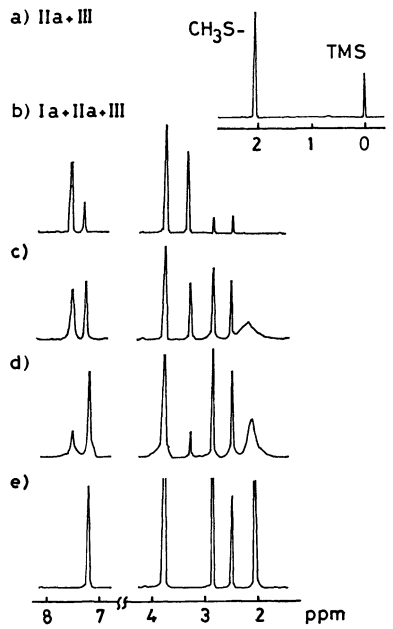


Fig. 1. NMR spectra of mixtures of Ia, IIa, and III in $CDCl_3$ at 35 °C.
a) IIa (1.82 M) and III (0.20 M) in $CDCl_3$
b) 9 min after Ia (0.91 M) was added to IIa and III. The yield of PhSMe was 21%.
e) 40 min after addition. PhSMe, 50%.
d) 60 min after addition. PhSMe, 79%.
e) 90 min after addition. PhSMe, 100%.
PhMeS- (δ, 7.52 ppm), PhSMe (7.25 ppm), C(COOMe)$_2$ (3.68 ppm), PhMeS- (3.30 ppm), Me_2S- (2.88 ppm), PhSMe (2.49 ppm), Me_2S (2.10 ppm).

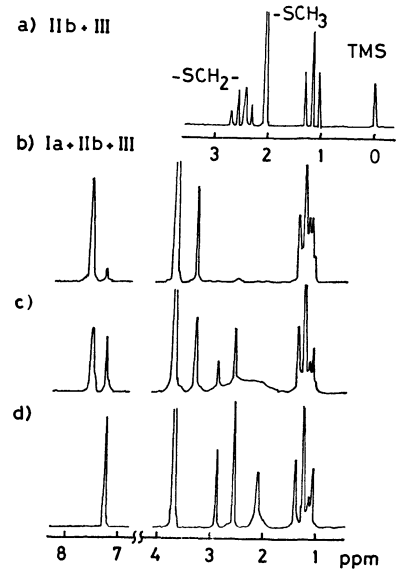

Fig. 2. NMR spectra of mixtures of Ia, IIb, and III in $CDCl_3$ at 35 °C.
a) IIb (2.51 M) and III (0.20 M) in $CDCl_3$.
b) 8 min after Ia (0.89 M) was added to IIb and III. The yield of PhSMe was 6%.
c) 82 min after addition. PhSMe, 27%.
d) 267 min after addition. PhSMe, 94%.
PhMeS- (δ, 7.53 ppm), PhMeS (7.26 ppm), C(COOMe)$_2$ (3.69 ppm), PhMeS- (3.32 ppm), MeEtS- (2.88 ppm), PhSMe (2.50 ppm), MeSEt (2.10 ppm).

When the NMR spectrum of a mixture of Ia, IIa, and III was determined, surprisingly the sharp singlet of IIa was not observed. The NMR spectrum of a mixture containing two components out of the three (Ia and IIa; IIa and III; or III and Ia) was simply the sum of the spectra of the corresponding components, and the methyl signals of IIa disappeared only when all of the three components were mixed. When the NMR spectrum of a mixture of Ia, IIa, and III was determined after about 50% completion of the transylidation, the methyl signal of the remaining IIa was observed as a broad absorption. Throughout the reaction, the methyl signal (PhMeS-, δ, 3.31 ppm) of ylid Ia showed no broadening. When ethyl methyl sulfide (IIb) or tetrahydrothiophene (IIc) was used in place of IIa, a similar broadening of the α-hydrogens (underlined in the formulas shown below) was observed. The results are summarized in Figs. 1 and 2.

$\underline{CH_3}\text{-S-}\underline{CH_3}$ $\quad$ $\underline{CH_3}\text{-S-}\underline{CH_2}\text{-}CH_3$ $\quad$ $(\underline{CH_2}CH_2)_2S$

Reports on broadening of NMR absorptions are mainly those concerning intramolecular rotation or inversion.[3]

Smallcombe and Caserio[4] reported on the rapid exchange of S–CH_3 between methyl disulfide and dimethylthiomethylsulfonium ion.

$$Me_2\overset{+}{S}\text{-S-Me} + CH_3\text{-S-S-}CH_3 \rightleftarrows Me_2S + MeS\text{-}\overset{+}{S}\text{-}SCH_3 \quad (\delta,\ 2.86\ \text{ppm}) \qquad (\delta,\ 2.3\ \text{ppm})$$

The NMR spectrum of the mixture did not show the S–CH_3 signals of two components, but a broad signal. The NMR data show that a rapid equilibrium is maintained as shown above.

We have investigated the transylidation catalyzed by a dialkoxy disulfide, and propose the following scheme which represents what is probably taking place in a mixture of I, II, and III.[2]

$$\begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!\overset{+\ -}{S}\text{-}C(COOMe)_2 + R\text{-S-S-}R \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [\text{complex}]$$

$$[\text{complex}] + \begin{matrix} R^3 \\ R^4 \end{matrix}\!\!>\!S \xrightarrow{k_2} \begin{matrix} R^3 \\ R^4 \end{matrix}\!\!>\!\overset{+\ -}{S}\text{-}C(COOMe)_2 + \begin{matrix} R^1 \\ R^2 \end{matrix}\!\!>\!S + R\text{-S-S-}R$$

The experimental results obtained so far can be summarized as follows.

1) In a mixture of an S-ylid and a catalytic disulfide, no broadening of NMR signals is observed.

2) In a mixture of an S-ylid and a sulfide, no broadening of NMR signals is observed, and almost no transylidation takes place at room temperature.

3) In a mixture of a sulfide and a catalytic disulfide, no broadening of NMR signals is observed.

4) When all of the three components (an S-ylid, a catalytic disulfide and a sulfide (or a pyridine)) are

Scheme.

mixed, the NMR signals of the α-hydrogens of the sulfide (or a pyridine) are much broadened.

5) A broadening of NMR signals is observed only when transylidation takes place.

6) When a sulfide (or pyridine) is not added, an olefin is formed.

7) In the case of a phenacylid, an olefin and a cyclopropane derivative are formed even when a sulfide is present.

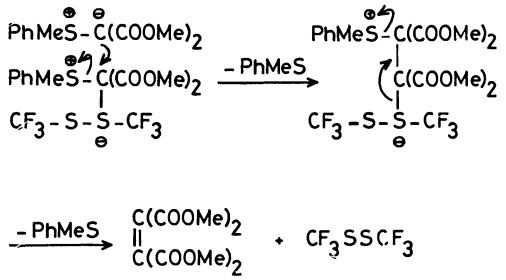
A plausible mechanism consistent with these results is shown in the Scheme.

The first step is the reversible formation of Complex I from Ia and III. Nucleophilic attack of an alkyl sulfide (or pyridine) on the sulfonium sulfur atom of Complex I results in the formation of the termolecular Complex II. The NMR data can be explained by assuming that the formation of Complex II from Complex I and the sulfide (or pyridine) is reversible and rapid, and molecules of the sulfide (or pyridine) rapidly combine with and depart from Complex I one after another. Therefore, the absorption of the α-hydrogens of the sulfide (or pyridine) is broadened between that of the free sulfide (or pyridine) and that of the sulfide (or pyridine) in Complex II. An example of the tetravalent sulfur atom with one unshared electron pair in Complex II is found in the case of sulfuranes.[5]

Formation of Complex I′ from Complex II by removal of methyl phenyl sulfide is probably slow and is the rate-determining step of the whole reaction. Decomposition of Complex I′ gives III and a new ylid I′. The step from Complex II to Complex I′ should be irreversible since a mixture of I′, III, and methyl phenyl sulfide does not give Ia under similar conditions.

The role of a catalytic disulfide is withdrawal of the negative charge on an ylid carbanion so that the nucleophilic attack of a sulfide on the sulfonium sulfur atom is facilitated. Therefore, disulfides possessing strongly electronegative substituents can act as the catalysts for transylidation. The combination of a catalytic disulfide with an S-ylid should be reversible, since the disulfide must be regenerated for repetition of the reaction.

When a sulfide (or pyridine) is not present in the medium, the negatively charged carbon atom of another molecule of the ylid attacks Complex I, and an olefin is produced.



Thus, the mechanism postulated above is consistent with all the experimental findings, and can explain the transylidation[2] and decomposition[6] of ylids in the presence of a catalytic disulfide.

Experimental

Materials. Sulfonium ylid Ia was prepared by the method described in the literature.[7] Methyl sulfide, tetrahydrothiophene, 4-methylpyridine were of reagent grade and used without purification. Bis(trifluoromethyl) disulfide was synthesized by the method of Tullock and Coffman.[8]

Measurements. NMR spectra were determined with a Hitachi NMR spectrometer R-203 (60 MHz). A $CDCl_3$ solution of I, II, and III containing nitromethane (internal standard) was placed in an NMR tube at 35 °C, and the intensity changes of the signals of the original ylid (I), new ylid (I′), and new sulfide (II′) were determined.[2]

Layered Compounds. XVI.[1] NMR Spectra of Multilayered [2.2]Paracyclophanes

Tetsuo OTSUBO, Shigeyoshi MIZOGAMI, Yoshiteru SAKATA, and Soichi MISUMI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

(Received August 10, 1973)

The NMR spectra of multilayered [2.2]paracyclophanes (I—XVI), in which benzene rings are closely stacked, have been examined. The assignment of the signals was made not only by integral strength, but also by solvent effect and the Nuclear Overhauser effect. The steric compression effect of transannular methyl groups on aromatic protons was observed in methylated cyclophanes. Enhanced ortho substitution shift was also observed. All the aromatic protons shift to remarkably higher field due to the anisotropy of stacked benzene rings as the number of layers increases. The shielding effect caused by these rings was empirically estimated.

In the NMR spectra of a series of [*m.n*]paracyclophanes, the aromatic protons appear at higher field beyond the usually accepted range of alkylbenzenes with decreasing number of methylenes in the bridges, *m* and *n*.[2] The upfield shift was considered to be ascribed to the anisotropy effect of one benzene ring on the aromatic protons of the other ring, and to the rehybridization effect of benzene carbon atoms due to ring deformation. By comparing the aromatic protons of [*m*]paracyclophanes ($m=7$—10)[3-5] with those of their open chain model compounds, the former effect is considered to be mainly responsible for the upfield shift, the latter effect being regarded as minor. Janusene,[6] [2.2]metacyclophane,[7] and [13]helicene,[8] in which aromatic rings are constructed parallel to overlap each other, also exhibit such an upfield shift of aromatic protons due to anisotropy of other aromatic rings.

According to X-ray crystallographic analyses,[9,10] both [2.2]paracyclophane and quadruple-layered [2.2]paracyclophane are of rigidly fixed structures with benzene rings fully superposed. We thus anticipated that the aromatic protons of multilayered [2.2]-paracyclophanes, consisting of two or more of [2.2]-paracyclophane system, would be affected by the anisotropy of more remote benzene rings besides the neighboring rings and that these cyclophanes would be appropriate model compounds for the study of magnetic anisotropy. The present paper reports a study on chemical shifts of aromatic protons in a series of multilayered [2.2]paracyclophanes (I—XVI), synthesis of which was described in the preceding paper.[1]

Results and Discussion

Assignment of Aromatic Protons. The NMR spectra of layered cyclophanes (I—XVI) are summarized in Table 1. Except for I, III, and IV, most of them show a few signals of aromatic protons depending upon magnetic environment. The signals are mostly assigned to the corresponding protons with the aid of integral strengths. However, there are some compounds with more than two layers, whose aromatic protons are difficult to assign by their integral strengths alone, *e.g.*, VI (Hb and Hc), XI, and XIV (Hb—He). In these cases, the solvent effect was found to be fairly

a) $\Delta\tau=\tau(CCl_4)-\tau(CDCl_3)$

effective for assignment of the protons. Thus, it was anticipated that the aromatic protons of outer benzene rings (outer ArH) would be strongly affected by solvent, while those of inner benzene rings (inner ArH) would not be influenced so much since they are closely sandwiched between the upper and lower benzene rings. The signals for aromatic protons of single- and double-layered compounds and for outer ArH of more than two layered ones (Table 1) display somewhat larger differences (0.10—0.16 ppm) between chemical shifts in carbon tetrachloride and in deuteriochloroform, while those for inner ArH give smaller differences (0.03—0.06 ppm). On the basis of such a solvent effect, assignments can be made for Hb (inner ArH) and Hc (outer ArH) of VI, and Ha (outer ArH) and Hb (inner ArH) of XI and XII. Dimethyl fivelayered compound XIV shows an integral ratio 2 : 1 : 1 : 1 : 1 of five aromatic proton signals at τ 4.04 (Ha), 4.47 (He), 4.64 (Hd), 4.96 (Hb), 5.08 (Hc) in carbon tetrachloride, and the assignment of those protons seems to be difficult at first. However, Ha, Hb, and Hc can be determined by comparison with the corresponding ones of non-substituted compound XIII, which are easily assigned by the integral strengths. The remaining protons, Hd and He, are distinguished as inner ArH and outer ArH, respectively, on the ground of the solvent effect.

Nuclear Overhauser Effect (NOE). In the spectrum of compound II, the aromatic protons of non-methylated benzene ring appear nonequivalently as

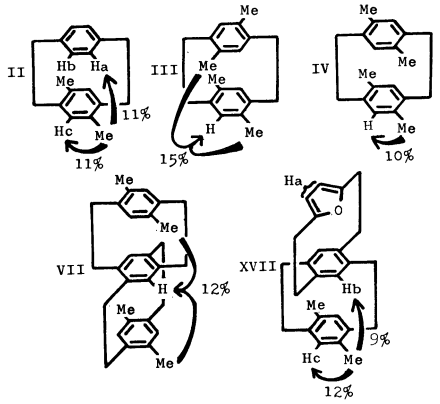

Fig. 1. Nuclear Overhauser effects of some layered cyclophanes in deuteriochloroform.

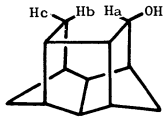
A_2B_2 pattern, possibly due to transannular proximity effect of methyl groups of the opposed benzene ring. Since NOE has successfully been used to assign such protons, we have attempted it on some layered compounds, whose aromatic protons could not be assigned by either the integral strength or the solvent effect. NOE was observed on the peaks at τ 3.22 and 4.00 and not for τ 3.64 peak of the compound II when methyl protons were irradiated in deuteriochloroform (Fig. 1). Since the peak at τ 4.00 is assigned to Hc proton from signal pattern, the peak at τ 3.22 is of the proton Ha at pseudo-gem position to methyl group and the remaining one at τ 3.64 of Hb at pseudo-ortho position.[11] The difference in the extent of NOE on aromatic protons of III and IV is related to the relative positions of the protons to methyl groups of opposed ring, that is, a larger value of the effect for compound III is attributable to both effects of pseudo-gem and ortho methyl groups.

The NOE caused by pseudo-gem methyl group was also observed on aromatic protons of triple-layered cyclophane VII and furanophane XVII. A value for the inner ArH of VII indicates an NOE depending upon efficient relaxation by the two methyl groups closely sandwiching the proton. On the other hand, the inner ArH of XVII exhibits a 9% area increase by irradiating the methyl group, and the protons which are unaffected by the saturation of methyl protons can easily be assigned to furan protons. In contrast to NOE on aromatic protons by saturation of methyl protons, the effect between aromatic protons was not detected on this series of compounds, *e.g.*, no change was observed in the areas of Ha and Hb when Hc of II was saturated. This seems to be well explained in terms of smaller interaction (dipole-dipole relaxation)[12] and longer transannular distances of H–H than those of CH_3–H.

Steric Compression Effect (CE). Hydrogen atoms which are significantly compressed with each other exhibit generally downfield shifts in NMR spectra.[13] This steric deshielding effect was found to be larger in more rigid compounds. Winstein reported unusually large deshielding effects (1—4 ppm) for the compounds with a half-cage structure related to the bird-cage hydrocarbons.[14] For example, the steric compression effect on Ha due to proximity of Hb in compound XVIII was seen to be in excess of 1 ppm. The



XVIII

effect has been observed also in layered cyclophanes containing proximate aromatic rings. Reich and Cram have described in NMR spectra of 4-substituted [2.2]-paracyclophanes that the protons pseudo-gem to the substituent displayed downfield shifts.[15] Similar steric compression effects of transannular methyl groups have been observed in the present multilayered [2.2]paracyclophanes. For example, obvious downfield shifts recognized by comparing the chemical shifts of Ha in dimethyl[2.2]paracyclophane (II) and of the aromatic protons in tetramethyl[2.2]paracyclophane (III) with those of the corresponding protons, to which pseudo-gem position is not substituted with methyl group. A similar deshielding of compressed protons is also observed for Hb of VI, VIII, XI, and XII and Hd of XIV (Table 1). An average value of these compression effects, σ_{CE} (pseudo-gem shift), of methyl groups, −0.36 ppm, is nearly equal to the value for 4-methyl-[2.2]paracyclophane given by Reich and Cram.[15] Of greater interest is a downfield shift of Hb in triplelayered compound VII, for the proton is a unique one sandwiched in between two methyl groups, that is, compressed from both upper and lower sides. They appear at lower field by twice (0.71 ppm) the above mean value for one methyl group. It is noteworthy that VII presents a novel example of steric compression on both sides and there is an additivity among steric compression shifts.

Whether bridged methylene groups of multilayered [2.2]paracyclophanes exert a similar effect can be solved with non-methylated multilayered cyclophanes such as the tripled one V. Thus, two types of outer aromatic protons in V, namely pseudo-gem and pseudo-ortho to methylene group, should exhibit different chemical shifts, provided that the methylene group can exert steric compression effect on the protons in question. However, this is not the case actually. They appear as a singlet pattern to demonstrate equal magnetic environment. This result may be interpreted in terms of out-of-plane bending of the methylene groups toward the opposite side to the proton in question.

A steric compression effect between two methyl groups themselves was also found in tetramethyl[2.2]-paracyclophane (IV). All methyl groups are eclipsed with each other, and their pseudo-gem distances

11) Nomenclature of pseudo-gem and pseudo-ortho was taken according to D. J. Cram, *J. Amer. Chem. Soc.*, **91**, 3505 (1969).
12) R. A. Bell and J. K. Saunders, *Can. J. Chem.*, **48**, 1114 (1970).
13) B. V. Cheney, *J. Amer. Chem. Soc.*, **90**, 5386 (1968), and literatures cited therein.
14) S. Winstein, P. Carter, F. A. L. Anet, and A. J. R. Bourn, *ibid.*, **87**, 5247 (1965).
15) H. J. Reich and D. J. Cram, *ibid.*, **91**, 3534 (1969).

are expected to be maintained within van der Waals distance (4.0 Å) on the basis of X-ray crystallography of [2.2]paracyclophane.[9] Thus, a difference in the chemical shifts of methyl protons of III and IV, 0.19 ppm, is related to the mutual compression effect between two methyl groups.

Enhanced Ortho Substitution Shifts. Reich and Cram reported that introduction of a substituent into the benzene ring of [2.2]paracyclophane caused a considerably large ortho shift compared to the corresponding open chain compounds, and that the enhancement of ortho shift might be due to the increased double bond character at C_4–C_5 bond in the bent ring.[15] On the other hand, the ortho substitution shifts in [3.3]paracyclophane are close to the normal, since the benzene rings are distorted from their planar configuration only by 6.4° in contrast to 15° for [2.2]-paracyclophane.[16]

The enhanced ortho shift σ_{OE} is observed also in methylated layered cyclophanes (Table 1). Thus, ortho protons to methyl groups appear at higher field by an average 0.42 ppm than the corresponding protons of non-substituted cyclophanes, *e.g.*, outer protons n each pair of VII *vs.* V, XI *vs.* IX, and XIV *vs.* XIII. The value 0.21 ppm, obtained by substracting the difference between durene and *p*-xylene (0.21 ppm) from the above average value, is the enhanced ortho substituent effect of methyl group in the layered [2.2]-paracyclophane system. Only one exception is the ortho shift in IV, 0.28 ppm. It is probable that strong mutual repulsion between the methyl groups may hinder electron delocalization of the moiety containing the methyl and its ortho proton.

Magnetic Anisotropy. Table 1 also shows that all the aromatic and methylene protons are shifted to a remarkably higher field as the number of layers increases. The more prominent of these is the upfield shift of inner aromatic protons caused by magnetic anisotropy of both upper and lower benzene rings. It is anticipated that there may exist a certain regularity among the chemical shifts of the aromatic protons, since each benzene ring is stacked at regular intervals in this series of multilayered cyclophanes.[10] From a number of examinations of the spectral data, the shielding effects due to additionally stacked benzene rings were estimated empirically (Table 2). It can be seen that the additional effect becomes less effective as the additional benzene ring lies further away from the proton in question.

Table 2. Shielding effect of additional benzene ring (ppm)

	Empirical	Calculated[a]
σ_1 (neighboring ring)	0.69	0.417
σ_2 (next ring but one)	0.22	0.157
σ_3 (next ring but two)	0.10	0.057
σ_4 (next ring but three)	0.03	0.028
σ_5 (next ring but four)	0.02	0.014

a) Values were calculated according to Johnson-Bovey's method.

It is known that the aromatic protons of [7]- and [8]-paracyclophanes[3,4] and [8][8]paracyclophane[17] appear within conventional range for alkyl benzenes, though they are in different steric environments due to individual ring deformation. Thus, their ring deformations hardly affect the chemical shifts of their own aromatic protons. It is known from X-ray crystallography of quadruple-layered cyclophane XII that the outside ring is distorted in a boat shape, and the inside ring in a twist shape,[10] and the ring deformations are considered not to differ so much in magnitude from those in [*m*]- and [8][8]-paracyclophanes. We assumed that the magnetic anisotropies of outside and inside benzene rings in multilayered cyclophanes were equal in magnitude in spite of different ring distortion.

From Table 2, the chemical shift of a given aromatic proton can be calculated by adding shielding effects of additional benzene rings to the chemical shift of the aromatic proton in standard alkylbenzene, *p*-xylene (τ 3.05) or durene (τ 3.26). For example, a calculated value of Ha in XIII is τ 4.09 ($3.05+\sigma_1+\sigma_2+\sigma_3+\sigma_4$), for Hb τ 4.96 ($3.26+2\sigma_1+\sigma_2+\sigma_3$), and for Hc τ 5.08 ($3.26+2\sigma_1+2\sigma_2$). Such a treatment

is also applicable to the cases of methyl derivatives by considering the secondary effects of methyl group such as σ_{CE} and σ_{OE}. In the case of XIV, the calculated value for Ha, Hb, and Hc are the same as those of XIII, but for Hd τ 4.60 ($3.26+2\sigma_1+\sigma_2+\sigma_3+\sigma_{CE}$) and for He τ 4.51 ($3.26+\sigma_1+\sigma_2+\sigma_3+\sigma_4+\sigma_{OE}$). These calculated values are in excellent agreement with the observed ones (Table 3), supporting the view that the evaluation of each shielding magnitude is reasonable. However, we see a tendency of slightly positive deviation for outer protons and negative for inner protons. This may reflect the fact that in multilayered compounds, π-electron density is richer on the inner benzene ring than on the outer ring as a result of the transannular electronic interaction.

On the other hand, magnetic anisotropy of benzene ring was calculated by means of the ring current equation of Johnson and Bovey,[18] where 3.03 Å was used for the average distance between two adjacent benzene rings and 2.40 Å for the distance from the center of the benzene ring to its own ring proton. The calculated values thus obtained are not quite equal to the empirically evaluated ones, the former values being less by a factor of about 0.6, but both are in good correlation (Table 2). The results show that our data for shielding effect can be used satisfactorily to anticipate chemical shifts of similarly constructed compounds, and that for more exact evaluation of magnetic anisotropy of benzene ring, one must take into account not only ring current but also the secondary effects such as anisotropies of carbon-carbon and carbon-hydrogen σ-bonds.

Experimental

NMR spectra were recorded on a Hitachi Perkin-Elmer R-20 spectrometer on dilute solutions (~10%) in carbon tetrachloride and/or deuteriochloroform using tetramethylsilane as an internal standard. The signals were measured by frequency counter with a precision of about ±1 cps. For NOE measurements a Varian HA-100 spectrometer was used. The effects were measured in degassed deuteriochloroform solution as area increase using the electronic integrator of the instrument. The errors are within ±5%.

The authors are greatly indebted to Mr. Y. Takai for NMR measurements and to Dr. E. Mizuta of Takeda Chemical Industries for NOE measurements. This research was supported by a grant-in-aid of the Ministry of Education.

Synthetic Studies of Bacitracin. IX.[1] Synthesis of Peptide Fragments for Bacitracins of Cycloheptapeptide Formula[2]

Eisuke MUNEKATA,* Tetsuo SHIBA, and Takeo KANEKO**

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 20, 1973)

In the synthetic study of bacitracins, peptide fragments corresponding to a branched part of bacitracin F, *i.e.*, (*S*)-2-(2-methylbutyryl)thiazole-4-carboxylic acid 1-succinimidyl ester (III) and L-leucyl-*γ*-*t*-butyl-D-glutamyl-L-isoleucine (IV), were prepared. As a macrocyclic part of bacitracin A and F of cycloheptapeptide formula, cyclo-(N^{α}-benzyloxycarbonyl-L-lysyl-N^{δ}-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidyl-*β*-benzyl-D-aspartyl-L-asparaginyl) (V) was synthesized through cyanomethyl ester method.

In the preceding paper,[1] the authors described the preparation of the intermediate heptapeptide derivative for the synthetic study of bacitracin A and F, the sequence of which was proposed by Stoffel and Craig.[3] Although Swallow and Abraham could not reduce four possibilities for the mode of linkage around L-lysine, L-aspartic acid and D-aspartic acid residues in the structure of bacitration A,[4] Stoffel and Craig proposed a structure I as the most probable one from rather inconceivable result of hydrazinolysis,[3] and this structure seemed to be accepted as the chemical structure of bacitracin A until 1966 when Ressler and Kashelikar revised the structure to formula II.[5] The latter group devised a new method for distinguishing asparagine and isoasparagine residues in peptide chain by dehydration of acid amide to nitrile followed by reduction and hydrolysis. Applying this technique to bacitration A, Ressler and Kashelikar recognized the presence of L-asparagine residue inside the peptide ring in lieu of D-isoasparagine residue outside the ring.[5] Recently, Craig and his collaborators also supported this structure II of a seven amino acids-membered ring

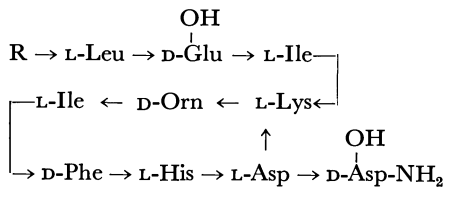
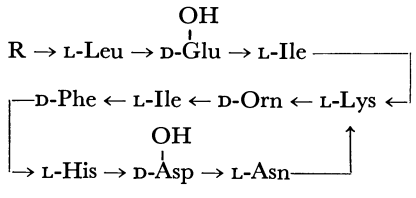
on a basis of their unpublished data.[6]

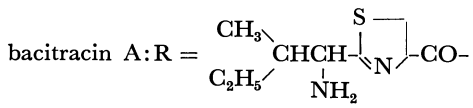


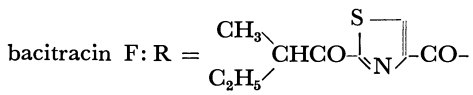
I



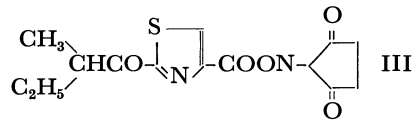
II

—— = CO→NH

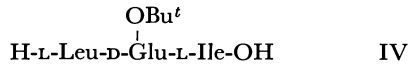




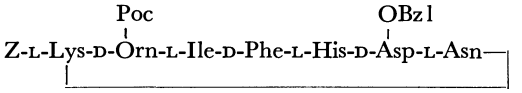
In this paper, we synthesized component fragments to build up the most reliable amino acid sequence II of bacitracin A and F, following the synthetic principle described in the previous paper[1] for an achievement of the total synthesis of the antibiotics. The principle is based on the coupling of thiazoline or thiazole moiety in the branched chain with macrocyclic peptide part. For the branched peptide part of bacitracin F, (*S*)-2-(2-methylbutyryl)-thiazole-4-carboxylic acid 1-succinimidyl ester (III) and L-leucyl-*γ*-*t*-butyl-D-glutamyl-L-isoleucine (IV) were prepared and for the macrocyclic part of the bacitracin A and F, cyclo-(*N*$^{\alpha}$-benzyloxycarbonyl-L-lysyl-*N*$^{\delta}$-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidyl-*β*-benzyl-D-aspartyl-L-asparaginyl) (V) was synthesized. These three peptide fragments cover the whole sequence of the antibiotic.



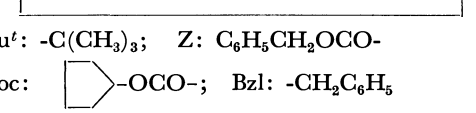
III



IV



V



For the synthesis of *N*-terminal part in bacitracin F, the 1-succinimidyl ester III was prepared by the usual manner for synthesis of the active ester using dicyclohexylcarbodiimide from (*S*)-2-(2-methylbutyryl)-thiazole-4-carboxylic acid, the preparation of which was already reported in our previous paper.[7] The synthetic route of the tripeptides derivative IV in the branched peptide chain of the antibiotic was shown in Scheme 1. Thus, benzyloxycarbonyl-D-glutamic acid *γ*-*t*-butyl *α*-1-succinimidyl ester was coupled with benzyl L-isoleucinate to give benzyloxycarbonyl-*γ*-*t*-butyl-D-glutamyl-L-isoleucine benzyl ester (VIa). Dipeptide derivative VIa thus obtained was hydrogenated using palladium charcoal as catalyst to give *γ*-*t*-butyl-D-glutamyl-L-isoleucine (VIIa). The resulting deblocked peptide derivative VIIa was acylated by *t*-butyloxycarbonyl-L-leucine 1-succinimidyl ester to obtain *t*-butyloxycarbonyl-L-leucyl-*γ*-*t*-butyl-D-glutamyl-L-isoleucine (VIIIa). In the alternative route for preparation of the tripeptide VIIIa, *t*-butyloxycarbonyl-L-leucyl-*γ*-*t*-butyl-D-glutamyl-L-isoleucine methyl ester (VIIIb) was synthesized as a precursor of VIIIa according to Scheme 1 through the methyl esters VIb and VIIb. However, the methyl ester of the resulting tripeptide derivative VIIIb was found to resist to alkaline hydrolysis and the wanted product VIIIa of a free carboxyl group could not be obtained. When *γ*-*t*-butyl-D-glutamyl-L-isoleucine (VIIa) was acylated with benzyloxycarbonyl-L-leucine 1-succinimidyl ester, other tripeptide derivative IX was obtained. This was hydrogenated in the presence of palladium charcoal to give L-leucyl-*γ*-*t*-butyl-D-glutamyl-L-isoleucine (IV).

The cycloheptapeptide derivative V corresponding to the macrocyclic part was synthesized starting from *C*-terminal L-asparagine residue as shown in Scheme 2. First, *t*-butyloxycarbonyl-*β*-benzyl-D-aspartyl-L-asparagine (X) was prepared by coupling of *β*-benzyl *t*-butyloxycarbonyl-D-aspartate with L-asparagine either by the mixed anhydride method or by the 1-succinimidyl ester method. Removal of *t*-butyloxycarbonyl group from X gave *β*-benzyl-D-aspartyl-L-asparagine (XI). When a principle of the stepwise elongation from *C*-terminal was applied to this dipeptide derivative XI, the resulting tripeptide derivatives, i.e., benzyloxycarbonyl or *t*-butyloxycarbonyl-L-histidyl-*β*-benzyl-D-aspartyl-L-asparagine, showed awfully hy-

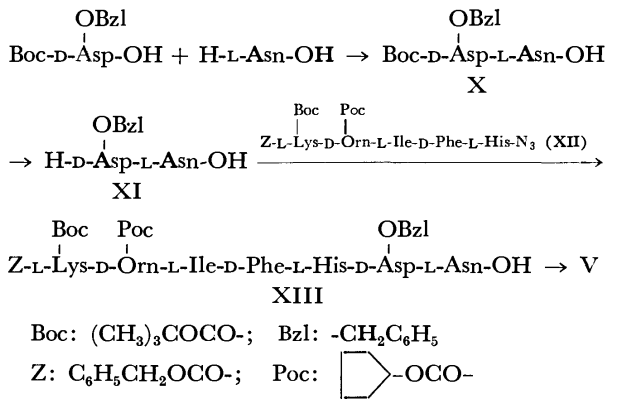

Scheme 2. Synthesis of the cycloheptapeptide derivative V corresponding to the macrocyclic part of bacitracin A and F of seven amino acids-membered formula.

groscopic and gelatinous properties which prevented isolation of a pure solid as the product. Furthermore, coupling of the deblocked product of the tripeptide mentioned above with *N*-acyl-D-phenylalanine could not give any pure tetrapeptide derivatives because of an extreme gelatinous character. Therefore, we turned to a route of coupling of XI with the acyl pentapeptide derivative XII, *i.e.*, N^{α}-benzyloxycarbonyl-N^{ε}-*t*-butyloxycarbonyl-L-lysyl-N^{δ}-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidine azide, the preparation of which was reported in the preceding paper,[1] and obtained the expected heptapeptide derivative XIII as demonstrated in Scheme 2. In this plan of building up the heptapeptide, we used the special cyclopentyloxycarbonyl group for a protection of δ-amino group of ornithine residue by reason of selective stability as far as a final synthetic step and of cleavability with hydrogen fluoride.[1]

We are now ready to total synthesis of bacitracin F of Ressler's formula by securing all peptide fragments required. However, for a cyclization of the heptapeptide XIII obtained above, the choice of the condensation reagent is limited by possible dehydration of the acid amide group in asparagine residue or undesirable side reaction on imidazole ring in histidine residue. In fact, attempt to cyclize XIII between the carboxyl group of asparagine residue and ε-amino group of lysine residue after removal of *t*-butyloxycarbonyl protection has not been succeeded yet when *N*-ethyl-5-phenylisoxazolium-5'-sulfonate described as safe reagent particularly for asparagine peptide was used for cyclization. Only when the cyanomethyl ester method was applied to this cyclization, the expected cyclo (N^{α}-benzyloxycarbonyl-L-lysyl-N^{δ}-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidyl-β-benzyl-D-aspartyl-L-asparaginyl) was obtained in one experiment. However, a yield of this product was extremely low and reproducibility of this cyclization reaction was strangely poor. These results may indicate that the activation of the carboxyl group of asparagine residue for cyclization of this heptapeptide is not adequate presumably owing to undesirable side reactions. Therefore, it must be required on this stage of the study that either the more effective cyclization method should be applied or a linkage to be connected for the cyclization has to be searched at another place to accomplish the total synthesis of bacitracins.

Experimental

All melting points are uncorrected. For silica gel column chromatography, Kieselgel 0.05—0.2 mm (70—325 mesh ASTM) Merck, was used. The infrared spectrum was obtained in Nujol mull with a Nihon Bunko IR-S spectrophotometer.

(S)-2-(2-Methylbutyryl)-thiazole-4-carboxylic Acid 1-Succinimidyl Ester (III). To a solution of (*S*)-2-(2-methylbutyryl)-thiazole-4-carboxylic acid[7] (2.1 g, 10 mmol) and *N*-hydroxysuccinimide (1.2 g, 10 mmol) in tetrahydrofuran (50 ml), there was added *N,N'*-dicyclohexylcarbodiimide (2.1 g, 10 mmol) under ice-cooling. The reaction mixture was stirred at this temperature for 1 hr and then at room temperature for 4 hr. Dicyclohexylurea deposited was filtered off, and the filtrate was evaporated *in vacuo*. A solid residue thus obtained was recrystallized from ethanol. Yield, 2.5 g (81%); mp 101—102 °C; $[\alpha]_D^{20}$ +13.4° (*c* 1, methanol).

Found: C, 50.07; H, 4.62; N, 9.00; S, 10.24. Calcd for $C_{13}H_{14}O_5N_2S$: C, 50.31; H, 4.55; N, 9.03; S, 10.33%.

Benzyloxycarbonyl-γ-t-butyl-D-glutamyl-L-isoleucine Benzyl Ester (VIa). A mixture of benzyloxycarbonyl-D-glutamic acid γ-*t*-butyl-α-1-succinimidyl ester[8] (8.7 g, 20 mmol), benzyl L-isoleucinate *p*-toluenesulfonate[9] (8.0 g, 20 mmol) and triethylamine (3 ml) in methylene chloride (300 ml) was stirred at 0 °C for 1 hr and then at room temperature for 17 hr. The solution was washed successively with 5% aqueous sodium carbonate, water, 0.5 M hydrochloric acid and water. The organic layer was separated, dried over anhydrous sodium sulfate, and then evaporated *in vacuo*. The residual solid was recrystallized from ethyl acetate-petroleum ether. Yield, 8.3 g (77%); mp 79—81 °C; $[\alpha]_D^{17}$ +8.8° (*c* 1, methanol).

Found: C, 66.36; H, 7.54; N, 5.35%. Calcd for $C_{30}H_{40}O_7N_2$: C, 66.64; H, 7.46; N, 6.18%.

γ-t-Butyl-D-glutamyl-L-isoleucine (VIIa) Hydrate. The protected dipeptide ester VIa (4.0 g, 7.4 mmol) was dissolved in methanol (100 ml) containing acetic acid (10 ml). Hydrogen gas was bubbled through the solution in the presence of palladium charcoal at room temperature for 8 hr. The catalyst was filtered off with the aid of celite. The filtrate was concentrated and a residual precipitate was collected by filtration. The product was recrystallized from methanol-water. Yield, 2.4 g (97%); mp 165—168 °C; $[\alpha]_D^{17}$ −32.4° (*c* 1, methanol).

Found: C, 53.66; H, 9.18; N, 8.41%. Calcd for $C_{15}H_{28}O_5N_2 \cdot H_2O$: C, 53.87; H, 9.04; N, 8.38%.

t-Butyloxycarbonyl-L-leucyl-γ-t-butyl-D-glutamyl-L-isoleucine (VIIIa). *t*-Butyloxycarbonyl-L-leucine 1-succinimidyl ester[10] (2.3 g, 7 mmol) in ethyl acetate (50 ml) was added to a cold solution of VIIa (2.4 g, 7 mmol) in chloroform containing triethylamine (1 ml). The mixture was stirred under ice-cooling for 1 hr and at room temperature for 8 hr. The solvent was removed *in vacuo* and the residue was triturated with petroleum ether. The product was collected, washed with water and recrystallized from ethyl acetate-petroleum ether. Yield, 2.5 g (68%); mp 142—143 °C; $[\alpha]_D^{17}$ +10.4° (*c* 1, methanol).

Found: C, 58.81; H, 9.05; N, 7.85%. Calcd for $C_{26}H_{47}$-

Benzyloxycarbonyl-γ-t-butyl-D-glutamyl-L-isoleucine Methyl Ester (VIb). A mixture of benzyloxycarbonyl-D-glutamic acid γ-*t*-butyl α-1-succinimidyl ester[8] (2.2 g, 5 mmol) and methyl L-isoleucinate *p*-toluenesulfonate (1.6 g, 5 mmol) in chloroform (100 ml) containing triethylamine (0.8 ml) was stirred at 0 °C for 1 hr and then at room temperature for 10 hr. The solution was washed successively with 5% aqueous sodium hydrogen carbonate, water, 0.5 M hydrochloric acid and water, and then dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure and a resulting precipitate was recrystallized from diisopropyl ether–petroleum ether. Yield, 1.8 g (78%); mp 61—62 °C; $[\alpha]_D^{18}$ +5.9° (*c* 1, methanol).

Found: C, 61.96; H, 7.82; N, 6.17%. Calcd for $C_{24}H_{36}O_7N_2$: C, 62.05; H, 7.81; N, 6.03%.

γ-t-Butyl-D-glutamyl-L-isoleucine Methyl Ester (VIIb) p-Toluenesulfonate. The dipeptide methyl ester VIb (10 g, 2.2 mmol) was dissolved in methanol (20 ml) containing a few drops of acetic acid. Hydrogen gas was bubbled through the solution in the presence of palladium charcoal at room temperature for 6 hr. The catalyst was removed by filtration and a filtrate was concentrated to a half volume of the original solution. To a residual solution, *p*-toluenesulfonic acid hydrate (0.5 g) in ether was added. The deposit was collected by filtration and recrystallized from methanol–ethyl ether. Yield, 0.7 g (64%); mp 157—158 °C; $[\alpha]_D^{19}$ −21.0° (*c* 1, methanol).

Found: C, 54.88; H, 7.69; N, 5.54; S, 6.40%. Calcd for $C_{23}H_{38}O_8N_2S$: C, 54.96; H, 7.62; N, 5.57; S, 6.38%.

t-Butyloxycarbonyl-L-leucyl-γ-t-butyl-D-glutamyl-L-isoleucine Methyl Ester (VIIIb). *t*-Butyloxycarbonyl-L-leucine 1-succinimidyl ester[10] (1.3 g, 4.1 mmol) and VIIb *p*-toluenesulfonate (2.1 g, 4.1 mmol) were dissolved in chloroform (100 ml). To this solution, triethylamine (0.8 ml) was added on cooling and the mixture was stirred at room temperature for 20 hr. The chloroform solution was washed with 5% aqueous sodium carbonate, water, 0.5 M hydrochloric acid and water successively. The organic layer was dried over anhydrous sodium sulfate and concentrated *in vacuo*. The residue was kept under ethyl ether and a solid thus obtained was collected by filtration and recrystallized from diisopropyl ether. Yield, 1.4 g (63%); mp 131—132 °C; $[\alpha]_D^{20}$ −4.3° (*c* 1, methanol).

Found: C, 59.45; H, 9.00; N, 7.62%. Calcd for $C_{27}H_{49}O_8N_3$: C, 59.64; H, 9.08; N, 7.73%.

Benzyloxycarbonyl-L-leucyl-γ-t-butyl-D-glutamyl-L-isoleucine (IX). A solution of benzyloxycarbonyl-L-leucine 1-succinimidyl ester[10] (3.6 g, 10 mmol), VIIa (3.3 g, 10 mmol) and triethylamine (1.5 ml) in chloroform (80 ml) was stirred under ice-cooling for 1 hr, and then at room temperature for 12 hr. The solvent was evaporated *in vacuo* and a residue obtained was dissolved in ethyl acetate. The solution was washed with 5% aqueous citric acid, and then water. After drying over sodium sulfate, the solution was concentrated *in vacuo*. A residue obtained was purified by silica gel column chromatography using methanol–chloroform as an elution solvent to give oily product. Yield, 3.4 g (63%). This material was used to the following deblocking reaction directly.

L-Leucyl-γ-t-butyl-D-glutamyl-L-isoleucine (IV) Hydrate. The oily product IX (3.4 g, 6.0 mmol) obtained above was dissolved in tetrahydrofran (50 ml). Through the solution, hydrogen was bubbled at room temperature in the presence of palladium charcoal for 5 hr. After filtration of the catalyst, a filtrate was concentrated to yield crystals. They were filtered and reprecipitated from methanol–water. Yield, 2.2 g (85%); mp 181—184 °C; $[\alpha]_D^{20}$ +58.9° (*c* 1, methanol).

Found: C, 55.71; H, 9.39; N, 9.14%. Calcd for $C_{21}H_{39}O_6N_3 \cdot 1\frac{1}{2}H_2O$: C, 55.24; H, 9.27; N, 9.20%.

β-Benzyl t-Butyloxycarbonyl-D-aspartate. This compound was prepared from β-benzyl D-aspartate[11] (33.5 g, 0.15 mol) and *t*-butyl azidoformate (22.0 g, 0.15 mol) according to the procedure for L-antipode by Sandrin and Boissonnas.[12] Yield, 2.7 g (56%); mp 102—103 °C; $[\alpha]_D^{19}$ −8.3° (*c* 1, acetic acid). Lit,[12] L-antipode, mp 101 °C; $[\alpha]_D^{22}$ +9±1° (c 2, acetic acid).

