The Microwave Spectra of Sulfur Tetrafluoride in the Excited Vibrational States. The Vibrational Assignment for ν_4 and ν_9

Hiroshi INOUE, Akio NARUSE, and Eizi HIROTA

Department of Chemistry, Faculty of Science, Kyushu University, Higashi-ku, Fukuoka 812

(Received January 16, 1976)

The vibrational satellites of SF_4 have been observed for the two lowest bending modes, ν_4 and ν_9. The relative intensities which were observed are consistent with the vibrational assignment of Frey *et al.* but are incompatible with Levin's assignment. Consideration of the Coriolis interaction between the two modes lead to the same conclusion. The centrifugal distortion constants are evaluated and are compared with the observed.

In 1970 Christie and Sawodny[1] revised the previous assignments for the vibrational modes of sulfur tetrafluoride, by observing the Raman spectra in the gaseous state. Shortly after Frey *et al.*[2] proposed an assignment in which they reversed the two antisymmetric stretching bands, ν_6 and ν_8, based upon comparison with the vibrational spectra of the related molecules. Christie *et al.*[3] recently arrived at the same conclusion by evaluating the force constants. On the other hand Levin[4] observed two bands at 245 cm^{-1} and 206 cm^{-1} in the Raman spectrum of solid SF_4, which he ascribed to the two lowest bending modes, ν_4 and ν_9. Berney[5] has, however, shown that the band at 206 cm^{-1} is due to randomly-oriented oligomers. Christie *et al.*[3] also critisized the assignment of Levin by comparing the calculated mean amplitudes with the observed.

The rotational spectra in the excited states may provide us with information on the vibrational assignment, particularly in cases where two modes in near resonance are coupled by the Coriolis interaction[6]. If the ν_4 and ν_9 vibrations are nearly degenerate in the gas phase as argued by Levin, the rotational spectra in the two excited states would exhibit the effects of the Coriolis resonance, provided that the coupling constant is large enough. In the present work we observed the rotational spectra of SF_4 in the excited states of the ν_4 and ν_9 modes and obtained results which are consistent with the vibtational assignment of Frey *et al.*

Experimental

A sample of sulfur tetrafluoride was obtained by a method described in Inorganic Syntheses.[7] It is known that SF_4 reacts easily with water to form SOF_2. Our sample contains about 5—10% of SOF_2. Fortunately the microwave spectra of SOF_2 have recently been investigated in detail,[8] and thus we could identify easily the lines of SOF_2 in our observed spectra. Sulfur tetrafluoride decomposes quite rapidly in a glass vessel, and hence we stored the sample in a stainless steel holder equipped with a needle valve. Sulfur tetrafluoride was found quite stable in a Stark cell; we did not observe any appreciable decrease in intensity for two hours. We observed the microwave spectra of SF_4 at room temperature using a microwave spectrometer with a 120 kHz square-wave oscillator as a Stark modulator.

Rotational Spectra

The intensities of the ν_4 satellites relative to those of the ground state are the same for all types of the transitions, whereas those of the ν_9 satellites are dependent upon the parity of the K_{+1} number because of the two pairs of the equivalent fluorine nuclei. Table 1 lists the relative intensities which are calculated at $T=300$ K for the two vibrational assignments. It is to be noted that Levin assigned the bands at 228 cm^{-1} and at 233 cm^{-1} to ν_4 and ν_9 (or ν_9 and ν_4) in the gas phase, respectively.

TABLE 1. RELATIVE INTENSITIES OF THE ν_4 AND ν_9 SATELLITES OF SF_4 AT 300 K[a]

Vibration	Transition	Frey *et al.*	Levin
ν_4 (A_1)	ee—oe, oo—eo	0.320	0.320
ν_9 (B_2)	ee—oe	0.103	0.187
	oo—eo	0.285	0.520

a) Relative to the ground-state transition.

Because several low-J R-branch transitions of $J=2\leftarrow 1$ and $J=3\leftarrow 2$ show characteristic Stark patterns, we first concentrated to search the vibrational satellites around the corresponding ground-state transitions, which were reported by Tolles and Gwinn[9]. Aside from the Stark patterns we also utilized the following relation among the three R-branch frequencies:

$$4\nu(3_{22}\leftarrow 2_{12}) = 3[\nu(2_{21}\leftarrow 1_{11}) + \nu(2_{11}\leftarrow 1_{01})].$$

Since the centrifugal distortion effects are very small for SF_4 as shown below, this relation holds accurately. In Fig. 1 we plotted $\nu(2_{11}\leftarrow 1_{01})/2$, $\nu(3_{22}\leftarrow 2_{12})/3$, and $\nu(2_{21}\leftarrow 1_{11})/2$ in equidistance. We adjusted the abscissa slightly so that the three ground-state lines are in line.

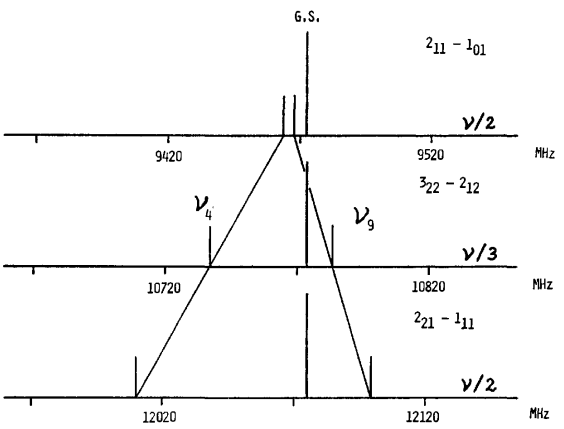

Fig. 1. Plot of the three R-branch frequencies, $\nu(2_{11}\leftarrow 1_{01})/2$, $\nu(3_{22}\leftarrow 2_{12})/3$, and $\nu(2_{21}\leftarrow 1_{11})/2$.

TABLE 3. ROTATIONAL CONSTANTS AND CENTRIFUGAL DISTORTION CONSTANTS OF SF_4 IN THE ν_4 AND ν_9 STATES (MHz)[a]

Constants	ν_4	ν_9
A	6641.7081 (84)	6707.7928 (71)
B	4095.8118 (89)	4075.9354 (94)
C	3213.7530 (90)	3217.9307 (93)
τ_{aaaa}	−0.01052 (76)	−0.0225 (19)
τ_{bbbb}	−0.00464 (63)	−0.0138 (19)
τ_{cccc}	−0.00136 (66)	0.0044 (43)
T_1[b]	−0.0085 (11)	−0.0178 (33)
T_2[b]	−0.00024 (84)	−0.0111 (27)

a) Values in parentheses denote the standard deviations and apply to the last significant digits. b) $T_1=\tau_{aabb}'+[(A-B)/(A-C)]\tau_{ccaa}'$ and $T_2=\tau_{bbcc}'+[(B-C)/(A-C)]\cdot\tau_{ccaa}'$.

Two sets of the vibrational satellites indicated in Fig. 1 obviously satisfy the above equation. Table 2 summarizes the observed frequencies of the two sets of the spectra. The rotational constants listed in Table 3 were determined by a least-squares analysis, where the centrifugal distortion effects were taken into account to the first order. The τ constants are not well determined as shown in Table 3.

Vibrational Assignment

The relative intensities of the two sets of the observed spectra are in good agreement with those given in Table 1 for the vibrational assignment of Frey *et al.* Further evidence which supports this conclusion is obtained by analyzing the Coriolis interaction.

The two modes under consideration couple with each other by the Coriolis interaction associated with the a-axis. Levin[4] gave the force constants of valence-force type, which reproduce the vibrational frequencies corresponding to the two assignments. These force constants result in the Coriolis coupling constants $\zeta_{4,9}^{(a)}$ which are listed in Table 4.

TABLE 4. CORIOLIS COUPLING CONSTANT AND VIBRATIONAL CHANGES OF THE A CONSTANTS OF SF_4 IN THE ν_4 AND ν_9 STATES

Constants	Frey *et al.*	Levin
$\zeta_{4,9}^{(a)}$	0.670	0.778
$\Delta A_\pm$ ν_4 (MHz)	−22.2	−723
$\Delta A_\pm$ ν_9 (MHz)	+22.2	+723

Obsd $A_4-A_0=-46.029$ MHz, $A_9-A_0=20.056$ MHz

In the second-order approximation the Coriolis interaction contributes $\Delta A_\pm=\pm D^2/\Delta E$ to the A rotational constant where

$$D = A[(\nu_4/\nu_9)^{1/2}+(\nu_9/\nu_4)^{1/2}]\zeta_{4,9}^{(a)},$$
$$\Delta E = \nu_4 - \nu_9,$$

and the + and − signs apply to ν_4 and ν_9, respectively.[10] Table 4 shows $\Delta A_\pm$ calculated for the two

TABLE 5. ROTATIONAL CONSTANTS AND CENTRIFUGAL DISTORTION CONSTANTS OF SF_4 IN THE GROUND STATE (MHz)[a]

Constants	Obsd	
	This work	Tolles, Gwinn (Ref. 9)

C	3219.949 (12)	3219.95

Constants	Obsd	Calcd	
	This work	Frey *et al.*	Levin
τ_{aaaa}	−0.0152 (11)	−0.0160	−0.0167
τ_{bbbb}	−0.0078 (11)	−0.0057	−0.0059
τ_{cccc}	−0.0049 (10)	−0.0034	−0.0032
T_1[b]	−0.0147 (20)	−0.0153	−0.0138
T_2[b]	−0.0052 (16)	−0.0027	−0.0031

a) Values in parentheses denote the standard deviations and apply to the last digits. b) See Footnote b) of Table 3.

assignments. The observed A_4 and A_9 constants differ from the ground-state A constant by −46.029 MHz and +20.056 MHz, respectively. The $\Delta A_{\pm}$ values for Levin's assignment are obviously too large in magnitude.

Centrifugal Distortion Constants

We remeasured some of the ground-state transitions reported by Tolles and Gwinn, and analyzed them with a few added lines by a least-squares analysis. Table 5 lists the rotational constants and the centrifugal distortion constants thus derived. The rotational constants which were obtained are in very good agreement with those of Tolles and Gwinn. The observed τ constants are compared with those calculated using the force fields mentioned previously. Both assignments give the τ constants which are in fair agreement with the observed.

Discussion and Conclusion

The vibrational satellites of SF_4 in higher excited states would be possible to observe, but it would be very hard to assign the ν_6 and ν_8 satellites, because there are too many lower states including the overtone and combination states of the lower-frequency modes. No information was thus obtained for the two antisymmetric stretching vibrations, but the present work eliminates definitely Levin's assignment for the ν_4 and ν_9 modes.

The computation in the present work was carried out at the Computation Center of Kyushu University.

The Crystal Structure and the Absolute Configuration of (−)-Argemonine Methiodide

Tsuguhiro KANEDA, Noriyoshi SAKABE, and Jiro TANAKA
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa, Nagoya 464
(Received January 30, 1976)

The crystal structure of (−)-argemonine methiodide has been investigated by the X-ray method. The crystal system is orthorhombic, and the space group is $P2_12_12_1$. The cell dimensions are $a=13.443$, $b=20.838$, and $c=8.485$ Å. The structure parameters were refined by the block-diagonal least-squares method, and the final R-value was 0.055. The absolute configuration was determined by the Mo$K\alpha$ anomalous scattering to be 1S5S, which is consistent with the CD result.

Argemonine is an alkaloid from *Argemone hispida G* and *Argemone munita*, and its structure was determined by Martell, Soine, and Kier[1] to be identical with (−)-*N*-methylpavine, which was synthesized by Battersby and Binks.[2] The absolute configurations of (−)-argemonine and its related alkaloids have been established by Barker and Battersby[3] by the chemical correlation method. Mason and his coworkers[4,5] have investigated the CD spectra of these molecules and further investigations on the conformation and the absolute configuration by the X-ray method will be of much interest.

In this paper we present a precise structure analysis of (−)-argemonine methiodide and its absolute configuration by the X-ray method.

Experimental

Argemonine methiodide was kindly gifted from Prof. T. O. Soine of Minnesota Univ., and it was recrystallized from water for the X-ray examination. The space group was determined from oscillation and Weissenberg photographs. The density was measured by the flotation method in a mixed solution of cyclohexane and carbon tetrachloride. The cell dimensions were determined by the least-squares method, using 12 reflections which had been carefully measured on a Hilger-Watts four circle diffractometer with Ni-filtered Cu$K\alpha$ radiation ($\lambda=1.5418$ Å). The crystal data are shown in Table 1.

Table 1. Crystal data

M.F.: $C_{22}H_{28}NO_4I\cdot 2H_2O$
M.W.: 533.41
Crystal system: orthorhombic
Space group: $P2_12_12_1$
$a=13.443(2)$, $b=20.838(2)$, $c=8.485(2)$ Å;
$V=2376.9$ Å^3, $Z=4$,
$D_m=1.486$, $D_c=1.491$ g·cm^{-3}
$\mu=15.81$ cm^{-1} (for Mo$K\alpha$ radiation).

Intensity data were measured on the diffractometer in ω-2θ scanning mode using Zr-filtered Mo$K\alpha$ radiation ($\lambda=0.7107$ Å) with the crystal whose size was $0.5\times0.7\times0.8$ mm. Non-zero data of 2766 independent reflections within $\theta\leq26°$ were collected and no correction were made for absorption or extinction.

Structure analysis

The crystal structure was determined by the heavy atom method. Iodine atom was found from a Patterson map and a Fourier synthesis using the coordinate of the iodine atom revealed all the other non-hydrogen atoms including two water molecules of crystallization. A diagonal-least-squares method was applied to the refinement of structure parameters by using all non-zero data and the R-value was reduced to 0.098. Successively a block-diagonal least-squares method was applied to further refinement with anisotropic thermal factors for all atoms and the R-value was converged to 0.055. No other significant peaks were found in the final Fourier and difference Fourier maps. All atomic scattering factors were taken from the International Tables for X-ray Crystallography.[6] The computation was carried out with the program of HBLS-IV coded by Prof. Ashida

The atomic coordinates and the anisotropic thermal parameters with their standard deviations are listed in Tables 2 and 3, respectively. The observed and calculated structure factors are listed in Table 4.[7]

Results and discussion

Argemonine is a rigid molecule which has a bicyclo-[3.3.1]nona-diene skeleton. Figure 1 shows the conformation and atomic labels, and thermal ellipsoids drawn by the program ORTEP coded by Dr. Johnson. The bond lengths and angles are shown in Tables 5 and 6, respectively. The average bond distance of dimethoxybenzene ring A {C(2), C(3), C(10), C(11), C(12), and C(13)} and that of dimethoxybenzene ring B {C(6) C(7), C(14), C(15), C(16), and C(17)} are 1.39 Å and

the B plane. The methoxyl carbons, C(22) and C(23), which are attached to oxygen atoms not taking part in hydrogen bonding, deviate 0.24 and −0.12 Å from the B plane, respectively, while C(20) and C(21) do not deviate from the A plane so much. The dihedral angle between A and B planes is 90.4°.

The absolute configuration was determined by the Bijvoet method using the anomalous scattering of Mo$K\alpha$ radiation by the iodine atom. The $\Delta f'$ and $\Delta f''$ values were taken from the International Tables for X-ray Crystallography.[6] The observed intensity differences and calculated ones between 22 Bijvoet pairs are listed in Table 9. The signs of observed values are in good agreement with those calculated based on the positional paramenters of Table 2 in the right-handed coordinate system. The absolute configuration thus determined is 1S5S as is illustrated in Fig. 1. This result is in perfect agreement with those by the chemical correlation method of Barker and Battersby,[3] and by the CD spectral analysis of Mason *et al.*[4,5] The structural data will be still useful for the theoretical calculation of the CD spectra.

The authors are gratefull to Professor T.O.Soine for his kind gift of the crystals.

Theoretical Calculations of the Raman Intensities by the Vibronic Method. II. The In-plane Vibrations of Ethylene

Hiroyuki SHINODA

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo 160

(Received January 20, 1976)

The values of the transition moment of Raman scattering have been calculated according to the formula derived from the vibronic method. The calculations have been performed for the in-plane vibrational modes of ethylene determined by three different sets of force constants. The electronic wave functions were calculated by the CNDO/2-CI method. From the relative Raman intensities of three A_{1g}-vibrations of ethylene in the respective cases, it was found that the Raman intensities are sensitive to the vibrational modes. Also, the Raman intensities of ethylene were calculated by the polarizability method in order to compare the results with those obtained from the vibronic method. From the results of these calculations, the conclusions of the previous work have been confirmed.

In a previous paper,[1] which will hereafter be called Part I, the Raman intensities of the symmetric stretching vibrations of several small molecules and of the normal vibrations of methane were calculated by means of the semi-empirical molecular orbital method.[2] In Part I, the Raman intensities were calculated by two methods: the polarizability method and the vibronic method. In the polarizability method, the values of the Raman tensor were obtained by fitting the calculated polarizabilities to a cubic function with respect to the normal coordinate and by taking the first derivative at the equilibrium molecular position. In the vibronic method, the expression of the Raman tensor was derived from the Kramers-Heisenberg dispersion formula by applying the Herzberg-Teller expansion. The results calculated by the two methods were compared with each other, and it was concluded that the vibronic method is more suitable for the theoretical calculation of the Raman intensity than is the other one.

The polarizability derivatives for small polyatomic molecules have been calculated by several investigators[3] by means of the semi-empirical molecular orbital technique. In all of those calculations, the vibrations of diatomic molecules or the symmetric stretching vibrations of some polyatomic molecules have been treated by means of the polarizability method. Moreover, Bleckmann[4] recently calculated the Raman intensities of the normal vibrations of cyclopropenon by the polarizability method. In his work, the polarizabilities were evaluated by means of the finite perturbation technique using the CNDO/2 method.[2] However, his results contradicted the observed ones because the calculated Raman intensities of some non-totally symmetric vibrations were stronger than those of the totally symmetric ones. He attributed the contradiction to the insufficiency of the method of calculation: when the z-axis has its direction perpendicular to the molecular plane, the zz-component of the Raman tensor for the in-plane vibrations of the planar molecules was always zero. Also, the result from the polarizability method in Part I was contradictory to the observed one; the calculated Raman intensity of the ν_2 vibration of methane was stronger than that of the ν_1 vibration, which is observed as the strongest Raman line. From these results (Ref. 4 and Part I), it may be considered that the polarizability method within the framework of the CNDO method leads to unsatisfactory results for the theoretical evaluation of Raman intensities.

In the present work, the Raman intensities of the in-plane vibrations of ethylene have been calculated by the vibronic method. It acquires additional interest from the fact that different kinds of sets of force constants of ethylene have been presented by various investigators.[5-7] Therefore, three sets of force constants have been used in this calculation, and the influence of the different sets on the calculated values of the Raman intensity has been discussed. In order to confirm the conclusion in Part I, furthermore, the calculation has been repeated by the polarizability method.

Methods of Calculation

The total intensity of a Raman line after averaging all the molecular orientations is given as follows:

$$I_{mn} = \frac{2^3\pi}{3^2c^4} I_0 \omega^4 \sum_{\rho,\sigma} |(\alpha_{\rho\sigma})_{mn}|^2, \tag{1}$$

where c is the velocity of light; I_0, the intensity of the incident light; ω, the frequency of the scattered light; m, the initial state; n, the final state, and $(\alpha_{\rho\sigma})_{mn}$, the $\rho\sigma$-th component of the polarizability tensor for the $m \rightarrow n$ transition. The sum goes over $\rho=x,y,z$ and $\sigma=x,y,z$, which refer to the molecular fixed coordinate system. The final expression of $(\alpha_{\rho\sigma})_{mn}$ has been given as follows:[1,8]

$$(\alpha_{\rho\sigma})_{mn} = A + B + C, \tag{2}$$

$$A = -\sum_a \sum_{r \neq g} \left[\frac{\langle g^\circ|R_\sigma|r^\circ\rangle\langle r^\circ|h_a|r^\circ\rangle\langle r^\circ|R_\rho|g^\circ\rangle}{(\varepsilon_r^\circ - \varepsilon_g^\circ - E_0)^2} + \frac{\langle g^\circ|R_\sigma|r^\circ\rangle\langle r^\circ|h_a|r^\circ\rangle\langle r^\circ|R_\rho|g^\circ\rangle}{(\varepsilon_r^\circ - \varepsilon_g^\circ + E_0)^2} \right] \langle \psi_m^g | Q_a | \psi_n^g \rangle, \tag{3}$$

$$B = -\sum_a \sum_r \sum_{s \neq r} \left[\frac{\langle g^\circ|R_\sigma|r^\circ\rangle\langle r^\circ|h_a|s^\circ\rangle\langle s^\circ|R_\rho|g^\circ\rangle}{(\varepsilon_r^\circ - \varepsilon_g^\circ - E_0)(\varepsilon_s^\circ - \varepsilon_g^\circ - E_0)} + \frac{\langle g^\circ|R_\rho|s^\circ\rangle\langle s^\circ|h_a|r^\circ\rangle\langle r^\circ|R_\sigma|g^\circ\rangle}{(\varepsilon_r^\circ - \varepsilon_g^\circ + E_0)(\varepsilon_s^\circ - \varepsilon_g^\circ + E_0)} \right] \langle \psi_m^g | Q_a | \psi_n^g \rangle, \tag{4}$$

and

$$C = -\sum_a \sum_{r \neq g} \sum_{s \neq g} \left[\frac{\langle g^\circ|h_a|s^\circ\rangle\langle s^\circ|R_\sigma|r^\circ\rangle\langle r^\circ|R_\rho|g^\circ\rangle}{(\varepsilon_r^\circ - \varepsilon_g^\circ - E_0)(\varepsilon_s^\circ - \varepsilon_g^\circ)} + \frac{\langle g^\circ|h_a|s^\circ\rangle\langle s^\circ|R_\rho|r^\circ\rangle\langle r^\circ|R_\sigma|g^\circ\rangle}{(\varepsilon_r^\circ - \varepsilon_g^\circ + E_0)(\varepsilon_s^\circ - \varepsilon_g^\circ)} \right.$$

$$+\frac{\langle g^\circ|R_\sigma|r^\circ\rangle\langle r^\circ|R_\rho|s^\circ\rangle\langle s^\circ|h_a|g^\circ\rangle}{(\varepsilon_r^\circ-\varepsilon_g^\circ-E_0)(\varepsilon_s^\circ-\varepsilon_g^\circ)}$$
$$+\frac{\langle g^\circ|R_\rho|r^\circ\rangle\langle r^\circ|R_\sigma|s^\circ\rangle\langle s^\circ|h_a|g^\circ\rangle}{(\varepsilon_r^\circ-\varepsilon_g^\circ+E_0)(\varepsilon_s^\circ-\varepsilon_g^\circ)}\Big]\langle\psi_m^g|Q_a|\psi_n^g\rangle, \quad (5)$$

where the superscript o denotes the equilibrium nuclear position in the electronic ground state; $|g^\circ\rangle$ is the electronic ground state, and $|r^\circ\rangle$ and $|s^\circ\rangle$ are the electronic excited states; ε_g°, ε_r°, and ε_s° are the energies of $|g^\circ\rangle$, $|r^\circ\rangle$, and $|s^\circ\rangle$ respectively; E_0 is the energy of the incident light; $|\psi_m^g\rangle$ and $|\psi_n^g\rangle$ are the wave functions of the m-th and n-th vibrational states respectively in the electronic ground state; Q_a is the normal coordinate of the a vibrational mode; R_ρ and R_σ are the operators of the ρ- and σ-components respectively of the electronic dipole operator, and $h_a=(\partial H/\partial Q_a)$, the first-order vibronic coupling operator introduced initially by Herzberg and Teller.[9] The Raman tensor for the a normal vibration, $(\alpha_{\rho\sigma}^a)'$, can be defined by the following equation:

$$(\alpha_{\rho\sigma})_{mn}=\sum_a(\alpha_{\rho\sigma}^a)'\langle\psi_m^g|Q_a|\psi_n^g\rangle \quad (6)$$

The wave functions of the electronic states and the molecular integrals appearing in the above expressions were calculated by the methods described in Part I.

The different sets of the force constants of ethylene used in the calculation will now be described. The first set, which will be called Set 0 for convenience, consists of the modified Urey-Bradley force constants offered by Scherer and Overend.[6] This set is a modification of the simplified Urey-Bradley force field obtained by adding the *trans*-interaction, so called by them; it may be the most reliable set because the transferability of their set of force constants was successful in discussing the experimental results of several bromoethylenes. The second and third sets of the force constants used in this work were Proposed by Crawford *et al.*;[7] these sets will be called Set I and II below. There are differences in their force constants with respect to the symmetry coordinates of the A_{1g} symmetry species. In the calculation with Set 0, the equilibrium configuration of ethylene followed the data in Ref. 6, while in the calculations with Sets I and II it followed the data in Ref. 7.

Results and Discussion

In the calculations, the wavelength of the incident light was fixed at 5145 Å, the wavelength of an Ar^+ laser line. Five Raman-active in-plane vibrations, which include three vibrations of A_{1g} symmetry species and two of B_{1g}, will be discussed. The other vibrations will be omitted from the discussion because the values of their calculated Raman intensities were practically equal to zero. The vibrational modes obtained by the usual **GF** method with Sets 0, I, and II of the force constants are shown in Figs. 1—3 respectively.

In this work, the differential cross section, $(d\sigma/d\Omega)_{//}$, instead of the total cross section has been calculated because there are the experimental results of $(d\sigma/d\Omega)_{//}$ which can be used in the discussion. $(d\sigma/d\Omega)_{//}$ is expressed as follows:

$$(d\sigma/d\Omega)_{//}=\frac{\omega^4}{c^4}\langle\psi_m^g|Q_a|\psi_n^g\rangle^2\left\{(\bar{\alpha}_a')^2+\frac{4}{45}(\gamma_a')^2\right\}, \quad (7)$$

where $\bar{\alpha}_a'$ and γ_a' are the mean part and the anisotropy part of the Raman tensor of the a normal vibration. The values of the $(d\sigma/d\Omega)_{//}$ caluculated by the vibronic method with Sets 0, I, and II are shown in Table 1; the experimental results are also included. The calculated values of the $(d\sigma/d\Omega)_{//}$ for the A_{1g}-vibrations are larger than the experimental ones. The cause of the overestimations in the calculated results will be discussed later on the basis of the results shown in Table 3. The rela-

a) The wavelength of the incident light is 3371 Å.
b) The values correspond to $(d\sigma/d\Omega)$ which expresses as $(\omega^4/c^4)\langle\psi_m^g|Q_a|\psi_n^g\rangle^2\{(\bar{\alpha}_a')^2+(7/45)(\gamma_a')^2\}$.
c) The wavelength of the incident light is 5145 Å.
d) The values are common for Set I and Set II.

tive Raman intensities among the A_{1g}-vibrations calculated with one set of force constants are different from those with another set. The results calculated with Set 0 appear to be in good agreement with the ones observed by Shimizu *et al.*[10] The results from Sets I and II differ from the experimental ones in the order of the intensities. If the suitabilities of Set I and Set II are compared with each other after the manner of the discussion by Crawford *et al.*, it appears, from the calculated Raman intensities, that Set II is appropriate to the force constants of ethylene, although Crawford *et al.* pointed out that Set I is more correct than Set II in view of the constancy of the C=C frequency of olefins. The reason for the situation in the present work is found partly in the similarity of the vibrational modes decided from Sets 0 and II (see Figs. 1 and 3).

In an effort to discuss the importance of the *trans*-interaction introduced to Set 0 of the force constants, $(d\sigma/d\Omega)_{//}$ value swere calculated while neglecting the *trans*-interaction term. The calculated values of the ν_1, ν_2, and ν_3 vibrations are 0.111×10^{-27}, 0.661×10^{-28}, and 0.593×10^{-28} cm^2 respectively. The relative intensities among them are less in agreement with the observed ones than with the results obtained with the original set including the *trans*-interaction term. The results show that the introduction of the *trans*-interaction to the set of force constants is very meaningful.

In the measurement of the Raman intensities, by Blumenfeld *et al.*,[12] for the ν_4 and ν_5 vibrations with B_{1g} symmetry species, the former was observed with a strong intensity and the latter, with a very weak one, although the assignment of the latter was somewhat uncertain. However, both the calculated intensities for these Raman lines are very weak and the intensity of the ν_4 vibration is weaker than that of the ν_5 vibration. A similar situation for the non-totally symmetric vibrations was obtained in the treatment for methane in Part I. The calculated Raman intensity of the ν_2 vibration is very weak, less than those of the ν_3 and ν_4 vibrations; this contradicts the observed result. It will be shown in a future paper that the 2p-orbitals of the hydrogen atom play an important role in the theoretical calculation of the Raman intensities for these non-totally symmetric vibrations.

The calculated values of the depolarization ratios,

a) See text. b) Sum of the terms *A*, *B*, and *C*.

ρ_n, are shown in Table 2. The values calculated with the different sets of force constants are similar to each other. The calculated values for the A_{1g}-vibrations are all about 0.23, with the one exception of 0.197, while those for the B_{1g}-vibrations are 0.857, this value being expected in view of the group theory.

The values of the elements of the Raman tensors calculated with the force constants of Set 0 are shown in Table 3. From these values, the effective terms in the theoretical calculation of the Raman intensities can be discussed. For the A_{1g}-vibrations, the term A gives the main contribution to the intensities; no off-diagonal elements of the Raman tensor contribute to the intensities. Moreover, the mean part of the Raman tensor is more effective on the intensities of the A_{1g}-vibrations than is the anisotropy part, judging from the results on ρ_n shown in Table 2. Therefore, it can be said that the intensity of the A_{1g}-vibrations arises mainly from the mean part referring to the term A, $\bar{\alpha}_a'(A)$, which is written as follows

$$\bar{\alpha}_a'(A) = \frac{1}{3}\sum_{\sigma}\sum_{r\neq g}\left[\frac{\langle g^\circ|R_\sigma|r^\circ\rangle\langle r^\circ|h_a|r^\circ\rangle\langle r^\circ|R_\sigma|g^\circ\rangle}{(\varepsilon_r^\circ-\varepsilon_g^\circ-E_0)^2} + \frac{\langle g^\circ|R_\sigma|r^\circ\rangle\langle r^\circ|h_a|r^\circ\rangle\langle r^\circ|R_\sigma|g^\circ\rangle}{(\varepsilon_r^\circ-\varepsilon_g^\circ+E_0)^2}\right]$$
$$= \frac{1}{3}\sum_{r\neq g}\left[\frac{1}{(\varepsilon_r^\circ-\varepsilon_g^\circ-E_0)^2}+\frac{1}{(\varepsilon_r^\circ-\varepsilon_g^\circ+E_0)^2}\right] \times \frac{\langle r^\circ|h_a|r^\circ\rangle}{(\varepsilon_r^\circ-\varepsilon_g^\circ)} f_{rg},$$

where f_{rg} is the oscillator strength of the electronic transition from the ground state to the r-th excited state. The value of f_{rg} calculated by the semi-empirical molecular orbital calculation is usually 2—3 times larger than the observed one.[13] This fact partly explains the overestimation of the $(d\sigma/d\Omega)_{//}$ of the A_{1g}-vibrations. In the calculated results for the non-totally symmetric vibrations, the contribution of the term C to the intensities is larger than that of the term B. This result is opposite to the usual conception that the contribution of the term C is small in comparison with that of the term B, because the energy separations between the electronic excited states appearing in the denominators of the term B are smaller than those between the electronic ground state and the excited states in the denominators of the term C. In the derivation of the terms B and C used in this work, there is only one approximation—the vibronic energy, E_{ri} in Eqs. 3 and 4 in Part I, is regarded as constant over the vibrational states. Therefore, if we want to determine the effective terms which contribute to the intensities of the non-totally symmetric vibrations, a theoretical calculation without the approximation described just above must be done.

The Raman intensities and the depolarization ratios of ethylene were calculated by the polarizability method with the force constants of Set 0 in order to compare these results with those obtained from the vibronic method. The polarizability method leads to undesirable results, as will be mentioned below (see Table 4). The intensity of the ν_4 vibration, the non-totally symmetric one, is stronger than that of the ν_2 vibration, the totally symmetric one. In the depolarization ratio, the value for the ν_3 vibration is larger than that generally found for the totally symmetric vibrations.

Conclusions

From the results in Tables 1—4, the following conclusions can be drawn;

(a) The conclusions in Part I are almost all confirmed in the present work.

(b) The Raman intensity calculated by the vibronic method is sensitive to the set of force constants used in the calculation.

(c) The *trans*-interaction in the modified Urey-Bradley force field introduced by Scherer and Overend plays an important role not only in the frequencies, but also in the Raman intensities.

The author is grateful to Professor Tomoo Miyazaki for giving him the opportunity of publishing this work. He is also indebted to Professor Hiroaki Takahashi for his helpful advice.

The Crystal and Molecular Structure of Silver(I) *N,N*-Diethyldithiocarbamate

Hiroko YAMAGUCHI, Azuma KIDO, Tetsuo UECHI,* and Kazuo YASUKOUCHI

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received June 16, 1975)

The crystal structure of silver(I) *N,N*-diethyldithiocarbamate was determined by the X-ray diffraction method. The crystals are monoclinic, with the space group $P2_1/c$, and with two hexameric molecules in a unit cell with dimensions of $a=10.90\pm0.02$, $b=24.72\pm0.01$, $c=11.51\pm0.02$ Å, and $\beta=125.8\pm0.1°$. The structure was solved by a heavy-atom method and was refined by block-diagonal least-squares methods to a final *R*-value of 0.029 for 2108 observed reflections. The structure consists of hexameric molecules, $[AgS_2CN(C_2H_5)_2]_6$. The hexameric structure was essentially consistent with Hesse's preliminary result (1960). The terminal silver atom in one molecule is bridged by a sulfur atom to that in the adjacent hexamer, forming a chain structure along the a axis. All the silver atoms are connected to five atoms (either 1Ag and 4S or 2Ag and 3S). The dithiocarbamate ligands are classified into three types: bidentate, intra-, and inter-molecule tetradentate.

The use of silver(I) *N,N*-diethyldithiocarbamate (Ag-EtDC) in the microdetermination of arsenic has been widely accepted in the last ten years,[1] and the mechanism of color development has been investigated in some detail.[2] The crystal and molecular structure of this interesting reagent was studied by Hesse. He reported that the molar ratio of metal and ligand contents was 1:1,[3] and that the six silver atoms of a hexameric molecule formed a doubly bent chain in the crystal,[4] although the detailed structure was left undetermined. Hitherto, the crystal structures of many other metal-EtDC complexes have also been studied; among them, the structure of Ag-PrDC[5] (silver dipropyldithiocarbamate) was reported by Hesse in detail.

Our precise determination of the crystal and molecular structure of Ag-EtDC was carried out in an attempt to reveal the relations between the arrangement of the silver atoms and the terminal alkyl group, and between the solubility and the molecular structure.

Experimental

Ag-EtDC (Dotite Arsemate of Dojindo Labs.) was recrystallized from pyridine. The crystals were light-yellow transparent prisms. The lattice parameters were determined using 15 reflections measured by a Syntex automated diffractometer ($P\bar{1}$) using Mo$K\alpha$ radiation monochromated with a graphite crystal (taken as 0.71069 Å). The density was measured by flotation in a mixed solution of methyl iodide and ethyl alcohol.

TABLE 1. THE CRYSTAL DATA

Silver (I) *N,N*-Diethyldithiocarbamate
Formula: $Ag_6[S_2CN(C_2H_5)_2]_6$
Crystal Class: Monoclinic prismatic
Space Group: $P2_1/c$
Cell Parameters:
$a=10.90\pm0.02$ Å
$b=24.72\pm0.01$ Å
$c=11.51\pm0.02$ Å
$\beta=125.8\pm0.1°$
Volume of Unit Cell: $V=2514.4\pm5.7$ Å^3
Density: $D_m=2.048$ g cm^{-3}
$D_x=2.082$ g cm^{-3}
Number of Formula per Unit Cell: $Z=2$
μ for Mo$K\alpha$: $\mu=31.3$ cm^{-1}

The crystal data are summarized in Table 1. A single crystal was ground by Bond's method[6] to make it a sphere with a diameter of 0.348 mm ($\mu r=0.545$ for Mo$K\alpha$ radiation); this sphere was then used for the intensity measurement. The intensity data were collected by the θ–2θ scan technique with a variable scan rate from 4.0 to 24.0°/min on a Syntex ($P\bar{1}$) four-circle diffractometer, using Mo$K\alpha$ radiation monochromated by a graphite crystal. The intensities were corrected for the Lorentz, polarization, and absorption effects. A total of 2108 observed reflections whose intensity was larger than three times their standard deviations was obtained within a range of $2\theta<40°$.

Structure Analysis

The positions of three unique silver atoms were deduced from a three-dimensional Patterson synthesis. The remaining non-hydrogen atoms were located by successive Fourier syntheses. Six cycles of block-diagonal least-squares refinement led an *R* value (defined as $\sum||F_o|-|F_c||/\sum|F_o|$) of 0.095 for the observed reflections. Subsequently, six further cycles of least-squares refinements with anisotropic thermal factors reduced the *R* value to 0.047. At this point, a difference Fourier synthesis was computed; all hydrogen atoms could be allocated with peak heights varying from 0.2 to 0.3 eÅ^{-3}. Introducing the hydrogen atoms with isotropic temperature factors brought the *R* value down to 0.032. Refinement was terminated when the shifts of the parameters for the non-hydrogen atoms were less than one-tenth of their estimated standard deviations. The final *R* value was 0.029. A final difference Fourier synthesis showed no significant features of the undulations, with ranged from −0.2 to 0.1 eÅ^{-3}. The atomic scattering factors for Ag^+, S, N, C, and H were taken from the International Tables for X-ray Crystallography.[7] The anomalous dispersion correction was not taken into account. In the least-squares procedure, the quantity minimized was $\sum w(k|F_o|-|F_c|)^2$, where *k* was a scale factor and $w=1$ for all the observed reflections. The final atomic coordinates and thermal parameters are given in Tables 2 and 3, along with their estimated standard deviations. The

calculated and observed structure factors are listed in Table 4.**

Results and Discussion

The Crystal Structure. The crystal structure of Ag-EtDC (except hydrogen atoms), projected along the c axis, is shown in Fig. 1. The crystal is composed of hexameric molecules, $[AgS_2CN(C_2H_5)_2]_6$. Each molecule has a center of symmetry. The molecular structure was essentially consistent with Hesse's preliminary result.[4] As is shown in Table 6, the distance between Ag(1) and S(2A″) in the neighboring molecule is 2.994 Å. The distance is longer than any other inner-hexameric bond, but it is nearly the same as that, 2.965 Å, of Hg–S in the β form of Hg-$(EtDC)_2$.[8] Since

** Table 4 is deposited as Document No. 7616 at the Office of the Editor of the Bulletin of the Chemical Society of Japan.

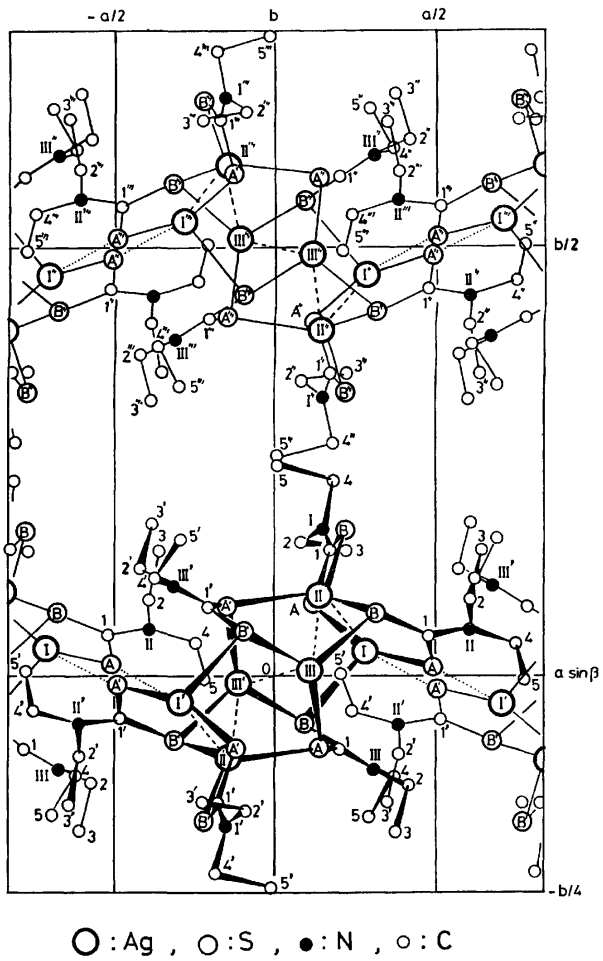

Fig. 1. The crystal structure of Ag-EtDC projected along the c axis.

the sum of the ionic radii of Ag and S (3.10 Å) is larger than the distance of Ag(1)–S(2A″) (2.994 Å), it is concluded that the terminal silver atom is bridged by a sulfur atom to the silver atom of the adjacent hexameric molecule and that the hexameric molecules form a chain polymer along the a axis. In the crystal, these chains sparsely contact with each other by van der Waals interaction. The inter-molecular distances are listed in Table 5; the limit of 0.3 Å is greater than the sum of the relevant van der Waals radii cited by Pauling.[9]

The Molecular Structure. A schematic drawing of the hexameric molecule of Ag-EtDC, which is a part of the chain polymer, is shown in Fig. 2. The hexamer contains three types of diethyldithiocarbamate ligands-1, 2, and 3. The atomic arrangement of the three types of ligands is shown in Fig. 3. The bond distances and angles are listed in Tables 6 and 7.

In the case of hexamers of univalent metal carbamates,[5,12,13] the geometrical arrangement of the metal atoms is usually octahedral, as is shown in Table 8. However, in the Ag-EtDC hexamer, the metal atoms do not form an octahedron, but instead form a doubly bent chain, as may be seen in Fig. 2. The silver-silver distances, Ag(1)–Ag(2), Ag(2)–Ag(3), and Ag(3)–Ag(3′) (2.841, 2.974, and 2.890 Å respectively), are similar to that of the metallic Ag–Ag bond (2.889 Å at

(3.786, 3.855, 3.673, and 5.928 Å respectively) are considerably longer than those of the octahedral conformation (3.20—3.28 Å). It seems that the unusual arrangement of the metal atoms causes the formation of a chain polymer and also a complicated coordination of the six ligands to the metal atoms, as will be discussed later. The thermal ellipsoids of atoms projected along the b axis are shown in Fig. 4. The atoms in the outer part of the molecule vibrate more than those of the inner part. The thermal vibrations of the terminal methyl carbons are the largest, as was expected.

The Coordination. All diethyldithiocarbamate

ligands are bidentate to the bivalent metals[8,15–17] and are bidentate[10] or tridentate[5,11–13] to the univalent metals. All six ligands in the hexamer, Cu(I)-PrMC,[12] Ag-PrDC,[5] and Ag-PrMC,[13] are tridentate. On the other hand, in the case of Ag-EtDC, there are three types of ligands in the hexameric molecules (i) Both sulfur atoms [S(1A), S(1B)] of the ligand-1 are monodentate (coordination number of the ligand-1, $p_1=2$). (ii) In the ligand-2, one [S(2A)] is mono- and the other [S(2B)] is bidentate. In addition, the sulfur atom [S(2A)] of the ligand-2 coordinates to another silver atom [Ag(1')] of the adjacent hexameric molecule ($p_2=3+1$). (iii) The two sulfur atoms [S(3A), S(3B)] of the ligand-3 are bidentate ($p_3=4$), as is shown in Figs. 2 and 3. Consequently, each silver atom in a hexamer has five combined atoms (one silver and four sulfur atoms, or two silver and three sulfur atoms). It seems that the greater coordination number tends to give the shorter distance of C–N, and the longer distance of C–S, as is shown in Table 6. It may be considered that these three types of coordinations have influence on the different electron transfer from the nitrogen through carbon to the sulfur atoms.

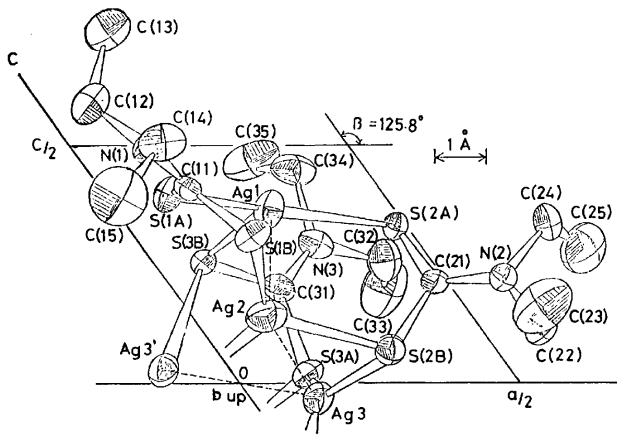

Fig. 4. Atomic arrangements of Ag-EtDC in an asymmetric unit (b axis projection).

The Ligand Structure. A comparison of the bond distances in various univalent metal-EtDC complexes is shown[8,15–19] in Table 8. The bond distances of S–C and C–N obtained in the present work are nearly the same as those of the other compounds. The bond distance of Ag–S in Ag-EtDC is, however, slightly longer than in the other Ag-complexes. This may be attributable to the doubly bent chain of the silver atom and to the formation of the chain polymer in the Ag-EtDC crystal. The distances between carbon and nitrogen show a double-bond character. All the ligands of the hexamer are planar except for the terminal alkyl groups, as is shown in Fig. 1. The terminal methyl groups of the ligands-1 and 2 take a *trans*-configuration, whereas those of the ligand-3 take a *cis*-configuration. This is the first example of an alkyldithiocarbamate complex in which the ligand molecules have both *trans*- and *cis*-type methyl groups. It may be caused by complicated packing among the hexameric molecules.

The C–H bond distances are around 0.96 Å, varying from 0.61 to 1.23 Å.

It seems that the solubility of a crystal depends on the polymerity of the molecule in the crystal. Whereas Ag-PrDC is a simple hexamer, in the case of Ag-EtDC the hexameric molecules form a chain polymer along the a axis. This agrees with the fact that Ag-PrDC is readily soluble, while Ag-EtDC is hardly soluble, in an organic solvent.

We wish to express our hearty thanks to Professor I. Ueda, Professor K. Ueno, and Assistant Prof. S. Kawano, Kyushu University, for their kind valuable advice throughout this work. Thanks are also due to Prof. T. Kato, Yamaguchi University, for his advice on the computation process. We wish also to thank to Prof. T. Kawasaki and his co-workers at the Faculty of Pharmacy of Kyushu University for making available the Syntex automated diffractometer.

(Received September 16, 1975)

Effects of solvent polarity upon the electron donor-acceptor interactions in the excited state of p-$(CH_3)_2N\,C_6H_4$-$(CH_2)_n$-(9-anthryl) (n=0, 1, 2, 3) and p-$(CH_3)_2NC_6H_4$-$(CH_2)_n$-(1-pyrenyl) (n=1, 2, 3) have been investigated by means of fluorescence spectral measurements and theoretical calculations based on some simplified models. The solvent-induced electronic structural changes during the excited state lifetime have been demonstrated for some of the above intramolecular exciplexes.

The nature of the CT (charge transfer) interaction in the excited electronic state is a subject under the most lively investigation at present. For example, it is well-known that many aromatic molecules in solution form exciplexes in the singlet excited state.[1] Detailed studies on the structures and dynamic behaviors of exciplex systems are now being made, mainly by means of time-resolved fluorescence measurements as well as transient absorption spectral measurements by the laser photolysis method. On the other hand, similar studies have been made on the excited state of CT complexes (which are stable in the ground state), such as the TCNB(1,2,4,5-tetracyanobenzene)-aromatic hydrocarbon complexes.[2-6] Owing to these investigations, the nature of the CT interactions in the excited electronic state has been elucidated to a considerable extent and the results of these investigations appear to be important from the viewpoint of the photochemical reaction mechanisms in solution.

Upon increasing the solvent polarity, both the fluorescence quantum yield and the decay time of some typical heteroexcimers, such as pyrene-DMA (*N,N*-dimethylaniline) and anthracene-DEA (*N,N*-diethylaniline), decrease, and the fluorescence yield decreases more rapidly with increasing solvent polarity than does the corresponding fluorescence lifetime.[7,8] There are two alternative interpretations of these observations.

(a) Solvent-induced Change of Electronic and Geometrical Structure of the Exciplex.[7] The exciplex state may be considered as a resonance hybrid of the electron transfer configuration (A^-D^+) mixed with the locally excited configuration (A*D) or (AD*). The solvation of the exciplex by the polar solvents will oppose the electronic delocalization between A and D since the solvation energy increases with increasing charge separation in the exciplex, *i.e.*, with its increasing dipole moment. This is true whether the solvation can be approximated by the interaction of a solute dipole with the surrounding dielectric continuum[9] or it is described by the 1 : n electrostatic complex formation with the polar solvent molecules.[10,11] Furthermore, the strong solvation may induce the change of geometrical structure of the exciplex leading to the decrease of the electronic delocalization interaction between A and D. Thus, the exciplex electronic structure may become more polar with increasing polarity of the solvent and this change of the electronic structure would lead to the decrease of the radiative transition probability. The radiationless transition probability, however, increases with solvent polarity because the energy gap between the relevant electronic levels becomes smaller in a more polar solvent and, furthermore, because of the ionic dissociation of the complex in a more or less polar solvent.

(b) Competition between the Ionic Dissociation and the Fluorescent Exciplex Formation in the Encounter Complex.[8]

$$A^* + D \rightarrow A^* \cdots D \begin{cases} \xrightarrow{k_c} (A^-D^+)^* \xrightarrow{k_f} \\ \xrightarrow{k_{ip}} (A_s^- \cdots D_s^+) \end{cases} \xrightarrow{k_d} A_s^- + D_s^+$$

where $(A^-D^+)^*$ is the fluorescent exciplex and ($A_s^- \cdots D_s^+$) represents a solvated ion-pair which is non-fluorescent. Almost complete charge transfer between D and A in the exciplex is assumed here, while partial charge transfer is postulated in the case of (a). It is assumed that k_{ip} and k_i are increased in polar solvents while k_c is almost independent of the solvent polarity and, moreover, the electronic structure of the complex may be independent of the solvent polarity.

According to the recent laser photolysis studies,[12] the solvent-induced electronic structural change does not seem to be very important for the interpretation of the effect of solvent polarity upon the fluorescence yield and decay time of such strongly polar exciplexes as pyrene-DMA and anthracene-DEA systems. However, the phenomenon of the solvent-induced electronic structural change may exist in principle and seems to be of some importance in general for the interpretation of electronic structures of molecular complexes in solution, since they have more flexible structures than the ordinary molecules. The observation by Schneider and Lippert[13] that the fluorescence spectra of 9,9'-bianthryl depends considerably on the solvent polarity, showing a red shift as the polarity is increased, seems to be a special case of a competition between the delocalization tendency and the solvation as described in (a). Namely, in the case of 9,9'-bianthryl, which consists of two weakly interacting identical moieties, there arise energy minima corresponding to solvated polar (unsymmetrical) states which are more stable than the nonpolar symmetrical ones at sufficiently high solvent polarities.[14]

* To whom all correspondence should be addressed.

Recently, we have examined the solvent effect upon the $S_n \leftarrow S_1$ spectra of this compound by using the mode-locked ruby laser.[15] Although the $S_n \leftarrow S_1$ spectra in hexane are not the same as those of anthracene, they are somewhat similar to each other. The spectra observed in acetone are quite different from those in hexane and rather similar to those of anthracene ions.[15] This is a direct demonstration of the solvent-induced electronic structural change. This result of a remarkable solvent effect on the $S_n \leftarrow S_1$ spectra is similar to the case of the solvent effect upon the $S_n \leftarrow S_1$ spectra of 9-(4-dimethylaminophenyl)anthracene which we have observed previously.[16]

Now, in order to elucidate the electronic structures and the mechanisms of the dynamical behaviors of exciplex systems, we have been making detailed studies of the following intramolecular exciplex systems: *p*-$(CH_3)_2N$ C_6H_4-$(CH_2)_n$-(9-anthryl) (n=0, 1, 2, 3, abbreviated as A_0, A_1, A_2, A_3, respectively) and *p*-$(CH_3)_2N$ C_6H_4-$(CH_2)_n$-(1-pyrenyl) (n=1, 2, 3, abbreviated as P_1, P_2, P_3, respectively). The solvent shifts of the fluorescence bands of these intramolecular exciplexes have been measured and analyzed by a theoretical method which is an extension of the previous ones,[17,18] and the solvent-induced electronic structural change has been demonstrated.

In the following the results of these investigations will be described from the viewpoint of the solvent-induced electronic structural change of the composite molecular systems and of the geometrical restrictions on the exciplex formation.

Experimental

Synthesis of the compounds, A_0, A_1, A_2, A_3, P_1, P_2, and P_3, will be reported in a separate paper.[19]

The following solvents were used for the measurements. (The numbers in parentheses are those attached to the observed points in the figures.) Hexane (3), methylcyclohexane (4), cyclohexane (5), dibutyl ether (9), diethyl ether (13), chloroform (14), isobutyl acetate (17), ethyl acetate (18), methyl acetate (19), tetrahydrofuran (20), dichloromethane (21), pyridine (23), isopentyl alcohol (25), 1-butanol (26), 1-propanol (28), acetone (29), and acetonitrile (31), were spectrograde reagents and used without purification. Isopentane (1), pentane (2), decalin (6), tetralin (7), diisopentyl ether (8), dipropyl ether (10), acetal (11), diisopropyl ether (12), 1-hexanol (24), isobutyl alcohol (27), and ethanol (30), were purified by the standard method.[20] Butylacetate (15), ethyl butyrate (16), 1,1,2,2-tetrachloroethane (22), were G. R. grade reagents and used without purification.

Fluorescence spectra were measured by an Aminco-Bowman or a Hitachi MPF-2A spectro-photofluorometer. Solutions were deaerated by means of the freeze-pump-thaw cycles or flushed with nitrogen. For the measurements at low temperatures, a cuvette was immersed in ethanol in a quartz Dewar vessel and the temperature of ethanol was controlled by dropping liquid nitrogen. For the measurements at higher temperatures than room temperature, the cuvette was immersed in hot water in the quartz Dewar.

Results and Discussion

Solvent Effects upon Fluorescence Spectra. Absorption spectra of A_1, A_2, A_3, P_1, P_2, and P_3 do not show any indication of the ground state interaction. However, the absorption spectra of A_0 are a little broadened compared with those of anthracene, indicating a weak ground state interaction between the two moieties. The longest wavelength absorption band of A_0 may be a superposition of the anthracene band slightly modified by the substitution and a very weak CT band.[16,21] Although the absorption spectra of these systems show little dependence on the solvent polarity, the latter affects considerably their fluorescence spectra. For instance, the fluorescence spectra of A_2 and P_1 show remarkable solvent dependence, as indicated in Fig. 1. Quite similar results have been obtained for A_1.

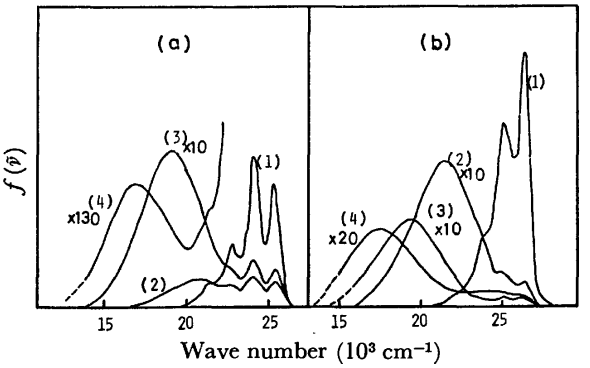

Fig. 1. Fluorescence quantum spectra of A_2 (a) and P_1 (b) in various solvents.
Solvents: 1. hexane, 2. diethyl ether, 3. isobutyl acetate, 4. isobutyl alcohol.

The fluorescence spectra of A_1, A_2, and P_1 in nonpolar solvent can be ascribed to the anthracene or pyrene part (LE (local excited state) fluorescence). In polar solvents, they show the exciplex fluorescence band in addition to the LE fluorescence band. The exciplex band shows a remarkable red shift with increase of the solvent polarity, while the wave number of the LE band does not depend on the solvent polarity. Thus, A_1, A_2 and P_1 show dual fluorescence spectra in polar solvents, but not in nonpolar solvents.

The fluorescence spectra of P_2 and P_3 in various solvents are indicated in Fig. 2. The results for A_3

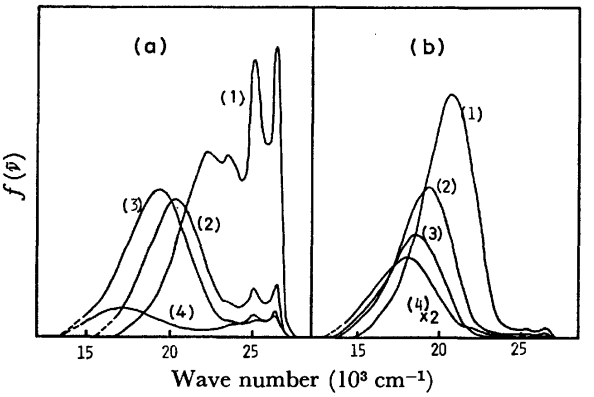

Fig. 2. Fluorescence quantum spectra of P_2 (a) and P_3 (b) in various solvents.

are rather similar to those in Fig. 2. In the case of these systems, both the exciplex fluorescence and the LE fluorescence bands can be observed even in nonpolar solvents, although the exciplex fluorescence yield of P_3 in a nonpolar solvent is much larger than that of P_2.

The above results for P_2 and A_2 suggest that the geometrical structure of P_2 is more favorable for the exciplex formation than that of A_2, since the electron affinity of pyrene is almost equal to or a little smaller than that of anthracene.

In contrast to the fluorescence spectra of $A_n(n=1,2,3)$ and $P_n(n=1,2,3)$, A_0 exhibits a single fluorescence band and shows a continuous red shift with increase of the solvent polarity.[16]

We have plotted the energy of the fluorescence ($h\nu_f$) of these compounds against the polarity parameter $f(\varepsilon,n)=(2(\varepsilon-1/2\varepsilon+1)-(n^2-1/2n^2+1))$, where ε and n are the dielectric constant and the refractive index of the solvent, respectively. Of course, the solute-solvent interaction may be a more or less specific molecular interaction, so that the points in the figures are rather scattered around the average values.

The plot for A_0 cannot be represented by one straight line; it is curved or represented by a superposition of several lines of different slopes.[16] This result indicates the solvent-induced change of excited electronic structure. The change of the electronic structure in the case of A_0 can be concluded also from the solvent dependence of the fluorescence yield and lifetime as well as the solvent effect on the $S_n \leftarrow S_1$ absorption spectra.[16,21]

In the case of A_1, A_2, and P_1, the CT fluorescence appears at the values of the polarity parameter $f(\varepsilon,n)\approx 0.3$—$0.4$, where its red shift with the solvent polarity is especially large. Compared with the case of sandwich type exciplexes, the stabilization of the CT state due to the Coulomb force between the pair may be smaller in these cases owing to the larger separation between

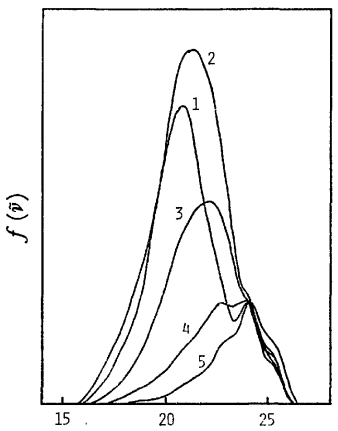

Fig. 6. Temperature effect on the fluorescence of A_1 in *n*-butylether. The spectra are normalized at the peak of anthracence LE fluorescence (24.2×10^3 cm^{-1}). Temperature (°C): (1) −61.5, (2) −25.3, (3) −3.5, (4) 26.5, (5) 78.5.

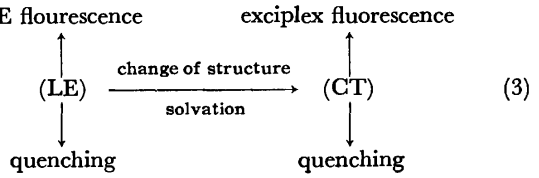
the exciplex fluorescence band appears, becomes stronger, and shifts to red. At sufficiently low temperatures, the LE band is again a little strengthened in addition to the further red shift of the exciplex band. At high temperatures, the CT state will not be stabilized sufficiently for the exciplex band to appear because of the weak solvation. There seems to be a competition between the LE fluorescence and the change of the excited electronic structure due to solvation. At sufficiently low temperatures, the solvation process as well as the accompanying structural changes may become slow because of the high viscosity, leading to a strengthening of the LE band.

The plot of the energy of the exciplex fluorescence against the solvent polarity parameter $f(\varepsilon, n)$ in the case of P_3 and A_3 can be represented approximately by an almost straight line. Therefore, only small solvent-induced electronic structural changes seem to arise in the case of these exciplexes and their electronic structures may be considerably polar even in a nonpolar solvent, since their CT states are presumably lower than the LE state even in nonpolar solvents due to the strong Coulomb interaction between the two moieties. The situation in the case of P_2 seems to be analogous. However, the plot of $h\nu_f$ against $f(\varepsilon, n)$ appears a little curved, indicating a small change of the electronic and, presumably, geometrical structures of the exciplex fluorescent state induced by the interaction with polar solvent molecules.

Remarks on the Mechanism of Charge Transfer Process in the Intramolecular Exciplex Systems. At any rate, the CT fluorescence state should be formed from the LE state owing to the solvation as well as the change of the geometrical structure, as indicated in Eq. 3.



(3)

For example, the fluctuation of the relative orientations of two aromatic rings into the configuration most suitable for the charge transfer will occur frequently in the case of A_1 and P_1. The charge transfer from the *N,N*-dimethylaniline group to an anthracene or pyrene nucleus might be induced by this orientational fluctuation as well as those of polar solvent molecules, and the generated CT state may be stabilized by the orientational relaxation of solvents, *i.e.*, by the solvation process.

The change of structure seems to be especially important for A_2 and P_2 as well as A_3 and P_3 to form the exciplex fluorescent state. In the case of A_2 and P_2, their structures in the ground and the excited FC state are presumably *trans* or *gauche* form with respect to the CH_2–CH_2 single bond. They will change partly to *cis* form where the charge transfer occurs, and will be solvated in the polar solvent, resulting in the exciplex fluorescence. As was pointed out already, the Coulomb interaction energy between the donor cation and acceptor anion in the *cis* form of P_2 seems to be larger than that of A_2, since the exciplex fluorescence of P_2 can be observed even in nonpolar solvents. The situation in the case of A_3 and P_3 seems to be analogous: namely, their ground state structure may be an extended form and the sandwich structure seems to be formed during the excited state lifetime.

Analysis of the Observed Results on the Basis of Some Theoretical Models. Now, we will try to explain the above experimental results on the basis of some theoretical models. We assume the wave function of Eq. 4 for the intramolecular exciplex systems.

$$\Psi = C_1\Psi(A^-D^+) + C_2\Psi(A^*D) + C_3\Psi(AD) \qquad (4)$$

where the 1st term represents the lowest CT configuration, the 2nd is the locally excited (^1L_a) configuration, and the last term is the ground configuration. The Hamiltonian of the system may be given by:

$$\mathcal{H} = \mathcal{H}_0 + \mathcal{H}' \qquad (5)$$

where $\mathcal{H}_0$ is the Hamiltonian of the exciplex in the absence of the solvent and $\mathcal{H}'$ represents the electrostatic interaction with the solvent molecules. Since the solute-solvent interaction is essentially "molecular" interaction between a solute molecule and the surrounding solvent molecules, the above treatment in terms of a dielectric continuum model may be only a rough approximation. Presumably, a more appropriate treatment is to regard the interaction of the solute with the nearest neighbor solvent molecules as a $1:n$ electrostatic complex formation and to approximate the interactions with solvent molecules further apart using the dielectric continuum model. This is a rather old problem in the theoretical treatment of the molecular interactions in liquid solutions, but even at present a rather difficult problem.

If we regard the solute-solvent interaction as an electrostatic molecular complex formation, we must calculate the interaction energy for an individual case by using the wave function of Eq. 4 in which it is necessary to assume some specified form of $\mathcal{H}'$ for several interacting molecules. However, such a calculation is rather difficult in practice. In view of the fact

that the solvent-induced changes of fluorescence spectra of A_1, A_2 and P_1 can be well interpreted by assuming the interaction of an excited solute dipole with the surrounding solvent molecules to be approximated by the dielectric continuum, we approximate here $\mathcal{H}'$ by a simple continuum model using the Onsager's reaction field. On the basis of this simplified model, we try to give an interpretation of the general features of the solvent effects on the exciplex fluorescence.

We put

$$\mathcal{H}' = -\vec{\mu}_{op}\vec{F} = -\vec{\mu}_{op}\vec{\mu}f_\varepsilon \tag{6}$$

where $\vec{\mu}_{op}$ is the dipole operator, $\vec{F}$ is the Onsager's reaction field, and $\vec{\mu}$ is given by:

$$\begin{aligned}\vec{\mu} &= \langle\Psi|\vec{\mu}_{op}|\Psi\rangle \simeq C_1^2\langle\Psi(A^-D^+)|\vec{\mu}_{op}|\Psi(A^-D^+)\rangle \\ &= C_1^2\vec{\mu}_0\end{aligned} \tag{7}$$

We denote the matrix elements of the Hamiltonian as follows:

$$\begin{aligned}\langle\Psi(A^-D^+)|\mathcal{H}|\Psi(A^-D^+)\rangle &= \langle\Psi(A^-D^+)|\mathcal{H}_0|\Psi(A^-D^+)\rangle \\ &\quad + \langle\Psi(A^-D^+)|\mathcal{H}'|\Psi(A^-D^+)\rangle \\ &= E_c - \langle\Psi(A^-D^+)|\vec{\mu}_{op}\vec{F}|\Psi(A^-D^+)\rangle \\ &= E_c - C_1^2\vec{\mu}_0^2 f_\varepsilon\end{aligned} \tag{8}$$

$$\left.\begin{aligned}&\langle\Psi(A^-D^+)|\mathcal{H}|\Psi(A^*D)\rangle \simeq \langle\Psi(A^-D^+)|\mathcal{H}_0|\Psi(A^*D)\rangle = \alpha \quad (a)\\ &\langle\Psi(A^-D^+)|\mathcal{H}|\Psi(AD)\rangle \simeq \langle\Psi(A^-D^+)|\mathcal{H}_0|\Psi(AD)\rangle = \beta \quad (b)\\ &\langle\Psi(A^*D)|\mathcal{H}|\Psi(A^*D)\rangle \simeq \langle\Psi(A^*D)|\mathcal{H}_0|\Psi(A^*D)\rangle = E_e \quad (c)\\ &\langle\Psi(AD)|\mathcal{H}|\Psi(AD)\rangle \simeq \langle\Psi(AD)|\mathcal{H}_0|\Psi(AD)\rangle = E_g \quad (d)\end{aligned}\right\} \tag{9}$$

In terms of these matrix elements, the secular equations may be written as:

$$\begin{aligned}&C_1(E_c - C_1^2\mu_0^2 f_\varepsilon - E) + C_2\alpha + C_3\beta = 0\\ &C_1\alpha + C_2(E_e - E) = 0\\ &C_1\beta + C_3(E_g - E) = 0\end{aligned} \tag{10}$$

Thus, the wave function Ψ depends upon the solute-solvent interaction $\mathcal{H}'$, while $\mathcal{H}'$ depends on the charge distribution determined by Ψ. Therefore, one must solve the nonlinear Eq. 10. However, in the present case, the solution can be obtained by solving Eq. 11, instead of doing an iterative calculation.

$$\left\{E_c - E - \frac{\alpha^2}{E_e - E} + \frac{\beta^2}{E}\right\}\left\{1 + \frac{\alpha^2}{(E_e - E)^2} + \frac{\beta^2}{E^2}\right\} = \mu_0^2 f_\varepsilon \tag{11}$$

In order to obtain the energies relevant to the frequency of the exciplex emission, one must add to the energy obtained from Eq. 11 the polarization energy of the solvent, $E_{pol} = (1/2)\vec{\mu}\vec{F}$. We denote the lowest and the 2nd lowest eigenvalues obtained from Eq. 11 as E_0 and E_1, respectively. Then, the energies of the excited equilibrium state (E_e^{eq}) and the FC ground state (E_g^{FC}) may be given by Eq. 12 and Eq. 13, respectively.

$$E_e^{eq} = E_1 + \frac{1}{2}\vec{\mu}_e^{eq}\vec{F}_e^{eq} = E_1 + \frac{1}{2}\mu_e^{eq'} f_\varepsilon = E_1 + \frac{1}{2}C_1^4\mu_0^2 f_\varepsilon \tag{12}$$

$$\begin{aligned}E_g^{FC} &= E_0 - \vec{\mu}_g^{FC}\vec{\mu}_e^{eq}(f_\varepsilon - f_n -) \mu_g^{FC'} f_n + \frac{1}{2}\mu_e^{eq'}(f_\varepsilon - f_n) + \frac{1}{2}\mu_g^{FC'} f_n \\ &= E_0 - C_1'^2 C_1^2 \mu_0^2 (f_\varepsilon - f_n) + \frac{1}{2}C_1^4\mu_0^2(f_\varepsilon - f_n) \\ &\quad - \frac{1}{2}C_1'^4\mu_0^2 f_n\end{aligned} \tag{13}$$

where μ_g^{FC} is the dipole moment of the FC ground state and C_1 and C_1' represent respectively the coefficients of $\Psi(A^-D^+)$ in the lowest excited and the ground state wave functions obtained by solving Eq. 10 and Eq. 11. Thus, the energy of the exciplex fluorescence may be given by

$$h\nu_f = E_1 - E_0 + \frac{1}{2}(C_1^4 + C_1'^4)\mu_0^2 f_n + C_1^2 C_1'^2 \mu_0^2 (f_\varepsilon - f_n) \tag{14}$$

The solvent shift of the fluorescence of A_1, for example, can be well reproduced by means of the following parameters, as indicated in Fig. 3: $E_c = 3.70$ eV, $E_e = 3.14$ eV, $|\vec{\mu}_0| = 28.0$ D, $\alpha = 0.05$ eV, and $\beta = 0$. Since α is very small and $\beta = 0$, this case can be regarded as a solvation induced reversal of two energy levels, which is the same conclusion as already obtained by the simplified procedure. We have obtained a similar calculated result for P_1. Although we have not made any detailed calculation for A_2, the circumstances in A_2 seems to be rather similar to those in A_1.

In the case of A_0, however, we cannot neglect β, but we must use fairly large values for both α and β in order to reproduce the observed result. We have confirmed that the result of calculation using the following values of parameters: $E_c = 3.1$ eV, $|\vec{\mu}_0| = 20.1$ D, $\alpha = 0.4$ eV, and $\beta = 0.3$ eV or $\beta = 0.4$ eV, is rather close to the experimental result. The calculated value of C_1^2 shows a gradual increase with the increase of the solvent polarity, in contrast to the case of A_1 where C_1^2 shows a sudden increase at $f(\varepsilon, n) \approx 0.33$. However, recent results[21] of detailed studies upon the solvent dependence of the fluorescence yield and lifetime of A_0 indicate a rather drastic change of electronic structure when the solvent is changed from diethyl ether ($f(\varepsilon, n) = 0.512$) to isobutylacetate ($f(\varepsilon, n) = 0.548$). In order to explain this drastic structural change, we need a more sophisticated theoretical treatment. Therefore, roughly speaking, the plot of $h\nu_f$ *vs.* $f(\varepsilon, n)$ for A_0 might be represented approximately by the superposition of two lines of different slopes. Nevertheless, the solvent-induced electronic structural change of excited A_0 is different from those in the case of A_1, A_2 and P_1, in the fact that A_0 shows a single fluorescence band. The single fluorescence band of A_0 seems to be ascribed to a stronger electronic interaction between two moieties than in the case of A_1, A_2 and P_1, which is consistent with the larger values of parameters α and β.

In the case of A_3 and P_3, the solvation induced electronic structural change is not large and the electronic structure of the exciplex seems to be considerably polar even in a nonpolar solvent. Actually, in order to reproduce the observed result, it was found for A_3 that $E_c = 2.90$ eV, which is lower than the LE state, leading to the strongly polar structure of the exciplex,

and $\alpha \approx 0$—0.3 eV and β can be neglected. The calculated result is compared with the experimental values in Fig. 3. The change of C_1^2 with solvent polarity was rather small. We have not made such a calculation for P_3, but the results may be very similar to the present one. Although we have not made any calculation in the case of P_2, a similar calculation with smaller values of the energy gap ($E_e - E_c$) than those for the case of $n=3$, might explain the observed results.

Concluding Remarks

We have demonstrated that the electronic structure of some molecular composite systems are liable to change remarkably by the interaction with polar solvent molecules in the excited electronic state. Although the strongly polar intermolecular exciplex systems undergo ionic dissociation, the present intramolecular exciplex systems cannot dissociate. Instead, some of them show the solvent-induced electronic structural change, and they show a quite large red shift of exciplex fluorescence in the strongly polar solvents, in which the fluorescence of the intermolecular exciplex cannot be observed because of the ionic dissociation. Thus, restricting the geometrical structure of the exciplex system by connecting two moieties with the methylene chain, we have found some new phenomena which cannot be observed in the case of the strongly polar intermolecular exciplexes. Furthermore, the present results indicate clearly that the plane parallel sandwich structure is not necessary for the fluorescent exciplex in polar solvents.

For the more detailed elucidations of the behaviors of these intramolecular exciplexes, measurements of fluorescence quantum yields, rise and decay times, and $S_n \leftarrow S_1$ spectra are necessary. We have made such studies and the results will be reported in a separate paper.

Studies of the Ruthenium(III) Complexes. XII[1] Kinetic Studies of the Deammonation-anation Reactions of Halogenopentaammineruthenium(III) Complexes in the Solid State

Akira Ohyoshi, Susumu Kohata, Masanobu Nishimori, Yoshiaki Shimura, and Noriko Iwasaki

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received June 9, 1975)

The kinetics of the thermal substitution reaction of chloro- and bromopentaammineruthenium(III) complexes has been studied in the solid state. The reaction rates and kinetic parameters were determined for these reactions: $[RuX(NH_3)_5]Y_2(s) \rightarrow [RuXY(NH_3)_4]Y(s) + NH_3(g)$, and (X=Cl, Br: Y=Cl, Br, I, NO_3). The values of the rate constant (s^{-1}), the activation energy (kcal mol^{-1}), and the activation entropy (cal mol^{-1} K^{-1}) were 1.70×10^{-5} (at 222 °C), 41.8, and 0.7 for $[RuCl(NH_3)_5]Cl_2$; 1.02×10^{-4} (at 226 °C), 30.2, and −19.6 for $[RuCl(NH_3)_5]Br_2$; 1.35×10^{-4} (at 208 °C), 25.3, and −26.6 for $[RuCl(NH_3)_5]I_2$; 8.47×10^{-3} (at 162 °C), 29.7, and −11.5 for $[RuCl(NH_3)_5](NO_3)_2$; 1.26×10^{-4} (at 219 °C), 21.8, and −35.1 for $[RuBr(NH_3)_5]Cl_2$, and 1.17×10^{-3} (at 162 °C), 14.7, and −40.0 for $[RuBr(NH_3)_5](NO_3)_2$ respectively. The S_N1-like mechanism is favorable for the deammonation-anation reaction of all the chloropentaamine series except for the iodide, while the S_N2-like mechanism is more probable for the corresponding reaction of the bromopentaammine series. The reaction mechanism is predominantly controlled by the coordinating ability of the inner-sphere halide ion and secondarily by that of the outer-sphere anion.

The thermal decomposition of a series of halogenopentaammine halides[2,3] and nitrates[4] of cobalt(III) has been studied. The results suggest that the thermal dissociation reaction involves the following steps:

$$[CoX(NH_3)_5](NO_3)_2(s) \longrightarrow [CoX(NO_3)(NH_3)_4]NO_3(s) + NH_3(g)$$

$$[CoX(NO_3)(NH_3)_4]NO_3(s) \longrightarrow [CoX(NO_3)_2(NH_3)_3](s) + NH_3(g)$$

$$[CoX(NO_3)_2(NH_3)_3](s) \longrightarrow Co_3O_4(s) + \text{decomposition products.}$$

A recent kinetic study[5] of the thermal decomposition reaction of the series of ammine complexes of chromium(III) has reported that the thermal substitution reaction of the chloropentaamminechromium(III) chloride proceeded through the intermediate of *trans*-$[CrCl_2(NH_3)_4]Cl$.

Our own previous papers[6,7] exhibited that the thermal reactions of halogenopentaammine- *cis*-dihalogenotetraammine- and hexaammineruthenium(III) complexes were initiated by the replacement of coordinated ammonia by the outer-sphere halide ion, and the reaction mechanisms of the hexaammine- and *cis*-dihalogenotetraammineruthenium(III) complexes were proposed. In this paper, the kinetic studies of the thermal anations of $[RuX(NH_3)_5]Y_2$ (X=Cl, Br; Y=Cl, Br, I, NO_3) will be demonstrated. The influence of both inner-sphere and outer-sphere ions on the reaction mechanism will be discussed in comparison with those of the hexaammine and tetraammine series of ruthenium(III) complexes.

Experimental

Preparation of Complexes. The complexes, $[RuX(NH_3)_5]X_2$ (X=Cl, Br), were prepared by the method described in the literature.[8] $[RuCl(NH_3)_5]Y_2$ (Y=Br, I, NO_3) and $[RuBr(NH_3)_5]Y_2$ (Y=Cl, I, NO_3) were precipitated from a cold solution of ammonium halide and nitric acid.

The complexes were confirmed by elemental analysis and by visible and UV spectral measurements. $[RuCl(NH_3)_5]Cl_2$. Found: ν_{max}, 30.5×10^3 cm^{-1}; ε, 1.89×10^3 cm^{-1} M^{-1}. Ref. Value[8]: ν_{max}, $30.5\times10^3 cm^{-1}$; ε, 1.93×10^3 cm^{-1} M^{-1}. $[RuCl(NH_3)_5]Br_2$. Found: H, 4.05; N, 18.85%. Calcd: H, 3.96; N, 18.36%. $[RuCl(NH_3)_5]I_2$. Found: H, 3.15; N, 14.57%. Differential Thermal Analysis, Thermogravimetry and Isothermal Kinetic Measurement. The differential thermal analysis (DTA) and the thermogravimetry (TG) of the complexes were carried out using a Shimadzu DTG 20-type micro-differential thermobalance. All the experiments were made in a constant helium stream at a heating rate of 5 °C/min., using about a 10 mg sample in each run. In the isothermal kinetic measurement, the temperature was rapidly elevated so as to depress the decomposition of the sample before measurement and was then kept constant within ±0.5 °C. The kinetic plots were made based on mass-loss measurements at several temperatures.

A Shimadzu UV-200 recording spectrophotometer and a JASCO Model DS-403G Grating Infrared spectrophotometer were used for the measurement of the absorption spectra of the initial compounds and the reaction products.

Results and Discussion

DTA and TG Studies. The DTA and TG curves of the chloropentaammineruthenium(III) bromide and iodide, and the bromopentaammineruthenium(III) chloride and iodide are given together in Fig. 1, while those of the nitrates are given in Fig. 2.

The DTA curves are characterized by endothermic peaks for the chloropentaammine series at 327 °C (bromide) and 291 °C (iodide). Shoulders were found, however, corresponding to the mass-loss of one or two

$[RuX(NH_3)_5](NO_3)_2$; (X=Cl, Br).

moles of ammonia at 310 °C and 285 °C respectively. For the bromopentaammine chloride, a small endothermic peak at 288 °C was clearly found, besides a large broad endothermic peak at 320 °C, and a broad endothermic peak was found at 284 °C for the bromopentaammine iodide. On the other hand, the DTA curves of the nitrates for both series are characterized by several exothermic peaks, different from those of the halides. For the bromopentaammine nitrate, the first exothermic peak at 158 °C was found, by the elemental analysis and the mass-loss measurement, to be corresponding to the liberation of $1/2 \cdot H_2O$. This may be attributable to the physico-chemical rearrangements of the crystalline lattice or the coordination structure after the coordinated water liberation. However, a detailed interpretation must await further investigations.

The initial temperature of mass-loss for the deammonation is as follows: $[RuBr(NH_3)_5](NO_3)_2$ (176 °C), $[RuCl(NH_3)_5](NO_3)_2$ (190 °C), $[RuCl(NH_3)_5]I_2$ (215 °C), $[RuBr(NH_3)_5]I_2$ (239 °C), $[RuCl(NH_3)_5]Br_2$ (243 °C), $[RuBr(NH_3)_5]Br_2$ (244 °C), $[RuCl(NH_3)_5]Cl_2$ (246 °C), $[RuBr(NH_3)_5]Cl_2$ (247 °C).

The main decomposition reaction, probably taking place during the first endo- or exothermic reaction, might be accompanied by the continuous evolution of such gases as ammonia, free halogen, or ammonium halide, as reported in a previous paper[6] on the halogenopentaammine halides. On the other hand, for the nitrates, only the ammonia gas was identified in the initial period of the thermal decomposition; the analyses of such gases as NO, N_2O, N_2 and H_2O which were identified in the thermal decomposition of halogenopentaamminecobalt(III) nitrate[4] have not yet been successful.

As a result, there were not so many differences among the thermal decomposition reactions of the halogenopentaammine series of complexes, except for those of the nitrates. However, the nitrates and the iodides all seem to be thermally unstable.

Stoichiometry and Kinetic Study. It has already been reported[6] that the thermal decomposition reactions of chloropentaammine chloride (at 246—396 °C) and bromopentaammine bromide (at 244—398 °C) can be expressed by Eq. 1:

$$[RuX(NH_3)_5]X_2 \longrightarrow [RuX_3(NH_3)_3] + 2NH_3 \quad (X=Cl, Br) \qquad (1)$$

In the present isothermal experiment it was found that the reaction actually proceeded *via* successive steps which were composed of unimolecular deammonations, because the isothermal decomposition products of the initial complex were each composed of one mole of ammonia and dihalogenotetraammine halides or nitrate. All the solid reaction products were identified by elemental analysis or absorption spectrophotometry; the results are listed in Tables 1 and 2. The results for the elemental analysis of a reaction product are not necessarily in agreement with the calculated value for chemical formulas corresponding to the liberation of one molar ammonia, except for the chlorobromotetraammine bromide. This might be attributed to the instability of the reaction product at the decomposition temperature or to the low reproducibility in this sort of thermal decomposition reaction. Unfortunately, the configurations of tetraammine complexes can not be clearly determined from the absorption spectra, especially for the mixed halide-ligand complexes. In the IR spectra of $[RuCl(NH_3)_5](NO_3)_2$ and its reaction

Initial spectrum	(25.2, 1.72)	(2.51, 1.95) (2.51, 1.92)[a]	(25.2, 2.20)	(25.2, 1.40)

a) Published value from Ref. 8.

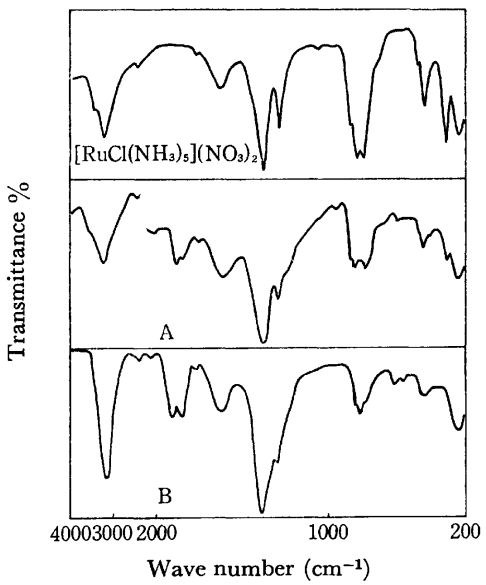

Fig. 3. IR spectra of initial complex and thermal decomposition products.
Chemical formura assigned
A: $[RuCl(NO_3)(NH_3)_4](NO_3)$
B: $[RuBr(NO_3)(NH_3)_4](NO_3)$

products, shown in Fig. 3, new absorption bands were found at 1850—1900 cm^{-1} and 570—600 cm^{-1}; the former was assigned to the ν(NO) of the coordinated NO_3^- and the latter, to the ν(Ru–NO_3) or ν(Ru–ONO_2).[9,10]

Thus, the thermal decomposition reaction can be expressed by Eqs. 2 and 3:

$$[RuCl(NH_3)_5]X_2 \longrightarrow [RuClX(NH_3)_4]X + NH_3 \quad (X=Br, I, NO_3) \quad (2)$$

$$[RuBr(NH_3)_5]X_2 \longrightarrow [RuBrX(NH_3)_4]X + NH_3 \quad (X=Cl, I, NO_3) \quad (3)$$

In the isothermal kinetic measurements, the ranges of temperature applied were decided with reference to the results of DTA and TG studies. Plots of $\ln\{a/(a-x)\}$ *vs.* the reaction time for Reactions 2 and 3 obtained from the isothermal measurements are illustrated in Figs. 4 and 5, where a is the initial mass of the sample, and $a-x$ the mass at the reaction time t. The plots give a straight line with a good reproducibility in each measurement. A similar relationship was obtained for the other complexes. As a result the thermal decomposition can be regarded as a first-order reaction with respect to the reactant. The Arrhenius plots for the reactions are given in Fig. 6, while the rate constants obtained from the slope of the straight line are listed in

Table 3, together with the kinetic parameters.

It can be seen that, in general, the rate constants for the deammonation reactions of the chloropentaammine series are smaller than those of the bromopentaammine series. In both cases, the influence of the outer-sphere anion species on the reaction rate is to enhance it in the following order; $Cl<Br<I<NO_3$.

By a comparison with the other ammine complexes, it was found that the rate constants decrease in the order of tetraammine>hexaammine>pentaammine, as has also been seen for the chromium(III) chloride complexes (Table 3). However, the activation energies do not necessarily decrease with the increase in rate constants. Moreover, the values of the activation entropy are smaller in this order: tetraammine>pentaammine≈hexaammine. These facts suggest that the reaction mechanisms for the deammonation and the anation of the outer-sphere anion are different from each other among the reactions of the three series of ammine complexes. It may be considered that the coordinated halide ligand is also one of the determinants on the reaction mechanism.

Reaction Mechanism of the Deammonation-anation. In a previous paper,[7] we discussed how the mechanism seems to belong to the S_N2 category for the substitution reaction of the hexaammine series of complexes, while the S_N1 mechanism is favorable for that of the tetraammine series, considering the values of the kinetic parameters and the contribution of the π-bonding nature between the metal and the ligand.

The reaction rates of the chloropentaammine series of complexes are smaller than those of the corresponding bromopentaammine series, and the former reveal large values of the activation energy. Yet the values of the activation entropy of the former (0——20 cal·mol^{-1}·K^{-1}) are larger than those of the latter (−34——45 cal·mol^{-1}·K^{-1}). Therefore, for the substitution reaction of the chloropentaammine series of complexes, the S_N1-like mechanism may be favorable.

The activation energies of deammonation-anation reactions should be rather close to each other, but there are some differences among the values of the activation energies for the reactions of complexes with different outer-sphere anions. This suggests that the substitution reaction mechanism is affected by the nucleophilic characters of the coordinated ligand and the outer-sphere anion. That is to say, in the chloropentaammineruthenium(III) iodide and nitrate, the deammonation-anation reaction may proceed *via* the S_N1-like (partially the S_N2-like) mechanism. On the other hand, considering the small values of the activation energy (15—26 kcal·mol^{-1}) and the large negative values of the activation entropy (−34——45 cal·mol^{-1}·K^{-1}), the mechanism for the reaction of the bromopentaammine series seems to belong to the S_N2 category.

Reviewing the thermal substitution reactions of the hexaammine-, pentaammine-, and tetraammineruthenium(III) complexes, the rate constants increase in the following order of the outer-sphere anion: $Cl<Br<I<NO_3$. That the nitrates gave the largest value of the rate constants may be attributable to the nucleophilic character, as has also been in the kinetic study[11] of the

deaquation-anation reaction of the aquapentaammine-ruthenium(III) series. The iodides also gave larger values of the rate constants than those for the other halide ions. This might be attributed to the back-donation of π-electrons from the 4d-orbital electron of the ruthenium(III) ion to the vacant d orbitals of the iodide ion, for the outer-sphere anion might be fixed by the lattice energy.

The reaction mechanisms thus determined can be classified by the order of the frequency factor as is shown in Table 3. The order of the frequency factor, A, is $10^3\,s^{-1}$—$10^7\,s^{-1}$ for the S_N2 mechanism, while that for the S_N1 mechanism ranges from $10^9\,s^{-1}$ to $10^{13}\,s^{-1}$. A reasonable discussion of this classification can now be undertaken.

Effects of Additives on Solid State Reaction. III. Effects of Halide Additives on the Formation of $MgFe_2O_4$

Shiro SHIMADA, Ryusaburo FURUICHI, and Tadao ISHII

Department of Applied Chemistry, Faculty of Engineering, Hokkaido University, Sapporo 060

(Received July 3, 1975)

The promoting effects of halide additives on the formation of $MgFe_2O_4$ have been studied on the basis of both kinetic and thermoanalytical data. A mixture of MgO and α-Fe_2O_3 powder containing 10 mol % additive (LiF, NaF, MgF_2, BaF_2, NaCl, or KCl) and that without additive were isothermally heated in a vacuum ($P_{O_2}=10^0$—10^1 mmHg) in the temperature range 666—1018 °C. High temperature X-ray analysis on MgO–Fe_2O_3 and MgO–Fe_2O_3–additive systems was carried out at a heating rate of 3 °C/min *in vacuo*, ($P_{O_2}=10^{-1}$ mmHg). In the case of fluoride, it seems that the reactions between the fluoride and the reactants, α-Fe_2O_3 or MgO, promote $MgFe_2O_4$ formation in the initial stage and that compounds produced by the initial reaction accelerate diffusion in the later stage. The same promoting mechanism seems to be applicable to the case of chloride additives. The interaction between solids of NaCl and α-Fe_2O_3 occurring just before the melting of NaCl seems to initiate $MgFe_2O_4$ formation.

Solid state reactions are affected by various factors such as impurity or additive,[1,2] preparation history of the reacting material[3] and atmosphere.[4-6] The mechanism for the promoting effects of fluoride and chloride additives on $MgAl_2O_4$ formation has been systematically discussed from kinetic and thermoanalytical viewpoints.[7-9] In the case of fluoride additives,[8,9] the formation of $MgAl_2O_4$ was initiated by the reaction between fluoride and reactants of α-Al_2O_3 and MgO, the cations of fluoride playing an important role in accelerating the reaction in the later stage. In the case of chloride,[7,8] the $MgAl_2O_4$ formation was accelerated *via* the dissolution process of MgO particle in molten chloride.

We have investigated the promoting effects of the halides of alkali and alkaline earth on $MgFe_2O_4$ formation on the basis of both kinetic and thermoanalytical results.

Experimental

Sample. α-Fe_2O_3 samples were prepared by calcining commercial ferric oxide (Kanto Chemical Co., 99% pure) at 1100 °C in the air. The particle size of α-Fe_2O_3 was microscopically determined to be in the range 0.5—2 μ with an average size of 1 μ. MgO particles (av. 0.1 μ) were prepared by a similar way to that described in the previous paper.[8] Powders of MgO, α-Fe_2O_3 and additive were thoroughly mixed in the molar ratio 1 : 1 : 0.1. The additives used were LiF, NaF, MgF_2, BaF_2, NaCl, or KCl (Kanto, Wako or Morita Companies), which were stored in a desiccator with silica gel before experiments. The mixtures were pressed into pellets at 150 kg/cm^2.

DTA and High Temperature X-Ray Diffraction Experiments. DTA experiments on MgO–Fe_2O_3 and MgO–Fe_2O_3–additive systems were carried out in a vacuum ($P_{O_2}=10^{-1}$ mmHg) at a heating rate of 10 °C/min. The temperature was measured with a Pt–Pt13Rh thermocouple. α-Al_2O_3 was used as a standard material. The high temperature X-ray diffraction experiments were carried out *in vacuo* ($P_{O_2}=10^{-1}$ mmHg) at a heating rate of 3 °C/min.

Isothermal Kinetic Experiments. The pellet was kept on a Pt boat placed in a fused-silica tube connected to a vacuum system ($P_{O_2}=10^0$—10^1 mmHg) and then heated isothermally in the Pt-furnace at 666—1018 °C. The temperature was measured with a Pt–Pt13Rh thermocouple. After heating, the pellet was quenched at room temperature by withdrawal of the tube from the hot zone of the furnace. Fractional conversion of $MgFe_2O_4$ was determined by measuring the amount of MgO or α-Fe_2O_3 remaining after the reaction. The MgO unreacted was extracted by dissolving the pellet in 10% NH_4Cl solution. The Mg^{2+} ion concentration of the solution was then determined by titration with a standard solution of EDTA. This procedure was applied to the products obtained in the experiments of both MgO–Fe_2O_3 and MgO–Fe_2O_3–additive (LiF or NaF) systems. The amount of α-Fe_2O_3 unreacted was determined by quantitative X-ray analysis by use of NaCl as an external standard. The method was applied to the products in MgO–Fe_2O_3–additive (MgF_2 or BaF_2) system.

Analyis of Fe^{2+}. The amount of Fe^{2+} ion in the samples, obtained after isothermal experiments or the high temperature X-ray diffraction experiments, was colorimetrically determined.[10] The solution for colorimetry was prepared by dissolving the sample in concd H_2SO_4. 2M NH_4F and 1% *o*-phenanthroline were used as masking agent for Fe^{3+} and color-producing agent for Fe^{2+}.

Results

Figures 1 and 2 show the rates of $MgFe_2O_4$ formation in MgO–Fe_2O_3 and MgO–Fe_2O_3–alkali fluoride systems, and MgO–Fe_2O_3–alkaline earth fluoride system, respectively. The rate of reaction between solid reactant particles is generally governed by either chemical reaction at phase-boundary or diffusion process.[11] The rate equations for the diffusion-controlled reaction have been given by Jander,[12] Serin-Ellickson,[13] Ginstling-Brounshtein,[14] and Carter.[15] It was found that the reaction rate of MgO–Fe_2O_3 system is best represented by Jander's equation:

$$[1-(1-\alpha)^{1/3}]^2 = kt \qquad (1)$$

where α=fractional conversion, k=rate constant, t=reaction time. A part of the data plotted according to Eq. (1) is shown in Fig. 3. We see that the data of all systems fit Jander's equation up to about $\alpha=70\%$. The straight lines obtained for NaF, MgF_2 and BaF_2 additives intersect at $t=0$ the ordinate with values corresponding to $\alpha=20$—30%. On the other hand, the lines for non-additive and LiF additive fall on the origin. The activation energies are given in Table 1,

for which the rate constants k were calculated from the results shown in Figs. 1 and 2 by means of Eq. (1). The samples obtained by the isothermal experiments of all systems showed no trace of Fe^{2+}.

Figure 4 shows DTA curves of $MgO–Fe_2O_3$–LiF (curve A) and $MgO–Fe_2O_3$–NaF (curve B) systems. Curve A has two endothermic peaks at 670 °C and 730 °C. The peak at 730 °C is considered to be due to the formation of the liquid phase, since an exothermic peak was obtained at *ca.* 730 °C by cooling the sample (curve A) from 930 °C as indicated by arrows. The liquid phase seems to result from melting of LiF.

TABLE 1. VALUES OF ACTIVATION ENERGY

Additive	E^* (kcal/mol)
Non-additive	70± 4
LiF	57± 4
NaF	59± 4
MgF_2	65±10
BaF_2	60± 5

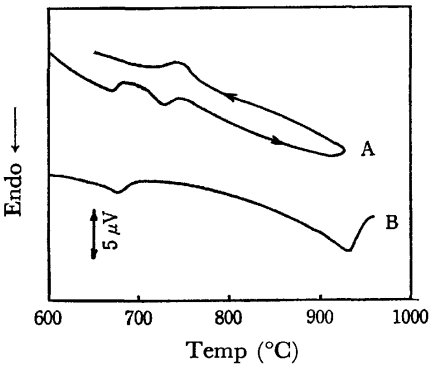

Fig. 4. DTA curves of reaction in $MgO–Fe_2O_3$–LiF (curve A) and $MgO–Fe_2O_3$–NaF (curve B) systems. Heating rate: 10 °C/min, sample weight: 400 mg, 1:1:0.1 mixture of MgO, Fe_2O_3, and LiF or NaF in molar ratio.

Similarly, curve B has two endothermic peaks at 670 °C and 930 °C. The peak at 930 °C probably corresponds to melting of NaF. DTA curves of the systems with non-additive, MgF_2 and BaF_2 additives showed no thermal change in the range 20—1000 °C except for the endothermic peak near 670 °C, which showed a reversible one. This peak corresponds to the Curie point of α-Fe_2O_3.[16,17]

Figures 5A–D and 6A–D show the results of high temperature X-ray diffraction analysis for the systems $MgO–Fe_2O_3$, $MgO–Fe_2O_3$–NaCl, $MgO–Fe_2O_3$–KCl, Fe_2O_3–NaCl, $MgO–Fe_2O_3$–LiF, $MgO–Fe_2O_3$–NaF, $MgO–Fe_2O_3–MgF_2$, and $MgO–Fe_2O_3–BaF_2$. We see that the amounts of α-Fe_2O_3 and MgO decrease at *ca.* 700 °C and then $MgFe_2O_4$ begins to appear at 820 °C (Fig. 5-A). Addition of NaCl (Fig. 5-B) lowers the initiation temperature of $MgFe_2O_4$ formation by more than 60 °C, as compared with that of the $MgO–Fe_2O_3$ system. This initiation temperature, 760 °C, is lower

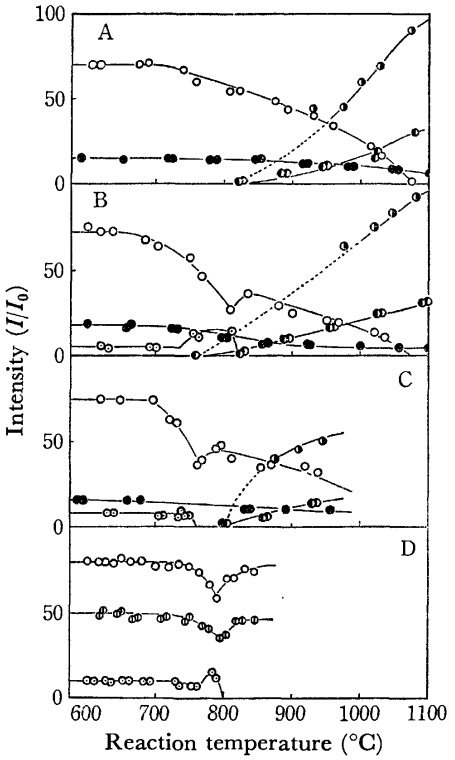

Fig. 5. High temperature X-ray diffraction patterns of the reaction in the systems for $MgO–Fe_2O_3$ (A), $MgO–Fe_2O_3$–NaCl (B), $MgO–Fe_2O_3$–KCl (C), and Fe_2O_3–NaCl (D).

than the melting point of NaCl (mp 808 °C). In the case of KCl (Fig. 5-C), $MgFe_2O_4$ begins to form at *ca.* 800 °C after melting of KCl (mp 776 °C). The discontinuous changes in the X-ray intensities of α-Fe_2O_3 and NaCl for $MgO–Fe_2O_3$–NaCl system (Fig. 5-B), and of α-Fe_2O_3 for $MgO–Fe_2O_3$–KCl system (Fig. 5-C) are observed just before the melting of chloride additives. Such phenomena are also observed in the binary system of $NaCl–Fe_2O_3$ (Fig. 5-D). Addition of LiF (Fig. 6-A) lowers the initiation temperature of $MgFe_2O_4$ formation to 700 °C. This temperature is close to that of the liquid phase formation (730 °C) in $MgO–Fe_2O_3$–LiF system (Fig. 4). In the case of NaF (Fig. 6-B), the initiation temperature is also lowered, the intensity of $MgFe_2O_4$ increasing abruptly at 1020 °C.

Table 2. The initiation temperature of $MgFe_2O_4$ formation

Additive	Init. temp (°C)
Non-additive	820
LiF	700
NaF	725
MgF_2	800
BaF_2	900
NaCl	760
KCl	800

In the case of MgF_2 (Fig. 6-C), $MgFe_2O_4$ begins to form at 800 °C. On the other hand, the initiation temperature of the system with BaF_2 (Fig. 6-D) is somewhat higher in comparison with that of other systems. The initiation temperatures of the $MgFe_2O_4$ formation in all the systems are summarized in Table 2. It is seen that α-Fe_2O_3 in $MgO–Fe_2O_3$ system disappears at temperatures higher than 1075 °C, but MgO still exists at these temperatures (Fig. 5-A). Similar phenomena are also observed at 1075 °C, 950 °C, 1060 °C, or 1050 °C in $MgO–Fe_2O_3$–NaCl, –NaF, $–MgF_2$, or $–BaF_2$, respectively. The samples obtained after the high temperature X-ray diffraction experiments (Figs. 5-A, -B and 6-A, -B, -C, -D) showed traces of Fe^{2+}.

Discussion

It was found[9] that the lower the melting point of the fluoride additives, the lower the initial temperature of $MgAl_2O_4$ formation, and that AlF_3 formed by the reaction between fluorides and α-Al_2O_3 initiates the formation of $MgAl_2O_4$. For the $MgO–Fe_2O_3$–fluoride systems, a linear correlation of the melting point of the fluoride with the initiation temperature of $MgFe_2O_4$ formation (Table 1) was also observed (Fig. 7). Deviation of the point for BaF_2 from a straight line may be due to the poor crystallinity of $MgFe_2O_4$ formed, since although the initial temperature of $MgFe_2O_4$ formation is at *ca.* 900 °C (Fig. 6-D), the fractional conversion

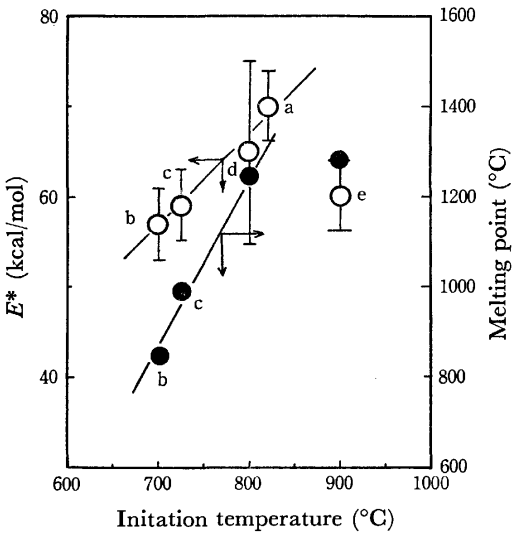

Fig. 7. Plots of the melting points of halide and the E^* values *vs.* the initiation temperature of $MgFe_2O_4$ formation.
a: non-additive, b: LiF, c: NaF, d: MgF_2, e: BaF_2

determined from the amount of unreacted α-Fe_2O_3 after the isothermal experiments goes up to $\alpha=36\%$ at 847 °C for 50 min in MgO–Fe_2O_3–BaF_2 system. The correlation in Fig. 7 suggests that the fluoride of lower melting point easily reacts with reactants α-Fe_2O_3 or MgO and that the reaction promotes the $MgFe_2O_4$ formation in the initial stage, as described for MgO–Al_2O_3–fluoride system. The reaction of fluoride with reactants may result in the formation of compounds such as magnesium or iron fluoride. The formation of such compounds results in the lowering of the melting point of LiF (mp 845 °C) or NaF (mp 992 °C) by more than 100 °C or 60 °C, respectively (Fig. 4). On the other hand, the melting point of the binary systems such as MgO–LiF or –NaF and Fe_2O_3–LiF or –NaF nearly agreed with that of pure LiF or NaF. However, X-ray analysis for the products obtained in the DTA experiments did not indicate the formation of compounds such as magnesium or iron fluoride, or Li–, Na–, or Ba–ferrite. This might be due to too small amounts of the compounds for detection by X-ray analysis.

Reijnen[18] studied the solid state reaction in the MgO–Fe_2O_3 system, and proposed two possible mechanisms of counter diffusion of cations for the formation of $MgFe_2O_4$ at a given oxygen pressure and temperature, *i.e.* Mg^{2+} and Fe^{3+}, or Mg^{2+} and Fe^{3+} or Fe^{2+} diffuse through the spinel layer. The Fe^{2+} diffusion is accompanied by the diffusion of one cation vacancy and by the transport of oxygen in the gas phase. Carter[19] assumed the mechanism of the counter diffusion of Mg^{2+} and Fe^{3+}. Lindner[20,21] reported that the activation energy for the self-diffusion of Mg^{2+} in MgO single crystal is 79 kcal/mol and that of Fe^{3+} in $ZnFe_2O_4$ polycrystal is 82 kcal/mol. These can be regarded as values for the volume or grain boundary diffusion. It was found from the results given in Fig. 3 and Table 1 that the formation rate of $MgFe_2O_4$ in MgO–Fe_2O_3 system is controlled by the diffusion with the activation energy of 70 ± 4 kcal/mol, which is comparable to the above values. Since no Fe^{2+} was found in the samples obtained by the isothermal experiments, it seems that $MgFe_2O_4$ formation in MgO–Fe_2O_3 system proceeds by the counter diffusion of Mg^{2+} and Fe^{3+} and that the volume or grain-boundary diffusion is operative in the formation of $MgFe_2O_4$. The presence of fluorides lowers the value of the activation energy E^* by 5—13 kcal/mol (Table 1), which might indicate that the fluorides accelerate the diffusion along grain boundary or within bulk. There is a possibility that the dissolution or incorporation of compounds formed by the reaction of fluoride with α-Fe_2O_3 into the $MgFe_2O_4$ layer facilitates the diffusion of Mg^{2+} or Fe^{3+}. It can be considered in the case of LiF or NaF additive that the liquid phase formation at *ca.* 700 °C or 800 °C accelerates further diffusion by acting as a vehicle of transporting MgO or α-Fe_2O_3. It is observed that the lower the E^* value, the lower the initiation temperature of $MgFe_2O_4$ formation (Fig. 7).

The accelerating mechanism of $MgFe_2O_4$ formation by the presence of chloride was explained as follows: MgO particles dissolve in molten chloride to spread uniformly over the outer surface of α-Al_2O_3 particles and then MgO particles transport into the inner part of α-Al_2O_3 particles consisting of crystallites. In the MgO–Fe_2O_3–NaCl system, discontinuous changes in X-ray diffraction intensities of α-Fe_2O_3 and NaCl were observed before melting of NaCl, the initial for mation of $MgFe_2O_4$ beginning simultaneously (Fig. 5-B). The discontinuous changes of X-ray intensities seem responsible for the initial formation of $MgFe_2O_4$, although no explanation can be given at present. In the case of KCl, $MgFe_2O_4$ was formed after melting of KCl, although a discontinuous change of α-Fe_2O_3 intensity was also observed (Fig. 5-C). There may be a difference in the action of solids NaCl and KCl on the $MgFe_2O_4$ formation. It is considered that after chloride melts, the formation of $MgFe_2O_4$ is promoted by the dissolution process of MgO particles in molten chloride.

It was found in the high temperature X-ray experiments that α-Fe_2O_3 disappears at temperatures where MgO still exists (Figs. 5 and 6) and that a trace of Fe^{2+} is present in the samples after the experiments. This suggests that a part of Fe^{3+} is reduced at high temperatures to ferrous ions by the dissolution of α-Fe_2O_3 in $MgFe_2O_4$ phase at relatively high vacuum ($Po_2=10^{-1}$ mmHg) in comparison with that in the isothermal experiments ($Po_2=10^0$—10^1 mmHg), and that the $MgFe_2O_4$ formation proceeds by the counter diffusion mechanism of Mg^{2+} and Fe^{3+} accompanied by partial participation of Fe^{2+} in the diffusion, as proposed by Reijnen.[18]

Indium(III) Complexes of DL-Penicillamine in Aqueous Solution. Evidence for the Formation of Protonated and Hydrolyzed Complexes

Nakao KOJIMA, Yukio SUGIURA, and Hisashi TANAKA

Department of Pharmaceutical Radiochemistry, Faculty of Pharmaceutical Sciences, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received September 8, 1975)

The penicillamine–In(III) system has been investigated with potentiometric titration over a wide range of metal concentration at 21°C and I=0.1 (KNO_3). In dilute concentration of metal (0.00025—0.0005 M) and ligand (free base), single species (InL and InL_2) are predominantly formed. In higher concentration of metal (0.0025—0.005 M) and ligand (with an equimolar HCl), the protonated and hydrolyzed complexes (InLH, InL(LH), and InL(OH)) are also formed together with the simple species. The formation constants calculated with non-linear least-squares program were found to be: log β_{110}=15.330, log β_{120}=29.789, log β_{11-1}=18.858, log β_{12-1}=33.391, and log β_{111}=11.25 for InL, InL_2, InLH, InL(LH), and InL(OH) species, respectively. The formation constants and ultraviolet spectra indicate that the proton in the protonated complex is attached to the amino-group of penicillamine.

^{113m}In[1] and ^{111}In[2] as well as ^{99m}Tc are a few of the radioisotopes recommended for the scanning of various organs or tissues among those introduced in the field of nuclear medicine. Recently, the use of some complexing agents with these radioisotopes has made a wide variety of scanning possible. However, knowledge of the complex formation of these metals is still insufficient for the development of new effective scanning agents. Some thiols, of which penicillamine is the most popular, have been used as the complexing agents with ^{99m}Tc. The complex formation together with hydrolysis reaction have been studied in connection with the preparation of the effective scanning agents which localize to some organs or tissues.[3] We planned a series of studies on the complex formation of In(III) with some complexing agents in an aqueous solution and also the reaction of In(III) with proteins for the better understanding on the mechanism of the localization of In(III) complexes *in vivo*. As the first step of this study, we adopted penicillamine as a complexing agent.

Although Habeeb and Tuck[4] have extensively investigated coordination compounds of In(III), most of which are prepared in organic solvent, studies on complex formation of In(III) in an aqueous solution are relatively few. Sarin and Munshi[5-7] reported that the order of the stability constants of β-substituted propionic acid–In(III) complexes decreases in the order SH>OH>NH_2 in various substituted groups. Their estimates for the stability constants are made on the assumption that three simple species, InL, InL_2 and InL_3 are present. On the other hand, Perrin and Sayce[8] detected the protonated penicillamine complexes with Zn(II) which has the isoelectronic configuration for d^{10}-In(III).

We have investigated the complex formation of In(III) with penicillamine with the use of potentiometric titration and absorption spectra. The presence of the protonated and hydrolyzed species is discussed.

Experimental

Materials. Indium metal (99.99%, Wako Pure Chemical Industries, Ltd.) was used. An accurately weighed amount of metal was dissolved in a small amount of hydrochloric acid by heating and diluted to 1 liter with deionized water after cooling. Solution of In(III) was freshly prepared and standardized with 8-quinolinol method.[9] Hydrochloric acid added to prevent hydrolysis of In(III) was standardized potentiometrically.

DL-Penicillamine (Sigma Chemical Company) was dried under vacuum over phosphoric oxide at room temperature. Stock solutions were stored under nitrogen, and checked by pH titration.

Carbonate-free potassium hydroxide solutions (1M and 0.1M) were prepared by an ion-exchange method,[10] and standardized by a conventional method. All other reagents used of commercial reagent grade.

Potentiometric Titrations. The potentiometric titrations were performed with a Radiometer titrator, Type TTT-2 equipped with a Radiometer G202B glass electrode and a K401 saturated calomel electrode. The pH readings with standard buffer solutions (0.05M potassium hydrogen phtalate, pH 4.00, and 0.05M sodium tetraborate, pH 9.22) were constant within 0.01 pH unit for periods exceeding 1 day. Titration was carried out with standard carbonate-free potassium hydroxide solutions with a specially designed, water-jacketed titration vessel at 21.00±0.05°C in an air-conditioned room (21±1°C), the solution being stirred continuously with a stirrer under pure nitrogen gas supply. In(III) (0—0.005 M), penicillamine (0.001—0.01 M) and potassium nitrate (0.1M) were placed in the vessel, and the total volume was adjusted to 20 ml by adding deionized water. All potentiometric measurements were repeated at least twice in order to obtain satisfactory reproducibility required for the computer-based analysis.

Absorption Spectra. Optical spectra were determined in an aqueous solution with a Shimadzu recording spectrophotometer, Model Double 40-R. Sample solutions consisted of penicillamine (0.00016M), or the ligand and In(III) (0.00008 M), and a very small amount of 1M potassium hydroxide and 1M hydrochloric acid was added for the adjustment of pH. The visible and ultraviolet spectra of the penicillamine solutions containing Fe(III), Cu(II), Pb(II), Hg(II), Cd(II), or Zn(II) were also measured.

Calculations

The proton dissociation constant(Ka_1) of the carboxyl-group in penicillamine was obtained by the usual method

from the potentiometric titration data for the sample solution containing 0.05 M penicillamine and an equimolar HCl. The remaining two ionization constants Ka_2 and Ka_3 for the amino- and thiol-groups are defined by the following equation which can be deduced from the total ligand concentration($[L]_T$) and electroneutrality.

$$[H^+]([L]_T-\gamma)Ka_2 + (2[L]_T-\gamma)Ka_2Ka_3 = \gamma[H^+]^2 \quad (1)$$

In this equation, γ is defined as

$$\gamma = [H^+] + [K^+] - [OH^-]$$

where $[K^+]$ is the concentration of base added. The Ka_2 and Ka_3 values were defined simultaneously by the linear least-squares method for Eq. (1) under the condition of $[L]_T=0.0015$ M. These three constants were further refined by the non-linear Fortran IV computer program on a FACOM 230-75 Computer, the Kyoto University Computer Center. The values of $pKw=14.130$[11] at 21°C and $[H^+]=10^{-pH}$ were used in the calculations.

The titration curve of 1:2 In(III) to penicillamine (free base) indicates the formation of the complex InL_2. Formation constants (K_1 and K_2) are defined as follows.

$$K_1 = [InL^+]/[In^{3+}][L^{2-}] \quad (2)$$

$$K_2 = [InL_2^-]/[InL^+][L^{2-}] \quad (3)$$

The constants were calculated by the least-squares method of the Irving and Rossotti equation.[12,13]

$$\bar{n}(\bar{n}-1)[L^{2-}] = (2-\bar{n})[L^{2-}]K_1K_2(\bar{n}-1) - K_1 \quad (4)$$

The theoretical $\bar{n}$ values are evaluated by the constants obtained. From the constants, theoretical titres (x ml) are also expressed as follows.

$$Ax^3 + Bx^2 + Cx + D = 0 \quad (5)$$

where

$$A = a(K_1K_2Qa^2+K_1PQa+P^2Q)$$

$$B = 3K_1K_2a^2b+K_1PQa(Va+2b)-0.5K_1[L]_TP^2Va + P^2Q(2Va+b)-[L]_TP^3V$$

$$C = 3K_1K_2a^2b+K_1PQb(2Va+b)-0.5K_1[L]_TP^2V(Va+b) + P^2QV(Va+2b)-2[L]_TP^3V^2$$

$$D = K_1K_2Qb^3+K_1PQVb^2-0.5K_1[L]_TP^2V^2b+P^2QV^2b - [L]_TP^3V^3$$

$$a = [OH^-] - [H^+] - [K^+]$$

$$b = V(2[L]_T+[Cl^-]+[OH^-]-[H^+])$$

$$P = 3(H^+)^3/Ka_1Ka_2Ka_3+2(H^+)^2/Ka_2Ka_3+(H^+)/Ka_3$$

$$Q = (H^+)^3/Ka_1Ka_2Ka_3+(H^+)^2/Ka_2Ka_3+(H^+)/Ka_3+1$$

V = initial volume

$[L]_T$ = total ligand concentration

$[Cl^-]$ = concentration of inorganic acid (if any)

Equation (5) was solved by the use of subroutine CALDND, Scientific Subroutine Library, the Kyoto University Computer Center.

No simple procedures exist for obtaining the stability constants of metal complexes from $[L^{2-}]$ and $\bar{n}$ values, if polynuclear, protonated or hydroxo complexes are formed. In such cases, various computer programs based on the non-linear least-squares method have been used.[14-17] At each point of the titration, equilibrium takes place among the various species expressed by the general formula $M_lL_mH_{-n}$ (M=metal, L=ligand), where n is positive for a hydrolyzed species and negative for a protonated species. The concentration of the species $M_lL_mH_{-n}$ at each point is given by

$$[M_lL_mH_{-n}] = \beta_{lmn}[M]^l[L]^m(H^+)^{-n} \quad (6)$$

where β_{lmn} is the formation constant of the species under consideration.

For each point, the followoing mass-balance equations should hold.

$$[M]_T = [M] + \sum l\beta_{lmn}[M]^l[L]^m(H^+)^{-n} \quad (7)$$

$$[L]_T = [L] + \sum m\beta_{lmn}[M]^l[L]^m(H^+)^{-n} \quad (8)$$

$$[H]_T = [H^+] + \sum(-n)\beta_{lmn}[M]^l[L]^m(H^+)^{-n} \quad (9)$$

where $[M]_T$, $[L]_T$ and $[H]_T$, are the analytical concentrations of the metal, ligand, and acid, respectively. The unknown parameters in these equations are [M] and [L] for each point and the stability constants β_{lmn}. The values of (H^+) are obtained from the potentiometric measurement. In the present case, [M] and [L] are obtained by considering a set of plausible values for the stability constants and by calculating the starting values of [M] and [L] from Eqs. (7) and (8) for each point, using the Newton-Raphson iteration. Computed [M] and [L] for the first point are used as initial estimates for the second point, and so on. Using the obtained [M] and [L], the concentration of $M_lL_mH_{-n}$ is calculated from Eq. (6), and $[H]_T$ from (9) for each data point. Theoretical titre of base is obtained from $[H]_T$. If the agreement between the experimental and calculated titres is not satisfactory, the values of the constants β_{lmn} are varied in turn so as to minimize the error-square sum in titre. The standard deviations of the parameters are the square-roots of the diagonal elements of the variance-covariance matrix of the parameters.

This program was also used for the calculation of pKa and hydrolysis constants of the metal ion.

Results and Discussion

Practical Association Constants. Table 1 shows the result of the calculation for "practical' association constants defined by the following equations.

$$\beta_{01-1} = [LH^-]/(H^+)[L^{2-}]$$

$$\beta_{01-2} = [LH_2]/(H^+)^2[L^{2-}]$$

$$\beta_{01-3} = [LH_3^+]/(H^+)^3[L^{2-}]$$

The constants were refined with non-linear program. The calculated $\log\beta_{01-1}$ and $\log\beta_{01-2}$ are in good agreement with that ($\log\beta_{01-1}=10.679$ and $\log\beta_{01-2}=18.714$) reported by Perrin and Sayce.[8] The value ($pKa_1=$

Total ligand concentrations are 0.0015, 0.0015, and 0.001 M, respectively. Each point on the curve (c) was calculated by the use of the formation constants. a=moles of KOH added per mole of protonated ligand with regard to the thiol- and amino-groups.

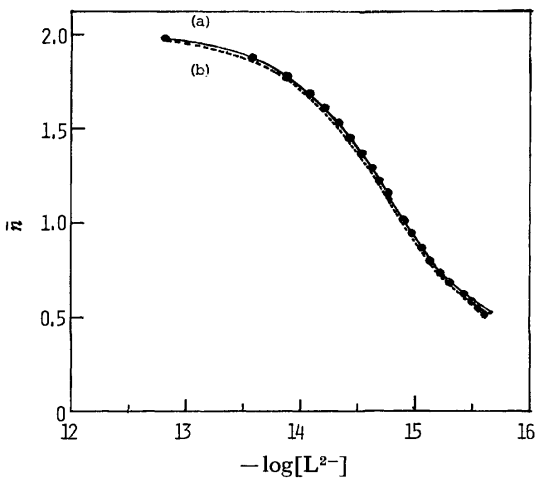

Fig. 2. Formation curves of the penicillamine (free base)–In(III) complexes: (a) L: In=2: 1, (b) L: In=3: 1. Total ligand concentrations are 0.001 and 0.0015 M respectively. Each point represents the calculated value as for curve (a).

2.065) obtained from $\log\beta_{01-3}$ and $\log\beta_{01-2}$ differs slightly from that (pKa_1=2.44) reported by Kuchinskas and Rosen.[18] The difference is due to the low concentration (0.0033 M) of the latter case.

Simple InL and InL_2 System. Figure 1 shows the titration curves of 2: 1 and 3: 1 penicillamine (free base) to In(III) (0.0005 M). The sharp inflections of pH were observed at a=1.33 and 2 in the 3: 1 and 2: 1 systems, respectively. The two formation curves could be superimposed (Fig. 2). It was impossible even under the condition of 3: 1 (ligand to metal) to obtain $\bar{n}$ values greater than 2. The findings indicate that in our experimental conditions the mononuclear species, InL and InL_2, are present predominantly. In the titration curve of the 3: 1 system, therefore, the inflections at a=1.33 and 1.67 are associated with the formation of the complex InL_2 and the dissociation of the thiol-group of the excess ligand, respectively.

The constants ($\log K_1$=15.44 and $\log K_1K_2$=29.85) were obtained from Eq. (4) using $\bar{n}$ and $[L^{2-}]$ values at each point. With use of these constants, theoretical $\bar{n}$ values were also calculated by Eq. (4). Validity of these constants was confirmed by the coincidence with the experimental and calculated formation curves (Fig. 2, (a)). From the K_1 and K_1K_2 values, the titration curve (Fig. 1, (c)) was recalculated by the use of Eq. (5) and compared with that obtained experimentally.

These constants determined by the Irving Rossotti method were further refined by the non-linear computer program. The final values ($\log\beta_{110}$=15.425±0.010 and $\log\beta_{210}$=29.844±0.006) fitted the data to within a standard deviation in titre of 0.0015 ml, as compared with the value (0.0021 ml) obtained in fitting the simple pKa titration data. From these constants, a distribution diagram of various complexes was calculated for various pH (Fig. 3).

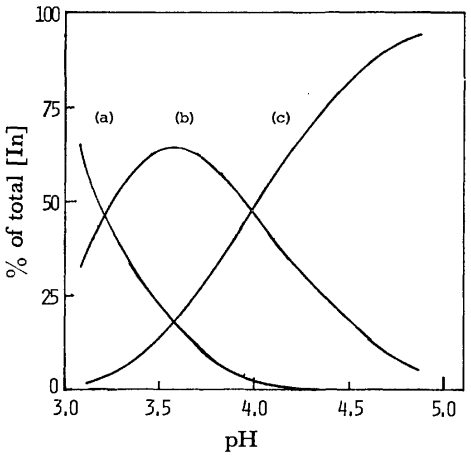

Fig. 3. Distribution diagram for the penicillamine (free base) (0.001M)–In(III)(0.0005M) system: (a) In^{3+}; (b) InL; (c) InL_2.

Penicillamine as a terdentate ligand has been predicted to form metal complexes with various coordination types. In dilute penicillamine(free base)–In(III) systems, however, the simple species InL and InL_2 only were formed. The constant ($\log\beta_{110}$=15.425) for the species InL is much larger than those for the corresponding penicillamine 1: 1 complex of Zn(II) (9.589), Ni(II) (10.749),[8] Cd(II) (10.92) and Pb(II) (12.88),[19] respectively. It is of interest that the formation constant is comparable to that (16.4) of the Hg(II) complex.[19]

InL, InL_2, InLH, InL(LH), and InL(OH) Systems. Titration was extensively carried out in the systems of various metal concentrations and metal-ligand ratios. An equimolar HCl was added to the penicillamine solution in order to protonate the carboxyl-group in the ligand. The total metal concentrations were 0.00025, 0.0005, 0.0025, and 0.005 M, and the total ligand concentrations were 0.001, 0.001, 0.01, and 0.01 M, respectively. Plots of $\bar{n}$ against $\log[L^{2-}]$ are shown in Fig. 4. Failure of superposition in the formation curve indicates that besides InL and InL_2, other complex species are formed with an increase in metal concentra-

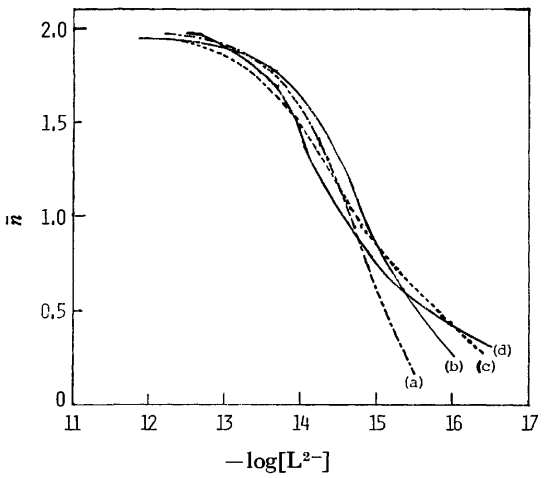

Fig. 4. Formation curves of the penicillamine (HCl)–In(III) complexes: (a) L: In=4: 1; (b) L: In=2: 1; (c) L: In=4: 1; (d) L: In=2: 1. Total ligand concentrations are 0.001, 0.001, 0.01, and 0.01M, respectively.

tion. However, the curves do not converge towards Biedermann and Sillén's "mononuclear wall."[20] Accordingly, the systems could contain no "core plus links" series of complexes.[21] Formation of mononuclear protonated and/or hydroxo species was assumed.

In order to characterize the hydrolyzed In(III) species which give the hydroxo complexes to associate with ligand, a brief inspection on the hydrolysis equilibrium of In(III) ion was carried out. Potentiometric titration of 0.0005 M In(III) solution containing 0.00026 M HCl at 21°C and I=0.1(KNO_3), afforded $\log \beta_{101} = -3.634 \pm 0.037$ after refinement by the non-linear program.

$$In^{3+} \rightleftarrows In(OH)^{2+} + H^+$$

$$[In(OH)^{2+}] = [InH^{2+}_{-1}] = \beta_{101}[In^{3+}](H^+)^{-1}$$

(β_{101} is not precisely the formation constant for the complex In(OH), but is related to it through $Kw = (H^+)(OH^-)$ since $\beta'[In^{3+}](OH^-) = \beta'[In^{3+}](H^+)^{-1}Kw$, *i.e.*, $\beta_{101} = \beta' \times Kw$, where β' is the true formation constant for the complex In(OH).) Besides a large amount of In(OH), a small amount of $In(OH)_2$ was also formed. Biedermann[22] reported $\log \beta_{202} = -5.21$ and $\log \beta_{304} = -9.90$ for 0.05 M In(III) perchlorate at 25° in 3 M $NaClO_4$. However, no such complexes were detected in our dilute system which is close to the "metal ion wall." The species In(OH) and $In(OH)_2$ were used as the hydrolyzed In(III) species which participate in the hydroxo complex formation with penicillamine.

On the other hand, the protonated mononuclear species to be considered are InL, InL_2, InLH, InL(LH), and $In(LH)_2$. The best fit to the experimental results was sought by the use of a computer program, with automatic refinement of estimated stability constants. The initial value of unknown constant for the complex InLH was estimated as below. Each equilibrium constant for the next three reaction were defined as follows.

$$In^{3+} + L^{2-} + H^+ \rightleftarrows InLH^{2+}; \quad \beta_{11-1}$$

$$In^{3+} + LH^- \rightleftarrows InLH^{2+}; \quad K^{In}_{InLH}$$

$$L^{2-} + H^+ \rightleftarrows LH^-; \quad K^{H}_{LH}$$

where β_{11-1} was given by

$$\beta_{11-1} = [InLH^{2+}]/[In^{3+}][L^{2-}](H^+)$$
$$= [InLH^{2+}]K^{H}_{LH}/[In^{3+}][LH^-]$$
$$= K^{In}_{InLH}K^{H}_{LH}$$

According to Sarin and Munshi,[5] the constant ($\log K_1$) for the In(III)–β-aminopropionic acid complex ($\widehat{NO}$ coordination type) was 2.72, which is much smaller than that of the In(III)–penicillamine complex. This suggests that the thiol-group coordinates to the metal in the protonated complex(InLH). The assignment of pKa value (10.67) to the dissociation of the protonated amino-group is supported by absorption spectral measurements. The constants ($\log K_1$) for the In(III) complexes of *N*-acetyl-*L*-cysteine ($\widehat{SO}$ coordination type) and 2-aminoethanethiol ($\widehat{SN}$ type) are 10.24 and 13.96, respectively. If the proton in InLH attaches to the carboxyl- or amino-group, $\log \beta_{11-1}$ values are obtained as follows.

$$\log \beta_{11-1} = 13.96 + 2.07 = 16.03$$

$$\log \beta_{11-1} = 10.24 + 10.67 = 20.91$$

The two values were refined by the program in the system of 0.005 M In(III) and 0.01 M penicillamine (HCl), together with the constants for the complexes

Table 2. Values (logarithmic units) of the formation constants in the successive trials for the In(III) (0.005 M)–penicillamine(HCl) (0.01 M) system[a]

Trial	Complex species						Std. dev. in titre (ml)
	InL	InL_2	InLH	InL(LH)	$In(LH)_2$	InL(OH)	
1	15.803 (0.016)	29.610 (0.038)					0.0168
2	15.778 (0.008)	29.860 (0.011)	18.662 (0.014)				0.0022
3	15.728 (0.008)	29.761 (0.012)	18.718 (0.012)			11.752 (0.045)	0.0015
4	15.688 (0.016)	29.865 (0.007)	18.754 (0.015)	33.000 (0.065)			0.0015
5		29.885 (0.010)	18.796 (0.020)	33.604 (0.017)	36.61 (1.03)		0.0018
6	15.696 (0.014)	29.804 (0.017)	18.747 (0.014)	32.79 (0.14)		11.47 (0.13)	0.0014

a) Standard deviations in parentheses.

InL and InL_2. In each case, the final value of $\log \beta_{11-1}$ converged to 18.662, *viz.*, the intermediate between two initial estimates (Table 2, trial 2). Introduction of this complex (InLH) gave a remarkable improvement as compared with trial 1. For trial 1 inclusion of the hydroxo complex (InL(OH)) caused no improvement, but for trial 2 it gave a better fit to the experimental data (trial 3). However, the inclusion of $InL(OH)_2$ did not significantly improve the fit. Trials 4—6 gave acceptable fits of a series of a trial and error approach. Trial 5 indicates that the complex $In(LH)_2$ is negligible. Trials 3 and 4 gave the equal standard deviations in titre. In trial 6, the standard deviation in titre is slightly improved, neverthless the standard deviations of the constants of InL(LH) and InL(OH) are larger. This result may be due to the fact that a small amount of the two species are formed in similar pH regions. It is difficult to make a selection from trials 3, 4, and 6 by pH titration. Figure 5 shows the distribution diagram of the complexes obtained from trial 6.

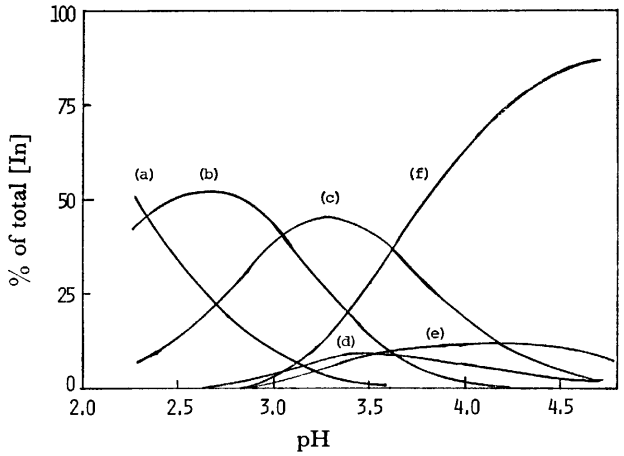

Fig. 5. Distribution diagram for the penicillamine(HCl) (0.01M)–In(III)(0.005M) system, as for Table 2, trial 6: (a) In^{3+}; (b) InLH; (c) InL; (d) InL(LH); (e) InL(OH); (f) InL_2.

The sulfur-bridged polymers are formed in aqueous solutions containing ligands of the types RS^- and the first transition metals.[8,23,24] However, introduction of various polynuclear or olated species caused no improvement in the results. Probably, the methyl groups in penicillamine prevent the formation of sulfur-bridging species.

The same investigation on the other three formation curves suggests that the presence of InL(LH) and InL(OH) becomes negligible with the decrease in concentration of the metal. A comparison with Figs. 3 and 5 also suggests that the species (InLH) becomes negligible, unless the system is acidified by addition of HCl in the lower metal concentration.

A final refinement of all these constants over the whole range of the experimental data (4 experiments, 166 data points) yielded the constants listed in Table 3. The calculated and experimental titres coincided within a standard deviation of 0.0087 ml. Although this value seems to be somewhat large, it is acceptable when the appreciable change in concentration of the complex

Table 3. Stability constants of In(III) complexes with DL-penicillamine at 21°C and I=0.1 (KNO_3)[a]

InL	$\log \beta_{110} = 15.330 \pm 0.058$
InL_2	$\log \beta_{120} = 29.789 \pm 0.038$
InLH	$\log \beta_{11-1} = 18.858 \pm 0.043$
InL(LH)	$\log \beta_{12-1} = 33.391 \pm 0.079$
InL(OH)	$\log \beta_{111} = 11.25 \pm 0.11$

a) Uncertainty intervals associated with all the values are the standard deviations.

species present in the various systems is taken into account.

Calculation of the constant for the protonated complex InLH yielded the intermediate value between the two initial estimates for the species of the $\widehat{SO}$ or $\widehat{SN}$ type. Figure 5 shows, however, that the two protonated species InLH and InL(LH) exhibit maxima at pH 2.7 and 3.3, respectively, where the carboxyl-group in penicillamine is fully ionized. Therefore, these protons are assumed to attach on the amino-group in the ligand. When the value of pKa_3=10.669 is assigned to the ionization constant of the amino-group, the constant K^{In}_{InLH} in the reaction ($In^{3+}+LH^- \rightleftarrows InLH^{2+}$) is calculated by the following equations using the refined constant $\log \beta_{11-1}$=18.858.

$$K^{In}_{InLH} = \beta_{11-1}/Ka = 10^{18.858}/10^{10.669}$$

$$\log K^{In}_{InLH} = 8.189$$

The value is smaller than that ($\log \beta_{110}$=10.242) of *N*-acetyl-L-cysteine complex with In(III). Presumably, the difference is attributed to the electrostatic effect, that is, the reaction species with In^{3+} is LH^- in penicillamine but L^{2-} in *N*-acetyl-L-cysteine. In the solutions containing 0.0015 M ligands, the 1 : 1 (ligand to metal) complexes reach their maxima at pH 3.5 and 5.0 in *N*-acetyl-L-cysteine and 2-aminoethanethiol, respectively. This indicates that the coordination of the amino-group occurs at a relatively high pH.

Ultraviolet Absorption Spectra. The absorption of penicillamine in the 228—236 nm region is based on the form of RS^- ion. The absorbances increased rapidly in the pH range 7.5—8.5, and slightly in 10.5—11.5. Hence, we can assign the ionization constant pKa_2=

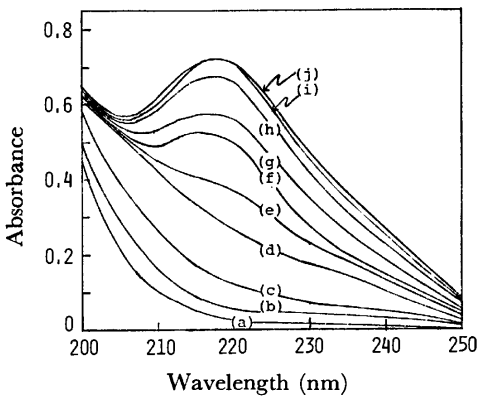

Fig. 6. Absorption spectra of the penicillamine (0.00016 M)–In(III)(0.00008M) system at various pH's: (a) pH 2.04; (b) pH 2.54; (c) pH 3.06; (d) pH 3.78; (e) pH 3.97; (f) pH 4.19; (g) pH 4.40; (h) pH 4.90; (i) pH 6.52; (j) pH 8.64.

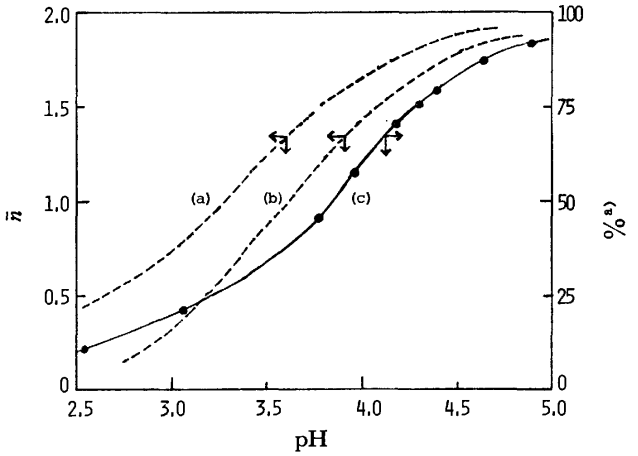

Fig. 7. Absorbance (solid line) and $\bar{n}$ values (dashed lines) of the 2: 1 (penicillamine to In(III)) solutions: Total metal concentrations are 0.005M (a), 0.0005M (b), and 0.00008M (c), respectively.
a) Absorbance at maximum is taken to be 100%.

8.105 to the thiol-group approximately, although the acid strength of the amino- and thiol-groups cannot be easily defined. According to Benesch and Benesch[25] the red shift with increasing pH is related to the change in the ratio of the forms of S^-RNH_2 and $S^-RNH_3^+$. Penicillamine gives a larger shift than cysteine, their thiol- and amino-groups microscopic constants pK_S and pK_N being 8.45 and 8.58, respectively.[26]

The absorption spectrum of the In(III) complex with penicillamine exhibits maximum at 217.5 nm ($\varepsilon = 4\times10^3$), which differs a great deal from that of penicillamine only. On the other hand, In(III) ion(d^{10}) shows no absorption. The absorption spectra of the solution containing 0.00008 M In(III) and 0.00016 M penicillamine are shown in Fig. 6. The absorption curvature at 215 nm appears at pH≈4, reaches its maximum at pH≈6 and is accompanied by a red shift of 2.5 nm, when pH increases. Figure 7 shows plots of the absorbance against pH. In this case, the absorbance at maximum is regarded as 100%. In the lower pH range (having no curvature), the absorbances at 215 nm are plotted. Figure 7 also contains plots of $\bar{n}$ against pH obtained from the pH titration data in the 0.01 M and 0.001 M penicillamine solutions containing 0.005 M and 0.0005 M In(III), respectively. Curves are parallel with a spacing, $\Delta\log[In]_T$, proportional to ΔpH. However, the relation does not hold below pH 3.5, the absorption and formation curves intersecting each other.

The In(III) complex with $\widehat{SO}$ type ligand has λ_{max} at ≈200 nm, and exhibits the tail in the range of ≈215 nm. The absorption spectra in the pH range 2—3.5 are similar to those of the corresponding $\widehat{SO}$ type complex (Fig. 6). These findings also support the formation of the protonated complex InLH ($\widehat{SO}$ type), which has λ_{max} at <200 nm and ε differing from that of the $\widehat{SNO}$ type complex InL. The absorption of InLH appears as a tail at 215 nm, and is considered to be superimposed upon that of InL. Crossing between the absorption and formation curves occurs below pH 3.5, where the species InL is absent.

The shift from 215 to 217.5 nm seems to be caused by the reaction $InL(LH)\rightarrow InL_2$, which leads to the change in the ratio of the forms of $S^-RNH_3^+$ and S^-RNH_2. Under the condition of $[In]_T=0.00008$ M, however, no formation of the species InL(LH) was confirmed from the pH titration data. The shift is, therefore, due to the reaction $InL\rightarrow InL_2$.

Precipitation of the meta hydroxide appears at pH 3.1 in 0.05 M metal ion solution, because of high hydrolyzability of In(III). The In(III) complexes with the usual amino-acids are unstable, whereas the In(III) complexes containing the thiol-group are very stable. The high stability might be attributed to the $d\pi$ back-donation of d^{10} electrons to the empty d orbitals of sulfur. This π-bonding character is reflected in the ultraviolet absorption. The charge transfer bands (λ_{max}) of the various metal-sulfide complexes[27] are correlated to the absorption maxima of the correspond-

Table 4. Charge transfer bands (λ_{max}) of sulfides- and penicillamine-metals complexes

Metal	Sulfide[a] (nm)	Penicillamine (nm)
Fe(III)	>500	570
Cu(II)	>375	520
Pb(II)		268
Hg(II)	300	260
Cd(II)	~250	217
Zn(II)	<200	217
In(III)		217.5

a) Ref. 27.

ing penicillamine–metal complexes (Table 4). The absorption at 217.5 nm of the penicillamine–In(III) complex is assigned to the charge transfer band. The band of Zn(II) complex, having an isoelectronic configuration for In(III), is at <200 nm for the sulfides, and at 217 nm for penicillamine. This is related closely to the fact that the corresponding band of In(III) is at <200 nm for β-mercaptopropionic acid, at ≈217 nm for penicillamine and 2-aminoethanethlol. Thus it seems that the absorptions at ≈217 nm in the penicillamine–In(III) and –Zn(II) result from M–S and M–N coordinations.

The authors thank Dr. H. Aiba, Kyoto University, for his helpful discussions, and the staff of the Kyoto University Computer Center for use of the FACOM 230-75 Computer.

(Received October 20, 1975)

The circular dichroism (CD) spectra of optical antipodes of $[Co(en)_3]^{3+}$ and $[Co(pn)_3]^{3+}$ were measured in the presence of L-tartrate, L-tartranilate or related dicarboxylate ions. L-Tartrate(2−) ions gave a large and stereoselective effect on the CD spectra; the CD change was greater for the Λ-complex than for the Δ-complex. Hydrogen-L-tartrate(1−) and L-tartranilate(1−) ions also caused stereoselective CD changes. On the other hand, succinates-(2−) and L-malate(2−) ions gave small and non-stereoselective CD changes, and undissociated tartaric acid gave no CD change. From a comparison of the results, it was concluded that two hydroxyl and one carboxylate groups of the L-tartrate ion form hydrogen bonds with three N–H groups of the tris(diamine)cobalt(III) ion of the *lel* form.

In a previous papar,[1] we reported the stereoselective hydrogen-deuterium exchange rate of optically active $[Co(en)_3]^{3+}$ ions in D_2O solutions containing L-tartrate ions; the rate was faster for the Δ-isomer of the complex than for the Λ-isomer. The stereoselectivity of L-tartrate ions for optically active $[Co(en)_3]^{3+}$ ions has also been observed in optical rotatory dispersion, circular dichroism, UV absorption spectra,[2-4] and electrophoresis;[5] values have been obtained for the association constants of L-tartrate ions with Λ- and Δ-$[Co(en)_3]^{3+}$.[2,6]

However, neither the orgin of the stereoselective interaction nor the structure of the ion-pair seems to have been established. Ogino[2] suggested that two carboxylate groups of a L-tartrate ion participate in hydrogen-bonding with a $[Co(en)_3]^{3+}$ ion, and that the right-handed screw of $^-COO-C-C-COO^-$ in the gauche structure with two hydroxyl groups at *trans* position to each other is particularly important for the stereoselectivity. In contrast to this suggestion, our preliminary experiments on the hydrogen-deuterium exchange showed that hydroxyl groups may take a role as important as that of carboxylate groups.

Therefore, the present study was undertaken to investigate the role of each group of the L-tartrate ion in the stereoselective ion-paring with $[Co(en)_3]^{3+}$ or $[Co(pn)_3]^{3+}$ by a comparison of the effect of added dicarboxylate ions on the CD spectra.

Experimental

$[Co(en)_3]Br_3 \cdot H_2O$ was prepared by the usual method and resolved into the optical isomers by using silver L-tartrate and D-tartrate. The $[\alpha]_D$ values of the Λ- and Δ-$[Co(en)_3]$-$Br_3 \cdot H_2O$ were +124° and −123°, respectively. Λ (+) $[Co\{(+)pn\}_3]Br_3$ and $\Delta(-)[Co\{(-)pn\}_3]Br_3$ were prepared according to the literature.[7] Their $[\alpha]_D$ values were +221° and −223°, respectively. L-Tartranilic acid was prepared in the same way as described by Montzka *et al.*[8] Found: C, 52.9; H, 4.89; N, 6.04%. Calcd for $C_4H_{11}NO_5$: C, 53.3; H, 4.92; N, 6.22%. The acids were neutralized with an equivalent amount of sodium hydroxide if necessary. Series of sample solutions, 0.01 M in either Λ- or Δ-$[Co(en)_3]$-Br_3 and 0—0.1M in one of the dicarboxylates, were prepared by mixing solutions of the components. Sample solutions were made in pairs; two solutions of a pair were equivalent to each other except that each contained one antipode of the complex. Series of sample solutions of the optically active $[Co(pn)_3]Br_3$ were also prepared in the same way with sodium L-tartrate and with sodium succinate.

Circular dichroism spectra of these solutions were measured in the region of the first absorption band (600 nm—350 nm) with a JASCO ORD/UV5 spectrophotometer by using a 1 cm quartz cell at 25±1 °C.

Results

A typical result is shown in Fig. 1. Λ-$[Co(en)_3]^{3+}$ shows a CD spectrum with two peaks in the region of the first absorption band (corresponding to the $T_{1g} \leftarrow A_{1g}$ transition in an octahedral ligand field). The positive peak at the larger wavelength has been assigned to the E component and the negative peak at the smaller wavelength to the A_2 component.[9] In the presence of L-tartrate(2−) ion, the CD spectrum was modified in such a way that the intensity of the E component decreased and that of the A_2 component increased, as

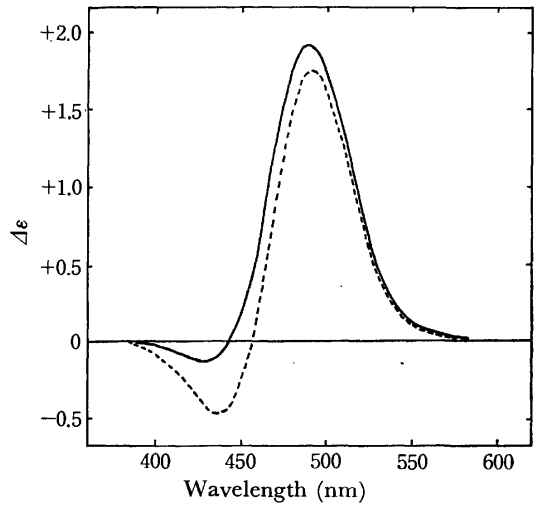

Fig. 1. CD spectra of 0.01 M Λ-$[Co(en)_3]Br_3 \cdot H_2O$ in the absence (—) and in the presence (---) of 0.15 M Na_2(L-tartrate) in the region of the first absorption band.

* The major part of the present study was presented at the 25th Annual Meeting of the Chemical Society of Japan, Tokyo, 1972.

None	0.30	0.30
Succinate(2−)	0.41	0.41
L-Tartrate(2−)	0.62	0.50

shown by the dotted line in Fig. 1. The same tendency was observed with all the carboxylates to some extent.

For ready comparison, the ratios of the CD intensity at the A_2 peak to that at the E peak (denoted by $|\Delta\varepsilon(A_2)/\Delta\varepsilon(E)|$) were plotted against the concentration of L-tartrate (Fig. 2). The effect of added L-tartrate was greater for the Λ-complex than for the Δ-complex. L-Tartaric acid, H_2 (L-tartrate), gave no change within the error of measurements and naturally showed no stereoselectivity. Nor did sodium bromide give appreciable effects.

Table 1 summarizes the $|\Delta\varepsilon(A_2)/\Delta\varepsilon(E)|$ values measured for several kinds of dicarboxylate ions which have carbon skeletons similar to a L-tartrate ion. Optically active L-malate(2−) gave only a small CD change, similar to that due to succinate(2−), and showed no stereoselectivity. On the other hand, *meso*-tartrate(2−) gave an effect almost identical to that of L-tartrate, but without any stereoselectivity. The L-tartranilate(1−) ion, in which a carboxylate group of the L-tartrate(2−) ion is replaced by an acid-anilide group, showed a distinct stereoselectivity. As is seen from Table 1, however, the magnitude of CD change due to L-tartranilate was smaller than that due to L-tartrate at the same carboxylate concentration. This can be ascribed to the difference in the charge between the L-tartranilate(1−) and L-tartrate(2−) ions. If the difference in the ionic charge is taken into account, L-tartranilate seems to be comparable to L-tartrate in the stereoselectivity for the optically active $[Co(en)_3]^{3+}$ ions. A similar result was observed with the monohydrogen-L-tartrate(1−) ion, H(L-tartrate)$^-$.

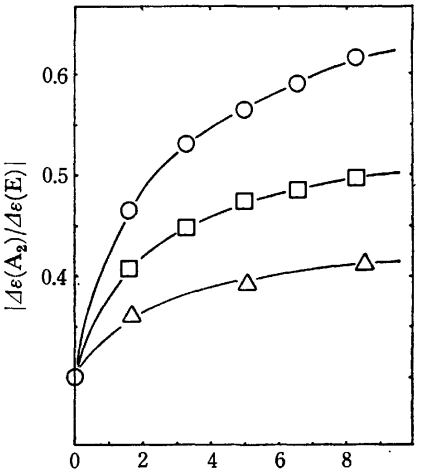

Fig. 3. Effects of the concentration of added L-tartrate and succinate ions on $|\Delta\varepsilon(A_2)/\Delta\varepsilon(E)|$ values of Λ-$[Co\{(+)pn\}_3]^{3+}$ and Δ-$[Co\{(-)pn\}_3]^{3+}$ (0.01 M). ○: Λ-complex, L-tartrate. □: Δ-complexes, L-tartrate. △: Λ- and Δ-complex, succinate.

Measurements on the optically active $[Co(pn)_3]^{3+}$, Λ-$[Co\{(+)pn\}_3]^{3+}$ and Δ-$[Co\{(-)pn\}_3]^{3+}$, resulted in nearly the same pattern of CD changes as those of Λ-$[Co(en)_3]^{3+}$ and Δ-$[Co(en)_3]^{3+}$, respectively. Figure 3 shows the relationship between the $|\Delta\varepsilon(A_2)/\Delta\varepsilon(E)|$ value and the concentration of L-tartrate (and of succinate, as a reference). The $|\Delta\varepsilon(A_2)/\Delta\varepsilon(E)|$ values at the same concentration of different carboxylates are compared in Table 1. A comparison of Fig. 3 with Fig. 2 shows that the stereoselectivity of L-tartrate for the optically active $[Co(pn)_3]^{3+}$ ion corresponds to that for the optically active $[Co(en)_3]^{3+}$ ion.

Discussion

The Λ-$[Co\{(+)pn\}_3]^{3+}$ ion is known to have the *lel* conformation and one of two N–H bonds at each end of the propylenediamine lies nearly parallel to the C_3 (or quasi-C_3) axis of the complex. Thus a set of three N–H hydrogens at each end of the complex can be conveniently used for hydrogen bonding with anions approaching the complex ion along the C_3 axis. This is also the case with the *lel* form of $[Co(en)_3]^{3+}$, which predominates over the *ob* form in aqueous solutions.

Thus the formation of an ion-pair between tris(diamine)-cobalt(III) and phosphate ions with a set of three N–H··· O hydrogen bonds was proposed by Mason and Norman in order to explain the marked changes in the CD spectrum of the complex observed in the presence of phosphate ions.[10]

A tartrate ion has two carboxylate and two hydroxyl groups which can be used for hydrogen bonding with the N–H groups of the complex ion. In analogy with Mason's model, it is very probable that three of these four groups participate in the hydrogen bonding. The two possibilities for the formation of three hydrogen bonds, with two carboxylate and one hydroxyl groups or with two hydroxyl and one carboxylate groups, will be discussed in connection with the experimental results.

From the fact that sodium bromide and tartaric acid (the fully protonated tartrate) caused only slight CD changes, the free carboxylate group seems to play an important role in causing CD changes. The fumarate-(2−) ion, of which only one of the two carboxylate groups can be used for hydrogen bonding with a tris(diamine)-cobalt(III) ion, caused only a small CD change, whereas the succinate ion capable of forming hydrogen bonds through two carboxylate groups caused greater CD changes. The L-malate ion which has two carboxylate and one hydroxyl groups caused a CD change similar to that caused by the succinate ion. These experimental results might be taken as an indication that carboxylate groups play a principal role in the CD changes of the tris(diamine)cobalt(III) ions. However, this is not likely to be the case, since further greater CD changes were caused by the hydrogen-L-tartrate(1−) ion which has only one free carboxylate group. The greatest CD changes were observed when the L-tartrate-(2−) ion was added to solutions containing tris(diamine)-cobalt(III) ions, especially of the *A*-form. Considering that introduction of the second hydroxyl group into the malate(2−) ion gives the tartrate(2−) ion, the second hydroxyl group seems to play an important role in the ion association and thus in the great CD changes.

Thus we propose a model of the ion-pair in which two hydroxyl and one carboxylate groups form hydrogen bonds with three N–H groups of tris(diamine)cobalt(III) ion of the *lel* form. This model of the ion-pair can also give a satisfactory explanation of the stereoselective CD changes, as can be seen from Fig. 4, which shows a schematic representation of the structures of tartrate and related ions. The clockwise arrangement of the COO^-, OH, and OH groups are characteristic of the isomers causing greater CD changes for the *A*-complexes. Thus the hydrogen-L-tartrate and L-tartranilate ions, which have the same configuration as that of L-tartrate as far as one carboxylate and two hydroxyl groups are concerned, caused stereoselective CD changes, which are large considering the lower ionic charge. The *meso*-tartrate ion has two asymmetric carbons of the *R* and *S* chiralities, and differs from the L-tartrate in that

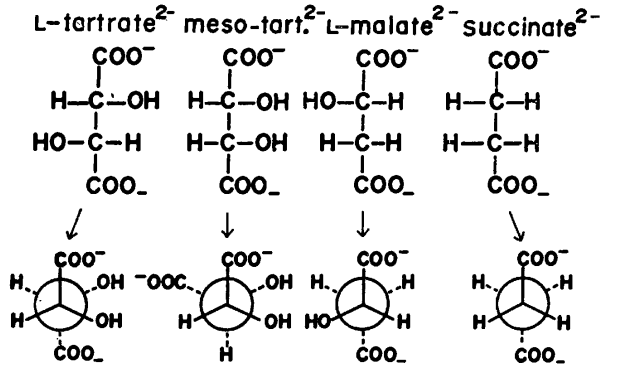

Fig. 4. Schematical representation of the structures of tartrate and related ions.

the carboxylate and hydrogen attached to the *S* carbon are interchanged. This appears to explain why meso-tartrate causes great CD changes in the CD spectra of both isomers of the complex.

During the preparation of this manuscript, an X-ray analysis was carried out on a crystal of *A*(+)$[Co(en)_3]$-Br(L-tartrate)·$5H_2O$ by Kushi *et al.*[11] Their result seems to confirm our model for the ion-pair described above. In addition, we recently prepared two types of optically active Sephadex cation exchangers with L-tartrate groups, and applied them to a direct column-chromatographic resolution of $[Co(en)_3]^{3+}$.[12] The exchanger with tartrate groups of the ester type showed higher efficiency than that with tartrate groups of the ether type. This is also a support for our model.

The authors wish to thank Dr. Yuzo Yoshikawa of Nagoya University for his helpful suggestions.

The Complexing of the Thallium(I) Ion with Other Solvents in Acetonitrile. Investigation Using a Cation-sensitive Glass Electrode

Toshio NAKAMURA

Chemistry Department, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received October 27, 1975)

The complexing of the thallium(I) ion with other common solvents has been studied in acetonitrile by using a univalent cation-sensitive glass electrode. A method similar to that developed to study the complexing of sodium[1] and lithium ions[2] was employed. Mono-, di-, and tri-solvated species were formed with DMF, SDMF, DMA, pyridine, formamide, and DMSO. Tetra-solvated species were also formed with *N*-methylformamide and HMPA. The complex formation constants for the mono-solvated thallium(I) ion were 4.1 with DMF, 5.6 with SDMF, 6.9 with DMA, 11 with pyridine and formamide, 12 with *N*-methylformamide, 15 with DMSO, and 1.0×10^2 with HMPA. Prior to these experiments, the cation-sensitive glass electrode was confirmed to respond to the thallium-(I)-ion activity in different solvents by comparing its behavior with that of a thallium-amalgam electrode. When water was the complexing solvent the potential of the glass electrode was not stable, and therefore, a thallium-amalgam electrode was used instead of a glass electrode to obtain the hydration constants of the thallium(I) ion in acetonitrile. Mono- and di-solvated species were formed with water and the hydration constant for the mono-solvated species was 1.1. The amalgam electrode and the glass electrode were used to obtain the constants with DMSO.

In previous papers,[1,2] the author and collaborators have reported a potentiometric method to obtain the formation constants of complexing for the sodium and lithium ions with other common solvent molecules in acetonitrile (AN). A univalent cation-sensitive glass electrode was used as an indicator. In the present experiment, a similar method was used to determine the formation constants of the complexing of the thallium(I) ion with other solvents in AN. Emf measurements of Cell I were carried out.

$$\underset{\text{glass electrode}}{\text{Ag}|0.005\text{M } AgNO_3(\text{AN})\|\underset{(A)}{0.1\text{M } Et_4NClO_4(\text{AN})}\|\underset{(B)}{5\times10^{-4}\text{M } TlClO_4+0.01\text{M } Et_4NClO_4(\text{AN}+\text{D})}|}$$

Cell I

A solution of 0.1 M of tetraethylammonium perchlorate (Et_4NClO_4) in AN was in compartment B in place of the 0.1 M of tetraethylammonium picrate(Et_4NPi) used in previous work,[1,2] in order to avoid the interaction between thallium(I) and picrate ions. The dissociation constant pK^d of thallium(I) picrate in AN at 25 °C has been determined using a conductometric method to be 2.6.[3] The validity of this substitution of the bridge electrolyte in compartment B has been discussed.[4,5] To obtain the complex formation constants the following relations were used:

$$\beta_x = \frac{(M^+_{xD})}{(M_s^+)[D]^x} \tag{1}$$

$$R_1 = \left\{\frac{(M_s^+)_{AN}}{(M_s^+)_{AN-D}} - 1\right\}/[D] = \sum_{i=1}\beta_i[D]^{i-1} \tag{2}$$

$$R_j = (R_{j-1}-\beta_{j-1})/[D] = \sum_{j=2}\beta_j[D]^{j-2} \tag{3}$$

$$\frac{(M_s^+)_{AN}}{(M_s^+)_{AN-D}} = 10^{(E_{AN}-E_{AN-D})/59} \tag{4}$$

All symbols have the same meaning as those in a previous report.[2] Assumptions similar to those in previous papers[1,2] were made: (i) solvent D in the AN–D mixtures is monomeric, (ii) the activity of AN does not change upon the addition of D and is equal to unity, (iii) the salt-effect activity coefficient of the thallium(I) ion, as calculated using the Debye-Hückel equation, is equal for both pure AN and AN–D mixtures, (iv) the amount of D consumed by the solvation of the ions of an indifferent electrolyte is negligible, and (v) the liquid-junction potential between the solutions in the salt bridge B and compartment C in Cell I does not change upon the addition of D. All of these assumptions appear to be satisfied approximately under the experimental conditions of these experiments when $[\text{AN}]\gg[\text{D}]$.

Using this method, formation constants β_x for such D as methanol, *N*,*N*-dimethylformamide (DMF), *N*,*N*-dimethylthioformamide (SDMF), *N*,*N*-dimethylacetamide (DMA), pyridine, formamide, *N*-methylformamide, dimethyl sulfoxide (DMSO), hexamethylphosphoric triamide (HMPA) were obtained, and the constants β_x for water were obtained with the thallium-amalgam electrode instead of the glass electrode, as will be described later.

Prior to the determination of the formation constants, the glass electrode was confirmed to respond well to the activity of the thallium(I) ions with a Nernstian slope in such diverse solvents as AN, methanol, DMF, and DMSO. This is shown in Fig. 1, where the relation between the potentials of the glass electrode and the thallium-amalgam electrode is plotted. When water was the solvent, the plot deviated from a straight line, as shown in Fig. 1, and more time was needed to attain a steady potential than in the cases of the other solvents.

Apparatus and Reagents

Apparatus. Most of the apparatus and experimental techniques for the determination of the formation constants β_x are the same as those in previous reports.[1,2] The arrangement of Cell I is that shown in Fig. 1 of Ref. 1, except that

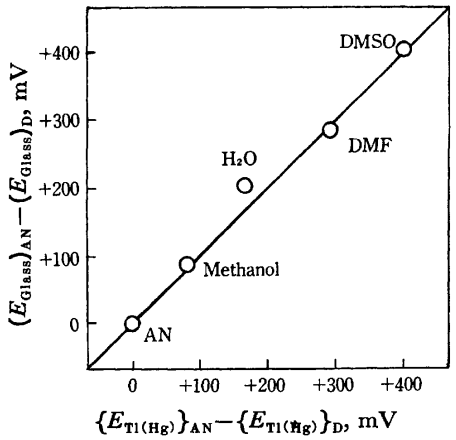

Fig. 1. Relation between potentials of monovalent cation-sensitive glass electrode and those of the thallium-amalgam electrode in various solvents both referred to the values in AN.

5×10^{-4} M of $TlClO_4$ was used in place of 10^{-3} M of $NaClO_4$ or 10^{-3} M of $LiClO_4$ in compartment C and 0.1 M of Et_4N-ClO_4 was used in place of 0.1 M of Et_4NPi in the compartment B. The thallium-amalgam electrode was used to obtain the hydration constants for thallium(I) ions in AN (*cf.* Cell II).

Reagents. Thallium(I) perchlorate was prepared by neutralizing perchloric acid with an aqueous thallium(I) hydroxide solution prepared by passing a thallium(I) formate solution through a column of Amberlite IRA 411 ion-exchange resin in OH-form[3] and was dried at 70 °C in a high vacuum. The SDMF was prepared from DMF and phosphorus pentasulfide, according to the method of Willstatter and Wirth.[6] The other solvents and reagents used in this experiment were prepared by the same methods as those described in previous reports.[1,2]

Results

Response of the Glass Electrode to the Activity of Thallium(I) Ions in Different Solvents. The glass electrode used in this study had a slope of 58 mV on a logarithm scale of the thallium(I)-ion concentration between 2×10^{-3} and 1.6×10^{-5} M in AN–0.01 M Et_4NClO_4. If corrected for a change in the salt-effect activity coefficient, the response to pa_{Tl^+} is very near the Nernstian slope of 59 mV. The glass electrode also responds well to differences in the activity of thallium(I) ions in several different solvents except water as indicated above and Ref. 4.

the formation constant β_X were calculated using Eqs. 2—4. The results are summerized in Table 1. The maximum concentrations of D added to the AN solution are also shown in Table 1. Figures 2—5 show several examples of the R_1–[D], R_2–[D], and R_3–[D] relations for the determination of the formation constants. When water was added as the complexing solvent D to the compartment C of the Cell I, the rate of potential change was very slow and the steady potential attained was not reproducible. Hydration constants were thus obtained using the thallium-amalgam electrode (Cell II) instead of the glass electrode (Cell I).

thallium-amalgam electrode

Cell II

The thallium content in the amalgam (5.4×10^{-2} M) was determined by the same titration method as that of Ref. 4. The amalgam electrode was sufficiently stable during the period of the emf measurements, so long as the solution in compartment C in Cell II was deaerated. Prior to the determination of the hydration constants of thallium(I) ions with DMSO in AN was also studied with the thallium-amalgam electrode and the formation constants obtained with the two different electrodes agreed fairly well (*cf.* Table 1). Figures 4 and 6 show some examples of the R_1–[DMSO], R_2–[DMSO], and R_1–[H_2O] relations obtained with the amalgam electrode.

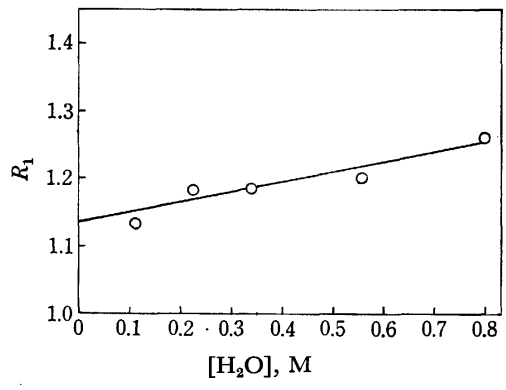

Fig. 6. R_1–[H_2O] relation.

Discussion

From Fig. 1, it appears reasonable to consider that the glass electrode can respond to the activity of thallium(I) ions in solvents of different species or compositions.

It was indicated in previous reports[1,2] that pyridine, which has a strong basic character but a low dielectric constant, solvates to sodium and lithium ions only to a small extent. The β_1 increased in the case of sodium ions in order: pyridine<methanol<H_2O<DMF<DMA<DMSO, and in the case of lithium ions: methanol<pyridine<DMF<DMSO<DMA. On the other hand, in the case of thallium(I) ions, β_1 increased in order: methanol<H_2O<DMF<DMA<pyridine<

DMSO. The strong complexing of pyridine with thallium(I) ions seems to be acceptable considering the strong basic character of pyridine. In the complexing of thallium(I) ions in AN with other solvents formation constants up to β_4 were obtained in the cases of *N*-methylformamide and HMPA. On the other hand, in the cases of lithium ions in AN with these solvents only β_1 and β_2 were obtained. The results may be explained by the fact that the radius (r_c) of the thallium(I) ion is considerably greater than that of the lithium ion. SDMF must solvate to thallium(I) ions more strongly than DMF on the basis of considerations of hard and soft acids and bases. This trend appears in the values in Table 1. In general, the degree of complexing β_x of thallium(I) ions with these solvents in AN was intermediate between those of lithium and sodium ions.

Table 2. Effect of the concentration of an indifferent electrolyte on the complex formation constants of thallium(I) ions with DMSO in AN

	1.3×10	3.7×10	$6._2\times10$

From the results of Table 2, the effect of the concentration of the indifferent electrolyte on complex formation constants of thallium(I) ions with DMSO in AN may be recognized, that is, the values of β_3 for 0.1 M of Et_4NClO_4 are about one-half of those in 0 and 0.01 M of Et_4NClO_4. In the presence of 0.1 M Et_4NClO_4, ion association between thallium(I) and perchlorate ions may occur. The association constant of thallium(I) perchlorate in AN is 32,[7] compared with the constants for sodium and lithium perchlorates of *ca.* 11[8] and *ca.* 4[9] respectively. The addition of DMSO to the AN solution may cause the dissociation of the ion-associated thallium(I) perchlorate and decrease the potential change, and then the apparent value of β_x may become small. Dissociation, of course, may occur as the DMSO content in AN increases. But a complete discussion cannot be made concerning the results in Table 2, because the reliability of these constants (β_x) obtained using the present method appears to be within $\pm10\%$ for β_1 for the dipolar aprotic solvents and might be somewhat less for β_1 for the other solvents and for β_2–β_4.

Many studies have been made concerning solvation phenomena of the sodium ion as noted previously.[1] Recently, Kuntz and Cheng have published the results of experiments on the solvation of some protic solvents with ions in non-aqueous systems using IR measurements,[10] in which the solvation constants (β_1) of lithium ions with methanol and sodium ions with water in AN were described to be 3.4 and 1.3, respectively. These values agree fairly well with those shown in Table 1.

The author wishes to express his sincere thanks to Prof. Kosuke Izutsu of the Chemistry Department of Shinshu University for his suggestions and discussions and to Mr. Yuji Goi for his earnest support. This work was supported in part by a Grant-in-Aid for Scientific Research from the Ministry of Education.

(Received December 27, 1975)

The crystal structure of the alkoxo-oxygen bridged tetranuclear copper(II) complex, $Cu_4\{(n\text{-}C_3H_7)_2N(CH_2)_2O\}_4Cl_4$, has been determined from the three-dimensional X-ray diffraction method. The crystals are orthorhombic with the space group Pbcn. The cell dimensions are $a=15.965$ (4), $b=14.941$ (1), $c=19.305$ (2) Å. The structure has been determined from the heavy atom method and refined by the block-diagonal least-squares method to give $R=7.52\%$. The complex is of a cubane type structure formed by four copper and four alkoxide oxygen atoms. Each copper atom has a distorted square pyramidal environment. The correlation between the magnetic property and the structure was discussed on some homologous compounds of cubane structure.

Hein and his coworkers[1] prepared a series of copper(II) complexes of *N,N*-dialkylaminoethanol with the general formula $Cu(R_2NCH_2CH_2O)X$ (R=CH_3, C_2H_5, n-C_4H_9 *etc.* and X=Cl, Br) whose basic structure was assumed to be a binuclear unit as shown in Fig. 1.

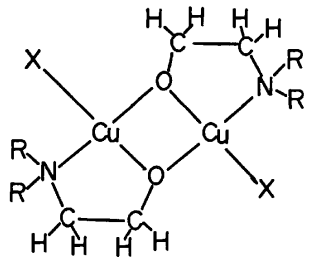

Fig. 1. An assumed basic structure of $[Cu(R_2(CH_2)_2O)X]$, where R=alkyl group and X=Cl, Br, NCS.

Uhlig and Staiger[2] measured magnetic moments and optical spectra, and found that their magnetic moments at room temperature distribute in a wide range (from 1.9 BM to practically zero). Recently Kida and his coworkers[3-5] prepared a number of copper(II) complexes of various aminoalcohols with the general formulas $[Cu(R_2N(CH_2)_nO)X]$ (hereafter abbreviated as Cu(R-n)X, where R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9 and X=Cl, Br, NCS) and $[Cu(R_2N(CH_2)_nNH(CH_2)_mO)]Y$ (hereafter abbreviated as [Cu(R-n-m)]Y, where n and m=2 or 3, and Y denotes a mono-negative ion), and proposed a new criterion for the classification of the extended series of alkoxo-bridged copper(II) complexes on the basis of temperature dependence of the magnetic susceptibilities,[5] *i.e.*, (A) those whose χ_A-T curves can be fitted by the Bleaney-Bowers equation[6], (B) those whose χ_A-T curves obey the Curie-Weiss law with positive Weiss constant, (C-1) those whose χ_A-T curves obey Curie-Weiss law with negative Weiss constant, and (C-2) whose χ_A-T curves can not be fitted by the Bleaney-Bowers equation, though showing subnormal magnetic moments at room temperature. They also showed that there is a close relationship between the presence of the near-ultraviolet absorption band and the intramolecular spin-exchange interaction.

In order to elucidate the above properties on the molecular structural basis, single-crystal X-ray analyses are desirable for a series of key compounds. The structures of some alkoxo-bridged copper(II) complexes were already determined.[7-12] In this study, crystal structure of chloro *N,N*-dipropyl-2-aminoethanolato copper(II), Cu(pr-2)Cl, which belongs to the above-mentioned C-1 group, was determined by the three-dimensional X-ray diffraction techniques. It was found that the compound is of a cubane type structure formed by four copper and four alkoxide oxygen atoms. This result and the already reported data of the three related compounds[7-9,12] make a series of cubane structures with stepwise differing magnetic properties. Thus, the present result has made it possible to discuss the correlation between magnetic property and molecular structure.

Experimental

The complex was prepared according to Hein.[1] Single-crystals were obtained by slow evaporation of absolute ethanol solution at room temperature. They are green rhombic prisms elonagated along the c-axis. Unit cell dimensions were determined by the least-squares method from fifteen reflections measured on a Syntex P$\bar{1}$ diffractometer. The crystal data are listed in Table 1. A suitable crystal for the intensity measurement was ground to a sphere of radius $r=0.151$ mm. Since the crystal is liable to decompose in the air, it was coated with clear varnish. Three-dimensional intensity data were collected by the 2θ-θ scan technique on a Syntex P$\bar{1}$ four-circle diffractometer using Mo$K\alpha$ radiation monochromated by a graphite plate. Three reflections were monitored after every measurement of 47 reflections, and the monitored data showed a satisfactory stability. Of 3929

independent reflections collected in $2\theta \leqq 48°$, 1557 ones greater than 2.33σ (F) were used in the analysis. They were corrected for Lorentz and polarization effects, but corrections for absorption were not applied ($\mu r = 0.32$).

Solution and Refinement

There are eight formula units (a formula unit = $Cu_2Cl_2O_2N_2C_{16}H_{36}$) in a unit cell. The structure has been determined by the heavy atom method. The positions of copper atoms were obtained from the three-dimensional Patterson syntheses. Those of chlorine atoms were obtained from the minimum function based on the copper atoms. A three-dimensional electron-density map was then calculated with all observed reflections phased by the copper and chloride atoms, thus obtaining the positions of oxygen and nitrogen atoms. By successive Fourier syntheses and the block-diagonal least-squares method the positions of all the nonhydrogen atoms were determined except some carbon atoms of the propyl group, whose most probable positions were determined by the D-Fourier syntheses. Six-cycles of the block-diagonal least-squares refinement was applied to the positional and isotropic thermal parameters of the non-hydrogen atoms. Further five-cycles refinement was carried out, introducing anisotropic temperature factors, and R decreased to 7.52%. Maximum shifts of the positional and thermal parameters in the final cycle did not exceed half of their standard deviations. The scattering factors for all the atoms were taken from the International Tables for X-ray Crystallography.[13] In the least-squares procedures, weight w was taken equal to one for $|F_o| \geqq 5.0$ and zero for $|F_o| < 5.0$. The F_o–F_c table is kept at the office of this Bulletin, as Document No. 7617. The final positional and thermal parameters with the standard deviations are shown in Table 2.

Description of the Structure

The projection along the b-axis and the numbering system are shown in Fig. 2. The unit cell contains four molecules, each of which has a so-called "cubane" structure formed by four copper and four alkoxide

these planes. The carbon atoms of the chelate ring, and nitrogen and chlorine atoms are situated far from the plane, probably due to a steric repulsion.

Discussion

The cubane type structure similar to the present complex has been known in the related complexes, Cu(et-2)Cl[7,8] and Cu(bu-2)Cl.[9] The copper complex with a tridentate ligand, Cu(eia), where eia is a Schiff base formed by the condensation of aminoethanol and acetylacetone has also been known to be of a cubane structure.[12] A remarkable trend is found in those compounds that in-plane Cu–O bonds involving chelate ring are of normal Cu–O bond lengths, while the other in-plane Cu–O bonds (labeled with (d) in Fig. 3) are considerably elongated.[7–9,12] It is also to be noted that in all the above complexes the bridging alkoxide group is involved in a five-membered chelate ring. No cubane type tetranuclear complex, which has a six-membered chelate ring involving bridging alkoxide, has yet been known.

Some bond distances and angles of the series of cubane type structure are listed in Table 6 in the order of

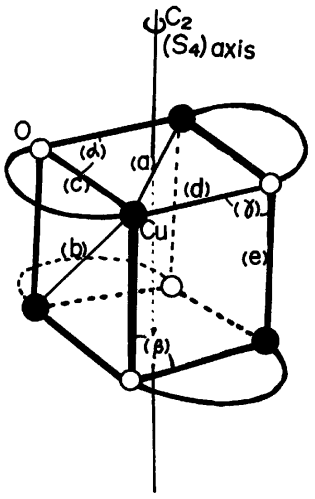

Fig. 3. The cubane type structure formed by the copper and oxygen atoms.
The bond distances and angles, which may be closely related to the magnetic property, are defined in the figure.

The notations of bonds are defined in Fig. 3.

increasing μ_{eff} values. As seen in Table 6, bond distances and angles are closely related to magnetic moments for the three homologous compounds.* In this series, Cu(et-2)Cl and Cu(bu-2)Cl take both extreme values in either structural and magnetic data. In the former, the in-plane Cu–O (d and c) bonds are much stronger than the out-of-plane Cu–O (e) bonds and the molecule may be regarded to be formed from two basic binuclear units of Fig. 1. On the other hand, in the latter the out-of-plane Cu–O (e) bonds are much shortened and Cu–O (d) bonds are elongated. Thus the axis of the squar pyramid of copper ion is changed from the Cu–O (e) (in the case of Cu(et-2)Cl) to the Cu–O (d) (in the case of Cu(bu-2)Cl) axis. The presently analysed complex, Cu(pr-2)Cl, lies between the both extremes in either structural and magnetic values. However, it should be remarked that the structural trend of Cu(pr-2)Cl is definitely similar to that of Cu(bu-2)Cl rather than that of Cu(et-2)Cl, *i.e.*, in Cu(pr-2)Cl and Cu(bu-2)Cl Cu–Cu (a)>(b) and Cu–O (d)>(e)>(c), though magnetically Cu(pr-2)Cl belongs to the same group C-1[5] as Cu(et-2)Cl, since they both give negative Weiss constant, while Cu(bu-2)-Cl gives positive Weiss constant as shown in Table 6. This implies that in this series of compounds the change of sign in Weiss constant accompanies no discontinueous change of structure.

The calculations were performed on the FACOM 230-75 computer of the Computer Center of Kyushu University, using the UNICS program system.[14]

We are grateful to Professor T. Komori of Kyushu University for the kind advices and allowing us to use the Syntex PĪ automatic diffractometer. Thanks are also due to Mr. T. Uechi of this university for valuable advices and discussion.

(Received January 12, 1976)

The complexation between copper(II) ion and large excess histidine has been studied by visible absorption, proton and C-13 NMR spectral methods, in comparison with histamine–copper(II) system. The predominant species were considered to be ML_2H^+ and $ML_2H_2^{2+}$ at $a=0$ and ML_2 at $a=1$ and 2, respectively from the spectral data in visible region, where a represents moles of base added per mole of diprotonated ligand. In ML_2H^+, one histidine is bound histamine-like with a carboxylate coordinated in apical position and the other glycine-like with a protonated imidazolium group, and in $ML_2H_2^{2+}$, both histidine molecules are bound glycine-like. Two histidine molecules are both tridentate with apical carboxylates in ML_2. In histamine–copper(II) system, the coordination of the third histamine molecule in the apical position was suggested at $a=1$ and 2. The proton and the C-13 NMR spectra were reasonably interpreted in view of the above situation. A difference in the line-broadening of PMR signals was observed between histidine–copper(II) and histamine–copper(II) systems. This is mainly due to the difference in the exchange rates of the coordinated ligands of two systems.

On account of the importance of interaction between imidazole group and copper(II) ion in biological systems, copper(II)–histidine complexes in aqueous solution have been studied by many workers. Most of the experiments were performed at stoichiometric conditions such as ligand to copper(II) ion ratio of 2: 1 or 1: 1. Sigel and McCormick investigated the interaction at ligand to metal ion ratio of 2×10^3 by means of proton NMR spectroscopy.[1] By comparing the line-broadening of imidazole proton signals of neutral histidine with that of its derivatives, they concluded that the predominant species is 2: 1 complex where one histidine is bound histamine-like and the other glycine-like. On the other hand, based on a kinetic consideration Sundberg and Martin have suggested that histidine may interact with copper(II) ion in only a monodentate mode at extraordinarily large ratios of ligand to metal ion.[2] The purpose of the present study is to obtain detailed information about the mode of complexation in the presence of large excess histidine by means of NMR and visible spectral methods.

Experimental

Materials. L-Histidine monohydrochloride monohydrate, histamine dihydrochloride, and $CuCl_2\cdot2H_2O$ were obtained from Nakarai Chemicals, Ltd., Kyoto. The deuterated compounds, D_2O, NaOD, and TSP (sodium 3-trimethylsilyltetradeuteriopropionate) were obtained from E. Merck AG, Darmstadt.

Visible Absorption Spectra. A Shimadzu Double 40-R spectrophotometer was used to obtain the visible absorption spectra. The measurements were carried out on the solutions containing a ligand (4×10^{-1} M) and copper(II) ion (2×10^{-3} M) or a ligand (2×10^{-2} M) and copper(II) ion (10^{-2} M) at room temperature. The spectra were obtained at various pH values corresponding to each a value, in which a represents moles of base added per mole of diprotonated ligand.

NMR Spectra. The proton NMR spectra were measured on a Varian A-60 NMR spectrometer. The spectra were obtained on the D_2O solutions of a ligand (0.25 M) in the absence and the presence of 1/500- or 1/2000-fold copper(II) ion at each a value. TSP was used as an internal reference The temperature variation was made with a Varian temperature variable accessory unit (V-6040) calibrated by ethylene glycol. The C-13 NMR spectra were measured on a Nippon Electric Varian NV-21 NMR spectrometer. The spectra were obtained on D_2O solutions of histidine (0.4 M) in the absence and the presence of 1/4000-fold copper(II) ion at each a value. Dioxane was used as an internal reference.

* Present address: Faculty of Medicine, Kyoto University, Sakyo-ku, Kyoto 606.

Results and Discussion

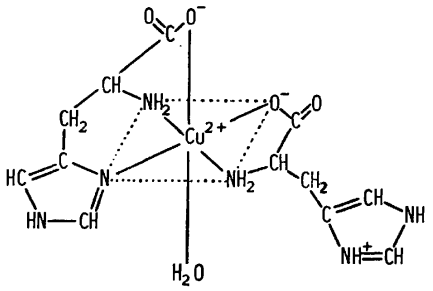
Visible Absorption Spectra. The spectral characteristics at each a value of the 200: 1 ligand–copper(II) system are shown in Table 1 together with those of 2: 1 complexes at $a=2$.

TABLE 1. VISIBLE ABSORPTION CHARACTERISTICS OF 200: 1 AND 2: 1 LIGAND–COPPER(II) SYSTEMS

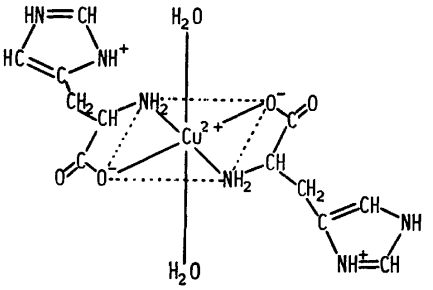
	a value[a]	λ_{max}(nm)	ε_{max}(cm^{-1} M^{-1})
Histidine–Cu(II) 200: 1	0 (3.66)	623	60
	1 (7.81)	640	86
	2 (11.70)	635	94
Histamine–Cu(II) 200: 1	0 (3.03)	800	20
	1 (8.09)	610	96
	2 (11.68)	610	105
Histidine–Cu(II) 2: 1	2 (7.60)	640	86
Histidine–Cu(II)–1-methylhistidine 1: 1: 1	2 (7.52)	615	60
1-Methylhistidine–Cu(II) 2: 1	2 (7.50)	628	57
Histamine–Cu(II) 2: 1	2 (7.85)	600	85

a) The value of a represents moles of KOH added per diprotonated ligand. The values in parentheses are pH values.

In the 200: 1 histidine–copper(II) system at $a=0$, an absorption maximum was observed at 623 nm, which is an intermediate between that in 1: 1: 1 histidinate–Cu(II)–1-methylhistidinate complex and that in 2: 1 1-methylhistidinate–Cu(II) complex. This finding sug-

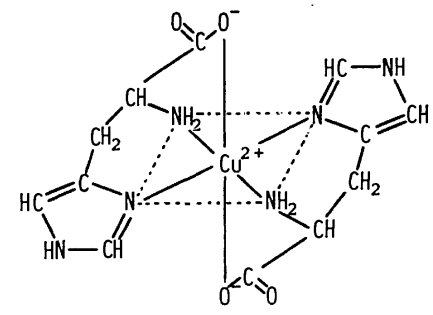


I, ML_2H^+

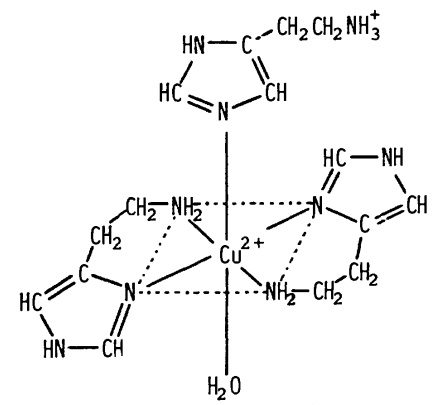


II, $ML_2H_2^{2+}$

gests the presence of the complex ML_2H^+(I), where one histidine is bound histamine-like with a coordinated apical carboxylate and the other glycine-like with a protonated imidazolium group and the complex $ML_2H_2^{2+}$(II), where both histidine molecules are bound glycine-like. Such complexes are known to be present in a weak acid pH region in the stoichiometric histidine–copper(II) systems, too.[2-4] On the other hand, the very weak ligand field (λ_{max}=800 nm) observed at a=0 in the 200: 1 histamine–copper(II) system means little complex formation between histamine and copper(II) ion. This remarkable difference in the degree of the complexation at a=0 between two systems suggests that the carboxylate group plays an important role in the complexation in the histidine–copper(II) system.



III, ML_2



IV, ML_2LH^{3+}

The spectral characteristic, λ_{max}=640 nm (ε=86), at a=1 in the 200: 1 histidine–copper(II) system agrees completely with that of the 2: 1 histidinate–copper(II) complex ML_2. This means the formation of ML_2 as an exclusively predominant species in the 200: 1 histidine–copper(II) system. The structure of the 2: 1 complex ML_2, which is shown by III, has been discussed in detail.[5] The spectrum at a=1 in the 200: 1 histamine–copper(II) system exhibits an absorption maximum at 610 nm (ε=96), which is longer than that of 2: 1 normal histamine–copper(II) complex. This result suggests the coordination of the third histamine molecule in the apical position as shown by IV (ML_2LH^{3+}).

A little blue shift of the absorption maximum at a=2 in 200: 1 histidine–copper(II) system shows the partial deprotonation from the pyrrole nitrogen of the coordinated histidine molecules.[5] In comparison of the absorption spectrum of the 200: 1 histamine–copper(II) system at a=2 with that at a=1 the λ_{max} was the same whereas the absorptivity was higher. This observation may be interpreted by the strengthening of the apical coordination due to the deprotonation of the ammonium group and the partial deprotonation from the pyrrole nitrogen.

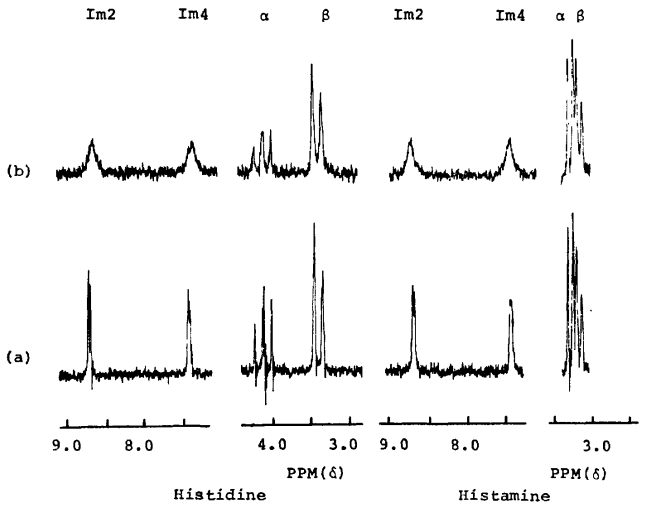


Fig. 1. PMR spectra of histidine and histamine at a=0 in the absence and the presence of 1/500-fold copper(II) ion: concentration of ligand=0.25 M; (a) ligand alone, (b) ligand+1/500 $CuCl_2$.

Proton Magnetic Resonance Spectra. The proton magnetic resonance spectra of histidine and histamine at a=0 in the absence and the presence of 1/500-fold copper(II) ion are shown in Fig. 1. In the 2000: 1 ligand–copper(II) systems, no evident broadening of the signals is observed. The signal of α-methine proton is broadened together with the signals of imidazole-2 and -4 protons in the 500: 1 histidine–copper(II) system, suggesting the involvement of the amino and the imidazole groups in the complex formation. This observation corresponds fully to the mode of complexation estimated by the visible spectral properties. The signals of the imidazole protons are broadened in the 500: 1 histamine–copper(II) system in the same manner

as in the 500: 1 histidine–copper(II) system. It is noteworthy that the broadening of imidazole signals is observed in the same degree in both systems in spite of the remarkable difference in the degrees of complex formation. This observation may be based on the different exchange rates in both systems.

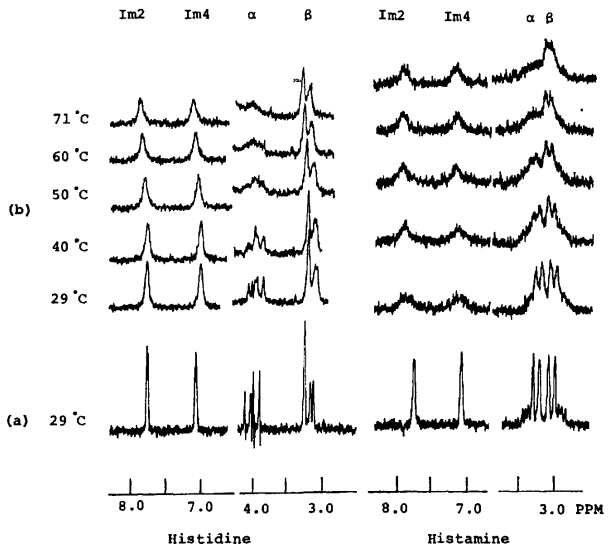

Fig. 2. PMR spectra of histidine and histamine at $a=1$ in the absence and the presence of 1/2000-fold copper (II) ion: concentration of ligand=0.25 M;
(a) ligand alone, (b) ligand+1/2000 $CuCl_2$.

Figure 2 shows the PMR spectra with temperature variation at $a=1$ in the histidine–copper(II) and the histamine–copper(II) systems. The broadening of the PMR signals is evident in both systems, giving remarkably different degrees of the broadening on the imidazole proton signals. This difference was observed on the solutions of histidine and histamine at pD 8.1 by Sigel and McCormick.[1] We measured the PMR spectra at constant a value, where the dissociation steps of both ligands are equal. In our experiment, a more remarkable difference in the broadening was observed. The previous workers concluded that such a difference is based on the different degrees of the participation of the imidazole group in complex formation, assuming that the exchange rates of the coordinated ligand are the same in both systems.[1] However, the validity of such assumption is difficult to justify. In the histidine–copper(II) system the line width of all the signals increases with increasing temperature. On the other hand, in the histamine–copper(II) system the line width of the imidazole proton signals decreases slightly with increasing temperature. This result suggests that the exchange rates of the coordinated ligands are different between two systems. In the presence of copper(II) ion, the line width at half height of signal $1/T_2$ is given by the following equation, if only one paramagnetic environment is present in solution.[6,7]

$$1/T_2 = 1/T_{2L} + P_M/P_L(1/(T_{2M}+\tau_M)) \quad (1)$$

Here, T_{2L} is the transverse relaxation time for the uncoordinated ligand, T_{2M} is that for the coordinated ligand, P_M/P_L is the ratio of the concentration of the coordinated ligand to that of the uncoordinated ligand, and τ_M is the life-time for chemical exchange of the coordinated ligand. Equation 1 is applicable to the histidine–copper(II) and the histamine–copper(II) systems to calculate the values of $1/(T_{2M}+\tau_M)$, because the presence of the main complex species, ML_2 for the histidine–copper(II) and ML_2LH^{3+} for the histamine–copper(II) systems are shown by the visible absorption spectra. We calculated the values of $1/(T_{2M}+\tau_M)$ using the line-broadening data on the imidazole-2 and -4 protons. In the histidine–copper(II) system, $1/(T_{2M}+\tau_M)$ is nearly equal to $1/\tau_M$, since the line width increases with increasing temperature and in this case τ_M is much larger than T_{2M}. The exchange rate $1/\tau_M$ is calculated to be about $3—5\times10^3\ s^{-1}$. On the other hand in the histamine–copper(II) system, $1/(T_{2M}+\tau_M)$ is calculated to be about $2—3\times10^4\ s^{-1}$. Since the line width of the imidazole proton signals in the histamine–copper(II) system decreases with increasing temperature, T_{2M} should be larger than τ_M.[6] Therefore, the exchange rate $1/\tau_M$ is much larger than $2—3\times10^4\ s^{-1}$. These results suggest that the difference in the line broadening in both systems is mainly due to different exchange rates. The relatively slower exchange rate histidine–copper(II) complex can be accounted for its coordination structure, that is, the copper(II) complex, where two histidine molecules are tridentate with apical carboxylates, is not easily accessible for an incoming ligand molecule.

In the PMR spectra at $a=2$, the signals are more broadened than those at $a=1$, especially in the histidine–copper(II) system, and the line width decreases slightly with increasing temperature. This may be explained on the basis of faster exchange rate caused by the deprotonation of the ammonium group.

$-COO^-$	173.02	1.53	174.35	0.95

C-13 Magnetic Resonance Spectra. Figure 3 shows C-13 NMR spectra of histidine in the absence and the presence of 1/4000-fold copper(II) ion at $a=0$ and 1 together with the assignments by Freedman *et al.*[8] The effect of copper(II) ion on the C-13 NMR signals is observed at each a value. To estimate the effect quantitatively, the relative signal heights in the presence and in the absence of copper(II) ion were compared. Table 2 shows the ratios of these heights, in which the smaller value means the larger effect of copper(II) ion, except for the carboxyl and the imidazole-5 carbons. The values for these signals are larger than 1.00 at $a=0$. This is probably due to their relatively long spin lattice relaxation times resulting from the lack of bound hydrogen atoms which can act as dipolar relaxers. By the addition of paramagnetic substance such as copper(II) ion, spin lattice relaxation time decreases and unsaturated signals may be recorded. At $a=0$ the value with the signal of α-methine carbon is smaller than those of the imidazole-2 and -4 carbons. On the other hand, the values with these three signals are roughly equal each other at $a=1$. These results give another support for the presence of ML_2H^+ and $ML_2H_2^{2+}$ at $a=0$ and ML_2 at $a=1$.

It the NMR line broadening experiments, histidine was suggested to interact with copper(II) ion in only a monodentate mode.[2] However, the present data show that histidine molecules bind to copper(II) ion in the tridentate or bidentate modes at extraordinarily large ratios of ligand to metal ion in a similar manner as at the stoichiometric conditions. The difference in the complexation between such two conditions has been found in the histamine–copper(II) system. The more remarkable difference has been observed in glycine-like ligands, which possess one amino and one carboxyl groups.[9]

NMR spectroscopic technique has been utilized to obtain structural information about copper(II) complexes. However, in NMR experiments attention should be called to the presence of large excess ligand. The mode of complexation at extraordinarily large ratios of ligand to metal ion may not be the same as those at stoichiometric ratios.[2] In addition, recently, Martin *et al.* have pointed out some criteria or disadvantage in the NMR line broadening method.[2,10] The use of visible spectral method together with NMR method will compensate such disadvantage and will give further detailed information about the mode of complexation of copper(II) ion in the presence of large excess ligand.

The authors wish to express their thanks to Miss M. Sugiura of Kobe Women's College of Pharmacy for the measurement of C-13 NMR spectra.

Liquid Phase Disproportionation of Propylene over MoO_3-Al_2O_3 Catalyst in the Presence of Solvents

Eisuke OGATA, Toshiaki SODESAWA, and Yoshio KAMIYA

Department of Reaction Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 26, 1975)

Liquid phase disproportionation of propylene using hydrocarbon solvents over MoO_3–Al_2O_3 (atomic ratio: Mo/Al=1/25) catalyst was investigated at 80 °C at a pressure of 50 kg/cm². The catalytic activity in heptane solution was preserved for a long time, because the small amount of polyolefins produced by polymerization reactions was entirely dissolved in the heptane and carried away from the catalyst surface. Selectivity for ethylene and butenes increased slightly in the heptane solvent. Benzene was not a suitable solvent because of poor solubility of the polymers and the formation of alkylbenzenes. A small amount of dissolved hydrogen also was found to be somewhat effective in lengthening the catalyst life. The polymers were found to be composed of larger amounts of ethylene than propylene and to have two molecular weight distribution maxima.

Disproportionation of olefins has been studied by numerous investigators in heterogeneous gas and homogeneous liquid phases. From an industrial point of view, it is important that the catalytic activity be preserved for a long time. In gas-phase disproportionation over MoO_3–Al_2O_3 catalyst, the catalytic activity decreases rapidly with reaction time on stream.[1,2] The catalyst life and selectivity have been improved by the addition of third materials to the catalysts, but this is not yet fully successful.[1–5] Previously,[6] the present authors have shown that the activity of MoO_3–Al_2O_3 in liquid-phase propylene disproportionation is preserved much longer than in the gas phase, and decreases very slowly after a long time at low temperatures. It was assumed that the main effect of deactivation of the catalyst was due to the covering of the active site with the polymers produced. If this is true, a longer life of the catalyst can be expected using a solvent which dissolves the polymers and maintains a clean active site for disproportionation.

In this paper, the catalytic activity, selectivity, and catalyst life in propylene disproportionation over MoO_3–Al_2O_3 catalyst in the presence of solvents were investigated. In addition, the formation of polymers was studied by measuring the molecular weight and constituents of the polymers produced.

Experimental

The disproportionation reaction was carried out in an ordinary up-flow system of a fixed-bed catalyst in the liquid phase at a total reaction pressure of 50 kg/cm². About 0.025 to 1.000 g of the catalyst and twice that amount of γ-alumina were used as a catalyst bed and packed in the middle of a tube reactor with an 8 mm inside diameter and a 400 mm length. The upper and lower spaces of the catalyst bed were filled with γ-alumina. Propylene and the solvent were introduced into the catalyst bed from two cylindrical pumps after mixing in the lower part of the catalyst bed. The reaction products were analyzed by gas chromatography as reported in a previous paper.[7]

The preparation method and composition of the MoO_3–Al_2O_3 (atomic ratio: Mo/Al=1/25) catalyst, pretreatment of the catalyst for activation, and propylene used were the same as indicated in a previous paper.[6] Heptane and benzene were of purities above 99.7% and added after drying with a 13X molecular sieve and the removal of the small amount of air in the solution by the bubbling of helium, nitrogen or hydrogen gases.

The polyolefins produced by a side reaction of the disproportionation were analyzed by the following method in order to determine their molecular weights. Polymers soluble in heptane and benzene were dried at 95 °C at 1 mmHg for 1 h. Polymers adhering to the catalyst surface were extracted by tetrahydrofuran using a Soxhlet extractor at 65 °C for 15 h, and the extracts were dried at 95 °C under 1 mmHg for 1 h. The number average molecular weight $\overline{M}_n$ for the polymers was measured in a tetrahydrofuran solution using a Mechrolab Inc. vapor pressure osmometer (Model 301A). The molecular weight distributions of the polymers were measured in a tetrahydrofuran soluble at 20 °C and 40 °C using a Toyo Soda Manufacturing Co., Ltd. high-speed liquid chromatograph of the gel-permeation type (Model HLC-801A). The column used was 4 feet in length and packed with a TSK GEL MIX. of the polystyrene type prepared by the Toyo Soda Co. Samples for liquid chromatography were prepared as about 1 wt% polymer solutions in tetrahydrofuran. Six kinds of paraffinic hydrocarbons (C_{12}–C_{32}) and eight kinds of mono-disperse polystyrene standards (with molecular weights of 2100—2000000) prepared by the Pressure Chemical Co. were used as standard molecular weight samples. The estimate of the molecular weight distribution was corrected for the mono-disperse polystyrene standard by multiplying by a factor of 0.6 and for paraffinic hydrocarbon by multiplying by a factor of 1.2. Infrared spectra of the polymers were measured using the KBr pellet method, as well as the film method using a Hitachi Co., Ltd. Model IRA-2.

Results and Discussion

Effects of Reaction Temperature. The results of propylene disproportionation over MoO_3–Al_2O_3 catalyst in the liquid phase are shown in Table 1 and Fig. 1. In a run at 0 °C, the propylene conversion was very low in the initial period and gradually increased with reaction time. The conversion showed a broad maximum after 100 to 200 h and was still at about 80% of the maximum even after 460 h. The reaction time when the conversion fell to one-half its maximum value ($\tau_{1/2}$) was more than 1000 h.

On the other hand, the activity of the MoO_3–Al_2O_3 catalyst at 80 °C increased rapidly and showed maximum conversion for as short as 25 h (Run No. 2). Thereafter, the catalytic activity decreased rapidly with in a $\tau_{1/2}$ of about 25 h.

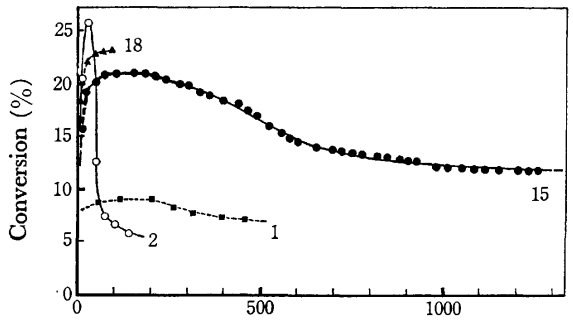

Fig. 1. Effects of reaction temperature and solvent on preservation of activity of MoO_3–Al_2O_3 catalyst in liquid phase disproportionation of propylene under 50 kg/cm².
Numbers correspond to the Run No. in Table 1.

Effect of Hydrogen. The effect of hydrogen in the liquid phase disproportionation of propylene was studied because it is known that hydrogen gas in the reaction system increases the catalytic activity and prolonges the catalyst life in the gas-phase disproportionation of propylene and 1-butene over a Co–Mo/Al_2O_3 catalyst.[8] As shown in Fig. 2, it was found that the catalyst retained its activity slightly longer in the presence of 0.1—3.5 mol% of dissolved hydrogen (Run No. 3—7). The hydrogen effect was much less marked than in the gas-phase reaction.[8] The product distribution shows that most dissolved hydrogen in the feed was consumed by the hydrogenation of propylene to propane, and the optimum amount of hydrogen in the reaction system was estimated to be about 0.1—0.3 mol% for ethylene and butenes production and for the prolongation of the catalyst life.

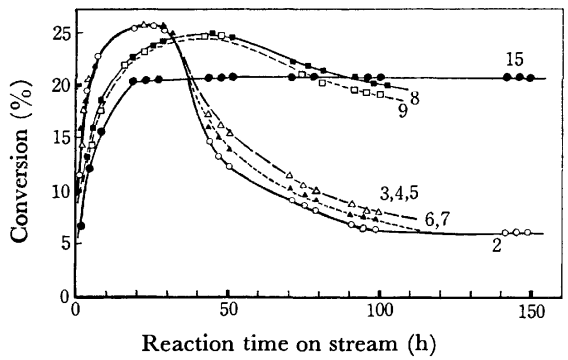

Fig. 2. Solvent and hydrogen effects on preservation of activity of MoO_3–Al_2O_3 catalyst in liquid phase disproportionation of propylene at 80 °C under 50 kg/cm².
Numbers correspond to the Run No. in Table 1.

Effect of Heptane Solvent. The effect of solvents was investigated at 80 °C where remarkable deactivation was observed. Since the catalyst activated in nitrogen was more active than that activated in air as reported previously,[6] oxygen must be poisonous to the active site of olefin disproportionation.[2] The decrease in activity of disproportionation in the heptane solvent purged by helium (Run No. 8) or nitrogen (Run No. 9)

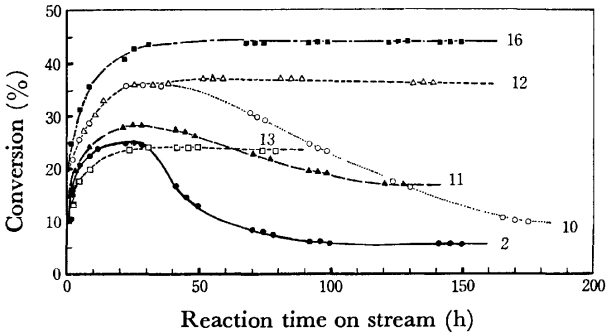

Fig. 3. Solvent effects on preservation of activity of MoO_3–Al_2O_3 catalyst in liquid phase disproportionation of propylene at 80 °C under 50 kg/cm².
Numbers correspond to the Run No. in Table 1.

was less extensive than that in the absence of the solvent (Run No. 2) as shown in Fig. 2. Heptane containing about 0.3 mol% hydrogen was more effective for prolonging the catalytic activity. As shown in Fig. 3, $\tau_{1/2}$ was increased by a factor of about three by using a half-liquid volume of heptane to feed (Run No. 10) as compared with neat propylene. The duration of catalytic activity and the pressure drop in the reactor were improved by increasing the heptane/propylene ratio (Run No. 12—16).