Found: C, 59.39; H, 6.60; N, 4.35%. Calcd for $C_{16}H_{21}O_6N$: C, 59.43; H, 6.55; N. 4.33%.

t-Butyloxycarbonyl-D-aspartic β-Benzyl α-1-Succinimidyl Ester. Esterification of β-benzyl *t*-butyloxycarbonyl-D-aspartate (10 g, 31 mmol) with *N*-hydroxysuccinimide (3.5 g, 30 mmol) was carried out according to the procedure for L-antipode by Laufer and Blout.[13] Yield, 11.8 g (94%); mp 100—102 °C; $[\alpha]_D^{20}$ +20.5° (*c* 0.5, dioxane). Lit,[13] L-antipode, mp 102—103 °C; $[\alpha]_D^{26}$ −20.0° (c 0.55, dioxane).

Found: C, 57.30; H, 6.00; N, 6.63%. Calcd for $C_{20}H_{24}O_8N_2$: C, 57.13; H, 5.75; N, 6.66%.

t-Butyloxycarbonyl-β-benzyl-D-aspartyl-L-asparagine (X).

(i) By the Mixed Anhydride Procedure: A mixed anhydride was prepared from β-benzyl *t*-butyloxycarbonyl-D-aspartate (3.3 g, 10 mmol) with isobutyl chloroformate (1.3 g, 10 mmol) and triethylamine (1.3 ml) in tetrahydrofuran (20 ml) at −5—0 °C. To the mixed anhydride solution, L-asparagine hydrate (1.5 g, 10 mmol) and triethylamine (1.4 ml) in water (30 ml) were added. The mixture was stirred under ice-cooling for 2 hr and at room temperature for 8 hr. The mixture was extracted with two 20 ml portions of ether and aqueous layer was acidified with solid citric acid to pH 2—3. A resulting oily precipitate was extracted with two 80 ml portions of ethyl acetate. An organic layer was washed with water and dried over anhydrous sodium sulfate. The solvent was removed *in vacuo* and a residual syrup was crystallized when kept under petroleum ether. The product was recrystallized from a large excess of ethyl acetate. Yield, 2.7 g (62%); mp 154—156 °C; $[\alpha]_D^{20}$ +37.1° (*c* 1, ethanol).

Found: C, 54.62; H, 6.43; N, 9.36%. Calcd for $C_{20}H_{27}O_8N_3$: C, 54.91; H, 6.22; N, 9.61%.

(ii) By the 1-Succinimidyl Ester Procedure: *t*-Butyloxycarbonyl-D-aspartic β-benzyl α-1-succinimidyl ester (14.4 g, 34 mmol) in tetrahydrofuran (160 ml) was added to an ice-cold solution of L-asparagine hydrate (5.2 g, 35 mmol) in water (200 ml) containing triethylamine (5 ml). The mixture was stirred at 0—3 °C for 1 hr and at room temperature for 8 hr. It was extracted with two 80 ml portions of ether and an aqueous layer was acidified with solid citric acid to pH 2—3. The resulting oily precipitate was taken up to ethyl acetate two times (500 ml, 200 ml). Combined ethyl acetate layer was washed with water and dried over anhydrous sodium sulfate. The solvent was removed *in vacuo* and a residue was solidified by addition of petroleum ether. The product was recrystallized from excess of ethyl acetate. Yield, 11.8 g (79%); mp 154—156 °C; $[\alpha]_D^{20}$ +37.1° (*c* 1, ethanol).

Found: C, 54.83; H, 6.39; N, 9.51%.

β-Benzyl-D-aspartyl-L-asparagine (XI) Trifluoroacetate. The dipeptide derivative X(4.5 g, 10 mmol) was dissolved in anhydrous trifluoroacetic acid (50 ml) and the solution was stirred at room temperature for 30 min. Excess tri-

fluoroacetic acid was evaporated *in vacuo* and the residue was diluted with ether. The deposited solid was collected by filtration, washed with ether and dried over potassium hydroxide *in vacuo*. The product was recrystallized from methanol-ether. Yield, 4.4 g (98%); mp 131—134 °C; $[\alpha]_D^{18}$ +1.7° (*c* 1, methanol).

Found: C, 45.64; H, 4.50; H, 9.08%. Calcd for $C_{15}H_{19}O_6N_3$-CF_3COOH: C, 45.24; H, 4.47; N, 9.31%.

N^{α}-Benzyloxycarbonyl-N^{ε}-t-butyloxycarbonyl-L-lysyl-N^{δ}-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidyl-β-benzyl-D-aspartyl-L-asparagine (XIII) Hydrate. A solution of sodium nitrite (0.5 g) in water (5 ml) was added to a solution of N^{α}-benzyloxycarbonyl-N^{ε}-*t*-butyloxycarbonyl-L-lysyl-N^{δ}-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidine hydrazide hydrate[1] (5.1 g, 4.9 mmol) in 70% acetic acid (300 ml) containing 20 ml of M hydrochloric acid at −1—−2 °C. The reaction mixture was stirred at this temperature for 20 min. A gelatinous mass started to deposit when excess cold water was added to the mixture. The resulting precipitate was collected by filtration and washed with water thoroughly. An azide XII thus obtained, which showed an absorption band at 2210 cm^{-1} in IR spectrum, was dissolved in ice-cold dimethylformamide (50 ml). This preparation was added to an ice-cold solution of XI trifluoroacetate (4.5 g, 10 mmol) in dimethylformamide (25 ml) containing triethylamine (1.3 ml) and the mixture was stirred at 2—5 °C for 24 hr and then at room temperature for 30 hr. The solution was concentrated *in vacuo* and a residue was triturated with water. The resulting amorphous material was collected by filtration and purified by silica gel column chromatography (elution solvent : chloroform–methanol, 8 : 2—7 : 3, v/v). Yield, 3.2 g (49%); mp 200—203 °C; $[\alpha]_D^{18}$ +12.6° (*c* 1, dimethylformamide).

Found: C, 59.30; H, 7.13; N, 12.37%. Calcd for $C_{66}H_{90}O_{17}N_{12}\cdot H_2O$: C, 59.09; H, 6.91; N, 12.53%.

Amino acid analysis: Lys+Orn, 1.93; Ile, 0.99; Phe, 1.00; His, 0.92; Asp, 2.00.

Cyclo-(N$^{\alpha}$-benzyloxycarbonyl-L-lysyl-N$^{\delta}$-cyclopentyloxycarbonyl-D-ornithyl-L-isoleucyl-D-phenylalanyl-L-histidyl-β-benzyl-D-aspartyl-L-asparaginyl) (V) dihydrate. To a solution of the protected heptapeptide XIII hydrate (7.0 g, 5.2 mmol) in dimethylformamide (70 ml), there were added chloroacetonitrile (4.5 ml) and triethylamine (6 ml). The reaction mixture was stirred at room temperature for 40 hr. After evaporation of the solvent under reduced pressure, water was added to the residue. Amorphous precipitate formed was filtered and dried *in vacuo* over phosphorus pentoxide. The product gave four spots on thin-layer chromatogram (developing solvent : methanol-chloroform, 2 : 8 v/v). One of them, showing positive Pauly and negative ninhydrin reaction, corresponds to the expected cyanomethyl ester while the other three spots seemed to an unreactive peptide and two cyanomethylated compounds on imidazole nuclei in histidine residues of the expected product and unreactive peptide from the coloring behaviors. The mixture (7.1 g) was dissolved in trifluoroacetic acid (80 ml) and stirred at room temperature for 45 min. Excess trifluoroacetic acid was removed by evaporation under reduced pressure, and ether was added to the residue. Precipitate thus formed was filtered and dried *in vacuo* over sodium hydroxide. A solution of this material in dimethylformamide (20 ml) and acetic acid (5 ml) was added to large excess of pyridine (800 ml) with stirring for 5 hr and then stirred at 45—50 °C for 20 hr. The solution was concentrated under reduced pressure. The reaction mixture showed five spots on thin-layer chromatogram (solvent system : methanol-chloroform 2 : 8, v/v). Among them, a spot of R_f 0.80 must be desired product, because it gave negative ninhydrin but positive Pauly reaction, while another spot of R_f 0.90 showing both negative ninhydrin and Pauly reactions seemed to be a cyclic peptide in which imidazole nucleus was cyanomethylated. All other three spots gave positive ninhydrin reactions. A product of R_f 0.80 was isolated by silica gel column chromatography (2.5×80 cm, elution solvent : methanol-chloroform, 1 : 19 (200 ml)—2 : 18 (300 ml) v/v). Fractions No. 21 to 42 (each fraction, 15 g) were collected and concentrated under reduced pressure to obtain a solid of the expected cyclic peptide (V) dihydrate, Yield, 90 mg (1.4%); mp 197—207 °C; $[\alpha]_D^{17}$ +11.4° (*c* 1, dimethylformamide).

Found: C, 58.96; H, 7.16; N, 13.63%. Calcd for $C_{61}H_{80}O_{14}N_{12}\cdot 2H_2O$: C, 59.02; H, 6.82; N, 13.54%.

Amino acid analysis: Lys+Orn, 2.11: Ile, 0.96; Phe, 0.94; His, 1.02; Asp, 2.00.

(Received October 27, 1972)

Hydrazinolysis of DL-1,4-dibromo-1,4-dideoxy-*chiro*-inositol (**3a**), followed by catalytic hydrogenation and acetylation, afforded di-*N*-acetyl-tetra-*O*-acetyl-*neo*-inosadiamine-1,3 (**6a**) and -*scyllo*-inosadiamine-1,3 (**7**) in 18% and 24% yields, respectively. From the intact hydrazinolyzate of **3a**, two new stereoisomeric 1,3-biimino-1,3-dideoxy-inositols (**4a** and **5a**) could be isolated, and their structures were established by correlating to the corresponding inosadiamines. A similar hydrazinolysis of 3,6-di-*O*-*p*-tolylsulfonyl-*muco*-inositol (**12**) gave sole crystalline 1,3-biimino compound (**13a**), whose structure was followed from its conversion into known di-*N*-acetyl-tetra-*O*-acetyl-*myo*-inosadiamine-4,6 (**14**). PMR spectra of four 1,3-biimino compounds were discussed.

We described a convenient synthesis of a biologically useful aminocyclitol, *myo*-inosadiamine-1,3, by hydrazinolysis of 1,3-di-*O*-*p*-tolylsulfonyl-*myo*-inositol (**1**) followed by hydrogenation.[2] The formation of 6,7-diazabicyclo[3.2.1]octane-2,3,4,8-tetrol (**2a**) of *myo*-configuration, which may be termed 1,3-biimino-1,3-dideoxy-*myo*-inositol,[3] was demonstrated by isolation of the free base. The synthesis seems to provide a convenient method for preparing an unaccessible inosadiamine having two amino groups in *cis*-1,3-positions from readily available di-*O*-*p*-tolylsulfonyl- or dihalodideoxy-inositol. On the other hand, the use of mono- or di-alkyl hydrazine gave *N*-alkyl- or di-*N*-alkyl-inosadiamine, *viz.*, *N*-methyl-*myo*-inosadiamine-1,3 and actinamine.[5]

In the present paper, we wish to report the synthesis of three new stereoisomers of 1,3-biimino-1,3-dideoxy-inositol and their conversion into the corresponding inosadiamines. In order to demonstrate the reaction mechanism of the hydrazinolysis, displacement reactions with azide ion were also studied.

Firstly, the hydrazinolysis of DL-1,4-dibromo-1,4-dideoxy-*chiro*-inositol (**3a**)[6] obtained by a drastic bromination reaction of *epi*-inositol was investigated. On treatment with hydrazine, two epoxide intermediates are expected to be formed by participation of vicinal *trans*-situated hydroxyl groups, since **3a** has two bromine atoms in *cis*-1,4 positions; this may satisfy the steric requirement for formation of a 1,3-biimino bridge. When **3a** was treated with excess hydrazine in boiling 2-methoxyethanol and the hydrazinolyzate was then subjected to hydrogenation and acetylation, di-*N*-acetyl-tetra-*O*-acetyl-*neo*-inosadiamine-1,3 (**6a**) and -*scyllo*-inosadiamine-1,3 (**7**) were isolated in 18 and 24% yields, respectively. The former was further characterized by conversion into its di-*N*-acetyl derivative (**6b**). The structure of **6a** was established by the following spectral evidence. The PMR spectrum of **6a** in dimethylsulfoxide-d_6 (DMSO-d_6) revealed six acetyl methyl protons as four singlets (2 : 2 : 1 : 1) at τ 8.27, 8.06, 7.90, and 7.88, which according to Lichtenthaler *et al.*,[7] can be readily assigned to two equatorial acetamido, and two equatorial, one axial and one axial acetoxy groups, respectively. On addition of deuterium oxide (D_2O) 2-proton sextet at τ 5.66 collapsed to a quartet (J=2.7 and 12 Hz), indicating that the signal was due to two magnetically equivalent protons at C–1 and C–3. Accordingly, the 2-proton quartet at τ 5.00 was assigned to the equivalent protons at C–4 and C–6, and the two narrow triplets (J=2.7 Hz) at τ 4.67 and 4.34 to H–2 and H–5, respectively. The structure of **6a** was thus fully established.

On the other hand, the reaction of **3a** or its acetyl derivative (**3b**) with sodium azide in aqueous 2-

3) According to the *R,S*-notation of configuration,[4] compound **2a** should be named 6,7-diazabicyclo[3.2.1]octane-2*R*,3*R*,4*S*,8*S*-tetrol. Since this designation lacks derivational perspicuity and is somewhat cumbersome, we prefer, for the sake of simplicity, the designation 1,3-biimino-1,3-dideoxy-*myo*-inositol for **2a**, retaining the respective configuration prefix of the basal inositol. Similarly, **4a** of 2*R*,3*S*,4*S*,8*S* configuration is termed 1,3-biimino-1,3-dideoxy-*neo*-inositol; **5a** (2*R*,3*R*,4*S*,8*R*)=1,3-biimino-1,3-dideoxy-*scyllo*-inositol; **13a** (2*R*,3*S*,4*S*,8*R*)=4,6-dideoxy-4,6-biimino-*myo*-inositol.

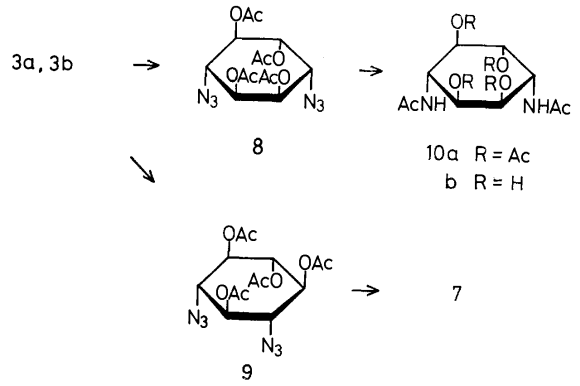
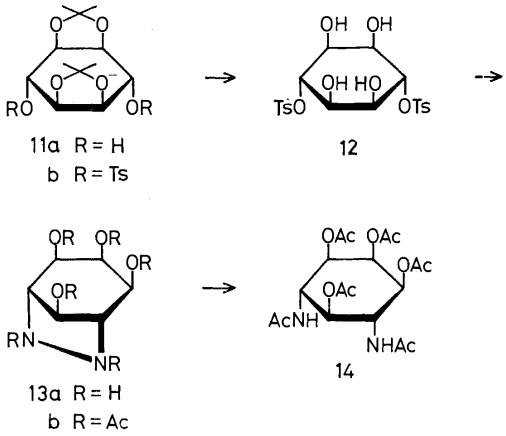


Scheme 2.

methoxyethanol under reflux followed by acetylation afforded tetra-*O*-acetyl-diazidodideoxy-*chiro*-inositol (**8**) in 68% yield, together with a small amount of tetra-*O*-acetyl-1,3-diazido-1,3-dideoxy-*scyllo*-inositol (**9**)[8] which was characterized by conversion into **7**. Hydrogenation of **8** and subsequent acetylation afforded hitherto unknown di-*N*-acetyl-tetra-*O*-acetyl-inosadiamine (**10a**) which was further converted into the di-*N*-acetyl derivative (**10b**). From the reaction sequence, the formation of **9** as the minor product suggested that the major diazidodideoxy-inositol should have 1,2- or 1,4-*chiro*-configuration. The physical and spectral properties of the former[9] were found to be quite different from those of **8**. In the PMR spectrum of **8** in deuteriochloroform ($CDCl_3$), the pattern of the signals due to the ring protons were shown to be substantially similar to those of **3b**.[6] The PMR spectrum of **10a** in DMSO-d_6 revealed four singlets (1 : 1 : 3 : 1) in the vicinity of τ 8; one equatorial (τ 8.22) and one axial (τ 8.11) acetamido groups, and three equatorial (τ 8.08) and one axial (τ 7.98) acetoxy groups, suggesting *chiro*-configuration.[7] Thus the structure of **8** was tentatively assigned to DL-tetra-*O*-acetyl-1,4-diazido-1,4-dideoxy-*chiro*-inositol. The preferential diaxial attack of azide ion at the intermediary epoxides can be assumed to be the prevailing mechanism for this azidolysis reaction.

The course of the nucleophilic displacement by hydrazine evidently differs from that of azide ion, and, the formation of a biimino bridge might be proposed in the hydrazinolysis of **3a**. Isolation of these anticipated intermediates was thus attempted. The crude hydrazinolyzate of **3a** was treated with Amberlite IRA-400 (OH^-) and successive treatment with aqueous ethanol gave the crystalline 1,3-biimino compound (**4a**) in 15% yield. From the mother liquor of **4a** upon acetylation, a small amount (1%) of di-*N*-acetyl-tetra-*O*-acetyl-1,3-biimino compound (**5b**) could be isolated, which afforded a monohydrochloride (**5a**) in 85% yield on hydrolysis with 3 M hydrochloric acid. Acetylation of **4a** in the usual way gave the hexaacetyl derivative (**4b**) which was found to differ entirely from **5b**. Neither **4b** nor **5b** showed any absorption in the amide II region in IR or a signal due to NH-protons in PMR spectra. Hydrogenation of **4a** followed by acetylation afforded **6a** in 73% yield. The PMR spectra of **4a** and **5a** (free base) in D_2O also supported the proposed structure. Consequently, the configuration of 1,3-biimino-1,3-dideoxy-inositol (**4a**) is unambiguously established to be *neo*- (2*R*, 3*S*, 4*S*, 8*S*), whilst **5a** is conclusively assigned to *scyllo*-configuration (2*R*, 3*R*, 4*S*, 8*R*).



Scheme 3.

Hydrazinolysis of 3,6-di-*O*-*p*-tolylsulfonyl-*muco*-inositol (**12**) was then carried out. Compound **12** was prepared from 1,2 : 4,5-di-*O*-isopropylidene-*muco*-inositol (**11a**)[10] by a reaction sequence involving *p*-toluenesulfonylation and de-*O*-acetylation (**11a**→**11b**→**12**). A similar treatment of **12** with hydrazine gave the sole crystalline 1,3-biimino compound (**13a**) in 52% yield. Acetylation of **13a** gave the hexaacetyl derivative (**13b**) in 73% yield, whose IR and PMR spectra showed a presence of a secondary amido group. Hydrogenation of **13a** and the subsequent acetylation afforded di-*N*-acetyl-tetra-*O*-acetyl-*myo*-inosadiamine-4,6 (**14**)[11] in 43 % yield. Thus the structure of **13a** was readily assigned to *myo*-configuration (2*R*, 3*S*, 4*S*, 8*R*).

The reaction of the corresponding dimesylate, 3,6-di-*O*-methylsulfonyl-*muco*-inositol, with excess sodium azide gave, by preferential diaxial cleavage of the intermediate epoxide, 3,6-diazido-3,6-dideoxy-*muco*-inositol almost exclusively.[12] In the case of hydrazinolysis, on the contrary, the hydrazino group introduced previously attacks the second epoxide intermolecularly to form a 1,3-biimino bridge.

PMR Spectra. The PMR spectra of the three stereoisomeric 1,3-biimino-1,3-dideoxy-inositols (**4a**, **5a**, and **13a**) together with **2a** were discussed. Since all the molecules have a plane of symmetry, the H-1 and H-5, and H-2 and H-4 protons are magnetically equivalent thus simplifying the interpretation of the signals. In **2a**, **4a**, and **5a**, a first-order analysis was successfully applied to interpret the signals from the ring protons. In **13a**, however, the signals due to

8) This compound could not be isolated in a crystalline state.

TABLE 1. CHEMICAL SHIFTS OF 1,3-BIIMINO-1,3-DIDEOXY-INOSITOL[a)]

Compound	H-1,5	H-2,4	H-3	H-8
2a	6.72(d)	6.32(t)	6.54(t)	5.38(s)
4a	6.47(d)	5.93(t)	6.18(t)	5.12(s)
5a	6.77(d)	6.48(t)	5.81(t)	5.58(t)
13a	6.43(t)	5.94(m)	5.94(m)	5.57(t)

a) Measured at 60 MHz in D_2O with sodium 3-(trimethylsilyl)-1-propanesulfonate as an internal reference. Chemical shifts are given in terms of τ-values, the signals being denoted by s (singlet), d (doublet), t (triplet), and m (complex multiplet).

TABLE 2. COUPLING CONSTANTS OF 1,3-BIIMINO-1,3-DIDEOXY-INOSITOL[a)]

Compound	$J_{1,2}$ ($J_{4,5}$)	$J_{1,8}$ ($J_{5,8}$)	$J_{2,3}$ ($J_{3,4}$)	$J_{2,8}$
2a	2.0	0	4.2	0
4a	5.0	0	4.7	0
5a	~1.0	4.7	6.6	~1.0
13a	4.0	4.7	—	~1.0

a) Values (Hz) are of first-order.

H-2, H-3, and H-4 protons overlapped to give rise to a complex multiplet (Tables 1 and 2).

Assignment of the configuration of the hydroxyl group at C-8 was based on the following results. The H-8 proton appeared as a triplet (J=4.7 Hz) at τ 5.58 and 5.57 in **5a** and **13a**, respectively, which shows that the dihedral angle $\phi_{1,8}$ and $\phi_{5,8}$ would approach 40°. The sharp singlets at τ 5.38 and 5.12 in **2a** and **4a**, respectively, could be assigned to H-8 protons, indicating that the dihedral angles $\phi_{1,8}$ and $\phi_{5,8}$ were nearly 90°.[13] In this case the *cisoid* protons (axial) resonated at lower field than the *transoid* protons (equatorial). The former might have been strongly deshielded by two axial hydroxyls at C-2 and C-4.[14,15]

In the PMR spectrum of **4a** (Fig. 1), the 2H-triplet at τ 5.94, 1H-triplet at τ 6.18, and 2H-doublet at τ 6.47 were assigned to H-2 and H-4, H-3, and H-1 and H-5, respectively. The observed coupling constants of $J_{1,2}$ and $J_{2,3}$ corresponded to the dihedral angles $\phi_{1,2}$ (45°) and $\phi_{2,3}$ (45°), which were derived from a molecular model of **4a**, the chair conformation being slightly distorted by incorporation of the 1,3-biimino bridge.[16] The coupling constants were shown to be in good accordance with the corresponding values of 1,5-lactone of (−)-quinic acid ((−)-quinide).[15]

However a remarkable flattening of the chair conformation was deduced from the PMR spectra, when three axial hydroxyl groups were located at C-2, C-3,

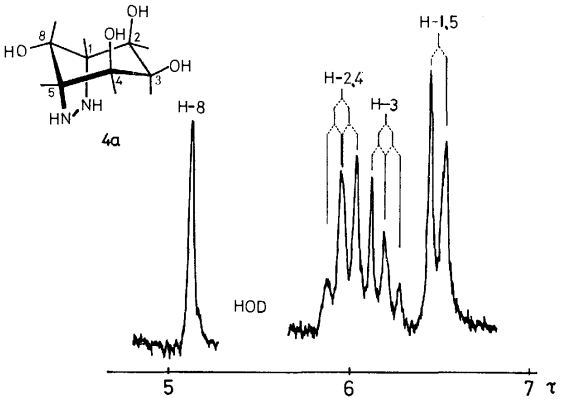

Fig. 1. Partial PMR spectrum (D_2O) of 1,3-biimino-1,3-dideoxy-*neo*-inositol (**4a**).

and C-4. In the PMR spectrum of **2a**, the small value of $J_{1,2}$ (2.0 Hz) may be rationalized by such a distortion that would increase the dihedral angles $\phi_{1,2}$ and $\phi_{2,3}$. Since $J_{1,2}$ was found to accord with the corresponding value of 3,4-*O*-isopropylidene-(−)-quinide,[15] the dihedral angle $\phi_{1,2}$ is likely to be nearly 60°.

In the case of **5a** having three axial substituents on both sides of the cyclohexane ring, a very small $J_{1,2}$ (less than 1.0 Hz) was observed, while $J_{2,3}$ (6.6 Hz) seems to indicate that the six-membered ring exists in a flattened boat conformation rather than in a chair form. The evidence for this can be deduced from the down-field shift of H-3 (τ 5.18) as compared with that of **2a** (τ 6.54), since the difference can be attributed to considerable deformation of the ring conformation with respect to carbons C_2-C_3-C_4. The non-bonded interaction between three axial hydroxyl groups at C-2, C-4, and C-8 was presumably sufficient to cause the six-membered ring to exist in this conformation.

A long range coupling ($J_{2,8}$ and $J_{4,8}$) was observed in **5a** and **13a**, which could be substantially accounted for by W-letter rule.[17]

On the other hand, the PMR spectra of the hexaacetyl derivatives of 1,3-biimino-1,3-dideoxy-inositols were expected to be complex owing to the hindered rotation of acetamido groups.[18] In **2b** and **4b**, the symmetry of the molecules was to some extent lost, and the six ring protons revealed individual signals.

The PMR spectrum of **4b** (Fig. 2) was interpreted as follows. By analogy with the assignment of the PMR spectrum of **4a**, the singlet at τ 4.12 and the triplet (J=5.0 Hz) at τ 5.02 could be assigned to H-8 and H-3 protons, respectively. Irradiation at the triplet (J=5.0 Hz) at τ 4.25 simplified the H-3 triplet to a doublet, and the doublet (J=5.0 Hz) at τ 5.30 to a singlet. Consequently, the triplet at τ 4.25 was assigned to H-2 (H-4) and the doublet at τ 5.30 to H-1 (H-5). The complex multiplet centered at τ 4.60

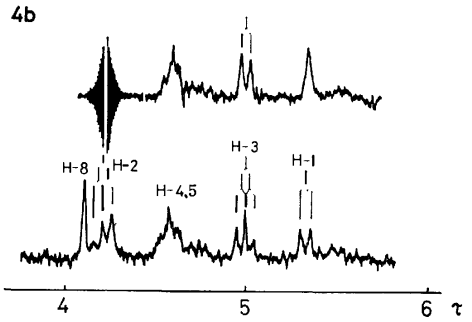

Fig. 2. Partial PMR spectrum ($CDCl_3$) of di-*N*-acetyl-tetra-*O*-acetyl-1,3-biimino-1,3-dideoxy-*neo*-inositol (**4b**), measured on a Varian Associates HA-100D (100 MHz) spectrometer.

should be attributed to H-4 (H-2) and H-5 (H-1) protons. We see from comparison with their counterparts that H-2 (H-4) and H-5 (H-1) protons are markedly deshielded (0.70 and 0.35 ppm, respectively) by the amide carbonyl groups most probably in a *cis*-relationship to them. Thus, it was deduced that the planes of two-secondary acetamido groups were somewhat twisted from that of the biimino ring due to the repulsion between the amido methyl groups.

No influence of the hindered rotation of acetamido groups was observed in the PMR spectrum of **5b**. This might be due to the existence of a rotamer having a plane of symmetry resulting from the deformation of the cyclohexane ring.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. IR spectra were measured on a Jasco IR-E spectrophotometer in KBr disks. PMR spectra were measured on Varian Associates A-60D (60 MHz) and HA-100D (100 MHz) spectrometer at a concentration of approximately 10% deuteriochloroform ($CDCl_3$), deuterium oxide (D_2O), or dimethylsulfoxide-d_6 (DMSO-d_6), with tetramethylsilane or sodium 3-(trimethylsilyl)-1-propanesulfonate, respectively, as internal standard. Chemical shifts are given in terms of τ-values, and signals being denoted by s (singlet), d (doublet), t (triplet), dd (double doublet), or m (complex multiplet). Values given for coupling constants are of first-order. All solutions were concentrated by a rotary evaporator at 40—50 °C under reduced pressure.

Hydrazinolysis of DL-*1,4-dibromo-1,4-dideoxy*-chiro-*inositol (**3a**). Preparation of di*-N-*acetyl-tetra*-O-*acetyl*-neo-*inosadiamine-1,3 (**6a**) and* -scyllo-*inosadiamine-1,3 (**7**).* A mixture of **3a** (1.00 g), anhydrous hydrazine (0.50 ml), and 2-methoxyethanol (50 ml) was refluxed for 90 min and the solution was evaporated to dryness. The residue was dissolved in water (50 ml) and, after treatment with Amberlite IRA-400 (OH^-) (10 ml), the solution was hydrogenated in the presence of Adam's platinum catalyst (50 mg) in a Parr shaker type apparatus (under 3.4 kg/cm² of initial hydrogen pressure) for 20 hr at room temperature. The catalyst was filtered off and the filtrate was evaporated to dryness. The residue was treated with acetic anhydride (5 ml) and pyridine (5 ml) overnight at room temperature. The reaction mixture was evaporated and the crude mixture was fractionated by crystallization from ethanol. The first crystals (0.40 g, 23.5%) were identified as **7** by the mode of melting (mp 245—249 °C with transition) and a comparison of its IR spectra with that of an authentic sample.[19] Crystals (0.31 g, 18%) of **6a** were then isolated, mp 280—285 °C. An analytical sample was obtained by further recrystallization from ethanol, mp 282—285 °C. IR: 3300, 1660, 1555 (NHAc), and 1755 cm^{-1} (OAc), PMR data are in the text.

Found: C, 50.44; H, 6.32; N, 6.39%. Calcd for $C_{18}H_{26}N_2O_{10}$: C, 50.23; H, 6.09; N, 6.51%.

*Di-*N*-acetyl*-neo-*inosadiamine-1,3 (**6b**).* Compound **6a** (150 mg) was treated with methanolic ammonia (15 ml) overnight at room temperature. The mixture was evaporated to give a crystalline residue which was crystallized from 90% aqueous ethanol to give an analytical sample (60 mg, 68%) of **6b**, mp 313 °C (dec.). IR: 1635 and 1555 cm^{-1} (NHAc).

Found: C, 43.10; H, 7.22; N, 9.90%. Calcd for $C_{10}H_{18}N_2O_6 \cdot H_2O$: C, 42.88; H, 7.14; N, 10.00%.

*Azidation Reaction of **3a** or **3b**. Preparation of* DL-*Di*-N-*acetyl-tetra*-O-*acetyl-1,4-diazido-1,4-dideoxy*-chiro-*inositol (**8**) and (**7**).* A mixture of DL-tetra-*O*-acetyl-1,4-dibromo-1,4-dideoxy-*chiro*-inositol (**3b**)[4] (1.00 g), sodium azide (1.40 g), and 90% aqueous 2-methoxyethanol (50 ml) was refluxed for 25 hr. The mixture was then evaporated and dried by codistillation with dry toluene several times. The residue was treated with acetic anhydride (20 ml) and pyridine (20 ml) overnight at room temperature. An insoluble material was removed by filtration and the filtrate was evaporated to give an oily product, which was extracted with chloroform and purified by a short column of active aluminum oxide. The solvent was evaporated and the crude product was crystallized from ethanol to afford colorless needles (0.89 g, 68%) of **8**, mp 109—113 °C. Recrystallization from ethanol gave an analytical sample, mp 112—114 °C. IR: 2150 (N_3), and 1750 cm^{-1} (OAc). PMR ($CDCl_3$): τ 7.95 (3, s, OAc), 7.91 (6, s, 2OAc), 7.84 (3, s, OAc), 6.18 (1, t, H-4, J=10.5 Hz), and 4.96 (1, dd, H-5, J=3 and 10.5 Hz).

Found: C, 42.46; H, 4.59; N, 20.85%. Calcd for $C_{14}H_{18}N_6O_8$: C, 42.21; H, 4.59; N, 21.10%.

The mother liquor of **8** was evaporated and the residue was hydrogenated in an ethanol solution (20 ml) in a similar way to that for **6a**. The hydrogenate was acetylated in the usual way to give colorless needles (28 mg, 1.9%) of **7**, mp 240—245 °C, after crystallization from ethanol. This compound was identified with an authentic sample[18] by comparison of IR spectra and mixed melting point.

Almost the same result was obtained from **3a**.

DL-*Di*-N-*acetyl-tetra*-O-*acetyl*-chiro-*inosadiamine-1,4 (**10a**).* A solution of **8** (0.54 g) in ethanol (50 ml) was hydrogenated in a similar way to that for **6a** for 15 hr. The catalyst was filtered off and filtrate was evaporated to dryness.

The residual product was acetylated in the usual way to give colorless needles (0.58 g, 77%) of **10a**, mp 120—126 °C. Recrystallization from acetone gave a hygroscopic crystals, mp 127—129 °C. IR: 3280, 1655, 1545 (NHAc), and 1750 cm^{-1} (OAc). PMR (DMSO-d_6): τ 2.55 (1, d, equatorial NHAc, J=9 Hz) and 1.68 (1, d, axial NHAc, J=8 Hz).

Found: C, 49.64; H, 6.14; N, 6.08%. Calcd for $C_{18}H_{26}N_2O_{10} \cdot 1/2H_2O$: C, 49.20; H, 6.19; N, 6.38%.

DL-*Di*-N-*acetyl*-chiro-*inosadiamine-1,4 (**10b**).* Compound **10a** (0.20 g) was treated with methanolic ammonia (30 ml) overnight at room temperature. The solution was then evaporated to give a crystalline residue which was recrystallized from 95% ethanol to afford colorless needles (90 mg, 74%) of **10b**, mp 254—256 °C. IR: 3480, 1630,

1580, and 1560 cm^{-1} (NHAc). PMR (D_2O): τ 7.97 (6, s, 2 NHAc).

Found: C, 46.00; H, 7.23; N, 10.36%. Calcd for $C_{10}H_{18}N_2O_6$: C, 45.79; H, 6.92; N, 10.63%.

1,3-Biimino-1,3-dideoxy-neo-*inositol* (**4a**) *and Di*-N-*acetyl-tetra*-O-*acetyl-1,3-biimino-1,3-dideoxy*-scyllo-*inositol* (**5b**). A mixture of **3a** (2.00 g), anhydrous hydrazine (1.6 ml), and 2-methoxyethanol (100 ml) was refluxed for 2 hr, and the mixture was evaporated to dryness. The residue was dissolved in water (30 ml) and treated with Amberlite IRA-400 (OH^-) for 5 hr. The solution was evaporated and the oily residue was crystallized from water–ethanol to afford crystals (0.17 g, 14.8%) of **4a**, mp 208 °C (dec.).

Found: C, 41.11; H, 6.79; N, 15.70%. Calcd for $C_6H_{12}N_2O_4$: C, 40.91; H, 6.87; N, 15.90%.

The mother liquor of **4a** was evaporated to dryness and the residue was treated with acetic anhydride (5 ml) and pyridine (5 ml) overnight at room temperature. The mixture was evaporated and the product was crystallized from ethanol–ether to give crystals (26 mg, 1%) of **5b**, mp 213 °C. IR: 1755, 1720 (OAc), and 1680 cm^{-1} (NAc).

Found: C, 50.68; H, 5.56; N, 6.45%. Calcd for $C_{18}H_{24}N_2O_{10}$: C, 50.47; H, 5.65; N, 6.54%.

Di-N-*acetyl-tetra*-O-*acetyl-1,3-biimino-1,3-dideoxy*-neo-*inositol* (**4b**). A 20 mg-portion of **4a** was acetylated with acetic anhydride (1.5 ml) and pyridine (1.5 ml) overnight at room temperature. The product was crystallized from ethanol–ether to give crystals (15 mg, 31%) of **4b**, mp 161—162 °C. IR: 1745 (OAc), and 1635 cm^{-1} (NAc). PMR data are in the text.

Found: C, 50.49; H, 5.94; N, 6.18%. Calcd for $C_{18}H_{24}N_2O_{10}$: C, 50.47; H, 5.65; N, 6.54%.

1,3-Biimino-1,3-dideoxy-scyllo-*inositol* (**5a**). A mixture of **5b** (120 mg) and 3M-hydrochloric acid (20 ml) was refluxed for 2 hr, and the mixture was evaporated to give a glassy residue, which crystallized upon addition of aqueous ethanol to afford monohydrochloride of **5a** (51 mg, 85%), mp 147—149 °C.

Found: C, 33.55; H, 6.29; N, 12.83%. Calcd for $C_6H_{12}N_2O_4 \cdot HCl$: C, 33.89; H, 6.16%; N, 13.17%.

PMR spectrum was measured for a free base which was obtained from monohydrochloride by treatment of the aqueous solution with Amberlite IRA-400 (OH^-).

Preparation of **6a** *from* **4a**. A solution of **4a** (20 mg) in water (3 ml) was hydrogenated similarly in the presence of Adams' platinum catalyst (10 mg) overnight. The product was acetylated in the usual way to give crystals (35 mg, 73%) of **6a**, which was identified with the product obtained before by comparison of their IR spectra.

1,2 : 4,5-Di-O-*isopropylidene-3,6-di*-O-p-*tolylsulfonyl*-muco-*inositol* (**11b**). To a solution of 1,2 : 4,5-di-*O*-isopropylidene-*muco*-inositol (**11a**)[8] (1.00 g) in dry pyridine (15 ml) was added *p*-toluenesulfonyl chloride (3.8 g, 5 equiv.) and the mixture was allowed to stand at room temperature for 20 hr. After being heated over a boiling water bath for 90 min, the mixture was poured into ice and water (70 ml). The resulting crystals were collected by filtration, washed with water and dried. The crude crystals weighed 1.85 g (82%), mp 213—220 °C. Recrystallization from 2-methoxyethanol afforded an analytical sample, mp 233—234 °C. PMR ($CDCl_3$): τ 8.83 and 8.61 (6 and 6, s, 2 isopropylidene C–CH_3), 7.56 (6, s, 2 OTs C–CH_3).

Found: C, 55.32; H, 5.89; S, 11.61%. Calcd for $C_{26}H_{32}O_{10}S_2$: C, 54.91; H, 5.67; S, 11.28%.

3,6-Di-O-p-*tolylsulfonyl*-muco-*inositol* (**12**). Compound **11b** (1.20 g) was treated with boiling 90% aqueous acetic acid (30 ml) for 2 hr. The mixture was then evaporated to give a crystalline residue. The crystals were collected by triturating with ethanol: yield 0.83 g (81%), mp 221—224 °C. Recrystallization from 2-methoxyethanol afforded an analytical sample, mp 223.5—224.5 °C.

Found: C, 49.19; H, 4.89; S, 12.91%. Calcd for $C_{20}H_{24}O_{10}S_2$: C, 49.17; H, 4.95; S, 13.13%.

4,6-Biimino-4,6-dideoxy-myo-*inositol* (**13a**). A mixture of **12** (0.50 g), anhydrous hydrazine (0.5 ml), and 2-methoxyethanol (30 ml) was refluxed for 7 hr. The reaction mixture was treated as for the preparation of **4a**. The crude product was recrystallized from water–ethanol to afford crystals (95 mg, 52%) of **13a**, mp 190 °C.

Found: C, 41.14; H, 6.74; N, 15.98%. Calcd for $C_6H_{12}N_2O_4$: C, 40.91; H, 6.87; N, 15.90%.

Di-N-*acetyl-tetra*-O-*acetyl-4,6-biimino-4,6-dideoxy*-myo-*inositol* (**13b**). Compound **13a** (35 mg) was acetylated with acetic anhydride (2 ml) and pyridine (2 ml) overnight at room temperature. The product was crystallized from ethanol–ether to afford crystals (63 mg, 73%) of **13b**, mp 145—147 °C. IR: 1745 (OAc), and 1650 cm^{-1} (NAc).

Found: C, 50.70; H, 6.05; N, 6.97%. Calcd for $C_{18}H_{24}N_2O_{10}$: C, 50.47; H, 5.65; N, 6.54%.

Di-N-*acetyl-tetra*-O-*acetyl*-myo-*inosadiamine-4,6* (**14**). Compound **13a** (27 mg) was hydrogenated in a similar way to that for **4a**. Subsequent acetylation gave crystals (28 mg, 43%) of **14**, mp 280 °C. Recrystallization from ethanol afforded pure sample, mp 288 °C, which was identified with an authentic sample[11] by comparison of IR and PMR spectra.

The authors are grateful to Professor Sumio Umezawa for his kind advice, and to Mr. Saburo Nakada for carrying out elementary analyses. Financial support from the Ministry of Education for this work is gratefully acknowledged.

The Electrochemical Fluorination of Dithiols and Cyclic Sulfides

Takashi ABE, Shunji NAGASE, and Hajime BABA

Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received April 26, 1973)

The electrochemical fluorination of dithiols [1,4-butanedithiol (I), 1,5-pentanedithiol (II), and 3-oxapentane-1,5-dithiol (III)] and cyclic sulfides [tetrahydrothiophene (IV), 2-methyltetrahydrothiophene (V), 3-methylthiophene (VI) and tetrahydrothiopyran (VII)] was conducted. Dithiols afforded the corresponding fully-fluorinated analogs of the starting dithiol ($SF_5(CF_2)_n SF_5$; n=4 from I, 5 from II; $SF_5CF_2CF_2OCF_2CF_2SF_5$ from III) and the cyclic products (perfluorotetramethylenesulfur tetrafluoride from I, perfluoro-2-methyltetramethylenesulfur tetrafluoride, perfluoro-3-methyltetramethylenesulfur tetrafluoride, and perfluoropentamethylenesulfur tetrafluoride from II, and perfluoro-4-oxapentamethylenesulfur tetrafluoride from III). The corresponding perfluoro-cyclic sulfur(VI) compounds were obtained from IV, V, VI, and VII in reasonable yields. The novel perfluoropolymethylene bis(sulfur pentafluoride)s are transparent heavy liquids. Their physical properties and ^{19}F NMR and IR data are reported.

So far little attention has been paid to the electrochemical fluorination of thiols,[1] though there have been intensive investigations of the electrochemical fluorination of sulfides.[2] However, it was shown recently that thiols were fluorinated electrochemically, and a number of partially-fluorinated alkyl-sulfur pentafluorides were found among the fluorination products.[3]

On the other hand, it has been known that perfluorocyclic sulfur(VI) compounds as well as the expected perfluoro-dialkylsulfur tetrafluorides were produced by the electrochemical fluorination of acyclic sulfur compounds containing one or more sulfur atoms in the alkyl chain.[2b,2c]

The present investigation was undertaken in order to elucidate the behavior of the electrochemical fluorination of such dithiols as 1,4-butanedithiol (I), 1,5-pentanedithiol (II), 3-oxapentane-1,5-dithiol (III), and also to investigate the possibility of their cyclization upon electrochemical fluorination and to compare the results with those of the fluorination of diols.[4] Further, the electrochemical fluorination of cyclic sulfides [tetrahydrothiophene (IV), 2-methyltetrahydrothiophene (V), 3-methylthiophene (VI) and tetrahydrothiopyran (VII)] was also examined.

Upon the electrochemical fluorination of dithiols, it was found that dithiols yielded a variety of products, as well as the corresponding novel perfluoropolymethylene bis(sulfur pentafluoride)s, as a result of fragmentation, degradation, and cyclization during the fluorination reaction.

On the other hand, the yields of the corresponding perfluorocyclic sulfur(VI) compounds upon the fluorination of cyclic sulfides were seriously affected by their ring size.

Results and Discussion

The reaction conditions and the results of the fluorination of dithiols and cyclic sulfides are summarized in Tables 1 and 2 respectively.