According to the catalytic activity duration test at a heptane/propylene volume ratio of two and a large liquid hourly space velocity of 120 (Run No. 15), the propylene conversion after 1250 h decreased to 58% of the maximum, and $\tau_{1/2}$ was estimated by extrapolation to be about 2000 h. As shown in Table 1, propylene conversion is mostly dependent on the space velocity of the propylene and is affected only slightly by the total space velocity. These results indicate that the adsorption of propylene on the active site is hardly affected by the use of heptane as the solvent.

The selectivity to ethylene and butenes always increases with reaction time on stream. The selectivity was 95—97% within the initial period of 20 h, and it increased to about 99% after 50 h. When heptane was used as the solvent, the selectivity of disproportionation was improved about 0.3% as compared with the case of neat propylene. As shown in Table 2, comparatively more polymers were produced doing the initial period and most oligomers and polymers produced were carried away from the catalyst surface by the heptane solution, because the amount of polymers (Polymer C) extracted from the catalyst bed was much less than that (Polymer B) soluble in heptane (Run No. 14). On the average, 0.028 wt% of solid products (Polymer E) based on the converted propylene was recovered by concentrating to one-fiftieth of the heptane solution obtained from Run No. 15. Further evacuation of the heptane solution gave viscous hydrocarbons (Polymer D, 0.32 wt% on the average). Small amounts of white solid polymers were observed in the space down stream of the reaction system after a reaction time of 1250 h.

These results show that various kinds of polymers, that is, very soluble, slightly soluble, and insoluble polymers, in heptane were produced by the accompanied

polymerization.

Effect of Benzene Solvent. When benzene was used as the solvent (Run No. 17 and 18), the conversion during the initial period was nearly equal to that for the heptane solution. However, after a comparatively short time on stream, the introduction of propylene and benzene mixtures became difficult due to the increased flow resistance, caused by the produced polymers adhering on the down stream side of the reaction system. As shown in Table 2, about 24% of the converted propylene was comsumed in the alkylation of benzene within the first 10 h (Run No. 17), but the alkylation decreased rapidly to 3.5% after 100 h (Run No. 18). The composition of alkylbenzenes decreased in the following order: cumene, butylbenzenes, diisopropylbenzenes, styrene and isopropylbutylbenzenes. From the results in Table 2, it is clear that large amounts of polymers (Polymer G) insoluble in benzene were produced, and the solubility of the polymers in benzene is lower than in heptane. Therefore, benzene was not a suitable solvent for the propylene disproportionation.

Molecular Weight Determination of Polymers Produced. When the reaction was carried out without any solvent at an LHSV below two (80 °C), large amounts of oligomers and polymers (Polymer A) were produced in the reaction system and propylene could no longer be introduced after 10 hr.

TABLE 3. NUMBER AVERAGE MOLECULAR WEIGHTS AND COMPONENTS OF POLYMERS PRODUCED IN PROPYLENE DISPROPORTIONATION AT 80 °C AND 50 kg/cm²

Polymers	States	$\overline{M}_n$[a]	Propylene content[b] (%)
Polymer A	Gummy materials	900	34
Polymer B	Viscous liquid	—	45
Polymer D	Viscous liquid	1300	23
Polymer E	Solid	1800	40
Polymer G[c]	Solid	—	20

a) Number average molecular weights determined using a vapor pressure osmometer. b) Propylene contents of polymers determined by infrared spectroscopic analysis on the assumption that the polymers were produced only by the polymerization of ethylene and propylene. c) Fraction of Polymer G slightly soluble in heptane.

Although the number average molecular weight $\overline{M}_n$ of all polymers determined was between 900 and 1800 (Table 3), very small amounts of lower molecular weight materials were observed in both gas and liquid chromatographic analyses of the products.

The molecular weight distribution of these polymers is shown in Fig. 4. Each polymer has two maxima at molecular weights of 300 to 500 and 20000 to 200000. Each sample includes a small amount of higher polymers with molecular weights of several millions. Polymers produced in the benzene solvent contained larger amounts of high molecular-weight fractions and of sligptly soluble polymers than the polymers produced in the heptane solvent. About 1 wt% of Polymers A, E, and G homogeneously dissolved in tetrahydrofuran at temperatures above 60 °C, while at 20 °C some of them precipitated. Therefore, still higher fractions than observed in Fig. 4 may be included in the original polymer solution.

Component of Polymers by Infrared Spectroscopic Analysis, Infrared spectra of the polymers produced in the propylene disproportionation are shown in Fig. 5. The absorption bands at 1380 and 1460 cm^{-1} are assigned respectively to the methyl symmetrical C–H bending vibration and the methylene C–H scissoring vibration. On the assumption that the polymers are produced only by the polymerization of ethylene and propylene, the propylene contents of the polymers were measured using the method of Corish[9] with the results shown in Table 3. The propylene contents varied with the polymer samples, but they were always less than that for ethylene. Methyl groups in polymers should also be produced to some extent by the polymerization of ethylene as the terminal and branched methyl groups. Therefore, the real propylene contents in each polymer may be lower than those measured by the method of

Corish.[9] Since the absorption band at 722 cm^{-1} was stronger than those at 733, 752, and 815 cm^{-1}, it is clear that the n-values in $\{CH_2\}_n$ are higher than four according to the reports of Bucci.[10] Hashimoto *et al.* reported that the polymerization rate of ethylene over MoO_3–Al_2O_3 catalyst reduced at 400 °C at a hydrogen pressure of 150 mmHg was larger by a factor of seven to ten than that for propylene.[11] In a previous paper[6] it was shown that the polymerization rate decreases in the following order: ethylene, propylene, and butenes. The tendencies of the polymerization and oligomerization rates of the various olefins over MoO_3–Al_2O_3 catalysts activated in nitrogen must be similar to those over reduced catalysts. As shown in Fig. 5 (A and B), polymers produced in the initial period have some absorption bands in the regions of 1700—1750 and 3400—3700 cm^{-1}, which may be related to oxygen compounds. These results imply that the oxygen compounds are produced by the oxidation of olefins with oxygen of the catalyst, reducing the catalyst at more highly active stated.

The authors wish to express their thanks to Dr. Etsuo Niki of the Faculty of Engineering, University of Tokyo for useful discussions.

Lanthanide Induced Shifts of the PMR Spectra of Polyaza-aromatic Compounds

(Received June 3, 1975, in revised form November 25, 1975)

The LIS's were determined with the equimolar mixtures of two monoaza-aromatic compounds, and the relative coordinating ability of each ligand was estimated from these LIS's. The coordinating ability index is defined as the ratio of the complexed species of the monoaza-aromatics to that of pyridine, and is proved to be transferable to the nitrogen atom of similar steric circumstances. Thus, $Eu(fod)_3$ induced shifts of the protons in several unsymmetrical naphthyridines and related heterocycles were estimated by the sum of the induced shifts of the corresponding monofunctional equivalents weighted by the relative abundances of the complexed species which were obtained from the coordinating ability measurements. The method is applicable to other bifunctional compounds of rigid conformation.

Since the first success reported by Hinckley,[1] lanthanide shift reagents have been applied to many stereochemical problems, and their uses are known as a routine technique of resolving the overlapping NMR signals. However, their application is limited within the monofunctional compounds in most cases, and relatively few examples have previously been reported concerning the lanthanide-induced shifts (LIS) of bi- and poly-functional compounds.[2] In the field of the chemistry of nitrogen heterocycles, their uses were focused on relatively simple compounds, such as pyridine, quinoline, and related compounds. An extensive work on six-membered nitrogen heterocycles including diazanaphthalenes has also been reported by Armarego and coworkers.[3] However, the discussion on the preferred site of complexation is qualitative and rather inconclusive.

In order to use shift reagents on polyfunctional compounds, it is necessary to decide the preferred site of complexation. Further, it is desirable to know quantitatively the relative abundances of the complexed molecules on two or more competing sites. In general, the coordinating ability of the ligand is affected by the electronic and steric factors.[4] In the case of shift reagent-substrate complexes, it is demonstrated that the coordinating ability is mainly governed by the steric factors which control the approach of the bulky Eu(III) complexes.

In this investigation, the LIS's were determined on the equimolar mixture of the two monofunctional compounds carrying similar functional groups in different steric circumstances. This offers an approach to determine the coordinating abilities of various substrates to the shift reagent by intermolecular competition.[5] Then, the LIS's of bifunctional compounds were estimated by the weighted summation of the induced shift of every equivalent monofunctional compound $[S_i^{(m)}]$. To accomplish this, the induced shifts of each monofunctional compound carrying a functional group of almost same circumstances as in the bifunctional one were measured first. Then, their induced shifts were again determined with an equimolar mixture of the two equivalent monofunctional compounds. The ratios of the induced shifts in the mixed solution to the one component LIS's give the relative abundances of the complexed monofunctional equivalents. The ratios thus obtained are nearly indifferent irrespective of the nature of protons in the molecule, and may be usable as a measure for the relative coordinating ability of the two substrates. The sequence of the relative coordinating ability indices will be a more reliable criterion for the steric effect than the LIS itself, since the steric factor of the McConnel-Robertson equation,[6] $(3\cos^2\theta-1)/r^3$, will also affect the LIS values

The coordinating ratios can be assumed to reproduce the complexation in two sites of the bifunctional compound. Then, the induced shifts (S_i) of each proton (i) in a bifunctional compound is calculated by summing up the each induced shift of the monofunctional model compound $(S_i^{(m)})$ weighted by the normalized relative abundance $(P^{(m)})$ obtained by the competitive complexation among the monofunctional model compounds.

$$S_i = \sum_{(m)} S_i^{(m)} \cdot P^{(m)} \qquad (1)$$

The above equation is derived by assuming that the electronic and other through bond effects between the two functional groups are negligible, and applies to the bifunctional compounds in which the two functional groups are located moderately apart from each other. Diaza-aromatic compounds carrying nitrogen atoms in different rings are suitable examples, and the LIS's of these heterocycles can be estimated properly from those of monoaza-aromatic compounds of similar structural feature.

Experimental

Materials used in this investigation were synthesized according to the methods previously reported,[7] or obtained by purification of commercially available materials. Proton NMR spectra were measured with chloroform-*d* solutions employing a JNM C-60H spectrometer operating at 60 MHz. The concentrations of the solutions were adjusted approximately at 0.3 $mol \cdot l^{-1}$ with respect to substrates, and $Eu(fod)_3$ was employed as the shift reagent throughout this work except the cases otherwise remarked. The induced shift was measured by adding the shift reagent in small portions to the solution containing an excess of the substrate. To eliminate the

* To whom correspondences should be addressed.

effect of imperfect complexation (equilibrium constants), the concentration of substrates were carefully adjusted to be constant throughout this investigation.

Results and Discussion

The LIS's of Monoaza-Aromatic Compounds and Evaluation of the $P^{(m)}$ *Values.* The lanthanide-induced shift was estimated, as usual, from the slope of the $\Delta\delta$ *vs.* [Eu(fod)$_3$]/[Substrate] plot, where $\Delta\delta$ refers to the chemical shift change induced by the shift reagent. The slope from the least squares fit of the plot was used as the LIS value (denoted by S in Tables and equations). The LIS's of various six-membered monoaza-aromatic compounds are given in Table 1. As expected, both the LIS's and the coordinating abilities (in Tables 2 and 5) decrease with increasing streic hindrance around the nitrogen atoms. This tendency is illustrated by the fact that the LIS decreases in the order of pyridine>2-methylpyridine>2,6-dimethylpyridine in the series of pyridine homologs. A remarkable difference is observed between the LIS's of 3- and 5-protons of 2-methylpyridine (**2**). Though the influence of the contact shift is not negligible for this compound, its contribution is concluded to be not predominant in the case of proton spectra.[8] Thus, the magnitudes of the LIS's can be interpreted that the bulkier methyl group expels the coordinated Eu(fod)$_3$ molecule to the opposite side of the C_4–N axis and changes the contribution of the steric factor on the 3- and 5-protons. This effect will be discussed quantitatively in the succeeding part of this paper. Similar deviations in coordination sites are also observed with 6-chloro-2-methylquinoline (**5**) and 6-chloro-8-methylquinoline (**6**). In the case of the 6-chloro-2-methyl derivative (**5**), the LIS of 7-proton is considerably larger than that in the 6-chloro-8-methyl derivative (**6**). This must also be the consequence of the different location of Eu(III) ion relative to the nitrogen ligand.

In order to determine the coordinating ability by intermolecular competition method, the LIS's of each substrate in the solution of the equimolar mixture of the two substrates were measured in a similar manner. Then the coordination ratio for every proton was calculated by comparison of the apparent LIS value ($S_i^{ap(m)}$) with that of each component ($S_i^{o(m)}$). By averaging the coordination ratios $P_i^{(m)}$ of all protons in the molecule m, the coordination ratio of the molecule ($P^{(m)}$) is calculated.[9] The coordination ratios of several aza-aromatic compounds to Eu(fod)$_3$ are given in Table 2. In the cases of shift reagents, the coordinating ability is mainly governed by the steric factor. Thus, the ability estimated from the coordination ratios of quinoline is nearly identical with those of 2-methylpyridine (**2**) and 6-chloroquinoline (**4**) with which the steric circumstances of the donor nitrogen atoms are similar to quinoline. Analogously, the coordinating abilities of 2,6-dimethylpyridine (**3**) and 6-chloro-8-methylquinoline (**6**) are almost identical with those of 6-chloro-2-methylquinoline (**5**) and 1-azaphenanthrene (**7**), respectively. 2-Methylpyridine might possess a little larger coordinating ability than 6-chloroquinoline, because the free rotation of the methyl group in the former can operate to lessen the steric hindrance in contrast to the rigid 8-H in quinoline. The same discussion is also applicable to the series of 2,6-dimethylpyridine (**3**), 6-chloro-2-methylquinoline (**5**), and acridine (**8**). The order of coordinating ability is: 2,6-dimethylpyridine>6-chloro-2-methylquinoline>acridine. However, the differences in coordinating abilities among these compounds are smaller than those among the compounds of dissimilar steric circumstances. In short, the competitive complexation experiments given in Table 2 reveal the fact that the steric circumstances are the dominating factor to the coordinating abilities of these heterocycles.

A shift to higher field is observed with the 2-H of 1,8-naphthyridine (**10**) by addition of Eu(fod)$_3$. 1,8-

* P_1 and P_2 are the coordinating ratios in percent, which are estimated by employing the following equation: $P_i = S_i^{ap}/S_i^{\circ}$

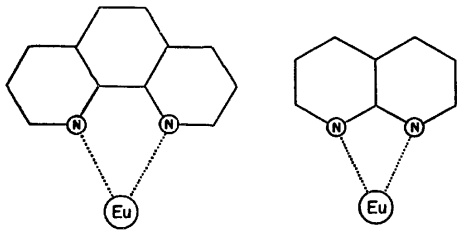

Fig. 1. Eu^{3+}–1,10-phenanthroline and 1,8-naphthyridine complexes. These bases behave as bidentate ligands in the complex formation.

naphthyridine (**10**) is a bidentate ligand, forming a chelate compound with $Eu(fod)_3$ (as shown in Fig. 1), and this may be the reason for its anomalous LIS. Thus, the system gains additional stabilization energy, and its coordinating power is strengthened remarkably. The above discussion applies to the peculiar stability of the 1,10-phenanthroline- and 2,2′-bipyridine-$Eu(fod)_3$ complexes.

The $P^{(m)}$ values are convenient to compare the coordinating abilities of the two nitrogen donors, but inconvenient for the comparison among several nitrogen donors of different steric circumstances. Thus, the coordinating ability index (C) is defined as the ratio of $P^{(m)}$ to the $P^{(m)}$ of pyridine. The most probable values of coordinating ability indices were calculated from the $P^{(m)}$'s listed in Table 2 by least squares optimization technique, and are given in Table 5.

The intermolecular competition offers a more reliable method to determine the abundances of the complexed species, since the LIS's depend not only on the population of the complexed species but also on the steric factor (in Eq. 3). The LIS's of some protons are shown in Table 3. These protons occupy nearly equivalent positions relative to the nitrogen atoms. By comparing these LIS's with the coordinating ability

a) Shift to the higher field.

indices in Table 5, it is shown that the LIS's are not always proportional to the coordinating abilities. The coordinating ability indices are rather insensitive to the electronic effect. Thus, the coordinating ability indices for quinoline and its 6-chloro-derivative are 0.153 and 0.145, respectively. However, a small but definite effect is observed when a substituent is attached directly to the hetero-aromatic ring. The coordinating ability indices for pyridine, 4-chloropyridine, and 4-methylpyridine are 1.00, 0.79, and 1.22, respectively, and, as expected, the electron donating ability of the substituent favors the complex formation. In conclusion the relative values of the coordinating ability indices are transferable to the nitrogen ligand of similar local steric circumstances.

Estimation of the LIS's of Polyaza-aromatic Compounds. As the coordinating abilities of the nitrogen atoms in the heterocycles are dependent mainly upon their steric circumstances, the LIS's of polyaza-aromatic compounds can be estimated from the coordinating abilities of monoaza-aromatic compounds of which nitrogen atoms occupy similar steric circumstances. The method is quite successful in estimating the LIS's of polyaza-aromatic compounds without polyaza-rings. Thus, the induced shifts of the ring protons of 1,6- and 1,7-naphthyridines were estimated from those of quinoline and isoquinoline. $Eu(fod)_3$ was employed as the shift reagent throughout this work, and the induced shift was measured by adding the shift reagent in small portions. To avoid the effect of the di-coordinated species $C_8H_6N_2 \cdot 2Eu(fod)_3$, the induced shift was estimated from the chemical shift displacement ($\Delta\delta$) in the range of lower [$Eu(fod)_3$]/[substrate] ratios. From the experiment of the competitive complexation with the equimolar quinoline–isoquinoline mixture in chloroform-*d*, the mean coordinating abilities for quinoline ($P^{(1)}$) and isoquinoline ($P^{(2)}$) have already been estimated to be 0.14 and 0.86, respectively. Then, the induced shifts for the protons in the naphthyridines were estimated by Equation 1 as shown in Table 4.

The estimated relative induced shifts agree almost quantitatively with the observed values except the case of 8-H in 1,7-naphthyridine. The lower estimated value of S_8 in 1,7-naphthyridine can be improved considerably by assuming the equal $S_i^{(2)}$ values for 6-H and 8-H of 1,7-naphthyridine (which correspond to those of 3-H and 1-H in isoquinoline, respectively). This assumption is exactly true if pyridine is employed as a model monofunctional compound.

Similar estimations again result proper relative values for the LIS's of 2-methyl- and 4-methyl-1,5-naphthyridines (as shown in Table 4). The magnitudes of the induced shifts can also be estimated in fair agreement by this method. However, the relative values fit more closely with the observed ones.

Estimation of the Locations of Eu(III) in the Shift Reagent-Substrate Complexes and Calculation of the $S_i^{(m)}$'s for the Protons Void in the Model Monofunctional Compounds. In order to correlate the coordinating ability with the location of Eu(III) ion and to use in estimating some LIS's of polyfunctional compounds, the most probable location of the complexed Eu(III) ion was determined by evaluating the agreement factors[10] defined by the folowing equation.

a) The distances and angles in paretheses refer to those of $Pr(fod)_3$–substrate complexes.

$$R = \left(\frac{[(S_{obsd})_i - (S_{calcd})_i]^2}{(S_{obsd})_i^2} \right)^{1/2} \quad (2)$$

The calculations were carried out with a HITAC 8250 digital computer by assuming the following: a) The lanthanide-substrate interaction is entirely, or at least predominantly, of pseudocontact nature usually evaluated by the McConnell-Robertson equation,

$$S = K(3\cos^2\theta - 1)/r^3 \quad (3)$$

where θ is the N–Ln–H internuclear angle and r is the Ln–H distance. b) The coordination site is located on the plane of the heteroaromatic ring. The Eu–N distances thus obtained are given, together with the relative coordinating ability indices, in Table 5. Some of the results are illustrated also in Fig. 2. The calculated locations of Eu(III) ions are in accordance with the degree of the steric hinrdance qualitatively estimated from the coordinating abilities. The results illustrate that there exists an approximately linear relation between the coordinating ability indices and the Eu–N distances. If the substrate molecule carries some groups, such as methyl, which cause the steric hindrance to the coordination, the coordination site of $Eu(fod)_3$ may shift, and both the Eu–N distance and the orientation of the Eu–N axis deviate from those of pyridine. The methyl and the benzo groups of 8-methylquinoline and 1-azaphenanthrene, respectively, hinder the access of the shift reagent more remarkably than those of 2-methylquinoline and acridine. Angular distortion of the Eu–N axes in the Eu complexes of the former may play an important role to increase the steric hindrance. The steric circumstances of the electron

a) The reference monoaza-aromatic compound is lacking in the aromatic ring illustrated by the broken line, and the $S_i^{(m)}$ values were estimated by the method described in the text.

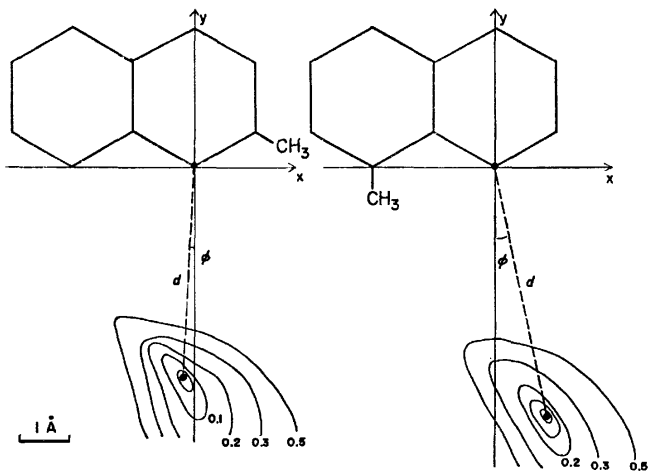

Fig. 2. The most probable location of europium (III) ion in the shift reagent–substrate complex estimated by the evaluation of the R values.

donating nitrogen atom affect remarkably the coordination with the shift reagent.

On estimating the induced shifts (S_i's) of the protons in bifunctional compounds by Eq. 1, the induced shifts of the monofunctional reference compounds ($S_i^{(m)}$'s) are required. When the reference monofunctional compounds have the same skeletal structure with that of the bifunctional compound, the $S_i^{(m)}$ values can be obtained experimentally, as exemplified by the cases (1) to (4) in Table 4. However, such reference monofunctional compounds are not always available easily when the bifunctional compound has a more complex structure. Even in such cases, the induced shifts $S_i^{(m)}$ of the protons on the rings distant from the functional group can be estimated from the d_{Eu-N} and ϕ values by employing the McConnell-Robertson equation. For example, the induced shifts of the protons in 5-methyl-1,6-diazaphenanthrene is estimated from the $S_i^{(m)}$'s of 2-methylquinoline and 1-azaphenanthrene (as shown in Table 6). Since 2-methylquinoline is void of the aromatic ring illustrated by the broken lines in Table 6, the $S_i^{(m)}$'s for the protons at 2, 3, and 4 positions due to the complexation on the 6-nitrogen atom are estimated by calculating relative LIS's of these protons by Eq. 3. As the induced shifts $S_i^{(m)}$'s of the distant protons are small, the approximation is permissible in spite of the considerable inaccuracy accompanying to this method of evaluation. The results are shown in Table 6, together with those of 5-methyl-4,6-diaza-, 6-methyl-1,7-diaza-, and 6-methyl-4,7-diaza-phenanthrenes. Here again the estimated LIS's are rather smaller than the observed ones, however, the agreement between the relative values is excellent in most cases. And the method is proved to be applicable to the prediction of the LIS's of the heteroaromatic compounds of this class.

The authors are grateful to Prof. Hiroshi Kakiuchi, Yokohama National University, for his valuable advice and encouragement throughout this work. They also express their hearty thanks to Mrs. Shigeko Yoshida for her technical assistance on of the measurements NMR spectra.

The Oxidation Activity and Acid-base Properties of Mixed Oxide Catalysts Containing Titania. I. The TiO_2-MoO_3 and TiO_2-V_2O_5 Systems

Mamoru Ai

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 1, 1975)

The amounts of both the acidic and basic sites of two series of catalysts, TiO_2–MoO_3 and TiO_2–V_2O_5, with different compositions were measured by studying the adsorption of the basic and acidic molecules in the gas phase, using both the static and pulse methods. The acidity of TiO_2–MoO_3 catalysts is very high at Mo=40—60 atom%, though those of the TiO_2-rich (Mo<30 atom%) and MoO_3-rich (Mo>80 atom%) catalysts are fairly low. The acidity of the TiO_2–V_2O_5 increases steadily with the V_2O_5 content. The basicity of the catalysts is remarkably enhanced by the introduction of a small amount of MoO_3 or V_2O_5. It can be said that the catalysts are basic at Mo <20 atom% or V<10 atom%, while the MoO_3-rich or V_2O_5-rich catalysts are acidic. The vapor-phase oxidation of 1-butene, butadiene,and acetic acid, the dehydration and dehydrogenation of isopropyl alcohol (IRA), and the isomerization of 1-butene were carried out in the presence of an excess of air, and the relationship between the catalytic behavior and the acid-base properties was investigated. It was concluded that the activities and selectivities can be relatively well explained by the acid-base properties between the catalyst and the reactant.

Single TiO_2 is impractical as a catalyst because of its low activity. However, mixed-oxide systems combining TiO_2 with such oxides as V_2O_5, MoO_3, P_2O_5, K_2SO_4, SiO_2, and ZnO are known to be effective for certain reactions.[1–5] These combinations seem to induce an unexpectedly great change in the catalytic behavior. Above all, the characteristic features of the selectivity become completely different as different sorts of oxides are introduced into TiO_2. However, the function of these second components has not yet been firmly established.

According to our recent studies,[6] it has been found that TiO_2, much like UO_3, SnO_2, and Fe_2O_3, is a metal oxide included in Group B, intermediate between such acidic metal-oxides as V_2O_5, MoO_3, and WO_3 (Group A) and such basic metal-oxides with a high oxidation powder as NiO, Co_2O_3, MnO_2, CuO, and Cr_2O_3 (Group C), and that its acid-base properties are significantly modified by the introduction of a small quantity of acidic or basic elements, such as P_2O_5, MoO_3, and K_2O.

It seemed, therefore, that it would be very interesting to find how the incorporation of certain oxides intoTiO_2 modifies the acid-base properties of the catalyst and how this modification in turn induces a change in the catalytic behavior.

The present paper will deal with the first part of an investigation concerning the oxidation activity of the TiO_2-based catalyst systems. We attempted to ascertain how the incorporation of various amounts of MoO_3 and V_2O_5 into TiO_2 modified the acid-base properties as well as the oxidation activity and selectivity, and examined to see whether or not the catalytic behavior can be explained by the acid-base properties of the catalyst system, as in the cases of the V_2O_5–MoO_3,[7] V_2O_5–P_2O_5,[8] MoO_3–P_2O_5,[9] MoO_3–Bi_2O_3–P_2O_5,[10–12] MoO_3–P_2O_5–X_nO_m[13] SnO_2–V_2O_5,[14,15] and SnO_2–MoO_3[14,16] systems.

Experimental

Catalysts. Two series of TiO_2-based binary catalysts, TiO_2–MoO_3 and TiO_2–V_2O_5, with different compositions were prepared as follows. The required quantity of $TiCl_4$ was dissolved in water containing ice. To this solution, dilute aqueous ammonia was added to precipitate the hydroxide. After filtering and washing, the paste-like hydroxide was added to an aqueous solution of $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ or NH_4VO_3–oxalic acid, and 10—20 mesh pumice was mixed with the solution; then the mixture was evaporated with vigorous stirring. The amount of pumice was 500 ml (about 150 g) per g atom of titanium and molybdenum or titanium and vanadium. The catalyst was calcined under flowing air at 500 °C for about 4—5 h.

Acidity and Basicity Measurements. Since the TiO_2–MoO_3 and TiO_2–V_2O_5 catalysts are colored and small in surface area, the determination of the acidity and basicity by an ordinary titration method seems to be difficult; therefore, the adsorption amounts of the basic and acidic molecules in the gas phase were measured, much as in a previous work.[12]

(a) Static Method: NH_3 and CO_2 were chosen as the basic and acidic adsorbates respectively. The adsorption measurements were carried out using an ordinary BET apparatus modified to measure small areas. About a 20-g portion of the catalyst was put in an adsorption vessel (about 25 ml) and heat-treated in an electric furnace at 500 °C for 2 h under a stream of dried air. Immediately after the vessel had then been taken out of the furnace, it was quickly connected to the adsorption apparatus and pumped out. A known amount of NH_3 or CO_2 was introduced into the adsorption system, after which it was allowed to stand for 20 min before the pressure changes were read. Subsequently, the catalyst was pumped out for 30 min at the same temperature. Similar adsorption procedures were then repeated, and the amount of readsorption was measured. The amount of NH_3 or CO_2 irreversibly adsorbed at the pressure of 300 mm Hg was obtained as the difference between the amount of readsorption and that of the first adsorption; this was adopted as a measure of the acidity or basicity of the catalysts.

(b) Gas-chromatographic Pulse Technique: The apparatus used was a conventional gas chromatograph equipped with a U-tube of stainless steel (4 mm in internal diameter and 40 cm in length). The catalyst (1.0 g) was packed in the U-tube and heat-treated in a stream of air at 500 °C for 1 h. Immediately after the U-tube had then been taken out from the furnace, it was quickly connected to the gas chromatographic column, unless otherwise indicated, and placed in another

furnace kept at 130 °C or 160 °C. Then the carrier gas (He: 50 ml NTP/min) was introduced into the system.

In the case of the basicity measurements acetic acid was chosen as the acidic adsorbate, much as in previous works.[12,15,16] A sequence of the pulses of an heptane solution of 1.0 M acetic acid was injected into the U-tube (130 °C) at intervals of about 2 min. The volume of the pulses was 3—10 μl, adjusted to be about one-tenth of the total adsorption amount obtained by preliminary measurements. The adsorbate uptake was obtained from the gas chromatographic analysis at both the inlet and the exit of the U-tube. The peak of acetic acid at the exit is not observed upon the initial injections; as the number of pulse increases, the catalyst is saturated with the acetic acid, and so the peak appears. Thus, the amount adsorbed can be evaluated. Subsequently, the carrier gas was allowed to pass through for 30 min at the same temperature. Then the same procedures were repeated, and the readsorbed amount was obtained. The amount irreversibly adsorbed was obtained as the difference between the amount of readsorption and that of the first adsorption; it was adopted as a measure of the basicity.

In the case of the acidity measurements, butene pulses consisting of 2 ml of a mixture of air and 1-butene (0.7 mol%) and pyridine pulses consisting of 2—5 μl of an hexane solution of 0.25 M pyridine were fed into the U-tube (160 °C) alternately and separately; the amount of pyridine required to inhibit the isomerization of 1-butene completely was adopted as a measure of the acidity.

Catalytic-activity Measurements. The vapor-phase oxidation of 1-butene, 1,3-butadiene, and acetic acid, the isomerization of 1-butene, and the dehydration and dehydrogenation of isopropyl alcohol (IPA) were carried out in an ordinary continuous-flow-type reaction system. The concentrations of butene, butadiene, acetic acid, and IPA were about 0.67, 0.67, 1.5, and 1.65 mol% respectively in air, unless otherwise indicated. The total flow rate (at 25 °C) was kept constant at 1.5 l/min, and the amount of the catalyst used was 1.0—25 g. The reactor and the experimental and analytical procedures were the same as those employed in previous works.[6-16]

Results

Surface Areas. The surface areas of the TiO_2–MoO_3 and TiO_2–V_2O_5 catalysts were checked by the BET method using nitrogen at −195 °C. The results are shown in Table 1. The surface area increases sharply upon the addition of even 2 atom% of MoO_3 to TiO_2, but with a further increase in the MoO_3 content it gradually decreases.

Table 1. Surface area of the TiO_2–MoO_3 and TiO_2–V_2O_5 catalysts used

Composition Mo/(Ti+Mo)	Surface area (m^2/g)	Composition V/(Ti+V)	Surface area (m^2/g)
0	2.0	0	2.0
0.02	45.2	0.02	4.3
0.05	38.8	0.05	5.7
0.10	38.5	0.10	8.0

0.70	14.9	0.70	4.0
0.80	10.0	0.90	4.8
0.90	8.5	1.0	2.8
0.95	7.5		
1.0	2.6		

Acidity. Since even single TiO_2 has a fair amount of acidic sites,[4,17,18] probably of a very weak acid strength compared with the MoO_3-rich or V_2O_5-rich catalysts, NH_3 was adsorbed even on the pure TiO_2 and on the TiO_2-rich catalysts to almost the same extent as on the MoO_3-rich or V_2O_5-rich catalysts at room temperature. However, at a higher temperature (more than 350 °C), the decomposition of NH_3 was enhanced and adsorption measurement became impossible.

In the case of adsorption measurements by the pulse method, the TiO_2-rich catalysts adsorbed pyridine at 130 °C to the same extent as the MoO_3-rich or V_2O_5-rich catalysts. This means that the pure TiO_2 has a fair amount of certain acidic sites and that this method is not proper.

Therefore, as a measure of the acidity, the amount of pyridine required to poison the isomerization of butene completely was adopted.[15,16,19] However, the defect of this method is that the isomerization must be catalyzed mainly by acidic sites; when the isomerization is catalyzed by other factors, *i.e.*, when the catalyst is basic rather than acidic, this method cannot be used. To remove this defect, prior to the adsorption measurements the heat-treated catalysts were placed under a stream of a mixed gas of air and 1-butene (0.67 mol%) at 250 °C for 30 min; this was done because of the experimental evidence that, under the circumstances of the oxidation of butene, the isomerization of butene is uniquely dependent on the acidic sites of the catalyst (as will be described below).

The acidity per unit of the surface area of the TiO_2–MoO_3 and TiO_2–V_2O_5 catalysts, as determined both by the amount of NH_3 irreversibly adsorbed at 200 °C and 250 °C and by that of pyridine required to poison completely the isomerization activity for 1-butene at 160 °C, is plotted as a function of the MoO_3 or V_2O_5 content in Figs. 1 and 2.

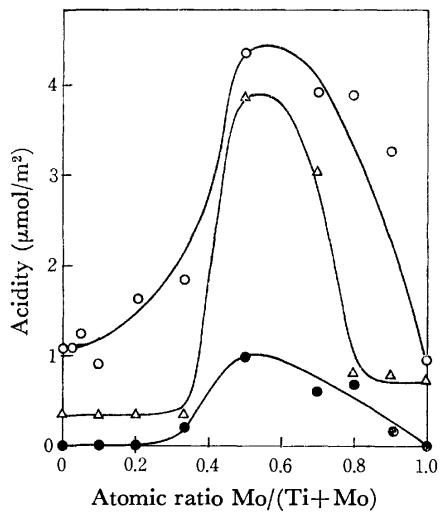

Fig. 1. Acidity of TiO_2–MoO_3 as a function of the MoO_3 content. Irreversible adsorption of NH_3 (static method) at 200 °C: ○, at 250 °C: △, pyridine required to poison the isomerization activity for 1-butene at 160 °C (pulse method): ●.

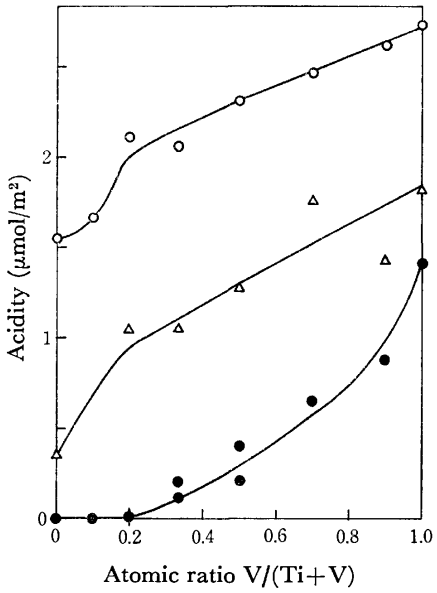

Fig. 2. Acidity of TiO_2–V_2O_5 as a function of the V_2O_5 content. Irreversible adsorption of NH_3 (static method) at 200 °C: ○, at 250 °C: △, pyridine required to poison the isomerization activity for 1-burene at 160 °C (pulse method): ●.

Parallels were found between the amounts of NH_3 obtained by means of the static method and those of pyridine obtained by means of the pulse method; these parallels may indicate the validity of these results, though the value of NH_3 was much higher than that of pyridine. It is believed that, even at 250 °C, NH_3 is still adsorbed on the acidic sites of a weak acid strength, which cannot serve to catalyze the isomerization.

The results show that the acidity is fairly low in the low range of the MoO_3 content (Mo<30 atom%), but that it increases rapidly with the MoO_3 content, shows a maximum at about Mo=40—60 atom%, and then decreases again to a very low value of pure MoO_3. It is also found that, in the case of the TiO_2–V_2O_5 catalysts, the acidity increases steadily with the V_2O_5 content.

Basicity. The basicity per unit of surface area of the TiO_2–MoO_3 and TiO_2–V_2O_5 catalysts, as determined by the irreversible adsorption of acidic molecules in the gas phase, is shown in Figs. 3 and 4 as a function of the MoO_3 and V_2O_5 content. Parallels were found between the amounts of CO_2 obtained by means of the static method and those of acetic acid obtained by means of the pulse method. The difference may be attributed to the difference in acid strength between CO_2 and acetic acid, and the acetic acid may be adsorbed on the basic sites of a lower base strength than CO_2.

It is evident at least that, with an increase in the MoO_3 and V_2O_5 content, the basicity sharply increases at first, passes through a maximum at about Mo=5 atom% or V=5 atom%, and then decreases of the very low value of the pure MoO_3 or V_2O_5 catalyst.

Dehydration and Dehydrogenation Activities for IPA. Because of the difficulty implicit in the titration method, we used, in our previous studies,[6–11,13,14] the catalytic activity for the dehydration of IPA to propylene as a measure of the acidity of the catalyst, and the (dehydrogenation rate)/(dehydration rate) ratio in the reaction of IPA as a measure of the basicity, assuming that the dehydration is catalyzed at acidic sites and that the dehydrogenation is catalyzed at both acidic and basic sites. It is, therefore, very interesting and important to confirm whether or not these measures of acidity and basicity obtained from the catalytic activities for IPA really represent their true values.

A gaseous mixture of IPA and air was passed through a bed of the catalyst held at a temperature of 165—185 °C. The amount of the catalyst was changed in the 3—30 g range. Apart from propylene and acetone, only di-isopropyl ether was found in the product, but the

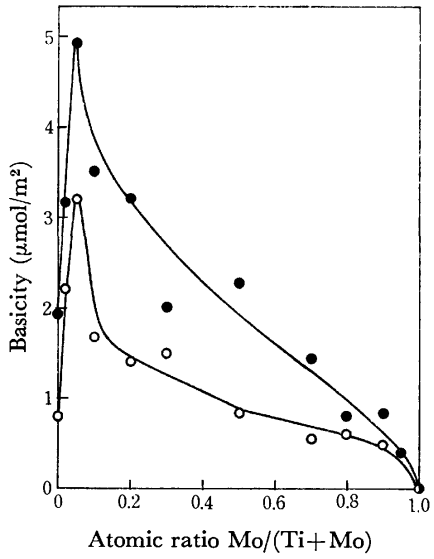

Fig. 3. Basicity of TiO_2–MoO_3 as a function of the MoO_3 content. Irreversible adsorption of CO_2 at 20 °C (static method): ○, acetic acid at 130 °C (pulse method): ●.

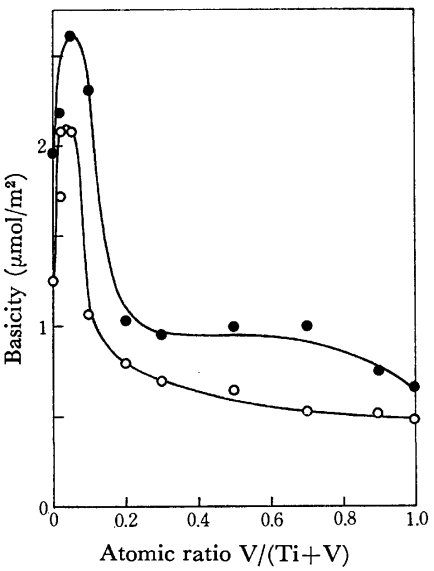

Fig. 4. Basicity of TiO_2–V_2O_5 as a function of the V_2O_5 content. Irreversible adsorption of CO_2 at 20 °C (static method): ○, irreversible adsorption of acetic acid at 130 °C (pulse method): ●.

amount of this ether was very small compared with the amount of the other two compounds. The initial rates of the dehydration and dehydrogenation at 175 °C, r_p and r_a (mol/h m²-cat), were measured; they are plotted, together with the r_p/r_a ratio, in Figs. 5 and 6.

At Mo<20 atom% or V<20 atom%, the dehydrogenation takes place rather than the dehydration, but at Mo>40 atom% or V>60 atom% the dehydration is predominant. As the content of MoO_3 or V_2O_5 increases, the values of r_p and r_a/r_p vary in the same direction as the acidity and basicity (Figs. 1—4).

Isomerization Activity for Butene. The isomerization of butene is sometimes accompanied by its oxidation. The relationship between the catalytic activity for the isomerization and the acid-base properties was investigated. The reaction was carried out at 0.67 mol% of 1-butene in air and at 225 °C by changing the catalyst amount in the 1—20 g range. As a measure of the isomerization activity, we adopted, for convenience, the ratio of (*cis*-2-C_4H_8+*trans*-2-C_4H_8)/(1-C_4H_8+*cis*-2-C_4H_8+*trans*-2-C_4H_8) corresponding to 1 m² of the catalyst, *I*.

The results are plotted as a function of the catalyst composition in Figs. 7 and 8. It is found that the isomerization activity changes in a manner similar to the acidity shown in Figs. 1 and 2.

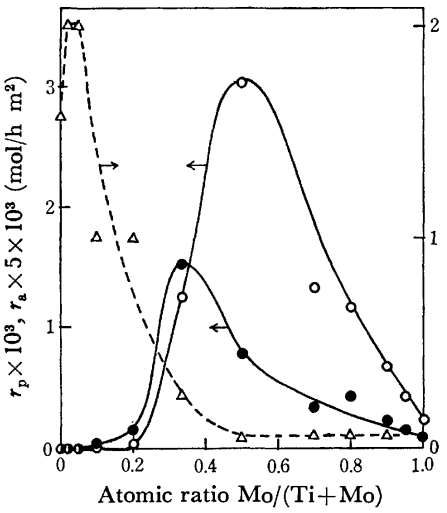

Fig. 5. The dehydration and dehydrogenation activities for IPA, r_p and r_a, and the r_a/r_p ratio as a function of the MoO_3 content.

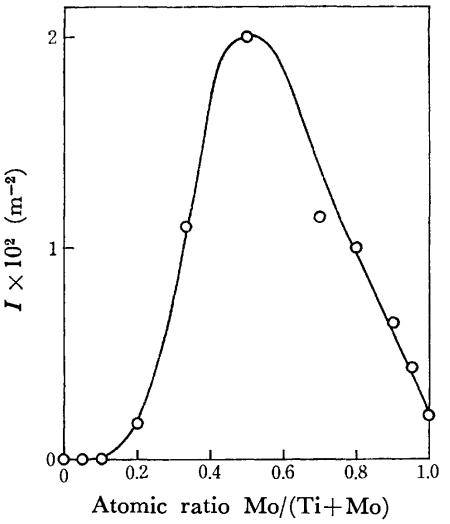

Fig. 7. The isomerization activity for 1-butene as a function of the MoO_3 content. Flow rate=1.5 l/min, 1-C_4H_8=0.67 mol% in air, T=225 °C, I=ratio of (*cis*-2-C_4H_8+*trans*-2-C_4H_8)/(1-C_4H_8+*cis*-2-C_4H_8+*trans*-C_4H_8) corresponding to 1 m² of the catalyst.

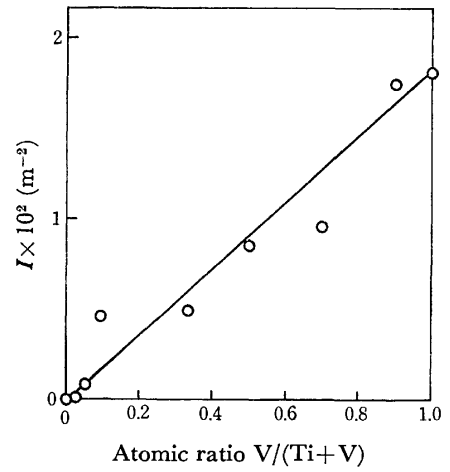

Fig. 8. The isomerization activity for 1-butene as a function of the V_2O_5 content. Total flow rate=1.5 l/min, 1-C_4H_8=0.67 mol% in air, T=225 °C,

Oxidation Activity for Butadiene. First, in order to examine the oxidation activity for basic reactants, butadiene was oxidized in an excess of air. The initial rate of the overall consumption of butadiene, at 320 °C

in the case of the TiO_2–MoO_3 catalysts and at 290 °C in the case of the TiO_2–V_2O_5, r_B (mol/h m^2-cat), was adopted, for convenience in the experimental procedures, as a measure of the oxidation activity. It is plotted as a function of the catalyst composition in Figs. 9 and 10.

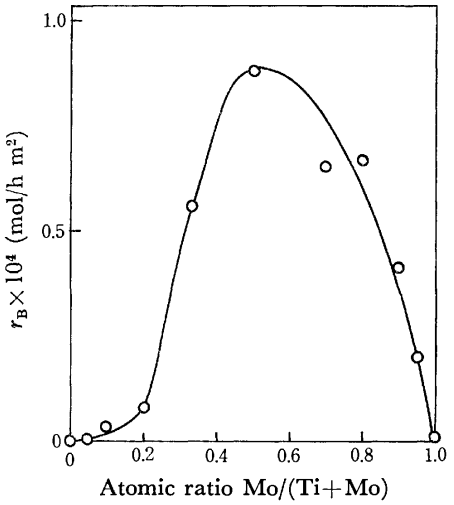

Fig. 9. The oxidation activity for butadiene as a function of the MoO_3 content. Catalyst=TiO_2–MoO_3, Butadiene=0.67 mol% in air, T=320 °C,

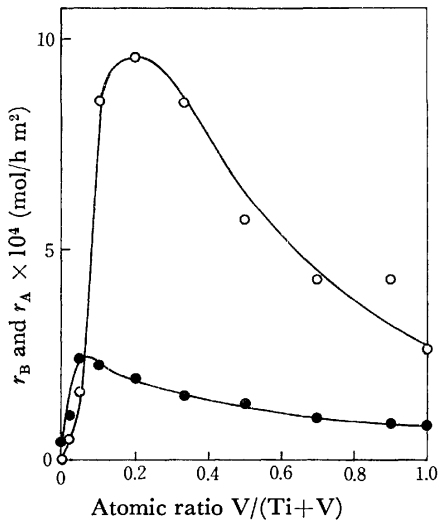

Fig. 10. The oxidation activities for butadiene and acetic acid as a function of the V_2O_5 content. Catalyst=TiO_2–V_2O_5,
○: butadiene, C_4H_6=0.67 mol% in air, T=290 °C,
●: acetic acid, $C_2H_4O_2$=1.5 mol% in air, T=290 °C.

The oxidation activity of TiO_2–MoO_3 catalysts increases with the MoO_3 content and attains a maximum at about Mo=50 atom%. The trend of the r_B curve is in agreement with that of the acidity shown in Fig. 1. On the other hand, in the case of TiO_2–V_2O_5 catalysts, the r_B increases sharply with the addition of even a small amount of V_2O_5 and attains a maximum at V=20 atom%. The trend of the r_B curve is quite different from that of the acidity shown in Fig. 2.

Oxidation Activity for Acetic Acid. Next, the oxidation activity for acidic compounds was examined in the case of TiO_2–V_2O_5 catalsts. Acetic acid was chosen as the acidic reactant, and the initial rate of the oxidation to CO_2 at 290 °C in the presence of an excess of air, r_A (mol/h m^2-cat), was taken as the oxidation activity. The results are shown in Fig. 10. The r_A increases with an increase in the V_2O_5 content and passes through a maximum at about V=10 atom%.

Selectivity in the Oxidation of Olefin. The starting materials in selective oxidations are mostly such basic compounds as olefinic and aromatic hydrocarbons. The reactions, therefore, can be divided into two types in terms of the acid-base characteristics of the products:[6,10–12,14–16]

Type 1: Basic reactant ⟶ acidic product
Type 2: Basic reactant ⟶ basic product

As a model reaction of Type 1, the oxidation of butadiene to maleic anhydride in the presence of an excess of air (0.67 mol% C_4H_8) was chosen. The

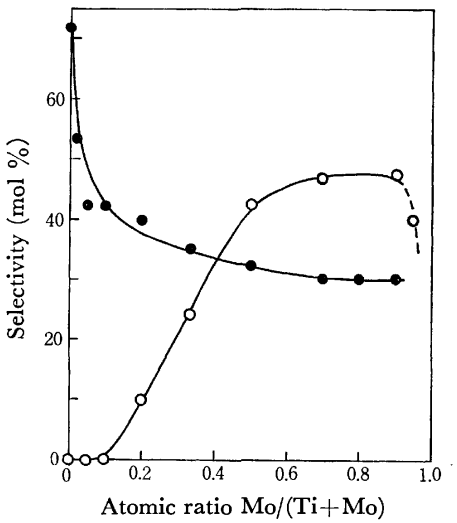

Fig. 11. Selectivity *versus* the MoO_3 content.
○: selectivity of butadiene to maleic anhydride,
●: selectivity of 1-butene to butadiene.

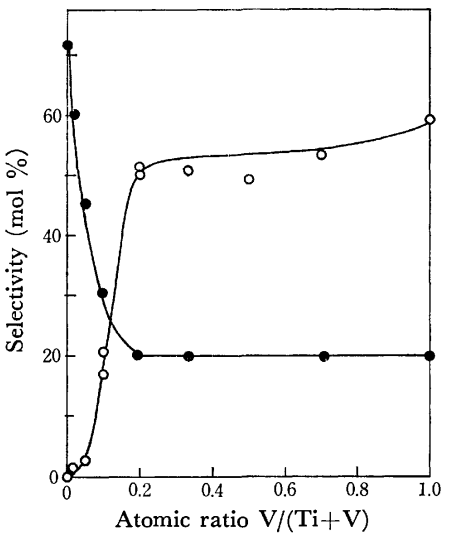

Fig. 12. Selectivity *versus* the V_2O_5 content.
○: selectivity of butadiene to maleic anhydride,
●: selectivity of 1-butene to butadiene.

selectivity at a conversion of about 40—50% was measured for every catalyst; it is plotted as a function of the catalyst composition in Figs. 11 and 12.

On the other hand, as a model of the Type 2 reactions, the oxidation of 1-butene to butadiene at a low oxygen concentration (O_2=0.34—1.3 mol% and C_4H_8=0.67 mol%) was chosen. The selectivity at a conversion of about 30—40% was measured; it is also plotted in Figs. 11 and 12.

A high selectivity to maleic anhydride is obtained over the acidic catalysts (Mo>50 atom% and V>20 atom%), while the selectivity to butadiene decreases steadily with the MoO_3 and V_2O_5 content.

Discussion

These experiments first show that the incorporation of MoO_3 and V_2O_5 induces a change in the surface area; this change directly contributes to the catalytic activity.

Next, the incorporation of MoO_3 and V_2O_5 modifies, to a significant extent, the acid-base properties of the catalyst systems. In a MoO_3-poor (Mo<20 atom%) or V_2O_5-poor (V<10 atom%) composition, the catalysts are basic; the catalysts containing more than 40 atom% Mo or 20 atom% V are acidic. It should be noted that, although MoO_3 and V_2O_5 are typical acidic elements, the incorporation of a minor amount of MoO_3 (Mo=2—10 atom%) or V_2O_5 (V=2—10 atom%) into TiO_2 remarkably enhances the basicity, much as in the cases where MoO_3 and V_2O_5 were combined with SnO_2 and Fe_2O_3.[14–16,20] This phenomenon resembles the fact that the incorporation of a minor amount of Bi_2O_3, which is a basic element, into MoO_3–P_2O_5 enhances the acidity.[10–12] The acidity per unit of the surface area of the TiO_2–MoO_3 system attains a sharp maximum at about 50 atom% Mo, much as in the case of the SnO_2–MoO_3 system. However, the acidity of the TiO_2–MoO_3 system at Mo=50 atom% is considerably lower than that of the SnO_2–MoO_3 at Mo=50 atom%.[14,16,20] The incorporation of V_2O_5 to TiO_2 never enhance the acidity per unit of the surface area more than V_2O_5 itself, unlike the case of the TiO_2–MoO_3 and MoO_3–V_2O_5 systems.[7]

A comparison of the catalytic activities for IPA with the acidity-basicity data reveals that the activity for the dehydration to propylene, r_p, respresents the acidity of the catalyst, and that the value of the r_a/r_p ratio is also valid enough as a rough index of the basicity, much as in the cases of the MoO_3–Bi_2O_3–P_2O_5,[12] SnO_2–V_2O_5,[15] and SnO_2–MoO_3 systems.[16] Therefore, this indirect method of acidity-basicity measurement, based on the catalytic activity, may be recommended especially in the cases of catalysts whose surface area are too small for the amount of adsorption to be measured.

The isomerization activity for butene is correlated only with the acidity, not with the basicity, and the product ratio of *cis*-/*trans*-2-butene is 1—2. These pieces of evidence prove that, under the circumstances of the oxidation, the isomerization is catalyzed only by the acidic sites.[4,17,18] The same results have been observed in all the catalyst systems examined by us, such as V_2O_5–MoO_3, V_2O_5–P_2O_5, MoO_3–P_2O_5, MoO_3–Bi_2O_3–P_2O_5, MoO_3–P_2O_5–X_nO_m, SnO_2–V_2O_5, and SnO_2–MoO_3.[6–16] This means that the basic sites which can also catalyze the isomerization in the absence of oxygen in a closed or a pulse-reaction system are poisoned by CO_2, H_2O, or other acidic oxidation-products under the circumstances o the oxidation.

The similarity of the r_B curve in Fig. 9 to the acidity curves in Fig. 1 suggests that, in the case of TiO_2–MoO_3 catalysts, the acidic sites play an important role in the oxidation of olefin, probably in the activation of the olefin, much as in the cases of the V_2O_5–MoO_3, V_2O_5–P_2O_5, MoO_3–P_2O_5, MoO_3–Bi_2O_3–P_2O_5, MoO_3–P_2O_5–X_nO_m, and SnO_2–MoO_3[7–14,16] systems.

On the other hand, in the case of the TiO_2–V_2O_5 system, the shapes of the r_B curves (Fig. 10) are completely different from those of the acidity curves in Fig. 2. This implies that acidic sites are not the sole factor deciding the oxidation activity for butadiene. To explain these results, we envisage that, when the catalyst is highly acidic and scarcely basic, as in the cases of the V_2O_5–MoO_3,[7] V_2O_5–P_2O_5,[8] and MoO_3–P_2O_5 systems,[9] the oxidation activity for such a basic reactant as olefin is controlled only by the activation of olefin, which is performed at the acidic sites of the catalyst. However, as the acidic property of the metal-oxide catalst decreases and as the basic property increases, the contribution of the acidic sites to the oxidation activity decreases, while that of the activation of oxygen, which is connected, presumably, with the number of basic sites, *i.e.*, O^{2-} sites, on the surface of the catalyst as well as with oxygen-mobility of the sites increases.[12,20] Practically, in the case of oxidation over such scarcely acidic catalysts as the Ni, Co, Cr, Mn, and Cu metal oxides, the oxidation activity must be controlled entirely by the activity of surface oxygen—that is, by the oxidizing power of surface oxygen.[6,21]

Therefore, it may be speculated that, in the case of the TiO_2–V_2O_5 system, both the acidic and basic sites participate in the oxidation to a certain extent; when the V_2O_5 content is low and the catalyst is rather basic, the oxidation is affected to a considerable extent by the activity of the surface oxygen, while, as the V_2O_5 content increases, the contribution of the acidic sites increases, and when the V_2O_5 content is high and the catalyst becomes highly acidic, the contribution of the acidic sites becomes predominant. The fact that the oxidation activity of the TiO_2–MoO_3 system is much lower than that of the TiO_2–V_2O_5 system, though the former has a much higher acidity than the latter, may also support the theory of the participation of the factor relating to the activation of surface oxygen.

The characteristics of the r_A curve in Fig. 10 are similar to those of the r_a curves in Fig. 6. This may suggest that basic sites play a fairly important role in the oxidation, probably in the activation of the acidic compound.[6,12,20]

It is evident at least that, when the V_2O_5 content is low (V<5 atom%) where the TiO_2–V_2O_5 catalyst is basic, the catalyst is less active for the oxidation of a base reactant such as butadiene than for the oxidation

of an acidic reactant such as acetic acid, while when the catalyst is rich in V_2O_5 content and highly acidic, the catalyst is more active for butadiene than for an acidic compound.

With regard to the selectivity, the characters of the maleic anhydride curves in Figs. 11 and 12 support our opinion[6-16] that one requirement for an effective catalyst in this type of reaction (acid-formation reaction) is the acidic property; this may be concluded for two reasons: (1) the acidic catalyst is active in the oxidation of the reactant, and (2) it is inactive in the degradation of the acidic compound produced. On the other hand, the character of the curve of the butadiene formation may reveal that TiO_2 itself has both the acidic and basic properties proper to the selectivity of this type of reaction (base-formation reaction) and that the increase in the acidic character as a result of the MoO_3 or the V_2O_5 addition leads to a decrease in the selectivity. It should be noted that, in the cases of SnO_2 and Fe_2O_3, which are less acidic and more basic than TiO_2,[14,16,20] the selectivity increases with the addition of a small amount of such acidic elements as MoO_3 and V_2O_5. It seems probable that the presence of the acidic character is desirable in enhancing the activity for the reactant; however, when the acidic character is too high, butadiene is oxidized more rapidly than butene,[10-12] because butadiene is more basic that butene (the ionization potential of butadiene 8.75—9.18 eV, is lower than that of butene, 9.3—9.8 eV). These results also support our opinion[6-16] that one requirement for an effective catalyst in a base-formation reaction is a moderate character both in an acid and a base.

It can be concluded that the oxidation activity and selectivity of the TiO_2–MoO_3 and TiO_2–V_2O_5 catalysts can be relatively well interpreted in connection with their acid-base properties, which are strongly changed by the catalyst composition.

Identification of Stereoisomers of Methyl Hexopyranosides by Mass Spectrometry of Their Trifluoroacetates

Susumu ANDO,* Toshio ARIGA,** and Tamio YAMAKAWA

Department of Biochemistry, Faculty of Medicine, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 20, 1975)

The mass spectra of the trifluoroacetates of methyl hexopyranosides and their partially deuterated derivatives were measured. The trifluoroacetyl derivatives were found to be very useful for identification of some stereoisomeric hexoses. The mass spectra were characterized by abundant peaks in the high mass range, the presence of a recognizable molecular ion, and sensitive spectral differences due to different stereoisomers. Glucose, galactose and mannose were distinguished from each other by comparing the intensities of the fragment ions due to the loss of trifluoroacetyl groups or cleavage of the pyranose ring. Alfa and β-anomers were distinguished by differences in the abundance of fragment ions produced by the loss of glycosidic methoxyl groups.

Monosaccharides have been examined by measuring the mass spectra of their methyl,[1,2] acetyl,[3] trimethylsilyl (TMS)[4-6] and isopropylidene derivatives.[7,8] However, use of the mass spectra of these derivatives has the disadvantages of the absence of a molecular ion and small differences in the specral patterns of different stereoisomers (*e.g.* epimers or anomers). Chizhov *et al.*[9] reported that the trifluoroacetyl (TFA) derivatives of alditols give sufficiently intense molecular ions to allow direct determination of their molecular weights. TFA derivatives were previously used in gas chromatographic analysis of methyl glycosides because of their high volatility.[10,11] The present paper reports studies on the mass spectra of the TFA derivatives of methyl hexopyranosides. The major fragmentation processes are proposed on the basis o results of deuterium-labeling experiments.

Experimental

Methyl α-D-glucopyranoside (Ia) and methyl β-D-glucopyranoside (Ib) were obtained from Sigma Chemical Co. Methyl α-, and β-D-galactopyranosides (IIa and IIb) were prepared by refluxing D-galactose with 1% methanolic HCl and were separated by Dowex (1×4) column chromatography as described by Matsushima and Miyazaki.[12] Methyl α-, and β-D-mannopyranosides (IIIa and IIIb) were obtained in a similar way. Deuteriomethyl α-, and β-D-galactopyranosides (VIa and VIb) were also prepared with the use of methanol-d_4 instead of methanol.

Methyl α-, and β-D-Glucopyranoside-2-d and Deuteriomethyl α-, and β-D-Glucopyranoside-2-d (IVa, IVb, Va, and Vb). Deuteration of the C_2 position was carried out as described by Lemieux and Stevens.[13] 2-*O*-benzyl-D-glucose[14] (750 mg) was dissolved in 3 ml of deuterium oxide (d, 99.5%) and lyophilized. The treatment was repeated three times. The lyophilized material was then dissolved in 3 ml of 1.7 M NaOD, and left to stand for 10 days at room temperature. The solution was neutralized with acetic acid-d_1 and extracted five times with 10 ml volumes of ethyl acetate. The extracts were combined and evaporated to dryness. The residue was recrystallized from ethyl acetate to yield 670 mg of 2-*O*-benzyl-D-glucose-2-*d*; mp, 176—178 °C; NMR(D_2O) ppm, 5.26(1-H_{eq}, singlet), 4.70 (1-H_{ax}, singlet), 7.4 (phenyl protons). 2-*O*-benzyl-D-glucose-2-*d* (600 mg) was dissolved in 20 ml of 95% ethyl alcohol and subjected to hydrogenolysis for 24 h under atmospheric pressure with 5% Pd on charcoal. The reaction mixture was filtered and evaporated to yield 540 mg of D-glucose-2-*d*; syrupy; NMR (D_2O) ppm, 5.24 (1-H_{eq}, singlet), 4.94 (1-H_{ax}, singlet). No detectable phenyl proton. Methyl α-, and β-glucopyranoside-2-*d* (IVa and IVb) and deuteriomethyl α-, and β-glucopyranoside-2-*d* (Va and Vb) were derived from D-glucose-2-*d* using acidic methanol and deuteriomethanol, respectively. Each anomer was purified by Dowex 1 column chromatography as described above.

Methyl α-, and β-D-glucopyranoside-6-d_2 (VIIa and VIIb). To a solution of methyl D-glucuronic acid methyl ester (100 mg) in 2 ml of water was added dropwise a solution of $NaBD_4$ (50 mg) in 3 ml of cold water. The mixture was left to stand for 6 h at room temperature, treated with Dowex 50 (H^+ form) and IR-45 (OH^-), and evaporated to dryness. VIIa and VIIb were separated on a column of Dowex 1.

Trifluoroacetylation of Sugars. The dried material (3 mg) was allowed to react with a mixture of 0.1 ml of ethyl acetate and 0.2 ml of trifluoroacetic anhydride at 100 °C for 8 min.[10] The reaction mixture was then evaporated under a stream of nitrogen at 40 °C and the residual trifluoroacetic acid was removed as an azeotropic mixture with carbon tetrachloride.

Mass spectra were measured on a Hitachi model RMS-4 mass spectrometer, temperature of the ion source being 200°C, ionizing potential 70 eV and accelerating voltage 3 kV. Samples were vaporized in a 1 l glass reservoir at 140 °C. Mass spectra were recorded on a photographic chart. Peak intensities were expressed in percentage of that of total ions above *m/e* 100 (% Σ_{100}).

Results and Discussion

The physical properties of the methyl hexopyranosides used are listed in Table 1. The deuterium contents in the deuterated sugars were determined from the isotope peaks. The deuterium content at position C_2 of IVa was 95.8% and that at C_6 of VIIa 97.1%. The deuterium content in the methoxyl group of VIa was 98.2%.

The major fragment ions of the TFA derivatives of methyl glucosides, galactosides and mannosides are listed in Table 2. The TFA derivatives of hexopyranosides all showed a molecular ion (*m/e* 578), whereas the acetyl,[3] methyl[1,2] and TMS derivatives[4-6] of monosaccharides gave $(M-CH_3CO)^+$, $(M-CH_3O)^+$ and $(M-CH_3)^+$, respectively, as the highest ions.

a) Peak intensity of β-anomer is greater than that of the corresponding α-anomer. b) Peak intensity of α-anomer is greater than that of the corresponding β-anomer. c) Intensities decrease in the order of mannoside, glucoside and galactoside.

A typical mass spectral pattern of the TFA derivative of methyl α-D-glucopyranoside is shown in Fig. 1-b, with that of the corresponding TMS derivative (Fig. 1-a) for comparison. Relatively abundand peaks were observed in the high mass range (above *m/e* 177) of the spectra of the TFA derivatives, whereas the mass spectra of the methyl,[1,2] acetyl[3] or TMS derivatives were characterized by peaks of extremely low intensity

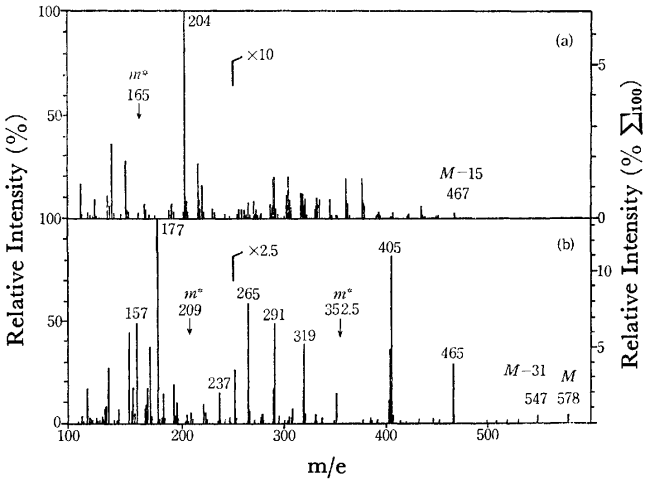

Fig. 1. Mass spectra of (a) TMS- and (b) TFA-derivatives of methyl α-D-glucopyranoside.

in the high mass range. TFA groups may effectively stabilize the molecular and fragment ions in the high mass range.

Fragmentation Process. Three modes of fragmentation are presented. The fragmentation mode in series **A** (Scheme 1) was produced by sequential elimination of

c) Intensities decrease in the order of mannoside, glucoside and galactoside.

TFA groups. A similar sequential elimination of TFA groups was reported in the mass spectra of TFA alditols.[9] In the course of the fragmentation, ring scissions occurred at C_1–C_2 and C_5–O bonds to produce the fragment ions *m/e* 405(**d**) or 404. The fragment ion **d** further released TFA groups to yield the ions **e** and **f**. These degradation processes were confirmed by the presence of the following metastable ions: *m/e* 352.5 (*m/e* 465→405), *m/e* 209.0 (*m/e* 405→291) and *m/e* 107.5 (*m/e* 291→177). All the deuterium atoms of IVa

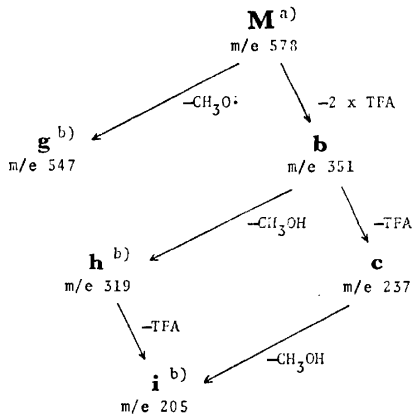
			195 (1.79)				155 (2.20)

and VIIa remained in fragment **a**, and 2-**d** (IVa) and 6-d_2 (VIIa) were still retained in **d** and **b**, respectively. The fragmentation, **c**→**f**, seems unlikely, because of the difference in the deuterium contents of the two fragments. The deuterium content at the C_2 position of fragment ion **c** was reduced to 47%, but not the deuterium content of fragment ion **f**. During the fragmentation from M^+ to **c**, elimination of TFA groups caused only a little loss of the hydrogens at the C_6 position. After the ring scissions at C_1–C_2 and C_5–O bonds, sequential elimination of TFA groups was not accompanied by removal of the hydrogen at the C_2 position. Scarcely any fragment ions due to loss of F-, CF_3-, or CF_3CO- radicals were detected.

The second fragmentation mode in series **B** was characterized by elimination of the methoxyl group from the parent molecule or the fragments **b** or **c** without ring opening (Scheme 2).



Scheme 2. Fragmentation due to elimination of methoxyl groups (Series B).
a) Peak intensity of β-anomer is greater than the corresponding α-anomer. b) Intensity of α-anomer, greater than the corresponding β-anomer.

The third mode of fragmentation in series **C** included several kinds of ring scissions. Simultaneous cleavage of C_1–C_2 and C_5–O linkages produced fragment ion *m/e* 405 from the tris-TFA fragment (**a**, *m/e* 465) (Scheme 1). The path was confirmed by the loss of deuteriomethoxyl groups from the corresponding fragment ion **a** of VIa and VIb. Other ring scissions produced some characteristic ions, *m/e* 265, 252, 193, 183, 170, 157 and 153, from the fragments **a**, **b** and **c** (Table 3).

Differentiation of Anomers. The relative intensities of the molecular ions of β-anomer were more than twice those of α-anomers (Table 2). Similar phenomena have been observed with the methyl ethers of methyl hexosides.[1,2] However, the difference in abundance of the high mass fragments of the methyl derivatives was not so large. The TFA derivatives of gluco-, galacto- and mannopyranosides gave reproducible results when they were introduced into a mass spectrometer through a heated reservoir or a gas chromatograph. The two anomers of the TFA derivatives were also distinguished by the difference in abundance of the fragment ions produced by the loss of glycosidic methoxyl groups (series **B**, Scheme 2, Table 2). The relative intensities of the fragment ions, **g**, **h** and **i**, derived from the α-anomers were about twice as large as those of the corresponding fragments from β-anomers. The difference in abundance of these ions may be caused by steric effects of the configuration of methoxyl groups.

Differentiation of Epimers. Differences in the spectra of some epimers have been reported.[2,3,7] Kochetkov and Chizhov[2] studied methylated hexosides and reported that the abundance of the fragment *m/e* 149 from galactose and that of the fragment *m/e* 145 from mannose were relatively large. DeJongh and Biemann[7] found differences in the spectra of the isopropylidene derivatives of glucose, galactose and mannose. However, no significant difference was observed between the spectra of acetylated hexoses.[3]

The TFA derivatives of glucose, galactose and mannose could be distinguished from each other by the abundance of various fragments (Table 2). In particular, differences in the abundance of the fragment ions, **c**, **e**, **j** and **k**, could be used to differentiate these monosaccharides. The two former ions are produced in the fragmentation process of series **A**, and the two latter in the process of series **C**.

Cyanamide Derivatives. Part 99.* Electrolytic Oxidation of Cyanamide

Koji KUBO,** Tsutomu NONAKA, and Keijiro ODO

Department of Electrochemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received September 25, 1975)

Cyanamide was electrochemically oxidized with a platinum anode in aqueous potassium hydroxide. Electrolysis was carried out at 1.30 V *vs.* SCE of anode potential. Oxidation products consist of several unknown 1,2,3,5-tetrazine compounds and known linear cyano compounds.

A number of studies have been performed on the catalytic and electrolytic reduction of cyanamide, but only one paper dealing with the oxidation of cyanamide was published by Calcagni and Lazzari.[1] They electrolyzed cyanamide in aqueous sulfuric acid but gave no details except for the formation of nitric and nitrous acids.

Cyanamide is considerably stable in strongly alkaline and acidic solutions because it is an amphoteric compound, while it is easily converted into dicyandiamide by dimerization and into urea by hydration in weakly alkaline and acidic solutions, respectively. Potassium hydroxide was used as an electrolyte in this work. The advantage of a strongly alkaline electrolyte is not only that cyanamide can be stabilized but also that its anionic form ($NC-NH^-$ or $NC-N^{2-}$) favorable to migration to an anode surface can be formed.

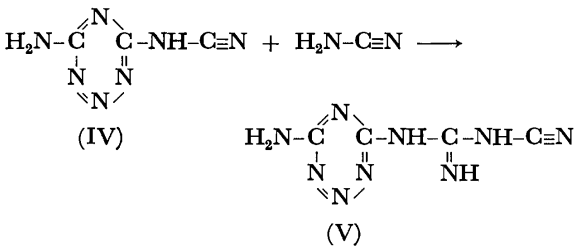
Results and Discussion

Cyanamide was electrolyzed with a platinum anode in 2 M potassium hydroxide. Several products were isolated from the anolyte neutralized with hydrochloric acid or carbon dioxide.

Of the products, dicyanoimine(I), cyanourea(II), and dicyandiamide(III) are known compounds and were identified with authentic samples, while the structures of VII and VIII could not been confirmed. Cyanic acid in the form of potassium salt was also confirmed IR-spectroscopically without being isolated. On the other hand, 4-amino-6-cyanamino-1,2,3,5-tetrazine (IV), 4-amino-6-cyanoguanidino-1,2,3,5-tetrazine(V), and 4-ureido-6-cyanoguanidino-1,2,3,5-tetrazine(VI) are new compounds with a rare 1,2,3,5-tetrazine ring.[2] Their structures were confirmed as follows.

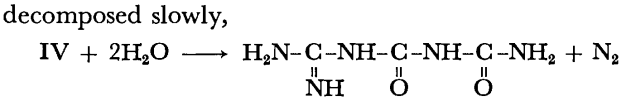
The potassium salts of these compounds exhibited the absorption for C≡N and cyclic –N=N–N– groups at 2160—2190 and 1200—1300 cm^{-1},[3] respectively.

IV was converted into V by addition of cyanamide in aqueous potassium carbonate.

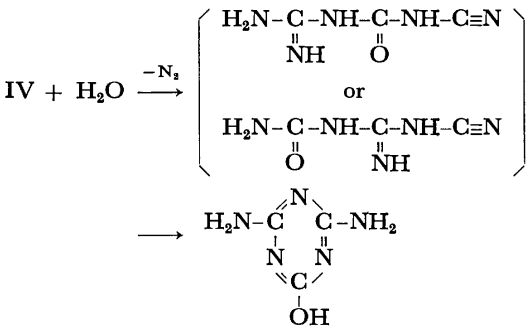


(IV) (V)

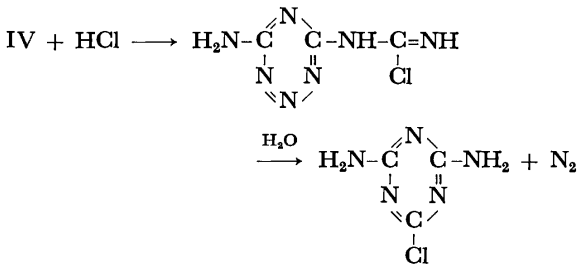
Amidinobiuret and nitrogen were formed in 73 and 80% yields, respectively, when IV was warmed at 40 °C in dilute sulfuric or hydrochloric acid. Neither carbon dioxide nor ammonia was detected. IV also decomposed slowly,



accompanied by evolution of nitrogen in aqueous potassium hydroxide at room temperature, and finally giving ammeline in a 45% yield after being left to stand for 24 h. The decomposition seems to involve cyanoamidinourea or cyanocarbamoylguanidine as an intermediate.[4]



In order to obtain the free acid of IV, hydrogen chloride gas was introduced into a dry acetone solution of potassium salt of IV. The resulting precipitate was not the desired free acid but the hydrochloride of a base which gave 2,4-diamino-6-chloro-1,3,5-triazine by treatment with water. The basic intermediate exhibited no absorption for –C≡N group. It is presumed to be 4-amino-6-(iminochloromethyl)amino-1,2,3,5-tetrazine on the basis of its elemental analysis.



V decomposed to melamine (yield, 88%), ammonia (91%), carbon dioxide (63%) and nitrogen (82%), when heated in dilute minearal acid.

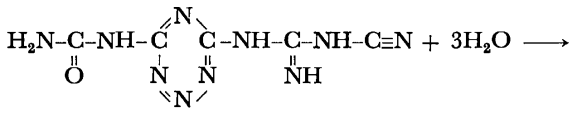
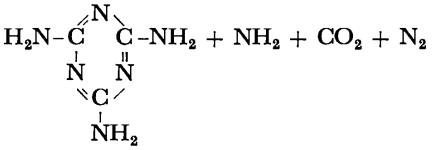
CO_2	0.70 (8)	+	+	0.20 (5)	1.11 (26)	0.35 (7)	—	+	5	0.45 (2)

a) 0.101 F of electricity was passed through an anolyte containing 4.20 g (0.10 mol) of cyanamide.
b) Monoammonium salt. c) Monopotassium salt. d) Dipotassium salt. e) ml under 1 atm at 0 °C.
f) Disilver salt.

VI also decomposed to melamine (yield, 80%), ammonia, carbon dioxide and nitrogen under similar conditions.



(VI)



No detailed mechanism could be established for hydrolytic decompositions of IV, V and VI. However, the above results might bring some reliable information for determination of the structures of these compounds. At least the formation of amidinobiuret and 2,4-diamino-6-chloro-1,3,5-triazine suggests the existence of the skeletons of N–C–N–C–N–C≡N and N–C–N–C–N–C≡N, respectively. The evolution of nitrogen in the course of decomposition also suggests that a –N=N– bond is involved in IV. The most probable structure of IV is thus represented as shown above. It is further supported by the fact that the decomposition of V derived from IV is reasonable from a stoichiometric aspect.

Only V could be successfully converted into the corresponding free acid. Although the free acid gave no molecular peak even in a high resolution mass spectrum measured carefully because of its thermolability, the spectrum indicated a N_3^+ fragment at *m/e* 42.0109 (pattern coefficient, 26%; calcd *m/e* 42.0125). This is an evidence for the existence of the –N=N–N– group. The highest *m/e* value of peak in the spectrum was 151.0601 (pattern coefficient, 15%) corresponding to a $C_4H_5N_7^+$ fragment (calcd *m/e* 151.0606) formed by elimination of N_2 from a molecule ($C_4H_5N_9$). The properties and the amounts of the products are listed in Tables 1 and 2, respectively.

The distribution of products derived from an anolyte neutralized with hydrochloric acid differs from that derived from the one neutralized with carbon dioxide. This suggests that an unstable intermediate may be left active in an anolyte even after electrolysis.

Experimental

Electrolytic Cell and Procedure. An H-type cell divided with a sintered glass diaphragm was used. Both anode and cathode were platinum plates (3×4 cm). 75 ml of 2 M potassium hydroxide was used as anolyte and catholyte. 4.20 g (0.10 mol) of cyanamide was added to the anolyte and electricity was supplied. The anode potential and the temperature of anolyte were maintained at 1.30 V *vs.* SCE (an initial anodic current density, 20 amp/dm²) and below 10 °C,

respectively, during electrolysis. When the anodic current density lowered to 2 amp/dm^2 after 3.5 h, electricity was turned off. The amount of passed electricity was 1.01 F/mol.

Separation of Products. After electrolysis, the anolyte was neutralized to pH 8—9 with carbon dioxide and then evaporated to dryness under reduced pressure at below 20 °C.[5] The residue was extracted with 150 ml of acetone. When the insoluble solid in acetone was treated with 50 ml of water, the crude monopotassium salt of V, which was purified by recrystallization from water, was left as a yellow solid. Found: C, 22.11; H, 2.18; N, 58.70%. Calcd for $C_4H_4N_9K$: C, 22.11; H, 1.86; N, 58.63%. The aqueous solution was neutralized to pH 6.5 with hydrochloric acid and 400 ml of ethanol was added. The resulting precipitate (potassium hydrogen carbonate) was filtered off and the filtrate was evaporated to dryness. When the residue was treated with 10 ml of water, dipotassium salt of VI, which was recrystallized from a small amount of water, was left as a yellow solid. Found: C, 20.29; H, 1.28; N, 47.63%. Calcd for $C_5H_4N_{10}OK_2$: C, 20.13; H, 1.35; N, 46.95%. 50 ml of ethanol was added to the aqueous solution and the resulting precipitate (potassium carbonate) was filtered off. After aqueous ammonia was added to the filtrate, it was evaporated to dryness. When the residue was extracted with 10 ml of acetone, monoammonium salt of II was left as a white solid. The ammonium salt was dissolved in dilute hydrochloric acid and the solution was evaporated to dryness. The residue was treated with ethanol in order to remove ammonium chloride. When the ethanolic solution was again evaporated to dryness, the free acid of II, which was recrystallized from ethanol, was left as a white solid. When the acetone solution was evaporated to dryness, ammonium salt of I, recrystallized from a mixture of acetone and ether, was left as white needles.

On the other hand, when the acetone solution prepared at the first stage was concentrated to one-third of its original volume, a small amount of VIII, which was recrystallized from acetone, crystallized out of the solution as white powder. Found: C, 16.62; H, 1.22; N, 49.24%. The structure of VIII could not be determined. The acetone solution was evapoated to dryness and the residue was extracted with ether. The ether extract was again evaporated to dryness and the residue was dissolved in dilute ammonia. When an aqueous solution of silver nitrate was added to the ammoniacal solution, disilver salt of recovered cyanamide precipitated as yellow powder. When the insoluble solid in ether was extracted with 10 ml of cold water, III, which was recrystallized from hot water, was left as a white solid. The aqueous solution was evaporated to dryness and the residue was again dissolved in 100 ml of acetone. When 20 ml of ether was added to the acetone solution, monopotassium salt of IV crystallized out of the solution as pale yellow needles. IV was purified by recrystallization from acetone containing a small amount of ether. Found: C, 20.23; H, 1.06; N, 55.94%. Calcd for $C_3H_2N_7K$: C, 20.56; H, 1.15; N, 55.97%.

In the case where an original anolyte was neutralized to pH 6.4—6.8 with dilute hydrochloric acid, the products were separated by a similar method to the above.

Decomposition of IV in Acidic Solution. 0.35 g (2 mmol) of potassium salt of IV, a small glass ampoule containing 2 ml of concentrated hydrochloric acid, and 50 ml of water were placed in a flask connected with a gas burette. The flask was heated at 40 °C and then the ampoule was broken with a magnet hammer. 36 ml (yield, 80%) of nitrogen generated for 30 min. The reaction mixture was evaporated to dryness and then was dissolved in dilute ammonia. When a saturated solution of ammonium picrate was added to the ammoniacal solution, 0.35 g (yield, 65%) of potassium picrate crystallized out of the solution. When the mother liquor was acidified with acetic acid, 0.55 g (yield, 73%) of amidinobiuret picrate crystallized out of the solution.

Decomposition of IV in Alkaline Solution. 0.35 g (2 m mol) of potassium salt of IV and 20 ml of 2M potassium hydroxide were placed in a flask similar to that described above. 20 ml (yield, 45%) of nitrogen generated for 24 h. 0.11 g (yield, 45%) of ammeline crystallized out of the solution, when the reaction mixture was neutralized with acetic acid.

Decomposition of IV with Hydrogen Chloride in Acetone. Dry hydrogen chloride gas was introduced into 50 ml of an acetone solution containing 0.075 g (0.43 mmol) of potassium salt of IV at 0 °C. After the resulting potassium chloride had been filtered off, the reaction mixture was evaporated to dryness. 0.067 g (yield, 75%) of white residue, which could not be purified, was presumed to be 4-amino-6-(iminochloromethyl)amino-1,2,3,5-tetrazine monohydrochloride. Found: C, 17.87; H, 2.11; N, 46.95; Cl, 32.44%. Calcd for $C_3H_5N_7Cl_2$: C, 17.16; H, 2.40; N, 46.68; Cl, 33.76%. This residue was converted into 2,4-diamino-6-chloro-1,3,5-triazine by treatment with water.

Decomposition of V in Acidic Solution. 0.49 g (2.2 mmol) of V was dissolved in 30 ml of cold 0.5M hydrochloric acid. The reaction mixture was heated at 75 °C for 1 h. The gas evolved consisted of 41 ml (yield, 82%) of nitrogen and 32 ml (yield, 63%) of carbon dioxide. When the reaction mixture was cooled in an ice bath, 0.32 g (yield, 88%) of melamine hydrochloride precipitated. The amount of ammonium chloride in the mother liquor was estimated to be 2.04 mmol (yield, 91%) by the hypobromite method.

Decomposition of VI in Acidic Solution. 0.24 g (0.8 mmol) of dipotassium salt of VI was decomposed by a similar procedure to that in the case of V. 0.10 g (yield, 80%) of melamine hydrochloride and 0.60 mmol (yield, 75%) of ammonia were obtained from the reaction mixture. The gaseous product consisted of nitrogen and carbon dioxide, but their volumes were not measured.

Free Acid of V. 0.27 g (yield, 58%) of the free acid of V precipitated as yellow powder, when 2 ml of 2M hydrochloric acid was added to 5 ml of cold aqueous solution containing 0.57 g (2.6 mmol) of potassium salt of V. The free acid was purified by recrystallization from water. Found: C, 26.63; H, 2.75; N, 69.12%. Calcd for $C_4H_5N_9$: C, 26.82; H, 2.81; N, 70.37%.

Vinyl Polymerization. 341.[1] A Proposal of a Mechanism for Radical Polymerization of Vinyl Monomers with Sodium Polymethallylsulfonate

Minoru IMOTO, Yoshiaki NAKAMURA, and Tatsuro OUCHI

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita-shi, Osaka 564

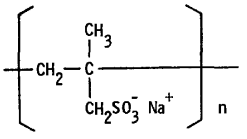
(Received October 1, 1975)

In aqueous solution, sodium polymethallylsulfonate (PMAS-Na) can initiate a radical polymerization of vinyl monomer which has positively charged vinyl group. In the polymerization of MMA, Michaelis-Menten equation was applicable. From the results obtained, a bimolecular initiation mechanism, involving hydrogen atom transfer, was concluded to be reasonable. The relationships between pH of the aqueous layer and conversion and between polymerization temperature and conversion were of downward bell type. By Stewart model, it was found that PMAS-Na has a very rigid conformation. This structure can be compared with a rigid tertiary structure of enzyme, and the reaction appearances of enzyme and PMAS-Na can be considered to resemble very much each other.

Recently we reported[2] that an aqueous solution of sodium polymethallylsulfonate (PMAS-Na) could polymerize some vinyl monomers in the absence of any usual initiator. In the present paper, we would like to propose a probable mechanism for the generation of an initiating radical species by the reaction of sulfonate group with vinyl monomer, *i.e.* a generation by the interaction of two molecules of vinyl monomer through the Flory's mechanism.[3]

Experimental

Materials. PMAS-Na was prepared by the polymerization of sodium methallylsulfonate with ammonium peroxodisulfate in water, as described in the former report[2]: [η] 0.08 dl/g (30 °C, in water). Peroxide group and metallic ion in PMAS-Na were hardly detected by KI-method and atomic absorption spectrometry technique, respectively.



PMAS-Na

Styrene (St), methyl methacrylate (MMA) and acrylonitrile (AN) were of commercial and purified by usual method. *p*-Nitrostyrene (*p*-NO_2-St)[4] and *p*-methoxystyrene (*p*-CH_3O-St)[5] were synthesized according to the literatures. Water was ion-exchanged.

Procedure. Vinyl monomer and an aqueous solution of PMAS-Na were placed in a tube and seald under vacuum after thawing with nitrogen. The tube was heated at 85 °C for 1 h under shaking. The content was poured into a large amount of methanol to precipitate the polymer. The collected polymer was washed throughly with water and the polymer of vinyl monomer was separated. After drying, the polymer was weighed.

Results and Discussion

Proof of Radical Mechanism. In a mixture of 3 ml of MMA and an aqueous solution of 0.05 g of PMAS-Na in 5 ml of water, diphenylpicrylhydrazyl, hydroquinone or benzoquinone was added in an amount of 0.1 g, as radical scavenger. Another polymerization without radical scavenger was carried out in air. In all cases, formation of poly-MMA was not observed. Thus, it was concluded that the polymerization proceeded through a radical mechanism.

Efficiency of Grafting. In the polymerization of MMA, the efficiency of grafting was measured by extracting the polymer obtained with benzene. The results showed that the grafting reaction did not take place.

Selectivity of Vinyl Monomer. A solution of 0.05 g of PMAS-Na in 5 ml of water and 3 ml of vinyl monomer were reacted as described in a former section. Five kinds of monomer were used. The conversions observed were drawn in Fig. 1. Here, "e" is the Alfey-Price's polymerization factor.[6] The conversion was found to be linearly proportional to the "+*e*"-value of the monomer. The "*e*"-value of −0.3 is considered to be the point at which a vinyl monomer behaves as a non-polarized molecule.

From the results, it was confirmed that only the vinyl monomer having plus-charged vinyl group could be polymerized by PMAS-Na. This conclusion agrees well with the consideration in which the plus-charged vinyl group is adsorbed on the minus-charged sulfonate group.

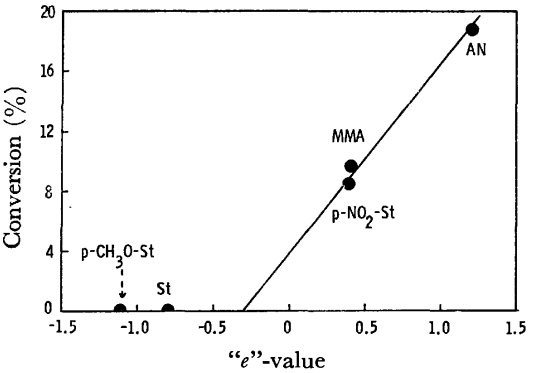


Fig. 1. Conversions of vinyl monomers *vs.* their "*e*"-values.

Relationship between Amounts of PMAS-Na and Polymer Yield. Using various amounts of MMA, the polymerization was carried out at 85 °C for 1 h to obtain the results shown in Fig. 2. The yield of polymer increased with the added amount of MMA and reached

a constant yield at a certain point of the amount of MMA. Beyond the point, the yield became to be independent of the amount of MMA. This relationship between the polymer yield and the feeded amount of MMA resembles well to the relationship between the rate of reaction and the amount of substrate in enzymatic reaction.

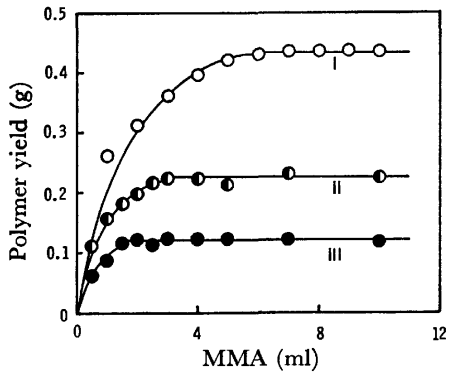

Fig. 2. Polymer yield *vs.* feeded amount of MMA.
H_2O: ○ 10 ml, ◐ 5 ml, ● 2.5 ml.
[PMAS-Na]=0.01 g per 1 ml of water. 85°C, 1 h.

Application of Michaelis-Menten Equation to the Polymerization of MMA. The results obtained in Fig. 2 were found to fit in Michaelis-Menten Equation (1);

$$E + S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_3} E + P \qquad (1)$$

where E is PMAS-ion, S is MMA, ES is a adsorbed complex of MMA on PMAS-ion and P is a radical initiator. From Eq. 1, Lineweaver-Burk's Equation (2) is obtained.

$$\frac{1}{R_p} = \frac{K_a}{k_3[E]} \times \frac{1}{[S]} + \frac{1}{k_3[E]}$$
$$K_a = (k_2+k_3)/k_1 \qquad (2)$$

Here, as "P", we adopted poly-MMA instead of radical initiator. Accordingly, R_p in Eq. 2 is the rate of polymerization. By application of Eq. 2, the reciprocals of R_p were coordinated with those of the feeded amounts of MMA, as shown in Fig. 3. Straight lines were obtained. From the intercepts of the ordinate at the zero point and from the inclinations of the lines, $k_3[E]$ and Michaelis-Constant, K_a, were calculated as shown in Table 1.

As can be seen, K_a was obtained as a constant value of 1.06 ± 0.09, and $k_3[E]$ was almost proportional to [E]. Thus it was confirmed that Michaelis-Menten Equation fits in the present polymerization.

Table 1. Values of K_a and k_3 [E]
(PMAS-Na 0.01 g/ml H_2O; 85 °C, 1 h)

Case	H_2O (ml)	K_a (g)	$k_3[E]$ g/h
III	2.5	1.15	0.222
II	5	0.98	0.285
I	10	1.05	0.500

Effect of pH of the Aqueous Phase on the Rate of Polymerization of MMA. The effect of pH of the aqueous phase on the conversion of MMA was observed as shown in Fig. 4. It was very interesting that this radical polymerization showed the most rapid rate at the pH near to 6. It is considered that at such pH the PMAS-ion can exist in a bare state as sulfate anion apart from Na^+ cation. At acidic area, sulfate anion of PMAS-Na becomes to unionized sulfonic acid and to be difficult to adsorb a positively charged vinyl group. On the other hand, in alkaline area, hydroxide ion surrounds a positive part of vinyl monomer to put it apart from sulfate ion.

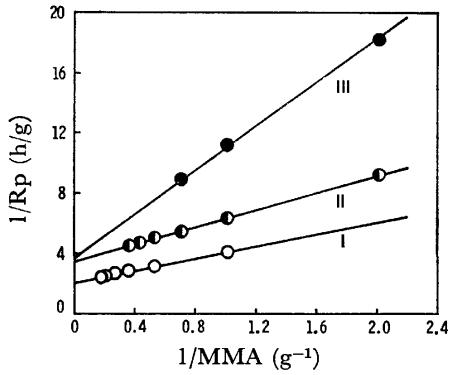

Fig. 3. Application of Eq. 2 to the results obtained in Fig. 2.

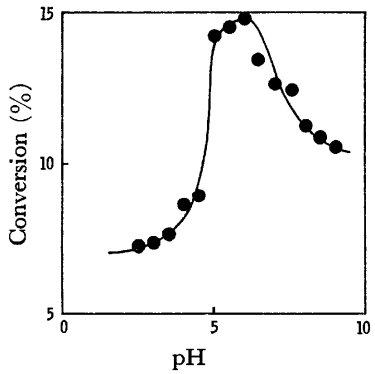

Fig. 4. Conversion of MMA *vs.* pH of the aqueous layer of the reaction system.
(MMA 3 ml, PMAS-Na 0.05 g, buffered water 5 ml; 85 °C, 1 hr. Buffer solutions were prepared by the following systems; pH 2.5—6.0, M/10 citric acid-M/5 Na_2HPO_4; pH 6.5—7.5, M/10 HCl-M/20 $Na_2B_4O_7$; pH 7.5—9.5, M/15 Na_2HPO_4-M/15 KH_2PO_4)

Effect of Reaction Temperature on the Rate of Reaction. The polymerization of MMA initiated with an aqueous solution of PMAS-Na was carried out at the temperature between 55 and 120 °C. The result can be seen in Fig. 5. The maximum conversion was obtained at 90 °C. Over this temperature, the degree of adsorption of MMA by $PMAS^{n-}$ is concluded to decrease.

From three points of A, B and C in Fig. 5, an overall activation energy, E, was calculated to be 12.8 kcal/mole, as shown in Fig. 6. Granting that $(2E_p-E_t)$ is 9.0 kcal/mol,[7] the activation energy of initiation, E_i, was calculated to be 16.6 kcal/mol from the equation, $2E=E_i+2E_p-E_t$. Here E_p and E_t are activation energies of propagation and termination reactions, respectively.

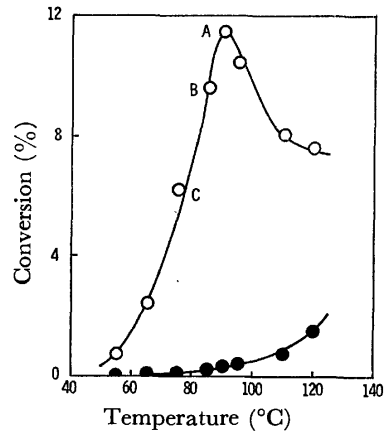

Fig. 5. Conversion of MMA *vs.* polymerization temperature. (MMA 3 ml, H_2O 5 ml, PMAS-Na 0.0 g (●) or 0.05 g (○); 1 h)

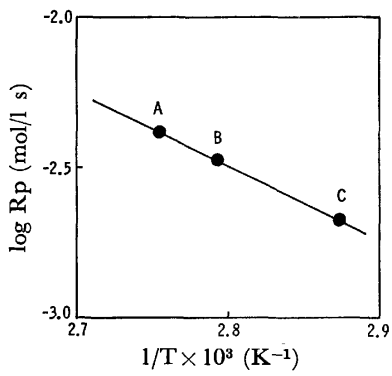

Fig. 6. Arrhenius plot of three points of A, B, and C in the former figure.

Mechanism of the Initiation Reaction. Figure 1 indicates that a mechanism which accomodates the results is one in which the plus-charged methylene of vinyl monomer is adsorbed to the SO_3^- group of PMAS^{n-} and goes into reaction. The formula of polarized vinyl monomer having "$+e$"-value on CH_2 group is expressed as the formula (3).

$$\overset{\delta+}{C}H_2{=}CH{-}R^{\delta-} \qquad (3)$$

On the other hand, $-SO_3^-$ groups of PMAS^{n-} repel each other and situate separately as far as they can. Thus, it is a reasonable consideration that the macromolecule of PMAS^{n-} has a structure near to syndiotactic configuration. A probable Stewart's model of PMAS^{n-} is shown in Fig. 7. In this model, only three units were taken. However, the structure of PMAS^{n-} was found to be very rigid. In Fig. 7, furthermore, two adsorbed molecule of acrylonitrile were also shown. From the model it was concluded that the two vinyl monomers could exist within a van der Waals distance.

The rigid structure of PMAS^{n-} is considered to correspond to a rigid tertiary structure of enzyme by which an enzyme can afford a specificitic reactivity to substrate.

As usually known, in enzymatic reaction, a relationship between rate of reaction and reaction temperature or pH of the reaction system is of downward bell type. Michaelis-Menten Equation was verified to be applicable. Thus, the observations obtained in the present paper agreed very well with enzymatic reaction figures.

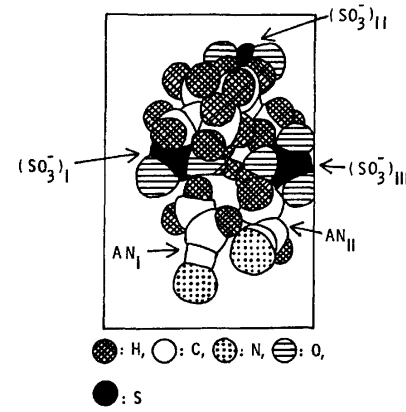

Fig. 7. Stewart's model of 3 units in PMAS^{n-}.

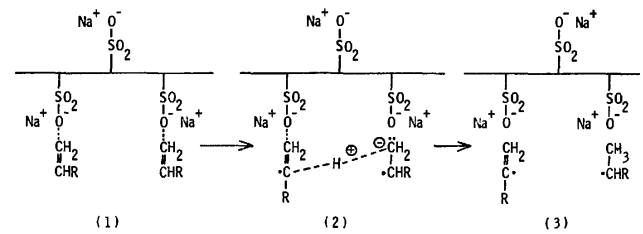
From the results obtained above, the mechanism of the initiation reaction was concluded to be as shown in the following Scheme 1.



Scheme 1. Initiation mechanism of vinyl monomer by PMAS-Na.

By complexing of $-SO_3^-$ anion with positively charged $CH_2=$ group of the monomer, a following partial electron transfer may proceed.

$$-\overline{O}^{-}\cdots\overset{\delta+}{C}H_2{=}CH{-}R \qquad (4)$$

Thus, electron density around the carbon atom of $=CH-$ increases and becomes easier to donate its electron. In other words, a charge-transfer complex (CT-complex) becomes easier to be formed.

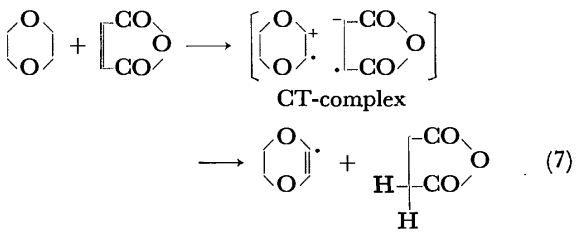
$$(1) \longrightarrow CH_2{=}\overset{+}{C}H\cdots\overset{-}{C}H_2{-}\dot{C}H \longrightarrow (2) \qquad (5)$$
$$\qquad\qquad\quad R \qquad\quad R$$
$$\text{CT-complex}$$

This initiating mechanism corresponds well to the Flory's mechanism which was proposed as Eq. (6) in 1937.[3]

$$2CH_2{=}CH \xrightarrow[\text{of H· atom}]{\text{Transfer}} CH_3{-}\dot{C}H + CH_2{=}\dot{C}\cdot \qquad (6)$$
$$\quad R \qquad\qquad\qquad\quad R \qquad\quad R$$

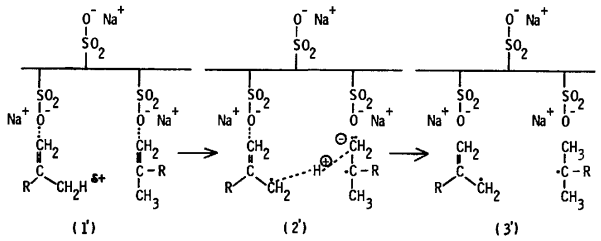
This mechanism was denied from the standpoint of the reaction energy. However, recently the Flory's mechanism involving hydrogen transfer was taken up as an initiation mechanism of the radical polymerization which proceeds through a charge-transfer (CT) complex. For example, one of the present authors (M. Imoto)[8]

assumed the following initiation mechanism as shown in Eq. (7):



(7)

Otsu and Sato succeeded to prove this H· transfer mechanism using the spin-trapping method.[9] Accordingly, the mechanism proposed as shown in Scheme 1 may be recognizable to be reasonable.



Scheme 2. Initiation of the polymerization of MMA. ($R\text{-}COOCH_3$)

In the case of MMA having no hydrogen atom at the vinyl carbon atom attached directly to the substituent, the transfering hydrogen atom is considered to be one in the α-CH_3 group. The mechanism is concluded to be as in Scheme 2. One of the generated radicals is an allyl radical which may make easier the hydrogen transfer.

The authors wish to express their hearty thanks to Dr. T. Takada of Toho Beslon Co. for his affording of methallyl sulfonate.

The Reaction between Hydrocarbon and Hydrogen Chloride in Silent Electrical Discharge. I. The Reaction of Ethylene with Hydrogen Chloride

Kazuaki KAWAMOTO, Keiko TAMURA, and Setsuko HIKASA

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu, Kagawa 760

(Received October 1, 1975)

Silent discharge was found to induce the reaction of ethylene and hydrogen chloride and to give mainly addition and telomerization products. Discharge on a mixture of ethylene and hydrogen chloride in an ozonizer under atmospheric pressure gave chloroethane, 1-chlorobutane, and 1,4-dichlorobutane as the main products. Besides these compounds, chloroethylene, 2-chlorobutane, 1,3-dichlorobutane, 2,3-dichlorobutane, 1,2-dichlorobutane, 1-chlorohexane, 1,2-dichloroethane, and gaseous products were also formed. The maximum yield of the liquid products was obtained when ethylene and hydrogen chloride were mixed in the ratio of approximately 1 : 1. The formation of telomers was favored by a low ratio of the hydrogen chloride to the ethylene concentration, and by a low temperature in the discharge reaction. On the other hand, gaseous products increased with the rise in the discharge temperature and with an increase in the ratio of ethylene to hydrogen chloride. Judging from the product distribution, the reaction may be explained in terms of radical reactions involving vinyl, ethyl, and chlorine radicals. Among the reactions between ethylene and HX, such as hydrogen cyanide, hydrogen sulfide, and hydrogen chloride, the highest conversion was obtained by using the hydrogen chloride as the reactant.

In recent years, the oxidation of hydrocarbons in silent electrical discharge has been studied by Sugino *et al.*[1]

In particular, the reactions of ethylene with ammonia or oxygen in silent electrical discharge have been reported by them and by Tsutsumi *et al.*[2]

In previous papers,[3] the reactions of a hydrocarbon (ethylene, propylene, and cyclohexane) with hydrogen cyanide, and of a hydrocarbon (ethylene and propylene) with hydrogen sulfide in a silent discharge were reported. When a mixture of ethylene and hydrogen cyanide was discharged in an ozonizer, acrylonitrile could be prepared in one step. Besides this compound, the formation of telomers was observed. Moreover, when a mixture of ethylene and hydrogen sulfide was discharged in an ozonizer, the formation of such telomers as ethanethiol and 1-butanethiol was also observed.

The reaction of ethylene with hydrogen halide has been reported by many investigators. The photochemical addition of hydrogen bromide to olefins has been investigated by Vaughan *et al.*[4] Hanford *et al.*[5] reported the formation of mixtures of straight chain primary alkyl chlorides, ranging from chloroethane to greases and waxes, by the reaction between ethylene and hydrogen chloride in the presence of catalysts and water at a high temperature under a high pressure. It was recognized by Raley *et al.*[6] that the vapor-phase addition of hydrogen chloride to ethylene, as initiated by ultraviolet light or peroxide, yielded chloroethane and small amounts of hydrogen and ethane.

Moreover, it was found by Ford *et al.*[7] that when the reaction of ethylene with hydrogen chloride was carried out in the presence of free-radical initiators and water under ethylene pressures of 100—1000 atm, telomerization took place. The radiation-induced addition of hydrogen chloride to ethylene produced 1-chlorobutane and chloroethane, and this reaction was supposed to be a vapor-phase radical chain reaction.[8] No detailed study of the interaction of ethylene and hydrogen chloride in the silent discharge has yet been reported.

The present study was undertaken to find out whether or not the direct formation of such chloro compounds as chloroethylene, chloroethane, and 1-chlorobutane results from the reaction of ethylene with hydrogen chloride in a silent electrical discharge. Moreover, the differences among the reactions of ethylene with hydrogen cyanide, with hydrogen sulfide, and with hydrogen chloride were discussed. In this research, the silent discharge was carried out in a Siemens ozonizer for 8 h, using a voltage of 15 kV.

Experimental

Materials. The ethylene was purchased from the Nihon Sekiyu Co., Ltd. (Kawasaki), the hydrogen chloride, chloroethylene, and chlorine from the Seitetsu Chemicals Co. (Osaka), and chloroethane from the Tokyo Kasei Co. (Tokyo). These materials were used without further purification. No impurity was found in these reagents by gas chromatographic analysis. (Columns of activated charcoal, Silica gel, and Silicone GE SF-96 were used.)

Apparatus. In this experiment, the apparatus illustrated in Fig. 1 was used. (1) Helium, hydrogen chloride, and ethylene coming from each bomb were passed over calcium chloride (A). (2) The molar ratios of ethylene, hydrogen chloride, chloroethane, chloroethylene, and chlorine were

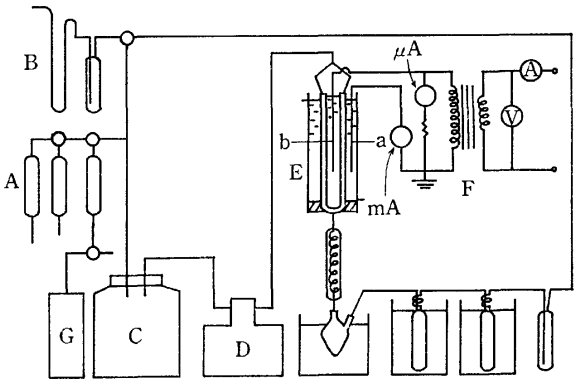

Fig. 1. Apparatus.

roughly determined by means of a manometer (B), and the quantitative analysis of the mixed gas in this experiment was performed by gas chromatography. (A column of Silicone GE SF-96 was used.) (3) The reservoir (C) was filled with a mixture of ethylene, hydrogen chloride, and helium. (4) The mixed gas was circulated by means of a pump (D) at the rate of 2 l/min. (5) The outside (a) of the discharge tube (E) was filled with water, and the inner tube (b) with a 3% copper sulfate solution. (6) The discharge tube (E) used was a Pyrex tube 25 cm in effective length, 3 cm in outside diameter, and with a space gap of 0.25 cm. (7) The electrical energy was supplied by a 15-kV transformer (F).

Procedure. Air in the system was completely replaced by helium, by repeated evacuation and introduction of helium. The volume of the reaction system was 20.7 l. As a diluent, one-third volume (about 6.9 l) of helium was put into the reaction system, then a mixture of ethylene and hydrogen chloride (chloroethane, chloroethylene, and chlorine) at the molar ratios shown in Tables 1, 3, and 5 was put into it. The mixed gas was made homogeneous by using a pump (D) for 30 min and was then passed through the discharge tube at a regular velocity of 2 l/min for the period of the reaction. A current of 60 cycles was passed through a voltage regulator and the voltage was stepped up by a transformer to give the required value. The products coming out of the discharge tube were condensed by passing them through a condenser, then they were collected by being passed through two traps cooled at −50 °C or −70 °C by acetone–Dry Ice. The liquid products were analyzed by the method described below, while the non-condensable gases were analyzed by gas chromatography at intervals of 30 min. The pressure in the system during the period of the reaction was measured at intervals of 30 min.

Identification and Analysis of the Reaction Products. The liquid products obtained by these reactions were identified by comparing their retention times on the gas chromatogram with those of authentic samples. (Columns of tricresyl phosphate, Silicone GE SF-96, Silicone DC 550). In addition, the reaction products were fractionally distilled, and the constituents of the fraction were identified by examining the infrared spectrum. The gaseous products obtained by these reactions were also analyzed by gas chromatography. (Columns of activated charcoal, tricresyl phosphate, silica gel, and Silicone GE SF-96). The gaseous products could not be determined quantitatively. The quantitative analysis of the liquid products in this experiment was performed by gas chromatography.

Results and Discussion

The results obtained by running ethylene with hydrogen chloride in an ozonizer under the conditions described in Tables 1 and 3 are summarized in Tables 2 and 4, respectively. Further, the results obtained by the reactions of chloro compounds with and without ethylene under the conditions listed in Table 5 are summarized in Table 6. The yields of each compound shown in these tables are an average of three experiments under constant operating conditions. The fluctuation in the yields of the compounds obtained in repeated experiments was less than 1 per cent. The gaseous products given by the reaction of ethylene and hydrogen chloride consisted of hydrogen, chlorine, methane, ethane, acetylene, propane, propylene, butane, 1-butene, and 1,3-butadiene.

Influence of the Molar Ratio of Ethylene to Hydrogen Chloride. As can be seen in Table 2, the yield of the reaction products depends upon the molar ratio of ethylene to hydrogen chloride; when the mixed components of the reactant were approximately in the ratio of 1 : 1, the maximum yield of the liquid reaction products was obtained. However, the product distribution depended upon the molar ratio of the reactants as follows: (1) In the case of the range of discharge temperatures from 5 to 50 °C, when ethylene and hydrogen chloride were mixed in the ratio of approximately 1 : 1, the proportion of chloroethane in the liquid products was at its maximum. (2) On the other hand, 1-chlorobutane decreased with the increase in the ratio of hydrogen chloride to ethylene. Thus, it may be said that the yield of telomer with $n=2$ is favored by a low ratio of the hydrogen chloride to the ethylene concentration. (3) The yields of dichloro and trichloro compounds of butane increased with the increase in the ratio of the hydrogen chloride to the ethylene. (4) A small amount of dichloro compounds of ethane were obtained, and their yields increased slightly with an increase in the ratio of the hydrogen chloride to the ethylene. (5) When the discharge reaction was performed at a higher ratio of the hydrogen chloride to the ethylene, a solid black deposit was formed on the wall of discharge tube, and the yield of the solid product thus obtained increased with a rise in the discharge temperature. Chloroethane, 1-chlorobutane, and 1-

chlorohexane seem to be formed by the telomerization between ethylene and hydrogen chloride. The formation of 1-chlorooctane (1 : 4 telomer) and one-to-five or more products could not be observed by gas chromatographic analysis.

Influence of the Discharge Temperature. The discharge reactions were performed at 5, 25, 50, and 75 °C, as shown in Table 1. As may be seen from the results of these experiments shown in Table 2, the conversion efficiency [grams of liquid product/grams of materials (ethylene+hydrogen chloride) used × 100] depends upon the temperature at which the discharge is carried out; when the molar ratio of the reactants was about 1 : 1, the maximum yield of the liquid products was obtained at 25 °C, the proportions of 1-chlorobutane and 1,4-dichlorobutane in the liquid product decreased with increasing temperature, and the gaseous products increased with the rise in the discharge temperature and the increase in the ethylene concentration. It may be said that the telomer formation with $n=2$ is favored by a low temperature.

Influence of the Discharge Time. The discharge reaction was carried out with various reaction times (1, 2, 4, and 8 h), as is shown in Table 3; the results are summarized in Table 4. The total pressure in the reaction system was measured at intervals of 30 min. The results shown in Fig. 2 and Table 4 show that lowering the total pressure increases the amount of the

liquid product. The yield of the reaction products and the velocity of the reduced pressure in the reaction system increased rapidly until 4 h of reaction time, while beyond this, they increased only gradually. Chloroethane in the reaction products decreased with the progress of the discharge time. As may be seen from Experiment No. 4 of Table 2 and Experiment No. 16 of Table 4, when the reaction product coming out of the discharge tube was cooled at −70 °C by acetone–Dry Ice, the conversion efficiency and the yield of chloroethane increased. When the reaction product coming out of the discharge tube was cooled at −50 °C, the yields of telomer with $n=2$ and dichloro compounds of butane increased. These results suggest that the noncondensable chloroethane is concerned in the secondary process.

The Reaction of Ethylene with Chloro Compounds

The mixture of ethylene and several chloro compounds, such as chloroethane, chloroethylene, hydrogen chloride, and chlorine was discharged in an ozonizer under the reaction conditions shown in Table 5; the results are summarized in Table 6. In the reaction of ethylene and chlorine, the main product was 1,2-dichloroethane. This suggests that the addition reaction occurs predominantly on account of the high reactivity of chlorine. As can be seen from Experiment Nos. 18 and 19 in Tables 5 and 6, when the mixtures of chloroethane and hydrogen chloride or of both compounds and ethylene

were discharged, they were mainly transformed into the dichloro compounds of butane. Similar experiments (Nos. 20 and 21) with chloroethylene showed formation of considerable amounts of the trichloro compound (1,2,4-trichlorobutane) and the dichloro compounds of butane. When a mixture of ethylene and hydrogen chloride was discharged in an ozonizer a small amount of chloroethylene in the liquid products was obtained. This suggests that the chloroethylene may be formed by the primary process, but will be rapidly involved in the secondary process owing to its great activity.

The Mechanism of the Formation of the Main Products Obtained by the Reaction of Ethylene and Hydrogen Chloride. The molecules excited by the silent discharge are considered to change into radicals or atoms, and into small amounts of ionized molecules as has been reported by many workers.[9] Accordingly, the reaction of ethylene with hydrogen chloride in a silent electrical discharge is guessed to be a vapor-phase radical reaction. Egloff *et al.*[10] reported that a vinyl radical was formed from ethylene in the electrical discharge, and that it was produced by breaking a carbon-hydrogen bond. Tsutsumi[11] reported that the vinyl radical was produced by two molecular processes,[12] as is shown below. Franklin *et al.*[13] reported the formation of activated monochloroethyl radicals in the photochlorination of ethylene. Golden and Ausloos[14] reported that the vacuum-ultraviolet photolysis of ethylene led essentially to three types of processes, as is indicated below.[15]

The mechanism of the formation of chloroethane, 1-chlorobutane, and 1-chlorohexane by the reaction of ethylene with hydrogen chloride may be represented as follows: The first step is the activation of the ethylene molecule and the hydrogen chloride molecule by electron impact, while the second step consists of both (1) the reaction of the excited ethylene molecule with a normal ethylene molecule to give the vinyl radical and the ethyl radical,[12] and (2) the decomposition of the activated molecules to give the vinyl radical, the chlorine radical, and the hydrogen atom. Chloroethane may be formed by four paths: (1) the combination of the ethyl radical and the chlorine radical; (2) the reaction of the chlorine radical with ethylene, and the reaction between hydrogen chloride and the monochloroethyl radical so formed; (3) the addition of hydrogen atom to the monochloroethyl radical produced by (2); and (4) the formation of chloroethylene by the combination of the vinyl radical and chlorine radical, and then the addition of hydrogen atoms to the chloroethylene thus obtained. The formation of acetylene, 1,3-butadiene, and 1-butene may show the existence of the vinyl radical. And the formation of ethane, butane, and 1-butene may indicate the production of the ethyl

radical. Since chloroethylene as described above has high activity in the presence of hydrogen chloride and ethylene under a silent discharge, it is changed into the dichloro compounds and the trichloro compound (1,2,4-trichlorobutane) of butane. The formation of 1-chlorobutane and 1-chlorohexane may be represented as follows:

$$CH_2{=}CH_2 + \cdot Cl \longrightarrow \dot{C}H_2CH_2Cl$$
$$\dot{C}H_2CH_2Cl + CH_2{=}CH_2 \longrightarrow \dot{C}H_2(CH_2)_3Cl$$
$$\dot{C}H_2(CH_2)_3Cl + HCl \longrightarrow CH_3(CH_2)_3Cl + \cdot Cl$$
$$\dot{C}H_2(CH_2)_3Cl + CH_2{=}CH_2 \longrightarrow \dot{C}H_2(CH_2)_5Cl$$
$$\dot{C}H_2(CH_2)_5Cl + HCl \longrightarrow CH_3(CH_2)_5Cl + \cdot Cl$$

The mechanism mentioned above is the telomerization reaction in which hydrogen chloride acts as the telogen. The addition reaction of the $\cdot CH_2(CH_2)_5Cl$ radical to ethylene in these reaction mechanisms need not be considered, since no products beyond 1-chlorooctane (1:4 telomer) were obtained. Compared with the yield of 1-chlorobutane (1:2 telomer), the yield of 1-chlorohexane (1:3 telomer) decreased remarkably. Therefore, it is considered that the unpaired electron of the end CH_2 and the Cl atom in the $CH_2(CH_2)_3Cl$ radical form a pseudo cyclic arrangement.* On the other hand, the formation of 1,4-dichlorobutane may proceed by two paths: (1) the reaction between $\cdot CH_2(CH_2)_3Cl$ radical and hydrogen chloride or chlorine radical, (2) the coupling reaction between two $\cdot CH_2CH_2Cl$ radicals. Other dichloro compounds of butane may be formed by various secondary processes. The formation of 2-chlorobutane was also observed. 2-Chlorobutane may be formed by two paths: (1) the isomerization of 1-chlorobutane, and (2) the reaction between hydrogen chloride or ethylene and chloroethylene, the addition of CH_3–$\dot{C}HCl$ radical thus obtained to ethylene, and then the reaction of the CH_3CHCl–CH_2–$\dot{C}H_2$ radical and hydrogen chloride.

The Reactions between HX, such as Hydrogen Cyanide, Hydrogen Sulfide, and Hydrogen Chloride, and Ethylene. The reactions of ethylene with hydrogen cyanide or hydrogen sulfide in the silent electrical discharge were carried out.[3] The results obtained are summarized in Table 7. In the case of the reaction between ethylene and hydrogen cyanide, the main product was acrylonitrile. Besides this compound, ethyl cyanide, butyl cyanide, and *s*-butyl cyanide *etc.* were obtained. No compound combined with two CN groups was obtained. In the case of the reaction between ethylene and hydrogen sulfide, the main product was ethanethiol. However, the product (1,2-ethanedithiol) combined with two SH groups was formed. As may be seen from Tables 2 and 7, when hydrogen chloride, hydrogen sulfide, and hydrogen cyanide as reactants (HX) were used, the yields of the liquid products decrease in the following order: HCl>H_2S>HCN. When the hydrogen chloride was used, the yield of liquid product was especially remarkable.

* Beer and Besprozvannyi[16] found, from their data on the telomerization of ethylene in carbon tetrachloride and chloroform, that compounds ($ClCH_2(CH_2)_3CCl_3$ and $CH_3(CH_2)_3CCl_3$) with $n=2$ were formed over a wide range of ethylene concentration. They suggested that the predominance of telomers with $n=2$ resulted from the stabilization of the trichloroamyl radical by a "pseudo cyclic" configuration between the unpaired electron of the end CH_2 and the electrophilic CCl_3 groups.

Chemistry of 1,3-Glycol Derivatives. I. The Reactions of 2,4-Pentanediol Derivatives

Osamu ITOH, Yasunori ICHIKAWA, Hiroaki KATANO, and Katsuhiko ICHIKAWA

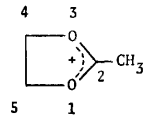
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

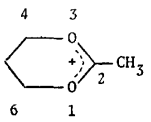
(Received October 16, 1975)

Cyclic orthoacetates of *meso*- and *dl*-2,4-pentanediol (*cis*- and *trans*-2-ethoxy-2,4,6-trimethyl-1,3-dioxane, **1**) were prepared and characterized by NMR. The stereochemical courses of the reactions of **1** with water, hydrogen chloride, trityl chloride, and acetic acid were investigated. The reactions with water gave 4-acetoxy-2-pentanol (**4**) with complete retention of configuration, while those with the other reagents gave 4-acetoxy-2-chloropentane (**3**) and 2,4-diacetoxypentane with complete inversion. Acetolyses of **3** and the tosylate of **4** gave 2,4-diacetoxypentane predominantly with retention in the absence of water. Hydrolysis of the tosylate gave **4** with almost complete inversion. These results can be explained by the mechanism that the reactions proceed mainly through acetoxonium cation intermediate involving six-membered ring. The fluoroborate salt of this acetoxonium cation was prepared and characterized by NMR.

As a case of neighboring group participation, acetoxy participation has been studied extensively by Winstein and his co-workers.[1] Participation of acetoxy group attached to the carbon α to the cationic carbon forms acetoxonium cation of five-membered ring (AcO-5 cation). Participation of the same group at the β-position should from acetoxonium cation of six-membered ring (AcO-6 cation).

AcO-5 cation





AcO-6 cation

So far, most part of the studies has been concerned with the former type of participation, and only few papers by Kovács and his co-workers[2] discussed the latter type, although the idea was reviewed by Schneider without presenting experimental data.[3]

This paper describes the preparation of *cis*- and *trans*-2-ethoxy-2,4,6-trimethyl-1,3-dioxane (*cis*- and *trans*-**1**) from *meso*- and *dl*-2,4-pentanediol (*meso*- and *dl*-**2**) and ethyl orthoacetate, and the formation of AcO-6 cation from **1**. The stereochemistry of the reactions of **1** with water, hydrogen chloride and trityl chloride is also reported together with the results of the acetolyses of 4-acetoxy-2-chloropentane (**3**) and the tosylate of 4-acetoxy-2-pentanol (**4**) which proceeded mainly through AcO-6 cation.

Preparation and Characterization of cis- *and* trans-*1*. From the reduction product of acetylacetone with sodium borohydride, *meso*- and *dl*-**2** were separated by the method of Pritchard and his co-workers.[4] The diols were converted to cyclic sulfite by the reaction with thionyl chloride and then subjected to fractional distillation. Hydrolysis of the lower boiling fraction gave pure *meso*-**2** and that of higher boiling fraction gave *dl*-isomer of 98% purity.

The method for the preparation of five-membered cyclic orthoester by Newman and his co-workers[5] was applied successfully to the present case of six-membered cyclic system. The reactions of *meso*- and *dl*-**2** with ethyl orthoacetate in benzene containing catalytic amounts of monochloroacetic acid gave *cis*-**1** and *trans*-**1** in more than 80% yields, respectively. Both *cis*-**1** and *trans*-**1** were very sensitive to atmospheric moisture and could not be stored for more than two days unless special precautions were made. However, both of them could be analyzed by gas chromatography, although slight extents of decomposition were observed.

NMR data of *cis*-**1** and *trans*-**1** are shown in Table 1.

TABLE 1. NMR DATA OF **1** IN DEUTERIOCHLOROFORM

	cis-**1**			*trans*-**1**		
	δ			δ		
C_2–CH_3	1.47	s	3H	1.45	s	3H

OCH_2CH_3	3.52	q	2H	3.55	q	2H

Eliel and his co-workers reported extensive studies on the conformational analyses of 1,3-dioxane system. When methyl group is attached to C_2 of 1,3-dioxane system, the equatorial position is preferred to the axial by 3.6—4.1 kcal/mol, because of the strong crowding between the axial methyl at C_2 and hydrogens or methyl groups at C_4 and C_6. On the other hand, alkoxy group at C_2 prefers the axial position (by 0.35 kcal/mol in the case of 2-alkoxy-1,3-dioxane) by a substantial anomeric effect.[6] Applying these conclusion, the configurations and conformations of *cis*- and *trans*-**1** are depicted in Fig. 1. The NMR data can be explained reasonably.

The protons of two methyl groups attached to C_4 and C_6 of *cis*-**1** give only one doublet at $\delta=1.16$ because the two methyl groups are equivalent, while those of *trans*-**1** give two doublets at $\delta=1.19$ and 1.34. Two methyl groups of *cis*-**1** must be equatorial, since the signals should be observed at much lower fields, if they were axial. Protons at C_4 and C_6 of *cis*-**1** give only one multiplet at 4.17 because they are equivalent, while those of *trans*-**1** give two multiplets at 4.06 and 4.26. In general, the diaxial repulsion in dioxane system is larger than that in cyclohexane system because of the shorter length of C–O bond than that of C–C. It appears, therefore, to be unnecessary to consider the possibility that all of the two methyl and ethoxy groups

are axial, since the steric effects will prevent the formation of such a highly strained compound. Since Eliel suggested that 2,2-*trans*-4,6-tetramethyl-1,3-dioxane takes skew boat conformation predominantly, the same conformation must be considered in the case of *trans*-**1**. To discriminate the chair and skew boat conformations, it is necessary to determine the coupling constants between C_4–H and C_5–H and C_5–H and C_6–H exactly. From the spectrum obtained, however, it is difficult to estimate these coupling constants. Whether the chair form or the skew boat form is preferred cannot be discussed at present. NMR data can be explained reasonably in terms of both conformations. In the case of *cis*-**1**, skew boat conformation appears to be unlikely because of the strong 1,3-repulsions.

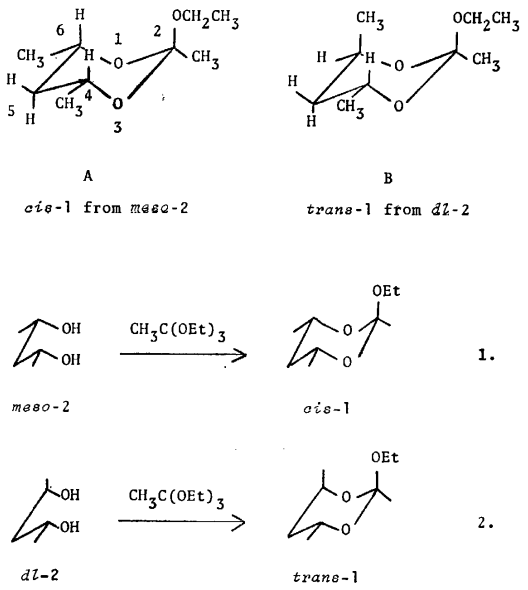

Fig. 1. Conformations and configurations of *cis*-**1** and *trans*-**1** and the stereochemistry of the formation of *cis*-**1** and *trans*-**1**.

Stereochemistry of the Reaction of **1** *with Water, Hydrogen Chloride, and Trityl Chloride.* Although a number of cyclic orthoester has been prepared by Newman and his co-workers, it appears that the stereochemistry of the nucleophilic substitution has been studied only for those with trityl chloride and trimethylsilyl chloride in methylene chloride by the same authors which proceeded with inversion. They explained the results by assuming the ionization of the substrates to AcO-5 cations and the subsequent attack of the nucleophile on the cations.[5] We have examined the stereochemical courses of the reactions of **1** with several kinds of reagent.

Treatments of *cis*- and *trans*-**1** with water–ethanol mixture (20: 80 by volume) at room temperature gave *erythro*- and *threo*-4-acetoxy-2-pentanol (**4**) in almost quantitative yields, respectively. The results show that the reactions proceeded with complete retention. On the other hand, the reactions of the same *cis*- and *trans*-**1** with trityl chloride (under reflux) or hydrogen chloride (at 0 °C) in methylene chloride gave *threo*- and *erythro*-4-acetoxy-2-chloropentane (**3**) also in almost quantitative yields, respectively. It is clear that the reactions proceeded with complete inversion. The sharp contrast of the stereochemical courses mentioned above makes it clear that the mechanism of the reactions with water–ethanol mixture is different from those with trityl chloride or hydrogen chloride in methylene chloride.

Since the stereochemistry of the latter reactions is the same as that of the case of five-membered cyclic orthoester by Newman, it appears that the mechanism is also the same.

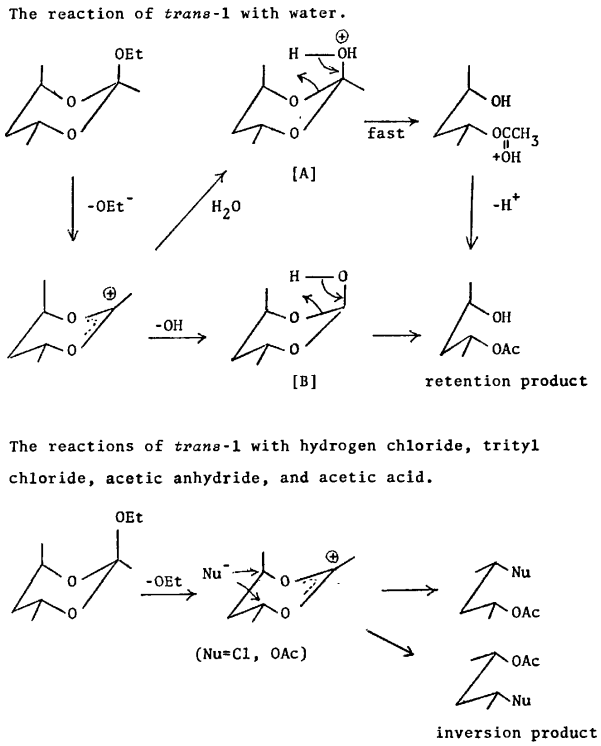

Fig. 2. Mechanisms of the reactions of *trans*-**1** (*cis*-isomer follows the same mechanism).

The most probable mechanism to explain the retentive course of the reaction with water–ethanol mixture is depicted in Fig. 2. If the product **4** is obtained by the reaction of water or hydroxide ion with the AcO-6 cation from **1** as in the cases of hydrogen chloride and trityl chloride, the stereochemistry should be inversion. The mechanism proposed to explain the results of retention assumes the ionization of **1** to form AcO-6 cation, the subsequent reaction with water or hydroxide ion to yield oxonium ion type intermediate (A) or its deprotonated type (B), and the collapse of A or B to form the final product **4** by bond reconstruction involving proton transfer. Since the stereochemistry of the reaction with the same water–ethanol (20: 80 by volume) mixture containing 2 M NaOH was also complete retention, it appears that both reaction routes through A and B are operative.

The steric courses of the reactions of **1** with several other reagents were examined qualitatively by analyzing the reaction mixtures at room temperature directly by gas-chromatography. Acetic anhydride which was completely free from water gave 2,4-diacetoxypentane

results reasonably. Here again, however, the acetolysis without participation as a minor reaction appears to be operative, since the products with inversion were obtained as the minor products. In moist acetic acid–acetic anhydride mixture, the primary main product of the reaction of *threo*-**3** was *erythro*-**4** with inversion showing that the reaction of water with AcO-6 cation is very fast as already mentioned. After a sufficient reaction time, the main product became *meso*-**6** by the acetylation of **4** under the condition. Undoubtedly, the acetylation does not change the configuration of the substrate since the bond breaking of C–OH is not involved in this reaction step. It is concluded, therefore, that the AcO-6 cation formation which was assumed in the reactions of steroid[7] and (2-acetoxycyclohexyl)-methyl cation system[2] is also important in the solvolysis of acyclic 1-acetoxy-3-ol system and that the presence of water changes the steric course of the reaction.

Structural assignments of 2, 3, 4, 5, and 6. The structural assignments of *erythro* and *threo* or *meso* and *dl* of the substrates and products can be made by converting them to **2** or **6** whose physical constants (mp) are known. By NMR, however, the discriminations are possible also. Methylene signal of *dl*-**6** is a doublet (J=8 Hz) of doublet (J=6 Hz), while that of *meso*-isomer is a doublet (J=14 Hz) of triplet (J=6 Hz). This difference is due to the fact that the *dl*-isomer is more symmetrical than *meso* about the the central carbon C_3. According to this principle, the assignments of the other compounds have been made. In the case of **4**, methylene signal of *threo*-isomer was a triplet (J=9 Hz) of doublet (J=3 Hz) at δ 1.61, while the signals of the *erythro* were two pairs of multiplet at δ 1.57 and 1.85. The relationship between the symmetry of the structure and the shape of the signal can be applied to the case of methine proton too. The methine signals of **5** at C_2 and C_4 should be different, since the substituents are different, although they are very similar. In the case of *erythro*-isomer, the two methine protons gave a sextet at δ 4.96 and a broad multiplet at δ 4.92 and those of *threo* gave a triplet-like signal at δ 1.79. NMR data are summarized in Table 3.

Preparation of Fluoroborate salt of 2,4,6-Trimethyl-1,3-dioxane-2-ylium Cation. Many kinds of 1,3-dioxolan-2-ylium cation (AcO-5 cation type) salt have been prepared by various methods.[8] On AcO-6 type cation salt, however, only few papers are found in the literature.[9] We have prepared the fluoroborate salt of the present AcO-6 cation.

Dropwise addition of boron trifluoride–ether complex to ether solution of **1** at room temperature resulted in the formation of oily drops which became colorless crystals after standing for several days in refrigerator. The crystals were so hygroscopic that elemental analysis and IR and mp measurements by usual methods were difficult. The raw crystals, just after filtration, were dissolved into dry nitrobenzene and subjected to NMR measurement. In Fig. 4, the spectra of the salt and

a) CH_3 bonded to phenyl, 2.50. b) Because of the overlapping with the peak of acetyl protons, the signals could not be determined. c) CH_3 bonded to phenyl, 2.47.

precursor **1** are shown. In the former, the signals due to ethoxy group disappeared and all signals shifted to lower fields as compared to the corresponding signals of **1**. The shifts are especially remarkable in those of C_2-methyl protons and C_4 and C_6 methine protons. In the case of the cation from *trans*-**1**, methyl protons attached to C_4 and C_6 gave only one doublet at δ 1.87 and two methine protons of the same C_4 and C_6 gave also only one multiplet at δ 5.67. It appears that the rapid flattering of the six-membered ring resulted in such observations. In the case of the cation from *cis*-**1** the flattering is considered to be difficult because the diaxial form should be much less stable than the di-equatorial form by the strong steric crowding.

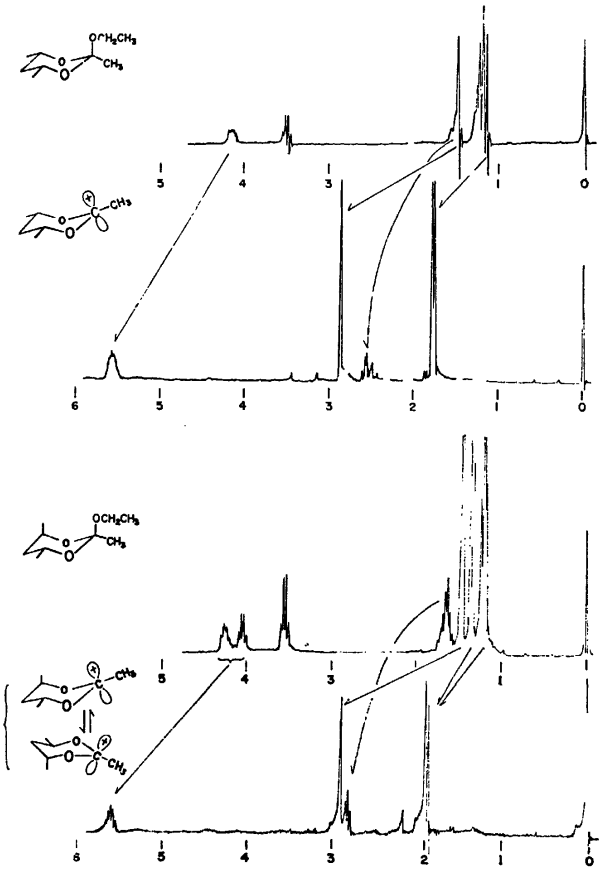

Fig. 4. NMR spectra of *cis*- and *trans*-**1** and fluroborate salts of the corresponding cations.

Experimental

Preparation of dl-*and* meso-**2**. According to the method reported by Pritchard *et al.*, 2,4-pentanediol, which was obtained by sodium borohydride reduction of acetylacetone, was converted to cyclic sulfite by equivalent amount of thionyl chloride. Fractional distillation gave *cis*-(bp 57.8 °C/6 Torr) and *trans*-sulfite fraction (bp 65.4 °C/6 Torr). Analyses by gas-chromatography (EGSS-X 1m column) showed that the purities were 96 and more than 98%, respectively. Hydrolyses of the both fractions gave *meso*-**2** (bp 85—87 °C/7 Torr) and *dl*-**2** (99—100 °C/11 Torr, mp 47.5—49 °C), respectively.

Preparation of cis- *and* trans-*1*. Into a benzene (50 ml) solution containing 11.4 g of *meso*-**2** and catalytic amount (ca. 100 mg) of monochloroacetic acid, 25 g of freshly distilled ethyl orthoacetate were added under stirring. After refluxing for 3 h, benzene and ethanol formed were removed. Distillation under vacuum gave *cis*-**1** (bp 81—83 °C/40 Torr, 15.1 g). IR (liquid film): 1255 (s, ν_{as} C–O–C), 1195 (m), 1150 (m), 1120 (m), 1100 (sh), 1060 (s, ν_s C–O–C) cm^{-1}.

By the same method, *trans*-**1** was obtained from *dl*-**2** in 87% yield (bp 82.5 °C/40 Torr). IR (liquid film): 1245 (s, ν_{as} C–O–C), 1180 (m), 1150 (m), 1140 (sh), 1115, and 1055 (s, ν_s C–O–C) cm^{-1}.

Reaction of 1 with Water. Into 80 ml of 80% ethanol, 27.9 g of *cis*-**1** were added under stirring at room temperature After 1 h, ethanol was distilled off from the reaction mixture. Ether extract of the residue was washed with aqueous saturated sodium chloride solution, dried with sodium sulfate and then distilled to give *erythro*-**4** (bp 107—109 °C/22 Torr) in 94% yield (22.2 g). Analysis by glc. with EGSS-X column showed that the purity was more than 98%. IR in CCl_4: ν_{OH}, 3620 (sh), 3480 (br); ν_{CO}, 1740 (br), 1720 (sh); 1150, 1110 (br), 1035, 1020, 955 cm^{-1}.

From 17.3 g of *trans*-**1**, 13.0 g (90% yield) of *threo*-**4** of more than 96% purity were obtained by the same procedure. IR in CCl_4: ν_{OH}, 3630 (w), 3520 (br); ν_{CO}, 1740 (sh), 1720; 1280 (sh), 1260, 1250, 1150, 1020, 1010, 970, and 940 cm^{-1}.

The half esters of *erythro*- and *threo*-**4** were converted to *meso*- and *dl*-**6** by acetylation with acetyl chloride in pyridine, respectively. The physical constants and IR and NMR spectra were identical with those of the authentic samples which were prepared from *meso*- and *dl*-**2** by the reported method.[10]

Reaction of 1 with Hydrogen Chloride. Into a methylene chloride (50 ml) solution of *cis*-**1** (3.5 g), dry hydrogen chloride (0.04 mmol, 2 equivalents) was added at 0 °C. After 30 min, the reaction mixture was washed with water, dried with sodium sulfate and subjected to distillation. *threo*-**3** was obtained (2.3 g, 70% yield, bp 82—84 °C/22 Torr). Analysis by GLC showed that no detectable amount of by-product was formed. By the same experimental method, the reaction of *trans*-**1** gave *erythro*-**3** in 68% yield (83.5—86.5 °C/25 Torr).

Reaction of 1 with Trityl Chloride. A mixture containing 3.48 g of *cis*-**1**, 5.58 g of trityl chloride and 50 ml of methylene chloride was kept at 42 °C for 3.5 h. Distillation of the reaction mixture gave 2.75 g of *threo*-**3** (83% yield). By the same experimental procedure, *erythro*-**3** (2.70 g) was obtained from *trans*-**1**. Both products were shown to contain no other products by GLC. The IR and NMR spectra were identical with those of the products obtained by acetylation of *erythro*- and *threo*-**4**, respectively.

Preparation of 3. Thionyl chloride (3.8 g) was added to an ether (15 ml) solution of *threo*-**4** (2.48 g). The mixture was heated under reflux for 2 h, washed with saturated aqueous solution of sodium hydrogencarbonate, extracted with ether, dried, and distilled. The product was *threo*-**3**, bp 82—84 °C/22 Torr, 1.83 g (65 % yield).

Similarly, *erythro*-**3**, bp 82—83 °C/22 Torr, was obtained from *erythro*-**2** in 78% yield.

Preparation of 5. Into pyridine (50 ml) solution of

Table 5. Analytical data

		Calcd for			Observed		
		C	H	Cl, S	C	H	Cl, S
cis-**1**	$C_9H_{18}O_3$	62.04	10.41		61.85	10.33	
trans-**1**					62.06	10.65	
meso-**2**	$C_5H_{10}O_2$	57.66	11.61		57.85	11.58	
dl-**2**					57.69	11.64	
erythro-**3**	$C_7H_{13}O_2Cl$	51.07	7.96	21.54	51.34	8.03	21.57

erythro-**4**	$C_7H_{14}O_3$	57.51	9.65		57.57	9.81	
threo-**4**					57.81	9.72	
erythro-**5**	$C_{14}H_{20}O_5S$	55.98	6.71	10.67	55.95	6.82	10.56
threo-**5**					56.02	6.89	10.66

erythro-**4** (2.96 g), *p*-toluenesulfonyl chloride (6.1 g) was added dropwise under cooling with ice bath. The mixture was kept in refrigerator (−15—−18 °C) for two days, poured into ice-water, extracted with ether and dried with K_2CO_3–Na_2SO_4. When ether was removed, oily product was obtained. This product was dissolved into 200 ml of petroleum ether, heated to about 40 °C and filtered to remove impurities. After standing in refrigerator for 24 h, crystals formed were collected and recrystallized from the same solvent, mp 32—34 °C (5.15 g, 86% yield). The structure of *erythro*-**5** was confirmed by NMR spectrum. From *threo*-**4**, *threo*-**5**, mp 60—61 °C, was obtained in 82% yield similarly.

Solvolysis Reactions. The reactions were carried out in ampoules. The experimental procedure was analogous to that of the reaction of **1** with water.

Preparation of 2,4,6,-trimethyl-1,3-dioxane-2-ylium fluoroborate. Into 15 ml of dry ether, 5.55 g of *cis*-**1** was dissolved. Boron trifluoride–ether complex (5.2 g) was added slowly. The mixture was kept in refrigerator for two days. Removing ether, 6.48 g of the salt were obtained and characterized by NMR. The same procedure gave the salt of *trans*-isomer.

NMR spectra were recorded on a Varian Associates HR-220 at 220 MHz at room temperature. Gas-chromatograph analyses were carried out with YANACO GC-550 TPH. IR spectra were recorded on HITACHI EPI-G2.

This work was partially supported by a Grant-in-Aid for Scientific Research from the Ministry of Education, Japan (No. 911503).

^{13}C NMR Spectra of Some Methyl Cyclohexanecarboxylates

Yasuhisa SENDA, Jun-ichi ISHIYAMA, and Shin IMAIZUMI

Department of Applied Science, Faculty of Engineering, Tohoku University, Aoba, Sendai 980

(Received October 23, 1975)

^{13}C NMR spectra of a series of stereoisomeric-substituted methyl cyclohexanecarboxylates have been obtained. The resonances for ring carbons of the isomers, in which both the methoxycarbonyl and the other groups have equatorial orientations, usually appear at a field lower than those of the isomers in which one of the two substituents has an axial orientation. No appreciable difference in shift due to the configurational change is observed in the resonances for the substituents. Observed chemical shifts are compared with predicted values.

In ^{13}C NMR spectra it is generally found that various substituents exert shielding effects which are additive for families of compounds. As a result, the positions of ^{13}C signals for closely related materials may often be predicted with good precision in a wide variety of systems.[1] It has been reported that the ^{13}C chemical shifts predicted from those of conformational isomers of cyclohexanol and substituent parameters already reported are in good agreement with those observed in previous studies on series of stereoisomeric substituted 1-methylcyclohexanols[2] and menthols.[3] This paper is a report on a study of the ^{13}C NMR spectra of some substituted stereoisomeric methyl cyclohexanecarboxylates. The ^{13}C chemical shifts observed are compared with those predicted.

Results and Discussion

Natural-abundance 25.15-MHz ^{13}CFT NMR spectra were obtained using the ^{1}H noise decoupling technique. The signals were assigned by comparing signal shifts due to differences of structure between closely related compounds and by the use of the ^{1}H off-resonance decoupling technique.[1] The chemical shifts δ obtained are listed in Table 1.

Ring Carbons. The resonances for ring carbons of isomers, in which the methoxycarbonyl and other groups have an equatorial orientation, usually appear at a field lower than those of isomers, in which one of the two substituents has an axial orientation, except for the C-3 and C-4 resonances in methyl 4-*t*-butylcyclohexanecarboxylate (Table 2).

From the observed ^{13}C chemical shifts of *t*-butylcyclohexane and of stereoisomeric methyl 4-*t*-butylcyclohexanecarboxylates, substituent parameters for a methoxycarbonyl group on ring carbons were estimated. These are tabulated in Table 2.

Parent cyclohexanecarboxylate exists in a conformational mixture, the population of which is estimated as being approximately 89.5% of the equatorial conformer and 10.5% of the axial conformer, since the conformational free energy of a methoxycarbonyl group on a cyclohexane ring is 1.25 kcal/mol.[4] As a cnsequence, the carbon chemical shifts predicted are obtained from those of each set of conformers according to a previously outlined procedure.[2] These values are in good agreement with those observed. Conformational free energies of a methyl and a hydroxyl group on a cyclohexane ring are 1.7 and 0.7 kcal/mol, respectively. The conformational distribution of *cis* 2- and 4- or

	Equatorial	16.6	2.2	−1.1	−1.0				

a) The numbering system follows the methyl *t*-butylcyclohexanecarboxylate. b) These values are taken from J. D. Roberts, F. J. Weigert, J. I. Kroschwitz, and H. J. Reich, *J. Am. Chem. Soc.*, **92**, 1338 (1970). c) These values are taken from M. Gordon, S. H. Grover, and J. B. Stothers, *Can. J. Chem.*, **51**, 2092 (1973).

trans 3-methylcyclohexanecarboxylates, therefore, are estimated to be approximately 67% of the equatorial methyl conformers and 33% of their axial methyl counterparts, and those of *cis* 2- and 4- or *trans* 3-hydroxycyclohexanecarboxylates are estimated to be approximately 28% of the equatorial hydroxyl conformers and 72% of their axial hydroxyl counterparts. Taking into account the substituent parameters of the methyl group reported by Grant and Dalling[5] and those of the hydroxyl group which are estimated from the chemical shifts for *t*-butylcyclohexane and stereoisomeric 4-*t*-butylcyclohexanols,[2] the chemical shifts predicted are obtained in a way similar to those of the parent cyclohexanecarboxylate. *cis* 1,2- and 1,4- or *trans* 1,3-Cyclohexanedicarboxylates undergo rapid interconversion between equivalent conformers, while alternatives exist exclusively in more stable conformations. These chemical shifts are also tabulated in Table 1. Most of them are in good agreement with those observed, deviations being within $\pm$0.9 ppm.*

Appreciable deviations between predicted and observed values appear in 2-substituted cyclohexanecarboxylates, especially for C-1 and C-2 resonances. The δ values observed are smaller than those predicted. Grant and Dalling[5] also found that the upfield shift caused by some of the gross effects appeared for the C-1 and C-2 resonances in 1,2-dimethylcyclohexanes. These shifts may be due to the bond deformation of these carbons by the gauche interaction between two vicinal substituents.

Substituents. The resonances for the carbonyl carbons of the ester groups in *cis* and *trans* 4-*t*-butylcyclohexanecarboxylates appear at δ 175.40 and 176.37, respectively. No shift difference is observed for the carbon of the ester methyl group in a set of stereoisomers. These results show that the orientational difference of the methoxycarbonyl group has a slight effect on the chemical shifts of their own carbons. Practically, very small shift differences occur in each pair of isomers. The ^{13}C NMR spectra of stereoisomeric 1-*t*-butyl-4-methylcyclohexanes show that the chemical shift for an axial methyl group in a cyclohexane ring is δ 17.53 and that that for an equatorial group is δ 22.53.[3] Using these δ values, the chemical shifts predicted for the methyl groups of methylcyclohexanecarboxylates are estimated (Table 1). In the case of 2-methylcyclohexanecarboxylate, there are appreciable shift differences between the observed and predicted values, while the chemical shifts for 3- and 4-methylcyclohexanecarboxylate are in good agreement with the predicted values, deviations being within $\pm$0.3 ppm. Such deviations for 2-methyl isomers suggest that the gauche interaction between these two vicinal substituents plays a major role in shifts to higher field.

The ^{13}C NMR spectrum of the lactone of 3-hydroxycyclohexanecarboxylic acid (1,3-cyclohexanecarbolactone) was obtained. The cyclohexane ring of this compound is considered to be more puckered than that of ordinary cyclohexanes produced by lactone formation. Since C-5 is the γ-position of both axial alkoxycarbonyl and acyloxy groups, a significant upfield shift is expected. The resonance at δ 18.50 corresponds to this carbon. The resonances at δ 37.67 and 28.75 cannot be assigned to specific carbons.

^{1}H NMR spectra of cyclohexanecarboxylates were also examined. ^{1}H signals for the methyl groups on the cyclohexane ring appear at about δ 0.83—0.90 and those for the methoxycarbonyl groups at about δ 3.60—3.67. Only a very small shift difference was observed in a set of stereoisomeric cyclohexanecarboxylates.

Since ^{13}C chemical shifts are affected by stereochemical differences, the predicted chemical shifts derived from the A values and the substituent parameters are helpful to a certain extent in assigning the resonance signals to specific carbons.

Experimental

NMR Spectra. The ^{13}CFT-NMR spectra were obtained at 25.15 MHz on a JEOL JNM-MH-100 instrument equipped with a JNM-MFT-100 Fourier transform accessory. The instrument was controlled with a JEC-6 spectrum computer. Samples were dissolved in $CDCl_3$, the deuterium signal of which provided a field frequency lock; the concentrations were 30% (w/v). Measurement conditions were as follows: pulse width, 27.5 μs (*ca.* 45°); repetition time, 4 s; spectral width, 6.25 kHz; data points, 8192; acquisition time, 0.655 s. Noise modulated proton decoupling was carried out at a nominal power of 20 W. All chemical shifts are expressed in δ (ppm downfield from internal Me_4Si). Each observed chemical shift is estimated to be accurate to within δ $\pm$0.05.

Materials. All the materials employed in this work are known compounds. *o*-Toluic acid was hydrogenated over PtO_2 in AcOH to give 2-methylcyclohexanecarboxylic acid. The composition of the resulting mixture was 92% of the *cis* and 8% of the *trans* acids. A part of this was refluxed with KOH in ethylene glycol giving mixture of 78% of the *trans* and 22% of the *cis* isomers. The PtO_2 hydrogenation of *p*-toluic acid gave a mixture of 95% *cis* and 5% *trans* 4-methylcyclohexanecarboxylic acids, the isomerization of which gave a mixture of 84% of the *trans* and 16% of the *cis* isomers. The

PtO_2 hydrogenation of *m*-toluic acid gave 83% of *cis* and 17% of *trans* 3-methylcyclohexanecarboxylic acids. Methyl hydroxycyclohexanecarboxylates were prepared by the method of Kilpatrick and Morse.[6] *cis* and *trans* Cyclohexane-1,2-dicarboxylic acids and *cis* cyclohexane-1,4-dicarboxylic acid were obtained commercially. Isomerization of *cis* cyclohexane-1,4-dicarboxylic acid with KOH, followed by recrystallization from H_2O gave pure *trans* isomer. Cyclohexane-1,3-dicarboxylates were prepared from isophthalic acid by the method of Smith and Byrne.[7] The Raney Ni hydrogenation of methyl *p*-*t*-butylbenzoate at high hydrogen pressure and high temperature gave a mixture of 60% *cis* and 40% *trans* methyl 4-*t*-butylcyclohexanecarboxylates. All carboxylic acids were converted to methyl esters by treatment with diazomethane in the usual manner. Each mixture of methyl 2-, 3- or 4-methylcyclohexanecarboxylates, or methyl 4-*t*-butylcyclohexanecarboxylates was subjected to preparative gas chromatography to give a pure *cis* or *trans* isomer.

Trifluoroacetylation at the 3 Position of 1-(2-Aminophenyl)-2,5-dimethylpyrrole in Trifluoroacetic Acid. Possible Remote Control of an Amino Group in Electrophilic Substitution

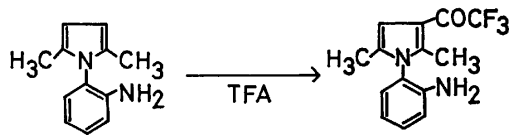
Kimie IMURO and Terukiyo HANAFUSA

Chemistry Department, Faculty of Science, Hiroshima University, Higashi-senda-cho, Hiroshima 730

(Received October 23, 1975)

Spontaneous trifluoroacetylation at the β position of the pyrrole ring in 1-(2-aminophenyl)-2,5-dimethylpyrrole (**1**) was observed in trifluoroacetic acid. The half-life of the reaction was about 3.5 h at 25 °C. This unexpected result might be explained in terms of the 1,5-participation of the amino group in the electrophilic substitution reaction.

The pyrrole ring is known as one of the most sensitive aromatics in electrophilic substitutions. Even trifluoroacetic anhydride, which dose not acylate benzene derivatives without a catalyst, reacted quite readily with a pyrrole to afford a trifluoroacetyl derivative.[1] The partial rate factor for the α position of pyrrole has been estimated up to 10^{18} compared with a single position of benzene.[2] We now wish to report the trifluoroacetylation of 1-(2-aminophenyl)-2,5-dimethylpyrrole (**1**) in trifluoroacetic acid (TFA).



(1) (2)

Results and Discussion

It was incidentally observed during the NMR measurement that the spectrum of **1** in TFA gradually changed from its initial pattern to another spectrum. When the solution was kept at 25 °C for 48 h, a substance (mp 84—86 °C) was isolated by quenching the solution with a base. Judging from the spectral data given in Table 1, the substance thus obtained was easily identified as the 3-trifluoroacetyl derivative (**2**) of **1**. Since the NMR spectrum of **2** in TFA was almost identical with the final spectrum of **1**, the substance (**2**) was shown to be the major product under the conditions.

Despite the presumption that the *N*-trifluoroacetylation of an amino group in **1** is more feasible than *C*-acylation at the β position of the pyrrole ring, the trifluoroacetylamino derivative could not be detected. Also, there was no such significant alteration in the NMR spectrum of the other substituted derivatives, including the 2-hydroxy (**5**), 2-iodo (**7**) and 4-amino substituents (**8**), in a solution of TFA, even at higher temperatures. In these cases, the materials were recovered without any substantial change after quenching. Thus, trifluoroacetylation at the β position of **1** may be regarded as a unique example among these pyrrole derivatives.

	X
1	2'-NH_2
3	2'-$NHCOCF_3$
4	H
5	2'-OH
6	2'-CH_3
7	2'-I
8	4'-NH_2
9	4'-Cl

The following explanation might be proposed for this phenomenon. Powerful mineral acids, such as nitric or sulfuric acids, function by themselves as electrophilic reagents toward aromatics. Since TFA is almost as acidic as nitric acid, it may be anticipated that TFA would autocatalytically produce a trifluoroacetyl cation which could in turn bring about electrophilic substitution with highly reactive aromatic compounds. Also, the electrophilic substitution of five-membered hetero-aromatics generally proceeds to the transition state very close to the intermediate cation, *i.e.*, the σ complex.[3] Thus, extraordinary stabilization would have to work in the reaction intermediate of the present example.

An amino group generally plays an important role in the neighbouring-group participation of various reactions in which cationic species are the intermediates. Especially, 1,5-participation by this group has been eminent in solvolytic displacement.[4] Since 1-(4-aminophenyl)-2,5-dimethylpyrrole and other derivatives did not give the trifluoroacetyl compound under the same conditions, 1,5-participation by the 2-amino group would operate in the rate-determining formation of the cationic intermediate, as is shown below.

Another possible interpretation is the rearrangement of the 2-trifluoroacetylamino derivative (**3**) into **2**. The

The Base-Catalyzed Condensation Reaction of *o*-Nitroisobutyrophenone in Liquid Ammonia

Kimiko YAMAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku Osaka 558

(Received October 29, 1975)

The base-catalyzed condensation reaction of *o*-nitroisobutyrophenone (III) with sodium acetylide in liquid ammonia gave 1-ethynyl-2-methyl-1-(*o*-nitrophenyl)-1-propanol (**G**) as the main product and *o,o'*-azoxybenzamide (**C**), 2-carbamoyl-2'-carboxyazoxybenzene (**C'**), 2,2-dimethyl-3-indolinone (**D**), 1-hydroxy-2,2-dimethyl-3-indolinone (**E**), and 1-hydroxy-2,2-dimethyl-1,2-dihydro-4-quinazolone (**F**) as minor products. On the other hand, with sodium amide the ketone (III) gave Compounds **C** and **C'** as the main products and Compounds **D**, **E**, and **F** as the minor products. These products were formed by the α-proton abstraction.

The base-catalyzed condensation of *o*-nitrophenones in liquid ammonia gave rise to abnormal reactions.[1]

The treatment of *o*-nitroacetophenone (I) with sodium acetylide in liquid ammonia mainly gave Compound (**A**): 1,3-dihydroxy-3-methyl-2-(*o*-nitrophenacylidene)-indoline.[2,3] In the case of *o*-nitropropiophenone (II), 2-(1-carbamoylethyl)-1-(*o*-hydroxyphenyl)-2-methyl-3-indolinone (**B**) was obtained as the main product.[4]

In this experiment, *o*-nitroisobutyrophenone (III) was subjected to a similar reaction. The structures of these products and the mechanisms of their formations will be discussed.

Results

o-Nitroisobutyrophenone (III) was synthesized by the following two methods, analogous to these used in preparation of *o*-nitropropiophenone: 1) the hydrolytic decarboxylation of methyl *o*-nitrobenzoyldimethylacetate,[5,6] and 2) the treatment of 2-diazopropane[7] with *o*-nitrobenzaldehyde.

The treatment of III with an equimolar amount of sodium acetylide in liquid ammonia at −70 °C gave **G** as the main product and **C**, **C'**, **D**, **E**, and **F** as the minor products. On the other hand, the reaction with sodium amide gave **C** and **C'** as the main products and **D**, **E** and **F** as the minor products (Chart 1).

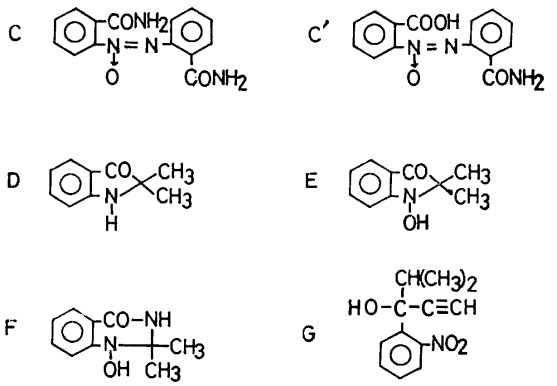

Chart 1.

Compound **C** was identified with *o,o'*-azoxybenzamide.[8] Compound **C'** was identical with the 2-carbamoyl-2'-carboxyazoxybenzene prepared by the alkaline reduction of *o*-nitrobenzamide with glucose or arsenious acid.[9]

The IR spectrum of **D** showed absorption bands of the NH group at 3380 cm^{-1} and of the C=O group at 1675 cm^{-1}. The UV spectrum of **D** revealed the absorption maxima at 237 (ε 4.33), 257 (3.78) and 398 nm (3.60) due to the 3-indolinone nucleus. Further, the NMR spectrum showed the signals for the methyl protons at δ 1.30 (s, 6H) and the imino proton at 5.15 (broad, 1H). These data were identical with those of 2,2-dimethyl-3-indolinone.[10]

The IR spectrum of **E** showed absorption bands of the OH group at 3310 cm^{-1} and of the C=O group at 1685 cm^{-1}. The UV spectrum revealed the absorption maxima at 240 (ε 4.37), 259 (3.81), and 381 nm (3.45) due to the 3-indolinone nucleus. **E** was methylated with diazomethane to give a methyl ether. The IR spectrum of the latter compound showed absorption bands due to the OCH_3 group at 2800 and 1150 cm^{-1} instead of those of the OH group at 3310 cm^{-1} of **E**. From these results, **E** was assumed to be 1-hydroxy-2,2-dimethyl-3-indolinone.

The IR spectrum of **F** showed absorption bands of the NH group at 3200 cm^{-1} and of the C=O group at 1655 cm^{-1}. The UV spectrum of **F** revealed the absorption maxima characteristic of the quinazoline nucleus at 228 (ε 4.42) and 328 nm (3.41). From the above results, **F** was assumed to be 1-hydroxy-2,2-dimethyl-1,2-dihydro-4-quinazolone, which was synthesized by the condensation of *o*-hydroxylaminobenzamide with acetone in acetic acid.

The IR spectrum of **G** showed the absorption bands of the C≡CH group at 3300 and 2101 cm^{-1}, of the NO_2 group at 1535, 1375, and 850 cm^{-1}, and of the OH group at 3550 cm^{-1}. The NMR spectrum of **G** showed the signals for the proton of alkyne at δ 2.77 (s, 1H), for the methyl protons at 1.05 (d, 3H), and 1.10 (d, 3H), for the methine proton at 2.75 (m, 1H), and for the hydroxyl proton at 3.00 (s, 1H). From the results, **G** was assumed to be 1-ethynyl-2-methyl-1-(*o*-nitrophenyl)-1-propanol.

Consequently, the reaction of III with sodium acetylide gave the normal condensation product without the participation of the nitro group.

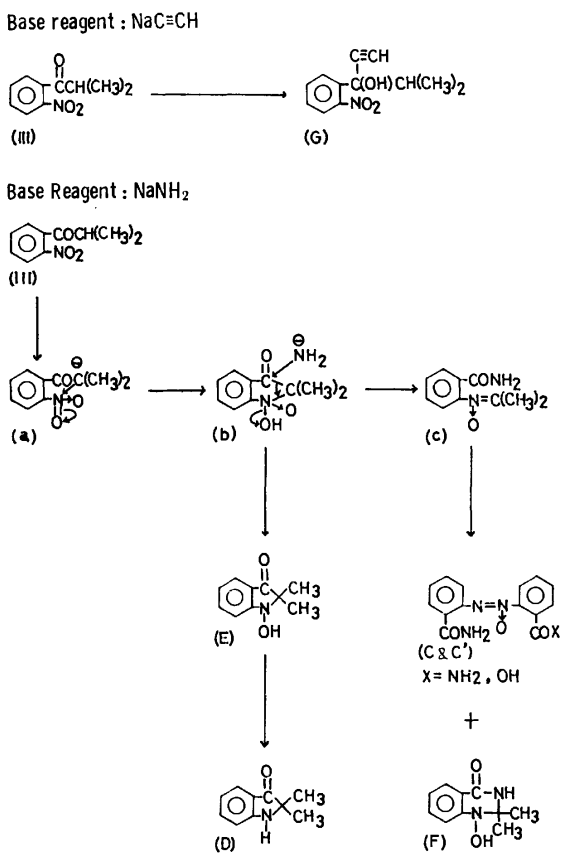
G was oxidized to confirm its structure. The ozonolysis of **G** gave an acid, 2-hydroxy-3-methyl-2-(*o*-nitrophenyl)butyric acid, and a neutral fraction having the absorption band of the CHO group at 1700 cm^{-1}. The latter compound was immediately oxidized with silver oxide or aqueous hydrogen peroxide to the same

acid which was obtained from the acid fraction. These acid fractions were further oxidized with lead tetraacetate to yield III. Further, the oxidation of **G** with potassium permanganate gave the acid described above.

Discussion

It has been pointed out that the base-catalyzed condensations of *o*-nitrobenzoyl derivatives undergo cyclization to isatogenes.[1]

The reaction of *o*-nitroisobutyrophenone (III) with sodium acetylide gave Compound **G** as the main product and Compounds **C**, **C'**, **D**, **E**, and **F** as minor products (Scheme 1).[1]



Scheme 1.

Various reasons for the results described above may be considered.[11,12] First, the increase in the number of alkyl groups on the α carbon of the carbonyl group decreases the acidity of the α-proton. Consequently, *o*-nitroisobutyrophenone (III) will react with the acetylide anion through nucleophilic addition at the carbonyl group rather than through the α-proton abstraction.

Second, in the *o*-nitrophenones, the increase in the steric hindrance between the alkyl and nitro groups competes with the repulsion by dipole-dipole interaction between the carbonyl and nitro groups.

In acetophenone or propiophenone, with small alkyl groups, the nitro group may be located in the neighborhood of the alkyl group undergoing the abstraction of the α-proton, but in the case of *o*-nitroisobutyrophenone, with a larger alkyl group, the situation is reversed.

On the other hand, with sodium amide the ketone (III) gave Compounds **C** and **C'** as the main products and Compounds **D**, **E** and **F** as the minor products.

These products are formed by the α-proton abstraction. The conjugate base of *o*-nitroisobutyrophenone causes an intramolecular reaction with the nitro group containing the electrophilic center to form an intermediate (b) of the 3-indolinone type, which is subsequently reduced to form the products, **D** and **E**.

In the next step, the addition of the amide anion to the carbonyl group of the intermediate (b) cleaved the heterocyclic ring to form a nitrone (c). The nitrone was derived to Compound **F**, an unknown product of the weak acidity, by the addition of the amide group to the C=N double bond of the nitrone.[13,14]

On the other hand, Compounds **C** and **C'** were assumed to be formed by the oxidation-reduction reaction of *o*-hydroxylaminobenzamide, which was formed by the cleavage of the intermediate (c).

Experimental

The IR spectra were measured with JASCO IR-E and Hitachi EPI-2 spectrophotometers, using neat or Nujol mull; the UV spectra, with a Hitachi EPS-2 spectrophotometer, using 95% EtOH as the solvent, and the NMR spectra, with JEOLCO C-60, using $CDCl_3$ as the solvent.

Preparation of o-Nitroisobutyrophenone (III). Methylation Method: A solution of 42 g (0.18 mol) of methyl *o*-nitrobenzacetate in 60 ml of absolute methanol was added in one portion to a sodium methoxide solution prepared from 4.1 g of sodium metal, followed by the drop-by-drop addition of an absolute methanol solution of methyl iodide (0.36 mol); then the mixture was refluxed at 65 °C for 30 min. The reaction mixture was cooled with ice–water, and then another molar equivalent of sodium methoxide was added in one portion. The mixture was subsequently treated with methyl iodide and refluxed at 65 °C for 3 h. The insoluble material was filtered off, and the filtrate was evaporated to give a residue, which was taken up with ether and washed thoroughly with 10% aqueous sodium hydroxide. This product was refluxed with a mixture of 13.5 ml of acetic acid, 7.5 ml of concd hydrochloric acid, and 7ml of water for 75 min. After being made alkaline with 20% aqueous sodium hydroxide, the reaction product was extracted with ether; the subsequent evaporation of the ethereal layer gave a crude product, which was distilled under reduced pressure; bp 115—130 °C/4 Torr. It was recrystallized from petroleum benzine; mp 46—47 °C; yield, 65—81%.

2-Diazopropane Method[7]: A solution of 25.7 g (0.17 mol) of *o*-nitrobenzaldehyde in an arbitrary volume of dry ether was added to 0.17 mol of 2-diazopropane (prepared from acetone-hydrazone) at −20 °C. The reaction mixture was stirred for 2 h at the same temperature and then warmed to room temperature. The insoluble material was removed by filtration. The filtrate was washed with a saturated sodium hydrogen sulfite solution to remove the unchanged aldehyde. The evaporation of the ether layer gave colorless crystals (mp 46—48 °C) from petroleum benzine; yield, 65—72%. IR (cm^{-1}): 1705 (C=O); 1530, 1350, and 860 (NO_2). Found: C, 62.52; H, 5.88; N, 7.23%. Calcd for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74; N, 7.25%.

The Condensation of o-Nitroisobutyrophenone (III) with Sodium Acetylide. A mixture of 0.23 g (0.01 g-atom) of sodium and 100—150 ml of liquid ammonia was saturated with dry acetylene. The mixture was cooled at −70 °C, and then a solution of 1.93 g (0.01 mol) of *o*-nitroisobutyrophenone in 10 ml of dry ether was added in one portion. After the mixture had stood at −60 °C for one hour, during which it turned from grey to yellow, ammonium chloride (1.0 g) was added; then the liquid ammonia was evaporated while 50 ml of dry ether was added. Next, 50 ml of water was added, the reaction mixture was filtered to remove an insoluble material (a), and the ethereal layer (b) was separated from the aqueous layer (c). The insoluble material (a) was recrystallized from water or dilute alcohol to give Compound **C** in a 0.2-g yield; mp 245—246 °C (lit,[8] mp 242 °C). Found: C, 59.10; H, 4.41; N, 19.52%. Calcd for $C_{14}H_{12}N_4O_3$: C, 59.15; H, 4.26; N, 19.71%. The aqueous layer (c) was acidified with 6M-HCl and continuously extracted with ether. The extract was evaporated and recrystallized from methanol to give Compound **C'** (mp 209—211 °C) in a 50-mg yield. Found: C, 59.04; H, 3.90; N, 14.79%. Calcd for $C_{14}H_{11}N_3O_4$: C, 58.94; H, 3.89; N, 14.79%. The ethereal layer (b) was successively extracted with aqueous sodium hydrogen carbonate and aqueous sodium hydroxide to leave a neutral fraction as the organic layer (d), which was purified by column chromatography on silica gel with chloroform to give **G** in 1.04 g (60.1%). Found: C, 65.31; H, 6.03; N, 6.39%. Calcd for $C_{12}H_{13}NO_3$: C, 65.74; H, 5.98; N, 6.39%.

The Condensation of o-Nitroisobutyrophenone (III) with Sodium Amide. Sodium amide was prepared from 0.23 g (0.01 g-atom) of sodium and 100—150 ml of liquid ammonia, using ferric nitrate($9H_2O$) as a catalyst. The mixture was cooled at −70 °C, and then a solution of 1.93 g (10 mmol) of *o*-nitroisobutyrophenone in 10 ml of dry ether was added in one portion. After standing at −60 °C for one hour, ammonium chloride (1.0 g) was added, and then the liquid ammonia was evaporated while 50 ml of dry ether was added. The post-treatment was then carried out as has been described above. The insoluble material (a) gave 1.7 g (23%) of **C** (mp 254—256 °C), and the aqueous layer (c) gave 0.9 g (12%) of **C'** (mp 209—211 °C). The ethereal layer (b), after have been washed an alkaline solution, gave 0.5—0.9 g (10—19%) of **D** (mp 86—87 °C) from petroleum ether. Found: C, 74.29; H, 6.90; N, 8.69%. Calcd for $C_{10}H_{11}NO$: C, 74.51; H, 6.88; N, 8.69%. The acid fraction obtained by the extraction with aqueous sodium hydroxide, after purification by column chromatography on silica gel with chloroform, gave 0.4 g (9.5%) of **F** (mp 196—197 °C (chloroform or ether)) and 0.1 g (2.3%) of **E** (mp 102—103 °C (petroleum benzine)). **E**, Found: C, 67.45; H, 6.32; N, 7.89%. Calcd for $C_{10}H_{11}NO_2$: C, 67.78; H, 6.29; N, 7.91%. **F**, Found: C, 62.10; H, 6.13%. Calcd for $C_{10}H_{12}N_2O_2$: C, 62.48; H, 6.29%. This compound was identified with the synthetic specimen (see below) by IR spectroscopy.

Preparation of F. A solution of 20 ml of acetone and 20 ml of acetic acid was added to 1.5 g (0.02 mol) of *o*-hydroxylaminobenzamide during refluxing at 85—86 °C for about 13 h. The black solution was evaporated under reduced pressure to leave a tar substance, which was then chromatographed on silica gel with chloroform. The first fraction was recrystallized from ether to give pearl grey and twinkle crystals; mp 197—200 °C; yield, 725 mg. IR (cm^{-1}): 3160 (OH), 1655, 1600 (CONH), and 1380 (CH_2). Found: C, 62.18; H, 6.36; N, 14.32%. Calcd for $C_{10}H_{12}N_2O_2$: C, 62.48; H, 6.29; N, 14.58%.

Ozonolysis of G. Ozone gas was passed into a solution of 2.8 g (13 mmol) of **G** in acetic acid at 5—6 °C for 30 min. The reaction mixture was then diluted with water and heated in a water bath. The solvent was removed under reduced pressure, and the residue was separated into acid and neutral fractions by the usual method. The oil from the acid part solidified in due time and was recrystallized from ether and petroleum benzine to give white crystals; mp 143—145 °C (1.0 g, 40.7%). The oil from the neutral part was oxidized with silver oxide or hydrogen peroxide in an alkaline solution to form the same product as the acid part. The IR spectrum of the acid part (cm^{-1}): 3550 (OH), 2900, 2500, 930 (COOH), 1720 (C=O), 1540, 1375, 825 (NO_2), and 770 (*o*-subst. benzene). Found: C, 55.70; H, 5.61 N, 5.83%. Calcd for $C_{11}H_{13}NO_5$: C, 55.23; H, 5.48; N, 5.86%.

Oxidation of G with $KMnO_4$. Formation of the Acid Fraction: Into an acetone (10 ml) solution of 32 mg (0.15 mmol) of **G** we added a small amount of $KMnO_4$; the purple color disappeared at once. The addition of $KMnO_4$ was continued at room temperature until the purple color remained ($KMnO_4$: 47 mg in total). The filtered reaction mixture was evaporated to remove the acetone, acidified with 2 M-HCl, and extracted with ether; the extract was then evaporated to give the acid compound.

Oxidation of Acid Compound with Lead Tetraacetate. Formation of III: A mixture of 100 mg (0.44 mmol) of an acid compound and 203 mg of $Pb(OAc)_4$ in 20 ml of dry benzene was stirred at reflux for 8 h. The reaction mixture was then cooled, and the $Pb(OAc)_2$ was filtered off and washed with ether. The combined filtrates were washed with a sodium hydrogen carbonate solution, dried with sodium sulfate, and evaporated to give 407 mg of III (mp 41—42 °C).

Aldol Condensation of Aldehydes with Ketones Promoted by the Copper(II) Ion. Orientation to the Chemical Model for Metalloaldolases

Masaaki IWATA and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received November 7, 1975)

The aldol condensation reactions of aromatic aldehydes such as **1** through **4** and **7** through **13**, and aliphatic aldehydes such as **5** and **6**, with a number of ketones promoted by the copper(II) ion were examined. The reactions were specifically promoted by the copper(II) ion, while such metal ions as zinc, cobalt(II), manganese(II), and magnesium were quite inactive as catalysts. All the aldehydes but **7** and **8** reacted with all the aliphatic ketones except ethyl acetoacetate, acetonitrile, and nitromethane to varying degrees in the Claisen-Schmidt type of reaction. Acetylacetone gave a condensation product of the Knoevenagel type. In the reaction of aldehydes with 2-butanone, aldehydes regiospecifically attacked the methylene group at C_3 of 2-butanone. Amines inhibited the reaction, while the coexistence effect of zinc or cobalt(II) was observed. It was shown that there existed a substrate selectivity depending greatly on the kinds of ketones in the reaction promoted by the copper(II) ion. As a consequence, possible intermediates in the reaction were proposed and the relationship of the aldol condensation reaction promoted by the copper(II) ion with the metalloaldolases was discussed, particularly in the light of the role of the metal ions in both catalytic mechanisms.

The aldol-condensation reaction is generally catalyzed by strong bases, such as alkali-metal hydroxide or alkoxide, or strong acids, such as hydrochloric or sulfuric acid.[1] However, no instances of an aldol condensation catalyzed by a transition-metal ion have been reported. This must be because there is no requirement of new catalysts superior to such bases or acids for general organic synthesis. In relation to enzymatic reactions, however, Rutter reported an important phylogenetic analysis in 1964 where he showed that there were two types of aldolases with distinct catalytic elements and molecular characteristics.[2] One type of aldolase (according to Rutter, Class I aldolases) catalyzes the aldol condensation of D-glyceraldehyde 3-phosphate with dihydroxyacetone phosphate to form fructose 1,6-diphosphate *via* a Schiff-base intermediate; the other type of aldolase (Class II aldolases) needs divalent metal ions to promote the same condensation reaction, the intermediate of which is evidently different from that of Class I aldolases. Later works by Rutter and his co-workers,[3-5] and by other groups[6] have given evidence of the presence of these two types of aldolases, and the catalytic mechanisms have been discussed. However, it has remained chemically unsolved whether or not the aldol-condensation reaction is really catalyzed by the transition-metal ion. On the other hand, we incidently found the novel aldol-condensation reaction promoted by the copper(II) ion of 2,6-dimethoxybenzaldehyde with acetone in the course of our studies concerning the demethylation of methoxy-substituted aromatic aldehydes,[7] and we briefly reported that the copper(II) ion specifically promoted the aldol condensation of acetone with several aromatic aldehydes to give benzylideneacetones.[8] In order to ascertain the scope and limitations of the aldol condensation promoted by the copper(II) ion and in order to approach a chemical elucidation of the role of metal ion in the catalytic mechanism of metalloaldolases, the method was further applied to the condensation of aliphatic and aromatic ketones with aliphatic and aromatic aldehydes. In this paper, the results obtained will be reported in detail and the relationship of the aldol-condensation reaction promoted by the copper(II) ion with enzymatic reactions will be discussed.

Results and Discussion

Reaction Systems. As aldehydes, benzaldehyde (**1**), *o*-anisaldehyde (**2**), *p*-anisaldehyde (**3**), 2,6-dimethoxybenzaldehyde (**4**), propanal (**5**), pentanal (**6**), salicylaldehyde (**7**), *p*-chlorobenzaldehyde (**8**), furfural (**9**), 2-thiophenecarbaldehyde (**10**), 2-pyridinecarbaldehyde (**11**), 3-pyridinecarbaldehyde (**12**), and 4-pyridinecarbaldehyde (**13**) were arbitrarily chosen. Acetone, 2-butanone, 2-pentanone, cyclopentanone, cyclohexanone, acetophenone, acetylacetone, and ethyl acetoacetate were used as ketones. Also, solvents with an active methylene group, such as acetonitrile and nitromethane, were examined as ketone analogues. In a typical experiment, we employed, unless otherwise stated, the procedure described in a previous report[8] where 8—10 mmol of a (hydrated) metal ion, such as zinc, cobalt(II), manganese(II), magnesium, or copper(II), all of which were selected in relation to the prothetic metal ions for the Class II aldolases,[3] and 5 mmol of an aldehyde were stirred in 20—30 ml (an excess amount) of the solvent ketone at room temperature. Also, on the basis of analogy with the enhancement effect of nucleophilic attack upon the addition of the zinc ion,[9] an amount of zinc chloride equimolar to that of the copper(II) ions was added to the reaction system.

Condensation of Aldehydes with Acetone. The results obtained in the presence of the copper(II) ion alone and in the coexistence of copper(II) and zinc ions are summarized in Table 1; the table shows that the yield of the condensation product after a comparable or shorter reaction time was strikingly increased by the addition of the zinc ion and that the **7** and **8** aldehydes gave no condensation product, presumably because of the occupation of the catalytic site of the metal ion by the electron-rich substituent or because of the decreasing electrophilicity of the aldehyde group as a result of the inductive and resonance effects of the

a) The configuration of the double bond was determined by the coupling constants of NMR spectra. b) No reaction occurred and the starting material was recovered. c) Yield after the column chromatographic separation.

substituents. It was also of interest, from the synthetical point of view, that the copper(II) ion-promoted reaction of **4** in the coexistence of the zinc ion gave 2,6-dimethoxybenzylideneacetone in a considerably high yields. Furthermore, the yield of 2-methoxybenzylideneacetone in the coexistence of copper(II) and zinc ions was dramatically ameliorated when acetone was purified (Fig. 1). The aliphatic aldehydes, **5** and **6**, appeared to give no condensation product with acetone.

Condensation of Aldehydes with 2-Butanone. The reactions of 2-butanone with the aldehydes **1** through **6** and **9** through **13** in the presence of the copper(II) ion alone and in the coexistence of the copper(II) and zinc ions were examined. The results obtained are listed in Tables 2 and 3. It is of particular interest to note that all aldehydes attack the methylene group at C_3 of 2-butanone, but not the methyl group at C_1. The regiospecificity suggests that the copper(II) ion functions as a proton-like catalyst because it has been generally known that the mineral-acid-catalyzed aldol condensation of aldehydes with 2-butanone preferentially occurs at C_3, while the strong base-catalyzed aldol condensation preferentially occurs at C_1.[1] Also, it was demonstrated

a) The condensation reaction gave dehydrated product, $RCH{=}C(CH_3)COOCH_3$, where R was the group in the aldehyde RCHO. b) The condensation reaction afforded addition product, $RCH(OH)CH(CH_3)COCH_3$, where R was the group in the aldehyde RCHO. c) Yield after the column chromatographic separation. d) On the basis of TLC spot. e) On the basis of gas chromatographic analysis (see Experimental part).

that the additional effect of the zinc ion was not so remarkable as has been shown in the case of acetone. It was of interest that the pyridinecarbaldehydes **11** through **13** gave only aldol-addition products to 2-butanone, but not dehydrated products, as was shown in all the other aldehydes, and that the aliphatic aldehydes **5** and **6** gave also the condensation products, unlike the case of acetone, but in a lower yield. The fact that the condensation of pyridinecarbaldehydes with 2-butanone gave the addition product led us to predict that the reaction of benzaldehydes with 2-butanone in the presence of pyridine would also afford the non-dehydrated product. However, no addition product was obtained; pyridine acted only as an inhibitor of the reaction.

Condensation of Miscelaneous Ketones and their Analogues with Aldehydes. The reactants and the results obtained are briefly shown in Table 4; no condensation product of aryl methyl ketone, β-keto ester, or alkyl (carbon number$>$3) methyl ketone was obtained in the presence of a copper(II) or copper(II)–zinc catalyst.

In addition, solvents with an active methylene group, such as acetonitrile and nitromethane, gave no condensation product with aldehydes in spite of the formation of certain copper complexes. On the other hand, of interest was the formation of 3-(2-methoxybenzylidene)-2,4-pentanedione (**14**) by the reaction of **2** with acetylacetone, while the reaction was not induced when bis(acetylacetonato)copper(II), which had previously been prepared by the reaction of copper(II) chloride dihydrate with twice the equimolar amount of acetylacetone, was treated with **2** in benzene. This seemed to indicate that it might be crucially important in the aldol condensation promoted by the copper(II) ion that the copper(II) ion was bound to the carbonyl moiety weakly, not tightly. Furthermore, it should be noted that, from the synthetical point of view, the formation of **14** was the first example of the Knoevenagel-type aldol condensation under weak acidic conditions; the reaction has usually been run in the presence of primary or secondary amines, ammonia, pyridine, or piperidine.[17]

Catalytic Activity of the Metal Ion. It is of particular interest to learn, in relation to the enzymatic reaction, whether the aldol condensation promoted by the copper(II) ion is specific for the copper(II) ion or equally applicable to other metal ions. In order to elucidate the specificity, zinc, magnesium, cobalt(II), and manganese(II) were examined under conditions similar to those of the copper(II) ion series. However, none of these metal ions which were prothetic to the Class II aldolases promoted the Claisen-Schmidt aldol condensation; that is, the aldol condensation promoted by the metal ion was specific for the copper(II) ion. The reaction was, however, affected by the addition of zinc or cobalt(II) in some aldehydes (see Experimental). As regards the effect of the counter anion of the copper(II) ion, copper(II) acetate was also effective in the condensation of **3** with acetone; the yield of the product was, however, considerably decreased in comparison with that catalyzed by copper(II) chloride.

Effect of Molar Ratio of Zn^{2+}/Cu^{2+} on the Condensation Reaction. The observations that the reaction yield of the aldol condensation promoted by the copper(II) ion depended greatly on the kinds of ketones and that it was greatly or slightly affected in the coexistence of the zinc ion led us to examine the possibility of the substrate selectivity of the aldol condensation. Thus, the effect of the molar ratio of Zn^{2+}/Cu^{2+} on the yields of the condensation reaction of *o*-anisaldehyde (**2**) as a representative aldehyde with acetone, 2-butanone, 2-pentanone, cyclopentanone, and cyclohexanone respectively was investigated. The results obtained are illustrated by plotting the molar ratio of Zn^{2+}/Cu^{2+} *vs.* the yield of the condensation product in Fig. 1. In the experiments, purified acetone was used, and a series of the reactions for each ketone was set up to keep consistency with respect to the reaction time and temperature in order to normalize the data. Also, the reaction yield was estimated by analyzing the gas chromatogram on the basis of the theoretical equation derived from several assumptions (see Experimental). The molar ratio of $Cu^{2+}/\mathbf{2}$ was at most 2, and that of $Zn^{2+}/\mathbf{2}$, at most 2. Figure 1 shows the following characteristic features; there is certainly a substrate selectivity in the condensation reaction in the presence of the copper(II) ion alone, since acetone and 2-pentanone hardly reacted with **2**, while cyclopentanone and cyclohexanone quantitatively gave the condensation product. In any cases, the condensation reaction was not induced without the copper(II) ion, and the zinc ion coexisting in the system affected the yield positively or negatively. Additionally, there was the optimum molar ratio of Zn^{2+}/Cu^{2+} to give the product in the best yield. The range showing the optimum ratio is limited in the case of 2-butanone, whereas it is very wide for acetone.

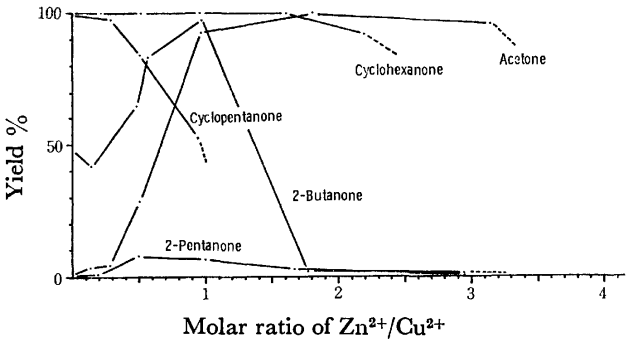

Fig. 1. The effect of the molar ratio of Zn^{2+}/Cu^{2+} on the condensation yield of various ketones with *o*-anisaldehyde (**2**).

Scope and Limitation of the Aldol Condensation Promoted by the Copper(II) Ion. In view of the stoichiometry of the reaction, 0.05 mol of **2** was treated with a mixture of 0.05 mol of 2-butanone, 0.01 mol of copper(II) chloride dihydrate, and 0.01 mol of zinc chloride in 30 ml of ethanol for 122 h. However, no benzylideneacetone derivative was obtained, and almost all of the starting materials were recovered. On the other hand, the reaction in which **3** and imidazole were added to the previously prepared acetone-copper(II) complex in the excess amount of acetone also gave no condensation

product. In addition, when the aceton–ceopper(II) complex which had previously been prepared was added to the mixture of **2** and 2-butanone, 3-(2-methoxybenzylidene)-2-butanone was produced after 28 h but no 2-methoxybenzylideneacetone was produced. Furthermore, it was of interest that methyl salicylate was formed in a 19% yield when **2** and the 2-butanone–copper(II) complex, previously prepared, were stirred in benzene for 48 h.

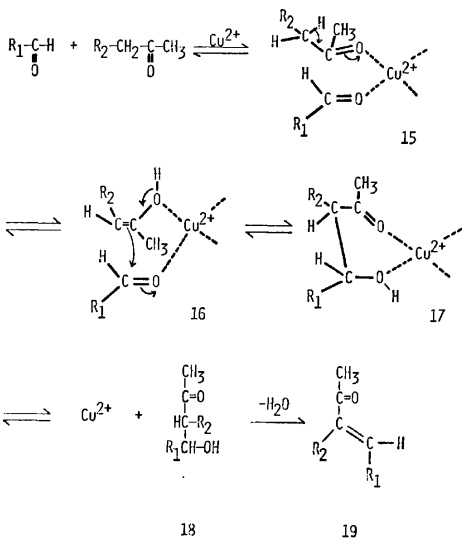
These observations, together with the afore-mentioned results, permit us to draw some conclusions with regard to the scope and limitations of the aldol condensation promoted by the copper(II) ion. That is, (a) the reaction will not stoichiometrically proceed with respect to ketone and thus should be conducted in a ketone solvent, which means that only liquid ketone can be used as a reactant for aldehyde. (b) A stable ketone–copper(II) complex such as bis(acetylacetonato)copper-(II) is unsuitable for the condensation with an aldehyde, while such an unstable ketone–copper(II) complex as acetone–copper(II), 2-butanone–copper(II), or an intermediarity formed copper(II) complex in a mixture of acetylacetone, aldehyde, and copper(II) ions will be effective for the condensation. This seems to be the case where enzymes catalyze the reactions in biological systems. (c) Ketone analogues with active hydrogen(s), such as acetonitrile, nitromethane, and the β-keto esters, are inactive in relation to the copper(II) ion. In the latter particularly, the hydrolysis of the ester rather than the condensation is promoted by copper(II) ion. (d) Aryl alkyl ketones will be unsuitable, while aliphatic ketones can be used. As regards aldehydes, hydroxyl, halogeno, and nitro substituents will inhibit the condensation, while the methoxy group and hetero atoms in the aromatic ring will allow the reaction.

Role of the Metal Ion in the Catalytic Mechanism of Metalloaldolases. The most remarkable feature of the aldol condensation promoted by the copper(II) ion is that the mixed condensation of aldehyde with ketone exclusively predominates over the self condensation of ketone, even if large excess amounts of ketone are present. This can be explained by the assumption that the ligation power of aldehydes to the copper(II) ion slightly predominates over that of ketones; thus, in the equilibrium, the copper(II) ion, present in twice the equimolar amount of aldehyde, coordinates both aldehyde and ketone. In fact, this assumption seems to be reasonable because the color of the intermediarily formed copper(II) complex in the reaction medium depends on the kinds of aldehydes and ketones used. In addition, such an intermediate will explain the inactivity of such metal ions as zinc, cobalt(II), magnesium, and manganese(II) in the consideration of coordination chemistry.[18]

Thus, we can deduce the processes of the aldol condensation promoted by the copper(II) ion from the initial formation of the mixed copper(II) complex of aldehyde and ketone, as is shown in Scheme 1. That is, in the initially formed copper(II) complex (**15**)-copper assists the enolization of ketone to give the intermediate (**16**), which then nucleophilically attacks the aldehyde moiety activated by the copper(II) ion to afford **17**. Subsequently, **17** releases the metal ion to prepare the addition product (**18**), which is then dehydrated to give **19** in almost all the aldehydes but the pyridinecarbaldehydes. In this reaction scheme, the dual role of the copper(II) ion, the enolization of ketone and the activation of aldehyde, is emphasized. If the mechanism has reality, it resembles the one proposed for the Class II aldolases with respect to the role of the metal ion.

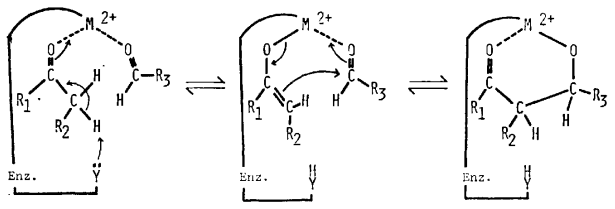
As regards the mechanism of the action of the Class I aldolases, direct chemical evidence has been provided by many workers.[6a,19,20] Alternatively, as for the role of the metal ion in the catlytic mechanism of the Class II aldolases which require a divalent metal ion and are not inhibited in the presence of sodium borohydride, Rutter and his co-workers have proposed some intermediates, which can be illustrated as **20**, **21**, and **22** in Scheme 2.[3-6] Now, the similarity of the dual role of the copper(II) ion in the aldol condensation promoted by the copper(II) ion to that of the metal ion in the Class II aldolases is apparent, and the mixed complex is likely to exist in both the chemical and enzymatic processes.

We are, however, confronted with a large gap regarding indispensable metal ions for the aldol condensation between the chemical model and the natural metalloaldolases, in which Zn^{2+}, Co^{2+}, Ni^{2+}, Mn^{2+}, and Fe^{2+} restore the enzymatic activity to varying degrees. while Cu^{2+}, Hg^{2+}, Cd^{2+}, Mg^{2+}, and Fe^{3+} fail to restore activity to any measurable extent.[3] Although a hasty



R_1=Aryl or Alkyl R_2=Alkyl

Scheme 1.



Scheme 2.

judgment may lead to an erroneous conclusion, we now consider that the gap is caused by the protein effects in enzyme such as proximity, orientation, strain, and microenvironmental factors; that is, the topochemical configuration of the catalytic site of a metal ion in the absence of an enzyme will be changed by these effects in the presence of enzyme. It is important to note that the coordination number and, thus, the stereochemical outcome are determined largely by the size and charge of the metal ion and ligand.[18] The investigation of the problem with which we are here concerned will bring about further fruitful results.

Experimental

The IR spectra were obtained using a Shimadzu IR-27 apparatus. The ^{1}H-NMR spectra were recorded on a Varian HA-100D apparatus, with tetramethylsilane as the internal standard. The chemical shift and the coupling constant were represented by δ and Hz units respectively. The mass spectra and exact mass measurements were obtained using a Japan Electron Optics Lab. Model JMS-OlSG instrument. Merck Art. 7734 (E. Merck, Darmstadt) was used for the preparative separation of the products on a silica gel column by elution chromatography, and Wakogel B-5 FM (Wako Pure Chem. Ind.), for the thin-layer chromatography (TLC). The measurements of the gas chromatography were performed by a Shimadzu GC-4A gas chromatograph with a flame ionization detector, using a 1.8 m×3 mm glass tube column packed with 5% Silicone GE-30 on Shimalite W 60—80 mesh and using helium gas as the carrier. The melting points are uncorrected. The elemental analyses were performed by the staff of the Organic Microanalysis Lab. in our Institute.

Materials. All the ketones and aldehydes, **1** through **13**, are commercially available.. Purified acetone was obtained by drying over Drierite after treatment with potassium permanganate, followed by distillation.[21] Copper(II) chloride dihydrate, zinc chloride, magnesium chloride hexahydrate, manganese(II) chloride tetrahydrate, cobalt(II) chloride, and copper(II) acetate monohydrate were used as metal chloride; all of them were commercially available.

Reaction Systems. The general procedure was described above. In the examination of the coexistence of copper(II) and zinc ions, an amount of zinc chloride equimolar to that of copper(II) chloride dihydrate was used unless otherwise stated. Although benzaldehydes are easily oxidized to the corresponding benzoic acid, the reaction system prevented the oxidation to a small extent, as has been shown by the comparative studies of the reaction of 2-butanone with benzaldehyde in the absence and in the presence of nitrogen gas. The final point of the reaction was decided by monitoring the TLC spots. After the completion of the reaction, the mixture was hydrolyzed by the addition of water and filtered through celite to remove the emulsive metal hydroxides. The filtrate was then extracted with ethyl acetate. The organic layer was dried over anhydrous sodium or magnesium sulfate, and the solvents were evaporated under reduced pressure. The residue was chromatographed on a silica gel column to give the products. In the case of the estimation of the yield by the aid of gas chromatography, the extract with ethyl acetate was used.

Analysis of Gas Chromatogram. In the case of the column chromatographic separation of the product, "yield" represents the real theoretical percentage of the product to the starting aldehyde. On the other hand, in the case of the estimation of the product yield by the use of gas chromatography, "yield" is evaluated on the basis of the following assumptions: (a) on the gas chromatogram, the product of the height of a band and the width of the band at half of its height nearly equals the relative area, which is directly proportional to the gram-molecular weight of the compound, and (b) the side products except for the condensation product are negligible (all the aldehyde consumed is converted to the condensation product). This second assumption (b) has a practical significance in this condensation reaction. According to these assumptions, the product yield ($Y_{\%}$) based on the gas chromatogram can generally be calculated by means of the following equation: $Y_{\%}=100\,r/(1+r)$, where r is the molar ratio of the condensation product to the aldehyde remaining on the gas chromatogram. Therefore, we can obtain the product yield by the estimation of r, which is calculated by the area ratio of the aldehyde to the product.

Under the conditions of the gas chromatograph (injection temp, 222 °C; detector oven temp, 230 °C; column temp, 89—189 °C (10 °C per min)) and a pressure of helium gas of 1.2—1.39 kg/cm^2, the retention times of *o*-anisaldehyde (**2**) and the condensation products were as follows: **2** was 5; 2-methoxybenzylideneacetone, 10; 3-(2-methoxybenzylidene)-2-butanone, 10; 3-(2-methoxybenzylidene)-2-pentanone, 12.7; 2-(2-methoxybenzylidene)cyclopentanone, 14; 2-(2-methoxybenzylidene)cyclohexanone, 9; 3-(2-methoxybenzylidene)-2,-4-pentanedione, 10.5; and 3-(2-furylmethylidene)-2-butanone, 20 min. Under an injection temp of 260 °C, a detector oven temp. of 220 °C, a column temp of 100—200 °C (10 °C per min), and a pressure of helium gas of 1.0—1.4 kg/cm^2, the retention time of 3-(2-thienylmethylidene)-2-butanone was 7, and that of thiophenecarbaldehyde, 1.8 min.

Additional Effect of Anhydrous $CoCl_2$ on the Aldol Condensation Promoted by the Copper(II) Ion. Various amounts of anhydrous $CoCl_2$ were added to the usual reaction system, and the mixture was stirred at the ambient temperature for 38 h. After a usual work-up, the yields of the product, 3-(2-methoxybenzylidene)-2-butanone, were determined on the basis of the analysis of the gas chromatogram. When 10, 5, 2.5, and 1.25 mmol of anhydrous $CoCl_2$ coexisted, the yields of the product were 59, 63, 69, and 70% respectively.

Condensation Product. Benzylideneacetone;[10] NMR (CCl_4); 2.32 (3H, s, $-CO\underline{CH_3}$), 6.65 (1H, d, $J=16.5$, C_β–H), and 7.45 (1H, d, $J=16.5$, C_α–H).

2-Methoxybenzylideneacetone[11] [mp 44—46 °C (lit, 50 °C)]; NMR (CCl_4); 2.34 (3H, s, $-COCH_3$), 3.90 (3H, s, $-OCH_3$), 6.66 (1H, d, $J=17.0$, C_β–H), and 7.80 (1H, d, $J=17.0$, C_α–H).

4-Methoxybenzylideneacetone[12] [mp 70—72 °C (lit, 73 °C)]; NMR (CCl_4); 2.26 (3H, s, $-CO\underline{CH_3}$), 3.82 (3H, s, $-OCH_3$), 6.50 (1H, d, $J=16.0$, C_β–H), and 7.37 (1H, d, $J=16.0$, C_α–H).

2,6-Dimethoxybenzylideneacetone[13] [mp 89—91 °C (lit, 88—90 °C)]; NMR (CCl_4); 2.26 (3H, s, $-CO\underline{CH_3}$), 3.88 (6H, s, $-O\underline{CH_3}$), 6.97 (1H, d, $J=16.6$, C_β–H), and 7.77 (1H, d, $J=16.6$, C_α–H).

3-Benzylidene-2-butanone;[14] NMR (CCl_4); 2.01 (3H, s, $C=C-\underline{CH_3}$), 2.40 (3H, s, $-CO\underline{CH_3}$), and 7.35 (1H, s, C_α–H).

3-(2-Methoxybenzylidene)-2-butanone[15]; NMR (CCl_4); 1.95 (3H, s, $C=C-\underline{CH_3}$), 2.42 (3H, s, $-CO\underline{CH_3}$), 3.87 (3H, s, $-O\underline{CH_3}$), and 7.63 (1H, s, C_α–H).

3-(4-Methoxybenzylidene)-2-butanone[16]; NMR (CCl_4); 2.02 (3H, s, $C-C-CH_3$), 2.37 (3H, s, $-COCH_3$), 3.82 (3H, s, $-OCH_3$), and 7.36 (1H, s, C_α–H).

3-(2,6-Dimethoxybenzylidene)-2-butanone; pale yellow crystals, mp 78—80 °C. Found: C, 70.59; H, 7.18%. Calcd for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%. NMR (CCl_4); 1.61 (3H,

s, C=C–$\underline{CH_3}$), 2.40 (3H, s, –CO$\underline{CH_3}$), 3.80 (6H, s, –O$\underline{CH_3}$), and 7.23 (1H, s, C_α–H).

3-(2-Thienylmethylidene)-2-butanone; a pale yellow liquid. Found: C, 65.17; H, 6.08; S, 19.10%. Calcd for $C_9H_{10}OS$: C, 65.03; H, 6.06; S, 19.29%. NMR (CCl_4); 2.10 (3H, d, J=0.7, C_β–CH_3), 2.36 (3H, s, –CO$\underline{CH_3}$), 7.09 (1H, d–d, J=3.75 and 5.0, ring C_4–H), 7.25 (1H, broad d, J=3.75, ring C_5–H), 7.46 (1H, broad d, J=5.0, ring C_2–H), and 7.58 (1H, d, J=0.7, C_α–H).

3-(2-Methoxybenzylidene)-2,4-pentanedione; light yellow crystals, mp 96—98 °C. Found: C, 71.51; H, 6.47%. Calcd for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47%. IR (neat); 1705 and 1685 cm^{-1}. NMR (CCl_4); 2.15 and 2.35 (3H each, s, two –CO$\underline{CH_3}$), 3.85 (3H, s, –O$\underline{CH_3}$), and 7.71 (1H, s, C_α–H).

3-Methyl-3-octen-2-one; a pale yellow liquid. Found: C, 76.94; H, 11.14%. Calcd for $C_9H_{16}O$ (140.22): C, 77.09; H, 11.50%. MS; *m/e* 140 (parent). Exact mass measurement; Calcd, 140.120; Found, 140.123. NMR (CCl_4); 0.98 (3H, m, –CH_3), 1.43 (4H, m, –CH_2CH_2–), 1.72 (3H, s, C_3–CH_3), 2.00 (2H, m, –CH_2–), 2.22 (3H, s, –CO$\underline{CH_3}$), and 6.51 (1H, broad t, J=7.5, –$\underline{CH}$=C).

4-Hydroxy-3-methyl-4-(2-pyridyl)-2-butanone; colorless crystals, mp 72—74 °C (sublimation). MS; *m/e* 179 (parent). exact mass measurement; Calcd for $C_{10}H_{13}O_2N$, 179.094; Found, 179.099. NMR (CCl_4); 0.93 and 1.05 (3H each, d, J=7.0, C_3–CH_3) (ratio, 8: 5) and 2.11 and 2.18 (3H each, s, –CO$\underline{CH_3}$) (ratio, 5: 8). These results gave evidence of the presence of rotamers between C_α and C_β of the side chain.

4-Hydroxy-3-methyl-4-(3-pyridyl)-2-butanone; a pale yellow liquid. MS; *m/e* 179 (parent). Exact mass measurement; Calcd for $C_{10}H_{13}O_2N$, 179.094; Found, 179.092. NMR ($CDCl_3$); 0.92 and 1.08 (3H each, d, J=7.0, C_3–CH_3) (ratio, 96: 117), and 2.18 and 2.24 (3H each, s, –CO$\underline{CH_3}$) (ratio, 75: 78). These results gave evidence of the presence of rotamers between C_α and C_β of the side chain.

4-Hydroxy-3-methyl-4-(4-pyridyl)-2-butanone; a pale yellow viscous liquid. Found: C, 66.92; H, 7.34; N, 7.78%. Calcd for $C_{10}H_{13}O_2N$ (179.21): C, 67.02; H, 7.31; N, 7.82%. MS; *m/e* 179 (parent). Exact mass measurement; Calcd, 179.094; Found, 179.097. NMR ($CDCl_3$); 2.21 and 2.22 (3H each, s, –CO$\underline{CH_3}$) (ratio, 1: 1). Those results gave evidence of the presence of rotamers between C_α and C_β of the side chain.

Methyl salicylate; yield, 19%, exact mass measurement, Calcd for $C_8H_8O_3$, 152.047; Found, 152.049. IR (neat); 3530 (OH) and 1740 (C=O) cm^{-1}. NMR (CCl_4); 3.82 (3H, s, –O$\underline{CH_3}$).

The author wishes to thank Mr. Jun Uzawa and Mrs. Tamiko Chijimatsu for their NMR spectral measurements, Mr. Yasuaki Ezumi and Miss Kyoko Sugita for their measurements of the mass spectra, and the staff of the Organic Microanalysis Lab. of this Institute for their elemental analyses. This study was supported in part by a Grant for Life Science from this Institute.

Transbutylation of Aromatic Hydrocarbons with Di-*t*-butylanisole[1)]

Keizo SHIMADA

Central Research Institute, Teijin Limited, 4-3-2, Asahigaoka, Hino, Tokyo 191

(Received November 18, 1975)

The trans-*t*-butylation of aromatic hydrocarbons with di-*t*-butylanisole in the presence of aluminum chloride was studied. It was found that the *t*-butyl group substituted at the *ortho* position to the methoxy group transfered easily to the hydrocarbons, but the *t*-butyl group of the *para* position did not transfer to the hydrocarbons. The transbutylation products did not suffer further isomerization when the catalyst aluminum chloride was less than 1/2 mol of the di-*t*-butylanisole used. Competitive trans-*t*-butylation was carried out and k_T/k_B, k_{m-X}/k_B, k_{O-X}/k_B, and k_{EB}/k_B were found to be 24, 2.2, 136, and 19, respectively.

Trans-*t*-butylation of aromatic hydrocarbons with *t*-butylbenzenes has been reported mainly in connection with the separation of *p*-xylene from a xylene mixture*.[2)] on the basis that *p*-xylene could not be *t*-butylated because of the steric hindrance of the *ortho* position to the methyl group.[3)]

However, no report is available concerning the use of a *t*-butylation reagent having substituents other than alkyl groups on the aromatic ring.

In this paper, the trans-*t*-butylation of aromatic hydrocarbons with 2,4-di-*t*-butylanisole is described.

Experimental

Materials. *Hydrocarbons*: Guaranteed pure reagents of benzene, toluene, ethyl- and isopropylbenzene were purified through distillation. The resulting purities were higher than 99.9%, as confirmed by gas chromatographic analysis. Guaranteed pure reagents of *m*-xylene were *t*-butylated with di-*t*-butyltoluene[2)] in the presence of $AlCl_3$ and the butyl-*m*-xylene separated by distillation was debutylated using toluene. The xylene fraction free of *p*-xylene thus obtained was purified by distillation. The resulting purity was greater than 99.5%. *o*-Xylene was purified in the same way. *t*-Butylbenzene was synthesized from benzene and *t*-butyl chloride.

Anisole: A guaranteed pure reagent of anisole was distilled after washing with a 10% sodium hydroxide aqueous solution and water, with a resulting purity greater than 99.5% (analyzed by gas chromatography).

t-Butyl chloride was synthesized from guaranteed pure reagents of *t*-butyl alcohol and hydrochloric acid (38%), washed well with water and distilled twice.

p-t-*Butylanisole*: To a solution of $AlCl_3$ (90 g) in anisole (756 g), maintained at 10 °C, *t*-butyl chloride (650 g) was added for 3 h. Afterward, the reaction mixture was stirred for 6 h, ice-water was added to the mixture and the catalyst was decomposed. The organic layer was washed with water and an alkaline aqueous solution, dried and distilled. The fraction boiling at 218—222 °C was collected. Yield 560 g. Further purification through redistillation was carried out (bp 220—221 °C, purity greater than 99.5%).

2,4-Di-t-butylanisole: To a solution of $AlCl_3$ (50 g) in anisole (540 g), 1100 g of *t*-butyl chloride was added and stirred for 6 h at 10 °C. After decomposition of the catalyst by the addition of ice-water, the organic layer was washed with water and an alkaline aqueous solution and dried. 2,4-Di-*t*-butylanisole was crystallized by cooling. It was recrystallized three times from methanol (mp 36 °C (lit, 36—37 °C),[4)] yield 350 g). An additional 110 g of pure 2,4-di-*t*-butylanisole was obtained from a parent solution (393 g) through distillation and recrystallization from methanol.

Reactions. To a mixture of 0.1 mol each of benzene or alkylbenzenes and di-*t*-butylanisole, the desired amount of $AlCl_3$ was added with stirring. In the case of competitive reactions, a desired amount of $AlCl_3$ was added to a mixture of 0.5 mol of each of the aromatic hydrocarbons and 0.1 mol of di-*t*-butylanisole with stirring. The competitive reaction of benzene and *o*-xylene was carried out using 0.5 mol of benzene and 0.1 mol of *o*-xylene. Samples were taken at appropriate times, poured into ice-water, washed and dried over calcium chloride. The samples were analyzed by gas chromatography using Apiezone L (10%) on a Diasolid S column (2 m) at 180 °C.

Results and Discussion

Butylation of Toluene: The results are shown in Table 1 and 2.

Friedel-Crafts *t*-butylation of toluene has been investigated by many authors. Allen and Yats[5)] have

concluded, on the basis of the results of Schlatter.[6] that the initial isomer distribution of *t*-butyltoluene consisted of 7% *m*- and 93% *p*-isomers. Steric hindrance prevents the formation of the *o*-isomer. Usually, in the alkylation and especially transalkylation reaction conditions, subsequent or concurrent isomerization of the reaction mixture takes place and the higher *m*-isomer contents are observed.

However, in the present case, the *t*-butyltoluene produced by transbutylation from di-*t*-butylanisole maintains a high *p*-isomer content throughout the reaction, and there is no sign of secondary reactions, such as isomerization and disproportionation. A slight increase in the *p*-isomer content toward the end of the reaction may be due to further *t*-butylation of *m*-*t*-butyltoluene, forming 3,5-di-*t*-butyltoluene. A low reaction temperature and a low catalyst concentration favor the high *p*-isomer content.

TABLE 3. BUTYLATION OF BENZENE WITH DI-*t*-BUTYLANISOLE AT 20 °C $AlCl_3$ 0.02 mol

Time	Reaction products mol %				
	Benzene	*t*-Butylbenzene			*p*-Isomer % in Dibutylbenzene
		mono-	*m*-di-	*p*-di	
5 min	96.1	2.0	0.2	1.7	90
20 min	92.8	2.7	0.4	4.1	91
40 min	90.6	2.8	0.6	6.0	91
1.5 h	87.4	2.8	0.7	9.1	93
3 h	83.3	4.1	0.9	11.7	93
24 h	73.5	3.0	1.5	22.0	94
120 h	59.4	3.0	2.4	35.2	94

Butylation of Benzene: The results were shown in Table 3. The content of di-*t*-butylbenzenes increased with time, whereas the *t*-butylbenzene content remained almost constant. These results were realized on the assumption that the *t*-butylbenzene initially formed is more reactive than benzene and that the transbutylation of benzene by di-*t*-butylbenzene did not occur.

TABLE 4. BUTYLATION OF ALKYLBENZENE WITH DI-*t*-BUTYLANISOLE AT 25 °C $AlCl_3$ 0.01 mol

Time	Ethylbenzene		Isopropylbenzene		*t*-Butylbenzene	
	Conversion (%)	*p*-isomer (%)	Conversion (%)	*p*-isomer (%)	Conversion (%)	*p*-isomer (%)

24 h	67.0	94.9	67.8	93.3	62.8	93.5

Butylation of Ethyl-, Isopropyl-, and t-*Butylbenzenes*: The results are shown in Table 4. In the course of the reaction, there was no sign of either disproportionation of ethyl- or isopropylbenzene, or isomerization of butylated products.

TABLE 5. REACTION OF TOLUENE WITH *p*-*t*-BUTYLANISOLE AT 25 °C $AlCl_3$ 0.01 mol

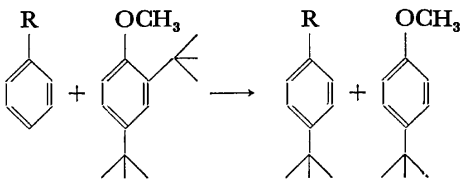
Time	Butyltoluene yield (mol %)	Composition of anisole deriv. (mol %)		
		Anisole	*p*-*t*-Bu-	2,4-(t-Bu)$_2$-
20 min	0	2	97.5	1.3
30 min	0	1.9	96.1	2.0
2 h	0	1	95.6	2.2
45 h	6.4	10.9	84.6	4.5

Reaction of Toluene with p-t-*Butylanisole*: The results were shown in Table 5. *t*-Butylation of toluene by *p*-*t*-butylanisole did not occur. Instead, disproportionation of *p*-*t*-butylanisole was observed. Formation of *t*-butyltoluene after 45 h was considered to be the result of trans-*t*-butylation by 2,4-di-*t*-butylanisole.

Thus the *t*-butyl group of the *para* position to the methoxy group did not participate in this transbutylation.

Furthermore, confirmation that the *t*-butyl group of the *ortho* position transfers to the hydrocarbons was obtained by the result that 4-methyl-2-*t*-butylanisole reacts with toluene to form *t*-butyltoluene and 4-methylanisole. This result will be reported elsewhere.

Therefore, the trans-*t*-butylation of aromatic hydrocarbons with 2,4-di-*t*-butylanisole is shown by the following reaction.



*Competitive Trans-*t-*butylation*: The results of the competitive *t*-butylations of benzene and toluene are shown in Table 6. When the amount of $AlCl_3$ catalyst was less than 1/2 mol to di-*t*-butylanisole, the competitive reaction proceeded normally. However, when an equimolar amount of a catalyst for di-*t*-butylanisole was used, secondary reactions took place and the apparent k_T/k_B value decreased.

Olah *et al.*[7] have investigated the Friedel-Crafts *t*-butylation of benzene and methylbenzenes with *t*-butyl bromide and with isobutylene. They pointed

m-Xylene	2.2	2.54	3.82
Ethylbenzene	22		

out that secondary isomerization occurred in the *t*-butylation conditions reported by Brown,[8] and found that k_T/k_B of the *t*-butylation was 14—16 for non-isomerized conditions. A higher k_T/k_B value (24) was observed in the trans-*t*-butylation with di-*t*-butylanisole.

The competitive *t*-butylation of toluene and C_8 aromatics was also carried out. The data obtained are summarized and compared with the results of Olah in Table 7.

From the data it is seen that the trans-*t*-butylation with di-*t*-butylanisole is the most selective *t*-butylation.

The author would like to acknowledge the continuing guidance and encouragement of Dr. Saburo Akiyoshi, now Professor Emeritus of Kyushu University. The author is also indebted to Dr. Shoichi Sakajiri, Director of the Central Research Institute, Teijin Limited, for publication permission.

The Reductive *N*-Methylation of Amines with Tetracarbonylhydridoferrate-Formaldehyde

Yoshihisa WATANABE, Sang Chul SHIM, Take-aki MITSUDO, Masakazu YAMASHITA, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received November 19, 1975)

Alcoholic tetracarbonylhydridoferrate combined with formaldehyde is an excellent reagent for reductive *N*-methylation of amines. The effects of reaction conditions such as temperature, atmosphere, and molar ratio (ferrate/formaldehyde/amine) on the reaction have been examined. The optimum condition for *N,N*-dimethylation of aniline is at 60 °C, under carbon monoxide, and at 1.0/2.2/1.0 for the molar ratio.

Recently, tetracarbonylhydridoferrate prepared from pentacarbonyliron and alkali metal hydroxide[1] has been shown to be a convenient, selective reagent for carbonylation and/or reduction of a variety of organic functional groups such as a nitro group,[2] an acetylenic bond,[2] olefinic bonds[3] of conjugated diene, enamine, and α,β-unsaturated carbonyl compound, alkyl halides,[4] and olefin oxides.[5] More recently, several works have demonstrated that the ferrate is effective for reductive alkylation of amines[6] and ketones[7] with carbonyl compounds. Several methods for the synthesis of *N*-alkylamines from amines and carbonyl compounds have been reported.[8] These methods generally give satisfactory results, but have limited applicabilities. For example, the Clarke-Eschweiler reaction, a simple method for *N*-methylation of amines using formaldehyde/formic acid, can be applied successfully only to aliphatic amines.

The present investigation deals with the reductive *N*-mono- and *N,N*-dimethylation of amines using the tetracarbonylhydridoferrate–formaldehyde system with a view to determine the factors affecting the reaction in some detail. A preliminary report of this work was published elswhere.[6b,c]

Experimental

Potassium tetracarbonylhydridoferrate was prepared according to the method described in a previous paper:[4a] 3.7—11 mmol of the ferrate was used in each run. Pentacarbonyliron, amines, and the other compounds employed were all commercial products.

Reaction Procedure. To the alcoholic ferrate, determined amounts of amines and aqueous formaldehyde were added at 50—78 °C under carbon monoxide or argon. After a certain reaction time, the reaction mixture was submitted to analysis.

Analytical Procedure. *N,N*-Dimethyl derivatives of aniline, toluidines, anisidines, benzylamine, and 2-aminoethanol were analyzed by GLPC using internal standards: a column (0.3 cm ϕ, 3 m) packed with 10% Versamid on Neopak 60—80 mesh. Other reaction products were isolated and identified by means of IR and NMR spectra, which were recorded on a 215 Hitachi grating spectrophotometer and a JEOL model 3H 60 NMR spectrometer, respectively. Products were isolated as follows: the reaction mixture was acidified with hydrochloric acid and solvents were evaporated to dryness. A residue was extracted with ether in the presence of sodium carbonate. The extract gave *N*-methylated amines after evaporating the solvent, and the amines were purified by vacuum distillation: *N*-methyl-2-aminopyridine, bp 57—58 °C/2 mmHg, yield 65%, NMR($CDCl_3$) τ 2.0 (m, 1H, α-H), 2.6 (m, 1H, γ-H), 3.5 (m, 2H, β-H), 5.0 (m, 1H, N–H), and 7.0 (m, 3H, N–CH_3); *N,N*-dimethyl-*o*-anisidine, bp 48—49 °C/2—3 mmHg, 82%, NMR($CDCl_3$) τ 3.25 (s, 4H, aromatic), 6.25 (s, 3H, O–CH_3), and 7.3 (s, 6H, $N(CH_3)_2$).

Results and Discussion

N-Methylation of Aniline. Aniline was converted into *N*-methyl- and *N,N*-dimethylaniline with tetracarbonylhydridoferrate–formaldehyde under different con-

ditions. The formation of *N*-methylated anilines was highly affected by such reaction variables as reaction temperature, atmosphere, molar ratio (the ferrate/formaldehyde/aniline), and the addition of water. The results are shown in Table 1 and Figs. 1 and 2.

As Fig. 1 shows, *N*-methylaniline is dominant at first and then *N,N*-dimethylaniline dominates when aniline is methylated at 60 °C under carbon monoxide at 1.0/2.2/1.0 of the molar ratio. This fact shows that aniline is almost quantitatively converted into *N,N*-dimethylaniline *via* *N*-methylaniline under this condition. The reaction proceeds smoothly with an absorption of carbon monoxide; the gas absorbed amounts to 1.8 mol/mol-ferrate.

The reaction condition optimum for preparation of *N,N*-dimethylaniline is that of Exp. No. 1: at 60 °C under carbon monoxide in moist ethanol when the molar ratio is fixed at 1.0/2.2/1.0. Lower or higher temperatures, argon atmosphere, and addition of excess water are less favorable for the dimethylation and give *N*-methylaniline in considerable yields. (See Exps. 1—6). Higher temperatures (70 °C and reflux in ethanol) have an inhibitory effect on the dimethylation and carbon monoxide absorption is significantly retarded. By addition of excess water, the gas absorption is also retarded. Under argon, the reaction stops at the first stage to give *N*-methylaniline. These results show that the reducing power of the ferrate increases with an absorption of carbon monoxide.

N-Methylaniline predominates as the reaction product at 1.0/40/4.0 of the molar ratio (Exp. 7). The reaction appears to be completed in 2—3 h and the yields of *N*-methyl- and *N,N*-dimethylaniline are 210 and 38%, respectively. Accordingly the selectivity for mono- and dimethylation can be readily controlled by the ferrate/aldehyde/aniline ratio, and one mole of the ferrate has the power to methylate about 2.8 N–H bonds at maximum. Therefore, one mole of the ferrate corresponds to about 1.4 mol of aniline for dimethylation. The machanism of the reaction is not clear, but the reduction seems to proceed *via* Schiff bases and immonium salts and to include the reduction of carbon-nitrogen bonds.

23	2-(Methylamino)ethanol	8	1.5	2-(Dimethylamino)ethanol	~200

a) At 60°C under carbon monoxide. Molar ratio: $KHFe(CO)_4$/HCHO/Amine=1.0/3.0/2.0. b) Mol/mol-$KHFe(CO)_4$. c) Determined by GLPC. Based on the amount of the ferrate used.

$$-NHCH_3 + HCHO \longrightarrow [-\underset{\underset{CH_3}{|}}{N}-CH_2OH \longrightarrow -\overset{+}{\underset{\underset{CH_3}{|}}{N}}=CH_2] \xrightarrow{KHFe(CO)_4} -N(CH_3)_2$$

Such a consideration may be supported by the fact that Schiff bases and immonium salts are reduced by the ferrate.[3d,6b] As a result, *N*-methylation of the N–H bond means reduction of the $-N=CH_2$ bond with the ferrate, and one mole of the ferrate with the power to methylate 2.8 N–H bonds corresponds to about 5.6 hydrogens as a reducing reagent in the reductive methylation of amines. At 1.0/6.6/3.0 of the molar ratio, in the presence of excess aniline, *N*-methylaniline is predominant as the product. (Fig. 2). For the reduction of conjugated diene and enamine, the most effective reaction variables are the atmosphere and the amount of water present.[3a,d] Under carbon monoxide in the presence of some water, the reaction proceeded most smoothly, and one mole of the ferrate corresponds to five hydrogens in the reduction of olefinic bonds.

N-*Methylation of Primary Amines.* Several primary amines were dimethylated under the conditions optimum for the dimethylation of aniline. The results are listed in Table 2. *o*-Methyl, methoxy, and chloro groups highly inhibit the dimethylation. For example, the dimethylation of *o*-anisidine required 36 h for completion, but that of *p*-anisidine only 7 h. Such effects of the substituents may be due to a steric hindrance, which would be the largest for the chloro group, followed by the methoxy and then the methyl group. *o*-Chloroaniline gave *N*-methyl-*o*-chloroaniline in 56% yield even after 3 days. 2-Aminopyridine gave only the *N*-monomethylated product. Benzylamine and 2-aminoethanol were dimethylated.

N-*Methylation of Secondary Amines.* As shown in Table 3, secondary amines were readily and almost quantitatively methylated to the corresponding tertiary amines by this method. The reaction completes in 3—8 h at 60 °C under carbon monoxide at 1.0/3.0/2.0 of the molar ratio.

Thermal *Cis*-to-*Trans* Isomerization of Substituted Azobenzenes II.[1] Substituent and Solvent Effects

Norio NISHIMURA, Toshinobu SUEYOSHI, Hideyuki YAMANAKA, Etsuko IMAI, Shunzo YAMAMOTO, and Shigeo HASEGAWA

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received November 25, 1975)

The thermal *cis*-to-*trans* isomerization rate of various azobenzenes was followed by means of spectrophotometric and flash photolysis techniques. For *para*-donor/*para'*-acceptor-substituted azobenzenes such as 4-nitro-4'-dimethylaminoazobenzene, the rate was distinctly accelerated, the activation energy decreasing with the increase in the polarity of solvents. Introduction of substituents in *para* positions with respect to azo group increased the rate irrespective of substituent. The effect is additive and a Hammett-type equation holds. For 4-dimethylamino- and 4-nitroazobenzenes, while the 2-methyl group accelerated the rate, the 2'-methyl group did not. The results suggest that the isomerization proceeds *via* inversion mechanism and the rate is controlled mainly by the resonance stabilization in the coplanar transition state. The inversion center for asymmetric azobenzenes is discussed.

The mechanism of *cis-trans* isomerization of azobenzenes and azomethines has attracted much attention from interest in its photochemistry. For their thermal *cis*-to-*trans* isomerization, two mechanisms have been proposed. One involves a rotation (torsion or twist) around the N=N double bond and includes a π-bond rupture. The other involves an inversion (in-plane lateral shift) through a linear state, the π-bond remaining intact.

The inversion mechanism has been assumed to hold for imines and azo compounds. However, recent accumulation of data of the isomerization has given rise to controversy on the mechanism.[2-9] Some authors explained their results in terms of different mechanisms,[6,7] and others suggested the possibility of a continuum of mechanisms between two limiting cases.[3] In addition to the study of activation parameters and solvent effects, a study of substituent effects on the rate of isomerization seemed to be the nearest way to solve the problem.

Recently, the present authors[1] presented a brief report on the *cis*-to-*trans* thermal isomerization of substituted 4-dimethylaminoazobenzenes as summarized below: (1) 2-Methyl group considerably accelerates the rate, while 2'-methyl group has virtually no effect on the rate. (2) All *para* substituents accelerate the rate, irrespective of the nature of the substituents. The effect is of an additive nature and an extended Hammett equation approximately holds:

$$\log k/k_0 = \sum\sigma_{c-t} \qquad (1)$$

where k and k_0 refer to the rate constants of *o*- and/or *p*-substituted and unsubstituted 4-dimethylaminoazobenzenes, respectively, and $\sum$ is the sum of the substituent constants for the substituents present in both benzene nuclei. (3) The logarithmic isomerization rate constants are roughly proportional to the molar extinction coefficients of the *trans*-isomers. The findings seemed to give us an useful suggestion regarding the rate-controlling factors for the isomerization.

This paper deals with the isomerization of various azobenzene derivatives for a better understanding of the isomerization mechanism and rate-controlling factors.

Experimental

Materials. The usual azobenzene derivatives were prepared by the procedures described previously.[10,11] For 2,6-dimethyl-4-dimethylaminoazobenzene derivatives, *N,N*-dimethyl-*m*-xylidine was prepared *via* 2,4,6-trimethylpyridinium perchlorate by the method of Diels and Alder.[12] It was then coupled with diazonium salts to give the final substances. Ryan's method[13] was used for the coupling. The final products were purified by dissolving them in benzene, passing through an alumina column, and then crystallizing them from benzene. *p*-Nitroazobenzene was prepared by condensing *p*-nitronitrosobenzene with aniline, the former being obtained by oxidation of *p*-nitroaniline with Caro's acid. Other *p*-nitroazobenzene derivatives were prepared by similar procedures. Melting point, NMR and UV spectra were utilized for identification. Elemental analysis was made for the new compounds. Their names, melting points and values in literature (in parentheses) are as follows: 4-Dimethylaminoazobenzene, 118—119 °C (119—120 °C); 4-Methyl-4'-dimethylaminoazobenzene, 169—170 °C (169.5—170 °C); 4-Chloro-4'-dimethylaminoazobenzene, 158—159 °C (158—158.5 °C); 3-Nitro-4'-dimethylaminoazobenzene, 157.5—158 °C (157—158 °C); 2-Methyl-4'-dimethylaminoazobenzene, 73—74 °C (73.5—74 °C); 2-Methyl-4-dimethylaminoazobenzene, 67—67.5 °C (68—68.5 °C); 2,4-Dimethyl-4'-dimethylaminoazobenzene, 136—137 °C (137 °C); 2-Methyl-4-chloro-4'-dimethylaminoazobenzene, 114—115 °C (117 °C); 2,4'-Dimethyl-4-dimethylaminoazobenzene, 125—126 °C (121 °C); 2-Methyl-4'-chloro-4-dimethylaminoazobenzene, 98—99 °C (96 °C); 2,2'-Dimethyl-5'-nitro-4-dimethylaminoazobenzene, 148—149 °C (148—148.5 °C); 2,2'-Dimethyl-4-dimethylaminoazobenzene, 77—78 °C (79—80 °C); 2,2',4'-Trimethyl-4-dimethylaminoazobenzene, 118—119 °C (120—121 °C); 2,2'-Dimethyl-4'-chloro-4-dimethylaminoazobenzene, 114.5—115 °C (115—116 °C); 4-Diethylaminoazobenzene, 96—97 °C (98 °C); 4-Methoxyazobenzene, 55—56 °C (55.5 °C); 4,4'-Bis(dimethylamino)azobenzene, sublimes at *ca.* 235 °C. Found: C, 71.73; H, 7.29; N, 20.58%. Calcd for $C_{16}H_{20}N_4$: C, 71.61; H, 7.51; N, 20.88%; 4,4'-Bis(diethylamino)azobenzene, 176—177 °C (171 °C); 4,4'-Dimethoxyazobenzene, 163.5—164.5 °C (164 °C); 4,4'-Dichloroazobenzene, 185 °C(183—184 °C); 4,4'-Dimethylazobenzene, 144 °C (144 °C); 4,4'-Dinitroazobenzene, 215 °C (216 °C); 4-Pyrrolidinoazobenzene, 166—167 °C (166—167 °C); 4-Aminoazobenzene, 125.5 °C (125—126 °C); 4-Amino-4'-methylazobenzene, 147—148 °C. Found: C, 74.20; H, 6.48;

Solvents. Benzene, toluene and acetone were purified, dried and distilled in the usual way. Cyclohexane was washed with a mixture of concentrated nitric acid and sulfuric acid. After repeated washing with distilled water, it was distilled over sodium wire. *N,N*-Dimethylformamide, dimethyl sulfoxide and pyridine of the reagent grade were used without further purification.

Measurements. An appropriate amount of the sample was dissolved in a solvent containing 0.2% piperidine* and allowed to stand overnight in the dark. The solution was transferred to a cylindrical cell (3 cm diam, 10 cm length) fitted with a glass window (3 mm thickness) at each end and equipped with a water jacket. Thermostated water was circulated. The solution was irradiated with a high pressure mercury lamp (Toshiba 400P) for 2 min. After irradiation, the absorbance at the peak of the conjugation band of *trans*-isomers was measured at appropriate time intervals with a Hitachi spectrophotometer Model 139. The rate constants were checked by duplicate runs, accuracy being within ±1%.

For rapid isomerization, flash technique was applied. A glass sample cell (1.5 cm diam, 10 cm length) was put into a flash box and a xenon flash lamp was fired at 100J (2 μF, 10 KV). After the flash, steady monitoring light beam from a tungsten projective lamp was passed through the cell perpendicular to the direction of the flash. After being passed through a Shimadzu prism monochromator, the transmitted light was received by a photomultiplier (Hamamatsu R 106) and transient signals were recorded on a dry-plate with the aid of an Iwasaki oscilloscope and a polaroid camera.

* Influence of adventitious catalytic action: When a solution of *trans*-isomers was irradiated by UV light in a quartz cell the solution was irreversibly photo-bleached. The rate of thermal isomerization was found to depend strongly on the time of irradiation. The factors affecting the rate have been studied by some authors.[14-16] When a small quantity of piperidine was added to the azobenzene solution and all light of $\lambda<310$ nm was cut by a glass filter, most azobenzenes restored the color almost completely after being kept in the dark. Reproducible data were obtained under the above conditions. However, some abnormal behavior was observed for azobenzene, 4-chloroazobenzene, 2,2′-dichloroazobenzene, and 2,2′-dibromoazobenzene. Since these substances did not reversibly return to the *trans*-form after visible light irradiation, they should have been partly decomposed. Therefore, the data for these substances were omitted.

Results

The thermal *cis*-to-*trans* isomerization of various kinds of azobenzene derivatives was carried out at various temperatures. The rate constants, estimated from excellent first-order plots, are listed in Tables 1—3 together with the activation parameters. Some of the rate constants (Tables 1 and 2) can be compared with those in literature (Table 4). The values of Schulte-Frohlinde[16] and Le Fèbre and Northcott[18] were estimated by interpolating the Arrhenius plot. It is to be noted that Schulte-Frohlinde, and Talaty and Fargo[17] used pure *cis*-isomers, while others used *trans*-isomers as the starting materials. In spite of the fact that the data were obtained under different conditions, the agreement is fair except for 4,4′-dinitro- and 4-nitroazobenzenes.

Table 2. Thermal isomerization rate constants for *para*-donor/*para*′-acceptor-substituted azobenzenes at 25 °C in various solvents

Solvent	k, min^{-1}		
	37[a]	38[b]	39[c]

Acetone	150	240	8.4
DMF	3000	5100	120
DMSO	7200	11400	600

a) 4-Nitro-4′-dimethylaminoazobenzene, $\varepsilon_{max}=33500$, $\lambda_{max}=445$ nm. b) 4-Nitro-4′-diethylaminoazobenzene, $\varepsilon_{max}=37200$, $\lambda_{max}=458$ nm. c) 4-Nitro-3′-methyl-4′-dimethylaminoazobenzene, $\varepsilon_{max}=22700$, $\lambda_{max}=410$ nm.

Discussion

Linear Free Energy Relationship. A general linear enthalpy-entropy relationship has been discussed in relation to the simple interaction mechanism.[19-25] ΔS^* tends to increase with increase in E_a, although there exists a considerable scatter (Fig. 1). Leffler[23] has shown that such a case is a result of more than two interactions whose vectors move independently on the E_a *vs.* ΔS^* plane. It is difficult to interpret the scatter, but a tentative explanation is as follows: The rate is mainly governed by the electronic effect of substituents, small perturbations due to solvation and steric effects being involved. The Arrhenius parameters fall in a reasonable range as compared with those reported.[16,18,22]

According to Schulte-Frohlinde,[16] the observation of preexponential factors as large as 10^{11-12} precludes the intervention of a triplet exited state involving a rupture of the N=N π-bond. The barrier to rotation around the N=N double bond was calculated to be 55—84 kcal/mol,[26-28] whereas the activation energy for the *cis*-to-

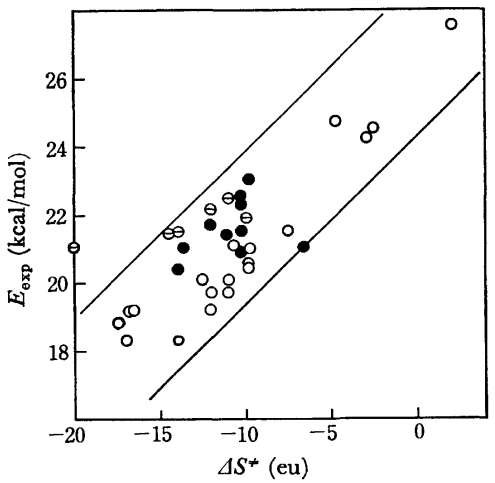

Fig. 1. Activation energy *vs.* entropy for the thermal *cis*-to-*trans* isomerization of azobenzenes.
○: This work; ●: Schulte-Frohlinde;[16] ◐: Brown and Granneman.[22]

trans thermal isomerization of azobenzene *via* inversion was calculated to be 32.9 kcal/mol by Ljunggren and Wettermark[28] by means of the CNDO/2 method, and improved to be 23.0 kcal/mol by Brown and Grannemann.[22]

On the other hand, Bineboym *et al.*[29] and Talaty and Fargo[17] suggested from the value of experimental activation energy that E_a of *ca.* 20 kcal/mol is too low to be compatible with the singlet transition state, because the corresponding isomerization of stilbenes considered to involve the rotation mechanism is followed by E_a of 34—37 kcal/mol in the liquid phase. They suggested therefore a transition state in which one or both azo-nitrogen atoms undergo a change in hybridization from sp^2- to sp-state. Thus it is likely that the lower activation energies support the inversion mechanism (Table 1).

However, recent evidence[30–32] has shown that there are some olefins and guanidinium salts which have activation energies of *ca.* 20 kcal/mol or even less, where only torsion is allowed. This has caused again much discussion on the mechanism of the *cis*-to-*trans* thermal isomerization of azomethines.[2–9] It was pointed out[4,7] that the lower activation energies cannot necessarily be regarded as a criteria of the inversion mechanism.

Solvent Effects. Although there are trials to relate the kinetic data to the properties of solvents such as dipole moment and dielectric constant, solvent effects in this field are generally ambiguous, and the rate varies only by a factor of a few times for most azobenzenes from solvent to solvent.[17,18] Wildes *et al.*,[9] however, observed a large solvent effect on the rate and activation energy for the thermal isomerization of *para*-donor/*para'*-acceptor-substituted azobenzenes. The isomerization rate of 4-diethylamino-4'-nitroazobenzene is about 10^5 times faster in *N*-methylformamide than in hexane. This seemed to contradict the former observation that the rate is not much affected by solvent.

Table 3. Activation parameters for the isomerization of **37** in various solvents

Solvent	E_a (kcal/mol)	ΔS^*(300K) (gibbs/mol)
Benzene	14	−14
Acetone	11	−20
DMF	10	−21
DMSO	9	−24

For the sake of confirmation, we followed the rate by means of the flash photolysis method, the results being given in Table 2. For 4-nitro-4'-dimethylaminoazobenzene, the activation parameters in various solvents are given in Table 3. The results are virtually in line with those of Wildes *et al.*[9] They suggested the rotation mechanism since the double bond character of the N=N bond and consequently the barrier to rotation would decrease with substituent.

Our view is as follows: Using a simple structure model, one can show that azobenzenes in no way take a coplanar

Table 4. Comparison of rate constants at 35°C

Azobenzene	$10^2 k$, min^{-1}

a) Shulte-Frohlinde;[16] in benzene; *k* at 35°C calcd by the Arrhenius equation. b) Talaty and Fargo;[17] in benzene. c) Le Fèvre and Northcott;[18] in benzene; *k* at 35°C calcd by the Arrhenius equation. d) Wildes, Pacifici, Irick and Whitten;[9] in benzene; temperature not specified. e) In cyclohexane containing 0.2% piperidine. f) In benzene containing 0.2% piperidine.

structure during rotation. On the other hand, if the inversion mechanism is accepted, a coplanar configuration is possible in the transition state (see **B–F** below). The dipole moment of this configurational structure may be as large as that for the *trans*-isomers (for example $\mu=$ 7.63D for **37**[10]). A considerable lowering in the free energy of activation and hence the increase in the rate for these species can be attributed to the large interaction with polar solvents. From a large decrease in the molar extinction coefficient (Table 2), the introduction of a methyl group in the *ortho* position with respect to the dimethylamino group would cause a considerable decrease in the dipole moment. This might be responsible for a much smaller solvent effect for **39** as compared with that for **37**. It should be noted that similarly substituted stilbenes, for which inversion is impossible, do not undergo facile thermal and photochemical isomerization in polar solvents.[33]

Table 5. Estimated substituent constants according to equation (1)

4-$C(CH_3)_3$		0.25		

*) DAAB is chosen as standard and σ-values are estimated from the possible combinations of the *k*-values of **1**—**14**. For σ-values with no asterisk, Talaty's *k*-value for azobenzene is chosen as a standard. a) *k*-values at 35 °C are used.

Substituent Effects. *para*-Substitutions invariably accelerate the isomerization rate, regardless of the nature of the substituents (Tables 1 and 2). This was first pointed out by Talaty and Fargo.[17] It was pointed out that this acceleration is of the additive nature and Eq. 1 is approximately valid for 4-dimethylaminoazobenzene derivatives.[1] From the data in Tables 1 and 2, the substituent constant, σ_{c-t} for various kinds of substituents has been estimated (Table 5). The first five σ_{c-t} values with an asterisk are obtained from the data of **1**—**14** in Table 1. Using these values, log k/k_0 are again plotted against σ_{c-t} according to Eq. 1 (Fig. 2). The correlation coefficient is calculated to be 0.987.

Using σ_{c-t}-values listed in the second column in Table 5, the same plots were made for substances **17**—**31** and **37**—**38** (Fig. 3) Although the correlation

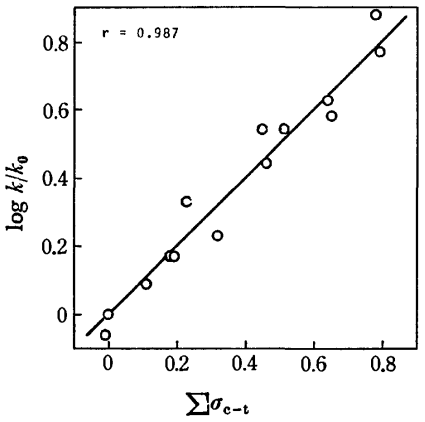

Fig. 2. Log k/k_0 *vs.* $\sum\sigma_{c-t}$ according to Eq. 1.

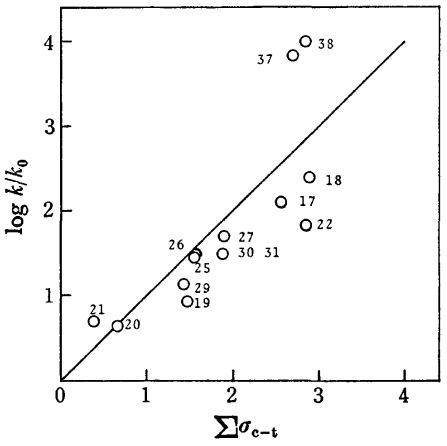

Fig. 3. Log k/k_0 against $\sum\sigma_{c-t}$ plot according to Eq. 1. Key is shown in Tables 1 and 2.

in this case is not so good as in Fig. 2, some interesting features may be noted. For 4-amino and 4-pyrrolidino derivatives, the deviation from the theoretical line is comparatively small. This means that the nature of these groups is virtually the same as that of dimethylamino group. For symmetrically substituted azobenzenes, the rate is usually not so accelerated as expected by the additivity rule. For *para*-donor/*para'*-acceptor-substituted azobenzenes, the rate is much more

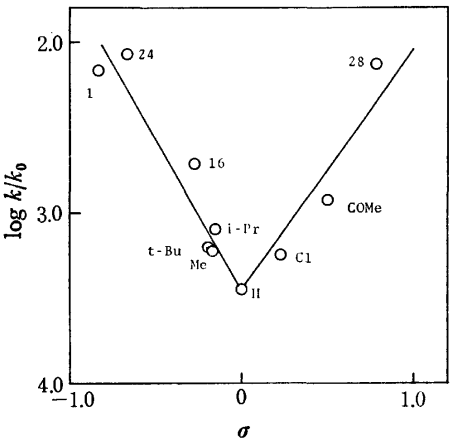

Fig. 4. The Hammett relationship. Key is shown in Table 1.

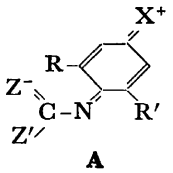
accelerated than expected from the rule. Hence the additivity rule, though it is useful to presume the effect of substituent on the rate of isomerization, has limited applicability.

In this connection, it may be worthwhile examining the Hammett relationship. The rate constants expressed in logarithmic scale, were plotted against σ for 4-monosubstituted azobenzenes. The plots are V-shaped with the minimum near σ equal to zero (Fig. 4).

Similar examples were reported recently by Hall *et al.*[6] and Herkstroeter[7] who found that the plots are all V-shaped for the isomerization of *N*-hexafluoroisopropylideneanilines, benzoylacetanilides, and pyrazolone azomethines. They explained the results in terms of the resonance stabilization in the transition state: If Z and Z′ in **A** are electron-accepting group, the rotation mechanism is



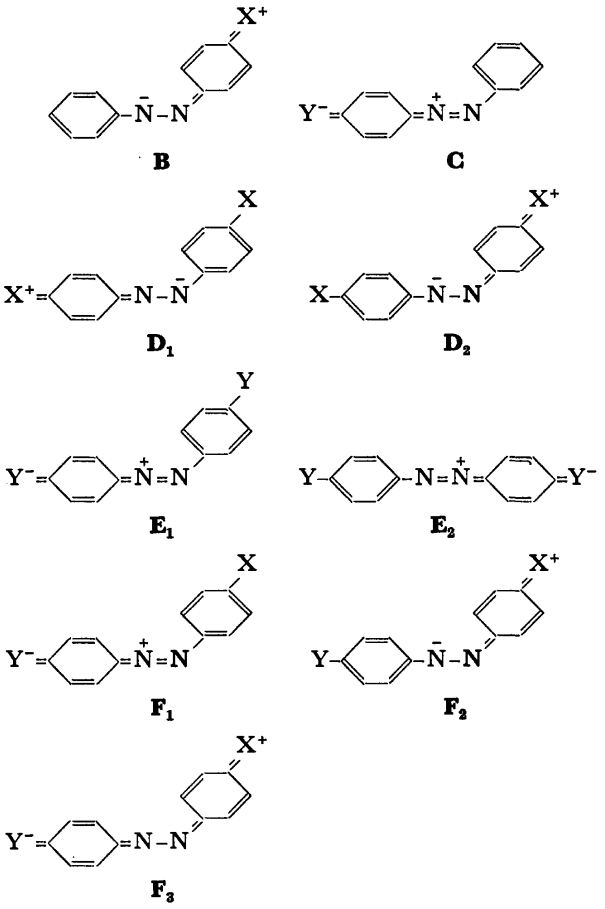
A

facilitated as the electron-donating strength of X increases as depicted, whereas growing electron-accepting capacity of X facilitates the isomerization by inversion, thus accounting for the V-plots. It is noted, however, that such a single bond character should substantiate only in the transition state through coplanar resonance structures. Such a coplanar structure is impossible through pure rotation. It does not seem plausible to assume such a drastic change in mechanism in going from electron-donating groups to electron-accepting groups. Further, the introduction of bulky substituent(s) to *ortho* position(s) with respect to azomethine nitrogen invariably accelerates the rate.[2,7,34-36] This cannot reasonably be explained in terms of the rotation mechanism, because the steric hindrance of R and R′ in **A** should destabilize the transition state a great deal. For the inversion mechanism, on the contrary, the steric effect may be less severe in the transition state than in the ground state for azomethines as has been explained successfully by Kessler *et al.* and others.[34-36]

The facilitated rate by *para*-substituents in azobenzenes, irrespective of their nature, may be explained in terms of a similar mesomeric effect, as depicted by resonance structures in the transition state **B**–**F**. If σ_{c-t} (or absolute Hammett σ) is regarded as a crude measure of the contribution of the resonance stabilization in the transition state, the deviation from the additivity rule may indicate that the contribution of the above resonance structures is not always additive (Fig. 3). As an example, an extra stabilization effect may arise from the resonance contribution depicted by $\mathbf{F}_3$, thus accounting for the upward deviation.

Steric Effects and Inversion Center. Complication arises for asymmetrical azobenzenes in which there are two distinct centers capable of inversion. In this case the empirical rate constant can be given by

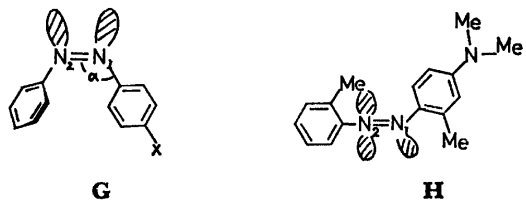
$$k = k_1 + k_2 = A_1 e^{-E_1/RT} + A_2 e^{-E_2/RT} \qquad (2)$$



B **C** $\mathbf{D}_1$ $\mathbf{D}_2$ $\mathbf{E}_1$ $\mathbf{E}_2$ $\mathbf{F}_1$ $\mathbf{F}_2$ $\mathbf{F}_3$

where the suffixes 1 and 2 denote the two rate processes.[22] The rate constants in Tables 1, 2 and 4 correspond to k in Eq. 2.

It is of interest to distinguish the two centers. According to Brown and Granneman,[22] the difference in the activation energies for the two distinct inversion routes is calculated to be 1—2 kcal/mol by the CNDO/2 method. They predicted that the amount of curvature in the Arrhenius plots would be quite small. In the present study, the Arrhenius plots failed to distinguish the two routes. The CNDO/2 calculations predict that the isomerization is aided by the electron-withdrawal by the ring adjacent to the rehybridizing nitrogen. We also have a similar idea summarized as follows: Due to the steric hindrance the ground *cis*-state may have a folded conformation as depicted by **G**.



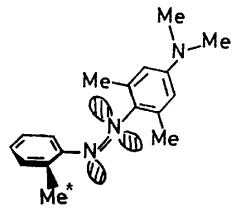
G **H**

If X is an electron-accepting group, the repulsive force among paired electrons on N_1 atom will be lowered, resulting in the increase in the s-character in the C–N_1 bond and the increase in the bond angle α. This should cause the inversion on N_1 atom more easily than on N_2. With X, as an electron donor, the reverse effect is expected.

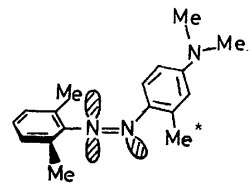
A large difference in the effect of 2- and 2'-methyl groups on the rate for 4-dimethylaminoazobenzenes seems to indicate that the main inversion center is N_2 as will be understood by the conformation **H**. If the above view is valid, it is expected that the 2'-methyl group should facilitate the rate, but not the 2-methyl in the case of 4-nitroazobenzenes. As seen in Table 1 (**28**—**31**), the 2-methyl group accelerates the rate, but the 2'-methyl group retards it, contrary to expectation.

As an alternative, one may postulate that if X is a strong electron donor or electron acceptor, the approximately planar X- -N_1=N_2- moiety can take a "stiff" conformation through conjugation in the ground *cis*-isomer. If this is the case, the inversion center should be N_2. The distinctly different *ortho* effects between 2- and 2'-methyl groups on the isomerization rate could be interpreted tentatively by this assumption.

A study was made using 2,6- and 2',6'-dimethylated 4-dimethylaminoazobenzene derivatives. The steric effects may become so severe for these substances that at least one of the benzene rings may be considerably twisted with respect to the C–N=N–C plane in the transition state as in the ground *trans*-isomer,* and this may be responsible for the considerable decrease in rate. The most favorable conformation will be determined by the compromise between the energy stabilization through conjugation and the steric hindrance. Thus, although it is by no means decisive, favorable conformations in the transition state of 2,6- and 2',6'-dimethyl-4-dimethylaminoazobenzenes will be given by **I** and **J**, respectively.



I



J

These conformations may be responsible for the acceleration effect due to the methyl group with an asterisk.

* A considerable decrease in the molar extinction coefficient of the conjugation band for **32**—**36** may be ascribed to the twist. For detail *cf.* Ref. 10.

Synthesis of Pseudo-β-DL-galactopyranose and Pseudo-α-DL-altropyranose

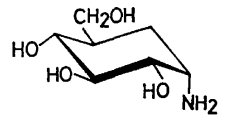
Tetsuo SUAMI,* Seiichiro OGAWA, Takashi ISHIBASHI, and Isamu KASAHARA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received December 20, 1975)

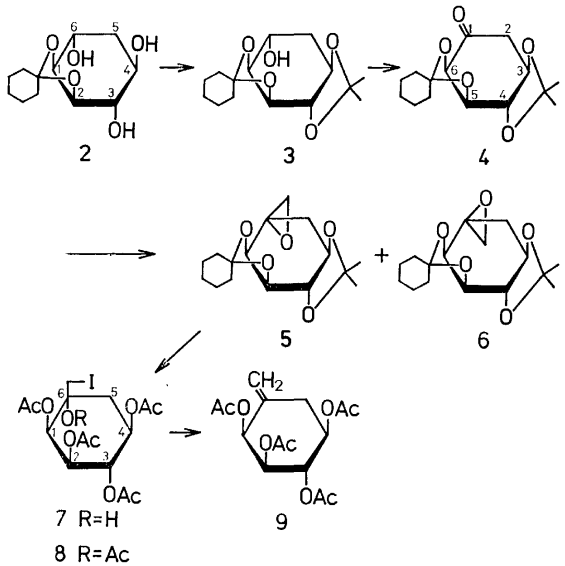
Pseudo-β-DL-galactopyranose and pseudo-α-DL-altropyranose pentaacetates (**10** and **11**) were obtained in a seven step reaction starting from DL-1,2-*O*-cyclohexylidene-5-deoxy-*chiro*-inositol (**2**).

The term "pseudo-sugar" was first given by McCasland and his coworkers[1] to a monosaccharide analog in which a ring oxygen is replaced by a methylene group. In connection with studies on aminocyclitols[2] and inositol derivatives,[3] we have attempted to synthesize validamine (**1**) which is a component of antibiotic validamycin.[4] Validamine has the structure (1*S*)-(1,2,4/3,5)-1-amino-5-hydroxymethyl-2,3,4-cyclohexanetriol[4] which is designated as pseudo-α-D-glucopyranosylamine.[5] It seems that a pseudo-hexopyranose with a proper configuration is the most promising intermediate for a synthesis of **1**.



1

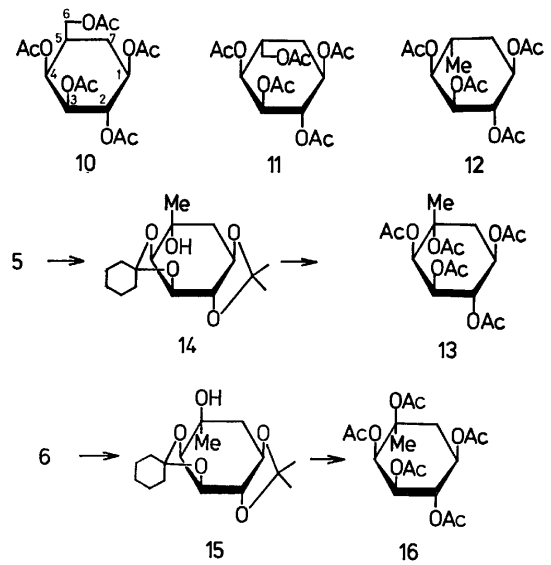
In the present study, DL-1,2-*O*-cyclohexylidene-5-deoxy-*chiro*-inositol (**2**) prepared from *myo*-inositol in four steps[6] was used as the starting material. Compound **2** was treated with 2,2-dimethoxypropane in the presence of a catalytic amount of *p*-toluenesulfonic acid to give DL-1,2-*O*-cyclohexylidene-5-deoxy-3,4-*O*-isopropylidene-*chiro*-inositol (**3**). Oxidation of **3** in dimethyl sulfoxide–acetic anhydride afforded DL-5,6-*O*-cyclohexylidene-2-deoxy-3,4-*O*-isopropylidene-*chiro*-inosose-1 (**4**) in 74% yield. Compound **4** was treated with diazomethane to give DL-1,1′-anhydro-5,6-*O*-cyclohexylidene-2-deoxy-1-*C*-hydroxymethyl-3,4-*O*-isopropylidene-*chiro*-inositol (**5**) and DL-1,1′-anhydro-2,3-*O*-cyclohexylidene-6-deoxy-1-*C*-hydroxymethyl-4,5-*O*-isopropylidene-*myo*-inositol (**6**) in 82 and 9% yields, respectively.



Compound **5** reacted with hydriodic acid under reaction conditions analogous to those employed by Angyal and his coworkers[7] for the preparation of methylenecyclohexanepentols, to give DL-1,2,3,4,6-penta-*O*-acetyl-5-deoxy-6-*C*-iodomethyl-*chiro*-inositol (**8**). Compound **8** was converted into DL-1,2,3,4-tetra-*O*-acetyl-5,6-dideoxy-6-methylene-*chiro*-inositol (**9**) by refluxing in glacial acetic acid in the presence of zinc powder.

Hydroboration[8] of **9**, followed by oxidation with alkaline hydrogen peroxide and subsequent acetylation afforded pseudo-β-DL-galactopyranose pentaacetate (**10**), pseudo-α-DL-altropyranose pentaacetate (**11**) and DL-1,2,3,4-tetra-*O*-acetyl-(1,3,4/2,5)-5-methyl-1,2,3,4-cyclohexanetetrol (**12**) in 13, 17 and 13% yields, respectively. Besides these compounds, DL-1,2,3,4,5-penta-*O*-acetyl-(1,3,4/2,5)-5-*C*-methyl-1,2,3,4,5-cyclohexanepentol (**13**) was obtained in 6.5% yield, which was identified with an authentic sample prepared by another route (**5**→**14**→**13**). This compound was an epimer of **16** prepared from **6** by an analogous reaction route (**6**→**15**→**16**).

In the above reaction from **9** to **10** and **11**, only two types of pseudo-hexopyranose pentaacetates, *viz.* β-DL-galacto and α-DL-altro type compound, can be obtained. Their PMR spectra were measured to distinguish the two compounds.



* To whom correspondence should be addressed.

The PMR spectrum of **10** revealed a singlet at δ 2.14 for an axial acetoxy group and three singlets at δ 2.05 (6H), 2.03 (3H) and 1.99 (3H) for three equatorial acetoxy groups[9] and one side chain acetoxy group.

The side chain methylene protons revealed an eight line signal pattern, each proton showing a pair of doublets at δ 4.03 and 3.86 with a geminal coupling of 11 Hz and vicinal couplings of 6 and 8.5 Hz. The ring methylene protons showed multiplets between δ 1.54—2.27 overlapped with a multiplet of the methine proton (H-5).

The ring proton (H-4) revealed its signal at δ 5.50 as a triplet with $J_{3,4}=J_{4,5}=3$ Hz. This was demonstrated on irradiating the H-5 proton (δ 2.3), the triplet collapsing to a doublet ($J_{3,4}=3$ Hz). The small coupling constant indicated the nonexistence of an axial-axial arrangement between H-4 and H-5. The proton H-3 revealed a pair of doublets at δ 4.90 with $J_{3,4}=3$ Hz and $J_{2,3}=10$ Hz, indicating the existence of two vicinal axial protons: H-2 and H-3. The proton H-2 showed a triplet at δ 5.40 with $J_{1,2}=J_{2,3}=10$ Hz. The proton H-1 showed an eight signal pattern centered at δ 4.94 with $J_{1,2}=10$ Hz, $J_{1,7a}=11.5$ Hz and $J_{1,7e}=5$ Hz. The PMR spectral assignment was consistent with the β-DL-galactopyranose pentaacetate, a side-chain equatorial favoring conformation. These spectral assignments are consistent with those of pseudo-α-DL-galactopyranose pentaacetate[1] except for the axial acetoxy group on C-1 in the case of the α-epimer.

The PMR spectrum of **11** revealed five sharp signals for the five acetoxy groups at δ 2.05, 2.06, 2.08, 2.10 and 2.12. These signals could not be attributed to an axial or an equatorial acetoxy methyl proton, owing to a deviation from their typical values.[9] This indicates that there is a rapid ring inversion between two chair conformations. This has also been deduced from the fact that methyl α-altropyranoside exists in two chair conformations: Cl and 1C.[10]

The PMR spectrum of **12** showed a similar signal pattern for the acetoxy methyl protons, suggesting an analogous ring inversion as was observed in the case of **11**. Thus the above described structure was proposed for **12**.

Experimental*

Melting points were determined in a capillary tube in a liquid bath and are uncorrected. PMR spectra were obtained on Varian A-60D (60 MHz) and Varian XL-100 (100 MHz) spectrometers in deuteriochloroform with reference to tetramethylsilane as an internal standard, peak positions being given in δ-values. Values given for coupling constants are of first order. Solutions were evaporated under diminished pressure at 40—50 °C. TLC was performed on silica gel plates (Wakogel B-10, Wako Pure Chemical Industries Ltd.).

DL-*1,2-O-Cyclohexylidene-5-deoxy-3,4-O-isopropylidene*-chiro-*inositol (3).* DL-1,2-*O*-Cyclohexylidene-5-deoxy-*chiro*-inositol[6] (**2**, 3.70 g) was treated with 2,2-dimethoxypropane (37 ml) in *N,N*-dimethylformamide (80 ml) at 85—95 °C for 40 min in the presence of *p*-toluenesulfonic acid (0.1 g). Sodium hydrogencarbonate (0.21 g) was added to the solution and the mixture was evaporated. The residue was extracted with warm ethyl acetate and the solution was evaporated. The residue was recrystallized from hexane to give 3.25 g (76%) of **3**, mp 82—83 °C; PMR: δ 1.42 (s, 6, $2CH_3$), 1.48—1.75 (m, 10, C_6H_{10}), 1.87—2.18 (m, 2, CH_2), 2.60 (s, 1, OH). Found: C, 63.18; H, 8.49%. Calcd for $C_{13}H_{24}O_5$: C, 63.36; H, 8.51%.

DL-*5,6-O-Cyclohexylidene-2-deoxy-3,4-O-isopropylidene*-chiro-*inosose-1 (4).* To a solution of **3** (5.0 g) in dimethyl sulfoxide (100 ml) was added acetic anhydride (15 ml). The reaction mixture was stirred in a refrigerator for 24 h and poured into ice cold sodium hydrogencarbonate solution. The crystalline precipitates were collected and recrystallized from ethanol to give 3.67 g (74%) of **4**, mp 138—139.5 °C; PMR; δ 1.48 (s, 6, $2CH_3$), 1.54—1.80 (m, 10, C_6H_{10}), 2.45 (q, 1, $J_{2a,3}=10.5$ Hz, $J_{gem}=18.0$ Hz, H-2a), 2.99 (q, 1, $J_{2e,3}=7.0$ Hz, H-2e), 3.55 (q, 1, $J_{3,4}=10.5$ Hz, $J_{4,5}=6.5$ Hz, H-4), 4.13 (m, 1, H-3), 4.50 (d, 1, $J_{5,6}=8.0$ Hz, H-6), 4.65 (q, 1, H-5). Found: C, 63.78; H, 7.69%. Calcd for $C_{15}H_{22}O_5$: 63.81; H, 7.85%.

DL-*1,1'-Anhydro-5,6-O-cyclohexylidene-2-deoxy-1-C-hydroxymethyl-3,4-O-isopropylidene*-chiro-*inositol (5) and* DL-*1,1'-anhydro-2,3-O-cyclohexylidene-6-deoxy-1-C-hydroxymethyl-4,5-O-isopropylidene*-myo-*inositol (6).* To an ethereal solution of diazomethane prepared from 50.0 g of nitrosomethylurea was added a solution of **4** (5.0 g) in chloroform (50 ml) under ice-cooling. The reaction solution was settled in a refrigerator for 17 h and evaporated. The crystals were filtered and washed with ethanol to give 484 mg (9%) of **6**, mp 196—197 °C; PMR: δ 1.46 (s, 6, $2CH_3$), 1.52—1.75 (m, 10, C_6H_{10}), 1.70—2.14 (m, 2, H-6a and 6e), 2.40 and 3.12 (dd,2, $J_{gem}=6.5$ Hz, CH_2), 3.66 (m, 1, H-5), 4.08 (q, 1, $J_{3,4}=8.0$ Hz. $J_{4,5}=9.5$ Hz, H-4), 4.30 (d, 1, $J_{2,3}=6.5$ Hz, H-2), 4.41 (q, 1, H-3).

Found: C, 65.10; H, 8.38%. Calcd for $C_{16}H_{24}O_5$: C, 64.84; H, 8.16%.

The filtrate and the ethanol washing were combined and evaporated to give 4.29 g (82%) of crude **5** as a syrup. PMR: δ 1.45 (s, 6, $2CH_3$), 1.51—1.82 (m, 10, C_6H_{10}), 2.08—2.41 (m, 2, H-2a and 2e), 2.81 and 2.95 (dd, 2, $J_{gem}=4.5$ Hz, CH_2), 3.56 (q, 1, $J_{3,4}=9.5$ Hz, $J_{4,5}=8.0$ Hz, H-4), 3.63 (d, 1, $J_{5,6}=6.0$ Hz, H-6), 3.74 (m, 1, H-3), 4.35 (1, 1, H-5).

DL-*1,2,3,4,6-Tetra-O-acetyl-5-deoxy-6-C-iodomethyl*-chiro-*inositol (7).* A 3.5-g portion of crude **5** was added to a saturated solution (25 ml) of sodium iodide containing 2.5 ml of concentrated hydriodic acid, and the mixture was agitated for 48 h. An insoluble matter was removed by filtration, and the filtrate was evaporated to dryness. The residue was acetylated in acetic anhydride (50 ml) with one drop of concentrated sulfric acid for 5 h. The solution was poured into ice-cold water (500 ml) to give 2.62 g (47%) of **7**, mp 209—211 °C; PMR: δ 1.98 (s, 3, OAc), 2.03 (s, 6, 2OAc), 2.15 (s, 3, OAc). Found: C, 38.46; H, 4.32; I, 26.84%. Calcd for $C_{15}H_{21}O_9I$: C, 38.15; H, 4.48; I, 26.87%.

The mother liquor was extracted repeatedly with chloroform and the chloroform solution was evaporated to give a mixture of **7** and **8** (1.96 g).

DL-*1,2,3,4,6-Penta-O-acetyl-5-deoxy-6-C-iodomethyl*-chiro-*inositol (8).* Compound **7** (2.62 g) was acetylated in acetic anhydride with a drop of concentrated sulfuric acid at 40 °C for 1 h, and the mixture was poured into ice cold water (400 ml) to give 2.37 g (83%) of **8**, mp 94—95 °C; PMR: δ 1.98 (s, 3, OAc), 2.03 (s, 6, 2OAc), 2.17 (s, 3, OAc), 2.21 (s, 3, OAc), 2.24—3.12 (m, 2, H-5a and 5e), 3.61 and 3.92 (dd, 2, $J_{gem}=11.5$ Hz, CH_2). Found: C, 39.91; H, 4.69; I, 24.52%. Calcd for $C_{17}H_{23}O_{10}I$: C, 39.90; H, 4.51; I, 24.68%.

Compound **8** (1.30 g) was obtained from a mixture of **7** and **8** (1.96 g) by the same procedure.

* Elemental analyses were performed by Mr. Saburo Nakada to whom our thanks are due.

DL-*1, 2, 3, 4-Tetra-*O*-acetyl-5, 6-dideoxy-6-methylene*-chiro-*inositol (9)*. A 3.0-g portion of **8** was heated in glacial acetic acid (40 ml) with zinc powder (25 g) under reflux for 1 h. The mixture was filtered and the filtrate was evaporated to give 1.2 g of crude **9**. The insoluble matter obtained by filtration was extracted twice with warm ethyl acetate and the ethyl acetate solution was evaporated to give another crop of **9**. Recrystallization from ethanol–hexane gave 1.44 g (75%) of **9**, mp 93—94 °C; PMR: δ 1.99 (s, 3, OAc), 2.01 (s, 3, OAc), 2.02 (s, 3, OAc), 2.10 (s, 3, OAc), 2.43—2.70 (m, 2, H-5a and 5e), 4.82 (m, 1, $J_{3,4}$=10 Hz, $J_{4,5a}$=10.5 Hz, $J_{4,5e}$=7.0 Hz, H-4), 4.86 (q, 1, $J_{1,2}$=3.5 Hz, $J_{2,3}$=10 Hz, H-2), 5.19 and 5.29 (dd, 2, J_{gem}=1.0 Hz, CH_2), 5.35 (t, 1, H-3), 5.65 (d, 1, H-1). Found: C, 54.91; H, 6.14%. Calcd for $C_{15}H_{20}O_8$: C, 54.88; H, 6.14%.

*Pseudo-β-*DL*-galactopyranose Pentaacetate (10) and Pseudo-α-*DL*-altropyranose Pentaacetate (11)*. Sodium tetrahydroborate (0.24 g) was added to a solution of **9** (0.60 g) in tetrahydrofuran (15 ml). A solution of freshly distilled boron trifluoride etherate (2.4 ml) in tetrahydrofuran (4.8 ml) was slowly added to the mixture. After the mixture was agitated for 4 h at 25 °C, 50% aqueous tetrahydrofuran (5.0 ml) was added. Then 3M sodium hydroxide (6 ml) and 30% hydrogenperoxide (3.0 ml) were added to the mixture. The mixture was agitated for 1 h at 35 °C and evaporated to dryness. The residue was acetylated in acetic anhydride (20 ml) with a drop of concentrated sulfuric acid overnight and the reaction solution was poured into ice cold water. The aqueous solution was extracted repeatedly with chloroform and the combined chloroform solution was evaporated. The residue was fractionated on a silica gel (Wakogel C-300, 40 g) column in 2-butanone–toluene (1:7, v/v). Fractions which showed a single spot at R_f 0.50 on TLC in 2-butanone–toluene (1:4, v/v) were combined and evaporated to give 93 mg (13%) of **10**, mp 123—124 °C; PMR: δ 1.99 (s, 3, OAc), 2.03 (s, 3, OAc), 2.05 (s, 6, 2OAc), 2.14 (s, 3, OAc), 3.86 (q, 1, $J_{5,6}$=6.0 Hz, J_{gem}=11.0 Hz, H-6), 4.03 (q, 1, $J_{5,6'}$=8.5 Hz, J_{gem}=11.0 Hz, H-6'), 4.90 (q, 1, $J_{2,3}$=10.0 Hz, $J_{3,4}$=3.0 Hz, H-3), 4.94 (qd, 1, $J_{1,7a}$=11.5 Hz, $J_{1,7e}$=5.0 Hz, $J_{1,2}$=10.0 Hz, H-1), 5.40 (t, 1, H-2), 5.50 (t, 1, $J_{4,5}$=3.0 Hz, H-4). Found: C, 52.52; H, 6.24%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.58; H, 6.23%.

Fractions showing a single spot at R_f 0.47 on TLC in the same solvent were combined and evaporated to give 119 mg (17%) of **11**, mp 115—116 °C; PMR: δ 2.05 (s, 3, OAc), 2.06 (s, 3, OAc), 2.08 (s, 3, OAc), 2.10 (s, 3, OAc), 2.12 (s, 3, OAc), 2.38 (m, 1, H-5), 4.16 (d, 2, $J_{5,6}$=6.0 Hz, H-6 and 6'). Found: C, 52.87; H, 6.29%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.58; H, 6.23%.

DL-2,3,4,5-Tetra-*O*-acetyl-(2,3,5/1,4)-1-methyl-2,3,4,5-cyclohexanetetrol (**12**, 77 mg, 13%), mp 111—112 °C, was obtained from fractions showing a single spot at R_f 0.60 on TLC. PMR: δ 0.96 (d, 3, J=6.0 Hz, CH_3), 1.45 (m, 2, CH_2), 1.97 (s, 3, OAc), 1.99 (s, 3, OAc), 2.00 (s, 3, OAc), 2.02 (s, 3, OAc). Found: C, 54.37; H, 6.73%. Calcd for $C_{15}H_{22}O_8$: C, 54.54; H, 6.71%.

From fractions showing a single spot at R_f 0.55 on TLC, DL-1,2,3,4,5-penta-*O*-acetyl-2-deoxy-1-*C*-methyl-*chiro*-inositol (**13**) was obtained as a syrup (46 mg, 6.5%), which was identified with an authentic sample prepared by the following reactions.

DL-*5, 6-*O*-Cyclohexylidene-2-deoxy-3, 4-*O*-isopropylidene-1-*C*-methyl*-chiro-*inositol (14)*. To a solution of compound **5** (516 mg) in tetrahydrofuran (14 ml) was added lithium aluminum hydride (0.3 g). The mixture was heated under reflux for 1.5 h and then cold water (3 ml) was added to the iced reaction mixture. The mixture was filtered and the filtrate was evaporated. The residue was recrystallized from hexane to give 228 mg (44%) of **14**, mp 113—114 °C. PMR: δ 1.40 (s, 6, $2CH_3$), 1.44 (s, 3, CH_3 at C-1), 1.50—1.75 (m, 10, C_6H_{10}), 2.00 (s, 1, OH), 3.43 (q, 1, $J_{3,4}$=10.5 Hz, $J_{4,5}$=9.0 Hz, H-4), 3.81 (td, 1, $J_{2a,3}$=$J_{3,4}$=10.5 Hz, $J_{4,5}$=9.0 Hz, H-3), 3.90 (d, 1, $J_{5,6}$=5.0 Hz, H-6), 4.31 (q, 1, H-5). Found: C, 64.12; H, 8.56%. Calcd for $C_{16}H_{26}O_5$: C, 64.40; H, 8.78%.

DL-*1, 3, 4, 5, 6-Penta-*O*-acetyl-2-deoxy-1-*C*-methyl*-chiro-*inositol (13)*. Compound **14** (120 mg) was heated in 80% aqueous acetic acid (10 ml) under reflux for 19 h. The solution was evaporated and the residue was acetylated with acetic anhydride and pyridine at 80—90 °C for 20 h. The acetate was purified on a silica gel column in 2-butanone–toluene (1:8 v/v). Fractions showing a single spot at R_f 0.38 on TLC in 2-butanone–toluene (1:6, v/v) were combined and evaporated to give 87 mg (56%) of **13** as a colorless syrup. PMR: δ 1.50 (s, 3, CH_3 at C-1), 1.96 (s, 3, OAc), 2.00 (s, 6, 2OAc), 2.11 (s, 3, OAc), 2.15 (s, 3, OAc), 2.22—2.91 (m, 2, CH_2 at C-2), 4.79—5.56 (m, 4, ring protons). Found: C, 52.86; H, 6.27%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.58; H, 6.23%.

DL-*2, 3-*O*-Cyclohexylidene-6-deoxy-4, 5-*O*-isopropylidene-1-*C*-methyl*-myo-*inositol (15)*. Compound **6** (600 mg) was treated with lithium aluminum hydride (0.37 g) in tetrahydrofuran (25 ml) as in the preparation of **14**, to give 567 mg (94%) of **15** as an amorphous solid, mp 86—88 °C. PMR: δ 1.30 (s, 3, CH_3 at C-1), 1.41 (s, 6, $2CH_3$), 1.51—1.80 (m, 10, C_6H_{10}). Found: C, 64.72; H, 8.67%. Calcd for $C_{16}H_{26}O_5$: C, 64.40; H, 8.78%.

DL-*1, 2, 3, 4, 5-Penta-*O*-acetyl-6-deoxy-1-*C*-methyl*-myo-*inositol (16)*. Compound **15** (560 mg) was heated in 80% aqueous acetic acid (20 ml) under reflux for 20 h. The solution was evaporated and the residue was acetylated. The acetate was purified on a silica gel column in 2-butanone–toluene (1:8, v/v). Fractions showing a single spot at R_f 0.32 on TLC in 2-butanone–toluene (1:6, v/v) were combined and evaporated to give 407 mg (56%) of **16** as a syrup. PMR: δ 1.69 (s, 3, CH_3 at C-1), 1.94 (s, 3, OAc), 1.99 (s, 6, 2OAc), 2.03 (s, 3, OAc), 2.15 (s, 3, OAc), 2.25—2.56 (m, 2, CH_2 at C-6), 4.76—5.55 (m, 4, ring protons). Found: C, 52.82; H, 6.35%. Calcd for $C_{17}H_{24}O_{10}$: C, 52.58; H, 6.23%.

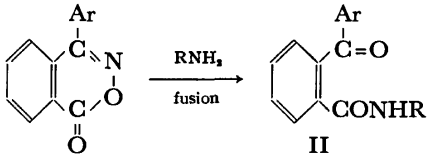
1*H*-2,3-Benzoxazin-1-ones. II. Action of Amines, Phenylhydrazine, Aluminium Chloride, and Grignard Reagents on 4-Aryl-1*H*-2,3-benzoxazin-1-ones

A. F. M. FAHMY, and Mrs. Nawal F. ALY
Faculty of Sciences, Ain Shams University, Cairo, Egypt
(Received September 30, 1974)

4-Aryl-1*H*-2,3-benzoxazin-1-one on reaction with amines by fusion gave *o*-aroyl benzamides. With benzylamine in benzene they gave (2-benzylcarbamoyl)-benzophenone oximes, and with phenylhydrazine they gave 1,3-diaryl-1,2-dihydrophthalazin-4-ones. However, with anhydrous $AlCl_3$ (12 mol) in reactive hydrocarbon substrates, they gave the corresponding *o*-aroylbenzophenone anils. With Grignard reagents they gave the corresponding *o*-aroyl-triaryl-methanols, which upon cyclization gave 1,1,4-triaryl-1(*H*)-2,3-benzoxazines.

Reaction of 1H-2,3-Benzoxazin-1-ones with Amines. We have found a new reaction of 1*H*-2,3-benzoxazin-1-one with amines.

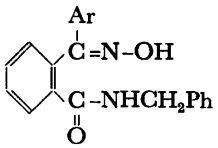
4-Aryl-1*H*-2,3-benzoxazin-1-ones (Ia and b) react with benzylamine, and aniline by fusion to give *N*-substituted *o*-aroyl benzamides (IIa—d).



I II

	Ar	R
a: C_6H_5	a: C_6H_5	C_6H_5-CH_2
b: $C_6H_4CH_3$(-*p*)	b: $C_6H_4CH_3$(-*p*)	C_6H_5·CH_2
c: C_6H_4Cl(-*p*)	c: C_6H_5	C_6H_5
	d: $C_6H_4CH_3$(-*p*)	C_6H_5

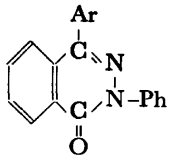
It was found that IIIa—c were formed from the reaction of Ia—c with benzylamine in benzene.



III

a: Ar=C_6H_5, b: Ar=$C_6H_4CH_3$(-*p*), c: C_6H_4Cl(-*p*).

Reaction of 1H-2,3-benzoxazin-1-ones with Phenylhydrazine. 4-Aryl-1*H*-2,3-benzoxazin-1-ones (Ia—c) react with phenylhydrazine to give the corresponding 1,3-diaryl-1,2-dihydrophthalazin-4-ones (IVa—c).



IV

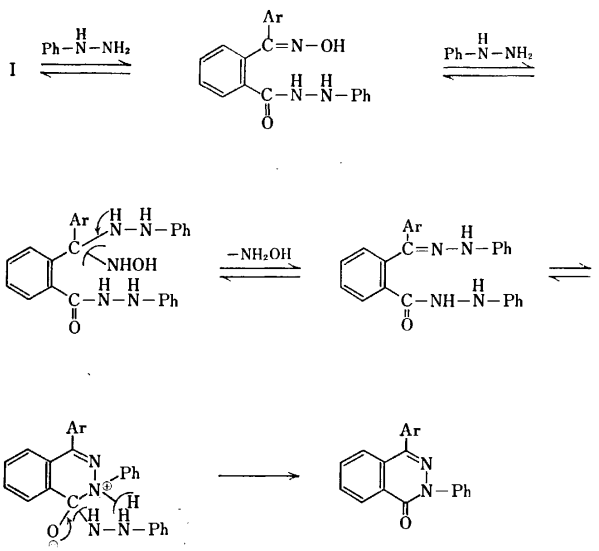
a: Ar=C_6H_5, b: Ar=$C_6H_4CH_3$(-*p*),
c: Ar=C_6H_4Cl(-*p*)

The structure of IVa—c was confirmed:

(i) *Via* the reaction of the corresponding *o*-aroylbenzoic acids (Va—c) with phenylhydrazine.[2,3]

(ii) *From IR spectra*: IVa—c showed $\nu_{C=O}$ in the region 1700—1690 cm^{-1}.

The reaction possibly takes place according to the following mechanism (Scheme 1).



Scheme 1. The above mechanism was proved from the fact that benzophenone oxime reacts with hydrazines to give benzophenone hydrazones.[4]

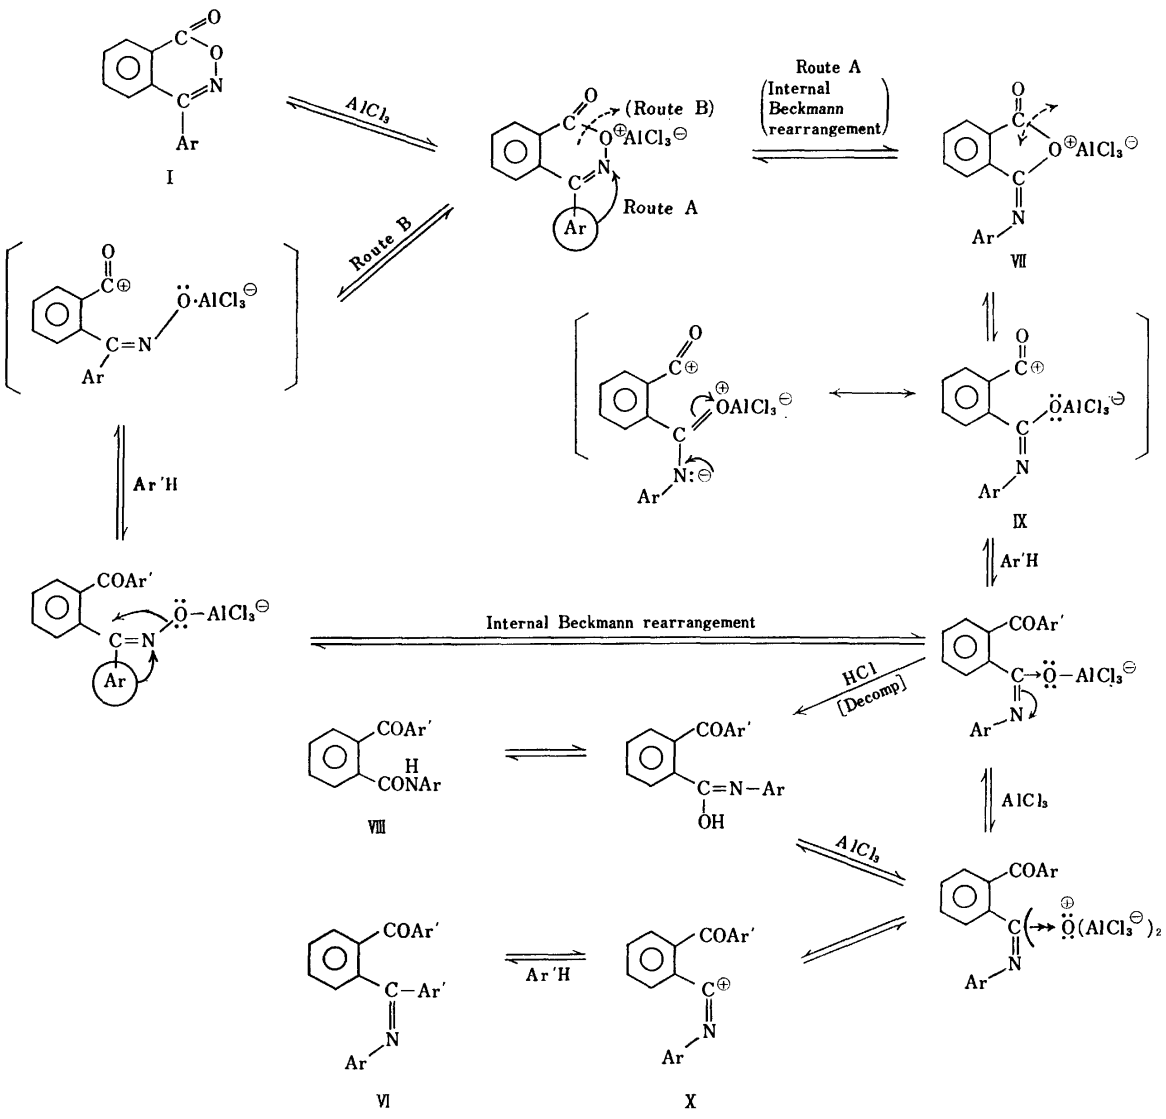
Action of Anhydrous $AlCl_3$ in Reactive Aromatic Hydrocarbon Substrates. 4-Phenyl-1(*H*)-2,3-benzoxazin-1-one (Ia) reacts with hot benzene, toluene, and anisole in the presence of 12 mol anhydrous $AlCl_3$ to give 2-benzoyl-; 2-(*p*-toluoyl)-4'-methyl; and 2-(*p*-anisoyl)-4'-methoxybenzophenone anils (VIa—c), respectively. Under the same conditions 4-(*p*-tolyl)-, and 4-(*p*-chlorophenyl)-1*H*-2,3-benzoxazin-1-ones (Ib, and c) gave the corresponding 2-aroylbenzophenone *p*-methyl anils (VId—f) and 2-aroylbenzophenone *p*-chloro anils (VIg—i) respectively.

The structure of VIa—i was confirmed from IR spectra which revealed the presence of $\nu_{C=O}$ in the region 1720—1700 cm^{-1}. The reaction possibly takes place according to the following mechanism (Scheme 2).

Route A in the above scheme is the most probable one for the following reasons: (i) 3-Phenyliminophthalide (VII) is found to undergo Friedel-Crafts reaction with benzene to give *o*-benzoylbenzanilide (VIII)[5] (ii) formation of *N*-arylphthalimides, when chlorobenzene was used as a substrate,[1] indicates that the carbonium ion (IX) is formed as an intermediate.

o-Aroylbenzanilide (VIII) was found to be an intermediate in the above mechanism from the following:

(i) It was formed from reaction of I with benzene,



Scheme 2.

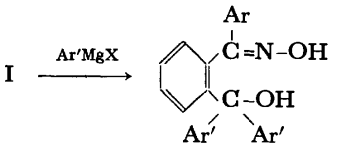
and toluene in presence of 6 mol $AlCl_3$.[1]

(ii) When VIIIa, and b were treated with benzene and toluene in 12 mol $AlCl_3$, they gave the corresponding *o*-aroylbenzophenone anils (VIa, and b) *via* carbonium ion X.

Action of Grignard Reagents. We have reinvestigated[6a,b] the problem of reaction of Grignard reagents with 4-aryl-1*H*-2,3-benzoxazin-1-ones (I).

Phenylmagnesium bromide reacts with 4-(*p*-tolyl)-, and 4(*p*-chlorophenyl)-1*H*-2,3-benzoxazin-1-ones (Ib and c) to give oximes of 2'-(*p*-toluoyl)-, and 2-(*p*-chlorobenzoyl)-triphenyl methanols (XIa and b), respectively.

Similarly, *o*-anisylmagnesium bromide reacts with



XI

Experimental

All mp's are not corrected, IR spectra were measured on a Unicam SP 1200 spectrophotometer by means of KBr wafer technique.

Action of Amines on 4-Aryl-1H-2,3-benzoxazin-1-ones (I a, b). Formation of IIa—d: A mixture of Ia, b (0.1 mol), and amine (0.6 mol) was heated at 150 °C on a sand bath for 12 hr. The excess amine was removed with concd-hydrochloric acid, and the solid product obtained was crystallized from methanol (Table 1).

Action of Benzylamine on Ia—c in Benzene. Formation of IIIa—c: To a solution of Ia—c (0.1 mol) in benzene (20 ml) was added benzylamine (0.3 mol). The reaction mixture was heated under reflux for about 12 hr, and then cooled. The solid product was filtered off, and crystallized from benzene (Table 2).

Action of Phenylhydrazine on Ia—c. Formation of IVa—c: A solution of Ia—c (0.1 mol) in glacial acetic acid (20 ml) was treated with phenylhydrazine (0.3 mol). The reaction mixture was heated under reflux for 2 hr and then cooled. The solid product was filtered off and crystallized from acetic acid (Table 3).

Action of Anhydrous $AlCl_3$ in Reactive Aromatic Hydrocarbon Substrates on Ia—c. Formation of VIa—i: Anhydrous aluminium chloride (12 mol) was added under stirring to a solution of Ia—c (0.1 mol) in dry aromatic substrates (20 ml). The reaction mixture was heated under reflux for 6 hr, and the complex formed was decomposed with ice-cold dilute hydrochloric acid. The solvent was steam distilled, and the residual solid was filtered off and crystallized from ethanol (Table 4).

Action of Anhydrous $AlCl_3$ (VIIIa, and b). Formation of VIa, and b: Anhydrous aluminium chloride (12 mol) was added under stirring to a solution of VIIIa and b (0.1 mol) in dry aromatic substrates (20 ml). The reaction mixture was

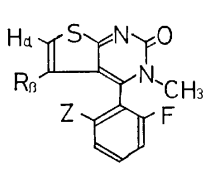
(Received September 10, 1975)

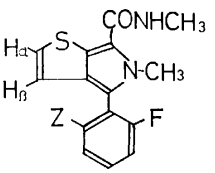
Synopsis. Bicyclic thiophene derivatives, 3-methyl-4-(*o*-fluorophenyl)-2,3-dihydrothieno[2,3-*d*]-pyrimidin-2-ones (I) and *N*,5-dimethyl-4-(*o*-fluorophenyl)-5*H*-thieno[2,3-*c*]-pyrrole-6-carboxamides (II), have been prepared. Two sorts of ^{1}H, ^{19}F spin coupling over six bonds attributable to a through-space mechanism have been observed in the ^{1}H NMR spectra of these compounds.

In previous papers,[1-2] we reported that long-range spin couplings over six or seven bonds are observed in various bicyclic thiophene derivatives; the coupling was considered to arise from a through-space mechanism. In the course of our synthetic studies of biologically active thiophenes, we have also found in the ^{1}H NMR spectra of other kinds of bicyclic thiophene derivatives, I and II, the presence of two long-range couplings, $^6J_{HF}$, between *N*-methyl protons and fluorine as well as between the H_β of the thiophene ring and the fluorine; these are also considered to be through-space couplings. Myhre *et al.* have already reported through-space couplings between fluorine and two different protons in a molecule of 2,4,6-tri-*t*-butylfluorobenzene.[4] In this paper, we will present our observations of the $^6J_{HF}$ in these new compounds. As is shown in Table 1,

TABLE 1. J_{HF} IN COMPOUNDS I AND II



I

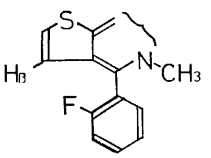


II

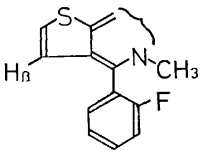
Compound	Z	R	$J_{H_\beta,F}$	$J(NCH_3,F)$
Ia[a]	H	H_β	0.6 d[b]	1.2 d
Ib[a]	F	H_β	1.0 t[c]	0.8 t
Ic	H	CH_3	—	0.5 d
IIa[a]	H	—	0.8 d	1.8 d
IIb[d]	F	—	1.0 t	1.3 t

a) J_{H_α,H_β}=6.3 Hz, b) doublet, c) triplet, d) J_{H_α,H_β}=5.3 Hz.

both *N*-methyl and H_β exhibit doublet signals in *o*-fluorophenyl-I and -II (Ia and IIa) and a triplet in 2,6-difluorophenyl-I and -II (Ib and IIb). These facts suggest the presence of a long-range coupling over six bonds between the *N*-methyl protons and fluorine as well as between the H_β of the thiophene ring and the fluorine. When the J_{HF} value of the *o*-fluorophenyl compound is compared with that of the corresponding 2,6-difluorophenyl compound, the $J(H_\beta, F)$ value is smaller for the former (Ia, 0.6 Hz; IIa, 0.8 Hz) than for the latter (Ib, 1.0 Hz; IIb, 1.0 Hz). On the contrary, the $J(CH_3, F)$ value is greater for the former (Ia, 1.2 Hz; IIa, 1.8 Hz) than for the latter (Ib, 0.8 Hz; IIb, 1.3 Hz). Since the torsional angle between the thiophene and the benzene-ring planes should be greater for the 2,6-difluorophenyl compound than for the *o*-fluorophenyl compound,[1] these facts reasonably suggest that, of the two possible conformers (A and B),



A



B

the B conformer in which the fluorine atom is more proximate to the *N*-methyl group, is much predominant in the *o*-fluorophenyl compounds, I and II. When H_β is replaced by a methyl group, the $J(CH_3, F)$ value is decreased from 1.2 Hz (Ia) to 0.5 Hz (Ic). This phenomenon can easily be understood because the torsional angle between the thiophene and the benzene planes should be greater for Ic than for Ia as a result of the steric hindrance between the methyl group of the thiophene and the benzene rings in Ic. This greater torsional angle should lead to an increase in the internuclear distance between the *N*-methyl protons and fluorine.

Experimental

Measurements. The ^{1}H NMR spectra were recorded on a Hitachi R-20-B spectrometer at 60 MHz, using $CDCl_3$ solutions (about 10%w/v) containing TMS as an internal reference at a probe temperature of 35 °C. The chemical shifts are expressed in δ (ppm) with a precision of $\pm$0.01. The coupling constants were measured by several sweepings at an expanded width (60 or 120 Hz) with an accuracy of $\pm$0.1 Hz. The IR spectra were recorded as Nujol mulls on a Hitachi EPI-G-3 spectrophotometer (wave number, cm^{-1}). The UV spectra (wavelength) were determined in 95% ethanol with a Hitachi-323 spectrophotometer. The melting points were measured on a Thomas-Hoover melting-point apparatus and are uncorrected.

Materials. The preparation of the following compounds has already been reported: 4-(*o*-fluorophenyl)-3-methyl-2,3-dihydrothieno[2,3-*d*]pyrimidin-2-one(Ia)[5] and

3,5-dimethyl-4-(*o*-fluorophenyl)-2,3-dihydrothieno[2,3-*d*]pyrimidin-2-one (Ic).[2] The other compounds were prepared by the following methods.

4-(2,6-Difluorophenyl)-3-methyl-2,3-dihydrothieno[2,3-d]pyrimidin-2-one (Ib). 2-Amino-3-(2,6-difluorobenzoyl)thiophene[1] and methyl isocyanate in benzene were heated under reflux to afford 4-(2,6-difluorophenyl)-4-hydroxy-3-methyl-1,2,3,4-tetrahydrothieno[2,3-*d*]-pyrimidin-2-one (yield, 36.9%; mp 212—217 °C), which was then heated at 240 °C to afford Ib. Yield, 11.0%; mp 188—190 °C (from ethanol–ether). IR: 3060, 1665, and 1620. NMR: 3.54 (3H, t, N–CH_3), 6.42 (1H, d–d, H_β) and 6.97 (1H, d, H_α). UV: 220.5 (19100), 251.5 (24300), 292 (2700) and 374 (5200). Found: C, 56.09; H, 3.09; N, 10.12%. Calcd for $C_{13}H_8N_2OSF_2$: C, 56.11; H, 2.90; N, 10.07%. The same procedure was applied to the synthesis of 3-methyl-4-phenyl-2,3-dihydroquinazolin-2-one by Metlesics *et al.*[6]

Compounds IIa and IIb. These compounds were prepared from 5-(*o*-fluorophenyl or 2,6-difluorophenyl)-1-methyl-1,3-dihydro-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-one[1,5] with sodium hydride and methyl iodide. The same procedure was applied to the synthesis of 5-chloro-*N*, 2-dimethyl-3-phenyl-1-isoindolecarboxamide by Fryer *et al.*[7]

N,*5-Dimethyl-4-(o-fluorophenyl)-5H-thieno[2,3-c]pyrrole-6-carboxamide (IIa).* Yield, 31.1%; mp 131—132 °C (from ether). IR: 3300 and 1625. NMR: 3.04 (3H, d, J=4.9, $NHC\underline{H}_3$), 4.01 (3H, d, N^5–CH_3), 5.07 (1H, broad s, NH), 6.88 (1H, d–d, H_β) and 7.00 (1H, d, H_α). UV: 224 (14700), 251 (15800) and 324 (18900). Found: C, 62.60; H, 4.56; N, 9.92%. Calcd for $C_{15}H_{13}N_2OSF$: C, 62.49; H, 4.54; N, 9.71%.

4-(2,6-Difluorophenyl)-N,5-dimethyl-5H-thieno[2,3-c]pyrrole-6-carboxamide (IIb). Yield, 36.4%; mp 165—166 °C (from ethanol). IR: 3300 and 1627. NMR: 3.04 (3H, d, J=4.8, $NHC\underline{H}_3$), 4.00 (3H, t, N^5–CH_3), 5.67 (1H, broad s, NH), 6.83 (1H, d–t, H_β) and 7.03 (1H, d, H_α). UV: 221 (16200), 250.5 (15700) and 321 (18900). Found: C, 58.77; H, 4.05; N, 9.18%. Calcd for $C_{15}H_{12}N_2SOF_2$: C, 58.81; H, 3.95; N, 9.14%.

The authors wish to thank Professor Masamichi Tsuboi, The University of Tokyo, and Dr. Makoto Sunagawa of this Institute for their valuable suggestions. and Mr. Hiromi Sato for his cooperation in the synthetic experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (5), 1397—1398 (1976)

A MINDO/2′-MO Study of the Inversion Barriers of Some Molecules Involving First-Row Atoms

Katsutoshi OHKUBO, Yutaka AZUMA, and Masahide OKADA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami 860

(Received July 28, 1975)

Synopsis. The inversion barriers of CH_3^-, NH_3, CH_3NH_2, $(CH_3)_2NH$, $(CH_3)_3N$, NH_2OH, NH_2CHO, and OH_3^+ were investigated by means of the MINDO/2′ method. Although the calculated bond lengths are in satisfactory agreement with the experimental values, the calculated bond angles are too large and resulted in relatively low inversion barriers in comparison with the observed values.

In general, pyramid-like molecules involving an unshared pair on its central atom instead of a fourth substituent indicate the intramolecular motions which lead to inversion.

Inversion barriers are intimately related to the configurations (especially, bond angles) of molecules,[1] for instance, the smaller angles of phosphine, arsine, *etc.*, as compared with those of ammonia, make inversion more difficult.[2]

Recently, Allen and Arents[3] have argued that carefully parametrized semiempirical adaptations of the SCF-MO method can be useful for investigating inversion barriers. Stevenson and Burkey[4] have compared the effectiveness of several different versions of the CNDO and INDO methods in predicting the inversion barriers of AR(R′) (R″), where A=C, N, O, Si, P, and S, and they demonstrated a predominant utility of the INDO method. However, all previous semiempirical calculations of the inversion barriers[5] were performed without optimization of the molecular geometries for the compounds investigated.[6]

On the other hand, a few *ab initio* calculations have also been performed on the inversion barriers of small molecules such as NH_3; Rauk *et al.*[7] have obtained an inversion barrier of 5.08 kcal/mol (exptl.=5.8 kcal/mol[8]) for NH_3 using an *ab initio* method with a large gaussian basis set, while Sambe and Felton[9] have reported a negative barrier of −62.77 kcal/mol for the same molecule using an LCAO-X_α method without the nitrogen d-orbitals.

The present authors report, here, on an extensive study of the inversion barriers of CH_3^-, NH_3, CH_3NH_2, $(CH_3)_2NH$, $(CH_3)_3N$, NH_2OH, NH_2CHO, and OH_3^+, which were investigated by means of the MINDO/2′ method.[10]

Method of Calculation

The MINDO/2′ method used for the present study is a modified version of MINDO/2[11] which has already been found to suffer from serious defects, including: (a) an overestimation of the dipole moments, (b) an underestimation of the strain energies of small rings, and (c) an incomplete treatment of heteroatoms.[12] The integrations and parametrizations involved in the present method will not be repeated here, because they have been described in detail in Ref 10.

The optimizations were performed on the geometrical parameters for the ground-state and transition-state molecules in which the geometries of the substituents (R, R′, and R″) were fixed by the use of the standard bond lengths and angles[13] in order to simplify the computation.

Results and Discussion

Let us first examine the optimized geometries of the compounds investigated in their ground and transition states. As can be seen from Table 1, the calculated bond lengths except that of the N–O bond in NH_2OH are in satisfactory agreement with the observed values and the differences between the ground-state and transition-state configurations are not too great. The bond length for the N–O bond in NH_2OH, which is too short, is mainly attributable to an underestimation (caused by the neglect of two-center integrals involving one-center overlap) of the lone pair-lone pair interactions in the present method.[14] This trend was also found for the bond lengths of O–O (in H_2O_2) and N–N (in N_2H_4) calculated by the MINDO/2′ method,[14] which were also too short. The calculated bond angles are too large in comparison to the observed values except for

those of NH_3. This may be a result of the fact that the MINDO/2′ method, as well as the original version called MINDO/2, is still unsatisfactory for the parametrization (α and B) of heteroatoms, such as nitrogen, and overestimates nonbonded hydrogen-hydrogen repulsions in such molecules as $(CH_3)_2NH$ and $(CH_3)_3N$.[15]

It should be stressed here that the present MINDO/2′ calculations for the compounds (with fixed geometries of the substituents) listed in Table 1 result in almost the same bond lengths and angles as the calculations with no geometrical assumptions (with all bond lengths and angles variable), for example, an MINDO/2′ calculation of $(CH_3)_3N$ with no geometrical assumptions gave N–C=1.44 Å, C–H=1.082 Å, $\angle$CNC=119.99°, and $\angle$NCH=114.91°. Therefore, there are no serious defects in the geometrical assumptions for the substituents (R, R′, and R″) in terms of the calculated bond lengths and angles.

In connection with the unsatisfactory results for the optimization of the bond angles, dipole moments (μ) are calculated incorrectly with marked deviations from the experimentally determined values, although the calculated ionization potentials (I_p)[19] are in good overall agreement with the observations (see Table 1).

Now, we turn our attention to the inversion barriers of the compounds investigated. In Table 2, the calculated inversion barriers were listed together with those evaluated by the CNDO/2 or INDO method. As Table 2 indicates, the CNDO/2 method results in remarkably high inversion barriers in comparison with the INDO or MINDO/2′ method, probably because it not only excludes the one-center atomic exchange integrals but suffers markedly from the parametrization.[20] With regard to the results of the present MINDO/2′ calculations, the inversion barriers were predicted to be relatively low in comparison with the experimental values. This is due to inadequate optimization (*viz.*, overestimation) of the bond angles for the ground-state configuration of the molecule.

Polarographic Studies on Bipyridine Complexes. IV. The Polarography of the Dicyanobis(2,2′-bipyridine)iron(II) Complex

Tetsuo SAJI and Shigeru AOYAGUI*

Faculty of Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received October 2, 1975)

Synopsis. Each electron added to the oxidant in the first two reduction waves of a polarogram for dicyanobis(2,2′-bipyridine)iron(II) is concluded to occupy a π^*-orbital localized on a bipyridine molecule, on the basis of the number of the reversible waves and the half-wave potential shift caused by the methyl substitution of ligand bipyridines.

In Parts I—III of this series,[1-3] the molecular orbital occupied by the electron added or removed in the course of oxidation-reduction reactions of tris(bipyridine) complexes of transition metals was discussed on the basis of the polarographic half-wave potentials. In this paper, the same discussion will be extended to dicyanobis(2,2′-bipyridine)iron (II).

Experimental

4,4′-Dimethyl-2,2′-bipyridine (4-dmbipy) and 5,5′-dimethyl-2,2′-bipyridine (5-dmbipy) were prepared according to the method of Sasse and Whittle.[4] Dicyanobis(2,2′-bipyridine)iron(II) and its dimethyl derivatives were prepared by the method of Shilt.[5] *N,N*-Dimethylformamide (DMF) was used as a solvent. The supporting electrolyte was 0.1 M tetrabutylammonium perchlorate (TBAP). The electrolysis cell[3] and the following experimental procedures have been described in previous papers: the preparation of TBAP and solutions,[6] the purification of DMF,[6] and the measurements of polarograms and cyclic voltammograms.[1] The measurements were carried out at room temperature. All the potentials were referred to a saturated calomel electrode (SCE).

Results and Discussion

Figure 1 shows a cathodic polarogram for $Fe(bipy)_2(CN)_2$ (bipy=2,2′-bipyridine). It exhibits three waves with half-wave potentials of −1.59, −1.90, and −2.6 V. The wave height at −2.6 V is higher than the others. The first two waves were concluded to be reversible one-electron wave on the basis of the cyclic voltammogram in Fig. 2, taken with an initial cathodic scan. They can be assigned to the following redox systems respectively: $Fe(bipy)_2(CN)_2/Fe(bipy)_2(CN)_2^-$ and $Fe(bipy)_2(CN)_2^-/Fe(bipy)_2(CN)_2^{2-}$.

Fig. 2. Cyclic voltammogram with initial cathodic scan for 1 mM $Fe(bipy)_2(CN)_2$ in DMF containing 0.1 M TBAP. Scan rate: 0.1 V s^{-1}.

TABLE 1. THE REVERSIBLE HALF-WAVE POTENTIALS FOR $FeL_2(CN)_2$ (L=bipy, 4-dmbipy, 5-dmbipy), $E^{red}_{1/2,C}$, IN DMF CONTAINING 0.1 M TBAP

Complex	$E^{red}_{1/2,C}$/V *vs.* SCE	
	1st wave	2nd wave
$Fe(bipy)_2(CN)_2$	−1.59	−1.90
$Fe(4\text{-}dmbipy)_2(CN)_2$	−1.69	−1.98
$Fe(5\text{-}dmbipy)_2(CN)_2$	−1.73	−2.05

Similar polarograms and cyclic voltammograms were also obtained for the methyl-substituted complexes. The half-wave potentials of the redox systems, $FeL_2(CN)_2/FeL_2(CN)_2^-$ and $FeL_2(CN)_2^-/FeL_2(CN)_2^{2-}$ (L=bipy, 4-dmbipy, 5-dmbipy), became more negative in this order: bipy<4-dmbipy<5-dmbipy (Table 1). It should be noted that an empirical rule has been obtained concerning the order of the reversible half-wave potentials of tris(bipyridine) complexes of transition metals:[1] When an electron is added to a ligand π^*-orbital by the electrochemical reduction of a complex, the reduction half-wave potential, $E^{red}_{1/2,C}$, is shifted, on the methyl-substitution of ligand bipyridines, to a more negative potential in this order: bipy<4-dmbipy<5-dmbipy. The relation between the reduction half-wave potentials of free ligand molecules, $E^{red}_{1/2,L}$, and the $E^{red}_{1/2,C}$ for $FeL_2(CN)_2/FeL_2(CN)_2^-$ satisfies Eq. 3 in Part I,[1] as shown in Fig. 3. Consequently, it may be concluded that the electrons added to $FeL_2(CN)_2$ in the first two reduction steps occupy ligand π^*-orbitals.

It has been noted that there exsists a correlation be-

* To whom correspondence should be addressed.

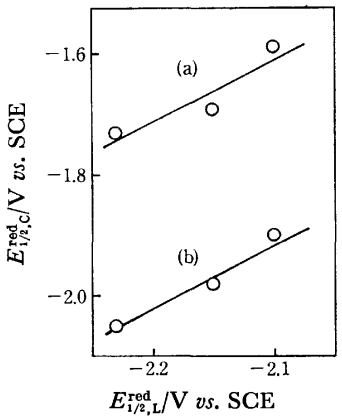

Fig. 3. Plot of half-wave potentials for (a) $FeL_2(CN)_2$/$FeL_2(CN)_2^-$ and (b) $FeL_2(CN)_2^-$/$FeL_2(CN)_2^{2-}$, $E^{red}_{1/2,C}$, *vs.* those for L/L^-, $E^{red}_{1/2,L}$, in DMF containing 0.1 M TBAP. L=bipy, 4-dmbipy, 5-dmbipy. The $E^{red}_{1/2,L}$ data can be found in Ref. 1.

tween the number of reversible reduction waves of a complex and the number of its ligands of a π-character:[1,7] The polarogram of this kind of complex is characterized by nearly neighboring one-electron waves, the number of which is identical with that of the ligands. This correlation can be found in the polarograms for bis(2,2′,2″-terpyridine)iron(II),[1,8,9] tris(4,7-diphenyl-1, 10-phenanthroline)iron(II),[7,10] tris(2,2′-bipyridine)iron(II),[1,8,11] tris(2,2′-bipyridine) ruthenium(II),[1,9] and tris(2,2′-bipyridine)osmium-(II).[1] It is evident that this rule holds also for Fe-$(bipy)_2(CN)_2$. This fact suggests that the lowest π^*-orbitals are nearly doubly degenerate. Thus, in the two reversible reduction waves for $Fe(bipy)_2(CN)_2$, each added electron should occupy one of the nearly degenerate orbitals successively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (5), 1401—1402 (1976)

Studies of the $\pi \rightarrow \pi^*$ Absorption Bands of 1,2-Naphthoquinone

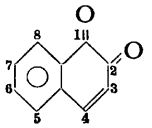
Akira KUBOYAMA and Hiroshi ARANO

National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151

(Received October 30, 1975)

Synopsis. The $\pi \rightarrow \pi^*$ S–S absorption spectra up to the vacuum UV region of 1,2-naphthoquinone in solutions were obtained. Based on MO calculations, the observed five $\pi \rightarrow \pi^*$ bands of 1,2-naphthoquinone are assigned, and the alkyl-group substitution effects on the excitation energy of the longest-wavelength $\pi \rightarrow \pi^*$ band are discussed.

Previously, the present authors have theoretically and experimentally studied the $\pi \rightarrow \pi^*$ absorption bands of *p*-quinones[1] and 9,10-phenanthrenequinone[2] up to the vacuum UV region. In this note, the $\pi \rightarrow \pi^*$ absorption spectrum of 1,2-naphthoquinone (1,2-NQ), which has been studied by few workers, is reported.



The absorption spectra were obtained in the same manner as in that described in previous reports.[1,2] The solvents, heptane and 1,1,1,3,3,3-hexafluoro-2-propanol (HFP) were the same as those used in previous works.[1,2] The 1,2-NQ was prepared according to the Fieser method[3] (mp 146 °C with decomp.).

TABLE 1. WAVELENGTHS AND MOLAR ABSORPTION COEFFICIENTS (IN PARENTHESES) OF THE ABSORPTION MAXIMA

Heptane	HFP	Band name
382 (nm)	425 (2180)	I
338 326	354 (3370)	II
251 245	255 (27500) 249 (27500)	III
195	196 (24300)	IV
	~170 (~22500)	V

In the P-P-P method calculations, the electronic integral values used were the same as those used in previous calculations,[1,2] except for the core resonance integral values for the carbon-carbon bonds. The latter were taken to be −1.5, −2.7, and −2.3 eV for the conventional single and double bonds, and the benzene-ring bonds, respectively. These values are close to those obtained by the Pariser-Parr method,[4] except for that of the double bond which is smaller than the latter by *ca.* 0.2 eV. In the CI calculation, all the singly-excited configurations were included. The molecular structure of 1,2-NQ was assumed to be planar. The lengths of the C–O bonds, the C(1)–C(2) bond, conventional C–C single and double bonds, and the benzene-ring bonds of 1,2-NQ were assumed to be 1.215, 1.49, 1.465, 1.35, and 1.40 Å, respectively.[1,2] All the valence angles in 1,2-NQ were assumed to be 120°.

TABLE 2. CALCULATED EXCITATION ENERGIES AND OSCILLATOR STRENGTHS OF THE SINGLET π, π^* EXCITED STATES AND THE CORRESPONDING $\pi \rightarrow \pi^*$ BANDS IN THE HEPTANE SOLUTION

	Calculated			Observed	
No.	Angle (°)	E (eV)	f	Band name	E (eV)
1	106	4.320	0.077	I	3.3
2	124	4.486	0.091	II	3.7
3	67	5.286	0.587	III	5.0
6	99	5.953	0.425	IV	6.4
7	23	6.189	0.585		
13	151	7.215	0.417	V	7.3[a]
14	168	7.412	0.344		

a) This value is that of the HFP solution.

The n$\rightarrow\pi^*$ absorption band of 1,2-NQ is near 520 nm.[5] In Fig. 1, five $\pi \rightarrow \pi^*$ bands can be observed for the HFP solution. These $\pi \rightarrow \pi^*$ bands are denoted as Bands I-V, as is shown in Table 1. As is seen in Fig. 1, the intensity ratio of Band I to Band II in the HFP solution is very different from that in the heptane

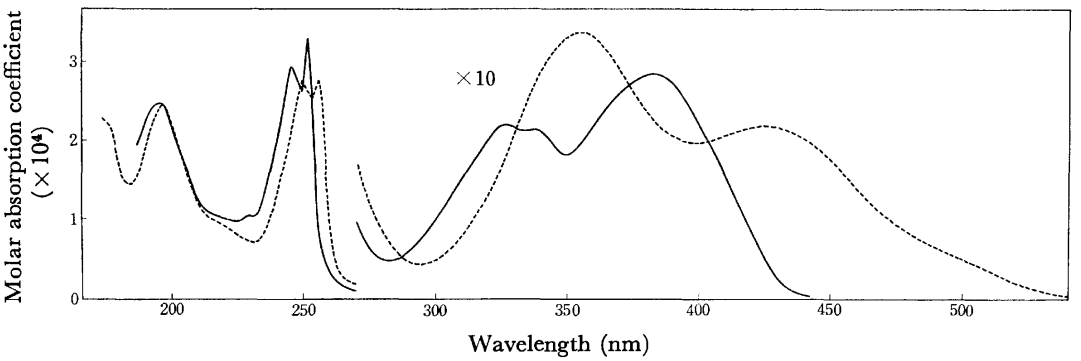


Fig. 1. Absorption spectra of 1,2-naphthoquinone in various solvents.
——: Heptane, ------: 1,1,1,3,3,3-hexafluoro-2-propanol.
In the heptane solution the scale of the ordinate is arbitrary.

solution and Bands I and II in the HFP solution show large red-shifts compared with those in the heptane solution. These facts may be due to the strong hydrogen-bond formation between 1,2-NQ and HFP.

In Table 2, the first column denotes an order based on the magnitude of the calculated excitation energies and the second column denotes the clockwise rotation angles of the directions of the transition moments with respect to the C(6)–C(7) bond axis. In this table, the data on the more highly-excited states with small *f*-values have been omitted. As may be seen in Table 2, the assignments of Bands I, II, and III based on the calculated results are reasonable, but those of Bands IV and V are not clear.

Table 3. The changes in the calculated excitation energy of the lowest π, π^* excited state of 1,2-NQ with alkyl-group substitutions at various positions

Position	ΔE (eV)[a]	Position	ΔE (eV)[a]
3	−0.067	6	+0.023
4	−0.018	7	−0.040
5	−0.043	8	−0.014

a) ΔE denotes the energy difference where the excitation energy of 1,2-NQ is subtracted from the corresponding energy for the substituted 1,2-NQ.

The changes in the calculated excitation energy of the lowest π,π^* excited states (state no. 1) with the alkyl-group substitutions are shown in Table 3. These calculations were carried out in the same manner as in previous works.[1,2] It is known that the methyl-group substitution at the 3-position of 1,2-NQ results in a relatively large red-shift of Band I.[6] In Table 3, the large energy decrease in the 3-position is consistent with this fact. In Table 3, the large energy increase in the 6-position is notable. Based on this result, a blue-shift of Band I of 6-alkyl-1,2-NQ compared with that of 1,2-NQ is expected. Since in 1,2-NQ the 6-position is the *para* position of the benzene nucleus with respect to the carbonyl group, this result is similar to that obtained for 9,10-phenanthrenequinone as reported in a previous paper.[2]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (5), 1403—1404 (1976)

An Observation of Compensation Effects between Enthalpy and Entropy Changes in the Interaction of Nickel-2,2′-bipyridine Complexes with Olefins

Akio YAMAMOTO and Takakazu YAMAMOTO

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

(Received November 13, 1975)

Synopsis. Compensation effects in the thermodynamic parameters $\Delta H°$ and $\Delta S°$ in the coordination of olefins with Ni(bpy) and NiR_2(bpy) (bpy=2,2′-bipyridine) and in the kinetic parameters $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ in reactions of NiR_2(bpy) with olefins have been observed; factors governing these compensation effects are discussed.

Coordination of an olefin to a transition metal having a σ-metal-carbon bond with a resultant activation of the metal-carbon bond constitutes a key step in various transition-metal promoted reactions of olefins. Despite the tremendous increase in the number of isolated olefin-metal complexes,[1] thermodynamic and kinetic data concerning the interaction of olefins with transition-metal complexes are quite meager and this situation seems to hinder the further understanding of the nature of the olefin-metal interaction. Dialkyl(2,2′-bipyridine)nickel(II), NiR_2(bpy) **1** (bpy=2,2′-bipyridine, R=CH_3, C_2H_5, C_3H_7, *i*-C_4H_9), and olefin-coordinated zerovalent nickel complexes, Ni(olefin)$_n$(bpy) **2** (n=1 or 2), have proved to be quite amenable to a quantitative investigation of the olefin-metal interaction.[2,3] Previous studies have established that the interaction of **1** with an olefin proceeds through the following reaction steps:

$$\underset{\mathbf{1}}{NiR_2(bpy)} + \text{olefin} \overset{K_1}{\rightleftharpoons} \underset{\mathbf{2}}{NiR_2(bpy)(olefin)} \qquad (1)$$

$$\underset{\mathbf{2}}{NiR_2(bpy)(olefin)} \xrightarrow{k} \underset{\mathbf{3}}{Ni(bpy)(olefin)} + 2R \qquad (2)$$

$2R=C_2H_6$, C_4H_{10} for R=CH_3, C_2H_5
$2R=C_3H_6+C_3H_8$, $C_4H_8+C_4H_{10}$ for R=C_3H_7, C_4H_9

Furthermore, the stability constants of the zerovalent olefin-nickel complexes in the following equilibria have been evaluated:

$$\text{Ni(bpy)(solvent)} + \text{olefin} \overset{K_2}{\rightleftharpoons} \underset{\mathbf{3}}{\text{Ni(bpy)(olefin)}} + \text{solvent} \qquad (3)$$

Examination of the enthalpy change ($\Delta H°$) and entropy change ($\Delta S°$) in equilibria (1) and (3) and of Eyring's enthalpy of activation ($\Delta H^{\ddagger}$) and entropy of activation ($\Delta S^{\ddagger}$) in the splitting of Ni–C bonds in **1** has revealed the presence of clear compensation effects between $\Delta H°$ and $\Delta S°$, as well as between $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$. Here, results are reported in order to provide the basis for further discussions on transition metal-olefin interactions.

Compensation Effects between ΔH° and ΔS° in the Coordination of Olefins with Ni(bpy) and NiR_2(bpy). Figure 1 clearly demonstrates the presence of compensation effects in equilibria (1) and (3). Plots of $\Delta H°$ and $\Delta S°$ values for reaction (3) give a straight line over a very wide range (line A in Fig. 1), except for maleic anhydride, the only α,β-disubstituted olefin among the olefins examined. The plot of $\Delta H°$ and $\Delta S°$ values for Eq. 1 also gives a straight line with a steeper slope (line B in Fig. 1).[4] For the sake of numerical comparison, the following expression is used

$$\Delta S° = C_1 \Delta H° + C_2, \qquad (4)$$

where C_1 and C_2 are constants derived from the slopes and intercepts of straight lines A and B in Fig. 1. These values are tabulated in Table 1.

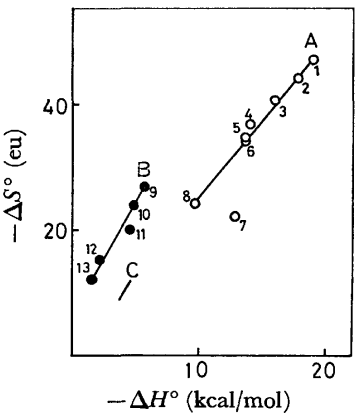

Fig. 1. The plots of $\Delta S°$ against $\Delta H°$ in the equilibria (1) and (3). Ni(bpy), line A: (1) acrylaldehyde, (2) acrylamide, (3) acrylonitrile, (4) methacrylonitrile, (5) methyl acrylate, (6) methyl vinyl ketone, (7) maleic anhydride, (8) methyl methacrylate. For NiR_2(bpy), line B: (9) R=C_2H_5, acrylaldehyde, (10) R=*n*-C_3H_7, acrylonitrile, (11) R=C_2H_5, acrylonitrile, (12) R=CH_3, acrylonitrile, (13) R=*i*-C_4H_9, acrylonitrile. The straight line C was taken from Fueno's paper.[5]

Table 1. The compensation effect between $\Delta H°$ and $\Delta S°$ in the coordination of olefins with metals

Metal	Olefin	$C_1 \times 10^3$ (eu/(cal/mol))	C_1T (at T=300)	C_2 (eu)
Ni(bpy)	β-Unsubstituted vinyl compound	2.1	0.6	+1
NiR_2(bpy)	β-Unsubstituted vinyl compound	3.3	1.0	+6
Ag^+	β-Unsubstituted vinyl ether[a]	3.0	0.9	−2

a) The values for the argentation of β-unsubstituted vinyl ethers were taken from Ref. 5.

Fueno and coworkers have previously observed a similar compensation effect in the argentation of vinyl ethers and alkenes over a narrower range as shown by line C in Fig. 1.[5] The C_1 and C_2 values are also included in Table 1. It is noteworthy to observe the presence of a compensation effect over such a wide range in the coordination of olefins bearing a variety of electron-withdrawing substituents with the nickel complexes, as well as in the argentation of olefins bearing electron-releasing substituents. Although it may be fortuitous, it is intriguing to observe that the extension of line A in Fig. 1 passes through line C. The presence of a compensation effect over this wide range implies that the interaction between the nickel complex and the variety of olefins is dominated by a single factor, namely, the complexation of the olefins with nickel through an olefinic double bond. The side-on coordination of methyl acrylate through the double bond to nickel in the solid Ni(bpy)(methyl acrylate)$_2$ has been recently established.[6] The lesser gradient in line A with a C_1T value of 0.6 at 300 K with respect to line B implies the greater contribution of the enthalpy effect on the stability of the π-olefin complexes **3**. This is in line with the anti-parallel relationship observed between log K_2 and the energy level of the π^*-orbital of the olefins,[2] a fact indicating the importance of back-donation from nickel to the olefin, which determines the stability of **3**.

In Eq. 1, on the other hand, the value of C_1T at room temperature is very close to unity, indicating the complete cancellation of the enthalpy change by the entropy change. In this case, the contribution of entropy is considered to be more important for the stabilization of the π-complexes **2** than in reaction (3) and the freedom of internal rotation of the nickel-bonded alkyl groups may exert a significant effect on the stability of **2** as reflected by the considerably smaller values of ΔS° and ΔH° observed in the complexation of acrylonitrile with the bulky isobutylnickel complex than those obtained for the propylnickel complex.

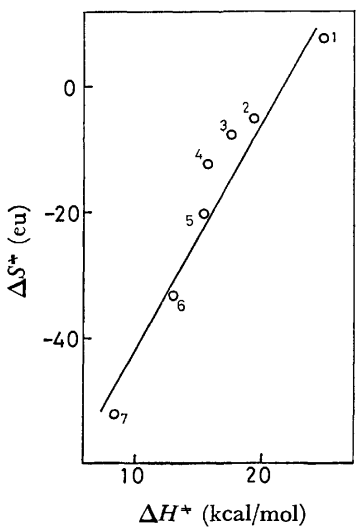

Fig. 2. Relationship between ΔH^* and ΔS^* in the reaction of Ni$(C_2H_5)_2$(bpy) with olefins. (1) methacrylonitrile, (2) acrylamide, (3) methyl vinyl ketone, (4) acrylaldehyde, (5) methyl acrylate, (6) styrene, (7) methyl methacrylate.

These results suggest that a seemingly small variation in the stability constant of a π-complex may not reflect a reater intrinsic change of interaction between an olefin and a transition-metal complex because of the presence of the compensation effect.

Compensation Effect between the Enthalpy of Activation and Entropy of Activation for the Splitting of Nickel–alkyl Bonds Induced by Olefin Coordination. Figure 2 shows that there is a fairly good correlation between ΔH^* and ΔS^* for reactions (1) and (2), which were taken from a previous paper.[2] The slope of the line in Fig. 2 is about 1/300 deg^{-1} which corresponds to a value of 1.0 for $T\Delta S^*/\Delta H^*$ at room temperature, indicating an almost complete cancellation of the entropy and enthalpy effects. The breaking of the Ni–C bond by the interaction with an olefin is a second-order reaction, whose rate constant can be expressed by K_1k in reactions (1) and (2). Since it is observed that $T\Delta S^\circ \fallingdotseq \Delta H^\circ$ in Eq. 1, the present compensation effect for the reaction allows us to deduce that there is a similar compensation effect for the splitting of Ni–alkyl bonds in the olefin coordinated diethyl (2,2′-bipyridine)nickel complex **2** given by reaction (2), namely, the acquired activation enthalpy is almost completely cancelled at room temperature by an increase in the entropy in the activated complex to be thermolyzed. A similar compensation effect in the thermolysis of alkylcopper complexes having tertiary phosphine ligands[7] has been observed.

The Oxygen Gas Permselectivity of Dried Cellulose Acetate Membranes

Yoshio TANIGUCHI and Shinkichi HORIGOME

Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo 185

(Received November 28, 1975)

Synopsis. The oxygen gas permselectivity of annealed cellulose di- and triacetate membranes were investigated. We have suggested that the permeation ratios of oxygen to nitrogen gases of these membranes attain 7—8 by annealing in air at 180 °C.

In recent years, cellulose diacetae membranes have came to play an important role in the reverse osmosis process. Therefore, there have been many investigations concerning the permselectivities for salts in aqueous solutions. However, the gas permselectivities of the cellulose acetate membranes have not been widely investigated. The cellulose diacetate membranes have, though, been found to show 2—3 times as much permeability to oxygen as to nitrogen.[1] Most polymer membranes thus far reported have oxygen permeation ratios to nitrogen ranging from 2 to 6.[2,3]

In this paper, we wish to report that the cellulose di- and triacetate membranes have a higher permeation ratio of oxygen gas than the reported values of this polymer, we have established this by investigating the conditions for the membrane preparation.

The cellulose di- and triacetate used in this study were Eastman's type E398-3 and Daicel's type LT-70 respectively. Two kinds of cellulose diacetate membranes, skinned and dense membrane, were prepared by the same procedure as in a previous paper.[4] Here, "skinned membrane" refers to the membrane consisting of a dense layer or skin, which is only 0.1 to 1.0 μm thick and which is responsible for the separation, on top of a highly porous structure which comprises about 99% of the overall thickness of the membrane. The skinned and dense membranes were both about 120 μm thick.

The cellulose triacetate dense membranes were prepared by a procedure essentially the same as that used for the cellulose diacetate dense membranes. In this case, the casting solvent consisted of 90 wt % dichloromethane and 10 wt % ethanol. The dense membranes were 10—30 μm thick. However, we could not make the skinned membrane of cellulose triacetate because we lack the knowledge of the most combination of solvents.

The skinned membranes were annealed in a water bath for 30 min at 80—90 °C and then freeze-dried in order to maintain the skinned structure of the membranes. The dense membranes were annealed in the air at 180 °C for 2 h.

The instrument for gas permeation measurment was driven by the pressure difference between the atmospheric and the diminished pressure; the gas permeation rates were calculated from the pressure change in the low-pressure region. Pure gases were used as the permeative gases.

The results of the gas permeation of the skinned membranes at 23 °C are shown in Fig. 1. In Fig. 1 the apparent gas permeation rates are used because the dense layer of the skinned membrane was not clear enough to be measured. Figure 1 shows some scatter, but this scatter seems to be result of the fluctuation in freeze-drying conditions. It is apparent from these results that the permeation ratio of oxygen to nitrogen increases with a decrease in the oxygen gas permeation rate, and with an increase in the annealing temperature; finally, it may reach the permeation ratio of the annealed dense membrane to be discussed below. It is also indicated that the non-annealed membranes deviate from this relationship, but the reason for this remains unknown.

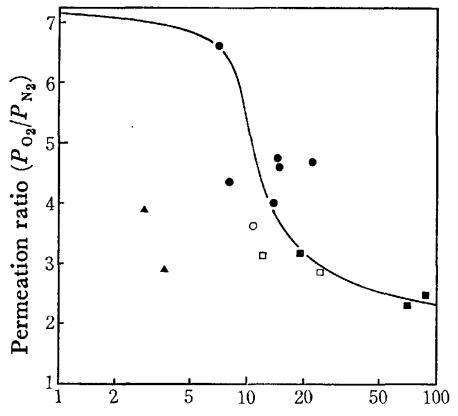

Fig. 1. Gas permeation property of skinned cellulose diacetate membranes.
▲: Non-annealed, ●: annealed at 90 °C, ○: annealed at 85 °C, □: annealed at 80 °C, ■: Gantzel's data.[1]

TABLE 1. GAS PERMEABILITY COEFFICIENTS OF DENSE CELLULOSE DIACETATE MEMBRANES

Annealing condition	Membrane thickness	P_{O_2} (cm²/s cmHg)	P_{O_2}/P_{N_2}
Non-annealed	30 μ	0.72×10^{-10}	3.2
4 h at 180 °C	30	0.93	7.3
Gantzel's data	—	0.78	2.8

TABLE 2. GAS PERMEABILITY COEFFICIENTS OF DENSE CELLULOSE TRIACETATE MEMBRANES

Annealing condition	Membrane thickness	P_{O_2} (cm²/s cmHg)	P_{O_2}/P_{N_2}
Non-annealed (1)	19 μ	1.6×10^{-10}	5.3
Non-annealed (2)	13	1.6	6.2
4 h at 180 °C (1)	18	1.9	7.8
4 h at 180 °C (3)	30	1.5	7.2

The results of the gas permeation of the dense membranes at 23 °C are shown in Tables 1 and 2. It can be noticed from these tables that upon the annealing of the dense membranes the oxygen gas permeation rates are

not affected, while the permeation ratios increase, and that the permeation ratios of cellulose di- and triacetate membranes attain 7.3 and 7.8 respectively. It is noteworthy that the oxygen gas permeation rate of the cellulose triacetate membrane is about twice that of the cellulose diacetate membrane.

It is well known that the gas permselectivity of polymer membranes is determined by the gas solubilities and the gas-diffusion coefficients of the membranes. We measured the oxygen and nitrogen gas solubilities of these membranes, but could not recognize any difference in the solubilities between the non-annealed and annealed membranes.[5] Consequently, we assume that the annealing process mainly influences the diffusion of the gases, and that the pore radii[6] in the cellulose di- and triacetate membranes might be made smaller by the annealing process. This annealing process would have greater effect on the diffusion of nitrogen gas, whose molecular size is larger than that of oxygen gas; therefore, the oxygen permeation ratio would increase.

As has been mentioned above, the cellulose triacetate membrane has a high permeability and permselectivity. Consequently, if one succeeded in making the skinned membrane of cellulose triacetate, it may be expected to be an excellent membrane for separating oxygen gas from nitrogen gas.

Magnetic Susceptibility of Perylene-Iodine Complex

Minoru KINOSHITA,* Hisao KANDA,** and Hideo AKAMATU***

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 5, 1975)

Synopsis. The magnetic susceptibility of a highly conductive 2:3 charge-transfer complex of perylene with iodine has been examined as a function of temperature. The paramagnetic susceptibility, which was found to be nearly independent of temperature, is considered to be due only to the perylene cation radical.

Recently, much interest has centered on the tetracyanoquinodimethane (TCNQ) anion radical salts with high electrical conductivity such as quinolinium-$(TCNQ)_2$, *N*-methylphenazinium-TCNQ and tetrathiofulvalenium-TCNQ. In these complexes, the form of the acceptor has been well established by various electronic, as well as by X-ray crystallographic, analysis. The charge-transfer complexes formed between aromatic compounds and halogens fall into another class of highly-conductive substances.[1-3] The form of halogens in these complexes, however, is not well established

Some time ago, Singer and Kommandeur showed that the spin density of the 2:3 perylene-iodine complex changes exponentially with temperature with an activation energy of 0.019 eV,† which is the same as that for electrical conduction.[4] They measured the ESR absorption intensity in order to obtain the spin density. If the iodine molecule in the complex takes the form of I_2^-, as is commonly supposed in analogy to the TCNQ anion radical salts, it contributes to the paramagnetism.

However, the paramagnetism of I_2^- in the complex can not be detected in the ESR experiments for the following two reasons: (i) the ESR absorption of I_2^- appears over a wide magnetic-field range[5,6] because of the large nuclear spin ($I=5/2$) and the large magnetic moment of the iodine atom, while the absorption of the complex shows a linewidth of several gauss†† at 100—300 K,[4] and (ii) the *g*-values of I_2^- in alkali iodides (V_k center) have been reported to be $g_{//}=1.86$—1.89 and $g_\perp=2.27$—2.30,[6] whereas the average *g*-value of the complex is 2.0033 and the anisotropy is very small.[4] The observed ESR absorption is therefore considered to be due only to the perylene cation radical, even though the acceptor has a paramagnetic form.

It is therefore worthwhile to examine the static magnetic susceptibility of the complex and to compare the results with those obtained by the ESR method. Therefore, the static susceptibility of the 2:3 perylene-iodine complex was measured in the temperature range of 77—296 K. In this note, the data are presented on the basis of the molecular unit of $(C_{20}H_{12})\cdot(I_2)_{1.5}$.

TABLE 1. MOLAR MAGNETIC SUSCEPTIBILITIES OF PERYLENE, IODINE AND THEIR COMPLEX AT ROOM TEMPERATURE

	This work	Literature	Ref.
Perylene ($C_{20}H_{12}$)	160	167	7
		159	2
		166—174	8
Iodine (I_2)	80.0	91.4	9
	77.8	89—92.4	8
Complex [$(C_{20}H_{12})\cdot(I_2)_{1.5}$]	217.8	210[a]	7
		217[b]	2

a) Mole ratio=1:1.34; b) Mole ratio=1:1.63.

The magnetic susceptibilities obtained for perylene, iodine and the complex at 290 K are given in Table 1. Although the values for iodine are a little different from those found in the literature, the present value of -80×10^{-6} emu/mol††† is used in the following. From these results, the diamagnetic contribution is estimated to be -280×10^{-6} emu/mol for $(C_{20}H_{12})\cdot(I_2)_{1.5}$. The discrepancy between the observed and calculated susceptibilities for the complex can then be reasonably ascribed to the paramagnetism resulting from the complex formation; *i.e.*, $\chi_p=62\times10^{-6}$ emu/mol at 290 K.

various temperatures is obtained as shown in Fig. 1, where the susceptibility calculated from the spin density data of Singer and Kommandeur is also shown for comparison.[4] If one considers the difficulty in the ESR intensity measurements, one may conclude that the results obtained by both methods are in complete agreement with each other.

The close agreement between the results by the resonance and static methods thus excludes the possibility that the iodine in the complex is in a paramagnetic form, such as I_2^-. The acceptor should be in diamagnetic form in the complex; it may be I_2, I_3^- or other higher polyiodides, although which cannot be said with certainty. In this connection, it may be noted that Matsunaga has suggested the existence of complex salts of phenothiazine, such as $(\text{phenothiazine})_2^+ \cdot (Br_2I)^-$,[10] and $(\text{phenothiazine})_2^+ \cdot (I_5^-)$[11] from the changes observed in the IR and electronic spectra and in the electrical resistivity when the iodine or phenothiazine was added to the phenothiazine bromide or phenothiazine-iodine complex.

The paramagnetic susceptibility of the complex was found to be independent of temperature. Similar results have been obtained for other systems such as highly conductive TCNQ complexes,[12] although no conclusive explanation has been given. One of the possible explanations is that the paramagnetism is due to the conduction electrons, as proposed by Singer and Kommandeur. In this case, there may be two possible ways to analyze the results. One is the way in which the phenomenon is regarded as Pauli paramagnetism; in which case, the susceptibility is expressed as

$$\chi_p = 2\mu_B^2 \cdot N(\varepsilon_F)$$

where μ_B is the Bohr magneton and $N(\varepsilon_F)$ is the density of states for one spin direction. By neglecting the diamagnetic contribution of the conduction electrons, the density of states for the complex is estimated to be about 1 $eV^{-1} \cdot molecule^{-1}$. This value can be compared with 7.5 $eV^{-1} \cdot molecule^{-1}$ for the quinolinium-$(TCNQ)_2$ complex.[12] The other is the way which has been adopted by Singer and Kommandeur.[4] They plotted $\ln(\chi_p \cdot T)$ against $1/T$ and obtained a straight line. However, in our case where the temperature range is much wider, as Fig. 1 shows, the plot does not give a straight line.

The experimental procedure was as follows. Synthesized perylene was recrystallized successively from benzene and glacial acetic acid, and finally sublimed in a vacuum. The iodine used was obtained by sublimation from a mixture of iodine, potassium iodide and calcium oxide in 10: 1: 2 weight ratios. Four samples of the complex were prepared by two different manners[2,3] and examined by the Faraday method using an apparatus described elesewhere.[13] The freshly-prepared polycrystalline complex was placed in a spherical (5 mm o.d.) thin-walled Pyrex glass container through a small capillary arm, and the container was sealed at the capillary portion with a small flame while the spherical part was immersed in a liquid nitrogen bath. After the measurement, the complex was taken out of the container and analyzed by the titration method.[2] The analysis showed that the complex examined was in a 1: 1.5 molar ratio to within the experimental error. Although only the typical results have been described here, the results obtained for other samples were essentially identical to within the range of experimental error.

Chelation Effect of Alizarin Dyes on the Semiconductor-Aqueous Solution Systems

Michio MATSUMURA, Yoichi NOMURA, and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received December 8, 1975)

Synopsis. The dye-sensitized photocurrents produced by some semiconductor (titanium dioxide single crystal or zinc oxide sinter) in electrolyte solutions containing alizarin dyes were studied. The photocurrent was concluded to be caused by the sensitization of the alizarin dyes chelated to the semiconductor electrodes.

When an *n*-type semiconductor is anodically polarized, a current is induced by light whose photon energy is greater than the band gap of the semiconductor.[1] In cases where the electrolyte solutions contain cyanine dyes or xanthene dyes, photocurrents arise by light absorbed by the dyes.[2] In many cases, such a dye-sensitized anodic photocurrent is believed to be caused by the electron transfer from the excited dye adsorbed on the electrode surface into the electrode.[3–7] However, the effect of light on the dye in the bulk of the solution to produce an electrochemically active species might also be present.[7] These two mechanisms cannot be distinguished experimentally, if one uses a dye-electrolyte solution, as has been done by most previous authors.

This paper presents some results on the sensitized photocurrent by alizarin dyes chelated to the semiconductor electrodes. Very recently, similar work was reported by Danzmann and Hauffe, mainly on azo dyes and zinc oxide single crystal.[8]

Experimental

Titanium dioxide single crystal disks with the (001) face and zinc oxide sintered disks, both *n*-type semiconductors, were used. The structure of the electrodes was mostly the same as described previously.[6,9] The surface of the TiO_2 disk was scratched by rough silicon carbide abrasive to make the surface area large. The potential of the semiconductor electrodes *vs.* the reference electrode (SCE) was controlled by a Hokutodenko HA-101 potentiostat and the current was measured with the aid of a Yokogawa Hewlett Packard LS-2D electrometer. A 500 W xenon lamp (Ushio electric Inc.) was used as a light source, the light being monochromatized by using a Japan Jarrell-Ash, 0.25 m, Ebert type monochromator. The solutions contained 0.2 mol/l Na_2SO_4 as the supporting electrolyte. Oxygen was removed by bubbling with high purity nitrogen gas before measurements. Alizarin, Alizarin S, and quinalizarin were used as the photosensitizer. They belong to the mordant dyes and are known to make lakes with metal oxides. A Simadzu SL-50L spectrometer was used for the measurements of absorption spectra.

Results and Discussion

When TiO_2 powder was added into an aqueous solution of alizarin at the pH of 4.3, the powder colored reddish purple. Figures 1 a) and b) show the absorption spectrum of an aqueous solution of alizarin and

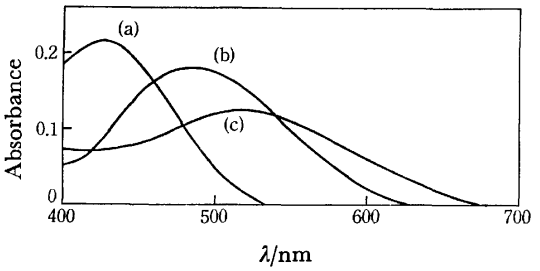

Fig. 1. Absorption spectra of alizarin and the colored powder; (a) a 5.2×10^{-6} mol/l aqueous solution of alizarin, pH=4.3, measured with a 10 cm cell, (b) colored TiO_2 powder in a KBr disk, the absorbance of TiO_2 powder being subtracted, (c) colored ZnO powder in a KBr disk, the absorbance of ZnO powder being subtracted.

that of a potassium bromide disk containing the colored powder, respectively. The absorption spectrum of an ethanol solution of titanium tetrachloride and alizarin nearly coincided with that of the colored TiO_2 powder. It is therefore concluded that the coloration is caused by a chelate compound formed between alizarin and titanium ion at the surface of the TiO_2 powder. The absorption spectrum of the chelate compound on a TiO_2 single crystal was measured through the single crystal, which was similar to that formed on the powder.

When ZnO powder was added into an aqueous alizarin solution, the powder colored purple whose absorption spectrum is shown by Fig. 1 c). This coloration is also considered to be due to the chelate formation at the ZnO surface.

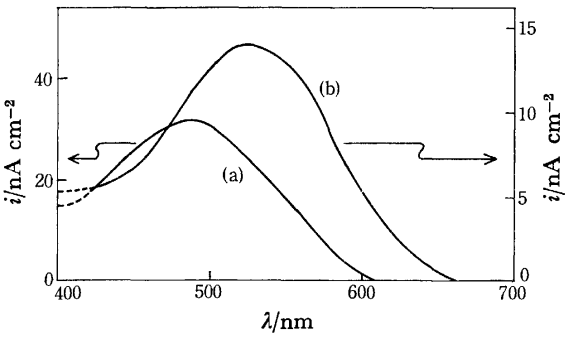

Fig. 2. Photocurrent action spectra in the solution of 5.2×10^{-6} mol/l alizarin at the anodic bias of 0.5 V. The photocurrents are corrected so that they correspond to the values for a uniform light intensity at all wavelengths. (a) For the TiO_2 electrode, with the illumination intensity $I=1.4\times10^{14}$ photons/cm² s. In these conditions the dark current i_d was 10 nA/cm². (b) For the ZnO electrode, $I=4.6\times10^{13}$ photons/cm² s. $i_d=4$ nA/cm².

Figure 2 shows the action spectra of the photocurrents for the TiO_2 and ZnO electrodes in the alizarin–electrolyte solution. They were obtained with a weak illumination intensity, so that the photocurrents did not change during the measurements and the wavelengths were scanned at the high speed of 250 nm/min. The intensity of the photocurrent was also confirmed to be proportional to the illumination intensity at several wavelengths. The action spectra nearly agree with the absorption spectra of the solutions. Consequently, the photocurrents are concluded to be caused by the sensitization due to the chelate compounds formed on the surface of the electrodes and not by the photochemical reactions of the dye in the solution. When each of the electrodes was dipped in a 5.2×10^{-6} mol/l alizarin solution for a while, washed with water, dipped into an electrolyte solution free from dye, and the photocurrents were measured, their action spectra agreed with those shown in Fig. 2. In this case, the intensities of the photocurrents were nearly the same as those observed in the alizarin–electrolyte solution systems. This indicates that the chelate compounds formed on the electrode surfaces are insoluble. The intensities of the photocurrent decayed gradually with illumination, the decay being the faster, the higher the illumination intensity. In the case of the TiO_2 electrode the decayed photocurrents recovered to the initial values, when the electrode was kept in the dark solution for a day. This seems to show that electrons are supplied by some means from the solution to the chelate compound.

Photocurrent measurements were also made for Alizarin S and quinalizarin which form chelate similar to that of alizarin. The action spectra for Alizarin S were confirmed to agree with the absorption spectra of the chelate compounds on the TiO_2 and ZnO powders. For the case of quinalizarin, the photocurrents also seem to be due to the chelate compounds, for their action spectra do not agree with the absorption spectrum of the dye in solution.

Concerning the photo-active species, two structures are considered; one is the alizarin dye directly coordinated to the metal ion which is still in the lattice of the oxide, and the other is the complete chelate compound physically adsorbed on the oxide surface. At present, we cannot decide which of the two models is the correct one. Trial to obtain a stoichiometric chelate compound in a pure state failed.

The present results show that the photo-electrochemical measurements provide a highly sensitive means to obtain the electronic spectra of very small quantities of materials on the solid–liquid interface.

The authors wish to express their gratitude to Wireless Research Laboratory, Matsushita Electric Industrial Co. Ltd. for the kind donation of zinc oxide sinter disks. The present work was partially supported by a Grant-in-Aid for Scientific Reserch from the Ministry of Education (No. 911504).

Charge-transfer Interaction in Supercooled Melts of Some Derivatives of *N*-Picrylaniline

Yoshio MATSUNAGA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 12, 1975)

Synopsis. Supercooled melts of *N*-picrylaniline and its derivatives, the molecules of which consist of electron-donating and -accepting moieties, are colored more deeply than the crystals. Many of them exhibit glass transitions.

Some derivatives of *N*-picrylaniline have been known to be obtained in differently colored forms. For example, Grison has prepared *N*-picryl-*p*-iodoaniline in yellow, orange, and red forms, and determined the crystal and molecular structures.[1] The arrangement of the molecules is quite different in these polymorphic forms, but the structure of the molecule itself remains almost the same. In addition, he has noted that the melt is readily supercooled. Such a sample is red-colored and can be kept at room temperature without crystallization over a period of months. As we have reported for the dimorphic forms of *o*- and *p*-anisyl-*p*-benzoquinones,[2] the difference in color may be explained by the difference in the intermolecular charge-transfer (CT) interaction between the electron-donating moiety of a molecule and the accepting moiety of the neighboring molecule. Both the intensity and the location of the CT absorption are expected to be modified, to some extent, by the mode of molecular packing. As the readiness of supercooling might be correlated with an enhanced CT interaction, the spectral measurement and thermal analysis of supercooled melts have been attempted for a number of the derivatives.

The *N*-picrylanilines were prepared by the condensation reaction between picryl chloride and anilines in boiling ethanol.[3] The latter carried one of the following substituents: methyl, methoxy, ethoxy, chloro, bromo, and iodo. The compounds were melted in small aluminum pans, and then they were quickly cooled by being placed on a cold metal block. For the spectral measurements, the supercooled melts were ground with sodium chloride in concentrations of the order of one weight percent. The spectra were measured by means of a Beckman DK 2A spectroreflectometer as the difference in reflectance between the mixture and pure sodium chloride, and were plotted using the Kubelka-Munk function, $f(R)=(1-R)^2/2R$, where R is the reflectance.[4] The calorimetric curves were recorded on a Rigaku Denki differential scanning calorimeter, Model 8001 SL/C, at a heating rate of 5 °C/min. The glass transitions were measured with samples stored for several days at room temperature.

The color of all the compounds examined here becomes deeper upon melting. The melts are easily supercooled without color change. The most remarkable changes were observed with the derivatives carrying methyl. methoxy, and ethoxy groups. For example, *N*-picryl-*m*-anisidine is yellow in the crystalline state and is reddish orange in the molten and supercooled states. As is shown in Fig. 1, this change is ascribed to the appearance of an additional absorption on the longer wavelength side of the main absorption, having a maximum at about 400 nm. The former may be assigned to the intermolecular CT absorption, and the latter to the intramolecular CT absorption involving the transfer of an electron from the electron-donating moiety to the accepting moiety. The molecular packing in the crystalline state seems to be unfavorable to the intermolecular CT interaction, but a contact between the two moieties may be allowed by the disorder introduced by melting. If the interaction operating in the melt is strong, the disorder is to be conserved below the melting point. The color change observed with *N*-picryl-*o*-anisidine is similar to the afore-mentioned: namely, reddish orange in the crystalline state and deep red in the supercooled state. In this case, the spectral change suggests that the main absorption in the former state arises from the intermolecular CT interaction (see Fig. 1). The maximum of the intramolecular CT absorption may be located at 400 nm.

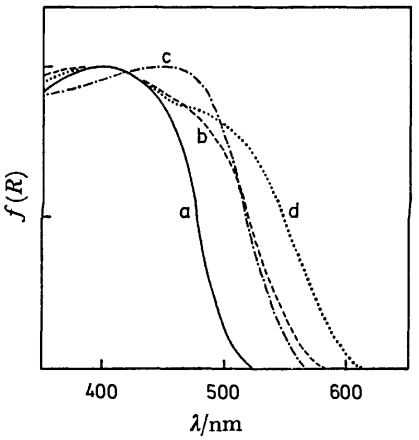

Fig. 1. Spectra of *N*-picryl-*m*-anisidine in the crystalline state (a) and in the glassy state (b) and those of *N*-picryl-*o*-anisidine in the crystalline state (c) and in the glassy state (d). The maximum is arbitrarily taken as 1.00 in each spectrum.

Another feature of interest is the appearance of a glass transition. For instance, the supercooled melt of *N*-picryl-*p*-iodoaniline described by Grison was found to show a small endothermic peak around 60 °C, a large exothermic one around 110 °C, and a large endothermic one near 190 °C. As the location of the last is close to the melting point of the red form, the large exothermic peak must be due to the crystallization of the supercooled melt. The above-mentioned temperature is consistent with Grison's observation that the crystallization into the orange form is rapid in the range from 100 to 120 °C. This form has been reported

a) Partial crystallization occurred, but the peak was too broad to be located.

to be transformed into the red form around 145 °C, but this transition was not detected on our calorimetric curves. One may consider the small endothermic peak around 60 °C as an indication of a glass transition. Such peaks, with areas of 0.3—0.8 kcal/mol at the present heating rate, could be observed with many derivatives, as summarized in Table 1. All the *m*- and *p*-halo derivatives exhibit the transitions. The temperatures in the *p*-derivatives are consistently higher than those in the corresponding *m*-derivatives. In each group, the transition temperature becomes progressively higher with increasing the atomic weight of the halogen. On the other hand, the *m*-ethoxy derivative shows a peak located 15°C lower than the *m*-methoxy derivative; therefore, the transition in the *o*-ethoxy derivative might be below room temperature. It is particularly interesting to note that no crystallization can be observed in derivatives carrying the substituent on the *o*- or *m*-position upon heating to their melting points, suggesting the presence of strong molecular entanglement assisted by an intermolecular CT interaction.

Ultrasonic Absorption Mechanism in an Aqueous Solution of Isopropyl Alcohol

Sadakatsu NISHIKAWA, Mitsuo MASHIMA, and Tatsuya YASUNAGA*

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840
**Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730*

(Received December 26, 1975)

Synopsis. Ultrasonic absorption measurements in an aqueous solution of isopropyl alcohol were made in the frequency range from 5 to 220 MHz and in the concentration range from 3 to 10 M. The excess absorption which is characteristic of a single relaxation process was observed. The mechanism of the excess absorption was interpreted in terms of a reaction expressed by AB⇌A+B, where A and B are monomeric molecules of alcohol and water respectively. The rate constants for forward and backward reactions were determined from the concentration dependences of the relaxation frequencies. The results obtained were compared with those of aqueous solutions of other alcohols which had already been published.

The structural properties of aqueous solutions of various alcohols have been studied in relation to biological reaction mechanisms. The ultrasonic studies have been also applied to the investigations of the dynamical properties of aqueous solutions of alcohols.[1-3] The present authors have previously reported the results of the ultrasonic absorption measurements in aqueous solutions of propyl, *t*-butyl, and allyl alcohols, and they have interpreted the excess absorptions from the point of view of reaction kinetics.[4,5] In this paper, we will report the results of the ultrasonic absorption measurements in an aqueous solution of isopropyl alcohol; the results will be compared with those of other alcohols.

Experimental

The isopropyl alcohol was a reagent-grade commercial product and was distilled once. No impurity was observed by gas-chromatography. The water used in the experiments was doubly distilled. The sample solutions were made at the desired concentrations by weight. The concentration range of the experiments was from 3.00 to 10.01 M. The apparatus for the ultrasonic absorption and velocity measurements have been previously described in detail.[4,6] The frequency range of the ultrasonic absorption measurements was from 5 to 220 MHz, while the sound velocity was measured at 1.92 MHz by a sing-around technique. All the measurements were made at 25 °C.

Results and Discussion

Figure 1 shows the representative ultrasonic absorption spectra in an aqueous solution of isopropyl alcohol. All the spectra in the solution can be described by the following expression of a single relaxation in the frequency range measured.

$$\alpha/f^2 = A/[1+(f/f_r)^2] + B \qquad (1)$$

where α is the absorption coefficient; f, the frequency; f_r, the relaxation frequency, and A and B, constants. The relaxation parameters were determined by the usual procedure.[5] In Table 1, the obtained values of ultrasonic parameters are listed together with the sound velocities and densities.

The sound absorption in aqueous solutions of propyl and *t*-butyl alcohols features a characteristic double relaxation; the mechanisms were interpreted in terms of the solute-solvent interaction and the molecular aggregation of alcohol by hydrophobic interaction. While, the excess absorption in an aqueous solution of allyl alcohol was expressed by a single relaxation process, and the mechanism was attributed to the solute-solvent interaction, as in a previous study.[5] Therefore, the cause of the ultrasonic absorption in an aqueous solution of isopropyl alcohol may be expected to be associated with the solute-solvent interaction, because the region of the relaxation frequency is roughly the same as that of allyl alcohol. The model for the relaxation process is as follows;

$$AB \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} A + B \qquad (2)$$

where A and B are the molecules of alcohol and water respectively, and k_{ij}, the rate constant. The relations for the relaxation frequency and the maximum excess absorption per wavelength are;

$$2\pi f_r = 1/\tau = k_{21}(C_2+C_3) + k_{12} \quad (3)$$

$$\mu_{max} = Af_r c/2 = \pi\rho c^2/[VRT(1/C_1+1/C_2+1/C_3-1/C_T)] \times (\Delta V-\alpha_p^\infty \Delta H/\rho C_p^\infty)^2 \quad (4)$$

All the symbols in these equations are defined as in the previous paper.[5] Equation 3 can be rewritten as:

$$2\pi f_r = 1/\tau = k_{21}\sqrt{(C_a-\beta C_w+K_{12})^2+4\beta C_w K_{12}} \quad (5)$$

where K_{12} is the equilibrium constant and C_a and C_w are the analytical concentrations of alcohol and water respectively. The parameter, β, is the mole fraction of the water monomer. The introduction of β into the interpretation of the excess absorption means that only the monomer of the water molecule can participate in the reaction expressed by Eq. 2. The values of k_{21}, β and K_{12} were determined so as to obtain a best fit of the data to Eq. 5. Here, the fact that the relaxation frequencies went through a minimum at the concentration of C_a=5.50 M was also used to estimate the parameters. The kinetic parameters obtained are listed in Table 2, along with those of aqueous solutions

Table 2. The reaction parameters and the stability of water structure in aqueous solutions of alcohols

Solute	k_{12} (s^{-1})	k_{21} ($M^{-1}s^{-1}$)	k_{23} a) ($M^{-2}s^{-1}$)	k_{32} a) (s^{-1})	β
t-Butyl alcohol	1.2×10^8	7.2×10^7	5.5×10^5	4.9×10^7	0.12
Propyl alcohol	1.6×10^8	6.2×10^7	2.2×10^5	6.9×10^7	0.15
Isopropyl alcohol b)	1.4×10^8	8.8×10^7	—	—	0.17

of other alcohols. The concentration dependence of the relaxation frequency calculated with these values and Eq. 5 is shown in Fig. 2 by a solid line; the circles indicate the experimental values. In order to confirm the excess absorption mechanism, it is appropriate to inspect the concentration dependence of the maximum excess absorption per wavelength, μ_{max}. From Eq. 4, μ_{max} may be expected to be approximately proportional to $\rho c^2(1/C_1+1/C_2+1/C_3-1/C_T)^{-1}$. In Fig. 3, the concentration dependence of the maximum excess absorption per wavelength is shown, together with that of the calculated values of $\rho c_2(1/C_1+1/C_2+1/C_3-1/C_T)^{-1}$. As may be seen in this figure, the tendency of the concentration dependence of the maximum excess absorption per wavelength is similar to that of the calculated curve (solid line). This confirms that the excess absorption mechanism in an aqueous solution of isopropyl alcohol may be attributed to the perturbation of the equilibrium expressed by Eq. 2.

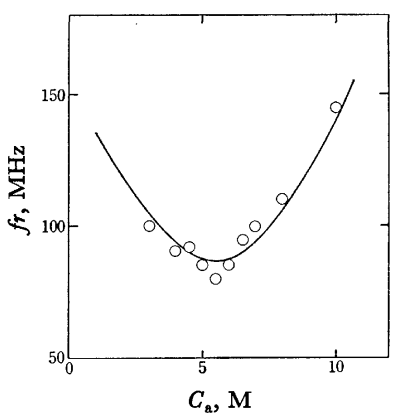

Fig. 2. Concentration dependence of the relaxation frequency in an aqueous solution of isopropyl alcohol.

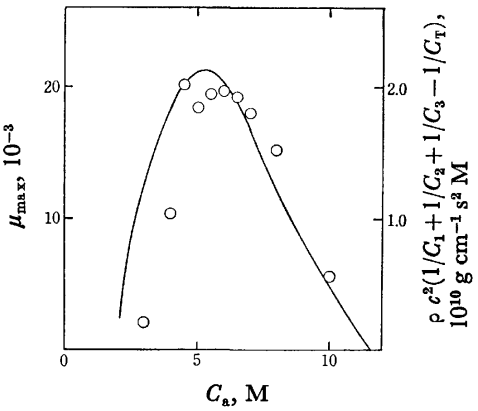

Fig. 3. The variations of μ_{max} and $\rho c^2(1/C_1+1/C_2+1/C_3-1/C_T)^{-1}$ with the concentration of isopropyl alcohol.

The dependencies of the forward and backward rate constants for the AB⇌A+B reaction on the solute molecules (see Table 2) are not remarkable. This may indicate that the complex formed by alcohol and water is due to a hydrogen bonding. However, the β parameter, which indicates the stability of the water structure, varies considerably depending on the solute molecules. When the strength of the hydrophobic interaction increases,[7] the β parameter decreases. In aqueous solutions of propyl and *t*-butyl alcohols, another excess absorption in the lower frequency range was observed; this mechanism was associated with the aggregation reaction of alcohol by hydrophobic interaction.[5] The strength of the hydrophobic interaction of isopropyl and allyl alcohols, however, is not so strong enough that these alcohols do not aggregate in aqueous solutions by hydrophobic interaction, and only a single relaxational absorption is observed in the frequency range measured

The Photoconductivity of Poly(*N*-vinylcarbazole). VII.[1] The Effect of the Singlet and Triplet Quenchers on the Photoconductivity

Ken-ichi OKAMOTO, Norikazu ODA, Akira ITAYA, and Shigekazu KUSABAYASHI

Department of Chemical Engineering, Faculty of Engineering, Yamaguchi University, Ube 755

(Received January 20, 1976)

Synopsis. The singlet quenchers significantly reduce the photocurrents of poly(*N*-vinylcarbazole) and of brominated poly(*N*-vinylcarbazole), but the triplet quenchers do not do so at all regardless of the high efficiency of the polymer-to-quencher triplet energy transfer. This result excludes the possibility of the photocarrier generation from the triplet excited state in these polymers.

The photocarrier generation process in poly(*N*-vinylcarbazole) (PVCz) films, in the case of the singlet π-π^* excitation, has been widely investigated in the last few years.[2-4] It is considered that photocarriers in PVCz films are generated from the singlet excited states *via* either the intrinsic charge transfer exciton state in the case of the higher π-π^* excitation or the extrinsic exciplex state in the case of the lower π-π^* excitation. The exciplex state is considered to be formed efficiently, even if some electron-accepting impurities have very low concentrations, because of the high efficiency of the singlet exciton migration.[5]

On the other hand, the triplet excitation energy also migrates very efficiently in this polymer.[6-8] Furthermore, the triplet excitation energy of PVCz is fairly high (E_T=3.02 eV; *cf.* the singlet excitation energy, E_S= 3.55 eV) as compared with that of other aromatic vinyl polymers, such as poly(1-vinylnaphthalene) (E_T=2.5 eV, E_S=3.8 eV[9]). Therefore, the photocarrier generation from the triplet excited state in the case of the singlet π-π^* excitation may be possible in PVCz, as has been suggested by Yokoyama *et al.*[7] In order to decide on this possibility, we examined the effect of the triplet and singlet quenchers on the photoconductivity of PVCz and brominated poly(*N*-vinylcarbazole) (BPVCz).

Experimental

PVCz was prepared by free-radical polymerization and brominated by using *N*-bromosuccinimide. The BPVCz thus obtained had one bromine atom per 1.1 carbazolyl groups.[10] The copolymer of *N*-vinylcarbazole (VCz) with 1-vinylnaphthalene (VN) was also prepared by free-radical polymerization. These polymers were purified by repeated reprecipitations. Naphthalene and fluorene were used as the triplet quenchers of the carbazolyl chromophore, while anthracene and perylene were used as singlet and triplet quenchers. The scintillation-grade reagents were used after being purified by repeated recrystallizations, vacuum sublimation, and zone melting. The electrical measurements were made by the DC method in a vacuum of 10^{-5} Torr, as has been described previously.[11]

Results and Discussion

BPVCz has photoconductive properties similar to those of PVCz.[11] The magnitude of the photocurrent in BPVCz is twice as large as that in PVCz in the case of the hole current and is a most the same in the case of the electron current.

In both PVCz and BPVCz, the triplet quencher mixed or copolymerized does not affect the photoconductive properties at all. Anthracene and perylene acting as both singlet and triplet quenchers significantly reduce the photocurrent in magnitude, but do not affect the other photoconductive properties, such as the

a) The relative photocurrent values in the doped films taking the photocurrent values in the corresponding undoped films as unity. The values in parentheses are the photocurrent values in the undoped films measured under the condition of 35000 V/cm, 1×10^{13} photons/cm^2 s, 20 °C, and 1×10^{-5} Torr. b) VCz–VN (5 mol % in feed) copolymer.

voltage and the temperature dependences of the photocurrent. Table 1 shows a comparison of the magnitude of the photocurrent among the films undoped and doped with triplet or singlet quenchers. From this table, it is clear that, at the quencher concentrations of 1.5—5 mol%, the singlet quenchers reduce the photocurrent by a factor of about 5, while the triplet quenchers do not do so at all.

In both polymers, the triplet quenchers trap the freely-migrating triplet excitons rather than the trapped ones, resulting in both a significant decrease in the host phosphorescence and the appearance of the sensitized guest phosphorescence.[8] The host phosphorescence is completely replaced by the guest one at guest concentrations above 1 mol%.[8] It is, therefore, clear that the concentration of the freely-migrating triplet exciton in the films doped heavily (more than 1 mol%) with the triplet quenchers is remarkably reduced as compared with that in the undoped films. The situation is the same as for the case of the singlet quencher. Therefore, the present effect of the singlet and triplet quenchers on the photoconductivity excludes the possibility of photocarrier generation from the triplet state in these polymers under ordinary experimental conditions.

It is noted that the photocarrier generation from the singlet excited state is predominant even in BPVCz, which has a low efficiency of the singlet exciton migration because of the very short lifetime of the singlet exciton due to the enhanced intersystem crossing.[12] A similar example has been reported of the photoconductivity in tetracene crystals, where the low efficiency of the singlet exciton migation is attributed to the enhanced singlet fission into two triplet excitons.[13] In tetracene crystals, the photocarrier generation from the triplet excited state is possible only in the presence of a strong electron acceptor like *p*-chloranil.

Under the present experimental conditions, the two photon processes are negligible because of the weak light intensity. In the case of the lower singlet π-π^* excitation, the extrinsic photocarrier generation process with the participation of some electron-accepting impurities must be considered, whether the singlet channel or the triplet one is chosen. From the simple energetic calculation, this process is considered to be endothermic in the case of a weak electron acceptor such as some photoxidation products of carbazolyl chromophores, the most conceivable acceptors. In such an endothermic process, the energy difference between the singlet excitation energy and the triplet one (0.5 eV) seems to be determined in the choice between the singlet channel and the triplet one, although it is much smaller than those of other aromatic vinyl polymers. This is the reason for the lack of the photocarrier generation process from the triplet excited state in these polymers.

Rate of Protonation of TCNQ Anion Radical in Water

Akihiko YAMAGISHI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 27, 1976)

Synopsis. The protonation of TCNQ anion radical has been studied with an oxygen-free stopped-flow apparatus. The protonation rate is proportional to the square of $TCNQ^-$ concentration, being independent of the proton concentration. It is suggested that there exists an intramolecular step in which the electronic structure of $TCNQ^-$ changes into another one ready to accept a proton.

In the previous work, the protonation of 7,7,8,8-tetracyanoquinodimethane (TCNQ) anion radical was investigated in methanol, ethanol and acetonitrile.[1] On the basis of kinetic results, it was confirmed that the first attack of H^+ on $TCNQ^-$ was reversible according to $TCNQ^- + H^+ \rightleftharpoons TCNQH^\cdot$.

This paper reports the protonation of $TCNQ^-$ in water. It was intended to examine the effect of a dimer species on the reaction rate, since $TCNQ^-$ is known to dimerize in water.[2] The rate was determined using an oxygen-free stopped-flow apparatus in order to avoid the decomposition of $TCNQ^-$ under air.

Experimental

Li^+TCNQ^- was prepared by reducing TCNQ with LiI in acetonitrile. $HClO_4$ of reagent grade was used as proton source. The concentration of proton was equated to the proton activity at the investigated ionic strength (10^{-4}—10^{-2} M).

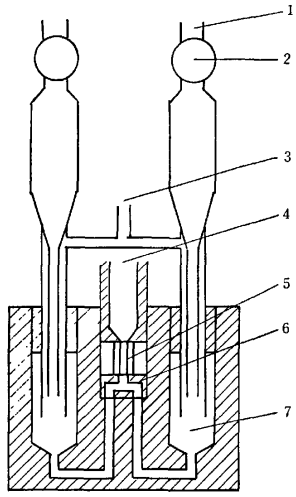

Fig. 1. A mixing part free from oxygen contamination; (1) to a vaccum line, (2) a gleaseless valve, (3) to a He tank, (4) to a rotary pump, (5) a quartz cell, (6) a mixer and (7) the reservoir of a sample solution.

The rate was measured with a Union Giken rapid scan stopped-flow spectrophotometer RA 1300. A mixing part free from oxygen contamination was newly constructed (Fig. 1).[3] The whole part was made of Teflon and Pyrex glass sealed by O-rings. About 10^{-3} mmHg vacuum was attainable under pumping. The sample solutions were directly drived by He gas pressure (*ca.* 0.5 kg/cm^2) without pistons. Thus the decomposition due to oxygen arose mainly from He gas impurity (nominal purity 99.9%). The samples were prepared in a vacuum line. The rate was followed by the absorbance change at 743 nm (a peak of $TCNQ^-$ monomer).

Results and Discussion

All measurements were performed under the condition that the initial concentration of $TCNQ^-$ was less than 10^{-5} M. At this concentration range, the contribution of a dimer to the total amount of $TCNQ^-$ is less than 5%. Thus the protonation rate is given by the decrease of a monomer species per unit time, $-d[TCNQ^-]/dt$, with a good approximation. The reactivity of a dimer may reflect on the observed rate through the rapid equilibrium below.[4]

$$2TCNQ^- \rightleftharpoons (TCNQ^-)_2 \qquad (1)$$

At the constant proton concentration, which is in large excess compared with $[TCNQ^-]$, the rate is expressed as below (Fig. 2).

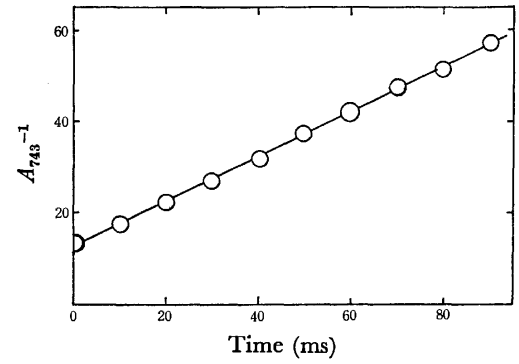

Fig. 2. Second-order plot of the disappearance of $TCNQ^-$; $[TCNQ^-]_0$ 3.9×10^{-6} M, and $[HClO_4]$ 3.98×10^{-3} M at 25±2 °C. The vertical scale is the reciprocal of the absorbance at 743 nm and the horizontal scale 20 ms/div.

$$-d[TCNQ^-]/dt = k[TCNQ^-]^2. \qquad (2)$$

k is found to be independent of the proton concentration for $[HClO_4]=(2.34\text{—}13.0)\times10^{-3}$ M. $k=(8.9\pm1.0)\times10^6$ $M^{-1}s^{-1}$ at 25±2 °C. From the temperature dependence of k between 14.5—35.0 °C, the apparent activation enthalpy is determined to be $\Delta H^*=10.1\pm0.3$ kcal mole^{-1}.

The second-order dependence of the rate on $[TCNQ^-]$ (Eq. 2) may seem to suggest the mechanism that the protonation takes place only by way of a dimer form, $(TCNQ^-)_2$. This possibility is, however, discarded on the following ground. If the dimer is an active species for protonation, k is expressed by

$$k = k_0 K_D$$

in which k_0 and K_D are the protonation rate of a dimer

and the equilibrium constant of reaction (1), respectively. Since k is independent of the proton concentration, k_0 may be the rate constant of some intramolecular step at which a dimer is activated. Taking $K_D = 2.5\times10^3\ M^{-1}$,[2] k_0 is obtained to be $3.6\times10^3\ s^{-1}$. Expressing k_0 as $\nu \exp(-\Delta H_0^*/RT)$, and equating $\Delta H_0^* = \Delta H^* - \Delta H_D$, in which ΔH_D is the enthalpy change of reaction (1), -10.4 kcal mol^{-1},[2] ΔH_0^* is obtained to be 20.5 kcal mol^{-1}. Substituting this value for the above expression of k_0, the frequentry factor, ν, is determined to be $3\times10^{18}\ s^{-1}$. ν exceeds the electronic vibration. It is very improbable to assume the presence of an activating mode with such a high frequency.

Therefore it is concluded that the second-order dependence of k on [TCNQ$^-$] arises from the same mechanism as observed previously in methanol, ethanol and acetonitrile. That is, the disproportionation takes place between protonated TCNQ$^-$, or HTCNQ$\cdot$, and TCNQ$^-$.

$$TCNQ^- + H^+ \rightleftharpoons HTCNQ\cdot \quad (3)$$

$$HTCNQ\cdot + TCNQ^- \longrightarrow HTCNQ^- + TCNQ \quad (4)$$

$$HTCNQ^- + H^+ \longrightarrow H_2TCNQ \quad (5)$$

The fact that k is independent of [H$^+$] suggests the presence of the intramolecular step in which TCNQ$^-$ is activated into a more basic species.

$$TCNQ^- \rightleftharpoons TCNQ^{-}* \quad (6)$$

Assuming the stationary conditions for both TCNQ^{-}* and HTCNQ$\cdot$, k is expressed by

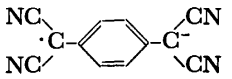
$$k = \frac{k_6k_3k_4[H^+]}{(k_{-6}+k_3[H^+])k_{-3}}$$

Under the condition that $k_{-6} \ll k_3[H^+]$, k is reduced to

$$k = k_6k_4/k_{-3}$$

which is independent of the proton concentration as observed in Eq. 2.

One of the possibilities for the nature of the intramolecular step (6) is that TCNQ$^-$ transforms electronically into another species which accepts more readily a proton. For example, one of the carbon atoms in TCNQ$^-$ may become carbon anion, C$^-$, by destructing partially the solvation structures by water molecules.



The author thanks Prof. Masatoshi Fujimoto for his encouragement.

The Crystal Structure of Bis[1-(2-thiazolylazo)-2-naphtholato]-iron(II)-Chloroform(2/3)

Masayasu KURAHASHI and Akira KAWASE*

National Research Institute for Metals, Nakameguro, Meguro-ku, Tokyo 153

(Received October 7, 1975)

Synopsis. The crystals of bis[1-(2-thiazolylazo)-2-naphtholato]iron(II)-chloroform (2/3) are triclinic, with unit-cell dimensions of: $a=12.509(7)$, $b=11.911(6)$, $c=10.460(4)$ Å, $\alpha=86.97(3)$, $\beta=97.24(4)$, and $\gamma=103.48(7)°$, $Z=2$ for $[Fe^{II}(C_{13}H_8N_3OS)_2]\cdot 1.5CHCl_3$, space group $P\bar{1}$. The complex is diamagnetic, and the iron atom is surrounded octahedrally by two terdentate ligands in the *mer* configuration.

The analytical use of heterocyclic azo dyestuffs, such as 1-(2-pyridylazo)-2-naphthol (Hpan) and 1-(2-thiazolylazo)-2-naphthol (Htan), has been the subject of a considerable number of papers; however, few crystallographic studies have been reported. We, therefore, have begun a systematic study of the structures of the metal chelates of these analytically important dyestuffs. It was thought that the determination of the crystal structures would be of great help in the design of new analytical reagents. The tan-complexes rather than the pan-complexes were selected because the coordination property of the thiazole ring appeared to be more interesting than that of pyridine. Thus far, the structures of Pd(II)-, Ni(II)-, Cu(II)-, and Co(III)-tan chelates have been determined.[1-4]

This note will deal with the structure of the Fe(II)-tan chelate, bis[1-(2-thiazolylazo)-2-naphtholato]iron(II) (abbr. as $[Fe^{II}(tan)_2]$). A preliminary work based on the photographic data has been published.[5]

Experimental

The single crystals of $[Fe^{II}(tan)_2]\cdot 1.5CHCl_3$ were obtained by recrystallization from a chloroform solution of $[Fe^{II}(tan)_2]$ by the slow evaporation of the solvent. The crystal data are: triclinic, $a=12.509(7)$, $b=11.911(6)$, $c=10.460(4)$ Å, $\alpha=86.97(3)$, $\beta=97.24(4)$, and $\gamma=103.48(7)°$, $V=1503.0$ Å^3, $D_m=1.63$, $D_x=1.64$ g·cm^{-3}, $Z=2$ for $[Fe^{II}(tan)_2]\cdot 1.5CHCl_3$, $\mu=95.7$ cm^{-1} (for Cu$K\alpha$), space group $P\bar{1}$. The specimen crystal had the dimensions of *ca.* $0.15\times0.3\times0.35$ mm. Both the determination of the cell constants and the collection of the intensity data were carried out on a Rigaku automated four-circle diffractometer using Cu$K\alpha$ radiation monochromatized with a graphite plate. The ω–2θ scan technique was employed at a scan rate of 4°/min in ω. Weak reflections with $|F|$ values less than $3\sigma(|F|)$ were omitted from the data, and a total of 1864 non-zero reflections ($\pm h, \pm k, l\geq 0$) were recorded in the range of $0°<2\theta<120°$. The intensities were corrected for the Lorentz and polarization factors, but not for absorption.

Structure Determination and Refinement

The centrosymmetric space group was indicated by the intensity statistics and has been used throughout. The structure was solved by the heavy-atom method. The analysis of a three-dimensional Patterson map gave the coordinates of Fe, S, and S′. The positions of the remaining non-hydrogen atoms were obtained from the successive Fourier and difference syntheses. After several cycles of least-squares refinement with isotropic temperature factors, anisotropic thermal parameters were introduced for Fe, S, S′, Cl(1), Cl(2), and Cl(3). At the final stage of the refinement, the calculated hydrogen positions and the isotropic temperature factor of 5.0 Å^2 were included in the structure factor calculations, but were not refined; the R value reached

* Present address: National Chemical Laboratory for Industry, 5–5, 1-Chome, Honmachi, Shibuya-ku, Tokyo 151.

0.124 for 1864 observed reflections. A unit weight was given to each reflection. The atomic scattering factors were taken from International Tables for X-ray Crystallography.[6] The final atomic parameters and the list of structure factors are kept as Document No. 7618 at the Chemical Society of Japan.

Description of the Structure and Discussion

The perspective view of the molecules and the numbering of atoms are given in Fig. 1, while the electron density map is shown in Fig. 2. The iron atom is six-coordinated, surrounded octahedrally by two terdentate ligands in the *mer* configuration. The ligand, 1-(2-thiazolylazo)-2-naphtholato (tan) group coordinates to the iron atom through the phenolic oxygen, the azo nitrogen adjacent to the naphthol ring and the thiazole nitrogen atoms giving two five-membered chelate rings. This mode of attachment of the tan to the metal is common in all the tan-complexes studied.[1-5] The metal environment of the $[Fe^{II}(tan)_2]$ complex is just the same as those of $[Ni^{II}(tan)_2]$ and $[Co^{III}(tan)_2]^+$, but differs from those of $[Pd^{II}Cl(tan)]$ and $[Cu^{II}(tan)(H_2O)_2]^+$.

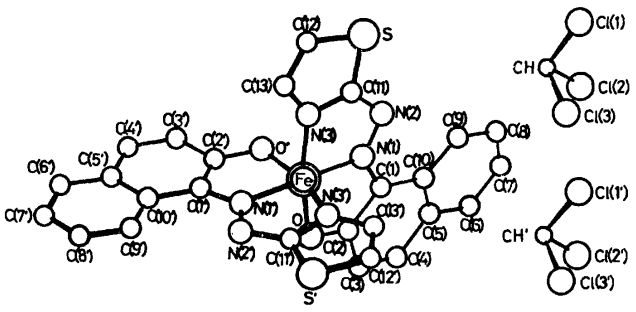

Fig. 1. Perspective view of the molecules and the numbering of atoms.

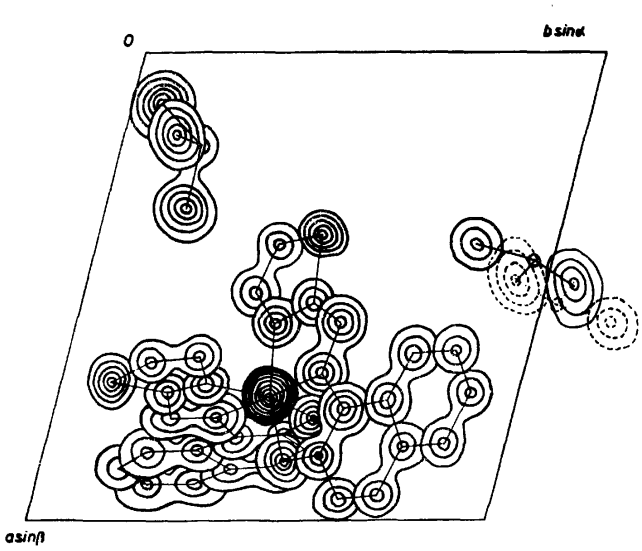

Fig. 2. Composite electron density map viewed down the c-axis. Contours are drawn at intervals of 2 e·Å^{-3} except for iron atom, the lowest contour being 2 e·Å^{-3}.

The average bond distances and angles, together with their e.s.d.'s, are given in Table 1. The bond angles around the metal, O–Fe–N(1) and N(1)–Fe–N(3), are compressed from the normal valence angles. This is attributable to the geometry of the tan ligand; a similar situation was observed for the other metal-tan complexes. The mean plane through Fe and the unprimed tan and that through Fe and the primed tan are roughly planar, and they are nearly perpendicular to each other.

It has been reported that the stability constants of metal chelates of tan and its analogues diminish in this order;[7]

$$Fe(II) > Ni(II) > Co(II) > Zn(II)$$

This order is the same as the stability series of Irving and Williams,[8] with the exception of Fe(II). This anomaly can be interpreted in terms of the orbital stabilization. Measurement of the magnetic moments confirmed that the iron atom utilizes d^2sp^3 orbitals, while the other three utilize sp^3d^2 orbitals.

The arrangment of the $[Fe^{II}(tan)_2]$ chelates is very similar to that observed in the crystals of $[Ni^{II}(tan)_2]$. However, the present crystal contains chloroform molecules (as a crystal solvent). One chloroform (CH, Cl (1), Cl (2), and Cl(3)) is in a general position, while the other chloroform (CH', Cl(1'), Cl(2'), and Cl(3'): half weight) is disordered and takes two possible orientations randomly and with equal probability about a center of symmetry at (1/2, 0, 0).

Calculations were carried out on the HITAC 5020F computer at the Computer Center of the National Aerospace Laboratory and on the NEAC 3100 computer at this Institute, using some UNICS programs.

The authors wish to express their deep thanks to Dr. Eiichi Asada and Mrs. Midori Goto of the National Chemical Laboratory for Industry, who kindly allowed them to use the X-ray diffractometer.

Effect of Hydroxylation on the Thermal Reactivities of Fluorapatite and Chlorapatite[1)]

Hideki MONMA and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received October 23, 1975)

Synopsis. Thermal self-decomposition of hydroxyapatite was notably suppressed by partial fluorination or chlorination. The volatility of halogen from fluorapatite and chlorapatite was reduced by the incorporation of hydroxide ions in the apatites. The reactivities of fluor-hydroxyapatite and chlor-hydroxyapatite with silica increased with increasing hydroxide content, which resulted in an increase in the halogen volatility.

In a preceding report by the authors,[2)] it was stated that in the presence of silica and water vapor, fluorapatite (FAp) and chlorapatite (CAp) could be dehalogenated by the substitution of hydroxide ions for halogen ions and by the subsequent destructive reaction of partially hydroxylated FAp or CAp with silica. The aim of the present study is to examine the effects of decreasing the ratios of F/OH and Cl/OH on the thermal and chemical stabilities of FAp-hydroxyapatite (HAp) solid solutions [$Ca_{10}(PO_4)_6F_{2(1-x)}(OH)_{2x}$, F_xAp] and CAp–HAp solid solutions [$Ca_{10}(PO_4)_6Cl_{2(1-x)}$-$(OH)_{2x}$, C_xAp]. The subscript x is the degree of substitution of OH^- for F^- or Cl^- and its value varies from 0 (for FAp or CAp) to 1 (for HAp).

Experimental

FAp (3.76% F), CAp (6.79% Cl) and HAp were prepared by the same methods as those described in a preceding paper.[2)] F_xAp was prepared by heating a mixture of $Ca_2P_2O_7$, CaF_2, and $CaCO_3$ having a molar ratio of 3: $(1-x)$: 8 at 1200 °C for 3 h in an atmosphere of water vapor (90—240 mmHg), followed by washing with a 10% NH_4Cl aqueous solution to remove the excess CaO. The formation of FAp–HAp solid solutions is judged from the fact that the thermal self-decomposition degree of F_xAp was not in proportion to the OH content (refer to Fig. 1). C_xAp was prepared by heating pure CAp in an atmosphere of water vapor (17—360 mmHg) for various retention times.[2)] The precise values of x for these solid solutions were determined by chemical analysis. The silica used was siliceous sand (α-quartz) for optical glass making. All the samples prepared were ground to a 200 inch-mesh before use. Heating runs were performed in flowing nitrogen gas (150 ml/min) containing a trace water vapor (0.6 mmHg). A heating time of 3 h and a mixing molar ratio of silica/apatite of 3 were adopted as adequate reaction conditions.[2)] The conversion fraction of F_xAp into tricalcium phosphate was determined by quantitative X-ray analysis the procedure for which is given in detail elsewhere.[2)] Fluorine and chlorine were analyzed by thorium nitrate and potassium thiocyanate titrations, respectively.

Results and Discussion

Fluor-hydroxyapatite. Figure 1 shows the conversion fractions for F_xAp. Scarcely any self-decomposition of F_xAp at 1300 °C was observed in the range of x of 0—0.8. However, F_xAp for values of x above 0.9 decomposed considerably. In other words, the thermal stability of HAp ($x=1$) was remarkably decreased by partially substituting F^- for OH^-. The decomposition of F_xAp by silica increased monotonically with x. The fluorine volatilities of F_xAp without silica during heating at 1000—1300 °C for 3 h were 8% for FAp ($x=0$) and less than 4% over the range of x from 0.1—1.0. The volatility was accelerated by the addition of silica. Figure 2 shows the fluorine volatilities from silica-added F_xAp. The volatility curves have trends similar to the

decomposition curves in Fig. 1. This similarity supports the idea that the volatilization was mostly due to the destructive reaction of F_xAp with silica. However, the volatilities, which should be practially consistent with the decomposition fractions, were less than these fractions. This relationship suggests that a fluorine compound such as SiF_4 produced simultaneously during the destructive reaction may recombine with unreacted F_xAp.

Chlor-hydroxyapatite. The values of x for unreacted apatites after the heating of C_xAp with and without silica were determined by using a calibration curve of the lattice constant *vs.* x. The results are summarized as follows. The x values after heating became higher than those of the starting apatite under heating conditions permitting the stability of the apatite structure. This change of x was due possibly to the replacement of Cl^- with OH^- or O^{2-} of which a small amount was contained in the atmosphere as water vapor.[2] Under condition permitting the apatites structure to be unstable, the value of x of unreacted apatite agreed with those before heating. The chlorine volatilities from C_xAp and silica-added C_xAp are shown in Fig. 3. C_xAp without silica was structurally stable over the range of x from 0—0.9. This fact means that Cl ions incorporated into HAp also have a stabilizing effect on the apatite structure similar to that of F ions. The chlorine volatilities of C_xAp decreased linearly with x, while the volatilities of the C_xAp–silica mixture decreased in the range from 0—0.3 in which the apatite structure was stable and increased thereafter along with the decomposition of the apatite by silica. In conclusion, the volatility behavior of C_xAp in the presence of silica could be interpreted by both a suppression effect due to the incorporation of OH and an accelerating effect due to the decomposition reaction.

The Preparation and the Magnetic Property of Bis(*N*-*o*-nitrophenylsalicylideneaminato)copper(II)

Tadashi Tokii, Norimitsu Ohno, and Yoneichiro Muto

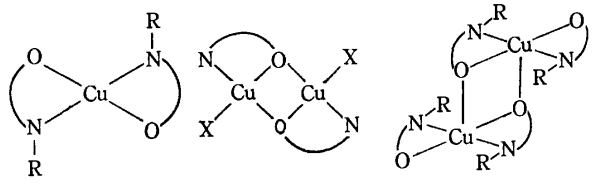
Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received October 27, 1975)

Synopsis. A synthesis of bis(*N*-*o*-nitrophenylsalicylideneaminato)copper(II) is reported. The magnetic properties of the complex and the corresponding *p*-nitro complex are discussed in terms of the steric effect of the nitro group.

In the preparation of bis(*N*-nitrophenylsalicylideneaminato)copper(II) complexes, it is much more difficult to prepare complexes with a nitro group at the *o*-position of the phenyl ring than complexes with the substituent at the *m*- or *p*-position. Thus, the synthesis of bis(*N*-*o*-nitrophenylsalicylideneaminato)copper(II), Cu(sal·*N*-*o*-NO_2·Ph)$_2$, can not be accomplished by any of the following reactions which are used for the preparation of various bis(*N*-R-salicylideneaminato)copper(II) complexes (Fig. 1. I):[1] (1) Cu(sal)$_2$+2 R·NH_2; (2) 2 H·sal·N–R+Cu(Ac)$_2$·H_2O; (3) 2 H·sal+2 R·NH_2+Cu(Ac)$_2$·H_2O (where H·sal=salicylaldehyde, R=alkyl or aryl, H·sal·N–R=*N*-R-salicylideneamine and Ac=CH_3COO).

Verter and Frost[2] successfully prepared the *o*-NO_2 complex by the method of Charles[3]—that is, by the reaction of H·sal, *o*-nitroaniline, and Cu(Ac)$_2$·H_2O in the presence of sodium acetate. We have also succeeded in isolating this complex and the analogous complexes (R=*o*-NO_2-*p*-CH_3·Ph and *o*-NO_2-*p*-CH_3O·Ph) by methods different from that of Charles. Cryomagnetic measurements of the *o*-NO_2 complex and the corresponding *p*-NO_2 complex have been carried out; the results will be discussed in terms of the shielding effect of *o*-substituents.



I II III

Fig. 1. Schematic representations of structures of I: Cu(sal·N–R)$_2$, II: [Cu(sal·N–R)X]$_2$, and III: [Cu(sal·N–R)$_2$]$_2$.

Preparation

A typical synthetic method was as follows: a mixture of Cu(sal)$_2$, Cu(Cl_2CHCOO)$_2$·$4H_2O$, and *o*-nitroaniline in a 1:1:2 mole ratio in ethanol was heated on a water bath under reflux for 1 h. The products were then recrystallized from *N*,*N*-dimethylformamide. They were all brown. The results of elemental analyses are given in Table 1, together with the calculated magnetic moments based on the observed magnetic susceptibilities at room temperature.

The synthesis of Cu(sal·*N*-*o*-NO_2·Ph)$_2$ was also achieved either by a similar procedure using Cu(Ac)$_2$·H_2O or Cu(ClO_4)$_2$·$6H_2O$ instead of Cu(Cl_2CHCOO)$_2$·$4H_2O$ or by the action of water on binuclear complexes of the II type shown in Fig. 1, [Cu(sal·*N*-*o*-NO_2·Ph)X]$_2$, which were prepared by the reaction of Cu(sal)$_2$, *o*-nitroaniline, and CuX_2(where X=Cl[4] or NO_3[5]).

Magnetic Property

The magnetic susceptibilities of Cu(sal·*N*-*p*-NO_2·Ph)$_2$ and Cu(sal·*N*-*o*-NO_2·Ph)$_2$ were measured in the temperature range of 80—300 K by the Gouy method; the results are shown in Fig. 2.

The cryomagnetic data for the *p*-NO_2 complex obeyed the Curie-Weiss law with a positive Weiss constant ($\theta \approx +2$ K), which was evaluated by extrapolating the $(\chi_m - N_\alpha)^{-1}$ *vs.* T curve; this indicated the existence of ferromagnetic interaction in this compound (where χ_m is the magnetic susceptibility per gram-ion of copper (II); N_α, the temperature independent paramagnetism per gram-ion of copper(II), and T, the absolute temperature). The ferromagnetic interaction was also reflected in the X-band ESR spectrum as measured on a powdered sample; *i.e.*, the spectrum showed a weak signal at *ca.* 1500 G due to the $\Delta M_s=2$ transition characteristic of magnetically coupled copper(II) ions,[6] and the intensity increased with a lowering of the temperature, suggesting that the ferromagnetic interaction leads to a triplet ground state. These magnetic properties are quite similar to those of such binuclear complexes as [Cu(sal·N–CH_3)$_2$]$_2$(*γ*-form),[7] [Cu(sal·N–CH_2CH_2–N·sal)]$_2$,[7,8] [Cu(dmg)$_2$]$_2$,[9] and [Cu(pyo)$_2$-

Pascal's constants were used for correction of diamagnetism (-255×10^{-6} emu/mol) and $N\alpha$ was assumed to be 60×10^{-6} emu.

$(NO_3)_2]_2$,[10] in which the coordination around the copper ion is square-based pyramidal, with the fifth position (out-of-plane) occupied by oxygen from an adjacent planar moiety (where dmg=dimethylglyoximato and pyo=pyridine *N*-oxide). The ferromagnetic spin interaction between copper ions in these complexes was interpreted in terms of a σ-type superexchange mechanism *via* the out-of-pane bonds.[7-10] Thus, the *p*-NO_2 complex very probably has a binuclear structure of the III type shown in Fig. 1, $[Cu(sal\cdot N\text{–}R)_2]_2$, in which the monomeric Cu(sal·N–R)$_2$ units are bridged by the Cu–O out-of-plane bonds.

On the other hand, for the *o*-NO_2 complex, magnetic behavior obeying the Curie law was observed within the range of experimental error. In the powder ESR spectrum, a strong signal at *ca.* 3100 G due to copper(II) ions with $S=1/2$ was observed, and, in contrast to the *p*-NO_2 complex, no absorption was detected near 1500 G over the temperature range of 80—300 K. On the basis of the magnetic data and the previous observation that the *o*-substituents in Cu(sal·N–Ph–Y)$_2$ complexes have a great tendency to shield the fifth coordination site of the copper ions,[4] it seems likely that, in the *o*-NO_2 complex, the shielding effect hinders the formation of a dimer of the III type; consequently, no magnetic interaction occurs between neighboring copper ions (where ph-Y=monosubstituted phenyl).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (5), 1425—1426 (1976)

The Synthesis of Single Crystals of $HgX_2 \cdot 2HgS$ (X=Halogen)

Kunio TAKEI and Hitoshi HAGIWARA

Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Miyazaki 880

(Received November 5, 1975)

Synopsis. Single crystals of $HgI_2 \cdot 2HgS$ ($3 \times 1.2 \times 0.2$ mm^3), $HgBr_2 \cdot 2HgS$ and $HgCl_2 \cdot 2HgS$ were prepared by means of a high-temperature vapor-phase reaction. X-Ray experiments showed that the crystal of $HgI_2 \cdot 2HgS$, the unit cell of which has dimensions of $a=9.36$ Å, $b=9.69$ Å, and $c=18.5$ Å, belongs to the rhombic system.

When powders of $HgI_2 \cdot 2HgS$ (yellow) and its related compounds are exposed to sunlight, they turn black in a few seconds; also, an absorption band is formed in all the visible regions. This process can be reversed, *i.e.*, bleaching occurs slowly in the dark after a few days or instantly when heated at 90 °C. The crystalline powders[1] of these compounds were easily prepared by the action of H_2S on the methanol solution of HgX_2. When a mixture of powdered HgX_2 and HgS (black) in a mole ratio of 1.1: 2 was heated at 170 °C for 1—2 h in an electric furnace, the same compounds as those of the hydrogen sulfide method were produced. In 1955, one of the present authors[2] synthesized a comparatively large single crystal by means of a vapor-phase reaction. About 30 g of a mixture of powdered HgI_2 and HgS (black) in a 1.1: 2 mole ratio were put into a glass tube (1 cm wide and 80 cm long) and placed in an electric furnace. After keeping the bottom of the tube at 520 °C for 30 min, the test tube was taken out and kept in the dark. Yellow crystals were observed inside the tube 40 cm from the bottom. These crystals were $HgI_2 \cdot 2HgS$, with rather small dimensions ($0.6 \times 0.7 \times 0.04$ mm^3). The purpose of the present investigation is to obtain a single crystal of $HgX_2 \cdot 2HgS$ as large as possible by using a more elaborate apparatus.

Vapor-phase Reaction between HgI_2, Hg, and S. A T-type glass tube (2 cm in inner diameter, 80 cm in length), whose two terminals were stopped with rubber stoppers, was put into a furnace consisting of two porcelain tubes (3 cm in inner diameter, 50 cm in length) and of 750 watts nicrom wires, as is shown in Fig. 1. The third terminal of the glass tube was connected to a water-stream pump in order to evacuate the inner air of the tube until the pressure became 748 mmHg. Asbestos was stuffed into the crevice between the furnace and the glass tube. The temperatures of the left and right parts of the furnace were kept at 280 °C and 500 °C respectively for 2 h by controlling the applied voltage at 50 V and 75 V with silidacs. Moreover, the temperatures at various positions of the two furnaces were measured by means of chromel–alumel thermocouples. The temperature of the B position (indicated in Fig. 1, 4—1 cm from the third terminal) was about 205—185 °C.

Next, a glass boat with 9 g of powdered HgI_2 was quickly placed into the left side of the glass tube, and another glass boat with 3 g of powdered black HgS was quickly put into the right side. The two terminals of the tube were closed again with rubber stoppers. HgI_2 molecules react in the vapor-phase with the Hg or S molecules produced by a decomposition of the HgS. These molecules also drive out oxygen in the tube. The reaction is as follows:

$$m\mathrm{HgI_2(g)} + n\mathrm{Hg(g)} + n\mathrm{S(g)} \longrightarrow \mathrm{HgI_2 \cdot 2HgS(s)} + (n-2)\mathrm{Hg(s)} + (n-2)\mathrm{S(s)} + (m-1)\mathrm{HgI_2(s)}$$

During the reaction, the temperature of the B part was higher than 180 °C. This shows that no crystals of $HgI_2 \cdot 2HgS$ were grown on the B position, because $HgI_2 \cdot 2HgS$ decomposes at 180 °C into HgI_2, Hg, and S. After the reaction had continued for 2 h, the applied voltage was slowly decreased and then cut off. It was observed that red and yellow crystals were deposited at the A and B cool parts respectively, and that gray powders were found at the C cool part, as is illustrated in Fig. 1. It is clear that the red crystals are HgI_2 and the gray ones are Hg and S. The yellow crystals ($3 \times 1.2 \times 0.2$ mm^3) show a phototropic character. The results of atomic light absorption analysis revealed the Hg content of this crystal to be 65.0% (calcd for $HgI_2 \cdot 2HgS$ 65.4%). These facts show that the crystals were $HgI_2 \cdot 2HgS$, which deposited upon cooling. In order to find the temperature which the crystal commences to deposit, the temperatures of the system while cooling were plotted against the time by using a big T-type glass tube (4 cm × 130 cm), two big furnaces, and 12 g of materials. When the temperatures of the left- and right-hand sides of the furnace were kept at 300 °C and 500 °C for 2 h and were then lowered at the rates of 5 °C and 7 °C per 10 min respectively, yellow crystals ($4 \times 2 \times 0.4$ mm^3) were found at a position corresponding to the C place in Fig. 1. In this case, the temperature of this position, which initially was 205 °C, was decreased at the rate of 2.5 °C per 10 min and then maintained between 175 °C and 150 °C for about 2 h.

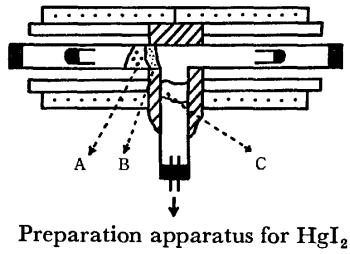

Fig. 1. Preparation apparatus for $HgI_2 \cdot 2HgS$.

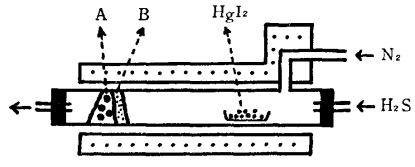

Fig. 2. Preparation apparatus for $HgI_2 \cdot 2HgS$.

It is certain that the crystals commenced to deposit in this temperature range.

High-temperature Reaction between HgI_2 and H_2S. Frerichs[3] prepared single crystals of CdS, CdSe, and CdTe by high-temperature reactions between Cd vapor and H_2S, H_2Se, or H_2Te. Crystals of $HgI_2 \cdot 2HgS$ could also be prepared by a similar method. As is shown in Fig. 2, a glass tube (2 cm in inner diameter, 2 m in length) was put into a horizontal electric furnace. At a point 20 cm from the entrance of the furnace, a glass boat with 5 g of HgI_2 powder was placed; a mixture of H_2S and N_2 was then introduced into the tube at a flow rate of 200 cm^3 per min. The temperature of the position near the glass boat was elevated up to 330 °C over a 1 h period and then kept at this condition for 2 h. After the electric source was cut off, it was observed that red and yellow crystals adhered to the A and B positions respectively, as is shown in Fig. 2. In the course of the reaction, the temperature of the B position was about 150 °C. The phototropy was observed from the yellow crystals deposited at the B place. These crystals are clearly $HgI_2 \cdot 2HgS$. By changing the experimental conditions, such a reaction was tried many times. It was found that $HgI_2 \cdot 2HgS$ crystals ($1.2 \times 0.5 \times 0.1$ mm^3) could also be obtained by this method.

Preparation of Single Crystals of $HgBr_2 \cdot 2HgS$ and $HgCl_2 \cdot 2HgS$. A glass tube (2 cm in inner diameter, 1 m in length) whose bottom had been sealed was placed in a vertical electric furnace. By putting into the bottom 5 g of a mixture of powdered $HgBr_2$ and HgS (black) in a mole ratio of 1 : 2 and by elevating temperature of the furnace, the temperature near the bottom was kept at 450 °C. A vapor-phase reaction was continued under their conditions for 30 h, as is shown in Fig. 3. The air in the tube was then evacuated by using a stream water pump. After the electric source had been cut off, yellow crystals ($1 \times 1 \times 0.5$ mm^3) were found inside the tube 25—29 cm from the bottom. It was easily confirmed by the curve between the temperature and the distance from the bottom that the temperature of this place was 160—200 °C. These crystals are clearly $HgBr_2 \cdot 2HgS$, because they showed phototropic behavior. When using a mixture of powdered $HgCl_2$ and HgS (black), white crystals ($1 \times 1 \times 0.5$ mm^3) were deposited 20 cm from the bottom. The temperature of this point was about 290 °C. These crystals correspond to $HgCl_2 \cdot 2HgS$. Their composition was confirmed by the atomic light absorption analysis; Hg content for $HgBr_2 \cdot 2HgS$: calcd 72.9%, obsd 72.5%; for $HgCl_2 \cdot 2HgS$: calcd 81.7%, obsd 81.3%.

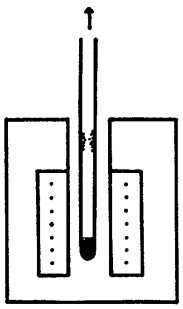

Fig. 3. Preparation apparatus for $HgBr_2 \cdot 2HgS$ or $HgCl_2 \cdot 2HgS$.

An investigation of the Laue photograph on a single crystal of $HgI_2 \cdot 2HgS$ showed that the Laue pattern is distributed with a 2-fold axis and that the symmetry planes of the spots are diagonal to each other. Observation of the single crystal by using a polarized microscope confirmed that this crystal has two light axes. The X-ray rotating-crystal method indicated the lattice constants of this crystal to be $a=9.36$ Å, $b=9.69$ Å, and $c=18.5$ Å. These facts established this crystal belongs to the rhombic system.

The X-ray experiments were carried out at the College of General Education, Kyushu University. The authors wish to express their hearty thanks to Professor Ikuhiko Ueda of Kyushu University for his continuous guidance and advice.

Aromaticity of Monocyclic Ions

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received February 17, 1975)

Synopsis. The infinitely-large annulenes with additional formal charges were employed as reference structures to evaluate the reference energies of monocyclic ions. On this basis, the Hückel (4r+2) rule of aromaticity was verified within the framework of the HMO theory. The results obtained agree well with the available experimental evidence.

The aromatic criterion of Hess and Schaad[1] has been very successful for interpreting the aromatic character of cyclic conjugated systems within the framework of the Hückel molecular orbital (HMO) theory.[2,3] The resonance energy of a compound is given by the difference between the total π-energy of the compound and the π-energy of a hypothetically non-aromatic reference structure with the same molecular geometry. In previous papers,[4,5] the author has reported that the π-energy of the reference structure could sometimes be estimated from infinitely-large species of the same type.

However, no one has attempted an analogous approach to the ionic species, although some cyclic ions, such as cyclopropenyl and cycloheptatrienyl ions, are known to be aromatic.[6-8] It is the purpose of this paper to show that the HMO theory can be used to analyze the aromaticity of some carbocyclic ions, provided the author's reformulation of the aromatic criterion is employed. The HMO theory in its simplest form is used. All energies are given in units of β.

Theoretical

The total HMO π-energy of a monocyclic ion with a general formula of $C_nH_n^m$ is calculated by summing the π-energies of all its occupied levels. In the chemical formula, n and m respectively signify the numbers of carbon atoms and formal charges, the sign of m being indicative of the type of charge. The total HMO π-energy of $C_nH_n^m$, $E_{\mathrm{HMO}}(n,m)$, is then expressed in the analytical form:[9]

$$E_{\mathrm{HMO}}(n,m) = 2\sum_k g_k \cos\frac{2\pi k}{n}, \tag{1}$$

where g_k is the number of electrons which are present in the kth orbital.

On the other hand, an infinitely-large annulene should be neither aromatic nor antiaromatic, even though it bears formal charges. It should be similar to a charged linear polyene. For this reason, the infinitely-large charged annulene was used as the non-aromatic basis for the evaluation of the aromatic stabilization of the $C_nH_n^m$ series. In this case, the ratio of the number of additional charges to the number of carbon atoms, R, in the infinitely-large system must be adjusted to that of the ion under consideration, *i.e.*, m/n. For example, the reference structure of a cycloheptatrienyl cation is to be derived from the infinitely-large annulene from which a seventh part of the occupied π-electrons are removed.

If n is sufficiently large, Eq. 1 can be rewritten as:

$$\begin{aligned} E_{\mathrm{HMO}}(n,m) &\approx 4n\sum_k \frac{1}{n}\cos\frac{2\pi k}{n} \\ &\approx 4n\int_{\mathrm{occ.}} \cos 2\pi x\,dx \\ &= 4n\left\{\int_0^{1/4(1-m/n)} \cos 2\pi x\,dx + \int_{1/4(3+m/n)}^{1.0} \cos 2\pi x\,dx\right\} \\ &= \frac{4n}{\pi}\cos\left(\frac{m\pi}{2n}\right), \end{aligned} \tag{2}$$

where the integration is made over all occupied energy levels of $C_nH_n^m$. The regions of integration are indicated by arrows in Fig. 1. When n approaches infinity, the integrated value becomes solely dependent upon the ratio m/n and is denoted as $I(m/n)$.

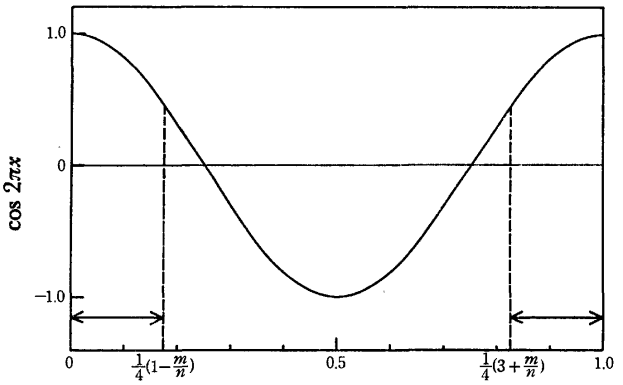

Fig. 1. The regions of integrations in Eq. 2.

Accordingly, the π-energy per π-bond, $E_{\mathrm{U}}(m/n)$, for an infinitely-large annulene with $R=m/n$ is derived from Eq. 2 as follows:

$$\begin{aligned} E_{\mathrm{U}}\left(\frac{m}{n}\right) &= \lim_{d\to\infty}\frac{E_{\mathrm{HMO}}(nd, md)}{nd} \\ &= 4I\left(\frac{m}{n}\right) = \frac{4}{\pi}\cos\left(\frac{m\pi}{2n}\right). \end{aligned} \tag{3}$$

The limiting π-energy per π-bond is exact. From this expression, the infinitely-large annulene can be regarded as a kind of alternant hydrocarbon, *i.e.*,

$$E_{\mathrm{U}}\left(\frac{m}{n}\right) = E_{\mathrm{U}}\left(-\frac{m}{n}\right). \tag{4}$$

Consequently, the π-energy, $E_{\mathrm{A}}(n,m)$, of the reference energy for $C_nH_n^m$ is defined as:

$$E_{\mathrm{A}}(n,m) = nE_{\mathrm{U}}\left(\frac{m}{n}\right) = \frac{4n}{\pi}\cos\left(\frac{m\pi}{2n}\right). \tag{5}$$

Such a derivation of the reference energy for a carbocyclic ion appears to be the best way imaginable at present, since the additive principle of localized π-bond

Table 1. Resonance energies of monocyclic ions in units of $|\beta|$

Species	E_{HMO}	E_A	E_{res}	Character
Two-Electron System ($n-m=2$)				
$C_3H_3^+$	4.0000	3.3080	0.6920	Aromatic

$C_{10}H_{10}^{2+}$	11.7082	12.1092	−0.4010	Antiaromatic
Ten-Electron Systems ($n-m=10$)				
$C_8H_8^{2-}$	9.6569	9.4106	0.2463	Aromatic
$C_9H_9^-$	11.5175	11.2851	0.2325	Aromatic
$C_{10}H_{10}$	12.9443	12.7324	0.2119	Aromatic
$C_{11}H_{11}^+$	14.0533	13.8631	0.1903	Aromatic
$C_{12}H_{12}^{2+}$	14.9282	14.7583	0.1699	Aromatic

energies is not applicable due to the lack of definite classical resonance structures. The resonance energy, E_{res}, for $C_nH_n^m$ is then given by the expression:

$$E_{res}(n, m) = E_{HMO}(n, m) - E_A(n, m). \quad (6)$$

The results obtained are presented in Table 1.

Results and Discussion

It is evident from Table 1 that the number of π-electrons is a significant factor which determines the aromaticity. All species with $(4r+2)$ π-electrons are predicted to be aromatic, because they have positive resonance energies, where r is an integer. Conversely, all species with $4r$ π-electrons are predicted to be antiaromatic with negative resonance energies. Note that this result is the best verification of the Hückel $(4r+2)$ rule of aromaticity within the Hückel theory.[10] These results are, of course, in qualitative agreement with the available experimental evidence.[6-8] In general, aromaticity or antiaromaticity decreases as the ring size increases.

Several years ago, Dewar and Venier defined a cyclic ion as being aromatic, if it has a greater π-energy than a corresponding open-chain system.[11] Their SCF-MO calculations appeared to be consistent with the predictions of the Hückel rule.[10] Subsequent free-electron molecular-orbital (FEMO) calculations, carried out by Hobey,[12] were also based on the same reference structures as were adopted by Dewar and Venier. However, one of the difficulties in using open-chain systems as reference structures appears to be that the molecular geometries and numbers of π-bonds are not preserved in them. To make the matter worse, the FEMO model cannot reproduce even the additivity of π-bond energies[1-5,11,13] for non-aromatic systems. However, the presently considered reference energies of monocyclic ions are free from these difficulties; the contributions from all π-bonds are counted in the present procedure. The HMO π-bond energies are sure to be additive in non-aromatic species.[1-5] For a general discussion, see Ref. 5.

Although our simple model neglects some significant effects arising from bond alternation and, more importantly, from interelectronic repulsion, the good agreement with experiment strongly suggests that the resonance energies obtained are good indices of aromaticity, at least, for the monocyclic ions investigated. It is expected that the gross features of the predicted aromatic character are not changed by these effects. On the contrary, it can be noted that the concept of aromaticity for ions thus introduced does not violate the simplicity and elegance of the HMO theory. Finally, it should be emphasized that the same approach can easily be extended to many other conjugated systems, as cited in Ref. 5.