In anhydrous hydrogen fluoride, it is known[5] that thiols and sulfides dissolve to form a state of the sulfonium ion similar to that of compounds which contain an oxygen atom (oxonium ion). When these sulfonium compounds are subjected to oxidative fluorination by the electrochemical process, perfluoroalkyl derivatives of sulfur hexafluoride (R_f-SF_5 and R_f-SF_4-R_f'; R_f= R_f'= perfluoro-alkyl group) are formed. At the same time, fluorocarbons and sulfur hexafluoride are also produced as major products as a result of the extensive cleavage of the C–S bond.

As may be seen in Table 1, the patterns of the fluorination products varied depending on the starting dithiols. It was also found that the composition of the products was drastically affected by the fluorination procedure. Thus, from I, perfluorotetramethylene bis(sulfur pentafluoride) was obtained in a yield of <1%, and from II, perfluoropentamethylene bis(sulfur pentafluoride) was obtained in a yield of 11.6%. However, perfluoro-3-oxapentamethylene bis(sulfur pentafluoride), $SF_5CF_2CF_2OCF_2CF_2SF_5$, could not be obtained from III (Run A) using the reaction procedure applied for the fluorination of I and II, but when III was fluorinated, while III was introduced into the electrolytic cell to maintain its concentration constant, a trace of the expected perfluoro-3-oxapentamethylene bis(sulfur pentafluoride) was obtained (Run B). These novel perfluoropolymethylene bis(sulfur pentafluoride)s are heavy, transparent, and odorless liquids. The physical properties and ^{19}F NMR and IR data of these compounds, together with those of perfluorotrimethylene bis(sulfur pentafluoride), which was prepared by the electrochemical fluorination of 1,3-propanedithiol (yield=2.5%), are shown in Tables 3, 4, and 5 respectively.

a) Mp 19—21 °C, glassy. b) Calculated value in parenthesis.

By analogy with the results of the electrochemical fluorination of diols,[4] the cyclic products (perfluorotetramethylenesulfur tetrafluoride from I. perfluoropentamethylenesulfur tetrafluoride, perfluoro-2-methyltetramethylenesulfur tetrafluoride, and perfluoro-3-methyltetramethylenesulfur tetrafluoride from II. perfluoro-4-oxapentamethylenesulfur tetrafluoride from III) were also formed. Among them, the yield of perfluorotetramethylenesulfur tetrafluoride from I amounted to 4.7%.

As for the results with the fluorination of cyclic sulfides (Table 2), five-membered perfluorotetramethylenesulfur tetrafluoride from IV was obtained in the highest yield (11.4%). However, the results of the fluorination of V, VI, and VII indicated that considerable ring isomerization took place, resulting in a reduction of the yield of the expected sulfur(VI) compounds. The perfluorotetramethylenesulfur tetrafluoride[6] and perfluoropentamethylenesulfur tetrafluoride are solid at room temperature and freeze to a glass, while perfluoro-2-methyltetramethylenesulfur tetrafluoride and perfluoro-3-methyltetramethylenesulfur tetrafluoride are liquids. Although the five- and six-membered perfluorocyclic sulfur(VI) compounds were obtained in this manner, the four-membered perfluorotrimethylenesulfur tetrafluoride could not be obtained by the electrochemical fluorination of trimethylene sulfide, as it immediately polymerized in anhydrous

6) T. Abe and J. M. Shreeve, *J. Fluorine Chem.*, **3**, 17 (1973/74).

hydrogen fluoride, thus giving an orange, gelatinous polymer.[7] The properties of these perfluorocyclic sulfur(VI) compounds, and those of perfluoro-*n*-amylsulfur pentafluoride and perfluoroisoamylsulfur pentafluoride are shown in Table 6. The structures of these perfluoroalkylsulfur(VI) compounds were determined by means of their ^{19}F NMR, mass, and IR spectra as well as by elemental analysis. However, the ^{19}F NMR spectra[8] of both perfluoro-2-methyltetramethylenesulfur tetrafluoride and perfluoro-3-methyltetramethylenesulfur tetrafluoride were too complicated to resolve because of the conformational rigidity of their molecules, which resulted in a non-equivalence of the geminal fluorines of the alkyl group, and also because they were a mixture of their respective geometric isomer.

Experimental

Reagents and Apparatus. All the reagents except 1,3-propanedithiol and 1,5-pentanedithiol were purchased from Tokyo Kasei Co., and were used as received. The 1,3-propanedithiol[9] and 1,5-pentanedithiol[10] were prepared by the reaction of the corresponding alkyl bromides with an alcoholic KSH solution, following the method of the reference. They were used after purification. The purity of the anhydrous hydrogen fluoride was higher than 99.5%.

All the features of the apparatus and the electrolytic cell (capacity, 1 l; electrode, Ni plates; effective anodic surface area, 9.2 dm^2) used for this fluorination were the same as have been described previously.[4] A Shibata micro-pump, Model SPC-100, was used to change the 3-oxapentane-1,5-dithiol into the cell during the electrolysis.

The IR spectrum measurements were accomplished by means of a Hitachi EPI-G3 spectrometer, using a 6-cm gas cell with KBr windows.

The ^{19}F NMR spectra were obtained by a JEOL C-60-H high resolution spectrometer (56.4 Mc for ^{19}F), using trifluoroacetic acid (external) and trichlorofluoromethane (internal) for the determination of the chemical shifts.

Procedures. The general procedures for the fluorination of dithiols and cyclic sulfides were the same as have been described previously.[4] As examples, the fluorination of 1,5-pentanedithiol, 3-oxapentane-1,5-dithiol (Run B) and tetrahydrothiopyran will be described.

Fluorination of 1,5-Pentanedithiol: A 27.2 g portion of 1,5-pentanedithiol was introduced into a cell which contained 1 l anhydrous hydrogen fluoride. Then the electrolysis was carried out with an anodic current density of 3.3 A/dm^2, a cell voltage 7.2—7.7 V, and cell a temperature of 5—6 °C. He (50 ml/min) was introduced from the bottom of the cell in order to agitate the solution. The electrolysis was then conducted for 177 A·hr.

The evolving gases from the cell were passed through a reflux condenser kept at −25 °C, over NaF pellets, and then bubbled through an alkaline solution of sodium sulfite, containing a small amount of potassium iodide in a series of Ichinose gas washers, and finally collected through traps immersed in liquid nitrogen. After the electrolysis was over, the transparent heavy liquid, which was later found to consist mostly of perfluoropentamethylene bis(sulfur pentafluoride), was drained from the bottom of the cell, washed with an alkaline solution, dried over anhydrous sodium sulfate, and subsequently analysed by glc.

The fluorinated products (39.6 g) collected in the cold traps were carefully separated into two fractions using the traps of the low-temperature distillation unit : Fraction 1 (compounds having lower bp's); (20.4 g), Fraction 2; (19.2 g). The compounds in Fraction 1 consisted mainly of SF_6. Then, the volatile compounds in Fraction 2 were removed by distillation. Thus, 12.6 g of the distillation residue were obtained. The volatile distillate was identified as a mixture of perfluoro-*n*- and -*iso*-pentane (*n*-C_5F_{12} : *iso*-C_5F_{12}=90 : 10) by glc (column: Kel F #3 30% on Chromosorb PAW, carrier; He) and on the basis of their known IR spectra. The cell drainings (17.4 g) and the distillation residue of Fraction 2 (12.6 g) were subsequently analysed by glc (column; Kel F #90 26% on Chromosorb PAW, and DNP 25% on Shimalite, carrier; He). The following perfluorinated sulfur(VI) compounds were thus obtained: $SF_5(CF_2)_5SF_5$ 11.7 g, *n*-$C_5F_{11}SF_5$ 12.8 g, $CF(CF_3)CF_2CF_2CF_2SF_4$ 0.6 g, $CF_2CF(CF_3)CF_2CF_2SF_4$ 0.2 g, $CF_2CF_2CF_2CF_2CF_2SF_4$ 0.3 g. These new compounds were characterized by means of their ^{19}F NMR, IR and mass data as well as elemental analyses (C and F).

Fluorination of 3-Oxapentane-1,5-dithiol (Run B): The fluorination was carried out in essentially the same manner illustrated above. However, the 3-oxapentane-1,5-dithiol was fed into the cell little by little by means of the micro-pump, which was connected with the sample injector,[2e] at a rate of about 5.5 ml/hr during electrolysis (anodic current density, 3.3 A/dm^2. cell voltage, 5.5—7.1 V. cell temp, 5—6 °C). For this sample feeding (27.6 g), 4 hr were required. Electrolysis was then continued for another hour. Thus, 151 A·hr of the electrolysis were conducted. No perfluorinated products were found in the cell drainings. The products (40.3 g), which was collected into traps immersed in liquid nitrogen, were similarly treated. The volatile $C_2F_5OC_2F_5$ and SF_6 were formed as major products. The following compounds were obtained by finally analysing the 4.7 g of the distillation residue: $SF_5CF_2CF_2OCF_2CF_2SF_5$ 0.2 g, $C_2F_5OC_2F_4SF_5$ 1.0 g, $SF_5CF_2CF_2SF_5$ 0.2 g, $(C_2F_5)_2SF_5$ 1.4 g, $CF_2CF_2OCF_2CF_2SF_4$ 0.3 g.

Fluorination of Tetrahydrothiopyran: Tetrahydrothiopyran (20.4 g) was subjected to electrochemical fluorination under the following electrolysis conditions: anodic current density, 3.3 A/dm^2. electricity passed, 129 A·hr. cell voltage, 4.9—7.0 V. cell temp, 5—6 °C. The fluorinated product (19.3 g) was collected in traps cooled in liquid nitrogen. The product was initially subjected to a low-temperature distillation. The fraction (7.5 ml, 14.6 g) which has a bp of above 0 °C was treated likewise, and the following compounds were obtained. $CF_2CF_2CF_2CF_2CF_2SF_4$ 1.0 g, $CF_2CF(CF_3)CF_2CF_2SF_4$ 1.3 g, $CF(CF_3)CF_2CF_2CF_2SF_4$ 0.5 g, *n*-$C_5F_{11}SF_5$ 1.9 g, *iso*-$C_5F_{11}SF_5$ 0.5 g. The ratio of the perfluoro-*n*- and -*iso*-pentane which was formed as a result of the cleavage of the C-S bond was as follows. *n*-C_5F_{12} : *iso*-C_5F_{12}=58 : 42.

The authors wish to thank Mr. Kazuo Kodaira for the mass measurements.

New Syntheses of Pyrimido[4,5-*d*]pyrimidines[1]

Fumio YONEDA and Masatsugu HIGUCHI

Faculty of Pharmaceutical Sciences, Kumamoto University, Oe-honmachi, Kumamoto 862

(Received May 23, 1973)

Novel conversions of pyrrolo-pyrimidines into pyrimido-pyrimidines are described. The treatment of 5-nitrosopyrrolo-pyrimidine (I) under Beckmann conditions causes ring expansion to give pyrimido-pyrimidine (II). Both the reduction of I with triphenylphosphine, potassium pyrosulfite, or sodium dithionite in dimethylformamide and the oxidation of 5-aminopyrrolo-pyrimidine with lead tetraacetate in dimethylformamide or acetic acid afford II. 5-Aminopyrimido-pyrimidine is prepared by the nucleophile-induced ring expansion of I. The possible mechanisms of these ring expansions are proposed.

The pyrimido[4,5-*d*]pyrimidine ring system not only resembles purine, but is isomeric with pteridine; it can, therefore, be expected to have biological activities similar to those of either purine or pteridine. In fact, certain pyrimido[4,5-*d*]pyrimidines have shown diuretic[2,3] and purine antagonistic[4] properties.

The known synthetic methods for the preparation of pyrimido[4,5-*d*]pyrimidines have involved the initial construction of suitably-substituted pyrimidine precursors and the subsequent annelation of the condensed pyrimidine ring in the reaction by using several carbon or carbon-nitrogen sources.[2-10] In this paper we will describe several new routes to the syntheses of pyrimido-[4,5-*d*]pyrimidines including ring expansions of pyrrolo-[2,3-*d*]pyrimidine derivatives.

Ring Expansion under Beckmann Conditions

It has been suggested that the ring expansion of 5-nitrosopyrrolo[2,3-*d*]pyrimidine to pyrimido[4,5-*d*]-pyrimidine by treatment under reflux with tosyl chloride or phosphorus oxychloride in dimethylformamide can be considered to occur *via* the usual Beckmann-type rearrangement.[11] Later we observed that the conversion of 3-nitrosoindole into quinazoline proceeds *via* the second-order Beckmann rearrangement.[12] This finding prompted us to look more closely into the ring expansion of 5-nitrosopyrrolo[2,3-*d*]pyrimidine described above.

The stirring of 1,3-dimethyl-5-nitroso-6-phenylpyrrolo[2,3-*d*]-2,4(1*H*,3*H*)-pyrimidinedione (**1a**)[11] with tosyl chloride in pyridine under cooling with ice water for 1 hr, followed by dilution with water, separated 6-(benzoylamino)-5-cyano-1,3-dimethyluracil (**2**), in which a nitrile absorption is present at 2215 cm^{-1} (Nujol) in the infrared spectrum. Compound **2** is extremely unstable, so even its purification by recrystallization from solvents or even its being maintained at room temperature for a few days results in cyclization into 4-iminopyrimido-1,3-oxazine (**3**). The heating of **1a** under a mild reflux with tosyl chloride or phosphorus oxychloride in pyridine formed **3** exclusively, while the refluxing of **1a** with the same reagents in dimethylformamide afforded 1,3-dimethyl-5-hydroxyl-7-phenylpyrimido[4,5-*d*]-2,4(1*H*,3*H*)-pyrimidinedione (**4a**), as has been described in the preceding paper.[11] The infrared spectra of **3** showed a strong imino absorption band at 3375 cm^{-1} (KBr). The heating of **3** under reflux in dimethylformamide resulted in the formation of **4a** *via* the Dimroth-type rearrangement. The treatment of **3** with an acid or base such as hydrochloric acid or benzylamine gave also **4a**. Compound **4a** was alternatively prepared by the following unequivocal synthesis. The heating of 6-amino-1,3-dimethyluracil with ethyl chloroformate in pyridine afforded 6-amino-1,3-dimethyl-5-(ethoxycarbonyl)uracil (**5**), which was then fused with benzamidine hydrochloride to give **4a**.

These facts show that this ring expansion proceeds *via* the second-order Beckmann rearrangement of the imino oxime tautomeric form of **1a**, followed by cy-

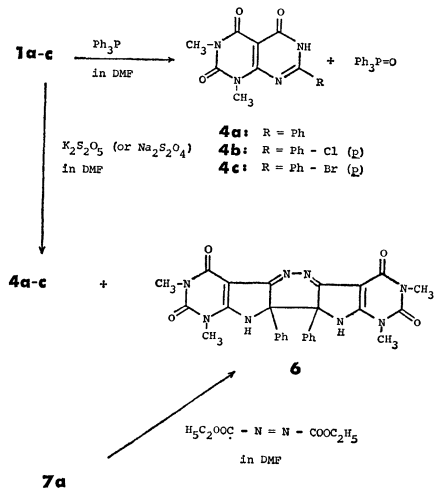
clization into the 4-imino-1,3-oxazine intermediate (**3**) and subsequent Dimroth rearrangement, as is depicted in Scheme 1.

Reductive Ring Expansion

The stirring of **1a** under a mild reflux with excess triphenylphosphine in dimethylformamide for 1 hr, followed by cooling, caused the separation of **4a** in 45% yield. The mother liquor was evaporated in dryness under reduced pressure, and the residue was chromatographed to give triphenylphosphine oxide in a 76% yield. Similarly, the 6-*p*-chlorophenyl and 6-*p*-bromophenyl analogs (**1b** and **1c**) of **1a** yielded the corresponding pyrimido[4,5-*d*]pyrimidines (**4b** and **4c**) in almost the same yields.

The refluxing of **1a** with excess potassium pyrosulfite in dimethylformamide for 1 hr and the subsequent cooling of the reaction mixture separated **4a** in a 50% yield. To our knowledge, the reaction is the first example in which potassium pyrosulfite has been successfully introduced into preparative origanic chemistry. In this reaction a dimeric product (**6**) was obtained as a by-product. The structure of **6** was assigned on the basis of an elemental analysis and a molecular-weight determination (a strong parent peak at *m/e* 536), and in consideration of its probable mode of formation. An analogous dimeric indole derivative is obtained in the oxidation of the 3-indoxyl derivative.[13] This dimeric product (**6**) was alternatively synthesized by the oxidative coupling of 3-aminopyrrolo[2,3-*d*]pyrimidine (**7a**) (*vide infra*) with diethyl azodicarboxylate in dimethylformamide.

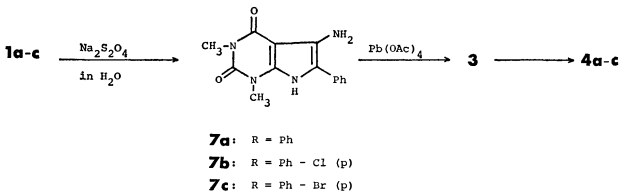


Scheme 2.

The treatment of **1b** and **1c** with potassium pyrosulfite under the same conditions gave, similarly, **4b** and **4c** in 58 and 40% yields respectively. The treatment of **1a** with sodium dithionite in dimethylformamide also yielded **4a**, although in a lower yield (34%), whereas this reaction in water gave the usual reduction-product, 5-aminopyrrolo[2,3-*d*]pyrimidines (**7**) (*vide infra*). When **1a** alone was refluxed in dimethylformamide, only a trace of **4a** was obtained, the starting material being almost entirely recovered.

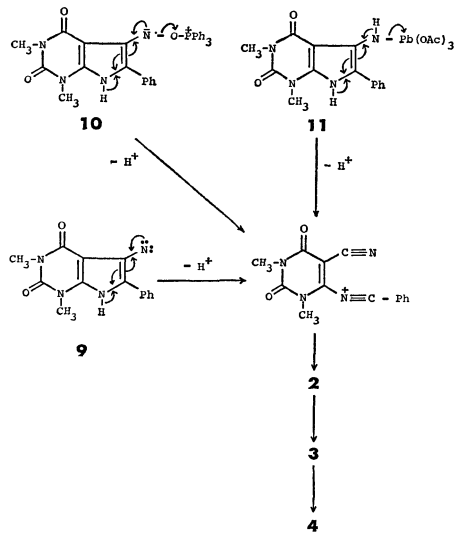
Oxidative Ring Expansion

It was found that the reaction of 5-amino-1,3-dimethyl-6-phenylpyrrolo[2,3-*d*]-2,4(1*H*,3*H*)-pyrimidinediones (**7a–c**) with lead tetraacetate gave **4a–c**. The starting materials, **7a–c**, were obtained by the reduction of **1a–c** with sodium dithionite in water. The heating of **7a–c** with excess lead tetraacetate in dimethylformamide or acetic acid at 90° for 3 hr, partial evaporation, and dilution with water caused the separation of **4a–c** in 90, 86, and 72% yields respectively. When the above reaction was carried out below 65°, an intermediate, the 4-imino-1,3-oxazine derivative (**3**), was obtained in a high yield.



Scheme 3.

Although a common intermediate, 5-nitrene (**9**), is formed in both the reductive and oxidative ring expansions described above, we could not demonstrate the presence of **9** by intermolecular trapping reaction with cyclohexene. Therefore, the more complex adducts, such as **10** and **11**, appear equally probable as precursors.



Scheme 4.

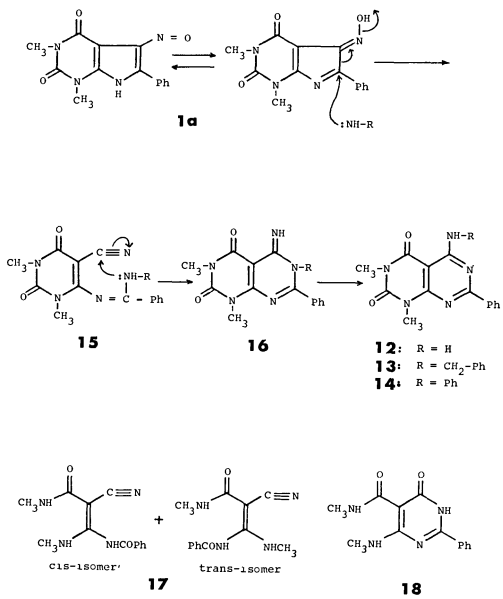
Nucleophile-induced Ring Expansion

The refluxing of **1a** in dimethylformamide while introducing dry ammonia over a 4-hr period yielded 5-amino-1,3-dimethyl-7-phenylpyrimido[4,5-*d*]-2,4(1*H*,3*H*)-pyrimidinedione (**12**) in a 60% yield. Re-

13) a) A. Hassner and M. Haddadin, *J. Org. Chem.*, **28**, 224 (1963). b) E. Giovannins, F. Farkas, and J. Rosales, *Helv. Chim. Acta*, **46**, 1326 (1963).

fluxing **1a** with urea in dimethylformamide also gave **12** in a 80% yield. The structure of **12** was assigned on the basis of the satisfactory elemental analysis and the spectral data, and finally by the conversion of **12** into **4a** by deamination with sodium nitrite in hydrochloric acid. Similarly, the refluxing of **1a** with benzylamine and aniline in dimethylformamide afforded 5-benzylamino- (**13**) and 5-anilino-1,3-dimethyl-7-phenylpyrimido[4,5-*d*]-2,4(1*H*,3*H*)-pyrimidinedione (**14**) in 59 and 64% yields respectively.

The following mechanism with the *N*-(5-cyanouracil-6-yl)amidine intermediate (**15**) rationalizes this ring expansion. A formal Beckmann-type rearrangement would also account directly for the formation of the 5-benzyl (**13**) and 5-anilino derivatives (**14**), without any need to postulate the subsequent Dimroth rearrangement of an imino intermediate (**16**). However, the formation of (benzoylamino)acrylonitrile (**17**) from **1a** by the action of alkali would eliminate the similar Beckmann process. That is, the refluxing of **1a** with 40% potassium hydroxide solution in a mixture of ethanol and water (1 : 1) for 1 hr yielded a nearly equimolar mixture of *cis*- and *trans*-isomers (**17**). The NMR spectra exhibited two pairs of three-proton singlets at 3.12 and 3.47 as well as those at 3.19 and 3.55. The former two singlets were assigned to the *N*-methyl groups of the *cis*-isomer, and the latter two, to those of the *trans*-isomer. The **17** mixture was converted into the corresponding pyrimidine derivative (**18**) in a quantitative yield by treatment with dry hydrogen chloride in ethanol. The characteristic nitrile band of **17** at 2190 cm^{-1} (Nujol) disappeared. The NMR spectrum displayed a pair of singlets at 3.10 and 3.45 corresponding to the *N*-methyl groups and phenyl protons at from 7.5 to 8.2.



Scheme 5.

Experimental

All the melting points are uncorrected. The NMR spectra were determined by means of a JNM 3H-60 spectrometer, using tetramethylsilane as the internal standard. The chemical shifts were expressed in δ values. The mass spectra (75 eV) were recorded on a Hitachi RMU-6D double-focusing spectrometer.

*6-(Benzoylamino)-5-cyano-1,3-dimethyluracil (**2**).* A mixture of 0.25 g (1 mmol) of **1a** and 0.6 g (3 mmol) of TsCl in 5 ml of pyridine was stirred under cooling with ice water for 4 hr. The subsequent dilution of the reaction mixture with H_2O gave 0.1 g (40%) of **2**.

*1,3-Dimethyl-5-imino-7-phenylpyrimido[4,5-d]-1,3-oxazine (**3**).* A mixture of 0.5 g (2 mmol) of **1a** and 1 g (5 mmol) of TsCl in 15 ml of pyridine was refluxed at 130—140 °C for 3 hr. The reaction mixture was then evaporated under reduced pressure, and to the residue 100 ml of H_2O was added. The crystals thus separated were recrystallized from DMF to give 0.45 g (90%) of colorless crystals; mp>285 °C (sublim.). *m/e* 284 (M^+). Found: C, 59.08; H, 4.21; N, 19.39%. Calcd for $C_{14}H_{12}N_4O_3$: C, 59.15; H, 4.26; N, 19.71%.

*Dimroth Rearrangement of **3** to **4a**.* *A.* A solution of 0.1 g (4 mmol) of **3** in 5 ml of DMF was refluxed for 3 hr and then allowed to stand overnight at room temperature. The crystals thus precipitated were washed with H_2O and dried to give 0.09 g (90%) of **4a**.

B. A solution of 0.05 g (0.2 mmol) of **3** in 10 ml of conc. HCl was refluxed for 3 hr. The reaction mixture was then diluted with H_2O and neutralized with aqueous NH_3 to separate 0.025 g (50%) of **4a**.

C. A solution of 0.25 g (1 mmol) of **3** and 0.16 g (2 mmol) of benzylamine in 50 ml of DMF was refluxed at 160° for 3 hr. After cooling, the crystals thus separated were washed with H_2O and dried to give 0.23 g (92%) of **4a**.

*6-Amino-1,3-dimethyl-5-(ethoxycarbonyl)uracil (**5**).* Three grams (19 mmol) of 6-amino-1,3-dimethyluracil were dissolved in 55 ml of pyridine, and to the solution we then added, drop by drop, 4.5 g (42 mmol) of ethyl chloroformate. After heating at 90 °C for 5 hr, the reaction mixture was evaporated *in vacuo*, and then 10 ml of H_2O was added. The crystals thus separated were recrystallized from EtOH to give 2.2 g (50.1 %) of colorless needles; mp 207—208 °C. Found: C, 47.74; H, 5.52; N, 18.68%. Calcd for $C_9H_{13}N_3O_4$: C, 47.57; H, 5.77; N, 18.49%.

*Reaction of **5** with Benzamidine Hydrochloride.* One gram (4 mmol) of **5** and 1.25 g (8 mmol) of benzamidine hydrochloride were thoroughly mixed, after which the mixture was fused at about 300 °C for 15 to 20 min. After cooling, reaction mixture was crushed in H_2O and washed with H_2O. The crushed mass was recrystallized from DMF to give 0.45 g (36%) of colorless plates (mp>300 °C), which were identical in all respects with the product (**4a**) prepared by the ring expansion of **1a**.

*Reductive Ring Expansion of **1a** with Triphenylphosphine.* A mixture of 1 g (4 mmol) of **1a** and 1.57 g (6 mmol) of triphenylphosphine in 20 ml of DMF was refluxed at 180 °C for 2.5 hr. After cooling, the crystals which separated were recrystallized from DMF to give 0.45 g (45%) of **4a**.

Similarly, 6-(*p*-chlorophenyl) (**1b**) and 6-(*p*-bromophenyl) (**1c**) analogs were converted into 7-(*p*-chlorophenyl)- (**4b**) and 7-(*p*-bromophenyl)-1,3-dimethylpyrimido[4,5-*d*]-2,4(1*H*,3*H*)-pyrimidinediones (**4c**) (see Table 1).

The evaporation of the mother liquor under reduced pressure and the column chromatography of the oily residue on alumina, using benzene-EtOH (7 : 3) as the eluant, gave triphenylphosphine oxide in a 75% yield.

*Reaction of **1a** with Potassium Pyrosulfite ($K_2S_2O_5$).* A mixture of 0.9 g (3 mmol) of **1a** and 0.9 g (4 mmol) of $K_2S_2O_5$ in 24 ml of DMF was heated under reflux at 180—190°C for 2.5 hr, during which time the color changed from red to

yellow. After cooling, the crystals which separated were recrystallized from DMF to give 0.45 g (50%) of colorless plates of **4a**.

The mother liquor was allowed to stand for 2 days to separate yellow crystals, which were then collected by filtration. The filtrate was concentrated *in vacuo* and diluted with H_2O to separate more yellow crystals. The combined crystals were recrystallized from DMF to give 0.15 g (17.6%) of colorless prisms of the dimer (**6**); mp 287—289 °C. *m/e* 536 (M^+). Found: C, 57.01; H, 5.07; N, 18.58%. Calcd for $C_{28}H_{24}N_8O_4.3H_2O$: C, 56.95; H, 5.09; N, 18.98%.

Under the same conditions, **1b** and **1c** were converted into **4b** and **4c** (see Table 1).

*Reaction of **7a** with Diethyl Azodicarboxylate.* To a solution 0.75 g (3 mmol) of **7a** in 30 ml of DMF, we added 0.5 g (3 mmol) of diethyl azodicarboxylate; the mixture was then heated under stirring at 130—135 °C for 6 hr. After cooling, the reaction mixture was evaporated to dryness. The residue was collected by filtration, washed with EtOH, and recrystallized from DMF to give 0.3 g (40.3%) of colorless plates (mp 287—289 °C) which were in all respects identical with the byproduct (**6**) formed by the reaction of **1a** with $K_2S_2O_5$.

*5-Amino-1,3-dimethyl-6-phenylpyrrolo[2,3-d]-2,4(1H,3H)-pyrimidinedione (**7a**).* A mixture of 6 g (21 mmol) of **1a** and 7.3 g (42 mmol) of $Na_2S_2O_4$ in 30 ml of H_2O was heated under reflux for 30 min. After cooling, the crystals which separated were recrystallized from EtOH to give 2.2 g (38.6 %) of pale yellow needles; mp 249—250 °C. *m/e* 270 (M^+). Found: 62.04; H, 5.37; N, 20.71%. Calcd for $C_{14}H_{14}N_4O_2$: C, 62.21; H, 5.22; N, 20.73%.

Similarly, 6-(*p*-chlorophenyl) (**7b**) (mp 250 °C, 40%) and 6-(*p*-bromophenyl) (**7c**) (mp 268 °C, 35%) analogs were obtained.

*Ring Expansion of **7a** with Lead Tetraacetate.* *A.* To a suspension of 0.81 g (3 mmol) of **7a** in 30 ml of acetic acid, we added, little by little, 2 g (5 mmol) of $Pb(OAc)_4$, after which the mixture was heated under stirring at 90 °C for 3 hr, during which time the color changed to a yellowish brown. After the solvent had been evaporated under reduced pressure, a small amount of H_2O was added to the resulting residue; the crystals which were thus separated were recrystallized from DMF to give 0.77 g (90%) of **4a**.

B. To a solution of 0.75 g (3 mmol) of **7a** in 30 ml of DMF, we added, little by little, 2 g (5 mmol) of $Pb(OAc)_4$, after which the mixture was heated at 65 °C for 3 hr. The reaction mixture was then diluted with H_2O to precipitate 0.08 g (91%) of **3**.

*5-Amino-1,3-dimethyl-7-phenylpyrimido[4,5-d]-2,4(1H,3H)-pyrimidinedione (**12**).* *A.* Three grams (11 mmol) of **1a** were dissolved in 30 ml of DMF, and to this solution we introduced dry ammonia at 140° over an 8-hr period, during which time the color changed to red. After the solvent had been evaporated, the resulting residue was recrystallized from DMF to yield 1.8 g (60%) of colorless needles; mp 259—260 °C. *m/e* 283 (M^+). Found: C, 59.70; H, 4.34; N, 25.15%. Calcd for $C_{14}H_{13}N_5O_2$: C, 59.35; H, 4.63: N, 24.72%.

B. A mixture of 0.5 g (2 mmol) of **1a** and 0.5 g (8 mmol) of urea in 10 ml of DMF was refluxed at 150—160 °C for 3 hr. The reaction mixture was evaporated under reduced pressure, and the resulting residue was diluted with H_2O. The crystals thus precipitated were recrystallized from DMF to give 0.4 g (80%) of **12**.

*Deamination of **12** into **4a**.* To a suspension of 0.1 g (0.4 mmol) of **12** in 20 ml of 10% dilute HCl, we added, portion by portion, excess $NaNO_2$ (0.5 g) under stirring and cooling with ice water; the mixture was then heated on a water bath for 1 hr. After cooling, the crystals which separated were washed with H_2O and dried to yield **4a** in a quantitative yield.

*5-(Benzylamino)-1,3-dimethyl-7-phenylpyrimido[4,5-d]-2,4(1H,3H)-pyrimidinedione (**13**).* To a solution of 0.5 g (2 mmol) of **1a** in 10 ml of DMF, we added 0.32 g (3 mmol) of benzylamine under stirring. The mixture was heated under reflux at 180 °C for 3 hr, during which time the color changed from yellow to red. After cooling, the product which separated were recrystallized from EtOH to give 0.38 g (58.5%) of colorless prisms; mp 228—229 °C. *m/e* 373 (M^+). Found: C, 67.39; H, 5.07; N, 18.51%. Calcd for $C_{21}H_{19}N_5O_2$: C, 67.54; H, 5.13; N, 18.76%.

*5-Anilino-1,3-dimethyl-7-phenylpyrimido[4,5-d]-2,4-(1H,3H)-pyrimidinedione (**14**).* To a solution of 0.5 g (2 mmol) of **1a** in 10 ml of DMF, we added 0.28 g (3 mmol) of aniline under stirring, after which the mixture was treated as has been described above to give 0.4 g (64%) of colorless needles; mp>300 °C. *m/e* 359 (M^+). Found: C, 66.73; N, 4.65; N, 19.40%. Calcd for $C_{20}H_{17}N_5O_2$: C, 66.84; H, 4.77; N, 19.49%.

1-Cyano-1-(N-methylcarbamoyl)-2-(benzoylamino)-2-(methylamino)ethylene (a Mixture of cis- *and* trans-*Isomers) (**17**).* To a solution of 0.75 g (3 mmol) of **1a** in 60 ml of EtOH, we added 15 ml of an aqueous solution including 1.5 g of KOH. After the mixture had been refluxed for 2 hr, the EtOH was evaporated and H_2O was added to the resulting residue. The undissolved material was filtered off, and the

The Reaction of β-Lactones with Acid Chlorides Catalyzed by Aluminum Chloride[1]

Tadaaki NAKABAYASHI, Yumo TANAKA, and Suketaka ITO

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Wakasato, Nagano 380

(Received May 28, 1973)

Aluminum chloride-catalyzed reactions of β-lactones with acid chlorides were studied. 3-Propanolide and 3-methyl- and 2-methyl-3-propanolide all undergo predominantly the O-alkyl bond fission to give mixed anhydrides of β-chloropropionic acid. The reaction was postulated to proceed *via* dichloraluminum β-chloropropionate.

3-Propanocide(I) is well known to be cleaved through either the alkyl-oxygen bond or the acyl-oxygen bond in reactions with various reagents.

The reactions of I with acid chlorides in the presence of sulfuric acid[2] or hydrogen chloride[3] have been shown to involve exclusively the fission of the O-acyl bond of I to give β-acyloxypropionyl chlorides (Path A).

On the other hand, it has been reported that I is

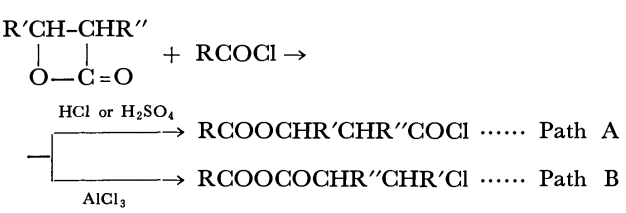
subjected to the O-alkyl bond fission, along with the O-acyl bond fission, in the aluminum chloride-catalyzed reaction with benzene to give β-phenylpropionic acid, 1-hydroindone, β-hydroxypropiophenone, and phenyl vinyl ketone respectively.[4]

The present paper will report that β-lactones undergo predominantly the O-alkyl bond fission in the aluminum chloride-catalyzed reaction with acid chlorides to afford mixed anhydrides of β-chloropropionic acids (Path B).



Results and Discussion

The reactions were carried out without any solvent.[5] To an acid chloride containing aluminum chloride as a catalyzer, β-lactone was added at near 0 °C. After the removal of the insoluble and the low-boiling products from the reaction mixture, the high-boiling acid anhydrides were obtained by means of molecular distillation. During distillation, disproportionation should take place; therefore, the resulting anhydrides were contaminated with the disproportionation products.

Acetic anhydride did not react with I under these reaction conditions. The results are summarized in Table 1.

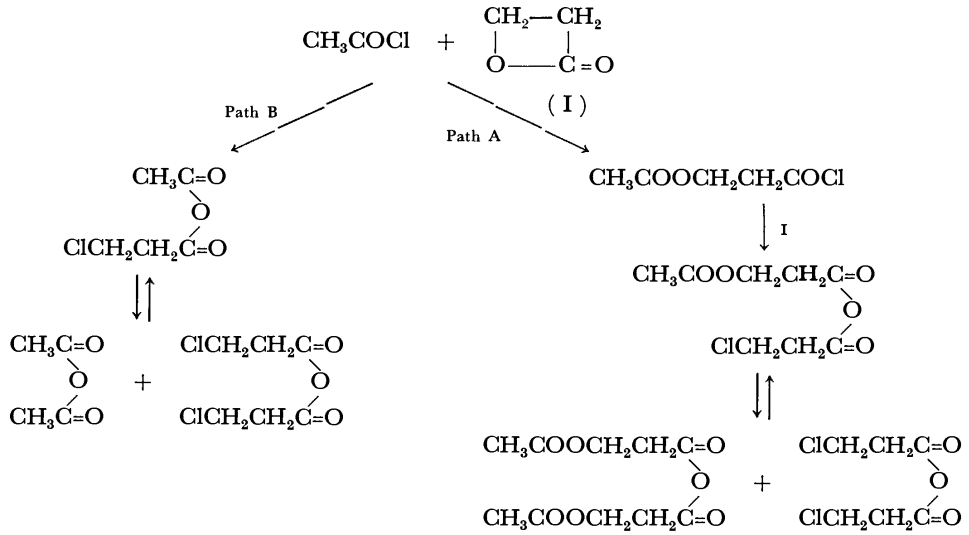
The molecular distillate of the product obtained by the reaction of acetyl chloride with I exhibited strong characteristic absorptions of acid anhydride, along with weak ones of ester, in its IR spectrum. The component acids of this fraction were determined by means of glc as methyl esters, which were derived by hydrolysis or methanolysis of the product, followed by treatment with diazomethane. The NMR analysis was also applied; its values were in fair agreement with the glc data (Table 2).

TABLE 2. THE MOLAR RATIO OF THE ACID COMPONENTS OF THE ACID ANHYDRIDES OBTAINED BY THE REACTION OF ACETYL CHLORIDE WITH I

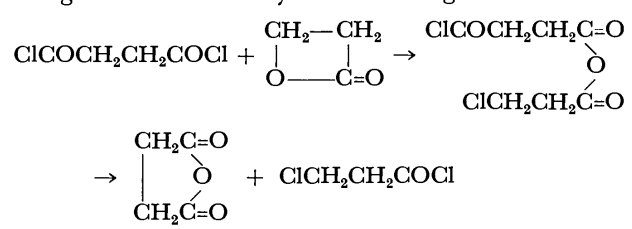
Method of analysis	$ClCH_2CH_2COOH$	$AcOCH_2CH_2COOH$	AcOH
1[a]	1.0	0.18	0.44
2[b]	1.0	0.18	0.47
3[c]	1.0	0.18	0.56

a) NMR. b) Methanolysis followed by treatment with CH_2N_2, glc. c) Hydrolysis followed by treatment with CH_2N_2, glc.

It follows from this that the acid anhydrides produced by the reaction are acetic β-chloropropionic anhydride, β-acetoxypropionic β-chloropropionic anhydride, and their disproportionation products. The reaction route can be illustrated as follows:



The reaction of I with succinyl chloride gave β-chloropropionyl chloride, β-chloropropionic anhydride, and succinic anhydride, which was precipitated from the reaction mixture in the course of the reaction. β-Chloropropionic β-chlorocarbonylpropionic anhydride should be the intermediate of the reaction, which gave succinic anhydride and β-chloropropionyl chloride through a chloride-anhydride exchange reaction:



The reaction of phthaloyl chloride with I proceeded in a similar manner. β-Chloropropionyl chloride afforded β-chloropropionic anhydride in a good yield.

4) K. Nagakubo, Y. Iwakura, M. Takei, and T. Okada, *Nippon Kagaku Zasshi*, **78**, 1209 (1957).

5) Use of a solvent such as carbon disulfide or nitrobenzene did not change or improve the reaction, and gave the same result as in the absence of a solvent.

The component acids of the molecular distillate obtained by the reaction of β-acetoxypropionyl chloride with I were β-acetoxypropionic and β-chloropropionic acid in a rough ratio of 1 : 1.

Although the crude products obtained by the reactions of succinyl, phthaloyl, and β-chloropropionyl chloride also showed weak absorptions which may be assigned to an ester group in the IR spectra, almost no detectable amounts of products of the O-acyl bond fission of I were observed in any molecular distillate; this may be because such a constituent containing a β-acyloxypropionyl group is hardly distillable under these operating conditions.

The reactions of propionyl, butyryl, and isobutyryl chloride with I proceeded in a manner similar to that of acetyl chloride; no significant difference between them was noticed except for the fact that isobutyryl chloride was somewhat less reactive, probably on account of its steric factor.

2-Methyl-3-propanolide(II) reacted with acetyl chloride in analogy with I. The molar ratio of the acid components of the distilled anhydrides is given in Table 3.

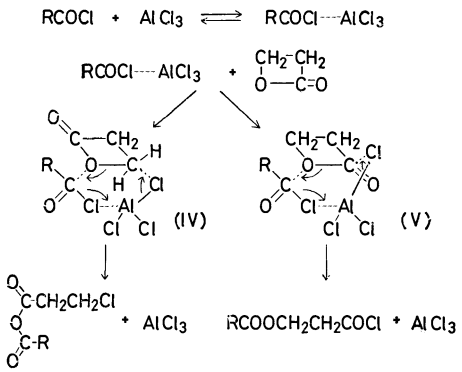
Table 3. The molar ratios of the acid coponents of the acid anhydrides obtained by the reaction of acetyl chloride with II and with III

β-Lactone	Component acid	Molar ratio[a)]
II	$ClCH_2CH(CH_3)COOH$	1.0
	$AcOCH_2CH(CH_3)COOH$	0.25
	AcOH	0.091
III	$ClCH(CH_3)CH_2COOH$	1.0
	$AcOCH(CH_3)CH_2COOH$	0.22
	AcOH	0.15

a) Determined by means of NMR.

3-Methyl-3-propanolide(III) was fairly less reactive and hardly reacted at all near 0 °C. III was ultimately allowed to react with acetyl chloride at 11—15 °C to give a mixture of mixed anhydrides (Table 3).

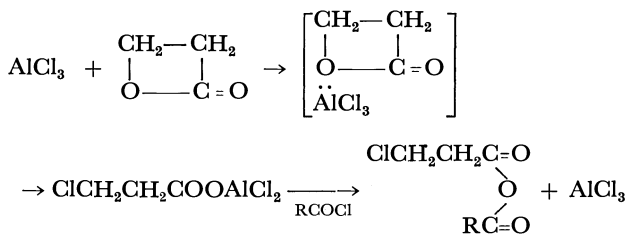
A mechanism of the reaction of I with acid chloride catalyzed by aluminum chloride may be postulated to be as follows (Scheme 1):



Scheme 1.

The preference of Reaction Path B to Path A can be attributed to the greater stability of the (IV) cyclic transition state, chiefly because of the lack of dipole-dipole interaction between the carbonyl oxygen of the lactone and the chlorine moieties of aluminum chloride, than that of the (V) cyclic transition state. The lower reactivity of 3-methyl-3-propanolide can be explained by the steric effect of the methyl group at the 3-position.

An alternate mechanism for the formation of anhydride can be given by assuming the formation of aluminum salt of β-chloropropionic acid as an intermediate (Scheme 2):



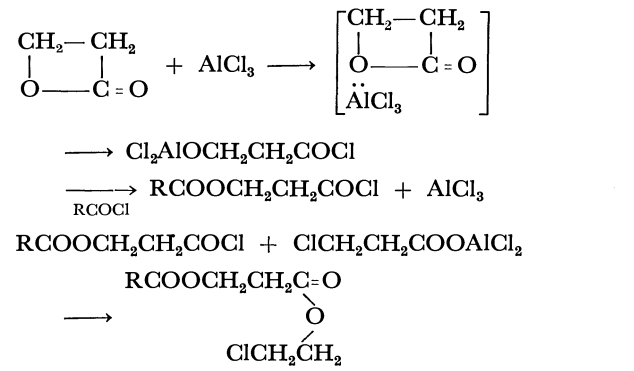
Scheme 2

When I was allowed to react with aluminum chloride (molar ratio, 1.3 : 1.0) in nitrobenzene, there was obtained a yellow homogeneous solution, in the IR spectrum of which the characteristic absorptions of β-lactone had almost disappeared. From this nitrobenzene solution, β-chloropropionic acid, along with a small amount of β-hydroxypropionic acid, could be obtained in an almost quantitative yield.[6)] Using the above nitrobenzene solution as a catalyzer instead of aluminum chloride, the same results were obtained in the reaction of I with acid chloride.

In addition, a slight rise in the temperature observed at the beginning of the addition of I to acid chloride containing aluminum chloride (see Experimental section) may be attributable to the exothermic reaction of I with aluminum chloride to form dichloraluminum β-chloropropionate.[7)]

The lower reactivity of 3-methyl-3-propanolide may be due to the steric influence of the 3-methyl group on the substitution at the 3-position of the lactone by a chlorine of aluminum chloride.

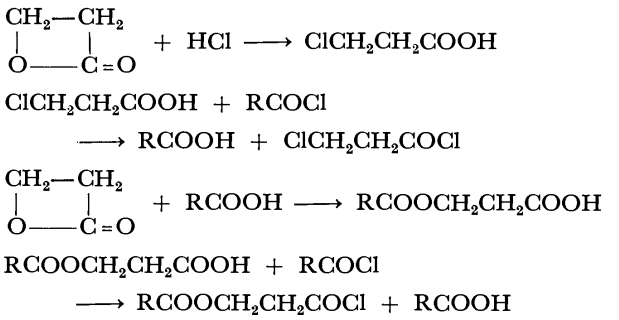
Although the first mechanism can not be rejected completely, in view of these experimental results the second mechanism is more reasonable, and the formation of the β-acyloxypropionyl group can be explained as follows:



6) Nagakubo and co-workers[4)] obtained β-chloropropionic acid as a by-product in the aluminum chloride-catalyzed reaction of β-propiolactone with benzene.

7) Dichloraluminum β-chloropropionate may be formed by a concerted reaction between β-lactone and aluminum chloride. The possibility of a four-membered cyclic transition state involving β-lactone has been suggested in literature; see J. Koketsu, S. Kojima, and Y. Ishii, This Bulletin, **43**, 3232 (1970).

An additional route for the O-acyl bond fission of β-lactones is possible, in which the fission is catalyzed by hydrogen chloride[2] present in aluminum chloride or acid chloride as an impurity:



In the reaction of 3,3-dimethyl-3-propanolide with acetyl chloride, the evolution of isobutene and carbon dioxide was observed, even near 0 °C.[8] From the resulting reaction mixture, most of the acetyl chloride was recovered; there was also obtained an undistillable viscous oil which exhibited the characteristic absorptions of ester in its IR spectrum. Because of the great stability of a tertiary carbonium ion, in this case the alkyl-oxygen bond of the lactone should be cleaved with ease by the action of aluminum chloride to give a carbonium ionic intermediate, which may decompose to isobutene and carbon dioxide, and which may competitively attack another molecule of the lactone to result in the formation of a polyester.

Experimental

General. The reactions of β-lactones with acid chlorides were conducted at 0—2 °C for 20 hr, unless otherwise noted. For the glc determination, a Shimadzu Gas Chromatograph Model GC-2C was employed. The IR spectra were measured with a JASCO DS-301 spectrometer. The NMR spectra were recorded at 100 MHz with a JEOL JNH-4H-100 spectrometer in carbon tetrachloride, with tetramethylsilane as an internal standard.

Materials. 3-Propanolide(I) provided by the Daicel Co., Ltd., was dried with calcium hydride and distilled; bp 54 °C/11 mmHg. 2-Methyl-3-propanolide (II, bp 41 °C/3 mmHg),[9] 3,3-dimethyl-3-propanolide (bp 40 °C/5 mmHg),[10] β-acetoxypropionyl chloride (bp 62—64 °C/5 mmHg),[2] and β-chloropropionyl chloride (bp 57—58 °C/30 mmHg)[2] were prepared according to the literature. 3-Methyl-3-propanolide-(III) from acetaldehyde and ketene; bp 41—43 °C/8 mmHg. The aluminium chloride used was purified by sublimation.

Reaction of I with Acetyl Chloride. To a solution of 78.5 g (1.0 mol) of acetyl chloride and 3 g (0.022 mol) of aluminum chloride cooled in an ice bath was added 72.0 g (1.0 mol) of I under stirring over a period of 1.5 hr. A slight temperature rise(~5 °C) was observed at the beginning of the addition, but after that the temperature remained constant at 1—2 °C. The reaction mixture was kept at this temperature for 18.5 hr; then it was submitted to vacuum distillation (~0.1 mmHg, ~60 °C) to give 24 g of a mixture of acetic anhydride and unaltered acetyl chloride. The residual liquid was distilled two times at 60—100 °C/1—3×10^{-3} mmHg, using a molecular still, to yield 72 g of a colorless liquid; this liquid showed the characteristic absorptions of acid anhydride at 1821, 1750, and 1065 cm^{-1} and those of acetate at 1367 and 1235 cm^{-1}. No absorption at 1790 cm^{-1} to be assigned to acid chloride was observed.

NMR(δ, ppm): 4.28(t, $AcOC\underline{H}_2CH_2C=O$), 3.75 (t, $ClC\underline{H}_2CH_2C=O$), 2.95(t, $ClCH_2C\underline{H}_2C=O$), 2.79(t, $AcOCH_2C\underline{H}_2C=O$), 2.21 (s, $C\underline{H}_3COOC=O$), 2.00(s, $C\underline{H}_3COOCH_2CH_2C=O$). A mixture of acetyl chloride, acetic anhydride, and a small amount of acetic acid was also collected in a cold trap; the total amounts of acetic anhydride and the recovered acetyl chloride were determined by means of glc (2.25-meter silicone grease DC 550 column, 110 °C; anisole as an internal standard) to be 8.6 and 19.5 g respectively.

An aliquot of the high-boiling product was hydrolyzed and titrated with a sodium hydroxide solution and then a silver nitrate solution. Acid: 11.5×10^{-3} mol/g sample, reactive chlorine(-COCl): 1.66×10^{-4} mol/g sample.

A portion of the product was allowed to react with methanol in a sealed tube at 100 °C for 30 min, and then treated with diazomethane. The resulting methyl esters in methanol were detected by means of glc using a 2.25-meter polyethylene glycol-6000 column at 50 °C, with *n*-propanol as an internal standard, and using a 2.25-meter DEGS column at 110 °C, with acetophenone as an internal standard. Methyl acetate, 3.90×10^{-3}; methyl β-chloropropionate, 5.99×10^{-3}; methyl β-hydropropionate, 1.08×10^{-3} mol/g sample. Assuming that the molecular distillate contains only acetic β-chloropropionic, β-chloropropionic β-acetoxypropionic, and β-chloropropionic anhydride, the yields of these anhydrides were calculated to be 0.20, 0.078, and 0.11 mol respectively.

A 20-g portion of the moelcular distillate was hydrolyzed with 20 ml of water at room temperature. The resulting aqueous solution was saturated with sodium chloride and extracted continuously with ether for 24 hr; the ether extract was then concentrated by fractionally distilling-off the solvent, and then treated with an etherial solution of diazomethane. Methyl acetate (5.14 g, 0.0715 mol), methyl β-chloropropionate (15.6 g, 0.127 mol), and methyl β-acetoxypropionate (3.25 g, 0.0223 mol) were determined by means of glc using a 2.25-meter polyethylene glycol-6000 column at 50 °C, with *n*-propanol as an internal standard, and a 2.25-meter DEGS column at 120 °C, with acetophenone as an internal standard, respectively.

Reaction of β-Acetoxypropionyl Chloride with I. I (72.0 g, 1.0 mol) was allowed to react with β-acetoxypropionyl chloride (150.5 g, 1.0 mol) in a similar manner. The yield of the molecular distillate was 192 g. IR: 1820, 1750(sh), 1050, 1740, 1368, 1240 cm^{-1}. NMR: 4.28(t), 3.73(t), 2.95(t), 2.79(t), 2.00(s). Molar ratio of $ClCH_2CH_2C=O$: $AcOCH_2CH_2C=O$ by the NMR analysis was 1.0 : 0.98.

A portion of the distillate was treated with methanol (10 hr, room temp.) and then with diazomethane to give methyl chloropropionate and methyl β-acetoxypropionate in 90.5% and 74.1% yields (based on β-chloropropionic β-acetoxypropionic anhydride) respectively.

The methanolysis of the distillate at 100 °C in a sealed tube, followed by treatment with diazomethane, afforded methyl acetate (3.89×10^{-3} mol/g sample), methyl β-chloropropionate (3.81×10^{-3} mol/g sample), and methyl β-hydroxypropionate (3.82×10^{-3} mol/g sample).

Reaction of β-chloropropionyl Chloride with I. I (18.0 g) 0.25 mol) was allowed to react with β-chloropropionyl chloride (38.8 g, 0.25 mol) in a similar manner. Unaltered acid

8) In water at room temperature, 3,3-dimethyl-3-propanolide decomposes rapidly to carbon dioxide and isotubene to the near exclusion of hydrolysis.[10]

9) Y. Yamashita, Y. Ishikawa, T. Tsuda, and T. Miura, *Kogyo Kagaku Zasshi*, **66**, 104 (1963).

10) T. L. Gresham, J. E. Jansen, F. W. Shaver, and W. L. Beears, *J. Amer. Chem. Soc.*, **76**, 486 (1954).

chloride (4.6 g) was thus recovered. The yield of the molecular distillate was 38.5 g, n_D^{20}: 1.4662. IR: 1820, 1750, 1050 cm^{-1}. NMR: 3.73(t, 2H), 2.95(t, 2H).

A mixture of 1.99 g (0.01 mol as pure β-chloropropionic anhydride) of the distillate and 40-ml portions of ethanol and benzene was refluxed for 1 hr, and then the bulk of solvent was removed by means of fractional distillation. From the residual liquid, 2.70 g(0.0198 mol) of ethyl β-chloropropionate was detected by means of glc using a 2.25-meter DEGS column at 120 °C, with acetophenone as an internal standard.

Reaction of Succinyl Chloride with I. The reaction was started at 10 °C to avoid the crystallization of succinyl chloride and then gradually brought to 0—2 °C. Succinic anhydride was precipitated from the reaction mixture. After the removal of the succinic anhydride (mp 115—117 °C) by filtration, followed by washing with ether, the residual liquid distilled to give β-chloropropionyl chloride (n_D^{20}: 1.4566, bp 58—59 °C/32 mmHg; anilide, mp 118—119 °C) and β-chloropropionic anhydride (n_D^{20}: 1.4666, bp 78 °C/0.02 mmHg).

Reaction of Phthaloyl Chloride with I. The reaction proceeded in the same way as above. The phthalic anhydride obtained was contaminated with a small amount of phthalyl chloride.

Reactions of Propionyl, Butyryl, and Isobutyryl Chloride with I. These reactions were conducted in a manner similar to that of acetyl chloride. The molar ratios of the acid components of the molecular distillates, determined by means of NMR, are as follows:

RCOCl	$ClCH_2CH_2$-COOH	$RCOOCH_2$-CH_2COOH	RCOOH
CH_3CH_2COCl	1.0	0.20	0.70
$CH_3CH_2CH_2COCl$	1.0	0.19	0.73
$(CH_3)_2CHCOCl$	1.0	0.20	0.51

Reaction of II with Acetyl Chloride. The reaction was conducted in a manner similar to that used for I. From 21.8 g (0.25 mol) of II and 19.6 g (0.25 mol) of acetyl chloride, 22.4 g of a molecular distillate was obtained. IR: 1825, 1750, 1240, 1040 cm^{-1}. NMR: 4.18(approx. d, $AcOC\underline{H}_2$-$CH(CH_3)C{=}O$), 3.68(octet, $ClC\underline{H}_2CH(CH_3)C{=}O$), 2.6—3.2 (m, $ClCH_2C\underline{H}(CH_3)C{=}O$, $AcOCH_2C\underline{H}(CH_3)C{=}O$), 2.23(s, $C\underline{H}_3COOC{=}O$), 2.01 (s, $C\underline{H}_3COOCH_2CH(CH_3)C{=}O$), 1.35 (d, $ClCH_2CH(C\underline{H}_3)C{=}O$), 1.27(d, $AcOCH_2CH(C\underline{H}_3)C{=}O$). Glc analysis (as methyl ester; columns: 2.25-meter polyethylene glycol-6000 column at 50 °C and 2.25-meter DEGS column at 110 °C; internal standards: *n*-propanol and acetophenone): Methyl acetate, 0.44×10^{-3}; methyl β-chloroisobutyrate, 5.22×10^{-3}; methyl β-acetoxyisobutyrate, 1.73×10^{-3} mol/g sample.

Reaction of III with Acetyl Chloride. III was almost unreactive near 0 °C. At 11—15 °C for 10 days, 12.9 g (0.15 mol) of III was allowed to react with 11.8 g (0.15 mol) of acetyl chloride to give 0.2 g of acetic anhydride, 4.7 g of unaltered acetyl chloride, 1.0 g of unaltered III, and 15.0 g of a high-boiling oil. The yield of the moelcular distillate was 10.6 g. IR: 1825, 1745, 1365, 1240, 1050 cm^{-1}. NMR: 5.18(m, $AcOC\underline{H}(CH_3)CH_2C{=}O$), 4.36(m, $ClC\underline{H}$-$(CH_3)CH_2C{=}O$), 2.90(approx. d, $ClCH(CH_3)C\underline{H}_2C{=}O$), 2.70 (m, $AcOCH(CH_3)C\underline{H}_2C{=}O$), 2.24(s, $C\underline{H}_3COOC{=}O$), 2.02 (s, $C\underline{H}_3COOCH(CH_3)CH_2C{=}O$), 1.64(d, $ClCH(C\underline{H}_3)CH_2C{=}O$), 1.36(d, $AcOCH(C\underline{H}_3)CH_2C{=}O$). Glc analysis (as methyl ester; columns: 2.25-meter polyethylene glycol-6000 column at 50 °C and 2.25-meter DEGS column at 110 °C; internal standards: *n*-propanol and acetophenone): Methyl acetate, 0.82×10^{-3}; methyl β-chlorobutyrate, 6.2×10^{-3}; methyl β-acetoxybutyrate, 1.5×10^{-3} mol/g sample.

Reaction of 3,3-Dimethyl-3-propanolide with Acetyl Chloride. The lactone (50.1 g, 0.5 mol) was allowed to react with acetyl chloride (39.3 g, 0.5 mol) containing aluminum chloride (1.5 g, 0.011 mol). In the course of the reaction, 4.8 g of isobutene was condensed in a cold trap. Most of the acetyl chloride used was recovered, and 45.0 g of a viscous, undistillable product was obtained; this product showed the characteristic absorptions of ester in the IR spectrum.

Reaction of I with Aluminum Chloride. To a solution of 1.5 g (0.011 mol) of aluminium chloride and 20 ml of nitrobenzene, was added 1.0 g (0.014 mol) of I in 5 ml of nitrobenzene at 0—2 °C with external cooling. After stirring for 1 hr (including the addition period) at this temperature, the IR spectrum of the reaction mixture was taken; it showed that most of the I had already been consumed. The reaction mixture was then hydrolyzed and extracted with ether, and the ether extract was reextracted with an aqueous sodium hydroxide solution. The aqueous solution was acidified and then extracted with ether continuously for 30 hr to give 1.1 g (92%) of β-chloropropionic acid and 0.07 g (7%) of β-hydroxypropionic acid (determined as methyl ester by means of glc using a 2.25-meter DEGS column at 110 °C, with acetophenone as an internal standard).

Condensation Reactions of Adenine Derivatives with 1-*O*-Acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose in Nitrophenols

(Received June 9, 1973)

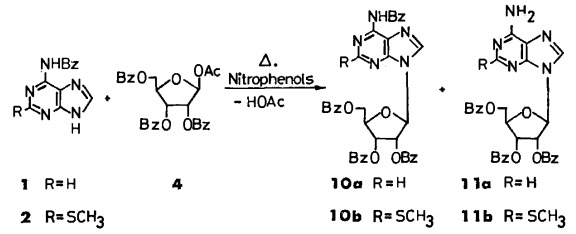
Intermolecular interaction between nitrophenols, such as *m*-, *p*-nitrophenol, 2,4-dinitrophenol, and picric acid, and adenine derivatives, such as $N_{(6)}$-benzoyladenine, $N_{(6)}$-benzoyl-2-methylthioadenine, and $N_{(6)}$-benzyladenine, was verified by the formation of the corresponding molecular compounds. On the basis of these results, condensation reactions of these adenine derivatives with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose were carried out in nitrophenols, which were used as the activating agents. They were proved to afford the corresponding nucleosides in good yields. In addition, a novel glycosyl rearrangement reaction was first observed in the case of the reaction of $N_{(6)}$-benzyladenine with the ribofuranosyl acylate.

In a previous paper[1] we described a new procedure for the synthesis of purine nucleosides involving the condensation reaction of a fully-acetylated sugar with a purine in the presence of activating agents. As an extension of this reaction, the authors now wish to report the reactions of some adenine derivatives, such as $N_{(6)}$-benzoyladenine(**1**), $N_{(6)}$-benzoyl-2-methylthioadenine(**2**), and $N_{(6)}$-benzyladenine(**3**), with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose(**4**) in nitrophenols as the activating agent, and a novel glycosyl migration reaction which was confirmed in the reaction of **3** with **4**.

Results and Discussion

The previous investigation[1] led us to assumptions that a purine may be activated by an activating agent through polarization bonding[2] and that the activated degree of a purine may be delicately varied in terms of both the mutual positions and the properties of each functional group on the aromatic nuclei of the agents and the purine nuclei. In attempts at the reactions of these adenine derivatives with **4**, a series of nitrophenols were used as potential activating agents because of their properties of forming the corresponding molecular compounds with the adenines. Such properties are conceivably intimately related to some species of intermolecular interaction such as polarization bonding; the purine counterparts may potentially be activated by forming them. In the same manner as had been described for the preparation of the molecular compound of theophylline with *p*-nitrophenol,[1] the adenines (1 mmol) were treated with an excess amount of *o*-(**5**), *m*-(**6**), *p*-nitrophenol(**7**), 2,4-dinitrophenol(**8**), or picric acid(**9**) to afford the corresponding molecular compounds, summarized in Table 1. As may be seen from the table, almost all of the molecular compounds are composed of the equimolar counterpart except those obtained from **2** and **8**, and from **3** and **7**, in the ratios of 2 : 1 and 1 : 2 respectively. The precipitated crystalline product in the cases of **1** with **9** and of **2** with **6**, however, showed broad melting points and analytically proved to have no definite integral ratio in their counterpart composition. At any rate, such differences in the ratios may provide quite an interesting problem relevant to the structures of these molecular compounds and the activation mechanism of their purine counterparts; it can thus be deduced that some intermolecular interaction such as polarization bonding[2] may play an important role in forming these compounds. Although no interpretation with respect to such phenomenon has yet been furnished, the problem is exceedingly complicated because of the following facts: 1) **5** was proved not to form a molecular compound with theophylline and showed no activating effect on it.[1] 2) *p*-Toluenesulfonamide activates theophylline to condense with an acetylated sugar, although it forms no molecular compound with it,[1] *etc.*

On the basis of the above evidence, the condensation reactions of **1**, **2**, and **3** with **4** were attempted in these potential activating agents under the conditions described in Table 2, in which the results thus obtained are summarized. In each case, a purine derivative was previously fused together homogeneously with the potential agent, and an equimolar amount of **4** was then added to the prefused mixture. The mixture was allowed to react under the corresponding conditions with continuous stirring under atmospheric pressure. After the removal of the agent, each resultant mixture was subjected to chromatography on a silica gel column by the use of a solvent system of cyclohexane–chloroform (1 : 1 v/v).



Scheme 1.

In a series of reactions of **1** with **4**, $N_{(6)}$-benzoyl-9-(2′,3′,5′-tri-*O*-benzoyl-β-D-ribofuranosyl)adenine(**10a**) and 9-(2′,3′,5′-tri-*O*-benzoyl-β-D-ribofuranosyl)adenine (**11a**) were produced, together with the corresponding nitrophenyl benzoates.[3] The failure to isolate the corresponding benzoate in the case of **8** may be ascribed to its stronger acidity(pK_a 4.11); thus, the

	Picric acid(**9**)[b]	—	—	—	—	—	—	—	—
$N_{(6)}$-Benzoyl-2-methylthio-adenine(**2**)	**6**[b]	—	—	—	—	—	—	—	—
	7	1 : 1	172—173	53.76	3.80	19.81	54.02	3.59	19.83
	8	2 : 1	195—200	51.10	3.45	22.25	51.02	3.43	22.24
	9	1 : 1	207—208	44.30	2.72	21.76	44.34	2.65	21.78
$N_{(6)}$-Benzyl-adenine(**3**)	**6**	1 : 1	135(169—175)[c]	59.33	4.43	23.07	59.09	4.40	22.71
	7	1 : 2	153—156	57.25	4.17	19.48	57.59	3.94	20.02
	8	1 : 1	190—193	52.81	3.69	23.95	53.05	3.46	24.23
	9	1 : 1	223—224.5	47.58	3.10	24.66	47.36	3.11	24.61

a) All the syntheses were carried out by the use of the adenines (1 mmol) and nitrophenols (3 mmol), respectively, in chloroform (30—40 ml) under reflux. b) Crystalline products in these cases showed broad melting point, and no definite integral ratio analytically in their counterparts. c) Dimorphism was observed in this case.

Table 2. Condensation reactions of adenine derivatives (**1**, **2**, and **3**) with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-*β*-D-ribofuranose (**4**) in the presence of nitrophenols[a]

Adenine derivatives	Nitrophenols	Reaction conditions: Temp, °C	Period, hr	Products (Yields, %): Nitrophenyl[b] benzoates	Nucleosides
1	**6**	130—135	1.5	81.5	**10a** (3.1), **11a** (50.5)
1	**7**	130—135	3	12.6	**10a** (2.1), **11a** (20), [**12**(46)]
1	**8**	140—145	1.5	—	**10a** (32.5), **11a** (3.5)
2	**6**	130—135	3	78.5	**10b** (3.7), **11b** (45.5)
2	**7**	130—135	3	9.5	**10b** (8.2), **11b** (7.3), [**12**(43)]
2	**8**	140—145	3	—	**10b** (45.5), **11b** (9.8)
3	**8**	140—145	1.5	—	**13c** (85[c])

a) All the reactions were carried out by the use of adenines (13 mmol) and **4** (10 mmol) in the presence of nitrophenols (50 mmol, except in the case of **3**; 65 mmol). b) These yields were calculated with reference to **1** or **2**. c) This yield stands for that of debenzoylated nucleoside by treating **13a** with methanolic sodium methoxide solution.

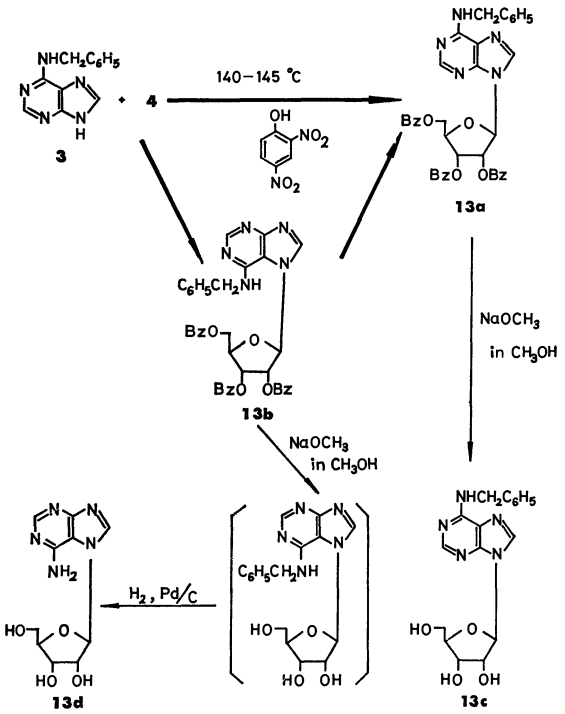
Table 3. NMR spectral data of $N_{(6)}$-benzyl-9-(**14a**) and -7-(2',3',5'-tri-*O*-acetyl-*β*-D-ribofuranosyl)adenine(**14b**)

Protons	Chemical shift[a]: **14a**	**14b**
CH_3-CO-O-	2.10 and 2.16 (9H)	2.14 (narrow d, 9H)
H-5'a, -5'b, and -4'	4.44 (m, 3H)	4.50 (m, 3H)
C_6H_5-CH_2-N-	4.82 (d, J_{CH_2-NH}=6Hz, 2H)[b]	4.97 (broad s, 2H)
H-3'	5.73 (m)	5.75 (m)
H-2'	5.98 (t, $J_{2',3'}$=5.1Hz)	5.98 (q, $J_{2',3'}$=5.5Hz)
H-1'	6.12 (d, $J_{1',2'}$=5.1Hz)	6.36 (d, $J_{1',2'}$=4.0Hz)
C_6H_5-CH_2-NH-	6.92 (t)[c]	—
C_6H_5-CH_2-	7.27 (s, 5H)	7.18 (s, 5H)
H-2 or H-8	7.86 (s, 1H)	7.84 (s, 1H)[d]
H-8 or H-2	8.45 (s, 1H)	8.21 (s, 1H)

a) These data were recorded in δ value, and determined in $CDCl_3$—TMS. b) The doublet was collapsed into a singlet on addition of deuterium oxide. c) The broad triplet was vanished by the addition of deuterium oxide. d) The signal was observed as an exceedingly broadened singlet comparing with that of **14a**.

predominant formation of **10a** in this case fully agrees with this fact. Moreover, **5** was found to be ineffective for the reaction, and **9**, inadequate, since a remarkable coloration, which may arise from the possible decomposition of the starting materials or products, was inevitably present even when we reduced the reaction period. These agents in this case can thus be ranked in effectiveness as **6**, **8**, **7**, and **5** on the basis of the total yields of the nucleosides, **10a** and **11a**, shown in Table 2, although the reaction temperature in the case of **8** must be about 10 °C higher than those in the other cases in order to make the reaction system homogeneous. It is of interest to compare the acidity of these agents, *e.g.*, **6**(pK_a 8.40) or **8**(pK_a 4.11), with that of *p*-toluenesulfonic acid(pK_a < 1.0), which has previously been used as the catalyst for the fusion method, or with that of acetic acid(pK_a 4.76), which has been shown to be ineffective as a catalyst.[4] The debenzoylation of **10a** and **11a** was carried out by treating it with a methanolic sodium methoxide solution at room temperature, thus affording $N_{(6)}$-benzoyladenosine and adenosine in 35% and 84% yields respectively. The UV spectral data of the former were substantially consistent with those of the $N_{(6)}$-benzoyl-2-deoxyadenosine phosphate derivatives.[5] Interestingly, moreover, *p*-nitrophenyl 2,3,5-tri-*O*-benzoyl-β-D-ribofuranoside (**12**) (46% yield) was obtained concomitantly in the reaction in **7**, unlike those in **6** or **8**; the small formation of the corresponding phenyl glycosides can be noticed by tlc in the latter two cases, although no reason for it has yet been given. This fact is also of interest for its contrast with the autocatalytic fusion reaction of fully-acetylated sugars with **6** and **7** respectively, in which scarcely no such difference in their reactivity is observed.[6]

In a series of reactions of **2** with **4**, the concomitant formation of $N_{(6)}$-benzoyl-2-methylthio-9-(2′,3′,5′-tri-*O*-benzoyl-β-D-ribofuranosyl)adenine(**10b**) and 2-methylthio-9-(2′,3′,5′-tri-*O*-benzoyl-β-D-ribofuranosyl)adenine (**11b**) was similarly observed; The tendencies of the relative yields of **10b**, **11b**, and the corresponding nitrophenyl benzoates[3] were, as may be seen in Table 2, similar to those observed in the reaction of **1** with **4**. The effectiveness of the agents, however, varied in this case, they can be ranked as **8**, **6**, **7**, and **5** on the basis of the total yields of the nucleosides, **10b** and **11b**. Unlike the case of **10a**, the selective de-*O*-benzoylation of **10b** could not be attained because of the instability of the $N_{(6)}$-benzoyl group of **10b**: however, the complete debenzoylation of **10b** and **11b** was successfully carried out by treating them with a methanolic sodium methoxide solution to give 2-methylthioadenosine in 87% and 60% yields respectively. The reaction in **7** afforded **12** in a 43% yield, much as in the preceding series of reactions.



Scheme 2.

In a series of reactions of **3** with **4**, on the other hand, **5**, **6**, and **7** exhibited no activating effect on **3**; only **8** was found to be effective for the reaction. Moreover, **9** was concluded to be inadequate for the reaction, since it brought about a remarkable coloration such as has been mentioned, although it promotes the reaction. The condensation reaction in **8**, followed by the removal of **8** and debenzoylation, afforded $N_{(6)}$-benzyladenosine(**13c**) in an 85% yield under the conditions shown in Table 2. On following this reaction by the tlc technique with the passage of time, we also detected a glycosyl migration reaction of 7-(2′,3′,5′-tri-*O*-benzoyl-β-D-ribofuranosyl)-$N_{(6)}$-benzyladenine (**13b**) to the corresponding 9-ribosyl isomer(**13a**). The outline of such a glycosyl migration can easily be detected, as is demonstrated in Fig. 1. The faster-moving spot (R_f 0.84) and the slower-moving one (R_f 0.70) were found to correspond to **13a** and **13b** respectively. After the removal of **8** from the resultant reaction mixture (reaction period: 90 min), the mixture was chromatographed on a silica gel column, and then concentrated *in vacuo* to afford a sirup of **13a** (43% yield) as the first fraction and **13b** (9% yield) as the second one. The usual debenzoylation of **13a** with a methanolic sodium methoxide solution gave **13c** in an 84% yield. **13b** was, on the other hand, easily crystallized on trituration with a small amount of acetone, and a portion of the crystals was converted into 7-β-D-ribofuranosyladenine(**13d**) by debenzoylation and by subsequent debenzylation with hydrogen on palladized charcoal. The UV spectral properties of this product were consistent with those reported by Montgomery and Thomas.[7] The anomeric configuration of **13b** was deduced to be β from its

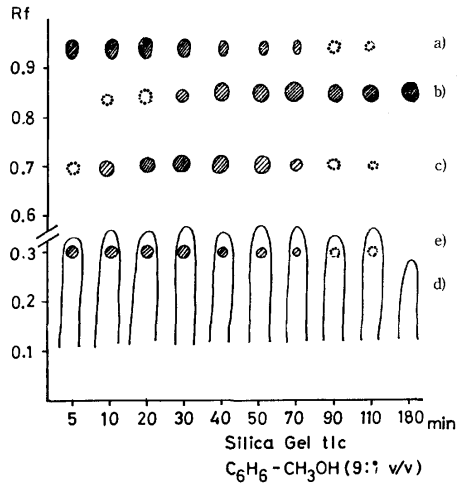

Fig. 1. The outline of the condensation reaction of $N_{(6)}$-benzyladenine(**3**) with 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-*β*-D-ribofuranose(**4**) in the presence of 2,4-dinitrophenol(**8**) observed in tlc; a: **4**, b: **13a**, c: **13b**, d: **8**, and e: **3**.

specific rotational value ($[\alpha]_D^{30}$ −65°). Subsequently, the above-observed glycosyl migration reaction of **13b** into **13a** was confirmed by fusing the sirup of **13b** in an excess amount of **8** at 140—145 °C with stirring and by following its process thin-layer chromatographically as has been described above. A novel glycosyl migration reaction was thus first observed in the fusion reaction of a fully-acylated sugar with a purine; it is of interest in contrast with the $N_{(3 \text{ or } 7)} \rightarrow N_{(9)}$ alkyl and glycosyl migration, which had been observed in the condensation reaction of adenine derivatives with alkyl or blocked glycosyl halides.[8]

In order to elucidate the possibility of the concomitant formation of the corresponding α-anomers in these reactions, a condensation reaction of 1,2,3,5-tetra-*O*-acetyl-*β*-D-ribofuranose with **3** in **8** was attempted, since the confirmation of the α-anomer formation may possibly be unattainable by nmr spectroscopy because of the benzyl aromatic proton signals, which are observed between δ 7.2—8.1.

The reaction was unexpectedly accompanied by a considerable coloration; however, the same treatment of the resultant mixture as has been described for the reaction of **3** with **4** afforded the sirups of $N_{(6)}$-benzyl-9-(**14a**)(20% yield) and -7-(2′,3′,5′-tri-*O*-acetyl-*β*-D-ribofuranosyl)adenine(**14b**)(9% yield). The NMR data of these products are summarized in Table 3; an examination of their anomeric proton region by means of the signal-to-noise enhancement (120 times) proved them to be composed of the *β*-nucleosides exclusively. Thus, these condensation reactions involving **4** were concluded to give the corresponding nucleosides with the anomeric configuration of *β*, although a more detailed investigation would be required to elucidate the mechanism of the glycosyl migration reaction.[9] **14a** was derived into **13c** by deacetylation with a methanolic sodium methoxide solution in a 93% yield; its structure was thus confirmed. The deacetylated product from **14b** was identified with that obtained from **13b** by thin-layer and paper chromatography and by studying the UV spectra.

In view of these results, the assumptions with respect to the activation mechanism of the purine counterparts,[1] described at the beginning of this article, can be said to be supported.

Experimental

All the melting points are uncorrected. The IR absorption spectra were taken with a Hitachi EPI-2S apparatus. The UV absorption spectra were measured on a Hitachi EPS-3T apparatus in purified ethanol or distilled water. The NMR spectra were determined with a Varian T-60 apparatus in deuteriochloroform, using tetramethylsilane as the internal standard. The plates for tlc examination were prepared with Wakogel B-5F, and the solvent system of 9 : 1 v/v benzene–methanol was used for the development. Paper chromatography was carried out using Toyo-Roshi No. 50 filter paper, while solvent system of 86 : 14 v/v *n*-butanol–distilled water was used for the development. The confirmation of each spot was done with a UV lamp (S. L. Light, Tokyo Machinery Co., Ltd.; 2537 and 3650 Å) or by spraying a diluted aqueous sulfuric acid solution on the tlc plates and then heating them.

Preparations of Molecular Compounds of $N_{(6)}$*-Benzoyladenine (**1**), $N_{(6)}$-Benzoyl-2-methylthioadenine(**2**), and $N_{(6)}$-Benzyladenine(**3**) with the Nitrophenols.* The method of preparation is exemplified by that of compound of **1** with picric acid(**9**): **1**(239 mg, 1 mmol) and **9**(687 mg, 3 mmol) were dissolved in chloroform(30—40 ml) under reflux, and the resultant solution was allowed to cool at room temperature for crystallization. After cooling overnight, the precipitated crystals were filtered by suction and dried over phosphorus pentoxide *in vacuo* at 110°C to give a molecular compound of **1** with **9**. The other molecular compounds were prepared in the same manner; all the results thus obtained are the summarized in Table 1.

The Condensation Reactions of $N_{(6)}$*-benzoyladenine(**1**) with 1-O-Acetyl-2,3,5-tri-O-benzoyl-β-D-ribofuranose (**4**) in the Presence of* m-*(6), p-Nitrophenol (**7**), or 2,4-Dinitrophenol (**8**).* *a)* The reaction with **6** : **1** (3.1 g, 13 mmol) and **6**(6.9 g, 50 mmol) were heated at 130—135 °C to fuse them homogeneously under stirring, and then **4**(5.0 g, 10 mmol)[10] was added to the prefused mixture. After the addition the mixture was stirred for 1.5 hr at that temperature under atmospheric pressure. The resultant mixture was dissolved in chloroform(300 ml), and the solution was successively washed with a 0.5 M aqueous sodium hydroxide solution to remove the co-produced acetic acid, unchanged **1**, and **6**, and with water, and then dried over anhydrous calcium chloride. After the desiccant had been removed by filtration, the organic layer was concentrated *in vacuo* to a pale brown glassy sirup. The resultant sirup was chromatographed on a silica gel column, packed with a ten-fold weight of Mallincrodt silicic acid(72 g) relative to the sirup, by the use of a solvent system of cyclohexane–chloroform(1 : 1 v/v) for the elution. *m*-Nitrophenyl benzoate (2.6 g, 81.5% yield;[11] recrystalized from ethanol, mp 92 °C[12]) was obtained as the first fraction, while glassy sirups of $N_{(6)}$-benzoyl-9-(2′,3′,5′-tri-*O*-benzoyl-*β*-D-birofuranosyl)adenine(**10a**) (0.12 g, 3.1% yield) and 9-(2′,3′,5′-tri-*O*-benzoyl-*β*-D-ribofuranosyl)adenine(**11a**) (2.9 g, 50.5% yield) were obtained as the second and third fractions.

8) M. Miyaki, Doctoral Thesis, Hokkaido Univ., 1968; B. Shimizu and M. Miyaki, *Chem. Pharm. Bull.* (Tokyo), **18**, 570 (1970); M. Miyaki and B. Shimizu, *Agr. Biol. Chem.*, **33**, 119 (1969).

9) This work is now in progress in our laboratory.

10) E. F. Recondo and H. Rinderknecht, *Helv. Chim. Acta*, **42**, 1171 (1959).

b) The reaction with **7**: To the prefused mixture prepared from **1**(13 mmol) and **7**(6.9 g, 50 mmol) at 130—135 °C, we added **4**(10 mmol); the resultant mixture was stirred at that temperature under atmospheric pressure for 3 hr. After it had been cooled at room temperature, the resultant mixture was dissolved in chloroform(300 ml); the solution was then treated and chromatographed in the way described in the previous experiment. A mixture of *p*-nitrophenyl benzoate (0.4 g, 12.6% yield,[11] mp 140 °C[13]) and *p*-nitrophenyl 2,3,5-tri-*O*-benzoyl-*β*-D-ribofuranoside [mp 124—125 °C, $[\alpha]_D^{20}$ −45° (*c* 1.0, $CHCl_3$). Found: C, 65.59; H, 4.22; N, 2.36%. Calcd for $C_{32}H_{25}O_{10}N$: C, 65.88; H, 4.32; N, 2.40%], which was easily fractionated by recrystallization from ethanol, was obtained as the first fraction. Glassy sirups of **10a** (0.15 g, 2.1% yield) and **11a** (1.2 g, 20% yield) were successively obtained as the second and third fractions respectively.

c) The reaction with **8**: To the prefused mixture prepared from **1** (13 mmol) and **8** (12 g, 65 mmol) at 140—145 °C, we added **4** (10 mmol); the resultant mixture was stirred at that temperature under atmospheric pressure for 3 hr. After cooling, the mixture was dissolved in chloroform (300 ml); the resultant solution was successively washed with an aqueous sodium bicarbonate solution and with water, and then dried over anhydrous calcium chloride. After the removal of the desiccant by filtration, the organic layer was concentrated *in vacuo* to a hard sirup. The residual sirup was subjected to chromatography as described in the previous experiments. Glassy sirups of **10a** (3.4 g, 59% yield) and **11a** (0.7 g, 12% yield) were obtained as the second and third fractions respectively. Prior to these fractions, the unchanged **4** (1.5 g) was recovered in a crystalline state. R_f values of **10a** and **11a** in tlc: 0.47 and 0.32 respectively.

*Structural Determination of **10a** and **11a** by Debenzoylation.*

a) **10a**: The glassy sirup of **10a** (679 mg, 1 mmol) was dissolved in absolute methanol (4 ml), and then a 1 M methanolic sodium methoxide solution (1 ml) was added to this solution. After the addition, the solution was stirred at room temperature for 1 hr and the solvent was evaporated to dryness. The residue was then dissolved in water (50 ml), the aqueous solution was washed with diethyl ether (50 ml × 2), and the aqueous layer was further treated with Amberlite IR-120B(NH_4 form)(1.5 equivalents to sodium ion), by batch. After the removal of the resin by filtration, the filtrate was concentrated *in vacuo* to about 1/4 volume of the original and the precipitated crystals were gathered by suctional filtration. The crystals were dissolved in a possibly smaller volume of water by warming, followed by decoloration with active charcoal, and then allowed to cool in a refrigerator. $N_{(6)}$-benzoyladenosine (139 mg, 35.4% yield) was obtained as fine needles. Mp 134—135 °C. $[\alpha]_D^{20}$ −30° (*c* 0.5, DMF). Found: C, 52.24; H, 4.97; N, 17.73%. Calcd for $C_{17}H_{17}O_5N_5 \cdot H_2O$: C, 52.44; H, 4.92; N, 17.99%. $\lambda_{max}^{pH\ 1}$ 292 nm(*ε* 23900), $\lambda_{min}^{pH\ 1}$ 263 nm(*ε* 9300); $\lambda_{max}^{pH\ 7}$ 281 nm (*ε* 23200), $\lambda_{min}^{pH\ 7}$ 245 nm(*ε* 11100); $\lambda_{max}^{pH\ 12}$ 303 nm(*ε* 25200), and $\lambda_{min}^{pH\ 12}$ 250 nm(*ε* 14300).[5] NMR(DMSO-d_6, DSS): *δ* 6.10 (H-1′ d, $J_{1',2'}$ =5.0 Hz).

Incidentally, a tlc examination of the above filtrate of recrystallization proved in to consist almost entirely of $N_{(6)}$-benzoyladenosine[R_f 0.55; developed with benzene-methanol (7 : 3 v/v)]; adenosine (R_f 0.32; developed with the same solvent) could be detected merely as a pale spot on the tlc.

b) **11a**: The glassy sirup of **11a** (575 mg, 1 mmol) was dissolved in absolute methanol(4 ml); the solution was mixed with a 1 M methanolic sodium methoxide solution (1 ml), and it was stirred at room temperature for 1 hr. The precipitated crystals were gathered by suctional filtration, washed with the absolute methanol (about 3 ml), and dried over phosphorus pentoxide at 110 °C *in vacuo* to give adenosine (224 mg, 84% yield) as fine needles. Mp 226.5—227 °C (natural product: mp 234—235 °C). $[\alpha]_D^{20}$ −61° (*c* 1.0, H_2O) [natural product: $[\alpha]_D$ −61.7° (H_2O)]. Found: C, 44.70; H, 4.91; N, 26.10%. Calcd for $C_{10}H_{13}O_4N_5$: C, 44.90; H, 4.90; N, 26.03%. UV: $\lambda_{max}^{pH\ 1}$ 257 nm(*ε* 15600), $\lambda_{min}^{pH\ 1}$ 230 nm(*ε* 6800); $\lambda_{max}^{pH\ 7}$ 258.5 nm(*ε* 15600), $\lambda_{min}^{pH\ 7}$ 226.5 nm (*ε* 3000); and $\lambda_{max}^{pH\ 12}$ 260 nm(*ε* 15700) [natural product: $\lambda_{max}^{pH\ 2}$ 257 nm(*ε* 14600), $\lambda_{min}^{pH\ 2}$ 230 nm(*ε* 3500); $\lambda_{max}^{pH\ 11}$ 260 nm (*ε* 14900), and $\lambda_{min}^{pH\ 11}$ 227 nm(*ε* 2250)].

*The Condensation Reactions of $N_{(6)}$-Benzoyl-2-methylthioadenine (**2**) with **4** in the Presence of **6**, **7**, or **8**.*

a) The Reaction with **6**: To a prefused mixture of **2** (3.7 g, 13 mmol) and **6** (10 g, 72 mmol) at 130—135 °C, we added **4** (5.0 g, 10 mmol) and the resultant mixture was stirred at that temperature for 3 hr. The mixture was then treated in the way described in the reactions of **1** with **4** to afford *m*-nitrophenyl benzoate [2.5 g, 78.5%;[11] mp 92 °C (lit,[12] mp 95 °C)], and the glassy sirups of $N_{(6)}$-benzoyl-2-methylthio-9-(2′,3′,5′-tri-*O*-benzoyl-*β*-D-ribofuranosyl)adenine(**10b**) (0.3 g, 3.7% yield) and 2-methylthio-9-(2′,3′,5′-tri-*O*-benzoyl-*β*-D-ribofuranosyl)adenine(**11b**) (2.8 g, 45.5% yield) as the first, second, and third fractions respectively. R_f values of **10b** and **11b** in tlc: 0.57 and 0.41 respectively.

b) The Reaction with **7**: The reaction was carried out by the use of **7** (10 g, 72 mmol) in place of **6** in the above reaction, and the resultant mixture was treated in the way described in *a*. The first fraction of the column chromatography afforded, after fractional recrystallization from ethanol, *p*-nitrophenyl benzoate (0.3 g, 9.5% yield) and *p*-nitrophenyl 2,3,5-tri-*O*-benzoyl-*β*-D-ribofuranoside (**12**)(2.5 g, 43% yield). Successively, the glassy sirups of **10b** (0.6 g, 8.2% yield) and **11b** (0.5 g, 7.3% yield) were afforded in turn.

c) The Reaction with **8**: To a prefused mixture of **2** (3.7 g, 13 mmol) and **8** (12 g, 65 mmol) at 140—145 °C, we added **4** (5.0 g, 10 mmol), after which the resultant mixture was stirred for 3 hr under atmospheric pressure. The resultant reaction mixture was treated in the way described in the reaction of **1** with **4** in the presence of **8**. By column chromatography, the glassy sirups of **10b** (3.3 g, 45.5% yield) and **11b** (0.6 g, 9.8% yield) were obtained as the second and third fractions, in addition to the first fraction, which was the unchanged **4**(1.8 g).