We are grateful to the Hokkaido University Computing Center for the use of their FACOM 230-60, on which all calculations were performed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (5), 1429—1430 (1976)

On the Number of Aromatic Sextets in a Benzenoid Hydrocarbon[1)]

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 15, 1975)

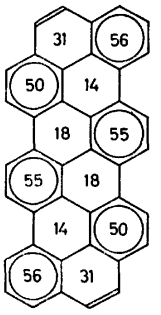
Synopsis. For a benzenoid hydrocarbon with a single sextet formula, the number of aromatic sextets in it is very close to the number of sextet-type resonance interactions per Kekulé structure.

An aromatic sextet is a benzene ring which can be isolated from a benzenoid hydrocarbon on condition that, if there is some residual π-system, at least, one Kekulé structure can be written for it.[2,3)] One or more aromatic sextets may be further isolated from the residual π-system. Clar has long stressed the importance of writing the structural formula of a benzenoid hydrocarbon with a maximum of aromatic sextets.[2,3)] These aromatic sextets, isolated from each other, have been considered as the only origin of aromatic stabilization. The structural formula thus defined is termed a sextet formula. Recently, Herndon showed,[4,5)] with the aid of a simple resonance theory, that the Dewar-type resonance energy[6–8)] of a benzenoid hydrocarbon is primarily associated with sextet-type resonance interactions, *i.e.*, resonance interactions related by a permutation of three double bonds within individual six-membered rings (sextets) of the structure.

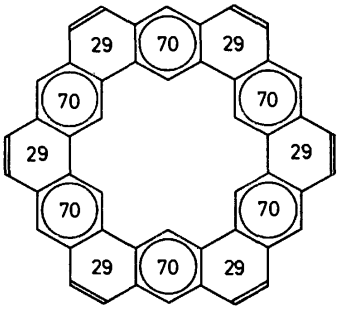
In this article, I would like to point out that Clar's way of enumerating the sextets which give rise to aromaticity in the hydrocarbon is essentially the same as Herndon's, except for polyacenes and their derivatives. A somewhat complicated situation for the polyacenes with plural sextet formulas has already been examined in a separate paper.[9)] The present discussion will, hence, be limited to the benzenoid hydrocarbons for which only one sextet formula can be written.

Let N_C be the number of aromatic sextets in Clar's sextet formula of a benzenoid hydrocarbon,[2,3)] and let N_H be the number of sextet-type resonance interactions, divided by the number of possible Kekulé structures. According to Herndon,[4,5)] the sextet-type resonance interactions are enumerated by the excision of each six-membered ring of the structure in turn, with a summation of the number of possible Kekulé structures for the residual π-systems. The present problem is thus reduced to a comparison of the two quantities, N_C and N_H. For this purpose, N_H-values are calculated for almost all the relevant hydrocarbons imaginable.

Those adopted first are 52 benzenoid hydrocarbons from benzene (C_6H_6) to tetrabenzoheptacene ($C_{42}H_{22}$), which are all cited in Ref. 2. For example, 157 Kekulé structures can be written for dipyreno-(1′.3′: 10.2); (1″.3″: 5.7)-pyrene (I). The number of sextet-type resonance interactions assigned to each six-membered ring is entered in the ring concerned. The aromatic sextets specified in the sextet formula are therein marked with circles. Note that the number of the resonance interactions of this type is comparatively large at these aromatic sextets. This aspect of the aromatic sextets



(I)



(II)

is common to all the hydrocarbons studied. The N_H-value is then calculated to be 5.707 for I, while the sextet formula is composed of six aromatic sextets and two fixed double bonds. Note, again, that the N_C-value of this compound agrees with the N_H-value within an accuracy of 5.1 percent of the latter value. The N_C-to-N_H value is 1.051. The analogous ratios for common hydrocarbons are as follows: phenanthrene, 1.000; pyrene, 1.000; dibenz[*a*,*h*]anthracene, 1.000; dibenz[*a*,*j*]anthracene, 1.000; triphenylene, 1.039; picene, 0.975; benzo[*d*]pyrene, 1.031; benzo[*ghi*]perylene, 1.000; peropyrene, 0.964; violanthrene, 0.988; ovalene, 1.000.

As may be suggested from these figures, the N_C-to-N_H ratios for the 52 benzenoid hydrocarbons were found to be densely distributed around 1.000. Interestingly, the number of aromatic sextets in the sextet formula nicely approximates the number of sextet-type resonance interactions per Kekulé structure, namely,

$$0.937 < N_C/N_H < 1.075. \quad (1)$$

It is noteworthy that, despite a variety of molecular geometries, the ratio for any compound with a single sextet formula is close to unity. It is possible to include in this relation two other hydrocarbons, coronene and circobiphenyl, which are classified as superaromatic species.[3)] Clar's sextet formulas for these two compounds can be written in two ways, although they are far from polyacene derivatives. Among the hydrocarbons investigated, coronene has the minimum ratio

of 0.9375, while hexa-*peri*-benzocoronene has the maximum ratio of 1.0749.

It goes without saying that the same features of the aromatic sextets are encountered in other kinds of benzenoid hydrocarbons which have not been referred to by Clar. In 1970, [12]coronaphene (II) was first prepared by Jenny *et al.*[10] 200 Kekulé structures can be written for this compound. The N_C-to-N_H ratio for II is calculated to be 1.010 with the use of $N_C=6$ and $N_H=5.940$. The numerical difference between the two ways of enumerating the sextets is only one percent of either value.

In conclusion, we can safely say that, as long as a maximum number of aromatic sextets are fixed in a benzenoid hydrocarbon, Clar's simple aromatic sextet theory[2,3] can predict the number of sextet-type resonance interactions in it; hence, it gives a rough estimate of the Dewar-type resonance energy.[7,8] Remember that the Dewar-type resonance energy, which has been the best aromaticity index available, is roughly proportional to N_H.[4,5] In this sense, Clar's concept of an aromatic sextet is evidently a simplified version of Herndon's theory of aromaticity.[4,5]

This resemblance between them reminds us of the correlation between Pauling's and Coulson's definitions of the bond order.[11] When only a single Kekulé structure is possible for a conjugated hydrocarbon, the double bonds in it indicate the correct locations where Coulson's bond order reaches its maximum values. In the same manner, we might say that, when a benzenoid hydrocarbon has a single sextet formula, the aromatic sextets in it specify the locations where the resonance energy is densely distributed.

Radical Anions Derived from 4-Picrylimino-2,6-disubstituted-2,5-cyclohexadiene-1-one

Eiichiro MANDA and Takehiko SHIMURA

National Chemical Laboratory for Industry Honmachi, Shibuya-ku, Tokyo 151

(Received July 10, 1975)

Synopsis. 4-Picrylimino-2,6-di-*t*-butyl (or bromo)-2,5-cyclohexadiene-1-ones were synthesized and radical anions were derived from them by one electron reduction with potassium metal. ESR measurement showed that an odd electron exists mainly on the quinone-imine moiety of the radical anion molecule.

A number of studies have been made on radical anions derived from quinones.[1] However, only one report[2] has appeared on radical anions derived from anils which are arylimino derivatives of *p*-benzoquinone. The title compounds are a new class of anils and are expected to give easily stable radical anions by one electron reduction since they have 2,6-disubstituted-*p*-benzoquinone and picryl moieties with known structures in the chemistry of stable radicals. In the present paper, we wish to report on the synthesis of the title compounds and some properties of radical anions derived from them.

Results and Discussion

Cyclohexadienones (II) were synthesized by ferricyanide oxidation of 4-*N*-picrylamino-2,6-disubstituted-phenols (I) prepared by the condensation of picryl chloride and 4-amino-2,6-disubstituted-phenol. The yield of each compound was moderate. One electron reduction of cyclohexadienone (II) (*ca.* 0.7 mg) in tetrahydrofuran (*ca.* 3 ml) with excess potassium metal was carried out *in vacuo* by using an apparatus shown in Fig. 2. The color of the reaction mixture turned immediately from yellow to violet (in case of *t*-butyl derivative), or to blue-violet (in case of bromo derivative). ESR measurement showed the presence of radical anions (III). Radical anions (III) were observed to change into some other species when they were in contact with excess potassium metal for some time, their color turning to brown in 20 min for the *t*-butyl derivative and in 3 min for the bromo derivative. Both radical anions (III) were found to be very stable in tetrahydrofuran when they were moved from excess potassium metal, remaining unchanged for a few days at room temperature *in vacuo*, though very unstable in air. ESR measurement for the decay of each radical anion (III) showed that radical anion (IIIa) was more stable than radical anion (IIIb). A solution of each radical anion (III) was therefore transferred to a cell

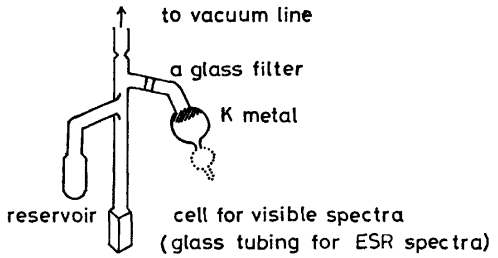

Fig. 2. An apparatus for reduction and spectral measurement.

from excess potassium metal before the color changed, and diluted to a suitable concentration for the spectral measurement with tetrahydrofuran condensed in a reservoir by chilling with liquid nitrogen. The absorption maxima in the electronic spectra of radical anions (III) is located at a greater wavelength (IIIa: 575 nm, IIIb: 583 nm) than the corresponding cyclohexadienones (IIa: 309 nm, IIb: 320 nm). These bathochromic shifts might be caused by the excitation of an odd electron in each radical anion molecule (III), as reported for many hydrocarbon radical anions.[3] The ESR spectrum of radical anion (IIIa) (Fig. 3) consists of a triplet (with hyperfine splitting of 4.38 G of an equal intensity) which might be due to an imino-nitrogen atom. The ESR spectrum of radical anion (IIIb) consists of a triplet (with hyperfine splitting of 6.25 G of an equal intensity) of a triplet (with hyperfine splitting of 1.88 G of intensity ratio=1:2:1) which might be due to an imino-nitrogen atom and two equivalent quinone-protons. The results suggest that unpaired electron distribution at an imino-nitrogen atom is maximal. The absence of the hyperfine splittings due to nitrogen atoms of picryl group suggests that an odd electron exists mainly on the quinone-imine moiety of the radical anion molecule (III). This may be explained by the fact that twisting of a picryl group disturbs the whole π-electron system of radical anion

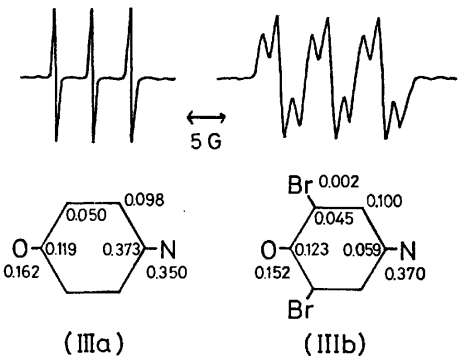

Fig. 3. ESR spectra and HMO spin density of radical anion (III).

(III),[4] and an odd electron exists on quinone-imine moiety which is considered to have greater electron affinity than a picryl group, since the electron affinity of 1,3,5-trinitrobenzene is 0.7 eV and that of 2,6-dibromo-*p*-benzoquinone is 1.2 eV.[5] The HMO unpaired electron distribution of each radical anion (III) was calculated by using parameters cited in the literature[6] for the π-electron system shown in Fig. 3, and the results are also shown in Fig. 3.

Experimental

4-N-Picrylamino-2,6-di-t-butyl (or bromo)-phenol (I). A saturated ethanol solution of 4-amino-2,6-di-*t*-butyl (or bromo)-phenol[7] (0.011 mol) containing pyridine (0.01 mol) was poured into a saturated ethanol solution of picryl chloride (0.01 mol). The reaction was continued for 3 h under refluxing in a stream of nitrogen. The solvent was distilled off as much as possible. The precipitates was filtered off, washed with cold hexane and water successively, and dried *in vacuo*. Recrystallization of each crude product from alcohol gave crystals of phenol (I). Phenol (Ia, R=*t*-butyl): red needles (1.4 g, 28%) from 1-propanol, mp 187—189 °C, Found: C, 55.76; H, 5.38; N, 12.96%; mol wt (MS) *m/e* 432 (M^+). Calcd for $C_{20}H_{24}O_7N_4$: C, 55.55; H, 5.59; N, 12.96%; mol wt 432.4. IR (KBr): 3640 (OH), 3350 (NH), 3070, 2960 (CH), 1625 (NH), 1590 (phenyl), 1530, 1340 (NO_2), 840 (CH) cm^{-1}; Phenol (Ib, R=Br): orange needles (3.0 g. 63%) from ethanol, mp 245—247 °C, Found: C, 30.32; H, 1.31; N, 12.02; Br, 33.41%; mol wt (MS) *m/e* 476 (M^+). Calcd for $C_{12}H_6O_7N_4Br_2$: C, 30.15; H, 1.27; N, 11.72; Br, 33.43%; mol wt 476.2, IR(KBr): 3400 (OH), 3300 (NH), 3070 (CH), 1615 (NH), 1590 (phenyl), 1525, 1355 (NO_2), 845 (CH) cm^{-1}.

4-Picrylimino-2,5-di-t-butyl (or bromo)-cyclohexadiene-1-one (II). The phenol (I) (0.001 mol) in benzene was oxidized with potassium ferricyanide (1.23 g, 0.004 mol) and potassium hydroxide (0.23 g, 0.0041 mol) in water (15 ml) by shaking the reaction mixture for 3 h at room temperature. The reaction mixture was then poured onto a large amount of water, and the organic layer was washed with water and dried over anhydrous sodium sulfate. A yellow powder was obtained after distilling off benzene from the organic layer, and each crude product was recrystallized from alcohol. Cyclohexadienone (IIa, R=*t*-butyl): yellow plates (0.37 g, 86%) from ethanol, mp 177—179 °C, Found: C, 54.29; H, 4.85; N, 13.53%; mol wt. (MS) *m/e* 430 (M^+). Calcd for $C_{20}H_{22}O_7N_4$: C, 55.81; H, 5.15, N, 13.02%; mol wt 430.4. IR (KBr) 3070, 2960 (CH), 1660 (C=N), 1640 (C=O), 1615 (C=C), 1550, 1345 (NO_2), 820 (CH) cm^{-1}. Cyclohexadienone (IIb, R=Br): yellow-brown plates (0.20 g, 42%) from ethanol, mp 220—221 °C. Found: C, 30.46; H, 0.92; N, 10.82; Br, 33.51%. Mol wt (MS) *m/e* 474 (M^+). Calcd for $C_{12}H_4O_7N_4Br_2$: C, 30.28; H, 0.85; N, 11.77; Br, 33.57%. Mol wt 474.2. IR (KBr); 3070 (CH), 1670 (C=O), 1615 (C=N), 1605 (C=C), 1535, 1350(NO_2), 825 (CH) cm^{-1}.

All the melting points were uncorrected. The infrared spectra were measured with a Shimadzu IR-27G grating spectrophotometer, the visible spectra with a Hitachi EPS-2U recording spectrophotometer and the ESR spectra with a Hitachi 771 electron spin resonance spectrometer.

The authors are indebted to Mr. Wasada for the mass spectra and Mr. Nishikawa for the HMO calculation.

The Reaction of the Butenyl Grignard Reagent with Trimethylchlorosilane

Hideki SAKURAI, Yoshihiko KUDO, and Heiichi MIYOSHI*

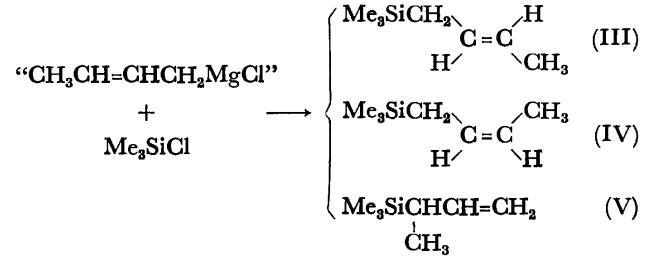
(Received September 5, 1975)

Synopsis. The reaction of trimethylchlorosilane with the butenyl Grignard reagent prepared from either 3-chloro-1-butene or 1-chloro-2-butene yielded *trans*-2-butenyltrimethylsilane, *cis*-2-butenyltrimethylsilane and 1-methyl-2-propenyltrimethylsilane, approximately in the ratio of 30/20/50. Structures of these isomeric butenylsilanes were elucidated by NMR and IR spectra.

During the course of a study on thermolysis of cyclopropylsilanes[1] and allyltrimethylsilane,[2] it became desirable to prepare *trans*- and *cis*-2-butenyltrimethylsilanes. Butenyltrimethylsilanes may be prepared by hydrosilylation of butadiene,[3] but these compounds can also be prepared by direct introduction of a butenyl group into silicon through an organometallic reagent. Accordingly, we prepared three allylic isomers of butenylsilanes by the reaction of trimethylchlorosilane with butenylmagnesium chloride. When the most of the work had been completed, we received reports of Seyferth and coworkers[4,5] who prepared the compounds in question with butenyllithium in the course of a study on the solution properties of the lithium reagent. Recently, they have published the detail of the experiment.[6] Slutsky and Kwart also reported the preparation of butenylsilanes recently.[7] In spite of these circumstances, we would like to publish our results briefly, since results with the Grignard reagent are somewhat different from those with the Grignard reagent in product distribution and we have elucidated the structures of butenyltrimethylsilane unequivocally by analyzing the complex NMR spectra.

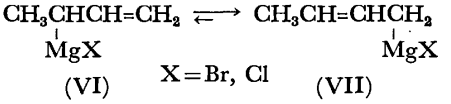
Addition of trimethylchlorosilane at room temperature to the Grignard reagent, which was prepared from either 3-chloro-1-butene (I) or 1-chloro-2-butene (II), resulted in the formation of a mixture of *trans*- and *cis*-2-butenyltrimethylsilanes (III and IV) and 1-methyl-2-propenyltrimethylsilane (V) in 60—90% total yield.



Product distribution was little affected by the structure of the starting chloride, by changing the solvent from ether to THF, and by the order of addition. Thus, relative yields of III/IV/V were, in %: (a) addition of trimethylchlorosilane to the Grignard reagent from I in ether, 27.7/20.4/51.9; (b) addition of trimethylchlorosilane to the Grignard reagent from II in ether, 30.1/21.5/48.4; (c) *in situ* reaction of trimethylchlorosilane, I and magnesium in THF, 26.7/19.8/53.4.

The reaction of the butenyllithium reagent, which was prepared from either *cis*- or *trans*-2-butenyltrimethyltin by *trans*-metallation, with trimethylchlorosilane gave an approximately 3/2 mixture of III/IV.[6] It was noted that V was not among the products in the reaction of the lithium reagent. This is the most significant difference between two reagents in the reaction with trimethylchlorosilane, although the same *trans*/*cis* ratio of approximately 3/2 is sustained in two experiments.

It is well established that the unsymmetric butenylmagnesium bromide consists mainly of the 2-butenyl isomer in mobile equilibrium with the very minor 1-methyl-2-propenyl isomer.[8] Therefore, the present finding confirms the rapid equilibration between two isomeric structures of the Grignard reagent.



A path for the dominant formation of V, which must occur only in the reaction of the Grignard reagent, may be provided by the S_E2' type reaction of VII,[9] since the direct displacement reaction of VI (S_E2 reaction) with trimethylchlorosilane is unlikely because of both steric reason and unfavorable equilibrium concentration. The reaction of a secondary Grignard reagent with trimethylchlorosilane usually resulted in the reduction of the chlorosilane.[10]

The NMR spectra of III and IV are very complicated and have not been analyzed completely yet. We have

determined all chemical shifts and coupling constants. by using triple resonance technique on pure samples The results are listed in Table 1. The data of IR spectra are listed in Table 2.

Experimental

NMR spectra were obtained at 100 MHz using a Varian HA-100 spectrometer. IR spectra were measured with a Nippon Bunko DS-402G Grating Infrared Spectrophotometer. 2-Chloro-1-butene and 1-chloro-2-butene were prepared from 1,3-butadiene and hydrogen chloride according to the literature.[11]

The Grignard reactions were carried out by the standard procedure. A typical example is shown below.

A solution of 1-chloro-2-butene (9.05 g, 0.1 mol) dissolved in ether (14 ml) was added to magnesium (3.16 g, 0.13 g-atom) in ether (14 ml) very slowly with stirring. After 6 h, a solution of trimethylchlorosilane (10.8 g, 0.1 mol) in ether (14 ml) was added to the mixture. After an exothermic reaction had ceased, the mixture was heated at reflux for 1 h and hydrolyzed with water. The dried organic layer was distilled using a short Vigreux column to give 9.5 g (74%) of a mixture of butenylsilanes, bp 110—118 °C.

The mixture was analyzed by GLC with a phenylacetonitrile–$AgNO_3$ column. Relative retention times were critically influenced by the silver content, and finally a column packed with *ca.* 30% by weight of an approximately 1 : 1 complex of $PhCH_2CN$–$AgNO_3$ on Celite 545 was used at 45 °C with 0.9 atom helium. Under these conditions the retention times were 2.0 min for III, 6.6 min for IV and 10.5 min for V. A portion of the mixture was also separated by GLC and identified by spectroscopic studies.

Mass spectra (25 eV) *m/e* (rel. intensity), (III): 128 (10.6), 113(5.5), 85(6.9), 73(100), 59(10.1), 55(11.1); (IV): 128(9.3), 113(4.8), 85(6.2), 73(100), 59(9.7), 55(14.5); (V): 128 (5.9), 113(4.3), 85(6.3), 73(100), 59(8.7), 55(6.7).

We wish to thank Dr. Y. Nakadaira for NMR measurements. We also thank Toshiba Silicone Co., Ltd., for gifts of chlorosilanes.

Reduction and Oxidation Potentials of Metal-free and Cobalt Tetra(*p*-substituted phenyl)porphyrins

Meguru TEZUKA, Yasukazu OHKATSU, and Tetsuo OSA*

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 26, 1975)

Synopsis. Both reduction and oxidation potentials of metal-free and cobalt tetra(*p*-substituted phenyl)porphyrins were determined by means of cyclic voltammetry. They are correlated with Hammett σ values of the substituents when the electron transfer occurs at the porphin ring, but not in the electron transfer step in which the cobalt atom participates.

Great interest has been shown in the electrochemistry of porphyrins and metalloporphyrins from the standpoint that their redox properties play a significant role in biological systems.[1-4] Felton and Linschitz studied the polarographic reduction of various metallotetraphenylporphyrins (MTPP) in order to see if they were reduced step-wise through a one-electron transfer to yield the porphyrin anion radicals followed by the formation of the dianions; in the case of cobalt tetraphenylporphyrin (CoTPP), however, the central metal was reduced in the first electron transfer step.[5] On the other hand, Wolberg and Manassen investigated the oxidation of transition metal complexes of tetraphenylporphyrins and phthalocyanines and concluded that in the cases of Fe, Co, and Ni tetraphenylporphyrins, the central metal was oxidized first, whereas oxidation of the ligand was observed for Cu and Zn porphyrins, subsequent oxidation occurring at the ligand in all cases.[6] From these results, Manassen discussed the catalytic behavior of MTPP in a few pure chemical reactions, such as oxidative dehydrogenation and symmetry-forbidden rearrangement.[7]

Although a number of studies have been made on porphyrins and metalloporphyrins, little has been done to make a systematic examination of the substituent effect on their redox properties. We have determined both reduction and oxidation potentials of metal-free and cobalt (*p*-substituted phenyl)porphyrins by the cyclic voltammetric method. The effects of substituents on the redox properties and on the catalytic activity in the autoxidation of acetaldehyde are discussed.

Experimental

Materials. Metal-free tetraphenylporphyrin (H_2TPP) and its *p*-substituted derivatives, *viz.*, tetra(*p*-methylphenyl)-porphyrin[H_2(*p*-CH_3)TPP], tetra(*p*-methoxyphenyl)porphyrin [H_2(*p*-OCH_3)TPP] and tetra(*p*-chlorophenyl)porphyrin-[H_2(*p*-Cl)TPP] as well as the cobalt complexes of these porphyrins were synthesized and purified according to conventional methods. *N,N*-Dimethylformamide (DMF) was dried over "Drierite" for several days and distilled twice under reduced pressure of nitrogen. Tetraethylammonium perchlorate (TEAP) was synthesized and purified according to conventional methods.

Cyclic Voltammetry. Cyclic voltammograms of the saturated solutions of porphyrins in DMF were recorded with a platinum plate of 0.40 cm^2 at 25 °C. TEAP was used as a supporting electrolyte. The concentration of porphyrins was less than 2 mM in most cases. The potential was referred to saturated calomel electrode (SCE).

TABLE 1. CYCLIC VOLTAMMETRY OF METAL-FREE AND COBALT TETRA(*p*-SUBSTITUTED PHENYL)PORPHYRINS

Porphyrin	Peak potential (V)			
	Oxidation		Reduction	
H_2TPP		+1.13	−1.04	−1.42
H_2(*p*-CH_3)TPP		+1.08	−1.06	−1.48
H_2(*p*-OCH_3)TPP		+1.02	−1.08	−1.50
H_2(*p*-Cl)TPP		+1.18	−0.98	−1.36
CoTPP	+0.58	+1.20	−0.80	−1.90
Co(*p*-CH_3)TPP	+0.57	+1.16	−0.80	−1.88
Co(*p*-OCH_3)TPP	+0.62	+1.10	−0.80	−1.90
Co(*p*-Cl)TPP	+0.75	+1.26	−0.76	−1.79

Measurements were made on a platinum electrode in 0.1 M TEAP–DMF solution at 25 °C. The concentration of porphyrins was less than 2 mM in most cases. Potential sweep rate: 0.10 V/s. (V *vs.* SCE).

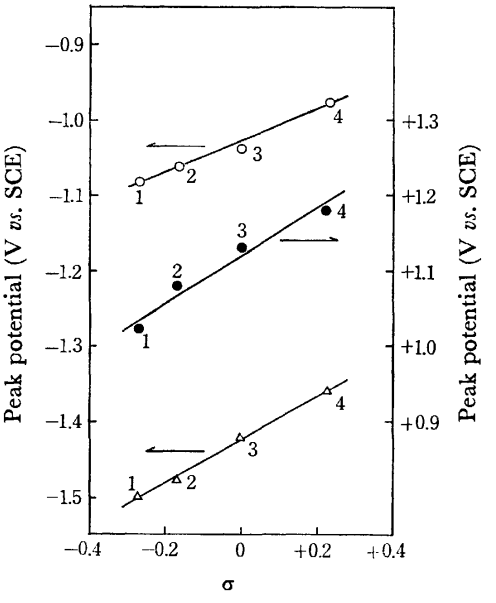

Fig. 1. Relation of peak potentials for the first (○), the second (△) reduction and oxidation (●) of metal-free tetra(p-substituted phenyl)porphyrins in DMF to Hammett substituent constants: 1, H_2(*p*-OCH_3)-TPP. 2, H_2(*p*-CH_3)TPP. 3, H_2TPP. 4, H_2(*p*-Cl)-TPP.

* Present address: Pharmaceutical Institute, Tohoku University, Aramaki, Sendai 980.

Results and Discussion

The cyclic voltammetric results are given in Table 1.

Metal-free porphyrins were reduced step-wise through a reversible one-electron transfer step to give porphyrin anion radicals followed by the formation of the dianions.[5] The irreversible waves, ascribed to the formation of porphyrin cation radicals, were also observed in the oxidation. These peak potentials of reduction and oxidation are correlated with Hammett σ values (Fig. 1). Each correlation is expressed as follows.

First reduction:

$$E_p = 0.205\sigma - 1.030\text{V} \quad (1)$$

Second reduction:

$$E_p = 0.295\sigma - 1.426\text{V} \quad (2)$$

Oxidation:

$$E_p = 0.317\sigma + 1.118\text{V} \quad (3)$$

The equations show that the electron-donating group increases the electron density on the porphin ring through the phenyl group, and consequently these peak potentials shift toward a negative direction while the reverse is seen for the electron-withdrawing group.

The reduction of cobalt porphyrins also proceeded reversibly through two one-electron steps. The first step has been accepted to be the addition of electron to cobalt, Co(II)→Co(I), and the second step also seems to involve the change in the valency of cobalt.[5,8] The oxidation consists of the two consecutive steps, the first and second steps being attributed to the oxidation of cobalt and porphin ring, respectively.[6] Contrary to the case of metal-free porphyrins, a good correlation with Hammett σ values was obtained in the second oxidation step (Fig. 2):

$$E_p = 0.296\sigma + 1.198\text{V} \quad (4)$$

whereas no distinct correlation was found in the first oxidation and reduction steps.

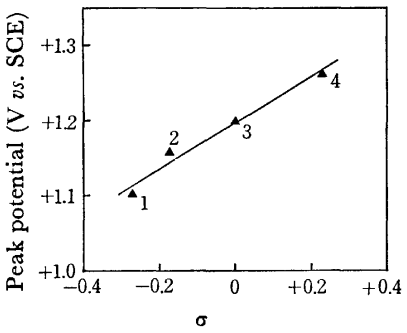

Fig. 2. Relation of peak potentials for the second oxidation of cobalt tetra(*p*-substituted phenyl)porphyrins to Hammett substituent constants: 1, Co(*p*-OCH_3)-TPP. 2, Co(*p*-CH_3)TPP. 3, CoTPP. 4, Co(*p*-Cl)-TPP.

It is thus concluded that the peak potentials are correlated well with Hammett σ values when the electron transfer occurs at the porphin ring as in the case of metal-free porphyrins or the second oxidation of cobalt porphyrins. This can be understood in terms of the resonance interaction between the substituents on phenyl groups and the porphin ring.[9] No correlation is substantially obtained when the electron transfer occurs at the cobalt atom. This indicates that the redox properties of central metal do not directly reflect those of the porphin ring.

CoTPP activates an oxygen molecule to the superoxide state through the electron donation from the central metal. The activated oxygen abstracts the hydrogen of acetaldehyde to initiate autoxidation. It was found that Co(*p*-CH_3)TPP possesses a remarkably high catalytic activity, almost ten times as much as those of the other cobalt porphyrins. The extraordinary activity of Co(*p*-CH_3)TPP cannot be explained in terms of the oxidation potentials of porphyrins. This is ascribed to the fact that the potentials indicate only the ease of the activation process of oxygen molecule. It seems that the substituent effect on the reactivity of an oxygen molecule which has been in activated condition should also be taken into account for clarifying the effect in autoxidation of acetaldehyde.

We would like to express our thanks to Prof. Taiseki Kunugi for his valuable advice and discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (5), 1437—1438 (1976)

The Chlorination of 1,3- and 1,5-Cyclooctadienes with Various Chlorinating Agents

Sakae UEMURA, Akira ONOE, Hajime OKAZAKI, Masaya OKANO, and Katsuhiko ICHIKAWA*

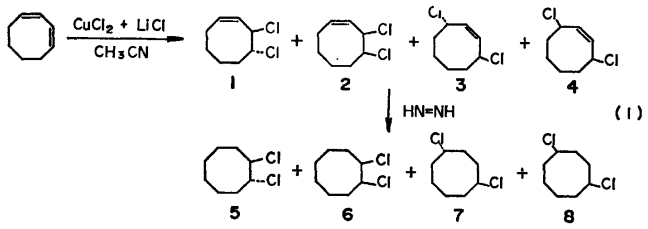
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

**Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606*

(Received October 13, 1975)

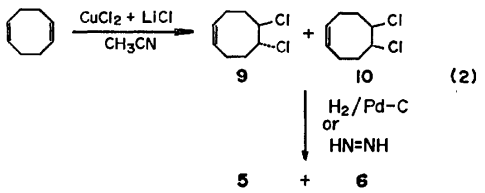
Synopsis. The chlorination of 1,3-cyclooctadiene with various chlorinating agents gave an isomeric mixture of *trans*-3,4-, *cis*-3,4-, *trans*-3,8-, and *cis*-3,8-dichlorocyclooctene. From 1,5-cyclooctadiene an isomeric mixture of *trans*- and *cis*-5,6-dichlorocyclooctene was obtained. The isomer distribution depended a great deal on chlorinating agents in both cases.

Recently Lasne and Thuillier[1] have reported the chlorination of 1,3-cyclooctadiene (1,3-COD) with (dichloroiodo)benzene or copper(II) chloride which gave both 1,2- and 1,4-addition products. Since it has previously been reported[2] that 1,3-COD was chlorinated with copper(II) chloride to give only two isomeric 1,2-addition products, we reexamined the reaction products in the previous paper[2] and also carried out the chlorination of both 1,3- and 1,5-COD with many other chlorinating agents with which norbornene[3] and norbornadiene[4] were treated.



Scheme 1.

The product mixtures obtained from the reaction of 1,3-COD with $CuCl_2$[2] were hydrogenated with diimide in methanol[5] to the mixture of four isomeric dichlorocyclooctanes (**5**—**8** in Scheme 1). Each isomer was identified by comparison of retention time in GLC and the spectroscopic data with those of each authentic sample by the reported method.[6-8] From this result four isomers were revealed to be *trans*-3,4-(**1**), *cis*-3,4-(**2**), *trans*-3,8-(**3**), and *cis*-3,8-dichlorocyclooctene (**4**), respectively. Since we confirmed in separate experiments that no isomerization occurred during hydrogenation, the isomer ratio in **1**—**4** is considered to be the same as that in **5**—**8**. This isomer ratio was reproducible in each run and was not affected so much by prolonging the reaction time. The ratio of 1,2- to 1,4-addition was 53—51 : 47—49, being nearly the same as the reported value.[1] In order to compare with the reported data[1] chlorination with $PhICl_2$ was carried out under several conditions. It was revealed that the proportion of 1,4-addition was quite high (69—81%) in our case under any conditions, compared with the reported value[1] of 30%. Typical results are shown in Table 1. The chlorination was also carried out with several other chlorinating agents in which $PbCl_4$, $SeCl_4$, and Cl_2 gave **1**—**4** (Table 1). Tetrachlorocyclooctane was not formed under any conditions shown in



Scheme 2.

a) Determined by GLC before reduction. b) Based on chlorinating agents charged as determined by GLC.
c) Under N_2. d) No improvement of the yield by prolonging the reaction time to 10 h.

Table 1, while variable amounts of high-boiling resinous products were always produced. In the case of $SbCl_5$ the yield of **1**—**4** was decreased by prolonging the reaction time or raising the temperature, producing the resinous products. In the case of Cl_2 it was necessary to carry out the reaction at low temperature. Otherwise very many unidentified products were formed as reported previously.[2] The reaction with $TlCl_3 \cdot 4H_2O$, VCl_4, and $MoCl_5$ at room or refluxing temperature gave only a trace amount of **1**—**4** together with lots of polymerized products.

The product mixtures obtained from chlorination of 1,5-COD with $CuCl_2$[2] were hydrogenated catalytically or with diimide to afford an isomeric mixture of **5** and **6** (Scheme 2), the ratio between two isomers being the same as that in the starting unsaturated compounds. The result showed that the products were *trans*-(**9**) and *cis*-5,6-dichlorocyclooctane (**10**). This means that both isomers have been assigned erroneously and reversely in the previous report.[2] Typical results were shown in Table 2 together with those of chlorination with some other metal chlorides and chlorine gas. The reactions were slow as compared to those of 1,3-COD and did not give tetrachlorocyclooctane in any cases. Although the chlorination of 1,5-COD with $SbCl_5$ gave an isomeric mixture of 2,8-dichlorobicyclo[3,2,1]octanes as the products,[9] such compounds were not formed by the use of chlorinating agents shown in Table 2. The characteristic *cis*-chlorination with $MoCl_5$ which has been observed with various olefins[10] was also found in this case.

Experimental

Experimental procedures were almost the same as those reported.[2-4] The IR and NMR spectra were recorded with a Hitachi EPI-S2 and a Varian A-60 or T-60 apparatus respectively. Gas chromatographies were carried out on Shimadzu 4BMPF apparatus using SE-30(3%)-Chromosorb-W (3 m) and EGSS-X(15%)-Chromosorb-W (3 m) columns (N_2 as carrier gas; ethyl benzoate as internal standard).

Anthentic Samples for GLC. **5** was prepared by the addition of chlorine to *cis*-cyclooctene.[6] A mixture of **5** and **6** (**5**:**6**=75:25) was prepared by the reaction of $PhICl_2$ with *cis*-cyclooctene.[7] A mixture of **7** and **8** (**7**:**8**=20:80) was prepared by the reaction of *cis*-cyclooctene with $PbCl_4$.[8]

Diimide Reduction of a Mixture of **1**—**4**. To a methanol (50 ml) solution of a mixture of **1**—**4** (0.6 g, 3.3 mmol, bp 62—69 °C/3 Torr) and hydrazine hydrate (80%, 10 g) was added 30% H_2O_2 (10 g) drop by drop at room temperature and then the mixture was heated to reflux for 1 h. The reaction mixtures were worked up by the following successive treatments; dilution with water, extraction with benzene, and then evaporation of benzene. The residue was analyzed by GLC on EGSS-X (3 m) column at 150 °C: **5** (21.7%), **6** (31.3%), **7** (2.2%), and **8** (44.8%); total yield, 3.1 mmol, 92%.

Similary a mixture of **9** and **10** was reduced to a mixture of **5** and **6** in a 95% yield as determined by GLC [EGSS-X or SE-30 (3 m) column at 150 °C].

Synthesis, Thermolysis and Photolysis of Trimethylammonium-*N*-diphenylphosphinylimine

Eiichi KAMEYAMA, Seiichi INOKUMA, and Tsunehiko KUWAMURA
Faculty of Engineering, Gunma University, Kiryu, Gunma 376

(Received October 14, 1975)

Synopsis. Ammonim-*N*-phosphinylimine was prepared from the corresponding hydrazinium salt. The ylid gave phosphinylnitrenes on thermolysis, predominantly in the singlet state. On photolysis, the ylid also gave a singlet product.

A number of aminimides have been studied extensively and reviewed.[1] Higher homologues of trialkylammonium-*N*-alkanoylimine and sulfonylimine have also been reported,[2,3] however, a similar type of nitrogen ylid with a phosphinyl group has received far less attention.

It is well known that the thermal decomposition of the aminimides gives corresponding isocyanates. In a previous paper,[3] the present authors have indicated that the photolysis of trialkylammonium-*N*-alkanoylimine was hindered by the introduction of a hydroxyl group into the 2-position of the alkyl chain attached to the positive nitrogen atom in the aminimide. Robson and Speakman[4] have found that trimethylammonium-*N*-dodecanoylimine afforded only an amide upon photolysis, and that a similar sulfonylimine underwent no photolysis, but instead thermally decomposed producing both singlet and triplet nitrenes.

This paper deals with the synthesis of a nitrogen ylid trimethylammonium-*N*-diphenylphosphinylimine (I), and the generation of phosphinylnitrene by the thermolysis and photolysis of I.

The nitrogen ylid I was synthesized from 1,1,1-trimethyl-2-diphenylphosphinylhydrazinium iodide (II), which was prepared from 1,1-dimethyl-2-diphenylphosphinylhydrazine (III) and methyl iodide.

The IR absorption frequencies assigned to the phosphinyl group of I are lower than those of II and III. A similar shift is known for a carbonyl group in aminimides and attributed to a delocalization of the negative charge on the imine nitrogen.[1] The shift was also found for a sulfonyl group in ammonium-*N*-sulfonylimines.[2] The base peak of the mass spectrum of I, due to the elimination of a methyl group, is a characteristic pattern for aliphatic amines. Three main peaks in the low mass region suggest that I decomposes to form phosphinylnitrene and trimethylamine. The differential thermal and thermogravimetric analysis data show that I has one mole of water of crystallization and decomposes producing trimethylamine at a temperature higher than its mp by about 60 °C. This decomposition temperature is higher than those for ammonium-*N*-acylimine and sulfonylimine.[2]

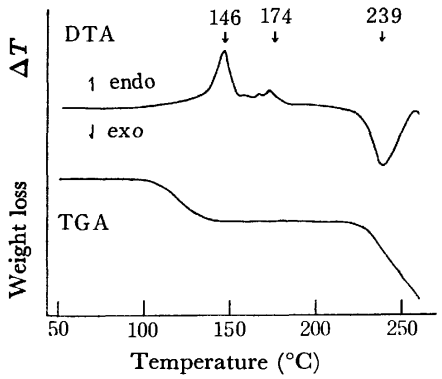

Fig. 1. DTA and TGA curves for $(CH_3)_3N^+N^-PO(Ph)_2$. α-Alumina standard; heating, 2.5 °C/min in air.

The aqueous solution of I was neutral, had a low electric conductivity and was titratable with an HCl aqueous solution at room temperature. When this acidic aqueous solution was boiled for a couple of minutes, I decomposed to give trimethylhydrazinium salt and diphenylphosphinic acid quantitatively.

Thermally, I was decomposed in DMSO and gave diphenylphosphinamide (IV) and *N*-diphenylphosphinyldimethylsulfoximine (V) with some unknown prod-

Table 1. Thermolysis of $(CH_3)_3N^+N^-$–X (5 h)

ucts. In 1-dodecanol, I gave IV and dodecyl diphenylphosphinate (VI). These results are shown in Table 1.

It can be assumed that diphenylphosphinylnitrene, produced in the singlet state, immediately reacts with DMSO to form V, on the other hand, in the presence of a poor singlet trap, the nitrene produces the triplet product IV by way of an intersystem crossing. The molar ratio of the singlet to triplet products was somewhat larger than that for the sulfonylimine. Moreover, I gave only V at 180 °C in DMSO. An almost identical proportion of I was decomposed in both DMSO and 1-dodecanol at a temperature lower than the mp of I.

Table 2. Photolysis of $(CH_3)_3N^+N^-$–X

a) $(CH_3)_2NCH_2CH_2OH$. b) $(CH_3)_2NCH_2CH_2OH$+cyclohexane.

As in the case of thermolysis, the photolysis of I resulted in the smooth production of the singlet nitrene as shown in Table 2. In the presence of 2-(dimethylamino)ethanol, I transferred no additional products of the nitrene to the amine.

Experimental

All the melting points are uncorrected. The IR spectra were obtained using a Hitachi EPI-G3 infrared spectrometer. The NMR spectra were recorded on a Varian A-60D spectrometer in $CDCl_3$ at 60 MHz, using tetramethylsilane as an internal standard. The mass spectra were measured using a Nihon Denki JMS07 mass spectrometer operating at 25 eV. Differential thermal and thermogravimetric analyses were carried out using a Rigaku Denki Thermoflex DG-CIH.

Preparation of Trimethylammonium-N-diphenylphosphinylimine (I). Diphenylphosphinic chloride, prepared from chlorodiphenylphosphine in the usual way,[5)] was added to a benzene solution of two moles of 1,1-dimethylhydrazine at room temperature. The precipitated white crystal was washed thoroughly with water, and gave 1,1-dimethyl-2-diphenylphosphinylhydrazine (III) in a 40% yield, mp 178.2—178.5 °C (167—168 °C)[6)]; IR 1110, 1123, 1190, 1205 cm^{-1}. In ethanol, III was refluxed with an excess of methyl iodide to give 1,1,1-trimethyl-2-diphenylphosphinylhydrazinium iodide (II) in a 90% yield; IR 1103, 1122, 1200 cm^{-1}. At room tempera- ture II was treated with a 10% NaOH aq. solution. From the alkaline solution, I was extracted with chloroform in a 69% yield, mp 178.3—178.5 °C (from acetone); IR 1027, 1048, 1110, 1150 cm^{-1}; NMR δ 3.0—3.1 (s, *ca.* 2H, H_2O), 3.31 (s, 9H, CH_3), 7.2—8.2 (m, 10H, phenyl); mass spectrum (peaks more than 30% of the base peak) *m/e* (%) 58 (78), 59(59), 216 (33), 259 (100), 273 (50), 274 (47, M^+). The DTA and TGA curves are shown in Fig. 1. Found C, 61.36; H, 7.15; N, 9.42; P, 9.9%. Calcd for $C_{15}H_{19}N_2OP \cdot H_2O$: C, 61.63; H, 7.24; N, 9.58; P, 10.6%.

Thermolysis. In a stream of nitrogen, an approximately 7% solution of I in DMSO was heated. After 5 h, the solvent was distilled off at reduced pressure. Two products, diphenylphosphinamide (IV) and *N*-diphenylphosphinyldimethylsulfoximine (V) were isolated from the reaction mixture by recrystallization and/or by column chromatography. In addition, two or three unknown products were detected by TLC in the residue. In the same way as described above, I was decomposed in 1-dodecanol, and gave IV and dodecyl diphenylphosphinate (VI). These products, IV and VI, were confirmed by direct comparisons with authentic samples. On the basis of elemental analysis, IR and NMR spectra, V (mp 168.0—168.5 °C (from acetone)) was identified. Trimethylammonium-*N*-benzoylimine was also decomposed in DMSO and gave *N,N'*-diphenylurea.

Photolysis. Solutions of I and other aminimides (about 1 g) in 250 ml of DMSO or 2-(dimethylamino)ethanol were irradiated using a 10W low-pressure mercury arc lamp at room temperature. The products were isolated and identified in the same way as described for thermolysis.

Catalytic Oxidation of Mercaptans by Iodine-Hydrogen Iodide System in Dimethyl Sulfoxide

Tetsuo AIDA, Takeshi AKASAKA, Naomichi FURUKAWA, and Shigeru OAE

Department of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31

(Received October 15, 1975)

Synopsis. Mercaptans were oxidized readily by a catalytic amount of iodine or hydrogen iodide (*i.e.*, aq. HI-solution) in the presence of dimethyl sulfoxide to afford the corresponding disulfides nearly quantitatively.

As reported previously,[1] the reduction of sulfoxides, especially dialkyl sulfoxides (*e.g.*, dimethyl sulfoxide) was found to take place catalytically by either bromine or hydrogen bromide. The mechanism for this reaction was proposed to proceed *via* an initial bromination of the sulfoxide affording the corresponding α-bromo sulfoxide which then reacts with another sulfoxide regenerating the corresponding sulfide and hydrogen bromide (Kornblum Reaction).[2] Meanwhile, hydrogen bromide is well known to reduce the sulfoxide to the corresponding sulfide.[3] Thus, the whole process may form a kind of the Oxidation-Reduction Cycle by the bromine–hydrogen bromide system in the sulfoxide.

Therefore, if the above reaction system is treated with a third component which reacts with either bromine or hydrogen bromide, a new synthetic application of this system will be resulted.

Meanwhile, it is known that the oxidation of mercaptans proceeds in dimethyl sulfoxide (DMSO) solution, but the reaction requires high temperature and a prolonged reaction time.[4] While, iodine (I_2) is a mild and convenient oxidizing reagent for the preparation of disulfides from the corresponding mercaptans,[5] and the reaction is considered to proceed through the following reaction path.

$$RSH + I_2 \longrightarrow RSI + HI$$

$$RSI + RSH \longrightarrow RSSR + HI$$

Thus, if iodine is regenerated from hydrogen iodide (HI), this oxidation may be carried out by the use of a small amount of iodine or hydrogen iodide under a mild condition. Actually, when the oxidation of mercaptan was carried out in DMSO with a catalytic amount of iodine (or hydrogen iodide), the oxidation proceeded nearly quantitatively at room temperature affording the corresponding disulfide. Therefore, our present method is to be a simple and convenient preparation of disulfides.

The oxidation of mercaptan by iodine or hydrogen iodide was carried out under various reaction conditions. The results obtained are summarized in Table 1.

Inspection of the data in Table 1 shows that the oxidation of mercaptan by iodine or hydrogen iodide took place only in the presence of DMSO (Runs 6 and 7), and gave a nearly equal amount of dimethyl sulfide (DMS) to that of the corresponding disulfide. These observations suggest clearly that the oxidation of mercaptan and the reduction of DMSO occur simultaneously. Namely, iodine undoubtedly initiates the oxidation of mercaptan affording disulfide and hydrogen iodide which is readily oxidized by DMSO to iodine. Therefore, iodine acts only as a catalyst for the present reaction.

In order to generalize this catalytic oxidation of mercaptan by iodine, various mercaptans were reacted in sealed tubes at room temperature. The results

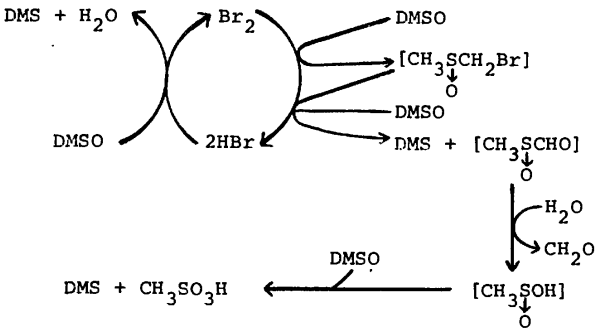
7	HI (2)	excess[b]	40	3.0	95	94	I_2[c]

a) Aqueous HI-solution (*ca.* 40%) was used. b) Six times excess to that of mercaptan used. c) Iodine was detected, but the yield was not determined.

obtained are listed in Table 2.

These results shown in Table 2 reveal clearly that this reaction is a facile method to prepare disulfide from the corresponding mercaptan, while the plausible reaction scheme may be depicted as shown in Scheme 1.



* DMS : Dimethyl Sulfide

Scheme 1.

Experimental

Materials. *Mercaptan*: Alkyl mercaptans and thiophenol were commercial products. *p*-Tolyl and *p*-chlorophenyl mercaptans were prepared from the corresponding sulfonyl chloride and zinc in sulfuric acid by a known method.[6]

Dimethyl sulfoxide: The commercial product was purified by usual method (dried over calcium hydride and then distilled).

Iodine and Hydrogen iodide: The commercial products (HI: *ca.* 40% aqueous solution) were used without further purification.

General Apparatus. GLPC analysis was performed with a Hitachi Gas Chromatography with a thermal conductivity detector, equipped with a 2 m×3 mmϕ stainless steel column packed with Silicon GE SE-30 on 60—80 mesh Chromosorb W (AW). Preparative column chromatography was performed with silica gel (Wakogel C-200) using benzene-hexane as an eluent.

Product Analysis. The yield of the disulfides was determined only by GLPC measurement, and the yield after the isolation slightly decreased. Dialkyl disulfides were separated by GLPC and preparative column chromatography and diaryl disulfides were separated by preparative column chromatography, and identified by comparing their mp and spectroscopic analyses with those of the authentic samples.

Oxidation of Mercaptan by Iodine. A typical run was as follows: Butyl mercaptan (0.2 g; 2.2 mmol), iodine (0.006 g; 0.02 mmol) and DMSO (1.0 g; 12.8 mmol) were dissolved in 5 ml of benzene. The mixture was placed in a sealed tube, and was allowed to stand at room temperature for 3 h. Then, the sealed tube was broken and 5 μl of the reaction mixture was directly injected into a column of GLPC to determine the amount of dimethyl sulfide. The yield was 95%. To the rest of the reaction mixture, 10 ml of aq. NaOH (1/10 M) solution was added, and after shaking the mixture vigorously, the benzene layer was separated. From the benzene layer, dibutyl disulfide was isolated by GLPC and preparative column chromatography. The yield was 97%. Meanwhile, the colorless reaction mixture turned to red at the completion of the reaction, and the red color faded away upon treatment with sodium hydrogen sulfite. This suggests that iodine was present in the reaction mixture.

All the other reactions were carried out as described above.

A Proton Magnetic Resonance Study of the Amide Configurations of 2-Acylaminopyrimidines

Michio KONDO

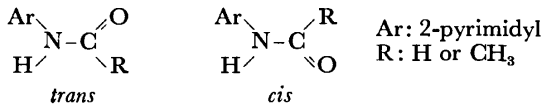
Central Research Laboratories, Sankyo Co., Ltd., Hiromachi, Shinagawa-ku, Tokyo 140

(Received October 16, 1975)

Synopsis. It has been found, from the ^1H NMR spectra at various temperatures, that 2-formylaminopyrimidine (**2**) exists in a *cis* configuration in chloroform and dimethyl sulfoxide, whereas 2-acetylaminopyrimidine (**3**) exists in a rapid rotational equilibrium between *cis* and *trans* configurations in $CDCl_3$, but almost exclusively in a *trans* configuration in DMSO at room temperature.

It is well known that *N*-monosubstituted amides undergo *cis-trans* rotational isomerism and that the equilibrium is a function of many factors. In the cases of acetylamino and higher acylamino derivatives, the isomers are almost all *trans*.[1] In polypeptides and proteins, it is also found that the peptide bonds are predominantly *trans*, except for a few peptide bonds in some cyclic oligopeptides.[2] For a few acetanilides with bulky *ortho* substituents, however, it has been reported that the *cis* isomers were appreciable.[3] On the other hand, formylamino derivatives usually exist as both *cis* and *trans* forms.[1b,4]

It seemed that it would be interesting, therefore, to find formylamino derivatives in a *cis* configuration exclusively or to find acetylamino derivatives without substituents in a *cis* configuration appreciably. This paper will be concerned with 2-acylaminopyrimidines as such compounds.



Experimental

2-Formylaminopyrimidine (2). Acetic anhydride (10 ml) was added to a solution of 2-aminopyrimidine (**1**) (5 g) in formic acid (20 ml). The reaction mixture became warm and foamed gently, and it was then allowed to stand overnight. Repeated recrystallizations of the precipitates from water gave pure **2**.

2-Acetylaminopyrimidine (**3**) was prepared from **1** and acetic anhydride.

The ^1H NMR spectra were recorded on a Varian A-60D spectrometer at various temperatures, using TMS as the internal standard. The concentration was 1% (w/v) unless otherwise noted. All the spectra were of the first order. The concentration dependence of the chemical shifts was examined for **3** in $CDCl_3$ and was found to be negligible for all protons but the amide proton.

Results and Discussion

The fact that H-4 and H-6 have the same chemical shift suggests a free flip-rotation around the C_{ring}–N_{amide} bond in **2** and **3** on the NMR time scale.

The chemical shift of the formyl proton is in good agreement with that reported for 2-formylamino-4-methylpyridine (**5**) in a *cis* form,[5] but it is fields lower than that of formanilide.[3a] This downfield shift can be attributed to a deshielding effect of an electric field due to the lone-pair electrons on the ring nitrogen atoms nearby.

The J_{CHONH} value was found to be about 10 Hz. A comparison of this value with two coupling constants for **5** (11 Hz for the *cis* and 2 Hz for the *trans* isomer)[5] leads to the conclusion that **2** in $CDCl_3$ and DMSO has a *cis* configuration almost exclusively. The two component peaks of the formyl proton signal in a DMSO solution coalesce at about 155 °C at almost the center of the doublet. This also seems to suggest a negligible contribution of **2** to the *trans* configuration, if any at all, because it has previously been reported that the formyl proton of **5** in the *trans* form resonated at a field higher by 0.92 ppm than did that in the *cis*.[5] Electrostatic repulsion between the lone-pair electrons on the ring nitrogen atoms and those on the carbonyl oxygen atom must play a key role, for **2** has a *cis* form, whereas 5 is subject to a *cis-trans* isomerism with a moderate equilibrium constant at room temperature.

The chemical shift of the acetyl protons of **3** in $CDCl_3$ is δ 2.53, lower by as much as about 0.4 ppm than that of acetanilide.[6] This fact strongly suggests that **3** has a configuration different from that of the latter compound, which has been proved to have a *trans* configuration. When the solvents were changed from $CDCl_3$ to DMSO, the acetyl signal was shifted upfield (−0.3 ppm); this shift was much larger than that observed for **4** upon the same solvent change. This large upfield shift could be explained in terms of a significant shift of the *cis-trans* equilibrium in **3** toward a *trans* preference, because the acetyl signal for the *trans* form can be expected to be at higher fields. It has been reported that the addition of DMSO to a $CDCl_3$ solution of formanilide shifted the equilibrium of the rotational isomers toward the intensification of the *trans* signal.[7]

Lowering the temperature of a $CDCl_3$ solution of **3** below 0 °C caused an appreciable broadening in the acetyl signal, and at −52 °C the acetyl signal split into a broad but clearly separated doublet (δ 2.33 and 2.73) with almost equal intensities. Of course, the amide proton gave two distinct signals, at δ 11.35 and 10.25. The ring proton signal also showed due complexity. The addition of a drop of DMSO to this solution caused an intensification of the upper-field signals for both the acetyl and amide protons at the expense of the lower-field ones. The acetyl proton signal of a solution of **3** in the $CDCl_3$–DMSO (3: 2) mixed solvent was observed at δ 2.23, almost equal to the value in DMSO. Lowering the temperature of the solution caused no splitting, but only a broadening, of the acetyl proton signal,

Table 1. Proton magnetic resonance spectral parameters of 2-amino- (**1**), 2-formylamino- (**2**), 2-acetylaminopyrimidine (**3**), and 2-acetylamino-4-methylpyridine (**4**)

a) A saturated solution. b) Almost insoluble. c) CH_3.

probably as a result of a reduced mobility of solute molecules at an increased viscosity of the solvent. These observations are indicative of an almost complete preponderance of the *trans* form for **3** in DMSO.

The replacement of a formyl proton by a methyl group would cause significant change in the van der Waals interactions with the pyrimidine ring, but not in the electronic structure, as may be seen by the very close similarity in their UV spectra. In the case of **2**, the *trans* form is unfavorable from the viewpoints of both the van der Waals interaction and the electrostatic repulsion between the lone-pair electrons on the ring nitrogen and the carbonyl oxygen atoms, as compared with the *cis* form. As for **3**, however, the *cis* form is preferable to the *trans* form from the point of view of the electrostatic repulsion; on the contrary, though, the *trans* form is preferable from the point of view of the van der Waals' interaction. Therefore, the *trans* form is not so unfavorable in **3** as in **2**, resulting in an appreciable contribution of the *trans* form for **3** even in $CDCl_3$.

Consistent with the description given above, two absorption bands in the IR spectrum of **3** in a dilute $CDCl_3$ solution assignable to NH stretching vibrations were observed at 3425 and 3395 cm^{-1}. As for **2**, on the other hand, a single NH band was observed at 3390 cm^{-1}. Needless to say, there were other broad bands due to the amide protons involved in intermolecular associations.

The benzene-induced upfield shift is large for the acetyl protons of **4** (+0.65 ppm), whereas it is small for **3** (+0.06 ppm). As for the amide protons, on the contrary, the benzene-induced shift is very small for **4** (+0.14 ppm), but very large for **3** (−1.1 ppm). These observations are also indicative of different situations in the acetylamino groups of these two compounds, taking the specific interactions[8] between benzene molecules and these amide groups into account.

The Photoreduction of *o*-Methoxycarbonylbenzophenone

Yuji TSUJIMOTO, Yasuo SHIGEMITSU, Takuji MIYAMOTO, and Yoshinobu ODAIRA

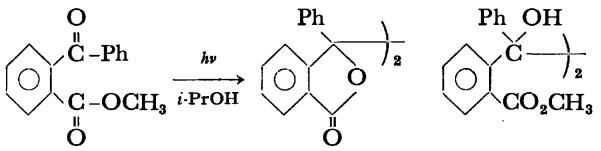
Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita-shi, Osaka 565

(Received October 27, 1975)

Synopsis. The photoreduction of *o*-methoxycarbonylbenzophenone (I) in a hydrogen-donating solvent, such as isopropyl alcohol and toluene, was shown to give diphthalidyl (II) or/and a coupling product (IV).

Recently we have studied the photoreactions of several aromatic compounds with the same carbonyl groups, such as tetramethyl pyromellitate[1] and *o*-dibenzoylbenzene.[2] In such a system, an interesting interaction between two carbonyls has been pointed out.[1-3] As an extension of these studies, we now wish to report the photoreduction of benzophenones substituted with an ester at the *ortho* position.

The irradiation of *o*-methoxycarbonylbenzophenone (I) in isopropyl alcohol through a Pyrex filter afforded diphthalidyl (II) in a good yield, together with an appreciable amount of methanol. However, no pinacol (III) was found at all.



(I) (II) (III)

Moreover, the photoreaction of I with toluene gave benzyl-phthalide (IV), along with II and bibenzyl, whereas with a non-hydrogen-donating solvent such as acetonitrile, I was recovered almost quantitatively and the formation of II was negligible.

A ketyl radical (V), formed by the hydrogen abstraction of the n-π^* excited triplet of I from a solvent, such as isopropyl alcohol or toluene, may give (III) or/and (VI). III and VI subsequently undergo the lactonization, accompanied by the elimination of methanol, to give II and IV respectively.

In order to obtain information about the photoexcited state of I, the phosphorescence spectrum of I was measured and photocycloaddition to norbornene was examined.

In the phosphorescence spectrum, the entire shape of I resembles that of benzophenone, though fine structures do not appear clearly. In addition, the photocycloaddition of I to norbornene gave oxetane (VII) as a major product. These observations strongly suggest that I has the lowest n-π^* triplet level of benzoyl carbonyl.

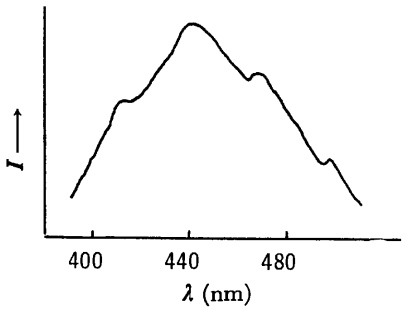


Fig. 1. Phosphorescence spectrum of I in MeOH–EtOH (1:3) at 77 K.

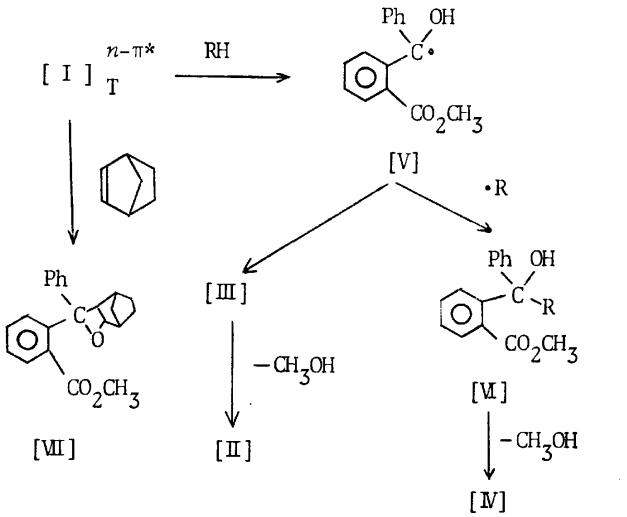
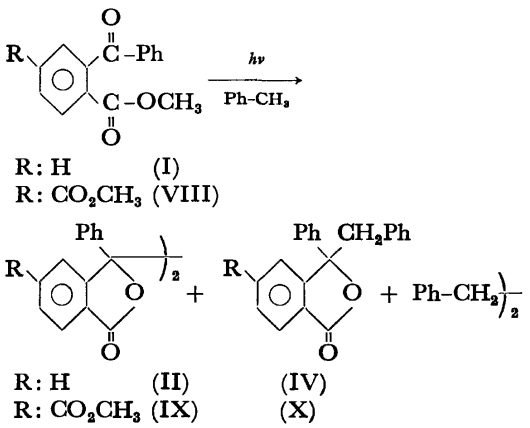
The following scheme may rationalize the above results:



Furthermore, the photoreduction of 2,5-dimethoxycarbonylbenzophenone (VIII) (bichromophoric system)[4] was examined. The irradiation of VIII in toluene afforded diphthalidyl (IX) and benzyl-phthalide (X).



Experimental

Materials. *o*-Methoxycarbonylbenzophenone (I) (mp 48—50 °C, lit,[5] 51—51.6 °C) was prepared by the esterification of *o*-benzoylbenzoic acid (84%). 2,5-Dimethoxycarbonylbenzophenone ((VIII), mp 96—98 °C, lit,[6] 100—101 °C) was prepared by the following procedure: the Friedel-Crafts reaction[7] of *p*-xylene with benzoyl chloride gave 2,5-dimethylbenzophenone (91%), while the subsequent oxida-

tion of 2,5-dimethylbenzophenone with potassium permanganate gave benzophenone-2,5-dicarboxylic acid (16%). Finally the esterification of the diacid afforded VIII (99%).

Irradiation Procedure. All the irradiations were carried out with a 500-W high-pressure mercury lamp through a Pyrex filter at room temperature. The solutions were flushed for 15 min with nitrogen prior to irradiation.

Photoreduction of I. In isopropyl alcohol: a solution of I (1.5 g, 6.25 mmol) in isopropyl alcohol (45 ml) was irradiated for 7 h. Then, the precipitated crystals were filtered off; subsequent recrystallization from ethyl acetate gave 3,3′-diphenyl-diphthalidyl (II) (990 mg, 76%); mp 252—254 °C, lit,[8] 269—270 °C. From the volatile parts, methanol was detected by GLC (20% PEG 20M on Celite 545). In toluene: a solution of I (1.5 g, 6.25 mmol) in toluene (63 ml) was irradiated for 11 h. After the solvent had been removed *in vacuo*, the residue was chromatographed using a silica gel column. The insoluble parts [(II), (400 mg, 28%)] of the residue in benzene were removed before chromatography. The eluent of benzene with petroleum ether (60%) gave 3-phenyl-3-benzyl-phthalide (IV) (950 mg, 54%), mp 100—100.7 °C, lit,[9] 103—105 °C.

Photocycloaddition of I to Norbornene. A solution of I (2.0 g, 8.3 mmol) and 2-norbornene (4.1 g, 43.6 mmol) in benzene (40 ml) was irradiated for 10 h. The subsequent evaporation of the solvent gave a residue (3.1 g), which was then chromatographed on silica gel. The eluent of benzene with petroleum ether (20%) gave VII[10] (688 mg, 39%); mp 148—151 °C; IR (KBr) 1720, 970 cm^{-1}; NMR ($CDCl_3$) δ, 0.4—2.2 (m, 8H), 2.7 (d, 1H, J=6.0 Hz), 3.6 (s, 3H), 5.9 (d, 1H, J=6.0 Hz), 7.0—7.4 (m, 9H). Found: C, 78.96; H, 6.66%. Calcd for $C_{22}H_{22}O_3$: C, 79.01; H, 6.63%.

Photoreduction of VIII in Toluene. A solution of VIII (800 mg, 2.68 mmol) in toluene (32 ml) was irradiated for 7 h. After the evaporation of the solvent, small amounts of benzene were added. The insoluble parts were removed, and then the soluble parts were chromatographed on silica gel. The recrystallization of insoluble parts from benzene gave 3,3′-diphenyl-5,5′-dimethoxycarbonyl-diphthalidyl (IX) (118 mg, 16%); mp 280—284 °C; IR (KBr) 1785, 1740 cm^{-1}. Found: C, 71.85; H, 4.07%. Calcd for $C_{32}H_{22}O_3$: C, 71.90; H, 4.15%. The eluent of benzene containing petroleum ether (30%) gave 3-phenyl-3-benzyl-5-methoxycarbonyl-phthalide (X) (276 mg, 29%); mp 154—155 °C; IR (KBr) 1775, 1725 cm^{-1}; NMR (CCl_4) δ, 3.5, 3.7 (AB quartet, 2H, J=14 Hz), 3.9 (s, 3H), 6.8—8.2 (m, 13H). Found: C, 77.38; H, 4.95%. Calcd for $C_{23}H_{18}O_4$: C, 77.08; H, 5.06%.

Bis(acetylacetonato)metal(II)-Catalyzed Addition of Acceptor Molecules to Acetylacetone[1]

Kaku UEHARA, Yoshiyuki OHASHI, and Makoto TANAKA

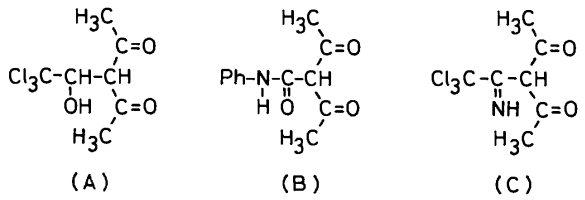
Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai-shi, Osaka 591

(Received November 6, 1975)

Synopsis. Bis(acetylacetonato)metal(II) ($M(acac)_2$) showed an effective catalytic activity for the addition of various acceptor molecules to acetylacetone to give 3-substituted 2,4-pentanediones.

Collman[2] found that $M(acac)_n$ undergoes electrophilic substitutions at the 3-position on the chelate ring in a similar manner to that of aromatic compounds and proposed that $M(acac)_n$ has some quasi-aromatic characters. However, the aromaticity of $M(acac)_n$ based on the electrophilic substitution is open to question.[3] In a previous communication,[4] we reported that $M(acac)_2$ undergoes an aldol addition of chloral to the 3-position on the chelate ring to give an adduct A and polychloral in the presence and absence of acetylacetone, respectively.

The present paper will show that $M(acac)_2$ undergoes not only the aldol addition but also another electrophilic reaction with a few acceptor molecules such as phenyl isocyanate and trichloroacetonitrile at the 3-position to give adduct B and C in the presence of acetylacetone. It is interesting to note that A can exist only in the keto form and that C is at first isolated as a crystalline keto-form but is easily transformed into an enolic form even in the solid state at room temperature within 24 h.

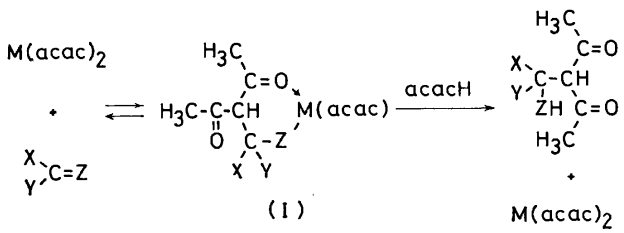


(A) (B) (C)

In the presence of piperidine instead of $M(acac)_2$ as a catalyst, chloral and trichloroacetonitile also reacted with acetylacetone to give the same reaction products (A and C), but not phenyl isocyanate since it reacted with piperidine to form urea. Carbon disulfide did not react with acetylacetone in the presence of $M(acac)_2$, but in the presence of piperidine it reacted to attack the 3-carbon of acetylacetone and the product was isolated as the piperidinium salt of dithiocarboxylic acid.[5] Acetonitrile was non-reactive to acetylacetone in the presence of either catalyst.

Bloodworth *et al.*[6] studied systematically the reactions of metal alkoxide with various acceptor molecules such as chloral, phenyl isocyanate, and carbon disulfide. They confirmed that these acceptor molecules were inserted into the oxygen-metal (O–M) bond of metal alkoxide (formation of O-adduct). However, we found that, for the $M(acac)_2$-catalyzed reaction of acetylacetone, the acceptor molecules which are highly polarized or have high polarizability react to attack the 3-position of acetylacetone and form C-adduct. This is not in line with the view that $M(acac)_n$ has the character of metal alcoholate. Hitherto, the initiation mechanisms of the polymerization of chloral and formaldehyde[7] and of the alternative copolymerization of maleic anhydride with epichlorohydrin[8] induced by $M(acac)_n$ have been explained in terms of the insertion of these monomers into the O–M bond of $M(acac)_n$ but without definite evidence.

Differing from the electrophilic substitution as reported by Collman,[2] these acceptors undergo only the electrophilic addition on the 3-carbon of $M(acac)_2$ without subsequent elimination of the proton. The present reaction, therefore, seem to be a novel type of reaction of $M(acac)_n$ as follows:



Attemps to isolate the adduct I from reaction mixtures were unsuccessful, presumably because the complex is unstable and readily decomposed to the acceptor molecule and $M(acac)_2$. However, there are several spectral evidences to support the existence of I in equilibrium with chloral and $M(acac)_2$. The tetrahydrofuran solutions of $Co(acac)_2$ and $Cu(acac)_2$ rapidly turned from pink to blue and from blue to green, respectively with the addition of chloral. The infrared spectrum ($CHCl_3$) shows the presence of $\nu_{C=O}$ (saturated ketone) at 1700 cm^{-1}, which is not detectable in chloral or $M(acac)_2$ (M=Co, Cu), independently.

Experimental

Materials. Chloral was prepared through the dehydration of commercial chloral hydrate by concentrated sulfuric acid and distilled under nitrogen prior to use. Phenyl isocyanate of G. R. grade was used without further purification. Commercial trichloroacetonitrile and carbon disulfide were distilled before use. Commercial acetylacetone was purified by distillation. $M(acac)_n$ and piperidine of G. R. grade were used without further purification.

Spectral Measurements. The IR spectra were measured with a Model 215 Hitachi grating infrared spectrophotometer. The NMR spectra were taken with a Hitachi Model R-20 spectrometer. Tetramethylsilan was used as an internal standard, and carbon tetrachloride as the solvent. The UV spectra were measured with a Shimadzu UV-200 spectrophotometer. The elemental analyses were carried out with a Yanagimoto Model MT-2 CHN analyzer.

Reaction of Chloral with Acetylacetone. To a mixture of 5.79 g (57.8 mmol) of acetylacetone and 8.48 g (57.5 mmol) of chloral was added 0.339 mmol of $M(acac)_2$(M=Mg(II), Co(II), Ni(II), Zn(II), Cu(II)). An exothermic reaction took place. The solution was cooled to 0 °C until the product was precipitated. The reaction mixture was poured into 20 ml of ligroin to give white crystals of 3-(1-hydroxy-2,2,2-trichloroethyl)-2,4-pentanedione (A). The yield was 91% ($Mg(acac)_2$) to 85% ($Cu(acac)_2$). Mp 83 °C (from benzene–ligroin). Found: C, 34.09; H, 3.62%. Calcd for $C_7H_9O_3Cl_3$: C, 33.97; H, 3.67%. IR spectrum (KBr disk); 3420 (s), 3300 (s), 1690 (vs, C=O), 1410 (m), 1360 (s), 1320 (m), 1275 (m), 1180 (s), 1150 (s), 1090 (s), 940 (m), 830 (w), 805 cm^{-1} (s). UV spectrum ($CHCl_3$); λ_{max} 290 nm, ε_{max} 140. NMR spectrum (CCl_4); 7.67 (6H, s, $COCH_3$), 5.35 (3H, m, OH, $Cl_3CCH(OH)$, and $CH(COCH_3)_2$). Spectral evidence for the aldol condensate is compatible with the structure A and shows that A exists only in keto form. A is reverted to chloral and acetylacetone in the presence of $M(acac)_2$ and other metal salts. The aldol reaction is also catalyzed by piperidine and gives the same product A in an 85% yield. $Co(acac)_3$ and $Cr(acac)_3$ are ineffective as catalyst.

Reaction of Phenyl Isocyanate with Acetylacetone. Phenyl isocyanate (2.12 ml, 19.5 mmol) was added to a mixture of $M(acac)_2$ (0.194 mmol, M=Mg(II), Co(II)) and acetylacetone (2 ml, 19.5 mmol) in dichloromethane (5 ml). An exothermic reaction took place. Ten ml of ligroin was added to the reaction mixture which was cooled to −78 °C, precipitating 3-phenylcarbamoyl-2,4-pentanedione (B) in a 76% yield (3.24 g). Mp 118—119 °C (lit,[9] 118—119 °C). IR spectrum (KBr disk); 3270 (NH) and 1640 cm^{-1} (C=O). The reaction mixture should not be allowed to stand for a long time in contact with air. In the presence of $M(acac)_2$, B is subject to hydrolysis to give acetic acid and acetoacetanilide as final products. In the presence of piperidine, phenyl isocyanate does not react with acetylacetone because it reacts with piperidine to form urea.

Reaction of Trichloroacetonitrile with Acetylacetone. Trichloroacetonitrile (3.96 g, 27.4 mmol) was added to a mixture of $Co(acac)_2$(0.0705 g, 0.274 mmol) and acetylacetone (2.74 g, 27.4 mmol). An exothermic reaction took place. Ten ml of ligroin was added to the reaction mixture which was cooled in an ice bath, precipitating 3-(1-imino-2,2,2-trichloroethyl)-2,4-pentanedione (C) in an 80% yield (5.37 g). C was precipitated as a keto-form crystal which was purified by the recrystallization from benzene–ligroin. It was easily transformed into the enol form even in the solid state, the color changing from white to pale yellow within 24 h on being left to stand at room temperature; mp of enol-form 58 °C (from benzene–ligroin). Found: C, 34.51; H, 3.07; N, 5.21%. Calcd for $C_7H_8O_2NCl_3$: C, 34.35; H, 3.27; N, 5.73%. IR spectrum of enol-form (KBr disk); 3340 (s, NH), 3080 (m), 1670 (s, C=N), 1595 (s, enol), 1450 (m), 1420 (m), 1360 (s), 1260 (s), 1220 (s), 1100 (m), 1030 (w), 1015 (w), 980 (m), 955 (m), 830 (s), 790 cm^{-1} (s). IR spectrum of keto-form (KBr disk); 3240 (s, NH), 1725 (s, C=O), 1700 (s, C=O), 1645 cm^{-1} (m, C=N). The reaction of trichloroacetonitrile with acetylacetone was also catalyzed by piperidine and gave C in a 1.0% yield.

Enzyme-like Reaction Catalyzed by Flavin-Reduced Keratin Systems. II. Binding Site in FAD-Reduced Keratin Complex[1)]

Fujio TAKAHASHI, Tatsuo OGASA, and M. B. RAHMAN*

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

**Department of Chemistry, University of Rajshahi, Rajshahi, Bangladesh*

Synopsis. In order to confirm the binding site in the FAD-reduced keratin (RK) complex, polarographic and fluorometric studies were carried out and the FAD–RK complex was isolated. An adenine moiety of FAD was found to form a 1 : 1 complex with RK.

It has been reported in a previous paper that complex formation between FAD and reduced keratin (RK) occurs and that the complex catalyzes the dehydrogenation of succinic acid to fumaric acid.[1)] The binding site of FAD and RK in the complex was discussed and an arginine residue of RK and an adenine moiety and a pyrophosphate linkage of FAD were suggested as probable paths of ionic bond formation. This paper presents the results obtained by polarographic and fluorometric studies and by the isolation of the FAD–RK complex which throw light on the binding site in the FAD–RK complex.

Experimental

The RK used was prepared by the reductive cleavage of human hair with 2-mercaptoethanol and urea in a sodium hydroxide solution in accordance with the usual method.[2)] Molecular weight; 2800 (by viscometry), S-content; 2.7% as thiol groups; 0.36 mgeq/g (PCMB method[3)]) (1.0 thiol group/molecule of RK). The other chemicals used were the same as described in a previous paper.[1)]

Measurements of absorption and fluorescence spectra were made with a Shimadzu spectrophotometer UV-200 and a JASCO fluorescence spectrophotometer FP-4, respectively. The polarograms were determined with a dropping mercury electrode.

Results and Discussion

Polarography. From the dissimilar behavior between FAD and FMN with RK, it was expected that FAD and RK in solution would give different polarograms from FMN and RK in solution.

The sample solutions contained 2.5 mM of FAD or FMN and the requisite amount of RK in a 0.1 M phosphate buffer (pH 5.6 and 7.0). The results are shown in Figs. 1 and 2. The half-wave potentials of FAD without RK in solution at pH 5.6 and 7.0 were observed at −0.38 and −0.44 V *vs.* SCE at 25 °C. The same values were obtained when FMN containing solutions were measured. The wave height of the half-wave potential decreased when RK was introduced in the FAD or FMN solution. Another half-wave potential was found at −0.69 V *vs.* SCE on the polarograms of the FAD–RK system at pH 5.6 The wave height at the second half-wave potential increased with increasing RK concentration. The total of the two wave heights

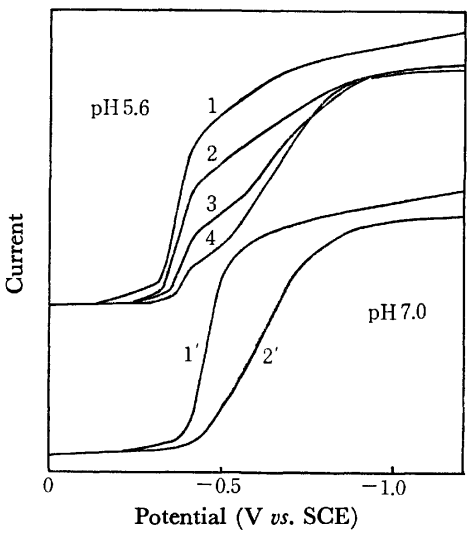

Fig. 1. FAD–RK polarography.
FAD 2.5 mmol/l
RK 1,1′: 0, 2: 0.07, 3: 0.14, 4,2′: 0.71 mmol/l

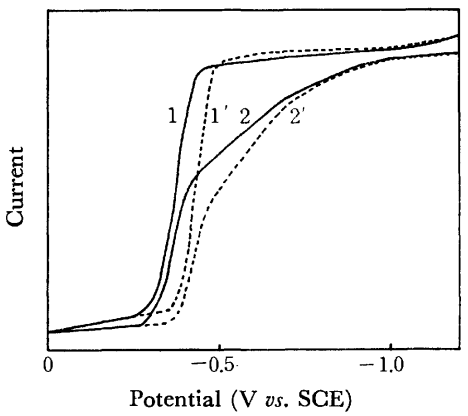

Fig. 2. FMN–RK polarography.
— pH 5.6, ---- pH 7.0
FMN 2.5 mmol/l
RK 1,1′: 0, 2,2′: 0.71 mmol/l

at the first and second half-wave potentials was found to remain constant.

It is known that sulfur- or nitrogen-containing compounds are readily absorbed on the surface of dropping mercury.[4)] Therefore, RK can very possibly be absorbed by mercury. The absorbed RK may interact with free FAD on the mercury surface and the reduction of FAD may be hindered so that the wave height at the first half-wave potential is decreased. Less influence on the wave height was observed for a solution containing FMN, for which complex formation with RK

was weaker than that for FAD. The second half-wave potential was assigned to the reduction of the FAD bound to RK. It is probably not possible that the reduction of free FAD is facilitated by the desorption of RK from the mercury surface at more negative potentials, because the second half-wave potential appeared at the same point, although the RK concentration had increased.

In the presence of an excess of RK, only the 1 : 1 complex is formed with RK. Then the equilibrium constant can be determined from the wave heights of the first and second half-wave potentials. The equilibrium constant was calculated to be about 2800 M^{-1} at pH 5.6 from Table 1.

Table 1. Equilibrium constant of the FAD-RK complex

FAD (mM)	RK (mM)	Wave height $(E_{1/2})_1$	Wave height $(E_{1/2})_2$	Equilibrium constant (M^{-1})
0.5	1.8	0.6	2.4	2.9×10^3
1.0	1.8	1.3	4.8	2.6×10^3
1.5	1.8	1.9	6.9	3.0×10^3

pH 5.6, 25 °C

Fluorescence Spectra. It was confirmed from the fluorescence spectra that the behavior of the interaction of FAD with RK was different from that of FMN with RK. The fluorescence intensity of FAD with RK (pH 7.0) at 522 nm (excited by 468 nm light) was found to be 7% higher than that of FAD without RK (Fig. 3). The fluorescence intensity of FMN was about 4 times stronger than that of FAD. It is known that the adenine moiety of FAD quenches the fluorescence caused by the intramolecular interaction.[5] It can be explained that quenching by RK may result in a decrease in the fluorescence intensity in the FMN-RK solution. In the FAD–RK case it is speculated that the interaction between the adenine moiety and isoalloxazine moiety may weaken when the adenine moiety bonds to RK, *i.e.*, the reduced influence of the adenine moiety on the isoalloxazine moiety decreases the quenching.

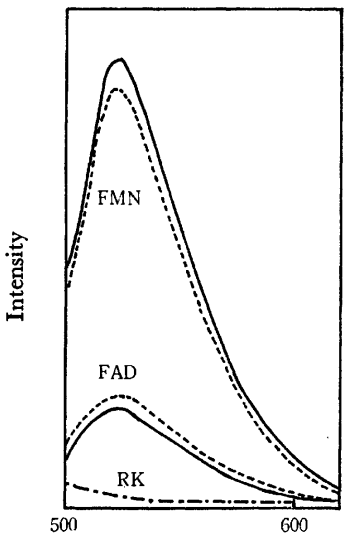

Fig. 3. Emission spectra of flavin-RK systems.
—— Flavin only, ------ Flavin-RK
Flavin 6 μmol/l, RK 3 μmol/l
λ_{EX}=468 nm, pH 7.0

Isolation of the FAD-RK Complex. Attempting further confirmation of complex formation in solution, the FAD–RK complex was isolated. Dissolving 0.071 mmol of RK and 0.11—0.42 mmol of FAD or FMN into distilled water and adding 1 M hydrochloric acid to adjust to pH 4, precipitation occurred. The precipitates were separated by centrifugation, washed by distilled water and dried. The determination of RK and flavin in the complex was carried out by analysis of the sulfur content and measurement of the absorption at 450 nm. It is seen from the results in Table 2 that a 1 : 1 complex was obtained from the FAD-RK solution. The FMN content in the precipitates obtained from the FMN-RK solution was found to be variable. These results confirm that the adenine moiety of FAD is a bonding site for RK.

Table 2. Analysis of flavin-RK complexes

	Flavin (mmol)	Flavin RK	Yield (%)	RK (mmol/g)	Flavin (mmol/g)
FAD	0.11	1.5	49	0.26	0.22
	0.42	5.9	50	0.30	0.26
FMN	0.11	1.5	37	0.33	0.09
	0.42	5.9	39	0.32	0.19

The authors express their sincere thanks to Professor Shuichi Suzuki of Tokyo Institute of Technology for his encouragement.

Aromatic Nucleophilic Substitution. VI.[1] ^{1}H Nuclear Magnetic Resonance Evidence for the Rearrangement of 1,3- to 1,1-Anionic σ Complex in the Reactions of 1-Dialkylamino-2,4-dinitronaphthalenes with Potassium Alkoxides

Shizen SEKIGUCHI, Shigeru FUJISAWA, and Yumiko ANDO

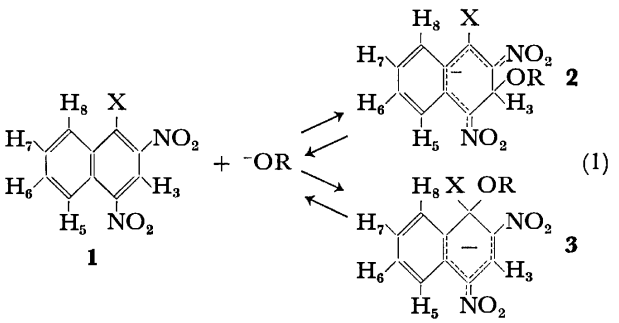
Synthetic Chemistry Department, Gunma University, Tenjincho, Kiryu, Gunma 376

(Received December 12, 1975)

Synopsis. By use of NMR spectroscopy the rearrangement of 1,3- to 1,1-anionic σ complex (Meisenheimer complex) in the reactions of 1-dialkylamino-2,4-dinitronaphthalenes (dimethylamino-, diethylamino-, and *N*-methyl-*N*-butylamino, piperidyl) with potassium alkoxides in DMSO has been studied. The alkoxides used are potassium methoxide, ethoxide, isopropoxide, and *t*-butoxide. In the reactions of 1-dialkylamino-2,4-dinitronaphthalenes with the alkoxides the rearrangement could be spectrometrically analyzed. However, in the reaction of 1-dimethylamino-2,4-dinitro naphthalene with potassium *t*-butoxide the rearrangement was too fast to be clearly analyzed.

Regarding the 1,3-anionic σ complex (hereinafter referred to as 1,3-adduct) in the reaction of 1-methoxy-2,4-dinitronaphthalene with sodium methoxide, Millot and Terrier[2] reported the existence of the 1,3-adduct by use of visible spectra [λ_{max} 505, 550—600 (sh) nm], but showed no NMR evidence for it although NMR measurement would be a more conclusive means for confirming adducts. Fendler *et al.*, however, found no NMR evidence for the 1,3-adduct in the same reaction.[3] Although we carried out the reaction of 1-dialkylamino-2,4-dinitronaphthalenes with sodium methoxide in DMSO, no 1,3-adducts could be found.[4] Crampton and Gold reported that *N*,*N*-dimethylamino-2,4,6-trinitrobenzene with sodium methoxide gave the 1,3-adduct only[5] in MeOH, while Fyfe *et al.* found the rearrangement of the 1,3- to 1,1-adduct in the reaction of 3,5-dinitrocyanobenzene with sodium methoxide in DMSO.

Following our preliminary work[6] we now report that in the reactions of 1-dialkylamino-2,4-dinitronaphthaleneswith potassium alkoxides in DMSO the rearrangement could be followed by use of NMR spectroscopy as follows:



(1)

Replacing of sodium alkoxides by potassium ones is found to make possible measurement of NMR spectra on 1,3-adducts, which may be ascribed to the larger nucleophilicity of alkoxide ion in potassium alkoxides than in sodium ones. This greater nucleophilicity is considered to be caused by the increasing solvation of the cation (K^+) with alcohols.[7]

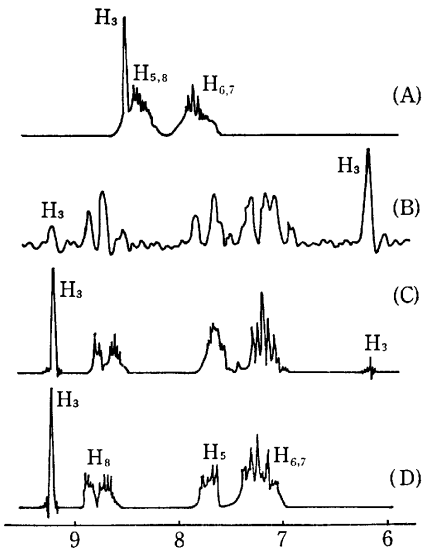


Fig. 1. NMR spectra relevant to the reaction of 1-piperidino-2,4-dinitronaphthalene (**1**, X=piperidino, 1.43×10^{-4} mol) with methanolic potassium methoxide (1.43×10^{-4} mol) in DMSO -d_6 (0.5 ml): A **1** before addition of potassium methoxide; B immediately after addition of potassium methoxide (500 Hz/50 s); C and D 2.5 min and 4 h after addition of potassium methoxide.

Immediately after addition of methanolic potassium methoxide (1.43×10^{-4} mol) to a DMSO solution (0.5 ml) of 1-piperidino-2,4-dinitronaphthalene (**1**, X=piperidino, 1.43×10^{-4} mol) at room temperature, the red solution gave the spectrum of Fig. 1B;[5,6,8] the poor resolution was due to the fast sweep time (500 Hz/150 s). The sharp singlet, attributable to H_3 of **2** (X=piperidino, R=CH_3), appeared at δ 6.21 with the resonance peak at δ 9.27, attributable to H_3 of **3** (X=piperidino, R=CH_3).[5,8] In 4 h after addition of potassium methoxide the 1,3-adduct (**2**) entirely rearranged to the 1,1-adduct (**3**). In addition, comparison of Fig. 1B with 1D shows that H_5, H_6, H_7, and H_8 resonance peaks of the 1,3- and 1,1-adducts do not substantially differ in position from each other. Similar results were obtained in other reactions of 1-dialkyl-

Table 1. H_3 Chemical shift (δ, ppm)[a]

Substrate[b]	$KOCH_3$		KOC_2H_5		$KOCH(CH_3)_2$		$KOC(CH_3)_3$	
	1,3-	1,1-	1,3-	1,1-	1,3-	1,1-	1,3-	1,1-
$CH_3\backslash N/CH_3$	6.33	9.31	6.39	9.27	6.52	9.31	—[c]	9.27
$C_2H_5\backslash N/C_2H_5$	6.37	9.27	6.26	9.23	6.51	9.27	6.58	9.27
$CH_3\backslash N/C_4H_9$	6.35	9.30	6.23	9.28	6.55	9.28	6.64	9.30
	6.21	9.27	6.25	9.20	6.35	9.24	6.28	9.23

a) In dimethyl sulfoxide with TMS as an internal standard. b) Only the substituents at C_1 of 2,4-dinitronaphthalene are indicated. c) Not clearly observed, perhaps owing to fast rearrangement.

amino-2,4-dinitronaphthalenes with potassium alkoxides studied. The fact that Fendler *et al.* could not find the existence of a 1,3-adduct is considered to be due to the fast rearrangement which is caused by the higher thermodynamic stability of **3** (X, OR; OCH_3) than **2** (X, OR; OCH_3).[3]

In the present case, therefore, both low reactivity of the 1-position of **2** and larger steric crowding at the 1-position of **3**, due to dialkylamino groups, would make the difference in stability between **2** and **3** smaller, and accordingly the rearrangement becomes so slow that the 1,3-adducts can be detected by use of NMR spectroscopy. Only the chemical shifts of H_3 of the adducts are summarized in Table 1.

In the reaction of 1-dimethylamino-2,4-dinitronaphthalene with potassium *t*-butoxide the low thermodynamic stability of **3** caused by addition of a bulky *t*-butoxide ion should make the difference in free energy between **2** and **3** larger, and accordingly make the rearrangement so fast that **2** can not clearly be observed.

Experimental

NMR spectra were recorded on a Varian A-60D spectrometer. 1-Dialkylamino-2,4-dinitronaphthalenes are prepared according to the method described in previous paper.[4]

We are grateful to the Ministry of Education and the Asahi Glass Foundation for the Contribution to Industrial Technology for financial support of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 49 (5), 1453—1454 (1976)

A New Synthesis of the Pungent Principles of Ginger — Zingerone, Gingerol and Shogaol —

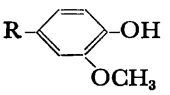
Kazuo BANNO[1] and Teruaki MUKAIYAMA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 22, 1975)

Synopsis. The pungent principles of ginger —zingerone, gingerol and shogaol— are synthesized starting with vanillin in good yields by utilizing the Lewis acid-promoted cross aldol reaction in each key step.

In recent publications we reported a potential synthetic method[2] for the preparation of various cross aldols by the $TiCl_4$-promoted reactions of silyl enol ethers with carbonyl compounds. In the present paper, a successful application of the above mentioned method to the syntheses of the pungent principles of ginger[3] —zingerone, gingerol and shogaol— is described. Of these compounds, zingerone and shogaol were synthesized by Nomura *et al.*[3] according to the conventional base catalyzed aldol reaction, however, there is no report concerning the synthesis of gingerol.

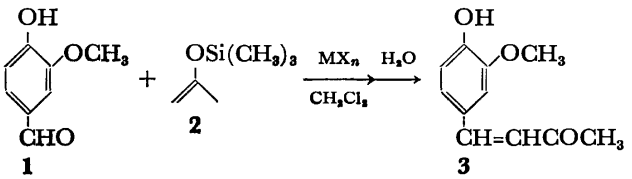


Zingerone R = $CH_2CH_2COCH_3$

Gingerol R = $CH_2CH_2COCH_2CH(CH_2)_4CH_3$ (OH)

Shogaol R = $CH_2CH_2COCH{=}CH(CH_2)_4CH_3$

Zingerone: When vanillin was treated with 2-trimethylsiloxy-1-propene (**2**) in the presence of $TiCl_4$, 2-methoxy-4-(3-oxo-1-butenyl)phenol(**3**) was obtained only in 7% yield and 90% of vanillin was recovered. Then, the reaction of **2** with vanillin was investigated in detail using various Lewis acids, and it was found that **3** was obtained in the optimum yield when $BF_3 \cdot OEt_2$ was employed (see the Table 1).

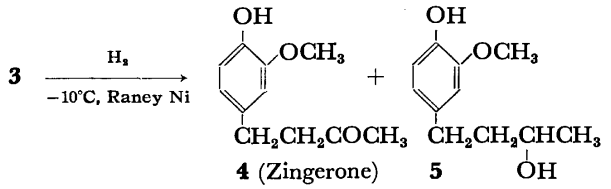


1 + **2** → (MX_n, H_2O, CH_2Cl_2) → **3**

TABLE 1. REACTION OF THE SILYL ENOL ETHER **2** WITH VANILLIN IN THE PRESENCE OF LEWIS ACID

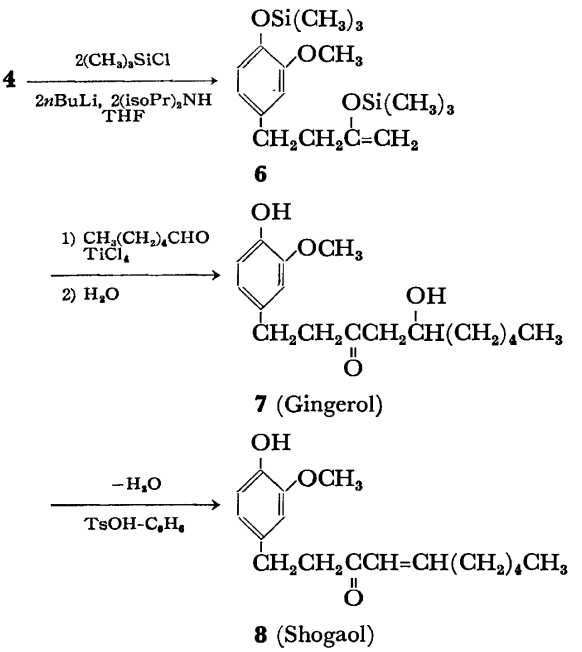
Lewis acid	Temp (°C)	Time (h)	Yield of **3** (%)
$TiCl_4$	0	2	7
$SnCl_4$	0	2	4
$AlCl_3$	0	2	5
$BF_3 \cdot OEt_2$	0	2	68
	r.t.	3	89

The catalytic hydrogenation of **3** over Raney nickel afforded 2-methoxy-4-(3-oxobutyl)phenol (**4**) (zingerone: colorless needles, mp 36—37 °C) and 2-methoxy-4-(3-hydroxybutyl)phenol(**5**) in 75% and 16% yields, respectively.



3 → (H_2, −10°C, Raney Ni) → **4** (Zingerone) + **5**

Gingerol and Shogaol: The silylation of **4** was carried out by a modification of House's method.[4] The treatment of a tetrahydrofuran solution of **4** with lithiodiisopropylamine, followed by addition of chlorotrimethylsilane, resulted in the formation of 2-methoxy-4-(3-trimethylsiloxy-3-butenyl)phenoxytrimethylsilane (**6**) in 69% yield. The reaction of **6** with hexanal in the presence of $TiCl_4$ gave *dl*-4-(5-hydroxy-3-oxodecyl)-2-methoxyphenol (**7**) (gingerol)[5] in 92% yield. 2-Methoxy-4-(3-oxo-4-decenyl)phenol (**8**) (shogaol) was obtained in 95% yield by the dehydration of **7** with TsOH–benzene. The structure of **8** was confirmed by comparison with the authentic sample (IR and NMR spectra).



4 → ($2(CH_3)_3SiCl$, $2nBuLi$, $2(isoPr)_2NH$, THF) → **6**

6 → (1) $CH_3(CH_2)_4CHO$, $TiCl_4$; (2) H_2O) → **7** (Gingerol)

7 → ($-H_2O$, $TsOH\text{-}C_6H_6$) → **8** (Shogaol)

Experimental

Preparation of Zingerone (**4**). A dichloromethane (10 ml) solution of 1.30 g (10 mmol) of **2** was added dropwise into a mixture of 0.76 g (5 mmol) of **1** and 0.705 g (5 mmol) of $BF_3 \cdot OEt_2$ in dichloromethane (40 ml) under an argon atmosphere at room temperature, and the reaction mixture was stirred for 3 h. After hydrolysis with water (50 ml) at the temperature, the resulting organic layer was extracted with ether (100 ml), and the extract was washed with saturated NaCl solution (80 ml × 3) and dried over anhydrous Na_2SO_4.

The ethereal solution was condensed and then petroleum ether (30 ml) was added into the residue. The yellow precipitate was filtered and recrystallized from ligroin to yield 0.768 g (80%) of **3**. After evaporation of the filtrate, the residue was purified by preparative TLC (silica gel) using dichloromethane as a developer to give 0.086 g (9%) of **3** (total yield 89%) [IR (KBr disk): 3400, 1640, 1620 cm^{-1}; NMR ($CDCl_3$): δ 2.39 (s, 3H), 3.93 (s, 3H), 6.12 (b, 1H), 6.60 (d, J=16 Hz, 1H), 6.9—7.1 (m, 3H), 7.53 (d, J=16 Hz, 1H)]. A methanol (50 ml) solution of 3.92 g (20 mmol) of **3** was treated with hydrogen for 2 h at −10 °C in the presence of 0.3 g of Raney nickel (commercially produced Raney nickel was thoroughly washed with methanol). About 480 ml of hydrogen was absorbed. After filtration, the filtrate was evaporated, and the residual oil was purified by column chromatography (silica gel) using dichloromethane as a developer to give 2.91 g (75%) of **4** (zingerone)[IR(KBr disk): 3420, 1715 cm^{-1}; NMR (CCl_4): δ 2.04 (s, 3H), 2.69 (quasi s, 4H), 5.90 (b, 1H), 6.4—6.8 (m, 3H)] and 0.630 g (16%) of **5** [IR (neat): 3390 cm^{-1}; NMR (CCl_4): δ 1.21 (d, J=6 Hz, 3H), 1.3—4.0 (m, 5H), 3.81 (s, 3H), 6.18 (b, 1H), 6.9—7.1 (m, 3H)].

Trimethylsilylation of Zingerone (**6**). A hexane solution of 110 mmol of *n*-BuLi was added in 200 ml of THF. The resulting solution was treated with 11 g (110 mmol) of diisopropylamine at −10 °C. To this solution, 9.7 g (50 mmol) of **4** was added dropwise over a 20 min period with stirring at −10 °C. After stirring for an additional 30 min at the temperature, 1.19 g (110 mmol) of chlorotrimethylsilane was added into the mixture. The resulting mixture was stirred for 30 min, diluted with 300 ml of ether, and washed rapidly with two 200 ml portions of cold aq. 10% $KHSO_4$ and cold aq. $NaHCO_3$. The resulting organic layer was dried and concentrated Fractional distillation of the residue with a spinning Teflon-band column gave fraction 1; bp 172—173 °C/5.5 Torr, consisting of the pure **6** (11.6 g, 69%) [IR (neat): 1620 cm^{-1}; NMR (CCl_4): δ 0.18 (s, 9H), 0.20 (s, 9H), 2.0—3.0 (m, 4H), 3.76 (s, 3H), 3.97 (s, 2H), 6.63 (s, 3H)] and fraction 2; bp 173—179 °C/5.5 Torr, containing **6** and unknown compounds (4.5 g).

Preparation of Gingerol (**7**). To a dichloromethane (40 ml) solution of hexanal (0.347 g, 3.3 mmol) and $TiCl_4$ (0.567 g, 3 mmol) was added a dichloromethane (10 ml) solution of **6** (1.017 g, 3 mmol) at −78 °C, and the reaction mixture was stirred for 1 h at the temperature. After usual work-up, the resulting mixture was chromatographed on silica gel. Elution with dichloromethane afforded 0.828 g (92%) of **7** (gingerol) [IR (neat): 3450, 1710 cm^{-1}; NMR (CCl_4): δ 0.86 (t, J=5 Hz, 3H), 1.0—1.8 (m, 8H), 2.44 (d, J=5.5 Hz, 2H), 2.67 (s, 4H), 3.73 (s, 3H), 3.8—4.0 (m, 1H), 6.3—7.0 (m, 3H)].

Preparation of Shogaol (**8**). A solution of **7** (0.60 g, 2 mmol) in dry benzene (50 ml) was refluxed with *p*-toluenesulfonic acid (0.2 g). The resulting crude product was chromatographed on silica gel. Elution with benzene gave 0.534 g (75%) of **8** (shogaol) [IR (neat): 3430, 1665, 1630 cm^{-1}; NMR (CCl_4): δ 0.88 (t, J=5 Hz, 3H), 1.0—2.3 (m, 8H), 2.76 (s, 4H), 3.78 (s, 3H), 5.71 (d, J=18 Hz, 1H), 6.0—6.8 (m, 4H)].

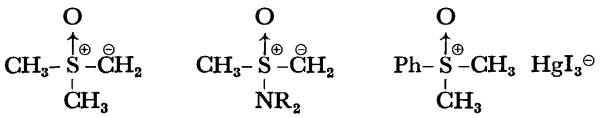
Oxosulfonium Salts. IV. Preparation and Reactions of Methylphenyloxosulfonium Methylide[1]

Katsumi RYOKE, Hiroshi MINATO, and Michio KOBAYASHI
Department of Chemistry, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received December 22, 1975)

Synopsis. Methylphenyloxosulfonium methylide was synthesized, and its reactions with several substrates possessing C=C and C=O bonds were investigated.

Sulfur ylides have proved to be very versatile and useful synthetic intermediates.[2,3] However, the majority of the ylides investigated so far are tri-coordinated ylides, and dimethyloxosulfonium methylide[4] (**1**) and (dialkylamino)methyloxosulfonium methylide[5] (**2**) are the only examples of tetracoordinated sulfur ylides reported in the literature.



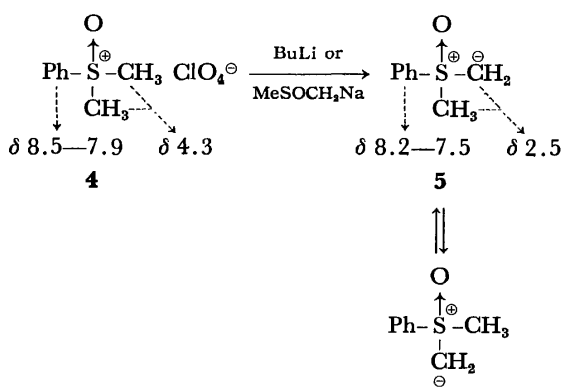
1 **2** **3**

Since oxosulfonium ylides are expected to show reactivities differing from those of sulfonium ylides and are of interest especially for application to asymmetric syntheses, we have investigated the synthesis of new oxosulfonium ylides.

The reason why oxosulfonium ylides other than **1** have not been investigated is that the syntheses of oxosulfonium salts are very difficult. Alkylation of sulfoxides always results in *O*-alkylation with very little *S*-alkylation,[6] although as an exceptional case the *methylation* of *dimethyl* sulfoxide produces trimethyloxosulfonium ion in a good yield.[4] We have overcome this difficulty by using mercury(II) iodide as the catalyst, and obtained dimethylphenyloxosulfonium salt **3** from methyl phenyl sulfoxide and methyl iodide in a 49% yield.[6]

3 was converted into perchlorate **4** by use of silver perchlorate, and **4** was converted into methylphenyloxosulfonium methylide **5** by use of butyllithium or dimsylsodium.

When **4** was treated with NaH in DMSO-d_6, the NMR spectrum of the methylide obtained showed multiplets at δ 8.2—7.5 ppm (5H; C_6H_5) and δ 2.5 (5H; $-CH_3$, and $-\bar{C}H_2$). This indicates that exchange of protons of $-CH_3$ and $-CH_2^-$ is rapid within the NMR time scale.



The aromatic hydrogens of **5** absorb in magnetic fields higher than those in **4**. This is reasonable since **5** has a negative charge next to the sulfonium sulfur atom.

The reactions between **5** and several substrates were investigated, and the results are summarized in the Table.

Other substrates examined were CO_2, $PhCH_2Br$, Me_3SiCl, PhNCO and $PhN_2^+BF_4^-$, but it was not

TABLE 1. PRODUCTS OF THE REACTIONS BETWEEN **5** AND SEVERAL SUBSTRATES

Substrate	mol/mol **5**	Products (mol % yield)[a]
Ph_2CO	1.02	$Ph_2C(O)CH_2$ (73%)
		PhSMe (63%)
PhCHO	1.02	PhCH(O)CH_2 (41%)
		PhSMe (32%)
	1.07	 (26%)
		PhSMe (39%)
trans-Stilbene	1.09	*trans*-Stilbene (88%)

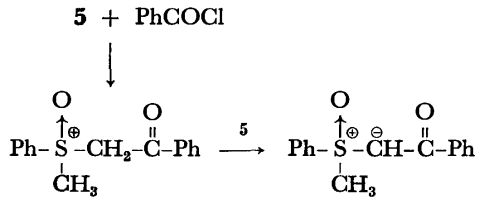
		PhSMe (44%)
		Dimethyl fumarate (4%)
$Me_3O^+BF_4^-$	1.35	 (42%)
PhCOCl	0.51	(70%)[b]

a) Based on the mol of **5** used. b) Based on half the mol of **5** used.

possible to isolate characterizable products.

As shown in the Table, the reaction between **5** and benzoyl chloride produced a stable oxosulfonium phenacylide. This can be explained by assuming the deprotonation of methylphenacylphenyloxosulfonium ion with **5**.



In the reaction with methyl maleate, the product of addition was not methyl cyclopropane-*cis*-dicarboxylate, but methyl cyclopropane-*trans*-dicarboxylate. One should note that methyl fumarate was produced in a 4% yield. These facts suggest that after **5** was added to methyl maleate the C=C bond in the adduct rotated, and the products were formed from the more stable conformation.

In the reaction with benzylideneacetophenone, **5** transfers the methylene to its C=C bond, whereas sulfonium ylide $PhMe\overset{+}{S}-\overset{-}{C}H_2$ transfers the methylene to the C=O bond.[7]

If optically-active $ArAr'\overset{+}{S}(\rightarrow O)\overset{-}{C}H_2$ could be synthesized, their reactions with various substrates would be of great interest.

Experimental

Conversion of 3 to 4. A saturated solution of $AgClO_4$ (25 g, 120.5 mmol) in acetone was added drop by drop to a stirred solution of **3** (25.5 g, 34.6 mmol) in acetone (400 ml), and the HgI_2 and AgI formed were filtered off. After the filtrate was evaporated in a vacuum, the residue was washed with ether and recrystallized three times from ethanol; the yield of **4**, 4.4 g (50%).

Conversion of 4 to 5. The following two methods were used. a) After **4** (0.8 g, 3.14 mmol) was dissolved in THF (30 ml; dried by refluxing with $LiAlH_4$ overnight) under a nitrogen atmosphere, the solution was cooled to −60 °C, and a hexane solution of butyllithium (1.6 M, 2.2 ml; 3.45 mmol) was added. The mixture was stirred for 1 h at −60 °C.

b) A slightly excess NaH (0.1 M mineral oil dispersion) was washed several times with petroleum ether in a three-necked flask under nitrogen, and then some DMSO (dried over CaH_2 for 3 h) was added. The mixture was heated to and kept at 70 °C until evolution of hydrogen ceased (about 1 h). After it was cooled to room temperature, a DMSO solution of **4** was slowly added.

Shock Tube Studies of the Rate Constant for Chemical Excitation of Hydroxyl Radicals

Tohru KOIKE and Kihei MORINAGA

Department of Chemistry, National Defense Academy, Hashirimizu, Yokosuka 239

(Received August 7, 1975)

The $OH(^2\Sigma^{+2}\text{-}^2\Pi)$ chemiluminescence in the partial equilibrium region of the H_2—O_2 reaction in mixtures with $H_2/O_2/Ar=2/2/96$, $P_1=5$, 10, 20 Torr was studied in 1250—2000 K incident shock waves. The comparison between the temperature dependence of the $OH(^2\Sigma^+)$ emission and that of the computer simulation of the H_2—O_2 reaction yields the activation energy of the chemical excitation process, assuming the same bi-radical process as former investigators used. The evaluated $OH(^2\Sigma^+)$ profile, based on a simulation in which the chemical excitation, radiative, and non-radiative processes are accounted for, depends on the pre-exponential factor of the chemical excitation process. The correlations between the temperature dependence of the evaluated $OH(^2\Sigma^+)$ profile and that of the emission profile in the partial equilibrium region gave the pre-exponential factor of the chemical excitation process. Thus, we could estimate the rate constant for $O+H+Ar=OH(^2\Sigma^+)+Ar$ to be $1.0\times10^9\times\exp(-11000\ \text{cal}/RT)$.

The reactions of hydrogen and/or hydrocarbons with oxygen are accompanied by the emission of $OH(^2\Sigma^+\text{—}^2\Pi)$ transitions. The origin of $OH(^2\Sigma^+)$, hereafter OH*, could be attributed to both thermal and chemical excitations.

Kinetic studies of the OH* emission have been performed in $H_2/O_2/N_2$ flame,[1] in shock heated H_2/air mixtures,[2] H_2/O_2/Ar mixtures,[3] H_2/O_2/CO/Ar mixtures,[4] and in a flow system of O and H associations.[5]

Gardiner *et al.*[3] made a detailed comparison between the growth constant of the OH* emission and that of the ground state OH concentration measured by the Bi-lamp absorption technique; they concluded that the chemical excitation process or pre-association process of OH* is $O+H+M=OH^*+M$. Schott *et al.*[4] reached the same conclusion through the comparison between the OH* growth constant and the O growth constant, which were observed *via* OH* emission and CO+O emission using their end-on technique in shock tube experiments.

Strong evidence for the above conclusion was given by Schiff *et al.*,[5] who made it clear that the intensity of the OH* emission which accompanies O+H association in a microwave discharge flow system is proportional to the concentration product of ground state O and H.

Further studies of the OH chemiluminescence in a shock heated hydrogen/oxygen reaction were performed in the present work to evaluate the rate constant of the chemical excitation process of hydroxyl radicals in gas phase, accepting the above mechanism and adpoting a computer simulation technique for the estimation of the over-all reaction scheme.

Experimental

Shock Tube. Incident shock waves were actuated in the shock tube shown in Fig. 1, where the driver section A is made of a mild steel pipe of inner diameter 8.9 cm and length 120 cm, and the test section B is an extruded rectangular brass tubing of inner cross section 3.2×7.2 cm, thickness 0.4 cm, and length 400 cm, with three quartz windows of 10 mm thickness located 300 cm downstream from the diaphragm section. The windows and a triggering thermal gauge whose location is 5 cm upstream from the windows were carefully flat mounted at the bottoms onto the test section, avoiding any aerodynamic disturbance in the tube. The triggering gauge is a vacuum deposited thin tin film and the other five thermal gauges positioned downstream from the windows at 10 cm intervals are of thin platinum deposited by the baking of brush-painted Hanovia solution. The diaphragm section D was devised to employ the two diaphragm method but natural bursts of a single diaphragm were adopted throughout the present experiments. The diaphragms were press scored aluminium plates of 0.2 mm thickness. The test section could be evacuated to less than 1 micron by an oil diffusion pump with a liquid nitrogen trap and showed a leak rate of less than 2 micron/30 min.

Optical System and Electronic Devices. The emission from the reacting gas was monitored by a S-13 response photomultiplier (Hamamatsu-TV R292) with a filter which consisted of 3 mm of Corning 9863 glass and 6 mm of 50 g/100 g solution of $NiSO_4\cdot6H_2O$. This filter combination

had about 50% transmission at 306.7 nm, and its high- and low-cutoffs were 360.0 nm and 240.0 nm, respectively. Between the photomultiplier and the shock tube window two 2 mm slits were installed at a 20 cm separation. The emission from the reacting gas was observed through the slits in the direction in accordance with the minor latus of the rectangular cross section of the shock tube. A laser schlieren technique was adopted to detect any abnormality of the shock waves and any data with an abnormal laser schlieren image was discarded. The signals from the thermal resistance gauges were displayed on a Raster sweep oscilloscope along with 5 micro-second time marks from a quartz oscillator. An oscillogram of the Raster sweep is shown in Fig. 2a.

Gas Mixtures. The gases were taken from commercial cylinders whose purities, as assayed by the manufacturer, were not less than 99.9%, and were used without further purifications. Gas mixtures of the desired compositions were prepared manometrically and left to stand for at least 24 h before use. Blank tests of the emission were performed in the same manner as in the actual runs with Ar gas and H_2/Ar gas, and no appreciable emission was observed in either case.

The Computer Program. The computer program used in the present work was provided through the courtesy of W. C. Gardiner, Jr.,* and C. B. Wakefield and was modified to match the NEAC 2200 system. It was devised to calculate any of the incident or reflected shock waves with ideal, laminar, or turbulent flows. The thermodynamic data from the JANAF thermochemical tables[6] are included in it in the form of virial equations. Given the reaction mechanism to be a group of elementary reactions with forward rate constants, the program integrates the assembly of first order linear differential equations of the forward and reverse reactions *via* an implicit Adams method or Gear method, and gives the concentration profile of any desired species in relation to the time elapsed after the shock arrivals.

Results and Discussion

In studying the chemical excitation of OH*, Gaydon,[7] Schiff,[5] Gardiner,[3] and Schott[4] were not entirely consistent in their treatments of the third body M, though they were in accord for the bi-radical reaction of O and H. Gaydon *et al.*[7] presumed that a direct bi-radical reaction formed OH* in an unstable $^2\Sigma^-$ state and was followed by a radiationless transition to the stable $^2\Sigma^+$ state in order to explain the features obtained by flame spectroscopy. They posited three body collisions of O, H, and M to form OH* as the main process of OH* formation in a flame, through a consideration of the heat of formations. Schiff *et al.*[5] regarded the chemical excitation of OH* as a bi-radical reaction without a third body in their O and H association process in a low pressure flow system. Gardiner *et al.*[3] and Schott *et al.*[4] proposed a bi-radical reaction with or without a third body M to represent the OH* formation in their shock tube reaction of H_2 and O_2.

In the present study, we treated the chemical excitation process with a third body M to obtain a tentative pre-exponential factor and activation energy of the rate constant for formation of OH*. Thus, the reaction which includes OH* may be written as follows:

$$O + H + M = OH^* + M \quad (a)$$

$$OH^* + M' = OH + M' \quad (b)$$

$$OH^* = OH + h\nu \quad (c)$$

The fate of the OH* formed in reaction (a) is to follow either the non-radiative quenching process (b) in which a third body M′ is considered, or the radiative process (c) whose emission in the partial equilibrium region is now under consideration.

The reverse process (b) could be explained as a thermal excitation of OH. The activation energy of the thermal excitation process was assumed to be 93.4 kcal/mol, whereas the chemical excitation process to form OH* was characterized by a much smaller activation energy.[3] In the temperature region lower than 2000 K,[3] the contribution of the thermal excitation process to form OH* seemed to be less dominant than the chemical excitation process. The features of thermally excited OH* will be shown later in Fig. 6, along with the concentration profiles; here both chemical and thermal processes are taken into ac-

* The University of Texas at Austin, Austin, Texas, 78712 U. S. A.

count. The reverse reaction (c) is a self-absorption process whose extinction coefficient is very small.[8]

The steady state assumption of [OH*] leads to the equation:

$$[OH^*] = k_a[O][H][M]/(k_{-a}[M]+k_b[M']+k_c) \quad (1)$$

where the reverse processes (b) and (c) are disregarded by comparison with reaction (a). The reverse reaction (a) is a endothermic reaction of about 12 kcal/mol, whereas the reaction (b) is a exothermic reaction of 93.4 kcal/mol. The term $k_{-a}[M]$ is assumed to be very small compared with the term $k_b[M']$.

Bennett and Dalby[9] obtained the radiation life time of OH* and the collision cross-section between OH* and H_2O. Accepting their collision cross-section of 70 Å^2, the rate constant of reaction (b) could be evaluated by collision theory as:

$$k_b = 8.22\times10^{13}\times T^{0.5} \quad (cm^3\ mol^{-1}\ s^{-1}) \quad (B\,1)$$

and the value of k_c from the radiation life time is:

$$k_c = 9.9\times10^5 \quad (s^{-1}) \quad (C\,1)$$

In the partial equilibrium region, the concentration of H_2O computed under a sample condition of P_1=10 Torr and T_2=1500 K with $H_2/O_2/Ar$=2/2/96 is 2.5×10^{-8} mol/cm^3; then the value of $k_b[M']$ is 8.0×10^7 (s^{-1}). Thus, the value of k_c is 1/80 of the value of $k_b[M']$. If the other collision partners of OH* are taken into account along with H_2O, the value of k_c is far less than that of $k_b[M']$ and the term k_c in the denominator of Eq. 1 could reasonably be neglected. Therefore, the emission intensity I in the partial equilibrium region is given by:

$$I = Ck_c[OH^*] = Ck_ck_a[O][H][M]/k_b[M'] \quad (2)$$

where C is a correlation factor for the detector.

A sample oscillogram of an OH* emission profile is shown in Fig. 2b, along with a laser schlieren trace. In the partial equilibrium region, the OH* emission exhibits a flat plateau for the present mixtures of $H_2/O_2/Ar$=2/2/96. In Fig. 3, the OH* emission intensity I obtained from the oscillogram plateau height at various starting pressures is plotted against the concentration product of O and H of the computer simulations for each of the starting pressures. The validity of Eq. 2 and also that of reaction (a) are accordingly established by the linear relations shown in Fig. 3.

As noted previously, the computer program for the simulation requires a reaction mechanism with the forward rate constants, and the reverse rate constants incorporated into the calculation are determined from the equilibrium constants based on the JANAF thermochemical tables. The aggregation of elementary reactions and the rates used in the present work are shown in Table 1.

It is obvious that C and k_c in Eq. 2 are independent of temperature, and the activation energy of reaction (b) could be very small, as it is the rate constant for the reaction of highly activated OH*. The temperature dependence of the value of [O][H] can be evaluated from Fig. 4, where the concentration products of O and H of the computer simulations are plotted against $1/T$. The slope of the linear relations or pseudo-

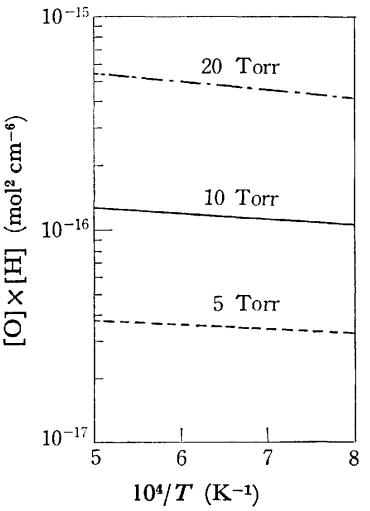

Fig. 4. The relation between concentration product ([O][H]) and $1/T$ for different starting pressures.

activation energy of the product, [O][H], is not so dominant. The above results yield the pseudo-activation energy of the product, [O][H], as 2500±700 cal/mol, where the limit of ±700 cal/mol represents the calculation's sensitivity to the variations (10-folds to 1/10-folds) of each of the rate constants in Table 1, except for the constant for the chain branching reaction of $H+O_2=OH+O$. For the latter rate constant, nearly equal values of the limit were obtained by 2-folds to 1/2-folds of the variations. The temperature dependence of the value of [M]/[M'] will be much less than that of the concentration product of O and H. Thus, it is concluded from Eq. 2 that the temperature dependence of I is the consequence of the temperature dependences of k_a and the [O][H] product in the temperature region where the thermal excitation is less dominant.[3] In Fig. 5, the emission intensity I in the partial equilibrium region was plotted against $1/T$. The apparent activation energy of the slopes

in Fig. 5, which depends on the activation energy of k_a and the pseudo-activation energy of the [O][H] product, was obtained from the figure to be 13500 cal/mol. Thus the activation energy of k_a could be estimated from the above values as the difference, 13500—2500 cal/mol, and k_a could be expressed as:

$$k_a = A\exp(-11000\ \text{cal}/RT) \qquad \text{(A1)}$$

where A represents the pre-exponential factor of k_a. It is subjected to the following speculations.

The reaction mechanism shown in Table 1, used in the computation of the [O][H] product, does not include reactions which involve OH* because the concentration of OH* is much less than that of ordinary radicals.

To simulate the profile of OH* in the reaction, we added reactions (a), (b), and (c) to the above mechanism with the forward rate constants expressed in (A1), (B1), and (C1). Along with the rate constant expressed in (B1), we added the following rate constant (B2), evaluated by collision theory in which the collision partner is taken to be O_2 with the collision cross section of 7 Å^2, after Carrington.[10]

$$k_b = 1.84\times10^{12}\times T^{0.5}\ (\text{cm}^3\,\text{mol}^{-1}\,\text{s}^{-1}) \qquad \text{(B2)}$$

As the third body M of Eq. (a), Ar was employed in the course of the reaction simulations. For OH* and $h\nu$, the thermochemical properties were calculated by the equations based on the Mayer and Mayer representations in the JANAF thermochemical tables.[6] The mass of OH* and $h\nu$ were assumed to be OH*=OH and $h\nu=E/c^2$, where E corresponds to the 306.7 nm emission and c is the light velocity. The latter mass was provisionary assigned to carry out the computer program.

In Fig. 6, the calculated OH* concentration in the partial equilibrium region is shown *vs.* $1/T$, with parameters of the pre-exponential factor A of the expression (A1). It is obvious that the slopes of the curves depend on the parametric values of A. Calculations testing the sensitivity to reasonable variations in other rate constants showed that the pre-exponential factor has almost the total effect on the slopes of log[OH*] *vs.* $1/T$ in a definite temperature region. As the emission intensity I is proportional to the OH* concentration in the partial equilibrium region, the slope of log I *vs.* $1/T$ should accord with that of log[OH*] *vs.* $1/T$. The observed slope in Fig. 5 was fitted to the curve in Fig. 6, as is shown by thick line

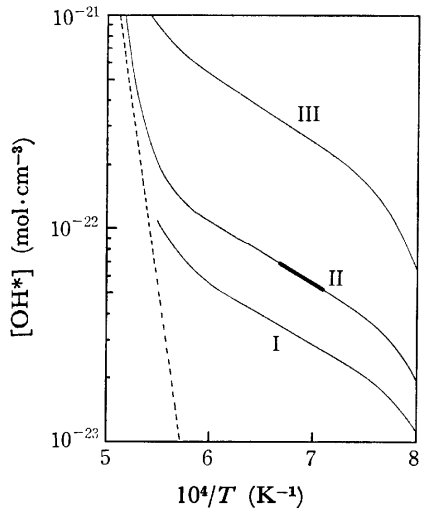

Fig. 6. The relation between calculated [OH*] and $1/T$. Broken line; The reactions (b) and (c) are taken into account. Solid line; The reactions (a), (b), and (c) are taken into account with the different A values of Eq. (A1).
I: $A=5.0\times10^8$, II: $A=1.0\times10^9$, III: $A=5.0\times10^9$.

in the latter figure. The best fit in the temperature range of 1400—1500 K was obtained when the parameter A was chosen to be 1.0×10^9 (cm^6 mol^{-2} s^{-1}).

Thus, we tentatively obtained the pre-exponential factor of reaction (a) assuming Ar as the collision partner M of the reaction. The rate constant k_a is expressed as:

$$k_a = 1.0\times10^9 \exp(-11000\ \text{cal}/RT) \quad (\text{cm}^6\ \text{mol}^{-2}\ \text{s}^{-1})$$

In the above expression of k_a, the activation energy is subjected to the error limit of the above discussion. Further investigations such as detection of the absolute emission intensity I are required to obtain a more rigorous pre-exponential factor A of the constant k_a.

The authors are grateful to Professor W. C. Gardiner, Jr. and Dr. C. B. Wakefield for providing us with the computer program "NIP", which was very helpful for the present studies.

Kinetic Parameters of Thermal Dehydration and Decomposition of Zeise's Salt Hydrates

Manabu SENŌ, Kazutoshi IWAMOTO, and Teruzo ASAHARA

Institute of Industrial Science, University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received November 17, 1975)

The kinetic parameters of the dehydration of Zeise's salt hydrates, $K[PtCl_3(olefin)]\cdot H_2O$, (olefin; $CH_2=CH_2$, $CH_3CH=CH_2$, $C_2H_5CH=CH_2$, n-$C_3H_7CH=CH_2$ and n-$C_4H_9CH=CH_2$) and the thermal decomposition of Zeise's dimers were determined by using DTA and TG. By comparing the kinetic parameters with the data of IR and the enthalpy change of dehydration, it was shown that the important factor in determining the kinetic behavior of the dehydration is an extent of deformation of lattice at the transition state. Similarly, it was suggested that the bulkiness of ligand olefin is an important factor in governing the kinetics of the thermal decomposition reactions.

In a previous paper,[1] it was shown from the investigation of the dehydration reaction of Zeise's salt that the dehydrated Zeise's salt contains some amount of the dimer. The content of the dimer was determined and the thermochemical properties of thermal decomposition reactions were examined. In the present paper, the kinetic parameters of the dehydration process of Zeise's salt and the thermal decomposition process of Zeise's dimer were determined from the data of differential thermal analysis (DTA) and thermogravimetry (TG). The activation energy and the activation entropy of dehydration process of Zeise's salts decrease remarkably as the ligand olefin becomes smaller. On the other hand, the decreasing order of the activation energy of the thermal decomposition process of Zeise's dimers is as follows;

$$[PtCl_2(n\text{-}C_4H_9CH=CH_2)]_2 > [PtCl_2(n\text{-}C_3H_7CH=CH_2)]_2 > [PtCl_2(C_2H_5CH=CH_2)]_2 \approx [PtCl_2(CH_2=CH_2)] > [PtCl_2(CH_3CH=CH_2)]_2$$

Experimental

Syntheses of Zeise's Salts $K[PtCl_3(olefin)]$. Zeise's salt hydrates $K[PtCl_3(olefin)]\cdot H_2O$ were prepared from K_2PtCl_4 and olefins according to the method described by MacNevin *et al.*[2] The products were recrystallized twice from 3% aqueous HCl solutions and dehydrated by storing in a $CaCl_2$ desiccator in 2—3 weeks. The purities were checked by elementary analyses.

Syntheses of Zeise's Dimers $[PtCl_2(olefin)]_2$. Dimers of Zeise's salts $[PtCl_2(olefin)]_2$ were prepared from Zeise's salts according to the method described by Moeller.[3] The products were confirmed by elementary analyses.

Measurements of Decomposition Processes. A thermal analyzer DT-20B (Shimadzu) and a thermo flex (Rigaku Denki) were used for characterization of thermal decomposition processes. Most of the measurements were carried out at the increasing rate of temperature of 1.25 °C/min under N_2 flow. The data of DTA, from which the kinetic parameters of the dehydration process were determined, were measured at the increasing rates of temperature of 5 °C/min, 10 °C/min, 20 °C/min and 40 °C/min, respectively.

Results and Discussion

Zeise's salt has one mole of crystalline water. The absorption peaks of the infrared spectra ascribed to the crystalline water in the complexes with various olefins are shown in Table 1. Asymmetric and symmetric stretching vibrations of the O–H band shift to a lower frequency side and the bending vibration shifts to a higher frequency side compared with those of a free water molecule, but these shifts are not so large as those in liquid water as being seen in Table 1. This means that the water molecule in Zeise's salt interacts with chlorine atoms to form partially hydrogen bonds. As a ligand olefin becomes large, the asymmetric stretching vibration shifts somewhat to a higher frequency. The other vibrations do not change so clearly as asymmetric stretching vibration.

TABLE 1. IR SPECTRA OF CRYSTALLINE WATER OF ZEISE'S SALT HYDRATE, $K[PtCl_3(olefin)]\cdot H_2O$

Complexes	Asym. stretch. vib.(cm^{-1})	Sym. strech. vib.(cm^{-1})	Bending vib.(cm^{-1})
$K[PtCl_3(C_2H_4)]\cdot H_2O$	3540	3480	1614
$K[PtCl_3(C_3H_6)]\cdot H_2O$	3540	3480	1618
$K[PtCl_3(\Delta'\text{-}C_4H_8)]\cdot H_2O$	3550	3500	1620
$K[PtCl_3(\Delta'\text{-}C_5H_{10})]\cdot H_2O$	3555	3500	1618
$K[PtCl_3(\Delta'\text{-}C_6H_{12})]\cdot H_2O$	3565	3500	1618
Free H_2O	3755.8	3654.5	1595.0[9]
Liquid H_2O	3430	3210	1650[9]

These observations are consistent with the results of X-ray analysis.[4,5] According to Black *et al.*,[5] $K[PtCl_3(CH_2=CH_2)]\cdot H_2O$ forms a monoclinic crystal, a= 10.750 Å b=8.405 Å, c=4.836 Å, β=97.73°. There are a chain of alternate potassium ions and triangles of chlorine atoms and a chain of hydrogen bonds ···Cl⁻···H–O–H··· parallel to the c axis and these two chains are cross-linked by the coordinate bonds within the complex ions and by the ionic interactions in chains of –O–K⁺– which are parallel to the b axis.

The dehydration reaction of Zeise's salt hydrates was analyzed by using DTA. Zeise's salt hydrates lose one mole of crystalline water by heating at about 60—80 °C. The activation energy and the order of dehydration reaction were estimated by using the method of Kissinger.[6] The following equations serve as a basis of analysis of DTA curve.

$$\ln\frac{\phi}{T_m^2} = \ln A - \frac{E_a}{RT_m} \quad (1)$$

$$n = 1.26S^{1/2} \quad (2)$$

$$S = \frac{(d^2x/dt^2)_1}{(d^2x/dt^2)_2} \quad (3)$$

Table 2. Activation energies and reaction orders of dehydration of Zeise's salt hydrate, $K[PtCl_3(olefin)]\cdot H_2O$

Complexes	Temp (°C)	n	E_a (kcal·mol^{-1})	ln A	$\Delta S^{\neq}$ (cal·K^{-1})	ΔH (kcal·mol^{-1})
$K[PtCl_3(C_2H_4)]\cdot H_2O$	67	0.72	46.7	70.0	80.7	15.5±0.5
$K[PtCl_3(C_3H_6)]\cdot H_2O$	76	0.90	30.8	44.8	30.6	15.3±0.5
$K[PtCl_3(\Delta'\text{-}C_4H_8)]\cdot H_2O$	73	1.11	26.8	38.4	17.9	16.0±1.0
$K[PtCl_3(\Delta'\text{-}C_5H_{10})]\cdot H_2O$	59	0.89	19.4	28.9	−1.0	13.3±1.0
$K[PtCl_3(\Delta'\text{-}C_6H_{12})]\cdot H_2O$	65	0.82	15.3	22.4	−13.9	14.0±1.0

ΔH is the enthalpy change in dehydration of Zeise's salt hydrate.[1]

In these equations, ϕ is the constant rate of temperature rise, T_m is the temperature giving a maximum rate of dehydration, n is the order of dehydration reaction, E_a is the activation energy, A is the frequency factor, R is the gas constant and S is called as a shape index. The values of T_m were determined at the rates of temperature rise ϕ of 5, 10, 20 and 40 °C/min and therefrom the kinetic parameters were obtained. The results of analyses are shown in Table 2. The activation energy of dehydration of the complexes decreases as the ligand olefin becomes larger. The values of $\Delta S^{\neq}$ are positive and larger for a smaller ligand olefin. The values of activation energy and activation entropy change greatly when the ligand olefin changes. On the other hand, the enthalpy change of dehydration does not change so remarkably as the activation energy and entropy. These results suggest that the bond energy of water in lattice is not an important factor which governs the transition state of dehydration reaction, but the energy required for deformation of lattice structure would be an important factor. During the process of dehydration, the lattice structure would be deformed markedly and the transition state would have a loose deformed structure, which ensures a large activation energy and a positive activation entropy.

For the complex with smaller ligand olefin such as ethylene, the transition state would be so far from the initial state and the deformation at the transition state becomes small as the ligand olefin is larger. This consideration accounts for the result in Table 2.

As being described in the preceding paper,[1] Zeise's salt hydrate loses crystalline water and at the same time rearranges partially into a dimer $[PtCl_2(olefin)]_2$. The above results for activation parameters of dehydration are for the overall reactions at the dehydration temperatures.

When the Zeise's salt is continued to heat after dehydration, it decomposes in two steps. The first step is the thermal decomposition of the dimer formed during the dehydration, as being revealed by the preceding paper.[1] The reaction order and the activation energy of the first step were calculated by using the Freeman-Carroll method.[7] The DTA curves of thermal decomposition of the dimers are too broad and obscure to calculate activation parameters by using the method of Kissinger and, since the decrease in weight is slow and large, the method of Freeman-Carroll is convenient. On the contrary, the dehydration process of Zeise's salt is too fast to measure exactly the weight loss, and the method of Kissinger is more convenient.

It was supposed[1] that the first step reaction proceeds as shown by Eq. 4,

$$[PtCl_2(olefin)]_2 \rightarrow Pt + PtCl_2 + Cl_2 + 2olefin \quad (4)$$

Then, the rate of decomposition reaction is tentatively assumed to be expressed by Eq. 5,

$$-\frac{dX}{dt} = kX^{\alpha} \quad (5)$$

where X is the amount of the reactant $[PtCl_2(olefin)]_2$ in the specimen, k is the rate constant and α is the reaction order with respect to the reactant. Now, the total amount of chemical species in this reaction system varies in progress of decomposition reaction and, therefore, we put

$$X=\frac{n}{N} \quad (6)$$

where n is the amount of the reactant and N is the total amount in molar unit in the reaction mixture at time t. Then,

$$\frac{-(E_a/R)\Delta(1/T)}{\Delta(\ln N-\ln n)} = \alpha + \frac{\Delta \ln(n\cdot dN/dt - N\cdot dn/dt) - 2\Delta \ln N}{\Delta(\ln N-\ln n)} \quad (7)$$

We could obtain the values of α and E_a from the plot $[\Delta\ln(n\cdot dN/dt - N\cdot dn/dt) - 2\Delta\ln N]/\Delta(\ln N-\ln n)$ against $\Delta(1/T)/\Delta(\ln N-\ln n)$ obtained by the thermogravimetric measurement. The results are shown in

Table 3. Activation energies, reaction orders and enthalpy changes of thermal decomposition of Zeise's dimers

Complexes	E_a (kcal mol^{-1})	α	ΔH[8] (kcal mol^{-1})
$[PtCl_2(C_2H_4)]_2$	36	3	15.5±0.5[a]
$[PtCl_2(C_3H_6)]_2$	30	−0.6	18.1±0.5*
$[PtCl_2(\Delta'\text{-}C_4H_8)]_2$	36	0	12.7±0.5[a]
$[PtCl_2(\Delta'\text{-}C_5H_{10})]_2$	42	2	7.4±1.0[b]
$[PtCl_2(\Delta'\text{-}C_6H_{12})]_2$	46	1	6.8±1.0[b]

a) Total enthalpy change in the two-step thermal decomposition. b) Enthalpy change in the second step of the thermal decomposition.

Table 3. These values would contain rather large errors and the reliability of α is estimated to be about ± 1, and that of activation energy to be about ± 2 kcal mol^{-1}. Except for the ethylene complex, the activation energy increases as the ligand olefin is larger.

There is no relation between the bond strength of π-bond and the activation energy. If the cleavage of π-bond is a rate determining step, the bond strength of π-bond would be closely related to the activation energy. The values of enthalpy change of Eq. 8 are different slightly among the complexes with various olefins.[8]

$$PtCl_4^{2-} + \text{olefin} \rightarrow [PtCl_3(\text{olefin})]^- + Cl^- \quad (8)$$

While, there is a fairly large difference between different olefin complexes in the activation energy of thermal decomposition. These results suggest that the bulkiness of ligand olefin would be an important factor in governing kinetics of thermal decomposition of Pt-olefin complexes.

Conductivity, Emf, and Spectrophotometric Study on the Participation of Na^+ and Cl^- into Acridine Orange-Poly(α,L-Glutamic Acid) Complex

Fumiyuki WATANABE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 26, 1975)

Conductivity, emf and spectroscopic investigations were made for the dimerization process of Acridine Orange (AO) and for the complex formation of AO with poly(α,L-glutamic acid) (PLG) in water. The increase of the dimer species of AO by adding the neutral salt was quantitatively explained, taking the ionic strength into account. From the emf measurements, the inclusions of Cl^- into PLG–AO complex were concluded to be negligible, whereas Na^+ was included into this complex to a fairly appreciable extent. The association of Na^+ with carboxylate groups in the PLG–AO complex was described on the basis of the ordinary law of mass actions. The association constant K_1 was unaffected by the presence of AO even in the helical region of PLG. These results strongly support Schwarz's theory on cooperative binding.

Many authors have studied the interactions between Acridine Orange (AO) and a number of polyelectrolytes from various standpoints.[1-7] These investigations have shown that the addition of electrolytes affects the properties of the poly(α,L-glutamic acid) (PLG)–AO complex such as absorption spectra, circular dichroism, helix-coil transition, and so on.

To interpret the effects of Cl^- on the PLG–AO complex, two different assumptions were adopted. Sato *et al.* assumed that (i) Cl^- associates with AO dimer in the following manner:[5,8]

$$2AO^+ + Cl^- \rightleftharpoons (AO)_2Cl^+ \quad (1)$$

and then (ii) this $(AO)_2Cl^+$ is bound to the ionized carboxyl groups ($-COO^-$) of PLG. On the other hand, Schwarz *et al.* have assumed that AO dimer does not involve Cl^-.[3,4,9,10]

$$AO^+ + AO^+ \rightleftharpoons (AO)_2^{++} \quad (2)$$

Lamm and Neville, however, have found that it is impossible to distinguish the two mechanisms above by spectral means alone.[11]

To interpret the kinetic results for the reaction between AO and PLG, Schwarz offered the cooperative binding theory in which the binding of Na^+ to $-COO^-$ plays an important part in determining the rates.[2,3] He assumed that (i) AO^+ binds to $-COO^-$ cooperatively, while Na^+ binds to $-COO^-$ non-cooperatively and (ii) and Na^+ bind to $-COO^-$ competitively one another.

Now the following questions arise:

(a) What kind of a participation of Cl^- occurs when AO self-associates to dimer species?

(b) How many Cl^- and/or Na^+ ions are included into PLG–AO complex?

(c) Are Schwarz's assumptions above described correct?

No complete study, however, has been made on the equilibrium among many ionic species in the present system. In order to answer the questions above, the present paper reports the results obtained by conductivity, emf and spectrophotometric methods.

Experimental

Materials. Sodium salt of PLG (Na·PLG) purchased from Protein Research Foundation was used without further purification. The molecular weight of the sample (66000 in the acid form) was deduced from the intrinsic viscosity (1.42 dl/g) in 0.2 M NaCl at pH 7.3, using the calibration determined by Wada.[12] The concentration of the glutamyl residue was calculated using a value of 169 for the mean residue weight of monosodium glutamate monohydrate.

Acridine orange hydrochloride (AO·HCl), purchased from Wako Fine Chemical was recrystallized five times from water-methanol mixture. The apparent molar absorption coefficient at 492 nm was $5.0\times10^4\ M^{-1}\ cm^{-1}$ under the following condition; $[AO]=1.0\times10^{-5}$ M, pH=6.0 and 293 K. The elemental analysis showed that the AO·HCl purified in this way contained 3% NaCl as a contaminant. For the measurement of the activity of Cl^-, the total amount of Cl^- added was corrected by this excess Cl^-. The conductivity of AO-HCl solution was corrected in the following way:

$$k(\text{corrected}) = k(\text{observed}) - k(\text{excess NaCl})$$

where k(corrected) and k(observed) denote a corrected specific conductance and an observed specific conductance, respectively. k(excess NaCl) was the specific conductance of the solution containing the same amount of NaCl only as in the sample solution. For the spectroscopic measurements, this excess Cl^- was neglected, considering that an added NaCl was in large excess at least by a factor of 100.

Acridine orange zinc chloride $AO\cdot HZnCl_3$ (Merck) was three times recrystallized from ethanol. Other materials were reagent grade. Water was deionized and distilled once.

Instruments. The absorption spectra were obtained by a Hitachi EPS-3T recording spectrophotometer. The emf was measured with a Radiometer "PHM-4d." The electrochemical cells used for the measurements of Cl^- and Na^+ activities are

$$HgCl_2(s)/Hg \;|\; \text{satd KCl} \;\|\; \begin{matrix}AO\cdot HCl\\ \text{or}\\ AO\cdot HCl + Na\cdot PLG\end{matrix} \;\|\; Ag/AgCl \quad (3)$$

and

$$HgCl_2(s)/Hg \;|\; \text{satd KCl} \;\|\; \begin{matrix}Na\cdot PLG + AO\cdot HCl\\ \text{or}\\ Na\cdot PLG\end{matrix} \;|\; \begin{matrix}Na^+ \text{ selective}\\ \text{glass electrode}\end{matrix} \quad (4)$$

respectively. A Na^+ selective glass electrode No. 1512-05T was offered by the Horiba Co., Ltd. A silver-silver-chloride electrode was prepared by slowly depositing crystalline silver electrolytically onto a platinum wire sealed into a pyrex glass tube. The silver chloride was formed by electro-deposition in a 0.1 M aqueous solution of hydrochloride

with the silvered platinum as the anode.[14] Horiba No. 2010A was used as a saturated calomel electrode. The reproducibility of the emf measurements was within ±1 mV.

Conductivity was measured with a universal bridge BV-Z-3B (Yokogawa Electric Work Ltd.) at a frequency of 1 kHz, using an ordinary conductivity cell whose cell constant was 0.45. The pH values of the solutions were measured with a Horiba M-7 pH meter.

Preparations and Measurements. All the measurements were performed at 298±0.5 K. The pH values in the Na·PLG–AO·HCl solutions were adjusted at pH=4.53 (±0.03) and pH=7.51 (±0.03). 5 mM sodiu macetate-acetic acid buffer and 5 mM phosphate buffer were used for the measurements of Cl^- activity. For the measurements of Na^+ activity, 5 mM tetraethylammonium $(Et)_4N^+$ acetate-acetic acid buffer and 5 mM $(Et)_4N^+$-phosphate-phosphoric acid buffer were used. Considering that tetrapropylammonium ion is known to bind only slightly to polyanion,[15] the effect of $(Et)_4N^+$ on the association of Na^+ with $-COO^-$ was neglected. The activity of Na^+ was determined by comparing the measured emf values at each pH with those for NaCl solutions adjusted to pH=4.53 or pH=7.51 by the corresponding buffer.[13]

The specific conductivity of water used was $2\times10^{-6}\ \Omega^{-1}\ cm^{-1}$. The equivalent conductivity was obtained by the usual procedures[16] and was reproducible to about ±(5—10) $\Omega^{-1}\ mol^{-1}\ cm^2$ on repeated measurements.

The dimerization constant K_d of AO was obtained by the same procedure as Schwarz and Balthasar.[3]

Results and Discussion

I) The Role of Cl^- on the Dimerization Process of AO.

A) Conductance Measurements of AO–HCl: It is well known that the increase of the concentration of the aqueous AO causes the spectral change due to the increase of the aggregates containing more than two AO molecules.[5,11,17] In Fig. 1 the equivalent conductivity Λ is plotted against the square root of the concentration of the aqueous AO·HCl. Λ increases as [AOHCl] increases at first and then reaches the maximum value. If AO·HCl behaves as a univalent electrolyte, Λ would show a linear depence on [AO–HCl] as shown in Fig. 1 with a dashed line (A) in arbitrary unit. If the association between AO aggregates and Cl^- occurs, Λ of AO–HCl would fall down more rapidly than the case of (A). The increase of Λ at the concentration region from 2×10^{-4} M to 8×10^{-4} M, therefore, may be explained by the formation of the AO aggregates which scarcely contain Cl^- ions. An extrapolation of this curve to [AO·HCl]=0 gives a rough value to 85; Λ_0(AO·HCl)=85. Substracting the limiting equivalent conductance of Cl^-, $\Lambda_0(Cl^-)=76$,[16] from this value, we have the coarse limiting equivalent value of AO^+, $\Lambda_0(AO^+)=7$. Adopting this value, $\Lambda_0(AO^+)=7$, to the Stokes equation,[18] an apparent diameter of AO^+ is calculated to be $r=10$ Å.

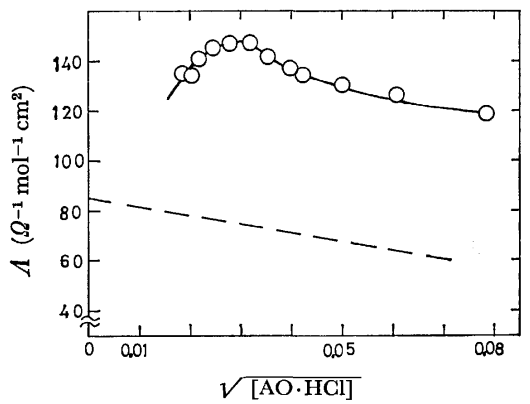

Fig. 1. The equivalent conductivity Λ of the aqueous AO·HCl plotted against square root of the concentration; ---- represents the equivalent conductivity in arbitrary unit, assuming that AO·HCl behaves as "strong electrolyte."

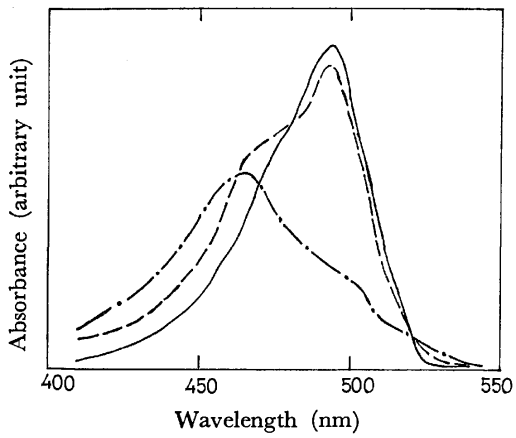

Fig. 2. Solvent dependence of AO-HCl spectrum: at 298 K.
—— in water/methanol 30/70 wt% mixture at [AO·HCl]=3×10^{-4} M. ---- in water at [AO·HCl]=1×10^{-5} M. —·— in water at [AO·HCl]=5×10^{-4} M. Coordinate is represented in arbitrary unit.

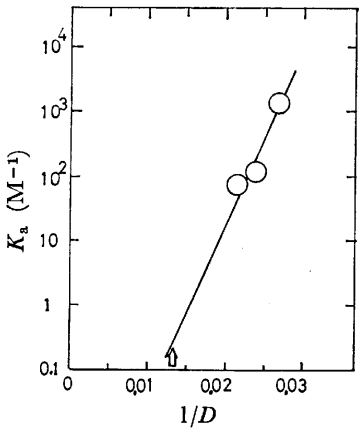

Fig. 3. The logarithm of the association constant K_a between AO^+ and Cl^- as a function of the reciprocal of the dielectric constant D. The notation ↑ indicates the point at $D=78.5$, which corresponds to that of water.

The conductivity measurements of AO–HCl were performed in water–methanol mixture at H_2O/CH_3OH =30/70, 20/80 and 10/90 (in wt.%). As shown in Fig. 2, the spectra of AO in these solvents clearly indicate that AO is present as monomer species.[17] Therefore the association constants, K_a, in the following equilibrium were obtained by the Shedlovsky's method.[19,20]

$$AO^+ + Cl \rightleftharpoons AOCl;\ K_a \qquad (5)$$

As shown in Fig. 3, the logarithm of K_a linearly decreases with the decrease of the reciprocal of the dielectric constant ($1/D$). From this linearity, it is reasonable to presume that even in water K_a should be dominated by a function of D in a way predicted by Bjerrum's theory.[16] Extrapolating the linear plot of log K_a *vs.* $1/D$ to the point $D=78.5$ which corresponds to the dielectric constant in water at 298 K, we obtained a rough value of K_a in water; $K_a=0.2\ M^{-1}$. It is concluded, therefore, that the association between AO^+ and Cl^- can be thoroughly neglected in the investigated AO–HCl concentration range.

B) Emf Measurements of Cl^- in the AO–$HZnCl_3$ System: In previous paper there have been reported the results of emf measurements of Cl^- activity in the aqueous AO–HCl solutions.[21] Figure 4 shows emf values plotted against the logarithm of the total amount of Cl^- added as AO·$HZnCl_3$, log[Cl]. The emf values for the AO–$HZnCl_3$ solution are in excellent agreement with those for the AO–HCl solution, that is, the emf values linearly decrease with log[Cl] at all concentrations from 1×10^{-5} to 5×10^{-3} M.

These results exclude the possibility that Cl^- might participate into the dimerization equilibrium of AO. This conclusion coincides with that in the results in section (*A*).

C) Effects of Ionic Strength on the AO Dimerization Equilibrium: The results in (*A*) and (*B*) exclude the possibility of the mechanism (1). Then the mechanism (2) should describe the dimerization process of AO correctly. The effect of the electrolyte on the dimerization equilibrium, therefore, would be interpreted in terms of the ionic strength.

Over the low concentration region, $(1-5)\times10^{-5}$ M, of AO at 298 K in water, there is an isosbestic point corresponding effectively to a monomer–dimer equilibrium.[11,22] The dimerization constant K_d is given by Eq. 6.

$$K_d = \frac{[(AO)_2{}^{2+}]}{[AO^+]^2} \qquad (6)$$

where $[AO^+]$ and $[(AO)_2{}^{2+}]$ denote the equilibrium concentrations of AO mono-cation and AO dimer, respectively. After Scatchard,[23] it is assumed that the activity coefficient, f_z, of a z-valent ion at an ionic strength I is given by the expression

$$-\log f_z = AZ^2\frac{\sqrt{I}}{1+1.5\sqrt{I}} \qquad (7)$$

where A is a constant. For aqueous solutions at 298 K, $A=0.5$. Assuming Eqs. 6 and 7, the Brønsted-Bjerrum equation becomes as follows:[24,25]

$$-\log K_d = \log K_t + 1.02\frac{\sqrt{I}}{1+1.5\sqrt{I}} \qquad (8)$$

where K_t is a tentative thermodynamic dimerization constant at $I=0$. In Fig. 5 the dimerization constant K_d was plotted against $\sqrt{I}/(1+1.5\sqrt{I})$. Ionic strength was varied from 7×10^{-3} to 0.2 M by NaCl, $NaNO_3$ and KCl. From the intercept of the straight line K_t was obtained to be $1\times10^4\ M^{-1}$. This value well coincides with Schwarz's value.[22] Thus the promotion

of the dimerization of AO by an addition of electrolyte is explained quantitatively, considering the increase of the ionic strength.

II) Inclusion of Cl^- into PLG–AO Complex. From the results obtained in (*I*) and also the large negative charges of PLG, the inclusions of Cl^- into PLG–AO complex would be concluded to be improbable. This is confirmed by emf measurements as described below.

The emf measurements of Cl^- activity were performed in the following systems:

(a) Na·PLG + NaCl at pH = 4.53,

(b) Na·PLG + AO·HCl at pH = 4.53,

where the concentration of glutamyl residue was kept constant, varying the concentration of AO·HCl, and finally,

(c) Na·PLG + AO·HCl at pH = 4.53,

where the glutamyl residue to dye ratio (R/D) was kept constant at R/D=10. The results were exhibited in Fig. 6. The emf values for both the Na·PLG+AO·HCl systems (b) and (c) coincide with those for the Na·PLG+NaCl system. The results exactly show that there is no essential difference in the Cl^- activity among the systems (a), (b) and (c). An effect of PLG on the emf of Ag/AgCl electrode was discussed in ref. 21. It is reasonable to conclude that no signifi-

cant inclusion of Cl^- takes place into PLG–AO complex.

III) Effects of Na^+ on the PLG–AO Complex. As stated previously, Schwarz and Balthasar explained the interaction between AO and PLG in the random coil conformation in terms of the cooperative binding theory.[3] The assumptions made in this theory have been verified to be valid.[26] In order to interpret the interaction between AO and PLG in helical conformation, it would be worthwhile to examine the validity of the assumptions even in the helical region.

Figure 7 exhibits the emf values of the following systems at pH=4.53:

(a) NaCl in water,

(b) Na·PLG in water,

(c) Na·PLG + AO·HCl in water at R/D = 10.

At pH=4.53 PLG is present in the helix conformation with carboxyl groups partially ionized. The concentration of the ionized carboxyl groups, [-COO^-], was calculated from the degree of PLG ionization, α, defined by

TABLE 1. ASSOCIATION CONSTANT K_1 BETWEEN Na^+ AND -COO^- [28]

	In the random coil region (pH=7.51)	In the helix region (pH=4.53)
In the presence of AO	90±20 M^{-1} a)	48±20 M^{-1}
In the absence of AO	87±20 M^{-1} a)	50±20 M^{-1}

a) Cited from Ref. 26.

$$\alpha = \frac{[\text{-COO}^-]}{[\text{-COOH}]+[\text{-COO}^-]} \tag{9}$$

where [-COOH] denotes the concentration of the protonated carboxyl groups in PLG. The value of α was assumed to be α=0.35 at pH=4.53 according to Jacobson's data.[27] The association constant K_1 between Na^+ and -COO^- in the helical Na–PLG was obtained according to Eq. 10,

$$K_1 = \frac{[\text{-COONa}]}{[\text{-COO}^-][\text{Na}]} \tag{10}$$

where [Na] indicates the free Na^+ concentration obtained from the emf measurement. [-COO^-] and [-COONa] are free carboxylate ions and ion-paired carboxylate ions, respectively. They were calculated by Eq. 11,

$$\begin{aligned}[\text{-COO}^-] &= [\text{-COO}^-]_t - [\text{-COONa}] \\ [\text{-COONa}] &= [\text{Na}]_t - [\text{Na}]\end{aligned} \tag{11}$$

where $[\ ]_t$ indicates the total concentration of each ion. K_1 was obtained to be 50±25 M^{-1} in the range of $[Na]_t$ from 1×10^{-4} M to 1×10^{-3} M.[28] This value well agreed with Nitta and Sugai's data;[29] 20—30% of $[Na]_t$ are present as the ion-pair at [Na·PLG]=0.011 M. In the presence of AO, K_1 was calculated to be 48±20 M^{-1}, assuming that the three carboxyl groups are bound to the three nitrogen atoms in one AO molecule.[6,7]

The agreement between the two K_1 values reveals that the association between Na^+ and -COO^- can be described with the single association constant K_1 irrespective of the presence of AO. This conclusion has been found to hold also in the random coil region (at pH=7.51) as represented in Table 1.

These results show that the assumption in Schwarz's cooperative binding theory as stated in the introduction section is valid; namely Na^+ binds with -COO^- to a certain extent non-cooperatively even in the helical region. It has been also known that the reaction between AO and PLG in the helix conformation displays a non-exponential relaxation curve.[4]

Considering these findings, it is expected that this reaction may be described by the theory which is similar to Schwarz's cooperative binding theory and in which the association between Na^+ and -COO^- is taken into account.

The author would like to express hearty thanks to Horiba Co., Ltd. for kindly offering a Na^+ ion selective glass electrode. Thanks are also due to Professor Masatoshi Fujimoto for his encouragement and to Dr. Akihiko Yamagishi for his fruitful discussions.

28) The association constant K_1 between Na^+ and $-COO^-$ varied considerably with the variation of α; for example, $K_1=78\pm35$ for $\alpha=0.30$, $K_1=50\pm20$ for $\alpha=0.35$, $K_1=36\pm15$ for $\alpha=0.40$ and $K_1=28\pm15$ for $\alpha=0.45$. At the present stage, therefore, we do not discuss whether K_1 in the helical region agrees with that in the random coil region or not.

Studies of the Effect of Ethanol and Sodium Chloride on the Micellization of Sodium Dodecyl Sulfate by Gel Filtration

Hitoshi SUZUKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received November 26, 1975)

The effects of the addition of ethanol and sodium chloride to aqueous solutions of sodium dodecyl sulfate (SDS) were studied by the gel-filtration method. With an increase in the concentration of ethanol, the CMC decreased and then increased after passing a minimum, while the micellar weight increased and then decreased, showing a corresponding maximum. Above about 40 vol% ethanol, no micelle formation was observed. The micellar weight and aggregation number in the presence of ethanol were measured in the SDS concentration range of a constant elution rate of micelles. A decrease in the CMC and an increase in the micellar weight of SDS were observed with an increase in the concentration of NaCl from 0 to 10 mmol/l. The gel-filtration study enabled us to make a direct experimental confirmation of the effects of ethanol and NaCl on the micelle formation of SDS.

A number of studies have been made on the effects of additives on the CMC and micellar size of SDS.[1] However, relatively few have been reported concerning the effect of mixed solvents. According to Ward,[2] the CMC of aqueous SDS decreased with the addition of ethanol up to 10 vol% and then increased, while above 40 vol% no micellization occurred. Herrmann and Benjamin[3] and Becher[4] found a decrease in the micellar weight in water with an increase in the ethanol concentration for nonionic detergents. As for the effect of ethanol on the micellar size of SDS, only a few reports are available.[4]

Contrary to the effect of alcohol, the addition of NaCl to an aqueous SDS solution is known to decrease the CMC and to increase the micellar size.[1,5] In the present report, the effects of ethanol and NaCl on the micellar size and on the CMC of SDS in the aqueous solution have been studied by the gel-filtration method, which gives us direct experimental information.

Experimental

Materials. Sodium dodecyl sulfate prepared from 1-dodecanol and chlorosulfuric acid was purified by the extraction of the 1-dodecanol with diethyl ether and by subsequent recrystallization from ethanol.[6] Distilled water was degassed by boiling prior to use. Poly(vinyl alcohol)s (PVA), products of the Nippon Gosei Kogyo Co., Itd., and Blue Dextran 2000 obtained from pharmacia, Uppsala, Sweden, were used as the standard substances of the molecular weight. The purest grade ethanol was used after dehydration and distillation. The sodium chloride was purified by recrystallization from an aqueous solution by the addition of ethanol.

Apparatus and Procedure. The apparatus used for gel-filtration was essentially the same as that reported in the preceding papers.[6,7] The gels used were Sephadex G-50 and CPG-10 of Electro-Nucleonics, Inc. The gels were equilibrated with the mixed solvent of a known ethanol-water composition to be studied, and 30 ml of a SDS solution of the same ethanol-water composition was charged on top of the gel column. The elution was performed by using a mixed solvent of the same composition. An elution curve was obtained by recording the electrical conductance of the efluent as a function of the elution volume. The elution curve for a solution with a concentration larger than CMC

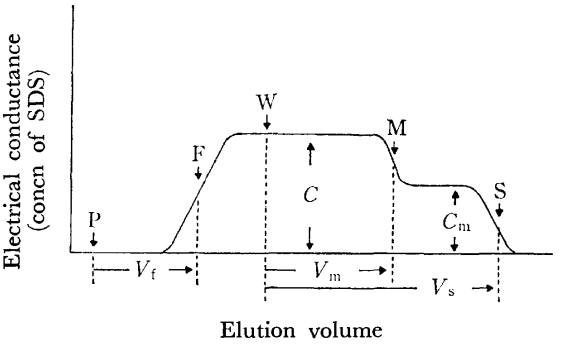

Fig. 1. Elution curve for SDS in ethanol-water solvent system.

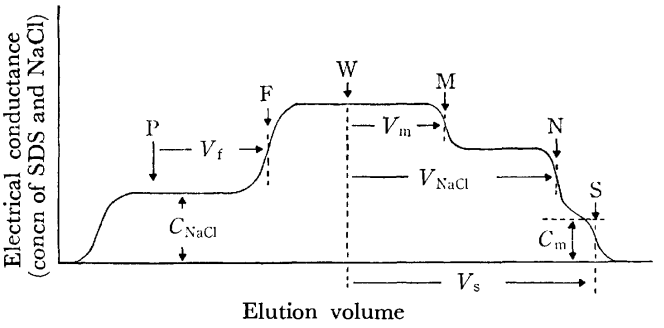

Fig. 2. Elution curve for SDS in aqueous sodium chloride solution, P, F, W, M, S, being the same as in Fig. 1. N; tail of NaCl.

is shown schematically in Fig. 1. In this figure, the ordinate is the conductance proportional to the concentration of SDS, while the abscissa is the volume eluted. P and W are the points of the sample and the water charges respectively, and F, M, and S, the front of the solution and the tails of micelles and single ions respectively. From this curve, the elution volumes of the SDS solution front, V_f; micelles, V_m, and single ions, V_s, were obtained; they are shown in Fig. 1. The lower plateau of Fig. 1 corresponds to the CMC of SDS (C_m), and the higher one, to the total concentration of SDS (C).

For the study of the effect of NaCl upon the CMC and the micellar size of SDS in aqueous solutions, Sephadex G-50 was used. The gel was equilibrated with an aqueous NaCl solution, and an aqueous solution of NaCl of the same

concentration, but containing SDS in addition, was charged on top of the gel column. The elution was performed by using an aqueous NaCl solution of the same concentration. The elution curve thus obtained is shown schematically in Fig. 2. The notations of P, W, M, S, and F are the same as in Fig. 1, while N is the tail of the NaCl solution. From the front and the three tails of the curve, the elution volumes of SDS front, V_f; the micelles, V_m; the single ions, V_s, and NaCl, V_{NaCl}, were obtained; they are shown in Fig. 2. The concentration of NaCl, C_{NaCl}, and the CMC of SDS, C_m, are estimated from the heights of the plateaus of the curve by using a conversion factor previously determined. The measurements were conducted at 30 °C throughout the experiments.

Results and Discussion

Effect of Ethanol and NaCl on CMC. The conductivity corresponding to the height of each plateau of the elution curve of SDS in the ethanol–water mixture shown in Fig. 1 is plotted against the total concentration of SDS in Fig. 3 for, for instance, the 10 vol% ethanol–water system. Three straight lines passing through a point which corresponds to the CMC of SDS in the mixture were obtained for both Sephadex and CPG-10 gel. The CMC's of the SDS obtained for ethanol–water mixtures are plotted as a function of the ethanol concentration at 30 °C in Fig. 4. Agreement is, as a whole, seen for both Sephadex and CPG gel. Since CPG-10 gel is more stable in a concentrated SDS solution than is Sephadex gel, plotting for a higher concentration has been possible for the former gel. Figure 4 shows that a small amount of ethanol in water lowers, while a larger amount raises, the CMC of SDS. The minimum at about 10 vol% of ethanol was in agreement with that reported by Ward.[2] The CMC above 20 vol% of ethanol was difficult to measure, since the step of the tail, M, corresponding to the micelles becomes obscure.

The elution volumes of front (V_f), micelles (V_m), and single ions (V_s) are plotted against ethanol concentrations up to 100 vol% at a constant SDS concentration (15 mmol/l) in Fig. 5. As may be seen, V_f increases above a 20 vol% ethanol concentration. From 30 up to 100 vol% ethanol, V_f becomes equal to V_s, the tail, M, disappears, and the elution curve observed is a simple one similar to that of the SDS solution below CMC. This means that in the solutions from 30 up to 100 vol% ethanol, the CMC is larger than 15 mmol/l. Presumably, at the SDS concentration a little above 30 mmol/l, as judged from the sharp rise of the curve of Fig. 4, CMC increases so rapidly that the micelle formation is practically prevented and the solute species is mainly of a single molecular type corresponding to V_s. A similar condition may prevail up to a 100% ethanol concentration, as may be seen from the coincidence of V_s and V_m in this region. Thus, the so-called micelles of the inverse type[8] could not be confirmed to form in an ethanol-rich solution or in a pure ethanol solution, at least experimentally by the gel filtration. The present results are rather in accord with those of Ward,[2] who reported a similar decrease in CMC upon the

NaCl	CMC
0 mmol/l	8.6 mmol/l
5 mmol/l	6.6 mmol/l
10 mmol/l	5.5 mmol/l
10 mmol/l	5.29 mmol/l[a)]

a) D. Sigter and K. J. Mysels, *J. Phys. Chem.*, **59**, 45 (1955).

ethanol addition and apparently no micellization in a mixed solvent with an ethanol concentration above 40 wt%.

As for the effect of ethanol addition upon CMC, a similar minimum in the concentration *vs.* partial molal volume of ethanol has been reported;[9)] this may suggest water-ethanol interaction affecting the micelle formation and CMC. However, it may be better explained by the fact that the solubilization of ethanol at low ethanol concentrations causes the decrease in the CMC, while the decrease in the amphipathy of the surfactant for a mixed solvent causes an increase in the CMC at high concentrations.

As for the effect of NaCl on CMC, the value of C_m in Fig. 2 is measured as a function of the NaCl concentration, which is shown in Table 1. As may be seen, C_m decreases with an increase in the concentration of NaCl and is in agreement with Stigter's data[13)] for the 10 mmol/l NaCl solution, which is also listed in the table. Further, the applicability of Eq. 8 derived in the previous paper:[6)]

$$\frac{R_m-R_s}{R_s}\cdot\frac{R_f}{R_m-R_f}=\frac{C}{C_m\cdot\alpha}-\frac{1-\alpha}{\alpha} \qquad (8)$$

was tested by plotting the left-hand side of Eq. 8 against the concentration of SDS (C). Here, R_f ($=V_s/V_f$), R_s($=V_s/V_s=1$), and R_m($=V_s/V_m$) ate the relative elution rates of the front, the single ions, and the micelles of SDS respectively; C, the total concentration of SDS; C_m, CMC, and α, the parameter of the rate of micelle decomposition.[6)] The results are shown in Fig. 6. As may be seen, the plots for 0, 5, and 10 mmol/l NaCl show straight lines passing through the point of origin, which confirms Eq. 8 to hold. The decomposition of micelles at the front is found to be instantaneous[6)] ($\alpha=1$) regardless of the NaCl concentration. The points of the intersections of these lines and the horizontal straight line of the ordinate, being unity, determine the C_m values, which are read for 0, 5, and 10 mmol/l NaCl solutions to be 8.6, 6.6, and 5.5 mmol/l respectively. These values are in agreement with the CMC estimated independently from the height of the plateaus of the elution curves, listed in Table 1. The effect of NaCl is also in accord with the general view of the effect of added salt on CMC.[1,10)]

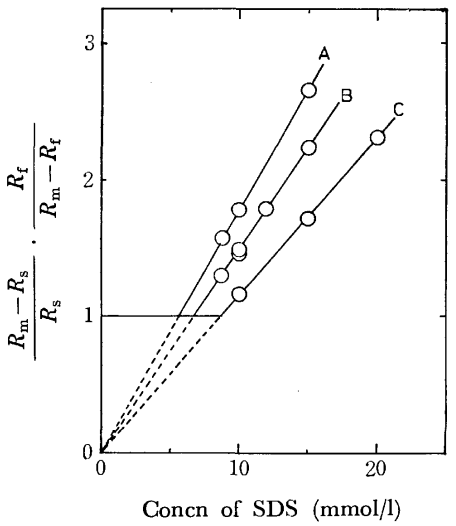

Fig. 6. Relationship between R_f and concentration of SDS in the presence of NaCl using CPG-10 gel. A, NaCl 10 mmol/l; B, NaCl 5 mmol/l; C, NaCl 0 mmol/l.

Effect of Ethanol and NaCl on Micellar Size. Since Sephadex gel suffers from a considerable shrinkage upon the addition of a concentrated ethanol solution, it is not suitable for micellar-size determination. Therefore, CPG-10 gel free from such an influence was mainly used in the gel-filtration, especially for the systems with high ethanol concentrations. Figure 7 shows the plots of R_m *vs.* the SDS concentration for each ethanol concentration. In the solutions with concentrations ranging from 0 to 20 vol% ethanol, it is seen that R_m, a measure of the micellar size, is constant independent of the SDS concentration from about 15 to 50 mmol/l SDS for each ethanol concentration, while the size decreases with an increase in the ethanol concentration. Up to 15 mmol/l SDS, R_m slightly increases with the increase of SDS for the system without ethanol.

The measurement of the micellar weight of SDS in an ethanol–water mixture is more complicated than that of SDS in an aqueous solution,[7)] although the basic principles are similar. For the micellar-weight determination of SDS in an aqueous solution, the calibration curve of the elution volume *vs.* the molecular weight of the unhydrated SDS micelle necessary for the calculation (SDS-W in Fig. 8) was obtained from the relation of the elution volume to the molecular

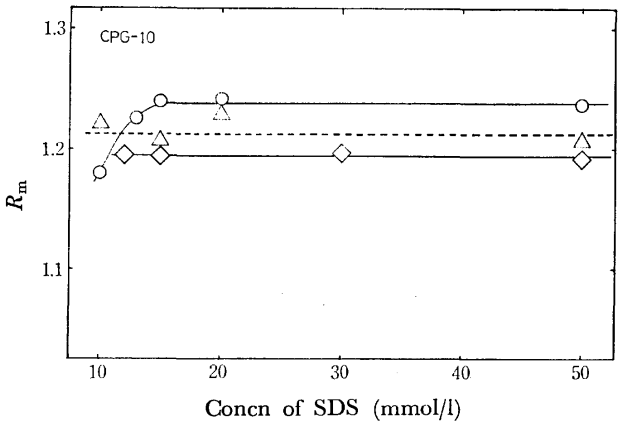

Fig. 7. R_m change of aqueous SDS solution as a function of ethanol concentration. ○, 0 vol% ethanol; △, 10 vol% ethanol; ◇, 20 vol% ethanol.

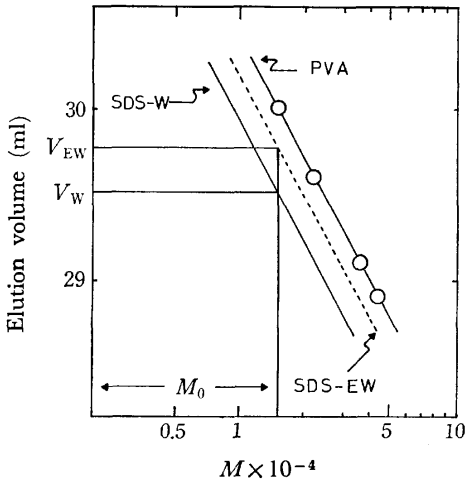

Fig. 8. CPG-10 system calibration curve showing the molecular weights of poly(vinyl alcohol)s relative to V_e as a linear log function.

weight of hydrated poly(vinyl alcohol) (PVA in Fig. 8). Thereby the difference between the amount of the hydration of poly(vinyl alcohol) and that of SDS was taken into account.[7]

To obtain a similar calibration curve for the micelles in an ethanol–water mixture, we measure the elution volume of the micelles both in water (V_W) and in the ethanol–water mixture (V_{EW}) and find the micellar weight (M_O) corresponding to V_W using the SDS-W relation shown in Fig. 8. Then the straight line passing through the point (M_O, V_{EW}) and parallel to the SDS-W line shown as the broken line (SDS-EW) in the figure may be drawn; it is used as the calibration curve for the determination of the micellar weight of SDS in an ethanol–water mixture. Actually, SDS micelles cannot be used for the measurement of V_W and V_{EW} since they undergo a change in size due to the change in solvent composition, while in the above calculation a micellar weight independent of the solvent composition is assumed.

To avoid this trouble, sodium poly(vinyl sulfate) of nearly the same elution volume as that of SDS micelles was used instead of SDS micelles, assuming that the chemical composition and the amount of hydration are like each other. From the measured elution volume of V_m in the ethanol–water mixture, we calculated the micellar weight and, the aggregation

Table 2.

Additives		Aggregation number of micelle		Amount of hydration of SDS (g/g)
		Standard M. W.	Laurent-Killander	
Ethanol	0 vol%	88	80	0.6
	10 vol%	102	—	0.1
	20 vol%	30	—	0.1
NaCl	5 mmol/l	93	91	0.6
	10 mmol/l	104	91	0.6

Concn of SDS, 15 mmol/l

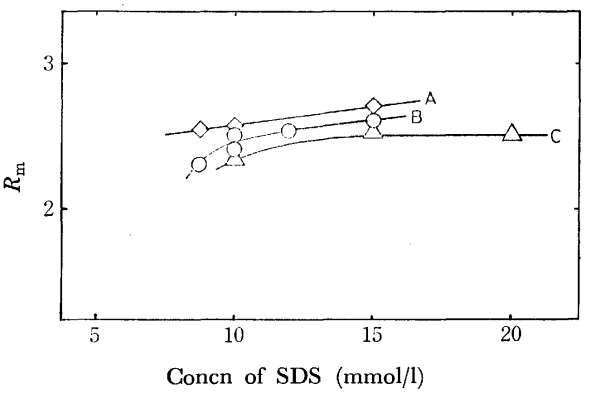

Fig. 9. Dependence of R_m on SDS concentration for different NaCl concentration. A, NaCl 10 mmol/l; B, NaCl 5 mmol/l; C, NaCl 0 mmol/l.

numbers of the SDS micelles. The results are listed in Table 2, together with the amount of hydration of SDS calculated. As may be seen, the aggregation number increases and then decreases with ethanol concentration after showing a maximum. The maximum corresponds to the minimum of CMC mentioned already. It may also be compared with the results of Becher[4] and Herrmann and Benjamin,[3] who showed a decrease in the micellar weight with an increase in the ethanol concentration for nonionic detergents. The amount of hydration is seen to decrease simply with an increase in the concentration of ethanol due to its dehydrating action.

The elution rate of micelles, R_m, in the presence of NaCl is further plotted against the total concentration of SDS (C) in Fig. 9. As may be seen, R_m increased with an increase in the concentration of NaCl.

For the determination of the micellar weight of SDS in an aqueous NaCl solution, a similar method was adopted, but replacing ethanol with NaCl. The elution volume *vs.* the molecular weight of unhydrated SDS micelles in an aqueous NaCl solution was obtained as in the case of Fig. 8. The results thus obtained are listed in Table 2.

The micellar radii of SDS were also calculated according to the Laurent-Killander equation, much as in an earlier report,[7] for both ethanol-water and aqueous NaCl systems; from the results, the aggregation numbers were calculated by taking account of the amount of hydration for the micelles of each system. The results are listed in Table 2. The aggregation numbers of micelles in the aqueous NaCl solution are, on the whole, in agreement with those given in the literature.[13,14] The micellar size was found to increase with an increase in the salt concentration, in agreement with the view that the reduction in the electrical repulsions of the head group of SDS facilitates micellization.[15] The difference in the aggregation numbers of an SDS micelle in water as estimated by the standard molecular weight method and by the Laurent-Killander equation may come from the difference in the methods of estimation, as has been seen in the literature.[13,14]

The author wishes to express his deep gratitude to

Professor Tsunetaka Sasaki of our University for his kind direction and valuable criticism throughout the work.

Transition Dipole Interaction and Intermolecular Potential of Carbon Disulfide and Sulfur Dioxide Crystals

Yoshihiro KURODA and Katsunosuke MACHIDA

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 11, 1975)

The optical active normal frequencies and the heats of sublimation of carbon disulfide and sulfur dioxide crystals have been calculated. The interaction between the transition dipoles associated with the infrared active intermolecular modes has been taken into account by introducing coupling terms between the equivalent coordinates of neighboring molecules. The coupling force constants estimated from the infrared absorption intensities explain the observed trend of the factor group splittings of the ν_3 mode of carbon disulfide and the ν_1 and ν_3 modes of sulfur dioxide. The splitting of the ν_2 mode of carbon disulfide has been reproduced by taking account of the long range Coulomb interaction between the atomic charges.

Appreciable factor group splittings in infrared and Raman spectra of crystals often arise from the interaction between the transition dipoles associated with the vibrations of neighboring molecules or ions.[1,2] The most straightforward way of incorporating this interaction in the potential function of crystal lattices is to introduce appropriate coupling constants between the equivalent coordinates of adjacent molecules in a unit cell. As shown by Decius,[3] such a coupling constant can be evaluated from the derivative of the molecular dipole moment with respect to the internal or the normal coordinate concerned.

For the crystals of alkaline earth carbonates, the dipole moment derivatives estimated from the factor group splittings agree with those obtained from the infrared reflection spectra.[4] On the other hand, the intermolecular coupling constants for the crystals of hydrogen chloride[5] and methyl chloride[6] have not fully been explained by the dipole moment derivatives obtained from infrared band intensities. Further studies are thus required to establish the theoretical basis of the coupling constants introduced empirically.

In this work, we have aimed at evaluating the intermolecular potential functions of carbon disulfide and sulfur dioxide crystals, and at clarifying how far the effect of the coupling terms are manifested in the observed vibrational spectra. In order to check the validity of the adopted potential parameters, the values of the potential functions for the equilibrium structure have also been calculated and compared with the heat of sublimation.

Method of Calculation

The frequencies of the optical active inter- and intramolecular normal modes were calculated according to the method of Harada and Shimanouchi.[7] The quadratic intramolecular force constants are those of the general valence type fitted to the observed fundamental frequencies in the gaseous state.[8] They are given in Table 1. The atomic coordinates were taken from the X-ray studies by Baenziger and Duax for carbon disulfide[9] and by Post *et al.* for sulfur dioxide.[10]

In order to distinguish the role of various types of intermolecular interactions, calculations were made for three kinds of intermolecular potentials. In calculation I, we took into account only the short range interactions due to the exchange repulsion and the van der Waals attraction, using the potential in the exp-6 form

$$V_{\mathrm{I}} = \sum_{i,j} [-Ar_{ij}^{-6} + B \exp(-Cr_{ij})], \tag{1}$$

where r_{ij} is the distance between the atoms i and j. Table 2 shows the values of the parameters A, B and C for the C···C, S···S and O···O interactions adopted in the present work.[11,12] The parameters for the asymmetrical C···S and S···O interactions were estimated from those for the two corresponding symmetrical interactions by taking the geometric means for A and B and the arithmetic means for C.[13] The summation limit for this short-range interaction was taken to be 6 Å.

Calculation II was carried out for the potential including the coupling terms due to the transition dipole interaction in the form

$$V_{\mathrm{II}} = V_{\mathrm{I}} + \sum_{a,b} \sum_{i} K_i^{ab} S_i^a S_i^b, \tag{2}$$

where S_i^a and S_i^b denote the i-th internal symmetry coordinate of the molecules a and b, respectively, and K_i^{ab} is the coupling force constant related to these coordinates. The summation limit was taken to cover only the nearest-neighbor interaction. The coupling constant was calculated, according to Decius,[3] by

$$K_i^{ab} = |\partial\mu/\partial S_i|^2[(\boldsymbol{e}_a \times \boldsymbol{R})\cdot(\boldsymbol{e}_b \times \boldsymbol{R}) - 2(\boldsymbol{e}_a \cdot \boldsymbol{R})(\boldsymbol{e}_b \cdot \boldsymbol{R})]/|\boldsymbol{R}|^5, \tag{3}$$

where $\boldsymbol{e}_a$ and $\boldsymbol{e}_b$ are the unit vectors along the transition dipoles formed in the molecules a and b, respectively, and $\boldsymbol{R}$ is the vector joining these dipoles. The transition dipoles were assumed to be at the central atoms (C for carbon disulfide and S for sulfur dioxide) for all the infrared active modes. The dipole moment derivatives for the normal coordinates, $\partial\mu/\partial Q_i$, were taken from the works on the infrared absorption intensities,[14,15] and were transformed into those for the internal symmetry coordinates, $\partial\mu/\partial S_j$, by assuming a simplified relation

$$\partial\mu/\partial S_j = (\partial\mu/\partial Q_i)/L_{ji}, \tag{4}$$

where L_{ji} is the $\boldsymbol{L}$ matrix element connecting Q_i with S_j. The relation is exact for the ν_2 and ν_3 modes of carbon disulfide and the ν_3 mode of sulfur dioxide, but not for the ν_1 and ν_2 modes of sulfur dioxide. The exact transformation in terms of the $\boldsymbol{L}^{-1}$ matrix elements[16] cannot be applied to these two modes since

a) In calculation III′ for SO_2, the values of A and B were multiplied by 4.

the relative signs of $\partial\mu/\partial Q_1$ and $\partial\mu/\partial Q_2$ are not known. The symmetric stretching and the angle deformation modes of sulfur dioxide do not appreciably couple with each other, and the errors due to the approximation (4) are not serious for a crude estimation of splittings. The numerical values of the coupling constants and the related quantities are summarized in Table 3.

In calculation III, we adopted the potential including the terms due to the Coulomb interaction between the atomic charges as given by

$$V_{III} = V_{II} + \sum_{i,j} e_i e_j / r_{ij}, \qquad (5)$$

where e_i and e_j denote the charges carried by the atoms i and j, respectively. The atomic charges for carbon disulfide and sulfur dioxide were so estimated as to reproduce the observed values of the electric quadrapole moment[17] and the dipole moment,[18] respectively; $e_C=-2e_S=0.58$ for the former and $e_S=-2e_O=0.46$ for the latter in the electronic charge unit.

The summation limit for the Coulomb terms in Eq. 5 was determined in two steps. When the atomic pairs to be included in the sum are selected directly by comparing the individual interatomic distances with a given threshold, the net charge under the summation sign does not generally vanish and a smooth convergence of the sum is not expected. Accordingly, we selected first appropriate molecular pairs by referring to the distances between the central atoms, and then picked up all the intermolecular atomic pairs involved in each of these molecular pairs. For the critical distance to be used for the selection of the molecular pairs, several values between 20 and 50 Å were tested, and the distance of 40 Å was found to be large enough to secure a convergent sum.

In order to confirm the consistency between the adopted model potential and the observed heats of sublimation, the values of the potential functions V_I and V_{III} were calculated for the equilibrium structure. They were then corrected for the crystal zero-point energies by using the average Debye temperature.[19] The value of V_{II} is the same as that of V_I at the equilibrium where the transition dipole terms do not contribute to the energies. The numerical calculation was carried out on a FACOM 230-75 computer at the Data Processing Center, Kyoto University.

Results and Discussion

Carbon Disulfide. According to X-ray analysis, the crystal of carbon disulfide belongs to the space group $D_{2h}{}^{18}$-C_{mca}, two molecules being contained in the Bravais unit cell.[9] The calculated and the observed values of the vibrational frequencies and the heat of sublimation are given in Table 4. Based on the

correlation diagram (Fig. 1), the factor group splitting is expected for all the fundamentals, ν_1, ν_2 and ν_3. For the originally degenerate mode ν_2, the site group splitting is also expected. In the observed spectra,[15,20] ν_1 shows no splitting, while ν_2 and ν_3 split into as many components as expected theoretically. No empirical assignment of each component to proper symmetry species has been made because of the difficulty in measuring the low-temperature spectra of oriented crystals. The splittings could not be reproduced by calculation I which includes only the short range non-bonded atom-atom interaction terms (Table 4). Calculation I failed also in predicting the rotatory lattice frequencies[20] and the heat of sublimation,[19] but gave a fairly reasonable result for the translatory lattice modes.[21]

In calculation II, the intermolecular coupling constants K_2^{ab}, K_3^{ab} and K_4^{ab} were introduced between each molecule and its nearest neighbors lying on a common layer parallel to the bc plane. Since the ν_3 band in the infrared spectrum is very strong, splitting in the range 30—50 cm^{-1} observed for this band has been attributed to the interaction between the transition dipoles associated with the ν_3 mode.[15,20] In agreement with this interpretation, calculation II reproduced the observed splitting of the ν_3 mode satisfactorily. On the other hand, the ν_2 band in the infrared spectrum is very weak and the interaction between the transition dipoles is hardly expected to cause the observed splitting of the ν_2 mode.[15] Actually, the coupling constants K_3^{ab} and K_4^{ab} estimated from the infrared band intensity was found to give only one-tenth as large a splitting as the observed. For the lattice frequencies, calculations I and II gave almost

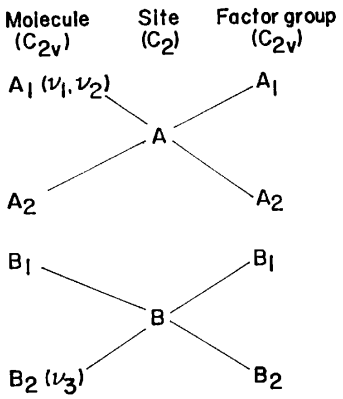

Fig. 2. Correlation diagram for vibrations of SO_2 crystal.

the same results, since the dipole-dipole coupling terms affect only the intramolecular modes in which the internal coordinates appearing in those terms vibrate appreciably.

As shown in Table 4, all the observed factor group and site group splittings were reproduced very well by calculation III. The long range Coulomb interaction exerts little effect on ν_3, for which the splitting has been explained to be due to the transition dipole interaction, but gives rise to the splitting of ν_2 into three components appearing at intervals of about 5 cm^{-1} just as in the observed spectrum. Addition of the Coulomb terms to the intermolecular potential does not much affect the lattice frequencies, but improves the heat of sublimation appreciably.

Sulfur Dioxide. A number of split bands have been observed in the infrared and Raman spectra of sulfur dioxide crystal, and have been interpreted in terms of the factor group splittings, the summation bands and the bands of the isotopic species $^{34}SO_2$.[22-24] According to the correlation diagram (Fig. 2), the factor group splitting of ν_3 is expected in both the infrared and Raman spectra while that of ν_1 and ν_2 only in the Raman spectrum. The calculated and the observed values of the vibrational frequencies and the heat of sublimation are listed in Table 5.

As in the case of carbon disulfide, none of ν_1, ν_2 and ν_3 is calculated to split appreciably when only the short range forces are taken into account (calculation I), whereas the observed splittings are 4 cm^{-1} for ν_1 and 18 cm^{-1} for ν_2.[24] The splitting of ν_3 is estimated to be between 10 and 30 cm^{-1} from the Raman spectrum at 77 K in which three peaks assignable to ν_3 appear in the region around 1300 cm^{-1}.[24] If the splittings of ν_1 and ν_2 are assumed to arise from the interaction between the transition dipoles, the high- and low-frequency components for each mode are attributed to the A_2 and the A_1 species, respectively, by using Eq. 3 with properly chosen vectors $\boldsymbol{e}_a$, $\boldsymbol{e}_b$ and $\boldsymbol{R}$. The result agrees with the assignment by Anderson and Savoie[24] based on a comparison of the infrared and Raman frequencies.

In calculation II, three coupling constants K_1^{ab}, K_2^{ab} and K_3^{ab} were introduced, each molecule being assumed to interact with the neighboring four molecules lying on a common layer parallel to the ac plane.

a) Ref. 24. b) Ref. 25. c) Ref. 19.

As shown in Table 5, the calculated splittings for ν_1 and ν_3 agree well with the observed ones, but not so for ν_2. In contrast to the case of carbon disulfide, addition of the Coulomb terms to the intermolecular potential of sulfur dioxide was found to give little effect on the magnitude of the factor group splittings, the discrepancy for ν_2 being left unreduced in calculation III. In order to obtain a satisfactory fit between the calculated and the observed splittings, it seems necessary to use more elaborate model potentials, for example by introducing polarizable charges.

The lattice frequencies and the heat of sublimation obtained in calculations I through III are far less than the observed values.[19,24,25] After several trials, the difficulty was overcome, without appreciable changes in the factor group splittings, by using about four times as large values of the parameters A and B for the O···O contact as those in calculations I, III and II (calculation III′, Table 5). Probably, the enhanced potential parameters do not faithfully represent the true feature of the non-bonded O···O interaction, but involve implicitly effects of some unknown interactions not considered herewith in this work.

Coulomb Interactions and Optically-active Vibrations of Calcite-type Carbonates[1)]

Akio YAMAMOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received December 22, 1975)

Polarizable-ion model calculations are made for optically-active vibrations of five carbonates with calcite structures: calcite, magnesite, dolomite, rhodochrosite, and smithsonite. The fit to the experimental TO-LO splittings of the internal modes is found to be greatly improved by the introduction of ionic polarizabilities. It is also ascertained that the electronic polarizabilities of constituent atoms must be regarded as anisotropic in order to interpret the optical anisotropy. The resulting force constants for non-bonded oxygen-oxygen interactions can give the correct orders of magnitude for the Lennard-Jones potential constants.

This paper is complementary to a preceding paper,[2)] denoted as Paper I hereafter, on the lattice dynamics of sodium nitrate. There we described a method of polarizable-ion (PI) model calculations[3)] for partially ionic crystals, together with an illustrative example. The object of the present paper is to report the results of a systematic application of the PI model to several important carbonates with a calcite structure, *viz.*, $CaCO_3$, $MgCO_3$, $CaMg(CO_3)_2$, $MnCO_3$, and $ZnCO_3$, and also to test the adequacy of the force field in Paper I.

The structure and symmetry properties of calcite-type crystals have been described on several occasions,[4)] the structure being rhombohedral with 10 atoms in the primitive cell. As is shown in Fig. 1, the space groups of dolomite and the others[5,6)] are $R\bar{3}$ and $R\bar{3}c$ respectively. Our lattice dynamical interest in carbonate crystals is a result especially of the fact that their chemical bonds are fairly intermediate between those of ionic and covalent crystals: both the splittings of the transverse optic (TO) and longitudinal optic (LO) branches and the internal vibrations of quite high frequencies bear little resemblance to typical ionic and/or covalent crystals.

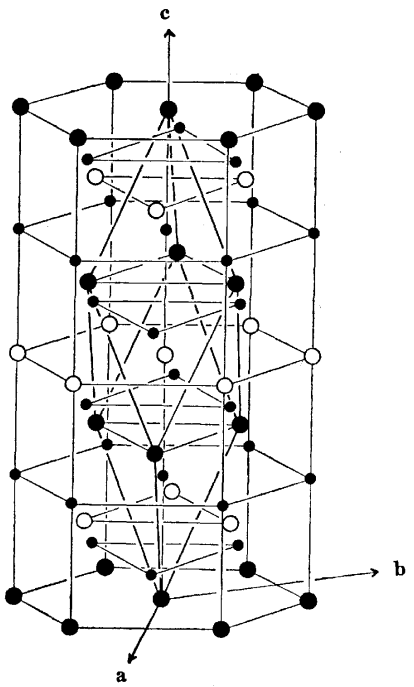

Fig. 1. Crystal structure of calcite-type carbonates. ○, ●: Metal, •: Carbonate.

In the vibration treatments, the estimation of the non-Coulomb contribution of carbonate groups to the potential energy is feassible by the use of a modified Urey-Bradley force field. On the other hand, the contribution due to the partially ionic nature of the bindings is characterized by using the method of lattice dynamics developed for simple crystals.[3)] One of the simplest models to take the Coulomb interactions explicitly may be the rigid-ion (RI) model[3,7)] with short-range forces. The present author and his coworkers have analyzed the optically-active vibrations of carbonate crystals[8,9)] on the basis of the RI model. It is concluded that the calculated TO-LO separations of the intermolecular vibration modes are fairly comparable with the experimental results, but that those of the intramolecular modes do not agree with the observed separations. Then we introduce a model where the effects of the electronic polarizabilities[3,10,11)] can be appropriately taken into account. The shell model[10)] may be one of the most elaborate models for such a purpose; it has been successfully used in the analysis of phonon dispersion relations and of specific heats of simple crystals. As for the shell model, however, we sometimes find it difficult to determine the unmanageable number of Coulomb parameters uniquely. Thus, the PI model of Born and Huang[3)] has been employed; this model is used with a certain extension in an attempt to incorporate the anisotropy of the electronic polarizability. The effects of the distortion of electronic distributions on the crystal vibrations can be rigorously estimated by the model; however, higher-order multipole effects are implicitly neglected, for we believe them to be much less important. In order to evaluate the Coulomb components of the dynamical matrix,[3)] we take the constituent atoms to be point ions of unknown charges and electronic polarizabilities; then those which can best explain the observed Coulomb interactions are determined to be the effective ionic charges and electronic polarizabilities.

Method of Calculation

The method has been described in detail in Paper I; here we shall merely quote the results relevant to the present work. From the Born and Huang theory,[3)] a dynamical matrix is constructed from four con-

stituents:

$$\mathbf{D} = \bar{\mathbf{M}}(\mathbf{F}^{N}+\mathbf{F}^{C}+\mathbf{F}^{I}+\mathbf{F}^{M})\bar{\mathbf{M}},$$

where $\bar{\mathbf{M}}_{\alpha\beta kk'}=\delta_{\alpha\beta}\delta_{kk'}m_k^{-1/2}$, where α and $\beta=x$, y or z, and where m_k and δ are the mass of the k-th kind of atom and the usual Kronecker delta symbol respectively. The first term arises from short-range non-Coulomb interactions; both the central force interactions of non-bonded atom pairs within 3.5 Å and the non-central force interactions of carbonate groups are taken into consideration. A complete description of them has been given elsewhere,[8,9] denoted by Papers II, and the notations of these papers are used here. The second and third terms are due to rigid-ion and induced-dipole interactions respectively. In the long-wavelength limit, the terms are thus far independent of the direction of the wave propagation. The last term is the macroscopic field part and is dependent on the direction.

Now, to proceed with the actual calculations we require the numerical values of the ionic charges and electronic polarizabilities of the constituent atoms. Unlike simple crystals, the situation is complicated here by the fact that the distribution of the ionic charges is not known in advance. Two disposable parameters, x and Z, have been introduced in order to represent the distribution under electrically neutral conditions: $Z_{Metal}=Z$, $Z_c=xZ$, and $Z_o=-(1+x)Z/3$. Furthermore, the ratio of Z_{Ca} to Z_{Mg} for dolomite was taken to be that of the Szigeti charges,[12] since the results do not depend on the ratio.[9] The electronic polarizability can be easily incorporated in tensor form by generalizing the Born and Huang expressions.[3] In order to reduce the number of disposable parameters, it is assumed that the off-diagonal elements of the polarizability tensors are negligibly small. It is then shown from the crystal symmetry that only two of the diagonal elements are independent, *i.e.*, $\alpha_{11}(k)=\alpha_{22}(k)$ $(=\alpha_\perp(k))\neq\alpha_{33}(k)(=\alpha_\parallel(k))$. The electronic polarizabilities of the constituent atoms were recalculated in order to take the anisotropy into account by using this expression:

$$\boldsymbol{\varepsilon}_\infty = \mathbf{I} + 4\pi v^{-1}\boldsymbol{\rho},$$

where $\boldsymbol{\varepsilon}_\infty$ is the macroscopic dielectric susceptibility tensor at a frequency higher than where the lattice vibration will contribute. $I_{\alpha\beta}=\delta_{\alpha\beta}$, v is the unit cell volume, and

$$\rho_{\alpha\beta} = \sum_{kk'}\{(\mathbf{I}'-\mathbf{AQ})^{-1}\mathbf{A}\}_{\alpha\beta kk'}.$$

In this expression, $I'_{\alpha\beta kk'}=\delta_{\alpha\beta kk'}$, $A_{\alpha\beta kk'}=\alpha_{\alpha\beta}(k)\delta_{kk'}$, $\boldsymbol{\alpha}(k)$ is the polarizability tensor of the k-th kind of atom, and $\mathbf{Q}$ denotes the Coulomb coefficient matrix. In practice, it has been found that the electronic polarizabilities of the metal atoms are fairly small as compared with those of carbonate groups[13] and that the frequencies given by the model are insensitive to the polarizabilities.[2] The polarizabilities were thus regarded as isotropic and set equal to the values determined by the other methods[13–16] in the final calculations.

The numerical work was performed using a TOSBAC 3400 TOPS 14 electronic computer at the Computing Center of Hiroshima University.

Results and Discussion

Electronic Polarizability. A considerable number of values have been reported for ionic and molecular polarizabilities.[13–16] Almost all of them have, however, been determined for isotropic crystals with simple structures; therefore, they cannot always apply to the present materials. As has been mentioned above, they were used only for less important metal atoms. The resulting electronic polarizabilities of oxygen and carbon atoms are shown in Fig. 2 for calcite, where all of the sets of values on the $\{\alpha_\perp(O), \alpha_\perp(C)\}$ and $\{\alpha_\parallel(O), \alpha_\parallel(C)\}$ curves were able to account for the high-frequency dielectric constants corresponding to the two refractive indices,[17,18] $n_\perp$ and $n_\parallel$ respectively. The determination of the electronic polarizabilities must, therefore, be based on a fit of the calculated to the observed vibrational frequencies.

In the present investigation, the off-diagonal elements of the polarizability tensor were neglected as a first approximation. The validity of the simplifying assumption is unclear at present, although it does predict the correct orders of magnitude for the Coulomb frequency splittings. It seems likely that the influence of the elements, if any, would be appreciable in the case of atoms with a lower site symmetry, such as oxygen atoms in the calcite lattices. Therefore, further work is required to clarify the significance of the off-diagonal elements.

Optically-active Vibrations. From the present calculations, certain frequency splittings in the intramolecular vibrations, *e.g.*, TO-LO and E_g-E_u splittings,[19–22] were found to be appreciably sensitive to the details of the electronic polarizabilities of oxygen and carbon atoms as well as to the charge distribution within the carbonate groups. The present calculations strongly suggest that the E_g-E_u splittings of the

x, charge distribution parameter; //, parallel component; $\perp$, perpendicular component.

CO stretching and OCO angle deformation modes depend very sensitively on the polarizability, $\alpha_\perp$(O) or $\alpha_\perp$(C). If the values about 0.3 $Å^3$ are assigned to the $\alpha_\perp$(O) polarizability, a satisfactorily good agreement can be obtained with the experimental results; therefore, the value was set as 0.3 $Å^3$. On the other hand, it was found that the charge distribution affects the TO-LO separations of the CO stretching modes quite a bit. The distribution parameter was adjusted to explain the experimental separations. For the A_{2u} or A_u modes, the effects of the polarizabilities can be examined only for the TO-LO splitting of the out-of-plane angle deformation modes; the polarizability dependence of the splitting is, however, not so remarkable as that of the E_u modes. It was shown, from a careful analysis of the calculated results, that a polarizability set with $\alpha_{//}(O) \approx 1.05$ $Å^3$ yields a good agreement with the observed splitting. Any choice of isotropic polarizabilities, *i.e.*, $\alpha_\perp(O) = \alpha_{//}(O) = 0.3$ $Å^3$ or 1.05 $Å^3$, was found either to overestimate or to underestimate the experimental results seriously.

Calcite: A large number of experimental studies of the vibrational spectra of calcite have been carried out by means of IR absorption[23,24] or reflection[25-27] and of Raman scattering;[23,24,28] furthermore, the dispersion relations have been in part determined by neutron inelastic scattering.[29] The observed and calculated frequencies are given in Table 1, together with the results of the RI model calculations for comparison. It is shown that the E -E_u splitting of the CO stretching

modes is fairly comparable with the experimental separation, whereas the splitting of the OCO deformation modes seems to be somewhat overestimated. Recently, Onomichi *et al.*[30] have reported more accurate and reliable spectroscopic data for calcite: 1439 cm^{-1} and 720 cm^{-1} for the E_g modes, and 1411 cm^{-1} and 712 cm^{-1} for the E_u modes. Therefore, the present calculations do not always predict a tendency of the Coulomb shift opposite to that of the experimental data. The optimized set of the Coulomb parameters is listed in Table 2.

The vibrational analysis has been performed by many investigators;[22,29-35] however, only a few attempts have been made so far to examine the effects of the Coulomb interactions. Onomichi[36] performed the RI model analysis of the optically-active vibrations; the reproducibility of the observed frequencies seems not to be very good on account of the rough estimate of the disposable parameters. Plihal and Schaack[37,38] have analyzed the intermolecular vibrations based on a shell model; they explained the experimental results fairly well. They regarded the carbonate group as one large ion in order to reduce the shell-model parameters to manageable proportions, and the calcium atom was assumed to be unpolarizable. Of considerable interest is the recent work by Cowley and Pant;[29] the observed frequencies of the optically-inactive A_{2g} modes are in fair accord with the present results (see Table 1). They have determined the shell-model parameters with reference to the dispersion curves for several intermolecular modes. The resulting charge of calcium is read as 2.3 in electron units; this is the largest of the published charges (*viz.*, 1.5,[12] 1.53,[37] and the 1.11 determined presently). There appears to be considerable variation in the charge not only with the calculation models but also with the types of vibration referred to. It should be noted that the present charge can account for both the high- and low-frequency vibrations simultaneously, whereas the published charges were estimated with reference to the low-frequency vibrations only.

The charge distribution within the carbonate ion has been determined from energetic studies of the static lattices. Ladd[39] has recently assigned the following charges: $Z_C=0.31$ and $Z_O=-0.77$ in electron units, where (Z_C+3Z_O) is normalized to the formal ionic charge. The charge distribution seems to be far closer to the present dynamical distribution than that determined previously.[40]

Magnesite and Dolomite: The IR and Raman spectra have been reported by several workers,[25,41-44] but the theoretical analysis of the vibrations has been little attempted in terms of any force models.[8,9,35,37,45] The observed and calculated frequencies of magnesite and dolomite are compared in Tables 1 and 3 respectively. As has been ascertained for calcite, the theoretical frequency splittings of the intramolecular modes are in better agreement with the observed Coulomb splittings than those based on the RI model. The best-fit Coulomb parameters are listed in Table 2. On account of the lowering of the crystal symmetry, the disposable parameters for dolomite number about twice as many as those needed for calcite or magnesite. Accordingly, the initial values of these parameters for fitting-procedures were estimated with reference to both the optimized values on the basis of the RI model[8,9] and those of the PI model for calcite and magnesite. It is obvious, from a close inspection of the effective charges of calcite and magnesite, that a larger dipole moment is induced at each atom site in magnesite

than in calcite; these features are well reflected in the observed TO-LO separations. The intermediate nature of dolomite between calcite and magnesite is appreciably brought out in the effective charges and short-range force constants; they are either calcite-like or magnesite-like.

Rhodochrosite and Smithsonite: There have been little vibrational data available for these crystals, and the crystal vibrations have not been analyzed in terms of any force models except in the work by Grandolfo[35] based on a short-range force model. The available data[28,46-48] are, however, barely sufficient to perform the detailed analysis. The observed IR reflectivities[48] were modified by employing the anisotropic refractive indices in the dielectric dispersion formulas: $n_\perp=1.818$ and $n_\parallel=1.595$ for rhodochrosite and $n_\perp=1.849$ and $n_\parallel=1.621$ for smithsonite.[17]

The optically-active vibrations of these crystals were analyzed on the basis of both the RI and PI models. The observed and calculated frequencies and the best-fit values of the Coulomb parameters are given in Tables 4 and 2 respectively. Because of the lack of reliable spectroscopic data for these crystals, the present results must be considered to be tentative. Although the physical significance of the values of the adjustable parameters is not clear, a general similarity in the values is found between these crystals and the other crystals investigated here.

Short-range Force Constants. The initial values of the force constants, f_1—f_6, were estimated with reference to those determined by the RI model,[8,9] and then they were refined by a least-squares method. The optimized values are listed in Table 5, where $F'=-0.1F$. The modified Urey-Bradley force field was ascertained to be satisfactory for the intramolecular vibrations of carbonate groups, although the physical meanings of the correction terms of relatively large values remain obscure. It is also found that some force constants between close atom pairs, such as intramolecular constants, are more affected by the ionic polarizabilities than those between distant pairs; an explanation of this can be found in the widely recognized concept that the interactions through the electronic polarizability are more short-range than the electrostatic interactions.

A rough estimation of the Lennard-Jones potential constants for non-bonded oxygen-oxygen interactions was possible from the resulting 17 force constants. The force constants are shown in Fig. 3. If the atoms are assumed to interact with central forces, the Lennard-Jones potential constants, A and B, of the form:[3,49]

$$U(r) = A\,r^{-9} - B\,r^{-6},$$

can be determined by the use of this relation:

$$f(r_0) = [\mathrm{d}^2U/\mathrm{d}r^2]_{r=r_0},$$

where $f(r_0)$ is the force constant at the interatomic distance of r_0. The optimized values for the potential constants were thus calculated to be $A=60\times10^{-82}$ erg·cm^9 and $B=350\times10^{-60}$ erg·cm^6. As Fig. 3 illustrates, the curve I of the carbonates seems to be intermediate between the curves II and III drawn from the self-consistent potential constants of oxides[49] and those of neon with the similar electron configuration to the O^{2-} ion[3] respectively. Figure 3 also indicates that Curve I is similar in the dependence on the interatomic distance to Curve II rather than to Curve III.

Comparison of PI Model with RI Model. The essential correctness of introducing the electronic polarizability is shown by the great improvement in the fit to the experimental Coulomb splittings of the

intramolecular modes. These splittings have been poorly accounted for on the basis of the RI model. With OCO angle deformation modes, the relatively weak absorption intensity makes it difficult to attain accurate and reliable determinations of the TO-LO separations. Consequently, the experimental separations seem to vary considerably with the five carbonates; nearly identical values are assigned to them in the case of CO stretching modes. We cannot, therefore, believe that all the variations arise from the specificity of each modification, although the Coulomb interactions of the angle deformation modes are seemingly reproduced less satisfactorily with the present model. Further experimentation is necessary to examine fully this apparent contradiction to the present results. The observed intermolecular mode frequencies are seen to be satisfactorily explained by both models: certain low-frequency modes are not very well fitted by the PI model, although this lack of fit is probably not significant.

As for the optically-active vibrations, the results of the present and of previous works[2] seem to indicate that the weak Coulomb interactions between moderately separated atoms can be fairly well accounted for by the RI model, and that, however, any strong interactions due to the distortion of electronic distributions can hardly be interpreted at all without the use of a model which takes rigorously ionic polarizations. Moreover, there are a large number of crystalline solids where we are obliged to be content with the oversimplified RI approximation because of the complexity inherent in elaborate models. Under these circumstances, we consider that the present work represents one step in the direction of obtaining a quantitative understanding of the Coulomb interactions in ionic crystals with intricate structures.

The author wishes to express his thanks to Professor Hiromu Murata for his continual encouragement during this work, and to Associate Professor Yuji Shiro for his valuable advice and discussion. Thanks are also due to Messrs. Masaru Ohsaku and Tamaki Utida and Miss Michiko Miura for their kind and helpful discussion and suggestions.

X-Ray Photoelectron Spectroscopy of the Molecules Containing the C≡N Group

Takashi FUJIKAWA, Toshiaki OHTA, and Haruo KURODA

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Tokyo 113

(Received December 24, 1975)

The gas-phase X-ray photoelectron spectra (with Mg$K\alpha$ radiation) were observed on acetonitrile, propionitrile, acrylonitrile and fumaronitrile. The ionization potentials were determined for all valence-electron levels of the above molecules by using the data derived from the observed valence-electron bands of X-ray photoelectron spectra and the reported data of ultraviolet photoelectron spectroscopy. It is shown that there is a linear relation between the observed ionization potential (IP) and the CNDO/2 orbital energy (ε): $IP=0.61(-\varepsilon)+3.2$ [eV], for σ-orbitals; $IP=0.38(-\varepsilon)+6.0$ [eV], for π-orbitals. The observed binding energies of the C 1s levels were analyzed by means of the electrostatic potential model and the charge densities calculated by CNDO/2 method. Discussion is given also on the shake-up satellite of core-electron peak.

The valence-electron levels of the molecules containing the C≡N group have been investigated by several authors by means of ultraviolet photoelectron spectroscopy (UPS), using He I resonance line as the stimulating radiation.[1-5] However, the informations which have been obtained by these UPS studies, are concerned mainly with the π-electron and lone-pair levels, and little has been known about σ-electron levels, in particular, those of higher ionization potentials.

For investigating valence-electron levels of a molecule, X-ray photoelectron spectroscopy (XPS) provides informations which are complementary to those obtainable by UPS; First, it is possible to investigate with XPS the deep-lying valence-electron levels which can not be studied by UPS, and, second, the prominent bands observable in the valence-electron region of a XPS spectrum are mostly associated with σ-orbitals, whereas, in UPS, π-orbitals usually give strong photoelectron bands.[6]

In the present paper, we report the gas-phase X-ray photoelectron spectra of the molecules containing the C≡N group. The valence-electron bands of the observed spectra will be analysed with the aids of the reported UPS data and the molecular orbital calculations by CNDO/2 method. Discussion will be also given on the core-electron peaks.

Experimental

The gas-phase X-ray photoelectron spectra of acetonitrile CH_3CN, propionitrile CH_3CH_2CN, acrylonitrile CH_2=CH-(CN) and fumaronitrile $^{NC}\diagdown CH{=}CH\diagdown^{CN}$ were measured with a McPherson ESCA 36 electron spectrometer, by employing Mg$K\alpha$ radiation (1253.6 eV). The purified sample of each compound was out-gassed by the freezing-and-pumping technique in a glass tube connected to the gas-handling system of the spectrometer, and then its vapor was introduced through the gas-handling system into the ionization cell installed in the sample compartment of the spectrometer.[7]

The binding energies of photoelectron peaks, referred to the vacuum level, were calibrated by using the N 1s peak (409.9 eV) of the nitrogen gas, mixed with the sample vapor, as the reference. The C 1s peak of the sample, induced by the weak Al$K\alpha$ radiation which came out as the secondary X-ray from the Al window of the X-ray source, was also used as a subsidiary reference for the calibrations of binding energies of valence-electron bands.

Results and Discussion

Valence-electron Bands. The valence-electron bands of the XPS spectrum of propionitrile is shown in Fig. 1, which exhibits five prominent peaks located at ~13, 17.5, 22.1, 25.2 and 29.7 eV, respectively. Since the propionitrile molecule has twenty two valence electrons, there must be eleven valence-electron levels. The UPS spectrum of propionitrile was studied by Lake and Thompson,[2] who observed seven photoelectron bands, and determined the vertical ionization potentials of the corresponding levels as 12.11, 12.91, 13.64, 13.86, 15.07, 16.59 and 17.46 eV, respectively. Lake and Thompson attributed the 12.11 eV band to the ionizations of the two π-orbitals localized on the C≡N group, and the 12.91 eV band to that of the lone-pair of the N atom, but gave no assignment on other photoelectron bands. Anyway, by the above UPS study, we already know the ionization potentials of eight levels among the eleven valence-electron levels, so that there remain only three levels on which the ionization potential must be determined. As we compare the XPS spectrum with the above UPS data, we note that there are three peaks (at 22.1, 25.5 and 29.7 eV) in the higher-energy region that can not be studied by UPS. Thus, we can safely conclude that these three peaks must be corresponding to the remaining three levels. By this way, we are able to know the ionization potentials of all valence-electron levels.

The relative intensities of valence-electron bands observed by XPS are known to have a relatively simple

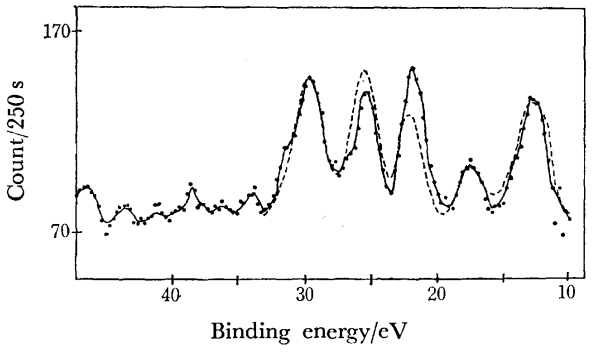

Fig. 1. Valence-electron bands of the XPS spectrum of propionitrile. The final results of simulation (see text) is shown with a broken line.

relation with the wave functions of the ionizing molecular orbitals. According to Gelius *et al.*, this can be approximately expressed as follows;[8]

$$I_j \propto \left(2+\frac{1}{2}\beta\right)\sum_{A\lambda} P_j(A\lambda)\,\sigma_{A\lambda}/\sigma_{C2s} \qquad (1)$$

where $P_j(A\lambda)$ is the atomic population on atom A from the atomic orbital $A\lambda$ in the ionizing molecular orbital j, $\sigma_{A\lambda}$ and σ_{C2s} are the photoionization cross sections of the atomic orbitals, $A\lambda$ and $C2_s$, for X-ray, and β is the asymmetric factor which can be taken as $\beta=2$ for σ-orbitals and -1 for π-orbitals. The relative photoionization cross section has been empirically determined by Gelius and others for various atomic orbitals.[8] The cross section of 2p orbital is reported to be almost one tenth of that of 2s orbital in the cases of the second row elements. Partly because of the small cross sections of 2p orbitals, and partly because of the asymmetric factor, π-orbitals usually have very small photoionization cross sections for X-ray as compared with σ-orbitals, whereas the photoelectron bands associated with π-orbitals strongly appear in the case of UPS. This situation gives us a way to distinguish the photoelectron bands due to π-orbitals from those due to σ- and n-orbitlas by comparing between the UPS and XPS spectra.

We calculated the molecular orbitals of propionitrile by CNDO/2 method, and estimated the relative intensities of XPS bands by using Eq. 1.[9] The results of the above calculations are given in Table 1. According to the calculated intensities, we should expect six prominent peaks in the XPS spectrum of propionitrile. We can safely assign the 22.1, 25.5 and 29.7 eV peaks of the observed spectrum to the 3σ, 2σ and 1σ orbitals, respectively. The 17.5 eV peak is likely to be mainly due to the ionization of the 4σ orbital. Then, we should consider that the band due to the 6σ orbital and the one due to the 7σ (lone pair) orbital are overlapping on each other to be a broad, strong peak at about 13 eV.

Since no peak is observed at 15 eV by XPS, we will attribute the 15.07 eV band observed by UPS, to the ionization of a π-orbital (1π). It is likely that in the XPS spectrum, the band corresponding to the 15.69 eV band of the UPS spectrum, is overlapping on the low-energy tail of the 17.5 eV peak. There remains some ambiguity as regards the assignments of the 13.64 and 13.86 eV bands observed by UPS. We will tentatively assign here the 13.64 eV band to the 2π orbital and the 13.86 eV band to the 6σ orbital. The ionization potential of each molecular orbital thus deduced is given in Table 1.

Using the ionization potentials mentioned above and the calculated relative intensities, we carried out a simulation of the valence electron bands of the XPS spectrum. We assumed here a Gaussian shape for each photoelectron peak, and adjusted peak width so that the best agreement was obtainable with the observed spectrum. The final result of simulation is shown in Fig. 1 with a broken line. We were able to obtain an excellent agreement between the calculated and observed spectra.

The valence-electron bands of the XPS spectrum of acetonitrile is shown in Fig. 2, which shows four peaks at 13.1, 17.3, 25.0 and 29.7 eV, respectively.[6] The situation is much more simple in this case than in the case of propionitrile. Lake and Thompson[2] observed four photoelectron bands (at 12.11, 13.14, 15.5

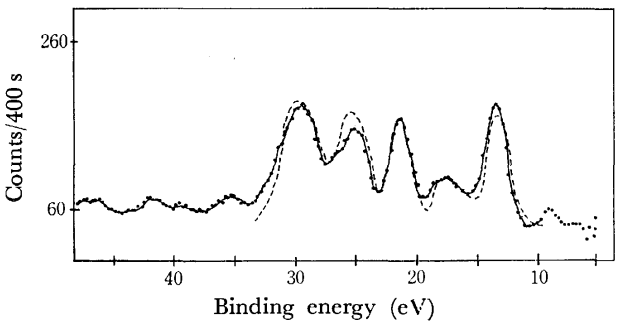

Fig. 3. Valence-electron bands of the XPS spectrum of acrylonitrile. The broken line is the result of simulation.

and about 17 eV) by UPS. By combining the above UPS data with our XPS ones, we can directly derive the ionization potentials of the six valence-electron levels of acetonitrile as 12.11, 13.14, 15.5, 17.3, 25.0 and 29.7 eV. At the same time, we can conclude that the 12.11 and 15.5 eV levels are of π-type since the bands associated with these levels do not appear in the XPS spectrum.

The orbital energies and relative intensities obtained by the CNDO/2 calculations are listed in Table 2. We will assign the 12.11 eV band observed by UPS to the ionization of the doubly-degenerated π-electron level, localized on the C≡N group, as reported by Lake and Thompson, and the 13.4 eV band to that of the lone pair. Then, other photoelectron bands can be assigned as shown in Table 2, assuming the sequence of levels as predicted by the CNDO/2 calculation.

The result of the simulation of the valence-electron bands of the XPS spectrum is shown in Fig. 2 with a broken line. Here, again, we obtained an excellent agreement between the calculated and observed spectra.

In the case of acrylonitrile, the ionization potentials are already known on seven levels among the total ten valence-electron levels through the UPS study by Lake and Thompson,[2] the reported values of the vertical ionization potentials being 10.91, 12.36, 13.04, 13.56, 14.43, 16.17 and 17.62 eV, respectively. By means of XPS, we can observe three prominent peaks at 21.3, 25.3 and 29.7 eV, in the region above 18 eV (see Fig. 3). Combining the above data, we were able to know the ionization potentials of all valence-electron levels.

The results of CNDO/2 calculations on acrylonitrile are shown in Table 3. According to Lake and Thompson, the 10.91 eV of the UPS spectrum is due to the π(C=C) orbital, and the 12.36 eV band to the π(C≡N) orbital. They assigned the 13.04 eV band to the ionization of the lone pair of the N atom. Thus we will attribute the 10.91, 12.36 and 13.04 eV bands to the 3π, 2π and 6σ orbitals, respectively. The calculation predicts a considerably high intensity for the 6σ band in the XPS spectrum. This is consistent with the observation which shows a prominent peak at about 13.3 eV. It is not possible to obtain a definite conclusion concerning the assignment of the 13.56 and

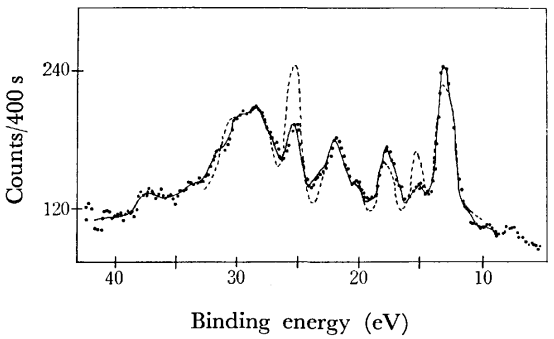

Fig. 4. Valence-electron bands of the XPS spectrum of fumaronitrile. The broken line is the result of simulation.

14.43 eV bands of the UPS spectrum. One of them must correspond to the 7σ orbital and the other to the 1π orbital. We tentatively assigned the 13.56 eV band to the 7σ orbital and the 14.43 band to the 1π orbital, since this assignment gave a better result in the simulation of the valence-electron bands of the XPS spectrum as compared with the alternative assignment. Seemingly, the weak band at about 17.5 eV in the XPS spectrum is due to the superposition of the two bands due to the 5σ and 4σ orbitals, which were separately observed by UPS at 16.17 and 17.62 eV.

We carried out the simulation of the XPS spectrum using the ionization potentials discussed above and the calculated intensities, and were able to obtain a good agreement between the calculated and observed spectra, as shown in Fig. 3.

As shown in Fig. 4, eight peaks were observed in the valence-electron region of the XPS spectrum of fumaronitrile, their maxima being located at 13.4, 15.6, 18.0, ~20, 22.2, 25.6, 28.5 and 30.2 eV, respectively. The UPS spectrum of fumaronitrile was studied by Bock and Stafast,[3] who observed nine photoelectron bands at 11.15, 12.78, 13.10, 13.44, 13.67, 14.41, 15.62, 18.2 and 19.7 eV, respectively, and carried out the assignments of these UPS bands on the bases of the analysis of vibrational structure and the molecular orbital calculation by extended Hückel method. By comparing the above UPS data with our XPS ones, we can conclude that the 11.15, 12.78, 13.10, 13.67 and 14.41 eV bands observed by UPS are due to the ionization of the π-orbitals because they are missing in the XPS spectrum.

The results of our CNDO/2 calculations are given in Table 4. The first strong peak at 13.4 eV in the XPS spectrum must correspond to the 13.44 eV photoelectron band observed by UPS, which was assigned to the ionization of the lone-pair. In effect, the 8σ orbital which has a character of the lone-pair orbital, is predicted to have a large photoionization cross section for X-ray. In the XPS spectrum, we can not find a peak corresponding to the ionization of the 9σ orbital. Seemingly, it is overlapping on the 13.4 eV peak. Assuming the sequence of other σ-orbitals as predicted by the CNDO/2 calculation, we will attribute the 30.2, 28.5, 25.6 and 22.2 eV peaks to the 1σ, 2σ, 3σ and 4σ orbitals, respectively. Since the 5σ orbital is predicted to have a relatively small intensity, we will attribute the weak peak at about 20 eV to the ionization of the above orbital. Then, the 18.0 and 15.6 eV peaks are attributable to the 6σ and 7σ orbitals. For the UPS bands associated with the π-orbitals, we will adopt the assignments given by Bock and Stafast since their results are consistent with our CNDO/2 calculation as regards the sequence of the orbitals. The ionization potential thus derived for each orbital is shown in Table 4.

The results of the simulation of the valence bands of the XPS spectrum is shown in Fig. 4 with a broken line, which is in a good agreement with the observed spectrum, except that the 15.6 and 25.6 eV peaks are predicted a little too strongly.

The results shown in Tables 1—4, clearly indicate that the observed ionization potentials are considerably

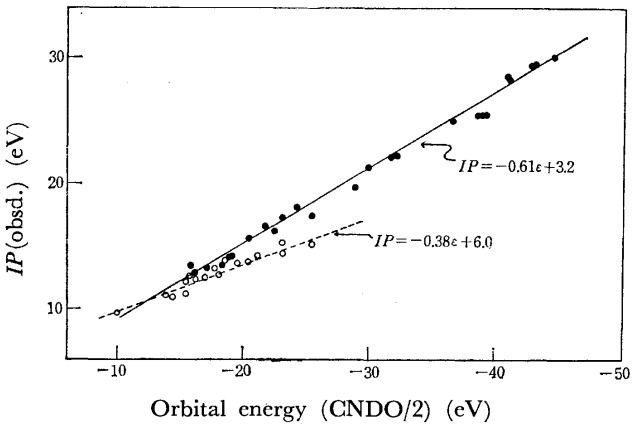

Fig. 5. Relation between ionization potential and CNDO/2 orbital energy: Filled circles are the data concerned with σ-orbitals, and open circles are those concerned with π-orbitals.

different from the values which are expected from the calculated orbital energies according to the Koopmans' theorem; the discrepancy between them is larger for deeper orbitals. In several UPS studies, it was mentioned that a reasonable value of ionization potential is obtainable when 4 eV is subtracted from the value given by Koopmans' theorem from the CNDO/2 orbital energy. However, the present data demonstrate that the above method is not satisfactory, in particular, for deeper orbitals.

In Fig. 5,[10] observed ionization potentials are plotted against CNDO/2 orbital energies. In this figure, the data concerned with π-orbitals are shown as open circles and those concerned with σ- and n-orbitals are shown as filled circles. Interestingly, the latters fall on a straight line and formers on another straight line. The relationship between the ionization potential (IP) and CNDO/2 orbital energy (ε) can be described as follows; for σ-orbitals,

$$IP = 0.61(-\varepsilon) + 3.2 \text{ [eV]} \quad (2)$$

and, for π-orbitals,

$$IP = 0.38(-\varepsilon) + 6.0 \text{ [eV]} \quad (3)$$

Probably, the above difference between the relation for σ-orbitals and that for π-orbitals is reflecting the problems concerned with the semiempirical parametrization in CNDO/2 method. It is also possible that the above difference is partly due to the difference in relaxation energy between σ- and π-orbitals. It should be noted that, because of the above relations between IP and ε, the locations of π-electron levels relative σ-electron levels are often incorrectly predicted by CNDO/2 method. This should be kept in mind when the results of CNDO/2 calculations are used for the assignment of photoelectron bands. The empirical relations, Eqs. 2 and 3, could be used to obtain the correct locations of valence electron levels, at least, in the cases of the molecules similar to those studied here.[11]

Core-electron Spectra. In all of the molecules studied here, one can generally expect that the charge density on the carbon atom of the C≡N group must be significantly different from those of other carbon

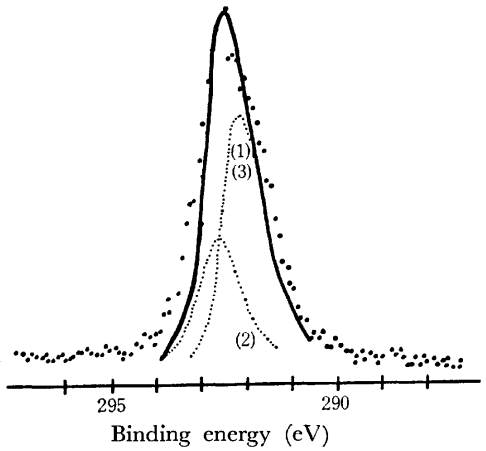

Fig. 6(a). C 1s peak of propionitrile. The observed data are shown by points. The solid line indicates the calculated peak shape which is obtained by superposing peaks due to different C 1s levels, illustrated with dotted lines. Their splitting being assumed as predicted from the CNDO/2 charge densities (see text). The peak number (i) is due to i-th C 1s (i= 1,2,3) (see Table 5).

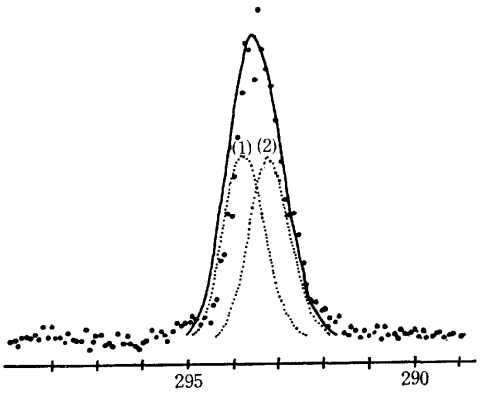

Fig. 6(b). C 1s peak of fumaronitrile. The observed data are shown by points. The solid line indicates the calculated peak shape which is a superposition of the two C 1s peaks shown with dotted lines. The peak number (1) is due to C(1) and (2) to C(2) (see Table 5).

atoms, and this difference of the charge densities will arise a relatively large splitting between the C 1s peak due to the former carbon atom and those due to the latter ones. However, the observed C 1s spectrum of each compound showed a single peak without a shoulder, although it is a little broad and asymmetric as illustrated by the spectra of propionitrile and fumaronitrile, shown in Fig. 6. This fact implies that the splitting of C1s levels must be smaller than 0.6 eV in all molecules studied here.

The net charge on each carbon atom, calculated by CNDO/2 method, is given in Table 5, where we can see that the carbon atom of the C≡N group has a charge of about $+0.09\,e$ whereas the net charges on other carbon atoms are $-0.02\,e \sim +0.02\,e$. According to the electrostatic potential model, the binding energy (E_i) of a core-electron level of the i-th atom can be

related to the charge densities on the atoms in the molecule by the following equation,

$$E_i = E_0 + kq_i + \sum_{i \neq j} (q_j/R_{ij}) \quad (4)$$

where E_0 and k are the constants depending on the kind of atom, q_i and q_j are the charge densities on the i-th and j-th atoms, respectively, and R_{ij} is the interatomic distance.[13] In a previous paper, we showed that the binding energies of the C 1s levels of monosubstituted benzenes can be expressed as follows;[14]

$$E_i = 290.2 + 22.67\, q_i + 14.39 \sum_{i \neq j} (q_j/R_{ij}) \text{ [eV]} \quad (R_{ij}; \text{ in Å}) \quad (5)$$

thus E_0=290.2 eV and k=22.67 eV/unit charge. We can assume the same k value for the C 1s levels of the present molecules, but the value of E_0 could be different in the present cases since it depends, to some extent, on the relaxation energy.

We calculated the relative chemical shift of each C 1s level in a molecule by the following equation,

$$\Delta E_i = E_i - E_0 = 22.67 q_i + 14.39 \sum_{j \neq i} (q_j/R_{ij}) \quad (6)$$

The results are given in Table 5. In all molecules studied here, the difference between the relative chemical shifts of the C 1s levels is predicted to be less than 0.6 eV. This implies that the splitting of the C 1s levels is less than 0.6 eV in agreement with the results of observation. In effect, when we simulated the C 1s peak shape, by using the calculated relative chemical shifts, a good agreement was obtained in all cases between the observed and predicted peak shape as shown in Fig. 6.

If we consider that the binding energy of the observed C 1s peak gives the average of the binding energies of the C 1s levels in the molecule, we can derive the following relation.

$$E_0 = E_{obsd} - \langle\Delta E\rangle \quad (7)$$

where $\langle\Delta E\rangle$ is the average of the relative chemical shifts calculated by Eq. 6. Using the observed C 1s binding energy and the calculated $\langle\Delta E\rangle$, we estimated E_0 for each compound. The results are given in the last column of Table 5. Note that the E_0 values thus obtained are about 292 eV in all cases. The above values are about 2 eV larger than the E_0 value which we have previously obtained for the monosubstituted benzenes. As we have already mentioned, E_0 is dependent partly on the relaxation energy which should, in principle, vary depending on the electronic structure of each molecule. One might reasonably assume that the contribution of relaxation energy is nearly the same for the molecules of the same type as in the case of monosubstituted benzenes. However, it can be appreciably different for the type of molecules studied here from that for benzene derivatives. Seemingly, the difference between the E_0 value obtained in the present study and that previously obtained for benzene derivatives, demonstrates the importance of the contribution of the relaxation energy.

TABLE 6. N1s BINDING ENERGY AND CNDO/2 CHARGE OF THE N ATOM OF C≡N GROUP

	N1s binding energy [eV]	CNDO/2 charge
CH_3CN	405.6	−0.160
CH_3CH_2CN	405.3	−0.162
$CH_2\text{=}CH(CN)$	405.3	−0.152
$\overset{CN}{\underset{NC}{CH\text{=}CH}}$	405.9	−0.140
C_6H_5CN	405.0	−0.166
(N_2	409.9	0.000)

For the four molecules studied here, one can not expect a splitting of N 1s level. In effect, N 1s spectrum appeared as a single sharp peak. The observed binding energies are given in Table 6. As compared with the N 1s binding energy of the nitrogen molecule (409.9 eV), the observed N 1s binding energy is smaller by more than 4 eV in the cases of acetonitrile, propionitrile and acrylonitrile, and by 3 eV in the case of fumaronitrile. This fact indicates that the nitrogen atoms of the C≡N group is negatively charged by considerable amount. This is consistent with the results of CNDO/2 calculation.

Core-electron peaks of XPS spectra are often accompanied by satellites associated with the shake-up or shake-off transitions. In the present study, a prominent satellite was able to be observed only in the case of the N 1s peak of fumaronitrile. In this case, a satellite band is at 4.5 eV from the main N 1s peak as shown in Fig. 7.

According to the theory based on the sudden approximation, the relative probability of a shake-up process which yields the final state Ψ_k where a secondary

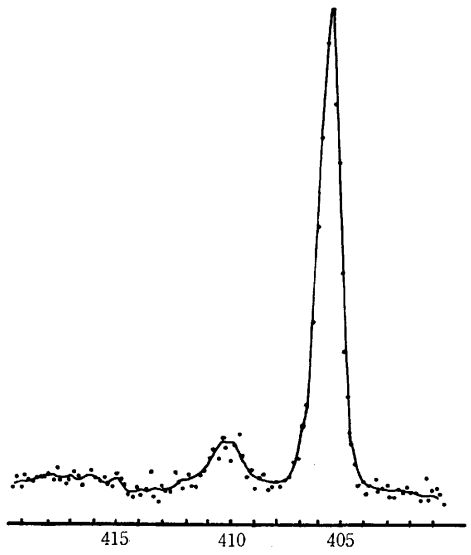

Fig. 7. N 1s spectrum of fumaronitrile: Note that there is a satellite peak at 4.5 eV from the primary peak.

excitation of a valence electron has occurred simultaneously with the photoionization of a core-electron level, can be given as follows;

$$P_k = |\langle \Phi_0 | \Psi_k \rangle|^2$$

where Φ_0 is the wave function of the core-hole ion, in which the valence-electron orbitals are taken the same as in the neutral molecule. By using the molecular orbitals obtained by CNDO/2 method,[15] we estimated the relative probabilities of various shake-up processes. In agreement with the observation, the above calculations predict the presence of a strong shake-up satellite only for the N 1s peak of fumaronitrile. In this case, the shake-up process associated with the lowest π-π^* transition was predicted to have probability of 10.8% relative to the total photoionization cross section of the N 1s level. No shake-up process is predicted to have a relative probability of more than 5% for the photoionizations of the C 1s levels of the same molecule. In the cases of the orther three molecules, all shake-up processes were predicted to have a relative probability of less than 5% for the ionizations of the C 1s levels as well as for those of the N 1s levels.

The Structure of the Cyclodextrin Complex. II. The Crystal Structure of α-Cyclodextrin-Methyl Orange (2 : 1) Complex

Kazuaki HARATA

Research Institute for Polymers and Textiles, Sawatari-4, Kanagawa-ku, Yokohama 221

(Received December 25, 1975)

α-Cyclodextrin(α-CDx) forms 2 : 1 complexes with Methyl Orange sodium salt (MONa) and Methyl Orange potassium salt (MOK). The structures were investigated by the X-ray method. The crystals of both complexes belongs to the orthorhombic space group $P2_12_12$ with $Z=2$; the cell dimensions are $a=22.099(6)$, $b=16.359(3)$, and $c=8.296(1)$ Å for the MONa complex, and $a=22.120(4)$, $b=16.419(4)$, and $c=8.292(1)$ Å for the MOK complex. Weak streaks were observed between the layer lines in the oscillation photographs around the c* axis. The structures were determined by using 1566 reflections for the MONa complex and 2544 reflections for the MOK complex, and were refined by the least-squares method to the final R-values of 0.11 and 0.10 respectively. α-CDx is a doughnut-shaped molecule with a large cavity. The crystals have channel structures built up by the stacking of α-CDx rings along the c axes. The Methyl Orange anions are located in the channel with a statistical disorder of four different arrangements. The azo group and the benzene ring are included in the cavity of α-CDx, but the dimethylamino and sulfonato groups protrude from the cavity and are in contact with the adjacent α-CDx rings. The azo group is located at the "neck" of the cavity. The sulfonato group is hydrogen-bonded to the primary hydroxyl groups of α-CDx. No significant structural difference was observed between the MONa complex and the MOK complex.

Cyclodextrins, which are cyclic oligosaccharides consisting of α-1,4-linked D-glucose residues, have a cavity in the center of the molecule and form inclusion complexes with a number of organic compounds. Lautsch and his co-workers have used cyclodextrin-dye complexes as an enzyme model.[1] Cramer *et al.*[2] have measured the rate constants and equilibrium constants for the association of α-cyclodextrin (α-CDx) with a series of azo dyes, and suggested that the dyes are enclosed in the cyclodextrin ring. They have also indicated that α-CDx and Methyl Orange can form complexes with higher stoichiometric ratio than a 1 : 1 ratio.

The crystal structures of several α-CDx complexes have been determined by X-ray analysis,[3-8] and it has been shown that the "guest" molecule is included in the cavity of α-CDx. α-CDx forms a 2 : 1 complex with Methyl Orange. The cell dimensions and the space group of Methyl Orange complex have been determined by McMullan *et al.*[9] and it has been suggested that the structure is of a channel type. The reported space group is $P2_12_12_1$, but we have found that the α-CDx-Methyl Orange complex crystallizes in the space group of $P2_12_12$, the same as that of the α-CDx-potassium acetate complex.[3] A Methyl Orange anion is longer than the depth of the cavity of α-CDx. Therefore, it is of interest to know in what manner Methyl Orange forms the complex with α-CDx. The present X-ray analysis was undertaken in order to find the geometry of the complex and the interaction between α-CDx and Methyl Orange. Both salts, sodium (MONa) and potassium (MOK), were studied in order to investigate the effect of cations in the complex structure.

Experimental

Crystals of α-CDx-Methyl Orange complexes, which were obtained by cooling a hot aqueous solution containing α-CDx and Methyl Orange with a 2 : 1 molar ratio, are orange prisms elongated along the c axis. The density was measured by the flotation method in a mixture of chloroform and hexane. On oscillation photographs around the c* axis, weak streaks were found between the layer lines, as is shown in Fig. 1. The intensity data were measured on a Rigaku AFC four-circle diffractometer with a 2θ-ω scanning mode. The crystal was enclosed in a quartz capillary with a small amount of solvent, since the crystal breaks up in air. For the MONa complex, 3108 independent reflections were obtained with a graphite monochromatized Mo$K\alpha$ radiation up to 50° in 2θ, by using a specimen with dimensions of $0.3\times0.5\times0.5$ mm, but 1542 reflections with $|F_o|<3\sigma(F)$ were considered to be unobserved. For the MOK complex, four sets of independent reflections were obtained with Cu$K\alpha$ radiation up to 120° in 2θ, by using two specimens with dimensions of $0.2\times0.4\times0.4$ mm and $0.3\times0.3\times0.4$ mm. By averaging the intensities of equivalent reflections, 2544 reflections with $|F_o|>3\sigma(F)$ were used for the structure determination. The usual LP corrections were applied, but no correction was made for absorption and extinction. The crystal data are shown in Table 1.

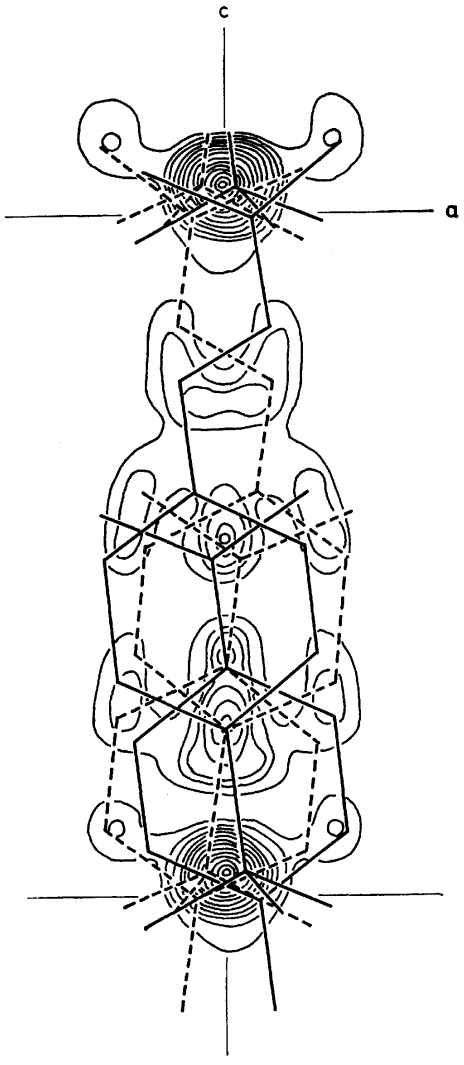

Fig. 2. The $Y=0$ section of a three-dimensional electron density map calculated by using the phases on the basis of α-cyclodextrin, showing Methyl Orange anion. The contours are at an arbitrary interval. The solid line represents a Methyl Orange anion and its shifted one overlapped in the same cell, and the broken line shows the anions related by the two-fold symmetry.

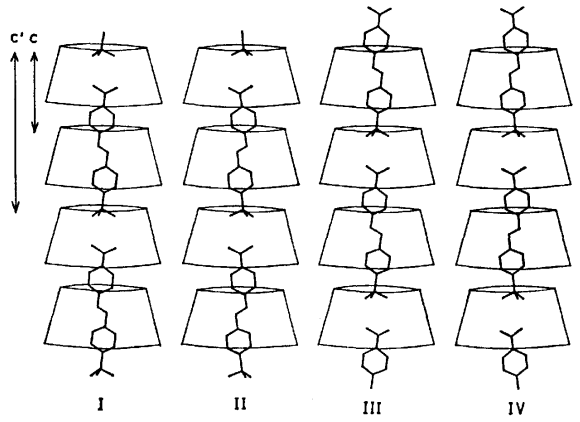

Fig. 3. Schematic drawings of the four arrangements of the Methyl Orange anion in the channel.

Determination and Refinement of the Structure

The cell dimensions of the crystals are similar to those of the α-CDx-potassium acetate complex[3] with the same space group. The potassium acetate complex gives $a=21.89$, $b=16.54$, and $c=8.30$ Å, and the space group is $P2_12_12$. Therefore, we considered that the framework of the crystal structure is the same as that of the potassium acetate complex. The positions and orientations of glucose residues were refined by the rigid-body least-squares method, starting from the same set of coordinates with the potassium acetate complex. Then, the parameters of each atom in α-CDx were refined by the block-diagonal least-squares method. At this stage, a Fourier map was calculated (Fig. 2). It showed that the Methyl Orange anion is located on the two-fold axis. The strongest peak was assigned to the sulfur atom of the sulfonato group; the arrangement of the anion was then considered to be as is shown in Fig. 2. The Methyl Orange anion is asymmetric, and in order to satisfy the two-fold symmetry required by the space group, the transposed structure must be considered. Since the length of the anion is nearly twice the c lattice unit, the shifted arrangement of anions along the c axis must be equally populated to accommodate a long molecule in a short cell. Therefore, the structure of the crystal must be

represented as a superposition of the four structures, I, II, III, and IV of Fig. 3, whose occupancies are 0.25 each.

The successive Fourier maps revealed the locations of the water molecules and cations. The cations are also statistically disordered with the population of 0.25, since there is only one Methyl Orange molecule in the unit cell in spite of four equivalent positions. On the electron density map, the sodium ion was not distinguished from water because of its low population. The location of the sodium cation was considered to be the same as that of the potassium cation, since no significant structural difference was observed between the MONa complex and the MOK complex. On

the difference-Fourier map, the residual electron density was observed near the position of the cation. We considered it to be a water molecule (O(W5)) which occupies the position with the occupancy of 0.75 when the cation is absent. The O(6) atoms in α-CDx were found to be disordered. The occupancies were estimated from the electron density map, but they were not refined.

At this stage, the positions, orientations, and thermal parameters of the SO_3^-, C_6H_4–N, and N–C_6H_4–N-$(CH_3)_2$ groups in Methyl Orange were refined by the rigid-body least-squares method. The bond distances and angles were those from Hanson.[10] In the successive block-diagonal least-squares refinement, the positional and thermal parameters of the Methyl Orange anion were fixed, since the absurd bond lengths of 1.2—1.7 Å were found in benzene rings when the atomic parameters of Methyl Orange anion were allowed to move. Hydrogen atoms can not be found on the difference-Fourier map, but the positions of the

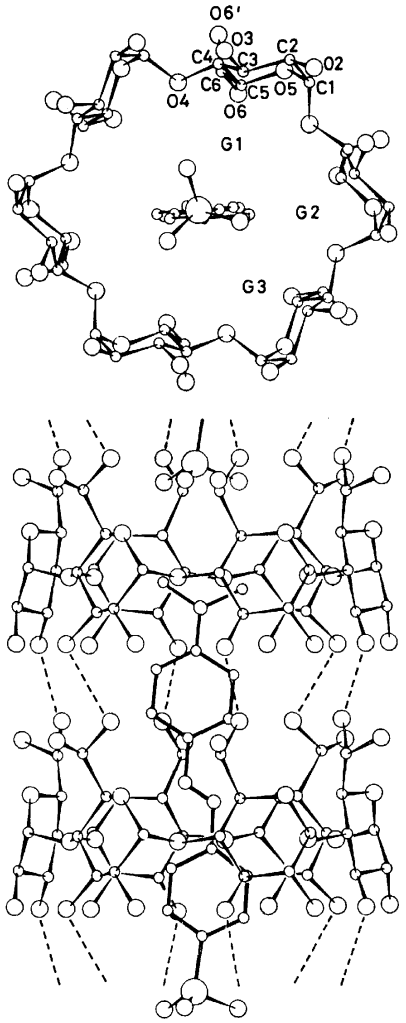

Fig. 4. The structure and numbering scheme of the complex. Dashed lines indicate O(3)···O(6) contacts.

hydrogen atoms attached to the carbon atoms in α-CDx were calculated and included in the structure factor calculation with isotropic thermal factors equal to those of the carbon atoms to which the hydrogen atoms are bonded. The final R-values were 0.11 for the MONa complex and 0.10 for the MOK complex. The quantity minimized was $\Sigma w(|F_o|-|F_c|)^2$ with $w=1.0$ for all the reflections used. The atomic scattering factors were taken from "International Tables for X-Ray Crystallography."[11] The atomic parameters are listed in Table 2, while the observed and calculated structure factors are given in Table 3.*

Description and Discussion of the Structure

The structure of the complex is shown in Fig. 4. Each glucose residue has the Cl chair conformation which is commonly found in α-CDx complexes. The α-CDx molecule is nearly hexagonal and has a two-fold symmetry axis. The α-CDx rings are stacked along the c axis with six hydrogen bonds which connect the O(3) with the O(6) of the adjacent α-CDx molecule, forming channels where Methyl Orange anions are located. The bond distances, angles, and conformation angles are listed in Table 4, the geometrical data for the α-CDx ring are given in Table 6, and the intermolecular distances less than 3.0 Å are shown in Table 7.

Bond Distances and Angles. No significant difference in bond distances and angles is observed between the MONa complex and the MOK complex. The C(1)–O(4*)–C(4*) angles of 117—121° are commonly observed values in α-CDx complexes. Similar values have been also observed in 1,4-linked disaccharides.[12–14]

In both MONa and MOK complexes, abnormally short distances are observed in the disordered C(6)–O(6) bonds. The effects of the thermal motion on the C(6)–O(6) and C(6)–O(6′) bonds were estimated according to Busing and Levy,[15] as is shown in Table 5. The shortening of C–O bonds may be ascribed to the riding motion, since the framework of the α-CDx ring is rigid. The corrected distances, however, are still too short, indicating that the correction for the riding motion is not strictly applicable in this case. The O(6) and O(6′) atoms are bonded to the C(6) atom, whose thermal motion is relatively large. The lower and upper limits for the corrected distances indicate that the effect of thermal motion is remarkably large. The normal C–O distance is found near the midst of the two limits or rather near the upper limit. Kim and Rosenstein[16] have found a similar phenomenon on the disordered C–O bond in α-L-sorbose; the C–O distances are 1.312 and 1.244 Å, and the C–C–O angles are 114.7 and 116.0°. They explained the shortening of the C–O bonds as being due to (1) the statistical overlap of the electron density of oxygen atoms with the hydrogen atoms attached to the carbon atom in the two disordered positions, and (2) a correlation of thermal displacements between C(6) and O(6), O(6)′ which has an effect similar to that of the anti-parallel thermal motion.

Conformation of α-Cyclodextrin. The glucose residues are in the Cl chair conformation and are α-1,4-linked. The disordered primary hydroxyl groups take two orientations: the C(6)–O(6) and C(6)-O(6′) bonds show *gauche-trans* and *gauche-gauche* conformations respectively. A similar disorder has been observed in the 1-propanol complex[7] and the *p*-iodoaniline complex.[8]

The macro-cyclic conformation of α-CDx is described by the conformation angles involving C(1)–O(4*)–C(4*) linkages: C(2)–C(1)–O(4*)–C(4*), O(5)–C(1)–O(4*)–C(4*)–C(1)–O(4*)–C(4*)–C(3*), and C(1)–O(4*)–C(4*)–C(5*). These angles in the Methyl Orange complexes are similar to those in the *p*-iodoaniline complex,[8] but a significant difference is observed in the water complex.[5] The two glucose residues in the water complex are inclined towards the inside of the cavity, thus reducing the empty volume and forming a hydrogen bond with water in it.

The α-CDx ring is distorted from the regular hexago-

nal symmetry. In the hexagon composed of O(4) atoms, the diagonal O(4,G3)···O(4,G3)* distance is longer by 0.8 Å than the O(4,G1)···O(4,G1)* distance (Table 6). In the 1-propanol complex, the diagonal O(4)···O(4) distances are 8.35—8.57 Å, indicating a nearly regular hexagon. In Methyl Orange complexes, the planarity of the six O(4) atoms is remarkably good; the deviation from the plane are less than 0.006 Å in the MONa complex and 0.012 Å in the MOK complex. In the other α-CDx complexes, the planarity is also rather good. The maximum deviations are 0.136 Å in the water complex, 0.144 Å in the 1-propanol complex, and 0.132 Å in the *p*-iodoaniline complex.

The α-CDx ring is tapered to the O(6) side. The diagonal distances of the cavity are smaller on the O(6) side than on the O(2), O(3) side (Table 6). Although the diagonal O(6)···O(6)* distances are shorter than the C(5)···C(5)* distances, the C(5)–H groups are oriented to the inside of the cavity and the diagonal H···H* distances are smaller than O(6)···O(6)* distances. This neck in the cavity is important in the geometry of the complex. The "guest" molecule may be included in the cavity to fit the slender part of the molecule to the "neck", as in the complexes with iodine and *p*-iodoaniline.

Geometry of Inclusion. The α-CDx molecules are stacked along the c axis to form endless channels with a head-to-tail arrangement, and the "guest" Methyl Orange anions are arranged in the channel. The azo group and one benzene ring are included

in the cavity; the azo group is located at the "neck" of the cavity. The dimethylamino and sulfonato groups protrude from the O(6) side and the O(2), O(3) side of the cavity respectively, and they are included in the cavities of the adjacent α-CDx molecules. The sulfonato group is located on the O(6) side of the cavity. In the potassium acetate complex, the acetate anion is located on the plane perpendicular to the c axis at a position similar to that of the sulfonato group. It is important that the ionized groups occupy the same position in both complexes, although the dimensions and shapes of the "guest" molecules are quite different. The sulfonato group may be hydrogen-bonded to the primary hydroxyl groups; the distances between oxygen atoms are 2.72, 2.89, 3.02, 3.11, 3.31, and 3.56 Å in the MONa complex, and 2.66, 3.01, 3.05, 3.08, 3.41, and 3.76 Å in the MOK complex. In the potassium acetate complex, the acetate anion is also hydrogen-bonded to four of the primary hydroxyl groups.

The Methyl Orange anion is almost planar except for the sulfonato group. The distortion of the hexagonal α-CDx ring may be ascribed to the inclusion of the bulky and planar "guest" molecule. A similar distortion has been observed in the *p*-iodoaniline complex.[8] The location of the benzene ring is nearly the same in the Methyl Orange complexes and in the *p*-iodoaniline complex. In both complexes, the longest diagonal O(4)···O(4)* distance is found to be nearly parallel to the benzene plane.

Crystal Structure. The framework of the crystal consists of stacked α-CDx molecules along the c axis.

The weak streaks observed in the oscillation photographs indicate that there is a repetition unit of c' which is twice as long as the c length. The Methyl Orange anion is nearly twice as long as the c length, so the repetition unit in one channel may be c' as is shown in Fig. 3. A structure analysis by taking the unit cell length of c' is possible, but we did not attempt it because

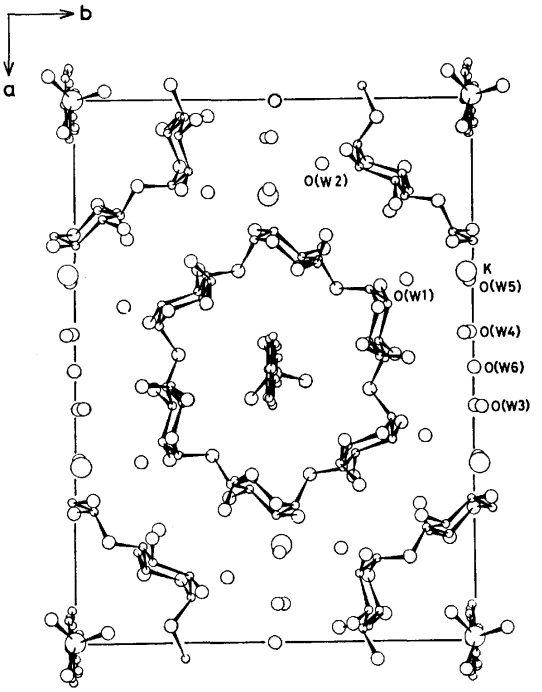

Fig. 5. The projection of the crystal structure of the α-cyclodextrin-Methyl Orange potassium salt complex along the c axis.

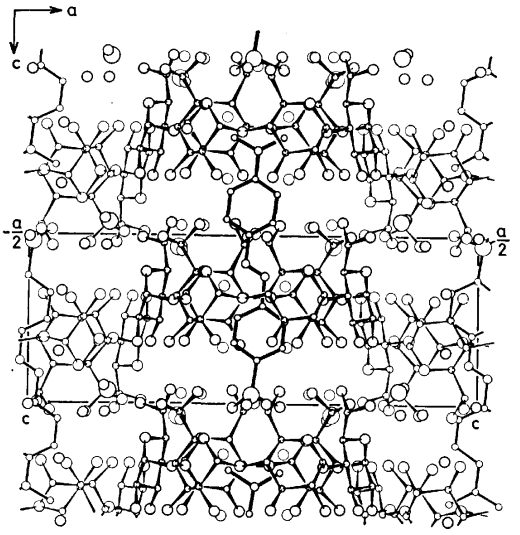

Fig. 6 The projection of the crystal structure of the α-cyclodextrin-Methyl Orange potassium salt complex along the b axis.

the reflections of $(l+1/2)$-th layers were so weak that no intensity measurement was tractable. The weak streaks can be explained if we assume some regularity that appears on the arrangements of the Methyl Orange anion, as is shown in Fig. 3. The disordered arrangements of "guest" molecules are plausible, since the inside of the channel has no contact with other channels. Therefore, the dimensions and shape of the "guest" molecule may be flexible in the channel-type structure, but the location of the ionized group may be very important because of the electrostatic interaction

Predictions of Molecular Geometries and Electronic Spectra of Complex Unsaturated Molecules from MC-LCAO-MO Method. II. 1,3-Butadiene and Cyclobutadiene

Mitsunobu NAKAYAMA, Moriyuki NISHIHIRA, and Yasumasa J. I'HAYA*

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

(Received December 26, 1975)

A multi-configuration (MC)-LCAO-MO method is applied to 1,3-butadiene and cyclobutadiene, predicting their molecular geometries and electronic spectra. The molecular ground state geometry, electronic spectrum and stabilization energy of the *trans*- to the *cis*-isomer of 1,3-butadiene are predicted to be in good accord with experiments and with those derived from the ordinary semi-empirical SCF-CI method. The results obtained for cyclobutadiene indicate that (a) the Jahn-Teller distortion occurs to favor a rectangular (D_{2h}) form, the stabilization energy being 0.3—0.9 eV depending on approximations, and (b) even in a square (D_{4h}) form a singlet (ground) state is more stable than a triplet state by *ca.* 0.3 eV. It is also shown that the lowest excited singlet and triplet states ($^3A_{2g}$ and $^1B_{1g}$) in the square form are not subjected to the Jahn-Teller effect. A discussion is given on a possible error in a CI treatment arising when degenerate molecular orbitals are expressed by real coefficients of atomic orbitals.

In previous papers,[1-4] a semi-empirical multi-configuration (MC)-LCAO-MO method in which a π-electron approximation is used was proposed in order to predict molecular geometries of ground and excited electronic states of unsaturated hydrocarbons, in particular those having open-shell MO's. The method was found to be useful, when applied to the benzene and triphenylene ions, for the examination of a static Jahn-Teller effect. One of the fruitful results obtained up to the present is that the method can be applied with the same degree of accuracy as the ordinary semi-empirical SCF-CI method to any unsaturated hydrocarbons independently of whether their electronic configurations are made up of closed shells or open shells and whether their MO's are degenerate or non-degenerate. This fact allows one to make use of the method securely for predictions of electronic structures of π-electron systems whose geometrical conformations are unknown.

The purpose of the present paper is twofold. One is to answer whether our MC-LCAO-MO method can be reliably used for predictions of molecular geometries and electronic structures of unsaturated open-chain molecules, thereby we have chosen 1,3-butadiene as a prototype of linear polyenes. As in the preceding paper[4] (called Part I of this series), we will compare the results obtained by our method with those of the usual SCF-CI calculation. We also discuss which isomer, *cis* or *trans*, is more stable.

The other is to complete our study of many years in a Jahn-Teller effect in unsaturated molecules by making use of the present method. We reported previously[5] a study of the effect in cyclobutadiene, which however was somewhat unsatisfactory in the selection of configuration functions taken for CI calculation and in the use of a bond order-bond length relationship that was found later to be not consistent with the whole scheme of the present MC-LCAO-MO method. Noting that there occur complicated CI mixings between different symmetry species of configuration functions when degenerate MO's are expressed by *real* coefficients of atomic orbitals, we carefully analyse the electronic structure of cyclobutadiene. We predict molecular geometry and spin multiplicity of the ground state, molecular geometries of some excited states, stabilization energies due to the Jahn-Teller effect and transition energies and oscillator strengths of square and rectangular cyclobutadiene.

Method of Calculation

In this section we will only give a brief outline of the method, the detail of which has been stated previously.

In order to construct a secular equation from which MO's are determined, we use throughout the calculation the formula

$$\alpha_p = -I_p - \sum_{q \neq p} (q : pp) \tag{1}$$

for the diagonal elements and the formulas

$$\beta_{pq} = \beta_0 \exp[-(r_{pq}-b)/a] \quad \text{(Approximation (1))} \tag{2a}$$

and

$$\beta_{pq} = -\frac{1}{2} K S_{pq}(I_p+I_q) \quad \text{(Approximation (2))} \tag{2b}$$

for the off-diagonal elements. Here I_p is an appropriate valence-state ionization potential of carbon p, (q : pp) the penetration integral, r_{pq} the carbon-carbon distance and S_{pq} is the overlap integral. The constants β_0, a, b, K, and I_p are set equal to the values -2.38 eV, 0.3938 Å, 1.397 Å, 0.86291, and 11.290 eV, respectively. Non-neighbor β_{pq}'s are also included.

The MO's thus obtained for a previously guessed molecular geometry are employed to calculate the matrix elements of the total Hamiltonian operator for CI mixing, in which the matrix elements of the one-electron Hamiltonian operator between MO's ϕ_i and ϕ_j are calculated to be

$$\varepsilon_{ij} = \delta_{ij}U_{ij} - \sum_p \sum_{q \neq p} C_{pi}C_{pj}(pp|qq) \tag{3}$$

where U_{ii} and C_{pi} are the eigenvalues and atomic orbital coefficients, respectively, of MO's ϕ_i. The two-center electronic repulsion integrals (pp|qq) are evaluated by the formula[6]

$$Z^{-1}(pp|qq) = 0.1227 - 0.005093\rho + 0.000070\rho^2 \tag{4}$$

(in a. u.) with $\rho = Zr_{pq}/a_0$. Here the effective nuclear

charge for carbon 2pπ AO's, $Z=3.250$, is assumed to be constant throughout the calculation and a_0 is the Bohr radius.

The π-bond orders P_{pq} obtained after each step of CI computation are used to revise the bond lengths in the next step of calculation through the relationship

$$r_{pq} = 1.523 - 0.193P_{pq} \quad (5)$$

and this process is repeated until a self-consistent solution is obtained with respect to bond lengths.

Electronic Structures of *trans*- and *cis*-1,3-Butadiene

To begin with, the MC-LCAO-MO method is applied to the calculation of the electronic structures of *trans*- and *cis*-1,3-butadiene; all the C–C–C bond angles are assumed to be 123° for both *trans*- and *cis*-butadiene. For comparison, the usual semi-empirical SCF-CI calculation is also carried out with the same atomic integrals, values of constants and species of configuration functions as in the MC-LCAO-MO method. The C–C bond lengths and C–C–C bond angles used in the SCF-CI calculation are taken from the experimental values obtained for the *trans*-isomer[7] (see the last column of Table 2), and assumed to be the same for the *cis*-form. The penetration integrals due to the hydrogen atoms are included for only nearest-neighbors, being given a constant value 0.627 eV.[6]

As shown in Table 1, the species of configuration functions employed in the CI calculation are classified according to the irreducible representations of the C_{2h} (*trans*) and C_{2v} (*cis*) symmetries. ϕ_i^k, ϕ_{ij}^{kl}, *etc.* are singly-, doubly-excited configuration functions, *etc.* (ϕ_i^k, for example, is constructed by promoting an electron in the occupied MO ϕ_i of the ground configuration ϕ_0 to the unoccupied MO ϕ_k) and are spin-eigenfunctions for the singlet and triplet states belonging to the corresponding symmetries. The explicit formulas of these singly- and doubly-excited configuration functions have been given previously[8]; triply- and quadruply-excited configuration functions are easily constructed in a similar way.

Table 1. Symmetry classification of configuration functions for *trans*- and *cis*-1,3-butadiene

C_{2h} (*trans*)	C_{2v} (*cis*)	Species of configuration function
^1A_g	$^1A_1$	ϕ_0, ϕ_2^4, ϕ_1^3, ϕ_{22}^{33}, ϕ_{22}^{44}, ϕ_{11}^{33}, ϕ_{11}^{44}, $\phi_{12}^{34}(1)$, $\phi_{12}^{34}(2)$, ϕ_{112}^{334}, ϕ_{122}^{344}, ϕ_{1122}^{3344}.
^3A_g	$^3A_1$	ϕ_2^4, ϕ_1^3, $\phi_{12}^{34}(I)$, $\phi_{12}^{34}(II)$, $\phi_{12}^{34}(III)$, ϕ_{112}^{334}, ϕ_{122}^{344}.
$^{1,3}B_u$	$^{1,3}B_2$	ϕ_2^3, ϕ_1^4, ϕ_{22}^{34}, ϕ_{11}^{34}, ϕ_{12}^{33}, ϕ_{12}^{44}, ϕ_{122}^{334}, ϕ_{112}^{344}.

Table 2. Bond lengths of 1,3-butadiene (Å)

Bond	Approximation (1)[a]		Approximation (2)[a]		Exptl.[7] (122.86°)[b]
	trans-	*cis*-	*trans*-	*cis*-	
1—2, 3—4	1.3454	1.3453	1.3484	1.3479	1.3439
2—3	1.4716	1.4713	1.4648	1.4659	1.4672

a) The columns under Approximation (1) and Approximation (2) are the results calculated with Eqs. 2a and 2b in the text, respectively. b) Observed C–C–C bond angle.[7]

In Table 2 are shown the bond lengths finally obtained for the ground states of *trans*- and *cis*-1,3-butadiene together with the corresponding observed values. It is found that the calculated values are in good accord with experiments.

The total energies for the two isomers of 1,3-butadiene are evaluated as

$$E_t = E + V. \quad (6)$$

Here the total electronic energy E is assessed through the formula

$$E = E_\pi + E_\sigma + E_c \quad (7)$$

where E_π and E_σ are, respectively, the π-electron and σ-electron energies to be obtained by the MC-LCAO-MO and/or the SCF-CI methods (the explicit forumla of E_σ depending upon bond lengths is given in Ref. 1; the value of E_σ determined by a fixed molecular geometry is to be just added in a SCF-CI calculation) and E_c is the sum of the effective internuclear interaction between π-electronless carbon cores and assumed to be

$$E_c = \sum_{p<q}\sum (pp|qq). \quad (8)$$

The term V is the sum of the energies due to the internuclear interactions between the non-neighbor carbon and hydrogen atoms (V_{CH}) and between the hydrogen atoms (V_{HH}), each being estimated according to Bartell's formulas[9] (in eV):

$$\left.\begin{aligned} V_{CH} &= 5.419[358\exp(-r/0.490) - 1]r^{-6} \\ V_{HH} &= 285.9\exp(-r/0.245) - 2.135r^{-6}. \end{aligned}\right\} \quad (9)$$

The C–H bond length is taken to be 1.094 Å.[7]

Table 3 gives the energy differences between *trans*- and *cis*-1,3-butadiene in their ground states calculated by the MC-LCAO-MO and the SCF-CI methods. The two methods predict the same result that the *trans*- is energetically more stable than the *cis*-species, though the difference in E appears to be negligibly small and the main term comes from the energy difference in V. The stabilization energies 0.11 eV calculated with Approximation (1) and 0.14 eV with Approximation (2) well compare with the value 0.12 eV obtained by a non-empirical SCF πMO method with a correction for nuclear repulsion[10] and with the value 0.22 eV obtained by an *ab initio* SCF-CI method.[11] The corresponding observed value is 0.10 eV, which was obtained a long time ago.[12]

Table 4 shows the calculated transition energies and oscillator strengths of the singlet and triplet transitions in 1,3-butadiene, together with the observed values. The MO's and the molecular geometries used are those obtained in the ground state calculation and the species of configuration functions listed in Table 1 are employed for the CI calculation. The first excited ^1A_g($^1A_1$ for *cis*) state comes out to be very close to the ^1B_u($^1B_2$ for *cis*) state which is to be expected as the lowest excited state and this is due to a strong interaction of the singly-excited configurations with the doubly-excited configurations, in the main with the configura-

a) This assignment appears to be incorrect.[13–15]

tion φ_{22}^{33}. A similar situation was found in an *ab initio* calculation.[11] As is well known, such lowering of the ^1A_g state is not obtained in the CI calculation in which only the singly-excited configurations are taken into account. Recent experimental[13] and more elaborate *ab initio*[14,15] studies of the electronic spectrum of *trans*-1,3-butadiene indicate that the transition in the 7.2 eV region should be assigned to a ^1B_u state of Rydberg character. We are not qualified for giving comments on this matter, since Rydberg-type transitions cannot be predicted by a minimal basis calculation such as the present treatment. The rest of the results shown in Table 4 appears to be in good agreement with experiments.

Electronic Structure of Cyclobutadiene

So far we have demonstrated that the present method is credible to reproduce the bond lengths and the electronic spectrum of 1,3-butadiene together with the stabilization energy of the *trans*-form against *cis*-, at least with the same accuracy as the usual SCF-CI method using a fixed molecular geometry. With this and accumulated confidence obtained in a series of papers hitherto, we challenge cyclobutadiene.

As for cyclobutadiene, if it exists as a stable entity, there are two problems of theoretical and experimental

interest: molecular geometry and spin multiplicity of the ground state. Up to date, various theoretical studies on cyclobutadiene have been carried out with CI[16-18] and without CI[19]; all of these results indicate that the molecule has a singlet ground state of a rectangular (the D_{2h} symmetry) form.[17-19] Recently, several authors[20,21] have reported studies of the photochemical synthesis and the infrared spectrum of cyclobutadiene and inferred its geometrical structure to be a square (the D_{4h} symmetry) form in its ground state. Cyclobutadiene, if it assumes to take a geometry of the D_{4h} symmetry, is considered theoretically to be subjected to the Jahn-Teller effect† in the ground and some excited states, because it has a pair of degenerate π-MO's partly occupied in the ground configuration.

In the following CI calculation for cyclobutadiene, we take account of all species of configuration functions which can be constructed by accommodating four π-electrons on four π-MO's, as in the case of 1,3-butadiene. The resulting configuration functions are classified into 20 singlets, 15 triplets and 1 quintuplet, the quintuplet state being not treated in the present study.

The four π-MO's are written, under the zero-differential overlap assumption, for cyclobutadiene of the D_{4h} geometry as in the following:

$$\left.\begin{array}{ll} a_{2u} & \phi_1 = \frac{1}{2}(\chi_1+\chi_2+\chi_3+\chi_4) \\ e_g & \left\{\begin{array}{l} \phi_2 = a(\chi_1-\chi_3) - b(\chi_2-\chi_4) \\ \phi_3 = c(\chi_1-\chi_3) + d(\chi_2-\chi_4) \end{array}\right. \\ b_{2u} & \phi_4 = \frac{1}{2}(\chi_1-\chi_2+\chi_3-\chi_4) \end{array}\right\} \quad (10)$$

where the orbital symmetries are determined by making use of the coordinate system shown in Fig. 1 and the MO's ϕ_2 and ϕ_3 are a pair of degenerate MO's. In the symmetry classification of configuration functions according to which each unit CI calculation is carried out, it should be noted that the irreducible representations to which some functions belong in the D_{4h} point group are varied depending upon whether the degenerate MO's are expressed by complex or real coefficients of atomic orbitals. This situation can be explained by taking up, for example, the singlet configuration functions having a g representation of the D_{4h} point group. If the degenerate MO's are expressed through the *complex* coefficients determined by the symmetry, that is, if the coefficients in Eq. 10 are set as $a=c=1/2$ and $b=d=-i/2$ (i: imaginary), then the species of configuration functions are classified as in Table 5. (Here we assume the ground configuration ψ_0 as $(\phi_1^2\phi_2^2)$, and as for the full symmetry classification of the other singlet and triplet configuration species,

† A word "second-order" or "pseudo" Jahn-Teller effect is sometimes used for the stabilization due to the second-order terms of an expanded Hamiltonian operator for the electronic motion in the field of nuclei. The ground state ($^1B_{1g}$) of cyclobutadiene is actually the case. On the other hand, the excited states ^1E_u and ^3E_u of cyclobutadiene receive the "first-order" Jahn-Teller effect. We hereafter use only the word "Jahn-Teller effect" for both ground and excited states of cyclobutadiene.

A_{2g}: $\psi_1^4-\psi_{122}^{334}$.

see Refs. 5 and 16). On the other hand, if the MO's are *real* and all the coefficients a, b, c, and d are set equal to 1/2, then the symmetry species are determined as in Table 6. It should be noted that the species of the A_{1g} and B_{1g} configuration functions shown in Table 5 are different from the corresponding ones listed in Table 6. Furthermore, when the coefficients in the real MO's are set as $a=d$ and $b=c$ but $a\neq b$, the configuration species of the A_{1g} and B_{1g} symmetries shown in Table 6 mix partly with those of A_{2g} and B_{2g}, respectively, and the CI mixings to be allowed become more complicated.

In the previous study on cyclobutadiene,[5] we have carried out each unit CI computation by making use of the symmetry species of configurations classified as in Table 5, despite of the fact that the degenerate MO's used are real. This probably led to an unsatisfactory result not only in the symmetry assignment of the electronic states but also in the magnitudes of the transition energies. In the present study, therefore, we have chosen all the 12 configuration functions having a g representation for a unit CI calculation, from which the eigenvalues and eigenfunctions of the singlet A_{1g}, A_{2g}, B_{1g}, and B_{2g} states are obtained. As for the other states, 7 and 8 configuration functions are taken for the triplet g state and the singlet and triplet u states, respectively.

Table 7 shows the bond lengths obtained for the square and rectangular forms together with the corresponding π-bond orders. It is found that the lowest $^3A_{2g}$ and $^1B_{1g}$ states in the square form are not subjected to the Jahn-Teller distortion; that is, self-consistent solutions do not converge to a rectangular form but to the square form. A similar situation has been seen in the lowest excited states of the benzene anion and cation.[1,2] This is caused by the fact that the configuration ψ_2^3 shown in Table 6 is the main term in the CI mixing and gives a bond-order distribution which favors a square geometry.

	ΔE[a]	ΔE_π	ΔE_σ	ΔE[a]	ΔE_π	ΔE_σ
$^1B_{2g}$	0.000	0.000	0.000	0.000	0.000	0.000
$^3A_{2g}$	0.272	0.247	0.025	0.306	0.250	0.056
$^1A_{1g}$	1.291	1.339	−0.048	1.195	1.336	−0.141
$^1B_{1g}$	1.616	1.502	0.114	1.766	1.535	0.231

a) Energy difference referred to the $^1B_{2g}$ state, $E=E_\pi+E_\sigma$.

In Table 8 are shown the energy levels obtained for the lower electronic states of cyclobutadiene in the D_{4h} geometry given in Table 7. The energy differences due to the term E_c in Eq. 7 were omitted, since they were found to be negligibly small. Table 8 shows that the $^1B_{2g}$ state is more stable than the $^3A_{2g}$ state by *ca.* 0.3 eV, that is, the ground state of cyclobutadiene is likely to be the singlet state in the D_{4h} geometry rather than a triplet state. This result is consistent with what obtained by Buenker and Peyerimhoff,[17] except that in their prediction the $^3A_{2g}$ state has a slightly rectangular equilibrium form, but conflicts with that of Dewar *et al.*;[19] the latter authors have predicted the triplet to be more stable than the singlet in a square form.

The instability due to the Jahn-Teller effect is calculated for the ground ($^1B_{2g}$) state and the lowest excited states (^1E_u and ^3E_u) in the D_{4h} geometry. The entries in Table 9 are the energy differences, $\Delta E=\Delta E_\pi+\Delta E_\sigma$, between the corresponding species of the D_{2h} and D_{4h} geometries. The table shows that cyclobutadiene is no doubt subjected to the Jahn-Teller distortion in the ground and some excited states and the singlet ground state of the rectangular form is energetically most favorable. The latter conclusion agrees with those of all the other theoretical studies in the past,[17-19] but is not in accord with the recent experimental inferences[20,21] which indicate that the molecule should prefer a square rather than a rectangular form, probably in its ground state.

The previous study on cyclobutadiene,[5] in which the CI treatment was considered to be incomplete as mentioned above, misassigned the singlet A_{1g} and B_{1g} states of D_{4h}-cyclobutadiene and predicted the lowest $^1B_{1g}$ state to be slightly lower than the lowest $^1A_{1g}$ state. However, the conclusion on the Jahn-Teller effect in cyclobutadiene obtained in the previous study is essentially consistent with that mentioned above, though the previously obtained stabilization energy for the ground state is less than the present value by 0.2 eV.

Lastly, we show the calculated results for transition energies and oscillator strengths of the D_{4h} and D_{2h} species of cyclobutadiene. The MO's and the molecular geometries used are those obtained for the singlet ground states of both species. Table 10 lists a part of the results obtained from the full CI calculation. There can be seen a fairly definite difference between the energies of the lower excited states calculated under Approximations (1) and (2) in the D_{2h} geometry. This difference is mainly caused by the fact that Approximation (1) leads the ground state of cyclobutadiene to receive a more remarkable Jahn-Teller distortion in its molecular geometry and energy than Approximation (2) (*cf.* Tables 7 and 9).

The results listed in Table 10 are partly in agreement with those obtained by Allinger and Tai;[18] in particular, the singlet spectrum of the square form resembles each other. Though we have no experimental datum to compare with our prediction, we feel confident that

the electronic spectra calculated for the square and rectangular forms of cyclobutadiene are about right from the viewpoint that the same method has been successful in reproducing the observed data for 1,3-butadiene and other unsaturated hydrocarbons.

Conclusion

The results obtained so far are summarized as in the following:

(a) The MC-LCAO-MO method can be applied, with about the same degree of accuracy as the usual semi-empirical SCF-CI method with fixed molecular geometry, to predictions of molecular geometries and electronic spectra of linear polyenes as well as cyclic polyenes, independently of whether configurations are made up of closed-shells or open-shells and whether MO's are degenerate or non-degenerate.

(b) The *trans*-1,3-butadiene is predicted to be stable than the *cis*- by 0.11—0.14 eV.

(c) The ground $^1B_{2g}$ state of square cyclobutadiene lies below the $^3A_{2g}$ state by 0.3 eV.

(d) The lowest $^3A_{2g}$ and $^1B_{1g}$ states in the square form are not subjected to the Jahn-Teller distortion.

(e) The Jahn-Teller distortion occurs to favor rectangular cyclobutadiene which has a singlet ground state, bond length expansion and contraction being 0.09 Å for the ground state and 0.04 Å for the lowest excited degenerate singlet and triplet states.

(f) The stabilization energy due to the Jahn-Teller effect for the ground state of cyclobutadiene is predicted to be 0.6 eV on the average, depending upon the approximation for the two-center core resonance integral.

An additional remark is as follows: When one uses degenerate MO's expressed by *real* coefficients of atomic orbitals, all the g (or u) state functions having the same multiplicity are recommended to be taken together in each unit CI calculation.

Hybridization in Some Three-Membered Ring Organic Molecules

Hiroshi FUJIMOTO, Tsutomu MINATO, Satoshi INAGAKI, and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 26, 1975)

The molecular structures of some simple three-membered ring compounds, cyclopropane, cyclopropanone, ethylene oxide and ethylenimine, were studied by means of the orbital interaction between the fragments of a molecule. The relation between the carbon-carbon distance and the bending angle of the carbon-hydrogen bonds in ethylenic part of the three-membered rings is attributed primarily to the greater extent of mixing of the unoccupied π-like MO of ethylenic fragment into the occupied MO's of rings. The increase in the bending angle as going from ethylene oxide to cyclopropane is interpreted in terms of the interaction of an occupied σ-like orbital with the unoccupied π-like orbital of ethylenic fragment through the overlap with the orbital(s) of the residual part of rings. INDO MO and localized orbital calculations support the orbital interaction scheme. The same conclusion is derived also from the electrostatic theory of molecular geometries.

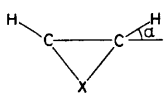
The differences in the structures of some three-membered ring molecules containing sulfur can be rationalized from the viewpoint of orbital interaction between the fragments, generated by a partitioning of the rings.[1] Thus, the long carbon-carbon bond in ethylene episulfone (1.590 Å)[2] in comparison with that in ethylene episulfide (1.492 Å)[3] was ascribed to the stronger interaction between ethylenic fragment and SO_2 than that between ethylenic fragment and sulfur orbitals. Although such an analysis is crude, it provides us with a theoretical insight into molecular geometry and suggests that, in some cases, the structure of molecules can be predicted simply by investigating the mode of orbital interaction between fragments.[4] In addition, the concept of orbital interaction primarily introduced in the theory of intermolecular interactions could be further extended to various chemical problems concerning the structure of molecules.[5]

We have developed a method for discussing the differences in the hybridized states of carbon atom in some simple three-membered ring molecules. The structures of cyclopropane, cyclopropanone, ethylene oxide and ethylenimine are given in Table 1.[6] The angle α, determined by the methylene plane and the carbon-carbon bond axis, increases with an increase in the carbon-carbon bond distance. The general tendency of the change in the bond distances with the change in hybridized states was studied by Bent, based on experimental observations.[7] The relation between the angle α and the bond distance of three-membered rings may be of interest for an MO theoretical study, since we frequently encounter similar problems in organic and inorganic chemistry.

Table 1. MOLECULAR STRUCTURES

	C–C Distance	Bending angle α
Cyclopropane	1.51 Å	30°
Cyclopropanone	1.575Å	29°7′
Ethylene oxide	1.472Å	20°36′
Ethylenimine	1.48 Å	20°36′[a]

a) Assumed.



Orbital Interaction

Let us consider the orbital interaction in three-membered ring molecules CH_2CH_2X (X=>CH_2, >C=O, >NH, >O). We proceed in our usual way first by dividing the ring into two parts, the deformed ethylenic part and X.[1] The rehybridization can appropriately be represented by the "sigma-pi" interaction between the σ-like part and π-like part of the ethylenic fragment.[8,9] A stronger interaction indicates a greater rehybridization. The mode of orbital interaction chiefly responsible for the differences in the structure of the rings is illustrated in Fig. 1.[10] We have three significant MO's, ψ_1, ψ_2 and ψ_3, each consisting of the occupied σ and the unoccupied π^* MO's of the ethylenic fragment and an orbital λ of X. All of them are antisymmetric with respect to the plane, bisecting the ring. Figure 2 shows schematically the ways of mixing these three basis MO's to yield the

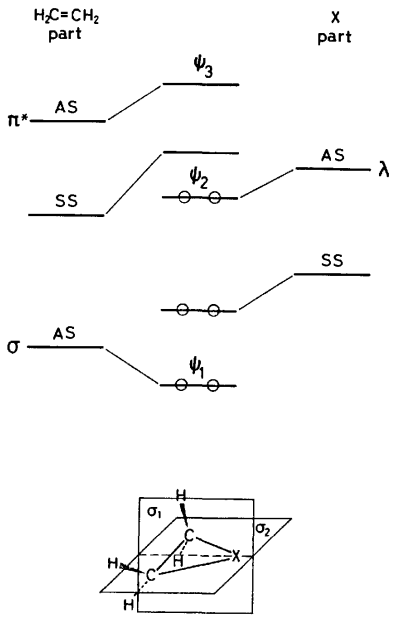


Fig. 1. A schematic illustration of orbital interaction between the fragments of three-membered rings.

Table 2. σ-π^* Mixing in ψ_1 and ψ_2 (ψ_2')

		Coefficient of σ	Coefficient of π^*	Product of coefficients	Orbital energy(λ)
Cyclopropane	ψ_1	0.9462	0.0977	0.0924	2.05 eV
	ψ_2	−0.2986	0.6295	−0.1880	
Cyclopropanone	ψ_1	0.8954	0.1336	0.1196	4.58 eV
	ψ_2'	−0.1318	0.6093	−0.0803	
	ψ_2	−0.4042	0.3261	−0.1318	
Ethylene oxide	ψ_1	0.9531	0.0982	0.0936	0.10 eV
	ψ_2	−0.2927	0.5336	−0.1571	
Ethylenimine	ψ_1	0.9560	0.0900	0.0860	1.73 eV
	ψ_2	−0.2779	0.5801	−0.1612	
			Orbital energy of π^*		3.95 eV

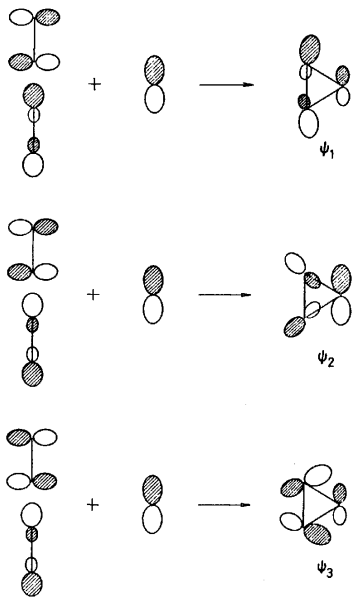

Fig. 2. The modes of orbital mixing.

MO's ψ_1, ψ_2 and ψ_3 of the composite system. The signs of the MO's σ and π^* were chosen in such a way as for both of them to have positive overlap integrals with the ortital λ. We then have no phase dislocation in ψ_1, one in ψ_2, and two in ψ_3.

Table 2 gives the products of the mixing coefficients of σ and π^* in ψ_1 and ψ_2 (and ψ_2' for cyclopropanone). The MO's were calculated by the INDO MO method,[11] and the expansion of the composite MO's in terms of the MO's of the fragments was carried out in the same way as in our previous works.[12] The remaining composite MO ψ_3 is unoccupied and has nothing to do with the electronic structure of the rings.[13] The calculation was carried out on an assumed geometry of cyclopropane, cyclopropanone and ethylenimine, holding the same framework of the ethylenic fragment as that in ethylene oxide. Greater extents of mixing of σ and π^* are observed in cyclopropane and cyclopropanone than in ethylene oxide and ethylenimine. It is noteworthy that the differences in the magnitude of the σ-π^* interaction are mainly attributed to ψ_2. This can readily be understood from the relative energy levels of σ, π^* and λ (Table 2) by application of simple MO perturbation theories.[14]

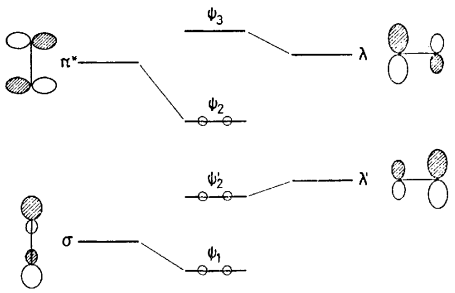

Fig. 3. The orbital interaction in cyclopropanone.

As the level λ comes closer to π^* in energy ($\varepsilon_\lambda < \varepsilon_{\pi^*}$), the contribution of π^* to ψ_2 becomes greater. If the MO λ happens to be higher than the π^* MO, the latter will be the dominant term in ψ_2. As a consequence, a greater extent of occupation of π^* results in the longer carbon-carbon bond and, at the same time, in a greater "sigma-pi" interaction. In the case of cyclopropanone, the high lying MO λ due to the anti-bonding property of the C=O bond would favor a greater contribution of π^* to ψ_2 and ψ_2' giving rise to the extraordinarily long carbon–carbon distance (Fig. 3). The σ-π^* mixing, however, is compatible with that in cyclopropane. Thus, the increase in α along with the stretching of the carbon-carbon bond can be generalized on the concept of the orbital interaction between the fragments.

Localized Orbitals

In order to work out the above reasoning quantitatively, we calculated the electron density of cyclopropane and ethylene oxide. Figure 4 shows the density distribution of valence electrons on the molecular plane. For the sake of comparison cyclopropane was subjected to such a deformation that the ethylenic fragment has the same nuclear framework as that of ethylene oxide. The points with the maximum electron densities in the carbon-hydrogen and the carbon-carbon bond regions are plotted. In cyclopropane, the locus of the maximum density extends from the carbon atom with somewhat larger α than that in ethylene oxide. In order to visualize this clearly, we transformed the MO's of cyclopropane and ethylene oxide into the localized orbitals, according to the

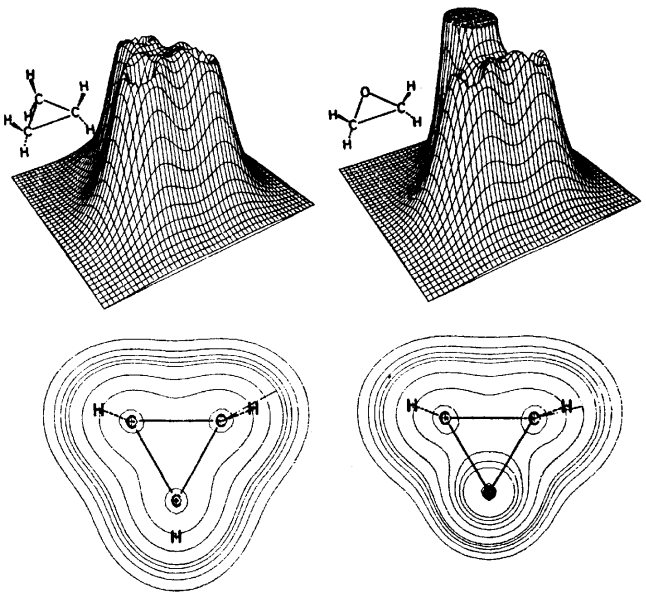

Fig. 4. The electron density distribution in cyclopropane and ethylene oxide.

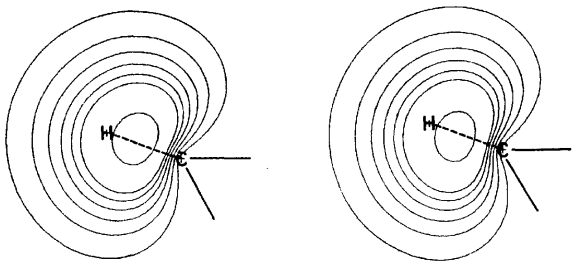

Cyclopropane Ethylene oxide

Fig. 5. The carbon-hydrogen bond orbitals in cyclopropane and ethylene oxide.

criterion postulated by Edmiston and Ruedenberg.[15] Figure 5 shows the cross sections of the localized MO's for a carbon-hydrogen bond on the ring plane. It is clear that the carbon-hydrogen orbital of cyclopropane tends to point to the "normal direction", opposing the geometrical constraint imposed upon the ethylenic fragment. To attain maximum bonding, the hydrogen resides in a position of a larger α than that assigned originally.

The localized orbital of cyclopropane is calculated to be

$$\phi_{C-H}(C_3H_6) = 0.390C_s + 0.298C_x + 0.476C_y - 0.148C_z + 0.709H_s - 0.011\lambda + \cdots\cdots$$

and the one for ethylene oxide is given by

$$\phi_{C-H}(C_2H_4O) = 0.412C_s + 0.299C_x + 0.474C_y - 0.083C_z + 0.711H_s - 0.007\lambda + \cdots\cdots$$

where C_s, C_x, C_y and C_z indicate the carbon 2s, $2p_x$, $2p_y$, and $2p_z$ atomic orbitals, respectively, and H_s denotes the hydrogen 1s atomic orbital. We see that the bond orbital of cyclopropane has a greater p_z component than that of ethylene oxide. By expanding the orbitals in terms of the MO's of the fragment, we obtain

$$\phi_{C-H}(C_3H_6) = 0.343\sigma + 0.089\pi^* + \cdots\cdots$$

and

$$\phi_{C-H}(C_2H_4O) = 0.356\sigma + 0.050\pi^* + \cdots\cdots$$

The σ-π^* mixing is more favorable in cyclopropane than in ethylene oxide, as was expected qualitatively from the consideration of the orbital interaction between the fragments.

In the above calculation, cyclopropane was compressed to have an unrealistic ethylenic fragment. In spite of such an artificial choice of atomic coordinates, the results of the calculation appear to be reasonable. Our intuitive interpretation of the differences in the ring structures based on a rather crude orbital interaction scheme seems to be supported by detailed numerical calculations.

Electrostatic Interaction

In addition to the orbital overlap interaction, the electrostatic effect should be taken into account. With an increase in the electronegativity of X, the charge shift from the carbon atoms to X is strengthened. Accordingly, the electrostatic interaction between the hydrogen atoms and X will be larger as X becomes more electronegative. However, such an electrostatic term in a classical sense, arising from the Coulombic interaction of the net charges, would not be so important in this case, since hydrogens have small net charges in general. Much more important is the binding force exerted on nuclei, originating from the overlap density.[16] Here, the electrostatic theory of molecular configurations proposed by Nakatsuji[17] might be useful. As the ethylenic fragment is distorted from planar structure, the exchange force developed by the carbon-hydrogen bonds and the carbon-carbon bond will pull carbon atoms back to the plane defined by the four hydrogen atoms. Thus, the ethylenic fragment is likely to remain in a planar or less distorted structure, opposing the "sigma-pi" interaction.

Chemical interaction between two systems generally causes electron redistributions, accompanied by the formation of new bonds between reaction sites and the weakening of old bonds of reactants to be broken in the course of reaction. The origin of the electron redistribution was analyzed in detail based on the concept of configuration interaction in chemical reactions.[18] In this case, the π like bonding between the carbon atoms of the ethylenic fragment is loosened and new bonds are formed between the fragments. The electron shift from the carbon-carbon bond region to the carbon-X bond regions takes place not through the mutual charge-transfer interaction between the fragments but through the crossing of the AS and SS type MO's.[19] The overlap density accumulated in the bond region between a carbon and X would attract the carbon toward X. The attracting force gets stronger as the overlap density becomes greater. The difference in the magnitude of the overlap density is determined mainly by the orbital overlap interaction between the π^* MO of the ethylenic fragment and λ of X. Thus, the overlap density is predominantly governed by the product of the mixing coefficients of

π^* and λ in ψ_2. The mixing in of π^* into ψ_2 gets poorer as the energy level of λ becomes lower (Table 2). The greater the electronegativity of X, the lower the energy level λ. The greater electronegativity of X indicates the smaller overlap density in the carbon-X bond region and less distorted ethylenic fragment.

Conclusion

The coupling of a partitioning analysis and an MO expansion procedure seems to be powerful in accurately reproducing MO quantity in a chemically acceptable manner, since we can obtain the exact expressions of the MO's of the composite system in terms of the MO's of the fragments. This kind of approach to the physical and chemical properties of molecular systems would be promising in discussing small but significant differences in similar systems. A simplified interpretation in regard to the difference in hybridization of three-membered rings given here seems to be independent of the approximation employed for the MO calculation.

The present semiquantitative calculation and qualitative concept for interaction revealed that the shorter carbon-carbon distance and smaller bending angle α in simple three-membered ring systems could be ascribed to the greater electronegativity of the central atom or group X. The concept developed here may be applicable to other cases in which changes in valence angles with the change in substituent is noticeable.[20] The assumption of the same bending angle α in ethylenimine as that in ethylene oxide deserves reinvestigation.

The MO computation was carried out at the Data Processing Center, Kyoto University with financial support from the Ministry of Education.

9) Sigma-pi separability (P. G. Lycos and R. G. Parr, *J. Chem. Phys.*, **24**, 1166 (1956); **25**, 1301 (1956).) does not hold in a strict sense, since the ethylenic fragment of the three-membered rings has the C_{2v} symmetry but not the D_{2h} symmetry. However, when the deviation from the planarity is small, the MO's of the fragment can approximately be classified into π-like MO's and σ-like MO's, each corresponding to the π and σ MO's of planar ethylene.

10) Considerable contribution of the MO's with other symmetry properties to the determination of the structure of the rings can be found. This is the case in the three-membered rings where d orbitals are available for X. The mixing of σ and π^* would be of importance even in these systems.

Infrared Dichroism and Molecular Orientation of Ethyl 2-Hydroxyimino-3-oxo-3-phenylpropionate in Thin Films on Pd Metal Surfaces

Masatoshi Ōsawa, Aritada Hatta, Kaoru Harada*, and Wataru Suëtaka

Laboratory of Interface Science of Metals, Faculty of Engineering, Tohoku University, Aramaki, Aoba, Sendai 980

**Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari, Ibaraki 300-31*

(Received January 5, 1976)

The infrared absorption spectra of ethyl 2-hydroxyimino-3-oxo-3-phenylpropionate, in differently oriented films, formed on Pd metal plates, were measured by using the high-sensitivity reflection method. The thin crystal film **A** was formed when the solvent was evaporated from the thin liquid film remaining on Pd. On the other hand, the film **B** resulted from the crystallization of the amorphous solid film which was initially formed on Pd when the liquid film was thick. From the infrared dichroism in the reflection spectra, the molecular orientations in thin films were obtained as follows. In the film **A**, the ketone C=O and C=N bonds are probably at a pseudo *s-cis* and are aligned in such a way that the C–C bond connecting the ketone carbonyl group with the C=N group are nearly parallel to the Pd surface. The NO bond is aligned parallel to the metal surface. The ester group is oriented nearly vertical to the metal surface, the C=O bond lying tilted to the surface. In the film **B**, the ester C=O and NO bonds are aligned nearly perpendicular to the Pd surface, while the ketone C=O bond is not so. The C···C axis of the ester is rather parallel to the surface. The orientation in the thin film **A** agrees well with the hypothetical chelation model.

The reflection infrared spectroscopy using the beam polarized parallel to the plane of incidence at high incident angles[1] (the high-sensitivity reflection method) is a very powerful tool of investigating various surface phenomena. The best known example is the absorption of gaseous molecules on metal surfaces.[2] In this method, the enhanced oscillating electric field normal to the metal mirror surface serves not only to detect the species adsorbed on the metal surface but also to obtain informations about the orientation of the adsorbed species.[3] This reflection method is also used successfully for the study of thin films of organic crystals formed on metal surfaces.[4] When an organic crystal is grown on a metal surface, the interaction with the metal surface may result in polymorphism or preferred orientation.[5] The preferred orientation and in particular the anomalous crystal structure are generally stable when the film is very thin. Since the crystal grows at the molecule strongly adsorbed on the substrate surface, which acts as the nucleous, the orientation of molecules in thin film crystal may be governed by that of the adsorbed molecule.[6,7] The orientation of adsorbed molecule may, therefore, be deduced from the infrared dichroism of thin crystal film.

On the other hand, the asymmetric synthesis of amino acids by hydrogenolytic asymmetric transamination using Pd hydroxide catalyst has been extensively investigated by one of the authors (Harada) and his co-workers.[8] They found that optically active α-amino acids could be synthesized from the Schiff base of α-keto acids or their esters with optically active α-alkylbenzylamines by catalytic hydrogenation and subsequent hydrogenolysis. In order to explain the reaction mechanism, Harada *et al.*[8] proposed the "chelate hypothesis" that the intermediate five membered cyclic complex[9] with a metal atom of the catalyst could be formed and then adsorbed on the catalyst surface. The intermediate complex assumed in elucidating the hydrogenation of ethyl 2-hydroxyimino-3-oxo-3-phenylpropionate is shown in Fig. 1.[10] Although there has been no direct evidence of the existence of such the chelate ring complex, it is perhaps reasonable to assume that an intermediate on the heterogeneous catalyst plays an important role in the determination of conformation of the resulting product. In this connection, it is interesting to observe the infrared dichroism arisen from the molecular orientation in the thin crystals of the Schiff base compounds formed on a palladium metal surface, because the molecular orientation of the intermediate may be deduced from the orientation of ethyl 2-hydroxyimino-3-oxo-3-phenylpropionate in thin films formed on the Pd surfaces, which can be determined by the high-sensitivity reflection technique.

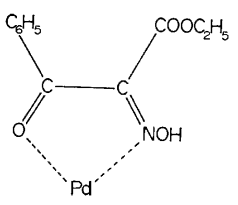

Fig. 1. Intermediate complex model.[10]

Experimental

The infrared spectra were taken by means of a JASCO IR-G grating spectrophotometer with an assembly of JASCO model PR-41 for double beam reflection. The sample of ethyl 2-hydroxyimino-3-oxo-3-phenylpropionate was prepared according to the method given in literature.[11] Pd plates (99.9% in purity) were used as substrate. To obtain high reflectivity, the Pd plate was polished with silicon carbide and chromium oxide to its maximum flatness. After treating with 20% NaOH aqueous solution at 80 °C, the Pd plate was subjected to ultrasonic cleaning for *ca.* 30 min in distilled water to remove remaining alkali and air dried. The Pd plate was then immersed into a 0.5% ethanol solution of the Schiff base. After standing for 24 h or more at 5 °C, the Pd plate was taken out of the solution, and was dried in air. Thin films of the compound were formed on the plates upon evaporation of solvent. Unstable amorphous or stable crystal films were obtained depending upon the quantity of the solution remaining on the Pd surfaces, as will be described below.

Results and Discussion

Assignments of vibrational bands. Since no infrared spectrum of ethyl 2-hydroxyimino-3-oxo-3-phenylpropionate, $C_6H_5COC(NOH)COOC_2H_5$ (abbreviated as EHOP) has appeared in literature, the infrared absorption bands of this compound must be assigned before the orientation of its molecule will be discussed. The assignment of the infrared bands of EHOP was made principally on the basis of comparison with the spectra of closely related compounds, $C_6H_5COC(NOH)COOCH_2C_6H_5$ (BHOP) and $CH_3COC(NOH)COOCH_2C_6H_5$ (BHOB), and their O-deuterated species.

Figure 2 shows the absorption spectrum of EHOP, obtained in KBr pellet in the range between 4000 and 600 cm^{-1}. The moderately strong band with maximum at 3310 cm^{-1}, which shifted on deuteration to 2445 cm^{-1}, can be assigned to the OH stretching vibration. A sharp band due to the free OH group was observed at 3555 and 3530 cm^{-1} in dilute CCl_4 and CS_2 solutions, respectively, and no band could be observed around 3310 cm^{-1}. The 3310 cm^{-1} band observed in the solid state is, therefore, certainly attributable to the intermolecular hydrogen bonded OH group. The strong bands at 1735 and 1675 cm^{-1} are assigned to the carbonyl stretching of ester and ketone, respectively.[12] Similar bands are observed in the solid state spectra of BHOP (1728 and 1682 cm^{-1}) and BHOB (1740 sh, 1732, and 1690 cm^{-1}).

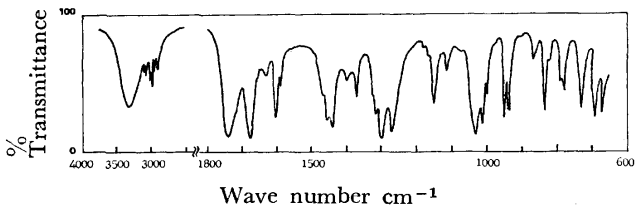

Fig. 2. Infrared absorption spectrum of $C_6H_5COC(NOH)COOC_2H_5$(KBr).

In most oximes, the C=N stretching band[13] appears at 1618—1660 cm^{-1}. This band corresponds to the weak one observed at 1627 cm^{-1} in this molecule. The weakness and low frequency of the C=N stretching band are probably due to the conjugations between the adjacent C=O groups.[14] The 1438 cm^{-1} band, which shifted to 1094 cm^{-1} on deuteration, is assigned to the OH in-plane deformation vibration.

In the region between 1300 and 1000 cm^{-1}, two intense bands are expected to appear,[12] *viz.*, the vibrations of ester C–O–C antisymmetric stretching and phenyl-carbonyl C–C stretching vibrations. EHOP does really give two strong bands, at 1298 (vs) and 1272 cm^{-1} (s), as is shown in Fig. 2. The 1298 cm^{-1} band disappeared on conversion of the ester group into COO^- group, while the 1272 cm^{-1} band remained unchanged. Therefore, the former band can be ascribed to the ester C–O–C antisymmetric stretching vibration and the latter to the phenyl–carbonyl C–C stretching vibration. This assignment is supported by the fact that BHOP also gives bands at similar frequencies, *i.e.*, at 1288 (vs) and 1273 (s), but BHOB shows only one band at 1240 cm^{-1} (s) around 1300 cm^{-1}.

Table 1. Observed frequencies and assignments of EHOP

Frequency (cm^{-1})	Assignment
3310 m	bonded OH str. (2445)
1735 s	ester C=O str.
1675 vs	ketone C=O str.
1627 vw	C=N str.
1597 m	phenyl ring
1583 w	phenyl ring
1452 sh	phenyl ring
1448 m	CH_3 asym. def.
1438 m	OH in-plane def. (1094)
1370 w	CH_3 sym. def.
1322 sh	CH_2 def.
1313 m	CH_2 def.
1298 vs	ester C-O-C anti-sym. str.
1272 s	phenyl-carbonyl C-C str.
947 m	OH out-of-plane def. (635)
935 m	NO str. (930)
693 m	phenyl C-H out-of-plane def.

Values in parentheses correspond to the peaks of O-deuterated compound.

Oximes give bands, in a range of 1000—900 cm^{-1} due to the NO stretching and OH out-of-plane deformation vibrations.[15] Because the band at 947 cm^{-1} decreased in intensity on partial deuteration and at the same time a new band appeared at 635 cm^{-1}, the 947 cm^{-1} band can be assigned to the OH out-of-plane deformation. The band at 935 cm^{-1} which shifted slightly toward lower frequency on deuteration may be attributed to the NO stretching, because the vibration is expected to be somewhat coupled with the OH in-plane deformation vibration. The assignments thus obtained are collected in Table 1.

Molecular Conformation. When EHOP was dissolved in CCl_4, the ester carbonyl band split into a doublet at 1752 and 1726 cm^{-1}. The doublet was also observed with BHOP at 1752 and 1725 cm^{-1} (see Fig. 3). Since the molecules are essentially free in the above mentioned dilute solutions, the observed bands at 1752 and 1726 cm^{-1} can be assigned to the nonbonded carbonyl group of ester.

It is well known that, in α,β-unsaturated carbonyl compounds, the carbonyl stretching band often splits in dilute solution into two bands corresponding to two rotational isomers. An example is seen in benzalacetone in CCl_4 solution.[16] Cromwell *et al.* ascribed to the band appearing at a high frequency to the *s-cis* form and the low frequency one to the *s-trans* form. By analogy, we assigned the 1752 and 1726 cm^{-1} bands mentioned above to the *s-cis* and *s-trans*, respectively (see Fig. 4). In the case of BHOB, solid state spectrum showed a doublet at 1740 (sh) and 1732 cm^{-1}, both ascribed to the carbonyl stretching of ester, while no doublet was observed in CCl_4 dilute solution but the ester carbonyl stretching band appeared at 1754 cm^{-1}. From its position, the 1754 cm^{-1} band is to be attributed

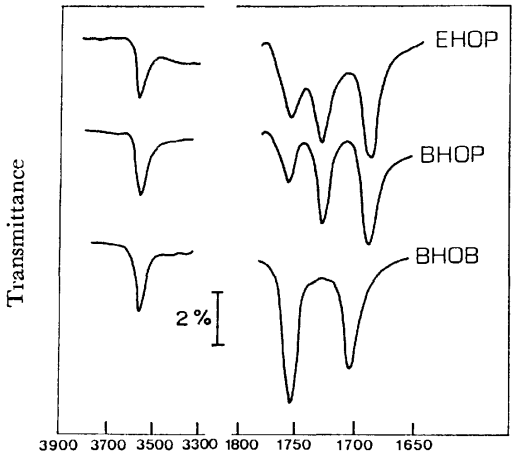

Fig. 3. Infrared spectra of ethyl 2-hydroxyimino-3-oxo-3-phenylpropionate (EHOP) and related compounds in 1×10^{-3} molal solutions in CCl_4 (0.5 mm layer): EHOP = $C_6H_5COC(NOH)COOC_2H_5$; BHOP = $C_6H_5COC(NOH)COOCH_2C_6H_5$; BHOB = $CH_3COC(NOH)COOCH_2C_6H_5$.

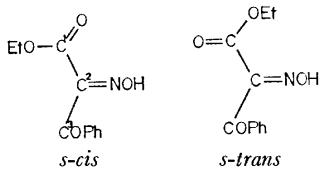

Fig. 4. Rotational isomers around the C^1–C^2 bond.

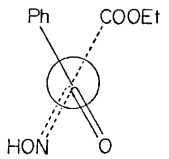

Fig. 5. Molecular conformation of EHOP, as viewed along the C^2–C^3 bond.

to the *s-cis* conformer. By structural analogy, the 1752 cm^{-1} (*s-cis*) band observed in the solution spectrum of EHOP probably corresponds to the 1735 cm^{-1} band observed in the solid phase, suggesting that the ester C=O (*s-cis*) group participates in the OH···O=C bond in the solid.

The rotational isomerism around the C^2–C^3 single bond is also possible in EHOP. However, the spectrum showed no doublet band of the ketone carbonyl stretching: the ketone C=O stretching band was observed at 1685 cm^{-1} in CCl_4 solution, slightly shifted toward higher wave numbers than the corresponding band in the solid phase.[16] This fact indicates that EHOP molecule exists in only one form around the C^2–C^3 bond. Taking into account the steric hindrance and electrostatic effects in this molecule, the most probable conformation of this molecule can be obtained as drawn in Fig. 5. In this figure the carbonyl bond adjacent to the phenyl group is assumed to be coplanar with the phenyl ring because of the predicted strong conjugation between them. The C=N bond and the ketone C=O bond are located at the non-planer *s-cis*

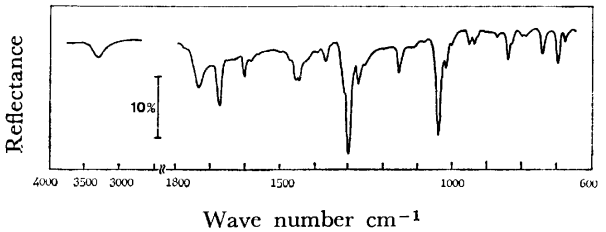

Fig. 6. High-sensitivity reflection spectrum of the thin film **A**.

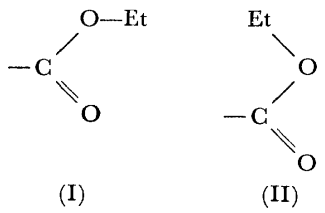
for the reason that the fixation of these groups at the *s-trans* position would result in the sever repulsion a between lone-pair electrons of oxygen atom of the ketone carbonyl and those of ethoxy group. This conformation can be strongly supported by the infrared dichroisms of oriented EHOP films, as will be described below. The rotation of the ethyl group around the ester C–O bond will be mentioned later.

Reflection Spectra and Orientations. The evaporation of solvent from the thin liquid film remaining on Pd resulted in a continuous thin crystal film **A**. On the other hand, when the liquid film was thick, an amorphous solid film was formed which was unstable and crystallized into islands. The resulting film is called as **B**.

The high-sensitivity reflection spectrum of the film **A** is shown in Fig. 6. The absorption bands of the film appear at almost the same frequencies as in the transmission spectrum of the bulk crystals. However, differences in relative intensities are noticed between the thin film and the bulk crystals. Because the spectrum gave no new band in Fig. 6 and the possibility of decomposition during the treatment can be ruled out. As mentioned above, the spectrum obtained by means of the high-sensitivity reflection method is regarded as a polarized spectrum, because it results from the interaction of molecular vibration with oscillating electric field polarized normal to the plane of reflection or the Pd mirror surface. Therefore, the observed changes in band intensity is obviously ascribed to the molecular orientation in crystals.[3,4,17] Since the relative intensities of the observed bands depends on the orientation of the vibrational transition moments, the molecular orientation can be determined, based on the relative intensities and the vibrational assignments as mentioned above.

When the molecular and crystal structure of this compound is known, the orientation of all the groups of the molecule may be determined. Unfortunately, however, X-ray diffraction data is not available and the orientation will be discussed based on the molecular conformation assumed above. Because the electric vector of infrared radiation in the vicinity of Pd surface is practically normal to that surface, absorption bands must have the maximum intensity, when the vibrating electric vector is perpendicular to the palladium surface. The most noteworthy feature in Fig. 6, is the enhanced intensity of the band due to the ester C–O–C antisymmetric stretching and weakness of the ester C=O stretching. These facts can be used in determining the probable conformation of the ester group from

the two possible forms:



(I) (II)

The directions of the transition moments of the C=O stretching and the C–O–C antisymmetric stretching are approximately normal with each other in the conformation (I) and is parallel in the conformation (II). The relative intensities of the two bands mentioned above lead to the deduction that the conformation (I) is likely; this conformation agrees well with that known for normal acetate esters.[18] The high dichroic ratio obtained for the ester C=O stretching and the C–O–C antisymmetric stretching bands further shows that the ester group lies in a plane as a whole and that its plane is normal to the metal surface. The enhanced intensity of the ν_{as} (C–O–C) band indicates that the C–C axis of the ester probably lies perpendicular to the metal surface, whereas the C=O bond is nearly parallel to the surface. The carbonyl stretching band of ketone appears as a moderately intense band, indicating that this bond probably lies obliquely oriented to the metal surface. The fact that the band at 1275 cm^{-1}, due to the phenyl–carbonyl C–C stretching is much decreased in intensity, indicates that the C–C bond is largely tilted from the direction normal to the palladium substrate. No information is available from C=N stretching band as it is too weak in the thin film as well as in the bulk state spectrum to provide any useful information.

Other noticeable features in the spectrum of Fig. 6 are much decreased intensities of the bands at 947 and 935 cm^{-1}, arising from the OH out-of-plane deformation and NO stretching vibrations, respectively. The former gives information about the hydrogen bond as well as the OH alignment with respect to the substrate and will be noted later, while the latter indicates that the NO bond is oriented nearly parallel to the substrate surface. Based on the discussion mentioned above, the most probable molecular orientation in thin EHOP film on the Pd substrate can be obtained as shown in Fig. 7.

Figure 8 shows the high-sensitivity reflection spectrum of the thin crystal film **B**. Since the spectrum obtained

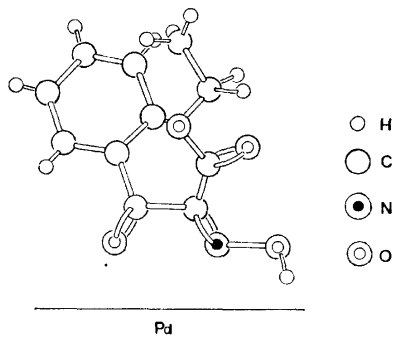


Fig. 7. Molecular orientation in the thin crystal **A**.

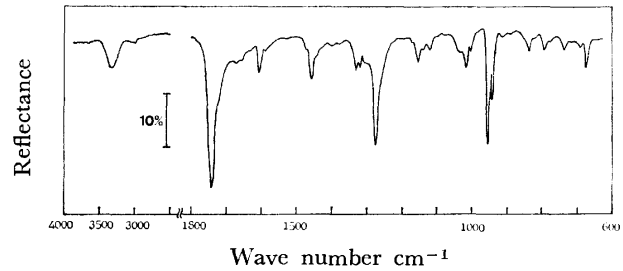

Fig. 8. High-sensitivity reflection spectrum of the thin film **B**.

just after evaporation of solvent ethanol was extremely weak and broad, this film may be regarded as amorphous. Although the relative intensity of the bands roughly agreed with that of the film **A**, the film was unstable and the crystallization soon occurred. After the crystallization, the absorption bands were much enhanced in intensity but the relative intensities of the bands differed remarkably from that in bulk spectrum of Fig. 2. The spectrum of the film **B** obtained by superposing the high-sensitivity reflection spectrum on the transmission one agrees well with the bulk spectrum, as will be described below. This fact clearly shows that the film was composed almost exclusively of EHOP and the change in relative intensity arose from the molecular orientation.

Most remarkable in Fig. 8 is the enhanced intensity of the band due to the ester C=O stretching and the extreme weakness of the ketone C=O stretching band. These facts indicate that the ester C=O bond is probably oriented perpendicular to the Pd surface, while the ketone C=O bond is not so.

The transmission measurement was carried out on film **B** formed on the sufficiently thin film of Pd deposited in a vacuum on a KBr window. The transmittance of the substrate plate used was about 30% throughout the examined frequency range. An ethyl alcohol solution of EHOP was put on the substrate surface. After evaporation of the solvent, the molecules soon crystallized in the same fashion mentioned above. To compensate the transmission loss of the substrate, a substrate prepared in the same procedure was placed in the reference beam. The signals were expanded by a factor of 5 on the recorder. The transmission spectrum obtained is shown in Fig. 9. Remarkable differences in band intensity can be seen when this spectrum is compared with that obtained by reflection method.

The spectrum obtained by superposing the reflection spectrum of the thin film on the transmission one is in good agreement with the spectrum of bulk sample

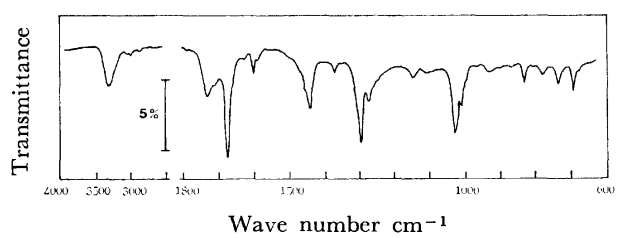

Fig. 9. Transmission spectrum of the thin film **B**.

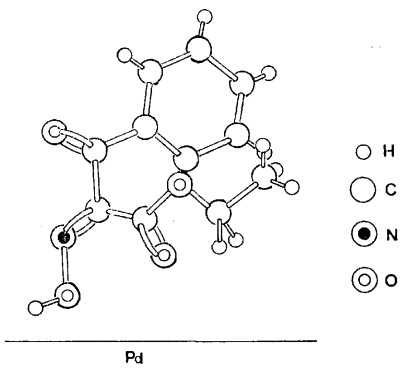

Fig. 10. Molecular orientation in the thin crystal **B**.

(Fig. 2), except slight shifts in band position caused by the difference in the measuring method. As can be seen in Fig. 9, the ketone carbonyl stretching and the ester C–O–C antisymmetric stretching bands are strongest in intensity, whereas the ester carbonyl stretching, the phenyl–carbonyl C–C stretching, and the NO stretching bands are weak. Because the electric field of incident radiation is parallel to the substrate surface and is orthogonal to that in the reflection method, the bands having enhanced intensity in the reflection spectrum must be weak in intensity in the transmission one, if the molecules are oriented. This is the case for the spectrum in Fig. 8 and that in Fig. 9, and the molecular orientation, mentioned above, is confirmed. The intensity of the OH out-of-plane deformation band is extremely weak in the spectrum of Fig. 9, indicating that the transition moment of the OH out-of-plane deformation vibration lies normal to the substrate surface. The transition moment of the OH in-plane deformation is in the plane of the OH···O unit and so stronger in intensity than the OH out-of-plane deformation in the transmission spectrum. These facts indicate that the OH···O plane in crystal **B** is lying nearly parallel to the Pd surface. Because the phenyl–carbonyl C–C stretching is observed as a moderately strong band in Fig. 8, the molecular orientation in the film **B** can be deduced as shown in Fig. 10. In accord with this orientation, NO stretching appears as an enhanced band as can be seen in Fig. 8.

In discussing the mechanism of the catalytic asymmetric hydrogenation, the direct determination of the orientation of species strongly adsorbed on the catalytic surface is quite desirable. However, the signal from such the species in a trace is too weak to provide any available information. It should be mentioned here that, according to recent experiments,[7] the orientation of molecules in a thin film is strongly governed by the orientation of the species which are adsorbed strongly on the substrate surface and which subsequently acts as the nuclei for crystal overgrowth. The molecular orientation thus taken place is generally maintained as far as the film is very thin. The orientations of the EHOP molecule in the thin film **A** may, therefore, correspond to that of species strongly adsorbed on the palladium surface. It must be mentioned that the molecular orientation in the extremely thin film **A** is essentially the same as the model proposed by Harada *et al.*[9] (see Fig. 1). Since the strain caused by crystallization may result in the change of orientation, and the molecular orientation in the film **B**, probably, does not correspond to that of the species strongly adsorbed on palladium.

Interactions of Calcium Ions with Carbohydrates: Crystal Structure of Calcium D-Glucarate Tetrahydrate

Tooru TAGA and Kenji OSAKI
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606

(Received January 12, 1976)

The crystal structure of calcium D-glucarate tetrahydrate has been determined from three dimensional X-ray data, and refined by the least squares method including an anisotropic temperature factor. The crystals are orthorhombic, space group $P2_12_12_1$ with $a=16.09$, $b=11.36$ and $c=6.68$Å. The calcium ion is bound to two glucarate molecules and three water molecules. The eight oxygen atoms form the calcium coordination shell of a distorted square-antiprism geometry. The carboxyl group including C(1) of D-glucarate has an eclipsed conformation relative to C(2) and O(2), and is coordinated with one calcium ion through the carboxyl oxygen O(1) and the α-hydroxyl oxygen O(2), and with the other calcium ion through the carboxyl oxygen O′(1) and the hydroxyl oxygens O(3) and O(4). The other carboxyl group including C(6) has an unusual staggered conformation relative to C(5) and O(5), and is not coordinated with calcium ions. However the oxygen atoms of the latter carboxyl group are attached by hydrogen bonds to a number of hydroxyl groups and water molecules, all of which are coordinated with calcium ions.

Studies on the binding of calcium ions to carboxylic sugars are important in relation to various biological systems which depend on the presence of calcium ions.[1-4] As part of a program of investigation of the structural characteristics of calcium binding, in this paper we describe the crystal structure of calcium D-glucarate tetrahydrate, $CaC_6H_8O_8\cdot 4H_2O$. D-Glucaric acid or D-saccharic acid, which is a dicarboxylic sugar acid derived from the oxidation of D-glyconic acid, is known to have a high affinity for calcium ions in alkaline solutions, and was expected to have structural characteristics typical of chelating agents.[5] In investigating the structure of calcium D-glucarate tetrahydrate we are interested therefore in interaction between calcium ions and the carboxyl groups and in particular the relationship between each carboxyl–calcium interaction and structural features which result from the conformation of the molecule as a whole.

Experimental

The crystals of strip shape were grown by slow evaporation from a dilute hydrochloride solution at room temperature. A preliminary examination showed that the crystals are orthorhombic, space group $P2_12_12_1$ as indicated by the systematic absences of $h00$, $0k0$ and $00l$ for h, k and l odd. $Z=4$, $D_x=1.74$ g/cm³, $D_m=1.77$ g/cm³ at 20 °C. The cell dimensions are $a=16.09(9)$, $b=11.36(7)$ and $c=6.68(5)$ Å. The reflection data were collected by visual estimations of the intensities from equi-inclination Weissenberg photographs obtained by rotating the crystal ($0.1\times0.15\times0.15$ mm) about the a- and c-axes, using Cu$K\alpha$ radiation. The reflection data were converted to structure amplitudes without absorption correction and the structure was solved by the direct method using the program MULTAN.[6] Three cycles of the full matrix least squares refinement using 913 reflections gave an R-value of 0.12. A further seven cycles of the block diagonal least squares refinement which included anisotropic thermal parameters reduced the R-value to 0.093. The weighting scheme used was $W^{-1}=(1+|F_o|+0.013|F_o|^2)$.[7] Scattering factors for all atoms were obtained from the International Table for X-ray Crystallography IV.[8] The positions of the hydrogen atoms were determined from the difference Fourier maps and included in the final cycle of the structure factor calculation.

Results and Discussion

The configuration and atomic numbering of the D-glucarate molecule are given in Fig. 1. The final heavy-atom parameters and their estimated standard deviations are listed in Table 1. Observed and calculated structure factors are listed in Table 2.[9] The bond distances and angles calculated from these parameters are given in Table 3. The C–C bond distances range from 1.52 to 1.58 Å with a mean value of 1.54 Å. The C–OH bond distances range from 1.42 to 1.47 Å with a mean value of 1.44 Å. The mean value for the C–C–C bond angle is 110.5° and the mean value for the C–C–OH bond angle is 110.1°. Each carboxyl group is symmetrical within the limits of experimental error. The four C–O bond distances range from 1.24 to 1.28 Å and the C–C–O angles range from 116° to 118°. The C–C–O bond angles are 126° and 128°. The carbon chain of D-glucarate has a bend conformation although the section C(2)–C(6) approximates to an extended planar zigzag. The C(1) atom is in a + synclinal position relative to C(4). (see Table 4) This conformation is unfavorable because of the repul-

sion between the parallel C(1)–C(2) and C(4)–O(4) bonds. (Jeffrey and Kim[10] have pointed out that parallel C–*n*-O [or C–*n*-C] and C–(*n*+2)-O [or C–(*n*+2)-C] bonds give rise to conformational instability in the carbohydrate chain.) The unfavorable C(1)–O(4) proximity in the +synclinal conformation is relaxed by a rotation of O(4) about the C(3)–C(4) bond. As a result of this rotation, O(3) and O(4) approach each other quite closely (2.64 Å). The carboxyl group at each end of the chain has a different conformation. The carboxyl group including C(1) is co-planar with the C(1)C(2)O(2) plane. The carboxyl oxygen O(1) is in an eclipsed position relative to C(2) and O(2), and is close to O(2) (2.61 Å). While the plane of the carboxyl group including C(6) is approximately perpendicular to the C(4)C(5)O(5) plane. The carboxyl oxygen O(6) is in a staggered position relative to C(4) and O(5) with the C(4)–C(5)–C(6)–O(6) torsional angle=67°. The latter staggered conformation is favorable with respect to the nonbonding interactions between the carboxyl oxygens and the atoms attached to C(5). However the former eclipsed conformation appears to be a feature of a number of carboxylic compounds. The stability of such an eclipsed form has been investigated by several workers without reaching any definite conclusion.[11–13]

The crystal packing and the coordination of calcium ions with glucarates and water molecules are shown in Figs. 2, 3, and 4. The calcium ion lies between three water molecules and two glucarate molecules which are related by translation along the c-axis, and is surrounded by eight oxygen atoms in a distorted square-antiprism arrangement. The Ca–O distances vary from 2.39 to 2.50 Å with a mean value of 2.46 Å. One glucarate molecule is coordinated with a calcium ion

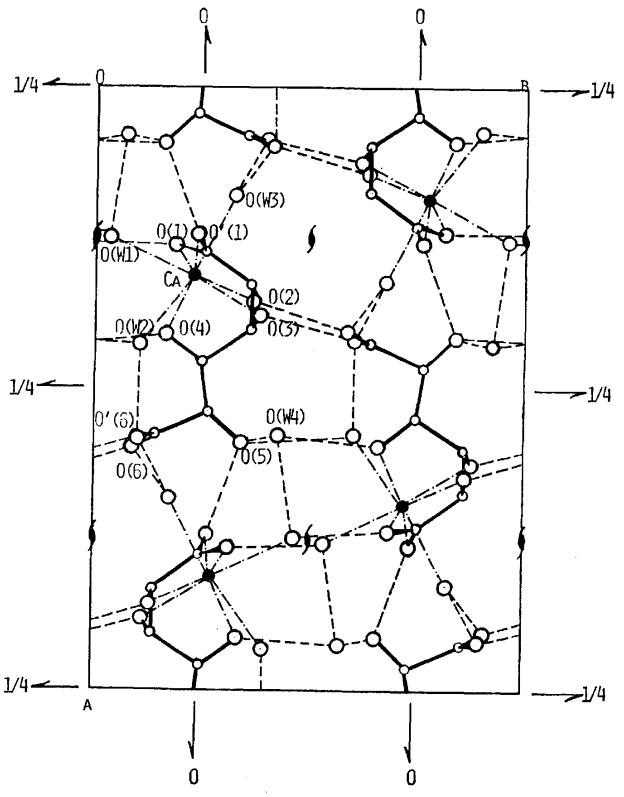

Fig. 2. The projection of the structure along the c-axis. The broken lines are hydrogen bonds.

through an O(1) carboxyl oxygen and an O(2) α-hydroxyl oxygen. The second glucarate is coordinated through the O′(1) carboxyl oxygen and the O(3) and O(4) hydroxyl oxygens arranged in a triangular form. The O–O distances in this formation are 2.64 Å for O(3)–O(4), 2.83 Å for O′(1)–O(3) and 2.91 Å for O′(1)–

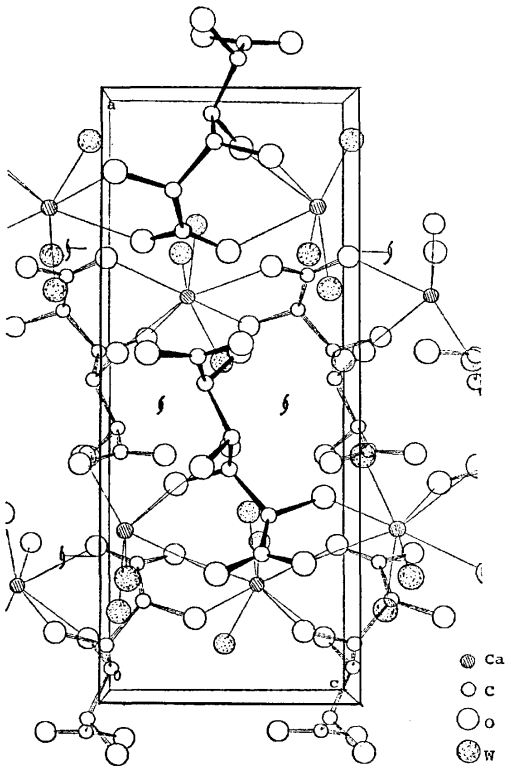

Fig. 3. A perspective view of the structure along the b-axis.

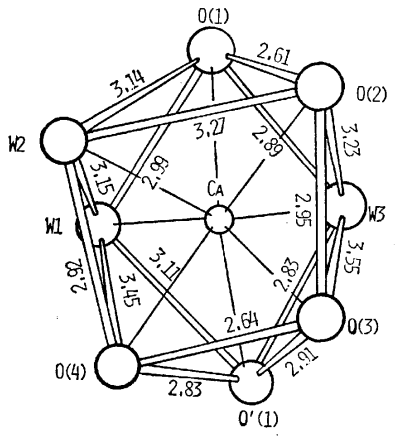

Fig. 4. The calcium coordination shell.

O(4). It has been demonstrated that in aqueous solutions the affinity of calcium ions for carboxylic acids is increased by the presence of an α-oxygen and this affinity is further enhanced by the presence of additional hydroxyl groups in the molecule.[14,15] In all the crystal structures of calcium salts of other carboxylic compounds determined to date,[16-23] the carboxyl oxygen and the α-oxygen are both coordinated with the calcium ion. Therefore the carboxylic oxygen and the α-hydroxyl oxygen in an eclipsed conformation as in O(1) and O(2) are generally coordinated with the calcium ion through the formation of a stable five membered ring O–C–C–O–Ca. The triangular structure of O'(1), O(3) and O(4) is a previously unobserved type of oxygen arrangement which excludes the α-oxygen atom. (In the structures determined for Ca D-xylo-5-hexalosonate $2H_2O$,[21] CaBr lactobionate $4H_2O$[22] and Ca arabonate $5H_2O$,[23] the α-hydroxyl oxygen is included in the 'oxygen triangle' coordinated with the calcium ion.) The nonbonding distance between O(3) and O(4) is shorter than that between O'(1) and O(3) and between O'(1) and O(4), and a stable five membered chelate ring including a calcium ion is formed through the O(3)–C(3)–C(4)–O(4) linkage.

C(5)-O(5)	1.449(16)	C(3)-C(4)-O(4)	106.9(1.0)
Ca-O(1)	2.478(11)	C(5)-C(4)-O(4)	108.9(1.1)
Ca-O'(1)	2.495(10)	C(4)-C(5)-O(5)	108.8(1.1)
Ca-O(2)	2.445(10)	C(6)-C(5)-O(5)	111.4(0.9)
Ca-O(3)	2.402(9)	O(1)-C(1)-O'(1)	126.0(1.0)
Ca-O(4)	2.569(10)	O(6)-C(6)-O'(6)	128.1(1.1)
Ca-O(W1)	2.395(11)		
Ca-O(W2)	2.490(11)		
Ca-O(W3)	2.386(11)		

Another interesting feature of the structure of calcium D-glucarate is that calcium ions are not directly bound to the C(6) carboxyl group. The O(6) carboxyl oxygen in a staggered position is far from the O(5) hydroxyl oxygen. The O(5)–O(6) distance of 2.87 Å is sufficiently great to prevent the formation of a stable chelate ring with a calcium ion. Generally in the carboxyl oxygen in the staggered conformation the electron lone pairs are unshielded by intramolecular atoms, thus the carboxyl oxygens are more capable of forming intermolecular hydrogen bonds than in the case of carboxyl oxygens in the eclipsed form. In fact, the oxygen atoms of the C(1) carboxyl group form only two hydrogen bonds, whereas the oxygen atoms of the C(6) carboxyl group form five hydrogen bonds with the water molecules and the hydroxyl groups of the adjacent molecules. The hydrogen bonding scheme and their distances are given in Fig. 2 and Table 5, respectively. All of the hydroxyl groups and water molecules attached by hydrogen bonds to the C(6) carboxyl group are coordinated with calcium ions. Conversely, the C(6) carboxyl groups link the adjacent calcium centered oxygen polyhedrons.

From the data described here, it is apparent that the calcium-hydroxyl interaction is important in

relation to the binding of calcium ions to carboxylic sugars. The intramolecular proximity of the hydroxyl groups and carboxyl oxygens is particularly relevant to the formation of a stable calcium chelate structure possibly accompanied by a conformational change of the ligand molecule to a more favorable arrangement of oxygen atoms. These structural characteristics readily account for the high stability of calcium D-glucarate crystals.

The authors wish to thank Dr. Robert Freeman for his kindness in the correction of this manuscript. All the computations were performed by using a new Kyoto X-Ray Program System, which is including the UNICS programs, on the FACOM 230-60 in the Data Processing Center, Kyoto University.

Aromatic Nucleophilic Substitution. VII.[1] Electronic Structure of 1,1-Disubstituted 2,4-Dinitronaphthalene Meisenheimer Complexes

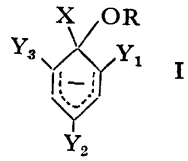
Shizen SEKIGUCHI,* Kinzo TSUTSUMI, Haruo SHIZUKA, Kohji MATSUI, and Takeshi ITAGAKI

Department of Synthetic Chemistry, Gunma University, Tenjincho, Kiryu, Gunma 376

(Received January 26, 1976)

The electronic structures of 1,1-disubstituted 2,4-dinitronaphthalene Meisenheimer complexes were studied by UV-visible and infrared spectrometry and compared with the results calculated by a semiempirical SCF-MO-CI method. The electronic transitions in the complexes were assigned to those of π-π^*. Calculated transition energies and intensities agree well with the observed values. The infrared spectra of the complex indicated that the complex is not a charge transfer complex or a radical anion, but an anionic σ complex.

Many Meisenheimer complexes such as I (hereinafter referred to as anionic σ complex) have been prepared by nucleophilic attack on polynitro aromatic compounds. These reactions have been extensively studied and the results are reviewed in detail.[2] Simple MO treatments of aromatic nucleophilic substitution have been attempted by several workers.[3] Abe[3g] has explained with the Hückel MO method the result that in the longer wavelength region one and two absorption bands are observed for di- and trinitrocyclohexadienate



I

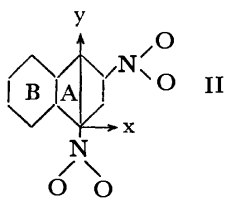
X=H, OR, halogen

(I, X=OCH_3, R=CH_3, Y_1=Y_2=NO_2, and Y_3=H; X=OCH_3, Y_1=Y_2=Y_3=NO_2), although the characters of the electronic transitions were not explained. Furthermore, Caveng *et al.*[3d] have reported with the aid of the HMO treatment that π-electrons in I (X=OCH_3, R=CH_3, Y_1=Y_2=Y_3=NO_2) are attracted by the three nitro groups such that the ring becomes positively charged. Criticizing the work of Abe and Caveng *et al.*, Hosoya *et al.*[3f] have indicated that nitro compounds are something beyond the limit of the HMO treatment, and they have performed the Pariser-Parr-Pople type SCF-MO-CI calculation for 1,3,5-trinitrocyclohexadienate (I, Y_1=Y_2=Y_3=NO_2, neglecting the effect of X and OR groups), indicating that the lower electronic transitions in this complex are assigned as due to charge transfer from the pentadienyl group to the nitro group. However, no SCF-MO-CI calculation has been performed for naphthalene anionic σ complexes. This paper will report the electronic transitions in 1,1-disubstituted 2,4-dinitronaphthalene anionic σ complexes with the aid of a semiempirical SCF-MO-CI calculation.

Method of Calculation

The π electronic structures of 1,1-disubstituted 2,4-dinitronaphthalene Meisenheimer complexes were studied by the variable β, γ procedure of semiempirical SCF-MO method combining with singly excited CI calculation. The parameters were taken as proposed by Nishimoto and Forster.[4] One-center repulsion integrals $\gamma_{\mu\mu}$ were estimated from the corresponding valence state ionization potentials (I_μ) and electron affinities (A_μ) by the Pariser-Parr approximation,[5] I_μ and A_μ being determined from spectroscopic data using the promotion energies of Hinze and Jaffé.[6] Two-center electron repulsion integrals $\gamma_{\mu\nu}$ were estimated by use of the Mataga-Nishimoto approximation.[7] Two-center core resonance integrals $\beta_{\mu\nu}$ were evaluated by the Nishimoto-Forster approximation.[4]

The geometry of the complex (II) was assumed as follows:



II

The C–C bond lengths and all bond angles were assumed to be 1.39 Å and 120°, respectively. The C–N and N–O bond lengths were assumed to be 1.486 and 1.210 Å, respectively. The computation was carried out with a HITAC 8800 located at the Computer Center of the University of Tokyo

Experimental

Materials. 1-Ethoxy-(III) and 1-methoxy-2,4-dinitronaphthalene (IV) were prepared by the action of $NaOC_2H_5$ on an ethanolic solution of 1-chloro-2,4-dinitronaphthalene (CDNN), mp 91—92 °C (lit, 93 °C[8] and 90—91 °C[9]) and 97—98 °C (lit. 97 °C[10] and 97.5—98 °C[11]). 1-Piperidino-(V) or 1-dimethylamino-2,4-dinitronaphthalene (VI) were prepared by the action of the corresponding amine on CDNN in DMSO according to the method of Orvik and Bunnett.[8] Recrystallization from 95% ethanol gave an analytical sample: V, yield 80%, mp 136—137 °C (Found: C, 60.05; H, 5.21; N, 14.23. Calcd for $C_{15}H_{15}N_3O_4$: C, 59.79; H, 5.02; N, 13.95%) and VI, yield 45%, mp 88—89 °C (Found: C, 55.39; H, 4,40; N, 16.30. Calcd for $C_{12}H_{11}N_3O_4$: C, 55.17; H, 4.24; N, 16.09%).

IR Spectra of the Reactions System of VI with $NaOCH_3$ in DMSO. 0.035 ml of methanolic $NaOCH_3$ (4.18 M) was added to a DMSO solution (0.15 ml) of VI (1.48×10^{-4} mol), in which the molar ratio VI to $NaOCH_3$ was one, and the spectra of the mixture were taken.

Results and Discussion

Absorption Spectra of the Reaction of 1-Ethoxy-2,4-dinitronaphthalene(III) with Piperidine and the Reaction of

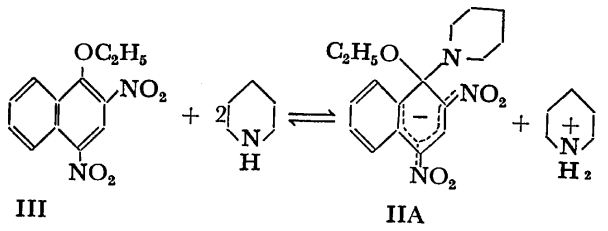
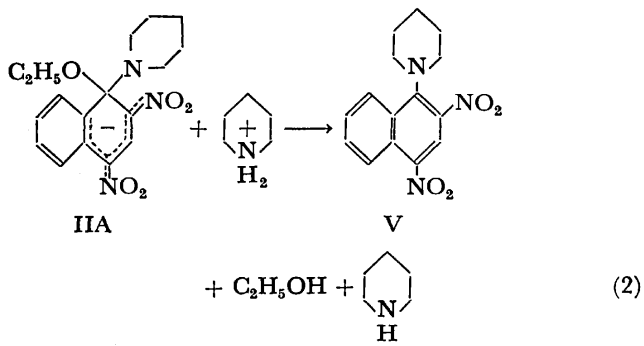
1-Methoxy-2,4-dinitronaphthalene(IV) with Dimethylamine in DMSO. Addition of excess piperidine to a DMSO solution of III at room temperature (III 2.60×10^{-5} M, piperidine 1.01 M) yielded a red solution, indicating the formation of an anionic σ complex as follows:[8,12,13]



(1)

The complex IIA was catalyzed with piperidinium ion to form the replaced product V as shown in Eq. 2.[8] The absorption spectrum measured immediately



(2)

after mixing is shown in Fig. 1, in which the positions and intensities are typical of 1,1-disubstituted 2,4-dinitronaphalene anionic σ complexes.[13–15] In the case of the reaction of IV with dimethyl amine, a similar spectrum to that in Fig. 1 was obtained. The absorption spectra of IIA and IIB (1-methoxy-1-dimethylamino-2,4-dinitronaphthalene anionic σ complex) comprise two allowed transitions, Band I (ε 2.4×10^4 at 522 nm) and Band II (ε 1.7×10^4 at 357 nm) for IIA, and Band I (ε 2.7×10^4 at 519 nm) and Band II (ε 1.6×10^4 at 364 nm) for IIB, respectively.

The calculated and observed transition energies, transition moments, and oscillator strengths of the anionic σ complex are listed in Table 1. The calculated transition energies are smaller than those of the observed values, because the complex in the excited state, S_1 or S_2, is more stabilized in DMSO, a comparatively polar solvent, than that in the ground state, S_0, as can be seen from the result that the dipole moment in the excited state is about twice larger than that in the ground state.

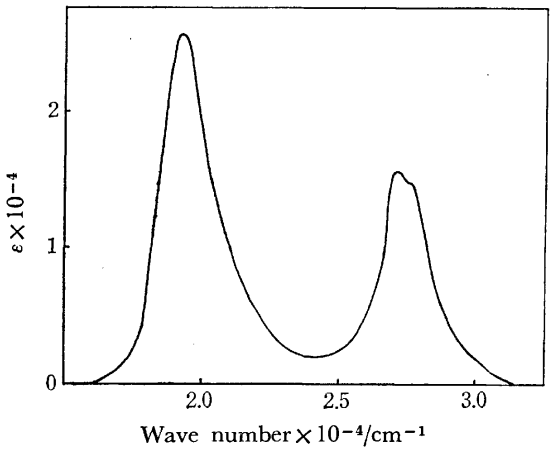


Fig. 1. Absorption spectrum relevant to the reaction of 2,4-dinitro-1-naphthylmethyl ether(IV, 3.30×10^{-5} M) with piperidine(2.00×10^{-1} M).

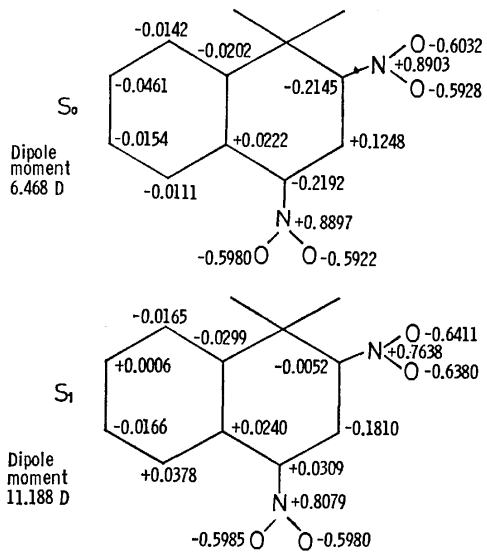

Fig. 2. π formal charge of the complex in the S_0 and S_1 states.

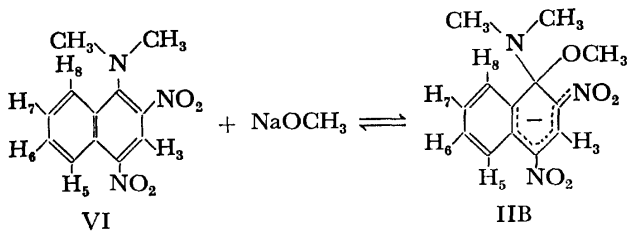
The π formal charges of the complex in the S_0 and S_1 states are shown in Fig. 2. In the S_0 state, the negative charge donated by a nucleophile to the π system is distributed on the two nitro groups to a large extent (*ca.* 60%). In the S_1 state, *ca.* 90% of

one negative charge is distributed on the two nitro groups, where the charge distribution on the nitro group attached to C_1 is larger in comparison with that on the nitro group attached to C_3 and *ca.* 10% of it distributed on the B ring. These facts indicate that Band I corresponds to that of an intramolecular CT. From the analysis of charge distribution in the complex, one can understand how the two nitro groups are responsible for electron acceptors resulting in the stability of II.

Naturally, the fact that the absorption spectra of IIA and IIB agree well with the result of SCF-MO-CI calculation of II based on the assumption of an 18 π-electron closed system indicates that IIA and IIB are not anion radicals but anionic σ complexes. Similar results have been obtained on 1,1-disubstituted tri- and dinitrocyclohexadienates by Hosoya *et al.*[3f]

IR spectra of the Reaction of N,N-*Dimethyl-2,4-dinitro-1-naphthylamine (VI) with Methanolic NaOCH$_3$ in DMSO.* We have recently found that VI reacts with NaOCH$_3$ in DMSO at room temperature to produce the same anionic σ complex as IIB,[9b] which is stable enough for a long time to be observed by IR measurement, different from IIB obtained in the similar way to Eqs. 1 and 2, as follows:[14]



(3)

The IR spectra of the reaction system in Eq. 3 are shown in Fig. 3. Ohsawa[15] has stated that the strong and broad band characteristic of the ketal-like structure $>C\langle^{OR}_{NH_2}$ in Meisenheimer complexes appears at 1020—1040 cm^{-1}. The band appeared at 1040 cm^{-1}, therefore, is clearly attributable to the structure of $>C\langle^{OR}_{N\langle}$ bond, which indicates that the hybrid orbital of C_1 changes from sp^2 to sp^3 in conversion of V to IIB. Furthermore, in conversion of V to IIB, H_3 and H_8 resonance signals are shifted downfield, and H_5, H_6, and H_7 ones upfield, the shifts of which are characteristic of an anionic σ complex.[14] All these results show that IIB is an anionic σ complex.

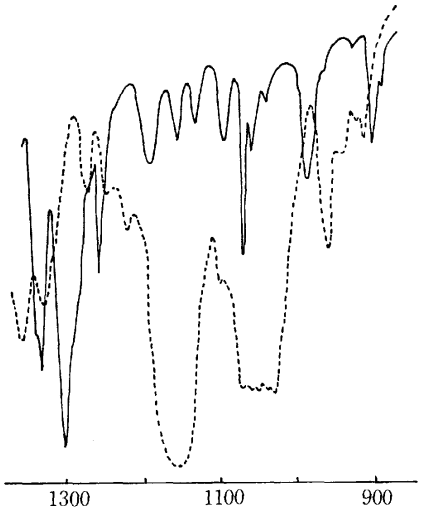


Fig. 3. Infrared spectra relevant to the reaction of *N,N*-dimethyl-2,4-dinitronaphthylamine(VI) with methanolic NaOCH$_3$ in DMSO.

Electronic Population Analysis Based on the Electron Pair Concept

Takashi OKADA and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received January 29, 1976)

The electronic population in molecular systems is analyzed on the basis of the spin coupling matrix. A proposal is made to define the pair-coupling population which is directly related to the electron pair concept. The theory is applied to the examinations of various types of wave functions used for three-centered two-, three-, and four-electron systems. The results permit clear comparisons of the characteristics of the various wave functions examined.

Recent progress in computer technology has made it possible to determine molecular electronic wave functions in fairly good accuracy. However, such wave functions are generally too intricate in form to permit naive interpretation by chemical intuition. Thus, a systematic procedure for obtaining a maximum insight into any type of wave function is necessitated. The first- and second-order reduced density matrices (hereafter referred to as 1- and 2-matrices, respectively) are the most appropriate starting point in this respect, because they contain enough information to specify the electronic structures in question. In particular, population analysis applied to the density matrices affords an interpretation of electronic structure in chemical language. Thus far, spinless 1- and 2-matrices have been successfully analyzed in several articles.[1–5]

In this paper, we analyze the spin coupling matrices, Q^0 and Q^2, and therefrom define the pair-coupling populations between AO's. The spin coupling matrices are directly related to the electron pair concept as studied in a previous paper.[6] Accordingly, the analysis of pair-coupling populations is expected to shed light on the classical Lewis-Langmuir theory as well as the valence bond interpretation. The specific examples which we will here investigate are the π-electron systems of C_3H_5, NO_2, HCO_2, and O_3 with 2 to 4 π-electrons. Population analysis has been carried out for various types of wave functions calculated by Linnett and coworkers.[7–10] The pair-coupling populations, together with the conventional populations so far employed, have been examined for each wave function. The results are compared, and the characteristics of molecules discussed.

I. Population Analysis

The 1- and 2-matrices in the Löwdin normalization[11] for an N-electron wave function $\Psi(x_1,x_2,\cdots x_N)$ are given by

$$\rho^{(1)}(x_1\,;\,x_1') = N\int \Psi(x_1,x_2,\cdots x_N) \times \Psi^*(x_1',x_2,\cdots x_N)\mathrm{d}x_2\cdots\mathrm{d}x_N \quad (1)$$

$$\rho^{(2)}(x_1,x_2\,;\,x_1',x_2') = \binom{N}{2}\int \Psi(x_1,x_2,x_3,\cdots x_N) \times \Psi^*(x_1',x_2',x_3,\cdots x_N)\mathrm{d}x_3\cdots\mathrm{d}x_N \quad (2)$$

The population analysis is to be made on spin-free density functions, so that we will make use of the following types of density matrices with space variables alone:

$$P_1(r_1\,;\,r_1') = \int_{s_1=s_1'} \rho^{(1)}(x_1\,;\,x_1')\mathrm{d}s_1 \quad (3)$$

$$Q_S(r_1\,;\,r_1') = 2\int_{s_1=s_1'} S_z(s_1)\,\rho_{st}^{(1)}(x_1\,;\,x_1')\mathrm{d}s_1 \quad (4)$$

$$P_2(r_1,r_2\,;\,r_1',r_2') = \int_{s_1=s_1',\,s_2=s_2'} \rho^{(2)}(x_1,x_2\,;\,x_1',x_2')\mathrm{d}s_1\mathrm{d}s_2 \quad (5)$$

$$Q^0(r_1,r_2\,;\,r_1',r_2') = \int_{s_1=s_1',\,s_2=s_2'} (-4/3)\boldsymbol{S}(s_1)\cdot\boldsymbol{S}(s_2) \times \rho^{(2)}(x_1,x_2\,;\,x_1',x_2')\mathrm{d}s_1\mathrm{d}s_2 \quad (6)$$

$$Q^2(r_1,r_2\,;\,r_1',r_2') = \frac{4(S+1)}{3(2S-1)}\int_{s_1=s_1',\,s_2=s_2'} [3S_z(s_1)\cdot S_z(s_2) - \boldsymbol{S}(s_1)\cdot\boldsymbol{S}(s_2)]\rho_{st}^{(2)}(x_1,x_2\,;\,x_1',x_2')\mathrm{d}s_1\mathrm{d}s_2 \quad (7)$$

where r_i and s_i are the space and spin variables, respectively, and where the subscript st denotes that a standard state with $\langle S_z\rangle = S$ is assumed.

The density functions defined as the diagonal elements of the spinless matrices (3) to (7) possess clear physical meanings. Thus, $P_1(r_1)$ and $P_2(r_1,r_2)$ stand for the charge and pair-electron densities. $Q_S(r_1)$ represents the spin density distribution. $Q^0(r_1,r_2)$ and $Q^2(r_1,r_2)$ are the spin-coupling functions,[6] which respectively denote the distributions of singlet- and triplet-type electron pairs.

In performing the population analysis, we assume that these density functions can be expanded by an atomic orbital basis set $(a,b,c,\cdots)$. The charge density function $P_1(r_1)$ is then expressed as follows:

$$P_1(r_1) = \sum_{a,b}\gamma_1(a\,|\,b)\,a(r_1)\,b^*(r_1) \quad (8)$$

The expansion coefficients $\gamma_1(a\,|\,b)$ lead to Mulliken's *gross* and *net populations*,[2] q_a and q_{aa}, for atomic orbital a as well as the *overlap population*[2] q_{ab} between atomic orbitals a and b:

$$q_a = \sum_b \gamma_1(a\,|\,b)\,s_{ab} \quad (9a)$$

$$q_{aa} = \gamma_1(a\,|\,a) \quad (9b)$$

$$q_{ab} = 2\gamma_1(a\,|\,b)\,s_{ab} \quad (9c)$$

where s_{ab} is the overlap integral between a and b. Populations of a total of N electrons are subject to the following constraints:

$$\sum_a q_a = N \quad (10a)$$

$$\sum_a q_{aa} + \sum\sum_{a>b} q_{ab} = N \quad (10b)$$

A similar partitioning procedure may be used for the other density functions. First, from the spin density function expressed in the form

$$Q_S(r_1) = \sum_{a,b} \delta_s(a|b)a(r_1)b^*(r_1), \tag{11}$$

we define the *spin population*:

$$q_a{}^s = \sum_b \delta_s(a|b)s_{ab} \tag{12}$$

Clearly, $q_a{}^s$ should satisfy the relationship:

$$\sum_a q_a{}^s = 2S. \tag{13}$$

Second, the two-particle density functions are expanded as follows:

$$P_2(r_1,r_2) = \sum_{a,b,c,d} \gamma_2(ab|cd)a(r_1)b(r_2)c^*(r_1)d^*(r_2) \tag{14}$$

$$Q^0(r_1,r_2) = \sum_{a,b,c,d} \delta^0(ab|cd)a(r_1)b(r_2)c^*(r_1)d^*(r_2) \tag{15}$$

$$Q^2(r_1,r_2) = \sum_{a,b,c,d} \delta^2(ab|cd)a(r_1)b(r_2)c^*(r_1)d^*(r_2) \tag{16}$$

from which we define the *pair populations*[12]

$$P_{aa} = \sum_{c,d} \gamma_2(aa|cd)s_{ac}s_{ad} \tag{17a}$$

$$P_{ab} = 2\sum_{c,d} \gamma_2(ab|cd)s_{ac}s_{bd} \tag{17b}$$

and the *pair-coupling populations*.

$$Q^0_{aa} = \sum_{c,d} \delta^0(aa|cd)s_{ac}s_{ad} \tag{18a}$$

$$Q^0_{ab} = 2\sum_{c,d} \delta^0(ab|cd)s_{ac}s_{bd} \tag{18b}$$

$$Q^2_{ab} = 2\sum_{c,d} \delta^2(ab|cd)s_{ac}s_{bd} \tag{19}$$

Obviously,

$$P_{aa} = Q^0_{aa}, \tag{20}$$

$$Q^2_{aa} = 0, \tag{21}$$

because the two electrons in the same AO have to be singlet coupled with each other.

The total sums of the above-defined two-particle populations are also bound. The pertinent relationships are as follows:

$$\sum_a P_{aa} + \sum_{a>b}\sum P_{ab} = N(N-1)/2 \tag{22}$$

$$\sum_a Q^0_{aa} + \sum_{a>b}\sum Q^0_{ab} = N/2 - 2S(S+1)/3 \tag{23}$$

$$\sum_{a>b}\sum Q^2_{ab} = 2S(S+1)/3 \tag{24}$$

It should be noted that a somewhat different method of population analysis has been proposed by Davidson[4] and Roby.[5] According to their proposal, the electronic population on each AO is defined as

$$n^0_{aa} = \sum_{b,c} s_{ab}\gamma_1(b|c)s_{ca} \tag{25}$$

The quantity n^0_{aa}/N is interpreted as expressing the probability that an electron belongs to orbital a. In this formalism, however, an electron in orbital a may be found simultaneously in orbital b, if a and b are not orthogonal to each other. Extension of this last method to two-particle density functions is easy. For example, the pair-coupling population is expressible in the form:

$$P^0_{ab} = 2\sum_{c,d,e,f} s_{ac}s_{bd}\delta^0(cd|ef)s_{ea}s_{fb} \tag{26}$$

The quantity is what we called the *generalized Penney-Dirac bond order* in a previous paper.[6] In this paper, however, we will not consider such populations as shown in Eqs. 25 and 26. For these populations, simple relations such as Eqs. 10a, 13 and 22—24 and as those that would be discussed in the next section do not hold.

II. Characteristics of the Populations

In a singlet state, the Q^0 function yields the charge density function by integrating over the second electron.[6]

$$P_1(r_1) = 2\int Q^0(r_1,r_2)\mathrm{d}r_2 \tag{27}$$

By expanding both sides of the above equation with respect to AO's and comparing the corresponding terms, we obtain the following relationship:

$$S = 0 : q_a = 2Q^0_{aa} + \sum_{b\neq a} Q^0_{ab} \tag{28a}$$

Thus, the gross population of each AO may be regarded as being composed of twice the ionic pair-coupling population on that AO and the sum of the covalent pair-coupling populations relevant to the same AO. This relationship is similar to that obtained on an orthogonalized AO basis set.[6] Analogous relations exist in the states with higher spin multiplicities.

$$S = \frac{1}{2}: \quad q_a = 2Q^0_{aa} + \sum_{b\neq a} Q^0_{ab} + q^s_a \tag{28b}$$

$$S \geqq 1: \quad q_a = 2Q^0_{aa} + \sum_{b\neq a} (Q^0_{ab} + Q^2_{ab}) \tag{28c}$$

The pair populations can likewise be related with the gross population.[12] The corresponding equations take the following forms:

$$P_1(r_1) = \frac{2}{N-1}\int P_2(r_1,r_2)\mathrm{d}r_2 \tag{29}$$

$$q_a = \frac{1}{N-1}(2P_{aa} + \sum_{b\neq a} P_{ab}) \tag{30}$$

For single-determinantal wave functions, 2-matrix can be expressed in terms of the products of 1-matrix. Hence, the pair and pair-coupling populations are expressed by

$$\begin{aligned}
Q^0_{aa} &= P_{aa} = \{(q_a)^2 - (q^s_a)^2\}/4 \\
Q^0_{ab} &= \{3(\boldsymbol{\gamma}_1\boldsymbol{s})_{ab}(\boldsymbol{\gamma}_1\boldsymbol{s})_{ba} - (\boldsymbol{\delta}_s\boldsymbol{s})_{ab}(\boldsymbol{\delta}_s\boldsymbol{s})_{ba} - 2q^s_a q^s_b\}/6 \\
Q^2_{ab} &= \{2(S+1)/3(2S-1)\}\{q^s_a q^s_b - (\boldsymbol{\delta}_s\boldsymbol{s})_{ab}(\boldsymbol{\delta}_s\boldsymbol{s})_{ba}\} \\
P_{ab} &= \{2q_a q_b - (\boldsymbol{\gamma}_1\boldsymbol{s})_{ab}(\boldsymbol{\gamma}_1\boldsymbol{s})_{ba} - (\boldsymbol{\delta}_s\boldsymbol{s})_{ab}(\boldsymbol{\delta}_s\boldsymbol{s})_{ba}\}/2
\end{aligned} \tag{31}$$

where $\boldsymbol{s}$ is the ordinary overlap matrix between AO's and where $\boldsymbol{\gamma}_1$ and $\boldsymbol{\delta}_s$ are the matrices composed of the expansion coefficients which appear in Eqs. 8 and 11, respectively.

The various populations investigated so far can be converted to atomic quantities by summing up the appropriate orbital populations. The resulting atomic and interatomic populations are invariant for the hybridization of AO's when the atomic orbitals on each atom are, as is usually the case, mutually orthogonal.

III. Applications to Three-center Systems

To illustrate the use of the population analysis above proposed, we apply it to various types of wave functions. The wave functions to be examined are those for the three-center systems calculated by Linnett and coworkers.[7-10] These have been chosen merely for the simplicity of arguments. The applications will clarify essential differences encountered on going from simple two-center cases to many-center problems. The sample systems here treated are the π-electron part of the allyl,[7] NO_2,[8] and HCO_2[9] radicals ($N=3$) as well as their cations ($N=2$) and anions ($N=4$). Ozone[10] ($N=4$) and its cation ($N=3$) and dication ($N=2$) will also be examined.

(A) Two-electron Systems. The three atomic orbitals involved are denoted as a, b, and c. The following basic functions constitute a complete set for the $^1A_1$ representation of the a–b–c system:

$$\begin{aligned}\Phi_1^{(2)} &= (a,b) + (b,a) + (b,c) + (c,b)\\ \Phi_2^{(2)} &= (a,c) + (c,a)\\ \Phi_3^{(2)} &= (a,a) + (c,c)\\ \Phi_4^{(2)} &= (b,b)\end{aligned} \tag{32}$$

Here, (a,b), for example, denotes a Slater determinant of the form:

$$(a,b) = \frac{1}{\sqrt{2}}\begin{vmatrix} a(1)\alpha(1) & b(1)\beta(1) \\ a(2)\alpha(2) & b(2)\beta(2)\end{vmatrix} \tag{33}$$

In all the Slater determinants the order of the spin function is $\alpha\beta$.

The wave function optimized over all these functions will be referred to as the configuration-interaction (CI) function $\Psi_{CI}^{(2)}$. In addition, the following approximate functions, each involving a smaller number of variational parameters, are considered.

1. Simple molecular orbital (MO) function:

$$\Psi_{MO}^{(2)} = (a+kb+c, a+kb+c) \tag{34}$$

2. Alternant molecular orbital (AMO) function[13]:

$$\begin{aligned}\Psi_{AMO}^{(2)} &= (a+k_1b+c, a+k_2b+c)\\ &\quad + (a+k_2b+c, a+k_1b+c)\end{aligned} \tag{35}$$

3. Valence bond (VB) functions:
Heitler-London type (HL)

$$\Psi_{HL}^{(2)} = (a,b) + (b,a) + (b,c) + (c,b) \tag{36}$$

Coulson-Fischer type (CF)

$$\begin{aligned}\Psi_{CF}^{(2)} &= (a+kb, b+ka) + (b+ka, a+kb)\\ &\quad + (c+kb, b+kc) + (b+kc, c+kb)\end{aligned} \tag{37}$$

Bond orbital type (BO)

$$\Psi_{BO}^{(2)} = (a+kb, a+kb) + (c+kb, c+kb) \tag{38}$$

4. Nonpaired spatial orbital (NP) functions:
Symmetrical form (NPA)

$$\Psi_{NPA}^{(2)} = (a+kb, kb+c) + (kb+c, a+kb) \tag{39}$$

Unsymmetrical form (NPB)

$$\begin{aligned}\Psi_{NPB}^{(2)} &= (a+kb, b+kc) + (b+kc, a+kb)\\ &\quad + (ka+b, kb+c) + (kb+c, ka+b)\end{aligned} \tag{40}$$

In Eqs. 34 to 40, k's are the variational parameters and the functions are not normalized.

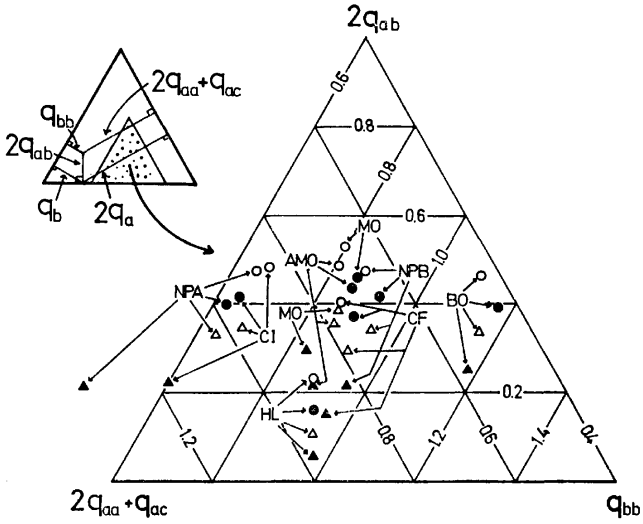

Fig. 1. The net and overlap populations for two-electron systems.
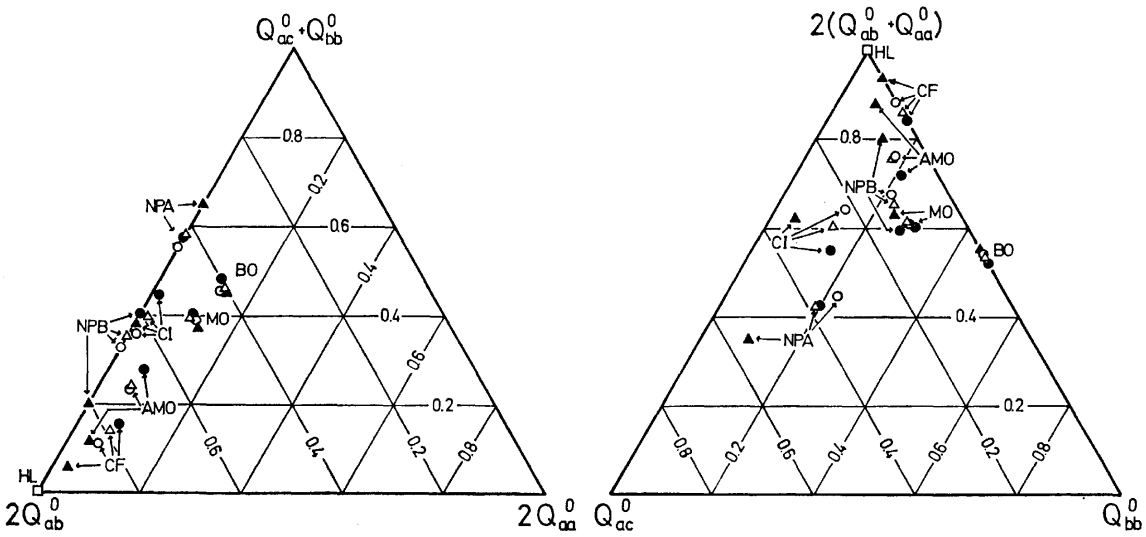
○: $C_3H_5^+$, △: NO_2^+, ●: HCO_2^+, ▲: O_3^{2+}
The length of the perpendicular from each point onto a base line shows the value of the population indicated at the opposite vertex.

The results of population analysis are shown in Figs. 1 and 2. The density distributions have been partitioned according to Eqs. 10b and 23. In two-electron systems, the function $P_2(r_1,r_2)$ is identical with $Q^0(r_1,r_2)$, so that there is no difference between the pair and pair-coupling populations. The numerical value for the population indicated at one vertex is equal to the length of the perpendicular onto the opposing base line (see Fig. 1). The sum of the lengths of three perpendiculars is invariant at any point. Thus, the gross populations q_a and q_b can be read simply as the lengths of the two perpendiculars drawn from the point at which the q_{ab} perpendicular intersects with the horizontal base line.

Let us first compare the results of the CI calculations for the four species: $C_3H_5^+$, NO_2^+, HCO_2^+ and O_3^{2+}. The polarity of molecules is reflected in the gross population q_a, which decreases in the order: $O_3^{2+} > HCO_2^+ \sim NO_2^+ > C_3H_5^+$. The overlap population q_{ab}, which corresponds to the strength of the bond a–b, decreases in the order: $C_3H_5^+ > HCO_2^+ > NO_2^+ > O_3^{2+}$. The pair-coupling populations shown in Fig. 2 are shifted regularly for $C_3H_5^+$, NO_2^+, and HCO_2^+; the populations, Q_{ab}^0 and Q_{ac}^0, decrease and increase, respectively, in that order. O_3^{2+} has a characteristic feature that Q_{bb}^0 is very small.

The shortcomings of the approximate functions compared with the CI treatment can readily be seen from Figs. 1 and 2. The molecular orbital method generally gives too large weights to the ionic terms Q_{aa}^0 and Q_{bb}^0. Moreover, q_b is overestimated. In the AMO method, the value of Q_{bb}^0 is improved, but the weight of the covalent term Q_{ab}^0 is unduly increased. In this latter sense, the AMO method cannot be regarded as an improvement over the MO method.

The valence bond functions (HL, CF, and BO) impart no weight to Q_{ac}^0. The variational parameters



(i) (ii)

Fig. 2. The pair-coupling populations for two-electron systems.
○: $C_3H_5^+$, △: NO_2^+, ●: HCO_2^+, ▲: O_3^{2+}

introduced in the CF and BO functions serve to improve the value of q_{ab} as compared with the HL function, but this is so only at sacrifice of the polarity to be predicted.

The methods of nonpaired spatial orbitals provide relatively good values for the ionic terms Q^0_{aa} and Q^0_{bb}, reflecting the success of Linnett's idea to incorporate the Coulomb type correlation. Another advantage of $\Psi_{\mathrm{NPA}}{}^{(2)}$ is, as can be seen from Fig. 1, the results that the charge distributions calculated by this method are close to those obtained by the CI treatment.

(B) Three-electron Systems. We shall adopt the convention that each Slater determinant has the spin function $\alpha\beta\alpha$. The basic functions are represented by:

$$\begin{aligned}\Phi_1{}^{(3)} &= 2(a,b,c) + (a,c,b) + (b,a,c)\\ \Phi_2{}^{(3)} &= (a,a,c) + (a,c,c)\\ \Phi_3{}^{(3)} &= (a,b,b) + (b,b,c)\\ \Phi_4{}^{(3)} &= (a,a,b) + (b,c,c)\end{aligned} \tag{41}$$

The expressions for the approximate functions are as follows:

1. Simple molecular orbital (MO) function:

$$\Psi_{\mathrm{MO}}{}^{(3)} = (a+kb+c,\ a+kb+c,\ a-c) \tag{42}$$

2. Alternant molecular orbital (AMO) function:

$$\Psi_{\mathrm{AMO}}{}^{(3)} = \boldsymbol{O}(a+k_1b+c,\ a+k_2b+c,\ a-c) \tag{43}$$

3. Valence bond functions:

Heitler-London type (HL)

$$\Psi_{\mathrm{HL}}{}^{(3)} = \{(a,b,c)+(a,c,b)\} + \{(a,b,c)+(b,a,c)\} \tag{44}$$

Coulson-Fischer type (CF)

$$\begin{aligned}\Psi_{\mathrm{CF}}{}^{(3)} = {} & (a+kb,\ ka+b,\ c) + (ka+b,\ a+kb,\ c)\\ & - (kb+c,\ b+kc,\ a) - (b+kc,\ kb+c,\ a)\end{aligned} \tag{45}$$

Bond orbital type (BO)

$$\Psi_{\mathrm{BO}}{}^{(3)} = (a+kb,\ a+kb,\ c) + (a,\ kb+c,\ kb+c) \tag{46}$$

4. Nonpaired spatial orbital functions:

A type (NPA)

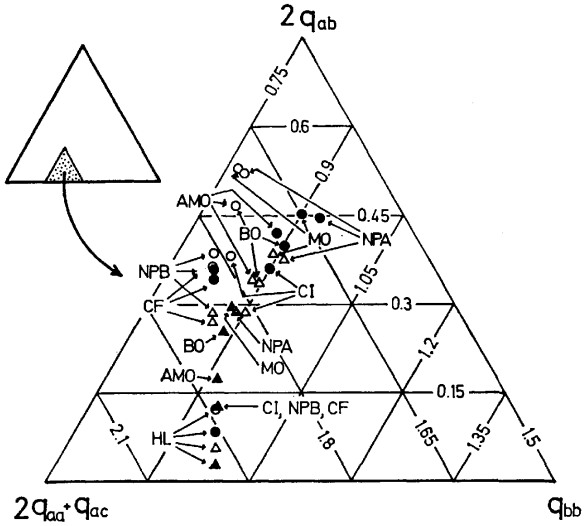


Fig. 3. The net and overlap populations for three-electron systems.
○:C_3H_5, △: NO_2, ●: HCO_2, ▲: O_3^+

$$\Psi_{\mathrm{NPA}}{}^{(3)} = \boldsymbol{O}(ka+b,\ b+kc,\ c) \tag{47}$$

B type (NPB)

$$\Psi_{\mathrm{NPB}}{}^{(3)} = \boldsymbol{O}(a+kb,\ b+kc,\ c) \tag{48}$$

where $\boldsymbol{O}$ is the projection operator to the $^2A_2$ state.

Figures 3 to 5 show the various populations obtained from the functions, $P_1(r_1)$, $Q^0(r_1,r_2)$, and $P_2(r_1,r_2)$, respectively. The pair populations P_{aa} and P_{bb} always take the same values as those of pair-coupling populations. Also, the relation, $Q^0_{ac}=(-1/2)Q^0_{ab}$, holds in these systems, so that we have shown only the sum of these pair-coupling populations in Fig. 4.

The results of the CI treatment characterize the O_3^+ ion as having extremely small overlap and ionic pair-coupling populations, thus indicating that the HL picture would be adequate for this species. For the other three radicals, the value of Q^0_{bb} becomes larger

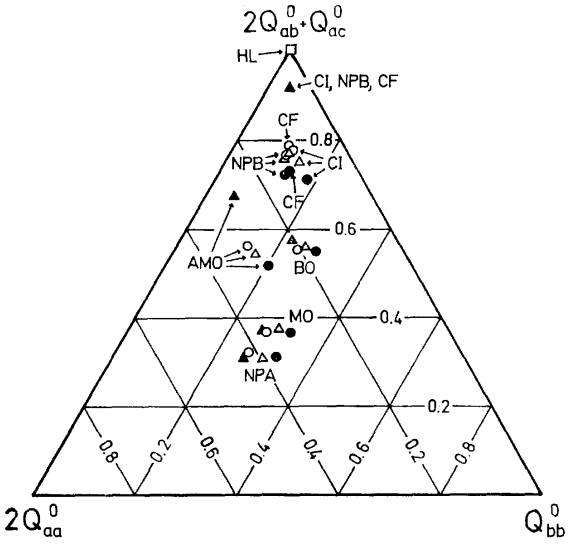

Fig. 4. The pair-coupling populations for three-electron systems.
○: C_3H_5, △: NO_2, ●: HCO_2, ▲: O_3^+
There exists a relation, $Q^0_{ac}=-\frac{1}{2}Q^0_{ab}$, so that these populations are not shown separately.

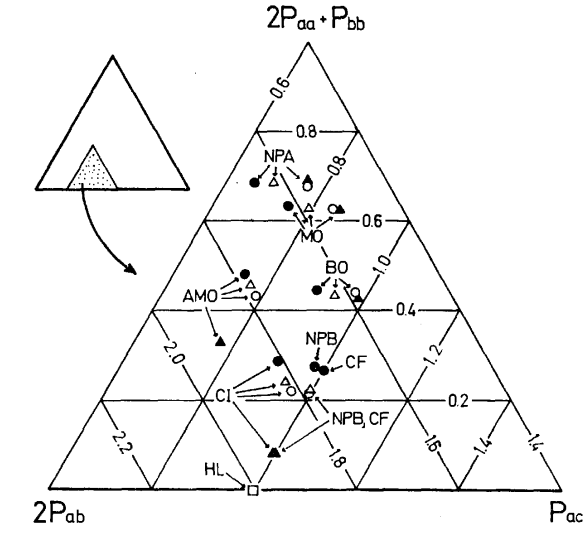

Fig. 5. The pair populations for three-electron systems.
○: C_3H_5, △: NO_2, ●: HCO_2, ▲: O_3^+
The pair populations P_{aa} and P_{bb} are identical respectively with the pair-coupling populations Q^0_{aa} and Q^0_{bb} shown in Fig. 4.

in the order, $C_3H_5<NO_2<HCO_2$, while the covalent pair-coupling population decreases simultaneously in the same order.

In the light of the above CI results, we examine the outcomings from the various approximate wave functions. Both $\Psi_{CF}^{(3)}$ and $\Psi_{NPB}^{(3)}$, providing the results close to each other, give good values for q_{ab}, $2Q^0_{ab}+Q^0_{ac}$, and $2Q^0_{aa}+Q^0_{bb}$. The shortcomings of these functions are that the ratios (Q^0_{aa}/Q^0_{bb}) and (P_{ab}/P_{ac}) are unreasonable and hence that the polarity of each species is not well reflected in the gross populations.

By contrast, all the other functions except $\Psi_{HL}^{(3)}$ give reasonable results for the above ratios. Thus, it

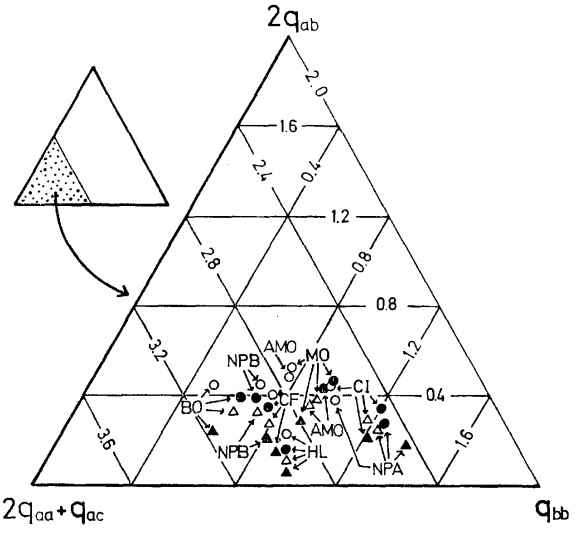

Fig. 6. The net and overlap populations for four-electron systems.
○: $C_3H_5^-$, △: NO_2^-, ●: HCO_2^-, ▲: O_3

may be suggested that a good wave function would result, if one combines the improvements from $\Psi_{HL}^{(3)}$ with the functions $\Psi_{CF}^{(3)}$ as well as $\Psi_{BO}^{(3)}$. For all kinds of populations, the AMO method gives much better results than does the MO treatment.

(C) Four-electron Systems. The order of the spin functions in all the Slater determinants is given as $\alpha\beta\alpha\beta$.

The basic functions pertinent to four-electron systems are

$$\begin{aligned}\Phi_1^{(4)} &= (a,a,b,c)+(a,a,c,b)+(c,c,b,a)+(c,c,a,b)\\ \Phi_2^{(4)} &= (a,b,b,c)+(c,b,b,a)\\ \Phi_3^{(4)} &= (a,a,c,c)\\ \Phi_4^{(4)} &= (a,a,b,b)+(c,c,b,b)\end{aligned} \tag{49}$$

The approximate wave functions to be considered are as follows:

1. Simple molecular orbital (MO) function:
$$\Psi_{MO}^{(4)} = (a+kb+c,\ a+kb+c,\ a-c,\ a-c) \tag{50}$$
2. Alternant molecular orbital (AMO) function:
$$\Psi_{AMO}^{(4)} = (a+k_1b+c,\ a+k_2b+c,\ a-c,\ a-c) + (a+k_2b+c,\ a+k_1b+c,\ a-c,\ a-c) \tag{51}$$
3. Valence bond functions:
Heitler-London type (HL)
$$\Psi_{HL}^{(4)} = (a,a,b,c)+(a,a,c,b)+(c,c,b,a)+(c,c,a,b) \tag{52}$$
Coulson-Fischer type (CF)
$$\Psi_{CF}^{(4)} = (a+kb,\ ka+b,\ c,c)+(ka+b,\ a+kb,\ c,\ c) + (c+kb,\ kc+b,\ a,\ a)+(kc+b,\ c+kb,\ a,\ a) \tag{53}$$
Bond orbital type (BO)
$$\Psi_{BO}^{(4)} = (a+kb,\ a+kb,\ c,\ c)+(c+kb,\ c+kb,\ a,\ a) \tag{54}$$
4. Nonpaired spatial orbital functions:
Symmetrical form (NPA)
$$\Psi_{NPA}^{(4)} = O(a,\ a+kb,\ kb+c,\ c) \tag{55}$$
Unsymmetrical form (NPB)
$$\Psi_{NPB}^{(4)} = O(a,\ a+kb,\ b+kc,\ c) \tag{56}$$

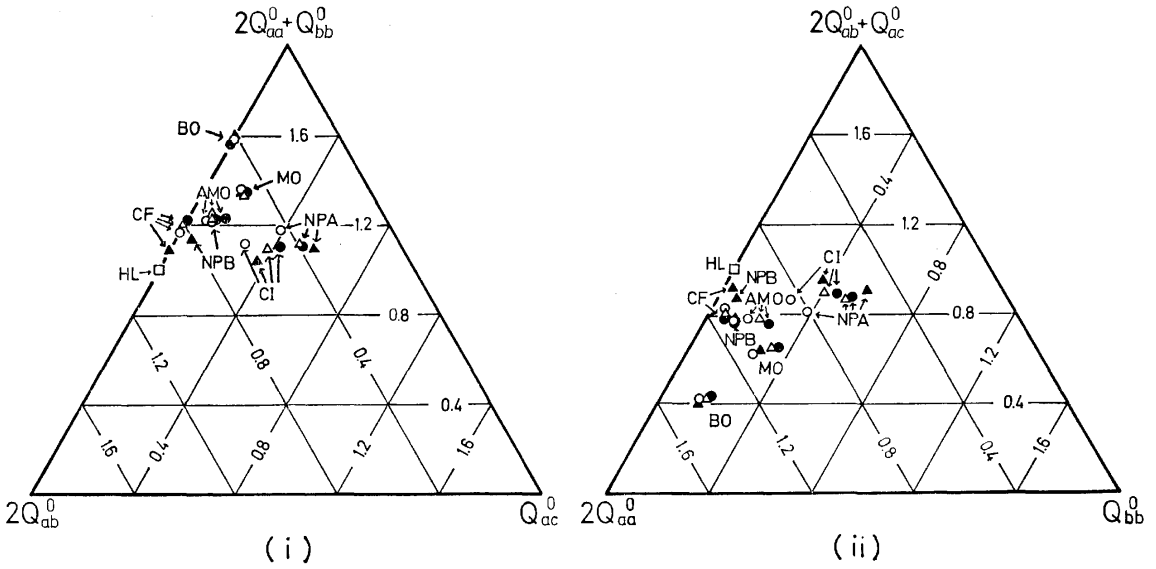

Fig. 7. The pair-coupling populations for four-electron systems.
○: $C_3H_5^-$, △: NO_2^-, ●: HCO_2^-, ▲: O_3

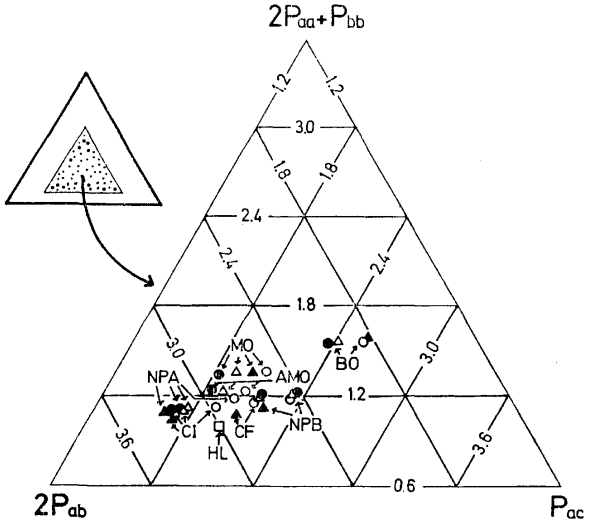

Fig. 8. The pair populations for four-electron systems.
○: $C_3H_5^-$, △: NO_2^-, ●: HCO_2^-, ▲: O_3
The pair populations for P_{aa} and P_{bb} are identical respectively with Q^0_{aa} and Q^0_{bb} in Fig. 7(ii).

Figures 6 to 8 show the results of population analysis for $C_3H_5^-$, NO_2^-, HCO_2^-, and O_3. It can be said from Fig. 6 that $C_3H_5^-$ concentrates its charge on the terminal atoms, while O_3 tends to have small values of q_{ab}. In Figs. 7 and 8, plots for the three ions $C_3H_5^-$, NO_2^-, and HCO_2^-, show a simple pattern that the three ratios, (Q^0_{ab}/Q^0_{ac}), (Q^0_{aa}/Q^0_{bb}), and (P_{ac}/P_{ab}), decrease in that order. The O_3 molecule shows a general trend that it takes relatively small values for the ionic pair-coupling populations, Q^0_{aa} and Q^0_{bb}.

Compared with other species, the value of Q^0_{ac} for O_3 is not particularly large. Therefore, it will be inadequate to attribute the well-known biradical character of ozone to the weight of the long-bond canonical structure, so far as Linnett's wave functions are concerned.

The function $\Psi_{NPA}{}^{(4)}$ appears to be the best of the approximate wave functions here examined, even though it fails to reproduce the CI results for ozone. The populations calculated from $\Psi_{CF}{}^{(4)}$ and $\Psi_{NPB}{}^{(4)}$ are nearly equal to each other. These latter wave functions can well give small ionic populations for ozone but do not improve other populations obtained by the HL treatment. The AMO treatment gives larger values for Q^0_{ab} than does the MO method, thus reducing the ionic pair-coupling populations. However, the improvements are still unsatisfactory.

IV. Concluding Remarks

We have shown in this study that the method of electronic population analysis can be extended to the analysis of the spin coupling matrices, by defining the pair-coupling populations. Interpretations of the electronic structure of molecules by the pair-coupling populations are similar to those by the resonance hybrid picture in the valence bond theory. The present method thus permits ready understandings of the characteristics of bonds by chemical intuition and yet is free from the arbitrariness in selecting the canonical structures.

It has frequently been found in the applications to three-center systems that an approximate wave function does not necessarily bring about improvements in populations, even when it improves energy. Of course, Linnett's wave functions are approximate ones even in the CI treatment. Nevertheless, the results for each species treated by use of various wave functions correctly demonstrate the characteristics of the molecular electronic structures to be represented by these wave functions. It should be emphasized that basic properties of the pair-electron density function $P_2(r_1,r_2)$ could best be understood when it is

looked at, as in this work, in the light of the distribution of pair-coupling populations in molecules.

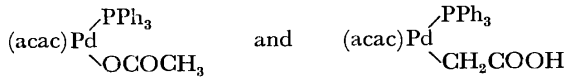
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received February 7, 1976)

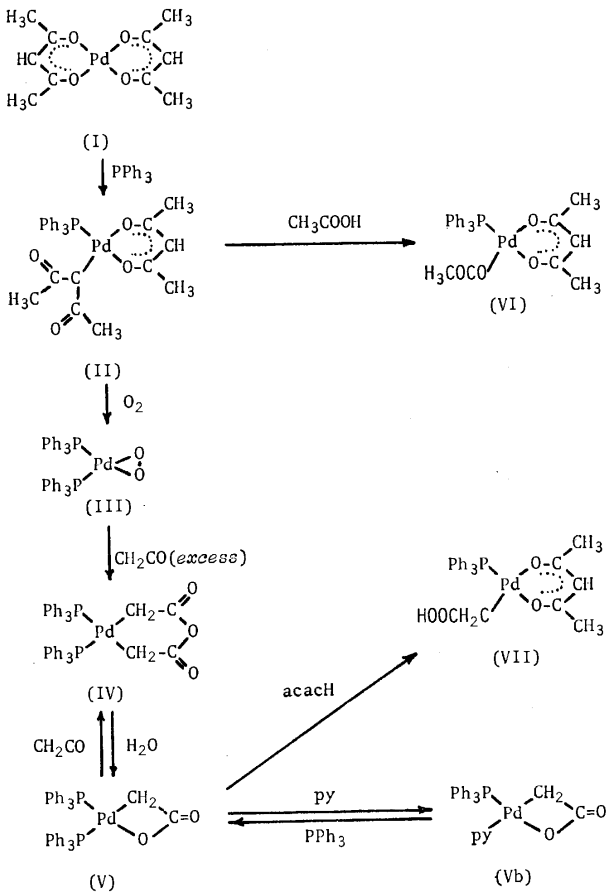
The molecular structure of (acetylacetonato)(carboxymethyl)(triphenylphosphine)palladium(II) [(acac)-(PPh_3)$PdCH_2COOH$] has been determined by means of X-ray diffraction. The crystal belongs to the triclinic system, space group $P\bar{1}$, with two formula units in a cell with dimensions of $a=10.433(2)$, $b=12.746(2)$, $c=10.224(2)$ Å, $\alpha=106.62(1)$, $\beta=112.41(2)$, and $\gamma=75.13(2)°$. $R=0.032$ for 4972 non-zero reflections. The palladium atom, σ-bonded to the methylene group of the acetic acid moiety (Pd-C=2.063(4) Å), has a square-planar geometry. The molecule forms a dimer with the adjacent molecule related by a center of symmetry through an inter-molecular hydrogen bonding between acetic acid moieties, O-H···O=2.621(4) Å.

Recently, in a series of studies of palladium complexes (Scheme 1), palladium(II) C,O-chelates of acetic acid have been prepared by the reaction of ketene and triphenylphosphine with bis(acetylacetonato)palladium(I) by Kawaguchi and his co-workers of Osaka City University.[1] In relation to this, the preparation of the following linkage isomers;



(VI) and (VII)

has also been reported.[3] The molecular structure of II, IV, and Vb have been determined and reported.[2,4] This paper will describe the molecular structure of VII. Interest in the Pd–C σ-bond also promoted this study.



Scheme 1.

Experimental

Pale yellow, polyhedral crystals of [(acac)(PPh_3)$PdCH_2$-COOH] were kindly supplied by Professor Kawaguchi and his co-workers of Osaka City University. Preliminary photographic data showed that the crystals belong to the triclinic system. Accurate unit-cell dimensions were determined by a least-squares fit of the 2θ values of 24 high-order reflections as measured on a Rigaku automated, four-circle, single-crystal diffractometer.

Crystal Data: $C_{25}H_{25}O_4PPd$, $F.W.=527.4$, triclinic, space group $P\bar{1}$, $a=10.433(2)$, $b=12.746(2)$, $c=10.224(2)$ Å, $\alpha=106.62(1)$, $\beta=112.41(2)$, $\gamma=75.13(2)°$, $U=1187.6(3)$ Å^3, $D_m=1.48$ g·cm^{-3} (by flotation in carbon tetrachloride/hexane), $Z=2$, $D_x=1.47$ g·cm^{-3}, $\mu=8.57$ cm^{-1} (Mo$K\alpha_1$, $\lambda=0.70926$ Å).

A crystal with approximate dimensions of $0.23\times0.35\times0.23$ mm was used. Data were collected at 20 °C on a Rigaku diffractometer, using graphite-monochromatized Mo$K\alpha$ radiation. All data within a 2θ sphere of 54° ($\sin\theta/\lambda=0.64$) were measured using the θ-2θ scan technique. The integrated intensity was determined by scanning over the peak at a rate of 4°/min and by subtracting the background obtained by averaging the two values measured for 5 s at both ends of a scan; the scan width of each reflection was: $\Delta\theta=1.0°+0.35°\tan\theta_c$, where θ_c is the calculated Bragg angle for λ(Mo$K\alpha_1$) $=0.70926$ Å. A total of 5207 reflections was collected, of which the number of independent, non-zero reflections was 4972. The intensities of three standard reflections (070, 444, and 500) were measured every 50 reflections; no intensity decrease in these reflections was observed during the experiment. Usual Lorentz and polarization corrections were made, but the absorption correction was ignored ($\mu=8.57$ cm^{-1} for Mo$K\alpha$).

Solution and Refinement of the Structure

The structure was established by the heavy-atom method. A three-dimensional Patterson function was computed and interpreted to give the coordinates of palladium and phosphorous atoms. The remaining non-hydrogen atoms were easily located on the successive Fourier maps.

The block-diagonal, unit weight, least-squares refinement was carried out using the HBLS-V program,[5] the function minimized being $\Sigma(|F_o|-k\cdot|F_c|)^2$. Throughout the early stages of the refinement, the first set of data (4307 reflections of relatively lower

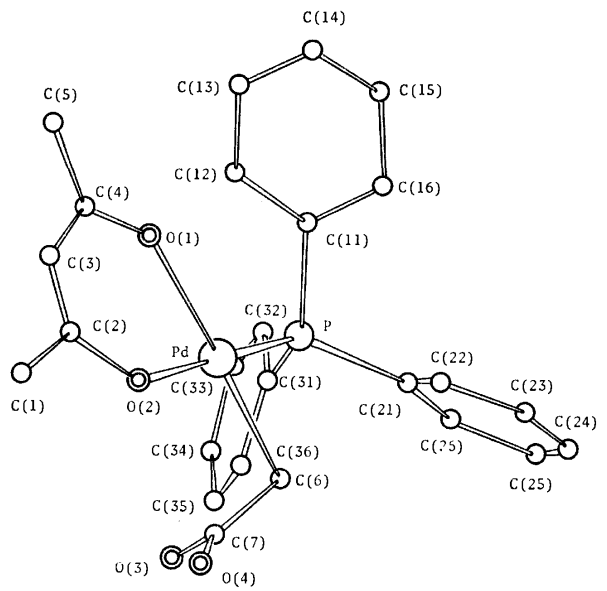

Fig. 1. Molecular structure of [(acac)(PPh_3)$PdCH_2COOH$] and numbering scheme of atoms.

diffraction angles) was used. After several cycles of isotropic refinement, $R_1=\Sigma||F_o|-|F_c||/\Sigma|F_o|=0.068$ for non-zero reflections. A further four cycles of refinement with anisotropic thermal parameters for all the non-hydrogen atoms reduced R_1 to 0.040. The difference synthesis could locate all the hydrogen atoms except the one attached to the carboxyl group; they were assigned to have equal thermal parameters, $B=3.0$ Å^2. The remaining 900 reflections were added to the first set of data. The difference Fourier map, computed after a few cycles of refinement, could locate the remaining hydrogen atom of the carboxyl group. Several cycles of refinement of all the atoms were carried out. The maximum shifts of the positional and thermal parameters for non-hydrogen atoms were about 0.14 σ and 0.08 σ respectively. The final R_1 is 0.032 ($R_2=\{\Sigma||F_o|-|F_c||^2/\Sigma|F_o|^2\}^{1/2}=0.041$) for 4972 non-zero reflections ($R_1=0.037$ for 5207 all reflections).

The atomic scattering factors used in all the calculations were those of Hanson *et al.*[6] The final positional and thermal parameters, along with their estimated standard deviations, are listed in Tables 1 and 2.*

Description of the Structure

Molecular Structure. The molecular structure of [(acac)(PPh_3)$PdCH_2COOH$] is shown in Fig. 1, which also indicates the numbering scheme. Figure 2 shows a stereoscopic view of the molecule, while the coordination geometry around the palladium atom is shown in

* The Table of structure factors is kept as Document No. 7621 at the Chemical Society of Japan.

Fig. 3. Tables 3 and 4 list the bond lengths and bond angles respectively. The least-squares best planes of several groups of atoms and the deviations of atoms from these planes are listed in Table 5.

The most remarkable feature of the overall molecular configuration is that the palladium atom is σ-bonded to the methylene group of acetic acid, as is to be expected from the IR and NMR studies.[2] A second feature is that this compound is dimeric, with intermolecular hydrogen bonding between carboxylic acid moieties. The palladium atom has a square-planar geometry established by one phosphorus, two enolate oxygen (O(1) and O(2)), and one carbon (C(6) in acetic acid) atoms; the mean and maximum deviations from the least-squares plane are 0.04 and 0.05 Å respectively.

The acetic acid moiety (C(6), C(7), O(3) and O(4)) is approximately planar, nearly perpendicular to the coordination plane; the dihedral angle between these planes is 88.5° (Fig. 3). The Pd–C(6)–C(7) angle (105.5(3)°) is slightly smaller than the tetrahedral

angle, and the acetic acid moiety is bent away from the triphenylphosphine ligand. The Pd–C(6) bond length is 2.063(4)Å, which is a normal value and which is in agreement with the sum of the covalent radii (2.07 Å). The carboxyl group is hydrogen-bonded to the carboxyl group of the adjacent molecule related by the center of symmetry. These hydrogen bonds are moderately strong. The hydrogen bond distance is O(3)–H···O(4)=2.621(4) Å (H···O(4)=1.81(5) Å), which is comparable with those found in the majority of the carboxylic acid dimers. The C–O bond lengths are unequal (C(7)–O(3) 1.296(5) and C(7)–O(4) 1.245(5) Å), as is normally observed in most of the carboxylic acid dimers and also in $[(\pi\text{-}C_5H_5)Mo(CO)_3CH_2\text{-}COOH]$.[7]

The acetylacetonate ligand takes a typical enolate-type coordination; the bond lengths and bond angles have normal values, implying that the π-electrons are completely delocalized, as are those in other metal chelates of acetylacetone. This ligand is approximately

planar, and has a pseudo-symmetry of C_{2v} with the unique direction along the Pd–C(3) axis. The dihedral angle between the least-squares planes of this ligand and the coordination plane is 8.0 °. Two Pd–O bond lengths are approximately equal, 2.058(3) and 2.064(3) Å; they are also equal, within the limits of error, to those found in $[Pd(acac)_2(PPh_3)]$ (2.048(10) and 2.062(10) Å).[4]

The Pd–P bond length is 2.235(1) Å, which is close to those in $[Pd(C_2H_2O_2)(PPh_3)(py)]$[2,8] (2.232(3) Å) and $[Pd(acac)_2(PPh_3)]$[4] (2.258(4) Å). However, the values are different from those in $[Pd(C_4H_4O_3)(PPh_3)_2]$[2,9] (2.320(2) and 2.349(2) Å). The bond angles around the phosphorus atom are much distorted from the tetrahedral angle. Similar distortions are generally observed in triphenylphosphine complexes.

Crystal Structure. Figure 4 shows a stereoscopic view of the molecular packing along the c axis. In Fig. 5, the crystal structure projected along the same c axis is given; the intermolecular hydrogen bonds being shown by the dotted lines. The crystal is composed of hydrogen-bonded dimers related by the center of symmetry. Intermolecular atomic short contacts within 3.5 Å are listed in Table 6; some of them are slightly shorter than the usual van der Waals distances.

Computations throughout the present study were carried out on a NEAC 2200-700 computer at Osaka University. Figures 2 and 4 were drawn on a NUMERICON 7000 system at Osaka University with a local version of ORTEP.[10]

The authors wish to express their thanks to Professor Shinichi Kawaguchi and his co-workers of Osaka City University for their kindness in supplying crystals and for their many helpful discussions.

Extrinsic Carrier Photogeneration in Poly(*N*-vinylcarbazole) Films Doped with Dimethyl Terephthalate

Masaaki YOKOYAMA, Yoshihiro ENDO, and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received February 21, 1976)

Based upon the previously reported experimental results that the exciplex fluorescence of poly(*N*-vinylcarbazole) films doped with dimethyl terephthalate is partly quenched by an electric field, a model is proposed for the extrinsic carrier photogeneration mechanism. Interaction between a migrating singlet exciton and an electron acceptor ("encounter complex") produces an electron-hole ion pair having a rather large separation through a charge-transfer process between the components and a thermalization process of the excess energy. This ion pair dissociates into free carriers with Onsager's probability of escaping the geminate recombination which gives a "relaxed fluorescent exciplex state". The field dependence of the initial separation of the ion pair is also discussed.

Poly(*N*-vinylcarbazole) (PVCz) films exhibit only excimer fluorescence, while PVCz films doped with dimethyl terephthalate (DMTP), a weak electron acceptor, give a broad exciplex fluorescence. In the previous letter,[1] we reported that this exciplex fluorescence is partly quenched by applying an electric field in the solid film state, and suggested that this quenching is due to a field-assisted thermal dissociation of the exciplex into free carriers:

$$D^* + A \longrightarrow (D^+\cdots A^-)^* \longrightarrow D^+ + A^-, \qquad (1)$$

where D and A represent donor (PVCz) and acceptor (DMTP) molecules, respectively.

The possibility of such extrinsic carrier photogeneration process in PVCz–DMTP system had been proposed by Okamoto *et al.*[2] from their observation that the exciplex formation in PVCz films doped with DMTP enhanced the photocurrent in the lowest π-π^* absorption region.

Our observation of the quenching of exciplex fluorescence by an electric field provided direct evidence for the above-mentioned exciplex mechanism in the extrinsic photogeneration of carriers, and also is believed more generally to provide an insight into the mechanism of an extrinsic photogeneration in organic molecular crystals. In the previous paper, however, no explanation was presented for the observed quadratic field-dependence of the fluorescence decrement. In the present paper, we present a mechanism of the field-assisted thermal dissociation of an exciplex, by which the observed field-dependence of the fluorescence decrement will be successfully explained.

Mechanism

The mechanism represented by process (1) assumes the formation of exciplex state and its dissociation into free ions (carriers). Nothing is known hitherto concerning the dissociation process of an exciplex in the solid state. We have, however, some informations in the dissociation process of an exciplex in solution.[3–5]

According to the recent time-resolved spectroscopic investigations of the photoionization processes of DA systems, it is believed that (a) when an excited donor (acceptor) molecule approaches to an acceptor (donor) molecule, the interaction occurs at comparatively large distance resulting in a formation of so-called "encounter complex"; (b) this state converts immediately into "charge transfer state" (ionic state) by a rapid electron transfer; (c) this ionic state is a "nonrelaxed exciplex" with respect to the orientation of the solvent molecules; (d) this state relaxes into the ordinary "fluorescent relaxed exciplex state" being assisted by reorientation of the solvent molecules which liberates polarization energy; (e) in favorable cases, this relaxation process accompanies emission of exciplex fluorescence of somewhat shorter wavelength, main part of the exciplex fluorescence being, however, from the relaxed state; (f) if solvent polarity is large enough, dissociation of relaxed and/or nonrelaxed exciplex state into solvated ions becomes possible.

In our present PVCz–DMTP system in a film, however, the lowering of the ionization or dissociation energy by solvent orientation is impossible. From a simple estimation of the energy relation, the fluorescent relaxed exciplex state, in which D^+ and A^- are separated only about 3—4 Å, is found to be so tightly bound by

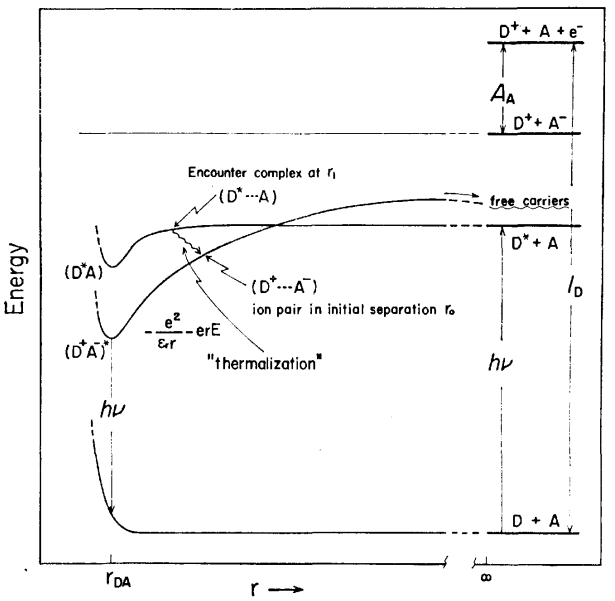

Fig. 1. Schematic energy diagram for the extrinsic photogeneration in DMTP-PVCz exciplex system. The abscissa indicates the separation of donor (D) from acceptor molecule (A), and an asterisk represents the excited state.

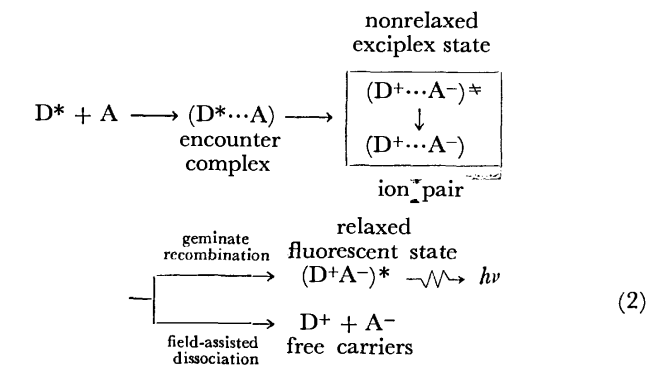
Coulombic force that its dissociation into free ions is impossible by the external field in the present experimental range. It is thus certain that any mechanism which involves the field-assisted thermal dissociation from the fluorescent relaxed exciplex state must be excluded in explaining our present results.

Photogeneration of an Ion Pair

Taking into account that (i) the singlet excited state of PVCz migrates effectively through the carbazole chromophores along the polymer chain,[6] and (ii) the major carrier is a hole, D^+, in a DMTP doped PVCz film as well as in a PVCz film, we propose that an electron-hole pair (ion pair), to which an external electric field is effective in assisting its dissociation, is not the relaxed fluorescent exciplex state, $(D^+A^-)^*$, but the one which is produced from the "*encounter complex*," $(D^*\cdots A)$, between a migrating singlet excition, D^*, and an electron acceptor, A, through a charge-transfer process between the components and a thermalization process of the excess energy. This mechanism is summarized in the following scheme and is depicted schematically in Fig. 1.



(2)

The "*nonrelaxed exciplex state*" named here is the one which is produced from an encounter complex through a rapid electron transfer at somewhat larger separation between the components in an encounter complex than in relaxed fluorescent exciplex state. Such a nonrelaxed exciplex state has the excess kinetic energy, and undergoes a thermalization of the excess energy to give an electron-hole ion pair at a separation r_0. This process is possible since the carbazole chromophores locate around an acceptor in high concentration and D^+ is mobile from molecule to molecule in the neighborhood of A^-. An electron-hole pair thus produced will either recombine geminately to give a "*relaxed fluorescent exciplex state*," or dissociate into free carriers being assisted by an external electric field. The field-assisted dissociation process will be treated in the next section.

Dissociation Process of an Ion Pair

As mentioned above, our model shown by Scheme (2) involves a field-assisted dissociation process of an ion pair state. To this process we have attempted to apply Onsager's theory[7] which predicts the field dependent probability of the dissociation of an ion pair into free ions.

Since this dissociation process is competing with geminate recombination into the relaxed fluorescent exciplex state in our case, we obtain the expression that predicts the ratio of the decrement of the exciplex fluorescence by an electric field to its zero field intensity, $\Delta F/F$, as follows:

$$\frac{\Delta F}{F} = \frac{F(0)-F(E)}{F(0)} = \frac{\eta\phi[1-P(0)]-\eta\phi[1-P(E)]}{\eta\phi[1-P(0)]} = \frac{P(E)-P(0)}{1-P(0)}, \tag{3}$$

where $F(E)$ is the exciplex fluorescence intensity in a field E, ϕ the quantum yield of the electron-hole pairs (field-independent), η the fluorescence quantum efficiency from the relaxed exciplex state, and $P(E)$ the efficiency as a function of E that an electron-hole pair will escape geminate recombination. Using the notation introduced by Geacintov and Pope[8] according to Onsager's theory, this efficiency will be expressed as,

$$P(E) = \int g(r)f(r,\theta,E)\,d\tau$$
$$g(r) = (4\pi r_0^2)^{-1}\delta(r-r_0)$$
$$f(r,\theta,E) = (\exp(-2q/r))\exp(-\beta r(1+\cos\theta)) \times \sum_{m,n=0}^{\infty} \frac{(2q)^m\beta^{m+n}r^n(1+\cos\theta)^{m+n}}{m!(m+n)!} \tag{4}$$

Here r_0 is the initial separation of electron and hole; θ, the orientation of the ion pair relative to the field direction; $q=e^2/2\varepsilon_r kT$; $\beta=eE/2kT$; e, electronic charge; ε_r, relative permittivity; kT, the thermal energy.

In Fig. 2 are shown the calculated curves $[P(E)-P(0)]/[1-P(0)]$ for various initial separations r_0 with $\varepsilon_r=3.0$ and $T=300$ K, together with the experimental data of $\Delta F/F$. Fitting of the experimental data with the theoretical curves gives approximately $r_0=26-30$ Å, although some discrepancies can be seen from a single r_0 value. This discrepancy will be discussed later. This r_0 value is in good agreement with the values obtained from the photocurrent measurements, *i.e.*, $r_0=35$ Å for 2,4,7-trinitro-9-fluorenone (TNF)–PVCz system by Melz[9] and $r_0=30$ Å for acid doped PVCz film by Pfister and Williams.[10]

Thus the quadratic field dependence in the decrement of the exciplex fluorescence is successfully explained on the basis of Onsager's model.

Field Dependence of Initial Separation of an Ion Pair

The deviation of experimental results from the prediction based upon Onsager's theory for the single r_0 value, was also pointed out by Melz[9] in his analyses of the carrier photogeneration from photocurrent measurements in TNF–PVCz films. However, any explanations have not yet been presented for this point.

We have attempted to explain this deviation with

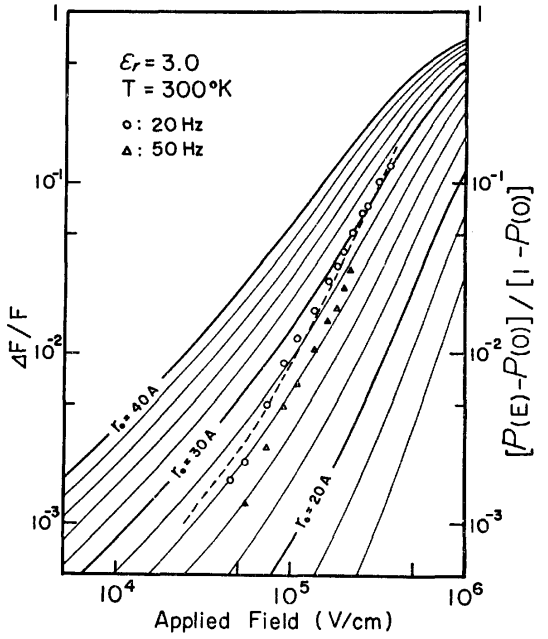


Fig. 2. Field dependence of fluorescence decrement in a 0.5 mol% DMTP doped PVCz film (12 μm thick) with square-wave applied voltage at 20 Hz (○) and 50 Hz (△), and theoretical prediction curves by Onsager's theory for an isotropic initial distribution of electron-hole pairs at various separations; $\varepsilon_r=3.0$, $T=300$ K; A dashed line represents the prediction curve including the field dependence of the initial separation r_0.