*Structural Determination of **10b** and **11b** by Debenzoylation.*

a) **10b**: A solution of **10b** (725 mg, 1 mmol) in absolute methanol(10 ml) was, after mixing with a 1 M methanolic sodium methoxide solution (1 ml), boiled under reflux for 1 hr. After cooling, the solvent was evaporated *in vacuo* to dryness, and the residue was triturated with a small amount of water to crystallize it. The resultant crystals were gathered by suctional filtration and then washed with a small amount of chloroform. The crystals were dried over phosphorous pentoxide at 110 °C *in vacuo* to give 2-methylthioadenosine (187 mg, 58% yield) as fine needles. Mp 215—217 °C, and remelted at 223.5—224.5 °C after resolidification. On admixture with an authentic specimen (mp 222—223 °C[14]), no depression was observed. $[\alpha]_D^{20}$ −1° (*c* 1.0, 0.1 M HCl-H_2O) [$[\alpha]_D^{18}$ −2° (*c* 0.51, 0.1 M HCl-H_2O)[14]].

b) **11b**: A solution of **11b**(621 mg, 1 mmol) in absolute methanol(6 ml) was, after mixing with a 1 M methanolic sodium methoxide solution(1 ml), stirred at room temperature for 2 hr. The precipitated crystals were gathered by suctional filtration, washed with absolute methanol (3 ml), and then

11) This yield was calculated based on the $N_{(6)}$-benzoyladenine.
12) G. Neumann, *Ber.*, **19**, 2979 (1886).
13) G. Neumann, *ibid.*, **19**, 2019 (1886).

dried over phosphorus pentoxide at 110 °C *in vacuo*. 2-Methylthioadenosine (271 mg, 86.5%) was thus obtained as fine needles. Mp 215—217 °C, and remelted at 223.5—224 °C after resolidification. On admixture with an authentic specimen (mp 222—223 °C[14]), no depression was observed. $[\alpha]_D^{20}$ −2° (*c* 1.0, 0.1 M HCl-H_2O) {$[\alpha]_D^{18}$ −2° (*c* 0.51, 0.1 M HCl-H_2O)[14]}.

The Condensation Reaction of $N_{(6)}$*-Benzyladenine (**3**) with **4** in the Presence of **8***. *a*) Preparation of $N_{(6)}$-benzyladenosine(**13c**): To a homogeneously-prefused mixture of **3** (3.0 g, 13 mmol) and **8** (12 g, 65 mmol), we added **4**(5.0 g, 10 mmol), after which the resultant mixture was stirred at 140—145 °C for 3 hr under atmospheric pressure. A solution of the mixture in chloroform (300 ml), after the removal of **8** by washing with an aqueous sodium bicarbonate solution and with water, and after drying over anhydrous calcium chloride, was concentrated *in vacuo*. The residual sirup showed a considerable coloration, although its tlc proved it to be pure (R_f 0.84). It was thus subjected to purification on a short column of silica gel by elution with chloroform. The fraction corresponding to $N_{(6)}$-benzyl-9-(2′,3′,5′-tri-*O*-benzoyl-β-D-ribofuranosyl)adenine(**13a**) was concentrated *in vacuo* to a hard, glassy sirup (6.3 g, 94.4% yield). The sirup was dissolved in absolute methanol (50 ml), and the resultant solution was, after having been with a 1 M methanolic sodium methoxide solution(5 ml), stirred at room temperature for 2 hr. The crystals thus precipitated were gathered by suctional filtration, washed with the absolute methanol(total 5 ml), and dried over phosphorus pentoxide 110 °C *in vacuo* to give **13c** (3.0 g, 90% yield). Mp 165—166 °C(lit,[15] mp 177—179 °C). $[\alpha]_D^{30}$ −68° (*c* 1.0, EtOH) {lit,[15] −68.6°(*c* 0.55, EtOH)}. Found: C, 57.16; H, 5.01; N, 19.92%. Calcd for $C_{17}H_{18}O_4N_5$: C, 57.13; H, 5.36; N, 19.60%. UV: $\lambda_{max}^{pH\ 1}$ 265 nm(ε 19200), $\lambda_{min}^{pH\ 1}$ 234 nm (ε 4050); $\lambda_{max}^{pH\ 7}$ 268 nm(ε 20000), $\lambda_{min}^{pH\ 7}$ 232 nm(ε 2740); $\lambda_{max}^{pH\ 12}$ 270 nm(ε 20100), and $\lambda_{min}^{pH\ 12}$ 233 nm(ε 3100) {lit,[15] λ_{max}^{acid} 266 nm (ε 20600), λ_{min}^{acid} 235 nm (ε 4140); $\lambda_{max}^{neutral}$ 268 nm(ε 20850), $\lambda_{min}^{neutral}$ 233 nm(ε 2570); λ_{max}^{base} 269 nm(ε 21300), and λ_{min}^{base} 237 nm(ε 3570)}.

b) Chromatographic Separation of **13a** and $N_{(6)}$-Benzyl-7-(2′,3′,5′-tri-*O*-benzoyl-β-D-ribofuranosyl) adenine (**13b**): The reaction described in *a* was stopped after 90 min, after which the mixture was treated in the same way as in *a*. The sirup obtained by removing **8** was chromatographed in the same way. This chromatography was successfully carried out by the use of either 9 : 1 v/v benzene-methanol or chloroform for the elution. The concentration of the fraction corresponding to the faster-moving spot (R_f 0.84) afforded a glassy sirup of **13a**(2.9 g, 43% yield), while that of the fraction corresponding to the slower-moving spot (R_f 0.70) afforded a glassy sirup of $N_{(6)}$-benzyl-7-(2′,3′,5′-tri-*O*-benzoyl-β-D-ribofuranosyl)adenine(**13b**)(0.6 g, 9% yield). The former was easily identified by deriving it into **13c** by debenzoylation. A small portion of the latter sirup was crystallized on trituration with a small amount of acetone; the crystals were, after filtration, recrystallized from ethanol and then dried over phosphorus pentoxide at 110 °C *in vacuo*. Mp 169—170 °C. $[\alpha]_D^{30}$ −65° (*c* 1.04, $CHCl_3$). Found: C, 68.16; H, 4.80; N, 10.76%. Calcd for $C_{38}H_{31}O_7N_5$: C, 68.15; H, 4.67; N, 10.46%. UV: λ_{max}^{EtOH} 300 nm(ε 9290), and $\lambda_{shoulder}^{EtOH}$ 285 nm(ε 8300) and 277 nm(ε 7300).

The latter sirup(200 mg) was dissolved in absolute methanol (4 ml), and the solution was, after having been mixed with a 1 M methanolic sodium methoxide solution(0.5 ml), stirred for 2 hr at room temperature. After the evaporation of the solvent *in vacuo* to dryness, the residue was dissolved in water(15 ml) and the solution was washed with diethyl ether (5 ml×3). The aqueous layer was, after neutralization with acetic acid, subjected to paper chromatography; the R_f value of this nucleoside was found to be 0.76 at 25 °C (*cf.* **13c**: 0.70). Subsequently, the UV spectrum of the spot was determined by extraction with ethanol, which had previously been distilled after treatment with sodium hydroxide under reflux: λ_{max}^{EtOH} 284 nm and 213 nm, and λ_{min}^{EtOH} 240 nm. Furthermore, the aqueous solution was, after acidification with acetic acid, stirred under a hydrogen atmosphere in the presence of 10%-palladized charcoal (30 mg) for 30 hr as usual. After the filtration of the catalyst, which was washed with water(5 ml×3), the filtrate and washings were combined and neutralized with a diluted aqueous sodium hydroxide solution. It was then concentrated *in vacuo* to several milliliters. The newly-appeared spot ($R_f^{25°C}$ 0.23) in the paper chromatography was extracted with pH 1, pH 7, and pH 12 water, and the UV spectrum of each extract was determined; $\lambda_{max}^{pH\ 1}$ 272 nm, $\lambda_{min}^{pH\ 1}$ 252 nm; $\lambda_{max}^{pH\ 7}$ 270 nm, $\lambda_{min}^{pH\ 7}$ 248 nm; $\lambda_{max}^{pH\ 12}$ 270 nm, and $\lambda_{min}^{pH\ 12}$ 249 nm {lit,[7] $\lambda_{max}^{0.1M\ HCl}$ 272 nm(ε 13600) and $\lambda_{max}^{0.1M\ NaOH}$ 270 nm(ε 9800); 7-β-D-ribofuranosyladenine}.

c) *The Condensation Reaction of **3** with 1,2,3,5-Tetra-O-acetyl-β-D-ribofuranose in **8***: To a homogeneously-prefused mixture of **3** (3.0 g, 13 mmol) and **8** (12 g, 65 mmol), we added 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (3.2 g, 10 mmol), and the resultant mixture was stirred at 140—145 °C for 1 hr; a considerable coloration was thus observed. After cooling, mixture was treated and chromatographed in the way described in *a*. 1,2,3,5-Tetra-*O*-acetyl-β-D-ribofuranose (1.6 g) was recovered as the first fraction. The glassy sirups of the acetates corresponding to **14a** (1.0 g, 21% yield) and **14b** (0.4 g, 8% yield) were obtained in turn as the second and third fractions. The NMR spectral data of these products are summarized in Table 3; in addition, no anomeric proton signals corresponding to their α-anomer could be detected on the enhancement of the signal-to-niose ratio by time-averaging (120 times). All the former sirup was subjected to deacetylation by stirring in absolute ethanol(4 ml)-1 M methanolic sodium methoxide solution(0.5 ml) at room temperature; white crystals began to precipitate within several minutes. They were, after 30 min, filtered, washed with absolute methanol(3 ml), and then dried over phosphorus pentoxide at 110 °C *in vacuo* to give **13c** (0.3 g, 84% yield). Mp 165—166 °C. No depression was observed on admixture with the authentic sample obtained in the previous experiment. Its UV spectral data were also consistent with the sample; $\lambda_{max}^{pH\ 7}$ 268 nm(ε 19000) and $\lambda_{min}^{pH\ 7}$ 231 nm(ε 2300). An attempt at the crystallization of the latter sirup resulted in failure; it was then subjected to deacetylation in the above way. After the evaporation of the solvent *in vacuo* to dryness, the residue was dissolved in water (*ca.* 5 ml), and washed with diethyl ether(5 ml×2). The UV spectrum of the resultant aqueous layer was determined, extracting the spot of the paper chromatogram (R_f 0.76); λ_{max}^{EtOH} 284 nm and 213 nm, and λ_{min}^{EtOH} 240 nm.

The authors are grateful to the Ministry of Education, Japanese Government, for a Scientific Research Grant-in-aid, and to the Kurata Foundation for a grant. They also wish to thank to the members of Laboratory of Organic Elemental Analysis, for the elemental analysis of the samples.

Effect of Pressure on the Rate of Solvolysis. Formolysis and Methanolysis of Secondary Alkyl Tosylates[1]

Akira SERA, Chisako YAMAGAMI, and Kazuhiro MARUYAMA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received June 16, 1973)

The effect of pressure on the formolysis and methanolysis rates of representative secondary alkyl tosylates was investigated, and the activation volumes, $\Delta V_0^{\ddagger}$, were estimated. The values of activation volume for formolysis were found to correlate excellently with σ^*. This conformity of $\Delta V_0^{\ddagger}$ to the Hammett-type correlation is interpreted as a consequence of the k_c-character of the reaction. The values of activation volume for methanolysis, however, converged to more negative values. The k_s-character of methanolysis is thought to be responsible for this behavior. The k_c-k_s-hybrid nature of the reaction is also discussed.

Solvolyses with tertiary substrates cannot be interpreted as direct displacement reactions, but many experimental results are consistent with the ionization hypothesis (**Lim**[2]), whereas primary substrates generally react by the direct displacement mechanism (**N**[2]). Since these two representations are intended to be extremes of a continuous sequence with no sharp dividing line, it is usual to refer to an intermediate set of borderline case for most of solvolyses of secondary substrates. Recently, the important participation of solvent molecule in solvolysis has come to be recognized even for secondary alkyl substrates. Schleyer[3] has interpreted the solvent assistance in the solvolysis of secondary alkyl substrates in terms of "a basic difference with respect to the magnitude of nucleophilic solvent participation: large in ordinary unhindered secondary (and primary) systems and small or absent in crowded substrates such as 2-adamantyl and tertiary derivatives."

Investigations of solvolytic displacement reactions under high pressure yield the activation volumes of the reactions, $\Delta V^{\ddagger}$, which will reflect the difference in degree of solvation between highly dipolar transition states and neutral initial states.[4] It may then be anticipated that the application of a high-pressure technique to the systematic study of solvolytic displacement reactions will permit us to analyse the reaction mechanism in terms of the activation volume. However, in previous reports on this subject, attention has been concentrated on the effect of the change in solvent composition on the activation volumes for solvolyses in aqueous binary solvent mixtures.[5] So far as we know, there have been only a few investigations in which the volume parameters were examined in terms of the substrate structure under otherwise identical conditions.[6] Moreover, no information is available about values of activation volume for solvolyses in polar solvents of low nucleophilicity.

The present paper will concern the investigation of the pressure effect on the solvolysis rates of representative secondary alkyl tosylates in two solvents—formic acid and methanol. Although a part of the desired rate data at atmospheric pressure can be gathered from the literature,[7] they were re-investigated in order to make an accurate estimate of $\Delta V_0^{\ddagger}$, the activation volume at atmospheric pressure.

Results and Discussion

The first-order rate constants for the formolysis and methanolysis of secondary alkyl tosylates under pressure are given in Table 1. All the measurements were carried out at 25.0 °C in order to avoid complicated corrections due to the temperature dependence of the reaction rate under pressure. The values of the activation volume at atmospheric pressure were determined by means of the following equation:

$$\Delta V^{\ddagger} = -RT(\partial \ln k/\partial P)_T \qquad (1)$$

where $\Delta V^{\ddagger}$ is the difference in the partial molal volumes between the transition state and the initial state. The evaluation of $\Delta V_0^{\ddagger}$ was made by the least-squares fit of the data to the following linear expression for $\ln k$ in the range from 1 to 700 kg/cm^2, because the plots of $\ln k$ against pressure were linear at least up to this pressure for most of the reactions examined:[8]

$$\ln k = a + bP \qquad (2)$$

The values of $\Delta V_0^{\ddagger}$ are listed in Table 2. The rate of each compound relative to the reference compound, isopropyl tosylate, is also shown.

Reaction Mechanism. As is shown in Table 1, the formolysis rate increased monotonously as the substituent became more electron-donating. The rate increase in formic acid was more significant than that in

a) Average of two or more experiments. Estimated error was less than 2% of its value.

methanol. An attempt to measure accurately the rate for the formolysis of (6) was unsuccessful because of its high reactivity under the conditions employed.[9] The correlation between log k at atmospheric pressure and σ^*_{add}[10] showed a good linearity with ρ^* of -3.7,[11] which is in good accord with the ρ^I value of -7.79 reported by Peterson *et al.* for the formolysis of unbranched alkyl tosylates.[7] In addition, the observed formolysis rates under pressure were also correlated to σ^*_{add} to give good straight lines.

Formic acid is considered to be a solvent in which a k_c-process proceeds quite readily because of its powerful ionizing ability as well as its poor nucleophilicity. Hence, the present reaction is thought to be k_c-like[12] in character. Moreover, the observed linear Hammett-Taft correlation indicates that the reaction is mainly controlled by the inductive effect of substituents, even in the case of 1-*t*-butylethyl tosylate (5), a sterically crowded substrate. On the other hand, the methanolysis rates varied irregularly along with the series of substrates. Although the high nucleophilic nature of this solvent facilitates a k_s-process,[13] this irregularity could not be interpreted as a manifestation of any single mechanism or as the predominance of one controlling factor over the whole range of substrates examined. This phenomenon must be a consequence of a change in the solvolysis mechanism from a k_s- to a k_c-process. In the absence of any appreciable steric hindrance in the transition state (for (1)∼(3)), the reaction must be strongly assisted by a solvent molecule (k_s-character). The contribution of k_s-process to the over-all rate process should, however, become less important with an increase in the steric hindrance. This causes an apparent rate retardation. This is the case for (4)—(7), as is shown in Table 1.[14] Remarkable rate increases were observed for (8) and (9). This means that the presence of extremely bulky substituents causes the substrates to be solvolyzed no longer through a k_s-process, but through a k_c-process predominantly. Actually, di-*t*-butylmethyl tosylate (8) has been reported to have no tendency to undergo k_s-solvolysis.[3d] A comparison of the (8)/(1) rate ratio in the two solvents is worth noting; it is 320 in formic acid and 6 in methanol. These figures suggest the intervention of solvent assistance in the methanolysis of an unhindered substrate(1).[3d]

All the points discussed above demonstrate that the formolysis exhibits a more k_c-character than does the methanolysis, and that in the methanolysis the mechanistic shift from the k_s- to the k_c-process actually

8) In the case of compounds (7)∼(9), the plots of ln k against pressure exhibit good straight lines except points at atmospheric pressure, which deviated downwards by about 3%. This phenomenon, not regarded as a result of experimental uncertainty, may imply existence of any factors which would be depressed by application of external pressure. In these cases, we estimated $\Delta V_0^{\neq}$ regardless of the points at atmospheric pressure.

9) A rough estimation showed that the formolysis rate constants amount to 9.6×10^{-4} s^{-1} for (6) and 1.2×10^{-2} s^{-1} for (8)[3d] at 25 °C.

10) $\sigma^*_{add}=\sigma^*_{R_2}+\sigma^*_{R_1}$. R. W. Taft, Jr., "Steric Effects in Organic Chemistry", ed. by M. S. Newman, John Wiley & Sons, Inc., New York (1956), p. 556.

11) Not including compound (4). Formolysis of this tosylate is 2.5 times as fast as that expected from the $\rho^*-\sigma^*$ relation. A compound with similar structural feature, 1-isopropylbutyl *p*-toluenesulfonate was reported to exhibit an analogous abnormal behavior in acetolysis, W. Pritzkow and K. H. Schöppler, *Chem. Ber.*, **95**, 834 (1962).

12) The definition of these terms, k_c-, k_s-, and k_Δ-processes of solvolyses, was made by Winstein (S. Winstein, E. Allred, R. Heck, R. Glick, *Tetrahedron*, **3**, 1 (1957). In the present paper, however, the term "k_c-process" signifies non-k_s-process, and hence can include k_Δ-process in some cases. Distinction between k_c- and k_Δ-processes is out of the purpose of the present investigation.

operates. The contribution of the k_s-character, if any, in the formolysis of some secondary substrates will be discussed later.

Activation Volume. All the activation volumes presented in Table 2 are negative. Negative values of $\Delta V^{\neq}$ have long been observed for solvolytic reactions and other unimolecular ionization processes. This phenomenon has been interpreted in terms of the presence of a predominant electrostrictive volume contraction (the $\Delta_2V^{\neq}$ term in the definition of Evans and Polanyi[15]) in the transition state which is undoubtedly more polar than the initial state.[4] In such circumstances, the change in $\Delta_1V^{\neq}$ (the contribution of a volume increase due to bond extension[15]) caused by variation in the substituents appears to play only a minor role. That is, the apparent values of $\Delta V^{\neq}$ must be governed by the change in $\Delta_2V^{\neq}$. Accordingly, the comparison of the values of $\Delta V^{\neq}$ for structurally-related substrates in a given solvent can be anticipated to provide useful information about the transition states.

The results shown in Table 2 clearly indicate the solvent dependence of the activation volumes. Since the $\Delta_1V^{\neq}$ term is insensitive to the solvent change,[16a] the different behavior of $\Delta V_0^{\neq}$ in the two solvents may be thought to be a reflection of a difference in the electrostrictive effect. In general, the magnitude of this electrostrictive term for solvolytic reaction depends on the degree of charge dispersion in the transition state; when the developed charge is dispersed more extensively over the whole molecule, the electrostrictive volume contraction becomes less significant, and hence a less negative value of $\Delta V^{\neq}$ appears.[6a,d-f] This concept should be verified in such a reaction as a limiting solvolysis. The application of this concept to the Hammett equation should reveal a correlation between $\Delta V^{\neq}$ and σ with a negative slope;[16b] this was really demonstrated in our laboratory for the limiting hydrolysis of 1-aryl-1-methylethyl chlorides.[6f] The formolysis of the present substrates conforms to this generalization. The activation volume for formolysis given in Table 2 actually shows a good linear correlation with respect to σ^*_{add},[17] as is shown in Fig. 1.

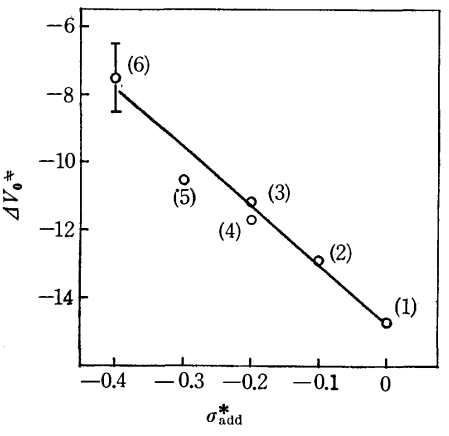

Fig. 1. Plot of $\Delta V_0^{\neq}$ against σ^*_{add} for the formolysis of secondary alkyl tosylates. Numeral denotes substrate number in Table 2; for (6) see footnote 17.

16) a) K. R. Brower, *J. Amer. Chem. Soc.*, **85**, 1401 (1963). b) For the linear correlation of $\Delta V^{\neq}$ with respect to σ, $-\delta\Delta V^{\neq}=2.303RT\sigma(\delta\rho/\delta P)_T$, see A. J. Ellis, W. S. Fyfe, R. I. Rutherford, A. Fischer, and J. Vaughan, *J. Chem. Phys.*, **31**, 176 (1959).

In contrast, the methanolysis of sterically-unhindered substrates afforded rather negative and leveled values of $\Delta V_0^{\neq}$, about -19 cm^3/mol. These results can best be understood if we assume that the transition state species are strongly solvated to nearly the same extent, regardless of their substituents. This is a result of the k_s-character of the reaction, in which the developed charge is mainly located on the reaction center. The mechanistic transformation from the k_s- to the k_c-process is seen to increase $\Delta V_0^{\neq}$ by 3~4 cm^3/mol (see Table 2). An incipient carbonium ion, screened from nucleophilic solvation, must be stabilized electronically by substituents within the molecule. Consequently, two factors [(a) the decrease in electrostatic interaction due to charge dispersion, and (b) the diminution of the k_s-character, that is, the disappearence of tight nucleophilic solvation to the transition state species] make the $\Delta V_0^{\neq}$ for k_c-process less negative. It will be worthwhile to examine whether the $\Delta V_0^{\neq}$ of k_c-type substrates correlates with σ^*_{add} in methanolysis as well as in formolysis. Unfortunately, the correlation under consideration was obscure because of the presence of steric factors that would more or less affect the volume of the molecule.

The observation of more negative activation volumes for k_s-processes than those for k_c-processes appears to be general in the solvolyses of neutral substrates, although Hyne[18] expected that "the $\Delta V^{\neq}$ associated with the more ion-like transition state of an S_N1 mechanism would be more negative than in the case of an S_N2 mechanism." Baliga and Whalley[6c] have studied the hydrolyses of methyl and isopropyl bromides in water at 60 °C and reported the $\Delta V_0^{\neq}$ values as -17 cm^3/mol for the former and -10 cm^3/mol for the latter. There is no doubt that the former has a more k_s-character. Further evidence is given by our finding of -6.9 cm^3/mol as the value for the formolysis of a typical k_c-type secondary alkyl substrate, 2-adamantyl *p*-toluenesulfonate.[19]

Although it might be true that a solvolysis in formic acid is more k_c-like in character than in methanol, the contribution of solvent assistance can not be ignored in the case of a secondary system characterized by "borderline case" behavior.[20] For example, isopropyl tosylate has been reported to be solvolyzed with considerable nucleophilic assistance, even in formic acid.[3c] Helpful data to estimate provisionally the degree of k_s-contribution to over-all reaction are summarized in Table 3. Among the substrates presently examined, the k_s-character is greatest in (1); it then decreases successively from (1) to (5). According to this trend, the activation volume of a substrate possessing a more k_s-character will become somewhat more negative even in a k_c-like solvent. Hence, in the formolysis of substrates of the k_c-k_s hybrid character, the substituent effect on the activation volume must be considered to depend on two factors: a) the charge dispersion in the transition state, and b) the degree of its k_s-character. An analogous discussion was made by Laidler and Martin[6d] for the hydrolysis of benzyl chlorides.

On the other hand, in nearly pure k_c-processes the activation volumes should depend essentially on the degree of charge dispersion in the transition states, while in nearly pure k_s-processes some leveling effect on the activation volumes should be observed. In view of this, in the absence of steric factors, the transition states of secondary alkyl tosylates in methanolysis may be thought to be highly solvated, as in the case of primary substrates.

In order to get a more comprehensive understanding, measurements of partial molal volumes of the substrates will be required. Investigations in this direction are now in progress.

Experimental

Solvents. Formic acid (98—100%) was dried over anhydrous cupric sulfate and distilled *in vacuo*. The purified formic acid was stored frozen to avoid decomposition. Methanol was dried over activated magnesium and then distilled.

Materials. The desired alcohols were prepared as have been described in the literature. 1-*t*-Butylethyl tosylate (8) and 1-*t*-butyl-2,2-diethylbutyl tosylate(9) were prepared from the corresponding alcohols by the alkyl lithium method (*n*-BuLi was used).[21] All the other tosylates were prepared by the usual pyridine–*p*-toluenesulfonyl chloride method. The purity of each material was found by NMR analysis to be satisfactory.

Rate Measurement. The high-pressure apparatus and tecnique have already been described.[6f] The rate of production of *p*-toluenesulfonic acid was followed by a conductometric method. For fast reactions having half-lives of less than 1 hr, the medium in the high-pressure vessel was pre-chilled at 20 °C. In this case, the thermal equilibrium in the vessel was settled in about 15 min after pressurizing.

Formolysis. About a 0.019 mol/l solution was employed in each case. The first reading of conductance was taken after at least a 10% progress of the reaction because of a failure in the linear conductance-concentration relationship in this region. The rate constant was determined by the Guggenheim method[22] for (1) and by usual first-order rate expression for the others, using the least-squares method.

Methanolysis. A 0.003 mol/l solution of a tosylate (150—200 ml) was divided into 15-ml portions and stored in a refrigerator below 0 °C. Each aliquot was used for a single kinetic run. The rate constant was determined by the usual first-order rate expression, using the least-squares method. For an infinite conductance, the theoretical value of conductance was employed.

17) A rough estimation gave $\Delta V_0^{\neq} > -10$ cm^3/mol for (6) in accord with the present view.

18) A. B. Lateef and J. B. Hyne, *Can. J. Chem.*, **47**, 1370 (1969).

19) Unpublished result.

20) It is of interest to compare the ρ^I values given by Peterson *et al.*[7] for folmolysis ($\rho^I = -7.79$) and trifluoroacetolysis ($\rho^I = -15.7$) of secondary alkyl tosylates. The smaller absolute value for the former seems to suggest the presence of some solvent assistance in formic acid.

Photochemical Reduction of Thiobenzophenone. Reduction by Dihydroaromatic and Related Compounds

Yutaka Ohnishi and Atsuyoshi Ohno

Sagami Chemical Research Center, 4-4-1, *Nishiohnuma, Sagamihara-shi, Kanagawa 229*

(Received June 19, 1973)

Photochemical reduction of thiobenzophenone by 1,4-dihydrobenzene, 1,4-dihydronaphthalene, 9,10-dihydroanthracene, 1,3,5-cycloheptatriene, and acridane was studied. Relative reactivities and product analyses have revealed that the reaction is initiated by hydrogen-abstraction (one-electron-transfer followed by a proton migration) with thiobenzophenone in the n,π^* triplet state. Inability of diphenylmethane to undergo the reaction can be interpreted by means of this mechanism.

Thiobenzophenone in the n,π^* triplet state is reduced to diphenylmethanethiol (**1**) by primary and secondary aliphatic alcohols or thiols, whereas it is necessary to excite thiobenzophenone to the π,π^* singlet state in order to reduce it by hydrocarbons such as cyclohexane and diphenylmethane.[1]

$$Ph_2C{=}S \xrightarrow{589\ nm} \longrightarrow {}^3(Ph_2C{=}S)_{n,\pi^*}$$

$$^3(Ph_2C{=}S)_{n,\pi^*} + R_2CHXH \rightarrow Ph_2CHSH + R_2C{=}X$$

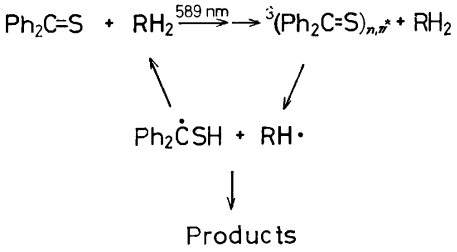
(X=O or S; R=H, alkyl, or aralkyl)

The low reactivity of diphenylmethane is anomalous, since the benzenethiyl radical can abstract a hydrogen from this hydrocarbon[2] and thiobenzophenone in the n,π^* triplet state is known to behave like a thiyl radical.[3] In order to obtain further information on the reactivity of photo-excited thiobenzophenone, we studied the reactions of thiobenzophenone with various dihydroaromatic hydrocarbons and some related compounds. The results are given in this paper together with a discussion on the mechanism of the reaction.

Results and Discussion

Although the reaction of thiobenzophenone with 1,4-dihydrobenzene (**2**) does not proceed thermally, photochemical reaction takes place under the influence of light from low-pressure sodium lamps (589 nm). Thiobenzophenone in the n,π^* triplet state abstracts hydrogens from **2** yielding **1** and benzene quantitatively. A similar but slower reaction takes place with 1,4-dihydronaphthalene (**3**) giving **1** and naphthalene in 43 and 91% yields, respectively. An even slower reaction proceeds with 9,10-dihydroanthracene (**4**) giving a mixture of complex composition of products including anthracene (26%), dibenzhydryl disulfide (24%), and **1** (17%). A similar trend of reactivity has been reported for reactions of these compounds with quinones.[4]

There is a distinct difference between dihydroaromatic hydrocarbons and diphenylmethane: the free radical produced from **2**, **3**, or **4** can eliminate a hydrogen unimolecularly yielding a stable aromatic hydrocarbon, whereas the diphenylmethyl radical has to undergo bimolecular reaction (dimerization) to form a stable molecule. Thus. reversibility of the initial hydrogen-abstraction explains the *net* reactivity of hydrocarbons toward thiobenzophenone in the n,π^* triplet state (Scheme 1).



Scheme 1.

In order to test the validity of the proposed mechanism, the reaction with 1,2-diphenylethane was carried out. The compound was found to reduce thiobenzophenone, yielding stilbene and **1**, which proves that, although thiobenzophenone in the n,π^* triplet state can abstract a hydrogen from diphenylmethane, the reverse reaction takes place faster, thus making the net reaction unrecognizable.

Stoos and Roček proposed that the enhanced reactivity of **2** in quinone-oxidation is due to a simultaneous two-hydrogen elimination assisted by the gain of aromatic stabilization energy.[5] However, "extra" stabilization energy of the cyclohexadienyl radical (24 kcal/mol) is extraordinarily large compared with that of open-chain free radicals (~15 kcal/mol).[6] In addition, if the gain of aromatic stabilization energy were to play an important role in the reactivity of these hydrocarbons, they should react faster, in contrast to observation (*vide infra*), than the corresponding nitrogen analogs since hydrocarbons can gain larger stabilization energy.[7,8] We thus propose that the oxidation of

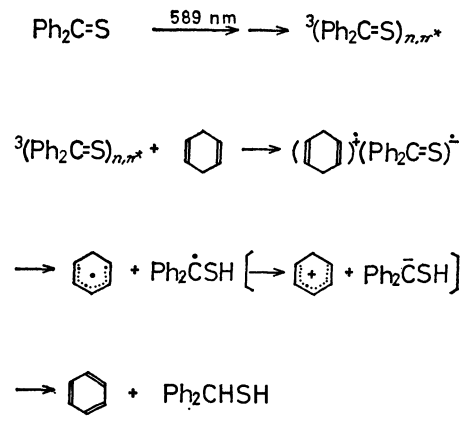
1,4-dihydroaromatic hydrocarbons proceeds by successive hydrogen-eliminations.[9]

Braude and co-workers reported that cyclohexadienyl carbonium ion is involved as an intermediate of the quinone-oxidation of **2**.[10] Although we have no evidence to predict this to be the case in the reaction with thiobenzophenone, we believe that the cyclohexadienyl radical is at least one of intermediates of the reaction. The idea is based on the comparison of reactions of **2** and 1,3,5-cycloheptatriene (**5**): the photoreaction of **5** with thiobenzophenone proceeded as fast as that of **2** and products isolated from the reaction mixture were 7-(1,3,5-cycloheptatrienyl)diphenylmethanethiol (35%), 7,7'-bi(1,3,5-cycloheptatrienyl) (2%), and **1** (4%) with several unidentified materials. Formation of 7,7'-bi(1,3,5-cycloheptatrienyl) implies that the reaction involves a transient cycloheptatrienyl radical, the "extra" stabilization energy (21 kcal/mol) of which is comparable to that of the cyclohexadienyl radical.[6] On the other hand, the intermediacy of the carbonium ion is fairly well-established in the oxidation of **5**.[11] The "extra" stabilization energy is calculated to be 49 kcal/mol for cycloheptatrienyl carbonium ion,[6] which is twice as large as that of the corresponding free radical. Since it is energetically unreasonable to expect the initially formed carbonium ion to be reduced to the free radical, the free radical should be the precursor of the carbonium ion. The fact that even such a stable carbonium ion is formed *via* a free radical suggests that cyclohexadienyl carbonium ion, if any, might be formed from the corresponding free radical.

Taking account of the results obtained by Braude and co-workers[10] together with the analogy to the mechanism of reactions of dihydropyridine derivatives (*vide infra*), we would like to propose an initial electron-transfer process for the formation of cyclohexadienyl radical (Scheme 2).



Scheme 2.

In contrast to the low reactivity of **4**, the photoreaction of acridane (**6**) with thiobenzophenone proceeds instantaneously giving a clear solution with precipitation of 9,9'-biacridanyl (31% yield). However, on standing the reaction mixture at room temperature for a day or at 50 °C for an hour, regeneration of 67% of the starting thiobenzophenone was observed by spectrophotometry. The forward and reverse reactions were repeated several times, and when no more thiobenzophenone was regenerated, **1** and 9,9'-biacridanyl were isolated in quantitative yields. Thus, it is obvious that a thermally unstable intermediate is formed by the photoreaction of **6** with thiobenzophenone.

A mixture of **6** and 4,4'-dimethoxythiobenzophenone in ethanol exibits absorption maxima at 295 and 355 nm due to **6** and the thioketone, respectively. When the mixture was irradiated with light (589 nm) for a short period (within 1 min), formation of acridine was recognized by the appearance of a new maximum at 250 nm and a fine structure at about 350 nm.[12] Longer irradiation, however, caused a decrease in absorption due to acridine (Fig. 1).

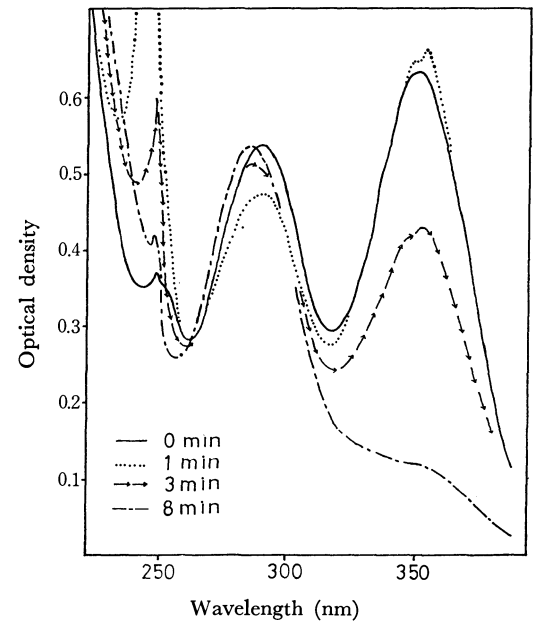


Fig. 1. Absorption spectra (in EtOH) of a mixture of acridane (1.53×10^{-5} mol/l) and 4,4'-dimethoxythiobenzophenone (1.48×10^{-5} mol/l) at different periods of photoirradiation.

Photochemical behaviors of acridine and acridane have been studied extensively.[12-15] The present result, combined with reported ones, suggests that the most plausible mechanism for the reaction of **6** with thiobenzophenone is as follows (Scheme 3): Undoubtedly only thioketone can absorb the irradiated light. Although we failed to obtain evidence supporting

9) We do not intend to specify the mechanism of the hydrogen-elimination process. It might be a one-electron-proton elimination or true hydrogen-elimination. The mechanism will be discussed below.

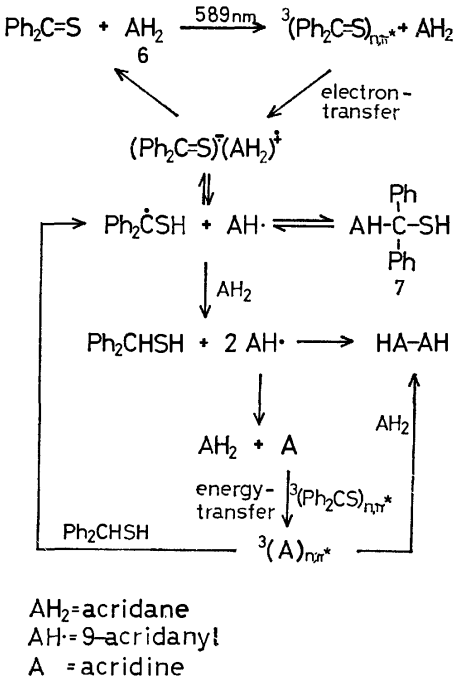

Scheme 3.

the formation of the intermediate **7**, formation of 1-(9-acridanyl)ethyl alcohol by the reaction of acridine with ethanol has been confirmed.[12] There is no doubt that **7** is the thermally unstable intermediate mentioned above, because acridine semiquinone[16] and radical anion from thiobenzophenone,[17] both considered to be intermediates, are known to have absorption maxima in a visible region, whereas the present reaction mixture is transparent in this region.

The one-electron-transfer process from acridane to benzophenone has also been proposed.[14] Since thiobenzophenone is a much better electron-acceptor than benzophenone[18] and the electron-acceptability of thiobenzophenone is enhanced more in the n,π^* triplet state than in the ground state,[19] the initial one-electron-transfer process from **6** to thiobenzophenone in the n,π^* triplet state is most plausible for explaining the great difference in the reactivity of **4** and **6**. It should be noted that *N*-benzyl-1,4-dihydronicotinamide reacts with thiobenzophenone at room temperature in the dark, whereas **2** requires light to undergo a similar reaction. The one-electron-transfer interaction has been proposed to be a driving force of the former reaction.[20]

The photo-sensitized transformation of acridine into 9,9'-biacridanyl shown in Scheme 3 was confirmed by a separate experiment: an ethanol solution of 4,4'-dimethoxythiobenzophenone and acridine was irradiated with light (589 nm) and the decrease in intensity at the absorption maximum (250 nm) was followed spectrophotometrically.[21]

Experimental

Materials. Thiobenzophenone and 4,4'-dimethoxythiobenzophenone were prepared as reported previously.[24] 1,4-Dihydrobenzene was prepared by the Birch reduction of benzene[25]: bp 86—89 °C (lit,[26] 88 °C). Acridane was obtained by the reduction of acridine with $LiAlH_4$: mp 170 °C (lit,[27] 169 °C). 1,4-Dihydronaphthalene, 1,3,5-cycloheptatriene, 9,10-dihydroanthracene, and 1,2-diphenylethane were purified by repeated distillations or recrystallizations of commercial reagents.

*Reaction with 1,4-Dihydrobenzene (**2**).* An ampoule containing **2** (2 ml), thiobenzophenone (486 mg, 2.46 mmol), and benzene (3 ml) was degassed by the usual thawing and freezing method and sealed in a high vacuum (10^{-6} Torr). The mixture was irradiated with light from low-pressure sodium lamps[3] at room temperature until the characteristic color of thiobenzophenone completely disappeared (20 hr). Removal of the volatile materials under a reduced pressure left diphenylmethanethiol (**1**) in quantitative yield (490 mg). From the reaction mixture in ethylbenzene as a solvent, benzene (100% yield) was detected on vpc (Hitachi K-53, FID, 20% XF-1150, 2 m, 90 °C).

*Reaction with 1,4-Dihydronaphthalene (**3**).* A benzene (10 ml) solution of thiobenzophenone (423 mg, 2.14 mmol) and **3** (284 mg, 2.19 mmol) in an ampoule was similarly irradiated. After the disappearance of thiobenzophenone (3 days), naphthalene (91% yield) was detected on vpc (20% Carbowax-20M, 2 m, 180 °C). Dibenzhydryl disulfide (48 mg, 11% yield) and **1** (180 mg, 43% yield) were isolated by subjecting the reaction mixture to column chromatography on silica gel with *n*-hexane as an eluent.

*Reaction with 9,10-Dihydroanthracene (**4**).* A mixture of thiobenzophenone (483 mg, 2.44 mmol) and **4** (440 mg, 2.44 mmol) in acetonitrile (15 ml) and ethyl ether (10 ml) was irradiated until complete decolorization of thiobenzophenone took place (one week). After the solvents were evaporated, the residue (900 mg) was chromatographed on silica gel column. Elution with *n*-hexane gave anthracene (100 mg, 26% yield), dibenzhydryl disulfide (210 mg, 24% yield), **1** (75 mg, 17% yield), and recovered **4** (45 mg). Two additional unidentified materials (200 and 150 mg) were obtained by eluting the column with a mixture of *n*-hexane–benzene (1 : 1).

Reaction with 1,2-Diphenylethane. A benzene (4 ml) solution of thiobenzophenone (40 mg) and 1,2-diphenylethane (400 mg) was irradiated for 1.5 months. The color of thiobenzophenone faded but not completely. Formation of small amounts of *trans*-stilbene, dibenzhydryl disulfide, and **1** was proved on vpc (20% XF-1150, 1 m, 180 °C) and tlc (silica gel).

*Reaction with 1,3,5-Cycloheptatriene (**5**).* A solution of thiobenzophenone (795 mg, 4.00 mmol), **5** (3 ml), and ben-

zene (5 ml) was irradiated until complete decolorization of thiobenzophenone took place (44 hr). After excess **5** and the solvent were removed, the residue was chromatograhped on a silica-gel column with a mixture of *n*-hexane–benzene (4 : 1) as an eluent. The following components were isolated: 7,7′-bi(1,3,5-cycloheptatrienyl) (17 mg, 2% yield), 7-(1,3,5-cycloheptatrienyl)diphenylmethanethiol (**8**) (550 mg, 35% yield), **1** (30 mg, 4% yield), and unidentified compounds (140 mg).

8: NMR (δ from TMS, $CDCl_3$) 2.43 (s, 1H), 2.61 (t of d, 1H), 5.44 (q, 2H), 6.14 (d or octet, 2H), 6.64 (t of d, 2H), and 7.0—7.6 (m, 10H). Mass spectrum (*m/e*) 290 (M^+), 257, 256, 199, 198, 179, 178, and 91 (base). IR 2570 cm^{-1} (ν_{SH}).