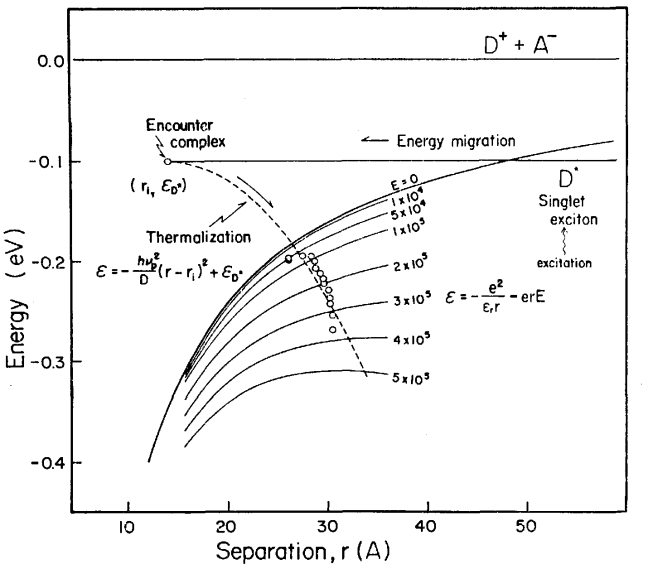

Fig. 3. Schematic representation for field dependence of the initial separations read from Fig. 2 (data at 20 Hz) plotted on the Coulomb potential curves for the corresponding field strengths.

the idea that the initial separation r_0 of the ion pair produced through the thermalization from nonrelaxed exciplex state might be field dependent.

The thermalization process from nonrelaxed exciplex state at the distance r_1 is considered to involve the separation process of an electron-hole pair dissipating the excess kinetic energy by phonon emission as is assumed in Knights-Davis' model.[11] The distance r_1 means the separation between a migrating excited donor and an acceptor at which the electron exchange interaction occurs. In our model, the thermalization begins to occur from this point r_1, but not from $r=0$ as in the case of the autoionization in an anthracene crystal. Therefore, the separation of the ion pair will be given by

$$r_0 - r_1 = \sqrt{Dt}, \tag{5}$$

where D is the diffusion coefficient, t the thermalization time, and r_0 the separation at the end of the thermalization, respectively. In the present case, the diffusion process involves only D^+, because D^+ is mobile from chromophore to chromophore while A^- is localized on an acceptor molecule.

The excess kinetic energy to be dissipated is taken to be equal to the energy difference between the singlet excition energy level (ε_{D^*}) and the Coulomb potential energy at r_0:

$$\varepsilon_{\text{excess}} = \varepsilon_{D^*} + \frac{e^2}{\varepsilon_r r_0} + er_0E, \tag{6}$$

Using the same treatment as described by Knights and Davis,[11] the time to be necessary to dissipate this energy is given by

$$t = \frac{\varepsilon_{\text{excess}}}{h\nu_p^2}, \tag{7}$$

where ν_p is a phonon frequency.

From Eqs. 5—7, we obtain the following equation for r_0 to be satisfied:

$$\frac{(r_0-r_1)^2}{D} = \frac{\varepsilon_{D^*} + \dfrac{e^2}{\varepsilon_r r_0} + er_0E}{h\nu_p^2}. \tag{8}$$

Hence,

$$-\frac{h\nu_p^2}{D}(r_0-r_1)^2 + \varepsilon_{D^*} = -\frac{e^2}{\varepsilon_r r_0} - er_0E. \tag{9}$$

The electron-hole initial separation r_0 at the end of the thermalization process, therefore, should be given as a crossing point of the following two curves in the energy diagram.

$$\varepsilon_1 = -\frac{h\nu_p^2}{D}(r-r_1)^2 + \varepsilon_{D^*}, \tag{10}$$

$$\varepsilon_2 = -\frac{e^2}{\varepsilon_r r} - erE. \tag{11}$$

Equation 10 represents the variation of the ion pair separation during the thermalization, which is given by a quadratic function of r with a curvature $h\nu_p^2/D$ and an apex at (r_1,ε_{D^*}). This equation is inherent to the system chosen. On the other hand, the Coulomb potential curve represented by Eq. 11 at an electric field E is field dependent. Thus, the crossing point, *i.e.*, the initial separation r_0 is field dependent.

In Fig. 3 the open circles represent the initial separations obtained from the experimental data (data at 20 Hz in Fig. 2) plotted on the Coulomb potential curves for the corresponding field strengths. Data points seem to trace something like a quadratic curve.

The thermalization curve is drawn so as to give a good fit by assuming ε_{D^*} to be 0.1 eV ($\Delta\varepsilon$) below the ($D^+ + A^-$) level and $r_1 = 14$ Å, taking into account that the electron exchange interaction in the triplet-triplet energy transfer occurs at the distance of ~15 Å between donor and acceptor molecules.[12] The value 0.1 eV for $\Delta\varepsilon$ gives the electron affinity (A_e) of DMTP to be about 1.0 eV, since the ionization potential (I_p) of PVCz in solid film would be about 4.7 eV[13] and the energy of the singlet exciton (E_{D^*}) of PVCz is estimated to be 3.55 eV from the fluorescence measurements (*i.e.*, $\Delta\varepsilon = I_p - A_e - E_{D^*}$). The value $A_e \sim 1.0$ eV seems to be fairly reasonable from our experience, although unfortunately we have no exact value at present.

Thus, we developed an expression to the field dependence of the initial separation of ion pair, and also showed that it gave a good fit with the experimental data. In Fig. 2 is shown also a prediction curve (dashed line) of the fluorescence quenching including the field dependence of the initial separation of ion pair given by the dashed curve in Fig. 3. As can be seen, the field dependence of the initial separation successfully explains the deviation of the experimental data from a single curve calculated on the basis of Onsager's theory as well as the quadratic field-dependence of fluorescence quenching.

We have developed a mechanism of the extrinsic carrier photogeneration due to a field-assisted thermal dissociation of an exciplex into free carriers. The ion pair which undergoes the dissociation with the assistance of an electric field, is produced through the electron transfer process and the thermalization process from an encounter complex between a migrating singlet exciton and an acceptor. The deviation of the experimental data from Onsager's theory can be explained taking into accout that the initial separation of the ion pair should be field dependent. We believe that the present model for the extrinsic carrier photogeneration would be applicable not only to the present DMTP–PVCz system, but also to organic molecular crystals. Experimental works on the temperature effect and the frequency dependence are now in progress.

Note added in proof. Slightly observed frequency dependence of $\Delta F/F$ values has turned out to be an instrumental artifact due to unexpected partial damage of a load resistance. With a correct resistance, no frequency dependence is observed and the correct values of $\Delta F/F$ are obtained as multiplied by 0.15 for each value at 20 Hz reported.

Since, however, among the curves predicted from the Onsager's theory shown in Fig. 2 the quadratic field-dependence is best reproduced in the case of $r_0 \cong 16$ Å for the initial separation of the ion pair,[9] we must slide down a prediction curve for $r_0 = 26$ Å so as to fit with the corrected values of $\Delta F/F$. Such shifting indicates the presence of a direct leak process from the nonrelaxed exciplex state $(D^+\cdots A^-)^*$ to the relaxed fluorescent state $(D^+A^-)^*$ not through the ion pair state in Eq. 2.

Thus, in more general form Eq. 3 should be corrected as follows:

$$\frac{\Delta F}{F} = \frac{\eta\phi[1-P(0)] - \eta\phi[1-P(E)]}{\eta\phi[1-P(0)] + \eta(1-\phi)} = \frac{\phi[P(E)-P(0)]}{1-\phi P(0)} \qquad (3)'$$

According to Eq. 3′ the fitting of the corrected values of $\Delta F/F$ with the theoretical curve for $r_0 = 26$ Å gives $\phi \cong 0.3$. Even in this case, however, some deviation from the prediction curve for the single $r_0 = 26$ Å value does exist. This deviation can be explained as well by the field-dependent initial separation of r_0 as described in the text.

The detailed analysis based upon the corrected experimental data will be published in this journal as soon as possible.

Spectral Smoothing in Correlation NMR Spectroscopy

Hiroshi OZAWA and Yoji ARATA*

Computer Center, The University of Tokyo, Bunkyo-ku, Tokyo 113

**Department of Chemistry, The University of Tokyo, Bunkyo-ku, Tokyo 113*

(Received February 26, 1976)

A method has been proposed to eliminate a baseline oscillation which appears in a correlation NMR spectrum when one wants to observe peaks on the tilted baseline. An interpolation process in correlation NMR spectroscopy is also discussed which minimizes the number of sampling points.

In correlation NMR,[1,2] only a necessary portion of the spectrum can be scanned, and therefore, dynamic range problems which are frequently encountered in pulse FT NMR is much less serious. We have described in previous papers[3-6] a system for correlation NMR and some of its applications. In the present system, the theoretical function method[2] has been used to compensate the effect of the linear sweep; a rapid scan response is Fourier transformed, and then multiplied by $\exp(-ibt^2/2)$ where b is the sweep rate in radians per second to obtain the free induction decay, which is Fourier transformed again to give the correlation NMR spectrum. In the Fourier transform of a discrete, finite sequence of values, the sequence is assumed to be periodic; the last point of a sequence is assumed to be followed by the first point of the next sequence. As a result of this, when the baseline of the rapid scan response is tilted to a great extent and the first and the last points of a data sequence are quite different in magnitude, the correlation NMR spectrum obtained by the process involving multiplication by $\exp(-ibt^2/2)$ may show an oscillation of the baseline. This situation is actually encountered when one wants to observe small peaks which lie on the shoulder of large one.

One possible way to circumvent the above difficulty is application of an exponential window to the free induction decay which is derived from the rapid scan response. However, this could improve the situation only at the expense of additional line broadening. Another possibility is to apply an apodization window to the rapid scan response. This procedure may cause distortion near either end of the spectrum. In the present paper, we will report a method involving a *wing processing* which was found to be quite useful in observing peaks on the tilted baseline.

Experimental

A JEOL PS-100 NMR spectrometer operating at 100 MHz was modified for correlation spectroscopy as previously described.[3,5] A general program CORNMR was written to process the rapid scan response with the theoretical function method described by Gupta, Ferretti, and Becker.[2]

Results and Discussion

Figure 1a shows a rapid scan response for 2 mM ethanol in H_2O where ethanol peaks are on the shoulder of the large water signal. The conventional correlation NMR procedure leads to a spectrum as reproduced in Fig. 1b. In the present method, the rapid scan response with N data points is provided on its both ends with *wings*; the first point is provided with a *wing* with $N/2$ identical values which is equal to that of the first point, and the last point with a *wing* with $N/2$ identical values equal to that of the last point. The *winged* rapid scan response with $2N$ data points thus obtained is processed by the theoretical function method, and the spectrum is cut out of the relevant part of the final result. The rapid scan response given in Fig. 1a is treated with the above method, and the *winged* rapid scan response (Fig. 2a) was used to obtain the final spectrum shown in Fig. 2b.

Although the oscillation of the baseline is considerably decreased, there is still some residual fine oscillation in Fig. 2b. As discussed above, this comes from the fact that there is a difference in magnitude between the first and the $2N$-th points of the *winged* rapid scan response. A quarter of each *wing* is then replaced by a quarter cycle of the sine function to smoothly connect the *wings*, giving rise to a repetition of smoothly connected rapid scan response. The *winged* rapid scan response obtained by this procedure (Fig. 3a) gave the spectrum which is reproduced in Fig. 3b,

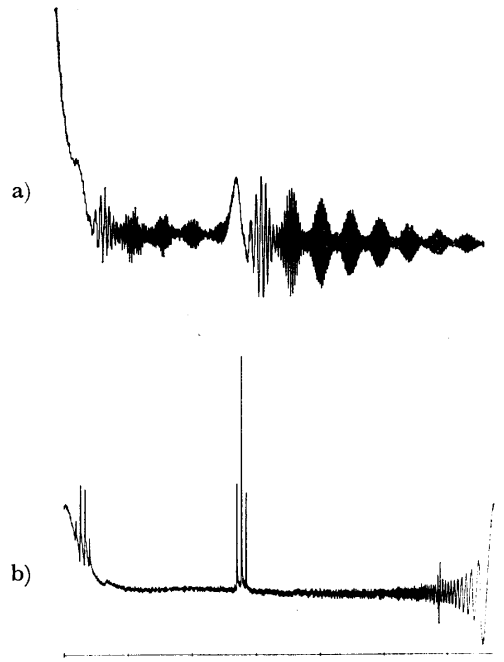

Fig. 1. (a) A rapid single scan response and (b) the correlation NMR spectrum at 100 MHz of 2 mM ethanol in H_2O. Sweep rate, 328.2 Hz/s; sampling time, 2.048 s; number of sampling points, 4096. One division is equal to 100 Hz.

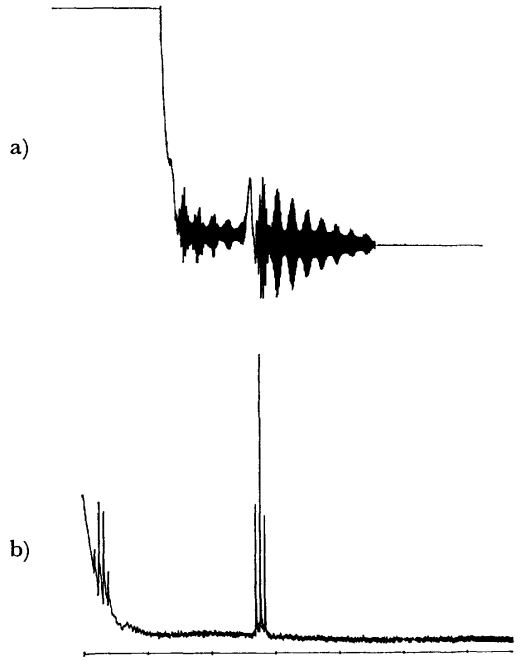

Fig. 2. (a) A rapid scan response in Fig. 1a supplemented with *wings* with 2048 points on its both ends, and (b) the correlation NMR spectrum obtained from it.

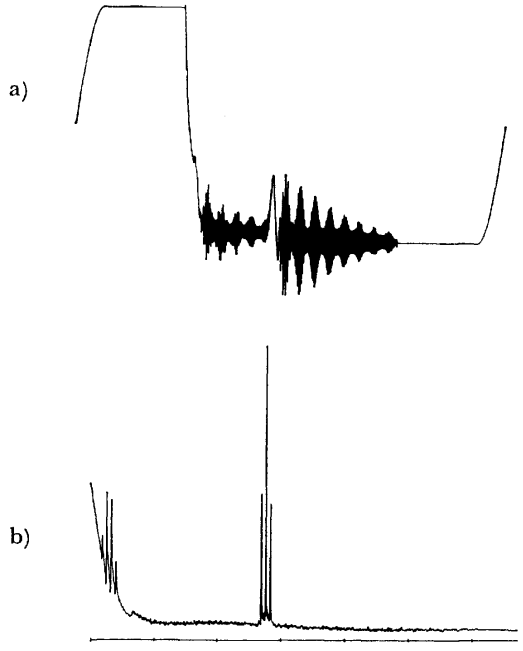

Fig. 3. (a) A rapid scan response in Fig. 2a with *wings* modified by replacing a quarter of each of them by the sine function, and (b) the correlation NMR spectrum obtained from it.

where the undesirable oscillation of the baseline is clearly eliminated. It should be noted that the procedure described here does not give rise to any distortion of the spectrum such as line broadening.

The resonance conditions are met sequentially in correlation NMR spectroscopy. Therefore, if only a necessary portion of the spectrum is scanned, the number of sampling points can be made very small without violating the sampling theorem. Sometimes, the final spectrum obtained using the minimum number of sampling points may not be smooth enough, so that it is quite difficult to find the peak maxima. However, interpolation can easily be done by supplementing a sufficient number of zeroes at the end of the free induction decay which is derived from the rapid scan response. Bartholdi and Ernst[7] have discussed the effect of supplementing zeroes at the end of the free induction decay obtained in the case of pulse FT NMR. In correlation NMR, this feature should especially be important when one wants to observe, for example, carbon-13 spectra where signals scatter over a wide range of frequency.

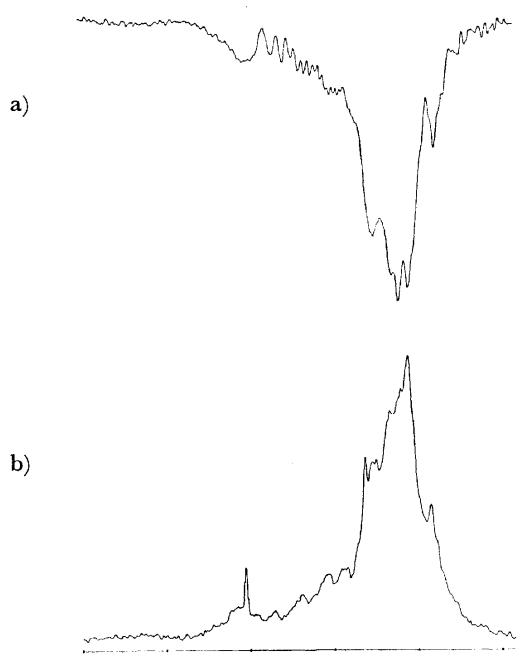

Fig. 4. (a) Rapid scan response and (b) the correlation NMR spectrum at 100 MHz of the aromatic region of hen egg white lysozyme in D_2O (10% (w/v) in 99.8% D_2O, pH=1.73, 35 °C). Sweep rate, 530.0 Hz/s; sampling time, 0.9728 s; number of sampling points, 2048; number of accumulations, 256; phase correction angle to obtain the spectrum, 180°. One division is equal to 100 Hz.

Figure 4a shows a rapid scan response for the aromatic region of hen egg white lysozyme in D_2O, where the sweep rate, sampling time, and number of sampling points are 530.0 Hz/s, 0.9728 s, and 2048, respectively. The spectrum obtained from this rapid scan response is given in Fig. 4b. Since the narrowest signal has a width of approximately 5 Hz, 256 data points should have been sufficient under the experimental condition to acquire all necessary information. The total of 256 data points which have been picked out of every eight points of the rapid scan response was used to obtain the free induction decay, from which the correlation NMR spectrum was derived; the histidine C-2 proton part of the spectrum is reproduced

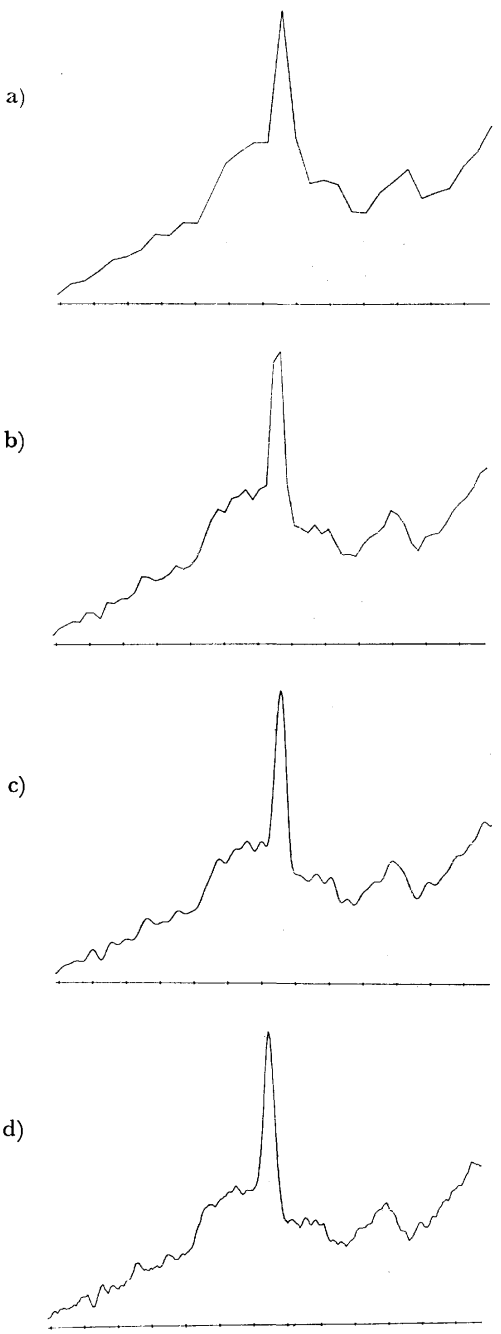

Fig. 5. Correlation NMR spectra of the histidine C-2 proton of hen egg white lysozyme in D_2O. Spectrum (a) was obtained by using 256 data points which are picked out of every eight points of the rapid scan response in Fig. 4a. The free induction decay used to obtain the spectrum (a) was made twice and eight times in length by supplementing zeroes at its end, from which spectra (b) and (c) were derived, respectively. The corresponding part of the spectrum shown in Fig. 4b is reproduced in (d). One division is equal to 10 Hz.

in Fig. 5a. The spectra in Figs. 5b and 5c are obtained when the number of data points of the free induction decay is made twice and eight times respectively in length by supplementing zeroes at its end. Figure 5c is quite similar with the exception of high-frequency noise to Fig. 5d which is a part of the spectrum in Fig. 4b derived using 2048 data points.

In conclusion, the present techniques to achieve spectral smoothing should allow additional freedom in using correlation NMR spectroscopy.

The authors wish to thank Professor S. Fujiwara for his continual encouragement.

Kinetic Study of Poly(acrylic acid)-Copper(II) Complex Formation

Hiroshi NISHIKAWA and Eishun TSUCHIDA

Department of Polymer Chemistry, Waseda University, Tokyo 160

(Received July 19, 1975)

The kinetics of poly(acrylic acid)–copper(II) (PAA–Cu) complex formation has been studied by a relaxation method. It was found that the greater stability of PAA–Cu complex than that of a monomeric analog is due to the increase of forward rate constant (k_f(PAA)/k_f(GA)=4) and decrease of the reverse rate constant (k_r(PAA)/k_r(GA)=1/4) in the polymer system. The results are explained in terms of an electrostatic effect of polyelectrolyte and a conformational change of the polymer ligand.

Several reports have appeared on the kinetics of complexation reactions of labile metal ions.[1–4] However, reaction with a polymer ligand has not been studied due to the complexity of the polymer system. Although polymer metal complexes, in particular polymer–copper(II) complexes exhibit high activity in the catalytic reaction in solution,[5,6] the mechanism of the catalysis has not been elucidated. In order to study the polymer–copper(II) complex catalyzed reaction in detail, it is necessary to clarify the effect of the polymer ligand on the complexation reaction. Static studies have been carried out on formation reaction of the polymer–copper(II) complexes by several investigators,[7–10] but the kinetics remains unclarified. The complexation reaction of copper(II) being very rapid, a relaxation method can be utilized for determining the reaction rate constant.

This paper deals with a kinetic study of the reaction of copper(II) ion with poly(acrylic acid) by means of the temperature-jump method. Discussion is given on the effect of polymer ligands in the kinetics of the complexation reaction.

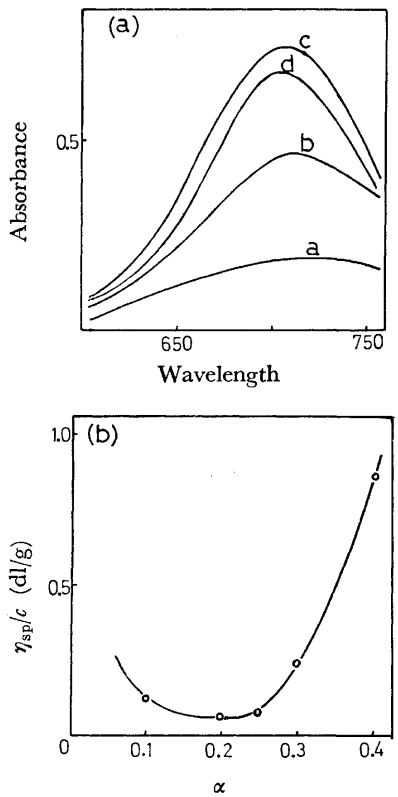

Fig. 1. Viscometric and spectroscopic change of poly(acrylic acid)-copper(II) solution with neutralization. [PAA]=1.0×10^{-2} unit·mol/l, [Cu]/[PAA]=1/10
(a) a: α=0.05, b: α=0.15, c: α=0.25, d: α=0.35

Experimental

Materials. Poly(acrylic acid) (PAA) was prepared by radical polymerization of acrylic acid, its average molecular weight being 1.2×10^5 as determined by viscometric measurement.

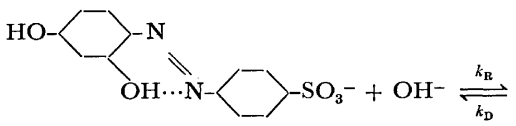
Commercial $CuCl_2\cdot H_2O$, gultaric acid, malonic acid, and other salts were used. The concentration of Cu(II) ion in solution was determined by chelate titration with use of EDTA.

All the solutions were prepared with freshly distilled water.

Methods. The acid dissociation constant of poly(acrylic acid) was determined by Henderson-Haselbach's method[7] by potentiometric titration with a Hitachi-Horiba M-1 pH-meter.

The viscosity of the polymer complex solution was measured at 25 °C with an Ubbelohde viscometer. Visible spectra of the polymer complex solutions were observed with a Shimadzu MPS50 spectrophotometer.

The complexation reaction of Cu(II)–PAA was followed with a temperature-jump apparatus (Union Giken RA-1200), the optical change in the indicator added (bromocresol green and bromochlorophenol blue) being observed. The rise-time of the temperature-jump apparatus is below 1 μs as confirmed from the discharge-curve, the other functions of the apparatus being checked through the reaction of proton exchange on trepaeolin 0,



Trepaeolin O + H_2O

k_R: 3.8×10^5 $M^{-1}\cdot s^{-1}$ (3.6×10^5 $M^{-1}\cdot s^{-1}$)
k_D: 7.6×10^3 s^{-1} (8×10^3 s^{-1})

where the values in parentheses were taken from the work of Eigen *et al.*[11]

The complexation reaction of each monomeric analog was studied by the same way as in the polymer system.

Result and Discussion

The spectroscopic result showing that the maximum wavelength of d-d absorption spectra of poly(acrylic acid)–copper(II) (PAA–Cu) complex is observed at 700 nm (Fig. 1(a)), near that of malonato copper(II) (MA–Cu) complex (659 nm), suggests that two acrylate units of PAA coordinate to a copper(II) ion, a chelate complex being formed. Thus the complexation re-

action of PAA with copper(II) can be expressed by Eq. 1, where L is a coordination unit consisting of two acrylate anions, and HL one consisting of an acrylate anion and an undissociated acrylic acid.

$$M^{2+} + L^{2-} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} ML \qquad k_f/k_r = K$$

$$M^{2+} + HL^{-} \underset{k_r'}{\overset{k_f'}{\rightleftharpoons}} ML + H^{+} \tag{1}$$

Analysis of the temperature-jump data requires a prior knowledge of appropriate equilibrium constants. The stability constant of polymer metal complex was determined by a modified Bjerrum's method reported by Gregor *et al.*[7] The acid dissociation constant of polyacid being affected by the charge on the partially dissociated polymer chain, the dissociation constant of PAA was determined by the following equations,

$$K' = \frac{[H^+][A]}{[N]}(Z)^{n-1} \qquad Z = \frac{\text{charged unit}}{\text{uncharged unit}}$$

$$K_1^a = \frac{[H^+][HL^-]}{[H_2L]} \qquad K_2^a = \frac{[H^+][L^{2-}]}{[HL^-]} \tag{2}$$

$$[A] = 2[L^{2-}] + [HL^-], \quad [N] = [HL^-] + 2[H_2L],$$

$$[L^{2-}] = \left[\frac{[A]}{[N] + [A]}\right]^2 [L]_t$$

where K' and n are given by Henderson-Haselbach plots, and [A], [N], and $[L]_t$ are concentration of acrylate anion unit, undissociated acrylic acid unit, and total concentration of uncoordinated ligand unit, respectively. Average coordination number, $\bar{n}$, is given by Eq. 3, where $[H_2L]_t$ and $[Cu(II)]_t$ are initial concentrations of ligand unit and copper(II) ion, the stability constant K of each system being given by the $\bar{n}$ *vs.* $p[L^{2-}]$ plots according to Bjerrum's theory.

$$\bar{n} = \frac{[H_2L]_t - [H_2L] - [HL^-] - [L^{2-}]}{[Cu(II)]_t} \tag{3}$$

The equilibrium constants used for analysis of PAA–Cu(II) system and its monomeric analog are given in Table 1.

The ranges of pH and concentrations of PAA and copper(II) ion available are strictly restricted by three factors: (1) decomposition of the chelate structure due to the electrostatic repulsion between carboxylate anions (Figs. 1(a) and 1(b)), (2) olation of the complex or copper ion, and (3) relatively small absorption change in the lower pH region.

By applying standard techniques for deriving relaxation time expressions,[3,12] we have

$$1/\tau = Ak_f + Bk_f'$$

$$A = \frac{[M^{2+}]}{1+\alpha} + [L^{2-}] + \frac{1}{K}$$

$$B = \frac{[M^{2+}]}{1+\alpha} + [HL^-] + \frac{1}{K \cdot K_2^a}\left([H^+] + \alpha\beta\frac{[ML]}{1+\alpha}\right) \tag{4}$$

$$\alpha = \frac{K_1^a[H^+] + \beta[H^+][HL^-] + [H^+]^2}{K_1^aK_2^a + 4\beta K_2^a[HL^-] + \beta K_2^a[L^{2-}]}$$

$$\beta = \frac{K_{In} + [H^+]}{K_{In} + [H^+] + [In^-]}$$

Since acid dissociation "constant" K_1^a or K_2^a changes in the polymer system with the charge on the polymer, K_1^a and K_2^a were calculated separately by Eq. 2 for each experimental point.

Plots $(\tau B)^{-1}$ *vs.* AB^{-1} for PAA–Cu(II) at the concentrations of PAA 1.0×10^{-2} M and 0.5×10^{-2} M (Fig. 2). The plots are almost linear, indicating that the standard relaxation techniques can be used for the polymer system. The same plots for the monomeric analog, glutarato–copper(II) (GA–Cu) and malonato–copper(II) (MA–Cu) complexes are illustrated in Figs. 3 and 4. The slopes give k_f's and intercepts k_f' respectively. The rate constants obtained are summarized in Table 2.

When the k_f values of Cu–PAA were compared with those of monomeric analog, the order acetic acid(AA)–Cu>MA–Cu>PAA–Cu>GA–Cu, was observed, which

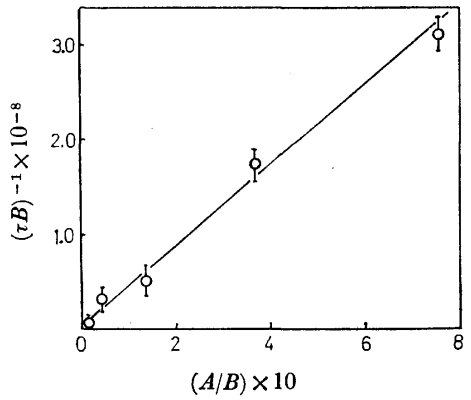

Fig. 4. Plots of $(\tau B)^{-1}$ *vs.* A/B for Cu(II)-MA system.

agrees with that of the stability constants except for the AA–Cu system.

Eigen and Wilkins proposed the following mechanism for bidentate complex formation.[1]

$$\underset{\text{I}}{W_2M\ W_1} + \text{A-B} \overset{K_{os}}{\rightleftharpoons} \underset{\text{II}}{W_2M\ W_1A\text{-B}}$$

$$\underset{\text{II}}{W_2M\ W_1A\text{-B}} \underset{k_1'}{\overset{k_1}{\rightleftharpoons}} \underset{\text{III}}{W_2M\text{-A-B}} + W_1 \qquad (5)$$

$$\underset{\text{III}}{W_2M\text{-A-B}} \underset{k_2'}{\overset{k_2}{\rightleftharpoons}} \underset{\text{IV}}{M\langle \overset{A}{B}) } + W_2$$

The first outer sphere complex formation step is very fast and diffusion controlled. If we assume that the outer sphere complex formation is in an equilibrium the forward rate constant k_f is given by

$$k_f = K_{os}k_1\frac{1}{1+(k_1'/k_2)} \qquad (6)$$

The equilibrium constant K_{os} for the outer sphere complex formation is affected by charge on both the metal ion and the ligand, the approximate value being given by[13]

$$K_{os} = 4Na^3/3000 \exp\frac{z_M z_L e_0^2}{\varepsilon a \kappa T} \qquad (7)$$

where N, a, κ and ε are the Avogadro number, the distance of the closest approach of the two ions, the Boltzmann constant and the dielectric constant, respectively, z_M and z_L being the corresponding net charges of metal and ligand.

Comparing the K_{os} value of each system calculated by Eq. 7, we find that the K_{os} values for MA–Cu and GA–Cu are about 7.5 times larger than that for AA–Cu. The K_{os} value of copper with PAA could not be calculated since the net charge of the ligand was not definite. However, it is certain that the K_{os} value for PAA–Cu is greater than that for the monomeric analog due to increase of ligand's net charge by carboxylate anions on the same chain. The large k_f value for PAA–Cu can be explained partially by the electrostatic effect of the neighboring carboxylate anions on the outer sphere complex formation.

The II→III step of each system examined is the substitution of water by carboxylate anion. If we assume that the k_1 values are the same for all the systems, the k_f/K_{os} value gives a measure of the difficulty of the chelate formation. The stability of the chelate ring is dependent on the number of atoms constituting the chelate and 5-(unconjugated system); 6-(conjugated system) membered ring is the most stable. Since the ligands in the complexes we examined are not conjugated, the chelate ring formation is considered to be rather slow in MA–Cu where a six-membered ring is formed, and much slower in GA–Cu where an eight-membered ring is formed. This is in line with the results obtained by means of Eq. 6 where the k_1'/k_2 value of GA–Cu is 30 times larger than that of MA–Cu.

The reduced viscosity of the polymer solution changes with the complexation (Fig. 1 (b)). This suggests that the conformation of the polymer ligand changes with chelate formation or dissociation. A larger k_1'/k_2 value and a smaller k_f/K_{os} value for polymer system as compared with those of monomeric analog are reasonable. However, the k_f value of PAA–Cu we obtained was larger than that of the GA–Cu system. This can not be explained by the effect of polymer ligand on the chelate formation step (III→IV).

The k_f value decreased with the increase of the polymer concentration. This might be due to the formation of intermolecular complex at higher polymer concentration since the anion concentration per one polymer molecule is lowered.

This work was partially supported by a Grant in Aid for Scientific Research from the Ministry of Education (No. 011011).

The Dissolution of Titanium Minerals in Hydrochloric and Sulfuric Acids

Masayuki IMAHASHI and Nobuki TAKAMATSU

Department of Chemistry, Toho University, Miyama-cho, Funabashi, Chiba 274

(Received July 23, 1975)

Kinetic dissolution experiments of powdered ilmenite and rutile were carried out in sulfuric and hydrochloric acids (0.03—1 M) at temperatures of 40, 65, and 90 °C in order to study the physico-chemical factors and the mechanism for the leaching of titanium and iron from these minerals and rocks under acidic conditions. The dissolution rate of ilmenite was strongly affected by the acidity and temperature of the acid solutions; the rate changes in the H_2SO_4 solutions were greater than those in the HCl solutions. The dissolution rate of rutile was much slower than that of ilmenite. Ilmenite was decomposed by the dissolution of titanium and iron in a nearly stoichiometric ratio under strongly acidic conditions such as 0.3—1 M. But under milder conditions, such as 0.03—0.1 M at 90 °C, the dissolution rate of titanium dropped rapidly in the initial step and the curved line for iron dissolution was nearly parabolic, suggesting the diffusion of iron through the residual layer of titanium.

Titanium is relatively abundant in the earth's crust: igneous rocks contain an average of approximately 0.44% of this element by weight.[1] Titanium is usually found in igneous and metamorphic rocks as titanomagnetite (Fe_2TiO_4–Fe_3O_4), ilmenite ($FeTiO_3$), and rutile (TiO_2), and is also found in pyroxene, hornblend, and biotite. Generally titanium remains undissolved in its host rocks even through the process of weathering and hydrothermal alteration of igneous rocks,[2] not only because it is present in the form of resistant minerals but also because it tends to form insoluble hydroxides in aqueous solutions. One of the authors[3] reported the titanium content of hydrothermally-altered rocks from the Tateyama Jigokudani area; while most of the titanium had remained immobile in the rocks, a part of it had been leached out under the strongly acid conditions. According to Noguchi *et al.*,[4] acid hot spring waters in Japan contain about $0.001n$—$0.1n$ mgTi/l and the titanium content of the waters tends to increase with increasing acidity. The titanium in the acid spring waters is likely to be derived from wall rocks by the attack of acid thermal solutions containing sulfuric and hydrochloric acids. The interaction between thermal solutions and rock-forming minerals may result in alterations of rocks, which would proceed through complicated processes: *i.e.*, hydration, ion exchange, dissolution, deposition, and recrystallization. All these processes should be affected by various physico-chemical factors, such as acidity, temperature, type of acid, *etc.* Some studies of the dissolution kinetics of rock-forming minerals have been reported,[5–8] but few reports on titanium minerals have been presented, except for the mineralogical studies of the alteration of ilmenite and other minerals.[9] In this study kinetic dissolution experiments on the decomposition of powdered ilmenite and rutile were carried out to examine the influence of the chemical character of active solutions and to analyze the mechanism of the decomposition of the minerals.

Experimental

Ilmenite and rutile were used in this study as titanium minerals. The dissolution experiments of powdered ilmenite (*cf.* Table 1) were carried out in H_2SO_4 and HCl solutions of 0.03—1 M at 40, 65, and 90 °C, and the experiments of rutile were also carried out in 1 M H_2SO_4 and HCl at 90 °C. The experiments were performed according to the procedure of Kamiya *et al.*[10] The acid concentration of the leaching solutions was adjusted by the addition of sulfuric and hydrochloric acid into distilled water, and at the same time the pH value of the solutions was measured in the range from 40 to 90 °C with a pH meter for high temperatures. Slight differences were found in the pH values of the initial and final solutions. 1 g of ilmenite (120—200 mesh) and/or rutile (under 120 mesh) was suspended in 250 ml of leaching solution, temperature-regulated at 40, 65, or 90 °C, which was stirred continuously with a magnetic stirrer coated with polyethylene. The dissolution rate of titanium and iron was determined by periodically pipetting a 10 ml aliquot from the bottle, centrifuging for a few minutes to remove the titanium minerals, and chemically analyzing the supernatant solution. Titanium and iron were determined colorimetrically by DAM (diantipyrylmethane) and *o*-phenanthroline respectively.

Results and Discussion

The amounts of titanium and iron leached from the powdered ilmenite at different times are shown in Figs. 1 to 6 and Figs. 9 and 10 respectively. These figures show that the leached amounts of titanium and iron are strongly affected by the acidity and temperature of the leaching solutions, and that these amounts in H_2SO_4 solutions are larger than those in HCl solutions at the same molality and temperature. As seen in Fig. 7, the amount of titanium leached from powdered rutile was very small compared with the ilmenite; the amount in the H_2SO_4 solutions was also larger than that in the HCl solutions. It can be seen from these figures that the titanium and iron ions are transported to the solution when hydrated protons diffuse into the solid, as indicated by Sanemasa and Katsura,[8] and that the dissolution rate of the ions from the minerals in the H_2SO_4 solutions is faster than that in the HCl solutions. Packter *et al.*[11] observed that the dissolution rate of gibbsite in the H_2SO_4 solutions was markedly faster than the rates in the HCl and $HClO_4$ solutions. They attributed the rate-promoting effect of sulfuric acid to the dipole interaction between the HSO_4^- ion or $H^+\cdots\cdots SO_4^{2-}$ ion pairs and the active sites on the solid surface. The study of olivine dissolution[7] also showed an effect from sulfuric acid similar to the case of gibbsite.

On the other hand, Kamiya *et al.*[10] reported that the dissolution of powdered quartz was catalyzed by sulfate and chloride ions and that the catalytic activity of the divalent sulfate ion was higher than that of the monovalent chloride ion. As described previously, the dissolution rates of titanium and iron from ilmenite were affected more highly by sulfate ions (and HSO_4^-) than by chloride ions, but the effect of sulfate ions on iron was not so large as on titanium. This may be due to the differences of valences and ionic radii between titanium and iron. Furthermore, the dissolution experiments of microcline[12] showed that Al^{3+} dissolution from the mineral was accelerated in the presence of sulfuric acid. These experiments, however, do not enable us to determine whether the interaction between titanium and sulfate (HSO_4^-) ion resulted from an electrostatic force or from an electronic force such as the bonding in coordination compounds. In any event, it is evident that sulfate and hydrogensulfate ions play an important role in the dissolution of ilmenite and rutile.

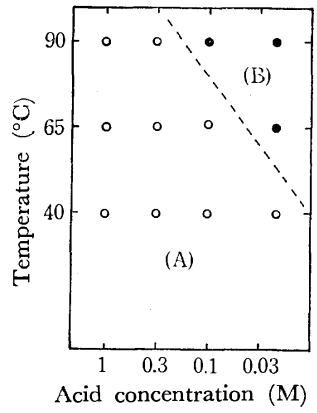

Fig. 8. Temperature and acid concentrations used in this experiment.

Figures 11 and 12 show the values of the molar ratio for the amount of titanium and iron dissolved at different times. The values were always smaller than 1, but these tended to become larger or smaller with time according to the conditions. Therefore, we have divided the conditions into the two groups shown in Fig. 8. Under the conditions of group A, the dissolution rate of iron from ilmenite was larger than that of titanium during the initial step of the dissolution, and over a very long time period the ratio of titanium to iron approached the stoichiometric ratio, *i.e.* Ti/Fe=1. On the other hand, under the conditions of group B, the values of the ratio tended to become smaller with time, and the amount of titanium leached in the course of the leaching experiments at high temperatures became less than that at low temperatures.

If we assume that the change in the surface of powdered ilmenite brings about the depression of the dissolution rate with time, we get the following approximate equations[10] for the A group:

$$m = K_1St + m_0 \qquad S = S_0(1-K_2t)$$
$$m - m_0 = K_1S_0 - K_1K_2S_0t^2$$

where m and m_0 are the amounts of dissolved titanium at time t and at the beginning, S and S_0 are the surface areas of powdered ilmenite at time t and at the beginning, and K_1 and K_2 are the constants for dissolution of titanium and for decrease in surface area, respectively. As the surface area of powdered ilmenite was not measured in our experiments, K_1S_0 represents the apparent dissolution rate of titanium at time zero. Figure 13 shows the values for K_1S_0 at different acid concentrations; the values tend to become smaller with decreasing temperature under the A conditions. On the other hand, under the B conditions (*e.g.*, 0.03 M at 90 °C) the amount of titanium leached at intervals of one hour was reduced rapidly in the initial step of the dissolution, as shown in Fig. 14. Therefore, under the B conditions it must be considered that some other factor besides the decrease of surface area brought about the depression of the dissolution rate. It might be thought to be the formation of insoluble

materials on the surface. And in fact, under the A conditions the curved line for iron dissolution was nearly linear, while the line was nearly parabolic under the B conditions. As shown in Figs. 15 and 16, an approximately linear relationship exists between the square of the leached amount of iron and time, *i.e.*, $m^2=kt+k'$, where m=leached amount of iron, t=time, and k=constant; this relationship is presumed to show that the iron ion diffuses through the residual layers into the solution. However, we could not discover any change of the structure of ilmenite by X-ray diffraction analysis after the 36 h leaching experiment at 90 °C in 0.1 M H_2SO_4. The amount of residual materials, therefore, is likely to be slight and the layer, if present, to be amorphous.

It may be concluded that ilmenite is decomposed by the dissolution of titanium and iron in a nearly stoichiometric ratio in the H_2SO_4 and HCl solutions ranging from 0.3 to 1 M, but in the solutions ranging from 0.03 to 0.1 M (pH 1—1.5) at 65—90 °C the dissolution rate of titanium decreases rapidly in the initial step. Consequently, the iron ion may diffuse into the acid solution through the insoluble residual layer of titanium. The insoluble materials of titanium

seem to be changed into resistant oxide minerals such as rutile over a long period, although we could not identify the minerals in this experiment in the limited time of 16 h. As described previously, the solubility of rutile in 1 M H_2SO_4 and HCl solutions was very much smaller than that of ilmenite, and rutile, therefore, does not seem to dissolve very much in acid

solutions having concentrations below 0.1 M or pH 1. This supports the view that rutile is a fairly common alteration product of other titanium minerals, chiefly ilmenite, titanomagnetite, sphene, and perovskite, as well as of its polymorphs anatase.[13] It is reasonable to expect, moreover, that titanium minerals such as ilmenite and titanomagnetite in igneous rocks are changed into a titanium oxide mineral during the hydrothermal alteration at high temperature for pH 1.5 or above. The high content of titanium in hydrothermally-altered rocks from acid hot spring areas[3] seems to be due to the insolubility of the oxide minerals described above.

The authors wish to express their deep gratitude to Professor Hiroshi Kamiya of Nagoya Institute of Technology for his valuable advice and for his critical reading of the manuscript. The authors also wish to express their thanks to Professor Kimio Noguchi of Toho University for his encouragement throughout this work.

Polarographic Anodic Wave of Hydrogen Peroxide in Alkaline Solutions

Kenji KIKUCHI and Teisuke MURAYAMA*

Shiga Prefectural Junior College, Hikone, Shiga 522

**Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432*

(Received August 1, 1975)

The anodic reaction of hydrogen peroxide in alkaline solutions has been studied by the polarographic method. Polarograms were recorded in solutions with pH values ranging from 10.0 to 13.5. Hydrogen peroxide in alkaline solutions shows a one-step anodic wave at the dropping mercury electrode. The plot of half-wave potential against pH consists of three segments, each corresponding to a different value of $d(E_{1/2})/d(pH)$: -57 mV for the values of pH below 11.6, -29 mV for the pH range from 11.6 to 13.2, and 0 mV for the values of pH above 13.2 The limiting current is controlled by diffusion. It is concluded that the anodic wave corresponds to the formation of the species $[Hg(O_2H)(OH)]$.

Recently Honda *et al.* reported on the anodic reaction of hydrogen peroxide in alkaline solutions at the dropping mercury electrode.[1] They proposed a reaction mechanism given by:

$$H_2O_2 \rightleftharpoons H^+ + HO_2^- \quad (1)$$

$$HO_2^- \rightleftharpoons HO_2(a) + e^- \quad (2)$$

$$OH^- \rightleftharpoons OH(a) + e^- \quad (3)$$

$$HO_2(a) + OH(a) \rightleftharpoons O_2 + H_2O \quad (4)$$

where (a) denotes the adsorbed state. Based on experimental observation, they concluded that the rate-determining step is Reaction 4. The present study, however, indicates that another interpretation is more appropriate.

Experimental

All chemicals used were of reagent grade. The water used for all solutions was prepared by distillation of deionized water with potassium permanganate. The concentration of hydrogen ions in solutions was controlled with acetate buffer (pH 3.5 to 5.6), phosphate buffer (pH 6.0 to 7.7 and 11.0 to 12.0), ammonia buffer (pH 8.8 to 11.0), and sodium hydroxide solution (above pH 12.0). Five one-thousandths of 1% gelatin was added as the maximum suppressor. The ionic strength of the test solutions was adjusted to 0.1 or 0.5 M with either sodium nitrate or sodium chloride. The pH value of the test solutions was measured by use of a TOA HM-5B pH meter with a TOA HG-4005 glass electrode. The concentration of hydrogen peroxide in the stock solution was determined by iodometry.[2]

Polarograms were recorded by a Yanagimoto Model P8 polarograph. The cell used was of a beaker type. A saturated calomel electrode (SCE) was used as a reference electrode. The dropping mercury electrode (DME) had the following characteristics (in 0.5 M sodium chloride solution at zero applied potential *vs.* SCE and at a mercury head of 80.0 cm): the rate of flow of mercury (m), 2.338 mg/s; the drop time (t), 3.88 s; the capillary constant ($m^{2/3}t^{1/6}$). 2.15 $mg^{2/3}s^{-1/2}$. All potentials reported in this paper were corrected for iR drop. The test solution was freed from oxygen by bubbling nitrogen through the solution for 50 minutes and thermostated at 20.0±0.1 °C. As soon as the DME was introduced into the test solution, the recording of polarograms was started; each was completed within 10 minutes. Changes in the concentration of hydrogen peroxide during the bubbling and the recording were found to be within 1% of the initial concentration.

Results

The anodic wave of hydrogen peroxide observed in the solutions with pH values below 10 was accompanied by a maximum, making any quantitative discussion impossible. Figure 1 shows typical polarograms obtained in solutions with pH values above 10. It illustrates that hydrogen peroxide produces a single anodic wave and that the wave shifts to negative potentials with increasing pH. Logarithmic plots of the wave are given in Fig. 2, where the experimental points form good straight lines with a reciprocal slope of 29 to 30 mV. In the construction of the plots the current was corrected by the residual current determined in the 0.1 or 0.5 M sodium nitrate solution, not by the one determined in a buffer solution as is usual. The reason for this procedure is that the buffer solution produces an anodic current due to the hydroxide ion which also participates in the anodic reaction of hydrogen peroxide, as will be shown later.

Figure 3 shows variations of the half-wave potential and limiting current with pH. The former consists of three segments with different slopes: -57 mV for values of pH below 11.7, -29 mV for the pH range from 11.7 to 13.2, and 0 mV for values of pH above 13.2. The limiting current decreases with increasing pH until the value of the pH becomes 11.7, then remains unchanged.

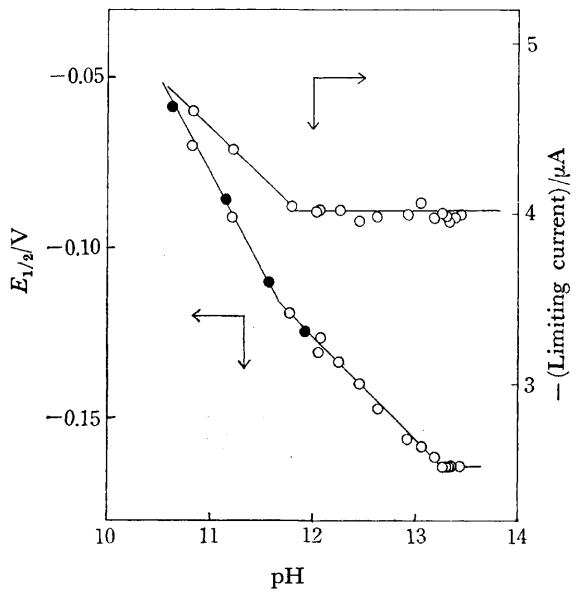

Fig. 3. Effect of pH on the half-wave potential and the limiting current.
Concentration of H_2O_2, 0.512 mM. Ionic strength: ○, 0.5 M; ●, 0.1 M.

When the pH of the solution was kept constant, the limiting current increased in proportion to the concentration of hydrogen peroxide and to the square root of the height of the mercury column. The temperature coefficient of the limiting current was 1.5×10^{-2} K^{-1}. These facts indicate that the limiting current is controlled by diffusion. The diffusion current of 0.512 mM hydrogen peroxide, i_d (μA), can be represented by

$$i_d = -5.07 + 0.57\ (\mathrm{pH}-10) \tag{5}$$

for pH values below 11.7, as shown in Fig. 3.

Discussion

Honda *et al.* considered that the oxidation reaction of HO_2^- is responsible for the anodic wave of hydrogen peroxide. It is, however, much more natural to assume that this wave corresponds to the dissolution of electrode mercury and the formation of a mercury(II) complex, as given by

$$Hg \rightleftharpoons Hg^{2+} + 2e^- \tag{6}$$

$$Hg^{2+} + HO_2^- + OH^- \rightleftharpoons [Hg(O_2H)(OH)] \tag{7}$$

The species HO_2^- is supplied by the acid dissociation reaction of H_2O_2.

$$H_2O_2 \rightleftharpoons HO_2^- + H^+ \tag{8}$$

The potential of DME may be written as

$$E = E^\circ + \frac{RT}{2F}\ln[Hg^{2+}]y \tag{9}$$

where E° is the standard potential of a mercuric-mercury electrode, R the gas constant, T the absolute temperature, F the Faraday constant, and y the activity coefficient of the mercuric ion. The concentration of mercuric ions at the electrode surface is given by

$$[Hg^{2+}] = \frac{\left(\frac{[H^+]}{K_a}+1\right)[H^+][Hg(O_2H)(OH)]}{\beta K_w([H_2O_2]+[HO_2^-])} \tag{10}$$

where K_a is the acid dissociation constant of H_2O_2, K_w the ionic product of water, and β the equilibrium constant of Reaction 7. Three equilibrium constants, K_a, K_w, and β, are defined as follows:

$$K_a = \frac{[H^+][HO_2^-]}{[H_2O_2]}$$

$$K_w = [H^+][OH^-]$$

$$\beta = \frac{[Hg(O_2H)(OH)]}{[Hg^{2+}][HO_2^-][OH^-]}$$

Introduction of Eq. 10 into Eq. 9 gives

$$E = E^\circ + \frac{RT}{2F}\ln\left\{\frac{y\left(\frac{[H^+]}{K_a}+1\right)[H^+]}{\beta K_w}\sqrt{\frac{D_1}{D_2}}\right\} + \frac{RT}{2F}\ln\frac{i}{i_d-i} \tag{11}$$

where i is the anodic current, i_d the anodic diffusion current, D_1 the common diffusion coefficient of species H_2O_2 and HO_2^-,[3] and D_2 the diffusion coefficient of the complex $[Hg(O_2H)(OH)]$. Equation 11 shows that a logarithmic plot should produce a straight line with the reciprocal slope of 29 mV if the solution is well-buffered with respect to hydrogen ions. Figure 2 shows that this is the case. The limiting current decreases with increasing pH in the range of pH values below 11.7. This indicates that the diffusion coefficient of HO_2^- is smaller than that of H_2O_2. A strong hydration caused by the charge on the HO_2^- ion may be responsible for this difference between the diffusion coefficients.

By introduction of the relation $i=i_d/2$ into Eq. 11 the half-wave potential at 20 °C becomes

$$E_{1/2} = E^\circ + \frac{0.058}{2}\log\left\{\frac{y\left(\frac{[H^+]}{K_a}+1\right)[H^+]}{\beta K_w}\sqrt{\frac{D_1}{D_2}}\right\} \tag{12}$$

When $[H^+]\gg K_a$, Eq. 12 becomes

$$E_{1/2} = E^\circ + \frac{0.058}{2}\log\frac{y}{\beta K_a K_w}\sqrt{\frac{D_1}{D_2}} - 0.58\,\mathrm{pH} \quad (13)$$

where the activity coefficient of the hydrogen ion is assumed to be unity. Because of Eq. 5 and the proportionality of $D_1^{1/2}$ to i_d, Eq. 13 may be rewritten as

$$E_{1/2} = E^\circ + \frac{0.058}{2}\log\frac{\alpha y}{\beta K_a K_w D_2^{1/2}} - 0.059\mathrm{pH} \quad (14)$$

In this equation α is a proportionality constant. When $[H^+] \ll K_a$, Eq. 12 becomes

$$E_{1/2} = E^\circ + \frac{0.058}{2}\log\frac{y}{\beta K_w}\sqrt{\frac{D_1}{D_2}} - \frac{0.058}{2}\mathrm{pH} \quad (15)$$

When pH is chosen as the independent variable, Eqs. 14 and 15 represent two straight lines. These straight lines intersect at the point whose pH value is equal to pK_a.

Equations 14 and 15 agree well with the experimental results shown in Fig. 3, except for a few points obtained in the solutions with pH values above 13.2. The abscissa of the intersection is 11.65, consistent with the value 11.65 reported for pK_a of hydrogen peroxide by Evans and Uri.[4]

Figure 3 shows that the half-wave potential deviates from the linear relation given by Eq. 13 above pH 13.2, although the points measured in this range are very few. Experimental difficulty prevented any measurements in solutions with higher pH values. Hence it is impossible to speculate on the electrode process above pH 13.2, at least at present.

Kinetics of the Proton-Transfer Reactions of Some *ortho*-Hydroxy Derivatives of Azo and Azomethine Compounds in Dioxane-Water Medium*

Noboru YOSHIDA and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received December 11, 1975)

The kinetics of the proton-transfer reactions between hydroxide ion and *o*-hydroxy azo and *o*-hydroxy azomethine compounds having a strong O–H···N or an O–H···π intramolecular hydrogen-bond are studied in 50% (v/v) dioxane–water by means of temperature-jump method. The forward and the backward rate constant k_f and k_r for the overall reactions $OH^- + HA \underset{k_r}{\overset{k_f}{\rightleftharpoons}} H_2O + A^-$ are evaluated to be in the range between 4.4×10^4 and 6.1×10^8 $M^{-1}s^{-1}$ and between 1.5×10^3 and 6.2×10^4 s^{-1} respectively. The values of the k_f for the azomethines are by several orders of magnitude higher than those of the corresponding azo compounds. The values of k_f and k_r in dioxane–water are found to be smaller than those in aqueous medium.

Eigen and coworkers have extensively investigated the kinetics of the proton-transfer reactions in aqueous media using chemical relaxation methods.[1-3] The protolytic reactions between so-called "normal" Brønsted acids and bases which can readily form hydrogen-bonded structure with solvent water molecules proceed almost diffusion-controlled. Thus the characteristic recombination rate constants k_f between hydrogen ion and normal bases are reported to be in the order of 10^{11} $M^{-1}s^{-1}$ and those between hydroxide ion and normal acids almost 10^{10} $M^{-1}s^{-1}$. The differences are attributed to the higher mobility of the hydrogen ion in aqueous solution.

Considerable decrease in the recombination rate constants k_f is observed, however, because of the following factors on the side of Brønsted acids and/or bases;[1-3] (1) the charge type, the size, and the shape of the reactants, (2) the liquid structure of the solvent water around the reacting species, (3) existence of the intramolecular hydrogen-bond at the periphery of the reaction site, and (4) intramolecular electronic rearrangement and/or the conformational orientation that activate the donor groups as CH acids and pseudo acids.[4]

The proton-transfer reactions in aqueous solutions between some *o*-hydroxy azo compounds and hydroxide ion have been reported in detail.[1-3),5),6] It was noted that the slowness of the recombination reaction would reflect the strength of the intramolecular hydrogen-bond. Eyring *et al.* reported the kinetics on the proton transfer between hydroxide ion and a number of Brønsted acids.[6-9] They suggested on the basis of the kinetic data the following order of the relative strength for intramolecular hydrogen-bonds:

O–H···N>O–H···O>N–H···N>N–H···O,

which is similar to that proposed by Freedman.[10]

Eigen pointed out that hydroxide ion can hardly approach the proton in the hydrogen-bridged structure of the Brønsted acid molecule and suggested a detailed mechanism involving pre-equilibrium between two states of the proton in Brønsted acids.[3]

Only a few attempts, however, have so far been made for the kinetic studies on the proton-transfer reactions in mixed solvents[11] as compared with equilibrium studies.[12] With respect to the reaction mechanism, the extensive kinetic studies are needed. Nevertheless, there prevail many complicated situations.

The dioxane–water medium has often been used for the determination of the acid dissociation constants and/or the complex formation constants of water-insoluble Brønsted acids. 1,4-Dioxane, a typical water-miscible dipolar aprotic solvent, can cover the wide range of the dielectric constant of the medium by mixing with water. These characteristics are convenient also in the fast proton-transfer reactions to evaluate the solvent effects such as electrostatic effects *etc.* In the present study we report the proton-transfer reactions between hydroxide ion and five *o*-hydroxy azo and four *o*-hydroxy azomethine compounds in 50% (v/v) dioxane–water system.

In general *o*-hydroxy azomethines are known to be weaker as acids than the corresponding azo derivatives.[13] Since *o*-hydroxy azomethines are only sparingly soluble and gradually hydrolyzed in water, it was difficult to measure the reaction rate in aqueous solutions.[14] Furthermore *o*-hydroxy azomethines are often unstable even in the mixed solvent containing water, so that we used a stopped-flow-temperature-jump technique.

It should be noted that the rate constants k_f and k_r obtained for the proton transfer in the mixed solvent are always lower than those in aqueous system. This tendency could not generally be observed in the reactions between "normal" acids and bases.[1]

Experimental

Materials. Reagents: All chemicals used were of analytical grade, unless otherwise specified. Water was deionized and distilled. Dioxane was distilled and the water content was determined to be 2.97 mg/ml by Karl Fischer titration. 10^{-3} M stock solutions of azomethines were prepared by dissolving in dioxane. The solutions were kept only for three weeks at room temperature.

o-Hydroxy Azo and o-Hydroxy Azomethine Compounds: The compounds used here are: Tropaeolin-O (I; TPO), 4-(2-pyridylazo)resorcinol (II; PAR), 1-(2-pyridylazo)-2-naphthol (III; PAN), *N*-salicylidene-2-aminopyridine (IV; SAP), *N*-(2-pyridylmethylene)-*o*-aminophenol (V; PMA), *N*-(2-hydroxy-1-naphthylidene)-2-aminopyridine (VI; NAP), *N*-salicylidene-2-aminothiazole (VII; SAT), 4-(2-thiazolylazo)-resorcinol (VIII; TAR), and 1-(2-thiazolylazo)-2-naphthol

* Presented in part at 25th Annual Meeting on Coordination Chemistry, Tokyo, October 8, 1975, Abstract, p. 123.

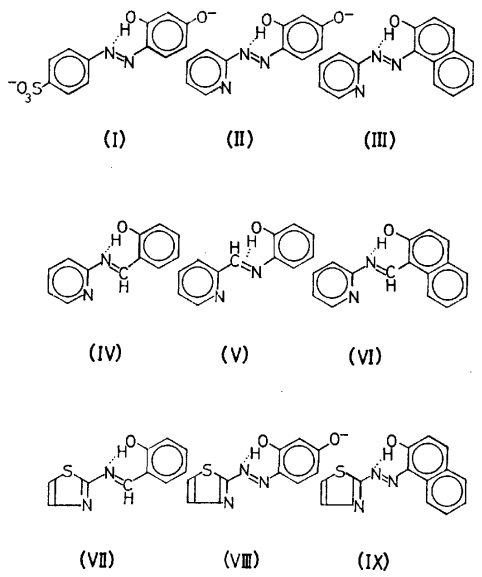

Fig. 1.

(IX; TAN). (See Fig. 1.)

The azo compounds (Dojindo) were purified by repeated recrystallization from 99.5% ethanol or ethanol-water. The azomethine compounds were prepared by condensation of aldehydes with amines, and recrystallized from 99.5% ethanol. As for the compound V, it was necessary to purify sufficiently the starting materials to prepare the pure crystalline compound.[15] Found: C, 72.8; H, 5.0; N, 13.9%. Calcd. for PMA, $C_{12}H_{10}N_2O$: C, 72.7; H, 5.1; N, 14.1%.

Measurements. *pH in the Mixed Solvents*: The analytical concentration C_H of the solvated proton in 50%(v/v) dioxane-water was determined titrimetrically. The pH* of the solution was measured with Hitachi-Horiba pH-meters, Model-P and Model M-7. For the potentiometric titrations of perchloric acid in the mixed solvent the ionic strength was adjusted with pure sodium perchlorate.[16] All measurements were carried out in nitrogen atmosphere.

Assuming the complete dissociation for the perchloric acid in the mixed solvent,[17] we used the following relation derived by Van Uitert and Haas[18] between the pH-meter readings (pH*) and $-\log C_H$ ($=pC_H$):

$$\log U_H = pC_H - pH^*,$$

where the function $\log U_H$ contains the term of activity coefficients γ_H's of the solvated proton and the liquid junction potential ΔE_j:[17]

$$-\log U_H = -\log \gamma_H^s \cdot \gamma_H^m + \Delta E_j.$$

The medium effect term γ_H^m depends on the solvent composition and the interionic attraction term γ_H^s varies with the ionic strength. The plot of pH* *vs.* pC_H gave an excellent linear relationship both in the acid and the alkaline region. The values of $\log U_H$ are thus evaluated in the range of pH*=3—12 at 25.0±0.1 °C to be −0.14±0.02 (μ=0.1) and +0.05±0.02 (μ=0.01).

Spectrophotometric Measurements of the Acid-Base Equilibria in the Mixed Solvent: The acid dissociation constants were determined spectrophotometrically with a Hitachi recording spectrophotometer Model EPS-3T. As for the Schiff bases, we used a Union Giken rapid-mixing apparatus Model MX-7 to avoid undesired hydrolysis. In the spectrophotometric measurements, potassium nitrate was used for the adjustment of the ionic strength to avoid the undesired behavior of the $NaClO_4$ as often observed on the wall of the optical cell in the case of the mixed solvents.

Kinetics of the Proton-Transfer Reactions: All measurements were carried out with a Union Giken co-axial-cable temperature-jump apparatus Model RA-105 equipped with a rapid-mixing device Model MX-7. The dead time of the mixer was about 5 ms. A temperature-rise of about 7 °C was attained within 2 μs (μ=0.1) by discharging a 0.0204 F capacitor, a co-axial cable of 200 m long, charged to 30 kV. The reaction was followed on the storage screen of an oscilloscope at the absorption maximum of the conjugated base of the Brønsted acid. All measurements were made at 25±0.1 °C.

Results

Equilibria of the Reaction. The potentiometric titrations were carried out at 25 °C and μ=0.1 and 0.01. The apparent ionic product K_w^c of water in dioxane–water medium was measured using the value of $\log U_H$ as mentioned above. A mixture of 2 V ml of the perchloric acid containing equal volume of water and dioxane was titrated with v ml of 0.1 M aqueous NaOH and v ml of dioxane in order to maintain the solvent composition at 50%(v/v). According to the fundamental theory of the acid-base equilibrium $C_H - C_{OH} = (VC_H^\circ - VC_{OH}^\circ)/2(v+V)$. Before the end point, $C_H \simeq VC_H^\circ(v_e - v)/2v_e(v+V)$ and after the end point, $C_{OH} \simeq VC_H^\circ(v - v_e)/2v_e(v+V)$, where C_H° and C_{OH}° denote the analytical concentrations of $HClO_4$ and NaOH added, respectively. The values of K_w^c are calculated to be $K_w^c = C_H \cdot C_{OH} = 4.23 \times 10^{-16}$ M^2 at μ=0.1 and 2.09×10^{-16} M^2 at μ=0.01.[19]

Since compounds IV, V, and VI are readily hydrolyzed in the mixed solvent in a few minutes, the absorption spectra were rapidly scanned immediately after mixing the solutions thermostated beforehand at 25±0.1 °C. The absorption spectra of PMA are shown in Fig. 2. The slow hydrolysis reaction did *not* affect the spectrophotometric measurement of pK_a^c as revealed by a definite isosbestic point. The stoichiometric

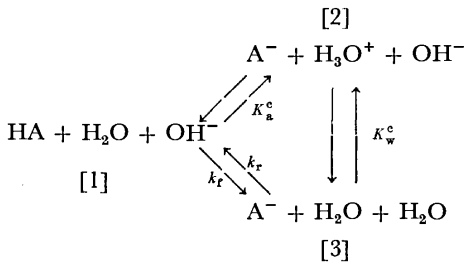
C_{HA}° (after mixing) = 1.279×10^{-4} M.
pH*: (1) about 6, (2) 8.82, (3) 10.71, (4) 11.21, (5) 11.45, (6) 11.88, (7) 12.09, (8) 12.30, (9) 0.1 M NaOH, at 25±0.1 °C, and μ=0.01 (KNO_3).

relation of the reactants is shown in the Scheme 1:



Scheme 1.

$$K_a^c = [H][A]/[HA] \quad (1)$$

$$K_b^c = k_f/k_r = [A]/[HA][OH] \quad (2)$$

$$K_w^c = [H][OH], \quad (3)$$

where [ ] represent the concentration, and charges are omitted. From Eqs. 1, 2, and 3 the following relationship is obtained:

$$K_a^c = (k_f/k_r)[H][OH] = K_b^c \cdot K_w^c. \quad (4)$$

The acid dissociation constants K_a^c's obtained spectrophotometrically are summarized in Table 1. As for PAR, the value of pK_a^c has so far been reported by several authors.[15,20]

In the present study it was found that the values of pK_a^c of the Brønsted acids increase with increasing dioxane content in the medium. The linear relationship between pK_a^c of weak acids such as acetic acid and the mole fraction of dioxane has been pointed out by Van Uitert and Haas[18] and Harned and Owen.[22] However the systematic kinetic study is needed in order to obtain the more useful information on the proton-transfer reactions in mixed solvents.

The equilibrium constant K_b^c and the rate constants for the reaction [1]⇄[3] were evaluated from the data of the temperature-jump study:

$$\tau^{-1} = k_f(\bar{C}_{OH} + \bar{C}_{HA}) + k_r. \quad (5)$$

Kinetics. Figure 3 shows a typical relaxation signal for SAT. The linear dependences of the reciprocal relaxation time on the sum of the equilibrium concentrations of the hydroxide ion and the Brønsted acid are given in Fig. 4. Serious deviation from the linear dependence of the observed τ^{-1} for the compound V at higher concentrations would be ascribed to the rising time of the temperature at $\mu=0.01$ comparable to the relaxation time of the reaction. The measure-

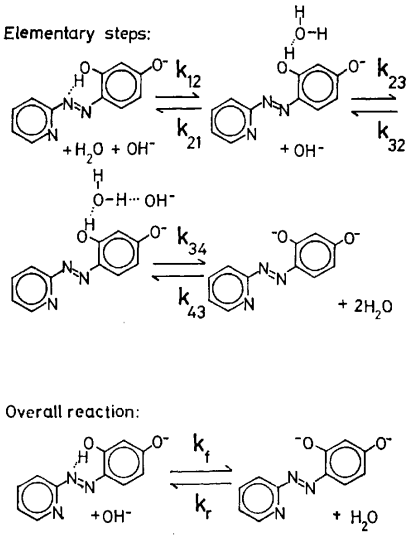
ments of the rate of the proton-transfer reactions for TAN, TAR, and NAP were tried, but the observed signal-amplitude was too small.

The rate constants given in Tables 2 and 3 were calculated from the slope and the intercept of the straight lines in Fig. 4. The equilibrium constants K_a^c evaluated as $K_a^c=K_b^c\cdot K_w^c$ from the kinetic data are compared with those from the equilibrium data given in Table 1. The values are in good agreement with each other for the aqueous media, whereas in 50%(v/v) dioxane–water, the values of K_a^c derived from the *kinetic* data are always 1—2 orders of magnitude smaller than the corresponding spectrophotometric *equilibrium* constants K_a^c. As for the water-soluble Brønsted acid such as TPO these differences are quite small. The reason will be discussed in detail elsewhere.

Discussion

The overall reaction of the proton transfer is shown in Scheme 1. Equation 7 indicates that the observed increase in pK_a^c derived from the kinetic data is due to both the kinetic term $k_f/k_r=K_a^c$ and to the calculated ionic product K_w^c of water in the bulk mixed solvent. On the basis of the suggestion by Eigen *et al.*[3] concerning the proton-transfer reactions in aqueous solution, we propose the following reaction mechanism also in the mixed solvent for the recombination with OH^- ion of the Brønsted acid having an intramolecular hydrogen-bond.[24]



In the step of the intramolecular rearrangement HA$\rightleftarrows$HA* the hydrogen-bonded proton sets free from the azo-nitrogen atom and interacts with a solvent *water* molecule. The second step $HA^*+OH^-\rightleftarrows HA^*\cdots OH^-$ involves the formation and the dissociation of an encounter complex between OH^- ion and an activated Brønsted acid HA* caused by thermal motion. The third step $HA^*\cdots OH^-\rightleftarrows A^-+H_2O$ is the net chemical transformation involving the proton-transfer through the intervening *water* molecule and the charge-neutralization or the charge-separation.

A rate equation for such a reaction is derived as follows. In general, the stationary-state approximation is applied for HA* and the encounter complex:

$$dC_{HA^*}/dt = 0 \tag{6}$$

$$C_{HA^*} = (k_{12}C_{HA} + k_{32}C_{enc})/(k_{21} + k_{23}C_{OH}), \tag{7}$$

and

$$dC_{enc}/dt = 0 \tag{8}$$

$$C_{enc} = (k_{12}C_{HA^*}C_{OH} + k_{43}C_A)/(k_{32} + k_{34}). \tag{9}$$

The rate equation is expressed as:

$$-dC_{HA}/dt = k_{12}C_{HA} - k_{21}C_{HA^*}. \tag{10}$$

For the small perturbation ΔC_{HA} near the equilibrium, it can be approximated as:

$$-dC_{HA}/dt = -d\Delta C_{HA}/dt \tag{11}$$

$$= \Delta C_{HA}\cdot\frac{k_{12}k_{23}k_{34}(\bar{C}_{OH} + \bar{C}_{HA}) + k_{21}k_{32}k_{43}}{k_{32}k_{21} + k_{34}k_{21} + k_{34}k_{23}\bar{C}_{OH}} \tag{12}$$

with the reciprocal relaxation time:

$$\tau^{-1} = \frac{k_{12}k_{34}k_{23}(\bar{C}_{OH} + \bar{C}_{HA}) + k_{21}k_{32}k_{43}}{k_{32}k_{21}+k_{34}(k_{21}+k_{23}\bar{C}_{OH})} \tag{13}$$

Assuming the second step is the rate-determining for the bimolecular reaction:

$$k_{21} \gg k_{23},\ k_{34} \gg k_{32}, \tag{14}$$

and considering the larger value for $k_{21}>10^{10}\ s^{-1}$ ($k_{23}=10^{10}\ M^{-1}\ s^{-1}$ and $\bar{C}_{OH}=10^{-4}-10^{-2}\ M$):

$$k_{23}\bar{C}_{OH} \ll k_{21}, \tag{15}$$

the reciprocal relaxation time is reduced to

$$\tau^{-1} = K_{12}k_{23}(\bar{C}_{OH} + \bar{C}_{HA}) + k_{32}/K_{34}, \tag{16}$$

where K_{12} and K_{34} represent k_{12}/k_{21} and k_{34}/k_{43} respectively. Equations 5 and 16 lead to the most important relation:

$$k_f = K_{12}k_{23} \tag{17}$$

and

$$k_r = k_{32}/K_{34}. \tag{18}$$

The values of k_f and k_r for the proton transfer in the dioxane–water media are found to be smaller than those in aqueous media. This effect is especially remarkable in the case of PAR. If as a first approximation the k_{23} in the mixed solvent also be equal to that of $k_{23}=10^9-10^{10}\ M^{-1}\ s^{-1}$ in aqueous system, this decrease in the overall rate constant k_f in the mixed solvent may primarily be attributed to the decrease in the value of the equilibrium constant K_{12}. Similarly the decrease in the k_r value is attributed to the increase in the value of equilibrium constant K_{34} assuming the change in the value of k_{32} is also small. With respect to these assumptions direct evidence is needed, which will be reported in the near future.

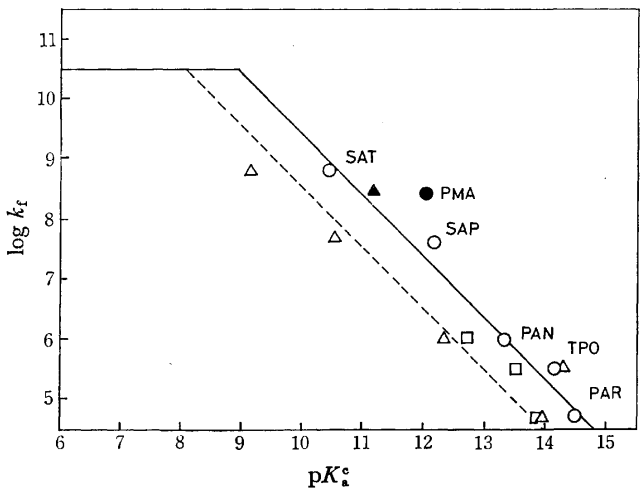


Fig. 5. Dependence of the recombination rate constants log k_f on the acid dissociation constants pK_a^c in 50%-(v/v) dioxane–water.
A full line shows the curve based on the value of $pK_w^c=15.68$ ($\mu=0.01$) and $pK_w^c=15.37$ ($\mu=0.1$). A broken line is the curve reproduced on the basis of the value measured for the azo compounds in aqueous solution. △ is the plot of log k_f *vs.* spectrophotometric pK_a^c. ○ is the plot of log k_f *vs.* kinetic pK_a^c using $pK_w^c=15.68$ ($\mu=0.01$). □ is the plot of log k_f *vs.* kinetic pK_a^c using $pK_w^c=15.37$ ($\mu=0.1$).

Figure 5 gives the Brønsted-plots with the slope $-\mathrm{d}\log k_f/\mathrm{d}\,pK_a^c=1$. If the reaction approaches the diffusion-controlled limit, the rate constants k_f do not reflect the thermodynamical stability of the hydrogen-bond. For the higher pK_a^c than 9.0, the recombination rate constants k_f show the linear dependence on the basicity of the Brønsted acid. This implies that the linear-free-energy relationship holds in this system. The intramolecular hydrogen-bonds in the azomethines are weaker than those in the corresponding azo compounds even for the same type of the intramolecular hydrogen-bonds O–H···N. Therefore the value of k_f for the azomethines is by 2—3 orders of magnitude larger than that for the azo compounds. The plot for PMA having an O–H···π-type intramolecular hydrogen-bond deviates from the straight line in Fig. 5.

Since the solvation on the given Brønsted acids with dioxane is involved, in particular, on the encounter-complex species in the transition state of the proton-transfer reaction, at present we allow for a possibility for a branched path involving a more or less preferential solvation of the reaction site with dioxane molecule to inhibit the formation of the hydrogen-bridged encounter complex available as a precursor of the proton-jump step. Further studies using the mixed solvent of various dioxane contents would give valuable informations on the liquid structure of the mixed solvent which may affect the protolytic behavior of the Brønsted acids.

Finally, it would be noteworthy from the biochemical standpoints[25] that the hitherto unknown data on the rate constants k_f and k_r for the proton-transfer reactions of the Schiff base were obtained in the present work.

The present work was supported by a grant-in-aid for Scientific Research from the Ministry of Education.

Note Added in Proof:

Recently Liphard and Jost reported the mechanism of the proton-transfer reaction of Brønsted acid Alizarin Yellow GG, which has an intramolecular hydrogen bond -COO$^-$···HO-, with hydroxide ion OH^- in aqueous solution. From the activation volumes of the overall reaction determined by the temperature-jump study under pressure they directly proved the existence of the first step $HA \rightleftharpoons HA^*$ and pointed out the significant role of *this* step in the proton-transfer reaction $HA + OH^- \rightleftharpoons A^- + H_2O$. [K. Q. Liphard and A. Jost, *Ber. Bunsenges. Physik. Chem.*, **80** (2), 125 (1976)].

24) Even if dioxane is involved in the solvation of an acid proton, the proton-jump from the acid to OH^- ion would proceed only through the formation of an encounter-complex involving the hydrogen-bridge of water. Therefore concerning the recombination step between the Brønsted acid and OH^- ion, it is evident that the reaction *does* proceed in accordance with this mechanism.

Color and Structural Changes of Bis(hexamethylenetetramine)cobalt(II) and nickel(II) Complexes in the Course of Thermal Dehydration in Solid State

Kenzo NAGASE, Hiroko YOKOBAYASHI, and Kozo SONE*

Colloge of General Education, Tohoku University, Kawauchi, Sendai 980

**Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112*

(Received December 18, 1975)

The stoichiometry of thermal dehydration of $MX_2(hmta)_2 \cdot nH_2O$ (hmta=hexamethylenetetramine; X= Cl^-, Br^-, I^-, NO_3^-, NCS^-; n=4—10) was established by the TG-DTA methods. The nature of the structural changes caused by complete or partial dehydration was studied on the basis of the accompanying changes in the electronic and vibrational spectra. Anions and hmta in general get into the coordination sphere with a decrease in the number of the coordinated water, but the bulky and weakly basic amine often gets coordinated in the last stage.

It has been known for a long time that hexamethylenetetramine (hmta=1,3,5,7-tetraazatricyclo[3.3.1.1.^{3,7}]decane) forms a number of peculiar complexes with various metals, among which those of cobalt(II) and nickel(II) are of special interest because their colors change strikingly in the course of dehydration. For example, the color of $Co(hmta)_2Cl_2 \cdot 10H_2O$ turns from pink to blue, while the corresponding nickel(II) complex changes first from bluish green to yellow, and then from yellow to violet, when they are heated up to about 423 K.[1] More recently these phenomena were studied by Lodzinskaya *et al.*,[2] who showed that the octahedral cobalt(II) complexes obtained from aqueous solutions are transformed into tetrahedral complexes by heating or treatment with ethanol. Kovacs *et al.*[3] found by X-ray analysis that the crystals of $Mg(hmta)_2Cl_2 \cdot 10H_2O$ and $Ca(hmta)_2Br_2 \cdot 10H_2O$ belong to the triclinic system and these complexes are formulated as $[M(H_2O)_6]X_2 \cdot 2hmta \cdot 4H_2O$. Buhannic and Guerchais[4] successfully assigned the IR bands of the complexes $MX_2(hmta)$ and $MX_2(hmta)_2$ (M=Co(II), Zn(II); x=halide or pseudohalide ions) to various vibrational modes of hmta, indicating that the T_d symmetry of free hmta is lowered to C_{3v} in $MX_2(hmta)_2$ and C_{2v} in MX_2 (hmta). Allan *et al.*[5] obtained the complexes of Mn(II), Fe(II), Co(II), Ni(II), Cu(II), Zn(II) and Cd(II) with different numbers of H_2O and hmta from ethanolic solutions, which they attempted to characterize on the basis of the electronic and vibrational spectra and magnetic moments.

Examining these previous works, the present authors came to the conclusion that a proper combination of thermal analyses with visible and infrared spectroscopy would lead to a better understanding on the nature of the dehydration process. The results of studies with some new information are presented in this paper.

Experimental

Materials. The complexes were crystallized at room temperature from aqueous solutions containing MX_2 and hmta in the molar ratio 1 : 2.5. Their compositions were checked by elemental analyses for C, H and N and weight-loss values in dehydration (Table 1).

Measurements. The infrared absorption spectra (400—4000 cm^{-1}) were measured with a Hitachi 215 spectrophotometer by the Nujol mull method. A Hitachi EPS-3T spectrophotometer equipped with a standard integrating sphere attachment was used for the measurements of the diffuse reflectance spectra (14000—30000 cm^{-1}). Deeply colored samples were diluted with finely powdered MgO. The X-ray diffraction charts were obtained with a Toshiba ADG-101 diffractometer using a manganese-filtered Fe$K\alpha$ radiation.

The TG-DTA curves were obtained with a Shinku Riko TGD-3000 differential thermal microbalance with a heating rate of 5K/min in static air. In each measurement, 15—20 mg of powdered sample in a platinum crucible was used.

hmta=$C_6H_{12}N_4$

anion) have always the same composition (Table 1). Powder X-ray diffraction analyses indicate that, except for the cobalt iodide complex which was too poor in crystallinity to calculate the lattice constants, the crystals of all the complexes belong to the tetragonal system. As an example, the X-ray diffraction lines of the cobalt chloride complex and their assignments are given in Table 2. The lattice constants also indicate that the value of c/a is almost the same for each pair of a cobalt complex and a nickel complex with the same X (Table 3).

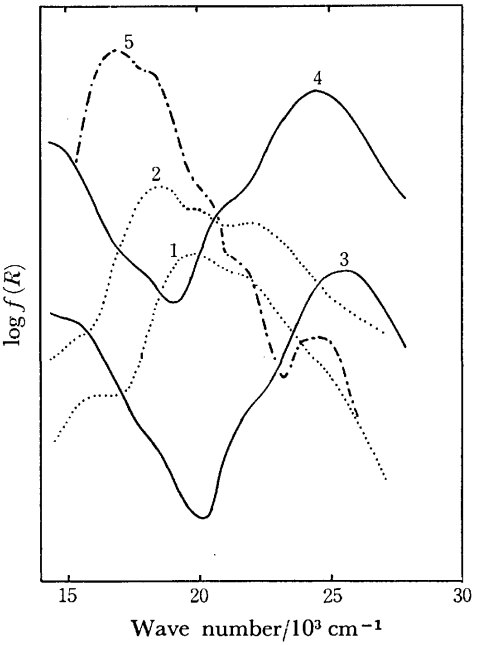

Fig. 1. Visible reflectance spectra of (1) $CoCl_2(hmta)_2 \cdot 10H_2O$, (2) $CoCl_2 \cdot 6H_2O$, (3) $NiCl_2(hmta)_2 \cdot 10H_2O$, (4) $NiCl_2 \cdot 6HO$ and (5) $CoCl_2(hmta)_2$.

The outlook of the visible reflectance spectra, the $\tilde{\nu}_{max}$ values of which are summarized in Table 4, show the existence of essentially octahedral coordination structures in all the complexes. The infrared spectra indicate that in all the complexes except the nickel thiocyanate complex, hmta molecules are not coordinated to the metals, since their symmetry was found to be T_d according to the criterion proposed by Buhannic and Guerchais.[4,6]

As examples, the visible reflectance spectra of $CoCl_2(hmta)_2 \cdot 10H_2O$, $NiCl_2(hmta)_2 \cdot 10H_2O$ and the anhydrous cobalt chloride complex are given in Fig. 1, together with those of $CoCl_2 \cdot 6H_2O$ and $NiCl_2 \cdot 6H_2O$

which were found, by X-ray analyses,[7] to be formulated as $[MCl_2(H_2O)_4]\cdot 2H_2O$. In general, the visible reflectance spectra of $CoX_2(hmta)_2\cdot nH_2O$ ($X=Cl^-$, Br^-, I^-, NO_3^-; $n=8$—10) are similar to each other, *i.e.*, they are essentially independent of the nature of X^-. The same can be said of the spectra of $NiX_2(hmta)_2\cdot nH_2O$. The spectra of $MCl_2(hmta)_2\cdot 10H_2O$ differ somewhat from those of $MCl_2\cdot 6H_2O$ (Fig. 1). In the case of the nickel compounds the difference seems to be rather small, but the $\bar{\nu}_{max}$ value of the hmta complex is somewhat higher. These facts suggest that X^- in these hmta complexes are not coordinated to the metals. This is supported by the fact that, in the case of the nitrate complexs, the infrared spectra indicate the presence of ionic NO_3^-. Moreover, the $\bar{\nu}_{max}$ values of these complexes (Table 4) are very close to those of the $[M(H_2O)_6]^{2+}$ ions (Co: 19600 cm^{-1}, Ni: 25300 cm^{-1}) observed in the absorption spectra of cobalt(II) and nickel(II) salts in aqueous solutions. These complexes are thus all hexaaqua complexes, and can be described as $[M(H_2O)_6]\cdot 2hmta\cdot(n-6)H_2O$.

$Co(NCS)_2(hmta)_2\cdot 4H_2O$ is characterized by the fact that it gives ν(O–H) at 3150 cm^{-1} which is considerably lower than that of an ordinary crystalline water (3400—3500 cm^{-1}), and that it begins to lose its water molecules at a temperature 20—30 K higher than the corresponding temperatures of the other complexes (Table 4). For this complex, the formulation as $[Co(NCS)_2(H_2O)_4]\cdot 2hmta$ seems to be the most probable.

On the other hand, $Ni(NCS)_2(hmta)_2\cdot 4H_2O$ seems to contain two sets of waters since it gives ν(O–H) bands, which can probably be attributed to both crystalline and coordinated water (3450 cm^{-1} and 3150 cm^{-1}), and loses about 1.5 water molecules at low temperature as in the case of the halides. The infrared bands of hmta in this complex seems to consist of two sets which correspond to two types of hmta having T_d and C_{3v} symmetries, respectively. The complex gives a single δ(NCS) at 482 cm^{-1}, indicating the presence of M–NCS bonds as in the case of the cobalt thiocyanate complex (Fig. 6).

Color and Structural Changes Caused by Thermal Dehydration. The TG and DTA curves of the complexes investigated are shown in Fig. 2. The curves of the cobalt complexes (except for the thiocyanate complex) have been published by Rodzinskaya *et al.*,[2] but their data differ somewhat from ours.

Except for the nickel chloride and bromide complexes, the complexes with halide ions give a smooth TG-DTA curve, although they contain both crystalline and coordinated water, all of which are lost in succession. If we compare the reflectance spectra of anhydrous products with the absorption spectra of typical cobalt and nickel complexes,[8] and their infrared spectra with the data of Buhannic and Guerchais,[4] we come to the conclusion that dehydration is accompanied with the changes octahedral→tetrahedral for the coordination structure and $T_d\rightarrow C_{3v}$ for the symmetry of hmta (Table 4), and that the metals are surrounded tetrahedrally by two X and two hmta in the final anhydrous products (*cf.* curve 5, Fig. 1, which shows characteristic features of a tetrahedral cobalt(II) complex[8]).

The nickel chloride and bromide complexes are dehydrated in two steps, although no distinct plateau could be observed on the TG curve in the case of the bromide complex. The nickel chloride complex gives a stable intermediate with the composition of $NiCl_2(hmta)_2\cdot 2H_2O$ in the first step, during which the T_d symmetry of hmta and the octahedral structure were retained. The visible spectrum of this dihydrate ($\bar{\nu}_{max}$: 22800 cm^{-1}) is now very close to that of $NiCl_2\cdot 2H_2O$ ($\bar{\nu}_{max}$: 22800 cm^{-1}), which is obtained by heating $NiCl_2\cdot 6H_2O$ at 383 K in the air (Fig. 3). Since the nickel in $NiCl_2\cdot 2H_2O$ was found by X-ray analysis[9] to be surrounded octahedrally by two water molecules

* Bidentate.

NO_3^- and two unidentate hmta.

$Co(NCS)_2(hmta)_2 \cdot 4H_2O$ loses four water molecules in one step to form the tetrahedral anhydrous complex. The infrared spectrum of the anhydrous complex indicates the presence of the unidentate hmta, and its ν(CN) and δ(NCS) are split into two by dehydration (Fig. 6). The anhydrous complex might thus be described as $[Co(NCS)_2(hmta)_2]$.

On the other hand, $Ni(NCS)_2(hmta)_2 \cdot 4H_2O$ loses its water molecules in two steps, the octahedral structure being kept through the dehydration steps. In the first step, the symmetry of hmta changes clearly to C_{3v}, a single band of δ(NCS) being observed at 480 cm^{-1} (Fig. 6). In the next step, the C_{3v} symmetry of hmta changes to C_{3v} or $C_{2v}+C_{3v}$ and δ(NCS) is split into two as in the case of the cobalt thiocyanate complex, although ν(CN) does not change. The nickel thiocyanate complexes formed at each of these dehydration steps can not be formulated at present because of incomplete data.

The color and structural changes caused by thermal dehydration of all the complexes investigated are summarized in Tables 4 and 5. We see that the decrease in the number of coordinated water molecules brings about the coordination of anions and hmta. However, in many cases the coordination of anions takes place first, and that of hmta only in the last stage of dehydration. This apparent reluctance of an amine, which usually shows a stronger coordination tendency than anions and water, toward coordination is probably due to the bulkiness of hmta and its weak basicity (pK_b=8.87). This might be the reason why hmta forms no amine complex and gives no hydroxide precipitate in aqueous solution, when a cobalt or nickel salt is mixed with hmta in it, precipitating only a "*complex*" which contains uncoordinated hmta molecules between hydrated cations and anions (or aqua-anion complexes such as $[M(H_2O)_4X_2]$). The only possible exception to this rule found in this study is the thiocyanate complex of nickel, but its actual structure is not known. Heating, however, drives out the water from the coordination sphere of each cation, enabling the reluctant amine to be coordinated, but this change can only occur after all the more avid anions have got their seats in the coordination sphere.

Bivalent Metal Complexes of *N,N*-Bis(2-hydroxyethyl)glycine

Yoshie INOMATA, Toshio TAKEUCHI, and Takao MORIWAKI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo 102

(Received December 20, 1975)

Complexes of *N,N*-bis(2-hydroxyethyl)glycine(BHEG) with a bivalent cation (Cu(II), Ni(II), Co(II), Zn(II), Fe(II), Cd(II), and Pb(II)) have been prepared and investigated by means of infrared absorption spectra, powder surface diffuse reflection spectra, electronic spectra, magnetic susceptibility, and thermal analysis. They can be classified into two types: (A) $ML_2 \cdot nH_2O$ and (B) $ML \cdot X \cdot nH_2O$, (M: metal, L: BHEG$^-$, X: Cl^- or NO_3^-). Ni(II), Co(II), Zn(II), and Fe(II) complexes are of type A, and those of Cd(II) and Pb(II) of type B. In the case of Cu(II) complexes, a blue A type complex (Cu(II)-A) has been prepared from a basic solution and a green B type one (Cu(II)-B) from an acidic solution. From detailed assignments of IR spectra, BHEG is found to have a zwitter ion structure. From magnetic moment data and reflection spectra, we presume that the A type complexes have a *trans* octahedral structure and the B type complexes a tetrahedral structure.

BHEG seems to have the properties of both an amino acid and an amino alcohol, since it has a *N*-substituted amino, a carboxyl, and two hydroxyl groups as coordinating groups in one molecule. Chaberek *et al.*[1] investigated bivalent metal chelates of BHEG in aqueous solution and discussed the coordination of the hydroxyl group, besides the amino and carboxyl groups. However, no metal complex of BHEG in solid state has yet been studied. Krause[2] synthesized nickel(II) and cobalt(II) complexes with *N*-(2-hydroxyethyl)imino diacetic acid, which is similar to BHEG, and reported that there are complexes in which the metal is coordinated with a hydroxyl and one carboxyl group, in addition to the normal complexes in which the metal is coordinated with a imino nitrogen and two carboxyl groups.

Many studies have been carried out on amino alcohol complexes.[3-5] Kida[6] studied the influence of pH on the coordination of a hydroxyl group.

In the present work, the bivalent metal complexes of BHEG have been prepared and investigated, and detailed assignments for the infrared absorption bands of BHEG and its complexes have been made. Discussion is given on how the hydroxyl group influences the coordination with the metal.

Experimental

Preparation of Compounds. Nickel(II) complex was prepared by adding 0.005 mol of nickel chloride hexahydrate to a hot solution containing 0.005 mol of BHEG and 0.005 mol of sodium hydrogencarbonate. The mixture was then stirred in a water bath. After the solution was condensed, a blue precipitate formed was filtered, washed with ethyl alcohol several times, and dried.

Cobalt(II) and copper(II)-B (green) complexes were prepared by the same procedure as for the nickel(II) complex.

Zinc(II), cadmium(II), lead(II), iron(II), and copper(II)-A(blue) complexes were prepared by means of almost the same procedure as that for the nickel(II) complex, except that: a) the condensed solution was poured into ethyl alcohol in the case of the zinc(II) and cadmium(II) complexes and into acetone in the case of the lead(II) complex; b) the iron(II) complex was prepared from iron(II) sulfate heptahydrate at room temperature and dried *in vacuo*; and c) in the case of the copper(II)-A complex, sodium hydroxide was used instead of sodium hydrogencarbonate in order to keep the pH of the solution high.

Deuteration of Compounds. The deuterated BHEG and its complexes were prepared by dissolving these compounds in 99.9% deuterium oxide and drying *in vacuo*. The NH and OH groups were deuterated by this method.

Thermal Analysis. Thermal analysis was carried out in the air with a Rigaku Denki TG-DTA M-8075 from room temperature to 400 °C. It was found that cadmium(II), lead(II), and iron(II) complexes have one molecule of water.

Magnetic Studies. Magnetic moments were obtained for the solid samples by the Gouy method at room temperature, using $Hg[Co(SCN)_4]$ as a calibration standard.

Powder Diffuse Reflection Spectra. Powder diffuse reflection spectra were observed from 700 nm to 400 nm for copper(II)-A, copper(II)-B, nickel(II), and cobalt(II) complexes with a Hitachi 624 digital spectrophotometer equipped with a standard Hitachi reflection attachment.

Electronic Spectra. Electronic spectra of metal complexes in 1M $NaClO_4$ solution were obtained from 900 nm to 190 nm with the same spectrophotometer described above. Since nickel(II) complex is insoluble in 1 M $NaClO_4$ solution, its spectra could not be obtained. The results of the elemental analysis and the values of magnetic moments, reflection spectra, and electronic spectra are given in Table 1.

Infrared Absorption Spectra. Infrared absorption spectra from 4000 cm^{-1} to 300 cm^{-1} were obtained with Hitachi EPI-G2 and EPI-L spectrophotometers, which were calibrated with polystyrene and atmospheric water vapor. Samples were prepared as potassium bromide discs and Nujol mulls. The observed absorption frequencies and the assignments for BHEG and the metal complexes are given in Table 2.

Results and Discussion

From the results of elemental analysis and infrared spectra, the eight complexes prepared can be divided into two types, nickel(II), cobalt(II), zinc(II), iron(II) complexes belonging to type A ($ML_2 \cdot nH_2O$), and cadmium(II) and lead(II) complexes to type B ($ML \cdot X \cdot H_2O$). As for copper(II) complexes, a blue A type complex (copper(II)-A) can be prepared from a basic solution and a green B type one (copper(II)-B) from an acidic solution.

Electronic Spectra and Magnetic Moments. Copper(II)-A and copper(II)-B complexes have magnetic moments of 1.86 B.M. and 1.90 B.M. respectively, which are the same as those for $Cu(gly)_2 \cdot H_2O$.[7]

In copper(II)-A, the reflection spectrum shows a band at 630 nm, and the electronic spectrum in 1M

a) Spin only value.

$NaClO_4$ solution shows a peak at 610 nm assigned to $^2E_g \rightarrow {}^2T_{2g}$. Laurie[8] investigated the reflection spectra of several forms of bis(tyrosinato)copper(II) complexes and concluded that the blue form of Cu(II)-DL-tyrosine complex, which shows a peak at 625 nm, has a *trans* configuration. Graddon[9] studied the electronic spectra for anhydrous copper(II) complexes of amino acids and found that copper(II) complexes, which have a peak in the region near 621 nm, have *trans* octahedral configurations. Therefore, we can assume that the copper(II)-A complex has a *trans* octahedral configuration.

It was found that the reflection spectrum of copper(II)-B has a peak above 700 nm and the electronic spectrum in 1 M $NaClO_4$ solution has an absorption maximum at 760 nm. Hare *et al.*[10] studied the effect of pH on the electronic spectra of a number of copper(II)-amino acid complexes and found that all species of Cu(aminoacidato)$^+$ have maximum extinction coefficients of about 30 at 724 nm, while those of bis(amino acidato)copper(II) have maximum extinction coefficients between 60 and 75 at 621 nm. We can thus assume that the copper(II)-B complex has a Cu(aminoacidato)$^+$ ion.

Nickel(II) complex has a magnetic moment of 3.36 B.M. The three peaks in its reflection spectrum are given in Table 1. The spectrum is similar to that of $Ni(gly)_2\cdot H_2O$[11] in solution and the absorption peaks are assigned to $^3A_{2g} \rightarrow {}^1E_g$, $^3A_{2g} \rightarrow {}^3T_{1g}$ (F), and $^3A_{2g} \rightarrow {}^3T_{1g}$ (P).

Cobalt(II) complex is a high spin complex with a magnetic moment 4.56 B.M. It seems that these nickel(II) and cobalt(II) complexes have the same octahedral structure as that of copper(II)-A complex.

The iron(II) complex is pale green and has a magnetic moment of 5.52 B.M., which is the same as that of the iron(II) ion itself.

It seems that the iron(II) complex is a high spin complex. Zinc(II), cadmium(II), and lead(II) complexes are diamagnetic and their electronic spectra show no peaks in the visible region. These eight complexes in 1 M $NaClO_4$ solution have absorption peaks below 300 nm, which are assigned to the electron transfer of BHEG.

Infrared Absorption Spectra. The assignments for BHEG and its metal complexes have been based on a comparison of the observed spectra with those of glycine,[12,13] betaine,[14] other α-amino acid,[15,16] NTA,[17] triethanolamine,[3] HIDA,[2] and their metal complexes, which have been throughly studied.

BHEG: The broad bands at 3186 and 3089 cm^{-1} are assigned to the OH stretching vibrations, because of their disappearance on deuteration and the absence of bands in this region for betaine. Since these OH vibrations have lower frequencies than those of free OH vibration, it seems that OH forms a hydrogen bonding.[18]

The fine bands from 2985 to 2843 cm^{-1} are due to CH_2 stretching vibrations. The N^+–H stretching vibration which is supposed to appear at about 3000 cm^{-1} is difficult to distinguish as it overlaps the OH and CH_2 stretching vibrations.

The very strong band at 1639 cm^{-1} is assigned to the COO^- antisymmetric stretching and N^+–H deformation vibrations. On deuteration, the N^+–H deformation vibration shifts to 1275 cm^{-1} and appears as the N^+–D deformation vibration. Moreover, BHEG has no carboxy(C=O) stretching vibration at 1700 cm^{-1}, which is characteristic of acid. Thus BHEG, like glycine, has a zwitter ion structure in solid state.

The bands at 1401 and 699 cm^{-1} are due to the COO^- symmetric stretching and scissors vibrations. The bands at 1207 and 737 cm^{-1}, which shift on deuteration, are assigned to OH in plane and out of plane deformation vibrations, since they are not observed in betaine and glycine.

Metal Complexes: Nickel(II), cobalt(II), and zinc(II) complexes show similar spectra. The spectrum of lead(II) complex differs slightly from the spectrum of cadmium(II) complex, because of the presence of a NO_3^- ion.

Abbreviations: s=strong, m=medium, w=weak, sh=shoulder, b=broad.

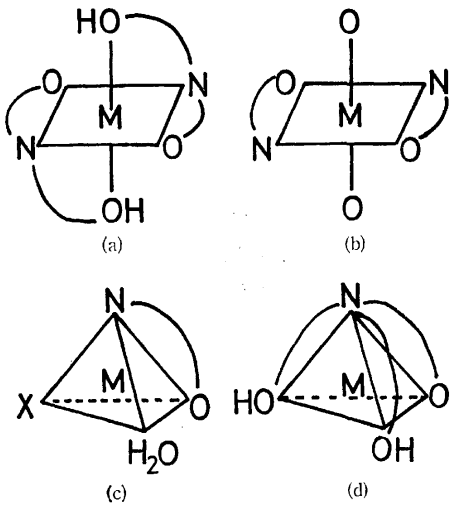

Fig. 1. Four possible configurations for BHEG complexes.
(a) Ni(II), Co(II), Zn(II), and Fe(II). (b) Cu(II)-A. (c) Cd(II) and Pb(II) ($X=Cl^-$ for Cd(II), NO_3^- for Pb(II)). (d) Cu(II)-B.

The broad bands above 3000 cm^{-1} for all complexes are assigned to OH stretching vibrations. In nickel(II), cobalt(II), zinc(II), and iron(II) complexes, one of these two OH stretching vibrations shifts *ca.* 100 cm^{-1} towards higher frequencies and the others towards lower frequencies as compared with those of the ligand. In the case of copper(II)-A, cadmium(II), and lead(II) complexes, all the vibrations shift to higher frequencies. This can be explained as follows. The OH vibration, which is at a lower frequency in the ligand due to hydrogen bonds, seems to become strong by the breaking of the hydrogen bonding when a complex is formed. When the OH group coordinates to a metal, the OH bond becomes weak and the OH stretching vibration shifts to lower frequencies. Therefore, in nickel(II), cobalt(II), zinc(II), and iron(II) complexes, one of these two OHs in one molecule does not coordinate, and the other slightly coordinates and forms a *trans* octahedral structure (Fig. 1-a).

On the other hand, in copper(II)-A, cadmium(II), and lead(II) complexes, neither of the OH groups coordinates. Copper(II)-A has a *trans* octahedral structure which extends above and below the basal plane like the alanine copper(II) complex[15] (Fig. 1-b), while cadmium(II) and lead(II) complexes take a tetrahedral structure with ligand, water, and anion (Fig. 1-c). In the copper(II)-B complex, the OH vibration markedly shifts to a lower frequency and the two OH groups seem to be coordinated to the metal to form a tetrahedral structrue with only one ligand (Fig. 1-d).

The bands at 1600 cm^{-1} assigned to COO^- antisymmetric stretching vibrations are observed at frequencies lower than those of the ligand. In the ligand the vibration shifts to higher frequencies because of the hydrogen bond, while in the complexes the hydrogen bonds are broken and the O–M bonds have a stronger ionic character. Fairly strong ionic coordination bonds are observed in NTA complexes.[17]

From 500 to 300 cm^{-1}, absorption bands which cannot be observed in the ligand appear in the complexes and are assigned to M–N stretching vibrations by comparison of the spectrum of the ligand with those of the metal complexes with glycine[12] and betaine.[14]

The frequency separation of the COO^- antisymmetric and symmetric stretching vibrations of the complexes in the same physical state increases in the order cobalt(II)<nickel(II)<zinc(II)<copper(II)-A (Table 1). The trend is the same as that in the corresponding series of complexes with various aliphatic α-amino acids, showing the corresponding order in the strengths of the metal-oxygen bond.

The copper(II)-A complex has a octahedral structure, like the glycine–copper(II) complex.[12] Nickel(II), cobalt(II), zinc(II) and iron(II) complexes have a *trans* octahedral structures, since BHEG acts as a tridentate ligand. However, cadmium(II) and lead(II) complexes have a four-coordinated structure with a 1 : 1 ratio of ligand to metal, differing from the *trans* octahedral structure of alanine–cadmium(II) complex.[15] The size and position of the CH_2CH_2OH group and the ionic radius of Cd^{2+} and Pb^{2+} seem to affect the formation of complexes.

Circular Dichroism of Cobalt(III) Complexes of the Type *cis*-$[CoN_2O_4]$ and *cis*-$[CoN_4O_2]$ Containing Acetylacetonate Ion, 2,2'-Bipyridine and 1,10-Phenanthroline

Kazuo KASHIWABARA (née KONYA),*[1] Kozo IGI,[2] and Bodie E. DOUGLAS

(Received February 16, 1976)

Two new cobalt(III) complexes, $[Co(acac)(bpy)_2]^{2+}$ and $[Co(acac)(phen)_2]^{2+}$ (acac=acetylacetonate ion, bpy=2,2'-bipyridine and phen=1,10-phenanthroline) were prepared from the reaction of $[Co(CO_3)(bpy)_2]^+$ and $[Co(CO_3)(phen)_2]^+$, respectively, with acetylacetone, and converted to the partially resolved optically active forms using a SP-Sephadex ion-exchange column. $[Co(acac)_2(bpy)]^+$ was also resolved partially with a SP-Sephadex column. $[Co(acac)_2(phen)]^+$ was resolved with a combination of silver dibenzoyl-*d*-tartrate and dibenzoyl-*d*-tartaric acid. The circular dichroism (CD) spectra for these four complexes and for $[Co(acac)_2(en)]^+$ and $[Co(acac)_2(tn)]^+$ (en=ethylenediamine, tn=trimethylenediamine) were measured. A marked solvent effect was observed in the d-d transition region for the CD spectra of the $[Co(acac)_2L]^+$ complexes. The absolute configurations for all these complexes were assigned on the basis of their CD spectra.

The preparation of mixed-ligand cobalt(III) complexes containing ligands which have strong coordinating ability to a cobalt(III) ion, *e.g.*, bipyridine, phenanthroline, acetylacetonate ion and cyanide ion *etc.*, is not easy because of disproportionation to form complexes for which all of the ligands are the same. Archer *et al.*[3,4] found $[Co(acac)_2(NO_2)_2]^-$ to be a good starting material for preparing $[Co(acac)_2(bpy)]^+$ and $[Co(acac)_2(phen)]^+$ complexes. A preliminary report of the mixed acac-bpy and acac-phen complexes has been made.[5] Here the preparation, optical resolution and circular dichroism (CD) of these complexes are reported.

Marked solvent effects were observed for the CD spectra in the d-d transition region for $[Co(acac)_2L]^+$ (L=bpy, phen, en, tn), but not for $[Co(acac)L_2]^{2+}$ (L=bpy, phen).

The assignments of the absolute configurations for these complexes were attempted on the basis of the CD spectra in the region of the d-d transitions and of the exciton bands. Both approaches have been applied to a variety of optically active metal complexes.[6] We assigned the absolute configurations of the $[Co(acac)L_2]^{2+}$ complexes from the CD in the exciton band region, and of the $[Co(acac)_2L]^+$ complexes using the d-d transition region.

Experimental

Preparation of Complexes. *1) Carbonatobis(2,2'-bipyridine)cobalt(III) Chloride Dihydrate*: Cobalt chloride hexahydrate, 4.7 g (0.02 mol) in 10 cm³ of water and 4 cm³ of 30% H_2O_2 were mixed in an ice-bath and added dropwise to a slurry of 12.0 g of $KHCO_3$ (0.12 mol) in 12 cm³ of water at 0 °C. After the addition, the mixture was stirred at 0 °C for 30 min. To this solution 6.25 g (0.04 mol) of 2,2'-bipyridine and 2 cm³ of ethanol were added and stirred for 1 h at 20 °C. The temperature was raised to 30—35 °C and stirring was continued for 3 h. Glacial acetic acid 2.4 g (0.04 mol) in 10 cm³ of water was added dropwise to the solution over a period of 15 min. After stirring for an additional 2 h at 50 °C, glacial acetic acid 2.4 g (0.04 mol) in 10 cm³ of water was again added over a period of 15 min. The solution was stirred for an additional 30 min at 50 °C and then cooled in an ice-bath for 2 h. The red crystals were filtered. The filtrate was concentrated to about half volume to obtain a second crop of crystals and then cooled overnight in a refrigerator to obtain another crop of crystals. These crude products were recrystallized from a small amount of hot water (80 °C), then filtered and washed with an acetone-water mixture, then acetone, and dried in air. If the filtrate is concentrated to half volume, more crystals are obtained. Total yield 8.4 g (90%). Found: C, 48.63; H, 4.29; N, 10.58%. Calcd for $[Co(CO_3)(bpy)_2]Cl\cdot 2H_2O$: C, 48.61; H, 3.90; N, 10.79%.

2) Carbonatobis(1,10-phenanthroline)cobalt(III) Chloride 4.5-Water: Cobalt chloride hexahydrate (4.7 g, 0.02 mol) in 10 cm³ of water and 4 cm³ of 30% H_2O_2 were mixed in an ice-bath and added dropwise to a slurry of 12.0 g of $KHCO_3$ (0.12 mol) in 12 cm³ of water at 0 °C. After the addition, the mixture was stirred at 0 °C for 30 min. To this solution 10 cm³ of 50% aqueous ethanol and 7.2 g (0.04 mol) of 1,10-phenanthroline were added and the resulting solution was stirred for 1 h at 20 °C. The temperature was raised to 30—35 °C and the stirring was continued for 2 h. After the addition of 10 cm³ of water, the stirring was continued for 1 h at 50 °C. Glacial acetic acid 2.4 g (0.04 mol) in 10 cm³ of water was added dropwise to the solution over a period of 15 min. After stirring for another 2 h at 50 °C, glacial acetic acid 2.4 g (0.04 mol) in 10 cm³ of water was again added over a period of 15 min. The reaction mixture was stirred for 30 min longer at 50 °C and filtered without suction. The filtrate was concentrated to half volume and cooled in a refrigerator overnight. The red crystals were filtered and washed with an acetone-water (small amount) mixture and then with acetone and dried in air. Yield 9.0 g (90%). Found: C, 50.66; H, 4.28; N, 8.83%. Calcd for $[Co(CO_3)(phen)_2]Cl\cdot 4.5H_2O$: C. 50.39; H, 4.22; N, 9.40%.

3) Acetylacetonatobis(2,2'-bipyridine)cobalt(III) Iodide 1.5 Water: Acetylacetone (0.6 g in 6 cm³ of water) and 1M HCl 6 cm³ were added to 2.3 g of $[Co(CO_3)(bpy)_2]Cl\cdot 2H_2O$ and the solution was warmed with stirring at 50—55 °C for 5 h. The solution was cooled to room temperature and filtered. Sodium iodide, 1.4 g in 2 cm³ of water, was added to the solution with stirring and the solution was cooled overnight in a refrigerator. The brownish-red product was filtered and washed with 2 cm³ of cold water and then with 4 cm³ of acetone. This crude product was recrystallized from 20 cm³ of hot water (80—85 °C). The red crystals were filtered and washed with a small amount of water-acetone mixture, then with acetone, and dried in air. Yield 0.6 g (17%). Found: C, 41.46; H, 3.20; N, 7.74%. Calcd

for $[Co(acac)(bpy)_2]I_2$: C, 41.16; H, 3.10; N, 7.95%.

The perchlorate of the complex was obtained by the addition of $NaClO_4$ to the filtrate from the recrystallization. It was filtered and washed with a small amount of cold water. Yield 0.4 g. Found: C, 42.94; H, 3.80; N, 7.75%. Calcd for $[Co(acac)(bpy)_2](ClO_4)_2 \cdot 1.5H_2O$: C, 43.12; H, 3.76: N, 8.04%.

4) Acetylacetonatobis(1,10-phenanthroline)cobalt(III) Iodide: This complex was prepared by using the same method as that for the 2,2'-bipyridine complex except that 2.6 g of $[Co(CO_3)(phen)_2]Cl \cdot 4.5H_2O$ was used. Fifty cm^3 of hot water was used for recrystallization. Yield 0.8 g (20%). Found: C, 43.21; H, 3.03; N, 7.24%. Calcd for $[Co(acac)(phen)_2]I_2 \cdot 1.5H_2O$: C, 43.57; H, 3.28; N, 7.14%.

The perchlorate was precipitated by the addition of $NaClO_4$ to the filtrate from the recrystallization. Yield 0.4 g. Found: C, 47.99; H, 3.43; N, 7.55%. Calcd for $[Co(acac)(phen)_2](ClO_4)_2 \cdot 0.5H_2O$: C, 47.95; H, 3.33; N, 7.71%.

5) Bis(acetylacetonato)(2,2'-bipyridine)cobalt(III) Iodide and Bis(acetylacetonato)(1,10-phenanthroline)cobalt(III) Perchlorate: These complexes were prepared according to the method reported by Archer *et al.*[3,4]

Optical Resolution of the Complexes. 1) $[Co(acac)(bpy)_2]^{2+}$: A solution of $[Co(acac)(bpy)_2]I_2$ (100—150 mg) was adsorbed on a SP-Sephadex C-25 resin (Pharmacia Fine Chemicals) column (2.5×120 cm) and eluted with 0.04 M sodium d-tartrate at a rate of 15—20 cm^3/h over a period of about 1 month. During this time, the red layer did not form separate bands although the band broadened considerably. Each fraction (100—150 cm^3) of the effluent was passed through a column of an anion exchange resin (Dowex 1-X8, 100—200 mesh) in ClO_4^- form, then evaporated to a small volume at 30 °C under reduced pressure, and then cooled overnight in a refrigerator. The red crystals of the perchlorate were filtered and washed with a small amount of cold water and dried under vacuum. Fifty mg of the perchlorate of the fast running fractions was again treated on the SP-Sephadex resin in the same way. The perchlorate of the fast running fraction (20 mg) was used for the CD measurement. Found: C, 42.94; H, 3.80; N, 7.75%. Calcd for $[Co(acac)(bpy)_2](ClO_4)_2 \cdot 1.5H_2O$: C, 43.12; H, 3.76; N, 8.04%.

2) $[Co(acac)(phen)_2]^{2+}$: The method was exactly the same as that for the 2,2'-bipyridine complex. Found: C, 47.99; H, 3.43; N, 7.55%. Calcd for $[Co(acac)(phen)_2](ClO_4)_2 \cdot 0.5H_2O$: C, 47.95; H, 3.33; N, 7.71%.

3) $[Co(acac)_2(bpy)]^+$: $[Co(acac)_2(bpy)]I$ (100—150 mg) was adsorbed on a SP-Sephadex C-25 column (2.5×120 cm) and eluted with 0.01 M sodium d-tartrate at a rate of 10—15 cm^3/h over a period of 2—3 weeks. During this time, the gray-violet layer did not form separate bands although the band broadened considerably. Each fraction (100—150 cm^3) of the effluent, to which a small amount of $NaClO_4$ was added, was evaporated to a small volume at 30 °C under reduced pressure. The resulting gray-violet product was filtered, washed with water, and dried under vacuum. Fifty mg of the perchlorate of the fast running fraction was again treated on the SP-Sephadex resin in the same way. The perchlorate of the fast running fraction (20 mg) was used for the CD measurement. Found: C, 46.25; H, 4.49; N, 5.18%. Calcd for $[Co(acac)_2(bpy)]ClO_4 \cdot 0.5H_2O$: C, 46.03; H, 4.44; N, 5.37%.

4) $[Co(acac)_2(phen)]^+$: The racemate, $[Co(acac)_2(phen)]ClO_4$ (5 g) and an anion exchange resin (Dowex 1-X8, Cl^- form, 20 g) were combined and stirred for 20 min in 250 cm^3 of methanol. The resin was filtered and washed with 20 cm^3 of methanol. The combined filtrate and washings were treated with a second portion (6 g) of resin. The resin was filtered and washed with 20 cm^3 of methanol. To the combined filtrate and washings were added silver dibenzoyl-*d*-tartrate (2.67 g) and dibenzoyl d-tartaric acid monohydrate (1.75 g) and the mixture was stirred for 10 min at 60 °C. Silver chloride was removed and washed with 30 cm^3 of hot methanol. To the combined filtrate and washings was added 90 cm^3 of ether and the resulting solution was cooled in a refrigerator. Fraction 1 (4.19 g) was separated by filtration. Fraction 2 (1.66 g) and fraction 3 (0.42 g) were obtained by further addition of ether and subsequent cooling. The filtrate (A) after the separation of the third fraction was used for the isolation of the opposite enantiomer. The solid fraction 1 (4.19 g) was dissolved in 560 cm^3 of methanol and 840 cm^3 of ether was added and the resulting solution was cooled in a refrigerator. The fraction 1—1 (1.99 g) was separated by filtration and the fractions 1—2 (0.85 g) and 1—3 (0.42 g) were obtained by the same method described above. The filtrate (B) after the separation of fraction 1—3 was also used for the isolation of the opposite enantiomer. Fraction 1—1 (1.99 g) was dissolved in 300 cm^3 of methanol and 500 cm^3 of ether was added and the resulting solution was cooled in a refrigerator. Two fractions were separated by fractional crystallization. Then, the various fractions with similar $\Delta\varepsilon$ values were combined and purified. Again, fractions of similar $\Delta\varepsilon$ were combined and purified. This kind of purification was repeated many times. Finally, 1.04 g of one diastereomer was obtained. This diastereomer was treated with an anion exchange resin (Dowex 1-X8, Cl^- form) in methanol to obtain the chloride salt. The resin was separated and ether was added to the methanol solution. Two fractions with low $\Delta\varepsilon$ value were separated, and the filtrate was evaporated to dryness under an air stream. The solid obtained by evaporation was purified twice by dissolving in methanol, adding ether and subsequent cooling in a refrigerator. Finally, brownish-violet flaky crystals were separated. Yield 92 mg. $\Delta\varepsilon_{523} = -2.30$ (solvent : water). Found: C, 53.69; H, 4.62; N, 5.24%. Calcd for $[Co(acac)_2(phen)]Cl \cdot H_2O$: C, 53.83; H, 4.93; N, 5.71%.

The filtrates (A) and (B) described above were combined and concentrated to 75 cm^3 using a rotary evaporator, and 150 cm^3 of ether was added. The resulting solution was cooled in a refrigerator. The first fraction (0.63 g) was separated by filtration. The filtrate was concentrated to 50 cm^3 with a rotary evaporator, 150 cm^3 of ether was added, the resulting solution was cooled in a refrigerator. Fraction 2 (0.34 g) and the fraction 3 (0.34 g) were separated in the same way. Fraction 1 was dissolved in 40 cm^3 of methanol, 70 cm^3 of ether was added and the resulting solution was kept in a refrigerator. The less active diastereomer (1—1) separated first and was filtered. This filtrate was evaporated to dryness to yield fraction 1—2 (0.19 g). The fractions 2, 3, and 1—2 were combined and treated in the same way as that of the other isomer. Finally, brownish-violet flaky crystals were obtained. Yield 0.28 g. $\Delta\varepsilon_{523} = +2.15$ (solvent : water). Found: C, 50.49; H, 5.55; N, 5.57%. Calcd for $[Co(acac)_2(phen)]Cl \cdot 3H_2O$: C, 50.15; H, 5.35; N, 5.31%.

The increase of $\Delta\varepsilon$ with each purification of the diastereomer was very small. Therefore, many purification steps were necessary.

5) $[Co(acac)_2(en)]^+$ and $[Co(acac)_2(tn)]^+$: These optical resolutions were carried out according to the methods reported.[7]

Measurements. Absorption spectra were obtained with a HITACHI 323 Recording Spectrophotometer and a Cary

14 spectrophotometer. CD spectra were measured with a J-20 Spectropolarimeter of Japan Spectroscopic Company and a Cary 61 recording spectropolarimeter. Optical isomers are identified by the sign of the CD in water at a specified wavelength. PMR spectra were measured with a Varian A-60 Spectrometer in a deuterium oxide solution containing sodium trimethylsilylpropanesulfonate(DSS) as the internal standard.

Ethanol and dimethyl sulfoxide for the measurements of absorption and CD spectra were spectroscopic grade.

Results and Discussion

Preparation and Properties. So far much attention has been paid to the tris-type complexes of cobalt(III) with identical bidentate ligands which have $\pi^*\leftarrow\pi$ ligand transitions, *e.g.*, $[Co(phen)_3]^{3+}$, for CD studies.[6] The complexes with two different ligands, *e.g.*, $[Co(bpy)_2(phen)]^{3+}$, have not been reported, presumably because of the difficulty of their preparation and optical resolution. Archer *et al.*[3,4] prepared $[Co(acac)_2(bpy)]^+$ and $[Co(acac)_2(phen)]^+$ by the reaction of bpy and phen, respectively, with $[Co(acac)_2(NO_2)_2]^-$. We attempted to prepare $[Co(acac)(bpy)_2]^{2+}$ and $[Co(acac)(phen)_2]^{2+}$ by the same reaction using increased amounts of bpy and phen, but disproportionation occurred. Then we tried the reactions of $[Co(CO_3)(bpy)_2]^+$ and $[Co(CO_3)(phen)_2]^+$ with acetylacetone instead of acetylacetonate ion. The yields were raised to about 20% by improving the reaction conditions, especially the reaction temperature and the amount of alcohol.

The optical resolution of these four complexes proved to be very difficult. To resolve $[Co(acac)(bpy)_2]I_2$ and $[Co(acac)_2(bpy)]I$, we used six resolving agents unsuccessfully: silver *d*-tartrate, silver dibenzoyl-*d*-tartrate, silver antimonyl *d*-tartrate, silver arsenyl-*d*-tartrate, silver *d*-α-bromocamphor-π-sulfonate and $(+)_{580}$-Ag[Co(edta)] (edta=ethylenediaminetetraacetate ion). For the optical resolution of $[Co(acac)_2(phen)]ClO_4$ five resolving agents were tried: silver *d*-α-bromocamphor-π-sulfonate, $(+)_{580}$-Ag[Co(edta)], $(-)_{561}$-Ag[Co(tmdda)(ox)][8] (tmdda = trimethylenediamine-*N*,*N*′-diacetate, ox=oxalate), a combination of silver *d*-tartrate and *d*-tartaric acid, and a combination of silver dibenzoyl *d*-tartrate and dibenzoyl *d*-tartaric acid monohydrate. In all trials the racemate was changed into the chloride salt using an anion exchange resin (Dowex 1-X8, Cl^- form) before the addition of resolving agents. The first four resolving agents were not effective at all, even though a mixture of both diastereomers was obtained. The last resolving agent showed the possibility of the separation of diastereomers, but the resolution was very laborious and took a long time. Therefore, the resolutions of the other complexes using these resolving agents were not tried. We attempted to use a SP-Sephadex resin which has been used for the isolation and optical resolution of cobalt(III) complexes.[9] The optically active forms for the other three complexes were obtained in this way, but complete resolution was not achieved. Low yields were obtained because of the small capacity of the resin. Although we tried to elute the complexes two times as described (Experimental), the increase of $\Delta\varepsilon$ for the complexes the second time was small.

PMR spectra of $[Co(acac)(bpy)_2]Cl_2\cdot 6H_2O$ and $[Co(acac)(phen)_2]Cl_2\cdot 4.5H_2O$ were measured. The chloride salts, which are more soluble than the perchlorates, were obtained using anion exchange columns. The former complex shows a methyl resonance at 2.28 ppm and a methine resonance at 6.11 ppm (δ relative to DSS). The latter complex shows a methyl resonance at 2.55 ppm and a methine resonance at 6.47 ppm. These signals show significant downfield shifts, especially for the methine resonances, compared to $[Co(acac)(en)_2]I_2$ (a methyl resonance at 2.17 ppm and a methine resonance at 5.78 ppm in D_2O solution[10]). This may be a consequence of the magnetic aniostropy of bpy and phen. The resonances of the bpy and phen ligands were observed at 7.7—9.7 ppm although these regions were not analyzed. The spectral pattern of $[Co(acac)(phen)_2]^{2+}$ in the region of the phenanthroline ligand is slightly different from that of $[Co(en)(phen)_2]^{3+}$.[11]

Circular Dichroism and Absolute Configuration. Figures 1 and 2 show the CD spectra and visible and ultraviolet absorption spectra in water and in ethanol for $[Co(acac)(bpy)_2](ClO_4)_2\cdot 1.5H_2O$ and $[Co(acac)(phen)_2](ClO_4)_2\cdot 0.5H_2O$, respectively, in the first eluates from a Sephadex column. For the absorption spectrum of $[Co(acac)(bpy)_2]^{2+}$, the first d-d band (~20000 cm^{-1}) and $\pi^*\leftarrow\pi$ ligand bands (33000—34000 cm^{-1}) are evident. The split exciton CD bands at about 34000 cm^{-1} are positive and then negative from lower energy, indicating a *A* configuration.[12] The positions of the exciton CD bands are similar to those of $[Co(bpy)_3]^{3+}$ (at 32500 cm^{-1}) and $[Co(bpy)_2(ox)]^+$ (at 33000 cm^{-1}).[13] The corresponding $\pi^*\leftarrow\pi$ absorption peaks for the

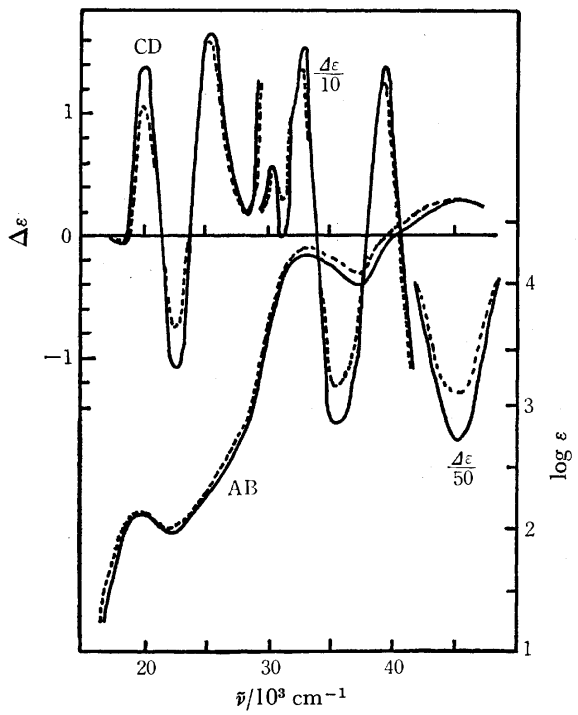

Fig. 1. Absorption (AB) and CD spectra of $(+)_{495}$-$[Co(acac)(bpy)_2]^{2+}$, in water (—) and in ethanol (---).

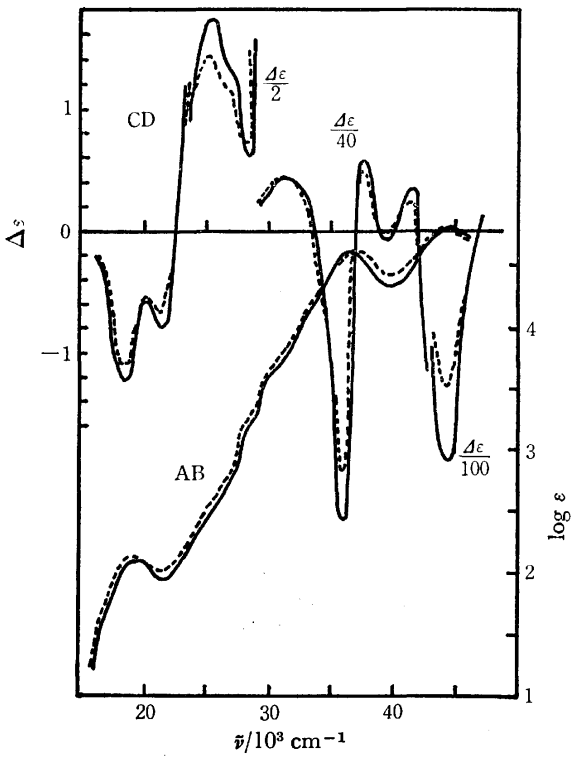

Fig. 2. Absorption (AB) and CD spectra of $(-)_{543}$-$[Co(acac)(phen)_2]^{2+}$, in water(—) and in ethanol(---).

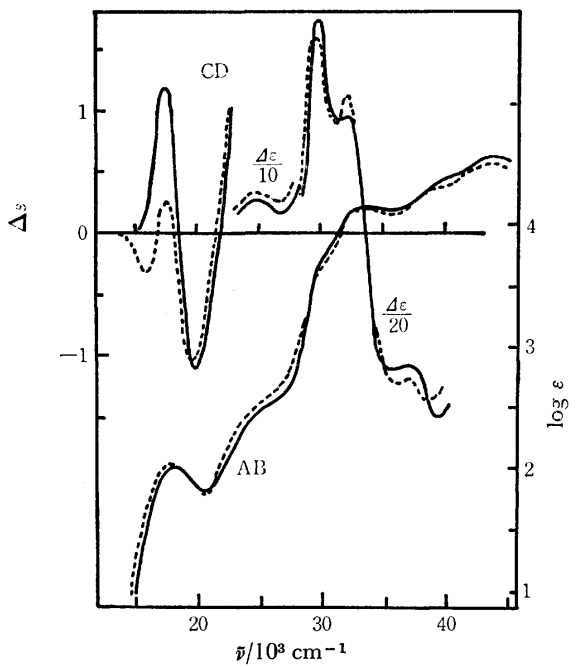

Fig. 3. Absorption (AB) and CD spectra of $(-)_{505}$-$[Co(acac)_2(bpy)]^+$, in water(—) and in ethanol(---).

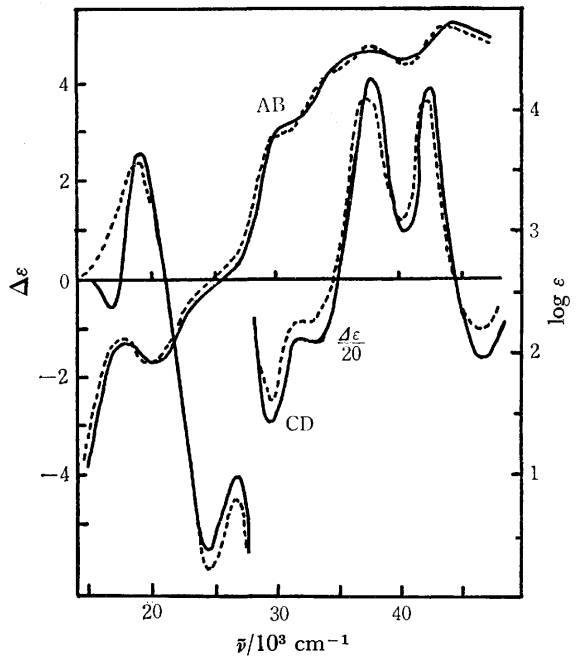

Fig. 4. Absorption (AB) and CD spectra of $(+)_{523}$-$[Co(acac)_2(phen)]^+$, in water (—) and in ethanol(---).

$[Co(acac)(phen)_2]^{2+}$ ion are observed at 36600 cm^{-1}, where the CD spectrum gives a negative and a positive band from lower energy, indicating the opposite or *Δ* configuration. The split exciton CD bands at about 37000 cm^{-1} correspond to those of $[Co(phen)_3]^{3+}$ (at 36300 cm^{-1}) and $[Co(phen)_2(ox)]^+$ (at 36800 cm^{-1}).[13] The CD curves in the visible region are quite different for the bpy and phen complexes. In each case one CD peak appears near the trough between the first d-d absorption band $[T_{1g}(O_h)]$ and the shoulder at higher energy, where the $T_{2g}(O_h)$ band is expected. Although assignments of the individual CD components cannot be made, the signs of the dominant CD peak (or the net rotational strength) in the T_{1g} region are consistent with the *Λ* configuration for $[Co(acac)(bpy)_2]^{2+}$ (Fig. 1, net positive) and **Δ** for $[Co(acac)(phen)_2]^{2+}$ (Fig. 2, net negative). The absorption spectra for $[Co(acac)(bpy)_2]^{2+}$ and $[Co(acac)(phen)_2]^{2+}$ in ethanol show slight red shifts relative to those in water. The CD spectral patterns in these solvents are almost the same, although the intensities of the peaks are slightly different.

In the case of the complexes containing two acetylacetonate ligands, the absorption spectra are very similar in water and in ethanol (Figs. 3, 4, 6. and 7). The CD spectra are also affected only to a small extent except in the region of the first absorption band. The CD spectrum of $[Co(acac)_2(bpy)]^+$ (Fig. 3, the isomer shown is from the first eluate from a Sephadex column) in ethanol shows three well-defined peaks of alternating signs in the first absorption band region, while in water there are only two peaks. For $[Co(acac)_2(phen)]^+$ (the enantiomer shown in Fig. 4 is from the more soluble diastereoisomer with hydrogen dibenzoyl *d*-tartrate) only one CD peak appears in ethanol in this spectral region, while two peaks appear in water. Note that the CD spectra throughout the d-d absorption region (Figure 5) are similar for $[Co(acac)_2(phen)]^+$ in dimethyl sulfoxide and in a KBr disc to that in ethanol. The solvent effects appear to be more remarkable in the case of $[Co(acac)_2(en)]^+$ and $[Co(acac)_2(tn)]^+$ (Figs. 6 and 7). In both cases there are two CD peaks in the first absorption band region for each solvent, but the lowest energy peak appears to change sign. It

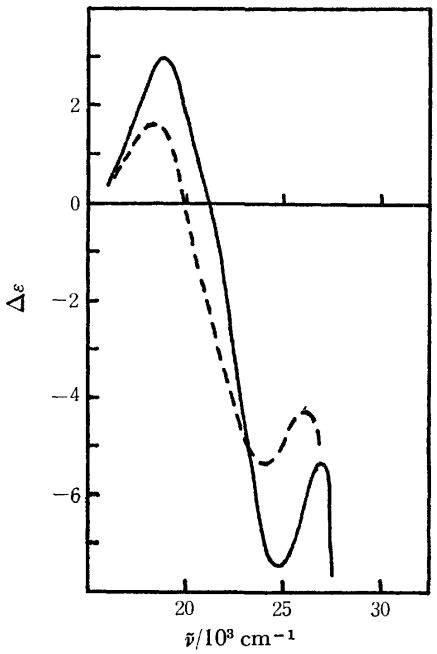

Fig. 5. CD spectra of $(+)_{523}$-$[Co(acac)_2(phen)]^+$, in dimethyl sulfoxide (—) and KBr disc(---) (arbitrary scale).

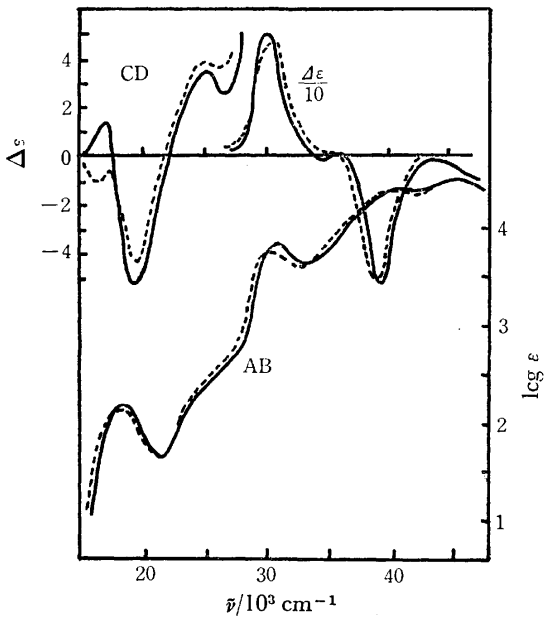

Fig. 6. Absorption (AB) and CD spectra of $(-)_{510}$-$[Co(acac)_2(en)]^+$, in water (—) and in ethanol(---).

should be noted that for both complexes the lowest energy (negative) CD peak is at lower energy in ethanol than the lowest energy (positive) peak in water.

The patterns of the CD spectra in the region of the first absorption band (Figs. 3, 4, 6, and 7) are not so erratic as might appear at first. For each of the four complexes, two CD peaks of opposite sign appear in water. The number of peaks and their signs vary in ethanol, except that the curves are similar for $[Co(acac)_2(en)]^+$ and $[Co(acac)_2(tn)]^+$. The variations are more

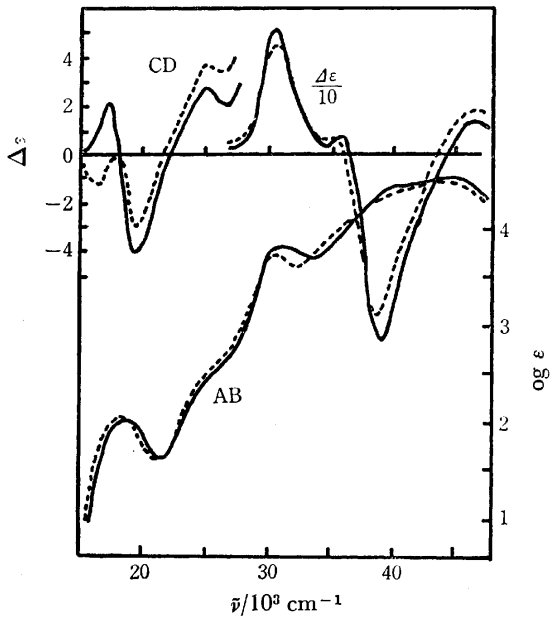

Fig. 7. Absorption (AB) and CD spectra of $(-)_{512}$-$[Co(acac)_2(tn)]^+$, in water (—) and in ethanol(---).

comprehensible if one considers the actual symmetry of the complexes, C_2. Three CD components are expected in the first absorption band region for C_2 symmetry, although often fewer components appear because of overlap resulting from small splittings. Three CD peaks actually appear for $[Co(acac)_2(bpy)]^+$ in ethanol. If one considers that there are actually three closely spaced components of alternating signs in each case, all of the spectra can be understood. It is expected that solvent changes or the addition of electrolytes will affect the relative intensities of the component and, to a lesser extent, their energies. The dominant component at highest energy in the first absorption band region, however, shows very slight solvent effect. For $[Co(acac)_2(bpy)]^+$ a lowering of the intensity of the lowest energy (negative) CD peak, or an increase of the intensity of the center (positive) CD peak, in going from ethanol to water would result in the two CD peaks observed in water (Fig. 3). The slight shift in the position of the positive peak toward lower energy in water would result from less cancellation by the lower energy negative peak. In the case of $[Co(acac)_2(phen)]^+$ (Fig. 4), the dominant CD peak in the first absorption band is positive, opposite in sign to that of $[Co(acac)_2(bpy)]^+$. In ethanol it would appear that the lowest energy component (also positive) for $[Co(acac)_2(phen)]^+$ completely cancels the middle (negative) component, resulting is a single positive CD peak. The middle (negative) peak shows up in water, because of lowering of intensity of the lowest energy component (or increase in intensity of the middle component). The CD curves for both $[Co(acac)_2(en)]^+$ and $[Co(acac)_2(tn)]^+$ (Figs. 6 and 7) in the first absorption band show two peaks of the same sign in ethanol, presumably the lowest and highest energy components, with the middle positive component being cancelled completely. For these complexes, two peaks of opposite sign appear in

water, with the lowest energy (negative) peak being cancelled completely.

The similarity of the CD patterns in the first band region in water for all complexes and the sign of the solvent insensitive intense peak on the higher energy side of the first absorption band provide a basis of relating the absolute configurations of the complexes. The sign of this peak is the same as the sign of the net rotational strength for the first absorption band region in each case. The CD spectral pattern for $(+)_{510}$-$[Co(acac)_2(en)]^+$ (the enantiomer of the isomer in Fig. 6) in water is strikingly similar up to 40000 cm^{-1} to that of Λ-$[Co(acac)_3]$, whose absolute configuration was determined by X-ray analysis.[14] Accordingly, $(+)_{510}$-$[Co(acac)_2(en)]^+$ should have the Λ configuration, as also assigned by Boucher[15] based on the sign of the dominant CD peak in the first band region. The enantiomers $(-)_{510}$-$[Co(acac)_2(en)]^+$ (Figure 6), $(-)_{512}$-$[Co(acac)_2(tn)]^+$ (Fig. 7), and $(-)_{505}$-$[Co(acac)_2(bpy)]^+$ (Fig. 3) have the Δ configuration and $(+)_{523}$-$[Co(acac)_2(phen)]^+$ (Fig. 4) has the Λ configuration. These assignments, based on the spectral sign pattern of Λ-$[Co(acac)_3]$, agree with those made based on the sign of the net rotational strength or of the intense solvent insensitive CD peaks in the first absorption band region.

The ultraviolet CD curves for $[Co(acac)_2(bpy)]^+$ and $[Co(acac)_2(phen)]^+$ are not very helpful in confirming the assignment of absolute configurations. The CD peaks for $[Co(acac)_2(bpy)]^+$ in the 32000—35000 cm^{-1} region (Fig. 3) overlap other peaks, so one cannot make reliable distinctions between charge transfer and possible exciton bands in this region. The $\pi^*\leftarrow\pi$ excition CD bands for other bis(acac) complexes have been observed at 40000 cm^{-1} or higher energy.[15] The characteristic split exciton CD bands require the coupling of two or more ligands with π-electron systems. No splitting of the $\pi^*\leftarrow\pi$ CD band occurs for $[Co(en)_2(phen)]^{3+}$ where there is only one ligand with a π-electron system.[17] The $\pi^*\leftarrow\pi$ transitions differ in energy for acac and bpy and it appears that such coupling between these ligands is not effective. If the absorption peak for $[Co(acac)_2(phen)]^+$ at *ca.* 43000 cm^{-1} corresponds to the $\pi^*\leftarrow\pi$ transition for acac, then the two CD peaks in this region, positive (at lower energy) and negative, could be the split exciton bands. This sign pattern is consistent [16] with the Λ configurations assigned from the first d-d band.

The encouragement and support of Professor Kazuo Saito during the part of the work carried out at Tohoku University are gratefully acknowledged.

Spectral Properties of Mixed Ligand Copper(II) Complexes Containing L-α-Amino Acids

Takeshi SAKURAI, Osamu YAMAUCHI, and Akitsugu NAKAHARA

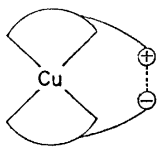
Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received March 4, 1976)

Absorption and circular dichroism (CD) spectral behaviors of ternary copper(II) complexes containing two L-α-amino acids or an L-α-amino acid and iminodiacetate (ida), 2,2′-bipyridine (bpy), 2-pyridinecarboxylate (pca), or 2,6-pyridinedicarboxylate (pdca), have been studied comparatively, and synthetic studies have given as crystals the mixed ligand complexes, [Cu(ida)(L-arg)]·$2H_2O$, [Cu(ida)(L-orn)]·$2H_2O$, [Cu(ida)(L-lys)]·$1/4H_2O$, [Cu(pdca)(L-arg)]·H_2O, and [Cu(pdca)(L-orn)]·$2.5H_2O$, where L-arg, L-orn, and L-lys denote L-arginine, L-ornithine, and L-lysine, respectively. The CD magnitudes of the systems Cu(ida)(L-arg), Cu(ida)(L-orn), and Cu(ida)(L-lys) were found to be enhanced appreciably as compared with the magnitudes estimated from the values for the corresponding binary systems. These ternary systems showed further magnitude enhancements in 50% aqueous ethanol. The enhanced magnitudes observed for Cu(L-glu)(L-arg), where L-glu is L-glutamate, were also intensified in 10, 20, and 50% aqueous ethanol, whereas they were weakened nearly to the estimated values in aqueous solutions with higher ionic strengths (μ=0.1 and 0.5($NaClO_4$)). These observations support the view that the pairs of ligands constituting the above ternary complexes are fixed around copper(II) by electrostatic ligand-ligand interactions between the oppositely charged side chains. Pyridine-containing ligands, bpy, pca, and pdca, in the ternary systems with L-α-amino acids affected the signs and the magnitudes of the CD spectra.

Mixed ligand complexes as potential biological models have been studied most extensively by the potentiometric method, which has made available valuable information about the stabilities and distributions of complex species in solution.[1,2] Because of the biological importance of copper, a great deal of attention has been paid to the ternary copper(II) complexes containing optically active amino acids and peptides, where circular dichroism (CD) has often proved to be a more direct and effective source of information.[3,4]

In our previous studies on the ternary copper(II) systems composed of α-amino acids and related compounds,[5,6] the synthetic and spectroscopic findings have been interpreted as supporting the existence of the intramolecular electrostatic ligand-ligand interactions between the oppositely charged side groups around the central copper(II) ion as tentatively shown in Scheme 1. Facile isolation of the corresponding



Scheme 1.

mixed ligand complexes implicated that such electrostatic bondings served as a driving force leading to the formation of mixed ligand complexes. While the ternary systems without the possibility of the ligand-ligand interactions exhibited the CD magnitudes equal to those estimated from the corresponding binary systems, most of the ternary systems expected to involve such interactions were accompanied by magnitude enhancements probably due to the structural rigidity.[5,6]

Martin and Prados[7] detected a CD magnitude enhancement and sign inversions for the systems Cu(2,2′-bipyridine)(L-phenylalanine) and Cu(2,2′-bipyridine)(L-alanine or L-leucine), respectively, and they ascribed the behaviors to the presence of the pyridine ring as a π-acceptor. On the other hand, Tsangaris and Martin[8] observed that the magnitudes were additive in the Cu(dipeptide) series.

Interests in the structural and spectral properties of the ternary systems and the demand for the relevant information prompted us to investigate the visible absorption and CD spectra of various ternary copper(II) systems containing two L-α-amino acids or an L-α-amino acid and iminodiacetate (ida), 2,2′-bipyridine (bpy), 2-pyridinecarboxylate (pca), or 2,6-pyridinedicarboxylate (pdca) under different conditions. We isolated for the present purpose several copper(II) complexes, Cu(A)(B), containing iminodiacetate or 2,6-pyridinedicarboxylate as ligand A and L-arginine (L-arg), L-ornithine (L-orn), or L-lysine (L-lys) as ligand B. The present paper describes the results obtained therefrom and the discussion of the structures and spectral behaviors of the ternary systems.

Experimental

Materials. L-Arginine, L-lysine dihydrochloride, L-ornithine monohydrochloride, L-glutamic acid (L-glu), L-aspartic acid (L-asp), L-alanine (L-ala), L-valine (L-val), iminodiacetic acid, 2,2'-bipyridine, 2-pyridinecarboxylic acid, and 2,6-pyridinedicarboxylic acid were purchased from Nakarai Chemicals, Ltd. All the chemicals used were of reagent grade or of highest grade available.

Synthesis of Mixed Ligand Copper(II) Complexes. [*Cu(ida)(L-lys)*]·*1/4H₂O.* Iminodiacetic acid (0.67 g, 5 mmol), L-lysine dihydrochloride (1.10 g, 5 mmol), and copper(II) perchlorate hexahydrate (1.85 g, 5 mmol) were dissolved in 30 ml of water, and the pH of the solution was adjusted at 7 with aqueous sodium hydroxide. After stirring for 1 h at room temperature the solution was concentrated *in vacuo* and filtered. Methanol was added to the filtrate to give blue crystals, which were recrystallized from aqueous methanol. Found: C, 34.88; H, 5.62; N, 12.25%. Calcd for $C_{10}H_{19}N_3O_6Cu \cdot 1/4H_2O$: C, 34.77; H, 5.69; N, 12.17%.

The following complexes were prepared at pH 7—10 in similar manners.

[Cu(ida)(L-arg)]·2H₂O. Found: C, 29.38; H, 5.58; N, 17.39%. Calcd for $C_{10}H_{19}N_5O_6Cu\cdot 2H_2O$: C, 29.66; H, 5.70; N, 17.30%.

[Cu(ida)(L-orn)]·2H₂O. Found: C, 29.88; H, 5.41; N, 11.41%. Calcd for $C_9H_{17}N_3O_6Cu\cdot 2H_2O$: C, 29.79; H, 5.84; N, 11.58%.

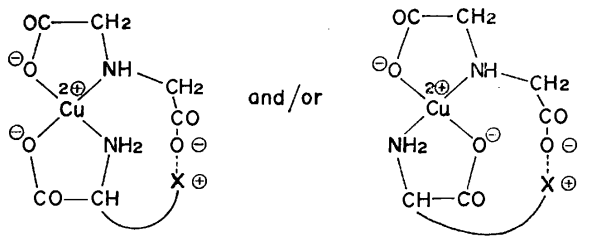
[Cu(pdca)(L-arg)]·H₂O. Found: C, 37.29; H, 4.70; N, 16.34%. Calcd for $C_{13}H_{17}N_5O_6Cu\cdot H_2O$: C, 37.10; H, 4.55; N, 16.64%.

[Cu(pdca)(L-orn)]·2.5H₂O. Found: C, 35.19; H, 5.15; N, 10.22%. Calcd for $C_{12}H_{15}N_3O_6Cu\cdot 2.5H_2O$: C, 35.51; H, 4.97; N, 10.35%.

Measurements of Absorption and CD Spectra. The spectroscopic measurements were performed in water or in aqueous ethanol at room temperature for the systems with the copper(II) : A : B ratios of 1 : 1 : 1 (ternary systems) and 1 : 2 : 0 and 1 : 0 : 2 (binary systems) at pH 5—11 at a copper(II) concentration of 5×10^{-3} M. The spectral samples were prepared from 0.1 M stock solutions of the ligands and copper(II) perchlorate. Because of the low solubility of 2,2′-bipyridine in water, a Cu(II)-bpy solution was used for preparation of the bpy-containing samples. The pH values were roughly adjusted with aqueous sodium hydroxide and dilute perchloric acid and finally determined after the spectroscopic measurements. The spectra of the Cu(L-glu)(L-arg) system were measured at different ionic strengths (μ) adjusted with sodium perchlorate. For the rest of the systems the ionic strengths of the solutions were not adjusted (μ= variable). Absorption spectra were recorded in the range 400—800 nm on a Union Giken SM-401 High Sensitivity recording spectrophotometer. CD spectra were measured in a 1- or 2-cm path length quartz cell in the range 350—800 nm with a JASCO MOE-1 spectropolarimeter.

Results and Discussion

Preparation of Mixed Ligand Copper(II) Complexes. Since iminodiacetate has a flexible molecular structure, it can be coordinated to copper(II) as a bidentate ligand, forming through the remaining carboxylate group electrostatic bondings with the positive group of the basic amino acid coordinated to the same copper(II) ion (**1**). Thus, iminodiacetate and the amino



1

acids afforded the complexes [Cu(ida)(L-arg)], [Cu(ida)(L-orn)], and [Cu(ida)(L-lys)]. Although isolation of a ternary complex depends both on the stability and the solubility, it gives evidence of occurrence of a considerable amount of the ternary complex.

On the other hand, the inflexibility of the structure of pdca seems to affect the ternary complex formation, because attempts to prepare [Cu(pdca)(L-lys)] resulted in isolation of $Na_2[Cu(pdca)_2]$ under the conditions employed. Molecular models suggest that the interactions as illustrated in Scheme 1 are sterically unlikely to occur, so that the successful preparation of [Cu(pdca)(L-arg)] and [Cu(pdca)(L-orn)] might be ascribed to the statistical effect[9] and the complex-stabilizing effect of the pyridine ring as a π-acceptor.[7,10] The absorption spectral data of the ternary systems in the visible region (Table 1) apparently indicate the presence of rather large amounts of the binary species $Cu(pdca)_2$ and $Cu(B)_2$ in consequence of the lower stabilities of the ternary complexes.

Effects of Ionic Strength and Polarity of Solvent on the CD Magnitude. For the ternary systems with possible ligand-ligand interactions, the CD magnitudes expressed in terms of the relative magnitude, which assumes as unity the sum of the half magnitude ($1/2\Delta\varepsilon$) exhibited by each of the optically active ligands in the complex, have been found to be larger than unity.[5,6] In accordance with the observation about the Cu(edma)(B) systems,[5] where edma refers to ethylenediamine-*N*-monoacetate, the enhanced magnitude for the Cu(L-glu)(L-arg) system[6] has now been shown to be affected by the ionic strength of the solution and the polarity of the solvent used. The relative magnitude thus decreased from 1.3 (μ=variable) to 1.1 (μ=0.1) and 1.05 (μ=0.5) (Table 2). It might be suspected that the magnitude decrease at higher ionic strengths would result from the enhanced magnitudes for the binary systems to be compared. However, the molar extinction coefficients (ε) for the binary and ternary systems remain constant at different μ values (Table 2), indicating that the observed decrease is not due to the shifts of the equilibria. We may therefore infer that the decrease is caused by the weakened ligand-ligand interactions at higher salt concentrations. The magnitude increase in 10, 20, and 50% aqueous ethanol confirms that the interactions are electrostatic attractions which are favored in non-aqueous solvent.

L-orn-Containing Ternary Systems. The δ-amino group of ornithine is known to form an apical bonding with copper(II).[5,11,12] We observed in the previous study[6] that the systems Cu(L-asp)(L-orn) and Cu(L-glu)(L-orn) suffered complex CD spectral changes at pH>8. Figure 1 illustrates the pH dependence of their spectra, whose numerical data are summarized in Table 3. Since aspartate binds with copper(II) as a terdentate ligand with the β-carboxylate group at the apical position,[13] the spectral behaviors suggest that L-asp and possibly L-glu compete with the δ-amino group of L-orn for the apical coordination.

ida-Containing Ternary Systems. Table 4 shows that the absorption maxima of the Cu(ida)(B) systems ($\approx$665 nm) are between those of $Cu(B)_2$ ($\approx$620 nm) and $Cu(ida)_2$ (682 nm) and expectedly at longer wavelengths than those observed for the systems Cu(edma)(B) ($\approx$620 nm).[5]

The relative CD magnitudes for the Cu(ida)(B) systems in aqueous solution are 1.2—2.0 and are enhanced up to >1.7 in 50% aqueous ethanol (Table 4). These values are comparable with those of the systems containing two L-amino acids with charged side chains[6] but somewhat lower than those exhibited by the Cu(edma)(B) systems.[5] Both edma and ida may affect the CD spectra through molecular asymmetry originat-

ing from their fixation in a geometrical structure around copper(II) by the ligand-ligand bonding. The difference between edma and ida is that the imino nitrogen atom of the former can be asymmetric in the absence of the ligand-ligand interactions if it is coordinated to copper(II),[14-16] whereas the nitrogen atom of the latter cannot.

For the systems without the mentioned interactions, the CD magnitudes were found to be close to the estimated values and insensitive to addition of ethanol. The unexpectedly small magnitude for Cu(ida)(L-val) may partly be attributable to incomplete complex formation under the present conditions, in addition to the change in the spectral pattern in 50% aqueous ethanol.

These comparisons as well as those made earlier[5,6] indicate that the CD magnitudes are considerably enhanced when the ligand-ligand interactions occur and otherwise are reasonably additive even in some different ligand fields.[5,12]

Ternary Systems Involving a Pyridine Ring. (1) bpy-Containing Systems. The ternary systems Cu(bpy)(L-arg), Cu(bpy)(L-lys), and Cu(bpy)(L-glu) exhibited positive CD extrema around 560 nm, contrary to the negative peaks observed for the binary systems Cu(L-amino acid)$_2$ (Table 5). As Martin and Prados[7] reported for Cu(bpy)(L-phenylalanine), these anomalous spectral behaviors are probably caused by the electronic effects due to π-back donation, which has been pointed out in many ternary systems involving pyridine rings.[10]

Figure 2 shows that the CD spectral pattern of the

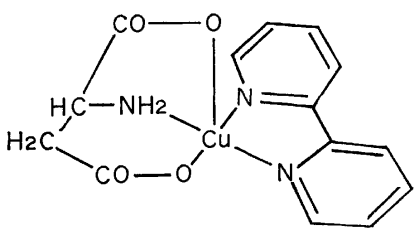
a) Estimated from the data for the systems Cu(L-amino acid)$_2$ (Ref. 5). b) Relative CD magnitude refers to $\Delta\varepsilon_{max}$(found)/$\Delta\varepsilon_{max}$(calcd). c) The data for the Cu(ida)$_2$ system are as follows: λ_{max}=682 nm; ε=38(at pH 8.1 and 9.3). d) The anomalous value is probably due to the increase of the positive extremum at >700 nm.

Cu(bpy)(L-asp) system at pH 9.6 appears to be similar to that of the Cu(bpy)(L-orn) system at pH 10.1 with the sign inverted. The fact may be explained as arising from the octahedral distortion, which allows L-asp to coordinate as a terdentate ligand through its α-amino and β-carboxylate groups occupying the planar position as expressed by **2**, where the α-carboxylate group of L-asp appears as if it assumed the same arrangement as that of D-ornithine. This explanation is in line with the argument that has been made by Wilson *et al.*[12] for the CD spectra of the Cu(L-orn)$_2$ system in alkaline solution. Based on the calculations by the crystal field approximation, Gil *et al.*[17] recently suggested the distorted octahedral coordination around copper(II) for Cu(bpy)(L-amino acid) and Cu(phenanthroline)(L-amino acid). They indicated the possibility that the two chelate rings formed by the ligands might be perpendicular to each other.



2

(2) pca- and pdca-Containing Systems. The pca-containing systems exhibited the absorption maxima centered around 635 nm (Table 1), from which formation of the ternary complexes may be inferred. For every L-amino acid employed, presence of pca in

the ternary system decreased the CD magnitude, but the effects were not so remarkable as to invert the CD sign.

The absorption spectra of the pdca-containing systems showed a broad peak with a shoulder, and the wavelengths of their CD peaks (Table 5) were very close to those of Cu(L-amino acid)$_2$.[5] These spectra are compatible with the view that the binary species contribute much to the observed spectral patterns. Considering that it is difficult to construct a molecular model having ligand-ligand interactions depicted in Scheme 1, pdca does not seem to provide a favorable condition for the intramolecular bonding, and the stabilities of the ternary complexes may be lower than those containing edma or ida in place of pdca.

Small CD magnitudes of the pdca series may indicate that L-amino acids are coordinated to copper(II) through the amino group in the tetragonal plane, whereas pdca occupies the rest of the coordination sites.[18] Murakami *et al.*[19] reported that L-amino acids in the mixed ligand complexes, Cu(diethylenetriamine)(L-amino acid), are bonded to copper(II) in neutral solution through the amino group in the square plane and the carboxylate group interacting at the apical position, which is occupied by a hydroxyl ion in alkaline solution.

The present observations demonstrate that the pyridine ring in the ternary systems studied does change the CD patterns probably through the π-back donation associated with the copper(II)-pyridine bonding and thus may affect the formation of mixed ligand complexes.

We wish to express our thanks to Miss Tazuko Ikebata for technical assistance and to Miss Teruko Kuroe for elemental analysis. This work was supported by a grant from the Ministry of Education.

Photoreactions of Cyclic Benzylidene Acetals with Ketones in the Presence and Absence of Dissolved Oxygen

Morio SUZUKI, Toshimi INAI, and Ryoka MATSUSHIMA

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

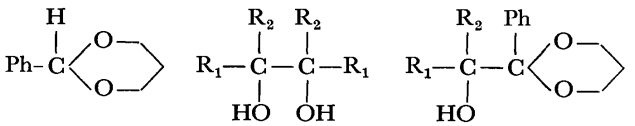
(Received September 4, 1975)

Photoreactions of 2-phenyl-1,3-dioxane (**1**) and 4,6-*O*-benzylidene-1,2,3-tri-*O*-acetylglucopyranose (**10**) in the presence of benzophenone, acetophenone, or acetone have been studied in both deoxygenated and aerated benzene solutions at room temperature. Photolysis of **1** with ketone in deoxygenated solution gave a dimeric product of **1** (**8**), cross adduct, and pinacol, while in aerated solution an oxidative ring cleavage product, *i.e.*, trimethylene glycol monobenzoate (**9**), was obtained instead of **8**, besides smaller amounts of pinacol and cross adduct. The yields of pinacol and cross adduct decreased with the change in ketone in the order benzophenone>acetophenone>acetone, while the yield of **8** or **9** was in the reverse order. Photolysis of **10** with ketone led to results parallel to those of **1**: photolysis under nitrogen atomosphere gave pinacol, cross adduct, and a dimeric product of **10** (**14**), while under bubbling air 4-*O*-monobenzoate and 6-*O*-monobenzoate derivatives of **10** were obtained instead of **14**, besides pinacol and cross adduct. The effects of temperature, oxygen, and structure on the course of the reaction, to produce dimeric or ring opening products, have been discussed.

Recently photoreactions of carbohydrate derivatives have been extensively studied.[1] Photochemical hydrogen abstraction from 2-alkyl-1,3-dioxanes[2] or from benzylidene derivatives of L-ribose[3] with acetone gives ring opening (β-cleavage) products, while photolysis of *o*-nitrobenzylidene derivatives of glucose gives oxidative ring opening products *via* intramolecular hydrogen abstraction followed by oxidation of the intermediate radicals.[4] Photoreactions of 2-aryl-1,3-dioxanes with ketone seem to have been little studied, though hydrogen abstraction from 2-phenyl-1,3-dioxanes by thermally generated *t*-butoxyl radicals[5] or NBS[6] produces ring opening products. In this work studies on the photoreactions of 2-phenyl-1,3-dioxane and its derivative of triacetylglucopyranose with ketone have been carried out, showing some different features from those referred to above.

Results

Photolysis of 2-Phenyl-1,3-dioxane with Ketone. Irradiation of a benzene solution of 2-phenyl-1,3-dioxane (**1**) in the presence of benzophenone, acetophenone, or acetone, at 15 °C under oxygen-free nitrogen atomosphere, gave the corresponding pinacol (**2**, **3**, or **4**, respectively), cross adduct (**5**, **6**, or **7**, respectively), and a dimer (**8**).



1 Pinacol Cross adduct

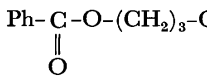
2: $R_1=R_2=Ph$ **5**: $R_1=R_2=Ph$
3: $R_1=Ph$, $R_2=Me$ **6**: $R_1=Ph$, $R_2=Me$
4: $R_1=R_2=Me$ **7**: $R_1=R_2=Me$

On the other hand, photolysis of the same solution under bubbling air gave trimethyleneglycol monobenzoate (**9**) instead of the dimer **8**, besides pinacol and cross adduct.



9

The results are summarized in Table 1. We see a significant change in the product distribution: the yields of pinacol and cross adduct decrease with the change in the ketone in the order benzophenone> acetophenone>acetone, while the yield of **8** or **9** is in the reverse order.

Photolysis of 4,6-O-Benzylidene-1,2,4-tri-O-acetyl-β-D-glucopyranose with Ketone. Irradiation of benzene solution of 4,6-*O*-benzylidene-1,2,3-tri-*O*-acetyl-β-D-glucopyranose (**10**) in the presence of benzophenone, acetophenone, or acetone, at 15 °C under oxygen-free nitrogen atomosphere, gave the corresponding pinacol (**2**, **3**, or **4**, respectively), cross adduct (**11**, **12**, or **13**, respectively), and a dimer (**14**). Photolysis of the same solution as above under bubbling air gave 4- and 6-*O*-benzoyl-1,2,3-tri-*O*-acetylglucopyranose (**15**) and (**16**), instead of the dimer **14**, besides pinacol and cross adduct. The results are summarized in Table 2.

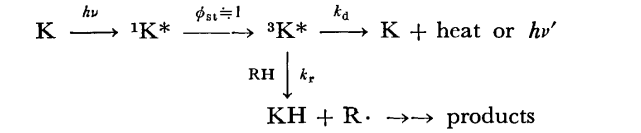
Quantum Yields for Hydrogen Abstraction. In order to see the structural factors affecting the efficiency for the abstraction of tertiary hydrogen atoms by excited state ketones, quantum yields for the hydrogen abstraction process have been measured for various substrate-ketone systems. On the basis of the following scheme



assumed for the photoreaction of a ketone (K) with a hydrogen donor (RH), the rate expression is given by

Table 1. Yields of the products by the photolysis of **1** (0.1 M) with ketone

Conditions			Products and yields[a]				Recovery of **1**, %
Atmosphere	Ketone, M		Pinacol, %	Adduct, %	**8**, %	**9**, %	
N_2	Benzophenone,	0.1	**2**, 28	**5**, 36	9.5	0	trace
N_2	Acetophenone,	0.1	**3**, 18	**6**, 30	13	0	20[b]
N_2	Acetone,	1.3	**4**, trace	**7**, 17	17	0	45
Air	Benzophenone,	0.1	**2**, 19	**5**, 27	0	35	10[c]
Air	Acetone,	1.3	**4**, 0	**7**, 5	0	70	40

a) Based on the consumed amount of **1**. b) Recovered yield of acetophenone was 19%. c) Recovered yield of benzophenone was 48%.

Table 2. Yields of the products of the photolysis of **10** (0.05 M) with ketone

Conditions			Products and yields[a]					Recovery of **10**, %
Atomosphere	Ketone, M		Pinacol, %	Adduct, %	**14**, %	**15**, %	**16**, %	
N_2	Benzophenone,	0.05	**2**, 26	**11**, 38	trace	0	0	15[b]
N_2	Acetophenone,	0.05	**3**, 16	**12**, 33	7	0	0	20[c]
N_2	Acetone,	1.3	**4**, trace	**13**, 23	9	0	0	46
Air	Benzophenone,	0.05	**2**, 19	**11**, 17	0	27	19	23[d]
Air	Acetone,	1.3	**4**, 0	**13**, trace	0	41	23	37

a) Based on the consumed amount of **10**. b) Recovered yield of benzophenone was 10%. c) Recovered yield of acetophenone was 17%. d) Recovered yield of benzophenone was 70%.

Table 3. Rate parameters for the abstraction of tertiary hydrogen atoms by excited state ketones[a]

Substrate	Ketone	ϕ	k_d/k_r, M
1	Benzophenone	0.64	0.056
1	Acetophenone	0.37	0.17
1	Acetone	0.11	0.77
$(EtO)_2CHPh$	Benzophenone	0.52	0.093
Ph_2CHOH	Benzophenone	0.67[b]	0.05
Me_2CHOH	Benzophenone	0.71[c]	0.18
Me_2CHPh	Benzophenone	0.30	0.23

a) Quantum yields at initial substrate concentration of 0.1 M. Initial concentrations of benzophenone and acetophenone were 0.1 M while that of acetone was 1.3 M. b) Ref. 7, p. 3. c) Data from S. G. Cohen, *Tetrahedron Lett.*, **1968** 4823.

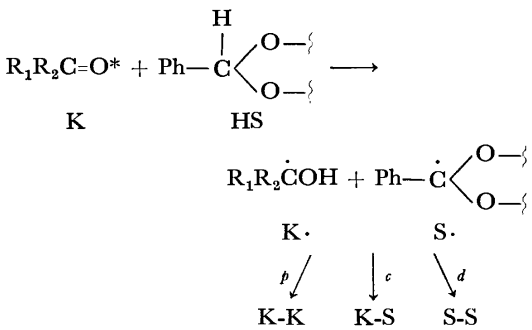
$1/\phi = 1 + k_d/k_r[RH]$,[7] where, ϕ is the quantum yield of disappearance of RH or K. If the equation is multiplied by the quantum yield ϕ_s of the disappearance of K, known for a standard system such as ketone–benzhydrol,[8] we have

$$\frac{\phi_s}{\phi} = \phi_s + \frac{k_d\phi_s}{k_r[RH]}$$

Thus, ϕ and k_d/k_r can be obtained from the slope and intercept of a plot of the relative disappearance ratio *vs.* 1/[RH], using a value of $\phi_s = 0.68$ for 0.1 M benzophenone and 0.1 M benzhydrol.[8] The results are given in Table 3.

Discussion

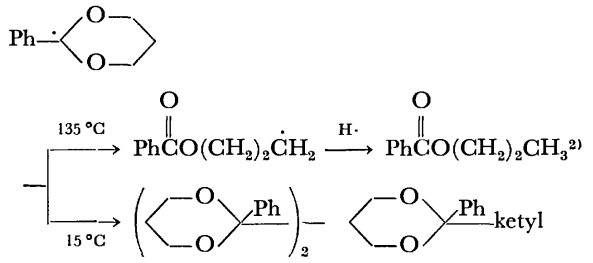
Effects of Temperature and the Substrate Structure on the Course of the Reaction. The variation in the product yields with the change in ketone (Tables 1 and 2) might be related to the relative stability of ketyl radicals (K·). The yields of pinacols (K-K) and cross adducts (S-K) would decrease in the decreasing order of relative stability of ketyl radicals; the yield of the dimer (S-S), whose formation process *d* being competitive with the process *c*, would increase.



Acetone ketyl radical would rapidly react with solvent, though no further investigation was made on the products. The product ratio of the photolysis of **1** with acetophenone, 3 : 6 : 8 = 1 : 2.3 : 1.4 (Table 1), is close to the statistical ratio 1 : 2 : 1 which is inferred for the two radicals with similar stability, suggesting that S· is as stable as the acetophenone ketyl radical.

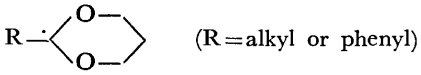
The reaction of S· shows a remarkable temperature dependence: at 15 °C S· (produced by hydrogen atom abstraction by excited state acetone) gives a dimer and cross adduct without ring opening (Table 1), while at 135 °C S· (produced by thermal hydrogen atom abstraction with *t*-butoxyl radical) gives a ring opening product.[5]

At low temperature, S· is stable enough to undergo collisional encounters with other radicals, resulting in dimerization and cross coupling reactions which are assumed to involve no significant activation processes and to be highly exothermic. At high temperature,



S· is somewhat activated or destabilized and unimolecular ring opening (β-cleavage), assumed to involve more or less activation process, would occur before bimolecular encounter of radicals.

A significant structural effect is observed on the features of the following intermediate radical:



Upon irradiation in the presence of acetone at room temperature 2-alkyl-1,3-dioxane undergoes ring opening to give $RC(=O)O(CH_2)_2CH_3$ as the main product,[2] in contrast with the present results of 2-phenyl-1,3-dioxane (Table 1). The difference might be correlated to the relative stability of the intermediate radicals: the radical with R=alkyl is not so stabilized as that with R=phenyl whose resonance stabilization energy due to the benzyl group is *ca.* 18 kcal/mol.[9] Thus, the ring opening process of 2-phenyl-1,3-dioxane is expected to be much more endothermic than that of 2-alkyl-1,3-dioxane.

The product yields of the photolysis of **10** with benzophenone, acetophenone, or acetone are almost the same as those of the photolysis of **1** under similar conditions. The yields of the dimer **14** are lower and those of the cross adducts are slightly higher in Table 2 than the yields of the corresponding products in Table 1. This may reflect a larger steric hindrance of the intermediate radical derived from **10** as compared to that from **1**. Mutual coupling of bulky radicals to form **14** would sterically be less favorable as compared to the cross coupling with less bulky benzophenone ketyl radical.

Effects of the Dissolved Oxygen. The yields of pinacols, cross adducts and dimers decrease in the presence of oxygen. Oxidative ring opening products (benzoates) are formed in a significant yield (Tables 1 and 2). This shows a high reactivity of oxygen with the intermediate radicals.[3,4]

The fact that the benzoate derivatives are formed by the photoreaction in the presence of oxygen whereas they are not formed under purified nitrogen atmosphere, indicates that the source of oxygen (necessary for the formation of the benzoates) is the dissolved oxygen. It is likely that the source of oxygen required for the formation of methyl-2(or 3)-*O*-benzoyl-β-D-ribofuranoside in acetone-sensitized photolysis of methyl-2,3-*O*-benzylidene-β-D-ribofuranoside under nitrogen (commercial nitrogen without further purification[3]), is the small amount of oxygen which might be contained in the commercial nitrogen.

Since the yields of the benzoate derivatives relative to those of the cross adducts or dimers depend on the concentration of the dissolved oxygen,[11] it seems that the formation of the benzoate derivatives takes place through the reaction of the radical S· with the dissolved oxygen and that this process is competitive with processes *c* and *d*.

When the consumption of **1** is 90%, that of benzophenone is only 52%, upon irradiation of an air-saturated benzene solution containing equimolar amount of **1** and benzophenone. The discrepancy in the consumption rates of **1** and benzophenone might be related to the reformation of benzophenone by the reaction of the benzophenone ketyl radical with the dissolved oxygen, according to the report by Pitts *et al.*:[12]

$$Ph_2\dot{C}OH + O_2 \longrightarrow Ph_2C{=}O + HOO\cdot$$

$$HOO\cdot + RH \text{ (substrate or solvent)} \longrightarrow H_2O_2 + R\cdot$$

However, the mechanism for the formation of the benzoate derivatives, *e.g.*, as to whether or not the reaction proceeds through radical chain process, is not clarified as yet. The radical chain mechanism does not seem to be supported by the apparent rate; the photoreaction in the presence of the dissolved oxygen seems to proceed less efficiently than that under nitrogen atmosphere, though the quantum yields for the photoreaction in the presence of the dissolved oxygen have not been measured.

Structural Effects on the Rates of Hydrogen Abstraction. We see a significant change in ϕ (Table 3) with the change in structure of the substrate or the ketone. The lowest triplet lifetimes (τ_T) of acetone, acetophenone, and benzophenone in benzene at room temperature are 0.94, 3.5, and 12 μs, respectively.[13] The results in the first three runs in Table 3 show that ϕ and k_d/k_r are closely related to τ_T, k_r/k_d being nearly proportional to τ_T. Thus, the efficiency of the hydrogen abstraction from the substrate **1** by different ketones is mainly controlled by the lowest triplet lifetimes of the ketones.

Since the bond dissociation energies of the benzylic hydrogen atoms of **1** and $(EtO)_2CHPh$ are assumed to be similar, the slightly low photoreactivity of $(EtO)_2$-CHPh as compared to that of **1** may be attributed to the steric hindrance due to the free rotation of the two ethoxyl groups in $(EtO)_2CHPh$. The intermediate radical $Ph_2\dot{C}OH$ is expected to be stabilized to a greater extent by the two phenyl groups as compared to $Me_2\dot{C}HO$. Nevertheless the efficiency for the hydrogen abstraction of Ph_2CHOH is not higher than that of Me_2CHOH. This may partly be due to a saturation effect (selectivity will be poor when hydrogen abstraction occurs on highly reactive substrates), as well as the steric hindrance.

Experimental

Materials. 2-Phenyl-1,3-dioxane[5] and 4,6-*O*-benzylidene-1,2,3-tri-*O*-acetyl-β-D-glucopyranose[14,15] were prepared according to methods in literature. Guaranteed benzophenone, acetophenone, and acetone (Wako Chemicals) were used.

*Photolysis of 2-Phenyl-1,3-dioxane (**1**) with Benzophenone.* After deoxygenation with purified nitrogen current for 1 h,

a 125 ml benzene solution containing **1** (0.1 M) and benzophenone (0.1 M) was irradiated at 15 °C under purified nitrogen atmosphere with a 100 W high pressure mercury lamp for 5 h. The photolyzed solution was condensed and chromatographed over silica gel to give **2** (1.25 g), **5** (1.59 g) and **8** (0.39 g). **2** gave mp, NMR and IR spectra identical with those of authentic benzpinacol. **5**: colorless crystal, mp 189—190 °C; IR: 1580, 3520 cm^{-1}; NMR ($CDCl_3$): δ 1.0—1.4 (m, 1H, H_{5e}), 1.9—2.7 (m, 1H, H_{5a}), 3.12 (s, 1H, OH), 3.5—4.1 (m, 4H, H_4H_6), 6.8—7.7 (m, 15H, phenyl). Found: C, 79.25; H, 6.47%. Calcd for $C_{13}H_{18}O_3$: C, 79.74; H, 6.40%. **8**: colorless prism, mp 235—236.5 °C; IR: 2850, 2950 cm^{-1}; NMR ($CDCl_3$): δ 0.8—1.3 (m, 2H, $H_{5e}H_{5e}'$), 1.5—2.3 (m, 2H, $H_{5a}H_{5a}'$), 3.0—3.4 (m, 8H, $H_4H_4'H_6H_6'$), 7.1—7.3 (m, 10H, phenyl). Found: C, 73.68; H, 6.95%. Calcd for $C_{20}H_{22}O_4$: C, 73.60; H, 6.79%. Upon irradiation under bubbling air for 7.5 h, a 125 ml solution of the same as that above gave **9** (0.71 g), **2** (0.21 g) and **5** (1.06 g), besides recovered **1** (0.20 g) and benzophenone (1.18 g). **9** showed IR and NMR spectra identical with those of authentic trimethyleneglycol monobenzoate.

*Photolysis of 2-Phenyl-1,3-dioxane (**1**) with Acetophenone.* A 125 ml benzene solution containing **1** (0.1 M) and acetophenone (0.1 M) was irradiated in a similar way for 6 h under nitrogen atmosphere. Separation of the photolyzed solution by column chromatography over silica gel gave **3** (0.45 g), **6** (0.84 g), **8** (0.41 g), besides recovered **1** (0.41 g) and acetophenone (0.27 g). **3**: colorless prism, mp 121—122.5 °C (lit, 123—124 °C)[16]; IR: 1600, 2960, 3550 cm^{-1}: NMR ($CDCl_3$): δ 1.43 (s, 6H, Me), 2.72 (s, 2H, OH), 7.0—7.3 (m, 10H, phenyl). **6**: mp 114—116 °C; IR: 1590, 2850, 2950, 3560 cm^{-1}; NMR: δ 0.84—1.4 (m, 1H, H_{5e}), 1.63 (s, 3H, Me), 1.8—2.5 (m, 1H, H_{5a}), 2.96 (broad s, 1H, OH), 3.4—4.0 (m, 4H, H_4H_6), 6.8—7.3 (m, 10H, phenyl). Found: C, 76.14; H, 7.22%. Calcd for $C_{18}H_{20}O_3$: C, 76.03; H, 7.09%.

*Photolysis of 2-Phenyl-1,3-dioxane (**1**) with Acetone.* A 125 ml benzene solution containing **1** (0.1 M) and acetone (1.3 M), after previous deoxygenation, was irradiated at 15 °C under purified nitrogen atmosphere with a 100 W high pressure mercury lamp for 20 h. Separation of the photolyzed solution by column chromatography over silica gel gave **7** (0.26 g), **8** (0.38 g) and **4** (a trace), besides recovered **1** (0.93 g). **7**: mp 90.5—92 °C; IR: 2900, 3550 cm^{-1}; NMR ($CDCl_3$): δ 1.10 (s, 6H, Me), 1.0—1.4 (m, 1H, H_{5e}), 1.6—2.4 (m, 1H, H_{5a}), 2.48 (s, 1H, OH), 3.4—4.0 (m, 4H, H_4H_6), 7.3—7.5 (m, 5H, phenyl). Found: C, 70.71; H, 8.42%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%. Upon irradiation under bubbling air for 30 h, 125 ml of the same solution as that above gave **7** (0.09 g), and **9** (0.95 g), besides recovered **1** (0.82 g).

*Photolysis of 3,6-O-Benzylidene-1,2,3-tri-O-acetyl-β-D-glucopyranose (**10**) with Benzophenone.* A 100 ml benzene solution containing **10** (0.05 M) and benzophenone (0.05 M) was deoxygenated with purified nitrogen current, and then irradiated at 15 °C under purified nitrogen atmosphere for 15 h. Separation of the photolyzed solution by column chromatography over silica gel gave **2** (0.43 g), **11** (0.93 g) and **14** (a trace), besides recovered **10** (0.30 g) and benzophenone (0.09 g). **11**: mp 235—236.5 °C; IR: 1750, 3520 cm^{-1}; NMR ($CDCl_3$): δ 1.99, 2.06 (2s, 9H, AcO), 3.05 (s, 1H, OH), 3.3—4.3 (m, 4H), 4.8—5.6 (m, 2H, H_2H_3), 5.72 (d, 1H, J=7.7 Hz, H_1), 6.7—7.9 (m, 15H, phenyl). Found: C, 66.57; H, 5.60%. Calcd for $C_{32}H_{32}O_{10}$: C, 66.66; H, 5.59%. Upon irradiation under bubbling air for 15 h, 100 ml of the same solution as that above gave **2** (0.10 g), **15** (0.43 g) and **16** (0.30 g), besides recovered **10** (0.45 g) and benzophenone (0.64 g). **15**: mp 152.5—153.5 °C; IR: 1708, 1740, 3550 cm^{-1}; NMR ($CDCl_3$): δ 1.90, 2.00, 1.10 (3s, 9H, AcO), 2.6 (broad s, 1H, OH), 3.4—4.0 (m, 3H, H_5H_6), 5.0—5.6 (m, 3H, $H_2H_3H_4$), 5.80 (d, 1H, J_{12}=7.5 Hz, 1H), 7.8—8.1, 7.8—8.2 (m, 5H, phenyl). Found: C, 55.82; H, 5.48%. Calcd for $C_{19}H_{22}O_{10}$: C, 55.61; H, 5.40%. **16** showed mp, IR and NMR spectra identical with those of an authentic sample of 6-*O*-benzoyl-1,2,3-tri-*O*-acetyl-β-D-glucopyranose which was prepared separately.

*Photolysis of 4,6-O-Benzylidene-1,2,3-tri-O-acetyl-β-D-glucopyranose (**10**) with Acetophenone.* A 100 ml benzene solution containing **10** (0.05 M) and acetophenone (0.05 M) was deoxygenated with purified nitrogen current for 1 h, and then irradiated at 15 °C under purified nitrogen atmosphere for 30 h. Separation of the photolyzed solution by column chromatography over silica gel gave **3** (0.16 g), **12** (0.68 g) and **14** (0,68 g), besides recovered **10** (0.39 g) and acetophenone (0.10 g). **12**: mp 209.5—210.5 °C; IR: 1740, 3510 cm^{-1}, NMR ($CDCl_3$): δ 1.72 (s, 3H, Me), 1.99, 2.09 (2s, 9H, AcO), 2.51 (s, 1H, OH), 3.4—3.8 (m, 3H, H_5H_6), 4.0—4.3 (m, 1H, H_4), 4.8—5.5 (m, 2H, H_2H_3), 5.71 (d, 1H, J_{12}=7.7 Hz, H_1), 7.0—7.4 (m, 10H). Found: C, 58.18; H, 5.68%. Calcd for $C_{38}H_{42}O_8$: C, 58.01; H, 5.38%.

*Photolysis of 4,6-O-Benzylidene-1,2,3-tri-O-acetyl-β-D-glucopyranose (**10**) with Acetone.* A 100 ml benzene solution containing **10** (0.05 M) and acetone (1.3 M) was deoxygenated with purified nitrogen for 1 h, and then irradiated at 16 °C under nitrogen atomosphere for 60 h. Separation of the photolyzed solution by column chromatography over silica gel gave **4** (a trace), **13** (0.28 g) and **14** (0.19 g), besides recovered **10** (0.91 g). **13**: mp 183—184.5 °C; IR: 1740, 3500 cm^{-1}; NMR ($CDCl_3$): δ 1.02 1.17 (2s, 6H, Me), 2.00—2.10 (2s, 9H, AcO), 2.00—2.15 (s, 1H, OH), 3.4—3.8 (m, 3H, H_5H_6), 4.0—4.3 (m, 1H, H_4), 4.7—5.3 (m, 2H, H_2H_3), 5.52 (d, 1H, J_{12}=7.7 Hz, H_1), 7.3—7.4 (m, 5H, phenyl). Found: C, 58.85; H, 6.44%. Calcd for $C_{22}H_{18}O_{10}$: C, 58.40; H, 6.24%. Upon irradiation under bubbling air, 100 ml of the same solution as that above gave **12** (a trace), **15** (0.53 g) and **16** (0.30 g), besides recovered **10** (0.72 g).

Quantum Yields. Quantum yields were estimated from the plot of relative disappearance ratio *vs.* the reciprocal concentration of **1**. Benzene solutions containing ketone and various concentrations of **1** in identical pyrex tubes were irradiated with a merry-go-round irradiation apparatus with a 400 W high pressure mercury lamp. Initial concentrations of **1** were 0.08, 0.10, 0.15, 0.20 and 0.25 M, while that of benzophenone or acetophenone was 0.1 M and acetone 1.3 M. Each solution was deoxygenated before irradiation. The irradiation time was 15 min for the **1**-benzophenone system, 40 min for the **1**-acetophenone system, and 7 h for the **1**-acetone system: the extent of reaction for each system was nearly 15%. The colorimetric method was used to determine the disappearance of benzophenone or acetophenone, while for the **1**-acetone system NMR signal intensity at δ=5.4 of **1** was measured to determine the disappearance of **1**.

A Study on the Photochemistry of α,β-Unsaturated γ-Lactones. III. Photodimerization of 2-Penten-4-olide[1]

Kazuya OHGA* and Taku MATSUO**

Departmnt of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

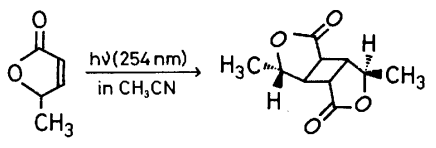
(Received September 23, 1975)

Irradiation of 2-pentene-4-olide (I) with 254 nm light afforded three anti dimers; two *head-to-tail* isomers and one *head-to-head* isomer. The photodimerization proceeds *via* the lowest triplet state. The quantum yields for the formation of the photodimers were determined as a function of the concentrations of I. Addition of I in the excited state to cyclopentene gave two isomeric cyclobutane derivatives. The photocycloaddition took place more rapidly than the photodimerization of I. The photodimerization was also quenched by anisole, probably through formation of an exciplex between I and anisole.

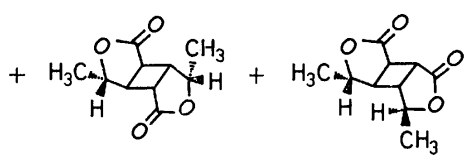
In a previous paper,[2] we reported an interesting photochemical behavior of α,β-unsaturated γ-lactones with a carbon-carbon double bond exocyclic to the lactone ring: the *cis-trans* isomerization proceeds *via* the lowest π,π* triplet, while the β,γ-isomer arises from the second n,π* triplet. On the other hand, no mechanistic detail of the photochemical behavior of an α,β-unsaturated γ-lactone with an endocyclic carbon-carbon double bond has been available partly due to experimental difficulties.[3] We have succeeded, for the first time, in obtaining the kinetic parameters by the use of 2-pentene-4-olide as a typical α,β-unsaturated γ-lactone with an endocyclic carbon-carbon double bond.

Results and Discussion

Structures of Photodimers. Irradiation of 2-penten-4-olide (I) in acetonitrile with 254 nm light afforded three products, Ia, Ib, and Ic (relative yields, 1 : 0.9 : 3). Each product was isolated by the use of both column chromatography on silica-gel and preparative VPC. The molecular weights, results of elementary analyses, characteristic IR bands, and the NMR spectroscopic data indicate that the isolated products are isomeric cycloadducts of I as in the case of 2-buten-4-olide[3] (Table 1).



I Ia



Ib Ic

Since no *trans*-fused photodimer with a five-four ring junction has been reported, the photodimers of I also are assumed to have a *cis*-fused structure. The proposed structures of the photodimers are supported by the NMR spectra. Each one doublet was observed for the methyl protons of Ia and Ic indicating that the two methyl groups in the respective dimer are at equivalent positions. Thus the signals due to the methine protons on the cyclobutane ring can be analyzed as a AA'BB'-system. The results of simulation are compared with the observed spectra (Fig. 1). The coupling constants obtained are summarized in Table 2.

In the case of cyclobutane ring protons, the *cis* vicinal coupling constants are generally larger than the *trans* couplings.[4] In the case of coumarine and carbostyryl photodimers, the long range coupling constants are positive in the *syn* configuration, while they are negative in the *anti* configuration.[4a] We thus conclude that Ia is an *anti*, *head-to-tail* dimer, while Ic is an *anti*, *head-to-head* dimer.

In the VPC (N_2, 55 ml/min) of the photodimers, the retention time of Ia (12.9 min) is shorter than that of Ic (18.1 min). This is in good agreement with the deduced structures, since it is suggested that a *head-to-tail* dimer has a shorter retention time than the corresponding *head-to-head* isomer due to the smaller dipole moment of the former.[5]

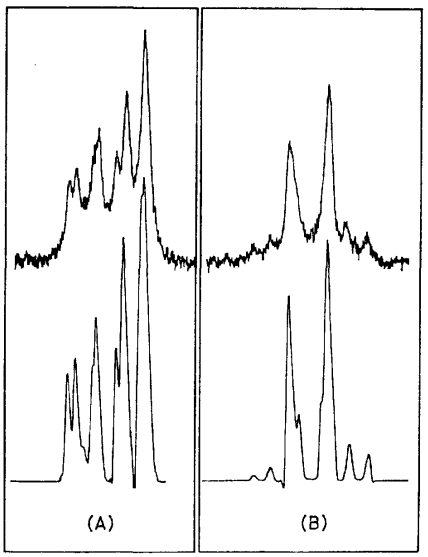


Fig. 1. NMR spectra of the cyclobutane protons: (A) Ia, (B) Ic. The simulated spectra are shown below the actually observed spectra.

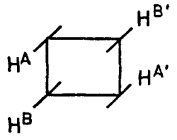
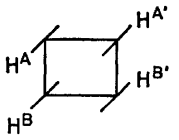
Table 2. NMR parameters estimated by simulation (Hz)

	Ia	Ic
$\Delta\delta\nu$	23.5	29.6
$J_{AA'}$	−0.9	1.9
$J_{BB'}$	−0.9	5.0
J_{AB}	7.4	6.8
$J_{AB'}$	3.4	−1.0



Ia

$J_{AB} > J_{AB'}$



Ic

$J_{AB} > J_{AA'}$, $J_{BB'}$

The solvent effects on the relative formation yields in acetone-photosensitized reactions are also in favor of the above assigned structures. On going from acetonitrile to benzene, Ic/Ia decreases rapidly (from 3.0 to 1.0) while Ib/Ia remains almost constant (0.93 and 1.1). Since Ib/Ia is little affected by the change in solvent polarity, it may be reasonable to assign an *anti, head-to-tail* structure to Ib and Ia. The shorter retention time in VPC for Ib (15.0 min) than Ic (18.1 min) is also in agreement with a less polar structure of the former. The assignment is further supported by the fact that the mass-spectrum of Ib is much closer to that of Ia than to that of Ic.

The configurations of the methyl groups were determined by means of NMR spectroscopy. The two methyl groups in either Ia or Ic are in equivalent positions. The vicinal coupling constants between the proton on the lactone ring and that on the cyclobutane ring are close to zero in both isomers (Table 1); 1.8 Hz for Ia and 0 Hz for Ic. It seems that the vicinal protons are roughly at right angle to each other. We see from the molecular model that such dihedral angles

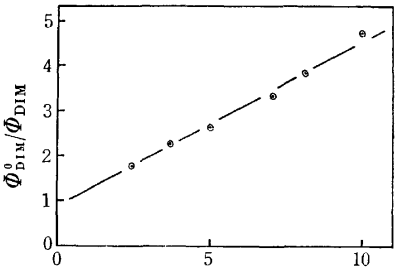


Fig. 2. Quenching of the photodimerization by 1,3-pentadiene.

can be obtained when the methyl groups are at the *exo* positions. If the methyl groups were at the *endo* positions, the dihedral angles should be nearly zero, and the vicinal coupling constants should be much larger. The methyl groups of Ib, on the other hand, are not equivalent as shown by the NMR spectra. Accordingly, Ib is concluded to be an *endo, exo*-isomer.

Reaction Scheme and Kinetic Parameters. The photodimerization of I can be sensitized by ketones (Table 3) with triplet energies higher than that of xanthone, and the reaction is quenched by 1,3-pentadiene. The relative yields of the photodimers in both the sensitizing and quenching experiments are the same as those in the case of the direct irradiation with 254 nm light. Moreover, the Stern-Volmer plot is linear, and the intercept is close to unity (Fig. 2). These results suggest that all of the three photodimers are formed through an identical excited triplet state.

On the basis of a series of sensitization experiments, the energy level of the excited triplet state is estimated to be about 70 kcal/mol in acetonitrile, since neither benzophenone nor fluorenone could sensitize the photodimerization any more as shown in Table 3. The energy level is close to that of the $T_1(\pi,\pi^*)$ state of 2-ethylidene-4-butanolide.[2]

The variations of the quantum yields for the formations of the dimers with the concentrations of I on

Table 4. Dimer quantum yields at various concentrations of I in acetonitrile

Concn M (10^{-1})	Quantum yield		
	Ia(10^{-2})	Ib(10^{-2})	Ic(10^{-2})
0.79	5.7	5.1	1.7
1.00	5.8	5.1	1.7
1.12	6.0	5.5	1.8
1.25	5.9	5.6	1.9
1.44	6.2	5.5	1.9
1.62	6.2	6.1	1.9
2.23	6.4	6.3	2.1
4.08	6.6	6.4	2.1
10.00	6.6	6.5	2.2

irradiation with 254 nm light in acetonitrile are shown in Table 4. The relative yields of the photodimers are independent of the concentrations of I in the concentration ranges investigated. It has been proposed by Wagner[6] and also by de-Mayo and his coworkers[7] that photodimers and/or photocycloadducts to olefins of α,β-unsaturated cyclic ketones are formed through metastable intermediates from the excited triplet states. The same mechanism may be used to explain the concentration dependence of the quantum yield for I:

$$I_0 \xrightarrow{h\nu} {}^1I^* \xrightarrow{\Phi_{ISC}} {}^3I^*$$

$${}^3I^* \xrightarrow{k_1} I_0$$

$${}^3I^* + I_0 \xrightarrow{k_r} {}^*I\text{-}I^*$$

$${}^*I\text{-}I^* \xrightarrow{k_e} \text{dimer}$$

$${}^*I\text{-}I^* \xrightarrow{k_{-r}} 2I_0$$

In this case, the relation between the quantum yield for the photodimerization, Φ_{DIM}, and the concentration of I, [I], may be given by the following equation:

$$\Phi_{DIM}^{-1} = \Phi_{ISC}^{-1}\Phi_P^{-1}(1+k_1/k_r[I])$$

where Φ_{ISC} and Φ_P denote the intersystem crossing yield for I and branching ratio for the decay to the final product from the metastable dimeric species, *I-I*. The rate constant for the unimolecular radiationless decay of the triplet I, $^3I^*$, and that for the addition of $^3I^*$ to I at the ground state are denoted by k_1 and k_r, respectively.

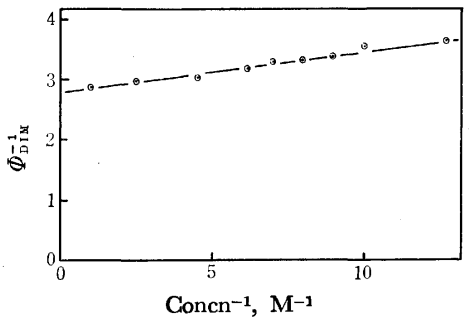

Fig. 3. Variations of the dimer quantum yield in acetonitrile as a function of the concentration of I.

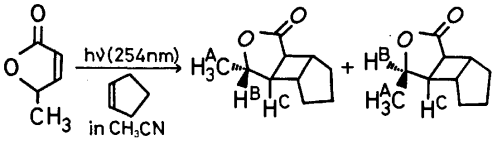
Table 5. Kinetic parameters for the photodimerization of I in acetonitrile

Compound	k_r, $M^{-1}s^{-1}$	k_1, s^{-1}	$\Phi_{ISC}\cdot\Phi_P$
I	2.2×10^3	5.5×10^3	0.36
Cyclopentenone	6.6×10^8	0.4×10^8	0.36

The experimental data were accordingly plotted (Fig. 3), and the kinetic parameters were evaluated (Table 5) on the assumption that a rate constant for quenching by 1,3-pentadiene is $1.0\times10^{10}\,M\,s^{-1}$ in acetonitrile.[6] While the values for k_r and $\Phi_{ISC}\cdot\Phi_P$ are almost the same between I and 2-cyclopentenone, the k_1-value for the former is only one-sevenths of that for the latter. It is surprising that replacement of methylene alpha to the carbonyl group with etherial oxygen atom caused a remarkable decrease in k_1. It is also interesting that the value for $\Phi_{ISC}\cdot\Phi_P$ is more than ten times as that for either thymine or uracil.[8] As a net result of these variations in the kinetic parameters, the photodimerization yield of I turned out to be one of the highest among the related compounds.

Photocycloaddition to Cyclopentene. On the irradiation of I in acetonitrile in the presence of excess cyclopentene with a 30 W low-pressure mercury lamp for 19 h, two isomeric 1 : 1 cycloadducts were obtained: Id(36%) and Ie(24%). In analogy to the case of 2-buten-4-olide,[9] the steric structures of the adducts were concluded to be *cis-anti-cis* form. Analysis of the NMR spectra indicates that the difference between the two isomers are due to the stereochemistry of the methyl group. On the basis of the vicinal coupling constants, Id(J_{BC}=1.8 Hz) and Ie(J_{BC}=6.3 Hz) were assigned to an *exo*- and *endo*-isomers, respectively.



I Id Ie

Acetonitrile solution of I(0.1 M) was irradiated at 254 nm in the presence of various amounts of cyclopentene. The relative yields between the photodimers, as well as the ratio of cycloadducts (Id/Ie), were independent of cyclopentene concentration. The photodimerization reaction itself was partly quenched by

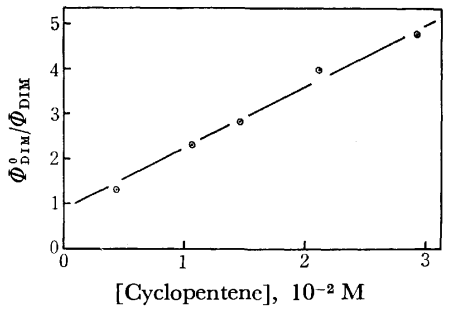


Fig. 4. Quenching of the photodimerization by cyclopentene in acetonitrile ([I])=0.1 M).

the addition of cyclopentene (Fig. 4). It is clear that both photodimerization and photocycloaddition proceed *via* the same excited species of I.

The rate constant (k_{ra}) for the reaction between ^{3}I* and cyclopentene is evaluated from the slope of the Stern-Volmer plot ($k_{ra}\tau=136$ M^{-1}) and the lifetime of ^{3}I* obtained in the analysis of the photodimerization (3.7×10^{-8} s at 0.1 M solution of I). The k_{ra}-value (3.7×10^9 s^{-1} M^{-1}), thus obtained, is more than ten times as large as k_r. The difference in the rate constants may be due to electrophilic property of ^{3}I*, which should favor more nucleophilic cyclopentene rather than I. In agreement with this suggestion, the photodimerization of I was quenched much more effectively by the use of 1,4-dioxene.

Interaction with Benzene Homologues. The above suggested electrophilic character of ^{3}I* was also varified by the investigation of interactions between ^{3}I* and benzene homologues. The photodimerization yields were measured in the presence of benzene, toluene, and anisole (Table 6). The amount of 254 nm light absorbed by the added benzene homologue was subtraced from the total intensity of light in evaluating the quantum yield. In other words, Φ_{DIM}/Φ^0_{DIM} should remain unity as far as the benzene homologues do not affect the reaction. In the case of benzene, however, the quantum yield increased, the photodimerization being apparently sensitized. A similar photosensitization would be expected to take place in the case of toluene and anisole. The experimental results indicate that the quantum yield was significantly reduced by anisole while it was hardly affected by toluene. It is clear that quenching and sensitization compete with each other in the presence of the benzene homologue. The highest quenching effect observed with anisole may be associated with the fact that the ionization potential of anisole is the lowest among the benzene homologues investigated. Quenching is quite likely to take place due to charge-transfer interactions between ^{3}I* and benzene homologues, which lead to the formation of exciplexes as an intermediate responsible for radiationless decay.

Table 6. Variations of the relative values, Φ_{DIM}/Φ^0_{DIM}, by the addition of benzene homologues

Compound	Concn 10^{-2} M	Light absorbed by I,[a] %	Φ_{DIM}/Φ^0_{DIM} Ia	Ib	Ic
Benzene	1.50	52.4	1.5	1.2	1.4
Toluene	1.47	52.2	0.98	0.93	0.95
Anisole	0.541	55.4	0.67	0.80	0.74

a) The fractions of 254 nm light absorbed by I.

Experimental

The NMR spectra were obtained on a Varian Model A-60 analytical spectrometer with tetramethylsilane as an internal standard. The IR and mass spectra were recorded on a JASCO Model DS-301 spectrometer and JEOL Model JMS-01SG mass spectrometer respectively. VPC analysis was carried out on a Shimadzu Model GC-3BF gas chromatograph equipped with a flame ionization detector, with the use of a column (2 m×3 mm) packed with 2% polyphenyl ether (six rings) on Diasolid L 60/80. The column temperature was 220 °C for the analysis of the dimers, 190 °C for that of the cyclopentene cycloadducts. The melting points were measured on a Yanagimoto micro melting-point measurement apparatus and are uncorrected.

Materials. The starting material, I, was prepared as described previously[10] and distilled under reduced pressure; bp 62.0 °C (3 mmHg). The distillate showed a single peak by VPC (10% polyphenyl ether (five rings) on Chamelite CS 60/80). *p*-Methylacetophenone (reagent grade) was purified by fractional distillation under reduced pressure just before use. Extra pure xanthone and fluorenone obtained from Tokyo Kasei Co. were used without further purification. Another ketone-sensitizers were purified as described previously.[2] 1,3-Pentadiene (76 : 24 *trans/cis* isomer ratio) was distilled at atmospheric pressure just before use, its purity being found to be 99.5% by VPC (20% benzyl cyanide and 12% silver nitrate on Chamelite CK 60/80). Cyclopentene was purified with ferric sulfate, followed by fractional distillation just before use. The distillate showed a single peak on inspection by VPC under the same conditions as those for 1,3-pentadiene.

Isolation of the Photodimers. The acetonitrile solution of I was irradiated with a 30 W low-pressure mercury lamp under the same conditions as those for the photodimerization of 2-buten-4-olide.[3] The three photodimers, Ia, Ib, and Ic were isolated from the reaction mixture by means of chromatography on silica gel with benzene–ethyl acetate (10 : 1) as an eluent, and successive preparative VPC with the use of a column packed with 1.5% polyphenyl ether (six rings) on Diasolid L. The photodimers were then recrystallized; mp : Ia, 194.0—195.0 °C (from benzene); Ib, 145.0—146.0 °C (from benzene–hexane); Ic, 222.5—224.0 °C (from ethyl acetate). MS(75 eV) : Ia, 196 (M^+, 19%), 181(M^+-CH_3, 38%), 108(M^+-2CO_2, 33%), 97(33%), 93($M^+-2CO_2-CH_3$, 88%), 80(74%), 79($M^+-2CO_2-2CH_3+H$, 100%); Ib, 196(12%), 181(15%), 108(44%), 97(24%), 93(94%), 80(63%), 79(100%); Ic, 196(3%), 181(5%), 108(9%), 97(12%), 93(100%), 80 (37%), 79(59%).

Quantum Yields for Photodimerization. Appropriate amounts of I were dissolved in acetonitrile of spectrograde purity ($0.79\times10^{-1}-10.00\times10^{-1}$ M). Eight ml of each acetonitrile solution was pipetted into the same sample tube[2] which was degassed by three freeze-pump-thaw cycles at less than 10^{-4} mmHg. The samples and the potassium ferrioxalate actinometer solution (6×10^{-3} M) were irradiated with light filtered through an aqueous solution containing $NiSO_4\cdot6H_2O$ (450 g/l), $CoSO_4\cdot7H_2O$ (150 g/l), and 5,7-dimetyl-1H-2,3-dihydro-1,4-diazepinium perchlorate (175 mg/l).[11] The irradiation apparatus used was described previously.[2] After irradiation at 20.0±0.1 °C for

1.5 h, the amount of each dimer was determined by VPC analysis with 4,4′-dimethoxydiphenylmethane as an internal standard. The yield of all dimers did not exceed 5%.

Photosensitized Dimerization of I. A solution of I and a sensitizer in acetonitrile was sealed after flushing with nitrogen and irradiated externally with a high-pressure mercury lamp (Riko-Sha UVL-700P) through Pyrex filter at near 21 °C for 3 h. The reaction was carried out in an ordinary glass sample tube except for the case of acetone sensitization where a Pyrex tube was used. Under such conditions, incident light is absorbed almost by the sensitizer alone. Dimer ratio was analyzed by means of VPC.

Quenching of the Photodimerization by 1,3-Pentadiene. The degassed samples containing I (1.00×10^{-1} M) and varying concentrations of 1,3-pentadiene in acetonitrile were irradiated with a merry-go-round apparatus. The relative quantum yields were determined with the same procedure as in the case of the determination of dimerization quantum yield except that an aqueous solution containing only 5,7-dimethyl-1*H*-2,3-dihydro-1,4-diazepinium perchlorate (177 mg/l) was used as a filter solution. By the use of the extinction coefficients measured at 254 nm on a Shimadzu Model UV-200 spectrophotometer, the amount of light absorbed by I was estimated after correcting the absorption due to 1,3-pentadiene.

Photocycloaddition of I to Cyclopentene. A 0.063 M solution of I in acetonitrile (160 ml) containing 0.56 M cyclopentene was irradiated with a 30 W low-pressure mercury lamp through quartz for 19 h under nitrogen gas. The VPC analysis of the irradiated sample, with oxanthrene as an internal standard, indicated that the cycloadduct, Id and Ie were formed in 36 and 24% yields, respectively. Preparative VPC was applied to isolate each cycloadduct. The cycloadduct Id was the sole adduct, but Ie was still contaminated by 3% Id after preparative VPC had been carried out twice. Id, Found: C, 71.99; H, 8.54%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%. IR(neat): 1776 (C=O), 1170 (C–O–C), 1450, 1471 cm^{-1} (cyclopentane ring). NMR($CDCl_3$): 1.27 (d, J_{AB}=6.3 Hz, 3H), 1.2—2.3 (m, 7H), 2.5—3.0(m, 3H), 4.66 (quartet-d, J_{AB}=6.3, J_{BC}=1.8 Hz, 1H). MS(75 eV): 166(M^+, 18%), 121 (M^+-CO_2-H, 27%), 99($C_5H_6O_2^+$+H, 75%), 68($C_5H_8^+$, 100%). Ie, Found: C, 71.95; H, 8.61%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%. IR(neat): 1770(C=O), 1175(C–O–C), 1450, 1469 cm^{-1} (cyclopentane ring). NMR($CDCl_3$): 1.43 (d, J_{AB}=6.3 Hz, 3H), 1.3—2.0(m, 6H), 2.1—3.0(m, 4H), 4.69(quintet, $J_{AB}=J_{BC}$=6.3 Hz, 1H). Study of the Synthesis of Histidine Peptides. II. Use of N^{im}-Tosylhistidine Derivatives in Conventional Solution Synthesis of Peptides[1,2]

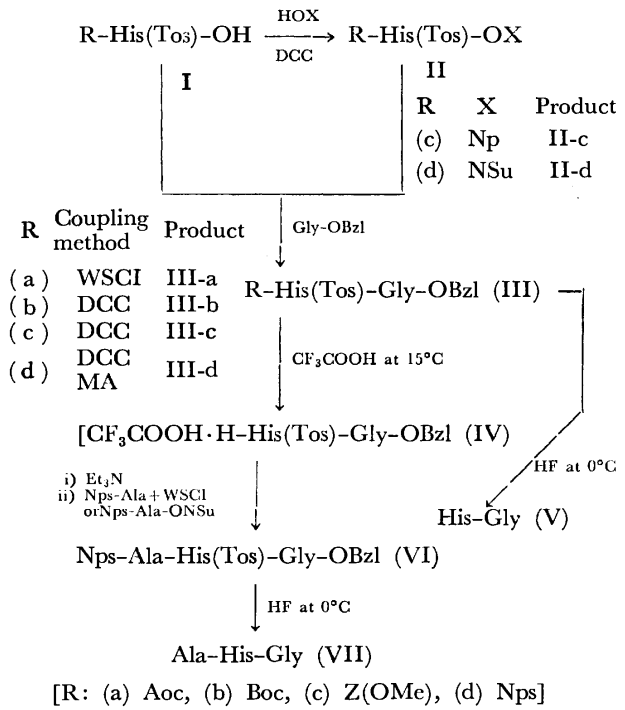
Toshiyuki FUJII,* Terutoshi KIMURA, and Shumpei SAKAKIBARA**

Peptide Institute, Protein Research Foundation, 476 Ina, Minoh, Osaka 562

(Received September 29, 1975)

His–Gly and Ala–His–Gly were synthesized by the conventional solution methods using various N^{α}-protected-N^{im}-tosyl-L-histidines as the key intermediates, and handling conditions of these His(Tos)-derivatives were examined. During treatment of an Nps-peptide with HF, the formation of a strongly photosensitive by-product was observed when anisole alone was used as the scavenger, however the side reaction was completely suppressed when skatole was added to the reaction mixture. In order to evaluate the usefulness of these His(Tos)-derivatives in general peptide synthesis, TRH and LH–RH were synthesized, and both products were obtained in pure form without any difficulty. Thus, it can be emphasized that the use of these His(Tos)-derivatives is efficient and convenient for introducing His-residues into peptides even in solution procedures.

Previously, the present authors published the basic ideas on the use of the tosyl group for the protection of histidyl residues in peptide synthesis,[1] and the usefulness of Aoc–His(Tos) was demonstrated in the solid-phase synthesis of IIe^5-Angiotensin II.[3] Since then, this procedure has been tested by many other researchers, and it is widely recognized that the procedure is the most promising one for the incorporation of histidyl residues into peptides by the solid-phase method.[4] In a preceding paper,[5] detailed conditions for the synthesis of various N^{α}-protected His(Tos)-derivatives were presented, and the behavior of the tosyl group was examined under ordinary conditions which are generally used for peptide synthesis. The present study is the evaluation of the N^{im}-protection method in conventional peptide synthesis.



Scheme 1. Peptide Synthesis.

First, the coupling conditions of various N^{α}-protected His(Tos)-derivatives with glycine benzyl ester were examined applying different coupling methods (Scheme 1). From these experiments, it was confirmed that the mixed anhydride method, the dicyclohexylcarbodiimide (DCC) method, and the active ester method gave reasonable results, but the application of the azide method was impractical because of the instability of the tosyl group during the conversion of the hydrazide to the azide followed by the coupling reactions with amine components.

In the case of applying DCC as the coupling reagent, methylene chloride gave the most promising results as the reaction solvent. When tetrahydrofuran (THF), *N,N*-dimethylformamide (DMF), or acetonitrile was used as the reaction solvent under ordinary conditions, the formation of acyl urea was not negligible; particularly the use of an excess amount of base is known to enhance acyl urea formation.

There was no problem in synthesizing the active esters of N^{α}-protected N^{im}-tosylhistidines such as *p*-nitrophenyl ester and *N*-hydroxysuccinimide ester, as far as the DCC method was applied. However, an attempt to synthesize Aoc–His(Tos)–ONSu by the trifluoroacetate method[6] was unsuccessful; in the reaction, the *N*-hydroxysuccinimide ester of *p*-toluenesulfonic acid was formed as the major product.

Aoc– or Z(OMe)–His(Tos)–Gly–OBzl which was obtained by the above-mentioned procedures was treated with trifluoroacetic acid to remove the N^{α}-protecting group, and the product was further coupled with Nps–Ala using 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (WSCI)[7] as the reagent or with Nps–Ala–ONSu. Both procedures gave the same product, Nps–Ala–His(Tos)–Gly–OBzl, in reasonable yields.

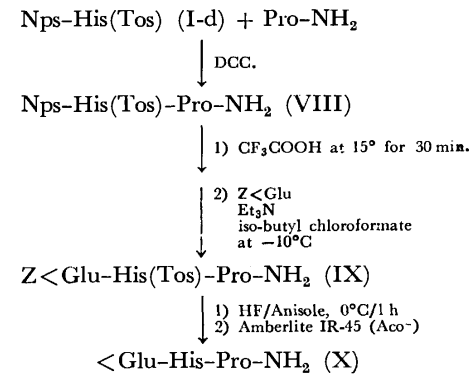
The removal of the protective groups from His(Tos)-containing peptides was tested under several different conditions, and the most promising results were obtained using the HF-method.[8] As had been expected, a single treatment of Z(OMe)–His(Tos)–Gly–OBzl with HF in the presence of anisole gave His–Gly without any problem. However, a peculiar phenomenon was observed when Nps–His(Tos)–Gly–OBzl or Nps–Ala–His(Tos)–Gly–OBzl was treated with HF using anisole as the scavenger: during processing of the reaction mixture, the formation of a yellow-colored material was observed, which was water-soluble and extremely

* Present address: Tanabe Seiyaku Co., Ltd., Yodogawa-ku, Osaka.

** To whom requests for reprints should be addressed.

photosensitive. This side product had a solubility similar to free peptide, quickly turned to brownish violet, and finally became black within two or three hours during the purification process of the peptide. Removal of the colored material from the principal product was not impossible, but the purification procedures reduced the yield of the final product considerably. The primarily-formed photo-sensitive material should be an Nps–anisole adduct, and it may have further changed to a complex compound through intermediates such as nitrosophenyl sulfoxide in an ordinary lighted room. The addition of excess skatole together with anisole in the HF-reaction mixture completely suppressed the formation of the black; a yellow compound was also formed in the reaction, but this colored material was soluble in chloroform and not so sensitive to visible light. This material was isolated from the reaction mixture as crystals, and the structure was confirmed to be 2-Nps-skatole. Recovery of His–Gly from Nps–His(Tos)–Gly–OBzl using the HF-reaction using skatole as the scavenger was about 80% efficient. The efficiency of the HF-Skatole procedure was also confirmed by obtaining Ala–His–Gly from Nps–Ala–His(Tos)–Gly–OBzl in a 64% yield after final purification.

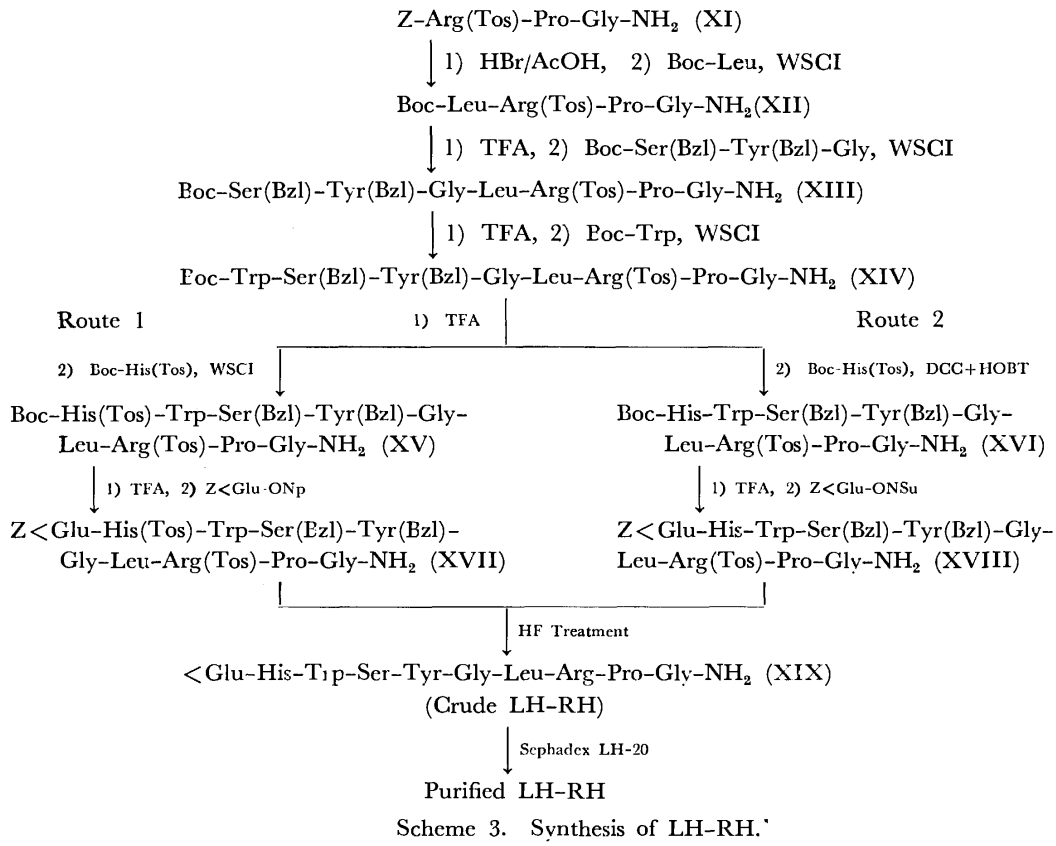
As shown above, the introduction of a tosyl group into the histidyl residue is advantageous not only in reducing the formation of side products during the coupling reactions, but also in enhancing the solubility of the histidine derivatives in organic solvents. On the other hand, the tosyl group is known to be susceptible to HOBT, HBr, HCl, NaOH, NH_3 and even to the amine-components to be coupled.[5] Therefore, partial



Scheme 2. Synthesis of Thyrotropin-releasing Hormone

cleavage of the tosyl groups is frequently observed during coupling reactions. Thus, in such cases, it may be favorable to remove all of the tosyl groups after the incorporation of the His-residues into peptides, because the major purpose of the protection of the histidyl residue will have been fulfilled after it has been incorporated into a peptide without forming considerable side products. These techniques were applied to the synthesis of biologically-active peptides, thyrotropin-releasing hormones (TRH)[9] and luteinizing-hormone releasing hormones (LH-RH),[10] in order to determine its efficiency.

The synthesis of TRH was carried out as shown in Scheme 2. Nps–His(Tos)[5] was coupled with proline amide[11] in a mixture of acetonitrile and DMF using DCC as the reagent. The Nps-dipeptide amide thus obtained was then treated with trifluoroacetic acid to remove the Nps-group, and the N^{α}-deprotected



Scheme 3. Synthesis of LH-RH.

dipeptide amide was coupled with Z<Glu using the mixed anhydride method. Since the N^{im}-tosyl group had been kept stable throughout the synthesis, the final protected tripeptide could be purified simply by means of silica-gel column chromatography. The purified, fully-protected tripeptide was treated with HF in the presence of anisole, the excess HF was removed under reduced pressure, and the residue was treated with a short column of Amberlite IR-45 (AcO^- form) to remove the remaining HF. Then, the final product was obtained by lyophilization as an amorphous powder which proved to be homogeneous without the application of any additional purification procedures.

The synthesis of LH-RH was carried out *via* two different routes as shown in Scheme 3. In route 1, Boc–His(Tos)[5] was coupled with Trp–Ser(Bzl)–Tyr-(Bzl)–Gly–Leu–Arg(Tos)–Pro–Gly–NH_2 using WSCI[7] alone as the coupling reagent. The reaction proceeded smoothly, and Boc–His(Tos)–Trp–Ser(Bzl)–Tyr(Bzl)–Gly–Leu–Arg(Tos)–Pro–Gly–NH_2 was obtained as the major product, but partially formed de-tosylated material had to be removed to obtain a single product. Then, the Boc-group was removed by treatment with trifluoroacetic acid, and Z< Glu–ONp was coupled to obtain fully-protected LH-RH. In route 2, the same reaction was carried out in the presence of HOBT analogously to the Geiger procedure.[12] In this case, the tosyl group was completely removed during the coupling reaction,[5] and detosylated nonapeptide was obtained in a high yield. Since no problem was observed in the final coupling reaction with Z<Glu–ONSu,[13] route 2 was considered to be more practical for large-scale synthesis of LH-RH. The final protected decapeptide amide was treated with HF, in the presence of anisole together with tryptophan, followed by purification on Sephadex LH-20, and highly-purified LH-RH was obtained in good yield. The chromatogram of the HF-reaction product indicated the formation of a side product (Fraction II in Fig. 1.). Amino acid analysis of an acid hydrolyzate of the side product indicated a remarkable decrement in the recovery of Tyr. Thus, this material was considered to be modified LH-RH at the Tyr-residue, which should form during the HF-treatment.

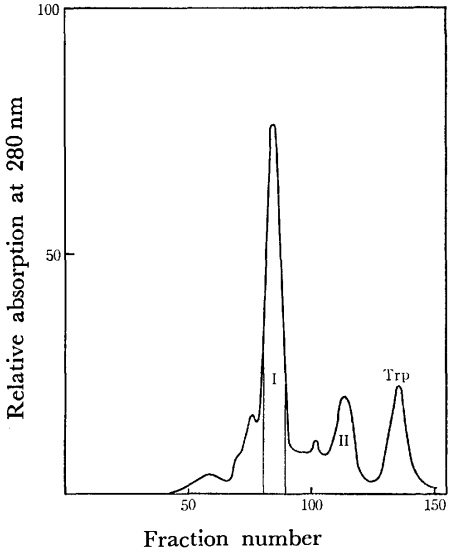


Fig. 1. Purification of crude LH-RH on Sephadex LH-20 column. Column size: 2.8×130 cm (Resin volume, 800 ml). Sample, 0.6 g; Eluent, 1% AcOH; Fraction volume, 6.3 ml; Flow rate, 75 ml/h.

As demonstrated above, the present method for the protection of histidyl residues by the tosyl group has proved to be useful not only in solid-phase synthesis, but also in conventional solution procedures.

Experimental

Melting points were measured by the capillary method and are uncorrected. Paper chromatography was carried out on Toyo filter paper No. 51, and thin layer chromatography on cellulose powder using the following solvent systems: R_f^1; 1-butanol : acetic acid : water (4 : 1 : 1), R_f^2; chloroform : methanol : 30% acetic acid (3 : 2 : 1), R_f^3; 1-butanol : acetic acid : water (4 : 1 : 5, upper phase). All materials obtained were dried over P_2O_5 *in vacuo* for 24 h at room temperature before being applied to the analysis. The IR spectra were recorded on a Shimadzu IR-27G spectrometer, and the UV spectra on a Hitachi EPS-2U spectrometer. The NMR spectra were recorded at 60 MHz with tetramethylsilane as the internal standard using a Hitachi R-20A spectrometer. The HF reactions were carried out using a PRF HF-Reaction Apparatus Type I.

Z(OMe)-His(Tos)–ONp (II-c). DCC (4.4 g, 21 mmol) was stirred into a solution of I-c[5] (9.5 g, 21 mmol) and *p*-nitrophenol (2.8 g, 21 mmol) in THF (100 ml) at −5 °C. The stirring was continued for 1 h at −5—0 °C and for additional 2 h at room temperature. After adding a few drops of glacial acetic acid at 0 °C, the mixture was stirred for 30 min, and then *N,N'*-dicyclohexylurea was removed by filtration; the parent solution was concentrated to a residue under reduced pressure. The residual oil was dissolved in ethyl acetate, the solution was washed successively with 5% aqueous sodium hydrogencarbonate and a saturated sodium chloride solution, and dried over magnesium sulfate. The dried solution was concentrated under reduced pressure, and the residue was recrystallized from methanol to obtain needles; wt. 10.0 g (84.7%), mp 93—5 °C, $[\alpha]_D^{23}$+ 41° (*c* 1, THF). Found: C, 56.43; H, 4.49; N, 9.48; S, 5.40%. Calcd for $C_{28}H_{26}O_9N_4S$: C, 56.56; H, 4.40; N, 9.42; S, 5.38%.

Nps–His(Tos)–ONSu (II-d). DCC (700 mg, 3.4 mmol) was stirred into a solution of I-d[5] (1.4 g, 3 mmol) and *N*-hydroxysuccinimide (350 mg, 3 mmol) in a mixture of ethyl acetate (50 ml) and THF (50 ml) at −5 °C. The stirring was continued for 1 h at −5—0 °C and for additional 2 h at room temperature, and then a few drops of glacial acetic acid were added to the reaction mixture at 0 °C. After 30 min, *N,N'*-dicyclohexylurea was removed by filtration, and the filtrate was concentrated under reduced pressure. The residue was dissolved in a small amount of ethyl acetate, the solution was charged at the top of a column (0.9×75 cm) of silica gel which had been equilibrated with a mixture of benzene and ethyl acetate (5 : 3). The column was developed using the same solvent mixture and fractions containing the second yellow band were collected and evaporated. The residue was treated with hexane producing amorphous solid; wt 1.5 g (89%).

Reaction of I-a with N-(Trifluoroacetoxy)succinimide (Formation of N-Tosyloxy-succinimide). *N*-(Trifluoroacetoxy)succinimide[6] (1.2 g, 5 mmol) was stirred into a solution of compound I-a[5] (2.1 g, 5 mmol) in dry pyridine (5 ml), and

the mixture was allowed to react overnight at room temperature. Then, the reaction mixture was poured into ice-water which precipitated colorless plates which were collected by filtration, washed with ice-water and dried. Then, the dried crystals were recrystallized from ethyl acetate; wt. 0.85 g (60.5%), mp 142.5—145 °C. IR (in Nujol) 1745 (C=O), 1595 (p-CH_3-C_6H_4), 1390, 1180 (SO_2-O-) cm^{-1}. NMR ($CDCl_3$, δ) 2.0—2.2 (d, 2H), 2.55—2.75 (d, 2H), 7.2 (s, 4H), 7.5 (s, 3H). Found: C, 49.10; H, 4.00; N, 5.29%. Calcd for $C_{11}H_{11}O_5NS$: C, 49.07; H, 4.12; N, 5.20%. An authentic sample was synthesized as follows: A solution of tosic anhydride[14] (3.2 g, 10 mmol) and *N*-hydroxysuccinimide (2.3 g, 20 mmol) in dry THF (30 ml) was refluxed for 5 h. Then, the solvent was evaporated out under reduced pressure, the residue was dissolved in ethyl acetate, the solution was washed well with water, and dried over anhydrous sodium sulfate. Concentration of the dried solution gave colorless plates; wt. 1.3 g (24%) mp 142—144 °C. This material showed the same IR and NMR spectra as the above obtained material.

Aoc-His(Tos)-Gly-OBzl (III-a). WSCI (190 mg, 1.2 mmol) was stirred into a solution of I-a (423 mg, 1 mmol) and Gly-OBzl·Tos-OH[15] (400 mg, 1.2 mmol) in THF (13 ml) at −5 °C; the mixture was allowed to react for 1 h at −5—0 °C and then for additional 15 h at room temperature. The solvent was exchanged with ethyl acetate, the solution was washed with 0.5 M sulfuric acid, 5% aqueous sodium hydrogencarbonate and water, and dried over anhydrous magnesium sulfate. Evaporation of the solvent under reduced pressure gave an oil; wt. 540 mg.

Boc-His(Tos)-Gly-OBzl (III-b). DCC (2.1 g, 10 mmol) was stirred into a mixture of compound I-b***,[5] (4.1 g, 10 mmol), Gly-OBzl·Tos-OH[15] (4.0 g, 12 mmol) and triethylamine (1.7 ml), in methylene chloride (40 ml) at −5—0 °C; the stirring was continued for 1 h at the same temperature and then for additional 15 h at room temperature. The *N,N'*-dicyclohexylurea formed was removed by filtration, and washed well with chloroform (100 ml); the solution and the washing were combined, washed successively with 0.5 M sulfuric acid, 5% aqueous sodium hydrogencarbonate and water, and dried over anhydrous magnesium sulfate. The dried solution was concentrated to dryness under reduced pressure, and the residue was washed with a mixture of ether and hexane, and dried. Recrystallization from ethyl acetate-hexane gave colorless needles; wt. 4.4 g (77.7%), mp 51—54 °C, $[\alpha]_D^{22}$ −1.1° (*c* 2, DMF); Found: C, 58.39; H, 6.27; N, 9.60%. Calcd for $C_{27}H_{32}O_7N_4S$: C, 58.26; H, 5.80; N, 10.07%.

Z(OMe)-His(Tos)-Gly-OBzl (III-c). *The DCC Method*: Compound I-c[5] (1.4 g, 3 mmol) and Gly-OBzl·Tos-OH[15] (1.2 g, 3.6 mmol) were coupled in chloroform (30 ml) at −5—0 °C in the presence of triethylamine (0.5 ml) using DCC (680 mg, 3.6 mmol) as described above. The reaction mixture was treated in the same manner, and the final product was recrystallized from methanol-ethyl acetate producing needles; wt. 1.5 g (80%), mp 166—167 °C, $[\alpha]_D^{22}$ +4.6° (*c* 2, DMF); Found: C, 60.13; H, 5.08; N, 9.12%. Calcd for $C_{31}H_{32}O_8N_2S$: C, 59.99; H, 5.20; N, 9.12%.

The Active Ester Method: A mixture of II-c (1.2 g, 2.1 mmol), Gly-OBzl·Tos-OH[15] (1.0 g, 3 mmol) and triethylamine (0.42 ml) in DMF (10 ml) was allowed to react for 15 h at room temperature. Then, it was diluted with chloroform (50 ml), and the solution was washed and treated as in the case of the synthesis of III-b; wt. 950 mg (76.6%), mp 166—167 °C, $[\alpha]_D^{22}$ +4.3° (*c* 1, DMF). The melting point of this compound showed no depression upon mixing with the product synthesized by the DCC method.

Nps-His(Tos)-Gly-OBzl (III-d). *The Mixed Anhydride Method*: A solution of isobutyl chloroformate (137 mg, 1 mmol) in toluene (1 ml) was stirred for 10 min into a mixture of compound I-d[5] (462 mg, 1 mmol) and triethylamine (0.14 ml) in chloroform (2 ml) and toluene (1 ml) at −10 °C. After stirring for additional 10 min, the solution was mixed slowly with a mixture of Gly-OBzl·Tos-OH[15] (350 mg, 1.05 mmol) and triethylamine (0.15 ml) in chloroform (2 ml) at −10—−5 °C. The stirring was continued for 2 h at room temperature; the reaction mixture was treated similarly to the case of the synthesis of III-b. Recrystallization of the final product from ethyl acetate gave yellow needles; wt. 470 mg (77.2%), mp 162—163 °C, $[\alpha]_D^{18}$ +56.7° (*c* 1, DMF). Found: C, 55.16; H, 4.19; N, 11.24; S, 10.44%. Calcd for $C_{28}H_{27}O_7N_7S_2$: C, 55.16; H, 4.46; N, 11.48; S, 10.51%.

The DCC Method: Compound I-d[5] (925 mg, 2 mmol) was subjected to a DCC reaction with Gly-OBzl·Tos-OH[15] (700 mg, 2.1 mmol) in methylene chloride as described above for the synthesis of III-b, and the same compound was obtained; wt. 850 mg (69.9%), mp 164—165 °C, $[\alpha]_D^{18}$ +57.5° (*c* 1, DMF). The melting point of this compound showed no depression upon mixing with the compound obtained by the MA method.

The Active Ester Method: Compound II-d (1.2 g, 2.1 mmol) was coupled with Gly-OBzl·Tos-OH (700 mg, 2.1 mmol) in DMF as in the case of the synthesis of II-c; wt. 910 mg (74.5%), mp 164—165 °C, $[\alpha]_D^{18}$ +57.7° (*c* 1, DMF). The melting point of this compound showed no depression upon mixing with the compound synthesized by the MA method.

Nps-Ala-His(Tos)-Gly-OBzl (VI). *The WSCI Method*: Compound III-a (450 mg, 0.8 mmol) was dissolved in trifluoroacetic acid (1 ml) at 15 °C. After 30 min, excess trifluoroacetic acid was evaporated out under reduced pressure, the residue was treated with dry ether (50 ml) to obtain an amorphous solid. After drying over sodium hydroxide *in vacuo*, this material was dissolved in methylene chloride (10 ml) together with Nps-Ala (160 mg, 1.1 mmol), and WSCI (100 mg, 0.7 mmol) was stirred into the solution at −5—0 °C for 30 min. The stirring was continued overnight at room temperature, then the solvent was removed by evaporation under reduced pressure, and the residue was dissolved in ethyl acetate. The solution was washed successively with 0.5 M sulfuric acid, aqueous 5% sodium hydrogencarbonate and water, and dried over anhydrous magnesium sulfate. The dried solution was concentrated under reduced pressure, the residue was triturated with hexane, and then recrystallized from ethyl acetate and hexane to obtain yellow needles; wt. 338 mg (62%), mp 88—89 °C, $[\alpha]_D^{17}$ −30.0° (*c* 1, AcOEt). Found: C, 54.34; H, 4.53; N, 12.35; S, 9.43%. Calcd for $C_{31}H_{32}O_8N_6S_2$: C, 54.69; H, 4.73; N, 12.34; S, 9.42%.

The Active Ester Method: Compound III-c (609 mg, 1 mmol) was treated with trifluoroacetic acid (1.2 ml) in the presence of anisole (0.4 ml) at 15 °C for 30 min. Excess trifluoroacetic acid was evaporated out under reduced pressure, the residue was treated with dry ether (50 ml) resulting in its solidification, and the solid (IV) was further washed with dry ether. The solid was dissolved in DMF (2 ml) together with Nps-Ala-ONSu (680 mg, 2 mmol)[16] and *N,N*-diethylglycine ethyl ester[17] (1 g), and the mixture was allowed to react overnight at room temperature. The reaction mixture was treated as described above, and the final product was recrystallized from ethyl acetate and hexane;

*** The melting point presented in the Table 1 in Ref. 5 should read 123—125 °C.

wt. 538 mg (79%), mp 87—88 °C, $[\alpha]_D^{18}$ −30.5° (*c* 1, AcOEt). The melting point of this compound showed no depression upon mixing with the compound synthesized by the WSCI method.

His–Gly (V). *A) The HF Treatment of III-c with Anisole*: Compound III-c (1.24 g, 2 mmol) was mixed well in an HF reaction vessel together with anisole (2.8 ml), and anhydrous HF (5 ml) was added to the vessel at −70 °C using an HF-reaction apparatus. The mixture was allowed to react at 0 °C for 1 h, and then excess HF was removed under reduced pressure. After remaining under vacuum for 3 more hours at 0 °C, the residue was extracted with water (10 ml), and the extract was washed well with ether (10 ml). The aqueous layer was treated with a small amount of active charcoal, and then the solution was passed through a column of Amberlite IR-45 (OH^- form) (10 ml), which was washed with water and with aqueous 5% acetic acid. The eluate and washing were combined and lyophilized, and the residue was crystallized from aqueous ethanol to obtain colorless needles; wt. 355 mg (84%), mp 190 °C (decomp.), $[\alpha]_D^{17}$ +24.7° (*c* 1, water). Reported:[18] mp 190 °C (decomp.), $[\alpha]_D$ +25±1° (*c* 2, water). The material showed a single spot of both ninhydrin and Pauly positive on paper chromatography (R_f^1 0.115), and on paper electrophoresis using a pyridine-acetate buffer (pH 4.8) as the solvent. Found: C, 43.61; H, 5.76; N, 25.4%. Calcd for $C_8H_{12}O_3N_4 \cdot {}^1/_2H_2O$: C, 43.43; H, 5.92; N, 25.32%.

B) The HF Treatment of III-d with Anisole: Compound III-d (1.22 g, 2 mmol) was treated in the same manner as described above except that the charcoal treatment was repeated until colorless material was obtained. Yield; 250 mg (56.6%), mp 190 °C (decomp.), $[\alpha]_D^{17}$ +24.5° (*c* 1, water), R_f^1 0.115.

C) The HF Treatment of III-d with Skatole: Compound III-d (1.22 g, 2 mmol) was treated with anhydrous HF (5 ml) in the presence of anisole (2 ml) together with skatole (600 mg, 4 mmol), as in the case of the synthesis of V, at 0 °C for 1 h. After removal of the excess HF under reduced pressure, the residue was dissolved in a mixture of water and chloroform. The aqueous phase was washed with ether, and then passed through a column of Amberlite IR-45 (OH^- form) (10 ml). The column was eluted with water and then washed with aqueous 5% acetic acid; the eluate and washing were combined and lyophilized. The residue was washed with methanol, and recrystallized from aqueous ethanol to obtain colorless needles; wt. 340 mg (80.5%), mp 189 °C (decomp.), $[\alpha]_D^{17}$ +24.3° (*c* 1, water), R_f^1 0.115.

Separation of the Side Product, 2-Nps-skatole: The chloroform layer, which was separated from the water-chloroform extract of the HF-reaction mixture, was washed with water and dried over anhydrous magnesium sulfate. The dried solution was concentrated to dryness, the residue was dissolved in a small amount of ethyl acetate, and the solution was charged at the top of a silica gel column (0.7×70 cm) which had been equilibrated with a solvent system of ethyl acetate and benzene (1 : 1). The column was developed with the same solvent mixture, the fractions containing the main peak were collected and evaporated. The residue was recrystallized from aqueous methanol; wt. 380 mg (67%), mp 139—141 °C, UV λ_{max}^{EtOH} 224 nm (ε 55200), 283 (ε 21400), 261 nm (ε 5600): NMR ($CDCl_3$, δ) 2.20—2.60 (s, 3H), 6.57—6.82 (m, 1H), 7.00—7.50 (m, 5H), 7.53—7.75 (m, 1H), 7.95—8.32 (m, 2H). Found: C, 63.60; H, 4.16; N, 9.60; S, 10.94%. Calcd for $C_{15}H_{12}O_2N_2S$: C, 63.38; H, 4.26; N, 9.89; S, 11.25%.

Ala–His–Gly (VII). Compound VI (1.36 g, 2 mmol) was mixed well with anisole (2 ml) and skatole (600 mg, 4 mmol) in an HF reaction vessel, and the mixture was treated with HF (7 ml) as above at 0 °C for 1 h. After removal of the excess HF, the residue was treated in the same manner as in the case of the synthesis of V (Procedure C). Compound VII thus obtained was recrystallized from aqueous ethanol producing colorless needles; wt. 360 mg (63.4%), mp 230 °C (decomp.), $[\alpha]_D^{18}$ +36.3° (*c* 1, AcOH). The homogeneity of this material was confirmed by ninhydrin and Pauly reagent on paper electrophoresis and paper chromatography; R_f^1 0.23. Amino acid ratios in an acid hydrolyzate: Ala 1.00, His 1.00, Gly 1.00. Ratio in an APM digest: Ala 1.00, His 1.00, Gly 0.98. Found: C, 46.87; H, 6.00; N, 24.70%. Calcd for $C_{11}H_{17}O_5N_4$: C, 46.63; H, 6.05; N, 24.72%.

Nps–His(Tos)–Pro–NH_2 (VIII). DCC (1.1 g, 5.3 mmol) was stirred into a solution of I-d[5] (2.3 g, 5 mmol) and Pro–NH_2[10] (0.57 g, 5 mmol) in a mixture of acetonitrile (50 ml) and DMF (20 ml) at −5 °C. Stirring was continued for 1 h at −5—0 °C and for additional 15 h at room temperature. The *N,N'*-dicyclohexylurea formed was removed by filtration, the filtrate was evaporated under reduced pressure, and the residue was redissolved in ethyl acetate. The ethyl acetate solution was washed successively with 0.5 M sulfuric acid, aqueous 5% sodium hydrogencarbonate, and water, and dried over anhydrous magnesium sulfate. The dried solution was concentrated to dryness, and the residue was washed with a mixture of methanol and ether, and dried. Recrystallization of the dried residue from ethyl acetate gave yellow needles; wt. 2.0 g (72%), mp 188 °C, $[\alpha]_D^{20}$ +15.1° (*c* 0.5, DMF). Found: C, 51.78; H, 4.62; N, 14.85; S, 11.07%. Calcd for $C_{24}H_{26}O_6N_6S_2$: C, 51.59; H, 4.69; N, 15.04; S, 11.47%.

Z<Glu–His(Tos)–Prc–NH_2 (IX). Compound VIII (0.79 g, 1.5 mmol) was dissolved in a mixture of trifluoroacetic acid (1.5 ml) and methylene chloride (1.5 ml) together with anisole (2 ml) at 15 °C. After 30 min, the methylene chloride and excess trifluoroacetic acid were removed by evaporation under reduced pressure, and the residue was treated with dry ether (50 ml) to give an amorphous powder. To a solution of Z<Glu (0.4 g, 1.5 mmol) and triethylamine (0.21 ml) in THF (4 ml), a solution of isobutyl chloroformate (0.21 g, 1.5 mmol) in toluene (2 ml) was added drop by drop at −10 °C for 10 min. After additional 10 min, the reaction mixture was stirred at once into an aqueous 5% sodium hydrogencarbonate solution of the powder obtained above at −5—0 °C; the pH of the solution was confirmed to be 7. After stirring for 1 h at room temperature, the solution was evaporated under reduced pressure, and the residue was extracted with chloroform (20 ml). The chloroform extract was washed successively with 0.5 M sulfuric acid, aqueous 5% sodium hydrogencarbonate, and dried over anhydrous magnesium sulfate. The solvent was evaporated to dryness, and the residue (0.63 g) was charged at the top of a column of silica gel (0.8×50 cm) which had been equilibrated with a solvent system of chloroform, ethyl acetate and ethanol (5 : 4 : 2). The column was developed with the same solvent mixture, and fractions containing the main band were combined and evaporated to dryness. The residue was washed well with dry ether to obtain an amorphous powder; wt. 450 mg (52.3%), mp 113—116 °C (decomp.), $[\alpha]_D^{15}$ −29.1° (*c* 1, DMF). Found: C, 57.09; H, 5.17; N, 12.86%. Calcd for $C_{31}H_{34}O_8N_6S$: C, 57.22; H, 5.27; N, 12.92%.

<Glu–His–Pro–NH_2 (X) (TRH). Compound IX (65 mg, 0.1 mmol) was treated with anhydrous HF (1 ml) in the presence of anisole (0.15 ml) at 0 °C for 1 h, as in the case of the synthesis of V, and then the excess HF was removed

under reduced pressure. After being kept under vacuum for 4 h at 0 °C, the residue was dissolved in water, the solution was washed with ether, and the aqueous layer was passed through a column (0.5×10 cm) of Amberlite IR-45 (AcO^- form). The column was eluted with water and washed with aqueous 5% acetic acid. The eluate and washing were combined and lyophilized to obtain a residual powder; wt. 37.6 mg (96.5%), $[\alpha]_D^{25}$ −44.8° (*c* 1, 95% AcOH). Reported:[19] $[\alpha]_D^{15}$ −45.1° (*c* 1, AcOH). The homogeneity of this material was confirmed by paper electrophoresis using a 0.1 M pyridine-acetic acid buffer (pH 4.7) and by paper chromatography, which were located using the Pauly reagent; R_f[2] 0.55. The amino acid ratio in an acid hydrolyzate: Glu 1.00, His 1.06, Pro 0.94. Found: C, 49.40; H, 6.34; N, 21.54%. Calcd for $C_{16}H_{22}O_4N_6 \cdot {}^3/_2H_2O$: C, 49.34; H, 6.47; N, 21.58%.

Z–Arg(Tos)–Pro–Gly–NH$_2$ (XI). A solution of Z–Arg(Tos)–Pro–Gly–OEt[20] (6.5 g, 0.01 mol) in methanol (150 ml) was saturated with ammonia gas at 0 °C. After being kept for 2 days at room temperature, the solution was concentrated to dryness and was triturated with ethyl acetate to obtain an amorphous powder: wt. 5.3 g (82%) mp 145.5—147 °C; $[\alpha]_D^{23}$ −20.2° (*c* 1, DMF). Found: C, 54.52; H, 6.13; N, 15.69; S, 5.13%. Calcd for $C_{28}H_{37}O_7N_7S$: C, 54.60; H, 6.05; N, 15.92; S, 5.20%.

Boc–Leu–Arg(Tos)–Pro–Gly–NH$_2$ (XII). Compound XI (3.7 g, 6 mmol) was dissolved in a 25% HBr solution in acetic acid (17 ml), and the solution was allowed to react for 50 min at room temperature. Then, the product was precipitated by adding a large volume of dry ether. The supernatant was removed by decantation, the precipitates were washed several times with dry ether, and dried over sodium hydroxide *in vacuo*. The dried material was dissolved in DMF (10 ml), the pH of the solution was adjusted to 7 with *N*-ethylmorpholine, and Boc–Leu–ONSu[21] (2.4 g, 7.2 mmol) was added to the solution. After being kept for 2 days at room temperature, the solution was diluted with excess chloroform. The chloroform solution was washed with 1 M hydrochloric acid, 10% sodium carbonate, and a saturated solution of sodium chloride, successively, and dried over anhydrous magnesium sulfate. The dried solution was concentrated under reduced pressure to a residue, which was crystallized from ethanol–hexane: wt. 3.1 g (75%), mp 152—153 °C, $[\alpha]_D^{27}$ −33° (*c* 1, DMF). Found: C, 52.81; H, 7.33; N, 15.78%. Calcd for $C_{31}H_{50}O_8N_8S \cdot {}^1/_2H_2O$: C, 52.89; H, 7.31; N, 15.92%.

Boc–Ser(Bzl)–Tyr(Bzl)–Gly–Leu–Arg(Tos)–Pro–Gly–NH$_2$ (XIII). Compound XII (3.1 g, 4.4 mmol) was dissolved in trifluoroacetic acid (10 ml) at 0 °C, and the solution was allowed to react for 1 h at room temperatdre. The solution was concentrated to a residue under reduced pressure; and the residue was dried over sodium hydroxide *in vacuo*. The dried material was dissolved in 30 ml of dried THF, and Boc–Ser(Bzl)–Tyr(Bzl)–Gly[22] (2.4 g, 4 mmol) was added to the solution together with HOBT (0.6 g, 4.4 mmol). Then, WSCI (0.8 ml, 4.4 mmol) was added to the mixture at 0 °C. The whole mixture was allowed to react overnight, and then, the solvent was evaporated out under reduced pressure. The residue was dissolved in chloroform (100 ml), the solution was washed well with water and dried for a short time over anhydrous magnesium sulfate. The dried solution was concentrated to a residue, which was purified by reprecipitation from chloroform-ethyl acetate; 4.6 g (97%), mp 118.5—123 °C, $[\alpha]_D^{20}$ −29.5° (*c* 1, DMF). Found: C, 59.35; H, 6.97; N, 12.22%. Calcd for $C_{60}H_{82}O_{13}N_{11}S \cdot 2H_2O$; C, 59.29; H, 6.97; N, 12.67%.

Boc–Trp–Ser(Bzl)–Tyr(Bzl)–Gly–Leu–Arg(Tos)–Pro–Gly–NH$_2$ (XIV). Compound XIII (3.8 g, 3.1 mmol) was dissolved in trifluoroacetic acid (12 ml) at 0 °C, and the mixture was allowed to react for 30 min at room temperature. Then, it was concentrated to a residue, which was washed with ether and dried over sodium hydroxide *in vacuo*. The dried material was dissolved in DMF (5 ml) together with HOBT (0.2 g), the pH of the solution was adjusted to 7 by adding triethylamine, and then, Boc–Trp–ONSu[21] (1.9 g, 4.7 mmol) was stirred into the solution. The whole mixture was allowed to react for 3 days, and then the product was precipitated out as a gelatinous powder by adding ethyl acetate. The product was collected by filtration, reprecipitated twice from DMF–ethyl acetate, washed with ether, and dried; wt. 3.9 g (90%), mp 142—149 °C (decomp.), $[\alpha]_D^{29}$ −27.4° (*c* 1, DMF). Found: C, 59.67; H, 6.60; N, 12.71%. Calcd for $C_{70}H_{89}O_{14}N_{13}S \cdot 2H_2O$: C, 59.85; H, 6.67; N, 12.96%.

Boc–His(Tos)–Trp–Ser(Bzl)–Tyr(Bzl)–Gly–Leu–Arg(Tos)–Pro–Gly–NH$_2$ (XV). Compound XIV (2.8 g, 2 mmol) was mixed well with 0.5 ml each of anisole and mercaptoethanol, and 10 ml of trifluoroacetic acid was added to the mixture at 0 °C; then, the solution was allowed to react for 30 min at room temperature. The solution was concentrated to a residue, which was triturated with dry ether and dried over sodium hydroxide *in vacuo*. The dried material was dissolved in a mixture of DMF and THF (10 ml each) together with I-b[5] (1.6 g, 4 mmol), and 0.62 ml of WSCI (4 mmol) was stirred into the mixture at 0 °C. Then, the mixture was allowed to react overnight at room temperature. THF was removed by distillation under reduced pressure, and the product was precipitated by the addition of water, which was collected by filtration and purified by reprecipitation from DMF-ethyl acetate; wt. 2.7 g (80%), mp 156—158.5 °C (decomp.), $[\alpha]_D^{20}$ −36.8° (*c* 1, DMF). Found: C, 58.40; H, 6.11; N, 13.00%. Calcd for $C_{83}H_{103}O_{17}N_{16}S_2 \cdot 2H_2O$: C, 58.74; H, 6.35; N, 13.2%.

Z<Glu–His(Tos)–Trp–Ser(Bzl)–Tyr(Bzl)–Gly–Leu–Arg(Tos)–Pro–Gly–NH$_2$ (XVII). Trifluoroacetic acid (3 ml) was stirred into a mixture of compound XV (252 mg, 0.15 mmol) and mercaptoethanol (0.05 ml) at 0 °C, and then the whole mixture was allowed to react for 40 min at room temperature. Excess trifluoroacetic acid was removed by distillation under reduced pressure, and the residue was treated with ether to precipitate the product as a powder, which was collected by filtration, washed with ether and dried over sodium hydroxide *in vacuo*. The dried material was dissolved in 1 ml of DMF, the pH of the solution was adjusted to 7 with *N*-methylmorpholine, and Z<Glu–ONp[23] (86 mg, 0.22 mmol) was stirred into the solution; the mixture was allowed to react for 2 days at room temperature. The reaction mixture was diluted with chloroform, the solution was washed successively with 1 M hydrochloric acid, water, 1 M sodium carbonate, and water, and dried over anhydrous magnesium sulfate. The dried solution was concentrated to a residue, which was purified by passage through a column of silica gel using a mixture of chloroform, methanol and acetic acid (95 : 5 : 3) as the solvent. Fractions containing the main band were collected and concentrated to a residue, which was purified by reprecipitation from chloroform–ether; wt. 150 mg (54.3%), mp 133.5—138.5 °C (decomp.), $[\alpha]_D^{20}$ −40.5° (*c* 1, DMF). Found: C, 59.39; H, 5.89; 13.41%. Calcd for $C_{91}H_{106}O_{19}N_{17}S_2 \cdot 3H_2O$: C, 59.33; H, 6.02; N, 12.93%.

Boc–His–Trp–Ser(Bzl)–Tyr(Bzl)–Gly–Leu–Arg(Tos)–Pro–Gly–NH$_2$ (XVI). Compound (XIV) (2.8 g, 2 mmol) was treated with trifluoroacetic acid as in the case of the synthesis of XV. The des-Boc-product was dissolved in

DMF (10 ml); HOBT (0.544 g, 4 mmol), Boc–His(Tos) (1.6 g, 4 mmol) and WSCI (0.62 ml, 4 mmol) were stirred successively into the DMF solution at 0 °C. After being allowed to react overnight at room temperature, the mixture was diluted with water to precipitate the product, which was collected by filtration and dried. Finally, the dried product was purified by reprecipitation twice from DMF–ethyl acetate; wt. 2.7 g (90%), mp 143.5—147.5 °C (decomp.), $[\alpha]_D^{25}$ −26.9° (*c* 1, DMF). Found: C, 58.95; H, 6.76; N, 14.23%. Calcd for $C_{76}H_{96}O_{15}N_{16}S \cdot 2H_2O$: C, 59.21; H, 6.54; N, 14.54%.

Z < Glu–His–Trp–Ser(Bzl) – Tyr(Bzl) – Gly–Leu–Arg(Tos)–Pro–Gly–NH_2 (XVIII). Compound XVI (2.3 g, 1.5 mmol) was treated with trifluoroacetic acid to remove the Boc-group as shown in the case of the synthesis of XVII. The des-Boc-compound thus obtained was dissolved in DMF (4 ml), together with HOBT (0.3 g, 2.2 mmol), the pH of the solution being adjusted to 7 by the addition of *N*-ethylmorpholine at 0 °C, and then Z<Glu–ONSu[12] (0.81 g, 2.25 mmol) was added. The whole mixture was allowed to react for 3 days at room temperature, and then excess water was added to precipitate the product, which was collected by filtration and dried. The dried material was reprecipitated twice from DMF–ethyl acetate for purification: wt. 2.2 g (88%), mp 132—138.5 °C (decomp.), $[\alpha]_D^{25}$ −25.4° (*c* 1, DMF). Found: C, 60.19; H, 6.18; N, 14.0%. Calcd for $C_{84}H_{99}O_{17}N_{17}S \cdot H_2O$: C, 60.45; H, 6.10; N, 14.27%.

<Glu–His–Trp–Ser–Tyr–Gly–Leu–Arg–Pro–Gly–NH_2 (LH–RH). (a): Compound XVIII (1 g, 0.58 mmol) was mixed well with tryptophan (0.1 g), phenol (0.5 g) and anisole (1 ml) in an HF reaction vessel; then, the mixture was treated with HF (10 ml) for one h at 0 °C as in the case of the synthesis of V. After removel of the excess HF under reduced pressure, the residue was extracted with 0.1 M acetic acid, the extract was washed with ether, and then passed through a Dowex 1×2 column (AcO^- form, 3×10 cm). The column was washed well with 0.1 M acetic acid, and the effluent and washing were combined and lyophilized to obtain 0.6 g of the crude product. The crude material was charged at the top of a column of Sephadex LH-20 (2.8×130 cm) which had previously been equilibrated with 1% acetic acid, and the column was eluted with the same solvent. Fractions containing the major product (Peak I in Fig. 1) were collected and lyophilized; the residue was further fractionated on the same type of column under the same conditions to obtain a homogenous product; wt. 220 mg, $[\alpha]_D^{25}$ −49.4° (*c* 0.4, H_2O), −51.0° (*c* 0.3, 1% AcOH). Reported: $[\alpha]_D^{28}$ −50.5° (*c* 1, 1%AcOH).[24] The homogeneity of this material was confirmed by paper electrophoresis using a 0.1 M pyridine-acetic acid buffer (pH 4.7) and by thin layer chromatography on cellulose powder, which were located using the Pauly reagent; R_f[3] 0.41. Found: C, 51.37; H, 6.58; N, 17.59%. Calcd for $C_{65}H_{75}O_{13}N_{17} \cdot 2C_2H_4O_2 \cdot 4H_2O$: C, 51.55; H, 6.67; N, 17.33%. The amino acid ratio in an acid hydrolyzate: His 1.00, Arg 0.96, Ser 1.00, Glu 1.04, Pro 1.01, Gly 1.98, Leu 0.96, Tyr 1.00, NH_3 1.06, Trp 0.97. The average recovery rate of the amino acids was 95%; Trp was determined by spectrophotometry. The amino acid ratio in an acid hydrolyzate of Fraction II: His 0.93, Arg 0.96, Ser 0.94, Glu 1.03, Pro 1.01, Gly 1.88, Leu 1.00, Tyr 0.28. *(b)*: Compound XVII (1 g, 0.53 mmol) was treated with HF in the same manner as described above. No major difference was observed at each step of the production of the final product; wt. 230 mg, $[\alpha]_D^{23}$ −48.7° (*c* 0.4, H_2O). Paper electrophoresis and thin layer chromatography showed this compound to be homogeneous and identical with the compound obtained above. Found: C, 51.74; H, 6.65; N, 17.67%. The amino acid ratio in an acid hydrolyzate: His 0.91, Arg 0.98, Ser 0.99, Glu 1.03, Pro 1.01, Gly 2.00, Leu 0.95, Tyr 1.00, NH_3 1.15, Trp 0.94. The average recovery rate of the amino acids was 94%.

Stereochemistry of the C and D Rings of C-Nor-D-homosteroids. II.[1] Synthesis of Etiojervane Analogs of Pregnan-3β-ol[2]

Akio MURAI, Takeshi NISHIMURA, and Tadashi MASAMUNE

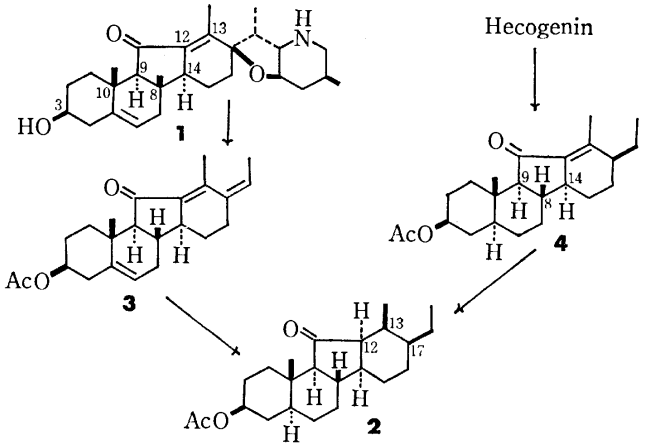
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received September 30, 1975)

The synthesis of C/D *trans*- and *cis*-fused C-nor-D-homo-5α-pregnan-3β-ol 3-acetates (**13a** and **32**) from jervine (**1**) is described. The configurations of both the compounds and the synthetic intermediates were determined on the basis of chemical and spectral evidence.

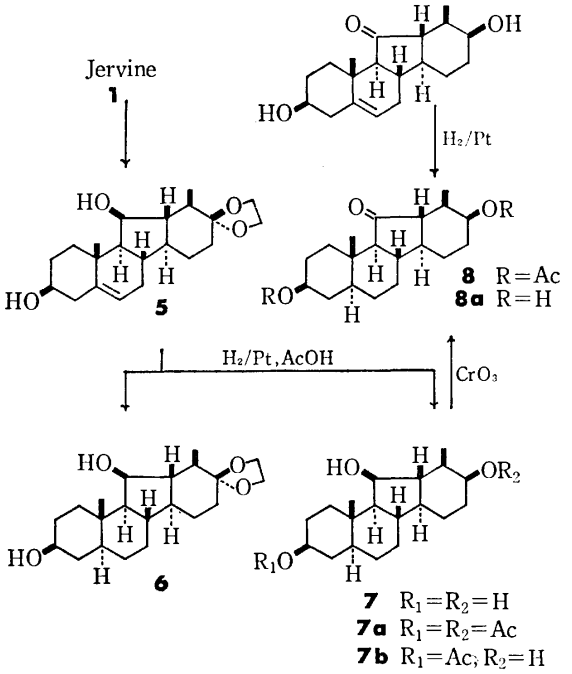
During the past decade synthetic studies of C-nor-D-homosteroid hormones have been reported by several groups.[3-7] In the present paper we describe the transformation of jervine (**1**) into etiojervane analogs of 5α-pregnan-3β-ol, which include both C/D *cis*- and *trans*-fused ring systems. In connection with the study on the synthesis and NMR spectra of (22S, 23R, 25S)-12α(not 12β)- and Δ^{12}-jervanines,[8] the results of the present work are useful for discussion[9] on conformations of the rings in etiojervanes.

In 1953, Fried and Klingsberg[10] isolated 17-ethyletiojervan-3β-ol-11-one 3-acetate (**2**) in 33% yield from the hydrogenation product of the corresponding $\Delta^{5,12,17(20)}$-triene derivative (**3**), obtained from jervine (**1**) by one-step fragmentation. Later, Mitsuhashi and Shimizu[5a] prepared the compound (**2**) in 80% yield by the same reaction of 17β-ethyletiojerv-12-en-3β-ol-11-one 3-acetate (**4**), which had been derived from hecogenin, and correlated both the alkaloid and sapogenin, elucidating the configurations of C_3, C_8, C_9, C_{10} and C_{14} in jervine (**1**). However, the spatial arrangement at C_{12} and C_{13} of the compound (**2**), a key intermediate for the correlation, has not been determined yet. The present work was undertaken with an aim to clarify these configurations.



Scheme 1.

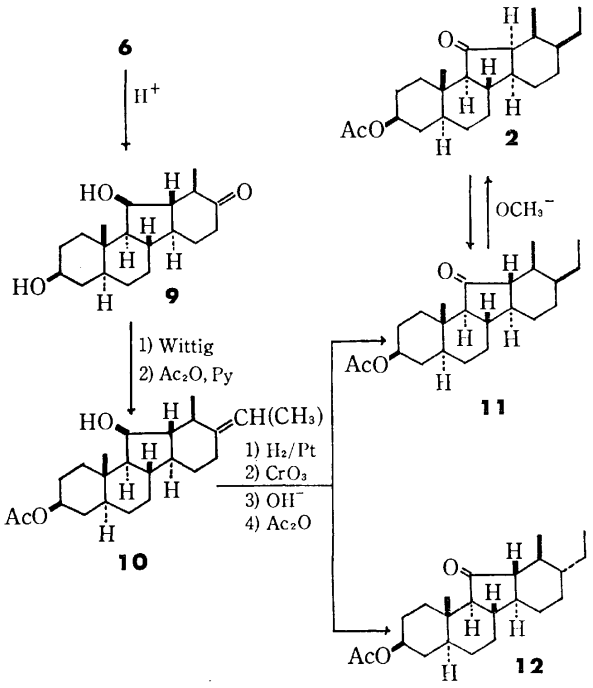
Hydrogenation of 12β-etiojerv-5-ene-3β,11β-diol-17-one 17-ethylene acetal[3b] (**5**), prepared from **3** by a four-stage process, over platinum in acetic acid afforded its 5α,6-dihydro derivative (**6**), mp 192—193 °C, in 88% yield along with triol (**7**), mp 235—236 °C (5%). Compound (**7**), with a molecular formula of $C_{19}H_{32}O_3$, is considered to be a hydrogenolysis product at C_{17}. On partial acetylation of compound (**7**) with acetic anhydride and pyridine afforded 3,17-diacetate (**7a**), mp 142—143 °C, which was oxidized with Jones' reagent to give 11-ketone (**8**), mp 120—121 °C. The ketone (**8**) was identified as 5α,12β-etiojervane-3β,17β-diol-11-one 3,17-diacetate by derivation from the corresponding 5,6-dehydro compound[11] with a well-defined configuration, indicating that triol **7** could be formulated as 3β,11β,17β-triol. In view of the fact that no hydrogenolysis product was isolated by the same treatment of the corresponding 11-deoxy (compound **15**) and 11-oxo derivatives,[9] the formation of **7** would reveal specific participation of the 11-hydroxy group to the catalytic reaction.



Scheme 2.

Treatment of 17-acetal **6** with acid produced 17-ketone (**9**), mp 188—190 °C, in 85% yield, whose NMR spectrum (19-C$\underline{H}_3$, δ 1.04) and ORD curve (Cotton effect, $a=-115°$) were consistent with the assigned configurations. The Witting reaction of **9** with ethylidenetriphenylphosphorane[12] proceeded smoothly and, after acetylation, gave the 17-ethylidene derivative (**10**), mp 156—157 °C, in a good yield (crude 82% and pure 41%). Compound **10**, when hydrogenated over platinum and then oxidized with chromium(VI) oxide, was transformed into a mixture of 17-epimeric 11-ketones (**11** and **12**), which showed a single spot differing from that of compound **2** on various solvent

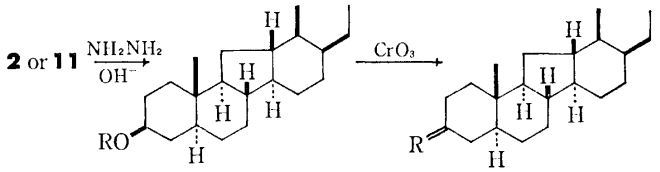
systems on TLC and resisted further purification. However, treatment of the mixture with sodium methoxide in refluxing methanol effected epimerization at the carbon atom(s) adjacent to the 11-oxo group and, on acetylation and subsequent purification by preparative TLC, led to isolation of the relevant compound (**2**) in 15% yield. Judging from chemical shifts of the 19-methyl protons of the mixture (**11** and **12**, δ 0.84) and the epimerized product (**2**, δ 0.90), this isomerization took place with configurational inversion only at C_{12}.[13] The transformation from compound **5** into the mixture (**11** and **12**) involves no epimerization at C_{12} and C_{13} (all compounds, 12βH and 13αH). The present result, combined with the Mitsuhashi work,[5a] confirms the compound in question to be represented correctly by formula **2** (12αH, 13αH and 17αH).



Scheme 3.

The afore-mentioned result suggests that a 12β-epimer of **2** with a 17β-ethyl group must be contained in the mixture. In fact, treatment of **2** with alkali in refluxing methanol followed by acetylation resulted in formation of a nearly 1 : 1 equilibrium mixture of **2** and the 12β-epimer, from which the latter (**11**), mp 121—123 °C, was isolated in 35% yield (crude 46%) by preparative TLC, showing practically the same IR spectrum as that of the mixture. In accordance with the assigned configurations, these 12-epimeric 11-ketones (**2** and **11**) exhibited negative Cotton effects with amplitudes of −82° and −170°, respectively, in the ORD curves.[14] On the other hand, the relevant hydrogenation mixture of **11** and **12** was treated with the base and then acetylated repeatedly, when most of one (**11**) of the two 12α-epimers was epimerized to the 12β-epimer (**2**), the other (**12**) being left as the main component of the mixture. This treatment led to isolation of compound **12** in 14% yield (crude 40%), mp 109—109.5 °C, suggesting that the mixture in question would contain almost equal amounts of 17-epimers (**11** and **12**). It is to be noted that, while the hydrogenation of double bonds at C_{12}—C_{13}, C_{13}—C_{17}, and C_{16}—C_{17} proceeded with the *cis*-addition mainly from the rear side, as illustrated by those of **4** and other compounds,[14] the hydrogen addition to a double bond at C_{17}–C_{20} took place from both sides.

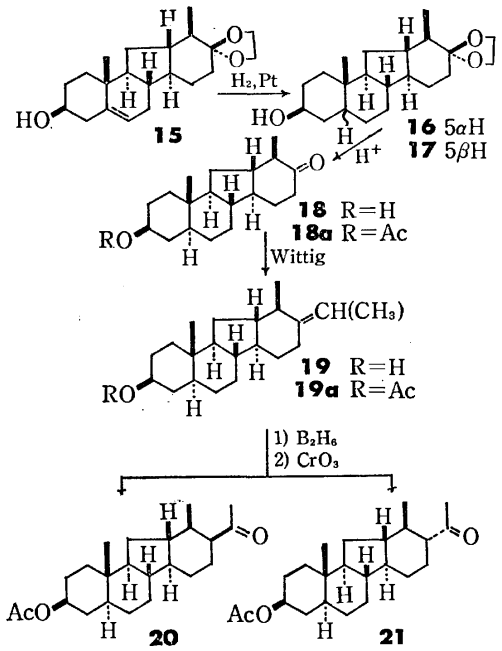
The Wolff-Kishner reduction of 11-ketone **2** by a modification of the Huang-Minlon[15] or the Barton procedure[16] effected removal of the 11-oxo group, giving 3β-alcohol (**13**), mp 124—125 °C, as the sole isolable product in a moderate yield. Compound **13** was also obtained from 12-epimeric 11-ketone **11** in almost the same yield by the same treatment. This compound was readily acetylated to 3β-acetate (**13a**), mp 94.5—95 °C, or oxidized to 3-ketone (**14**), mp 119—121 °C, in good yield, the latter being further transformed into the ethylene acetal (**14a**), mp 98—100 °C. The following experiments were undertaken with a view to clarify the configuration at C_{12} of this compound (**13**).



13 R=H **14** R=O
13a R=Ac **14a** R=$-OC_2H_4O^-$

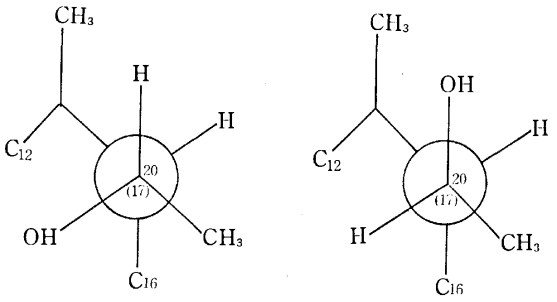
Hydrogenation of 12β-etiojerv-5-en-3β-ol-17-one 17-ethylene acetal[4d] (**15**) over platinum gave its 5α,6-dihydro derivative (**16**), mp 177—179 °C, in 80% yield, along with its 5β-isomer (**17**), mp 107—109 °C. The major product (**16**) on acid hydrolysis formed 17-ketone (**18**), mp 179—180 °C, in 90% yield, which was readily derived into 3β-acetate (**18a**), mp 134.5—135 °C. The assigned configurations (5αH, 12βH and 13αH) at C_5, C_{12} and C_{13} of these 17-ketones were confirmed by the NMR spectra (19-methyl protons, **18**, δ 0.75 and **18a**, 0.78) and the ORD curves (Cotton effect, both **18** and **18a**, $a=-105°$). Compound **18** was then submitted to the Wittig reaction[12] to give an oily mixture of the 17-ethylidene derivatives (**19**) in 97% yield, which exhibited two sharp singlets with relative intensity of 4 to 3 due to the 19-methyl protons at δ 0.73 and 0.76 in the NMR spectrum. However, the mixture (**19**) and also its hydrogenation product, 17-ethyletiojervan-3β-ols, again resisted further purification, showing a single spot on TLC. Thus the mixture **19**, after being converted into 3-acetates (**19a**), amorphous, in 79% yield, was submitted to hydroboration[17] and subsequent oxidation with sodium dichromate in sulfuric acid,[18] giving a 4 : 3 mixture of 17β- and 17α-acetyletiojervan-3β-ol 3-acetates (**20**), mp 189—191 °C, and (**21**), mp 110.5—111 °C, which were isolated in 28 and 18% yields, respectively, along with the unreacted starting material (**19a**) (9%). The configurations at C_{17} of these compounds were assigned on the basis that the former (**20**) (17β(axial)-acetyl] was epimerized quantitatively with base to the latter (**21**)

[17α(equatorial)-acetyl].

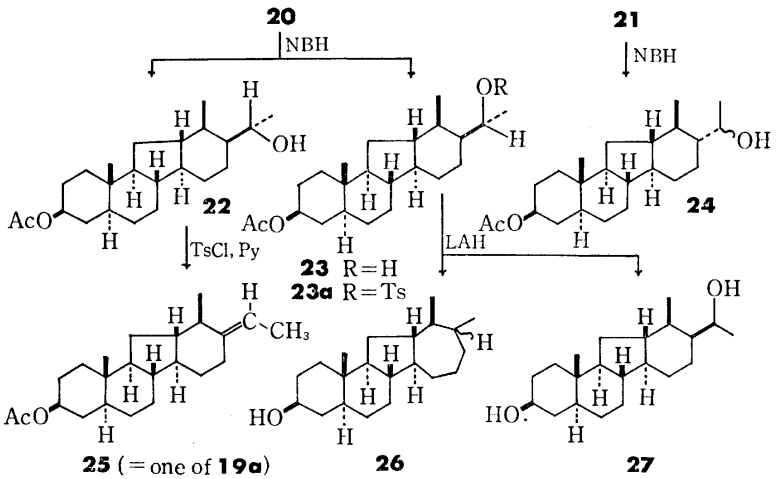


Scheme 4.

Reduction of 20-ketone (**20**) with sodium borohydride (NBH) in ethanol produced nearly equal amounts of 20α-(*S*)- and 20β-(*R*)-alcohols (**22**), mp 150—151 °C, and (**23**), mp 117—118 °C, which were readily isolated by preparative TLC. The configurational assignment to C_{20} of these epimeric alcohols was deduced from chemical shifts of the respective 18-methyl protons (**22**, δ 0.94 and **23**, 1.04); in each of these compounds the respective 21-methyl groups would be located at the most remote position from the D-ring as shown in **22A** and **23A**, and hence the 21-hydroxy group in **23** would be disposed 1,3-diaxial to the 18-methyl and deshield the 18-methyl protons more seriously in **23** than those in **22** in the NMR spectra. On the other hand, reduction of the isomeric 20-ketone (**21**) with sodium borohydride under comparable conditions gave an inseparable mixture of the corresponding 20-alcohols (**24**), mp 115—118 °C, in a moderate yield. The R_f values of these alcohols (**24**) on TLC clearly differed from those of alcohols **22** and **23**, indicating that the afore-mentioned hydride reduction took place without any configurational change at C_{17}.



Attempted removal of the 20-hydroxy groups in compounds **22** and **23** did not proceed as expected. 20α-(*S*)-Alcohol (**22**), when treated with *p*-toluenesulfonyl chloride in pyridine, formed no tosylate but produced olefin (**25**), mp 92—92.5 °C, with a molecular formula of $C_{23}H_{36}O_2$ in 94% yield. The structure [one of 17-ethylideneetiojervanes (**19a**)] and configuration were assigned on the basis of the spectral data [Mass, *m/e* 344; NMR, δ 0.77 (3H, s, 19-C<u>H</u>$_3$), 1.66 (3H, d J= 6 Hz, 21-C<u>H</u>$_3$), and 5.15 (1H, q J=6 Hz, <u>H</u> at C_{20})] and the conformation (**22A**) of the starting alcohol (**22**). Naturally, the NMR spectrum of **25** closely resembled that of **19a**. On the other hand, 20β-(*R*)-alcohol (**23**) was converted under the same conditions as **22** into the corresponding tosylate (**23a**), amorphous, showing a single spot on TLC. Treatment of **23a** with lithium aluminium hydride gave two products (**26**), amorphous, and (**27**), mp 190—191 °C, which were isolated in 24 and 37% yields, respectively, by preparative TLC. The latter (**27**) was derived by simple hydrolysis of **23** and hence identified as 3,20-glycol, resulting only from hydrogenolysis of the O–S bond. The former (**26**) displayed three methyl proton signals, one singlet (19-C<u>H</u>$_3$) and two doublets (both J=

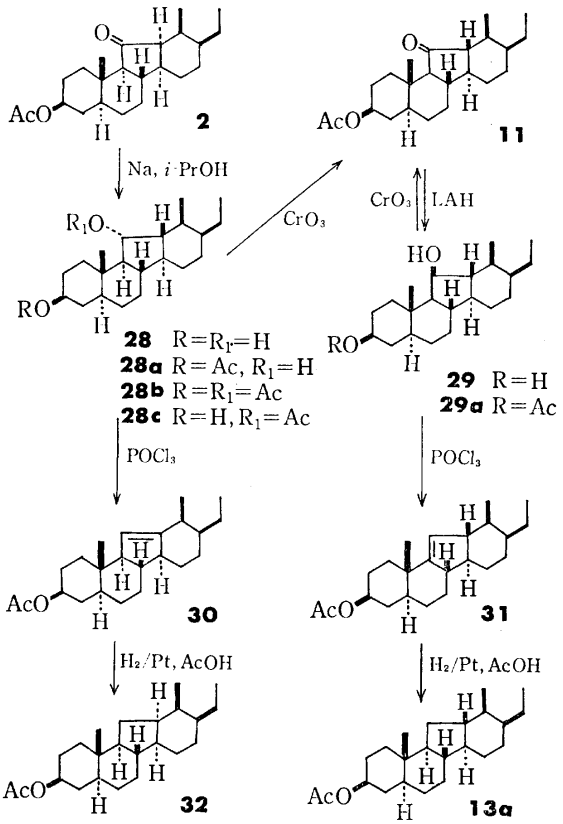


Scheme 5.

6 Hz) at δ 0.75, 0.97 and 1.19 in the NMR spectrum. These spectral data, as combined with consideration of the conformation (**23A**) of the starting alcohol, led to tentative assignment of formula **26** to the amorphous product.

The configuration at C_{12} of compound **13** was finally elucidated as follows. Reduction of 5α,12α-etiojervan-3β-ol-11-one 3-acetate (**2**) with sodium in isopropyl alcohol afforded 3β,11α-alcohol (**28**), mp 158—161 °C, in a good yield, whose configuration at C_{11} was consistent with the NMR spectrum: δ 0.775 (3H, s, 19-CH_3) and 4.00 (1H, br W_H=12 Hz). Treatment of **28** with acetic anhydride and pyridine gave a four-component mixture, from which the corresponding 3-acetate (**28a**), mp 128—129 °C, was isolated as the main product by preparative TLC in a moderate yield (pure 35%, and crude 65%). This compound (**28a**), when oxidized with chromium(VI) oxide, gave 5α,12β-etiojervan-3β-ol-11-one 3-acetate (**11**) in a good yield. Reduction of the 11-ketone (**11**) with lithium aluminium hydride in refluxing dioxane led to formation of the corresponding 3β,11β-alcohol (**29**), mp 186—188 °C, showing the following NMR spectrum: δ 1.02 (3H, s, 19-CH_3) and 4.06 (1H, do d J=6 and 8 Hz). This alcohol (**29**) underwent monoacetylation to give 3-acetate (**29a**), mp 151—152 °C, which was reconverted by oxidation into 12β*H*-11-ketone (**11**). The results indicate that 11-alcohols **28** and **29** are epimeric to each other only at C_{11} and the reduction of 11-ketone (**2**) to 11α-alcohol (**28**) is accompanied by configurational inversion at C_{12} (12αH to 12βH). The hydride reduction of 12α*H*-11-ketone (**2**) under the same conditions as that of 12β*H*-11-ketone (**11**) resulted only in hydrolysis of the 3-acetoxy group owing to severe steric hindrance due to β-oriented methyl and ethyl groups at C_{13} and C_{17}, respectively, leading to the recovery of the starting ketone after acetylation.

Treatment of 12α*H*-11α-alcohol (**28a**) with phosphoryl chloride in pyridine gave olefin (**30**), oil, in 90% yield. The same treatment of 12β*H*-11β-alcohol (**29a**) also produced olefin (**31**), oil, in quantitative yield, which was evidently different from olefin **30**. The structure of these olefins was assigned as shown in formulas **30** and **31**, respectively, on the basis of chemical shifts of the respective 19-methyl protons (**30**, δ 0.77 and **31**, 0.92) as well as the reaction mode. The chemical shift difference (0.15 ppm) in question between olefins was in good accord with that (0.175 ppm) in the corresponding normal steroid olefins,[19] and the formation of these olefins was interpreted by assuming that the dehydration proceeds in an E2-type *trans*-elimination manner. Hydrogenation of the latter olefin (**31**), 12β*H*-$\Delta^{9(11)}$-olefin, over platinum in acetic acid led to formation of the compound (**13a**) in question, mp 92—94 °C, establishing all the configurations of **13a** (5αH, 12βH, 13αH and 17αH). The same reaction of another olefin (**30**), 9α*H*-Δ^{11}-olefin, produced an isomeric compound (**32**), amorphous, formulated as 5α,12α-etiojervan-3β-ol 3-acetate. These compounds (**13a** and **32**) are regarded as C/D *trans*- and *cis*-etiojervane analogs of 5α-pregnan-3β-ol 3-acetate.



Scheme 6.

Experimental

All the melting points are uncorrected. The homogeneity of each compound was always checked by TLC on silica gel (Wakogel B-5) using various solvent systems, and the spots were developed with ceric sulfate in dil sulfuric acid and/or iodine. The optical rotations, ORD curves and IR spectra were measured in chloroform, dioxane and Nujol, respectively, unless otherwise stated. The NMR spectra were obtained in deuteriochloroform at 60 and/or 100 MHz, and the chemical shifts were given in δ-values, TMS being used as an internal reference. The abbreviations "s, d, t, q, br, m and do" in the NMR spectra denote "singlet, doublet, triplet, quartet, broad, multiplet and double," respectively.

17β-Ethyl-5α,12α-etiojervan-3β-ol-11-one 3-Acetate (2). a) A solution of 17-ethyletiojerv-5,12,17(20)-trien-3β-ol-17-one 3-acetate[10] (**3**, 8.33 g), mp 183—185 °C, in acetic acid (AcOH, 700 ml) was hydrogenated over Adams platinum (Pt, 5.76 g as $PtO_2 \cdot H_2O$) at room temperature (temp) for 16 h, when 2060 ml of hydrogen (3.5 mol) had been consumed. After removal of the catalyst by filtration and the solvent *in vacuo* by azeotropization with benzene, the residue was dissolved in methanol, and the methanol solution was concentrated to 70 ml and cooled to yield a crystalline substance, which was collected by filtration. Recrystallization from methanol afforded **2** (3.02 g), mp 115.5—116.5 °C (lit,[10] 114—116 °C); $[\alpha]_D$ −15.8° (lit,[10] −8.6°); ORD, $[\Phi]^{trough}_{334}$ −4520°, $[\Phi]^{trough}_{323}$ −2180°, $[\Phi]^{peak}_{293}$ +3680°, a=−82°; IR, ν_{max} 1730, 1260 and 1025 cm^{-1}; NMR, δ 0.72 (3H, d J=7 Hz, 18-CH_3), 0.90 (3H, s, 19-CH_3), 2.01 (3H, s, OCO-CH_3) and 4.65 (1H, br, H at C_3). This compound proved to be identical with a sample[5a], mp 118.2—118.9 °C and $[\alpha]_D$ −15.5°, obtained from hecogenin by direct comparison (IR, mixed mp and TLC). The mother liquors obtained on the concentration and recrystallization consisted of a

multicomponent mixture and resisted further purification.

b) A solution of **10** (156 mg), in AcOH (10 ml) was hydrogenated over Adams Pt (204 mg) at room temp, and 1.1 mol of hydrogen was consumed for 45 min. The reaction mixture gave an amorphous substance (142 mg) after usual work up; NMR, δ 0.84 (3H, t J=6 Hz, 21-C$\underline{H}_3$), 0.97 (3H, d J=6.5 Hz, 18-C$\underline{H}_3$), 1.06 (3H, s, 19-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), 4.01 (1H, br W_H=15.5 Hz, $\underline{H}$ at C_{11}) and 4.67 (1H, br, $\underline{H}$ at C_3). This was mixed with a complex prepared from chromium(VI) oxide (CrO_3, 215 mg) and pyridine (Py, 2 ml) under cooling and stirred at room temp overnight. The mixture was poured into water and extracted with ether, and the ether solution was washed with 1 M hydrochloric acid, 5% aqueous sodium hydrogencarbonate and saturated brine, dried and evaporated to leave a crystalline mixture (140 mg) of **11** and **12**, which showed a single spot on TLC.

The mixture was treated with 1 M sodium methoxide in refluxing methanol (15 ml) under nitrogen for 2 h. The solution was evaporated *in vacuo* and shaken with chloroform and water, and the chloroform solution was washed, dried and evaporated to leave amorphous residue (132 mg), which was acetylated with acetic anhydride (Ac_2O, 1 ml) and Py, (1.3 ml) at room temp overnight. The reaction mixture gave amorphous residue (143 mg) after usual work up, which showed two spots and was separated by preparative TLC (7 plates) with a 3 : 2 mixture of benzene and chloroform. The less mobile fraction gave a crystalline substance (18 mg), which on trituration with methanol had mp 114—117 °C. The more mobile fraction gave an amorphous material (84 mg), showing the same spot as the starting mixture, which was again treated in the same manner as the aforementioned mixture to give the crystalline substance (10 mg) besides the main amorphous material (73 mg). The crystalline substances were combined and recrystallized from methanol to yield **2** (9 mg), mp 118—119 °C, which was identical with an authentic sample (TLC, IR, NMR and optical rotation). The main amorphous material (73 mg) was treated twice in the same manner as described above and after usual work-up, gave a new crystalline substance (56.5 mg) with the same R_f value as the more mobile part. The substance was triturated with methanol to yield **12** (20 mg), mp 106—107 °C, and was recrystallized repeatedly from methanol to give an analytical sample, mp 109—109.5 °C; $[\alpha]_D$ −94.6°; ORD, $[\Phi]_{334}^{trough}$ −11350°, $[\Phi]_{323}^{trough}$ −6370°, $[\Phi]_{315}$=0°, $[\Phi]_{291}^{peak}$ −10520°, a=−219°; IR, ν_{max} 1732, 1234 and 1022 cm^{-1}; NMR, δ 0.85 (3H, s, 19-C$\underline{H}_3$). Found: C, 76.53; H, 10.04%. Calcd for $C_{23}H_{36}O_3$: C, 76.62; H, 10.07%.

*5α,12β-Etiojervane-3β,11β-diol-17-one 17-Ethylene Acetal (**6**) and 5α,12β-Etiojervane-3β,11β,17β-triol (**7**).* A solution of etiojerv-5-ene-3β,11β-diol-17-one 17-ethylene acetal[3b] (**5**, 2.50 g), mp 173—174 °C, in AcOH (50 ml) was hydrogenated over the Adams Pt (0.80 g) at room temp for 1 h, when 445 ml of hydrogen had been taken up. After removal of the catalyst and solvent, the residue was dissolved in chloroform, and the chloroform solution was washed with 5% aqueous sodium hydrogencarbonate and water, dried over anhydrous sodium sulfate and evaporated to leave an amorphous substance (3.08 g), which crystallized on trituration with acetone and was collected by filtration to yield **6** (1.36 g), mp 182—184 °C. The filtrate, showing two spots, was separated by preparative TLC (30 plates) over silica gel (Wakogel B-5, 10 g per plate) with ether as solvent. More mobile fractions, eluted with acetone, gave amorphous residue (0.60 g), which crystallized as needles on trituration with acetone to give **6** (0.35 g), mp 183—188 °C. Two recrystallizations from acetone gave an analytical sample, mp 192—193 °C; $[\alpha]_D$ +39.4°; IR, ν_{max} 3490, 3340, 1108 and 1031 cm^{-1}; NMR, δ 0.98 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 1.03 (3H, s, 19-C$\underline{H}_3$), 1.50 and 2.01 (each 1H, s, $\underline{OH}$) and 3.85 (4H, s, $OC_2\underline{H}_4O$). Found: C, 71.88; H, 9.81%. Calcd for $C_{21}H_{34}O$: C, 71.96; H, 9.78%.

Less mobile fractions, eluted with chloroform, gave crystalline triol (**7**, 0.64 g), which on recrystallization from acetone had mp 231—234 °C and amounted to 0.11 g. This was recrystallized from acetone for analysis: mp 235—236 °C; $[\alpha]_D$ +63.3° (MeOH); IR, ν_{max} 3340, 1715 (acetone ?) and 1044 cm^{-1}. Found: C, 73.76; H, 10.47%. Calcd for $C_{19}H_{32}O_3$: C, 73.98; H, 10.46%.

*5α,12β-Etiojervane-3β,17β-diol-11-one 3,17-Diacetate (**8**).*

a) A solution of etiojerv-5-ene-3β,17β-diol-11-one[11] (107 mg) in AcOH (4 ml) was hydrogenated over Adams Pt (59 mg) at room temp for 1 h, when 1.27 mol of hydrogen had been consumed. After removal of the catalyst by filtration and the solvent *in vacuo* by evaporation, the residue was diluted with water and the solution was extracted with chloroform. The chloroform extracts were washed with 5% aqueous sodium hydrogencarbonate and water, dried, and evaporated to leave an amorphous residue (111 mg), which showed three spots and was separated by preparative TLC (8 plates) with ether. The most mobile part gave an amorphous substance (10 mg), which would be 5β,12β-etiojervane-3β,17β-diol-11-one from its NMR data, but was not further examined: δ 0.97 (3H, s, 19-C$\underline{H}_3$), 1.26 (3H, d J=4 Hz, 18-C$\underline{H}_3$), 3.77 (1H, br s W_H=8 Hz, $\underline{H}$ at C_{17}) and 4.07 (1H, br s W_H=9 Hz, $\underline{H}$ at C_3).

The middle part gave a crystalline substance (66 mg), which on trituration with acetone–isopropyl ether gave **8a** (61 mg), mp 179.5—180.5 °C. Recrystallization from the same solvent mixture afforded an analytical sample, mp 180.5—181 °C; $[\alpha]_D$ −44.2° (MeOH); IR, ν_{max} 3290, 1727 and 1028 cm^{-1}; NMR, δ 0.83 (3H, s, 19-C$\underline{H}_3$), 1.25 (3H, d J=5.5 Hz, 18-C$\underline{H}_3$), 3.59 (1H, br W_H=24 Hz, $\underline{H}$ at C_3) and 3.76 (1H, br s W_H=8 Hz, $\underline{H}$ at C_{17}). Found: C, 74.48; H, 9.91%. Calcd for $C_{19}H_{30}O_3$: C, 74.47; H, 9.87%. The least mobile part gave a crystalline substance (11 mg). The NMR spectrum indicated the compound to be etiojerva-3β,11β,17β-triol-11-one, but this was not further examined: NMR, δ 1.02 (3H, s, 19-C$\underline{H}_3$), 1.24 (3H, br s W_H=5 Hz, 18-C$\underline{H}_3$), 1.56 (s, disappeared on addition of D_2O, $\underline{OH}$), 6.43 (1H, br W_H=27 Hz, $\underline{H}$ at C_3), 3.81 (1H, br s W_H=8 Hz, $\underline{H}$ at C_{17}) and 4.08 (1H, do d J=6 and 10 Hz, $\underline{H}$ at C_{11}).

Compound **8a** (45 mg) was acetylated with Ac_2O (1 ml) and Py (1 ml) at room temp for 22 h. The reaction mixture gave amorphous residue (61 mg) after usual work up, which was crystallized from dil methanol to yield a crystalline substance (**8**), mp 123—125 °C; IR, ν_{max} 1743—1724, 1251, 1234 and 1024 cm^{-1}; NMR, δ 0.86 (3H, s, 19-C$\underline{H}_3$), 1.14 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 1.99 and 2.04 (each 3H, s, 2OCOC$\underline{H}_3$), 5.42 (1H, br W_H=24 Hz, $\underline{H}$ at C_3) and 4.94 (1H, br s W_H=7.5 Hz, $\underline{H}$ at C_{17}).

b) Compound **7** (72 mg) was acetylated with Ac_2O (1 ml) and Py (1 ml) at room temp for 3 h. The reaction mixture was worked up as usual to give an amorphous residue (91.5 mg), showing two spots, which was separated by preparative TLC (2 plates) over silica gel using a 1 : 1 mixture of ether and benzene. More mobile fractions, eluted with acetone, gave an amorphous residue (45 mg), which crystallized on trituration with isopropyl ether to give 3,17-diacetate **7a** (12 mg), mp 138—139 °C. Recrystallization from isopropyl ether gave an analytical sample, mp 142—143 °C; $[\alpha]_D$ +64.8°; Mass, m/e 332 (M^+-CH_3COOH), 314, 299, 272 and 254; IR, ν_{max} 3515, 1729, 1715, 1254, 1241 and 1025

cm^{-1}; NMR, δ 0.99 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 1.07 (3H, s, 19-C$\underline{H}_3$), 1.99 and 2.02 (each 3H, s, 2OCOC$\underline{H}_3$), 4.10 (1H, do d J=8 and 5.5 Hz, $\underline{H}$ at C_{11}), 4.70 (1H, br, $\underline{H}$ at C_3) and 5.00 (1H, br s W_H=6Hz, $\underline{H}$ at C_{17}). Found: C, 69.51; H, 9.55%. Calcd for $C_{23}H_{36}O_5$: C, 70.37; H, 9.24%.

Less mobile fractions, eluted with acetone, gave a crystalline residue (42 mg), which on trituration with acetone–isopropyl ether afforded triol 3-monoacetate (**7b**, 24 mg), mp, 172.5—173 °C. Recrystallization from the same solvent mixture gave an analytical sample: mp 173—173.5 °C; $[\alpha]_D$+35.6°; Mass, *m/e* 332 (M^+-H_2O), 314 and 272; IR, ν_{max} 3465, 3305, 1734, 1243, 1026 and 1018 cm^{-1}; NMR, δ 1.06 (3H, s, 19-C$\underline{H}_3$), 1.09 (3H, d J=7 Hz, 18-C$\underline{H}_3$), 2.02 (3H, s, OCOC$\underline{H}_3$), 3.81 (1H, br s W_H=6 Hz, $\underline{H}$ at C_{17}), 4.08 (1H, do d J=8.5 and 5 Hz, $\underline{H}$ at C_{11}) and 4.71 (1H, br W_H=24 Hz, $\underline{H}$ at C_3). Found: C, 71.82; H, 9.71%. Calcd for $C_{21}H_{34}O_4$: C, 71.96; H, 9.78%.

A solution of **7a** (40 mg) in acetone (4 ml) was treated with Jones' reagent (0.2 ml) in an ice-bath under stirring for 1 h. After addition of ethanol and evaporation of the solvent *in vacuo*, the resulting residue was diluted with water and extracted with chloroform. The chloroform solution was washed with 5% aqueous sodium hydrogencarbonate and water, dried and evaporated to give an amorphous residue (41 mg), which showed a single spot on TLC. Trituration with dil methanol afforded a crystalline substance (**8**, 19 mg), mp 120—121 °C, which was identical with an authentic sample.

*5α,12β-Etiojervane-3β,11β-diol-17-one (**9**).* Compound **6** (1.314 g) was dissolved in a solution of acetone (130 ml) and water (13 ml) containing *p*-toluenesulfonic acid (PTS, 146 mg), and refluxed for 3 h under stirring. After evaporation of the solvents below 25 °C the residue was made alkaline with 5% aqueous sodium hydrogencarbonate and extracted with chloroform repeatedly. The chloroform solution was washed with water, dried and evaporated to leave a crystalline material (1.497 g), which on recrystallization from acetone–isopropyl ether gave **9** (977 mg), mp 187—189 °C. Two recrystallizations from the same solvent mixture afforded an analytical sample, mp 188—190 °C; $[\alpha]_D$ +11.2° (MeOH); ORD, $[\Phi]_{318}^{trough}$ −4440°, $[\Phi]_{310}^{trough}$ −4080°, $[\Phi]_{274}^{peak}$ +7090°, a=−115°; IR, ν_{max} 3410, 1701 and 1037 cm^{-1}; NMR, δ 1.04 (3H, s, 19-C$\underline{H}_3$), 1.12 (3H, d J=7 Hz, 18-C$\underline{H}_3$), 3.55 (1H, br, $\underline{H}$ at C_3) and 4.12 (1H, br W_H=15 Hz, $\underline{H}$ at C_{11}). Found: C, 74.56; H, 9.76%. Calcd for $C_{19}H_{30}O_3$: C, 74.47; H. 9.87%.

*17-Ethylidene-5α,12β-etiojervane-3β,11β-diol 3-Acetate (**10**).* A suspended mixture of sodium hydride (Wako, 309 mg, *ca.* 50% in oil) in pentane (10 ml) was stirred for 2 min and then decanted, and the procedure was repeated five times to remove the oil. After removal of the pentane *in vacuo* the residual hydride was mixed with dimethyl sulfoxide (DMSO, 5 ml), which had been dried over calcium hydride and distilled, in a stream of nitrogen, stirred at room temp for 15 min and then at 70—73 °C for 50 min, and cooled, when the mixture became homogeneous and gray. To the solution was added dropwise a solution of ethyltriphenylphosphonium bromide (2.232 g, 6 mmol) in dry DMSO (12 ml) at room temp during 3 min under nitrogen, and the solution was stirred at room temp for 15 min. To the resulting dark red solution was added a solution of **9** (464 mg, 1.5 mmol) in dry tetrahydrofuran (THF, 5.5 ml) at room temp during 5 min under nitrogen. The whole mixture was further stirred at room temp for 15 min and then at 50—51 °C (bath temp) for 22 h. The reaction mixture was poured into ice-water and after being salted out, extracted with ether repeatedly. The ether solution was washed with saturated brine, dried and evaporated to leave oily residue (2.165 g). This was treated with Ac_2O (5 ml) and Py (10 ml) at room temp for 3 h and then worked up as usual to give an amorphous substance (1.908 g), showing two spots, which was separated by preparative TLC (25 plates) with benzene. The minor fraction amounted to 75 mg but was not further examined.

The main, less mobile fraction gave a crystalline substance (380 mg), which on recrystallization from acetone afforded **10** (191 mg), mp 152—154 °C. This was recrystallized twice from isopropyl ether for analysis: mp 156—157 °C; $[\alpha]_D$ +53.3°; IR ν_{max} 3505, 1713, 1267 and 1031 cm^{-1}; NMR, δ 1.04 (3H, s, 19-C$\underline{H}_3$), 1.19 (3H, d J=5.5 Hz, 18-C$\underline{H}_3$), 1.61 (3H, d J=6 Hz, 21-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), 4.10 (1H, br W_H=14.5 Hz, $\underline{H}$ at C_{11}), 4.64 (1H, br, $\underline{H}$ at C_3) and 5.17 (1H, q J=6 Hz, $\underline{H}$ at C_{20}). Found: C, 76.52; H, 10.08%. Calcd for $C_{23}H_{36}O_3$: C, 76.62; H, 10.07%.

*17β-Ethyl-5α,12β-etiojervan-3β-ol-11-one 3-Acetate (**11**).* a) Compound **2** (730 mg) was dissolved in methanol (48 ml) containing 5% potassium hydroxide and refluxed for 1 h under nitrogen. The solution was diluted with water under stirring to yield an amorphous substance (650 mg), which was collected, dried and treated with Ac_2O (4 ml) and Py (7 ml) at room temp overnight. After removal of the solvents by azeotropization with benzene, the residue crystallized on trituration with methanol. This crystalline material, showing two spots on TLC (chloroform : benzene=1 : 1), was dissolved in benzene and chromatographed on a mixture of silicic acid (22 g) and celite (1.5 g). Fractions eluted with benzene gave crystals (245 mg), which showed a single spot on TLC. Recrystallization from methanol afforded an analytical sample of **11**, mp 121—123 °C; $[\alpha]_D$ −66.8°; ORD, $[\Phi]_{334}^{trough}$ −9930°, $[\Phi]_{323}^{trough}$ −5810°, $[\Phi]_{293}^{peak}$ +7120°, a=−170°; IR, ν_{max} 1730, 1245 and 1025 cm^{-1}; NMR, δ 0.84 (3H, s, 19-C$\underline{H}_3$), 0.94 (3H?, t J=7 Hz, 21-C$\underline{H}_3$?), 1.16 (3H?, d J=6.5 Hz, 18-C$\underline{H}_3$), 2.02 (3H, s, OCOC$\underline{H}_3$) and 4.65 (1H, br, $\underline{H}$ at C_3). Found: C, 76.78; H, 10.32%. Calcd for $C_{23}H_{36}O_3$: C, 76.62; H, 10.07%.

b) A solution of compound **28a** (34 mg) in acetone (3.5 ml) cooled in an ice-bath was treated with Jones' reagent (0.05 ml) for 1 h under stirring. After addition of ethanol to decompose excess of chromium(VI) oxide (CrO_3), the solution was evaporated *in vacuo* below 40 °C, and then shaken with water and chloroform. The chloroform solution was worked up as usual to give a crystalline substance (35 mg), which on recrystallization from methanol afforded **11** (24 mg), mp 120—121 °C. This was identical with an authentic sample obtained by epimerization of **2**.

Equilibrium Measurements. Compound **2** (51 mg) in methanol (1 ml) was mixed with methanol (4 ml) containing 5% potassium hydroxide and allowed to stand at room temp for 60 h. After removal of methanol *in vacuo* the residue was shaken with chloroform and water. The chloroform solution gave a mixture (46 mg) of 12-epimeric alcohols, which was acetylated with Ac_2O (0.24 ml) and Py (0.48 ml) at room temp overnight. The reaction mixture was mixed with water (100 ml) under stirring to give an amorphous substance, which was collected by filtration and dried thoroughly. The resulting mixture (44 mg) of **2** and **11** had an optical rotation of $[\alpha]_D$ −43.2°.

Compound **11** (51 mg) was treated in the same manner as **2** produced a mixture of **2** and **11**, which showed an optical rotation of $[\alpha]_D$ −44.3°. The specific rotations in both experiments were practically the same, indicating that the equilibrium mixture consisted of 45% of the former (**2**) and 55% of the latter (**11**).

*17β-Ethyl-5α,12β-etiojervan-3β-ol (**13**) and Its 3-Acetate (**13a**).* a) Freshly-distilled diethylene glycol (DEG, 75 ml) containing sodium (2.0 g) was heated to 180 °C, and anhydrous hydrazine[20] (40 ml) was added to the solution, and refluxed for a while and cooled. After addition of compound **2** (3.52 g) the mixture was refluxed (at *ca.* 145 °C) for 16 h, cooled and the condenser was removed. The solution was heated to 180 °C to distill off excess of the hydrazine, and a new condenser was then set up. The solution was again refluxed at the temp for 24 h, cooled and mixed with water (450 ml), giving an amorphous powder (3.08 g), which was collected, dried and crystallized from methanol. Recrystallization from methanol afforded **13** (1.72 g), mp 124—125 °C; $[\alpha]_D$ + 75.9°, IR, no absorption near 1700 cm^{-1}; NMR, δ 0.74 (3H, s, 19-C$\underline{H}_3$), 0.84 (3H?, d J=6 Hz, 18-C$\underline{H}_3$) and 3.64 (1H, br, $\underline{H}$ at C_3). Found: C, 82.68; H, 11.45%. Calcd for $C_{21}H_{36}O$: C, 82.83; H, 11.33%.

Compound **13** (52 mg) was treated with Ac_2O (0.7 ml) and Py (1 ml) at room temp overnight. After usual work up the residue (57 mg) afforded **13a** (29 mg), 94.5—95 °C, on trituration with acetone and subsequent recrystallization from acetone; $[\alpha]_D^{14}$ + 55.3°; IR, ν_{max} 1742 and 1244 cm^{-1}; NMR, δ 0.76 (3H, s, 19-C$\underline{H}_3$), 0.83 (3H, d J=6.5 Hz, 18-C$\underline{H}_3$), 0.85 (3H, t J=6.5 Hz, 21-C$\underline{H}_3$), 2.03 (3H, s, OCOC$\underline{H}_3$) and 4.72 (1H, br, $\underline{H}$ at C_3). Found: C, 79.98; H, 11.13%. Calcd for $C_{23}H_{38}O_2$: C, 79.71; H, 11.05%.

b) The Wolff-Kishner reduction of compound **11** (240 mg) was carried out in the same way as mentioned above and produced crude **13** (221 mg), having mp 108—120 °C. Recrystallization from methanol afforded **13** (93 mg), mp 120—122 °C, in pure state, which was identical with that prepared from **2**.

*17β-Ethyl-5α,12β-etiojervan-3-one (**14**) and Its Ethylene Acetal (**14a**).* To a pasty complex prepared from Py (15 ml) and CrO_3 (1.5 g) was added **13** (1.50 g) dissolved in Py (15 ml), and the mixture was stirred at room temp for 15h. After removal of the solvent the mixture was extracted with chloroform, and the chloroform solution was washed with 1 M hydrochloric acid, 10% aqueous sodium hydroxide and water, dried and then evaporated to leave an oily substance, which crystallized on trituration with methanol and recrystallized from the same solvent to yield **14** (1.16 g), mp 118—119 °C. This sample was recrystallized from methanol for analysis: mp 119—121 °C; $[\alpha]_D$ +113.5°; IR, ν_{max} 1707 cm^{-1}; NMR, δ 0.85 (3H, d J=6 Hz, 18-C$\underline{H}_3$) and 0.94 (3H, s, 19-C$\underline{H}_3$). Found: C, 83.51; H, 11.20%. Calcd for $C_{21}H_{34}O$: C, 83.38; H, 11.33%.

A solution of **14** (352 mg) in benzene (60 ml) containing PTS (18 mg) and ethylene glycol (1.75 ml) was refluxed for 8 h under a Dean-Stark apparatus and then cooled, when the solution was separated into two layers. The upper layer was separated, washed with 5% aqueous sodium hydrogencarbonate (60 ml) and water (60 ml), dried and evaporated *in vacuo* to leave a crystalline residue. Recrystallization from acetone gave **14a** (247 mg), mp 98—100 °C; $[\alpha]_D$ +63.5°; IR, ν_{max} 1110, 1080 and 1066 cm^{-1}; NMR, δ 0.77 (3H, s, 19-C$\underline{H}_3$), 0.85 (3H?, d J=7 Hz, 18-C$\underline{H}_3$) and 3.93 (4H, s, $OC_2\underline{H}_4O$). Found: C, 79.96; H, 11.02%. Calcd for $C_{23}H_{38}O_2$: C, 79.71; H, 11.05%.

*5α,12β-Etiojervan-3β-ol-17-one 17-Ethylene Acetal (**16**) and Its 5β-Isomer (**17**).* A solution of 12β-etiojerv-5-en-3β-ol-17-one 17-ethylene acetal[4d] (**15**, 777 mg), mp 175—177 °C, in AcOH (20 ml) was hydrogenated over Adams Pt (150 mg) at room temp and 95 ml of hydrogen was consumed for 30 min. The reaction mixture was worked up as usual to give an amorphous substance (860 mg), which crystallized on trituration with isopropyl ether and was collected by filtration. This crystalline substance (**16**, 612 mg), mp 177—179 °C, was recrystallized twice from isopropyl ether for analysis: mp 177—179 °C; $[\alpha]_D$ +50.4°; IR, ν_{max} 3445, 1110, 1077 and 1043 cm^{-1}; NMR, δ 0.74 (3H, s, 19-C$\underline{H}_3$), 0.83 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 3.55 (1H, br, $\underline{H}$ at C_3) and 3.87 (4H, s, $OC_2\underline{H}_4O$). Found: C, 75.21; H, 10.15%. Calcd for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25%.

The filtrate, obtained on crystallization of **16**, was evaporated and then separated into three parts by preparative TLC (10 plates) with a 1 : 2 mixture of ether and benzene. The middle part (77 mg) showed the same IR spectrum and R_f value as **16**. The most mobile part (46 mg) crystallized on trituration with isopropyl ether, had mp 107—109 °C and amounted to 9 mg. The NMR and IR spectra indicated this compound to be a 5β-isomer of **16**; $[\alpha]_D$ +43.5°; IR, ν_{max} 3340, 1086, 1042 and 1031 cm^{-1}; NMR, δ 0.82 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 0.89 (3H, s, 19-C$\underline{H}_3$), 3.91 (4H, s, $OC_2\underline{H}_4O$) and 4.06 (1H, br W_H=8.5 Hz, $\underline{H}$ at C_3). Found: C, 75.28; H, 10.40%. Calcd for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25%

*5α,12β-Etiojervan-3β-ol-17-one (**18**) and Its 3-Acetate (**18a**).* Compound **16** (560 mg) was dissolved in acetone (50 ml) and water (5 ml) containing PTS (53 mg) and refluxed for 3 h. After removal of most of the solvents the residue was made alkaline with 5% aqueous sidium hydrogencarbonate and extracted with chloroform repeatedly. The resulting solution was washed with water, dried and evaporated to leave a crystalline residue, which was recrystallized from acetone-isopropyl ether (1 : 1) to yield **18** (439 mg), mp 176—179 °C. Recrystallization from the same solvent mixture afforded an analytical sample: mp 179—180 °C; $[\alpha]_D$ +5.0°; ORD, $[\Phi]_{318}^{trough}$ −4300°, $[\Phi]_{310}^{trough}$ −3500°, $[\Phi]_{273}^{peak}$ +6200°, a=−105°; IR, ν_{max} 3500, 3430, 1691 and 1035 cm^{-1}; NMR, δ 0.75 (3H, s, 19-C$\underline{H}_3$), 0.97 (3H, d J=6.5 Hz, 18-C$\underline{H}_3$) and 3.52 (1H, br, $\underline{H}$ at C_3). Found: C, 78.39; H, 10.34%. Calcd for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%.

Compound **18** (206 mg) was treated with Ac_2O (1 ml) and Py (2 ml) at room temp for 5 h, and the mixture was mixed with water under cooling and extracted with ether repeatedly. The ether solution gave a crystalline residue, which was recrystallized from isopropyl ether to yield **18a** (207 mg), mp 132—134 °C. This was recrystallized from the solvent for analysis: mp 134.5—135 °C; $[\alpha]_D$ −1.84°; ORD, $[\Phi]_{318}^{trough}$ −4900°, $[\Phi]_{309}^{trough}$ −4200°; $[\Phi]_{274}^{peak}$ +5600°, a=−105°; IR, ν_{max} 1736, 1702, 1244 and 1024 cm^{-1}; NMR, δ 0.78 (3H, s, 19-C$\underline{H}_3$), 0.99 (3H, d J=6.5 Hz, 18-C$\underline{H}_3$), 1.99 (3H, s, OCOC$\underline{H}_3$) and 4.68 (1H, br, $\underline{H}$ at C_3). Found: C, 75.92; H, 9.66%. Calcd for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%.

*17-Ethylidene-5α,12β-etiojervan-3β-ol (**19**) and Its 3-Acetate (**19a**).* The Wittig reaction of **18** was conducted in practically the same manner as that of **9**. To a red-brown solution, prepared from sodium hydride (313 mg, *ca.* 50% in oil) and ethyltriphenylphosphonium bromide (2.137 g, 5.76 mmol) in DMSO (14 ml), was added **18** (412 mg, 1.42 mmol) in THF (5.5 ml) at room temp during 2 min under stirring in a stream of nitrogen, and the mixture was stirred at room temp for 20 min and then at 50 °C (bath temp) for 22 h under nitrogen. The reaction mixture gave an amorphous residue (1.983 g) after usual work up, which was submitted to column chromatography over alumina (Merck, acidic 25 g, 20.5 cm in length and 1.6 cm in diameter), using hexane as solvent, to remove triphenylphosphine oxide. Fractions eluted with hexane-benzene (1 : 2, 150 ml), benzene (600 ml), benzene-ether (1 : 1. 800 ml) and ether (750 ml) were collected, evaporated and purified by preparative TLC (21 plates), using a 1 : 2 mixture of ether and

benzene. The main fraction was extracted with acetone and, after evaporation, dissolved in chloroform. The chloroform solution was worked up as usual to leave an oily mixture (**19**, 413 mg); IR, ($CHCl_3$), ν_{max} 3420 and 1027 cm^{-1}; NMR, δ 0.73 and 0.76 (total 3H, each s, intensity ratio 4 : 3, 19-CH_3), 0.95 (3H, d J=6 Hz, 18-CH_3), 1.60 (3H, d J=6 Hz, 21-CH_3), 3.56 (1H, br, H at C_3) and 5.15 (1H, q J=6 Hz, H at C_{20}).

The mixture (**19**, 410 mg) was treated with Ac_2O (2 ml) and Py (4 ml) at room temp for 12 h; it afforded the acetates (**19a**, 385 mg), amorphous, showing only a single spot on TLC; IR (film), ν_{max} 1738, 1241 and 1026 cm^{-1}; NMR, δ 0.74 and 0.77 (total 3H, each s, intensity ratio 4 : 3 19-CH_3), 0.97 (3H, d J=6.5 Hz, 18-CH_3), 1.58 (3H, d J=7.5 Hz, 21-CH_3), 2.00 (3H, s, $OCOCH_3$), 4.67 (1H, br, H at C_3) and 5.15 (1H, q J=7.5 Hz, H at C_{20}).

Hydrogenation of ***19***. A solution of **19** (315 mg) in AcOH (14 ml) was hydrogenated over Adams Pt (109 mg) at room temp for 40 min, when 25 ml (1 mol) of hydrogen had been consumed. After usual work up the reaction mixture gave a gelatinous substance, which was purified by preparative TLC (18 plates) with a 1 : 2 mixture of ether and benzene. The main fraction gave an oily substance (294 mg), showing a single spot, which exhibited an NMR spectrum superimposable over that of **13** and crystallized partially on standing in hexane. The crystalline material thus obtained amounted to 21 mg, had mp 83—88 °C (*cf.*, **13**, mp 124—125 °C) and showed an IR spectrum almost the same as that of **13**. The hydrogenation product would be a mixture of **13** and its 17-epimer but resisted further purification.

*17β-Acetyl-5α,12β-etiojervan-3β-ol 3-Acetate (**20**) and Its 17α-Isomer (**21**).* a) Diborane was generated by addition of boron trifluoride etherate (4 ml) in diglyme (22 ml) to excess of sodium borohydride (NBH) in diglyme, and was passed through a solution of **19a** (1.258 g) in ether (65 ml) at room temp during 25 min under stirring in a stream of nitrogen, and the resulting solution was stirred at room temp for 45 min and then heated at 70—80°C for 1 h. To the solution was added water (10 ml) and then an aqueous solution (25 ml) containing sodium dichromate (5.0 g as dihydrate) and conc sulfuric acid (3.7 ml) during 10 min under stirring and cooling with an ice-bath, and the whole mixture (two layers) was further stirred at room temp for 18 h. The aqueous layer was shaken with ether, and the ether and diglyme solutions were combined, washed with 5% aqueous sodium hydrogencarbonate repeatedly and then with saturated brine, dried and evaporated to leave amorphous residue (1.241 g), showing absorption maxima at 3435, 1735 and 1717 cm^{-1} in the IR spectrum (neat), wihch gave four spots on TLC and was separated by column chromatography with silica gel (Mallinckrodt, 26 g) with benzene.

The first fraction (115 mg) showing the largest R_f value proved to be the unreacted starting material (**19a**). The second fraction yielded crystalline substances (**20**, 269 mg), mp 189—190.5 °C. The third fraction yielded oily substances (226 mg). The fourth (389 mg) with the least R_f value was again dissolved in ether (6 ml), oxidized with the acidic chromate solution (6 ml) for 14 h and separated by preparative TLC (20 plates) with benzene. Each fraction was detected with iodine, eluted with acetone and, after evaporation, dissolved in chloroform and the chloroform solution was washed with 5% aqueous sodium hydrogencarbonate and water, treated with active carbon to remove iodine, dried and evaporated. The first fraction yielded crystalline substances (**20**, 80 mg), but the second fraction, which would be boron adducts (241 mg), was not examined further. The crystalline substances were combined and recrystallized from methanol to yield an analytical sample of **20**, mp 189—191 °C; $[\alpha]_D$ +36.8°; ORD, $[\Phi]_{309}^{peak}$ +2700°; $[\Phi]_{289}$=0°, $[\Phi]_{252}^{trough}$ −2560°, a=+52.6°; Mass, *m/e* 360 (M^+); IR, ν_{max} 1729, 1709, 1253 and 1021 cm^{-1}; NMR, δ 0.77 (3H, s, 19-CH_3), 0.93 (3H, d J=6 Hz, 18-CH_3), 1.98 (3H, s, $OCOCH_3$), 2.09 (3H, s, 21-CH_3), 2.83 (1H, br W_H=11 Hz, H at C_{17}) and 4.70 (1H, br, H at C_3). Found: C, 76.64; H, 10.10%. Calcd for $C_{23}H_{36}O_3$: C, 76.62; H, 10.07%.

The oily substances (the third fraction, 226 mg) were triturated with aqueous methanol to yield the crystalline substances (**21**, 136 mg), mp 92—110 °C. Recrystallization from the same solvent afforded an analytical sample, mp 110.5—111 °C; $[\alpha]_D$ +24.3°; ORD, $[\Phi]_{322}^{trough}$ −2110°; $[\Phi]_{302}$=0°, $[\Phi]_{255}^{peak}$ +6050°; a=−81.6°; Mass *m/e* 360 (M^+); IR ($CHCl_3$), ν_{max} 1722, 1258 and 1027 cm^{-1}; NMR, δ 0.76 (3H, s, 19-CH_3), 0.81 (3H, d J=6 Hz, 18-CH_3), 1.99 (3H, s, $OCOCH_3$), 2.09 (3H, s, 21-CH_3) and 4.68 (1H, br, H at C_3). Found: C, 76.85; H, 10.03%. Calcd for $C_{23}H_{36}O_3$: C, 76.62; H, 10.07%.

b) A solution of **20** (25 mg) was refluxed with 1 M sodium methoxide in methanol (10 ml) for 25 h under nitrogen. After removal of the solvent *in vacuo* the residue was mixed with water and extracted with chloroform. The chloroform solution was washed with water, dried and evaporated to leave a crystalline substance (27 mg), which was treated with Ac_2O (0.5 ml) and Py (0.5 ml) at room temp for 16 h. The reaction mixture gave **21** (13 mg), mp 110.5—111 °C, after being worked up as usual, which was identical with the afore-mentioned sample **21** [IR ($CHCl_3$) and TLC]. The starting material (**20**) could not be detected by TLC.

*17β-Ethyl-5α,12β-etiojervane-3β,20α-diol 3-Acetate (**22**) and Its 20β-Isomer (**23**).* A solution of **20** (212 mg) in ethanol (30 ml) was treated with NBH (622 mg) at room temp for 16 h under stirring. After dropwise addition of AcOH (2.4 ml) under cooling with ice-bath during 15 min, the solution was evaporated below 30 °C *in vacuo*, and the residue was mixed with water and extracted with chloroform repeatedly. The chloroform solution gave amorphous material (232 mg), which was separated by preparative TLC (10 plates) with a 1 : 10 mixture of ether and benzene. The most mobile part (81 mg) crystallized on trituration with acetone-isopropyl ether to give **22** (77 mg), mp 149.5—150 °C. This was recrystallized from the same solvent mixture for analysis: mp 150—151 °C; $[\alpha]_D$ +48.7°; IR, ν_{max} 3520, 1725, 1267 and 1028 cm^{-1}; NMR, δ 0.76 (3H, s, 19-CH_3), 0.94 (3H, d J=5 Hz, 18-CH_3), 1.22 (3H, d J=6.5 Hz, 21-CH_3), 2.01 (3H, s, $OCOCH_3$), 4.07 (1H, br m W_H=10 Hz, H at C_{20}) and 4.67 (1H, br, H at C_3). Found: C, 76.17; H, 10.37%. Calcd for $C_{23}H_{38}O_3$: C, 76.19; H, 10.57%.

The middle part (96 mg) crystallized on trituration with hexane to give **23** (73 mg), mp 117—118 °C. Recrystallization from hexane afforded an analytical sample: mp 117—118 °C; $[\alpha]_D$ +44.8°; IR ν_{max} 3530, 1726, 1260 and 1031 cm^{-1}: NMR, δ 0.78 (3H, s, 19-CH_3), 1.04 (3H, d J=5 Hz, 18-CH_3), 1.21 (3H, d J=6 Hz, 21-CH_3), 2.02 (3H, s, $OCOCH_3$), 3.99 (1H, br m, W_H=16 Hz, H at C_{20}) and 4.70 (1H, br, H at C_3). Found: C, 76.43; H, 10.63%. Calcd for $C_{23}H_{38}O_3$: C, 76.19; H, 10.57%.

The least mobile part gave a crystalline substance (42 mg) which would be a mixture of 3-alcohols but was not further examined.

*17α-Ethyl-5α,12β-etiojervane-3β,20ξ-diol 3-Acetate (**24**).* A solution of **21** (62 mg) in ethanol (10 ml) was treated with NBH (209 mg) at room temp and the reduction was practically complete after 3 h (*cf.*, the same reduction of **22**).

The reaction mixture was worked up as mentioned above to leave an amorphous residue (61 mg), which was purified by preparative TLC (3 plates) with a 10 : 1 mixture of benzene and ether. The crystalline, main fraction (39 mg), which showed a single spot differing from those of **22** and **23**, was recrystallized from isopropyl ether-hexane to give **24** (13 mg), mp 115—118 °C; $[\alpha]_D$ +21.2°; IR, ν_{max} 3410, 1733, 1710 (shoulder), 1245 and 1040 cm^{-1}; NMR, δ 0.78 (3H, s, 19-C$\underline{H}_3$), 0.91 (3H?, d J=5 Hz, 18-C$\underline{H}_3$), 1.10 (3H?, t J=6 Hz, 21-C$\underline{H}_3$), 2.13 (3H, s, OCOC$\underline{H}_3$), 4.07 (1H, br m W_H=15 Hz, $\underline{H}$ at C_{20}) and 4.65 (1H, br, $\underline{H}$ at C_3). Found; C, 76.10; H, 10.41%. Calcd for $C_{23}H_{38}O_3$: C, 76.19; H, 10.57%.

Treatment of **22** *with* p-*Toluenesulfonyl Chloride.* To a solution of **22** (74 mg) in Py (1.2 ml) was added *p*-toluenesulfonyl chloride (168 mg) and the mixture was stirred at room temp for 42 h. Water was poured onto the mixture and the resulting suspension was extracted with ether. The extracts were worked up as usual to give a crystalline substance (76 mg), showing a single spot on TLC, which was triturated with methanol to give **25** (66 mg), mp 92—92.5 °C. This was recrystallized from methanol for analysis: mp 92—92.5 °C; $[\alpha]_D$ +55.4°; Mass, *m/e* 344 (M^+); IR, ν_{max} 1738, 1657 (w), 1237 and 1024 cm^{-1}; NMR, δ 0.77 (3H, s, 19-C$\underline{H}_3$), 0.99 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 1.66 (3H, d J=6 Hz, 21-C$\underline{H}_3$), 2.00 (3H, s, OCOC$\underline{H}_3$), 4.70 (1H, br W_H=24 Hz, $\underline{H}$ at C_3) and 5.15 (1H, q J=6 Hz, $\underline{H}$ at C_{20}). Found: C, 79.05; H, 10.26%. Calcd for $C_{23}H_{36}O_2$: C, 80.18; H, 10.53%.

*Reaction of 20-Tosylate (***23a***) of* **23** *with Lithium Aluminium Hydride (LAH).* A solution of **23** (67 mg) in Py (1 ml) was treated with *p*-toluenesulfonyl chloride (158 mg) at room temp for 42 h under stirring. The reaction mixture was worked up in the same manner as **22** and afforded oily tosylate (**23a**, 96 mg), which gave a single spot on TLC and showed absorption maxima at 1724, 1600, 1492, 1380, 1257, 1176, 1027 and 900 cm^{-1} in the IR spectrum ($CHCl_3$); NMR, δ 0.77 (3H, s, 19-C$\underline{H}_3$), 0.88 (3H, d J=7 Hz, 18-C$\underline{H}_3$), 1.31 (3H, d J=7 Hz, 21-C$\underline{H}_3$), 2.00 (3H, s, OCOC$\underline{H}_3$), 2.43 (3H, s, C$\underline{H}_3$C$_6$H$_4$) and 4.80 (2H, br, 2$\underline{H}$ at C_3 and C_{20}). This tosylate, without further purification, was refluxed with LAH (160 mg) in THF (15 ml) for 24 h and gave oily residue (75 mg) after usual work up, which showed two spots on TLC and was separated by preparative TLC (7 plates) with a 1 : 2 mixture of ether and benzene. The more mobile part (17 mg) gave an oily substance (**26**); NMR, δ 0.75 (3H, s, 19-C$\underline{H}_3$), 0.97 and 1.19 (each 3H d J=6 Hz, 2C$\underline{H}_3$ at C_{13} and C_{17a} or *vice versa*) and 3.68 (1H, br, $\underline{H}$ at C_3). The less mobile part (25 mg) crystallized on trituration with acetone-isopropyl ether to give **27** (8 mg), mp 182—185 °C. This was recrystallized from the same solvent mixture for analysis: mp 190—191 °C; $[\alpha]_D$ +46° (MeOH); IR, ν_{max} 3400, 3340, 1042 and 1030 cm^{-1}; NMR, δ 0.75 (3H, s, 19-C$\underline{H}_3$), 1.02 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 1.19 (3H, d J=6 Hz, 21-CH$_3$), 3.65 (1H, br, $\underline{H}$ at C_3) and 4.00 (1H, br m W_H=17 Hz, $\underline{H}$ at C_{20}).

*17β-Ethyl-5α,12β-etiojervane-3β,11α-diol (***28***) and Its Acetates (***28a—28c***).* To a refluxing solution of **2** (241 mg) in isopropyl alcohol (40 ml) were added sodium pellets (1.6 g) in small portions during 1 h, and the mixture was further refluxed for 1 h.[21] After being cooled the mixture was diluted with water (20 ml) and evaporated below 42 °C *in vacuo*. The residue was mixed with water and extracted with chloroform repeatedly. The chloroform solution gave oily substance (263 mg), which crystallized on trituration with acetone-isopropyl ether to yield **28** (160 mg), mp 145—146.5 °C. Recrystallization from acetone afforded an analytical sample: mp 158—161 °C; $[\alpha]_D$ +0.42°; IR, ν_{max} 3355, 3295 and 1041 cm^{-1}; NMR, δ 0.775 (3H, s, 19-C$\underline{H}_3$), 0.89 (3H?, t J=6 Hz, 21-C$\underline{H}_3$?), 0.98 (3H, J=6 Hz, 18-C$\underline{H}_3$), 3.65 (1H, br, $\underline{H}$ at C_3) and 4.00 (1H, br W_H=12 Hz, $\underline{H}$ at C_{11}). Found: C, 78.57; H, 11.30%. Calcd for $C_{21}H_{36}O_2$: C, 78.69; H, 11.32%.

Compound **28** (112 mg) was acetylated with Ac_2O (0.4 ml) and Py (1.2 ml) at 17 °C for 2 h. The product (133 mg) was separated into 4 fractions (oil 35 mg, amorphous 72 mg, oil 12 mg, and crystalline 22 mg) by preparative TLC (7 plates) with a 1 : 5 mixture of ether and benzene. The last fraction afforded the unreacted material (**28**, 12 mg), which had mp 176—177 °C and 158—160 °C on recrystallization from acetone-isopropyl ether and acetone, respectively. The first and third fractions proved to be 3,11-diacetate (**28b**) and 11-acetate (**28c**), respectively, on the basis of the IR and NMR spectra: **28b**; oil, IR ($CHCl_3$), ν_{max} 1726, 1255 and 1027 cm^{-1}; NMR δ 0.84 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 0.885 (3H, s, 19-C$\underline{H}_3$), 1.99 (6H, s, 2OCOC$\underline{H}_3$), 4.70 (1H, br, $\underline{H}$ at C_3) and 5.24 (1H, br W_H=12 Hz, $\underline{H}$ at C_{11}): **28c**; oil, IR ($CHCl_3$), ν_{max} 3600, 3400, 1727, 1253 and 1031 cm^{-1}; NMR, δ 0.84 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 0.875 (3H, s, 19-C$\underline{H}_3$), 1.98 (3H, s, OCOC$\underline{H}_3$), 3.65 (1H, br, $\underline{H}$ at C_3) and 5.28 (1H, br W_H=13 Hz, $\underline{H}$ at C_{11}).

The second, main fraction crystallized on trituration with isopropyl ether to give **28a**, which on recrystallization from the same solvent afforded a pure sample (40 mg), mp 128—129 °C; $[\alpha]_D$ +42.0°; IR, ν_{max} 3570, 1724, 1255 and 1031 cm^{-1}; NMR, δ 0.79 (3H, s, 19-C$\underline{H}_3$), 0.98 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 2.00 (3H, s, OCOC$\underline{H}_3$), 3.98 (1H, br W_H=11 Hz, $\underline{H}$ at C_{11}) and 4.68 (1H, br, $\underline{H}$ at C_3). Found: C, 76.16; H, 10.47%. Calcd for $C_{23}H_{38}O_3$: C, 76.19; H, 10.57%.

Attempted Hydride Reduction of **2**. a) A solution of **2** (51 mg) in dry THF (10 ml) was refluxed with NBH (30 mg) for 11.5 h and cooled. After addition of acetone (4 ml) the mixture was evaporated *in vacuo* and the residue was mixed with water and extracted with chloroform. The chloroform solution was washed with water, dried and evaporated to leave an amorphous substance, which crystallized on trituration with methanol, had mp 112—114 °C, and amounted to 32 mg. This was identified as the starting material **2** (IR, mixed mp and TLC).

b) A solution of **2** (51 mg) in THF (15 ml) was refluxed with LAH (260 mg) for 2.5 h under stirring. After addition of ice-water the mixture was acidified with 2 M hydrochloric acid (15 ml) and extracted with chloroform. The chloroform solution gave an oily substance (54 mg), which showed absorption maxima at 3615, 3440, 1728, 1031 and 1016 cm^{-1} in the IR spectrum. Treatment of **2** with the same reagent under more vigorous conditions (reflux in dry dioxane for 13 h) gave practically the same result.

*17β-Ethyl-5α,12β-etiojervane-3β,11β-diol (***29***) and Its 3-Acetate (***29a***).* A solution **11** (263 mg) in dioxane (20 ml) was refluxed with LAH (513 mg) for 45 h under stirring. After decomposition of excess reagent with methanol and water, the resulting precipitate was removed by filtration and washed with methanol. The filtrate and washings were combined and concentrated to dryness under reduced pressure. The residue was dissolved in chloroform and worked up as usual to give a crystalline substance (250 mg), which on trituration with acetone afforded **29** (220 mg), mp 185—186 °C. This was recrystallized from acetone for analysis: mp 186—188 °C; $[\alpha]_D$ +52°; IR, ν_{max} 3330, 1077, 1043 and 1033 cm^{-1}; NMR, δ 1.02 (3H, s, 19-C$\underline{H}_3$), 3.60 (1H, br, $\underline{H}$ at C_3) and 4.06 (1H, do d J=6 and 8 Hz, $\underline{H}$ at C_{11}). Found: C, 78.75; H, 11.22%. Calcd for $C_{21}H_{36}O_2$: C,

78.69; H, 11.32%.

Compound **29** (207 mg) was acetylated with Ac_2O (1 ml) and Py (2 ml) at 18 °C for 3 h. The product (235 mg) was triturated with acetone–isopropyl ether to yield **29a** (115 mg), mp 149—151 °C. This was recrystallized from the same solvent mixture for analysis: mp 151—152 °C; $[\alpha]_D$ +44°; IR, ν_{max} 3490, 1713, 1260 and 1033 cm^{-1}; NMR δ 1.04 (3H, s, 19-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$) and 4.07 (1H, do d J=6 and 8 Hz, $\underline{H}$ at C_{11}). Found: C, 75.92; H, 10.30%. Calcd for $C_{23}H_{38}O_3$: C, 76.19; H, 10.57%.

*17β-Ethyl-5α-etiojerv-11-en-3β-ol Acetate (**30**).* To a solution of **28a** (101 mg) in freshly distilled Py (1 ml) was added freshly distilled phosphoryl chloride (0.1 ml) at 0 °C under stirring. A white salt was immediately precipitated. After being stirred at room temp for 1 h, the mixture was poured onto ice–water (30 ml). The resulting suspension was extracted with chloroform repeatedly. The extracts were washed with 1 M hydrochloric acid, 5% aqueous sodium hydrogencarbonate and water, dried, and evaporated to leave oily residue (111 mg), which showed a single spot on TLC and was chromatographed on silica gel (5 g) impregnated with 10% silver nitrate with benzene to afford pure oily substrance (**30**, 85 mg). Mass, *m/e* 344 (M^+), 315 ($M^+-C_2H_5$) and 255 ($M^+-C_2H_5-AcOH$); IR ($CHCl_3$), ν_{max} 1725, 1257 and 1022 cm^{-1}; NMR, δ 0.77 (3H, s, 19-C$\underline{H}_3$), 0.88 (3H, t J=7 Hz, 21-C$\underline{H}_3$), 1.02 (3H, d J=6 Hz, 18-C$\underline{H}_3$ 2.04 (3H, s, OCOC$\underline{H}_3$), 4.72 (1H, br, $\underline{H}$ at C_3) and 5.33 (1H, br s W_H=6 Hz, $\underline{H}$ at C_{11}).

A solution of **30** (6 mg) in AcOH (1 ml) was allowed to stand at room temp for 1 h. The mixture was diluted with water and extracted with chloroform. The extract was worked up as usual to give oily substance (6 mg), which was identical with the starting material substance (NMR and TLC).

*17β-Ethyl-5α,12β-etiojerv-9(11)-en-3β-ol Acetate (**31**).* To a solution of **29a** (192 mg) in freshly-distilled Py (2 ml) was added freshly-distilled phosphoryl chloride (0.3 ml) at 0 °C under stirring. The mixture was stirred at room temp for 1 h and poured onto ice–water (30 ml). After usual work up, the mixture afforded oily residue (235 mg), which was purified by column chromatography on silica gel (5 g) with benzene to give pure oily substance (**31**, 188 mg); Mass, *m/e* 344 (M^+), 329 (M^+-CH_3), 315 ($M^+-C_2H_5$), 284 (M^+-AcOH), 269 ($M^+-AcOH-CH_3$) and 255 ($M^+-AcOH-C_2H_5$); IR ($CHCl_3$), ν_{max} 1725, 1253 and 1024 cm^{-1}; NMR, δ 0.87 (3H, t J=8 Hz, 21-C$\underline{H}_3$), 0.92 (3H, s, 19-C$\underline{H}_3$), 0.98 (3H, d J=6.5 Hz, 18-C$\underline{H}_3$), 2.03 (3H, s, OCOC$\underline{H}_3$), 4.71 (1H, br, $\underline{H}$ at C_3) and 4.61 (1H, br s W_H= 6 Hz, $\underline{H}$ at C_{11}).

A solution of **31** (11 mg) in AcOH (1 ml) was stirred at room temp for 2 h. The mixture was worked up as usual to afford an oily residue (11 mg), which was identical with the starting material (NMR and TLC).

*17β-Ethyl-5α,12α-etiojervan-3β-ol Acetate (**32**).* A solution of compound **30** (76 mg) in AcOH (3.5 ml) was hydrogenated over Adams Pt (151 mg) at room temp for 55 min, when 5.9 ml of hydrogen (1.11 mol) had been consumed. The product (77 mg), oil, showed a single spot on TLC: $[\alpha]_D$ +0.5°; Mass, *m/e* 286 (M^+-AcOH, base); IR ($CHCl_3$), ν_{max} 1728, 1256 and 1025 cm^{-1}; NMR, δ 0.81 (3H, s, 19-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$) and 4.73 (1H, br, $\underline{H}$ at C_3).

*17β-Ethyl-5α,12β-etiojervan-3β-ol Acetate (**13a**).* A solution of compound **31** (171 mg) in AcOH (4 ml) was hydrogenated over Adams Pt (118 mg) at room temp for 35 min, when 8.8 ml of hydrogen (0.74 mol) had been consumed. The catalyst (101 mg) was further added to the reaction mixture and hydrogenation was continued for 30 min, when 24.4 ml of hydrogen had been taken up. The product (164 mg) crystallized on trituration with methanol, had mp 74—75 °C, and amounted to 125 mg. It was recrystallized twice from aqueous methanol and then from acetone to give a pure material, mp 92—94 °C, which was identical with compound **13a** in all respects.

(Received September 30, 1975)

The synthesis of C/D *trans*- and *cis*-fused C-nor-D-homoandrostan-3β-ol 3-acetates (**11a** and **34a**) from jervine (**1**) is described. The configurations of both the compounds and the synthetic intermediates are defined clearly on the basis of the chemical and spectral evidence.

As one of the continuing studies of C-nor-D-homosteroid hormones, we describe herein the transformation of jervine (**1**) into etiojervane analogs of androstan-3β-ol, which include both C/D *cis*- and *trans*-fused ring systems. This synthetic study has also been carried out with an aim to clarify the conformation of C and D rings of etiojervanes on the basis of the NMR and other spectra,[3] and the titled compounds will be useful as reference compounds for a series of these researches.[4,5]

The synthesis of C/D *trans*-fused C-nor-D-homoandrostan-3β-ol (**11**), and its derivatives started from 12β-etiojerv-5-en-3β-ol-11,17-dione 3-acetate[6,7] (**2**), prepared from jervine (**1**) *via* a five-step process. Treatment of **2** with sodium borohydride or with hydrogen over platinum in ethanol effected only reduction of the 17-oxo group to give a 30 : 1 or 2 : 1 mixture[8] of readily separable 17α- and 17β-alcohols (**3a** and **4a**), mp 208.5—209 °C and 173.5—174 °C, in which the hydroxy group at C_{17} was assigned α- and β-configurations, respectively, on the basis of signal patterns of the protons at C_{17}: **3a**, δ 3.08 and W_H=16 Hz; **4a**, δ 3.78 and W_H=6 Hz.[9] In fact, compound **3a** was transformed by the Wolff-Kishner reduction to a known compound, 12β-etiojerv-5-ene-3β,17α-diol[8] (**5**), in good yield. These alcohols, which on acetylation formed the respective 3,17-diacetates (**3b** and **4b**), mp 176—177 °C and 187—188 °C, were reconverted quantitatively into the original ketone (**2**) by oxidation, respectively, confirming the configurational retention at C_{12} and C_{13} during these reactions.

5

In order to remove the oxygen function at C_{17} and C_{11}, compound **3a** was converted into 17-tosylate (**3c**), mp 106—108 °C, which on treatment with lithium aluminium hydride afforded 3β, 11β-alcohol (**6**), mp 181—183 °C, in good yield. The chemical shift (δ 1.26) of 19-methyl protons in **6** was consistent with the assigned β-configuration to the 11-hydroxy group. Hydrogenation of **6** over platinum in acetic acid gave its 5α,6-dihydro derivative (**7**), mp 148—150 °C, in 83% yield, which was also obtained by the Wolff-Kishner reduction of a well-defined compound **8**,[1] indicative of the retention at C_{12} during the hydride reduction. This glycol **7**, on partial acetylation followed by oxidation with chromic anhydride, produced 11-ketone (**9**), mp 114—114.5 °C, in 70% yield. The transformation of **6** to **9** by the reverse process proceeded in almost the same yield; step 1, partial acetylation of **6** followed by oxidation to Δ^5-11-ketone (**10**), mp 156—157 °C, 69%, and step 2, hydrogenation of **10** to **9**, 76%.

Reduction of 11-ketone **9** by a modification[10] of the Wolff-Kishner reaction produced an aimed compound, 5α,12β-etiojervan-3β-ol (**11**), mp 119—120 °C, in 62% yield, which on acetylation formed 3-acetate (**11a**), mp 72.5—73.5 °C. The β-configuration at C_{12} of this compound (**11**) was determined in an unambiguous manner described below. 5α,12β-Etiojervan-3β-ol-17-one 3-acetate[1] (**12**) with the established configurations at C_{12} and C_{13} was treated with sodium borohydride to give a mixture of 17-alcohols, from which 17α- and 17β-alcohols (**13** and **14**), mp 119—119.5 °C and 96—96.5 °C, were isolated by preparative TLC in 75 and 24% yields, respectively. Treatment of **13** with *p*-toluenesulfonyl chloride followed by reduction with lithium aluminium hydride resulted in formation

of 3-alcohol, mp 118—119 °C, with a small amount of 3β,17α-glycol[8] (**13a**), mp 166—168 °C. The former was completely identical with compound **11** in all respects.

5α,12α-Etiojervan-3β-ol-11-one 3-acetate (**25**), a 12-epimer of **9**, was synthesized as described below. Treatment of etiojerva-5,12-dien-3β-ol-11,17-dione 3-acetate[6b,7] (**15**) with sodium borohydride in methanol led to only reduction of the 17-oxo group to give a mixture of 17α- and 17β-alcohols (**16** and **17**), mp 170—171 °C and 236—238 °C, which were isolated in 78 and 5% yields, respectively. The configurations at C_{17} of these alcohols were decided on the basis of signal patterns of the protons at C_{17} (**16**, δ 4.20 with W_H of 20 Hz, and **17**, δ 4.06 with W_H of 7 Hz) and optical rotations (**16**, $[\alpha]_D$=−128 °C, and **17**, $[\alpha]_D$=−211°). The assigned configurations were in good accord with the fact that the allylic equatorial proton in cyclohexene systems is more shielded than the corresponding axial,[11] and also with the Mills rule.[12]

Hydrogenation of compound **16** over Adams platinum in acetic acid produced four stereoisomeric tetrahydro derivatives (**18**—**21**), mp 154—156 °C, 178.5—179 °C, 141—142 °C, and 132—133 °C, in 22, 27, 16, and 25% yields, respectively. The configuration of each product was deduced as described below. Compound **18**, when treated with sodium methoxide in refluxing methanol for 24 h, gave 3,17-alcohol (**18a**), mp 174.5—175 °C, which formed 3,17-diacetate (**18b**), mp 174.5—175 °C. This diacetate (**18b**) was also derived by direct acetylation of monoacetate **18**, indicating that the compound (**18**) was stable under the alkaline conditions. Moreover, glycol **18a** was also obtained by hydrogenation of compound **3** with established configurations in 54% yield. This fact, as coupled with the spectral data (a broad signal at δ 4.65 with W_H of 23 Hz due to the proton at C_3, and a negative Cotton effect with a=−160°,[13]), indicated that compound **18** possessed 5αH, 12βH, 13αH and 17βH configurations. Compound **19** was determined to be a 5-epimer of **18** on the basis of the spectral data: NMR, δ 0.97 (3H, s, 19-C$\underline{H}_3$), 1.27 (3H, d J=6 Hz, 18-C$\underline{H}_3$), and 5.01 (1H, br s W_H=6 Hz, $\underline{H}$ at C_3); ORD, a negative Cotton effect, a=−145°. On the other hand, compound **20** was found to be a 12-epimer of **18** on the following evidence. While compound **20** gave 3,17-diacetate (**20a**), mp 106—109 °C, it was epimerized at C_{12} by treatment with alkali under the same conditions as **18** to give glycol having mp 172—173 °C, quantitatively, which was identical with the afore-mentioned glycol (**18a**) in all respects. These results led to assignment of 5αH, 12αH, 13αH and 17βH configurations to **20**, which was supported by the NMR (19-C$\underline{H}_3$, **20** δ 0.88 and **18** δ 0.84) and ORD spectra (a negative Cotton effect, a=−83°).[13] Finally, the configurations of compound **21** were assigned as shown in the formula (5βH, 12αH, 13αH and 17βH) on the spectral data: NMR, δ 0.88 (3H, d J=7.5 Hz, 18-C$\underline{H}_3$), 1.01 (3H, s, 19-C$\underline{H}_3$), and 5.01 (1H, br s W_H=6 Hz, $\underline{H}$ at C_3); ORD, a negative Cotton effect, a=−77°. As reported previously,[13] hydrogenation of jervine (**1**) under the same conditions as **16** led to formation of C/D *trans*- and *cis*-fused tetrahydro derivatives with α-oriented hydrogens at C_5. The present result was of interest as compared with the hydrogenation result of jervine, because compounds **19** and **21** with β-hydrogens at C_5 were produced in better yields than those **18** and **20** with α-hydrogens at C_5.

5α,12α-Etiojervane-3β,17α-diol-11-one 3-acetate (**20**) was then treated with *p*-toluenesulfonyl chloride in pyridine, and the resulting 17-tosylate (**20b**), amorphous, was refluxed with lithium aluminium hydride in ether to give a single product (**22**), mp 213—214 °C, in 59% yiels from **20**. Contrary to the expectation that the oxygen function at C_{17} would be removed by these reactions, compound **22** had a molecular formula of $C_{19}H_{30}O_2$ and resisted hydrogenation over platinum in acetic acid. The IR spectrum showed the presence of both hydroxy and ether groups at 3405, 1150, 1075, 1060 and 1028 cm^{-1} and the NMR spectrum revealed the existence of three protons on carbon atoms bearing the oxygen functions at δ 3.55 (br W_H=19 Hz, $\underline{H}$ at C_3), 3.90 and 4.31 (each 1H, br s W_H=7 and 5 Hz, 2$\underline{H}$ at C_{17} and C_{11} or *vice versa*). Acetylation of **22** with acetic anhydride in pyridine afforded only monoacetate (**22a**), mp 123—125 °C, which exhibited no hydroxy group in the IR spectrum. All these results indicated this compound to be represented by formula

22. Likewise, the 5β-isomer (**21**) was treated in the same manner as **20** to give 17-tosylate (**21a**), mp 120—121 °C, which was submitted to the hydride reduction to yield the corresponding ether compound (**23**), mp 153—154 °C, in moderate yield (crude 89%, pure 24%). Compound **23** also had the same molecular formula, $C_{19}H_{30}O_2$, as **22**, and formed monoacetate (**23a**), mp 128—130 °C, showing the absence of a hydroxy group in the IR spectrum.

In order to remove the oxygen function at C_{17}, compound **20** was treated with phosphoryl chloride in pyridine to give olefin (**24**), mp 77—78 °C, in 56% yield, as an only isolable product. The assigned structure with a double bond at C_{16} and C_{17} was deduced from the NMR spectrum; δ 5.84 (2H, t J=5.5 Hz). Hydrogenation of **24** over platinum in acetic acid afforded quantitatively 12α-etiojervan-3β-ol-11-one 3-acetate (**25**), amorphous, which showed a negative Cotton effect of a=—70° in the ORD curve, indicating the configurational retention at C_{12} during the aforementioned reactions. It is to be emphasized that the 19-methyl protons (δ 0.89) of **25** were deshielded 0.04 ppm more than those (δ 0.85) of the corresponding C/D *trans*-fused compound (**9**),[14] and the same difference in chemical shift was observed between the respective 17β-ethyl derivatives.[1] Compound **25**, when treated with alkali in refluxing methanol and then acetylated, gave a quantitative yield of crystalline substance having mp 109—110 °C. This compound was identical with compound **9** in all respects, confirming the 12αH configuration of **25**.

Compound **21** was also treated in the same manner as **20** to give 16,17-olefin (**26**), mp 150—152 °C, in 69% yield, which on hydrogenation produced 5β,12α-etiojervan-3β-ol-11-one 3-acetate (**27**), mp 110—110.5 °C, in 70% yield. Treatment of these 12α-etiojervanes (**26** and **27**) with sodium methoxide in methanol under reflux followed by acetylation effected epimerization at C_{12} to give the corresponding C/D *trans*-fused (12βH) etiojervanes (**28** and **29**), mp 119.5—121 °C and 106—107.5 °C, in quantitative yields, respectively. As expected, the 19-methyl protons of the 12α-epimers (**26** and **27**) were deshielded slightly but definitely (0.02—0.04 ppm) as compared with those of the respective 12β-epimers.

28 Δ^{16}
29 no Δ^{16}

The synthesis of 5α,12α-etiojervan-3β-ol 3-acetate (**34a**), a 12-epimer of compound **11a**, started from 17α-acetyl-5α,12α-etiojervan-3β-ol[4,15] (**30**). The Baeyer-Villiger oxidation of **30** with perbenzoic acid afforded 17-acetate (**31**), amorphous, which on oxidation and subsequent hydrolysis of the resulting 3-ketone (**32**), amorphous, gave 17-hydroxy-3-ketone (**32a**), mp 145—147 °C, in 35% yield from **30**. This compound (**32a**), when oxidized with Jones' reagent, was converted into 3,17-diketone (**33**), mp 173—175 °C, which was identical with the known sample,[16] confirming the 12αH and 13αH configurations of **32a**. This keto-alcohol (**32a**) was transformed smoothly into 17-tosylate (**32b**), amorphous, which on reduction with lithium aluminium hydride in refluxing ether gave rise to the 17-deoxy derivative (**34**), mp 122—124 °C, in 48.5% yield from **32a**. The β-configuration was assigned to the hydroxy group at C_3 on the basis of the NMR spectrum; δ 3.60 (1H, br W_H=20 Hz,

H at C_3). Hence compound **34**, which readily formed 3-acetate (**34a**), mp 97—97.5 °C, was identified as 5α,12α-etiojervan-3β-ol, because the transformation from **30** to **34** involved no epimerization at all asymmetric centers other than C_3. The 19-methyl protons of these C/D *cis*-fused etiojervanes (**34** and **34a**) were observed at lower fields (δ 0.80 and 0.81) than those (δ 0.75 and 0.75) of the corresponding C/D *trans*-fused (**11** and **11a**). These chemical shift differences of 19-methyl protons will be discussed with those of 18-methyl protons in the following paper.[3]

Experimental

All the melting points were uncorrected. The homogeneity of each compound was always checked by TLC over silica gel (Wakogel B-5), using various solvent systems, and the spots were developed with ceric sulfate in dil sulfuric acid and/or iodine. The optical rotations, ORD curves and IR spectra were measured in chloroform, dioxane and Nujol, respectively, unless otherwise stated. The NMR spectra were obtained in deuteriochloroform at 60 and/or 100 MHz, and the chemical shifts were given in δ-values, TMS being used as an internal reference. The abbreviations "s, d, t, q, br, m, and do" in the NMR spectra denote "singlet, doublet, triplet, quartet, broad, multiplet, and double," respectively.

*12β-Etiojerv-5-ene-3β,17α-diol-11-one (**3**), 12β-Etiojerv-5-ene-3β,17β-diol-11-one (**4**), and Their Derivatives (**3a—3c**, **4a** and **4b**).* a) A solution of 12β-etiojerv-5-en-3β-ol-11,17-dione 3-acetate[6,7] (**2**, 344 mg) in ethanol (32 ml) was hydrogenated over Adams platinum (Pt, 181 mg as $PtO_2 \cdot H_2O$) at room temperature (temp), when 24 ml (1.1 mol) of hydrogen had been consumed for 1 h. The amorphous product (397 mg) showed two main and two minor spots on TLC, the latter two (total 40 mg) being not examined further. The two major components were separated by preparative TLC (16 plates) with a 2 : 3 mixture of ether and benzene. More mobile fractions gave crystalline substance (90 mg), which on recrystallization from acetone-isopropyl ether afforded 17β-alcohol (**4a**, 72 mg), mp 172—173 °C. This was recrystallized twice from the same solvent mixture for analysis: mp 173.5—174 °C; $[\alpha]_D$ −169°; ORD, $[\Phi]_{332}^{trough}$ −10,000°, $[\Phi]_{321}^{trough}$ −6600°, $[\Phi]_{291}^{peak}$ +5800°, a=−158°; IR ν_{max} 3590, 1723, 1244, and 1038 cm^{-1}; NMR δ 1.03 (3H, s, 19-C$\underline{H}_3$), 1.29 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), 3.78 (1H, br s W_H=6 Hz, H at C_{17}), 4.50 (1H, br, H at C_3), and 5.43 (1H, br d J=4 Hz, H at C_6). Found: C, 72.83; H, 8.64%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%.

Less mobile fractions gave crystalline material (219 mg), which on trituration with acetone-isopropyl ether afforded 17α-alcohol (**3a**, 158 mg), mp 208—209 °C. This was recrystallized twice from the same solvent mixture for analysis: mp 208—209 °C; $[\alpha]_D$ −173.6°; ORD, $[\Phi]_{334}^{trough}$ −12900°, $[\Phi]_{332}^{trough}$ −8800°, $[\Phi]_{292}^{peak}$ +5500°, a=−184°; IR, ν_{max} 3340, 1733, 1247, and 1040 cm^{-1}; NMR δ 1.03 (3H, s, 19-C$\underline{H}_3$), 1.32 (3H, d J=4 Hz, 18-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), 3.08 (1H, br m W_H=16 Hz, H at C_{17}), 4.56 (1H, br, H at C_3), and 5.39 (1H, br d J=5 Hz, H at C_6). Found: C, 72.74; H, 8.74%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%.

Compound **3a** (54 mg) was treated with acetic anhydride (Ac_2O, 1 ml) and pyridine (Py, 1 ml) at room temp overnight and gave **3b** (50 mg), mp 176—177 °C, on trituration with acetone-isopropyl ether. This was recrystallized from the same solvent mixture for analysis: mp 176—177 °C; $[\alpha]_D$ −168.2°; IR, ν_{max} 1733, 1723, 1649, and 1242 cm^{-1}; NMR, δ 1.04 (3H, s, 19-C$\underline{H}_3$), 1.21 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 2.02 and 2.04 (each 3H, s, 2OCOC$\underline{H}_3$), 4.49 (2H, br m, 2H at C_3 and C_{17}), and 5.43 (1H, br d J=4 Hz, H at C_6). Found: C, 70.99; H, 8.22%. Calcd for $C_{22}H_{32}O_5$: C, 71.10; H, 8.30%.

Compound **3a** (53 mg) was refluxed with 1 M sodium methoxide in methanol (5.3 ml) for 2 h under a stream of nitrogen. The solvent was evaporated *in vacuo* and the residue was diluted with water and extracted with chloroform, repeatedly. The chloroform solution was washed with water, dried and evaporated to leave crystalline residue (66 mg). The residue showed a single spot on TLC and was triturated with acetone to give **3** (35.5 mg), mp 209—212 °C. Recrystallization from the same solvent afforded an analytical sample, mp 212.5—213 °C; $[\alpha]_D$ −158.2° (MeOH); ORD, $[\Phi]_{333}^{trough}$ −11000°, $[\Phi]_{321}^{trough}$ −7360°, $[\Phi]_{291}^{peak}$ +5700°, a=−167°; IR, ν_{max} 3510, 3310, 3230, 1731, and 1044 cm^{-1}. Found: C, 75.00; H, 9.31%. Calcd for $C_{19}H_{28}O_3$: C, 74.96; H, 9.27%.

Compound **3** (18 mg) was treated with Ac_2O (1 ml) and Py (1 ml) at room temp overnight and gave **3b** (12 mg), mp 175—176 °C, on recrystallization from acetone-isopropyl ether. This sample was identical with the afore-mentioned **3b** (mixed mp, IR and TLC).

A solution of **3a** (708 mg) in Py (10 ml) containing *p*-toluene-sulfonyl chloride (TsCl, 413 mg) was stirred at room temp for 18 h. After further addition of the chloride (534 mg) the whole mixture was allowed to stand at room temp for additional 24 h and poured into ice-water. The resulting precipitates crystallized on trituration with ether-isopropyl ether, had mp 88—90 °C (dec) and amounted to 988 mg. Recrystallization from ether afforded an analytical sample of **3c**, mp 106—108 °C (dec); $[\alpha]_D$ −109.4°; IR, ν_{max} 1733, 1598, 1249, 1190, and 1180 cm^{-1}; NMR, δ 1.03 (3H, s, 19-C$\underline{H}_3$), 1.16 (3H, d J=4.5 Hz, 18-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), 2.44 (3H, s, $C_6H_4C\underline{H}_3$), 4.00 (1H, br, H at

C_{17}), 4.55 (1H, br, H at C_3), and 5.38 (1H, br d J=5 Hz, H at C_6). Found: C, 67.20; H, 7.27, S, 5.78%. Calcd for $C_{28}H_{36}O_6S$: C, 67.18; H, 7.25; S, 6.40%.

Compound **4a** (53 mg) was acetylated in the same manner as mentioned above and afforded **4b** (40 mg), mp 186—187 °C, on trituration with acetone–isopropyl ether. This was recrystallized from the same solvent mixture for analysis: mp 187—188 °C; $[\alpha]_D$ −111.6°; IR, ν_{max} 1734, 1723, 1651, and 1242 cm^{-1}; NMR, δ 1.06 (3H, s, 19-CH_3), 1.20 (3H, d J=5 Hz, 18-CH_3), 2.01 and 2.06 (each 3H, s, 2OCOCH_3), 4.61 (1H, br, H at C_3), 4.99 (1H, br s W_H=6 Hz, H at C_{17}), and 5.44 (1H, br d J=5 Hz, H at C_6). Found C, 71.07; H, 8.32%. Calcd for $C_{22}H_{32}O_5$: C, 71.10; H, 8.30%.

A solution of **4a** (202 mg) was refluxed with 1 M sodium methoxide in methanol (20 ml) for 2 h under nitrogen. After removal of the solvent *in vacuo*, the residue was diluted with water and extracted with chloroform. The chloroform solution was washed with water, dried and evaporated to leave crystalline substance (227 mg), which showed two spots on TLC and crystallized on trituration with acetone–isopropyl ether. This substance (165 mg), mp 168—170 °C, showed a single spot on TLC, and was recrystallized from the same solvent mixture to give an analytical sample of **4**, mp 168—170 °C; ORD, $[\Phi]_{331}^{trough}$ −11060°, $[\Phi]_{319}^{trough}$ −6900°, $[\Phi]_{290}^{peak}$ +6700°, a=−177.6°; IR, ν_{max} 3220 and 1722 cm^{-1}; NMR, δ 1.03 (3H, s, 19-CH_3), 1.33 (3H, br s, 18-CH_3), 3.52 (1H, br, H at C_3), 3.79 (1H, br s W_H=7 Hz, H at C_{17}), and 5.38 (1H, br, H at C_6). Found: C, 75.07; H, 9.42%. Calcd for $C_{19}H_{28}O_3$: C, 74.96; H, 9.27%.

Compound **4** (20 mg) was treated with Ac_2O (1 ml) and Py (1 ml) at room temp overnight and gave its 3,17-diacetate (13 mg), mp 184—185 °C, on trituration with methanol. This compound was identical with the afore-mentioned sample (**4b**) in all respects.

b) To a solution of **2** (1.104 g) in methanol (130 ml) cooled at −7 °C (bath temp) was added sodium borohydride (NBH, 202 mg), and the mixture was stirred at the temp for 1 h. After addition of acetic acid (AcOH, 0.4 ml) the mixture was stirred at room temp for 15 min and concentrated below 30 °C *in vacuo*. The residue was diluted with water and extracted with chloroform repeatedly, and the chloroform solution was washed with 5% aqueous sodium bicarbonate and water, dried and evaporated to leave crystalline residue (1.23 g). Recrystallization from acetone afforded 17α-alcohol (**3a**, 786 mg), mp 206—207 °C, which was identical with the afore-mentioned sample (method a) in all respects.

The filtrate, obtained on recrystallization, was evaporated and separated into three fractions by preparative TLC (10 plates) with a 2 : 3 mixture of ether and benzene. The most mobile part gave amorphous substance (81 mg), which crystallized on trituration with isopropyl ether, had mp 171—173 °C and amounted to 27 mg. This compound was identified as 17β-alcohol (**4a**). Likewise, the middle part (104 mg) afforded **3a** (42 mg), mp 202—204 °C, on trituration with acetone. The least mobile part gave amorphous material (80 mg), which crystallized on trituration with isopropyl ether to give a new 17-alcohol (41 mg), mp 167—171 °C. Recrystallization from acetone–isopropyl ether afforded an analytical sample, mp 173—174 °C; $[\alpha]_D$ −217.1°; ORD, $[\Phi]_{328}^{trough}$ −12400°, $[\Phi]_{317}^{trough}$ −8600°, $[\Phi]_{289}^{peak}$ +5100°, a=−175°; IR, ν_{max} 3520, 1722, 1247, 1038 and 1026 cm^{-1}; NMR, δ 0.83 (3H, d J=7 Hz, 18-CH_3), 1.04 (3H, s, 19-CH_3), 2.02 (3H, s, OCOCH_3), 3.75 (1H, br W_H=16 Hz, H at C_{17}), 4.61 (1H, br, H at C_3), and 5.43 (1H, d J=5 Hz, H at C_6). Found: C, 72.79; H, 8.86%. Calcd for $C_{21}H_{30}O_4$: C, 72.80; H, 8.73%. The ORD curve and NMR spectrum of this alcohol indicated that this compound would be a 13-epimer of 17α-alcohol (**3a**) and formed from the corresponding 17-ketone included in the starting material as an impurity. This was supported by the spectral data of its 17-acetate described below.

Treatment of the alcohol (50 mg) with Ac_2O (1 ml) and Py (1 ml) at room temp overnight produced its 17-acetate (40 mg), mp 196—198 °C, after trituration with acetone–isopropyl ether. This was recrystallized from the same solvent mixture for analysis: mp 198—199 °C; $[\alpha]_D$ −163.4°; IR, ν_{max} 1734, 1652, 1253, and 1044 cm^{-1}; NMR, δ 0.84 (3H, d J=7 Hz, 18-CH_3), 1.04 (3H, s, 19-CH_3), 2.03 (6H, s, 2OCOCH_3), 4.70 (2H, br m, 2H at C_3 and C_{17}), and 5.43 (1H, br d J=4.5 Hz, H at C_6). Found: C, 71.07; H, 8.42%. Calcd for $C_{23}H_{32}O_5$: C, 71.10; H, 8.30%.

*Oxidation of **3a** and **4a** to **2**.* Compound **3a** (21 mg) was stirred with a complex prepared from chromic anhydride (CrO_3, 104 mg) and Py (1 ml) at room temp for 14 h. The mixture was diluted with water and extracted with ether, and the ether solution was washed with 1 M hydrochloric acid, 5% aqueous sodium bicarbonate and saturated brine, dried and evaporated to yield amorphous material (24 mg), which crystallized on trituration with isopropyl ether. Recrystallization from the solvent afforded **2** (13 mg), mp 170—171 °C, which was identical with an authentic sample in all respects.

Compound **4a** (25 mg) was treated in the same manner as mentioned above and gave **2** (13 mg), mp 172—173 °C.

*12β-Etiojerv-5-ene-3β,17α-diol (**5**).* To freshly distilled diethylene glycol (DEG, 15 ml) was added sodium (400 mg); the mixture was then heated for a while and cooled. To this solution was added anhydrous hydrazine (6.5 ml), and the mixture was stirred at room temp for a while. After addition of compound **3a** (201 mg), the whole mixture was heated under reflux for 24 h. The excess hydrazine was then removed by distillation and the mixture was again refluxed for additional 17 h. The cooled solution was poured into water (100 ml) and extracted with chloroform. The extracts were washed with 1 M hydrochloric acid, 5% aqueous sodium bicarbonate and water, dried and evaporated to leave oil (446 mg), which was purified by preparative TLC (9 plates) with a 3 : 7 mixture of ethyl acetate and benzene. Main fractions were extracted twice with methanol to give crystalline substance (122.5 mg). This was recrystallized from acetone to afford a pure sample of **5**, mp 180—182 °C, which was identical with an authentic sample[8] in all respects.

*12β-Etiojerv-5-ene-3β,11β-diol (**6**).* 17-Tosylate (**3c**, 921 mg) was treated with lithium aluminium hydride (LAH, 2.0 g) in refluxing tetrahydrofuran (THF, 150 ml) for 18 h under stirring and then cooled with ice–water. After careful addition of water to decompose excess of the hydride, the mixture was submitted to filtration, and the filtrate was evaporated below 30 °C *in vacuo* and then extracted with chloroform. The chloroform solution was worked up as usual to yield amorphous substance (498 mg), which crystallized on trituration with acetone to give **6** (431 mg), mp 180—181 °C. Recrystallization from acetone afforded an analytical sample, mp 181—183 °C; $[\alpha]_D$ −54.5°; IR, ν_{max} 3430 and 1058 cm^{-1}; MNR, δ 1.02 (3H, d J=4 Hz, 18-CH_3), 1.26 (3H, s, 19-CH_3), 3.54 (1H, br, H at C_3), 4.19 (1H, br, m, H at C_{11}), and 5.24 (1H, br s W_H = 9 Hz, H at C_6). Found: C, 78.38; H, 10.25%. Calcd for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%.

*5α,12β-Etiojervane-3β,11β-diol (**7**).* a) A solution of **6** (662 mg) in AcOH (30 ml) was hydrogenated over Adams Pt (205 mg) for 30 min, when 57 ml (1.1 mol) of hydrogen had been consumed. The reaction product (870 mg),

obtained on usual work up, crystallized on trituration with isopropyl ether to give **7** (557 mg), mp 148—150 °C, which showed a single spot. Recrystallization from acetone–isopropyl ether afforded an analytical sample, mp 148—150 °C; $[\alpha]_D$ +34.8°; IR, ν_{max} 3380, 1033, and 1024 cm^{-1}; NMR, δ 1.00 (3H, d J=7.5 Hz, 18-C$\underline{H}_3$), 1.03 (3H, s, 19-C$\underline{H}_3$), 3.52 (1H, br, $\underline{H}$ at C_3), and 4.04 (1H, br m, $\underline{H}$ at C_{11}). Found: C, 77.84; H, 11.10%. Calcd for $C_{19}H_{32}O_2$: C, 78.03; H, 11.03%.

b) To a solution of ethylene glycol (10 ml) containing potassium hydroxide (1.1 g) was added 80% hydrazine hydrate (1 ml) and the solution was refluxed for 10 min. To the cooled solution was added compound **8**[1] (74 mg), and the mixture was refluxed for 17 h. After removal of excess of the hydrazine by distillation for 4 h, the reaction mixture was cooled, poured into ice–water (100 ml), and extracted with chloroform. The chloroform extracts gave crystalline substance (90 mg), showing a single spot. Tirturation with acetone–isopropyl ether afforded **7** (55 mg), mp 137—141 °C, which was identical with the afore-mentioned sample (method a).

*5α,12β-Etiojervan-3β-ol-11-one 3-Acetate (**9**).* a) Compound **7** (503 mg) was treated with Ac_2O (2.5 ml) and Py (5 ml) at room temp for 3 h and then poured into ice–water. After being salted out the mixture was extracted with ether, and the ether solution was worked up as usual to yield amorphous residue (655 mg), showing a single spot, which was dissolved in Py (10 ml) and oxidized by careful addition of CrO_3 (1 g) under cooling during 2 min and subsequent stirring at room temp for 12 h. The mixture was dissolved in water (50 ml) under cooling and extracted with ether repeatedly. The ether solution was shaken with 2 M hydrochloric acid to remove the resulting insoluble material by filtration, washed again with 2 M hydrochloric acid, 5% aqueous sodium bicarbonate and saturated brine, dried and evaporated to leave amorphous residue (664 mg), which crystallized on trituration with hexane to give **9** (407 mg), mp 113.5—114 °C. This was recrystallized from hexane for analysis: mp 114—114.5 °C; $[\alpha]_D$ −89.6°; ORD, $[\Phi]_{334}^{trough}$ −9600°, $[\Phi]_{323}^{trough}$ −5400°, $[\Phi]_{293}^{peak}$ +7900°, a=−175°, IR, ν_{max} 1730, 1238, and 1031 cm^{-1}; NMR, δ 0.85 (3H, s, 19-C$\underline{H}_3$), 1.16 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 2.00 (3H, s, OCOC$\underline{H}_3$), and 4.69 (1H, br, $\underline{H}$ at C_3). Found C, 75.74; H, 9.63%. Calcd for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%.

b) A solution of compound **10** (382 mg), described later, in AcOH (18 ml) was hydrogenated over Adams Pt (204 mg) at room temp for 1 h, when 25 ml (1.1 mol) of hydrogen had been taken up. The reaction product (405 mg) crystallized on trituration with hexane, had mp 112—113 °C and amounted to 291 mg. Recrystallization from hexane afforded a pure sample of **9**, needles, mp 114—114.5 °C, which was identical with the afore-mentioned sample.

*12β-Etiojerv-5-en-3β-ol-11-one 3-Acetate (**10**).* Compound **6** (411 mg) was treated with Ac_2O (2 ml) and Py (4 ml) at room temp for 3 h, and the resulting crude acetate (517 mg), showing a single spot, was dissolved in Py (6 ml) and poured onto a complex, prepared from CrO_3 (1.05 g) and Py (10 ml), under cooling. The mixture was stirred at room temp for 20 h and, after addition of ethanol (20 ml), evaporated below 30 °C *in vacuo*. The residue was shaken with ether and water, and then filtered to remove insoluble material formed. The ether filtrate gave crystalline residue (516 mg), which was recrystallized from aqueous acetone to yield **10** (364 mg), mp 153—155 °C. Recrystallization from the same solvent afforded an analytical sample, mp 156—157 °C; $[\alpha]_D$ −162.9°; ORD, $[\Phi]_{334}^{trough}$ −12200°, $[\Phi]_{322}^{trough}$ −8300°, $[\Phi]_{292}^{peak}$ +5600°, a=−178°; IR, ν_{max} 1732, 1647, 1248, 1240, and 1043 cm^{-1}; NMR, δ 1.05 (3H, s, 19-C$\underline{H}_3$), 1.19 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), 4.57 (1H, br, $\underline{H}$ at C_3), and 5.39 (1H, br d J=5 Hz, $\underline{H}$ at C_6). Found: C, 76.46; H, 9.27%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%.

*5α,12β-Etiojervan-3β-ol (**11**) and Its 3-Acetate (**11a**).* a) To freshly distilled DEG (15 ml) was dissolved sodium (400 mg) by heating, and to the solution were added anhydrous hydrazine (8 ml) and **9** (193 mg). The solution was refluxed for 22 h and, after removal of the condenser, heated to 230 °C to remove excess of the hydrazine. A new condenser was set up and the solution was again refluxed at the temp for 22 h. After being cooled the solution was poured into water (100 ml) and extracted with chloroform. The chloroform solution gave oily substance, which was purified by preparative TLC (8 plates) with a 3 : 1 mixture of benzene and chloroform. The main fraction was extracted with acetone and, after evaporation, dissolved in chloroform. The chloroform solution was washed with 5% aqueous sodium bicarbonate and water, dried and evaporated to leave crystalline residue (118 mg), which on recrystallization from hexane afforded **11** (89 mg), mp 117.5—118 °C. Further recrystallization from hexane gave an analytical sample, mp 119—120 °C; $[\alpha]_D$ +54.2°; Mass, *m/e* 276 (M^+) and 258; IR, ν_{max} 3360, 3320, and 1033 cm^{-1}; NMR, δ 0.75 (3H, s, 19-C$\underline{H}_3$), 0.84 (3H, d J=5 Hz, 18-C$\underline{H}_3$), and 3.61 (1H, br, $\underline{H}$ at C_3). Found: C, 82.60; H, 11.72%. Calcd for $C_{19}H_{32}O$: C, 82.54; H, 11.66%.

Acetylation of **11** (62 mg) with Ac_2O (1 ml) and Py (1 ml) at room temp overnight gave **11a** (68 mg), mp 72—72.5 °C, on recrystallization from aqueous methanol. This was recrystallized from the same solvent mixture for analysis: mp 72.5—73.5 °C; $[\alpha]_D$ +40.5°; Mass, *m/e* 258 (M^+); IR, ν_{max} 1742, 1240, and 1029 cm^{-1}; NMR, δ 0.75 (3H, s, 19-C$\underline{H}_3$), 0.83 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 1.99 (3H, s, OCOC$\underline{H}_3$) and 4.74 (1H, br, $\underline{H}$ at C_3). Found: C, 79.12; H, 10.64%. Calcd for $C_{21}H_{34}O_2$: C, 79.19; H, 10.76%.

b) Compound **13** (50 mg), described later, was mixed with TsCl (54 mg) in Py (1 ml) under cooling with ice–water and stirring, and the mixture was continuously stirred at room temp for 42 h and then dissolved in chloroform. The chloroform solution, after being worked up as usual, yielded amorphous residue (84 mg), which gave only a single spot and showed absorption maxima at 1722, 1263, and 1174 cm^{-1} in the IR spectrum. This was then dissolved in dry THF (10 ml) and refluxed with LAH (288 mg) for 12 h. After careful addition of water to decompose the hydride, the mixture was extracted with ether repeatedly. The ether solution, on usual work up, gave amorphous residue (68 mg), showing two spots, which was separated by preparative TLC (2 plates) with benzene. The more mobile part (31 mg) crystallized on trituration with hexane to yield **11** (15 mg), mp 118—119 °C, which was identical with the afore-mentioned sample.

The less mobile part (18 mg) gave **13a** (7 mg), mp 166—168 °C, which was identical with an authentic sample of 5α,12β-etiojervane-3β,17α-diol.[8]

*5α,12β-Etiojervane-3β,17α-diol 3-Acetate (**13**) and 5α,12β-Etiojervane-3β,17β-diol 3-Acetate (**14**).* Compound **12**[1] (155 mg) was treated with NBH (74 mg) in methanol (15 ml) at 0 °C for 1 h under stirring. After addition of AcOH (0.2 ml) the mixture was stirred for 10 min, evaporated below 30 °C *in vacuo* and extracted with chloroform repeatedly. The chloroform solution gave amorphous material (173 mg), which was separated into two parts by preparative TLC (7 plates) with a 1 : 3 mixture of ether and benzene. The

more mobile part (38 mg) crystallized on trituration with hexane, had mp 94—94.5 °C and amounted to 10 mg. Recrystallization from hexane afforded an analytical sample of **14**, mp 96—96.5 °C; $[\alpha]_D$ +47.7°; IR, ν_{max} 3535, 3490, 1724, 1239, and 1036 cm^{-1}; NMR δ 0.76 (3H, s, 19-C$\underline{H}_3$), 0.94 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 1.98 (3H, s, OCOC$\underline{H}_3$), 3.78 (1H, br s W_H=5 Hz, $\underline{H}$ at C_{17}), and 4.69 (1H, br, $\underline{H}$ at C_3). Found: C, 75.59; H 10.25%. Calcd for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25%.

The less mobile part (117 mg) gave **13** (84 mg), mp 119—119.5 °C, on trituration with isopropyl ether. This was recrystallized from isopropyl ether for analysis: mp 119—119.5 °C; $[\alpha]_D$ +26.7°; IR, ν_{max} 3370, 1736, 1241, and 1032 cm^{-1}; NMR, δ 0.76 (3H, s, 19-C$\underline{H}_3$), 0.97 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 1.98 (3H, s, OCOC$\underline{H}_3$), 3.17 (1H, br m W_H=17 Hz, $\underline{H}$ at C_{17}), and 4.68 (1H, br, $\underline{H}$ at C_3). Found: C, 75.68; H, 10.11%. Calcd for $C_{21}H_{34}O_3$: C, 75.40; H, 10.25%.

*Etiojerva-5,12-diene-3β,17α-diol-11-one 3-Acetate (**16**) and Etiojerva-5,12-diene-3β,17β-diol-11-one 3-Acetate (**17**).* To a solution of **15**[6b,7] (2.01 g, mp 180—181 °C) in methanol (200 ml) was added NBH (400 mg) under stirring. After being stirred at room temp for 3 min, the yellow mixture became colorless, and to this mixture was added AcOH (1.5 ml) to decompose excess of the hydride. After being kept at room temp for 10 min, the mixture was concentrated below 35 °C *in vacuo*, and the resulting residue was diluted with water (100 ml) and extracted with chloroform. The chloroform solution, after being worked up as usual, left crystalline residue (2.05 g), which was separated into two parts by preparative TLC (43 plates) with a 1 : 2 mixture of ether and benzene. The more mobile part (143 mg) crystallized on trituration with acetone, had mp 236—237 °C and amounted to 133 mg. Recrystallization from acetone-isopropyl ether afforded an analytical sample of **17**, mp 236—238 °C; $[\alpha]_D$ −211.0°; IR, ν_{max} 3535, 1726, 1703, 1633, 1239, 1231, and 1041 cm^{-1}; NMR, δ 1.05 (3H, s, 19-C$\underline{H}_3$), 2.00 (3H, s, OCOC$\underline{H}_3$), 2.23 (3H, s, 18-C$\underline{H}_3$), 4.06 (1H, br s W_H=7 Hz, $\underline{H}$ at C_{17}), 4.58 (1H, br W_H=18 Hz, $\underline{H}$ at C_3), and 5.38 (1H, br s W_H=9 Hz, $\underline{H}$ at C_6). Found: C, 73.33; H, 8.23%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

The less mobile part (1.837 g) gave **16** (1.622 g), mp 170—171 °C, on trituration with acetone-isopropyl ether. This was recrystallized from the same solvent mixture for analysis: mp 170—171 °C; $[\alpha]_D$ −128.0°; IR, ν_{max} 3320, 1738, 1710, 1639, 1243, and 1045 cm^{-1}; NMR, δ 1.06 (3H, s, 19-C$\underline{H}_3$), 2.00 (3H, s, OCOC$\underline{H}_3$), 2.18 (3H, s, 18-C$\underline{H}_3$), 4.20 (1H, br W_H=20 Hz, $\underline{H}$ at C_{17}) 4.57 (1H, br W_H=20.5 Hz $\underline{H}$ at C_3), and 5.38 (1H, br s W_H=8.5 Hz, $\underline{H}$ at C_6). Found: C, 73.24; H, 8.26%. Calcd for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

*Hydrogenation of **16**.* A solution of **16** (1.401 g) in AcOH (50 ml) was hydrogenated over Adams Pt (504 mg) in AcOH (10 ml) at room temp for 10 h, when 2.2 mol of hydrogen had been consumed. The reaction product (1.613 g), after being worked up as usual, showed four spots on TLC and was separated by preparative TLC (77 plates) with a 1 : 1 mixture of ether and benzene. The most mobile fraction, extracted with acetone, gave crystalline substance (306 mg), which on recrystallization from acetone-isopropyl ether afforded 5α,12β-etiojervane-3β,17α-diol-11-one 3-acetate (**18**, 155 mg), mp 154—156 °C. This was recrystallized from the same solvent mixture for analysis: mp 155—156 °C; $[\alpha]_D$ −74.6°; ORD, $[\Phi]_{333}^{trough}$ −8200°, $[\Phi]_{323}^{trough}$ −4500°, $[\Phi]_{292}^{peak}$ +7800°, a=−160°; IR, ν_{max} 3375, 1732, 1244, and 1034 cm^{-1}; NMR, δ 0.84 (3H, s, 19-C$\underline{H}_3$), 1.27 (3H, d J=5.5 Hz, 18-C$\underline{H}_3$), 1.98 (3H, s, OCOC$\underline{H}_3$), 3.11 (1H, br W_H=20.5 Hz, $\underline{H}$ at C_{17}), and 4.65 (1H, br W_H=23 Hz, $\underline{H}$ at C_3). Found: C, 72.27; H, 9.18%. Calcd for $C_{21}H_{32}O_4$: C, 72.38; H, 9.26%.

The second mobile fraction gave crystalline substance (390 mg), which on recrystallization from acetone-isopropyl ether afforded 5β,12β-etiojervane-3β,17α-diol-11-one 3-acetate (**19**, 312 mg), mp 177—178 °C. This was recrystallized from the same solvent mixture for analysis: mp 178.5—179 °C; $[\alpha]_D$ −80.6°; ORD, $[\Phi]_{331}^{trough}$ −7500°, $[\Phi]_{322}^{trough}$ −4700°, $[\Phi]_{289}^{peak}$ +6900°, a=−144°; IR, ν_{max} 3505, 1723, 1229, and 1045 cm^{-1}; NMR, δ 0.97 (3H, s, 19-C$\underline{H}_3$), 1.27 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), 3.06 (1H, br W_H=20.6 Hz, $\underline{H}$ at C_{17}), and 5.01 (1H, br s W_H=6 Hz, $\underline{H}$ at C_3). Found: C, 72.09; H, 9.26%. Calcd for $C_{21}H_{32}O_4$: C, 72.38, H, 9.26%.

The third fraction gave crystalline material (317 mg), which afforded 5α,12α-etiojervane-3β,17α-diol-11-one 3-acetate (**20**, 152 mg), mp 139.5—140.5 °C, on trituration with acetone-isopropyl ether. This was recrystallized from the same solvent mixture for analysis: mp 141—142 °C; $[\alpha]_D$ −10.1°; ORD, $[\Phi]_{331}^{trough}$ −3500°, $[\Phi]_{290}^{peak}$ +4800°, a=−83°; IR, ν_{max} 3505, 1729, 1240, and 1031 cm^{-1}; NMR, δ 0.88 (3H, s, 19-C$\underline{H}_3$), 0.89 (3H, d J=7 Hz, 18-C$\underline{H}_3$), 1.98 (3H, s, OCOC$\underline{H}_3$), 3.81 (1H, br s W_H=9 Hz, $\underline{H}$ at C_{17}), and 4.67 (1H, br W_H=20 Hz, $\underline{H}$ at C_3). Found: C, 72.77; H, 9.47%. Calcd for $C_{21}H_{32}O_4$: C, 72.38; H, 9.26%.

Compound **20** (18 mg) was acetylated with Ac_2O (0.2 ml) and Py (0.2 ml) at room temp for 38 h, and gave crystalline substance (21 mg), which showed a single spot on TLC and yielded **20a**, mp 106—109 °C, on trituration with isopropyl ether: NMR, δ 0.88 (3H, s, 19-C$\underline{H}_3$), 0.92 (3H, d J=7 Hz, 18-C$\underline{H}_3$), 2.00 (6H, s 2OCOC$\underline{H}_3$), 4.68 (1H, br W_H=26 Hz, $\underline{H}$ at C_3), and 4.80 (1H, br s W_H=10.5 Hz, $\underline{H}$ at C_{17}).

The least mobile fraction (393 mg) was triturated with acetone-isopropyl ether to give 5β,12α-etiojervane-3β-17α-diol-11-one 3-acetate (**21**, 237 mg), mp 130—132 °C. Recrystallization from the same solvent mixture afforded an analytical sample, mp 132—133 °C; $[\alpha]_D$ −17.4°; ORD, $[\Phi]_{330}^{trough}$ −3900°, $[\Phi]_{290}^{peak}$ +3800°, a=−77°; IR, ν_{max} 3530, 1731, 1240, and 1024 cm^{-1}; NMR, δ 0.88 (3H, d J=7.5 Hz, 18-C$\underline{H}_3$), 1.01 (3H, s, 19-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), 3.80 (1H, br s W_H=9.5 Hz, $\underline{H}$ at C_{17}), and (1H, br s W_H=6 Hz, $\underline{H}$ at C_3). Found: C, 72.46; H, 9.26%. Calcd for $C_{21}H_{32}O_4$: C, 72.38; H, 9.26%.

*5α,12β-Etiojervane-3β,17α-diol-11-one (**18a**) and Its 3,17-Diacetate (**18b**).* a) Compound **3** (95 mg) was dissolved in AcOH (6 ml) and hydrogenated over Adams Pt (60 mg) at room temp, when 1 mol of hydrogen had been taken up for 1 h. The resulting amorphous product (112 mg) was purified by preparative TLC (4 plates) with ether to give amorphous substance (84 mg), which on trituration with acetone-isopropyl ether crystallized, had mp 168—170 °C and amounted to 46 mg. This was recrystallized from the same solvent mixture to give **18a** in pure state, mp 175—176 °C; $[\alpha]_D$ −66.6°; IR, ν_{max} 3420, 1725, and 1029 cm^{-1}; NMR, δ 0.83 (3H, s, 19-C$\underline{H}_3$), 1.29 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 3.07 (1H, br W_H=18 Hz, $\underline{H}$ at C_{17}), and 3.60 (1H, br W_H=22 Hz, $\underline{H}$ at C_3). Found: C, 73.33; H, 10.02%. Calcd for $C_{19}H_{30}O_3 \cdot 0.5CH_3COCH_3$: C, 73.39; H, 9.92%.

Compound **18a** (32 mg) was treated with Ac_2O (0.2 ml) and Py (0.2 ml) at room temp overnight and gave **18b** (33 mg), mp 226—226.5 °C, on trituration with acetone-isopropyl ether. This was recrystallized from the same solvent mixture for analysis: mp 226—226.5 °C; IR, ν_{max} 1731, 1244, and 1025 cm^{-1}; NMR, δ 0.86 (3H, s, 19-C$\underline{H}_3$), 1.18 (3H, d

J=6 Hz, 18-CH_3), 1.99 and 2.02 (each 3H, s 2OCOCH_3), and 5.50 (2H, br m, 2H at C_3 and C_7). Found: C, 70.98; H, 8.78%. Calcd for $C_{23}H_{34}O_5$: C, 70.74; H, 8.78%.

b) A solution of **18** (50 mg) in methanol (10 ml) was refluxed with 1 M sodium methoxide under a stream of nitrogen. Ths solution was concentrated *in vacuo* and the resulting residue was diluted with water and then extracted with chloroform. The chloroform solution was washed with water, dried and evaporated to leave amorphous substance (60 mg), which showed a single spot on TLC and gave diol (36 mg), mp 174.5—175 °C, on trituration with acetone–isopropyl ether. This compound was identical with the afore-mentioned sample of **18a**.

Compound **18** (30 mg) was also treated with Ac_2O (0.5 ml) and Py (0.5 ml) at room temp overnight and gave its 17-acetyl derivative (32 mg), mp 225.5—226 °C, on trituration with acetone–isopropyl ether. This was identical with an authentic sample of **18b**, described in the section a.

c) A solution of compound **20** (22 mg) in methanol (10 ml) was refluxed with 1 M sodium methoxide under a stream of nitrogen for 24 h. The solution was worked up as usual to leave foamy residue (26.5 mg). This showed a single spot on TLC and was triturated with acetone–isopropyl ether to give crystalline substance (12 mg), mp 172—173 °C, which was identical with an authentic sample of **18a** in all respects.

*11β,17β-Oxido-5α,12α-etiojervan-3β-ol (**22**) and Its 3-Acetate (**22a**).* A solution of **20** (40 mg) in Py (1 ml) containing TsCl (102 mg) was stirred at room temp for 40 h and poured into ice–water, and then extracted with chloroform repeatedly. The chloroform solution was washed with 1 M hydrochloric acid, 5% aqueous sodium bicarbonate and water, dried and evaporated below 30 °C to leave 17-tosylate (**20b**, 56.5 mg), amorphous, which showed a single spot on TLC; IR ($CHCl_3$), ν_{max} 1730, 1600, 1492, 1253, 1177, and 1027 cm^{-1}; NMR, δ 0.79 (3H, d J=6 Hz, 18-CH_3), 0.87 (3H, s, 19-CH_3), 1.98 (3H, s, OCOCH_3), 2.42 (3H, s, $C_6H_4CH_3$), 4.55 (2H, br W_H=15 Hz, 2H at C_3 and C_{17}), and 7.30 and 7.75 (each 2H, d J=8 Hz, $C_6H_4CH_3$).

Tosylate **20b** (56.5 mg) was treated with LAH (170 mg) in refluxing ether (15 ml) for 5 h under stirring and then cooled with ice–water. After careful addition of water, the mixture was extracted with ether repeatedly. The ether solution gave crystalline material (41.5 mg), which showed practically a single spot and was purified by preparative TLC (2 plates) with a 2 : 1 mixture of ether and benzene. The main fraction, extracted with acetone, gave crystalline substance (19.5 mg), which on recrystallization from isopropyl ether afforded **22** (13 mg), mp 207—208 °C. Recrystallization from acetone–isopropyl ether yielded an analytical sample, mp 213—214 °C; $[\alpha]_D$ −18.5 °; IR, ν_{max} 3405, 1150, 1075, 1060, and 1028 cm^{-1}; NMR, δ 0.95 (3H, d J=6 Hz, 18-CH_3), 0.98 (3H, s, 19-CH_3), 3.55 (1H, br W_H=19 Hz, H at C_3), 3.90 and 4.31 (each 1H, br s W_H=7 and 5 Hz, 2H at C_{11} and C_{17} or *vice versa*). Found: C, 78.73; H, 10.42%. Calcd for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%.

Compound **22** (15 mg) was acetylated with Ac_2O (0.4 ml) and Py (0.4 ml) at room temp overnight to give **22a** (9 mg), mp 123—125 °C, on trituration with aqueous methanol: Mass, *m/e* 332 (M^+); IR, ν_{max} 1741, 1246, 1146, 1060, 1023, and 1005 cm^{-1}; NMR, δ 0.94 (3H, d J=6 Hz, 18-CH_3), 0.99 (3H, s, 19-CH_3), 1.99 (3H, s, OCOCH_3), 3.92 and 4.31 (each 1H, br s W_H=7 and 6 Hz, 2H at C_{11} and C_{17} or *vice versa*), and 4.68 (1H, br W_H=26 Hz, H at C_3).

*11β,17β-Oxide-5β,12α-etiojervan-3β-ol (**23**) and Its 3-Acetate (**23a**).* A solution of **21** (103 mg) in Py (1.5 ml) containing TsCl (204 mg) was stirred at room temp for 40 h and poured into ice–water and then extracted with chloroform repeatedly. The chloroform solution gave crystalline substance (185 mg), which showed a single spot and afforded 17-tosylate (**21a**, 130 mg) mp 120—121 °C, on trituration with isopropyl ether: IR, ν_{max} 1732, 1602, 1351, 1245, 1188, 1177, 1030, 1021, 840, and 819 cm^{-1}; NMR, δ 0.80 (3H, d J=7.5 Hz, 18-CH_3), 0.99 (3H, s, 19-CH_3), 2.03 (3H, s, $OCOCH_3$), 2.44 (3H, s, $C_6H_4CH_3$), 4.59 (1H, br s W_H=8.5 Hz, H at C_{17}), 5.04 (1H, br s W_H=7 Hz, H at C_3), and 2.65 and 2.21 (each 2H, d J=8 Hz, $C_6H_4CH_3$).

Tosylate **21a** (129 mg) was treated with LAH (238 mg) in refluxing ether (10 ml) for 4 h under stirring and then cooled with ice–water. After careful decomposition of excess of the hydride with water, the mixture was extracted with ether repeatedly. The ether solution gave crystalline substance (74 mg), which showed a single spot and afforded **23** (20 mg), mp 153—154 °C, on trituration with isopropyl ether: IR ($CHCl_3$), ν_{max} 3600, 3390, 1146, 1090, and 1003 cm^{-1}; NMR, δ 0.95 (3H, d J=7 Hz, 18-CH_3), 1.10 (3H, s, 19-CH_3), and 3.92, 4.04 and 4.30 (each 1H, br s W_H=8, 6 and 5 Hz, 3H at C_{11}, C_3 and C_{17} or *vice versa*).

Compound **23** (75 mg) was acetylated with Ac_2O (1 ml) in Py (1 ml) at room temp overnight and gave **23a** (70 mg), mp 121—123 °C, on trituration with aqueous methanol. Recrystallization from the same solvent mixture afforded an analytical sample, mp 128—130 °C; $[\alpha]_D$ −11.0°; Mass, *m/e* 332 (M^+); IR, ν_{max} 1741, 1247, 1096, and 1027 cm^{-1}; NMR, δ 0.96 (3H, d J=6.5 Hz, 18-CH_3), 1.11 (3H, s, 19-CH_3), 2.01 (3H, s, OCOCH_3), and 3.91, 4.33 and 5.04 (each 1H, br s W_H=7, 6 and 6 Hz, 3H at C_{11}, C_{17} and C_3 or *vice versa*). Found: C, 75.95; H, 9.66%. Calcd for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%.

*5α,12α-Etiojerv-16-en-3β-ol-11-one 3-Acetate (**24**).* A solution of **20** (77 mg) in dry Py (1.5 ml) was treated with phosphoryl chloride (0.3 ml) at room temp for 15.5 h. The mixture was poured into crushed ice and extracted with chloroform. The chloroform solution gave oily substance (61 mg), which was purified by preparative TLC with a 1 : 10 mixture of ether and benzene. The resulting oily residue (41 mg) was triturated into aqueous methanol to yield **24** (19 mg), mp 77—78 °C; $[\alpha]_D$ +53.7°; IR, ν_{max} 3010 (sh), 1735, 1722 (sh), 1640, 1240, 1027, and 695 cm^{-1}; NMR, δ 0.87 (3H, s, 19-CH_3), 0.92 (3H, d J=6.5 Hz, 18-CH_3), 2.00 (3H, s, OCOCH_3), 4.66 (1H, br W_H= 31 Hz, H at C_3), and 5.84 (2H, t J=5.5 Hz, 2H at C_{16} and C_{17}).

*5α,12α-Etiojervan-3β-ol-11-one 3-Acetate (**25**).* Compound **24** (53 mg) was hydrogenated over Adams Pt (31 mg) in AcOH (3 ml) at room temp for 30 min, when 1.2 mol of hydrogen had been consumed. The catalyst was removed by filtration and the filtrate was concentrated below 30 °C under reduced pressure and dissolved in chloroform. The chloroform solution was worked up at usual to give **25** (50 mg), amorphous, which resisted crystallization: $[\alpha]_D$ −11.1°; ORD, $[\Phi]_{333}^{trough}$ −3010°, $[\Phi]_{316}$ 0°, $[\Phi]_{290}^{peak}$ +3980°, a= −69.9°; Mass, *m/e* 332 (M^+); IR ($CHCl_3$), ν_{max} 1728 and 1245 cm^{-1}; NMR, δ 0.90 (3H, s, 19-CH_3), 0.92 (3H, d J= 6 Hz, 18-CH_3), 2.02 (3H, s, OCOCH_3), and 4.67 (1H, br W_H=24 Hz, H at C_3).

*Epimerization of **25** to **9**.* A solution of compound **25** (33 mg) in methanol (15 ml) containing 5% potassium hydroxide was refluxed under nitrogen for 2 h. The solution was evaporated, diluted with water and extracted with chloroform. The extracts were washed with water, dried and evaporated to leave amorphous residue (27.4 mg), which was acetylated with Ac_2O (0.5 ml) in Py (0.5 ml) at room temp overnight. After usual work up, the amorphous

reaction mixture (31 mg) crystallized on trituration with aqueous methanol to give crystalline substance (7 mg) having mp 108.5—110 °C, which was identical with an authentic sample of **9** in all respects.

5β,12α-Etiojerv-16-en-3β-ol-11-one 3-Acetate (26). A solution of compound **21** (144 mg) in dry Py (2.5 ml) was treated with phosphoryl chloride (0.5 ml) at room temp for 14 h. The mixture was worked up in the same manner as the corresponding 5α-mixture to leave oily residue (141 mg), which was purified by preparative TLC (9 plates) with a 1 : 10 mixture of ether and benzene. The main fraction was extracted with acetone and afforded crystalline residue (94 mg), which on trituration with aqueous methanol yielded **26** (63 mg), mp 146—152 °C. Recrystallization from the same solvent mixture gave an analytical sample, mp 150—152 °C; $[\alpha]_D$ +47.4°; IR, ν_{max} 3010, 1729, 1640, 1240, 1023, and 699 cm^{-1}; NMR, δ 0.92 (3H, d J=7 Hz, 18-C$\underline{H}_3$), 1.02 (3H, s, 19-C$\underline{H}_3$), 2.03 (3H, s, OCOC$\underline{H}_3$), 5.04 (1H, br s W_H=7.5 Hz, $\underline{H}$ at C_3), and 5.86 (2H, t J= 6 Hz, 2$\underline{H}$ at C_{16} and C_{17}). Found: C, 76.13; H, 9.18%. Calcd for $C_{21}H_{30}O_3$: C, 76.32; H, 9.15%.

Epimerization of 26 to 28. Compound **26** (32 mg) in methanol (12 ml) was treated with 1 M sodium methoxide under reflux for 17 h. After evaporation of the solvent, the mixture was diluted with water and extracted with chloroform. The chloroform solution left crystalline substance (25.5 mg), showing a single spot on TLC, which was acetylated with Ac_2O (0.4 ml) and Py (0.4 ml) at room temp overnight to give crystalline material (30 mg). This was triturated with aqueous methanol to give **28** (20 mg), mp 119.5—121 °C; NMR, δ 1.00 (3H, s, 19-C$\underline{H}_3$), 1.30 (3H, d J= 6 Hz, 18-C$\underline{H}_3$), 2.04 (3H, s, OCOC$\underline{H}_3$), 5.04 (1H, br s W_H=7 Hz, $\underline{H}$ at C_3), and 5.49 (2H, br s W_H=10 Hz, 2$\underline{H}$ at C_{16} and C_{17}).

5β,12α-Etiojervan-3β-ol-11-one 3-Acetate (27). A solution of compound **26** (50 mg) in AcOH (1 ml) was hydrogenated over Adams Pt (30 mg) at room temp for 2 h, when 1.2 mol of hydrogen had been consumed. The reaction mixture, after being worked up as usual, gave amorphous substance (54 mg), which showed a single spot on TLC and was triturated with aqueous methanol to yield **27** (35 mg), mp 106—109 °C. Recrystallization from the same solvent mixture gave an analytical sample, mp 110—110.5 °C; $[\alpha]_D$ −15.9 °; IR, ν_{max} 1727, 1250, 1240, and 1029 cm^{-1}; NMR, δ 0.91 (3H, d J=7.5 Hz, 18-C$\underline{H}_3$), 1.03 (3H, s, 19-C$\underline{H}_3$), 2.02 (3H, s, OCOC$\underline{H}_3$), and 5.02 (1H, br s W_H= 8 Hz, $\underline{H}$ at C_3). Found: C, 75.77; H, 9.59;% Calcd for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%.

Epimerization of 27 to 29. Compound **27** (39 mg) in methanol (17 ml) was treated with 1 M sodium methoxide under reflux for 17 h. After being worked up as usual, the mixture gave crystalline substance (29.5 mg), which was acetylated with Ac_2O (0.4 ml) and Py (0.4 ml) at room temp overnight. The resulting amorphous acetate crystallized on trituration with aqueous methanol to yield **29** (20 mg), mp 106—107.5 °C; IR, ν_{max} 1743, 1725, 1237, 1028, and 1017 cm^{-1}; NMR, δ 1.00 (3H, s, 19-C$\underline{H}_3$), 1.17 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 2.03 (3H, s, OCOC$\underline{H}_3$), and 5.02 (1H, br s W_H=6 Hz, $\underline{H}$ at C_3).

5α,12α-Etiojervan-17α-ol-3-one (32a). To compound **30** (809 mg) in chloroform (10 ml) was added a chloroform solution (10 ml) containing perbenzoic acid (activity 83.3%, 611 mg) at 0 °C, and the mixture was allowed to stand at room temp for 86 h. The perbenzoic acid solution (10 ml) was again added to the mixture, and the whole solution was kept at room temp for additional 71 h. The solution was washed with 0.1 M aqueous sodium thiosulfate (4×20 ml), 5% aqueous sodium bicarbonate (2×10 ml) and water (2×20 ml), dried and evaporated to leave amorphous residue (**31**, 863 mg), which showed almost a single spot on TLC; IR ($CHCl_3$), ν_{max} 3620, 3460, 1720, 1252, and 1029 cm^{-1}.

To a cooled solution of the whole residue in acetone (20 ml) was added Jones' reagent (1 ml) under stirring, and the mixture was stirred at 0 °C for 50 min. After addition of ethanol (1.2 ml) the mixture was stirred for another 15 min and concentrated *in vacuo*. The residue was worked up as usual to give resinous substance (802 mg), which without purification was refluxed in a methanol solution (16 ml) containing 5% potassium hydroxide under nitrogen for 1 h. The resulting amorphous product (614 mg) showed two spots and was separated by preparative TLC (25 plates) with a 1 : 3 mixture of ether and benzene. More mobile fractions gave oily substance (204 mg), which on trituration with a mixture of acetone and isopropyl ether afforded crystalline substance, mp 82.5—84 °C, which would probably be the unreacted starting material: Mass, *m/e* 316 (M^+); NMR, δ 0.80 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 0.99 (3H, s, 19-C$\underline{H}_3$), and 2.16 (3H, s, 21-C$\underline{H}_3$). Less mobile fractions gave crystalline material (318 mg), which on recrystallization from acetone-isopropyl ether afforded **32a** (248 mg), mp 143—145 °C. This was recrystallized from the same solvent mixture for analysis: mp 145—146.5 °C; $[\alpha]_D$ −5.5°; Mass, *m/e* 290 (M^+); IR, ν_{max} 3497, 1708, 1065, and 1036 cm^{-1}; NMR, δ 0.96 (3H, s, 19-C$\underline{H}_3$), 1.00 (3H, d J=6 Hz, 18-C$\underline{H}_3$), and 3.45 (1H, do t J=10, 10 and 4 Hz, $\underline{H}$ at C_{17}). Found: C, 78.40; H, 10.32%. Calcd for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%.

5α,12α-Etiojervane-3,17-dione (33). To a cold solution of compound **32a** (50 mg) in acetone (2 ml) was added Jones' reagent (0.2 ml) under stirring, and the mixture was stirred at 0 °C for 70 min. After addition of ethanol (0.3 ml), the mixture was concentrated *in vacuo*, and the residue was diluted with water and then extracted with chloroform. The chloroform solution was worked up as usual to yield oily substance (54 mg), which on trituration with acetone gave **33** (27 mg), mp 160—162 °C. This was recrystallized twice from ether to give a pure sample, mp 173—175 °C, which was identical with an authentic sample, prepared by the procedure of Johns and Laos (lit,[16] mp 169—170 °C).

5α,12α-Etiojervan-3β-ol (34) and Its 3-Acetate (34a). To a cold solution of compound **32a** (100 mg) in Py (2 ml) was added TsCl (100 mg), and the mixture was stirred at room temp for 48 h, diluted with water and extracted with chloroform. The chloroform solution gave oily substance (146 mg); IR ($CHCl_3$), ν_{max} 1707, 1601, 1176, 918, and 894 cm^{-1}.

The oily substance was dissolved in dry ether (20 ml) and refluxed with LAH (300 mg) under stirring for 13 h. After careful decomposition of excess of the hydride with water, the resulting heterogeneous mixture was shaken with 1 M hydrochloric acid and extracted with ether. The ether extracts left amorphous residue (97 mg), showing a single spot on TLC, which was triturated with acetone to give **34** (46 mg), mp 121—123 °C. This was recrystallized twice from aqueous acetone for analysis: mp 129.5—130 °C; $[\alpha]_D$ −31.0°; Mass, *m/e* 276 (M^+), 258, and 243; IR, ν_{max} 3380, 1045, and 1030 cm^{-1}; NMR, δ 0.79 (3H, s, 19-C$\underline{H}_3$), 0.79 (3H, d J=6 Hz, 18-C$\underline{H}_3$), and 3.58 (1H, br W_H= 22 Hz, $\underline{H}$ at C_3). Found: C, 82.68; H, 11.28%. Calcd for $C_{19}H_{32}O$: C, 82.54; H, 11.66%.

Compound **34** (42 mg) was acetylated with Ac_2O (1 ml) and Py (1 ml) at room temp overnight and gave oily substance (46 mg), which on trituration with methanol crystallized to yield **34a** (32 mg), mp 95.5—96 °C. This was recrystallized from the same solvent to give an analytical

sample, mp 97—97.5 °C; $[\alpha]_D$ −47.4°; Mass, *m/e* 258 (M^+); IR, ν_{max} 1738, 1234, and 1022 cm^{-1}; NMR, δ 0.80 (3H, d J=6 Hz, 18-CH_3), 0.81 (3H, s, 19-CH_3), 2.00 (3H, s, $OCOCH_3$), and 4.71 (1H, br W_H=27 Hz, H at C_3). Found: C, 79.23; H, 10.52%. Calcd for $C_{21}H_{34}O_2$: C, 79.19; H, 10.76%.

Stereochemistry of the C and D Rings of C-Nor-D-homosteroids. IV.[1] The Relative Stabilities and NMR Spectra of 17-Substituted C/D *trans*- and *cis*-Fused Etiojervanes[2]

(Received September 30, 1975)

(1) The relative stabilities between 17-substituted C/D *trans*- and *cis*-fused 11-oxoetiojervanes were investigated by treatment of both or either one of these 12-epimeric compounds under equilibrating conditions. The equilibrium ratios thus obtained were estimated qualitatively in terms of the configuration and bulkiness of substituent(s) at C_{17}. (2) The chemical shifts of 19- and 18-methyl protons in a number of etiojervanes were examined collectively. The "principle of additivity" holds satisfactorily for the 19-methyl protons of all etiojervanes, with two exceptional cases, irrespective of the configuration at C_{12} and also for the 18-methyl protons of 12β-etiojervanes. However, the principle is not applicable for the latter protons of 12α-etiojervanes, suggesting that the D ring would take different conformations depending on the 17-substituents.

The Relative Stabilities. The relative stabilities of *trans*- and *cis*-hydrindanone systems have been investigated extensively and found to depend delicately upon structural change.[3] This variety has been illustrated by simple[4] and complex hydrindanone systems[5] as well as normal (D ring) and modified (A and B rings) steroidal ketone.[3,6,7] Qualitative, sometimes temporizing, explanations have been given for these results, but no general understanding appears to be available. Recently, a few of attempts to rationalize the observed relative stabilities by calculational methods have been reported and applied successfully to a variety of these compounds.[8,9] Nevertheless, it is still desirable to accumulate experimental results concerning the stabilities of hydrindanone systems incorporated into large and complex natural products.[10] For example, House and Rasmusson have reported that the *trans*-fused isomer (**1**) of 7-methyl-3a,4,7,7a-tetrahydro-1-indanone is greatly stable as compared with the *cis*-fused isomer (**2**),[11] while the situation has become completely opposite with the corresponding etiojervane analogs with a bulky substituent (S) at C_{17} (**3** and **4**).[12] This fact, as combined with the previously observed results, has led us to have interest in more detailed examination of the relative stabilities of the titled compounds. Recently, we reported the summarized result concerning this stability relationship as a preliminary communication.[13] We describe herein the details and also, in connection with this, discuss the NMR spectra of C/D *trans*- and *cis*-fused etiojervanes.

Prior to the epimerization studies, several 17-substituted etiojervanes were newly prepared, and syntheses of two representative compounds, 17-methyl- and 17-hydroxy-17-isopropyl-11-oxoetiojervanes, are described below. 5α,12β-Etiojervane-3β,11β-diol-17-one[14] (**5**) underwent the Wittig reaction[15] and subsequent acetylation to give the 17-methylene derivative (**6**), mp 172—173 °C, in 67% yield. Hydrogenation over Adams platinum produced a mixture of the 17β- and 17α-methyl compounds (**7** and **8**) in 84% yield, which was oxidized with chromic anhydride to mixture of the corresponding 11-oxo derivatives (**9** and **10**). While each of these mixtures showed a single spot on various TLC and resisted further purification, the mixture of compounds **9** and **10**, on treatment with sodium methoxide in refluxing methanol and subsequent acetylation, gave a product, which consisted mainly of the unreacted starting material but showed two spots clearly on TLC. Repeated epimerizations followed by acetylation effected isolation of a 12α-epimer (**11**), mp 163.5—164 °C, in 16% yield. Conversely, the same treatment of the 12α-epimer (**11**) produced the 12β-epimer (**9**), mp 140—141 °C, in good yield. As expected, these 12-epimeric 11-ketones (**9** and **11**) displayed negative Cotton effects with amplitudes of −157° and −77° in the ORD curves[12a] and signals due to the 19-methyl protons at δ 0.86 and 0.90 in the NMR spectra. The β-configuration of 17-methyl groups in both compounds was deduced from the fact that the epimerization of compound **9** to **11** took place, as discussed later.

17-Hydroxy-17-isopropyl-11-oxoetiojervanes were prepared from 12β-etiojerv-5-en-3β-ol-11,17-dione 17-ethylene acetal[16] (**12**). Hydrogenation of **12** over platinum in acetic acid produced the 5α,6-dihydro derivative (**13**), mp 172—174 °C, in 97% yield, which on hydrolysis with acid gave 11,17-diketone (**14**), mp 159—162 °C, in good yield. Treatment of **14** with

isopropylmagnesium bromide in ether produced a complex mixture, from which four compounds (**15**—**18**), having mp 180—182 °C, 168—170 °C, 136—138 °C and 193—195 °C, could be isolated by repeated preparative TLC in 16, 19, 1.5 and 4% yields (crude 40, 41, 3 and 5.5%), respectively. Contrary to the expectation, two major products (**15** and **16**) were formulated as 3β,11β,17β-triol and 3β,11β-diol-17-one, respectively, on the basis of the spectral data, indicating that reduction of the sterically hindered 11-carbonyl group occurred as a main reaction. While the former **15** revealed no absorption maximum in the carbonyl region, the latter **16** exhibited the maxima at 3400 and 1700 cm^{-1} and also a negative Cotton effect (a= −88°).[16,17] On the other hand, two minor products (**17** and **18**) were expected 17-isopropyl adducts. In accordance with the assigned structures, both the compounds (**17** and **18**) showed absorption maxima at 1732 and 1733 cm^{-1} in the IR spectra and also negative Cotton effects (a= −151° and −157°) in the ORD curves. Moreover, the configurations of two substituents at C_{17} were assigned as shown in the formulas (**17** and **18**) by epimerization experiments in the same manner as that compound **9**.

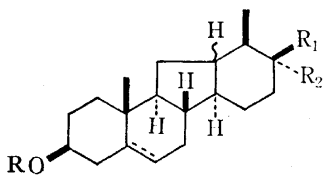
Equilibration studies were carried out by treatment of both or either one of C/D *trans*- and *cis*-fused 17-substituted 11-oxo-etiojervanes (**19** in Table 1) with 1 M sodium methoxide in refluxing methanol for several hours, and the summarized result, including the reported ones, is listed in Table 1.



19 A=12βH
B=12αH

As shown in Table 1, 17-unsubstituted 12β-etiojervanes (IA and IIA in Table 1), regarded as reference compounds, were not epimerized completely, and the corresponding 12α-epimers (IB and IIB) could not be detected even by repeated TLC. Conversely, compounds IB and IIB were transformed quantitatively into IA and IIA, respectively. In view of the small equilibrium ratio (3 : 1) between *trans*- and *cis*-methylhydrindanones[11] (**20** and **21**), the present result would be rationalized by assuming that the five-membered C ring in etiojervanes **19** is fused in a *trans*-manner with the B ring and would therefore take a half-chair form rather than an envelope form. This conformation would lead to remarkable stabilization of *trans*-fused isomers (IA), as compared with *trans*-methylhydrindanone (**20**), and would also explain well the result that 12β-etiojervanes [IIIA (=**13**), IVA (=**12**) and VA[17]] with the same two substituents were much more stable than the corresponding 12α-epimers. Naturally, 12β-etiojervanes (VIA—IXA) with only one α-oriented (equatorial) substituent, apart from that (XA) with a bulky substituent,[12] were extremely favored under the equilibrating conditions over the respective 12α-epimers.