To a suspension of NaH (30 mg) in 30 ml of THF was added dropwise a solution of the thiol (310 mg) in 20 ml of THF at room temperature. After 2 hr, when the solution became clear, 2 ml of MeI was added and stirred for 2 hr at room temperature. The solution was acidified with 2N-hydrochloric acid and extracted with chloroform yielding 260 mg of an oil. The oil was chromatographed on a silica-gel column with the eluent of *n*-hexane–benzene (8 : 1) mixture. Triphenylethylene[28] (60 mg) and 7-(1,3,5-cycloheptatrienyl)diphenylmethyl methyl sulfide (**9**) (100 mg) were isolated.

9: NMR (δ from TMS, $CDCl_3$) 1.63 (s, 3H), 2.38 (t of t, 1H), 5.48 (q, 2H), 6.24 (d of sextet, 2H), 6.77 (t, 2H), and 7.0—7.6 (m, 10H). Mass spectrum (*m/e*) 304 (M^+), 256, 213, 198, 179, 165, 121, and 91 (base).

*Reaction with Acridane (**6**).* A solution of thiobenzophenone (560 mg, 2.83 mmol) and **6** (1,000 mg, 5.55 mmol) in ether (20 ml) was irradiated at the temperature of ice-water. After 30 min, the color of thiobenzophenone faded completely. From this reaction mixture, 310 mg of 9,9′-biacridanyl (31% yield) was isolated as precipitates. In a separate run, the characteristic color of thiobenzophenone reappeared, when the reaction mixture was heated at 50 °C for 1 hr. Spectroscopic observation showed that 67% of thiobenzophenone was recovered. After all the thiobenzophenone had been consumed by a repetition of the above procedure, 950 mg of 9,9′-biacridanyl (mp 260 °C (lit[29] 261—262 °C)) was isolated as precipitates. From the filtrate, additional 9,9′-biacridanyl (30 mg) (total yield; 98%) and **1** (540 mg, 97% yield) were obtained.

Formation and consumption of acridine during the reaction were followed with a Carry-14 Spectrophotometer at suitable concentrations of 4,4′-dimethoxythiobenzophenone and **6** in ethanol or ethyl ether (Fig. 1).

Photo-sensitized Reaction of Acridine. An ethanol solution of acridine (8.05×10^{-7} mol/l) and 4,4′-dimethoxythiobenzophenone (1.56×10^{-5} mol/l) was irradiated at room temperature for 2 min. The decrease in intensity at the absorption maximum (250 nm) was followed with a Carry-14 Spectrophotometer (Fig. 2).

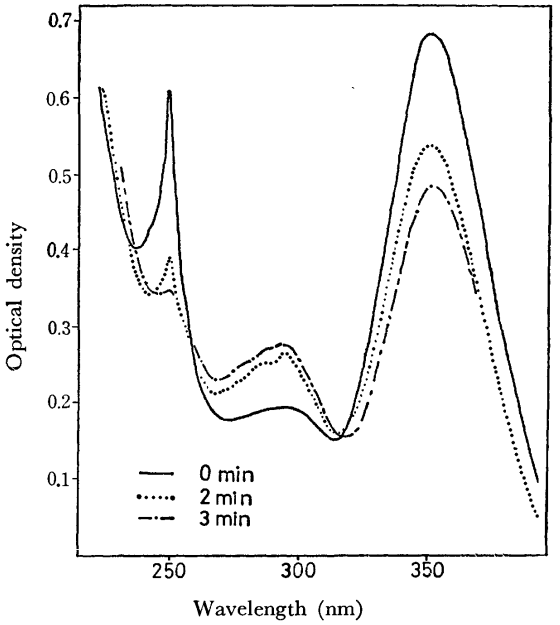

Fig. 2. Absorption spectra (in EtOH) of a mixture of acridine (8.05×10^{-7} mol/l) and 4,4′-dimethoxythiobenzophenone (1.56×10^{-5} mol/l) at different periods of photo-irradiation.

Tri(hetero)substituted Carbonium Ions. VIII. The Hydride Reduction of Cyclic and Open-chain Dithiocarbamidium Salts

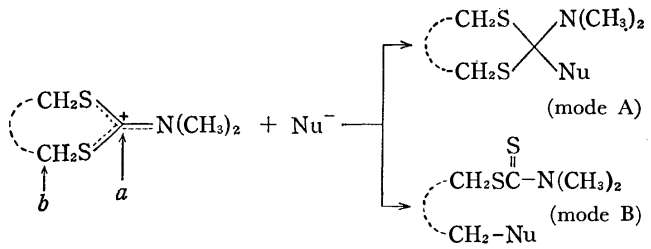
Kazuhisa HIRATANI, Takeshi NAKAI, and Makoto OKAWARA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

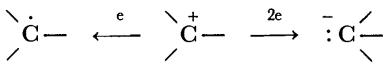
(Received June 20, 1973)

Studies were carried out on the hydride reduction of the following five stable *N,S,S*-tri(hetero)substituted carbonium ions: *N,N,S,S'*-tetramethyldithiocarbamidium ion (**1a**), 2-dimethylamino-1,3-dithiolanylium ion (**1b**), 2-dimethylamino-1,3-dithianylium ion (**1c**), 2-methylthio-3-methyl-4,5-dihydrothiazolium ion (**1d**), and 2,3,5,6-tetrahydrothiazolo[2,3-*b*]thiazolium ion (**1e**). Sodium dihydrobis(methoxyethoxy)aluminate (RDB) was found to be a suitable reducing agent. The RDB reduction of the carbonium ions at −5 °C gave the corresponding formamide thioacetals (**2**) in moderate yields. This provides a practical method for the synthesis of formamide thioacetals. The RDB reduction of **1d** at higher temperature, however, yielded abnormal products, thiazolin-2-thione (**3**) and thiazolidine (**4**) instead of the formamide thioacetal (**2d**). The mechanism for the formation of **3** and **4** has been discussed in terms of the ambident character of the cation (**1d**). Pyrolytic reactions of the thioacetals (**2**) and unsuccessful attempts to abstract the methine proton of **2b** by various bases are also described.

In previous studies[1-5] we established that (i) dithiocarbamidium ions (**1**) have two electrophilic sites (the ambident character) and (ii) in general, hard nucleophiles attack selectively site at *a* (mode A) while soft nucleophiles react at site *b* (mode B).



Reduction reactions of carbonium ions have recently drawn much attention since one- and two-electron reductions of carbonium ions might lead to carbon radical and carbanion frameworks, respectively. Although papers have appeared on the reduction of stable carbonium ions,[6] little information has been available on the reduction of stable tri(hetero)carbonium ions.



In this work, the hydride reduction (two-electron reduction) of cyclic and acylic dithiocarbamidium ions by means of metal hydride has been studied. On the basis of the selectivity rule it is anticipated that hydride ion, one of the hardest nucleophiles, attacks specifically at site *a* giving formamide thioacetals. The present paper describes the hydride reductions of the dithiocarbamidium ions which give the corresponding formamide thioacetals in moderate yields.

Results and Discussion

Hydride Reductions of the Carbonium Salts. The following dithiocarbamidium salts were used: *N,N,-S,S'*-tetramethyldithiocarbamidium perchlorate (**1a**),[4] 2-dimethylamino-1,3-dithiolan-2-ylium perchlorate (**1b**),[1] 2-dimethylamino-1,3-dithian-2-ylium perchlorate (**1c**),[3] 2-methylthio-3-methyl-4,5-dihydrothiazolium iodide (**1d**),[5] and 2,3,5,6-tetrahydrothiazolo[2,3-*b*]thiazolium perchlorate (**1e**).[5] Metal hydrides examined were sodium hydride, sodium borohydride (SBH), lithium aluminium hydride (LAH) and a 64% benzene solution of sodium dihydrobis(2-methoxyethoxy)aluminate (RDB).

In order to find the best reducing agent, the reactions of **1b** with the above four metal hydrides were carried out in tetrahydrofuran (THF) or ether in the range from −10 °C to room temperature for 2—4 hr. In most cases except for RDB, both reactants were almost insoluble in the solvents. It was found that sodium hydride can not reduce the cation under the conditions. The reduction using SBH and LAH gave the expected product 2-dimethylamino-1,3-dithiolane (**2b**) in *ca.* 30% and *ca.* 20%, respectively. The optimum yield (71%)was obtained by using RDB in THF at −5—0 °C. The result shows that RDB has an advantage over SBH and LAH presumably due to the greater solubility of RDB in organic solvents such as ether and THF. Thus, the hydride reductions of the other dithiocarbamidium salts were undertaken by means of RDB under similar conditions. The yields and physical properties of the formamide thioacetals thus obtained are summarized in Table 1. Their elemental analysis and NMR spectra are given in Table 2.

It should be noted that there is a well-defined trend for the absorption due to the methine proton in the formamide thioacetals to shift remarkably to a lower field in the order: **2a** (acyclic), **2c** (six-membered), and **2b** (five-membered) although their N–CH_3 signals were essentially independent of the ring size (Table 2). In view of the fact that the inductive effect on the me-

2e	5.83(s)	—	—	[-S-CH_2CH_2-N=] 3.16(m)	

thine proton is nearly constant in the system concerned, two possible explanations can be suggested; (i) the ring-size effect on the conformation of the thioacetal ring[7] and (ii) the ring-size effect on the extent of the 3p–3d interaction between the two sulfur atoms in the ring recognized in UV spectra for cyclic thioacetals and orthothioformates.[8] At the present stage, however, it is difficult to determine which factor is more operative since no information is available on the conformational analysis and acidity of cyclic formamide thioacetals. Our attampts to abstract the methine proton of **2b** by various bases were unsuccessful.

Thus, the hydride reduction of the stable carbonium salts, which were readily prepared by the previously-reported method,[1,3–5] may provide a practical method[9] for the synthesis of formamide thioacetals which have recently attracted much attention as a synthetic intermediate.[10]

The Ambident Behavior of the Cation ***1d*** *in the Hydride Reduction.* During the course of our search for the optimum reduction conditions for the cation **1d**, we found that a change in reaction temperature from −5 °C to room temperature resulted in a complete change of the product structure; the reduction of **1d** at −5 °C gave the normal product **2d** while the reduction at room temperature (15—20 °C) yielded 3-methylthiazolidin-2-thione (**3**) and 3-methylthiazolidine (**4**) in 12% and 30% yields, respectively. The thin layer chromatogram of the crude mixture excluded any possibility of the presence of a product other than **3** and **4**. Product **3** was identical with an authentic sample.[11] The other product **4** was identified by elemental analysis and IR and NMR spectroscopic methods.

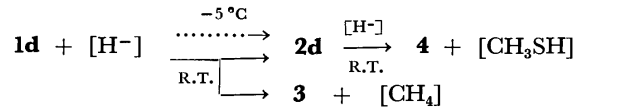
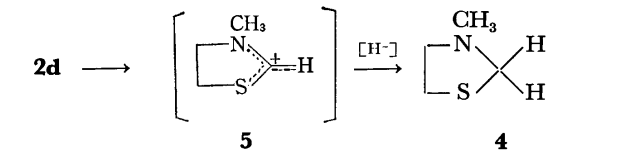
The abnormal behavior of **1d** is in contrast to the reductions of the other carbonium salts in which the corresponding formamide thioacetals were formed in the range from −10 °C to room temperature. The effect of reaction temperature on product structure is of particular interest in connection with the ambident behavior of the tri(hetero)carbonium ions. The mechanisms for the formation of **3** and **4** in the RDB reduction of **1d** were investigated in some detail.

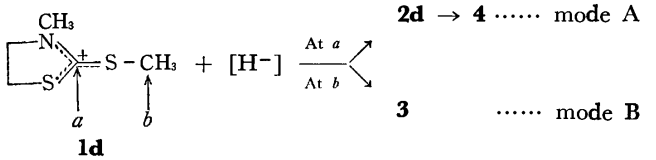
In order to ascertain whether the normal product **2d** is an intermediate for the formation of the abnormal products, **2d** was treated with RDB at room temperature. Only 3-methylthiazolidine (**4**) was obtained, and product **3** was not detected in the reaction mixture. Furthermore, it was found that **3** did not react with RDB under the same conditions and was recovered unchanged. The result of the control experiments led us to suggest that **4** is formed *via* hydride reduction of **2d** and that **3** is not formed *via* **2d** but directly *via* the reaction between the cation **1d** and hydride ion as follows.



Formation of **4** *via* **2d** can be easily explained as the result of an initial reductive cleavage of the C–SMe bond followed by hydride reduction of the 3-methyl-4,5-dihydrothiazolium ion (**5**); a similar reductive cleavage of C–S bonds by hydride ion has been established for thiazolidines[12] and α-dimethylaminobenzylsulfides.[13]

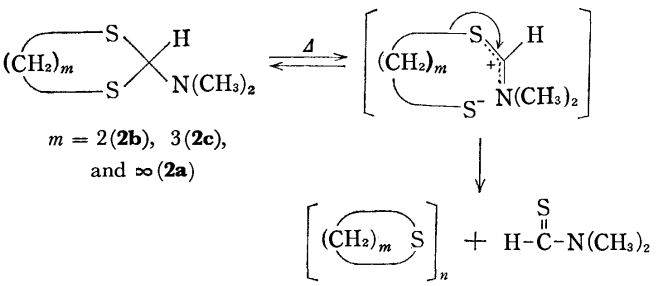


Formation of **3**, on the other hand, can be best explained in terms of a direct attack at site *b* by hydride ion (mode B). This indicates that a change in reaction temperature from −5 °C to room temperature resulted in a partial shift of the reaction course from mode A to mode B.



This is the first example demonstrating the important role played by the reaction temperature in determining the reaction course of ambident electrophiles such as dithiocarbamidium ions. In view of our previous findings that the reaction course for the tri(hetero)-carbonium ions depends mainly upon the nucleophilicity and bulkness of an attacking reagent and upon the stability of the cations concerned, it might be concluded that external factors such as reaction temperature should also be taken into account as an additional factor determining the reaction course for some ambident electrophiles.

Reactions of Formamide Thioacetals. Pyrolytic reactions of the formamide thioacetals were studied. When **2b** was heated in bulk at 160—170 °C for 12 hr under nitrogen atmosphere, *N,N*-dimethylthioformamide (**6**) was obtained as a major product along with polymeric ethylene sulfide. Both products were identified through agreement of their IR spectra with those of authentic samples. Pyrolysis of **2a** and **2c** under similar conditions also yielded **6** as a major product. Formation of **6** in these reactions can be explained by assuming an initial thermal cleavage of the C–S bond reported for the thermal reactions of ortho(thio)carbonate derivatives.[14] In contrast, **2d** was more easily pyrolyzed under the conditions to yield the cyclic thione **3** with retention of the ring structure along with a small amount of 3-methylthiazolidin-2-one.



Attempts were made to abstract the methine proton of **2b** with various bases. When **2b** was treated with *n*-butyllithium followed by addition of deuterium oxide, it was found by IR and NMR spectroscopy that no deuterium was incorporated in the resulting thioacetal. Attempts with other bases under various conditions were also unsuccessful. In view of the ease to abstract 2-hydrogens in 1,3-dithianes by *n*-butyllithium, difficulty to abstract the methine proton in **2b** suggests that the resulting carbanion (**7**) is very unstable due to large repulsion between its sp^3 nonbonding electrons and the lone pair of electrons on the nitrogen atom.

Experimental

General. All melting and boiling points are uncorrected. IR and UV spectra were recorded with Hitachi EPI-S2 and EPS-3T spectrophotometers, respectively. NMR spectra were obtained with a Japan Electron Optics JNN H-100 spectrometer. Chemical shifts are given in ppm with tetramethylsilane as an internal standard. All carbonium salts were prepared according to the literature methods.

*Reactions of the salt **1b** with Metal Hydride. a) With RDB*: A suspension of 68 g (0.27 mol) of **1b**[1] in 150 ml of THF was placed in a 500-ml three-necked flask equipped with a mechanical stirrer, dropping funnel and thermometer, and was then cooled to −5 °C. To the stirred mixture was added dropwise 8.5 g (0.27 mol) of a 64% benzene solution of RDB[16] over a period of 2 hr. The reaction mixture was then stirred at −5—0 °C for 4 hr. After removal of THF at room temperature under reduced pressure, ether and water were added to the resulting mixture. The ethereal layer was separated and dried over anhydrous sodium sulfate. After removal of the drying agent followed by distillation of ether, distillation of the liquid residue gave 28.5 g (71%) of **2b**.

Found: C, 40.16; H, 7.43; N, 9.25%. Calcd for $C_5H_{11}NS_2$: C, 40.23; H, 7.42; N, 9.38%.

b) With LAH: In a similar manner, the reaction of **1b** (3.0 g, 12 mmol) with LAH (1.0 g, 27 mmol) in 50 ml of ether at 0 °C gave 0.4 g (22%) of **2b**.

c) With SBH: In a similar manner, the reaction of **1b** (15 g, 61 mmol) with SBH (4 g, 110 mmol) in 100 ml of ether at 0 °C yielded 3.0 g (33%) of **2b**. When ethanol was used as the solvent in place of ether, a similar reaction of **1b** (75 g, 0.3 mol) with SBH (1.0 mol) gave 27 g (60%) of **2b**.

RDB Reductions of Other Carbonium Salts. By the same procedure as in the case of RDB reduction of **1b**, 35 g (0.14 mol) of **1a**[4] and 47 g (0.14 mol) of the RDB solution gave 8.0 g (38%) of **2a**.

Found: C, 39.75; H, 8.76; N, 9.25%. Calcd for $C_5H_{12}NS_2$: C, 39.70; H, 8.66; N, 9.25%.

In a similar fashion, the RDB reductions of **1c**,[3] **1d**[5], and **1e**[5] gave the corresponding formamide thioacetals (**2**) in 34%, 36%, and 57% yields, respectively.

2c, Found: C, 44.56; H, 8.12; N, 8.46%. Calcd for $C_6H_{13}NS_2$: C, 44.13; H, 8.02; N, 8.58%.

2d, Found: C, 39.98; H, 7.38; N, 9.31%. Calcd for $C_5H_{11}NS_2$; C, 40.23; H, 7.43; N, 9.38%.

2e, Found: C, 39.87; H, 6.25; N, 9.26%. Calcd for $C_5H_9NS_2$: C, 40.78; H, 6.16; N, 9.51%.

*The RDB Reduction of **1d** at Room Temperature (15—20 °C).* To a suspension of 5.5 g (0.02 mol) of **1d** in 40 ml of THF was added dropwise 5.8 g (0.02 mol) of the RDB solution at room temperature. After the mixture was stirred at room temperature, THF was removed by distillation. Ether and water were added to the residue and the ethereal layer was separated. The ethereal solution was dried over anhydrous sodium sulfate and the ether was evaporated under reduced pressure. The thin layer chromatogram (silica gel, chloroform) of the oily residue showed two spots which were assigned to *N*-methylthiazolin-2-thione (**3**) and *N*-methylthiazolidine (**4**) by comparison of the R_f values with those of authentic samples. Distillation of the residue under reduced pressure gave 0.60 g (30%) of 3-methylthiazolidine (**4**), 39—41 °C/4 mmHg, n_D (20 °C) 1.518 (lit,[15] bp 151—152 °C/760 mmHg, n_D (25 °C) 1.520), and a solid residue which was then recrystallized from water giving 0.32 g (12%) of 3-methylthiazolidin-2-thione (**3**), mp 68—69 °C (lit,[11] 69.5 °C).

4: NMR ($CDCl_3$); 2.22 (s, 3H, NCH_3), 2.87 (m, 4H, SCH_2CH_2N) and 3.90 (s, 2H, SCH_2N). Found: C, 47.48; H, 9.06; N, 13.39%. Calcd for C_4H_9NS: C, 46.59; H, 8.80; N, 13.58%.

*Control Experiments. a) Reaction of the Formamide Thioacetal (**2d**) with RDB*: A mixture of 0.3 g of **2d** and 0.7 g of the RDB solution in 10 ml of benzene was stirred at room temperature for 24 hr. Water was then added to the mixture and the solution was extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate and the ether was evaporated completely to give 0.27 g of an oily residue. The oil was found to consist of **4** and unreacted **2d** by IR and NMR spectroscopy and thin layer chromatography.

*b) Reaction of **3** with RDB*: A mixture of 1.35 g of **3** and 3.0 g of the RDB solution in 30 ml of THF was stirred at room temperature for 3 hr. The mixture was poured into cold water followed by extraction with ether. The ether solution was dried over anhydrous sodium sulfate and the ether was evaporated completely giving 1.32 g of unchanged **3**.

Pyrolyses of the Formamide Thioacetals. 1.0 g of **2a** was placed in a 10 ml flask equipped with a reflux condenser and gas inlet. The flask was dipped in an oil bath heated at 150 °C and allowed to stand for 24 hr at 130—150 °C under nitrogen atmosphere. After cooling, the mixture was subjected to column chromatography (silica gel). Two products were obtained; the major product (*ca.* 30% yield) was identical (IR and UV) with an authentic sample of *N,N*-dimethylthioformamide (**6**) prepared by method in literature;[17] the minor product was identified to be methyl *N,N*-dimethylthiolcarbamate by comparison of its IR spectrum with that of an authentic sample.[4]

In a similar manner, pyrolysis of **2b** (1.5 g) at 160—170 °C for 12 hr gave an oil along with a white solid on the wall of the reflux condenser. The oil was dissolved in chloroform and chromatographed on silica gel. Elution with chloroform gave 0.57 g (64%) of the thioformamide (**6**). The white solid was identified as polymeric ethylene sulfide by IR spectroscopy and elemental analysis. No further identification was made.

The pyrolysis of **2c** (0.5 g) at 150 °C for 12 hr also gave **6** as a major product.

Pyrolysis of **2d**, (0.5 g, 3.4 mmol) at 160 °C was complete after only 3 hr. After the resulting mixture had been cooled, it was subjected to column chromatography (silica gel) to give 0.3 g (66%) of 3-methylthiazolidin-2-thione (**3**) and 0.1 g of 3-methylthiazolidin-2-one.[5] The structures of the products were determined by comparison of their IR spectra and physical properties with those of the corresponding authentic sample.

*Reaction of **2b** with n-Butyllithium.* A solution of 3.0 g (0.02 mol) of **2b** in 50 ml of THF was placed in a 100 ml three-necked flask equipped with a magnetic stirrer, gas inlet tube and thermometer. The mixture was stirred at −70 °C under nitrogen atmosphere and then 8.0 g of a 15% *n*-hexane solution of *n*-butyllithium was added dropwise to the mixture. After the mixture was stirred at −70 °C for 3 hr, 0.5 g of deuterium oxide was added and the mixture was allowed to stand until the temperature rose to room temperature. The white precipitates formed were filtered and the solvents were removed from the filtrate under reduced pressure at room temperature to give an oily residue. The IR and NMR

spectra of the oil agreed with those of **2b**.

A similar reaction with *n*-butyllithium-*N*,*N*,*N*′,*N*′-tetramethylethylene diamine complex resulted in the recovery of **2b** unchanged.

An attempt to abstract the methine proton in **2b** with *t*-BuOK—*t*-BuOD was unsuccessful.

(Received June 25, 1973)

A general synthetic route to unsymmetric 3,6-dialkylidene and 3-alkylidene-6-arylidene-2,5-piperazinediones is described. The condensation reaction of ethyl 2-oxocarboxylates with chloroacetamide in the presence of several acidic catalysts afforded *N*-chloroacetyldehydroamino acid esters. These compounds were cyclized in saturated ethanolic ammonia to give 3-monoalkylidene and benzylidene-2,5-piperazinediones (**2**). Compound **2** and 1-monoacetyl- or 1,4-diacetyl-3-alkylidene and benzylidene-2,5-piperazinediones, derived from a reaction of **2** with acetic anhydride, were condensed with alkyl and arylaldehyde in the presence of bases to afford **5**.

Many monocyclic or polycyclic 2,5-piperazinedione derivatives have recently been found in nature as antibiotics or alkaloids.[2-9]

One of the authors (C.S.) has investigated the syntheses and chemistry of several derivatives,[10-13] and succeeded in the synthesis of albonoursin,[11] 3-benzylidene-6-isobutylidene-2,5-piperazinedione, the first cyclic dehydrodipeptide isolated from the culture of *Streptomyces (St.) albus var. fungatus* and *St. noursei*.

It is well-known that the cyclization of two molecules of amino acids yields the saturated symmetric 3,6-disubstituted-2,5-piperazinedione[14] and the condensation reaction glycine anhydride with arylaldehyde gives unsaturated symmetric 3,6-disubstituted-2,5-piperazinedione.[15,16] However, natural 2,5-piperazinedione derivatives usually have an unsymmetric structure.

As unsymmetric derivatives, only a few 3-monoalkylidene-2,5-piperazinediones (**2**) have been reported. Bergmann *et al*[17] and others[18,19] have synthesized 3-methylidene derivative (**2a**) from glycylserine by halogenation and amination. One of the present authors (C.S.) succeeded in the preparation of isopropylidene derivative (**2d**) *via* ethyl 2-chloroacetamido-3-methyl-2-butenoate (**1d**) obtained by the reaction of dehydrovaline ethyl ester or the tautomeric imine with chloroacetyl chloride.[10,12,13] Similarly, 3-isobutylidene derivative (**2f**) was synthesized *via* ethyl 2-chloroacetamido-4-methyl-2-pentenoate (**1f**) derived by esterification of the free acid.[11] Recently, Dominy and Lawton reported the preparation of 3-benzylidene derivative (**2g**) by the reaction of *N*-acetyldehydrophenylalanylglycine with acetic anhydride.[20] Gallina and Liberatori reported another synthetic method for **2** from the reaction of 1,4-diacetyl-2,5-piperazinedione with alkyl or arylaldehyde.[21] Consequently,

N-chloroacetyldehydroamino acid esters (**1**) seem to be a suitable intermediate for obtaining 3-monoalkylidene and benzylidene derivatives (**2**).

In a previous communication we reported briefly a general synthesis of **2** by the reaction of **1**, derived from ethyl 2-oxocarboxylates and chloroacetamide, with ammonia.[22]

This paper deals with the synthesis of **1** in detail under several experimental conditions and syntheses of unsymmetric 3,6-dialkylidene and 3-alkylidene-6-arylidene-2,5-piperazinediones (**5**) by the condensation of **2** or a mixture of 1-acetyl (**3**)- and 1,4-diacetyl-3-alkylidene-2,5-piperazinediones (**4**) with alkyl or arylaldehyde in the presence of bases.

Results and Discussion

3-Alkylidene-2,5-piperazinediones. Various acidic catalysts were examined in the synthesis of ethyl 2-chloroacetamido-2-pentenoate (**1c**) by the condensation of an equimolar amount of ethyl 2-oxopentanoate and chloroacetamide in refluxed dry benzene. Concentrated sulfuric acid and phosphorylchloride were found to be the most effective.[22]

The effect of the molar ratio of chloroacetamide to ethyl 2-oxopentanoate and the reaction time in the presence of phosphorylchloride were also examined. When the reaction was continued for 8 hr, the yield of **1c** gradually increased as the molar ratio increased to 1.5 : 1 and reached a maximum 44.2% yield. At molar ratio of 1.5 : 1, the yield increased until the reaction time of 12 hr, and reached a 51.0% yield. It was found that the yield of **1c** was best at the molar ratio of 1.5 : 1 and reaction time 12 hr.

The structure of **1** obtained under the same conditions as for **1c** was confirmed by elementary analysis and IR spectrum. It is very similar to that of **1d** and **1f** prepared from a different synthetic route.[10,11]

When a cooled ethanol solution of **1** was saturated with dry ammonia and then allowed to stand at room temperature at least for one day, cyclization reaction occurred gradually to deposit colorless crystals. The crystals were recrystallized from boiling water to afford **2** in pure state as colorless amorphous.[22]

The structure of **2** was confirmed by elementary analysis as well as IR and UV spectrum, the pattern being essentially similar to those of **2d** and **2f** derived in the independent preparation.[10,11]

Acetylation and Condensation Reaction. When **2** was heated with acetic anhydride at 120—130 °C for half an hour, two kinds of crystals which were confirmed to be 1-acetyl (**3**)- and 1,4-diacetyl (**4**) derivatives of **2** were obtained in a ratio of *ca.* 3 : 7. Recent studies on the photoisomerization of carbon-carbon double bond of 3-benzylidene-2,5-piperazinediones by Sammes and co-workers[23,24] and a novel

preparative method for **3**[21] stimulated us to find a simple method for the isolation and determination of these isomers. The two compounds were separated by chromatography on silica-gel column by elution with a mixture of benzene and acetone (20 : 1). The melting points of **3** approximately agreed with those of the products obtained by Gallina and Liberatori.[21] From the results and the spectroscopic data (Table 1), it was assumed that compound **4** is *E*-conformer and **3** is *Z*-conformer with respect to carbon-carbon double bond. It was deduced that, in the case of *Z*-conformer, the steric hindrance of alkyl group hindered acetylation at 4-position of **2**.[24]

Since the isolation of **3** and **4** was tedious and time-consuming, the following method was adopted for the subsequent condensation reaction. On treatment of the mixture of **3** and **4** with arylaldehyde in the presence of triethylamine at 120—130 °C for about 3 hr, the expected 3-alkylidene-6-arylidene-2,5-piperazinedione (**5**) was obtained (Procedure A). On the other hand, **5** was also obtained by direct condensation of **2** with aralkyl or alkylaldehyde in acetic anhydride in the presence of sodium acetate at 120—130 °C for about 5 hr (Procedure B).

The structures of **3**, **4** and **5** were confirmed by elementary analysis as well as IR, UV and NMR spectra. The IR spectrum of **5** showed the absorption bands of NH (3200—3160 and 3100—3020 regions), carbon-oxygen double bond (1690—1670 region) and carbon-carbon double bond (1640—1635 cm^{-1} region). The physical constants, yields and spectral data are given in Tables 1, 2 and 3.

Experimental

All melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-S2 Spectrometer. The UV spectra were recorded with a Shimadzu UV-50 Spectrometer. The NMR spectra were measured with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.) using tetramethyl silane as an internal standard.

*N-Chloroacetyldehydroamino Acid Ethyl Esters (**1**).* In a 200 ml round-bottomed flask, fitted with water separater, were placed the appropriate ethyl 2-oxocarboxylate (0.1 mol), chloroacetamide (0.15 mol), phosphorylchloride (6 ml) and dry benzene (100 ml). The mixture was refluxed for about 12 hr until no water separated out. The reaction mixture was removed in a separating funnel and washed with water and then extracted with benzene. The benzene extract was washed with water, dried over anhydrous magnesium sulfate and then evaporated. The residual dark brown syrup was distilled under reduced pressure to give yellow oil.[22] In a similar manner, the condensation reaction of ethyl 2-oxophenylpropanoate with chloroacetamide was performed, and ethyl 2-chloroacetamide-3-phenyl-2-pentenoate (**1g**) was obtained as a yellow syrup, which gradually crystallized at room temperature. The crystalline product was collected and recrystallized from ethanol to give yellow needles (38.7%), bp 151—155 °C/1.5 mmHg (mp 103—104 °C). IR (KBr): 3270, 1720, 1680, 1520 cm^{-1}.

a) Measured in $CDCl_3$.

Found: C, 58.44; H, 5.12; N, 5.61%. Calcd for $C_{13}H_{14}NO_3Cl$: C, 58.32; H, 5.23; N, 5.23%.

3-Alkylidene- and Benzylidene-2,5-piperazinediones (2). A solution of **1** (0.1 mol) in ethanol (100 ml) was saturated with dry gaseous ammonia under cooling. When the solution was allowed to stand at room temperature for one day, crystalline substance precipitated. Ethanol was evaporated under reduced pressure and the residual crystals were collected and washed successively with cold water, ethanol, and then ether. Recrystallization from boiling water afforded colorless amorphous.[22]

In a similar manner, cyclization reaction of **1g** with ammonia was performed, and 3-benzylidene-2,5-piperazinedione (**2g**) was obtained as pale yellow prisms (58.8%), mp 279—280 °C(decomp.).[20] IR(KBr): 3200, 3050, 1690, 1620 cm^{-1}.

Found: C, 65.31; H, 4.86; N, 13.81%. Calcd for $C_{11}H_{10}N_2O_2$: C, 65.35; H, 4.95; N, 13.86%.

Acetylation of 2. A suspension of **2** (0.01 mol) in acetic anhydride (6 ml) was heated at 120—130 °C for half an hour, and the resulting solution was allowed to stand at room temperature for 1 hr. The reaction solution was concentrated under reduced pressure to dryness giving a crystalline residue. The crystalline product was collected and recrystallized from ethanol to afford two kinds of crystals, which were separated by chromatography on a silica-gel column by elution with a mixture of benzene and acetone (20 : 1) to give **3** and **4**. The results are summarized in Table 1.

Unsymmetric Unsaturated 3,6-Disubstituted-2,5-piperazinediones (5). a) Condensation of Mixture of 3 and 4 with Arylaldehyde in the Presence of Triethylamine (Procedure A). A mixture of **3** and **4**(*ca.* 3 : 7 ratio, *ca.* 2.4×10^{-3} mol) and the appropriate arylaldehyde (2.4×10^{-3} mol) was heated in the presence of triethylamine (0.12 g) at 120—130 °C for 3 hr. The resulting reddish solid mass was treated with ethanol and filtered. The collected crystals were recrystallized from glacial acetic acid to give the expected condensation product. The results are summarized in Table 2.

b) Condensation of 2 with Aralkyl- or Alkylaldehyde in the Presence of Sodium Acetate (Procedure B). A mixture of **2** (6×10^{-3} mol), the appropriate aldehyde (16×10^{-3} mol), and anhydrous sodium acetate (2.5 g) in acetic anhydride (4 ml) was heated at 120—130 °C for 5 hr and then allowed to stand overnight at room temperature. The mixture was treated with a small quantity of water and ether and filtered. The crystalline product was washed successively with ether and ethanol. Recrystallization from glacial acetic acid afforded the expected condensation product. The results are summarized in Table 3.

The One-Electron Reduction of Carbonium Ions. V. A Kinetic Study on the Reduction of the Substituted Cyclopropenium Ions with Cr(II)[1]

Kunio OKAMOTO, Koichi KOMATSU, and Akira HITOMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received July 13, 1973)

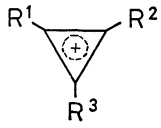
The one-electron reduction of a series of phenyl- and/or *n*-propyl-substituted cyclopropenium ions with Cr(II) has been carried out in a 10% HCl solution. The reduction of triphenylcyclopropenium (Ia), diphenyl-*n*-propylcyclopropenium (Ib), and phenyldi-*n*-propylcyclopropenium (Ic) ions quantitatively gives dimers of the respective cyclopropenyl radicals, *i.e.*, the bis(cyclopropenyl) derivatives, whereas the tri-*n*-propylcyclopropenium ion (Id) is quite unreactive. A kinetic study has shown that the reactivity of these stable carbonium ions toward the one-electron reductant (Cr(II)) is lowered with a decrease in the number of the phenyl substituent: $k_2^{25\,°C}$= 3.0×10^{-4} l/g-ion·s for Ia, 2.7×10^{-6} l/g-ion·s for Ib, 2.8×10^{-9} l/g-ion·s for Ic, and $<10^{-11}$ l/g-ion·s for Id. The added NaCl was found to accelerate the reduction rate of Ia, whereas the added HCl showed an initial rate enhancement effect, followed by a slight rate-retarding effect. A plot of log k_2 against the electron affinities of the respective cations, estimated from the transition energies of the charge-transfer bands for Ia,b with pyrene, has been found to fit a linear correlation previously obtained for a series of tropylium ions. The values of log k_2 also exhibit a linear free-energy relationship with the pK_{R^+} of these cations.

In previous papers of this series[2] we have reported on the reducibility of various substituted tropylium ions with Cr(II). It was demonstrated that log k_2 for the one-electron reduction of the tropylium ions has a linear free-energy relationship with the electron affinity, the polarographic half-wave potential, and also with the pK_{R^+} values; thus, the log k_2 can be regarded as a relative measure for the electron affinity of the carbonium ions in solution. In order to examine the applicability of this method for stable carbonium ions other than the tropylium ions, we have now investigated the chromous-ion reduction of a series of phenyl- and/or *n*-propyl-substituted cyclopropenium ions.

In their systematic studies of the synthesis and stability of substituted cyclopropenium ions,[3] Breslow and his coworkers have reported on the polarographic reduction of some *p*-substituted triphenylcyclopropenium ions[3c] and have interpreted the results on the basis of HMO calculations. They have also reported on the zinc reduction of the triphenylcyclopropenium ion to give its dimer,[3b] but no kinetic study of the one-electron reduction for this series of stable carbonium ions seems to have been carried out. In this paper, the results of the kinetic measurements and their correlation with the electron affinities and pK_{R^+}'s of the cyclopropenium ions will be discussed in comparison with the results[2] previously obtained for a series of substituted tropylium ions.

Results and Discussion

One-Electron Reduction of the Cyclopropenium Ions (Product Study). A series of cyclopropenium ions substituted with a phenyl and/or *n*-propyl group (Ia-d) was prepared according to the method of Breslow *et al.*,[3d,f] except for Ic, which is a new compound and which was synthesized by analogy with the synthesis of Id.[3f]



I

	R_1	R_2	R_3
Ia	Ph	Ph	Ph
Ib	Ph	Ph	*n*-Pr
Ic	Ph	*n*-Pr	*n*-Pr
Id	*n*-Pr	*n*-Pr	*n*-Pr

The reduction of the cyclopropenium ions, Ia-d, with the chromous ion was carried out in 10% HCl (2.9 M) under an atmosphere of nitrogen at an appropriate temperature (Ia : 25 °C, Ib: 75 °C, Ic,d: 125 °C).[4] Ia, Ib, and Ic were found to be reduced with Cr(II) to give dimers in almost quantitative yields, as in the case of the zinc reduction of Ia.[3b] The reduction products of Ia and Ib were purified by thin-layer chromatography and were identified as bis(1,2,3-triphenyl-2-cyclopropen-1-yl) (II) and bis(1,2-diphenyl-3-*n*-propyl-2-cyclopropen-1-yl) (III) respectively. On the other hand, the reduction of Ic with Cr(II) was too slow to give the reduction product in an amount sufficient for the structural analysis. Therefore, Ic was reduced with zinc powder for the purposes of the product analysis. Preparative thin-layer chromatography showed that the product was the same as in the case of the chromous-ion reduction and that it contained bis(1,2-di-*n*-propyl-3-phenyl-2-cyclopropen-1-yl) (IV) and bis(2,3-di-*n*-propyl-1-phenyl-2-cyclopropen-1-yl) (V) in almost equal amounts. The cation, Id, was quite inert to the chromous-ion reduction and gave a trace of an unidentified oil only, after a reaction time of 48 hr at 125 °C.

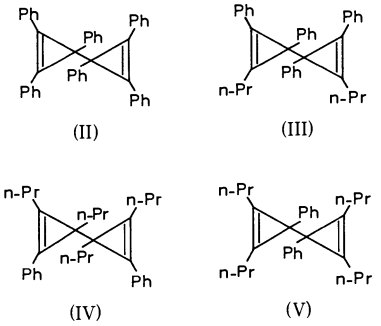
4) A control experiment showed that either the carbonium ion or the chromous ion was stable enough at the respective temperature.



Kinetic Measurements for the Reduction of the Triphenylcyclopropenium Ion with Cr(II). The Effect of the Added Anion. The reactions of the triphenylcyclopropenium ion (Ia) with a large excess of Cr(II) were conducted in 2.9 M HCl under an atmosphere of nitrogen, and the decrease in the unchanged carbonium ion was followed by ultraviolet spectroscopy; in all cases, good first-order behavior was observed. The first-order rate constants thus obtained were proportional to the initial concentrations of Cr(II), as is shown in Fig. 1 for the reactions at 30 °C, indicating that the overall reaction rate can be expressed by the ordinary second-order rate equation: rate$=k_2$[Ia]·[Cr(II)]. The second-order rate constants determined in this way at various temperatures are listed in Table 1. From the Arrhenius plot, the values of an activation energy and an activation entropy were estimated to be 13.9 kcal/mol and −7.1 e.u. at 25 °C.

In a previous mechanistic study,[2b] the chloride ion added either as HCl or NaCl was shown to accelerate the chromous-ion reduction of the tropylium ion, possibly because of the effectiveness of the chloride ion in forming an electron-transfer bridge between the two

reagents. It was observed that this rate-increasing effect gradually reaches its maximum in the anion concentration range of 3—4 g-ion/l; consequently, the reaction was expected to proceed completely by way of the chloride-ion bridging in this concentration range. Therefore, 10% HCl (2.9 M) was chosen as the standard solvent for the previous study on the reduction of the substituted tropylium ions[2c] and also for the present study.

However, the effects of the added HCl and NaCl[5] on the reduction rate of the triphenylcyclopropenium ion characteristically showed different tendencies from each other, as is shown in Fig. 2; addition of NaCl brings about a remarkable rate-enhancement, whereas the increase in the HCl concentration results in an initial rate-enhancement, followed by a slight rate-retarding effect. On the other hand, the effects of the concentration of added HCl and/or NaCl on the solubility (saturation concentration) of the carbonium ion (Fig. 3) exhibit a reversal of the tendency of the reduction rate (Fig. 2). From a comparison of the tendencies shown in Figs. 2 and 3, it may be supposed that undissociated HCl molecules (or $[H\text{-}Cl\text{-}H]^+$ ions), which are predominant at higher HCl concentrations, strongly stabilize or solvate the carbonium ion, thus icreasing the solubility but preventing an attack by Cr(II), whereas the free Cl^- ions from the added NaCl suppress the solubility but facilitate the chromous-ion reduction by means of a ready formation of a Cl^- bridge between the two reagents.

Kinetic Measurements for the Reduction of the Cyclopropenium Ions with Cr(II). The second-order rate constants for the chromous-ion reduction of Ia, Ib, Ic, and Id are listed in Table 2. It is apparent that the substitution of *n*-propyl group for the phenyl group brings about a great suppression in the reactivity of the cyclopropenium ions. This is in accord with the increase in the stability of the cyclopropenium ion by the substitution of the *n*-propyl group, as has already been reported;[3f] this is the same trend as is seen in the reduction of the substituted tropylium ions, although the latter reaction is much more rapid.[2]

Correlation of the Reducibility with the Electron Affinity and with pK_{R^+}. Several examples of charge-transfer (C.T.) interactions between carbonium ions and some aromatic hydrocarbons have been reported,[6] and the relationship between the C. T. transition energy and the electron affinity of the carbonium ion has been discussed.[6c,e,f] We also observed the C.T. band when the cyclopropenium ions, Ia and Ib, were added to a 1,2-dichloroethane solution of pyrene. The values of the electron affinity were estimated from the C.T. transition energies by a method previously reported by Feldman and Winstein,[6e] and the correlation of $\log k_2$ with the electron affinity was examined together with

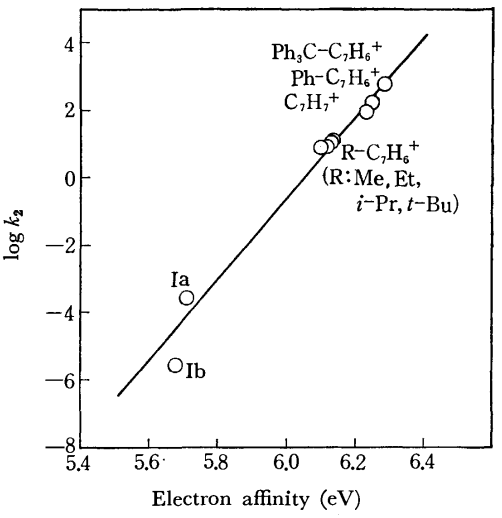

Fig. 4. The correlation of $\log k_2$ with electron affinities of the carbonium ions.

5) Because of the poor solubility of the triphenylcyclopropenium ion in a dilute HCl solution (<1M), the effect of HCl in concentrations of less than 1 M was not examined.

a) The logarithmic value of the rate constant for the chromous-ion reduction of the respective carbonium ion. b) Measured in 1,2-dichloroethane with pyrene as a donor. c) Estimated by the method reported by Feldman and Winstein from the relation, $E_{CT}=[I_p]_{Donor}-[E_{Aff}]_{Acceptor}+Const.$ (Ref. 6e) d) Measured spectrophotometrically in 23% ethanol. e) Determined by potentiometric titration in 50% aq. acetonitrile. f) Data from Ref. 2c.

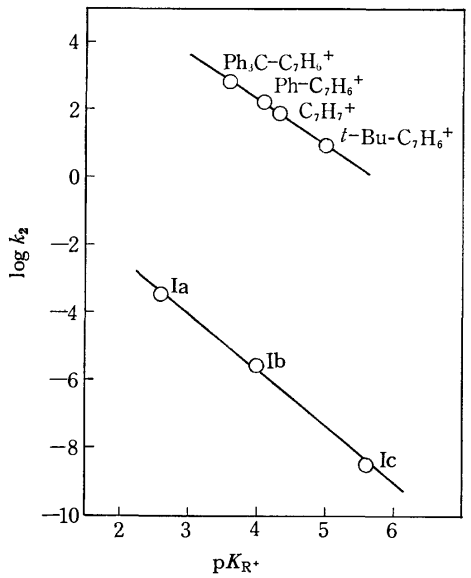

Fig. 5. The correlation of log k_2 with pK_{R^+}.

the cases of substituted tropylium ions. From the results shown in Table 3 and Fig. 4, it may be seen that the linear relationship observed between the chromous-ion reducibility and the electron affinity of the substituted tropylium ion extends also to the cyclopropenium system, suggesting that the reduction of the tropylium and cyclopropenium ions proceeds by a similar mechanism, with the electron-transfer step as the rate-determining one.[7] Thus, it seems that the value of log k_2 for the chromous-ion reduction may be regarded as a chemical criterion for the electron affinity of the stable carbonium ions in solution.

A plot of log k_2 against the pK_{R^+} values measured spectrophotometrically in 23% ethanol[3f] also exhibits a good linear relationship, as is shown in Fig. 5. The straight line thus obtained apparently lies parallel with that obtained in the case of the substituted tropylium ions. From the definition, pK_{R^+} value is represented as the difference between log k_b and log k_f, where k_f denotes the rate constant for the hydrolysis of the carbonium ion, and k_b, that for the reverse reaction.

$$R^+ + H_2O \underset{k_b}{\overset{k_f}{\rightleftharpoons}} ROH + H^+$$

It may be supposed that log k_2 (a measure for the electron affinity) might linearly correlate with log k_f (a measure for the electrophilicity of R^+), but not with k_b (a measure for the nucleophilicity of ROH). This may be one of the reasons for the separation of the plot of log k_2 *vs.* pK_{R^+} into two lines (in Fig. 5); further relevant studies remain to be done before we can account for these tendencies.

Experimental[8]

Materials. All the reagents employed were of a reagent-grade quality except when otherwise noted. Acetonitrile and ethyl acetate were refluxed and distilled over phosphorus pentoxide; acetonitrile, bp, 81.0—81.3 °C; ethyl acetate, bp, 77.0—77.5 °C. Ethyl ether was dried over sodium metal.

7) In view of the effects of the added HCl and NaCl, the reduction of cyclopropenium ions in 2.9 M HCl may not proceed completely by way of Cl^- bridging, and thus the values of k_2 measured in 2.9 M HCl may be rather smaller than those for the complete Cl^- bridging. However, this uncertainty is assumed to be within one unit in the log k_2 scale; therefore, the log k_2-E_{Aff} plot (Fig. 4) may be regarded as still linear, even if we take this uncertainty into consideration.

8) The melting points and boiling points are uncorrected. The microanalyses were performed by the Microanalytical Center, Kyoto University, Kyoto. The infrared and ultraviolet spectra were taken on Shimadzu models IR-27 and UV-50 M spectrometers respectively. The 60 MHz and 100 MHz NMR spectra were obtained with a JEOL model JNM-3H-60 spectrometer and a Varian model HA-100D spectrometer respectively, with tetramethylsilane as the internal standard.

Triphenylcyclopropenium fluoroborate ($Ia \cdot BF_4^-$) was prepared from triphenylcyclopropenyl methyl ether[3a] as follows. Into a solution of 0.964 g (3.23 mmol) of triphenylcyclopropenyl methyl ether in 15 ml of methanol, we added 1.0 ml of 42% aqueous fluoroboric acid. The white precipitates which were immediately formed were collected, washed with dry ethyl ether, and dried under reduced pressure to give 0.925 g (2.62 mmol) of $Ia\text{-}BF_4^-$ as white crystals; 81.1% yield; mp 308—310 °C (dec); $\lambda_{max}^{2.9M\ HCl}$ 259 nm (ε, 18100), 309 nm (64100), 324 nm (54500).

Diphenyl-*n*-propylcyclopropenium fluoroborate ($Ib \cdot BF_4^-$) was prepared following the method of Breslow *et al.*;[3f] mp 175—177 °C (dec) (lit,[3f] mp 179 °C (dec)); $\lambda_{max}^{2.9M\ HCl}$ 246 nm (ε, 15700), 293 nm (33600), 307 nm (34400) (lit,[3f] $\lambda_{max}^{1M\ HCl-23\%\ EtOH}$ 292 nm (ε, 32000), 305 nm (33000)).

Di-*n*-propylphenylcyclopropenium prechlorate ($Ic\text{-}ClO_4^-$) was prepared from the di-*n*-propylcyclopropenium ion[3f] as follows. To a suspension of 1.503 g (6.74 mmol)of di-*n*-propylcyclopropenium perchlorate in 10 ml of dry ethyl ether, we slowly added 20 ml of a 1 M ethereal solution of phenyllithium (20 mmol) with vigorous stirring at −78 °C. The stirring was continued for 1 hr at −78° C and then for an additional hour at room temperature. To the reaction mixture we then added 30 ml of 1M HCl, and the aqueous layer was extracted with three 40-ml portions of ethyl ether. The combined ethereal solution was washed with 10% NaCl and dried over $MgSO_4$. The solvent was removed *in vacuo* to give 1.60 g of a brownish oil which was supposed to be crude 1,2-di-*n*-propyl-3-phenyl-1-cyclopropene. To this oil we then added a solution of 0.769 g (2.25 mmol) of triphenylmethyl perchlorate[9] in 24 ml of acetonitrile, and the whole mixture was left to stand for 30 min at room temperature. The solvent was evaporated under reduced pressure. Then, 10 ml of ethyl acetate and 100 ml of dry ethyl ether were added to the dark-brown residual oil to cause the formation of white precipitates. The precipitates were collected, washed with dry ethyl ether, and dried *in vacuo* to give 0.537 g (1.89 mmol) of $Ic \cdot ClO_4^-$ as white crystals, which can be recrystallized from chloroform-ethyl ether; 80.0% yield, based on triphenylmethyl perchlorate; mp 157.5—158.5 °C (dec); $\lambda_{max}^{2.9M\ HCl}$ 262 nm (ε, 26400); NMR (100 MHz), τ_{CDCl_3} 2.89 (d, 2H, *ortho* protons), 3.10 (t, 1H, *para* proton), 3.25 (t, 2H, *meta* protons), 7.08 (t, 4H, α-methylene protons), 8.23 (sext, 4H, β-methylene protons), 9.07 (t, 6H, methyl protons); ν_{max}^{KBr} 695, 780, 1095, 1440, 1460(sh), 1500, 1600, 2900, 3000 cm^{-1}.

Found: C, 60.26; H, 6.49%. Calcd for $C_{15}H_{19}ClO_4$: C, 60.30; H, 6.41%.

Tri-*n*-propycylopropenium perchlorate ($Id \cdot ClO_4^-$) was prepared according to the method of Breslow *et al.*;[3f] mp 183.5—185 °C (lit,[3f] 184—185 °C)

A solution of chromous chloride in 2.9 M HCl was prepared as previously reported.[2c]

One-Electron Reduction of the Cyclopropenium Ions. Reduction of Ia with Cr(II). In a 200-ml, four-necked flask equipped with a mechanical stirrer, a serum rubber cap, and a nitrogen inlet and outlet, there was charged a solution of 0.105 g (0.295 mmol) of $Ia \cdot BF_4^-$ in 100 ml of 2.9 M HCl. To this solution we then added 20 ml of a 1.17 M solution of chromous chloride in 2.9 M HCl by the use of a hypodermic syringe. The solution was stirred at 25 °C for 21 hr under an atmosphere of nitrogen, and then the organic product was extracted with four 100-ml portions of *n*-hexane, washed with 10% NaCl, and dried over $MgSO_4$. The solvent was subsequently removed *in vacuo* to give 0.0758 g (0.142 mmol) of bis(1,2,3-triphenyl-2-cyclopropen-1-yl) (II) as white crystals; 96.2% yield; mp 223—225 °C (lit.,[3c] mp 225—226 °C); NMR (60 MHz), τ_{CDCl_3} 2.65 (br.s, phenyl protons).

Reduction of Ib with Cr(II). In the same manner, the reduction of 0.131 g (0.409 mmol) of $Ib \cdot BF_4^-$ with 46 mmol of chromous chloride was carried out in 160 ml of 2.9 M HCl at 75 °C for 22 hr under a nitrogen atmosphere. The reaction mixture was worked up in the same way to give 0.0927 g of a crude product, which was then purified by the use of preparative thin-layer chromatography over silica-gel (Merck, Kieselgel PF_{254}), with *n*-hexane–benzene (3 : 1) as the solvent, to give 0.0781 g (0.168 mmol) of bis(1,2-diphenyl-3-*n*-propyl-2-cyclopropen-1-yl) (III) as white crystals; 82.1% yield; mp 152—159 °C (with rapid resolidification[10]); λ_{max}^{EtOH} 267 nm (ε, 16300); ν_{max}^{KBr} 690, 700, 760, 800, 1025, 1090, 1265, 1440, 1495, 1600, 1850, 3000 cm^{-1}; NMR (100 MHz), τ_{CCl_4} 2.78, 2.97 (m and s, 20H, phenyl), 7.30 (t, 4H, α-methylene), 8.30 (sext, 4H, β-methylene), 8.99 (t, 6H, methyl).

Reduction of Ic with Zn and with Cr(II). In a similar manner, 2.0 g (30 mg-atom) of zinc powder was added to a solution of 0.201 g (0.670 mmol) of $Ic \cdot ClO_4^-$ in 85 ml of 0.1 M HCl; the mixture was then magnetically stirred at 20 °C for 5 hr under an atmosphere of nitrogen. Then the unchanged zinc was filtered off and washed with four 50-ml portions of ethyl ether. The aqueous solution was extracted with three 70-ml portions of ethyl ether, and the combined ethereal solution was washed with 10% NaCl, dried over $MgSO_4$, and evaporated to give 0.130 g of a partially-solidified yellowish oil, which gave three main spots (R_f, 0.23, 0.4—0.5, and 0.67) on a silica-gel thin-layer plate, with *n*-hexane–benzene (9 : 1) as the solvent. By the use of preparative thin-layer chromatography, a component with R_f 0.67 was isolated as 0.0512 g of a colorless oil and was identified as bis(1,2-di-*n*-propyl-3-phenyl-2-cyclopropen-1-yl) (IV: 0.129 mmol; 38.5% yield; $\nu_{max}^{CCl_4}$ 695, 1380, 1440, 1460, 1490, 1600, 1830, 2900, 2970, 3000 cm^{-1}; NMR (60 MHz),[11] τ_{CCl_4} 2.70 (s, 10H, phenyl), 7.80 (m, 8H, α-methylene), (m, ~8H, β-methylene), 9.00 (m, ~12H, methyl). In the same way, a component with R_f 0.23 was isolated as 0.0527 g of white crystals and was identified as bis(2,3-di-*n*-propyl-1-phenyl-2-cyclopropen-1-yl) (V); 0.133 mmol; 39.7% yield; mp 26.0—28.0 °C; λ_{max}^{EtOH} 240 nm (ε, 9400), 273 nm (sh) (1100), 280 nm (763); $\nu_{max}^{CCl_4}$ 700, 1380, 1440, 1450, 1460, 1490, 1600, 1870, 2900, 2970, 3000 cm^{-1}; NMR (100 MHz),[12] τ_{CCl_4} 3.00 (s, 10H, phenyl), 7.56 (t, 8H, α-methylene), 8.43 (sext, 8H, β-methylene), 9.04 (t, 12H, methyl). On the other hand, the component with R_f 0.4—0.5 gave 0.0202 g of a pale yellow oil, which exhibited an infrared spectrum quite similar to those of IV and V, though its structure was not fully identified.

For the purpose of comparing the reaction products, a reduction of Ic with Cr(II) was conducted in the following way. To a solution of 0.0164 g (0.0548 mmol) of $Ic \cdot ClO_4^-$ in 8.0 ml of 2.9 M HCl placed in a 20-ml ampoule we added

9) H. J. Dauben, Jr., L. R. Honnen, and K. M. Harmon, *J. Org. Chem.*, **25**, 1442 (1960).

10) This resolidification may indicate a thermal rearrangement of III to a tetraphenyldi-*n*-propylbenzene derivative, as was observed in the case of II,[3b] but no further investigation on the rearranged material was attempted.

11) The chemical shift of the phenyl protons shows that the phenyl group is attached to an olefinic carbon; also the complex multiplicity of the signals of propyl groups seems to indicate the presence of two types of propyl groups with different magnetic environments.

12) The phenyl group has been shown to be attached to a saturated carbon, while the propyl group is supposed to be of only one type for reasons previously presented.[11]

8.0 ml of a 1.3 M solution of chromous chloride in 2.9 M HCl by the use of a hypodermic syringe under a stream of nitrogen. The ampoule was immediately sealed under nitrogen and immersed in an oil bath thermostated at 125 °C. After 20 hr the organic products were extracted with three 20-ml portions of ethyl ether, washed with 10% NaCl, and dried over $MgSO_4$. The evaporation of the ethereal solution under reduced pressure gave 0.0112 g of a partially-solidified, yellowish oil, which was found to contain the same products in the same composition as in the case of the zinc reduction of Ic described above, on the basis of an analysis with thin-layer chromatography.

Attempted Reduction of Id with Cr(II). The reaction of 0.0193 g (0.0730 mmol) of $Id \cdot ClO_4^-$ with the chromous ion (2.64 mg-ion) in 4.0 ml of 2.9 M HCl at 125 °C was attempted in an ampoule in the same way as has been described above. After 48 hr, the solution was worked up in the same way to give 0.0031 g of an unidentified oil. This was shown to contain the same components as in the case of the control experiments in which the cation, Id, alone was kept at 125 °C under the same conditions. The acidic aqueous layer was made alkaline with 10% NaOH, and the turbid solution which resulted was worked up in the usual way to give 0.0093 g of a colorless oil which was tentatively identified as 1,2,3-tri-*n*-propyl-2-propen-1-one on the basis of its infrared spectrum and also by analogy with the alkaline ring opening of Ia giving 1,2,3-triphenyl-2-propen-1-one;[3a] 0.056 mmol; 77% yield; $\nu_{max}^{CCl_4}$ 1380, 1460, 1665, 2900, 2980 cm^{-1}.

Kinetic Measurements. The rates of the reduction of Ia and of Ib were measured in the following way. A solution of a weighed amount of the cyclopropenium salt in 40 ml of 2.9 M HCl was charged in a 100-ml, four-necked flask equipped with a mechanical stirrer, a serum rubber cap, and a nitrogen inlet and outlet. The solution was bubbled with nitrogen for 10 min, while the reaction flask was placed in a thermostated bath. To this solution we then added a known amount (4.0—12.0 ml) of a 1.30 M solution of chromous chloride in 2.9 M HCl by the use of hypodermic syringe, and the solution was stirred under an atmosphere of nitrogen. At appropriate time intervals, 2.00-ml aliquots were sampled out by the use of a hypodermic syringe, extracted with three 5-ml portions of *n*-hexane, and diluted to a 100-fold volume with 2.9 M HCl. The amount of the unchanged cyclopropenium ion was analyzed on the diluted solution by means of ultraviolet spectrophotometry, using 308 nm (ε, 52800) as the characteristic band for Ia and 307 nm (ε, 34400) for Ib. The rate constants were calculated from the first-order rate equation and treated as has been described in text. The initial concentrations of the cyclopropenium ion and of the chromous ion were determined by ultraviolet spectroscopy and by iodometry respectively.

The kinetic measurements of the reduction of Ic were conducted by the use of the sealed-ampoule technique. To 1.0-ml portions of the solution of Ic in 2.9 M HCl placed in ampoules we added 1.0-ml portions of a 1.30 M solution of chromous chloride in 2.9 M HCl under a stream of nitrogen. The ampoules were immediately sealed and immersed in a thermostated bath. At appropriate time intervals the ampoules were opened and the amount of the unchanged cyclopropenium ion was determined spectrophotometrically, using 262 nm (ε, 26400) as the characteristic band; the results were then treated according to the first-order rate equation.

As has been mentioned in the previous section, the cation, Id, was not appreciably reduced with the chromous ion and was recovered in a 77% yield under the given reaction conditions. Even when it is assumed that the unrecovered amount corresponds to the reduction products which might have been decomposed to unidentified materials, a 77% recovery after the reaction time of 48 hr in the presence of 0.66 M of the chromous chloride gives the value of 2.3×10^{-6} $M^{-1} \cdot s^{-1}$ for the upper limit of the apparent second-order rate constant; the real rate constant must be much smaller than this value.

The solubility of $Ia \cdot BF_4^-$ in Aqueous HCl with and without NaCl. In 10-ml test tubes with ground glass stoppers we placed various mixture of 0.010-g portions of $Ia \cdot BF_4^-$ with 2.0-ml portions of either aqueous HCl or aqueous HCl containing NaCl; the mixtures were shaken vigorously for 50 hr at 15—21 °C. Each mixture was then filtered, and amount of Ia dissolved in the filtrate was determined by ultraviolet spectroscopy; the results are shown in Fig. 3.

Measurements of the Charge-Transfer Bands with Pyrene. 1,2-Dichloroethane solutions of the cyclopropenium ion (3×10^{-3} g-ion/l) and of pyrene (2×10^{-3} M) were mixed in the dark[13] to give a slightly orange-colored, yellowish solution, and its visible spectrum was immediately recorded. In the cases of Ia and Ib, a widely-absorbing shoulder, which was not observed in the spectrum of either single component, appeared at the longer wavelength. These new absorptions were supposed to be due to formation of charge-transfer complexes; the values of the wavelength corresponding to the midpoint of the new band are listed in Table 3.

On the other hand, only the end absorption was observed in the region of wavelengths longer than pyrene in the cases of Ic and Id.

Determination of pK_{R^+}*'s.* The pK_{R^+}'s of Ia, Ib, and Ic were determined in 23% aqueous ethanol at 25 °C, as has been described by Breslow and Chang,[3d] by the use of the spectrophotometric method. Because the characteristic bands of the cations were found to decrease during the measurements for Ib and Ic, the absorbancy, which was extrapolated to the time of the dissolution of the cations, was plotted against pH to give classical titration curves, whose inflection points were taken as pK_{R^+}'s. The pH's were read on a Horiba model H pH meter calibrated with standard buffers before use.

The authors wish to thank Mr. Osamu Murai for assistance in the measurements of the charge-transfer spectra.

13) It was observed that the exposure of the mixed solution to room light caused the appearance of new absorption bands at 430 and at 455 nm which seemed to be due to some photochemical reaction products, but the nature of the reaction was not investigated further.

Acidity of Hydrated Sulfates Revealed by the Enolization of Acetone

Ken-ichi TANAKA

Research Institute for Catalysis, Hokkaido University, Sapporo 060

(Received April 10, 1973)

In previous papers,[1,2] an equation for electronegativity of the metal ions was derived by extending Mulliken's electronegativity concept[3] as follows.

$$X_i = \frac{\partial \sum I_j}{\partial Z} = (1+2Z)X_0 \qquad (1)$$

where I_j, is the j-th ionization potential, Z is the valence number of the ion and X_0 is the electronegativity of the metal ($Z=0$) with the Pauling scale. The electronegativity of the metal ions given by Eq. (1) has been found to be a good parameter of the acidity of the metal ions;[1,2,3] the ionization equilibrium (pK_a), $M(H_2O)_m^{\alpha+}+H_2O \leftrightharpoons H_3O^+ + M(H_2O)_{m-1}(OH)^{\alpha-1}$, being represented by

$$pK_a = 20\left(1-\frac{X_i}{14}\right) \qquad (2)$$

and the zero point of charge (ZPC) of the immersed oxides in water being formulated as follows.

$$ZPC = 16.8\left(1-\frac{X_i}{22}\right) \qquad (3)$$

The catalytic activities of the sulfates for reactions such as hydration of propylene, dehydration of formic acid and polymerization of acetaldehyde are well correlated with the electronegativity of the metal ions.[2,4]

In this paper, the enolization of acetone is adopted as a monitor of the acidity of the hydrated sulfates, which has been found to be subject to general acid catalysis in homogeneous catalysis.

Experimental

A flow system with nitrogen carrier gas was employed. The carrier gas was bubbled through evaporating chambers of acetone (spectro grade) and of D_2O (99.8%), the total flow rate being kept at 72 ml/min for all experiments. The temperature of the acetone chamber was kept at 9.5 °C, and the concentration of acetone vaporized into the carrier was 1.3_1 vol% as determined by gas chromatographic analysis. The content of D_2O in the carrier gas was controlled by adjusting the temperature of the D_2O chamber. The concentration of D_2O was previously calibrated by measuring the weight increase of silica gel adsorbent when the carrier gas was passed through the silica-gel bed for a given time. All experiments other than those for the determination of D_2O pressure dependence were carried out with a constant D_2O concentration of 1.6_5 vol%.

The sulfates of 0.13 g (Fe^{3+}, Al^{3+}, Cr^{3+}, Cu^{2+}, Ni^{2+}, Zn^{2+}, and Mg^{2+}) were used without any supporting materials by treating at 140 °C for 4—5 hr in air and ground. The carrier gas containing D_2O and acetone was made to flow over the catalyst bed for about 30 min to reach a steady state, and then an acetone sample for the mass spectrometric analysis was collected at the outlet of the reactor by a liquid nitrogen trap. Analysis was carried out by using parent peaks at 10 eV with the correction of the natural abundance of ^{13}C.

The surface areas of the sulfates were measured by the BET method after they had been heated at 140 °C for 3 hr in air and evacuated at room temperature. The contact time of the reactant through the catalyst bed was estimated from the retention volume of the sulfates packed in a gas chromatographic column. The relative catalytic activity k_r was obtained by normalizing the reaction rate with surface area S and contact time t for each of the sulfates; $k_r = -2.303/St \cdot \log (d_0/d_0^0)$, in which d_0^0 and d_0 are the fraction of acetone-d_0 of the initial and of the trapped samples.

The isotope effect on the enolization of acetone was studied with acetone-d_6(99.5%) and H_2O over a nickel sulfate under the same experimental conditions as mentioned above.

Results and Discussion

A typical deuterium distribution of acetone obtained over a nickel sulfate is given in Table 1, the deuterium distribution obtained on the other sulfates being similar to that on the nickel sulfate. The deuterium distribution reveals that the hydrogen exchange of acetone proceeds consecutively, *viz.*, the desorption and adsorption of acetone are rapid as compared with the exchange reaction rate. When the deuteration of acetone proceeds with the consecutive exchange of d_0 to d_1, d_1 to d_2, *etc.*, the values of d_1 can be calculated by assuming that the second step ($d_1 \rightarrow d_2$) is 5/6 of the first step ($d_0 \rightarrow d_1$); $d_1 = (e^{-k_1 t} - e^{-k_0 t})/(1 - k_1/k_0)$, where $k_1/k_0 = 5/6$. However, the calculated values are larger than the experimental values (Table 1) by factors of 1.2 at 98 and 110 °C, at 121 °C and 1.5 at 130 °C. The fact that the experimental value of d_1 is smaller than the calculated value may be due to partly occurring multiple exchange of adsorbed acetone.

The effect of D_2O pressures on the deuteration of acetone studied over nickel sulfate by changing D_2O

pressures from 3.2 to 14.7 mmHg is shown in Fig. 1.

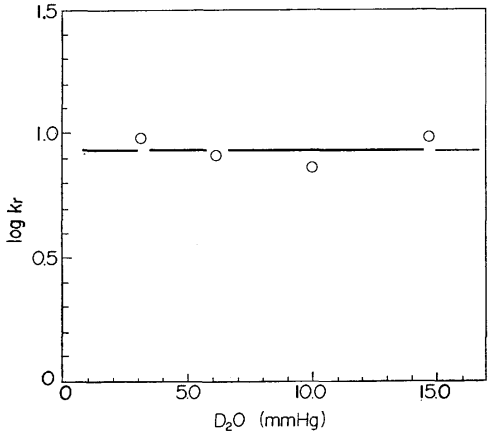

Fig. 1. D_2O pressure effect on the deuteration of acetone over a nickel sulfate at 98 °C.

It is seen that D_2O pressure has little influence on the hydrogen exchange rate between acetone and D_2O. This shows that the surface of the sulfate is covered with D_2O during exchange reaction, which is consistent by comparing with the temperature of the monohydrated nickel sulfate formation, 150 °C.[5]

It has been established that the enolization of acetone is subject to general acid catalysis in solutions with the rate-determining step of deprotonation of α-C–H.[7] If the enolization of acetone over the sulfates occurs with the same slow step, a large kinetic isotope effect is expected when α-C–H is replaced by α-C–D. For the sake of confirmation, the exchange reaction between acetone-d_6 and H_2O was carried out on a nickel sulfate under the same conditions; a flowr ate of 72 ml/min of carrier gas containing 1.3_1 vol.% of acetone-d_6 and 1.6_5 vol.% of H_2O. The exchange reaction between ordinary acetone and D_2O, denoted by Ni(H) in Fig. 2, is much faster than that between acetone-d_6 and H_2O, Ni(D), with $k_H/k_D \simeq 2.7$ at 100 °C. This supports a rapid prototation forming $(CH_3)_2COD^+$ followed by a slow deprotonation of α-C–H. With the increase of the acidity of H_2O or D_2O hydrated over the sulfates, the pre-equilibrium shifts to the protonated form causing an increase in the exchange reaction rate.

The deuteration of acetone carried out over the various sulfates is shown in Fig. 2, in which the ordinate is the logarithm of the relative catalytic activity (k_r). The activity sequence of the sulfates is in the order of $Fe^{3+}>Al^{3+}>Cr^{3+}>Cu^{2+}>Ni^{2+}>Zn^{2+}>Mg^{2+}$.

It has been shown that the proton activity of water hydrated over the oxides as well as the water hydrated around the metal ions is well correlated with the parameter X_i in the form of Eqs. (2) and (3). These relations reveal that the proton activity of the water hydrated over the sulfates may also be expressed by a similar equation of logarithmic form. Figure 3 shows the relation between the catalytic activities of the sulfates at a given temperature, indicated by a

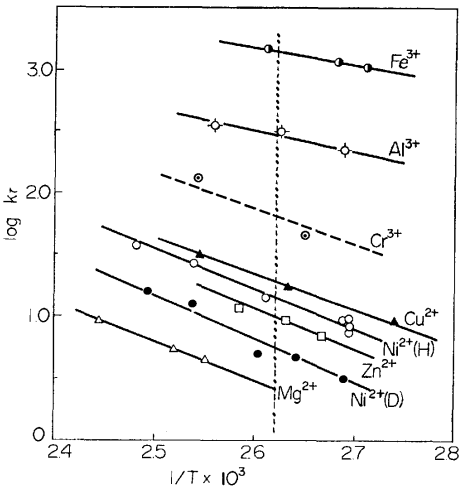

Fig. 2. Relative catalytic activities of the sulfates. Ni(D) is the reaction of acetone-d_6 with H_2O.

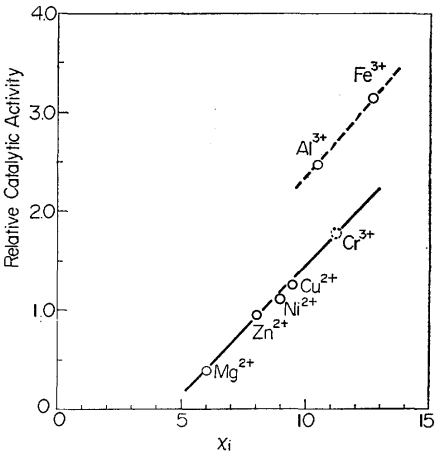

Fig. 3. Relation between the catalytic activity of the sulfate and the electronegativity of the metal ion.

dotted line in Fig. 2, and the electronegativity of the metal ion. It is seen that the logarithm of the catalytic activities increases linearly with X_i as expected, but the activities are separated in the two groups, divalent sulfates and trivalent sulfates, in which the values for Cr^{3+} are much obscure because of its small surface area and the low apparent activity. It should be noted that the apparent activation energies over the trivalent sulfates are approximately half of those over the divalent sulfates.

It may be concluded that the acidity of the hydrated sulfates is well expressed by using the electronegativity of the metal ions on which water hydrates or adsorbs. The acidity discussed here apparently differs from that observed by Tanabe and his co-workers,[6] which strongly depends on the dehydration temperatures of the sulfates attaining maximum acidity and catalytic activity just before reaching the anhydrous state.

The Solubilities, Critical Micelle Concentrations, and Krafft Points of Bivalent Metal Alkyl Sulfates

Masakatsu HATŌ and Kōzō SHINODA*

Research Institute for Polymers and Textiles, Sawatari-4, Kanagawa-ku, Yokohama 221

** Department of Chemistry, Faculty of Engineering, Yokohama National University, Ooka-2 Minami-ku, Yokohama 233*

(Received June 29, 1973)

According to the phase separation model (as well as the mass action model) for a micellar solution,[1] a Krafft point is interpreted as a triple point at which a solid hydrated surfactant, micelles (a liquid state), and a singly-dispersed surfactant are in equilibrium with each other. If so, the CMC values should be smaller than the solubility values above the Krafft point, equal at the Krafft point, while the solubility values should be smaller than the CMC values below the Krafft point. These relations hold for 1–1 ionic surfactants in either the absence or the presence of added salts.[1,2]

Miyamoto[3] has determined the solubilities and CMC's of several bivalent metal dodecyl sulfates. The CMC values of lead, cupric, and manganese dodecyl sulfates he obtained differ considerably from the solubility values at the Krafft points, whereas those of the other metal dodecyl sulfates agree within *ca.* 20%. This raises a serious question as to whether or not the triple point model holds for bivalent metal salts of ionic surfactants. In the present paper, the solubilities, the CMC's, and the Krafft points of various bivalent metal alkyl sulfates will be studied in order to confirm our model.

Experimental

The bivalent metal dodecyl and tetradecyl sulfates have been prepared by adding an aqueous solution of a respective metal chloride to aqueous solutions of sodium dodecyl and tetradecyl sulfates. Extremely pure sodium dodecyl sulfates (C_{12}>99.9%, and no minimum in the surface tension *vs.* concentration curve) and sodium tetradecyl sulfates (C_{12}=0.2%, C_{14}=99.3%, C_{16}=0.5%) were obtained from the Kao Soap Co. through the kindness of Dr. Arai. The metal chlorides were of an extra-pure grade and were used without further purification. The products were recrystallized 4 or 5 times from water and then washed with petroleum ether for 20 hr. No sodium ion was detected by a flame test. It is found from elementary analysis that all the compounds have two surface active anions in each molecule.

The solubility was determined by electrical conductivity measurements. The solutions were stirred for 4—5 hrs in a thermostat controlled within 0.02 °C. Further stirring caused no change in the solubility. The procedures were described in detail in a preceding paper.[4] The solubility was also determined by weighing the dried solution. The two measurements agreed with each other within an error of 1%. The CMC was determined either by conductivity measurements or by a dye method[5] (not by a dye titration method which gives a smaller CMC value, but by observing the color change in a series of solutions of different concentrations after an equilibrium had been reached). The two measurements agreed well with each other.

Results and Discussion

Figure 1 shows the solubilities and the CMC's of bivalent metal dodecyl and tetradecyl sulfates as a unction of the temperature. The supercooled micelles of cupric and manganese salts were fairly stable, the CMC values below the Krafft points were also determined. The solubility data on cupric dodecyl sulfate were less accurate (±3%) than the others (±0.5%) because of the low Krafft point. The concentration was expressed in terms of a molality based on the anhydrous surfactant. It is found from Figure 1 that the solubility increases abruptly at a definite temperature, just as those of 1–1 ionic surfactants do,[1,2] this temperature is the Krafft point above which the micelles are formed. The Krafft points determined from Fig. 1 have been listed in Table 1, together with the CMC values at the Krafft points. The data obtained by Miyamoto[3] and Schwuger[6] are also listed. The CMC values determined by surface tension measurements[3,6] or by conductivity measurements[7] agree well with the present results. It is clear from Figure 1 that the

a) Ref. 3. b) Ref. 6. c) Moles of anhydrous salts/10^3 g of H_2O, the values from references 3 and 6 are expressed in mol/l. d) A value estimated from the solubilities of 0.5 and 1 wt% aqueous solutions.

CMC and solubility curves of all the compounds examined intersect exactly at the Krafft point, and that the CMC values of supercooled micelles are larger than the corresponding solubility values. This is in accord with the model.[1] No anomalous behavior has been observed in the cases of cupric and lead dodecyl sulfates. Similar results have been obtained in the case of fluorinated surfactants, $C_9F_{19}SO_3l/2Mg2H_2O$.[4,8] From the foregoing discussion, the heats of fusion, ΔH_f (from a hydrated solid to a micellar state), of the bivalent metal alkyl sulfates can be calculated from the temperature dependence of the solubility or CMC by the aid of the following equations[9] (the values are listed in Table 1),

$$\Delta H_f = \Delta H_s + \Delta H_m \quad (1)$$

$$\Delta H_s = 3RT^2(\partial \ln C_2/\partial T) \quad (2)$$

$$\Delta H_m = -(2+K_g)RT^2(\partial \ln CMC/\partial T) \quad (3)$$

where ΔH_s is the heat of solution of a hydrated solid agent; ΔH_m, the heat of micelle formation; C_2, the solubility, and K_g the experimental constant. K_g is 0.57_2 for calcium dodecyl sulfate[10] and is assumed to be 0.57_2 for the other surfactants. As these hydrated solids have a vapor pressure very close to that of pure water, the anhydrous solid was equilibrated with an aqueous solution of potassium chloride (0.001 mol/l and $P/P^\circ > 0.997$) in order to determine the number of hydrated water at 26.5±0.3 °C. Calcium dodecyl and tetradecyl sulfates were found not to take up the water of hydration. After a lapse of 5 days (for manganese tetradecyl sulfate) or of 20 days (for cupric tetradecyl sulfate), the salts come to a constant weight, giving a value of 6±0.4 H_2O. The lower Krafft point of manganese (or cupric) tetradecyl sulfate than that of calcium tetradecyl sulfate may result from the larger entropy of fusion of the former, which is partly attributable to the entropy change in hydrated water.

Infrared Spectra of Deoxyribonucleic Acids with Different Base Compositions in Their D_2O Solutions

Yoshifumi NISHIMURA, Kosuke MORIKAWA, and Masamichi TSUBOI
Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received September 14, 1973)

In this note we present the result of our examination of the infrared absorption spectra of six DNA's with different guanine+cytosine (GC) contents in their heavy water solutions in the spectral region of 1750—1480 cm^{-1}. A similar examination was once made by Fritzsche[1] with deuterated DNA *films*, and he found that the relative intensity of the absorption bands at 1485 and 1505 cm^{-1} depends on the guanine+cytosine (GC) content of the deuterated DNA samples. In our study in D_2O *solution*, on the other hand, a number of bands characteristic of the guanine-cytosine (G–C) and adenine–thymine (A–T) base-pairs are found in the 1700—1550 cm^{-1} region as shown below.

TABLE 1. DNA SAMPLES USED IN THE PRESENT WORK

Source	GC content (%)
Tetrahymena pyriformis GL	25[a]
Clostridium perfringens	31[b]
Calf thymus	43[b]
Escherichia coli	51[b]
Pseudomonas aeruginosa	65[c]
Micrococcus lysodeikticus	72[b]

a) Estimated from the melting temperature (61.8 °C in 0.015 M NaCl+0.0015 M Na-citrate) and buoyant density in a CsCl density gradient centrifugation (1.686, as given by R. A. Flavell and I. G. Jones, *Biochem. J.*, **116**, 811 (1970).
b) S. Ulitzur, *Biochim. Biophys. Acta*, **272**, 1 (1972).
c) N. Sueoka and T. Y. Cheng, *J. Mol. Biol.*, **4**, 161 (1962).

The DNA samples used in the present study are listed in Table 1. Preparation of DNA from *Tetrahymena pyriformis* was made according to the method described by Allen and Gibson.[2] The cells were kindly provided by Dr. Takashi Mita, National Cancer Center Research Institute. Lysis was effected by adding 10% sodium lauryl sulfate, and within 1 min phenol was added. After treatments with ribonuclease A (Sigma Chemical Co., 50 μg/ml, at 37 °C, for 30 min), with pronase E (Kaken Chemical Co., 1 mg/ml, at 37 °C, for 1 hr), and with α-amylase (Boehringer-Mannheim 50 μg/ml), DNA was precipitated with 2-propanol. DNA samples from *Clostridium perfringens* and Calf thymus were purchased from Miles Laboratories, Inc. DNA preparation from *Escherichia coli*, *Pseudomonas aeruginosa* (kindly provided by Dr. Toshio Ando, The Institute of Medical Science, University of Tokyo), and *Micrococcus lysodeikticus* was made, according to Marmur,[3] by lysing the micro-organism with sodium lauryl sulfate, followed by a shaking with chloroform–isoamyl alcohol, precipitation with ethanol, treatment with ribonuclease A (Sigma Chemical Co., 50 μg/ml, at 37 °C, 30 min), and again precipitation with ethanol.

The purities of the DNA samples were judged by the ultraviolet absorption curves and the optical melting profiles (*i.e.*, the melting temperatures T_m and the amounts of hyperchromicity). The phenol extraction, protease treatment, and ribonuclease treatment were repeated until a proper set of values of T_m and hyperchromicity was reached. To remove disturbing anions the DNA solution was dialyzed against 10^{-3} M Tris buffer+10^{-3} M NaCl and lyophilized.

For infrared absorption measurement, concentrated D_2O solution (about 1.5%) was prepared. The solvent used was Tris buffer (pD≒7). To promote the rate of dissolving of DNA into D_2O, sonication with UMEDA 20 kcycle/s (150 W) was applied for 10 min. It was confirmed that this procedure does not pracitcally affect the ultraviolet and infrared absorption spectra of the DNA solution. The solution was placed in a cell with CaF_2 windows and optical path 50 μ. A Perkin-Elmer 621 infrared spectrophotometer was

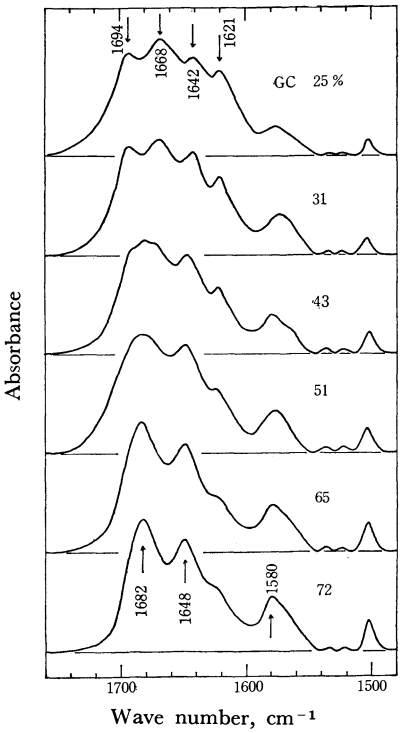

Fig. 1. Infrared absorption curves of DNA's in D_2O solutions at about 40 °C. From the top: DNA's from *Tetrahymena* (GC 25%), *C. perfringens* (31%), Calf thymus (43%), *E. coli* (51%), *P. aeruginosa* (65%), and *M. lysodeikticus* (72%).

used for the absorption measurement.

The observed infrared absorption curves are shown in Fig. 1. As may be seen in the figure, the absorption peaks at 1621, 1642, 1668, and 1694 cm^{-1} become more prominent on lowering the GC content, while those at 1580, 1648, and 1682 cm^{-1} become more prominent as the GC content becomes higher. In fact, after a proper adjustment of the absorbance scale in each absorption curve, the absorbance at each of these frequencies is found to have an almost linear relation with the GC content (see Fig. 2). This fact indicates that the A–T base-pairs (or the G–C base-pairs) in all of these DNA structures are in a similar environment to one another in an average. The vertical stacking interactions between the base-pairs in a double-helical polynucleotide structure should certainly affect the infrared absorptions of the base-pairs,[4,5] but this is not clearly detected in our present examination of DNA's in the range of GC content 25—72%.

The effect of the vertical stacking interaction becomes apparent when the examination is extended to the range of the GC content 0% or 100%. In Fig. 3, infrared absorption curves of a hypothetical A–T base-pair and a hypothetical G–C base-pair are shown which are obtained by an extrapolation of absorbance *versus* GC content relations illustrated in Fig. 2. These are appreciably different from actually observed spectra of A–T and G–C base-pairs, respectively. Thus, the spectrum of the hypothetical A-T pair placed in an average environment of natural DNA's is different from the spectrum actually observed of the A–T pair in poly(dA–dT)–poly(dA–dT), *i. e.*, the double-helical complex containing strands of alternating deoxyribo-adenylate and deoxyribothymidylate residues (purchased from Miles Laboratories, Inc). In the latter structure every A–T pair is considered to be always sandwiched by two T–A pairs. The spectrum of the hypothetical G–C pair placed in an average environment of natural DNA's is also different from the spectrum actually observed[6] of the G–C pair in poly(rG)–poly(rC), the double-helical complex of riboguanylate and ribocytidylate homopolymers. This difference should be attributed not only to the difference in the base-sequence but also to the difference between the DNA B structure[7] and the double-helical RNA structure.[8]

Chemical Studies of Minerals Containing Rarer Elements from Far East District.[1] LXVI. Cookeite from Nagatare, Fukuoka Prefecture, Japan

Kin-ichi SAKURAI, Akira KATO, Kikuo MIYOKAWA,* and Kozo NAGASHIMA*

Department of Geology, National Science Museum, Ueno Park, Tokyo 110

** Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Tokyo 112*

(Received May 23, 1973)

Granite pegmatite dikes exposed at Nagatare, Fukuoka Prefecture, are famous for the occurrence of lepidolite,[2] petalite,[3] amblygonite-montebrasite series minerals,[4] and pollucite,[1] the last three being unique occurrences in Japan. Hand specimen of a white or pink mass collected from the dump derived from one of the pegmatite dikes turned out to be the first cookeite in Japan, though contaminated by quartz. This note describes the results of X-ray, chemical and optical studies.

The analyzed material is a part of a light pink mass over 5 cm across and 150 grams in weight. The mass is composed of the aggregate of larger quartz grains and mixture cookeite flakes with minor lepidolite, which is variable in amount.

X-Ray powder data coincide well with known ones[5] (Table 1), the calculated lattice constants being a_0= 5.188 Å, b_0=9.077 Å, c_0=14.278 Å (all±0.003 Å), and β=97.8±0.1°.

a) Recalculated after deducing quartz.

Chemical analysis, the results of which are given in Table 2 was carried out on the material contaminated by quartz which can not be removed by heavy liquids, suggesting the specific gravity to be neary equal in each, *i.e.* about 2.7. The procedure of chemical analysis was as follows: Li_2O—atomic absorption analysis; Na_2O and K_2O—flame photometry; SiO_2, Al_2O_3 and H_2O—gravimetry; Fe_2O_3—spectrophotometry; F—volumetry. Boron, though too low to be determined colorimetrically, was detected by emission spectrographic analysis. The present cookeite is specified due to its higher fluorine content as well as the relation K >Na in mole ratio.

The crystallochemical formula calculated from the analytical data based on O=10 for the layered part and (OH, F)=8 for the interlayering one is $[(Al_{1.995}Fe_{0.005})(OH_{1.916}F_{0.084})Al_{0.958}Si_{3.042}O_{10}]^{-0.958}[(Li_{1.369}K_{0.030}Na_{0.013}Al_{1.849})(OH_{5.746}F_{0.254})]^{+0.959}$ satisfying the crystallochemical formula by Cerny.[6]

It is optically biaxial negative, 2V is very small, refractive indices are α=1.560, $\beta \fallingdotseq \gamma$=1.591, $\gamma-\alpha$= 0.031; colorless in thin section. The pink color in the hand specimen may be due to the presence of manganese as surmised by Kanaoka and Kato.[7]

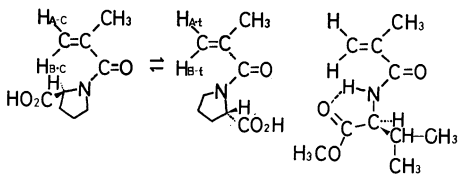
Conformation of Methacryloyl-L-proline

Koji NISHIHARA, Hisao NISHIHARA, and Naokazu SAKOTA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Bunkyo-cho, Matsuyama 790

(Received April 16, 1973)

Many conformational studies have been made on the hindered internal rotation about amide bonds since the first investigation by Pauling.[1] However, very few investigations have been reported on that of α,β-unsaturated acid amide except for the work by Rogers and Woodbrey.[2] They determined the activation free energy for the hindered internal rotation about the amide bond of N,N-dimethylacrylamide to be 16.1 kcal/mol at 25.2 °C. The alternating photocopolymerization of methacryloyl-L-valine methyl ester (MAVM) with maleic anhydride suggested that the amide compounds has a specific planar conformation.[3] For the purpose of elucidating the participation of the amide proton in this specific conformation, we synthesized methacryloyl-L-proline (MAP) and examined the effect of the temperature on its NMR and CD spectra. The results indicate that the following two isomeric



cis *trans*

MAP MAVM

Fig. 1. Conformations of MAP and MAVM.

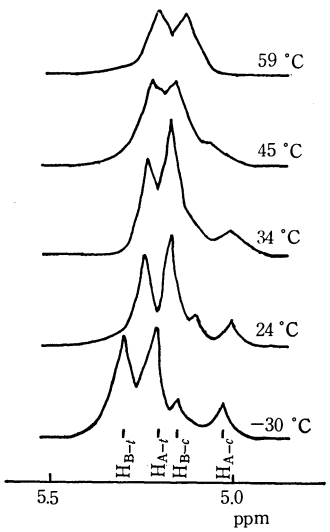


Fig. 2. The NMR spectra assigned to the vinyl protons of MAP from HMDS at 100 MHz in $CDCl_3$.

MAP, *cis* and *trans* conformers exist at lower temperature.

Temperature dependence of the NMR signals assigned to the vinyl protons of MAP is shown in Fig. 2. The four signals at −30 °C are seen to decrease to the two signals with the rise in temperature. The results suggest the coexistence of the rotational isomers. H_A and H_B of the *cis* and *trans* isomers were assigned on the basis of the study by Bovey *et al.* on polysarcosine.[4] In deutero methanol and dimethyl sulfoxide-d_6, the vinyl protons gave a similar NMR pattern to that in $CDCl_3$. For example, in deutero methanol at −50 °C, they gave four resonance peaks at 5.09, 5.21, 5.28, and 5.36 ppm assigned to H_{A-c}, H_{B-c}, H_{A-t} and H_{B-t} respectively, and at 42 °C they gave only three peaks at 5.06, 5.20, and 5.26 ppm assigned to H_{A-c}, an overlapped signal of H_{B-c} and H_{A-t}, and H_{B-t} respectively.

The activation free energy ($\Delta F^{\neq}_{T_c=318}$) for the transformation between the two isomers of MAP was calculated to be 16.4±0.2 kcal/mol from the NMR data in deutero chloroform by the equation

$$\Delta F_{Tc}^{\neq} = 2.303RT_c \log \frac{\sqrt{2}\kappa k T_c}{\pi \Delta \nu h} \qquad (1)$$

where T_c is the coalescence temperature, and $\Delta\nu$ is the difference between the chemical shifts of the two isomers. Transmission coefficient κ was assumed to be unity. The enthalpy change for the *cis–trans* transformation was calculated to be −1.5±0.2 kcal/mol by the temperature dependence of the equilibrium constant (K) in Table 1, where K values obtained from the *cis–trans* area ratio of NMR spectra were used.

Figure 3 indicates the positive CD maximum of L-proline at 219 nm, and the negative CD maximum at 227 nm with a shoulder at about 246 nm for MAP

Table 1. Equilibrium constants for the *cis–trans* transformation between the two isomers of MAP ($CDCl_3$)

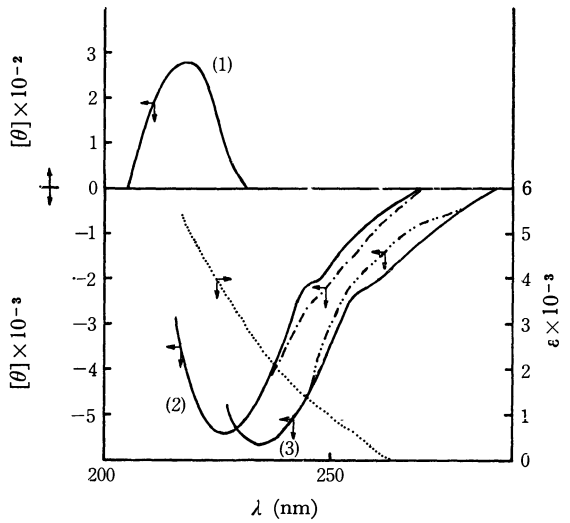

Fig. 3. The UV spectrum of MAP in methanol at 25 °C (……) and the CD spectra of L-proline and MAP.
(1) The CD spectrum of L-proline in methanol at 25 °C.
(2) The CD spectra of MAP in methanol at 25 °C (——) and −50°C (—·—).
(3) The CD spectra of MAP in dioxane at 25°C (——) and 52°C (—··—).

in methanol at 25 °C. The negative CD maximum of MAP is presumably associated with the n→π* transition of the methacryloyl amide group. The CD spectra of MAP measured at 52 °C in dioxane and at −50 °C in methanol differ from those obtained at 25 °C in the corresponding solvents. The difference in the CD curve near the shoulder of absorption might be ascribed to the coexistence of the two different conformations of MAP.

Experimental

MAP was prepared by the reaction of methacryloyl chloride with L-proline according to the method of Sakota.[5] mp 103.0—104.5°C; $[\alpha]_D^{29}$ −79.2 ($c=1$, methanol).

NMR spectra were recorded with a JEOL Model JNM-4H-100 Spectrometer operating at 100 MHz. CD spectra were measured with a Jasco Model ORD/UV 5 Spectropolarimeter. UV spectrum was measured with a Shimadzu Double Beam Spectrophotometer UV-200.

Oxosulfonium Salts. III. Methylation of Optically Active Sulfoxides.[1]

Kenji KAMIYAMA, Hiroshi MINATO, and Michio KOBAYASHI

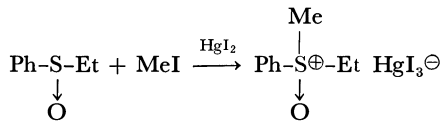
Department of Chemistry, Faculty of Science, Tokyo Metropolitan Universisy, Fukazawa, Setagaya, Tokyo 158

(Received, May 8, 1973)

A report was previously given on the synthesis, optical resolution and determination of absolute configuration of ethylmethylphenyloxosulfonium perchlorate.[2] The oxosulfonium salt was prepared by methylation of racemic sulfoxide followed by optical resolution. Since optically active sulfoxides can be prepared by the reaction of the optically active menthyl sulfinates with the Grignard reagents, methylation of such sulfoxides seems to be an attractive route for the synthesis of optically active oxosulfonium ions. Methylation of optically active ethyl phenyl sulfoxide was therefore investigated.

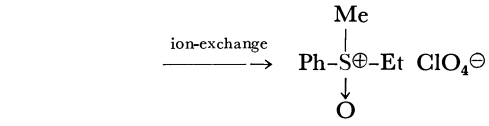
R-(+)-Ethyl phenyl sulfoxide ($[\alpha]_D^{24}=+176.2°$) [I], prepared from (−)-menthyl benzenesulfinate, was refluxed in excess methyl iodide in the presence of mercury (II) iodide (1/3 mol per mol I) under a nitrogen atmosphere for 63 hr. When unchanged I and methyl iodide were removed by extraction with ether and the remaining crystals were recrystallized from methanol, ethylmethylphenyloxosulfonium mercuritriiodide [II] was obtained in 27.7% yield (based on the moles of HgI_2 used).

Since its specific rotation was very small, II was converted into perchlorate by use of an ion-exchange resin column; $[\alpha]_D^{22}=+9.8°$ ($c=2.2$, acetone); optical purity, 72%.[3]



[I] [II]

$[\alpha]_D^{24}=+176.2°$



[III]

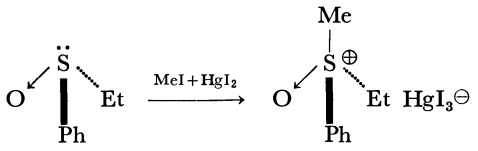
The dextrorotatory III should have an *R*-configuration, since it was established that (+)-III obtained by optical resolution has this configuration.[2] This shows that alkylation of sulfoxides proceeds with retention of configuration.

1) Organic Sulfur Compounds, Part XLIV.

2) M. Kobayashi, K. Kamiyama, H. Minato, Y. Oishi, Y. Takada, and Y. Hattori, *Chem. Commun.*, **1971**, 1577.

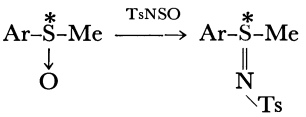
3) Optically active II was found not to racemize under the reaction conditions. Therefore, the low optical purity observed is probably due to the racemization of the sulfoxide during the reaction (*cf.* the following work by Modena *et al.*).

4) G. Modena, U. Quintly, and G. Scorrano, *J. Amer. Chem. Soc.*, **94**, 202 (1972); K. Mislow, T. Simmons, J. T. Melillo, and A. L. Ternay, Jr., *ibid.*, **86**, 1452 (1964).

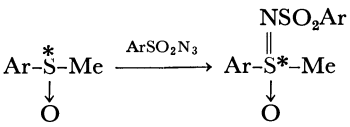


The reaction among, I, methyl iodide, and mercury(II) iodide is rather complex and the yield of II is often very small unless the reaction conditions are carefully controlled. Products other than II were ethylmethylphenylsulfonium salt, dimethyl ether, and iodine.

Conversion of optically active sulfoxides into sulfilimines was found to proceed with retention of configuration.[5]



Another example of reactions proceeding with retention of configuration is the formation of sulfoximines from sulfoxides.[6]



The conversion of I into II is unique in that a sulfur–carbon bond is formed with retention of configuration without breaking any bond in the sulfoxides. Since optically active sulfoxides are readily available from (−)-menthyl sulfinates, this method is better for formation of optically active oxosulfonium ions in comparison with the optical resolution of racemic oxosulfonium ions.[2]

Experimental

(+)-Ethyl Phenyl Sulfoxide [I]. Benzenesulfinic acid and (−)-menthol were condensed by dicyclohexylcarbodiimide in dichloromethane,[7] and the diastereomeric mixture of menthyl sulfinates formed was separated by recrystallization; one diastereomer crystallized more readily. The crystalline diastereomer was allowed to react with ethylmagnesium iodide, and (+)-I was obtained;[8] bp, 92—94 °C/2 mmHg; IR, 1050 cm^{-1} (ν_{S-O}); $[\alpha]_D^{24}=+176.2°$ ($c=1.03$, acetone); optical purity, 94% (176.2/187.5×100).

Methylation of I. After a mixture of mercury(II) iodide (1.20 g, 2.64 mmol) and methyl iodide (5 ml) was stirred for 40 min under nitrogen, (+)-II (0.968 g, 6.27 mmol) was added, and the mixture was refluxed for 63 hr. Evaporation of methyl iodide under reduced pressure gave a brown oil, which was converted into crude crystals by washing out the remaining I with ether. They were recrystallized twice from methanol, and pure II was obtained; yield, 0.547 g (11.6%) (27.7% based on HgI_2); mp 69.5—70.5 °C; IR, 1210, 1240 cm^{-1}; NMR, δ, 1.55(3H, t), δ, 4.39 (3H, s), δ, 4.54 (2H, q), δ, 8.10 (5H, m).

Conversion of I to II. A small amount of an acetone–water (5 : 1) solution of I (0.520 g) was added to an anion-exchange column (Amberlite IRA 400) which had been adjusted to ClO_4^- type. Elution with acetone–water (1 : 1) and evaporation of the eluate (150 ml) gave an oil, which crystallized upon addition of ethanol. Recrystallization was repeated twice, and the pure II amounted to 0.150 g (80.7%); mp, 70.5—72.0 °C; $[\alpha]_D^{22}=+9.8°$ ($c=2.2$, acetone); optical yield 72.1%; IR, 1240, 1210, 1100 cm^{-1}; Found: C, 40.77; H, 4.98. Calcd for $C_9H_{13}SO_5Cl$: C, 40.23; H, 4.88.

The Dimerization of Thymine Glycol and the Splitting of the Dimer by γ-Irradiation in an Aqueous System

Tateki HAYASHI, Osamu OGISO, and Mitsuo NAMIKI

Department of Food Science and Technology, Faculty of Agriculture, Nagoya University, Chikusa-ku, Nagoya 464

(Received June 11, 1973)

It has been known that the radiolysis of thymine in an aqueous system provides thymine glycol as the main radiolysis product in either the presence[1] or absence of air.[2] In our studies of the radiation chemistry of nucleic acid bases, we have found that, in the radiolysis of thymine under anaerobic conditions, there exists a novel reversible reaction between thymine and thymine glycol, and that the reverse reaction from the later is caused by the action of hydrated electrons.[3] It has also been observed that the radiolysis of thymine glycol gives several other products with the characteristic UV absorption (260 nm) positive or negative. This paper will deal with the isolation and identification of a novel dimer compound of thymine glycol as the main radiolysis product under N_2O saturation, and also with the dimer splitting to 5-methylbarbituric acid on radiolysis.

Results and Discussion

An aqueous solution of thymine glycol (I) (4 mM) was irradiated with γ-rays in the presence of N_2O to

3) M. Namiki and T. Hayashi, *Int. J. Radiat. Biol.*, **17**, 197 (1970); T. Hayashi and M. Namiki, *Agr. Biol. Chem.*, **36**, 551 (1972).

eliminate the action of hydrated electrons on thymine glycol ($e_{aq}^- + N_2O \rightarrow \cdot OH + OH^- + N_2$).[4] The irradiated solution was then concentrated and chromatographed on a column of Dowex 50W-H^+; a colorless crystalline product was thus obtained in the eluate. From the results of an elementary analysis ($C_{10}H_{10}N_4O_6$) and from the NMR{(100 MHz, DMSO-d_6 δ1.64 (s, $-CH_3$, 3H), δ11.14 (s, >NH, 2H)} and the IR {(KBr disk) 3200 (-NH), 1710, 1725, and 1750 cm^{-1} (C=O)} spectral data, the structure of this compound was assigned to be 5,5′-dimethyl-5,5′-bibarbituric acid (II).

To confirm the (II) structure, an authentic sample was prepared by a modification of the method used by Davidson and Baudisch in the synthesis of 6,6′-biisobarbituric acid,[5] using potassium ferricyanide in alkali as a condensing agent; it was demonstrated that the IR spectrum of the irradiate product agreed perfectly with that of an authentic one, as is presented in Fig. 1. The product (II) is considered to be a novel compound, and it seems to be the main radiolysis product, judging from the glc analysis of the irradiated products silylated with bis(trimethylsilyl)trifluoroacetamide (BSTFA) (Procedure A).

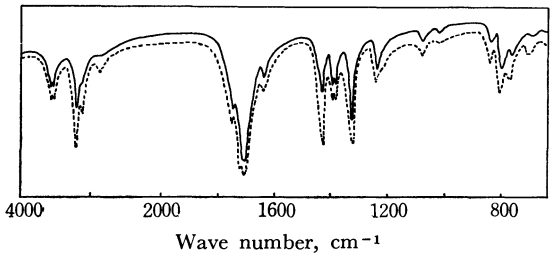

Fig. 1. IR spectra of synthesized (solid line) and isolated (broken line) II.

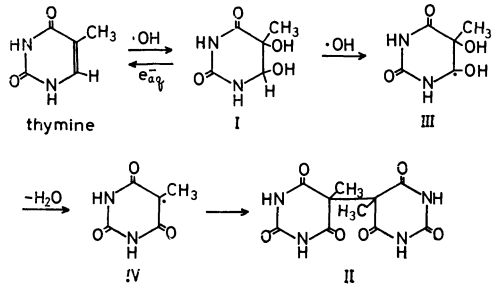
When its yields under various irradiation conditions were compared with those in air, in N_2 and in N_2O, it was shown that the formation was especially prominent in the case of the irradiation in the presence of N_2O, suggesting that the dimer formation is caused by the reaction with OH radicals. It may thus be proposed that the reaction is initiated by the abstraction of the C-6 hydrogen of I with the OH and/or H radical to form (III) radical, followed by dehydration to give the (IV) radical in a manner similar to that which has been proposed in the case of ethylene glycol;[6] subsequent dimerization then gives the product (II).



Scheme 1.

Judging from this dimer formation from I, it seems reasonable to assume that the dimer may exist in the radiolysis products of thymine in the absence of air, especially in the presence of N_2O. The glc experiments (Procedure A) have been perfomed to try to detect the dimer product (II) among the radiolysis products of thymine, but no appreciable amount of the dimer (II) was detected with the irradiations in air, in N_2, even in N_2O up to 2 Mrad.

Further investigations of the radiolysis of the dimer (II) were carried out especially in an attempt to ascertain the behavior of the reaction with a hydrated electron.

An aqueous solution of II (4 mM) was irradiated with 2 Mrad under the following conditions: a) in N_2 as an anaerobical one, b) in the presence of KSCN to scavenge OH radicals, and c) saturated with N_2O to scavenge hydrated electrons. The irradiated solutions showed the UV spectra shown in Table 1. On the tlc (cellulose) of the irradiated solutions, both a) and b) provided a prominent spot at R_f 0.3 (*n*-PrOH: H_2O) or 0.6 (*t*-BuOH: Methyl ethyl ketone: Formic Acid: H_2O), which coincided well with that of the authentic V, which c) did not show any appreciable changes in the chromatogram, suggesting a further degradation of V. In addition, the main peak (R_f 10 min) in the gas chromatograms of the products obtained with a) and b) also agreed with that of authentic V, and the $G(+V)$ values as estimated by the glc analysis (Procedure B) were 1.5, 1.3, and 0.2 for the conditions of a), b), and c) respectively. These results indicate that II reacts readily with hydrated electrons to give V as the prinicpal product, while it hardly reacts at all with OH radicals to form V.

Table 1. UV max. (nm) of irradiated II and related compounds

	In 0.1 M NaOH	In 0.1 M HCl

initial reactions of the hydrated electrons with II.

Experimental

Materials. I (*cis*-type) was obtained by the method of Baudisch and Davidson[7] and was recrystallized from water until it gave a single spot on tlc. V was prepared according to the procedure of Doumas and Biggs.[8]

Irradiation of I. A solution of I (1.28 g) in triply-distilled water (200 ml) was bubbled with purified N_2 gas for 5 min and subsequently with N_2O gas for 15 min; then it was irradiated up to 2 Mrad with γ-rays of Co-60 at room temperature. The irradiated solution was concentrated to 100 ml under reduced pressure at 50 °C, and was chromatographed over a column (diameter of 4 cm) of Dowex 50W-X8, 100—200 mesh, H^+-type (250 ml) by elution with distilled water. After the elution of the UV-absorbing and yellow fractions about 120 ml, the following fractions, containing unchanged material, easily provided a colorless crystalline product. The product was recrystallized by dissolving it in alkali and making acid, thus giving II as white prismatic crystals (37 mg); mp above 300 °C; Found: C, 42.59; H, 3.49; N, 19.62%. Calcd for $C_{10}H_{10}N_4O_6$: C, 42.56; H, 3.57; N, 19.85%. Molecular weight as determined by the vapor-pressure method: 276±28 in DMF. UV: λ_{max} 238 nm in alkali, end absorption in neutral and acid.

Irradiation of Dimer (II). A solution of II (4 mM) in 0.01 M NaOH with triply-distilled water (final pH 10—11) was irradiated with 2 Mrad under the following conditions: a) bubbling with N_2 gas for 15 min before irradiation, b) in the presence of 25 mM KSCN, bubbling with N_2 gas for 15 min before irradiation, and c) bubbling with N_2 gas for 5 min and then with N_2O gas for 15 min before irradiation.

Glc Analysis. The analyses were carried out on a Shimadzu GC-4BMPF apparatus.

Procedure A: The freeze-dried samples were treated with BSTFA in acetonitrile (50%) and then heated at 140 °C for 1 hr. A glass column (1 m) packed with 1.5% Silicone OV-17 was used. The retention time of II was 8 min at 240 °C with 40 ml/min of N_2.

Procedure B: To the solution of V or the irradiated solution of II we added uracil as the internal standard, and then the mixture was freeze-dried. These samples were treated with bis(trimethylsilyl)acetamide in acetonitrile (25%) and then heated at 100 °C for 30 min. The column utilized was 1.5% OV-1 in a 2-m Pyrex glass tube. The column conditions were a 2-min initial hold, followed by a 7 °C/min temperature program from 130 °C to 220 °C.

Studies on Seven-Membered Heterocyclic Compounds Containing Nitrogen. XII. Schmidt Reaction of Seven-Membered Heterocyclic Ketones

Heizan KAWAMOTO, Tadashi MATSUO, Shiro MOROSAWA, and Akira YOKOO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

((Received September 1, 1973)

It has been reported that the Schmidt reaction of benzo-fused, six-membered heterocyclic ketones (I, X=O[1], NH[2], or NMe[3]) chiefly gave the lactam (II) rather than the isomer (III) by the migration of the alkyl chain. The present authors assumed that the double bond character between the heteroatom and the aryl group of I might bring a strain, so that the aryl migration was restricted. In view of this, the strain might, more or less, be removed and the aryl migration would predominate in the corresponding seven-membered ketones (IV, X=O[4] or NH[5]). The idea was confirmed from the reactions below, and we wish to report a mechanism having an intermediate of a carbonium ion for the Schmidt reaction.

The seven-membered ring ketone (IV, X=O) gave two isomeric lactams (V, X=O, and VI, X=O) in a ratio of 7 : 3. The nitrogen analog (IV, X=NH) of the ring ketone as well as its N-tosyl derivative[5] afforded unexpected benzimidazole derivative (VII) along with a small amount of eight-membered lactam (V, X=NH). The structure of VII was determined by elementary analysis, molecular weight (by mass spectrum), and NMR and UV spectra. From the evidence for the formation of VII from IV (X=NH), a carbonium ion (A or B), which depends on the migratory aptitude of the alkyl chain and the benzene ring, should be an intermediate for the Schmidt re-

action as shown in Fig. 1.

In the Schmidt reaction of IV (X=O), the lactam (V, X=O) was a dominant product and was considered to be formed by the addition of water molecule to the intermediate (A, X=O), in which the benzene ring migrated, the minor isomeric lactam (VI, X=O), being formed from the intermediate (B, X=O), in which the alkyl migration occurred. The nitrogen analog (IV, X=NH) also seemed to facilitate the migration of benzene ring to give the intermediate (A, X=NH). In this case, however, the lone pair of electrons on the nitrogen atom was considered to attack the carbonium ion to give VII. A normal product, the lactam VI (X=NH) could also be detected in a minor extent, which might indicate the formation of intermediate (B, X=NH) followed by the addition of water molecule.

Experimental

The ratio of the reaction product was determined by estimating two kinds of the methylene proton signals (δ(TMS) in $CDCl_3$, 2.90—3.80, $NHCH_2$, and 2.10—2.60, $COCH_2$) using a Hitachi High-resolution NMR Spectrometer. The chemical shifts (δ in $CDCl_3$) of the signals in the following compounds were also referred: benzoylmethylamine (2.93, d, NCH_3), acetoanilide (2.10, s, $COCH_3$), *o*-aminobenzoylmethylamine (2.94, d, NCH_3), *o*-methoxyacetoanilide (2.10, s, $COCH_3$).

The Schmidt reaction of I (X=NH or NMe) was re-investigated using NMR spectra, and it was found that the tendency of the migration of alkyl chain was the same as that of litertures.[2,3] The characteristic chemical shifts (δ in $CDCl_3$) of the products are follows: 2,3,4,5-tetrahydrobenzo[*f*]-1,4-diazepin-5-one (3.30—3.80, m, $CONHCH_2$ and $C_6H_4NHCH_2$), 2,3,4,5-tetrahydrobenzo[*b*]-1,4-diazepin-4-one (2.68, t, $COCH_2$, 3.30—3.80, m, $NHCH_2$), 1-methyl-2,3,4,5-tetrahydrobenzo[*f*]-1,4-diazepin-5-one (3.30, broad s, $NHCH_2$ and $NMeCH_2$), 1-methyl-2,3,4,5-tetrahydrobenzo[*b*]-1,4-diazepin-4-one (2.50, t, J=6 Hz, $COCH_2$, 3.51, t, J=6 Hz, $NMeCH_2$).

*2,3,4,5-Tetrahydro-6*H*-benzo*[b]*-1,4-oxazocin-5-one (V, X=O) and 2,3,4,5-tetrahydro-*6H*-benzo*[b]*-1,5-oxazocin-6-one (VI, X=O).* To a stirred mixture of 0.75 g of 2,3,4,5-tetrahydrobenzo[*b*]-oxepin-5-one (IV, X=O) and 10 g of trichloroacetic acid, maintained at 55—60 °C, was added 0.50 g of sodium azide in the period of 1 hr. After being stirred for 6 hr at the same temperature, ice was added and the resulting mixture was neutrallized by adding 20% aqueous solution of sodium hydroxide. Sodium sulfate formed was removed by filtration and the aqueous solution was extracted with chloroform. Drying over anhydrous sodium sulfate and evaporation of chloroform left a residue, which was washed with ether to give 0.80 g of crude crystals. The crystals were found to be a mixture of V and VI in a ratio of 7 : 3 from the NMR spectrum. Recrystallization from benzene gave 0.30 g of V (X=O) as colorless needles of mp 157—159 °C. IR (KBr): 1670 cm^{-1} (lactam C=O); NMR (δ in $CDCl_3$): 1.70—2.20 (2H, m, C-3), 2.20—2.60 (2H, m, C-4), 4.22 (2H, t, J= 7 Hz, C-2), 6.80—7.80 (4H, m, Ar), 8.76 (1H, broad s, NH). Found: C, 67.60; H, 6.29; N, 8.21%. Calcd for $C_{10}H_{11}O_2N$: C, 67.78; H, 6.26; N, 7.91%. The isomeric lactam, VI (X=O), was not isolated, but the signal at δ 2.90—3.20 ($NHCH_2$) in the crude product proved its contamination.

*1,2-Dihydro-3*H*-pyrrolo[1,2-*a*]benzimidazole (VII) and 1,2,3,4,5,6-hexahydrobenzo*[b]*-1,4-diazepin-5-one (V, X=NH).* To a stirred solution of 1.0 g of 1-tosyl-2,3,4,5-tetrahydrobenzo-[*b*]azepin-5-one (IV, X=NTs) in 5 ml of concentrated sulfuric acid was added 0.31 g of sodium azide in a small portions at a room temperature. After being stirred for 2.5 hr, the mixture was worked up as above to give 0.45 g of crude crystals. Recrystallization from cyclohexane yielded 0.21 g of VII as colorless crystals of mp 108—110 °C. No carbonyl absorptions were found in the IR spectrum. NMR (δ in $CDCl_3$): 2.00—3.10 (4H, m, C-2 and C-3), 3.91 (2H, t, J=7 Hz, C-1), 7.10 (3H, m, C-6, -7, and -8), 7.60 (1H, m, C-5). UV: λ_{max} (in phosphate buffer, pH 8.0) nm (ε), 243 (5300), 248 (4900), 266 (3800), 271 (5100), 278 (5200), quite similar to that of 1-methylbenzimidazole.[6] Mass spectrum: *m/e*, 158 (M^+). Found: C, 76.20; H, 6.53; N, 18.06%. Calcd for $C_{10}H_{10}N_2$: C, 75.92; H, 6.37; N, 17.71%. Judging from the weak absorption of lactam grouping at 1660 cm^{-1}, the crude product was found to contain a small amount of V (X=NH). The absence of signals at δ 3.30—3.60 region indicates that the crude product includes no such compound as VI (X=NH) in it.

Further investigations of the effect of the above-mentioned double bond character on the migratory aptitude and of the extensive possibility of the mechanism are in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 46, 3900—3901 (1973)

The Solvent Effect on the Stability of α-Pyridoin

Hiroyasu INOUE, Masanori MATSUMOTO, Satoshi KIYOI, and Makoto YAMANAKA

Department of Applied Chemistry, Faculty of Technology, Kanagawa University, Kanagawa-ku, Yokohama 221

(Received July 23, 1973)

α-Pyridoin is known to take an endiol form (1,2-di-2-pyridylethenediol-1,2) from its infrared absorption spectrum,[1,2] dipole moment,[1] chemical reactivity,[3,4] and crystal analysis.[5] This is in contrast to the case of benzoin.

Recently, in our laboratory the endiol-form compound of benzoin, 1,2-diphenylethenediol-1,2, has been produced photochemically from benzil in particular solvents, but it is too unstable to be isolated.[6] On the other hand, α-pyridoin is relatively stable in some solvents at room temperature.

In this paper, we wish to report about the solvent effect on the stability of α-pyridoin.

Experimental

The α-pyridoin was obtained commercially (Aldrich Chemical Co., Inc.); mp 154.5 °C (lit,[7] 154—155 °C). The solvents used here were purified by the ordinary procedures for each solvent. The ultraviolet absorption spectra were recorded on a Shimadzu Spectrophotometer UV-200, using 1-cm quartz cells. The infrared spectra were measured with a Hitachi Infrared Spectrophotometer EPI-G3, using a 0.025 mm cell.

Results and Discussion

α-Pyridoin has its ultraviolet absorption band around 380 nm in various solvents. Its stability can be seen from the decrease in the absorbance of this band with the time elapsing after the preparation of the solution. The results are shown in Fig. 1. Nitrogen was flushed into the solvent while dissolving the α-pyridoin, except when cyclohexane, benzene, and *N*,*N*-dimethylformamide were used as solvents. In a mixed solvent of ethanol, for example, the absorption spectrum changed as is shown in Fig. 2. Thirty min after the preparation of the solution, the α-pyridoin was almost completely changed into 2,2′-pyrizil. The product was identified on the basis of the ultraviolet[4] and infrared spectra.[8] Therefore, α-pyridoin was oxidized by a trace of oxygen in the solution.

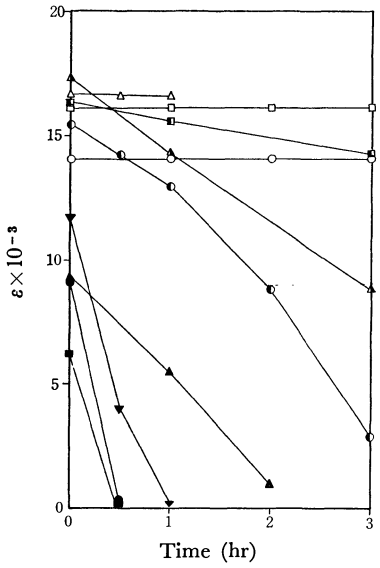

Fig. 1. Change in absorbance of the 380 nm band with time after the preparation of solution.

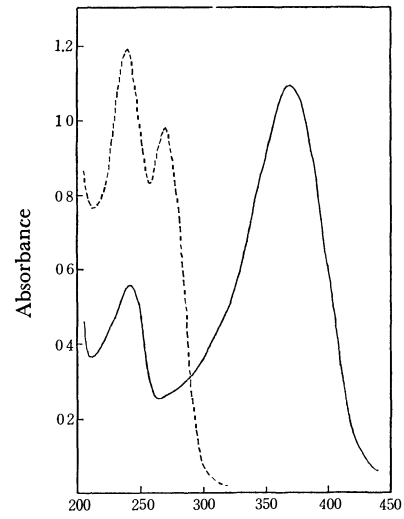

Fig. 2. Spectral change of α-pyridoin in mixed solvent of ethanol and water (1:1).
—— measured immediately after the preperation of the solution, ---- after being allowed to stand for 30 min in contact with the atmosphere.

As may be seen from Fig. 1, the solvents can be grouped into three classes with respect to the stability of α-pyridoin. The results are summarized in Table 1, in which the positions of the long-wavelength band of the α-pyridoin in each solvent are also presented. It can be seen from this table that, in a solvent containing water, α-pyridoin is unstable, Therefore, water seems to play a role in making α-pyridoin unstable. Further-

Table 1. Solvent effect of stability of α-pyridoin and the position of the long wavelength band

Class A[a]		Class B[b]		Class C[c]	
Solvent	λ_{max} (nm)	Solvent	λ_{max} (nm)	Solvent	λ_{max} (nm)
Cyclohexane	387	Di-*n*-butylamine	385	*n*-Butylamine	380
Benzene	383	Ethanol	377	Ethanol + H_2O (1 : 1)	370
N,N-Dimethyl-formamide	378			Formamide	374
		2-Propanol	378	2-Propanol + H_2O (1 : 1)	372

a) In this solvent α-pyridoin is stable when allowed to stand in contact with the atmosphere. b) In this solvent α-pyridoin is gradually oxidized when allowed to stand in contact with the atmosphere, but is stable when nitrogen is flushed into solution. c) In this solvent α-pyridoin is oxidized even when nitrogen is flushed into solution.

more, it can be said that, in a solvent with a primary amino group, α-pyridoin is less stable than in the corresponding alkylated solvent, *i.e.*, formamide—*N,N*-dimethylformamide, *n*-butylamine—di-*n*-butylamine. In the cases of *n*-butylamine and formamide, α-pyridoin is oxidized to picolinic acid.

It is noteworthy that the position of the long wavelength band shifts to the blue upon the addition of water to an alcohol solution or upon going from *N,N*-dimethylformamide and di-*n*-butylamine to formamide and *n*-butylamine respectively. Moreover, the position of the band is at a relatively longer wavelength in non-polar solvents such as cyclohexane and benzene than in a polar solvent. This is in contrast to the ordinary behavior of a π-π^* band. The absorption intensity is significantly lower in each solvent of Class C than in the solvents of Classes A and B. Accordingly, it is considered that an intermolecular interaction of α-pyridoin with water and primary amines takes place, thus resulting in the lability of α-pyridoin. It has been presumed that α-pyridoin is stabilized through two intramolecular hydrogen bonds between the enolic OH groups and the heterocyclic nitrogen atoms.[5]

Consequently, the solvent effect on the stability and on the position of the band can be interpreted as being due to the breaking of the intramolecular hydrogen bonds, because of the formation of intermolecular hydrogen bonds between α-pyridoin and each solvent of Class C. That is to say, α-pyridoin may form a hydrogen-bonded complex with solvent molecules as is illustrated below. This is clearly indicated by the infrared spectra presented in Fig. 3. In carbon tetrachloride, the OH stretching band appears at a very low wave number (2740 cm^{-1}) because of the intramolecular hydrogen bondings,[1] whereas in *n*-butylamine the OH band appears at 3300 cm^{-1}, though

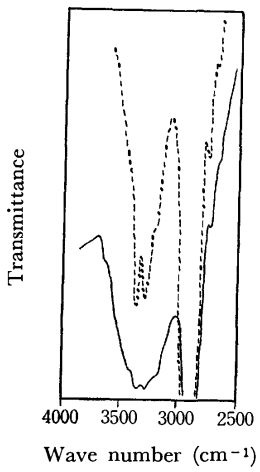

Fig. 3. Infrared absorption spectra of α-pyridoin.
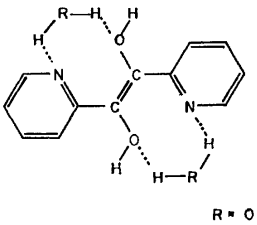
—— in *n*-butylamine, ---- *n*-butylamine



there is some overlapping with the NH band of *n*-butylamine.

That α-pyridoin is gradually oxidized in each solvent of Class B may be interpreted as a result of weak hydrogen bonding between the heterocyclic nitrogen atoms and the NH or OH group of the solvent molecule, because no solvent of Class A has the ability to form such a hydrogen bond.

A Method of Synthesizing Pyrimidine Derivatives. II

Isao SHIBUYA and Masahiro KURABAYASHI

National Chemical Laboratory for Industry (Tokyo Kogyo Shikensho) 6th Div., Mita, Meguro-ku, Tokyo 153

(Received June 28, 1973)

2,4,6-Triphenyl-1,3,5-oxadiazin-1-ium perchlorate (**1**), a six-membered heterocycle, is an oxonium salt similar to 2,4,6-triphenylpyrylium salt. Since **1** has two nitrogen atoms, more negative than carbon, in the ring, it is expected that there might be some difference in the reactivity between the two salts, though **1** would, on the whole, behave toward many nucleophiles in a manner similar to the pyrylium salt. Several papers[1-3] and the review[4] by Dimroth *et al.* have shown that the pyrylium salt reacts with active methylene compounds to give benzene derivatives. On the other hand, present authors have reported that **1** gave 4-benzoylamino-5-substituted-2,6-diphenylpyrimidine (**2a**, **b**, **c**) when **1** was refluxed with substituted acetonitrile.[5] This work was undertaken in an attempt to make clear the behavior of **1** toward a variety of active methylene compounds as well as the substituted acetonitriles by comparison with the behavior of the pyrylium salt.

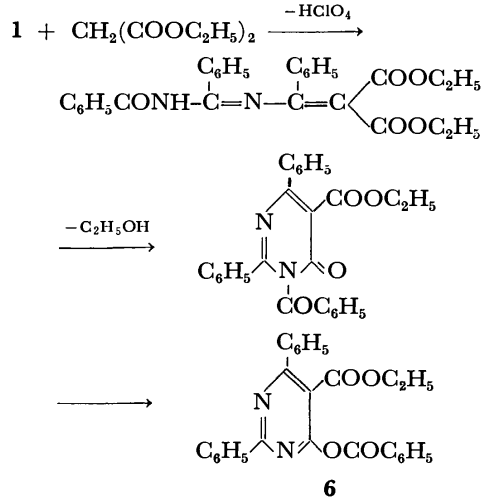
Results and Discussion

Ethyl Benzoylacetate, Benzoylacetonitrile, and Dibenzoylmethane. When ethyl benzoylacetate was refluxed with **1**,5-ethoxycarbonyl-2,4,6-triphenylpyrimidine (**3**)[6] was obtained. The mass and IR spectra of **3** agreed with those of an authentic sample. The reaction of the pyrylium salt with ethyl acetylacetate, which is analogous to this reagent, was also examined and found to give ethyl 2,4,6-triphenylbenzoate.[1] Benzoylacetonitrile with **1** afforded another product (**4**), together with **2c**,[5] when allowed to stand at room temperature for a week. The mol. wt of **4** was determined by mass spectroscopy to be 333. The IR spectrum of **4** was indicated absorptions assignable to a cyano group (2200 cm^{-1}) and a pyrimidine ring (1520 cm^{-1}) alone. These results and those of the elemental analysis provide a basis for the identification of **4** with 5-cyano-2,4,6-triphenylpyrimidine. On the other hand, benzoylacetonitrile with the pyrylium salt gave only 2,4,6-triphenylbenzonitrile. Dibenzoylmethane with **1** gave **5** under conditions similar to the above. The mol. wt of **5** was determined to be 412; its IR spectrum was similar to that of **4** except for the difference between their absorptions assigned to the cyano and benzoyl groups. Therefore, **5** was determined to be 5-benzoyl-2,4,6-triphenylpyrimidine. Every reaction of **1** with these three reagents possessing a benzoyl group gives 5-substituted-2,4,6-triphenylpyrimidine, with the liberation of benzoic acid.

Diethyl Malonate. Upon refluxing in dioxane, diethyl malonate with **1** gave **6** in a low yield. Its mol. wt was 424. The major peaks of the mass spectrum, 395, 380, 351, and 105, were ascribed to $M^+-C_2H_5$, M^+-CO_2, $M^+-COOC_2H_5$, and the benzoyl cation respectively. 4-Benzoyloxy-5-ethoxycarbonyl-2,6-diphenylpyrimidine satisfied these data. The reaction course is assumed to be in which this reagent attacks the 2-position of the oxadiazinium ring, the 1–2 bond of the ring is broken, and then the resulting open-chain intermediate cyclizes, with the liberation of ethanol followed by the benzoyl migration to afford **6**. This reaction is analogous to the formation of **2a** from malonitrile and **1** with the shift of the benzoyl group. In regard to the pyrylium salt, this reagent gives 2-hydroxy-3-ethoxycarbonyl-4,6-diphenylbenzophenone, with the liberation of ethanol.[3]



6

Cyanoacetamide and Benzoylacetamide. Cyanoacetamide with **1** afforded **7** at room temperature, while benzoylacetamide gave **8** upon refluxing. The measurement of the mass spectra resulted in failure since their vapor pressures are very low. Their IR spectra are very similar to each other. **7** was identified with 4-hydroxy-5-cyano-2,6-diphenylpyrimidine,[7] and con-

5	b	MeCN	181.2	69	84.44 (84.46)	4.89 (4.93)	6.79 (7.01)	1663, 1520, 1491, 1441, 1385, 1260.	412, 129, 105, 103.
6	a	EtOH	157.5	12	73.53 (73.57)	4.59 (4.75)	6.83 (6.60)	1756, 1730, 1558, 1525, 1263, 1243, 1023, 1008.	424, 395, 380, 351, 129, 105.
7	b	DMF	>300	45	74.71 (74.55)	4.06 (4.23)	15.38 (15.30)	3060, 2925, 2200, 1651, 1530, 1376, 1303, 1224.	
8	a	DMF	296.0	88	78.18 (78.39)	4.66 (4.58)	8.15 (7.95)	3030, 2925, 1673, 1629, 1559, 1544, 1447, 1380.	

a) Under refluxing. b) Under allowing to stand at room temperature.

sequently **8** was determined to be 4-hydroxy-5-benzoyl-2,6-diphenylpyrimidine. These results showed that the reaction of **1** with reagents possessing a carbamoyl group gives 4-hydroxypyrimidines.

Thus, it was proved that the 1,3,5-oxadiazinium salt gives pyrimidines with a number of functional groups on the 4 and 5-positions when it is treated with several active methylene compounds.

Experimental

The melting point of all products were measured by means of a Mettler FPI apparatus in capillary tubes with the elevating rate of 2 °C/min. The IR spectra were recorded in KBr disks on a JASCO DS-403G apparatus. The mass spectra were obtained on a Hitachi RMU6E mass spectrometer, with a direct inlet and an ionization energy of 70 eV.

*General Procedures for Preparing Pyrimidines (**3**—**8**).* To a solution of 4 mmol of an active methylene compound and 6 mmol of triethylamine in 20 ml of dioxane, 4 mmol of **1** were added; the mixture was subsequently stirred for ten minutes and then (a); refluxed for an hour or (b); allowed to stand for a week at room temperature. The resulting mixture was poured into dilute hydrochloric acid. The precipitate was collected by filtration and purified by recrystallization from an appropriate solvent. The reaction conditions, the yields, the melting points, the solvents for recrystallization, the results of elemental analyses, the main absorptions of the IR spectra, and the major peaks of the mass spectra are all listed in Table 1.

In Memory of Professor Jitsusaburo Sameshima

Professor Jitsusaburo Sameshima, professor emeritus of the University of Tokyo, honorary member and former president of the Chemical Society of Japan, passed away on 30 April 1973, at the age of 82. There is no need to mention his great contributions to the development of chemistry in Japan through his outstanding activities in research and chemical education. In particular, it should be remembered that Professor Sameshima was the virtual originator of the Bulletin of the Chemical Society of Japan, the first chemical periodical to carry articles mostly in English, but also in French and German. He emphasized the necessity of publishing the journal and worked, essentially alone, as the first editor-in-chief, taking care of the editing, proofreading, and delivery of the issues.

Since its first publication in January 1926, the Bulletin has gradually developed and acquired international recognition. The name of Professor Sameshima will always be remembered in association with the Bulletin of the Chemical Society of Japan. (For a biography of Prof. Sameshima, *cf.* This Bulletin, Vol. 23, No. 3, August, 1950).