On the other hand, 17β-substituted 12β-etiojervanes (XIA—XIVA) would be destabilized by the axially disposed substituents, as compared with the refernce compounds (IA and IIA). This destabilization would increase in passing from the small[18] (OH, XIA), medium (CH_3, XIIA=**9** and C_2H_5, XIIIA) to the large(S, XIVA) substituent, leading to decrease of the

a) The symbols "A and B" refer to the configuration of C_{12}, and the numbers on parentheses to the references in which the compounds are cited. The symbols "**13** (=IIIA) and Exp" denote "compound **13** described in the text and compounds characterized in Experimental part in this paper." The formulas "$CHCH_3$, C_2H, C_3H_7 and S" mean "ethylidene, ethinyl, isopropyl groups, and a 17-substituent of **3** and **4**," respectively. b) The equilibrium ratio was obtained by measuring the amounts of isolated products.

ratio (12βH : 12αH) in question. The observed result was indeed in good accord with this presumption. Fortunately, a 12α-isomer (XIB), mp 237—239 °C, of XIA could be isolated by repeated epimerizations, showing a negative Cotton effect with amplitude of −69°. It is to be noted that the equilibrium ratio between XIIIA and XIIIB with a 17β-ethyl group was found to be about 1 : 1, suggesting that the energy difference between the reference compounds (IA and IB or IIA and IIB) would nearly equal the conformational energy (1.8 kcal)[18] of an ethyl group.

The afore-mentioned results indicated that the relative stabilities between 12-epimeric etiojervanes (XV—XX) with two substituents at C_{17} would depend on the relative bulkiness of β- and α-substituents. 12β-Etiojervanes (XVA and XVIA)[19] with two similar or those (XVIIA[19] and XIXA) with larger α-oriented substituents must be much more stable than the corresponding 12α-epimers. Indeed it was the case. On the other hand, the relative stabilities between 12-epimeric etiojervanes (XVIII and XX) with larger β-substituents must become comparable, and the unstable epimers might be isolable. The observed results were completely in accordance with this expectation, and 17β-ethyl-17α-hydroxy- and 17β-isopropyl-17α-hydroxy-12α-etiojervanes (XVIIIB and XXB), mp 149—150 °C and amorphous, could be isolated from the epimerization mixtures of the respective 12β-epimers (XVIIIA[19] and XXA (=**17**)].

In summary, the relevant stabilities depend upon the configuration and bulkiness of substituents at C_{17} and the equilibrium ratios are estimated roughly on the basis of these factors. This rationalization not only holds for both reactants and products, as mentioned in this paper, but also is applicable to reaction intermediates, as reported in the previous papers.[20,21] Moreover, the result suggests that both the C and D rings would probably take a somewhat fixed conformation at least in 12β-etiojervanes, and this conformational rigidity will be supported by the NMR spectra described in the following sections.

The NMR Spectra. During synthetic studies on C-nor-D-homo-steroid hormones, we have synthesized a number of etiojervanes. In view of the close similarities of structure within these etiojervanes, an intercomparison of the NMR spectra of a series of these compounds would be valuable in confirming certain stereochemical points as well as promoting the structure determination of new derivatives. In the previous papers on the NMR spectra of 22,27-imino-17,23-oxidojervanes [(22S,23R,25S)jervanines][22] and etiojerva-12,14,16-trienes with an aromatic D ring,[23] we have reported that the effects of many different substituents on the chemical shifts of 19-methyl protons are additive. However, these data have been confined to the correlation of the chemical shifts with changes of substituents only at C_3, C_4, C_5 and C_{11}. Moreover, it has not been reported whether or not the "principle of additivity" is applicable to the chemical shifts of 18-methyl protons. Hence we examined collectively the NMR spectra of a series of stereochemically well-established 17-substituted 12β- and 12α-etiojervanes, paying special attention to the influence due to the difference of C/D ring junctures and the

a) The shifts refer to the assigned chemical shifts for 19-methyl protons of hypothetical compounds without any substituent. Solvent, $CDCl_3$. b) The figures in the parentheses refer to numbers of examples. c) The negative sign denotes shielding effect. d) The $\Delta\delta$ values of a number of 17-substituents, 0.00.

contribution of substituents at C_{17}. The result follows as.

19-Methyl Protons: In order to examine both additivity and magnitude of the shielding effects, all the compounds were first classified into two groups, A and B. The group A includes compounds having a C/D *trans*-fused ring (12βH) and those having an unsaturated carbon atom at C_{12} (Δ^{11} or Δ^{12}), and the group B compounds possessing a C/D *cis*-linkage (12αH). Each group was further divided into two groups, T (5αH, Δ^4 and Δ^5) and C (5βH), according to the mode of A/B ring juncture, as usually done in the normal steroid series. While reference compounds of the respective groups, 5- and 12-epimeric etiojervanes without any substituent, are not known, 5α,12β- and 5α,12α-etiojervan-3β-ols (**22** and **23**) and their acetates[1] (**22a** and **23a**) have recently been prepared and, moreover, a number of pairs of etiojervanes differing only by the configuration at C_5 have also been reported. In view of the well-known deshielding effects (0.02 and 0.03 ppm) of 3β-hydroxy and 3β-acetoxy groups for the chemical shift of 19-methyl protons,[22,23] the reference chemical

Table 3. The chemical shift of the 18-methyl protons of 12β-etiojervanes. substituents and chemical shifts (δ)[a]

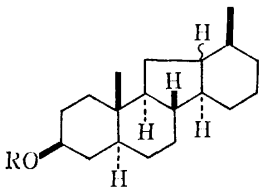
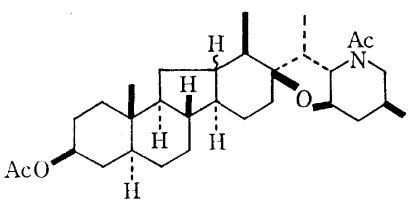
shifts in the respective groups were assigned as shown in Table 2. The contributions of various functional groups were obtained by pairing compounds which differed only by the single group in question and by taking the average of difference of the chemical shifts. The calculated values, having available the reference shifts and the contributions listed in Table 2, were in good agreement, usually within 0.02 ppm (the deviation of 30 examples among 430 compounds examined, 0.03 ppm) except two exceptional cases, with the observed chemical shifts, indicating that the shielding effects are really active.

On the results given in Table 2, some comments are presented in the following. (1) The reference 19-methyl protons (δ 0.74 and 0.87) of the C/D *trans*-fused groups (A-T and A-C) appear at lower field than the corresponding protons (δ 0.71 and 0.83) in the iminooxidojervane series,[22] but still at higher field than those (δ 0.792 and 0.925) in the normal steroid series.[24] However, the difference (0.13 ppm) between their



22 12βH, R=H **23** 12αH, R=H
22a 12βH, R=Ac **23a** 12αH, R=Ac



24 12βH
25 12αH

chemical shifts is equal to those (0.12 and 0.133 ppm) in the latter two series. (2) The 19-methyl protons of compounds in the C/D *trans*-fused groups (A-T and A-C) were observed at about 0.05 ppm high fields as compared with those in the corresponding C/D *cis*-fused groups (B-T and B-C). This chemical shift difference is represented by the reference shifts of two paired groups in Table 2: A-T and B-T, δ 0.74 and 0.79; A-C and B-C, δ 0.87 and 0.92. This difference is also almost the same as that (0.07 ppm) between diacetyl-5α,6,12β,13-tetrahydrojervine (**24**) and its 12α-epimer[12a] (**25**), a sole compound known as 12α-iminooxidojervane, supporting the 12α-configuration of the latter (**25**). (3) Each functional group in the A, B and C rings of compounds included in the C/D *trans*-fused groups (A-T and A-C) provides almost the same deshielding effect as the same group in the iminooxidojervane system, and it would not be necessary to repeat the previous discussions on the contribution of these groups. However, it is emphasized that this result, as coupled with the afore-mentioned reference shifts, implies that the chemical shifts of 19-methyl protons in the iminooxidojervane series can be estimated from Table 2, by assuming the contribution of 17-substituents of iminooxidojervane to be −0.04 ppm (up-field shift). (4) Each functional group in the C/D *cis*-fused groups (B-T and B-C) displays the contribution similar to the same group in the C/D *trans*-fused (A-T and A-C), as far as the functional groups in question exist in the A, B, and C rings. This indicates that the steric relation of these groups to the 19-methyl group hardly suffers change in passing from the *trans*-fused C/D linkage to the *cis*-fused, though the C-ring is expected to undergo distortion owing to the different C/D ring junctures. (5) Most of the functional groups in the saturated D ring exert no influence on the chemical shifts of 19-methyl portons. This has been demonstrated by a number of substituents at C_{17} in the C/D *trans*-fused as well as *cis*-fused compounds. Only exceptional functions are a 17β-ethinyl group in the group A-T and two 13,17-epoxy in that B-T. The deshielding effect of the former 17β-ethinyl group would be explained well by assuming that the substituent is oriented axial on the D ring with a slightly deformed chair conformation, though no reasonable interpretation is given for the effect of the two groups owing to obscure conformations of the D ring. (6) Several unsaturated functional groups (Δ^{12}, $\Delta^{13(17)}$, $\Delta^{17(20)}$ and 17=O) in the D ring of compounds with an unsaturated carbon atom at C_{12} provide deshielding effects, which would result from deformation of the C and D rings. On the other hand, unsaturated groups in the D ring in the C/D *cis*-fused groups (B-T and B-C), specially a double bond at C_{13}–C_{17} and a 17-carbonyl group, make important contributions to the relevant chemical shifts. According to a molecular model, the D ring in these compounds is disposed on the upper side of the molecule and the carbon atom at C_{17} approaches the 19-methyl group. These shielding effects would therefore be understood well as a result of the magnetic anisotropy of suchlike unsaturated groups. (7) Two exceptional cases for which the "additivity rule" does not hold were observed for a few of isojervine derivatives. This abnormality had already been discussed in the previous paper.[25]

18-Methyl Protons: In Tables 3 and 4 are summarized the chemical shifts of 18-methyl protons of a number of 12β- and 12α-etiojervanes with a β-methyl group at C_{13} (not with an unsaturated carbon atom at C_{13}). The signals due to the 18-methyl protons were distinguished without difficulty in most of the spectra, but the chemical shifts were given not so exactly as those due to the sharp 19-methyl protons, because the protons usually appeared as relatively indistinctly resolved doublets or overlapping signals above the background of methylene and methine protons. This inaccuracy was observed in many cases when the substituents at C_{17} were complex and, specially, the "S" group containing secondary methyl groups, and these undiscernible chemical shift data were not included in Tables 3 and 4. The present data seem at first to be confined to the correlation of the chemical shifts only with changes of substituents in the C and D rings. However, it must be emphasized that various functional groups in the A and B rings exert no important influence on the relevant chemical shifts, as far as the B and C rings are fused in a *trans*-manner (8βH and 9αH).

On the basis of the data summarized in Table 3, we examined the contributions of substituents at C_{11} and C_{17} for the 18-methyl protons of 12β-etiojervanes in the same manner as those for the 19-methyl protons, and found that the "additivity rule" holds roughly

Table 5. The contribution ($\Delta\delta$) of functional groups to the chemical shift of the 18-methyl protons of 12α-etiojervanes

a) The chemical shift of 18-methyl protons of compounds without any substituent in the C and D rings. Solvent, $CDCl_3$. b) The figures in the parentheses refer to numbers of examples. The negative sign denotes shielding effect. c) The contributions due to these 17α-substituents were assumed to be the same as those due to the corresponding 17β-substituents.

for the relevant shifts; namely, the observed chemical shifts are in good agreement (within 0.04 ppm) with the calculated values, assuming the chemical shift (δ 0.84) of compounds containing no substituents in the C and D rings to be the reference shift and having available the contributions of functional groups at C_{11} and C_{17} listed in Table 5. The following points are noted from Table 5. (1) In contrast to the contributions for the 19-methyl protons, 11β-hydroxy and acetoxy groups exhibited almost the same deshielding and shielding effects ($\Delta\delta$ 0.15 and −0.05 ppm) for the 18-methyl protons as the corresponding 11α-groups ($\Delta\delta$ 0.16 and −0.05 ppm). These effects are nearly equal to those in the iminooxidojervane series.[22] To the contrary, the deshielding effect ($\Delta\delta$ 0.33 ppm) of the carbonyl group at C_{11} is remarkably large as compared with that ($\Delta\delta$ 0.02 ppm) in the iminooxidojervane series,[22] indicating that the methyl group is oriented equatorial in the D ring with a fixed, slightly deformed chair form and hence located in the plane of the trigonal carbon atom in question. (2) The chemical shifts of 18-methyl protons depend largely on the β- and/or α-substituent(s) and extend from δ 0.84 to 1.46. Interestingly, the relevant signals of two compounds having the same substituents at C_{11} and/or C_{17} but differing only in the configuration at C_{17}, apart from the functional groups in the A and B rings, were found in almost the same fields except in the case of 17-acetyl-12α-etiojervanes (see Table 3). It follows that a substituent at C_{17}, whether the configuration is β or α, provides almost the same contribution (see Table 5). (3) The deshielding effects ($\Delta\delta$ in Table 5) of several 17-substituents (=O, β- and α-OH, and β- and α-OAc) are roughly the same as those ($\Delta\delta$ 0.22, 0.15, 0.21?, 0.00 and 0.05) of the corresponding substituents at C_1 in 5β-androstane series,[26] but completely different from those in 5α-androstane series.[26] This similarity in the deshielding effect between the first two series would support the afore-mentioned conformation in respect to the D ring.

The following comments are given for the chemical shifts of 18-methyl protons of 12α-etiojervanes in Table 4. (1) Contrary to the previous results, the "additivity rule" does *not* hold for the chemical shifts in question. This was exemplified clearly by the variety of shelding effects of a 11-carbonyl group ($\Delta\delta$ −0.14—+0.12 ppm), indicating that the D ring would not take a fixed conformation in the C/D *cis*-fused etiojervanes. (2) The 18-methyl protons in 12α-etiojervanes having no substituents at C_{11} were observed in higher or lower fields than those in the corresponding 12β-etiojervanes. These up- and down-field shifts ($\Delta\delta$ −0.04—+0.09 ppm) naturally depend on the functional groups at C_{17} as well as on the conformations of D ring and are therefore too difficult to be estimated. However, it is noteworthy that several β-oriented substituents (OH, OAc and Ac) at C_{17} exhibit essentially the same contributions ($\Delta\delta$ 0.24, 0.11 and 0.02 ppm) as the corresponding α-oriented, although this does not always imply that the 18-methyl group would have the similar steric relation for the respective 17β- and 17α-grops. (3) The 18-methyl protons in 11-oxo-12α-etiojervanes appeared at remarkably high field ($\Delta\delta$ −0.26—−0.52 ppm) as compared with those in the corresponding 12β-etiojervanes. This large up-field shift evidently results from the conformational change of the D ring

in passing from C/D *trans*-fused compounds to *cis*-fused; the D ring would assume a twist boat or more probably a half-chair conformation, and the β-methyl group at C_{13} would become equatorial in either of the conformations and hence located on the upper side of the C ring and in the conical region extending above the plane of the trigonal carbon atom of a 11-carbonyl group.

Experimental

All the melting points were uncorrected. The homogeneity of each compound was always checked by TLC on silica gel (Wakogel B-5) with various solvent systems, and the spots were developed with ceric sulfate in dil sulfuric acid and/or iodine. The optical rotations, ORD curves and IR spectra were measured in chloroform, dioxane, and Nujol, respectively, unless otherwise stated. The NMR spectra were obtained in deuteriochloroform at 60 and/or 100 MHz, and the chemical shifts were given in δ-values, TMS being used as an internal reference. The abbreviations "s, d, t, m, br, and do" in the NMR spectra denote "singlet, doublet, triplet, multiplet, broad, and double," respectively.

*17-Methylidene-5α,12β-etiojervane-3β,11β-diol 3-Acetate (**6**).* A suspended mixture of sodium hydride (Wako, 510 mg, *ca.* 50% in oil) in pentane (20 ml) was stirred for a while and then decanted under a stream of nitrogen. This procedure was repeated several times to remove the oil. After removal of the pentane *in vacuo* the residual hydride was mixed with fresh dimethylsulfoxide (DMSO, 6 ml), which had been dried over calcium hydride and distilled twice under nitrogen, stirred at 62—72 °C for 1 h and cooled, when the mixture became homogeneous and gray. To the solution was added dropwise a solution of dry methyltriphenylphosphonium bromide (2.863 g) in DMSO (10 ml) at room temperature (temp), and the whole solution was stirred at room temp for 20 min. To the resulting yellow, gel-like mixture was added a solution of 5α,12β-etiojervane-3β,11β-diol-17-one (**5**, 610 mg) in tetrahydrofuran (THF, 10.5 ml) at room temp under nitrogen during 10 min. The whole mixture was stirred at 50 °C (bath temp) for 22 h, cooled and poured into ice-water and, after being salted out, extracted with ether repeatedly. The ether solution was washed with saturated brine, dried over sodium sulfate and evaporated to leave oily residue (2.667 g). The residue was treated with acetic anhydride (Ac_2O, 5.5 ml) and pyridine (Py, 10 ml) at room temp for 3 h, poured onto crushed ice, salted out, and extracted with ether repeatedly. The ether extracts were washed with 2M hydrochloric acid, 5% aqueous sodium bicarbonate and saturated brine, dried and evaporated to give amorphous substance (2.164 g). A suspended mixture of the substance in hexane containing a trace of benzene was passed through an alumina column (Merck, acidic) with a 5 : 1 mixture of hexane and benzene to remove resin, and the whole eluate was then purified by preparative TLC over silica gel (Wakogel, 32 plates) with benzene to give crystalline substance (511 mg), showing a single spot, as a main fraction. This was triturated with acetone-isopropyl ether, collected by filtration to give **6** (409 mg), mp 171.5—172 °C. This was recrystallized twice from the same solvent mixture for analysis: mp 172—173 °C; $[\alpha]_D$ +40.9°; IR, ν_{max} 3600, 3080, 1724, 1640, 1262, 1024, and 891 cm^{-1}; NMR, δ 1.04 (3H, s, 19-C$\underline{H}_3$), 1.15 (3H, d J=6 Hz, 18-C$\underline{H}_3$), 1.97 (3H, s, OCOC$\underline{H}_3$), 4.15 (1H, br W_H=16 Hz, $\underline{H}$ at C_{11}), and 4.65 (3H, br m, 2$\underline{H}$ at C_{20} and $\underline{H}$ at C_3). Found: C, 76.28; H, 9.97%. Calcd for $C_{22}H_{34}O_3$: C, 76.26; H, 9.89%.

*Hydrogenation of **6**.* A solution of **6** (354 mg) in acetic acid (14 ml) was hydrogenated over pre-reduced Adams platinum (232 mg as $PtO_2 \cdot H_2O$) for 1 h, when 1.02 mol of hydrogen had been consumed. After removal of the catalyst, the solution was evaporated *in vacuo* below 40 °C and then treated with benzene (azeotropization) to give crystalline residue, which was dissolved in chloroform. The chloroform solution, after being worked up as usual, gave crystalline residue (355 mg), which on trituration with acetone afforded a mixture (295 mg) of 17β- and 17α-methyl-5α,12β-etiojervane-3β,11β-diol 3-acetates (**7** and **8**), mp 184—187 °C, showing a single spot. This was recrystallized from acetone-isopropyl ether and had mp 189—190 °C; $[\alpha]_D$+36.1°; IR, ν_{max} 3480, 1704, 1263, and 1031 cm^{-1}; NMR, δ 0.84 (3H, d J=7 Hz, 17-C$\underline{H}_3$), 1.01 (3H, d J=5.5 Hz, 18-C$\underline{H}_3$), 1.04 (3H, s, 19-C$\underline{H}_3$), 1.98 (3H, s, OCOC$\underline{H}_3$), 4.07 (1H, do d J=5 and 8 Hz, $\underline{H}$ at C_{11}), and 4.68 (1H, br m W_H=23 Hz, $\underline{H}$ at C_3). Found: C, 75.86; H, 10.52%. Calcd for $C_{22}H_{36}O_3$: C, 75.81; H, 10.41%.

*Oxidation of a Mixture of **7** and **8**.* A solution of a mixture of **7** and **8** (the preceding section, 248 mg) in Py (3 ml) was added chromic anhydride (CrO_3, 344 mg) under stirring during 30 min, and the whole mixture was further stirred at room temp for 14 h. The mixture was poured into ice-water (50 ml), extracted with ether (4×50 ml), and the ether solution was washed with 1M hydrochloric acid (3×20 ml), 5% aqueous sodium bicarbonate (2×20 ml) and saturated brine, dried and evaporated to leave crystalline residue (263 mg), showing a single spot. This was triturated with methanol-isopropyl ether to give a mixture of 17β- and 17α-methyl-5α,12β-etiojervan-3β-ol-11-one (**9** and **10**); the first crop (145 mg), mp 137—138 °C, the second (50 mg), mp 134—135 °C, and the third (11 mg), mp 130—131 °C. These were collected and recrystallized from methanol to give a mixture having mp 138.5—139 °C; $[\alpha]_D$ −74.1°; ORD, $[\Phi]_{334}^{trough}$ −9940°, $[\Phi]_{322}^{trough}$ −5510°, $[\Phi]_{293}^{peak}$ +8320°, a=−182.6°: IR, ν_{max} 1732, 1727, 1241, and 1027 cm^{-1}; NMR, δ 0.81 (3H, d J=6 Hz, 17-C$\underline{H}_3$), 0.87 (3H, s, 19-C$\underline{H}_3$), 1.14 (3H, d J=5.5 Hz, 18-C$\underline{H}_3$), 2.01 (3H, s, OCOC$\underline{H}_3$), and 4.68 (1H, br W_H=23 Hz, $\underline{H}$ at C_3). Found: C, 76.26; H, 9.90%. Found: C, 76.26; H, 9.89%.

*17β-Methyl-5α,12α-etiojervan-3β-ol-11-one 3-Acetate (**11**).* A solution of the mixture of **9** and **10** (the preceding section, 186 mg) was treated with 1M sodium methoxide in refluxing methanol (20 ml) for 2 h under nitrogen. After being cooled, the solution was evaporated, poured into water (30 ml) and extracted with chloroform repeatedly. The chloroform solution was worked up as usual to give crystalline residue (188 mg), which was treated with Ac_2O (1 ml) and Py (2 ml) at room temp for 3 h. The product (196 mg), showing two spots on TLC, was separated by preparative TLC with a 2 : 3 mixture of chloroform and benzene into two fractions; the starting crystalline mixture (168 mg) with larger R_f value and a new crystalline substance (17 mg) with smaller R_f. These treatments (epimerization, acetylation and subsequent purification by TLC) were repeated three times for the recovered starting mixture and led to isolation of 56 mg of the new material with 125 mg of the recovered, unchanged material. The latter had mp 127—129 °C on recrystallization from methanol-isopropyl ether and amounted to 116 mg. The former was recrystallized from isopropyl ether to give **11** (31 mg), mp 163—164 °C. This was recrystallized from the same solvent for analysis: mp 163.5—164 °C; $[\alpha]_D$ −18.2°; ORD, $[\Phi]_{334}^{trough}$ −4350°, $[\Phi]_{323}^{trough}$ −2210°, $[\Phi]_{292}^{peak}$ +3350°, a=−77°; IR, ν_{max} 1726, 1239, 1036, and 1027 cm^{-1}; NMR, δ 0.74 (3H, d J=7 Hz, 17-

CH_3), 0.88 (3H, d J=5 Hz, 18-C$\underline{H}_3$), 0.90 (3H, s, 19-C$\underline{H}_3$), 1.99 (3H, s, OCOC$\underline{H}_3$), and 4.69 (1H, br W_H=23 Hz, $\underline{H}$ at C_3). Found: C, 76.32; H, 9.92%. Calcd for $C_{22}H_{34}O_3$: C, 76.26; H, 9.89%.

*17β-Methyl-5α,12β-etiojervan-3β-ol-11-one 3-Acetate (**9**).* A solution of compound **11** (46 mg) was refluxed with 1M sodium methoxide in methanol (7 ml) for 2 h under nitrogen, cooled and then evaporated to leave oily residue. The residue was mixed with water (30 ml) and extracted with chloroform. The chloroform extracts gave a crystalline mixture (36.5 mg), which was treated with Ac_2O (0.5 ml) and Py (0.5 ml) at room temp for 3 h and then worked up as usual to give a crystalline acetate mixture (37 mg), showing two spots. This was separated by preparative TLC over silica gel (3 plates) with a 3 : 2 mixture of benzene and chloroform into two fractions; one (29 mg) with larger R_f value and the other (5 mg) with smaller R_f. The latter had mp 155—158 °C on trituration with isopropyl ether, amounted to 2.5 mg, and was identified as the starting material (**11**). The former was recrystallized from isopropyl ether–methanol to give **9** (21 mg), mp 138.5—139 °C. This was recrystallized from the same solvent mixture for analysis: mp 140—141 °C; $[\alpha]_D$ −80.2°; ORD, $[\Phi]_{334}^{trough}$ −8150°, $[\Phi]_{324}^{trough}$ −4450°, $[\Phi]_{292}^{peak}$ −7600°, a=−156.5°; IR, ν_{max} 1732, 1727, 1241, and 1027 cm^{-1}; NMR, δ 0.81 (3H, d J=5.5 Hz, 17-C$\underline{H}_3$), 0.86 (3H, s, 19-C$\underline{H}_3$), 1.14 (3H, d J=5.5 Hz, 18-C$\underline{H}_3$), 2.02 (3H, s, OCOC$\underline{H}_3$), and 4.67 (1H, br W_H=28 Hz, $\underline{H}$ at C_3). Found: C, 76.13; H, 9.95%. Calcd for $C_{22}H_{34}O_3$: C, 76.26; H, 9.89%.

*5α,12β-Etiojervan-3β-ol-11,17-dione 17-Ethylene Acetal (**13**).* A solution of 12β-etiojerv-5-en-3β-ol-11,17-dione 17-ethylene acetal (**12**, 3.56 g) in acetic acid (220 mg) was hydrogenated over Adams platinum (1.78 g) at room temp for 1.5 h, when 340 ml (1.21 mol) of hydrogen had been consumed. The reaction mixture was worked up as usual to give oily residue, which crystallized on trituration with isopropyl ether, had mp 162—164 °C and amounted to 3.33 g. This was recrystallized from isopropyl ether and then from acetone–isopropyl ether to give **13**, mp 172—174 °C; $[\alpha]_D$ −47°; ORD, $[\Phi]_{334}^{trough}$ −7310°, $[\Phi]_{278}^{peak}$ +6960°, a=−143°, IR, ν_{max} 3480, 3350, 1731, 1099, 1077, 1064, and 1030 cm^{-1}; NMR δ 0.83 (3H, s, 19-C$\underline{H}_3$), 1.16 (3H, d J=6.5 Hz, 18-C$\underline{H}_3$), 3.65 (1H, br, $\underline{H}$ at C_3), and 3.91 (4H, s, OC$\underline{H}_2$C$\underline{H}_2$O). Found: C, 71.91; H, 9.21%. Calcd for $C_{21}H_{32}O_4$: C, 72.38; H, 9.26%.

*5α,12β-Etiojervan-3β-ol-11,17-dione (**14**).* A solution of compound **13** (756 mg) in acetone (62 ml) and water (10 ml) was refluxed with *p*-toluenesulfonic acid (150 mg) for 4 hr. The solution was made neutral with 5% aqueous sodium bicarbonate, evaporated and extracted with chloroform. The chloroform solution was worked up as usual to give oily residue, which crystallized on trituration with acetone, had mp 159—162 °C, and amounted to 516 mg. This was recrystallized from acetone–isopropyl ether to give **14**, mp 169—172 °C; $[\alpha]_D$ −81°; ORD, $[\Phi]_{334}^{trough}$ −9980°, $[\Phi]_{332}^{trough}$ −8070°, $[\Phi]_{280}^{peak}$ +11430°, a=−214.1°; Mass, *m/e* 304 (M^+); IR, ν_{max} 3470, 1732, 1712, 1694, and 1033 cm^{-1}; NMR, δ 0.83 (3H, s, 19-C$\underline{H}_3$), 1.29 (3H, d J=6.5 Hz, 18-C$\underline{H}_3$), and 3.51 (1H, br, $\underline{H}$ at C_3).

*Reaction of **14** with Isopropylmagnesium Bromide.* To a mixture of dried magnesium ribbons (10.0 g) in dry ether (450 ml) was added dropwise isopropyl bromide (57.6 g) during 40 min, and the mixture was further stirred at room temp for 40 min. To the cooled, suspended mixture was added compound **13** (1.10 g) in ether containing a small amount of THF under stirring, and the whole mixture was refluxed for 4.5 h under nitrogen. After addition of saturated aqueous ammonium chloride (80 ml), the ether layer was separated and the aqueous layer was extracted with ether repeatedly. The ether solutions were combined and then worked up as usual to give oily residue (1.18 g), which was separated by preparative TLC over silica gel (45 plates) with a 1 : 1 mixture of benzene and ethyl acetate into four fractions, named fractions A—D in the order of R_f value. Fraction D (448 mg), the least mobile fraction showing a single spot, was crystallized on trituration with acetone–isopropyl ether and then recrystallized from the same solvent mixture to give 5α,12β-etiojervane-3β,11β,17α-triol (**15**, 189 mg), mp 180—182 °C; IR, ν_{max} 3380, 1098, 1058, 1023, and 970 cm^{-1}. This was converted into the diacetyl derivative (**15a**), amorphous; $[\alpha]_D$ 0.0°; Mass, *m/e* 332 (M^+−60), 314, 272, and 254; NMR, δ 1.04 (3H?, d J=6 Hz, 18-C$\underline{H}_3$), 1.06 (3H, s, 19-C$\underline{H}_3$), 2.00 and 2.03 (total 6H, each s, 2O-COC$\underline{H}_3$), 4.17 (1H, br W_H=15 Hz, $\underline{H}$ at C_{11}), and 4.65 (2H, br m, 2$\underline{H}$ at C_3 and C_{17}). Fraction C (455 mg), showing a single spot, crystallized on trituration with acetone–isopropyl ether and was then recrystallized from the same solvent mixture to yield **16** (204 mg), mp 168—170 °C; $[\alpha]_D$ −4.0°; ORD, $[\Phi]_{318}^{trough}$ −3300°, $[\Phi]_{276}^{peak}$ +5510°, a=−88°; Mass, m/e 306 (M^+); IR, ν_{max} 3560, 3440, 1700, 1100, 1053, and 864 cm^{-1}; NMR, δ 1.06 (3H, s, 19-C$\underline{H}_3$), 1.14 (3H?, d J=6.5 Hz, 18-C$\underline{H}_3$), 3.58 (1H, br W_H=24 Hz, $\underline{H}$ at C_3), and 4.18 (1H, br W_H=13 Hz, $\underline{H}$ at C_{11}). Fraction A (29 mg), the most mobile fraction, was identified as the starting material (IR and TLC). Fraction B (335 mg) were further separated by repeated preparative TLC over silica gel (18 plates), 8 : 1, 4 : 1 and 2 : 1 mixtures of benzene and ether being used successively as solvents, into several fractions. One (55 mg) of the two major fractions crystallized on trituration with acetone–isopropyl ether and was recrystallized from the same solvent mixture to give **17** (26 mg), mp 136—138 °C; $[\alpha]_D$ −11.7°; ORD, $[\Phi]_{327}^{trough}$ −9590°, $[\Phi]_{287}^{peak}$ +5500°, a=−151°; Mass, *m/e* 348 (M^+); IR, ν_{max} 3460, 1732, 1042, and 972 cm^{-1}; NMR, δ 0.83 (3H, s, 19-C$\underline{H}_3$), 0.92 [6H?, d J=6.5 Hz, CH(C$\underline{H}_3$)$_2$], 1.21 (3H?, d J=7 Hz, 18-C$\underline{H}_3$), and 3.65 (1H, br m, $\underline{H}$ at C_3). The other (127 mg) of the two major fractions was crystallized and recrystallized from acetone–isopropyl ether to yield **18** (60 mg), mp 193—195 °C; $[\alpha]_D$ −5.6°; ORD, $[\Phi]_{332}^{trough}$ −8330°, $[\Phi]_{290}^{peak}$ +7370°, a=−157°; Mass *m/e* 348 (M^+); IR, ν_{max} 3570, 1733, 1050, and 988 cm^{-1}; NMR, δ 0.84 (3H, s, 19-C$\underline{H}_3$), 0.93 [6H, d J=6 Hz, CH(C$\underline{H}_3$)$_2$], 1.23 (3H?, d J=6.5 Hz, 18-C$\underline{H}_3$), and 3.58 (1H, br m, $\underline{H}$ at C_3).

Equilibration Experiments. The studies were carried out for all the compounds listed in Table 1. Each reactant was treated with 1M sodium methoxide in methanol under reflux for several hours, and the product, after acetylation when necessary, was separated by preparative TLC, as had been illustrated in the sections of the preparation of compounds **9** and **11**. The equlibrium ratio was determined by measuring the amounts of isolated products and the result is summarized in Table 1. Each epimerzation experiment is not described here, and only new compounds, obtained during these studies, are characterized in the following.

12β-Etiojerv-5-ene-3β,17α-diol-11-one. Mp 212.5—213 °C (from acetone); $[\alpha]_D$ −158.2° (CH_3OH); ORD, $[\Phi]_{333}^{trough}$ −10990°, $[\Phi]_{321}^{trough}$ −7360°, $[\Phi]_{291}^{peak}$ +5710°, a=−167°; Found: C, 75.00; H, 9.31%. Calcd for $C_{19}H_{28}O_3$: C, 74.96; H, 9.27%.

12α-Etiojerv-5-ene-3β,17β-diol-11-one (XIB). Mp 237—239 °C (from methanol). The 3,17-diacetate. Mp 140—141 °C (from methanol); ORD, $[\Phi]_{333}^{trough}$ −3750°, $[\Phi]_{322}^{trough}$ −5520°, $[\Phi]_{294}^{peak}$ +1290°, a=−68.1°; IR, ν_{max} 1732, 1241, and 1056 cm^{-1}; NMR, δ 0.93 (3H, d J=7 Hz, 18-C$\underline{H}_3$),

1.12 (3H?, s, 19-C$\underline{H}_3$), 2.06 (6H, s, 2OCOC$\underline{H}_3$), and 4.83 (2H, br W_H=21 Hz, 2$\underline{H}$ at C_3 and C_{17}), and 5.50 (1H, br s, $\underline{H}$ at C_6).

17β-Ethyl-12α-etiojervane-3β,17α-diol-11-one 3-Acetate (XVIIIB) Mp 149—150 °C (from acetone–isopropyl ether); $[\alpha]_D$ −60°; ORD, $[\Phi]_{332}^{trough}$ −5290°, $[\Phi]_{291}^{peak}$ +1840°, a=−71.3°; IR, ν_{max} 3546, 1725, 1258, and 1032 cm^{-1}; NMR, δ 0.71 (3H, d J=7.5 Hz, 18-C$\underline{H}_3$), 0.91 (3H, t J=7 Hz, 21-C$\underline{H}_3$), 1.11 (3H?, s, 19-C$\underline{H}_3$), 2.02 (3H, s, OCOC$\underline{H}_3$), 4.58 (1H, br m, $\underline{H}$ at C_3), and 5.42 (1H, br s, $\underline{H}$ at C_6). Found: C, 73.71; H, 9.29%. Calcd for $C_{23}H_{34}O_4$; C, 73.76; H, 9.15%.

17β-Isopropyl-5α,12α-etiojervane-3β,17α-diol-11-one (XXB). Amorphous, $[\alpha]_D$ −5.6°; ORD, $[\Phi]_{334}^{trough}$ −2330°, $[\Phi]_{296}^{peak}$ +4640°, a=−69.7°; IR ($CHCl_3$), ν_{max} 3500, 1730, and 1043 cm^{-1}; Mass, m/e 348 (M^+); NMR, δ 0.80 (3H, d J= 7 Hz, 18-C$\underline{H}_3$), 0.89 (3H?, s, 19-C$\underline{H}_3$), and 3.54 (1H, br m, $\underline{H}$ at C_3).

Retardation of Autoxidation in the Presence of Water, Alcohols and Carboxylic Acids

Koji UKEGAWA and Yoshio KAMIYA*

National Research Institute for Pollution and Resources, Kawaguchi, Saitama 332

**Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received October 11, 1975)

The oxidation of alcohols and α-substituted toluenes in water, methanol and acetic acid was studied at 60—70 °C in the presence of 0.040 M AIBN. The rate of oxidation of alcohol, $k_p/(2k_t)^{1/2}$, considerably increases when the alcohol is diluted with an inert solvent. The rate remarkably decreases with the addition of water, methanol or various carboxylic acids. However in the presence of tetralyl hydroperoxide, *viz.*, when the hydroperoxyl radical is replaced by the tetralyl peroxyl radical, no further inhibition effect due to water, methanol or carboxylic acids is observed. The rate of oxidation of 1,4-cyclohexadiene decreases with the addition of water or acetic acid. However in the presence of 0.20 M tetralyl hydroperoxide, no further inhibition effect is observed. The rate of oxidation of 1-phenylethanol decreases with the addition of benzoic acid but not with that of methylbenzoate. The rate of oxidation of (2-chloroethyl)benzene, ethylbenzene and isopropylbenzene does not decrease with the addition of 0.224 M acetic acid, but that of *N,N*-dimethylbenzylamine, *N,N*-diethylbenzylamine, benzyl alcohol, 1-phenylethanol and methyl benzyl ether decreases. It is concluded that hydroperoxyl and alkylperoxyl radicals with α-substituents such as hydroxyl, carbonyl, alkoxyl or amino groups undergo deactivation due to hydrogen bonding with water, alcohols and carboxylic acids.

Although the autoxidation of hydrocarbons has been studied thoroughly by a number of workers,[1–5] many points are still left unclarified. Hendry and Russell,[6] and Howard and Ingold[7] reported that the solvent effect on the rate of autoxidation can be correlated as a function of dielectric constant and neither π-complex formation nor hydrogen bonding of alkylperoxyl radical is observed.

Zaikov and Maizus[8] suggested that the deactivation of peroxyl radical occurrs owing to hydrogen bonding with water in the autoxidation of methyl ethyl ketone. Imamura *et al.*[9] reported that the autoxidation of acetaldehyde is considerably retarded in the presence of vaious carboxylic acids. Bimolecular interaction of hydroperoxyl radicals is known to be strongly retarded in the presence of water.

In the course of studies on the autoxidation of alcohols, we found that hydroperoxyl radicals can be deactivated by water, alcohol and carboxylic acids. Furthermore, peroxyl radicals with α-substituent containing nitrogen or oxygen atoms were found to be deactivated by hydroxyl compounds. The deactivation effect, which is hardly observed in the case of alkylperoxyl radicals, can be explained only in terms of hydrogen bonding.

Experimental

The technique of oxidation was described elsewhere.[10] All the experiments were carried out at 60—70 °C in the presence of α,α'-azobisisobutyronitrile as an initiator under atmospheric pressure of oxygen. Hydroperoxide produced was determined by iodometric titration, where hydroperoxide was treated with KI in 80% aqueous acetic acid at room temperature in the dark.

Tetralyl hydroperoxide obtained by the autoxidation of tetralin was purified several times by recrystallization from heptane. The other materials were used after distillation or recrystallization of extra pure reagents.

Results and Discussion

Peroxyl radicals formed in the autoxidation of alcohols decompose to ketones and a hydroperoxyl radical, the hydroperoxyl radical being the chain carrier in the autoxidation of alcohols.[11] However, the α-hydroxyperoxyl radical can also be the chain carrier in the oxidation of some alcohols.[12]

The oxidation of an alcohol initiated by AIBN (α,α'-azobisisobutyronitrile) proceeds according to the following mechanisms.

Initiation reaction:

$$\mathrm{AIBN} + \mathrm{RH} + \mathrm{O_2} \xrightarrow{R_i} \mathrm{RO_2\cdot(HO_2)}$$

Propagation reaction:

$$\mathrm{RO_2\cdot} + \mathrm{RH} \xrightarrow{k_p} \mathrm{ROOH} + \mathrm{R\cdot}$$

$$(\mathrm{HO_2\cdot} + \mathrm{RH} \longrightarrow \mathrm{HOOH} + \mathrm{R\cdot})$$

$$\mathrm{R\cdot} + \mathrm{O_2} \xrightarrow{\text{fast}} \mathrm{RO_2\cdot}$$

Termination reaction:

$$2\mathrm{RO_2\cdot}(2\mathrm{HO_2\cdot}) \xrightarrow{k_t} \text{non-radical products}$$

When the concentration of oxygen is sufficiently high, the rate of oxidation can be expressed by

$$-\mathrm{dO_2}/\mathrm{d}t = (\mathrm{RH})R_i^{1/2}k_p/(2k_t)^{1/2}$$

where k_p and k_t are the rate constants of chain propagation reaction and chain termination reaction, respectively, and R_i is the rate of initiation reaction. When (RH) and R_i are given, $k_p/(2k_t)^{1/2}$ can be calculated by measuring the rate of oxidation:

$$k_p/(2k_t)^{1/2} = -\mathrm{dO_2}/\mathrm{d}t/(\mathrm{RH})R_i^{1/2}.$$

It has been reported[13] that the value of $k_p/(2k_t)^{1/2}$ of hydrocarbon solution remains constant when the substrate is diluted with an inert solvent having a dielectric constant similar to that of the hydrocarbon. $k_p/(2k_t)^{1/2}$ was not constant in the oxidation of 1-phenylethanol, when the alcohol was diluted chlorobenzene having a dielectric constant similar to that of the alcohol. As shown in Fig. 1, $k_p/(2k_t)^{1/2}$ of 1-phenylethanol decreases markedly with the increase in the concentration of alcohol. This does not seem to have been reported in the autoxidation of hydrocarbons.

$k_p/(2k_t)^{1/2}$ increased with decreasing substrate concentration when other alcohols such as benzyl alcohol

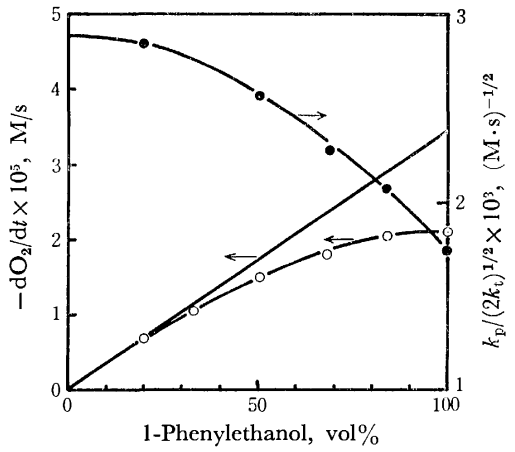

Fig. 1. The rate of oxidation of 1-phenylethanol as a function of alcohol concentration, 70 °C, $P_{O_2}=760$ mmHg, (AIBN) = 0.040 M, Solvent: chlorobenzene.

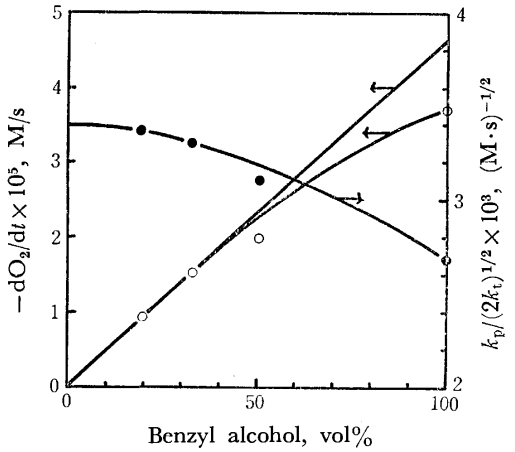

Fig. 2. The rate of oxidation of benzyl alcohol as a function of alcohol concentration, 70 °C, $P_{O_2}=760$ mmHg, (AIBN) = 0.040 M, Solvent: chlorobenzene/acetophenone = 1/2 by vol.

(Fig. 2) and 2-propanol were diluted with inert solvents whose dielectric constants were approximately equal to those of alcohols.

The values indicate that the hydrogen abstraction of alcohols is retarded by the hydrogen bonding between two hydroxyl compounds or by the hydrogen bonding of peroxyl radical with hydroxyl compound. The hydrogen bonding between alcohol molecules has no significant effect on the rate of hydrogen abstraction, since water no more retards the oxidation when a hydroperoxyl radical is replaced by a tetralylperoxyl radical.

The extrapolated values of $k_p/(2k_t)^{1/2}$ to zero alcohol concentration are given in Table 1. The ratio of $k_p/(2k_t)^{1/2}$ at 0% alcohol to $k_p/(2k_t)^{1/2}$ at 100% alcohol is between 2.0 and 1.3.

The effect of hydroxyl compounds on the rate of oxidation of 1-phenylethanol is shown in Fig. 3. *t*-Butyl alcohol accelerated the rate of oxidation, but water and methanol strongly retarded it; methanol did not retard the oxidation of tetralin (Table 2).

The result of *t*-butyl alcohol is probably due to steric hindrance for hydrogen bonding. Similarly,

Table 1. Effect of alcohol concentration on the rate of oxidation of alcohol

70 °C, $P_{O_2}=760$ mmHg, (AIBN) = 0.040 M

Alcohol	Solvent	$\frac{(k_p/(2k_t)^{1/2})(RH)=0\%}{(k_p/(2k_t)^{1/2})(RH)=100\%}$

○: 2-propanol at 60 °C, (AIBN) = 0.040 M. ●: 1-phenylethanol at 60 °C, (AIBN) = 0.040 M, H_2O/*t*-butyl alcohol = 1/2 by vol. □: *p*-isopropyltoluene at 70 °C, (AIBN) = 0.040 M, H_2O/*t*-butyl alcohol = 3/20 by vol.

the rate of oxidation of 2-propanol was inhibited in the presence of water, but the rate of oxidation of *p*-isopropyltoluene (Fig. 4) was not affected by the addition of methanol and water.

The rate of oxidation of 2-propanol in the presence of 0.20 M tetralyl hydroperoxide is plotted against water concentration (Fig. 5). The hydroperoxide method was proposed by Howard *et al.*[14] In the presence of tetralyl hydroperoxide, the chain carrier completely changes from the hydroperoxyl radical to the tetralylperoxyl radical at hydroperoxide concentrations above 0.1 M (Fig. 6). In the presence of tetralyl hydroperoxide, *viz.*, when the hydroperoxyl radical

is replaced by the tetralylperoxyl radical, no further inhibition effect due to water is observed.

Thus it can be concluded that hydroxyl compounds such as water and alcohols except *t*-butyl alcohol, deactivate by hydrogen bonding only hydroperoxyl and α-hydroxyalkylperoxyl radicals and not ordinary alkylperoxyl radical.

The hydrogen bonding of peroxyl radical with hydroxy compound lowers both k_p and k_t. It is suggested that $k_p/(2k_p)^{1/2}$ decreases because the extent of decrease of k_p is greater than that of $\sqrt{2k_t}$.

The relative rate constant of oxidatikn of 1-phenylethanol, $k_p/(2k_t)^{1/2}{}_{rel.}$, is plotted against the concentration of carboxylic acids (Fig. 7). We see that the rate constant of oxidation of 1-phenylethanol, $k_p/(2k_t)^{1/2}{}_{rel.}$, is not affected by the addition of oxalic acid, decreasing remarkably by the addition of *p*-nitrobenzoic acid, decreasing to a similar extent by the addition of various carboxylic acids such as acetic, benzoic, butyric, chloroacetic acids. The effect of

fatty acid and benzenecarboxylic acid seems to be independent of acid strength. The very small effect of oxalic acid may be due to intramolecular hydrogen bonding of oxalic acid. A similar solvent effect was observed in the oxidation of 2-propanol in the presence of carboxylic aicds (Fig. 8).

Acetic acid has no retardation effect on the hydrogen abstraction step by alkyl peroxyl radical (Table 3). This was confirmed by the hydroperoxide method, since the retardation effect due to acetic acid on the oxidation of 2-propanol is almost eliminated in the presence of tetralyl hydroperoxide (Fig. 9).

Denisov and Solyanikov[15] reported that the decreasing rate of formation of hydrogen peroxide during the oxidation of 2-propanol is attributable to decomposition of hydrogen peroxide by the carboxylic acid formed during the course of oxidation. However, from our results it can be concluded that the rate of oxidation of 2-propanol decreases due to the deactivation of peroxyl radicals.

The effect of acetic acid on the hydroperoxyl radical is also confirmed in the autoxidation of 1,4-cyclohexadiene (Table 4), because in this case the chain carrier is hydroperoxyl radical[16].

The rate of oxidation of 1,4-cyclohexadiene was remarkably decreased by the addition of acetic acid (Table 4). The effect of association of hydroxyl compounds on the rate of oxidation of alcohol can be disregarded since 1,4-cyclohexadiene does not associate with acetic acid.

The rate of oxidation of 1-phenylethanol in the presence of phthalic acid or isophthalic acid is given in Table 5. It is clear that the rate of oxidation of 1-phenylethanol in the presence of isophthalic acid is smaller than that in the presence of phthalic acid. Phthalic acid has a greater dissociation constant than isophthalic acid, and the stability of intramolecular hydrogen bonding of phthalic acid should be higher than that of isophthalic acid.[17]

The relative rate constant of oxidation of 1-phenylethanol in the presence of 0.05 M isophthalic acid (0.815) is nearly equal to that in the presence of 0.1 M benzoic acid (0.798). It is concluded that the rate of oxidation of alcohols in the presence of dicarboxylic acid, which can form an intramolecular hydrogen bond, is greater than the rate in the presence of dicarboxylic acid, which has difficulty to form an intramolecular hydrogen bond.

The very small effect of oxalic acid on the autoxidation of 1-phenylethanol can be explained on the basis of intramolecular hydrogen bonding (Fig. 7).

The effect of substituent on the benzene nucleus was studied using substitued benzoic acid in the autoxidation of 1-phenylethannol (Table 6). Except for the nitro group, no significant difference was observed in the retardation effect of benzoic acids.

The rate of oxidation of 1-phenylethanol, plotted against the concentration of benzoic acid or methyl benzoate (Fig. 10) apparently decreases with carboxylic acid and not ester. It can be said that carboxylic acids deactivate the chain carrier of alcohol, *viz.*, hydroperoxyl and α-hydroxyalkylperoxyl radicals, due to a hydrogen bonding, but not alkylperoxyl radicals.

The effect of α-substituent of toluene on the rate of autoxidation in the presence of hydroxyl compounds should be investigated.

Addition of water to *N,N*-dimethylbenzylamine and benzyl ether decreased the rate of oxidation by factors of 0.14 and 0.79, respectively (Table 7).

The effect of acetic acid in the autoxidation of ten kinds of α-substituted toluenes is given in Table 8.

The rate of oxidation of *N,N*-dimethylbenzylamine, benzyl alcohol, *N,N*-diethylbenzylamine, 1-phenylethanol and methyl benzyl ether decreased with the addition of acetic acid. On the other hand, the rate of oxidation of (2-chloroethyl)benzene, ethylbenzene, cumene and diphenylmethane was unaffected.

It can be concluded that the hydroperoxyl radical and alkylperoxyl radicals with α-substituents such as hydroxyl, alkoxyl and amino groups are capable of forming hydrogen bonding with hydroxyl compounds.

We tried to correlate these results in terms of substituent effect. It is suggested that resonance effect takes part and increases the electron density of the peroxyl radical accelerating the formation of hydrogen bonding (Fig. 11).

According to Zaikov and Maizus,[8] the oxidation of methyl ethyl ketone is remarkably inhibited in the presence of water, and according to Imamura *et al.*[9] the rate of oxidation of acetaldehyde is retarded by the addition of various carboxylic acids.

Thus, alkylperoxyl radicals should have α-substituent such as hydroxyl, carbonyl, amino and alkoxyl groups for the formation of hydrogen bonding with water, alcohols and carboxylic acids. These results also indicate that the structure of hydrogen bonding of peroxyl radicals is very complex and it is difficult to

present any quantitative explanation. Solvation of peroxyl radical and association of hydroxyl compounds should take part. However, a bridged cyclic structure involving nitrogen or oxygen atoms of α-substituents can be proposed for hydrogen bonding between water and peroxyl radicals.

It seems that the results[2] showing that the termination rate constant of the hydroxyl radical is markedly affected by the solvent, *viz.*, 10^9 (l/mol·s) in neutral solvent but 10^6 in aqueous solution, and also that the hydroperoxyl radical is inactive in aqueous solution can be explained convincingly on the basis of hydrogen bonding effect.

Ring-opening Reactions of Cyclic Ethers. IX.[1] Molecular Weight Distribution of Adducts in the Acid-catalyzed Reactions of Epichlorohydrin with Alcohols

Shizen SEKIGUCHI,* Yasushi HASEGAWA, Kenji NAKAMURA, Kohji MATSUI, and Kensuke NAGAHAMA

Department of Synthetic Chemistry, Gunma University, Tenjincho, Kiryu, Gunma 376

(Received November 21, 1975)

It was found that the molecular weights of adducts in the acid-catalyzed reactions of epichlorohydrin with alcohols obey the Weibull-Nycander distribution but not the Flory distribution. The distribution constants ($C=k_i/k_0$) were found to be smaller than 1, indicating that the reaction rate of the initial stage (k_0), *i.e.*, the reaction of epichlorohydrin with a starting alcohol, is greater than the rates of the later stages (k_i), *i.e.*, the reactions of epichlorohydrin with its adducts. The results indicate that the reaction proceeds *via* an "borderline" A-2 mechanism.

Nonionic surface active agents, prepared from the successive addition reaction of alkylene oxides to aliphatic carboxylic acids, aliphatic amines, and esters of polyhydric alcohols, have recently attracted much attention. They are used as commercial surfactants to a greater extent than anionic ones.

Several papers have appeared dealing with basic studies on the preparation of surfactants. The molecular weight distribution (MWD) of the adducts in the sodium hydroxide-catalyzed addition reaction of ethylene oxide (EO) or propylene oxide to lower alcohols was determined by Shigematsu *et al.*,[2,3] who indicated that it obeys the Weibull-Nycander distribution.[4] Shoda *et al.*[5] studied the MWD of the products in the sodium hydroxide-catalyzed addition reaction of EO to the reduced alcohol of coconut oil and showed that it obeys the Flory distribution,[6] that is, the Poisson one. Nagase and Sakaguchi[7] indicated that the MWD of the adducts in the sodium-catalyzed addition reaction of EO to dodecyl alcohol obeys the Weibully-Nycander distribution better than the Flory one. Karabinos and Quinn[8] studied the potassium hydroxide-catalyzed reactions of EO with lauryl alcohol and showed that the MWDs of the adducts deviate from the Flory distribution. Tischbirek[9] discussed the effects of reaction temperature, pressure of reaction systems, concentration of EO, rate of stirring, and kinds of alcohols and catalysts on the MWD of the adducts in the acid- or base-catalyzed reactions of EO with alcohols (C_2, C_6, and C_{12} alcohols). Thus few papers have appeared on the MWD of adducts in the acid-catalyzed reactions of epoxides with alcohols.

On the other hand, the mechanism of the acid-catalyzed ring-opening reactions of epoxides has been discussed by many workers.[10-13] Briggs *et al.*[14] discussed the mechanism of the acid-catalyzed alcoholysis of epoxides in detail, criticizing our previous work.[11]

In order to confirm the mechanism of the acid-catalyzed alcoholysis of epichlorohydrin (EpCl), we have determined the distribution constant (C), which is the ratio of the rate constant of the later stages (k_1, k_2, ...) to that of the initial stage (k_0), and which distribution the MWD in these reactions would obey.

Experimental

Materials. Methyl, propyl, butyl, *s*-butyl, and isobutyl alcohols were purified by the usual method. Boron trifluoride etherate ($BF_3\cdot Et_2O$) and EpCl were repeatedly distilled through a rectifying column (Kyowa VI-DL Concentric Tube Fractionater, theoretical plate number 80); $BF_3\cdot Et_2O$ bp 125 °C; EpCl 114—115 °C, d_4^{30} 1.1682, n_D^{30} 1.4326.

Synthes is of 1 : 1 (EpCl·ROH) and 2 : 1 (3EpCl·ROH) Adducts. Epichlorohydrin reacts with an alcohol in the presence of an acid to give the following adducts.[11,15,16]

$$\mathrm{ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2} + \mathrm{ROH} \longrightarrow \underset{(\mathrm{EpCl\cdot ROH})}{\mathrm{ClCH_2CH(OH)CH_2OR}} \quad (1)$$

a) Figures in parentheses indicate the temperature of measurement.

$$ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2 + ClCH_2CH(OH)CH_2OR \rightarrow ClCH_2CH(OH)CH_2OCH(ClCH_2)CH_2OR \quad (2)$$
(2EpCl·ROH)

Higher adducts are formed, depending on the reaction conditions, especially on the molar ratio of EpCl to alcohol. These adducts were synthesized for the preparation of calibration curves in vapor phase chromatography (VPC).

In the case of EpCl·CH_3OH, a typical procedure is described below. One hundred and forty grams (1.5 mol) of EpCl was added dropwise at room temperature to a stirred solution of 480 g (15 mol) of methyl alcohol and 2.8 g (2.7×10^{-2} mol) of H_2SO_4. EpCl had to be carefully added to prevent bumping. After addition of EpCl the mixture was further refluxed for 12 h. After the mixture had been neutralized with a concentrated sodium hydroxide solution, and dried over anhydrous sodium sulfate, methyl alcohol was distilled off and the residue was distilled under reduced pressure.

The reaction conditions, boiling points and yields for the preparation of the adducts are shown in Table 1, and the physical properties and results of elemental analyses in Table 2.

Determination of Unreacted Alcohols and Epichlorohydrin, and Adducts. The amount of the unreacted EpCl and Alcohols, and adducts were determined by VPC on a column packed with 10% polydiethylene glycol succinate (2 m) on Diasolid M at 100 °C for unreacted EpCl and alcohols (toluene used as an internal standard), 190 °C for 1 : 1 adducts and 200 °C for 2 : 1 adducts (in these cases, nitrobenzene used as an internal standard). Helium was used as a carrier gas.

Theoretical

Theories on molecular weight distribution have been worked out by several workers, the Flory[17] and Weibull-Nycander distributions[18] being often used. Molecular weight distribution can be calculated if certain assumptions are made on the relative reactivities of a starting alcohol and its adducts.

The reaction path of addition is expressed as follows:

$$ROH \xrightarrow[ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2]{k_0} ClCH_2\text{-}\underset{OH}{\underset{|}{CH}}\text{-}CH_2\text{-}OR \xrightarrow[ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2]{k_1}$$
(EpCl·ROH)

$$ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2\text{-}OR \xrightarrow[ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2]{k_2} ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2\text{-}O\text{-}CH_2\text{-}\underset{OH}{\underset{|}{CH}}\text{-}CH_2Cl$$
(2EpCl·ROH)

$$ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2\text{-}OR \xrightarrow[ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2]{k_3} ClCH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2\text{-}O\text{-}CH_2\text{-}\underset{\backslash O /}{CH}\text{-}CH_2\text{-}O\text{-}CH_2\text{-}\underset{OH}{\underset{|}{CH}}\text{-}CH_2Cl$$
(3EpCl·ROH) (3)

Flory distribution (or Poisson distribution)

If $k_0=k_1=k_2=\cdots=k_n=\cdots$ in Eq. 2, we obtain

$$\frac{n_i}{n_{00}} = e^{-v}\cdot\frac{v^i}{i!} \quad (4)$$

Weibull-Nycander distribution

If $k_0=k_1=k_2=\cdots=k_n=\cdots$ in Eq. 1 we have

$$v = C\cdot\ln\frac{n_{00}}{n_0} - (C-1)\left(1-\frac{n_0}{n_{00}}\right) \quad (5)$$

and

$$\frac{n_i}{n_{00}} = \frac{C^{i-1}}{(C-1)^i}\left\{\frac{n_0}{n_{00}} - \left(\frac{n_0}{n_{00}}\right)^C \sum_{j=0}^{i-1}\frac{1}{j!}\left[(C-1)\ln\frac{n_{00}}{n_0}\right]^j\right\} \quad (6)$$

n_{00}; mole of a starting alcohol
n_i; mole of i-th mer (iEpCl·ROH)
v; average mole of added EpCl per one mole of the starting alcohol
C; distribution constant (k_i/k_0)

Thus we can calculate the v-value if the amount of unreacted EpCl is determined. Once the v-value is determined, the expected amounts of i-th mers formed in the Flory distribution can be calculated by means of Eq. 4. Furthermore, if the amount of unreacted alcohol is also determined, a C-value can be calculated by means of Eq. 5. Using the C-value and Eq. 6, one can estimated the expected amounts of i-th mers in the Weibull-Nycander distribution.

a) Thirty grams (0.324 mol) of EpCl was used. The molar ratio of each alcohol to EpCl is one. b) Based on the amount of EpCl.

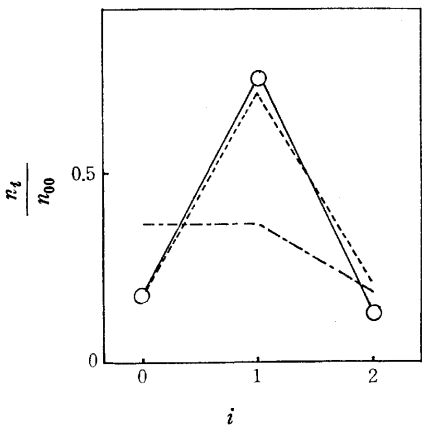

Fig. 1. The relationship between n_i/n_{00} and i.
——: observed, – – –: Flory distribution, ----: Weibull-Nycander distribution.

Results and Discussion

The results of determination of the adducts are given in Table 3. Through all runs, the recovery of initial EpCl summing up unreacted and transformed EpCl ranged from 95 to 100%, and, moreover, most of it was found to be transformed EpCl. Thus it seems that a very small amount of initial EpCl changed into unidentified products.[19)]

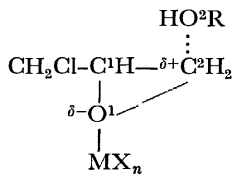
The results indicate that the distribution constant was smaller than 1, the 1 : 1 adduct being produced to a greater extent than the 2 : 1 one in every case. The observed values (n_i/n_{00}) in the case of Run 9 are compared with those calculated on the basis of the Flory and Weibully-Nycander distributions by use of C (0.14) (Fig. 1). The MWD in Run 9 clearly obeys the Weibully-Nycander one. Similar results were also obtained in the other runs.

The mechanism of acid-catalyzed ring-opening reactions of epoxides have been discussed by several workers. Long *et al.*[10)] concludedthat the acid-catalyzed hydrolysis of epoxides proceeds *via* a "borderline" A-1 mechanism,[10,20)] *viz.*, the carbonium ion formed through the co-ordination of an acid (catalyst) to the oxygen atom of epoxides reacts with nucleophiles.

On the other hand, Koskikallio and Whalley[12)] and leNoble and Duffy[13)] found that the volume of activation ($\Delta V^{\neq}$) is negative in the acid-catalyzed hydrolyses of epoxides and they concluded that the hydrolysis proceeds *via* an A-2 mechanism. Briggs *et al.*[14)] reported that the acid-catalyzed alcoholysis of styrene oxide proceeds *via* a "borderline" A-2 mechanism.

Entropy of activation as a criterion for reaction mechanism is discussed by many workers.[21)] Whalley[22)] deduced that (i) if $\Delta S^{\neq}$ is less than zero the reaction was probably A-2 and (ii) if $\Delta S^{\neq}$ is greater than zero the mechanism can be either A-1 or A-2. And, Stimson[23)] and Stimson and Watson[24)] showed that the hydrolysis of *t*-butyl benzoate and *t*-butyl formate in acidified 60% aqueous acetone gives $\Delta S^{\neq}$ values of +9.5 and −23.7 e.u., respectively, indicating that the former hydrolysis proceeds by an A-1 mechanism and the latter by an A-2 mechanism and that the hydrolysis of *t*-butyl 2,4,6-trimethylbenzoate in acidified 90% ethanol–water gives $\Delta S^{\neq}$ value of +8.1 e.u. by an A-1 mechanism.

We reported that the acid-catalyzed reaction of EpCl with alcohols or their adducts (nEpCl·ROH; n=1,2,3) proceeds via an "borderline" A-2 mechanism with $\Delta S^{\neq}$ values of −20∼−10 e.u., which were greater



to some extent than those of usual A-2 mechanism and proposed the following transition state.[11)] The distribution constants of *ca.* 0.10 correspond to this

proposition, since if this transition state is assumed, the reaction rate of the first stage will be greater than those of the later ones owing to the steric crowding of the bulkier adducts (RO^2H) at C^2 atom. If the carbonium ion such as $ClCH_2(\bar{O}MX_n)\overset{+}{C}H_2$ were formed, the 1 : 1 adducts should be produced less than as shown in Fig. 1 and the MWD should obey the Flory distribution since this situation indicates that $k_0=k_1=\cdots$.

Although Briggs *et al.* stated that the choice of EpCl is not appropriate for the elucidation of the mechanism or ring-opening reaction of epoxides, we found that the determination of MWD of adducts in the acid-catalyzed reaction of EpCl with alcohols is very useful. It is concluded that in the presence of acidic catalysts EpCl reacts with alcohols *via* an "borderline" A-2 mechanism.

Syntheses and Reactions of Fluorine-containing Aromatic Ketones

Hiroshi KIMOTO, Hiroshige MURAMATSU, and Kan INUKAI

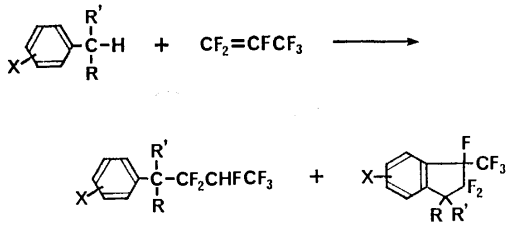
Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received November 27, 1975)

Phenyl 1,1,2,3,3,3-hexafluoropropyl ketone(I) and 2,2,3-trifluoro-3-(trifluoromethyl)indanone(II) were synthesized by the radical-addition reaction of benzaldehyde to hexafluoropropene. The reduction with $NaBH_4$ and the Grignard reaction with methylmagnesium iodide of these ketones gave the corresponding secondary and tertiary alcohols respectively. A Clemmensen reduction, alkaline hydrolyses, and reactions with hydroxylamine and with diazomethane were also carried out.

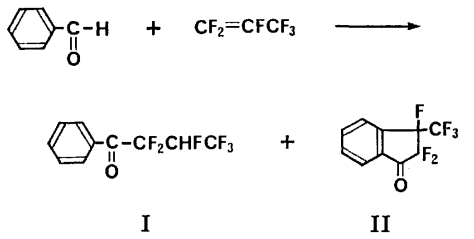
Fluorine-containing ketones have become of interest for their characteristic chemical properties due to the presence of an electron-deficient carbonyl group. Especially hexafluoroacetone and its chlorine-substituted derivatives have been widely studied and found to have unique reactivities.[1] However, few investigations of the syntheses and reactions of phenyl fluoroalkyl ketones are known.

In previous papers, we reported that the radical-addition reaction of alkylbenzenes to hexafluoropropene gave the 1 : 1 adducts, together with the cycloadducts,[2] and that the ratio of the products could be controlled by the reaction conditions.[3]



(R, R′=H, CH_3)

To ascertain the applicability of the above-mentioned radical reaction to the preparation of phenyl fluoroalkyl ketones, we attempted the addition of benzaldehyde to hexafluoropropene and obtained phenyl 1,1,2,3,3,3-hexafluoropropyl ketone(I) as a 1 : 1 adduct and 2,2,3-trifluoro-3-trifluoromethylindanone(II) as a cycloadduct.



I II

Since the carbonyl group of these ketones conjugates with the aromatic ring, and since its electron density is decreased by the adjacent highly electronegative fluorine atoms, these ketones seem to have a high reactivity toward the nucleophiles. Therefore, we attempted some reactions of these ketones.

Results and Discussion

Addition Reaction of Benzaldehyde to Hexafluoropropene. The addition reaction of benzaldehyde to hexafluoropropene (HFP) was carried out in the presence of di-*t*-butyl peroxide in a stainless steel autoclave. Four kinds (A—D) of reaction conditions were employed: to investigate the effect of dilution with a solvent, 1,1,2-trichlorotrifluoroethane was used as an inert solvent in Methods B and C, and to study the effect of the molar ratio, an excess of HFP was used in Methods A and B, whereas an excess of benzaldehyde was used in Methods C and D. The reaction conditions and product yields are given in Table 1.

TABLE 1. THE RADICAL ADDITION REACTION OF BENZALDEHYDE TO HEXAFLUOROPROPENE

Method	A	B	C	D
C_6H_5CHO (mol)	0.400	0.400	0.800	1.201
HFP (mol)	0.575	0.563	0.333	0.467
DTBP (mol)	0.410	0.410	0.100	0.041
$C_2Cl_3F_3$ (mol)	—	1.000	0.535	—
[I]/[II][a]	2.8	1.6	5.5	
Yield[b] [I] (%)	21.5	18.5	8.8	trace
Yield[b] [II] (%)	7.4	8.4	1.8	—
Higher boiling products (g)	59	56	22	2

a) Determined by the peak areas of GLC. b) Yields are calculated on the basis of the amounts of benzaldehyde consumed.

The I/II ratios could be controlled by changing the reaction conditions. As compared with Method A, Method B gave a smaller value of I/II due to the effect of dilution. As compared with Method B, Method C gave a larger value of I/II due to the excess of benzaldehyde. These results can be explained in the same manner as in the addition reaction of alkylbenzenes described previously;[3] the I/II ratio is determined by the competition between the intermolecular hydrogen abstraction and the intramolecular cycloaddition, followed by the loss of a hydrogen radical. Only a trace of I was obtained by Method D, although the alkylbenzenes gave the 1 : 1 adducts in good yields under the same conditions.[2] In the cases of the addition reaction of benzaldehyde, a relatively larger amount of the initiator was required because it was consumed by the reaction with benzaldehyde yielding *t*-butyl benzoate.

The structures of I and II were elucidated by means of their IR, NMR, and mass spectra, which are shown in Table 2. The mass spectrum of I is very different from that of II. A large molecular ion peak was observed in II, whereas a very small one appeared in I. The large ions of I, *m/e*: 105 C_6H_5CO and *m/e*:

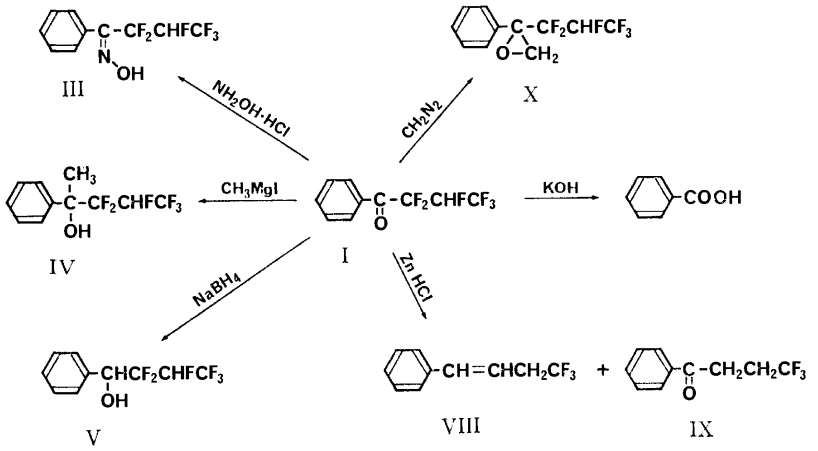


Fig. 1.

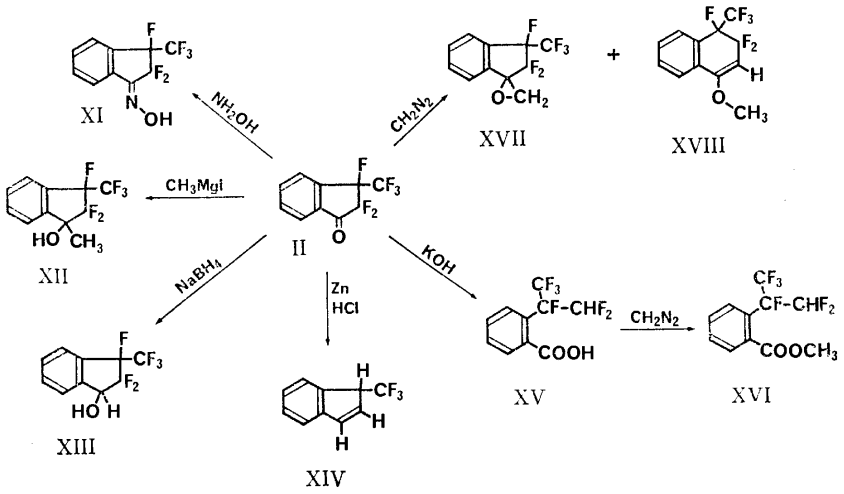

Fig. 2.

77 C_6H_5, are generated by the cleavage of the C–C bond connected to the carbonyl group.

In the NMR spectra, the signals of the fluorines of each CF_2 group on both I and II have AB patterns. For I, the non-equivalence is due to the adjacent asymmetric carbon atom. The configurations of the non-equivalent fluorines (^aF and ^bF) of II were estimated by means of the fluorine-fluorine coupling constants with a CF_3 group. From a consideration of the through-space coupling, it is assumed that the fluorine (^aF, δ= 41.7) with a smaller value (J=3.6 Hz) is on the opposite side of the indanone framework from the CF_3 group, whereas the fluorine (^bF, δ=47.1) with a larger value (J=14.0 Hz) is on the same side.

Some Reactions of Fluorine-containing Ketones. The reactions of I and II are summarized in Fig. 1 and Fig. 2 respectively. The corresponding ketoximes (III and XI) were prepared in high yields from I and II under acidic conditions, but under basic conditions haloform cleavages were competitive with the formation of oximes, III was not obtained, and the yield of XI fell to 45.3%.

Although the Beckmann rearrangement of these ketoximes was attempted under refluxing in trifluoroacetic acid or by heating at 100 °C in concentrated sulfuric acid, no corresponding acid amides were obtained; only ketoximes were recovered unchanged. In the reaction with 2,4-dinitrophenylhydrazine, II gave the corresponding hydrazone (mp 176 °C), but I did not yield the hydrazone under the same conditions. Some fluorinated ketones have been reported not to react with substituted hydrazines.[4]

The Grignard reaction of I with methylmagnesium iodide gave the corresponding tertiary alcohol (IV) in a 94% yield. GLC and the ^{19}F NMR spectrum indicated the presence of two diastereoisomers in the ratio of 65 : 35. On the other hand, the reaction of II with methylmagnesium iodide gave XII, which contained only one stereoisomer, in a 78% yield. The methyl group of XII seems to be on the opposite side of the trifluoromethyl group in the indane framework. In the reaction of cyclic fluoroketone(II), methylmagnesium iodide might attack the carbonyl carbon from a sterically favorable side, that is, opposite to the trifluoromethyl group.[5]

The reductions of I and II with sodium tetrahydroborate gave the corresponding secondary alcohols (V and XIII) in almost quantitative yields. The GLC of V indicated the formation of equal amounts of two diastereoisomers, whereas XIII consisted of two

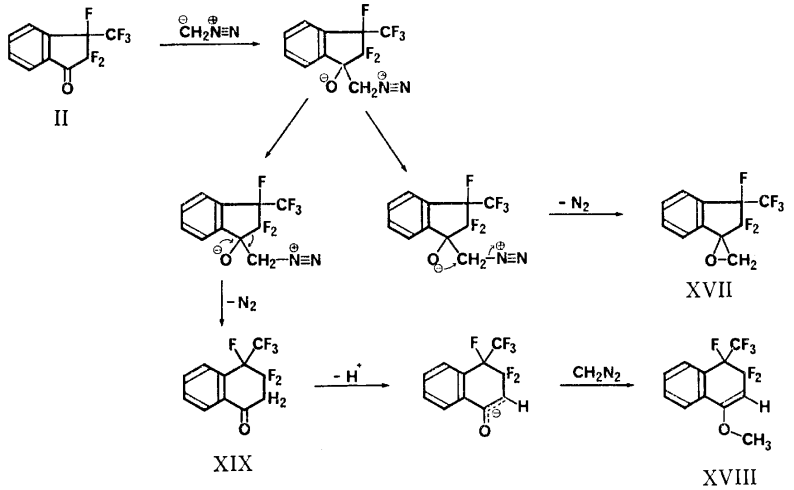

Fig. 3.

stereoisomers in the ratio of 90 : 10. The predominant isomer isolated by recrystallization was found to have a hydroxyl group on the same side of the trifluoromethyl group in the indane framework. The predominance of this isomer showed that the reduction proceeded mainly by the nucleophilic attack of the BH_4^- ion which, in effect, transferred H^- to the carbon[6] from the opposite side of the trifluoromethyl group.

The substitution of the hydroxyl group of V for bromine was carried out *via* the formation of tosylate

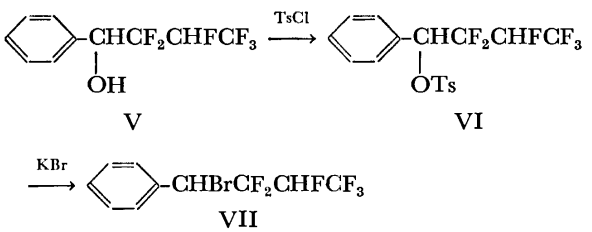
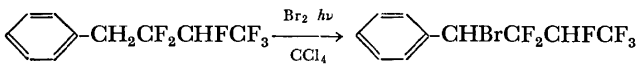
(VI) as an intermediate. Bromide(VII) was obtained in a 60.2% overall yield. The same product was also synthesized by the photobromination of the 2,2,3,4,-4,4-hexafluorobutylbenzene obtained by the radical addition of toluene to hexafluoropropene.[2)]



V VII



VII

The Clemmensen reduction of I gave several products, 1-phenyl-4,4,4-trifluorobutane, *trans*-1-phenyl-4,4,4-trifluoro-1-butene(VIII) and phenyl 3,3,3-trifluoropropyl ketone(IX), whose composition varied with the reaction conditions. Whereas the reduction at 70—80 °C for 2 h gave VIII as the main product in a 63.3% yield, the reduction at 0 °C gave IX in a 54.5% yield. The reduction of I in the presence of toluene at 90—100 °C gave a mixture of about equal amounts of four products,

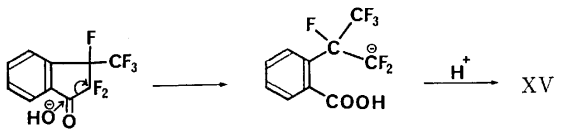
a) Mixture of stereoisomers.
b) °C/mmHg; decomposed at 200 °C and atmospheric pressure.

1-phenyl-4,4,4-trifluorobutane, VIII, IX, and an unidentified compound. The reduction of cyclic ketone (II) at 60—70 °C gave 1-trifluoromethylindene(XIV) in a 42.3% yield.

Both the elimination of α-halogen and the formation of olefin are known to be side reaction in the Clemmensen reduction.[7] The formation of olefin was especially enhanced when a double bond formed conjugated with a phenyl group. In the treatment of the fluorinated ketones, I and II, with zinc amalgam and hydrochloric acid, the reduction of the fluorines on the α- and β-carbons of the ketones seemed to occur first, followed by the reduction of the carbonyl or olefin formation, which were dependent on the reaction conditions.

The haloform cleavage of these ketones was observed. The reaction of I with aqueous potassium hydroxide gave benzoic acid, whereas the reaction of the cyclic ketone(II) gave *o*-(hexafluoroisopropyl)benzoic acid (XV), which was isolated as the methyl ester(XVI) in a 50.3% yield. The mechanism of the alkaline degradation of II is as follows:



The reaction of I with diazomethane gave only the epoxide (X) in a 75.9% yield. On the other hand, the reaction of II gave ring-expanded enol ether(XVIII), together with the epoxide (XVII). The postulated mechanism of the formation of XVII and XVIII is shown in Fig. 3. The reaction of ketones with diazomethane has been extensively studied; non-fluorinated ketones react in three alternative ways, yielding epoxide and/or ketones in which a methylene group has been inserted.[8] The presence of electronegative substituents on ketones has been reported to enhance the reactivity with diazomethane and to give mainly oxides instead of the expanded ketones. α-Fluoroketones have been reported to give only epoxides in high yields.[9] In agreement with the information in the literature, the linear ketone(I) gave only epoxide. The cyclic fluorinated ketone(II), however, gave the ring-expanded product (XVIII) together with the epoxide(XVII). The reaction of II and diazomethane, with the migration of the difluoromethylene carbon, seems to lead to the ring-expanded ketone(XIX). Since the methylene group of XIX is adjacent to the electron-withdrawing difluoromethylene and carbonyl group, the acidic hydrogen dissociates as a proton and an enolate anion is generated. Another molecule of diazomethane reacts with the enolate anion to give enol ether(XVIII). The intermediate ketone (XIX) was not isolated. The NMR showed that both epoxides, X and XVII, were mixtures of two stereoisomers, in the ratios of 50 : 50 and 60 : 40 respectively.

The mass and NMR spectral data of the products are shown in Table 3 and Table 4 respectively. The physical properties and analytical data are shown in Table 5.

Experimental

The IR and mass spectra were measured using a Hitachi Model EPI-G3 grating spectrometer and a Model RMU-7 double-focussing mass spectrometer at 70 eV respectively. The NMR spectra were obtained on a Hitachi Model R-20B (^{1}H : 60 MHz; ^{19}F : 56.45 MHz), using TMS as an internal standard for ^{1}H and trifluoroacetic acid as an external standard for ^{19}F. The analytical GLC was carried out in a stainless steel column (3 m long × 3 mm diameter) packed with 20% Silicone DC550-Celite 545 or 20% Silicone DCQF-1-Chromosorb W on a Shimadzu GC-3AH. In the preparative scale work, an aluminum column (6 m long × 10 mm diameter) was used on a Varian Model 920.

Addition Reactions of Benzaldehyde to Hexafluoropropene. General Procedure: A mixture of benzaldehyde, HFP, DTBP, and 1,1,2-trichlorotrifluoroethane in the molar ratio shown in Table 1 was heated in a stainless steel autoclave at temperatures gradually rising from 130 °C to 160 °C. The products were separated by vacuum distillation. Phenyl 1,1,2,3,3,3-hexafluoropropyl ketone(I) and 2,2,3-trifluoro-3-trifluoromethylindanone(II) were obtained as colorless liquids, together with a large amount of a tarry residue.

Preparation of Oximes. Phenyl 1,1,2,3,3,3-Hexafluoropropyl Ketone Oxime (III): To a solution of I (2.5 g, 0.01 mol) in 4 ml of ethanol, 2 ml of a 50% aqueous hydroxylamine hydrochloride solution was added; the mixture was then refluxed for 8 h. After the ethanol had then been allowed to evaporate, 20 ml of water was added and the organic products were extracted with ether. After the solvent had been removed, III was obtained as an oily residue (1.9 g, 70.1%), which crystallized on standing overnight. Recrystallization from chloroform gave pale yellow needles (mp 84 °C).

2,2,3-Trifluoro-3-(trifluoromethyl)indanone Oxime (XI): In a similar proceddre, II (1.25 g, 0.005 mol) gave XI (1.3 g, 98.2%) as colorless needles (mp 118 °C).

Grignard Reactions with Methylmagnesium Iodide. 2-Phenyl-3,3,4,5,5,5-hexafluoro-2-pentanol (IV): Methylmagnesium iodide was prepared from methyl iodide (1.5 g, 0.011 mol) and magnesium turnings (0.25 g, 0.010 atom) in 20 ml of ether. Then a solution of I (2 g, 0.008 mol) in 10 ml of ether was added, drop by drop, with cooling in an ice bath. The mixture was stirred for one hour at room temperature and then poured into dilute hydrochloric acid. The ether layer was separated and dried over magnesium sulfate. After the removal of the solvent, the residue was distilled *in vacuo*; IV (2.0 g, 94.2%) was thus obtained as a colorless liquid.

1-Methyl-2,2,3-trifluoro-3-(trifluoromethyl)-1-indanol (XII): By a similar procedure, XII (1.0 g, 78.4%) was obtained from II (1.2 g, 0.005 mol). Recrystallization from chloroform gave colorless prisms (mp 100 °C).

Reduction with $NaBH_4$. 1-Phenyl-2,2,3,4,4,4-hexafluoro-1-butanol (V): Sodium borohydride (4.0 g, 0.106 mol) and 60 ml of anhydrous ether were placed in a 200 ml Erlenmeyer flask; a solution of I (20.5 g, 0.08 mol) in 30 ml of ether was then added, drop by drop at room temperature. After the addition had been completed, stirring was continued for 3 h. The mixture was then poured into ice water, and the ether layer was separated and dried. After the removal of the solvent, the residue was distilled *in vacuo*; V was thus obtained as a colorless liquid (16.6 g, 80.4%).

2,2,3-Trifluoro-3-(trifluoromethyl)-1-indanol (XIII): By a similar procedure, XIII (3.6 g, 89.5%) was obtained from II (4.0 g, 0.015 mol) as a colorless liquid. Crystallization from chloro- form gave colorless prisms (mp 39 °C).

Clemmensen Reductions. trans-*1-Phenyl-4,4,4-trifluoro-1-butene (VIII)*: Zinc ribbon (20 g, 0.306 atom) was added to a 10 ml aqueous solution of mercuric chloride (2 g, 0.007 mol). After 5 minutes' shaking, the water layer was decanted and 5 ml of water and 20 ml of concentrated hydrochloric acid were added. A solution of I (5 g, 0.020 mol) in 10 ml of ethanol was then added, drop by drop, the temperature rose to 70—80 °C, after which stirring was continued for 2 h. The mixture was extracted with 20 ml of toluene, and then the organic layer was washed with water and dried. Vacuum distillation gave VIII (2.3 g, 63.3%) as a colorless liquid which was proved by GLC to contain small amounts of 1-phenyl-4,4,4-trifluorobutane and phenyl 3,3,3-trifluoropropyl ketone.

Phenyl 3,3,3-trifluoropropyl ketone (IX): A reduction similar to that described above was carried out at 0 °C under cooling in an ice bath. IX (2.2 g, 54.5%) was thus obtained as the main product from I (5 g, 0.020 mol).

1-*Trifluoromethylindene (XIV)*: By a procedure similar to that described above, II (2.6 g, 0.010 mol) gave XIV (0.8 g, 42.3%) as a colorless liquid.

Alkaline Hydrolysis. Benzoic Acid: Powdered potassium hydroxide (2 g, 0.036 mol) and 10 ml of hexane were placed in a 50 ml Erlenmeyer flask, and then a solution of I (3 g, 0.012 mol) in 10 ml of hexane was added. After 1 hour's stirring, the mixture was acidified with dilute hydrochloric acid. Benzene (30 ml) was then added, and the organic layer was separated. The solvent was allowed to evaporate to give a white solid (1.5 g). Recrystallization from hexane gave benzoic acid (1.0 g) as colorless needles (mp 123 °C).

o-*(Hexafluoroisopropyl)benzoic Acid (XV) and Its Methyl Ester (XVI)*: By a similar procedure, II (3 g, 0.012 mol) gave a pale yellow oil XV (1.9 g, 59.2%). A solution of XV in 20 ml of absolute ether was cooled in an ice bath, and then a freshly prepared diazomethane solution in ether was added. After the mixture had stood for 30 min, the solvent was removed. The vacuum distillation of the residue gave XVI (1.7 g, 50.3%) as a pale yellow liquid.

Reaction with Diazomethane. 2-Phenyl-3,3,4,5,5,5-hexafluoro-1,2-epoxypentene (X): A solution of I (2.0 g, 0.008 mol) in 20 ml of absolute ether was cooled in an ice bath; subsequently a freshly prepared diazomethane ether solution was added until the yellow color was no longer discharged. After the mixture had stood at room temperature for 3 h, the solvent was removed to give a pale yellow oily residue (1.6 g, 75.9%). Further purification was done by preparative GLC.

2,2,3-Trifluoro-1,1-methyleneoxy-3-trifluoromethylindane (XVII) and 1,2,2-Trifluoro-1-trifluoromethyl-4-methoxy-1,2-dihydronaphthalene (XVIII): By a similar procedure, II (2.0 g, 0.008 mol) gave a pale yellow residue (1.5 g) which contained XVII and XVIII in a ratio of 3 : 4 (GLC). They were separated by preparative GLC. Recrystallization from ethanol gave XVIII as colorless prisms (mp 76 °C).

Bromine Substitution of the Alcohol (V). 4-Bromo-1,1,1,-2,3,3-hexafluoro-4-phenylbutane (VII): To a mixture of V (10.4 g, 0.04 mol) and *p*-toluenesulfonyl chloride (10 g, 0.05 mol), 20% aqueous sodium hydroxide (15 ml) was added, drop by drop. After the reaction mixture had been heated at 100 °C for 6 h, it was poured into 100 ml of water and extracted with dichloromethane. The evaporation of the solvent gave tosylate(VI) (12.1 g, 73.4%) as colorless prisms (mp 106 °C), which were then recrystallized from ethanol.

A solution of VI (10 g, 0.024 mol) and potassium bromide (12 g, 0.10 mol) in ethylene glycol (20 ml) was heated at 160 °C for 6 h. The reaction mixture was poured into water and extracted with dichloromethane. After the solvent had been removed, the oily residue was distilled *in vacuo*. Bromide (VII) (6.4 g, 82.1%) was obtained as a colorless oil.

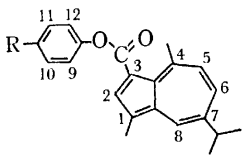
(Received Dcember 8, 1975)

Thermolysis of *p*-acetylphenyl 3-guaiazulenecarboxylate (**1**) results in loss of the ester group. In contrast, thermolysis of phenyl 3-guaiazulenecarboxylate (**2**) or *p*-methoxyphenyl 3-guaiazulenecarboxylate (**3**) gives (i) loss of the ester group, (ii) loss of the 1-methyl group with concomitant rearrangement of the ester group to the 1-position, (iii) interchange of the ester and 1-methyl groups, and (iv) cyclization to 5-isopropyl-7-methyl-1,2-dihydrocyclopenta[*c*,*d*]azulen-1-one (**9**).

Previous studies[2-5] showed that thermolysis of 3-acylguaiazulenes at 200—260 °C resulted in loss of the acyl group, migration of the acyl group to the 2-position, and/or interchange of the acyl and the 1-methyl groups. It was observed that the nature of the acyl substituent determined the course of the reaction. Thus formyl gave deacylation, acetyl and benzoyl gave migration, and methoxycarbonyl gave acyl-methyl interchange as the main reactions. The mode of reaction in these cases varies with the electron density at the acyl carbons and with the relative stabilities of the corresponding acylium ions. Thus the ability of the acyl substituent to stabilize a positive charge on the carbonyl carbon seemed to be important. To test this hypothesis further, we have prepared *p*-acetylphenyl- (**1**), phenyl- (**2**), and *p*-methoxyphenyl (**3**) 3-guaiazulenecarboxylates and examined their thermolytic behavior. Differences in the products from **1** to **3** due to steric factors would be small.

Results and Discussion

Esters **1**—**3** were prepared by the reaction of S-guaiazulene (**4**) with phosgene to form S-guaiazulene-3-carbonyl chloride, and the latter was treated with the corresponding phenol.[6] Compounds **1** and **3** are new and were characterized by their UV, IR, NMR and mass spectra. During the isolation of **3** a crystalline by-product was obtained which was shown to be bis(*p*-methoxyphenyl) carbonate. This indicates that the acid chloride product contained phosgene in this case.



1: R=Ac
2: R=H
3: R=OMe

Thermolysis of the esters was carried out at 250 °C for one hour. As anticipated, differences in the products formed or in their relative amounts were found. Only elimination of the carbonyl moiety to give **4** was observed with the *p*-acetylphenyl ester (**1**). In sharp contrast, the phenyl (**2**) and *p*-methoxyphenyl (**3**) esters formed four azulenic products resulting from (i) loss of the ester group (**4**) (ii) migration of the ester group to C-1 with concomitant loss of the 1-methyl group (**5** or **6**), (iii) interchange of the 1-methyl and 3-ester group (**7** or **8**), and (iv) cyclization of the 4-methyl group (**9**). The NMR spectra of compounds **5**—**8** exhibited a characteristic marked low field chemical shift of 8-hydrogen due to the peri ester function. The structures of **5**—**8** were confirmed by conversion to the corresponding known methyl esters (**10** and **11**) by the method of Reimer and Downes.[7] The yield data are summarized in Table 1. There is a definite correlation between the yields of rearranged products and the ability of the aryl portion of the ester function to supply electrons to the carbonyl carbon. This supports the hypothesis of an ionic mechanism wherein an increase in positive charge on the carbonyl carbon is involved. In that the loss of the ester group to form **4** demonstrates the presence

TABLE 1. YIELDS OF THERMOLYSIS PRODUCTS

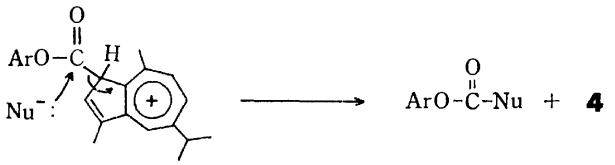
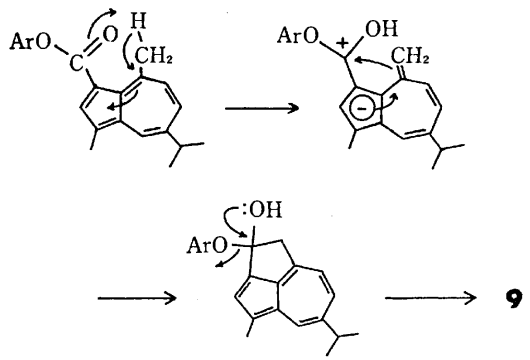
of a source of protons (perhaps in a decomposition product), reversible electrophilic substitution processes provide the simplest explanation for these reactions. The intermediacy of pi-complexes[8] can explain the formation of the rearrangement products. It is to be noted that all of the products have less steric hindrance than the starting esters and this is presumably the principal driving force. Of interest is the inverse correlation of the yields of **4** with those of the rearranged products. A possible explanation is that **4** is formed, for the most part, directly from the conjugate acid (**12**) through reaction with a nucleophile (*e.g.* the anion of the proton acid). The stability of **12** in terms of the tendency of the ester function to dissociate as a positive ion, or migrate *via* a pi-complex would decrease with the electron-donating ability of the ester aryl group, in agreement with the results obtained.



12

The formation of **9** is explicable in terms of the juxta-position of the acidic 4-methyl group[9] and a basic carbonyl oxygen. A simplified scheme is shown. The decreased oxygen basicity in **1** would correlate with the absence of **9** as a product in this case.



Experimental

NMR spectra were taken in $CDCl_3$, unless otherwise specified, on a JEOL MH-100 spectrometer (100 MHz) with TMS as internal standard. Mass spectra (MS) were obtained at 70 eV with a Hitachi-RMS-4 instrument. UV spectra were recorded in cyclohexane on a Hitachi 624 Digital Spectrophotometer with a Hitachi 056 Recorder, and IR spectra (liquids as films; solids as KBr disks) on a Hitachi EPI-S2 spectrophotometer. Mps are uncorrected. Kanto-Kagaku silica gel was used for chromatography unless otherwise specified. GLC was carried out on a Shimadzu GC-3AH instrument.

*p-Acetylphenyl 3-Guaiazulenecarboxylate (**1**), Phenyl 3-Guaiazulenecarboxylate (**2**), and p-Methoxyphenyl 3-Guaiazulenecarboxylate (**3**)* were prepared from guaiazulene according to the method of Treibs[6] in 44.3%, 31.4% and 29.8% crude (one spot on TLC) and 31.2%, 6.65% and 22.4% pure overall yields, respectively. Ester **1** was obtained from hexane as reddish-purple needles, mp 117.2—117.7 °C. TLC (benzene) R_f 0.11. λ_{max}: 251 (log ε 4.70), 305 (4.70), 318 (4.69), 388 (4.36), 524 (sh ε 612), 562 (755), 613 (sh 570), 673 (sh 175). IR: 1668 and 1702 cm^{-1}. NMR (δ): 1.38 (6H, d, J= 7.0 Hz $(CH_3)_2CH$), 2.57 (6H, s, 1-CH_3 and $COCH_3$), 3.02 (3H, s, 4-CH_3), 3.12 (1H, m, J=7.0 Hz, $(CH_3)_2CH$), 7.27 (2H, d, J=8.0 Hz, 9-H and 12-H), 7.30 (1H, d, J=11 Hz, 5-H), 7.5 (1H, dd, J=11.0 and 2.0 Hz, 6-H), 7.95 (2H, d, J=8.0 Hz, 10-H and 11-H), 8.11 (1H, s, 2-H), and 8.20 (1H, d, J=2.0 Hz, 8-H). MS: *m/e* 360 (M^+ for $C_{24}H_{24}O_3$) and 225 ($M^+ - CH_3COC_6H_5O$).

Ester **2** was isolated as violet plates from ethanol mp 62—63 °C (lit,[6] 69—70.5 °C). TLC (benzene) R_f 0.38. λ_{max}: 249 (log ε 4.40), 304.5 (4.53), 315 (sh 4.46), 386 (4.02), 482 (sh ε 190), 567 (527), and 650 (sh 404). IR: 1718 cm^{-1}. NMR (δ): 1.39 (6H, d, J=7.5 Hz, $(CH_3)_2CH$), 2.66 (3H, s, 1-CH_3), 3.12 (3H, s, 4-CH_3), 3.18 (1H, m, J=7.5 Hz, $(CH_3)_2CH$), 7.36 —7.56 (6H, 4 lines, C_6H_5 and 5-H), 7.68 (1H, dd, 6-H, J=2.0 and 10.9 Hz), 8.35 (1H, s, 2-H) and 8.42 (1H, d, J=2.0 Hz, 8-H). MS: *m/e* 318 (M^+ for $C_{22}H_{22}O_2$) and 225 ($M^+ - C_6H_5O$). NMR (δ) (CF_3COOH) of the conjugate acid: 1.60 (6H, d, J=6.8 Hz, $(CH_3)_2CH$), 2.55 (3H, m, J=1.4 and 2.7 Hz, 1-CH_3), 3.17 (3H, s, 4-CH_3), 3.57 (1H, m, J=6.8 Hz, $(CH_3)_2CH$), 5.48 (1H, m, 3-H), 6.8—7.6 (6H, C_6H_5 and 2-H), 8.71 (2H, s, 5-H and 6-H), and 8.75 (1H, s, 8-H) showing ring protonation at C-3.

Ester **3** separated from hexane as violet crystals, mp 96.8—97.3 °C. TLC (benzene) R_f 0.29. λ_{max}: 247 (log ε 4.85), 303 (4.89), 315 (sh 4.54), 387 (4.22), 531 (sh ε 586), 569 (728), 621 (sh 549), 684 (sh 193). IR: 1110 (C–O–C), 1170 (C–O–C) and 1703 cm^{-1} (C=O). NMR (δ): 1.35 (6H, d, J=7.0 Hz, $(CH_3)_2CH$), 2.57 (3H, s, 1-CH_3), 3.02 (3H, s, 4-CH_3), 3.08 (1H, m, J=7.0 Hz, $(CH_3)_2CH$), 3.75 (3H, s, OCH_3), 6.88 (2H, d, J=8.9 Hz, 10-H and 11-H), 7.10 (2H, d, J=8.9 Hz, 9-H and 12-H), 7.25 (1H, d, J=10.9 Hz, 5-H), 7.48 (1H, dd, J=10.9 and 2.1 Hz, 6-H), 8.11 (1H, s, 2-H) and 8.20 (1H, d, J=2.1 Hz, 8-H). MS: *m/e* 348 (M^+ for $C_{23}H_{24}O_3$) and 2.25 ($M^+ - CH_3OC_6H_4O$).

In the preparation of **3**, the treatment of the crude ester product with petroleum ether — 1% benzene afforded an insoluble crystalline product which was chromatographed on silica gel (benzene) and then recrystallized from methanol. The colorless needles, mp 98.1 °C, TLC (benzene) R_f 0.51 (spot developed with HNO_3–H_2SO_4), had spectral properties consistent with those expected for bis(*p*-methoxyphenyl) carbonate. IR: 1234 (C–O), 1763 (C=O) and 2830 cm^{-1} (ether C–H). NMR (δ): 3.77 (6H, s, OCH_3), 6.84 and 7.11 (8H, A_2B_2, J_{AB}=9.0 Hz, C_6H_4).

*Thermolysis of Esters **1**, **2** and **3**.*[10] The general procedure was to heat the ester (deoxygenated under high vacuum) sealed in a glass tube under nitrogen at 250 °C for 1 h. The treatment of the glass tube with acid or alkali gave no notable effect on thermolysis. The material was chromatographed on silica gel using a Toyo Kagaku Sangyo SF-160K automatic fraction collector. Benzene eluted S-guaiazulene (**4**) in the first fraction, then in the case of **1**, unchanged starting material. In the cases of **2** and **3**, a mixture of isomerized products, phenyl or *p*-methoxyphenyl 4-methyl-7-isopropyl-1-azulenecarboxylate (**5** or **6**) and the corresponding 3,4-dimethyl-7-isopropyl-1-azulenecarboxylate (**7** or **8**) was eluted after **4**, then unchanged starting material and, finally, benzene–ether (10 : 1) eluted 5-isopropyl-7-methyl-1,2-dihydrocyclopenta[*c*,*d*]azulen-1-one (**9**). Some tary material was obtained as the last fraction in the cases of **1** and **2**. The purity of the starting ester and of each product was checked by GLC

(SE 30 on Chromosorb W at 170—270 °C). The properties (R_f on TLC, IR, NMR and MS) of **4** were shown to be the same as those of an authentic sample. The complete separation of **5** and **7** and of **6** and **8** were very difficult and the yields reported include small correction factors based on GLC and NMR peak ratios.

From 151.8 mg of **1** were obtained 44.5 mg (29.3%) of **4** and 17.7 mg (11.7%) of tary material.

From 1.169 g of **2** were isolated 137.5 mg (11.8%) of **4**, 51.2 mg (4.4%) of unchanged **2**, and 636.8 mg (54.5%) of tar. The mixture of ester products was separated by chromatography on Amberlite IRC-50 (CG-50 Type 2) with 80% ethanol to give 39.6 mg (3.4%) of **5** and 18.8 mg (1.6%) of **7**. Ester **5** was obtained as a reddish violet oil. TLC (benzene) R_f 0.51. λ_{max}: 241 (log ε 4.43), 298 (4.62), 304 (4.64), 336.5 (3.72), 344 (3.75), 364 (3.99), 377 (4.09), 510 (sh ε 677), 532 (827), 570 (749) and 623 (300). IR: 1696 cm^{-1} (C=O). NMR (δ): 1.38 (6H, d, J=7.4 Hz, $(C\underline{H}_3)_2CH$), 2.93 (3H, s, 4-CH_3), 3.19 (1H, m, J=7.4 Hz, $(CH_3)_2C\underline{H}$), 7.23—7.51 (7H, m, C_6H_5, 3-H and 5-H), 7.70 (1H, dd, J=10.7 and 2.2 Hz, 6-H), 8.46 (1H, d, J=4.6 Hz, 2-H), and 9.84 (1H, d, J=2.2 Hz, 8-H). MS: *m/e* 304 (M^+ for $C_{21}H_{20}O_2$) and 78 ($C_6H_6^+$). Ester **7** was obtained as a violet oil. TLC (benzene) R_f 0.51. λ_{max}: 248 (log ε 4.48), 302 (4.64), 309 (4.66), 314 (sh 4.57), 377 (4.05), 389 (4.14), 562 (ε 887), 602 (sh 730) and 665 (258). IR: 1690 cm^{-1} (C=O). NMR (δ): 1.33 (6H, d, J=7.5 Hz, $(C\underline{H}_3)_2CH$), 2.82 (3H, s, 3-CH_3), 3.06 (3H, s, 4-CH_3), 3.15 (1H, m, J=7.5 Hz, $(CH_3)_2C\underline{H}$), 7.12—7.32 (6H, m, C_6H_5 and 5-H), 7.47 (1H, dd, J=10.7 and 2.0 Hz, 6-H), 8.21 (1H, s, 2-H), and 9.72 (1H, d, J=2.0 Hz, 8-H). MS: *m/e* 318 (M^+ for $C_{22}H_{22}O_2$), 225 ($M^+-C_6H_5O$) and 211 ($M^+-C_6H_5OCH_2$). Ketone **9** (16.6 mg, 1.4%) crystallized from hexane as dark violet needles, mp 99—100 °C. TLC (10 : 1 benzene–ether) R_f 0.13. λ_{max}: 235 (log ε 4.44), 242 (4.44), 258 (4.26), 268 (4.35), 300 (sh 4.36), 304 (4.47), 312 (4.51), 318 (4.62), 350 (sh 3.86), 362 (3.98), 375 (sh 3.96), 381 (4.03), 524 (sh ε 425), 544 (sh 538), 559 (659), 584 (616), 609 (692), 640 (sh 316) and 674 (324). IR: 1651 cm^{-1} (C=O). NMR (δ): 1.42 (6H, d, J=7.5 Hz, $(C\underline{H}_3)_2CH$), 2.65 (3H, s, 7-CH_3), 3.22 (1H, m, J=7.5 Hz, $(CH_3)_2C\underline{H}$), 4.04 (2H, s, CH_2), 7.32 (1H, d, J=12.8 Hz, 3-H), 7.68 (1H, s, 8-H), 7.82 (1H, dd, J=12.8 and 1.7 Hz, 4-H) and 8.29 (1H, d, J=1.7 Hz, 6-H). MS: *m/e* 224 (M^+ for $C_{16}H_{16}O$), 209 (M^+-CH_3), and 165 ($M^+-C_3H_7O$).

From 814.0 mg of **3** were obtained 41.5 mg (5.1%) of **4** and 437.3 mg (53.7%) of unchanged **3**. The mixture of ester products was treated as described above for the isolation of **5** and **7** and gave 26.9 mg (3.3%) of **6** and 49.8 mg (6.1%) of **8**. Ester **6** was obtained as a red oil. TLC (benzene) R_f 0.32. λ_{max}: 241 (log ε 4.45), 299 (4.59), 304 (4.61), 309 (sh 4.51), 364 (3.94), 377 (4.03), 513 (sh ε 738), 535 (888), 569 (715) and 623 (301). IR: 1692 (C=O) and 2830 cm^{-1} (O–CH_3). NMR (δ): 1.35 (6H, d, J=6.6 Hz, $(C\underline{H}_3)_2CH$), 2.85 (3H, s, 4-CH_3), 3.10 (1H, m, J=6.6 Hz, $(CH_3)_2C\underline{H}$), 3.72 (3H, s, OCH_3), 6.78 (2H, d, J=9.3 Hz, H-10 and H-11), 7.01 (2H, d, J=9.3, H-9 and H-12), 7.08 (1H, d, J=4.3 Hz, 3-H), 7.22 (1H, d, J=10.7 Hz, 5-H), 7.48 (1H, dd, J=10.7 and 2.2 Hz, 6-H), 8.24 (1H, d, J=4.3 Hz, 2-H) and 9.60 (1H, d, J=2.2 Hz, 8-H). MS: *m/e* 334 (M^+ for $C_{22}H_{22}O_3$) and ($M^+-CH_3OC_6H_4O$). Ester **8** crystallized from hexane as dark violet crystals, mp 91—92 °C. TLC (benzene) R_f 0.32. λ_{max}: 249 (log ε 4.57), 289 (sh 4.53), 300 (4.71), 308 (4.73), 314 (sh 4.66), 373 (4.14), 388 (4.21), 526 (sh ε 760), 562 (990), 604 (sh 826) and 666 (301). IR: 1700 cm^{-1}. NMR (δ): 1.35 (6H, d, J=7.2 Hz, $(C\underline{H}_3)_2CH$), 2.83 (3H, s, 3-CH_3), 3.05 (3H, s, 4-CH_3), 3.08 (1H, m, J=7.2 Hz, $(CH_3)_2C\underline{H}$), 3.80 (3H, s, OCH_3), 6.94 (2H, d, J=9.6 Hz, H-10 and H-11), 7.16 (2H, d, J=9.6 Hz, H-9 and H-12), 7.19 (1H, d, J=10.5 Hz, 5-H), 7.48 (1H, dd, J=10.5 and 2.0 Hz, 6-H), 8.23 (1H, s, 2-H) and 9.76 (1H, d, J=2.0 Hz, 8-H). MS: *m/e* 348 (M^+ for $C_{23}H_{24}O_3$) and 225 ($M^+-CH_3OC_6H_4O$). The yield of ketone **9** was 45.8 mg (5.6%).

*Methyl 4-Methyl-7-isopropyl-1-azulenecarboxylate (**10**).* *A. From **5**.* A solution of 20.98 mg of **5** in an excess (0.7 ml) of 0.03 M potassium methoxide in methanol was shaken in a sealed tube for 20 h. The mixture was then diluted with water (30 ml) and extracted with ether (3×10 ml). Chromatography of the concentrate from the ether extract on silica gel (benzene) separated 12.60 mg (75.4%) of **10** identical (UV, IR and NMR) with an authentic specimen.[11]

*B. From **7**.* The procedure given in *A* afforded 8.97 mg (85.4%) of **10**, identical (IR, NMR) with that from *A*, from 14.43 mg of **7**.

*Methyl 3,4-Dimethyl-7-isopropyl-1-azulenecarboxylate (**11**).* A. *From **6**.* In the manner described for the preparation of **10**, 4.42 mg of **6** was converted to 2.05 mg (57.6%) of **11** identical (UV, Vis, TLC) with an authentic specimen.[4]

*B. From **8**.* The procedure indicated in *A* gave from 5.96 mg of **8** a yield of 3.98 mg (90.9 %) of **11** identical with that from *A*.

Synthesis of Eriostoic Acid and Eriostemoic Acid[1]

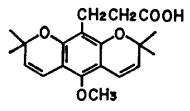
Masao TSUKAYAMA

Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima 770

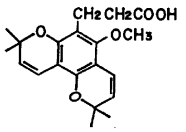
(Received December 8, 1975)

A 1,8-dioxaanthracenepropionic acid derivative (**5**), after being converted into methyl ester-methyl ether (**6**), was reduced with sodium borohydride to give methyl eriostate (**7**). Hydrolysis of the ester (**7**) with alkali afforded eriostoic acid (**1**). On the other hand, eriostemoic acid (**2**) was synthesized from methyl eriostemate (**10**), which was obtained from a 1,5-dioxaphenanthrenepropionic acid derivative (**8**) *via* four steps.

Eriostoic acid has been isolated from *Eriostemon difformis* and the structure has been elucidated to be a linear-type benzodipyran (10-methoxy-2,2,7,7-tetramethyl-2*H*,7*H*-1,8-dioxaanthracene-9-propionic acid) (**1**) on the basis of degradation and spectral evidence.[2] On the other hand, eriostemoic acid isolated from *Eriostemon tomentellus* has been shown to be an angular-type benzodipyran derivative (9-methoxy-2,2,6,6-tetramethyl-2*H*,6*H*-1,5-dioxaphenanthrene-10-propionic acid) (**2**) which is closely related to **1**.[3] The present paper reports on the synthesis of **1** and **2** for confirmation of the proposed structures of natural eriostoic and eriostemoic acids.

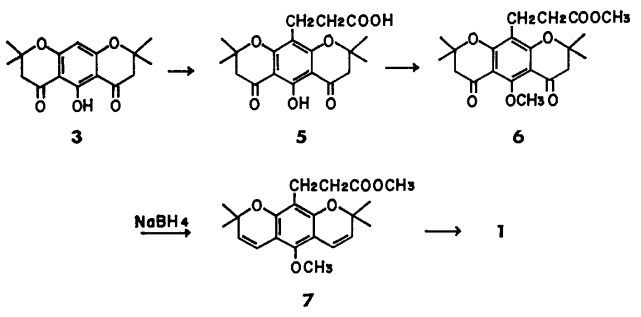


1



2

The condensation of a 1,8-dioxaanthracene derivative (**3**)[4] with acrylic acid in the presence of polyphosphoric acid gave a 1,8-dioxaanthracenepropionic acid derivative (**5**). The exhaustive methylation of **5** with dimethyl sulfate afforded the corresponding methyl ester-methyl ether (**6**). The reduction of **6** with an excess of sodium borohydride[5] in dry methanol containing a small amount of pyridine gave directly methyl eriostate (**7**). The NMR spectrum showed the presence of four vinylic protons as two overlapping doublets at δ 5.45 (2H) and 6.48 (2H) ppm, and the IR spectrum showed an olefinic group at 1630 cm^{-1} and the disappearance of the carbonyl group. Hydrolysis of **7** with 4% aqueous methanolic sodium hydroxide smoothly produced the desired acid (**1**) (mp 173—174 °C),[2] which was shown to be identical with natural eriostoic acid on the basis of a mixed-melting-point determination and by NMR, IR, and UV spectral comparisons.



3 5 6 7

Scheme 1.

In a similar manner, the 1,5-dioxaphenanthrenepropionic acid derivative (**8**), which was obtained by the condensation of a 1,5-dioxaphenanthrene derivative (**4**)[4] with acrylic acid and whose structure was confirmed by NMR and IR spectra, was converted into the corresponding methyl ester-methyl ether (**9**). The reduction of **9** with sodium borohydride gave methyl eriostemate (**10**) in a poor yield. Hydrolysis of **10** with dilute alkali afforded the desired acid (**2**) (mp 101—102 °C),[3] which was shown to be identical with natural eriostemoic acid on the basis of a mixed-melting-point determination and by NMR, IR, and UV spectral comparisons.

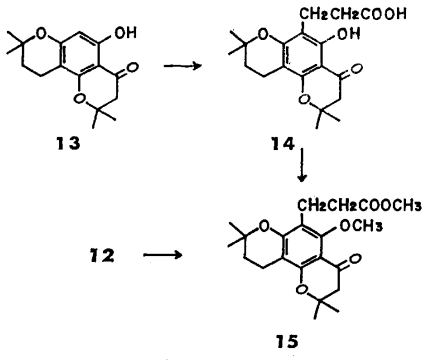
Scheme 2.

In view of the low yield of methyl eriostemate, an alternate method of preparing this compound was further investigated. The methyl ester-methyl ether (**9**) was converted into an alcohol derivative (mp 114—115 °C) (**11**) by catalytic reduction with Raney nickel in methanol under atmospheric conditions. The dehydration of the alcohol (**11**) with freshly-fused potassium hydrogensulfate in dry toluene was smoothly effected to give the corresponding dihydro-1,5-dioxaphenanthrenepropionic acid derivative (**12**). The NMR spectrum showed the presence of one vinyl group as a pair of doublets at δ 5.37 and 6.48 ppm and one methylene group as a singlet at δ 2.51 ppm, and the IR spectrum showed the presence of an olefinic group at 1637 cm^{-1} and the disappearance of the hydroxyl group. The reduction of **12** with sodium borohydride in dry tetrahydrofuran gave methyl eriostemate (**10**) in a 37% yield, which was identical with the sample synthesized in the manner described above.

The reduction of **12** with palladium charcoal in methanol gave the corresponding tetrahydro-1,5-dioxaphenanthrenepropionic acid derivative (**15**), which was identical with that derivative (**15**) obtained from



Scheme 3.

a tetrahydro-1,5-dioxaphenanthrene derivative (**13**)[4] *via* two steps, as shown in Scheme 3. Therefore, structure of the alcohol derivative (**11**) was elucidated on the basis of the facts described above.

Experimental

The melting points are uncorrected. The IR spectra were taken with a Hitachi 215 Spectrophotometer, and the UV spectra with a Hitachi 124 Spectrophotometer. The NMR spectra were determined with a JOEL PS-100 Spectrometer (100 MHz) using tetramethylsilane as an internal standard (δ, ppm). Column chromatography was carried out on Kieselgel 60 (70—230 mesh) (Merck).

*10-Hydroxy-2,2,7,7-tetramethyl-4,5-dioxo-3,4,5,6-tetrahydro-2*H,*7*H-*1,8-dioxaanthracene-9-propionic Acid (**5**).* 10-Hydroxy-2,2,7,7-tetramethy-4,5-dioxo-3,4,5,6-tetrahydro-2*H*,7*H*-1,8-dioxaanthracene (**3**) (5.6 g), which was prepared according to a procedure described by Jefferson *et al.*,[4] and acrylic acid (3 g) were heated in the presence of freshly-prepared polyphosphoric acid (90 g) with stirring at 80—85 °C for 2 h and then poured into ice-cold water (300 ml). The diluted reaction mixture was allowed to stand overnight at room temperature to afford a white precipitate. The precipitate, after being dissolved in chloroform (200 ml), was extracted with 5% aqueous sodium carbonate (50 ml×3), and the alkalin solution was acidified with dilute hydrochloric acid to give acid **5** (3 g, 43%), which produced a light brown ferric chloride reaction in ethanol and which was obtained as colorless needles upon recrystallization from methanol: mp 190—191 °C; IR ν_{max}^{KBr}: 1610, 1675, 1735 cm^{-1}; NMR ($CDCl_3$) δ: 1.46 (s, 12H, CH_3 × 4), 2.66 (s, 4H, CH_2CO × 2), 2.37—2.92 (m, 4H, CH_2CH_2), 13.76 (s, 1H, OH). Found: C, 62.73; H, 6.19%. Calcd for $C_{19}H_{22}O_7$: C, 62.97; H, 6.12%.

*Methyl 10-Methoxy-2,2,7,7-tetramethyl-4,5-dioxo-3,4,5,6-tetrahydro-2*H,*7*H-*1,8-dioxaanthracene-9-propionate (**6**).* A mixture of acid **5** (3 g), dimethyl sulfate (7 g), and anhydrous potassium carbonate (8 g) was heated under reflux in dry acetone (100 ml) for 25 h. The resulting product was recrystallized from methanol to give methyl ester-methyl ether (**6**) (2.5 g, 77%) as colorless needles: mp 121.5—122.5 °C; IR ν_{max}^{KBr} 1693, 1730 cm^{-1}; NMR ($CDCl_3$) δ 1.43 (s, 12H, CH_3 ×4), 2.63 (s, 4H, CH_2CO×2), 2.34—2.96 (m, 4H, CH_2CH_2), 3.67 (s, 3H, OCH_3), 3.87 (s, 3H, OCH_3). Found: C, 64.61; H, 6.73%. Calcd for $C_{21}H_{26}O_7$: C, 64.60; H, 6.71%.

*Methyl Eriostate (**7**).* Sodium borohydride (0.16 g) was added portionwise to a solution of methyl ester-methyl ether **6** (0.39 g) in a mixture of dry methanol (15 ml) and pyridine (3.5 ml) with stirring for 1 h at room temperature, and the mixture was further warmed at 45 °C for 9 h. The reaction mixture was then cooled, acidified with dilute hydrochloric acid and extracted with ether, and the ethereal solution was washed with a saturated aqueous solution of sodium chloride and dried, and the solvent was evaporated. The residue was purified by column chromatography with silica gel and benzene to give an oil (**7**) (61 mg, 17%), which was crystallized from hexane as colorless prisms (mp 96—97 °C, lit, mp 94 °C[2]): IR ν_{max}: 1630, 1735 cm^{-1}; NMR ($CDCl_3$) δ: 1.39 (s, 12H, CH_3×4), 2.36—2.94 (m, 4H, CH_2-CH_2), 3.66 (s, 3H, OCH_3), 3.70 (s, 3H, OCH_3), 5.45 and 6.48 (each d, 2H, J=10 Hz, CH=CH). Found: C, 70.13; H, 7.40%. Calcd for $C_{21}H_{26}O_5$: C, 70.37; H, 7.31%.

*Eriostoic Acid (**1**).* Methyl eriostate (**7**) (22 mg) was hydrolyzed with 4% aqueous methanolic sodium hydroxide (20 ml) at 80 °C for 30 min. The reaction mixture was then acidified with dilute hydrochloric acid to afford eriostoic acid (**1**) as white precipitates, which was recrystallized from ethyl acetate as colorless prisms (20 mg, 95%) (mp 173—174 °C, lit, mp 173—174 °C,[2]) no depression in a mixed-melting-point determination with natural eriostoic acid): IR ν_{max}^{KBr}: 1630, 1718 cm^{-1}; NMR ($CDCl_3$) δ: 1.40 (s, 12H, CH_3×4), 2.43—2.97 (m, 4H, CH_2CH_2), 3.70 (s, 3H, OCH_3), 5.45 and 6.48 (each d, 2H, J=10 Hz, CH=CH); UV λ_{max}^{EtOH} nm (log ε): 259 (4.60), 268 (4.59), 340 (3.52). Found: C, 69.87; H, 7.18%. Calcd for $C_{20}H_{24}O_5$: C, 69.74; H, 7.02%.

*9-Hydroxy-2,2,6,6-tetramethyl-4,8-dioxo-3,4,7,8-tetrahydro-2*H,*6*H-*1,5-dioxaphenanthrene-10-propionic Acid (**8**).* 9-Hydroxy-2,2,6,6-tetramethyl-4,8-dioxo-3,4,7,8-tetrahydro-2*H*,6*H*-1,5-dioxaphenanthrene (**4**)[4] (6 g) and acrylic acid (3 g) were heated in the presence of freshly-prepared polyphosphoric acid (90 g) with stirring at 80—85 °C for 2 h. The reaction mixture was similary treated as described for the preparation of **5** to give acid **8** (3.4 g, 45%), which showed a light brown ferric chloride reaction in ethanol, as colorless needles: mp 192—193 °C; IR ν_{max}^{KBr}: 1632, 1687, 1706 cm^{-1}; NMR ($CDCl_3$) δ: 1.45 (s, 6H, CH_3×2), 1.53 (s, 6H, CH_3×2), 2.63 (s, 2H, CH_2CO), 2.72 (s, 2H, CH_2CO), 2.44—2.96 (m, 4H, CH_2-CH_2), 12.94 (s, 1H, OH). Found: C, 62.83; H, 6.12%. Calcd for $C_{19}H_{22}O_7$: C, 62.97; H, 6.12%.

*Methyl 9-Methoxy-2,2,6,6-tetramethyl-4,8-dioxo-3,4,7,8-tetrahydro-2*H,*6*H-*1,5-dioxaphenanthrene-10-propionate (**9**).* A mixture of acid **8** (4 g), dimethyl sulfate (7 g), and anhydrous potassium carbonate (8 g) was heated under reflux in dry acetone (100 ml) for 25 h. The product was recrystallized from methanol to give methyl ester-methyl ether **9** (3.5 g, 81%) as colorless needles: mp 105—106 °C; IR ν_{max}^{KBr}: 1683, 1725 cm^{-1}; NMR ($CDCl_3$) δ: 1.45 (s, 6H, CH_3×2), 1.49 (s, 6H, CH_3×2), 2.64 (s, 4H, CH_2CO×2), 2.36—2.94 (m, 4H, CH_2CH_2), 3.65 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3). Found: C, 64.45; H, 6.77%. Calcd for $C_{21}H_{26}O_7$: C, 64.60; H, 6.71%.

*Methyl Eriostemate (**10**).* Sodium borohydride (0.24 g) was added portionwise to a solution of methyl ester-methyl ether **9** (0.5 g) in a mixture of dry methanol (20 ml) and pyridine (4 ml) with stirring for 1 h at room temperature, and the mixture was maintained at 45 °C for 9 h. The reaction product thus obtained was purified by column chromatography with silica gel and benzene to give methyl eriostemate (liquid) (**10**) (28 mg, 6%): IR ν_{max}: 1635, 1735 cm^{-1}; NMR (CCl_4) δ: 1.38 (s, 6H, CH_3×2), 1.40 (s, 6H, CH_3×2), 2.28—2.79 (m, 4H, CH_2CH_2), 3.60 (s, 3H, OCH_3), 3.67 (s, 3H, OCH_3), 5.33 (d, 2H, J=10 Hz, CH=CH), 6.38 and 6.48 (each d, 1H, J=10 Hz, CH=CH). Found: C, 70.24; H, 7.40%. Calcd for $C_{21}H_{26}O_5$: C, 70.37; H, 7.31%.

*Eriostemoic Acid (**2**).* Methyl eriostemate (**10**) (25 mg) was hydrolyzed with 4% aqueous methanolic sodium hydro-

xide (20 ml) at 80 °C for 30 min. The reaction mixture, after being acidified with dilute hydrochloric acid, was extracted with ether and the ethereal solution was washed with water and dried, and the solvent was evaporated. The residue was eluted over a silica gel column with chloroform–ethyl acetate (4 : 1) to give the desired acid (**2**) (20 mg, 83%), which was recrystallized from hexane as colorless prisms (mp 101—102 °C, lit, mp 101 °C,[3]) no depression in a mixed-melting-point determination with natural eriostemoic acid): IR ν_{max}^{KBr}: 1640, 1708 cm^{-1}; NMR ($CDCl_3$) δ: 1.39 (s, 12H, $CH_3\times4$), 2.43—2.93 (m, 4H, CH_2CH_2), 3.69 (s, 3H, OCH_3), 5.45 (d, 2H, $J=10$ Hz, CH=CH), 6.46 and 6.59 (each d, 1H $J=10$ Hz, CH=CH). UV λ_{max}^{EtOH} nm (log ε): 206 (4.29), 254 (4.33), 258 (4.33), 280 (4.13), 331 (3.39), 347 (3.29). Found: C, 70.03; H, 7.09%. Calcd for $C_{20}H_{24}O_5$: C, 69.74; H, 7.02%.

*Methyl 4-Hydroxy-9-methoxy-2,2,6,6-tetramethyl-8-oxo-3,4,7,8-tetrahydro-2H,6H-1,5-dioxaphenanthrene-10-propionate (**11**).* Methyl ester-methyl ether **9** (0.95 g) was hydrogenated over Raney nickel (6 g) in methanol (30 ml) under atmospheric pressure at room temperature. After the uptake of hydrogen ceased, the solution was filtered and the solvent was evaporated under reduced pressure. The residue thus obtained was purified in column chromatography with silica gel and chloroform–ethyl acetate (20 : 1) to afford a colorless solid, showing lower R_f value (0.32) than that (0.39) of the starting material. The solid was recrystallized from light petroleum ether (40—50 °C) to give alcohol derivative **11** (0.44 g, 46%) (mp 114—115 °C) as colorless prisms: IR ν_{max}^{KBr}: 1665, 1738, 3460 cm^{-1}; NMR ($CDCl_3$) δ: 1.39 (s, 3H, CH_3), 1.47 (s, 6H, $CH_3\times2$), 1.53 (s, 3H, CH_3), 2.04 (d, 2H, CH_2), 2.68 (s, 2H, CH_2CO), 2.37—2.95 (m, 4H, CH_2CH_2), 3.68 (s, 3H, OCH_3), 3.78 (s, 3H, OCH_3), 4.92 (t, 1H, CHOH). Found: C, 64.12; H, 7.28%. Calcd for $C_{21}H_{28}O_7$: C, 64.27; H, 7.19%.

*Methyl 9-Methoxy-2,2,6,6-tetramethyl-8-oxo-7,8-dihydro-2H,6H-1,5-dioxaphenanthrene-10-propionate (**12**).* Alcohol **11** (0.45 g) was refluxed with freshly-fused potassium hydrogensulfate (2 g) in toluene (5 ml) for 7 h. The mixture was then filtered and the filtrate was evaporated under reduced pressure to give a colorless oil, which was purified over a silica gel column with chloroform–methyl ethyl ketone (50 : 1) to give colorless needles **12** (0.4 g, 93%) (mp 85—86 °C, crystallization from light petroleum ether): IR ν_{max}: 1637, 1678, 1735 cm^{-1}; NMR (CCl_4) δ: 1.45 (bs, 12H, $CH_3\times4$), 2.51 (s, 2H, CH_2CO), 2.27—2.83 (m, 4H, CH_2CH_2), 3.61 (s, 3H, OCH_3), 3.73 (s, 3H, OCH_3), 5.37 and 6.48 (each d, 1H, $J=10$ Hz, CH=CH). Found: C, 67.09; H, 7.11%. Calcd for $C_{21}H_{26}O_6$: C, 67.36; H, 7.00%.

*Another Synthesis of Methyl Eriostemate (**10**).* Sodium borohydride (90 mg) was added portionwise to a solution of methyl ester **12** (0.145 g) in dry tetrahydrofuran (15 ml) with stirring for 1 h at room temperature, and the mixture was refluxed for 6 h. The reaction mixture was cooled and treated as described above to give an oil. The oil was eluted over a silica gel column with benzene to give methyl eriostemate (liquid) (**10**) (52 mg, 37%), the identity of which was confirmed by spectroscopic comparison with the methyl eriostemate synthesized above. The starting material **12** (90 mg) was also recovered.

*9-Hydroxy-2,2,6,6-tetramethyl-8-oxo-3,4,7,8-tetrahydro-2H,6H-1,5-dioxaphenanthrene-10-propionic Acid (**14**).* 9-Hydroxy-2,2,6,6-tetramethyl-8-oxo-3,4,7,8-tetrahydro-2*H*,6*H*-1,5-dioxaphenanthrene (**13**)[4] (1.9 g) and acrylic acid (1.5 g) were heated in the presence of polyphosphoric acid (45 g) with stirring at 60—65 °C for 1.5 h, and the reaction mixture was poured into ice-cold water (200 ml). The mixture was allowed to stand overnight at room temperature, and a white precipitate was collected and purified by column chromatography with silica gel and a mixed solvent of chloroform–methanol (190 : 9) to give an acid **14** (0.5 g, 21%) (mp 202—203 °C; recrystallization from methanol as colorless prisms). It gave a dark blue ferric chloride reaction in ethanol: IR ν_{max}^{KBr} 1635, 1708 cm^{-1}; NMR ($CDCl_3$) δ 1.33 (s, 6H, $CH_3\times2$), 1.44 (s, 6H, $CH_3\times2$), 1.74 and 2.53 (each t, 2H, $J=6$ Hz, CH_2), 2.43—2.95 (m, 4H, CH_2CH_2), 2.65 (s, 2H, CH_2CO), 12.17 (s, 1H, OH). Found: C, 65.50; H, 7.04%. (s, 2H, CH_2CO), 12.17 (s, 1H, OH). Found: C, 65.50; H, 7.04%. Calcd for $C_{19}H_{24}O_6$: C, 65.50; H, 6.94%.

*Methyl 9-Methoxy-2,2,6,6-tetramethyl-8-oxo-3,4,7,8-tetrahydro-2H,6H-1,5-dioxaphenanthrene-10-propionate (**15**).* A mixture of acid **14** (0.13 g), dimethyl sulfate (0.3 g), and anhydrous potassium carbonate (2 g) was heated under reflux in dry acetone (50 ml) for 24 h. The product was purified by column chromatography on silica gel with chloroform–ethyl acetate (20 : 1) to give a colorless oil (**15**). The oil was crystallized from light petroleum ether (40—50 °C) as colorless prisms (70 mg, 50%) (mp 79—80 °C): IR ν_{max}: 1673, 1735 cm^{-1}; NMR ($CDCl_3$) δ: 1.33 (s, 6H, $CH_3\times2$), 1.43 (s, 6H, $CH_3\times2$), 1.75 and 2.52 (each t, 2H, $J=6$ Hz, CH_2), 2.36—2.94 (m, 4H, CH_2CH_2), 2.60 (s, 2H, CH_2CO), 3.68 (s, 3H, OCH_3), 3.77 (s, 3H, OCH_3). Found: C, 66.97; H, 7.59%. Calcd for $C_{21}H_{28}O_6$: C, 67.00; H, 7.50%.

*Additional Synthesis of **15**.* Methyl ester **12** (0.11 g) was hydrogenated over palladium charcoal (95 mg) in methanol (20 ml) at room temperature. After the uptake of hydrogen ceased within 40 min, the solution was filtered and the filtrate was evaporated under reduced pressure. The residue was purified by column chromatography on silica gel with chloroform–ethyl acetate (20 : 1) to give a colorless oil (0.10 g, 90%). The oil was crystallized from light petroleum ether to give colorless prisms **15** (mp 79—80 °C; not depressed upon mixture with the sample synthesized above).

The author wishes to express his deep gratitude to Professor Shūichi Hayashi and Dr. Mitsuru Nakayama, Hiroshima University, for their guidance and encouragement throughout the course of this work, and also to Professor P. R. Jefferies, Department of Chemistry, University of Western Australia, Nedlands, W. A., for supplying the samples of natural eriostoic acid and eriostemoic acid.

A Facile Method for the Oxidation of Alcohols

Kazuhiko SAIGO, Anri MORIKAWA, and Teruaki MUKAIYAMA

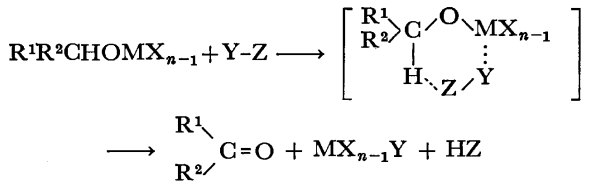
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 19, 1975)

Trialkyltin alkoxides, prepared from alcohols and trialkyltin methoxide by azeotropical removal of methanol, are easily oxidized by bromine in the presence of trialkyltin methoxide, a hydrogen bromide captor, to give the corresponding aldehydes or ketones in good yields. Alcohols are oxidized directly in one step to the corresponding carbonyl compounds by utilizing bis(tributyltin) oxide and bromine.

Selective oxidation of alcohols to the corresponding aldehydes or ketones is important in organic synthesis, and a number of methods have been reported. Reagent such as aluminum triisopropoxide (the Oppenauer oxidation),[1] CrO_3–AcOH complex (Jones reagent),[2] CrO_3–pyridine complex (Collins reagent),[3] dicyclohexylcarbodiimide–dimethyl sulfoxide,[4] dimethyl sulfide–chlorine or *N*-chlorosuccinimide[5] and others[6] are commonly employed for oxidizing alcohols to aldehydes or ketones, but they bring about certain difficulties. For example, further oxidation of the desired aldehyde to carboxylic acid and of carbon–carbon double bonds or isomerization of carbon–carbon double bonds sometimes takes place reducing the yields of the desired aldehydes or ketones. This prompted us to look for efficient reagents for the oxidation of alcohols to the corresponding aldehydes or ketones.

The study was initiated to examine the effective combination of a metal alkoxide ($R^1R^2CHOMX_{n-1}$) and an oxidant (Y-Z) based on the following consideration: If oxidant Y has a strong affinity to alkoxide M and oxidant Z also has an affinity toward hydride, the oxidation would be effectively promoted *via* 6-membered cyclic intermediate to give the desired carbonyl compound accompanied by the formation of $MX_{n-1}Y$ and HZ as illustrated in the following scheme.

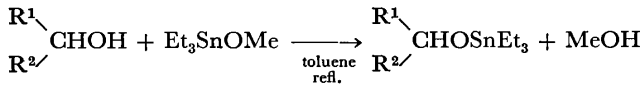


After several trials with cinnamyl alcohol as a model alcohol, cinnamaldehyde was obtained in a moderate yield when triethyltin cinnamyl oxide was treated with bromine[7] as briefly reported in a previous communication.[8] In this report, details of the oxidation are described with additional results.

The starting materials, triethyltin alkoxides, were prepared according to a modification of the method in literature.[9] Alcohol was allowed to react with triethyltin methoxide[10] in toluene under refluxing, the methanol formed being removed continuously. The corresponding triethyltin alkoxide was obtained in a good yield after distillation under reduced pressure (Table 1).

It was found that, in the absence of the hydrogen bromide captor, the starting triethyltin alkoxide was destroyed by the rapid reaction with hydrogen bromide to form triethyltin bromide and the alcohol, and that in order to improve the yield of the carbonyl compound it is necessary to capture hydrogen bromide produced at the same time. Of several hydrogen bromide captors examined, the best result was obtained when

Table 1. Preparation of triethyltin alkoxides



Alcohol	Reaction time (h)	Isolated yield (%)	Bp (mmHg)
Geraniol	8	92	134—6 °C (1.0)
Cinnamyl alcohol	2	84	145—7 °C (0.75)
(*E*)-2-Hexen-1-ol	14	78	105—7 °C (2.4)
Piperonyl alcohol	6	86	153—6 °C (0.8)
Benzyl alcohol	9	78	108 °C (0.7)
1-Phenylethanol	5	78	108—9 °C (1.4)
2-Octanol	4	86	108—9 °C (1.8)

Cinnamyl alcohol	92[b]
(*E*)-2-Hexen-1-ol	71[b]
Piperonyl alcohol	96[a]
Benzyl alcohol	81[b]
1-Phenylethanol	79[b]
2-Octanol	85[b]

a) Isolated yield. b) Yield determined by GLC.[11]

triethyltin methoxide was employed as a captor (Table 2).

The effect of the solvent on the oxidation of triethyltin 1-phenylethoxide with bromine was studied in tetrahydrofuran (THF), dichloromethane and benzene, and the corresponding ketone, acetophenone, was obtained in 78%, 70% and 66% yields, respectively.

Optimum yield was obtained when a THF solution of bromine was added dropwise to a THF solution of triethyltin alkoxide in the presence of triethyltin methoxide as a hydrogen bromide captor. The oxidation of various triethyltin alkoxides was attempted and the corresponding aldehydes or ketones were obtained in good yields (Table 3).

Similarly, tributyltin alkoxide, easily prepared from bis(tributyltin) oxide and an alcohol, was oxidized with bromine in the presence of tributyltin methoxide as a hydrogen bromide captor. As an example, tributyltin benzyl oxide was oxidized to give benzaldehyde in 82% yield.

$$C_6H_5CH_2OSnBu_3 \xrightarrow[Bu_3SnOMe,\ THF]{Br_2} C_6H_5CHO + [2Bu_3SnBr + MeOH]$$

The yield decreased when chlorine or iodine was employed as an oxidant instead of bromine.

It is remarkable that the reaction is completed as soon as the titration of a bromine solution is over. It is noteworthy that the oxidation of geraniol affords geranial in a high yield, no by-products such as a further oxidized product (geranic acid), an isomerized product (neral) and brominated products formed by the addition of bromine to the olefinic linkages being detected.

The present method involves the following two processes: (1) Preparation of trialkyltin alkoxides from alcohols and trialkyltin methoxide or bis(trialkyltin) oxide, and (2) oxidation of trialkyltin alkoxides to the carbonyl compounds with bromine in the presence of trialkyltin methoxide. In order to find a one step procedure for the oxidation of alcohols, oxidation with bromine utilizing bis(tributyltin) oxide[12] was studied on the basis of the following: Bis(tributyltin) oxide reacts with alcohols to give the corresponding tributyltin alkoxides and tributyltin hydroxide,[13] and with hydrogen halide to give tributyltin halide and tributyltin hydroxide. Thus tributyltin alkoxides would be formed *in situ* from alcohols and bis(tributyltin) oxide, and the alkoxides would be similarly oxidized with bromine in the presence of bis(tributyltin) oxide, a hydrogen bromide captor.

Actually, cinnamaldehyde was obtained in 84% yield by adding a bromine solution into a solution of an equimolar amount of cinnamyl alcohol in the presence of bis(tributyltin) oxide. It was found that THF is also better than benzene or dichloromethane as a solvent similarly to the case of oxidation of isolated trialkyltin alkoxides (Table 4).

In the case of the oxidation of 2-octanol, 2-octanone was obtained only in 60% yield under these conditions. After several trials it was found that the optimum yield is obtained for 2-octanone when the mole ratio of alcohol, bis(tributyltin) oxide and bromine is 1 : 2 : 2. In the case of hindered alcohols such as 1-phenylethanol, benzhydrol and 3β-cholestanol, the yields were improved by treatment of alcohol with bis(tributyltin) oxide in the presence of molecular sieves[14] at 50—60 °C for several hours before the addition of bromine. The oxidation of several alcohols was examined under these conditions and the corresponding aldehydes or ketones were obtained in good yields (Table 5).

a) Isolated yield. b) Yield determined by GLC.[11] Values in parentheses indicate the yields when alcohols were allowed to react with bis(tributyltin) oxide in the presence of molecular sieves before the addition of bromine.

By this procedure, alcohols are directly oxidized by bromine in the presence of bis(tributyltin) oxide without isolation of the intermediates, trialkyltin alkoxides, which was necessary in the former procedure.

The present procedures utilizing organotin derivatives and bromine as an oxidant provides convenient and efficient methods for the oxidation of alcohols to the corresponding aldehydes or ketones. It is expected that these methods will find widespread use.

Experimental

Preparation of Triethyltin Alkoxides. A solution of an alcohol (20 mmol) and triethyltin methoxide (24 mmol) in toluene (50 ml) was refluxed for 2—14 h (Table 1) under an argon atmosphere, and methanol formed was azeotropically removed. After removal of the solvent, the corresponding triethyltin alkoxide was obtained by distillation under reduced pressure.

General Procedure for Oxidation of Triethyltin Alkoxides with Bromine. To a THF solution of triethyltin alkoxide (1 M) and triethyltin methoxide (1.2—1.7 M) was added dropwise a THF solution of bromine (1 M) at room tem-

perature under an argon atmosphere. As soon as the addition of bromine was over, the reaction mixture was quenched with a 5% aq. $Na_2S_2O_3$ solution and a 5% aq. NaOH solution, and the resulting mixture was extracted with ether. The ethereal layer was washed with a 5% aq. NaOH solution and brine, and dried over anhydrous Na_2SO_4. The yields of the corresponding carbonyl compounds were determined by vapor phase chromatographic analysis or by isolation using thin layer chromatography (silica gel).

Oxidation of Triethyltin Geraniloate with Bromine. To a solution of triethyltin geraniolate (679 mg, 1.89 mmol) and triethyltin methoxide (754 mg, 3.18 mmol) in THF (20 ml) was added drop by drop a solution of bromine (310 mg, 1.94 mmol) in THF (10 ml) over a period of 15 min at room temperature under an argon atmosphere. The reaction mixture was then quenched with a 5% aq. $Na_2S_2O_3$ solution (5 ml) and a 5% aq. KOH solution (20 ml). The resulting mixture was extracted with ether (60 ml), and the ethereal layer was washed with a 5% aq. KOH solution (20 ml) and with brine (20 ml). After evaporation of the solvent, geranial (269 mg, 94%), identified by NMR spectrum and GLC analysis on comparison with an authentic graphy.

Preparation of Tributyltin Benzyl Oxide. A solution of benzyl alcohol (2.67 g, 25.5 mmol) and bis(tributyltin) oxide (7.61 g, 12.8 mmol) in benzene (70 ml) was refluxed for 4 h under an argon atmosphere; water was continuously removed. After removal of the solvent, tributyltin benzyl oxide was isolated by distillation under reduced pressure (7.61 g, 75%, bp 140—142 °C/0.9 Torr).

Oxidation of Tributyltin Benzyl Oxide with Bromine. To a THF (20 ml) solution of tributyltin benzyl oxide (461 mg, 1.16 mmol) and tributyltin methoxide (374 mg, 1.17 mmol) was added a THF (10 ml) solution of bromine (185 mg, 1.16 mmol) within a period of 20 min at room temperature under an argon atmosphere. After a similar work-up, GLC analysis indicated a yield of 82% of benzaldehyde (pentylbenzene as an internal standard with 10% Carbowax 20 M column).

General Procedure for the Oxidation of Alcohols with Bromine Utilizing Bis(tributyltin) Oxide. A solution of alcohol (1 M) and bis(tributyltin) oxide (2 M) in THF was stirred for 30 min at room temperature or for 1—2 h at 50—60 °C in the presence of molecular sieves (3 A) (in the case of hindered alcohols) under an argon atmosphere. To the mixture was added dropwise a THF solution of bromine (2 M) in the course of 30 min at room temperature. *Work-up (a) Isolation of the Product*: To the reaction mixture was added powdered $Na_2S_2O_3$, and the resulting suspension was stirred for 30 min. After filtration, the solvent was evaporated under reduced pressure. To the remaining residue were added NH_4F, H_2O and ether. The mixture was stirred for 30 min, and the precipitate formed was filtered off. The ethereal layer was washed with water and dried over anhydrous Na_2SO_4. After removal of the solvent, the corresponding carbonyl compound was isolated by preparative thin layer chromatography or column chromatography (silica gel). *(b) Determination of the Product by GLC*: The reaction mixture was quenched with a 5% aq. NaOH solution and a 5% aq. $Na_2S_2O_3$ solution, the resulting mixture being extracted with ether. The ethereal layer was washed with a 5% aq. NaOH solution and brine, and dried over anhydrous Na_2SO_4. The yield was indicated by GLC analysis with an internal standard.

Oxidation of 2-Octanol with Bromine Utilizing Bis(tributyltin) Oxide. A solution of 2-octanol (127 mg, 0.97 mmol) and bis(tributyltin) oxide (1260 mg, 2.17 mmol) in THF (20 ml) was stirred for 30 min at room temperature under an argon atmosphere. To the solution was added dropwise a solution of bromine (347 mg, 2.17 mmol) over a period of 30 min. After quenching with a 5% aq. $Na_2S_2O_3$ solution (5 ml) and a 5% aq. NaOH solution (20 ml), the mixture was extracted with ether, and the ethereal layer was washed with a 5% aq. NaOH solution (20 ml) and dried over anhydrous Na_2SO_4. GLC analysis indicated a yield of 90% of 2-octanone (ethylbenzene as an internal standard).

Oxidation of 3β-Cholestanol with Bromine Utilizing Bis(tributyltin) Oxide. A THF (20 ml) solution of 3β-cholestanol (379 mg, 0.975 mmol) and bis(tributyltin) oxide (1169 mg, 1.961 mmol) was heated at 50—60 °C in the presence of molecular sieves for 1 h. A THF (10 ml) solution of bromine (313 mg, 1.96 mmol) was then added drop by drop within a period of 30 min at room temperature. The reaction mixture was quenched with powdered $Na_2S_2O_3$ (1.0 g), stirred for 30 min and filtered. After concentration of the filtrate under reduced pressure, NH_4F (10 g) in water (10 ml) and ether (10 ml) were added to the remaining residue. The mixture was stirred for 30 min, and the resulting precipitate was filtered off. The ethereal layer was washed with removal of the solvent, 3-cholestanone (337 mg, 89%) was isolated by column chromatography (silica gel).

(Received January 11, 1976)

1,2,3,4-Tetrahydronaphthalene was oxidized in the presence of copper(II) acetate in glacial acetic acid. An addition of lithium chloride which formed complexes with copper(II) ion highly accelerated the reaction, and the initiating process was found to be the decomposition of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide by the copper(II)-chloride ion complexes. However, only about 8% of the decomposition contributed the initiation, and it was suggested that the larger part of the decomposition proceeded through a non-ionic mechanism. Spectrophotometric and ESR experiments suggested that one of the accelerating effects of the chloride ion was due to its action to decompose the inactive copper(II) acetate dimer and form active copper(II)-chloride ion complexes and that the order of the activity of the complexes was $CuCl^+ < CuCl_2 < CuCl_3^-$, $CuCl_4^{2-}$.

Copper(II) salts are well-known to form complexes with alkali chloride in glacial acetic acid, in aqueous solutions, or in acetonitrile, and extensive data on these complexes are available.[1-6]

Previously we carried out the oxidation of cyclohexene catalyzed by copper(II) salts in glacial acetic acid and found that the reaction was highly accelerated by an addition of various alkali chlorides.[7] During the reaction, however, the chloride ion was consumed by a chlorination of cyclohexene or of the oxidation products and a rapid deactivation of the catalyst occurred.[8] However, the mechanism of the oxidation has not been discussed in detail.

This paper deals with the oxidation of 1,2,3,4-tetrahydronaphthalene and the decomposition of 1,2,3,4-tetrahydro-1-naphthyl hydroperoxide by copper(II) acetate–lithium chloride for the investigation of the catalytic action and of the effect of the chloride ion.

Experimental

Commercial 1,2,3,4-tetrahydronaphthalene (tetralin) was washed with 5% aqueous sodium hydroxide and concentrated sulfuric acid, and distilled twice under a reduced pressure. 1,2,3,4-Tetrahydro-1-naphthyl hydroperoxide (THP) was obtained by an autoxidation of tetralin and purified twice by recrystallization from petroleum ether.[9] Glacial acetic acid and acetonitrile were purified by the usual methods, and anhydrous copper(II) acetate was obtained by a dehydration of copper(II) acetate dihydrate. 1,2,3,4-Tetrahydro-1-naphthol (α-tetralol) was prepared by the reduction of 1,2,3,4-tetrahydro-1-naphthalenone (α-tetralone) followed by a fractional distillation.[10] Commercial α-tetralone and other G. R. grade reagents were used without further purification.

The apparatus used in the oxidation and the procedures were the same as described in the previous paper.[7] The rate of the oxidation was confirmed not to be controlled by the diffusion of oxygen into the liquid phase.

The decomposition of THP was carried out under a nitrogen atmosphere. In a 100 ml reaction vessel immersed in a constant temperature water bath, acetic acid and a known amount of THP were stirred until a desired temperature (usually 37 °C) was reached. Then a known amount of the catalyst solution was added and the reaction started. The reaction was followed by an iodometry of the remaining THP.

The analysis of the products was carried out using a Hitachi 063 gas chromatograph. The conditions were as follows: (1) Column packing-PEG 6000 (1 m); Carrier gas-N_2 (30 ml/min); Column temperature-150 °C, 180 °C, and (2) Column packing-Chromosorb 101 (1 m); Carrier gas-He (30 ml/min); Column temperature-150 °C.

The ESR and electronic spectra of the catalyst were observed at room temperature by the use of a JES-PE spectrometer and a Hitachi 125 spectrophotometer, respectively.

Results and Discussion

Visible Spectra of Copper(II) Acetate–Lithium Chloride in Glacial Acetic Acid. Visible spectra of the copper(II) acetate–lithium chloride were observed in glacial acetic acid varying the concentration of lithium chloride and the result is shown in Table 1. As the concentration of lithium chloride is increased, the absorption maximum shifts from 680 nm to the higher wavelength region, and the color of the solution gradually changes from blue to green and finally to yellow. The result suggests that the acetate anion of copper(II) acetate is replaced by the chloride ion and complexes which posess copper–chloride ion bondings are formed.[1] In the subsequent sections, we

$$Cu^{2+} \underset{K_1}{\overset{Cl^-}{\rightleftharpoons}} CuCl^+ \underset{K_2}{\overset{Cl^-}{\rightleftharpoons}} CuCl_2 \underset{K_3}{\overset{Cl^-}{\rightleftharpoons}} CuCl_3^- \underset{K_4}{\overset{Cl^-}{\rightleftharpoons}} CuCl_4^{2-} \quad (1)$$

call these complexes Cu(II)–Cl.

Oxidation of Tetralin Catalyzed by Cu(II)-Cl at 80 °C. Tetralin was oxidized at 80 °C in the presence of Cu(II)-Cl. Figure 1 shows that the chloride ion has an accelerating effect on the reaction, while copper(II) acetate itself was inactive in the absence of lithium chloride. In Fig. 2 the maximum rate of oxidation (R_m) and the induction period are plotted against the molar ratio of chloride ion to copper(II) ion at the constant concentration of copper(II) ion. It is shown that, with the increase in the concentration of chloride ion, R_m increases and reaches a maximum at the molar ratio near five and, then, remains constant. The induction period also takes a minimum at the molar ratio of five and is rather prolonged in the higher concentration region of chloride ion.

In Fig. 3 the accumulation of the oxidation products is shown. The yield of α-tetralone is much higher than that of α-tetralol. The yield of THP is considerably low and there is no steady state concentration of THP. The low yield of THP suggests the high activity of Cu(II)-Cl to decompose THP.

The color of the solution changed in the course of the reaction from yellow to green and finally to blue, which suggested that the state of the catalyst gradually changed. The visible spectra of the reaction mixture were observed during the reaction and the result is given in Table 2. We see that the absorption maximum of the catalyst shifts to the shorter

wavelength region as the reaction proceeds, and after 40 min the absorption at 680 nm begins to appear. The chloride ion seems to be consumed during the reaction and change to inactive organic chlorine compounds.[7,8,11] The quantity of the chloride ion consumed during the reaction was roughly estimated from Table 2 by the use of the chloride ion to copper(II) ion molar ratio *vs.* absorption maxima data listed in Table 1, and the result is shown in Fig. 4. It may be seen that the consumption of chloride ion occurs as soon as the induction period is over. The state of the catalyst changes in this manner during the reaction, so, it is impossible to carry out a kinetic discussion from the measurement of R_m's.

Decomposition of THP Catalyzed by Cu(II)-Cl. THP was decomposed by Cu(II)-Cl in glacial acetic acid at 37 °C and the result is shown in Fig. 5.[12] Copper(II) acetate without lithium chloride was found to be inactive as in the oxidation of tetralin. Kochi reported that copper(II) salts do not decompose hydroperoxides directly and that an induction period exists at the initial stage of the reaction.[13] In the present result, however, no induction period exists, indicating that Cu(II)-Cl decomposes THP directly.

Figure 6 shows the rate dependence on the concentration of chloride ion at the constant concentration of copper(II) ion. The rate increases with the increase of chloride ion up to the molar ratio of chloride ion to copper(II) ion of eight, after which it remains almost constant. It was found that Cu(II)-Cl gradually changed to inactive copper(II) acetate during the reaction, and the amount of THP decomposed before the catalyst was deactivated increased with the increase of the concentration of chloride ion. The accelerating effect of chloride ion shown in Fig. 6 resembles to that in the oxidation of tetralin (Fig. 2), which indicates that the catalytic action of Cu(II)-Cl in the decomposition of THP is correlated to that in the oxidation of tetralin.

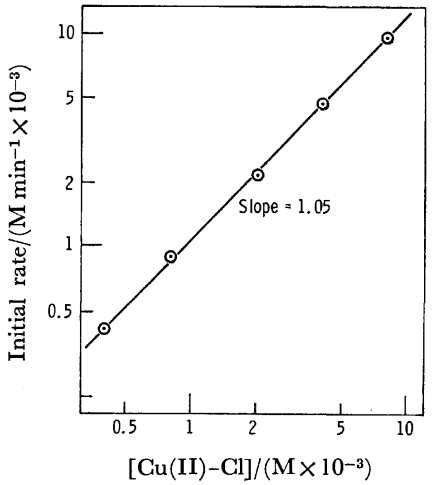

Fig. 7. Decomposition of THP catalyzed by Cu(II)-Cl in AcOH at 37 °C.

[THP]=0.17 M; $[Cu(OAc)_2]=8.0\times10^{-3}$ M; $[LiCl]=8.0\times10^{-2}$ M.
a) The Products were analyzed after the decomposition was completed. b) Based on the initial concentration of THP.

Figure 7 shows the rate dependence on the concentration of Cu(II)-Cl ($Cl^-/Cu=10$). From this and the result shown in Fig. 5, the initial rate of the decomposition of THP by Cu(II)-Cl ($Cl^-/Cu=10$) is expressed as

$$-d[THP]/dt=k[Cu(II)\text{-}Cl]^{1.05}[THP]^{1.28} \quad (2)$$

The products in the decomposition of THP were α-tetralol, α-tetralone, α-tetralyl acetate, water, and a high-boiling unknown product. In Table 3 the yields of α-tetralone and α-tetralol after the reaction was completed are shown. The yield of α-tetralone is much higher than that of α-tetralol, and water is producuced almost quantitatively. Triphenylmethane,

which is a good hydrogen donor in radical reactions, does not increase the yield of α-tetralol, suggesting that the reaction proceeds mainly by an ionic or a molecular mechanism. In the case of acetonitrile solvent, chloride ion also accelerated the decomposition of THP catalyzed by copper(II) acetate and the product distribution was similar to that in glacial acetic acid. (see Table 3). Although the unknown product was not analyzed and the amount of α-tetralyl acetate was not determined, the disagreement in the material balance shown in Table 3 is considered to be due to the formation of these by-products.[7,8]

Oxidation of Tetralin Initiated by Cu(II)–Cl–THP at 37 °C. As shown in the previous sections, the catalytic activity of Cu(II)–Cl in the oxidation of tetralin was correlated to that of the decomposition of THP; the decomposition of THP by Cu(II)–Cl is suggested to be effective in initiating the oxidation. Therefore, a series of experiments was carried out as described below, assuming that the intiation step is the decomposition of THP by Cu(II)–Cl. A known amount of THP was added at the beginning of the oxidation and the rate dependences on the concentrations of THP, tetralin, copper(II) acetate, and chloride ion were observed. Figure 8 shows an example of

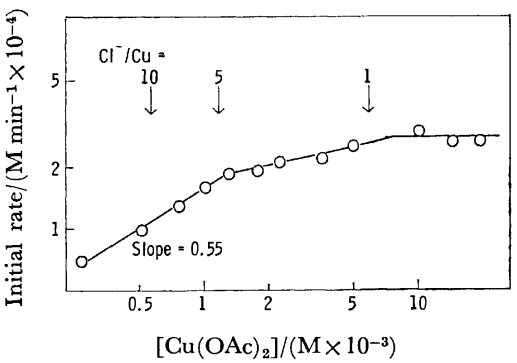

Fig. 10. Effect of $Cu(OAc)_2$ in the oxidation of tetralin catalyzed by Cu(II)–Cl–THP in AcOH at 37 °C.
$[LiCl]=6.0\times10^{-3}$ M, [THP]=0.1 M, [Tetralin]=1.26 M.

the oxidation catalyzed by Cu(II)–Cl–THP at 37 °C. The reaction proceeds without any induction period and at a constant rate, which enables us to carry out the kinetic investigation from the measurement of the initial rates. The change of the catalyst state due to the consumption of chloride ion will be neglected in the initial stage of the reaction.

The effect of chloride ion was investigated again and the results are shown in Figs. 9 and 10. Figure 9 shows the rate dependence on the chloride ion concentration at a constant concentration of copper(II) ion. The rate is proportional to $[Cl^-]^{0.54}$ up to the chloride ion to copper(II) ion molar ratio of five, then remains constant, and is rather decreased by an addition of excess chloride ion. As Fig. 10 shows, at the constant concentration of chloride ion, the rate is proportional to $[Cu(II)]^{0.55}$ unless the molar ratio becomes less than five. In the molar ratio range below five, the rate does not increase so much with the increase in the copper(II) ion concentration. When the concentration of copper(II) ion exceeds that of chloride ion, the rate becomes independent of the copper(II) ion concentration; that is, an excess copper(II) ion over chloride ion does not take part in the oxidation. The effect of chloride ion shown above is the same as that in the decomposition of THP except that an excess chloride ion (more than ten molar ratio) retards the oxidation. These observations indicate clearly that the presence of copper–chloride ion bonds is inevitable for the catalyst to be active and that the most active catalyst is formed in the chloride ion to copper(II) ion molar ratio range from five to ten.

The rate dependences on the concentrations of tetralin, Cu(II)–Cl ($Cl^-/Cu=10$), and THP are shown by dotted lines in Figs. 11—13. From these results, the apparent rate equation for the oxidation of tetralin is obtained as shown below.

$$-dO_2/dt = k_1[RH]^{1.05}[Cu(II)\text{-}Cl]^{0.53}[THP]^{0.68} \quad (3)$$

RH : Tetralin

Oxidation Mechanism. On the basis of the results obtained in the preceding sections, it is suggested that Cu(II)–Cl produces active radicals by an interaction with THP in the initiation step. Therefore, the mechanism of the oxidation of tetralin is

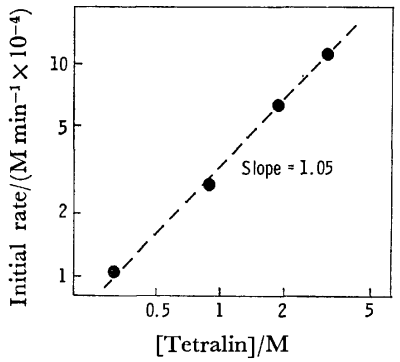

Fig. 11. Oxidation of tetralin catalyzed by Cu(II)-Cl-THP in AcOH at 37 °C. Rate dependence on [Tetralin].

0.130	1.30×10^{-4}
0.260	2.88×10^{-4}

a) Reaction condition is the same as described in Fig. 13.

Table 5. Dependence of R_i on catalyst concentration[a)]

[Cu(II)-Cl]/M	R_i/M min^{-1}
5.0×10^{-4}	1.75×10^{-5}
1.0×10^{-3}	3.45×10^{-5}
3.0×10^{-3}	8.07×10^{-5}
6.0×10^{-3}	1.78×10^{-4}

a) Reaction condition is the same as described in Fig. 12.

$$-dO_2/dt = k_p/\sqrt{2k_t}[RH]\sqrt{R_i} + R_i/2 \qquad (8)$$

From this rate expression, the dependences of R_i on the concentrations of Cu(II)-Cl and THP were investigated as follows. The value of $k_p/\sqrt{2k_t}$ was obtained as $4.0\times10^{-3}\,l^{1/2}\,s^{-1/2}$ in the oxidation of tetralin initiated by AIBN at 37 °C.[14] This value was substituted into Eq. 8, and the values of R_i are calculated at each concentration of the reactants from the data shown in Figs. 12 and 13. The results are listed in Tables 4 and 5, and afford R_i expressed as

$$R_i = k_2[\mathrm{Cu(II)\text{-}Cl}]^{0.98}[\mathrm{THP}]^{1.25} \qquad (9)$$

We see that the rate dependences on the concentrations of Cu(II)-Cl and THP are similar to those in the decomposition of THP by Cu(II)-Cl. (Eq. 2)

As mentioned before, when the kinetic chain length is short, the contribution of $R_i/2$ cannot be neglected in Eq. 8. Therefore, the values of $R_i/2$ are calculated from Tables 4 and 5, and substracted from the overall rates of the oxidation shown by dotted lines in Figs. 12 and 13. The solid lines thus obtained afford the following rate expression in which the contribution of $R_i/2$ is excluded.

$$-dO_2/dt = k_3[RH]^{1.05}[\mathrm{Cu(II)\text{-}Cl}]^{0.47}[\mathrm{THP}]^{0.63} \qquad (10)$$

This is in good agreement with rate relation (11) which is obtained by substituting Eq. 9 into the first term of the right of Eq. 8.

$$-dO_2/dt \propto k_p/\sqrt{2k_t}[RH]^{1.0}[\mathrm{Cu(II)\text{-}Cl}]^{0.49}[\mathrm{THP}]^{0.63} \qquad (11)$$

From the discussion shown above, it can be concluded that the formation of active radicals by the interaction of Cu(II)-Cl with THP is the main initiating step in the oxidation of tetralin.

Efficiency of the Initiation by Cu(II)-Cl-THP. In order to investigate the nature of the decomposition of THP by Cu(II)-Cl, the efficiency of the initiation by Cu(II)-Cl-THP was investigated. As described in the previous sections, the rate of the initiation (R_i) was expressed by Eq. 9. Under the same condition, the rate of the decomposition of THP (R) was observed.

Table 6. Efficiency of radical production in the decomposition of THP catalyzed by Cu(II)-Cl in AcOH at 37 °C

Cu(II)-Cl/M	R/M s^{-1}	R_i/M s^{-1}	Efficiency/%[a]
5.0×10^{-4}	2.25×10^{-4}	1.75×10^{-5}	7.8
8.0×10^{-4}	3.70×10^{-4}	2.80×10^{-5}	7.6
1.0×10^{-3}	4.70×10^{-4}	3.45×10^{-5}	7.3
			a. v. 7.6

a) Efficiency $=R_i/R\times100$

In Table 6 the values of R_i and R are listed. The fourth column in the table shows the values of $R_i/R\times100$ which indicate the efficiency of the production of active radicals in the reaction of Cu(II)-Cl with THP shown by Eq. 4. We see that only 7—8% of the decomposition contributes to the initiation. From this and the effect of triphenyl methane upon the product distribution shown in Table 3, it is suggested that the larger part of the decomposition proceeds through an ionic or a molecular mechanism such as a dehydration of THP to produce ketone and water as the product distribution shows.

$$\text{THP} \xrightarrow{\text{Cu(II)-Cl}} \begin{cases} \text{Non-radical mechanism} \\ \vee \qquad (H_2O+R{=}O) \qquad (12) \\ \text{Radical mechanism} \qquad (13) \end{cases}$$

ESR and Electronic Spectra of Cu(II)-Cl in Glacial Acetic Acid. Copper(II) ion forms various chloro complexes in glacial acetic acid as shown by Eq. 1. To clarify the active species both in the oxidation of tetralin and in the decomposition of THP, and also to investigate the effect of chloride ion, ESR and electronic spectra of Cu(II)-Cl were observed

As copper(II) ion has an unpaired electron in its 3d-orbitals, its ESR signal must be observed. However, as shown in Fig. 14, copper(II) acetate in glacial acetic acid has no signal. This phenomenon can be explained by the following fact. That is, copper(II) acetate has a dimer structure as indicated by Fig. 15 and the distance between each copper atom is only 2.64 Å, indicating an extensive quenching of the

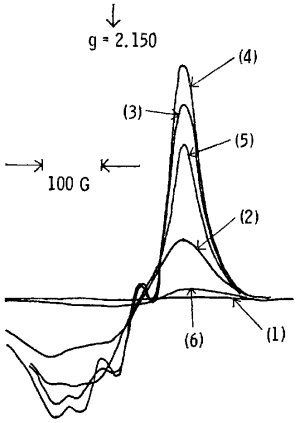

Fig. 14. ESR spectra of Cu(II)-Cl in AcOH measured at room temperature.
$[Cu(OAc)_2]=2.8\times10^{-3}$ M, Cl$^-$/Cu: (1) 0, (2) 1, (3) 3, (4) 5, (5) 10, and (6) 200.

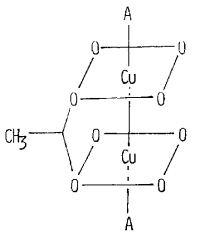

Fig. 15. Structure of $Cu(OAc)_2$. Only one bridging group is shown.[17]

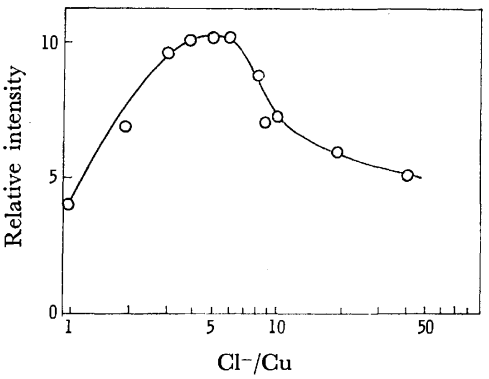

Fig. 16. Relative intensity of the ESR spectrum of Cu(II)-Cl in AcOH measured at room temperature. $[Cu(OAc)_2]=2.8\times10^{-3}$ M.

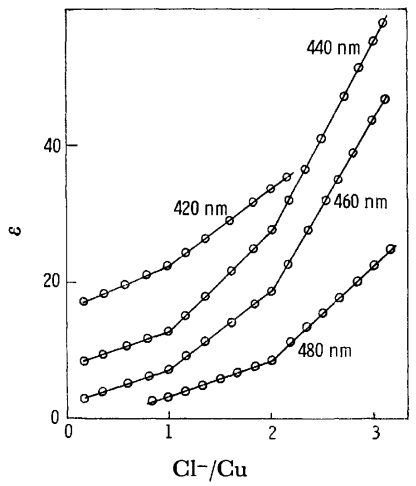

Fig. 17. Molar ratio plot for Cu(II)-Cl in AcOH measured at room temperature.

spin moments of the copper(II) ions.[17] When lithium chloride is added, an asymmetric signal with two small peaks near the center appears, which suggests that the copper(II) acetate dimer is decomposed and monomer species are formed. By means of spectrophotometry and magnetic susceptibility measurement, Sawada *et al.*, also reported that copper(II) acetate is dimerized in glacial acetic acid and that an addition of chloride ion affords monomer species which have copper–chloride ion bonds.[18] In Fig. 16 the intensity of the signal relative to that of the Mn^{2+} external standard is plotted against the molar ratio of chloride ion to copper(II) acetate. The intensity increases with the increase of the concentration of chloride ion

and reaches a maximum at the molar ratio from four to eight. In the oxidation of tetralin, the active catalyst was formed in the molar ratio range from five to ten, and, in the decomposition of THP, the maximum rate is attained at the molar ratio of eight and, then, remains constant. Although a slight discrepancy in the effect of chloride ion exists between these two cases, it is clear that one of the accelerating effects of the chloride ion is to decompose the dimer structure of copper(II) acetate (inactive) and to form monomer species (active) by coordinating to the copper(II) ion.

The formation of Cu(II)–Cl was investigated spectrophotometrically on the basis of the molar ratio method. Figure 17 shows the plots of ε, the absorption coefficient of Cu(II)–Cl, at 420, 440, 460, and 480 nm against the chloride ion to copper(II) acetate molar ratio. At the molar ratios of one and two, the slopes of the ε-molar ratio lines change. This indicates that the equilibrium constants, K_1 and K_2, are large enough to afford mono- and dichloro complexes almost quantitatively at the corresponding molar ratios. However, the catalytic activity of Cu(II)–Cl continues to increase up to the molar ratio of five or above both in the oxidation of tetralin and in the decomposition of THP. This indicates clearly that the order of the activity of Cu(II)–Cl is $CuCl^+ < CuCl_2 < CuCl_3^-$, $CuCl_4^{2-}$.

Thanks are given to Mr. Nobuaki Onishi for his assistance in the experimental work.

The Photoreaction of Benzyl 1-Cycloalkenyl Ketone in Acidic or Protic Media*

Masaru TADA, Hiroshi SAIKI, Kyo MIURA, and Hiraku SHINOZAKI

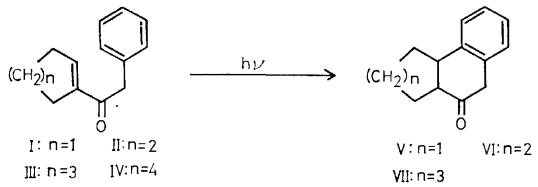
Department of Chemistry, School of Science and Engineering, Waseda University, Shinjuku, Tokyo 160

(Received January 12, 1976)

Three benzyl 1-cycloalkenyl ketones, I—III, were irradiated in the presence of boron trifluoride–diethyl ether (0.05 mol/l) in benzene to give the products V—VII, formed by the bonding between the β-position of $\alpha\beta$-unsaturated ketone and the *ortho* position of the benzene ring. Benzyl 1-cyclooctenyl ketone (IV) was inactive to the photocyclization because of the preferential geometrical isomerization of the olefin moiety. Trifluoroacetic acid promotes the reaction exceedingly, but the reaction takes place also in methanol. The reaction in methanol was deduced from quenching experiments to be a triplet process. The reaction takes both singlet and triplet processes when irradiation is carried out in the presence of boron trifluoride–diethyl ether. The participation of the complex between benzyl 1-cycloalkenyl ketone and boron trifluoride is proposed for the singlet process.

It has been reported that a photochemical Friedel-Crafts reaction takes place upon the irradiation of cycloalkene and benzene derivatives in the presence of a catalytic amount of Lewis acid.[1] A strained *trans*-cycloalkene has been considered to be an active intermediate which gives a carbonium ion in the presence of an acid catalyst. In this paper we will report the photochemical cyclization of benzyl 1-cycloalkenyl ketones (I—III) under various reaction conditions.

The external irradiation (a 450-W medium pressure Hg lamp) of solutions of I, II, and III in benzene containing boron trifluoride–diethyl ether (0.05 mol/l) through a Pyrex tube for 3 h gave the reaction products of V, VI, and VII in 79, 87, and 90% yields respectively. However, the starting material was recovered when benzyl 1-cyclooctenyl ketone (IV) was irradiated. These experimental results are in sharp contrast with the fact that an attempted thermal cyclization of benzyl 1-cyclohexenyl ketone (II) with Lewis acid recovered the starting material.[2-4] Elemental analyses and the molecular peaks of mass spectra due to the products V (m/e=186), VI (m/e=200), and VII (m/e=214) show the products to be the isomers of the starting ketones. All the products show the infrared absorption for the saturated ketone at 1720 (V), 1710 (VI), and 1717 cm^{-1} (VII) and the absorptions for *ortho*-disubstituted benzene ring at 750 (V), 755 and 765 (VI), and 753 cm^{-1} (VII). NMR spectra of the

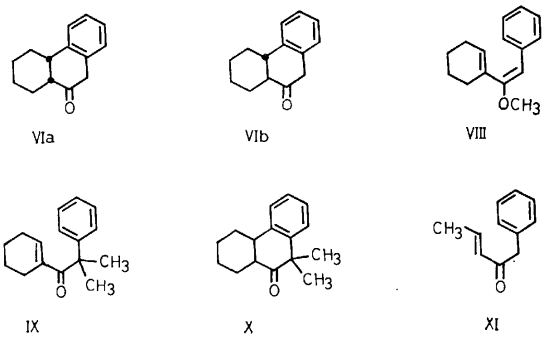


I: n=1 II: n=2
III: n=3 IV: n=4

V: n=1 VI: n=2
VII: n=3

products V, VI, and VII show signals (singlet) due to the methylene adjacent to the carbonyl group at δ= 3.62 (V), 3.48 (VI), and 3.50 ppm (VII). These spectral data define unequivocally the structures of the products except for the stereochemistry of the ring junction. The V and VII products were found to be homogeneous by GLC analyses (SE-30 and OV-17 on Chromosorb W), but the VI product consisted of two isomers, VIa and VIb. VIa was deduced to be *cis*-1,2,3,4,4a,10a-hexahydro-10-phenanthrone by the transformation of VIa into *cis*-1,2,3,4,4a,9,10,10a-octahydrophenanthrene.[1,5] The thioketal obtained by the action of 1,2-ethanedithiol–borontrifluoride–diethyl ether to VIa was reduced by Raney-Ni, and the reduced product was identified with the authentic octahydrophenanthrene by a comparison of their GLC and IR spectra. The formation of VIa and VIb was not due to the isomerization of the product under the present reaction conditions. The acid or base treatment of the VI product with varying ratios of the two isomers did not change the original ratio, and the base-catalyzed deuteration of the VI product by deuterium oxide gave only the dideuterated derivative, indicating that the enolization took place only in the direction of the benzylic position. The reaction occurs in reaction systems other than boron trifluoride–diethyl ether as will be described below, and the ratio of VIa and VIb is dependent on the solvent of the reaction, VIa : VIb=*ca.* 1 : 1 for boron trifluoride–diethyl ether/benzene, 4 : 1 for methanol, and 5 : 1 for acetonitrile. Base-catalyzed enolization takes place only in the direction of the benzylic position, and no epimerization can be expected for V and VII. The stereochemistry of these products, therefore, remains undetermined.

The benzyl 1-cyclohexenyl ketone (II) was subjected to a wide variety of the reaction conditions for the purpose of understanding the nature of the reaction. Trifluoroacetic acid is as effective a catalyst as boron trifluoride–diethyl ether for the photocyclization of II, and enol ethers of VIa and VIb were isolated from the reaction using methanol as the solvent. Polar solvents, such as methanol and acetonitrile, provide a good reaction system for the photo-cyclization even without



VIa VIb VIII

IX X XI

* Part of this work was reported as a preliminary report: *J. Chem. Soc., Chem. Commun.*, **1975**, 55.

acid catalyst. The reactivity in various reaction systems decreases in the following sequence, judging by the time required for the completion of the reaction: 0.05 M boron trifluoride–diethyl ether/benzene≈0.05 M trifluoroacetic acid/benzene ≈ methanol>0.05 M boron trifluoride–diethyl ether/acetonitrile≫acetonitrile>benzene.

One possible mechanism is an electrocyclization of the formal triene system in the enol form of the II ketone, however, this possibility was eliminated by the following observations. The enol ether VIII caused only geometrical isomerization upon irradiation, and the dimethyl derivative, IX, gave the cyclized product, X (molecular peak m/e=228, IR 1709 cm^{-1}), which was difficult to isolate in a practical yield due to its photo-lability.

The failure of the photocyclization of VI must be due to the rapid relaxation of the excited state by isomerization to the *trans*-cyclooctene system.[6] This was further supported by the irradiation of the benzyl 1-propenyl ketone (XI), which caused no cyclization, but only geometrical isomerization. In methanol, compound I, which has a cyclopentene moiety was converted smoothly into V (the conversion was completed within 120 min), while compound II, with a cyclohexene moiety, reacted more slowly to give VI. Compound III, with a cycloheptene moiety, was not, however, converted into VII under the same reaction conditions. The cyclization of I in methanol was quenched effectively by 1,3-pentadiene to give linear Stern-Volmer plot, $k_q\tau$=16 M^{-1}. This quenching experiment shows that the photocyclization proceeds by means of a triplet process. In contrast to the reaction in methanol, all three compounds, I, II, and III, caused a facile cyclization to give V, VI, and VII in benzene containing boron trifluoride–diethyl ether (0.05 mol/l). The Stern-Volmer plots of the quenching experiments of the reaction in the boron trifluoride–diethyl ether/benzene system using 1,3-pentadiene as the quencher are shown in Fig. 1. The curvatures of the plots and plateaus at Φ_0/Φ=1.8 for I and Φ_0/Φ= 1.3 for II show that both singlet and triplet processes are encountered in the reaction of I and II. In the region showing the plateaus, the triplet process is almost completely quenched, and the following relation exists: $\Phi_0=(\Phi_S+\Phi_T)$ and $\Phi=\Phi_S$, where Φ_S and Φ_T denote the quantum yield of the reaction by the use of a singlet and a triplet process respectively. This analysis reveals that 56% and 77% of the reactions of I and II respectively proceed through a singlet process.[7] On the contrary, the reaction of compound III is essentially not quenched by 1,3-pentadiene and gives a linear Stern-Volmer plot with a small negative slope. This means that the cyclization of III takes place *via* only a singlet process. The negative slope is accounted for by the quenching of the triplet decay of the cyclized product, VII, which was substantiated by the irradiation of the isolated product.

Carbonyl compounds form complexes with boron trifluoride–diethyl ether,[8] and the UV absorption of II in hexane containing boron trifluoride–diethyl ether (0.05 mol/l) shows a new absorption around 270 nm, with concomitant decrease in the intensity

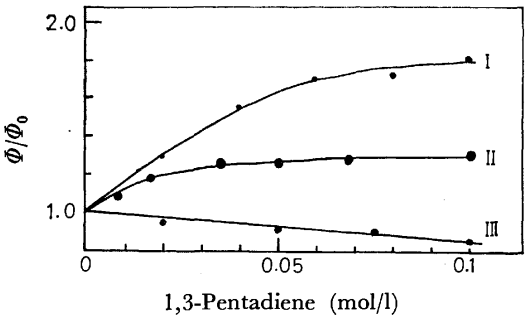


Fig. 1. Quenching of photocyclization of I, II, and III (0.1 mol/l) in benzene containing BF_3-etherate (0.05 mol/l).

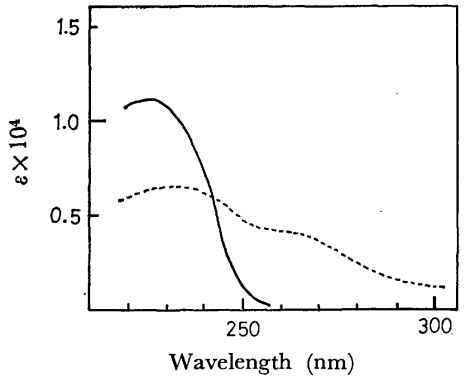

Fig. 2. UV spectra of benzyl 1-cyclohexenyl ketone (II) in hexane (——) and in hexane containing BF_3-etherate (0.05 mol/l) (----).

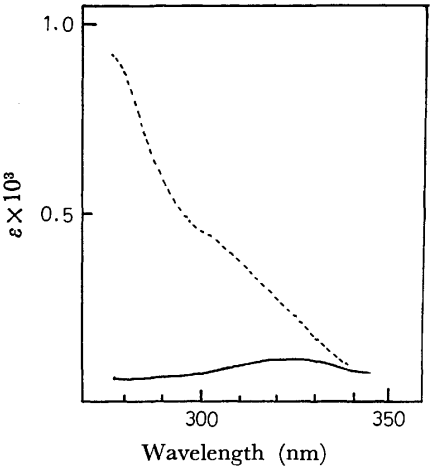

Fig. 3. UV spectra of benzyl 1-cyclohexenyl ketone (II) in benzene (——) and in benzene containing BF_3-etherate (0.05 mol/l) (----).

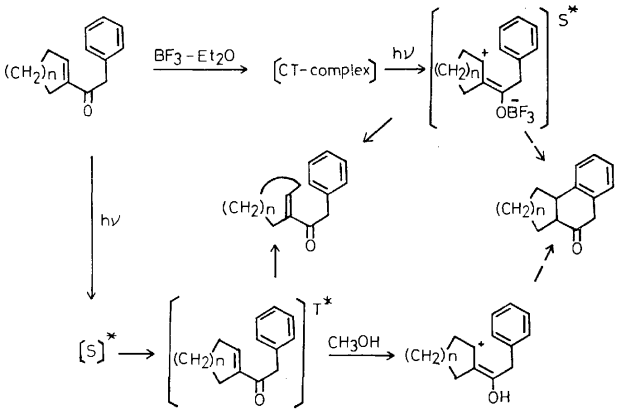
of the π-π^* absorption at 224 nm (Fig. 2); the absorption in benzene containing boron trifluoride–diethyl ether (0.05 mol/l) is very different from the absorption in the absence of the acid in n-π^* region (Fig. 3). This spectroscopic behavior, in conjunction with the quenching experiments, suggest that the excitation of the complex between the corbonyl compound and boron trifluoride is reponsible for the photochemical cyclization by a singlet process. This conclusion is supported by the facts that compound III reacts in the presence

of boron trifluoride–diethyl ether, but no reaction takes place in methanol, and that the importance of the singlet process decreases with the decrease in the ring size of the cycloalkene moiety of compounds III (100%), II (77%), and I (56%).

The most important process in the energy dissipation of the triplet excited state is a geometrical isomerization of the double bond in the cycloalkene moiety. With compound I, with a cyclopentene moiety, in which the geometrical isomerization is impossible, the triplet cyclization in methanol is an effective process, whereas compound III, with a cycloheptene moiety, preferentially deactivates to the *trans* isomer of III and no cyclization takes place in methanol. On the same ground, the relative importance of the triplet process for the cyclization in benzene containing boron trifluoride–diethyl ether increases in the order of compound III (0%), compound II (23%), and compound I (44%). As has been described earlier, the benzyl 1-cyclooctenyl ketone (IV) and the benzyl 1-propenyl ketone (IX) do not undergo the photocyclization in either methanol or benzene containing boron trifluoride–diethyl ether. This means that the energy dissipation by the geometrical isomerization of the cycloalkene moiety is also important in the singlet excited state of the complex. The geometrical isomerization from the excited state of the complex is an important competitive process with photocyclization in the cases of compounds IV and XI.

The importance of the acidic function in the photocyclization is demonstrated by the fact that the reaction proceeds more rapidly in methanol than in acetonitrile, which is a more polar solvent than methanol. These facts prompt us to propose the reaction mechanism depicted in Scheme 1, where S* and T* denote a singlet and a triplet excited state respectively. The reaction in an aprotic solvent such as acetonitrile must proceed in a fassion similar to the reaction in methanol, but without a protonated intermediate.

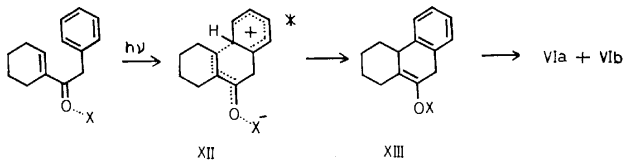


Scheme 1.

The excitation of the complex between the carbonyl compound and boron trifluoride may be expected to produce a more polar state which accumulates a more positive charge on the β-position of the unsaturated carbonyl compound.[9] On the other hand, the carbonyl compound can be expected to acquire an intensified basicity in its triplet excited state and to abstract a proton from a protic solvent, and the increase in the positive charge on β-position can also be expected.[10] Thus, the β-carbons of compounds I, II, and III must become more electrophilic by excitation to attack the benzene ring intramolecularly.

The irradiation of a mixture of 1-acetylcyclohexene and toluene in the presence of boron trifluoride–diethyl ether does not bring about an intermolecular reaction of a type similar to that of the benzyl 1-cycloalkenyl ketone. This implies an interaction between the enone system and the benzene ring in the excited state. The participation of the benzene ring in the excited state and the oriented structure of this intramolecular exciplex, XII, may be essential factors in making possible the facile intramolecular cyclization (Scheme 2).

The stereochemistry of the product must be governed by the mode of protonation to the intermediate enol derivative, XIII, and must be dependent on the polarity of the solvent in the case of the reaction of the benzyl 1-cyclohexenyl ketone (II).



Scheme 2.

Experimental

Syntheses of Starting Materials. A) Benzyl 1-Cycloalkenyl Ketones (I—IV): Ketones I—IV were synthesized by the method of Cook and Hawett for the synthesis of the II ketone,[2] using carbon disulfide as the solvent. The benzyl 1-cyclopentenyl ketone (I), the benzyl 1-cyclohexenyl ketone (II), the benzyl 1-cycloheptenyl ketone (III), and benzyl 1-cyclooctenyl ketone (IV) were obtained in 16, 54, 21, and 35% yields respectively. The $\alpha\alpha$-dimethylbenzyl 1-cyclohexenyl ketone (IX) was synthesized by a similar method, but using dichloromethane as the solvent and at a reaction temperature of −60 °C. The crude product (IX) obtained by distillation contained three isomeric impurities; the material for the photoreaction was purified by succesive chromatography on silica gel eluted by benzene and preparative GLC (8% Carbowax 20 M on Chromosorb P, He). I: mp 64 °C. Mass: M^+=186. IR(CCl_4): 1660 cm^{-1}. Found: C, 83.63; H, 7.64%. Calcd for $C_{13}H_{14}O$: C, 83.83; H, 7.58%. II: mp 46 °C.[2] Mass: M^+=200. IR(CCl_4): 1655 cm^{-1}. III: bp 120 °C/0.9 mmHg. Mass: M^+=214. IR(neat): 1650 cm^{-1}. Semicarbazone; mp 171—172 °C. Found: C, 71.10; H, 7.92; N, 15.75%. Calcd for $C_{16}H_{21}ON_3$: C, 70.82; H, 7.80; N, 15.49%. IV: bp 170—172 °C/0.65 mmHg. Mass: M^+=228. IR(neat): 1560 cm^{-1}. Semicarbazone; mp 170—172 °C. Found: C, 71.46; H, 8.33; N, 14.73%. Calcd for $C_{17}H_{23}ON_3$: C, 71.54; H, 8.12; N, 14.73%. IX: bp 170—172 °C/0.35 mmHg. Mass: M^+=228.1499. Calcd for $C_{16}H_{20}O$: 228.1513. IR(neat): 1650 cm^{-1}

B) Benzyl 1-Propenyl Ketone (XI): Benzylmagnesium chloride prepared from benzyl chloride (12.6 g, 0.1 mol) and magnesium (2.4 g, 0.1 mol) in 60 ml of ether was added to crotonaldehyde (7.0 g, 0.1 mol) diluted with ether (60 ml) over a 1-h period under cooling in an ice-bath. The reaction

mixture was then agitated for a further hour at the ambient temperature. The reaction mixture was then treated with a saturated solution of ammonium chloride (22 ml), and the organic layer was condensed after drying over sodium sulfate to give crude 1-phenyl-3-penten-2-ol. This alcohol was oxidized by means of the Saret reagent (CrO_3 10 g/pyridine 100 ml) at room temperature for 24 h. Ether was added to the reaction mixture, and it was filtered; the filtrate was then washed with water and a saturated solution of cupric sulfate. The condensate of the solution, after drying over sodium sulfate, gave a rather complex mixture. The Benzyl 1-propenyl ketone (200 mg) was isolated from the mixture by repeated chromatography on silica gel eluted with a mixed solvent of chloroform and hexane. Mass: M^+= 160.0886. Calcd for $C_{11}H_{12}O$: 160.0888. IR(neat): 1660 and 1680 cm^{-1}. NMR(CCl_4): 1.40 (3H, double doublet, J=6 and 2 Hz), 3.63 (2H, singlet), 6.05 (1H, double doublet, J=13 and 2 Hz), and 6.80 ppm (δ) (1H, double quartet, J=13 and 6 Hz).

General Procedure of Photocyclization. The solvents and reagents used in the photochemical reaction were purified in the following ways. The methanol was refluxed over magnesium methoxide and distilled. The benzene was washed with concd H_2SO_4 and distilled after refluxing over sodium. The acetonitrile was purified by distillation after drying over phosphorus pentoxide. Boron trifluoride-diethyl ether was distilled under a nitrogen atomosphere and stored in a sealed tube in a cold and dark place. The trifluoroacetic acid was a commercially available reagent, and used without purification. The irradiation of the starting ketones, placed in a Pyrex tube, was carried out using a 450-W USHIO medium-pressure Hg lamp mounted in an imersion jacket and using a RIKOSHA merry-go-round-type irradiation apparatus—the distance between lamp and reaction tube was *ca.* 5 cm. The progress of the reaction was monitored by means of an IR spectrum of the aliquot; we observed the disappearance of the absorptions due to unsaturated carbonyl groups.

Photochemical Reaction in the Presence of Boron Trifluoride-Diethyl Ether. The starting ketones, I—IV, IX, and XI (1—1.5 mmol), in 10 ml of benzene containing boron trifluoride-diethyl ether (0.05 mol/l) were placed in Pyrex tubes, and the air was replaced by nitrogen or argon. Irradiation was then continued until the starting materials had completely disappeared. The reaction mixtures were then passed through an alumina column (10×100 mm, Merck activity II—III) to remove the boron trifluoride; the benzene eluate was condensed under reduced pressure to give the cyclized ketones in yields of 79% (V), 87% (VI), and 90% (VII). The yield of the X ketone was poor due to its photo-lability, which was proved by the irradiation of the isolated X ketone. Some improvement in the yield was, however, achieved by using a soft glass filter instead of a Pyrex filter. The irradiation of the benzyl 1-cyclooctenyl ketone (IV) and the benzyl 1-propenyl ketone (IX) recovered the starting materials even after a prolonged reaction period (8 h). V: bp 105—110 °C (bath)/1.0 mmHg. Mass: M^+= 186.1034. Calcd for $C_{13}H_{14}O$, 186.1045. IR(CCl_4): 1720 cm^{-1}. NMR (CCl_4): 3.62 ppm(δ) (2H, singlet). VI: bp 145—155 °C (bath)/0.9 mmHg. Mass: M^+=200. IR (CCl_4): 1710 cm^{-1}. NMR(CCl_4): 3.48 ppm (δ) (2H, singlet). Found: C, 84.16; H, 8.32%. Calcd for $C_{14}H_{16}O$: C, 83.96; H, 8.05%. VII: bp 145—150 °C (bath)/0.2 mmHg. GLC analyses (5% OV-17 and Carbowax 20 M on Chromosorb W, N_2) showed the V and VII ketone to consist essentially of one stereoisomer. VI ketone, however, showed two peaks due to the isomers (VIa and VIb) *cis* and *trans* with respect to the ring junction, and the IR and NMR spectra of VI were identical with those of 1,2,3,4,4a,10a-hexahydro-10-phenanthrone obtained by Parham *et al.*[11] The two isomers were separated by preparative GLC and have similar spectroscopic properties in every respect. The faster moving isomer, VIa, was deduced to be *cis*-1,2,3,4,4a,10a-hexahydro-10-phenanthrone.

Photochemical Reaction in Methanol. Irradiations were carried out in the manner described above except for the use of methanol instead of boron trifluoride-diethyl ether/benzene as the solvent system. The benzyl 1-cyclopentenyl ketone (I) and the benzyl 1-cyclohexenyl ketone (II) were consumed within 2 and 3 h respectively, and they gave the cyclized products, V and VI, in 90 and 80% yields respectively. The benzyl 1-cycloheptenyl ketone (III), however, does not cyclize to VII under those reaction conditions.

Photochemical Reactions in Other Solvent Systems. The irradiation of II ketone was carried out in acetonitrile, in acetonitrile containing boron trifluoride-diethyl ether (0.05 mol/l), in benzene, and in benzene containing trifluoroacetic acid (0.05 mol/l). The ratio of VIa to VIb was dependent upon the solvent used, VIa : VIb were 1 : 1 in the boron trifluoride-diethyl ether/benzene, 5 : 1 in the acetonitrile, and 8 : 1 in the methanol.

Transformation of VIa into cis-*1,2,3,4,4a,9,10,10a-Octahydrophenanthrene.* The VI ketone (VIa : VIb=8 : 1), dissolved in 3 ml of 1,2-ethanedithiol, was treated with 2 ml of boron trifluoride-diethyl ether, after which the reaction mixture was stirred for 15 min at room temperature. An excess amount of saturated aqueous sodium hydrogencarbonate was then added to the mixture and it was extracted with hexane. The hexane extract was condensed after drying over sodium sulfate to give a yellow residue. The residue was dissolved in 10 ml of ethanol containing 1.5 g of Raney-Ni, and the mixture was stirred for 15 h at the ambient temperature. The subsequent evaporation of the ethanol after filtration gave 55 mg of the product (62%). GLC and NMR analyses of the product identified it as *cis*-1,2,3,4,4a,-9,10,10a-octahydrophenanthrene[1] containing a small amount of the *trans* isomer.

Attempted Equilibration of VI. The VI ketone (VIa : VIb=1 : 1 and 8 : 1, 50 mg) was dissolved in 10 ml of methanolic potassium hydroxide (1 mol/l), after which the solution was stirred for 24 h at room temperature under nitrogen. The reaction mixture was then neutralized with dil H_2SO_4, diluted with water, and extracted with ether. The evaporation of ether after drying over sodium sulfate recovered the starting material. GLC analysis of the recovered material showed an identical peak ratio due to the two components of the starting ketones. The attempted equilibration of the VI ketone using H_2SO_4 instead of the base catalyst gave the same result.

Deuteration of the VI Ketone. The VI ketone (5 mg) was dissolved in 1 ml of a mixed solvent of deuterium oxide and tetrahydrofuran (1 : 4) and 20 μl of pyridine was added to it, after which the mixture was kept at the ambient temperature for 45 h. After the evaporation of tetrahydrofuran under reduced pressure, the aqueous mixture was extracted with hexane. The mass spectrum of the ketone, VI, recoverd from the hexane extract showed intensified (M+1) and

$(M+2)$ peaks, $(M+1)/M=2.07$ and $(M+2)/M=1.50$, whereas the ratio of $(M+3)$ to $(M+2)$ was the one expected from the natural abundance of ^{13}C, $(M+3)/(M+2)=0.15$.

Irradiation of Enol Ether, VIII. The *Z* and *E*-forms of enol ether, VIII, were isolated in pure forms from a mixture of enol ether prepared from the II ketone and trimethyl orthoformate by the catalysis of H_2SO_4. The *Z* or *E*-form of the enol ether in 2 ml of benzene was placed in a Pyrex tube and was externally irradiated. GLC analysis (5% OV-17 on Chromosorb W, N_2) of either solution showed only a geometrical isomerization of the enol ether at the double bond, and a photo-equilibrated mixture of the same composition resulted from the irradiation of either isomer for 2 h, 58% *Z* and 42% *E*.

Quenching of the Photoreaction in Boron Trifluoride-Diethyl Ether/Benzene by 1,3-Pentadiene. The I, II, and III ketones (0.5 mmol each) were dissolved in 5 ml of benzene containing boron trifluoride-diethyl ether (0.05 mol/l) and 1,3-pentadiene (0.01—0.1 mol/l). Pyrex tubes containing the reaction mixture with varying amounts of 1,3-pentadiene were placed in a merry-go-round-type irradiation apparatus and irradiated in the same manner as in the preparative experiments for 5—15 min when more than 70% of the starting materials persisted. After irradiation, the same quantity of the internal standard was added to each reaction tube for the measurement of the peak intensity of the product by GLC analysis (5% OV-17 on Chromosorb W, N_2). In the case of the reaction of II, the GLC peak due to one of the products (VIa) was not well separated from that of the starting material, and so the peak due to VIb was employed for the quenching experiments. The experimental results are shown in Fig. 1. 1,3-Pentadiene was not consumed in the presence of boron trifluoride-diethyl ether to an extent detectable by the NMR analysis of the reaction mixture under the present reaction conditions.

Quenching of the Photoreaction in Methanol-Benzene by 1,3-Pentadiene. The I ketone (20 mg) was dissolved in 40 ml of a mixed solvent of methanol and benzene (1 : 4) containing varying amounts of 1,3-pentadiene (0.01—0.1 mol/l); an experiment similar to that described above was then performed. Benzene was added to the solvent system to get a homogeneous solution of 1,3-pentadiene. Stern-Volmer plot of this experiment showed a straight line with the slope of $k_q\tau=16\ M^{-1}$.

The authors wish to thank Professor Yasuji Yamade for the measurement of the high resolution mass spectra and Professor W. E. Parham for giving us the spectroscopic data for VIa and VIb. The financial support by Matsunaga Science Foundation is greatefully acknowledged.

(Received January 30, 1976)

Thermal reaction of tropone has been studied at temperatures ranging from 420 to 490 °C and at residence times ranging from 1.5 to 6.9 s using a conventional flow apparatus. Tropone undergoes first-order unimolecular decarbonylation. The value of kinetic parameters for this reaction are evaluated as being: $A=10^{14.2}$ s^{-1}, $E_a=54.1$ kcal mol^{-1}, $\Delta S^{\neq}=2.8$ eu, $\Delta H^{\neq}=52.6$ kcal mol^{-1}, and $\Delta G^{\neq}=50.6$ kcal mol^{-1}. These values indicate that the decarbonylation takes place by one-step concerted mechanism *via* a norcaradienone-like transition complex. The latter complex is characterized by a partial transannular C_2–C_7 bond formation and concerted elongation of C_1–C_2 and C_1–C_7 bonds in tropone. The proposed transition complex is in conformity with reported thermal behavior of 1,3,5-cycloheptatriene as well as with molecular orbital symmetry theory.

A considerable attention has been directed to the pyrolysis of seven-membered conjugate systems. They include 1,3,5-cycloheptatriene,[2)] 7,7-dicyanonorcaradiene,[3)] 7-cyano-7-(trifluoromethyl)norcaradiene,[3)] 7,7-dimethoxycycloheptatriene,[4)] tropone ethylene acetal,[5)] thiepine derivatives,[6)] thiepine 1,1-dioxide,[7)] and azepine.[8)]

Concerning thermal reactivities of troponoid compounds, Dauben and his coworkers suggested in 1960 on the basis of their mass-spectroscopic observation that in the pyrolysis of 7-methoxycycloheptatriene benzene and carbon monoxide could be produced through an intermediary formation of tropone.[9)] It was supposed along with Woodward-Hoffmann Rule[10)] that the troponoid compounds exhibited the behavior to heat different from that to photoirradiation, on which bicyclo[3.2.0]hepta-3,6-dien-2-ones were formed.[11)] As our expectation, we have found quite unique, thermally induced rearrangements of troponoid compounds such as quantitative decarbonylation of tropone and comprehensive transformation of tropones and tropolones leading to benzenoid compounds.[1,12)] It has been expected then that further investigations on this novel reaction would provide with valuable informations as to norcaradiene skeleton frequently assumed but still controversial intermediate for the reactions of seven-membered conjugate system. The investigations should also be reckoned important, since the reaction may serve as an example of the thermal reaction of seven-membered compounds to test molecular orbital theory advanced by Woodward and Hoffmann.[10)] This paper deals with the kinetics for the decarbonylation reaction of tropone in details.

Experimental

Materials. Tropone of sufficient purity for use with the present kinetic measurements was prepared from an authentic sample of tropone picrate (mp 99—100 °C, yellow needles). The picrate was treated with aqueous ammonia and tropone was extracted with chloroform. After the extract was washed with water and dried over anhydrous sodium sulfate, chloroform was evaporated off from the extract and the residual oil was distilled at 80 °C under 5 mmHg. Gas chromatographic analysis of the distillate revealed no evidence of contamination of tropone. Toluene used as solvent was of reagent grade and of not less than 99.95 mol% purity. Cylinder helium used as carrier gas was of not less than 99.9 mol% purity. Both of these were used as received.

Kinetic Measurements. Toluene carrier technique was employed using a conventional all-glass flow apparatus. A touelne solution of 11.04 mol% tropone was introduced into the apparatus from a glass syringe of 19.3 mm in inside diameter. Reaction vessel was made of a quartz tubing, 20 mm in inside diameter and 140 mm in length, and was equipped with a thermo-sheath placed along its central axis. The vessel was fitted in an electrically heated aluminum-bronze block furnace, the temperature of which was controlled electronically within ±0.1°. Temperature profiles of the reaction vessel were determined, during each run while the reaction was taking place, by a movable Pt-Pt·Rh thermocouple in the sheath. Annular space of the vessel was filled with quartz tips, leaving a free volume of 14.30 ml. Injection of the solution was maintained at a rate of 20.75 $ml \cdot min^{-1}$ by a microfeeder to which the syringe was mounted. The tropone–toluene vapor was then carried into the reaction vessel along with a stream of helium dried over magnesium perchlorate. Rate of the latter stream, varying from 16 to 90 $ml \cdot min^{-1}$ (STP), was controlled by a needle valve and was measured by a soap-film flow meter within ±0.5%. Tropone in the reaction vessel was thus doubly diluted both by toluene and by helium that the pressure of tropone was kept below 30 mmHg throughout the present investigation. The pressure limitation such as described above was found important to eliminate carbonaceous materials formed otherwise. The reaction was carried out under conditions varied over the following ranges: temperature, 420—490°; residence time, 1.5—6.9 s. Product gases were passed through a train of traps, chilled by ice and methanol-Dry Ice, in which condensable components were collected for analysis. Non-condensable components were first led to a gas sampling tube immersed in liquid nitrogen to separate carbon monoxide, and were then purged after measurements of their flow velocities.

Definition of Temperature and Residence Time. From the observed temperature profiles of the reaction vessel, the following approximation was found valid. Where z is the length in mm along the reactor axis and other symbols

$$\int_{z=0}^{z=140} \exp(-E/RT)\,dz \approx \int_{z=20}^{z=100} \exp(-E/RT)dz$$

** Present address, Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560.

*** Present address, Yokkaichi Work, Mitsubishi Petrochemical Co. Yokkaichi, Mie 510.

have their usual significances. Effective reactor length was therefore 80 mm, corresponding to an effective reactor volume, V, of 8.17 ml. The average reaction temperature, T_{av} could then be defined by a graphic integration according to the following equation. The value of activation energy,

$$T_{av} = \frac{2.303E}{R} \log \left\{ \int_{z=20}^{z=100} \exp(-E/RT)\mathrm{d}z/80 \right\}$$

E, used with the above equation should coincide with the resulting value, E_a, determined from temperature dependence of specific reaction rate. This match was attained by trial-and-error calculations. Residence time, t, in s was calculat-

$$t = PVT/760\ T_{av}F$$

ed by the equation, where F is the corrected total flow rate of the reactant gas mixture in ml s^{-1}, T the room temperature, and P the atmospheric pressure in mmHg.

Analysis. Condensable components collected in the traps, consisting of benzene, toluene and unreacted tropone, were analyzed gas chromatographically using a combined column composed of 3 m Thermol-3 and 3 m Silicone Grease DC-550 at 150° with 40 ml min^{-1} of helium as a carrier gas. Under the given conditions, retention volumes were: benzene, 352 ml; toluene, 456 ml. Error involved in the analysis was estimated to be approximately ±2% of recorded values. Carbon monoxide collected in the gas sampling tube was also analyzed by gaschromatograph using a 5 m Molecular Sieve 5A column at 0° with 40 ml min^{-1} of helium as a carrier gas. In a few runs, results obtained by the gas-chromatographic analysis were confirmed by a mass-spectrographic analysis.

Results

Thermal Reaction of Tropone and the Related Compounds. Threshold temperature of tropone pyrolysis was found to be approximately 400°C, and as will be shown later the rate of the reaction could be most conveniently measured at temperatures between 420 and 500 °C. Besides tropone unreacted and toluene used as solvent, the pyrolyzates were consisted exclusively of benzene and carbon monoxide. Neither polymerization nor condensation products were detected both in the pyrolyzates and on the wall of the reaction vessel. Analysis of the products revealed that the amount of benzene was consistently in equi-molar with that of carbon monoxide. Therefore the reaction can be characterized simply by the following stoichiometry:

$$\text{Tropone} \rightarrow \text{Benzene} + \text{Carbon Monoxide}$$

In a few preliminary runs, however, a considerable amount of biphenyl was formed at temperatures exceeding 800°. Since an entirely different principle may operate in the pyrolysis at extremely high temperatures, the biphenyl forming reaction will be ignored in our present discussion.

Order and Molecularity of the Reaction. Summarized in Table 1 are the results of twenty-six kinetic measurements carried out under the specified conditions. In each of these runs, conversion of tropone was kept below 25% and was usually in the range of 1—15%. This precaution was taken to avoid data which were inadequate for use with the following kinetic analysis. Illustrated in Fig. 1 are the plots of $-\log(1-x)$ *vs.* t, where x denotes fraction of tropone consumed. With exceptions of runs where conversions were higher, experimental data are all fitted with well-defined straight line passing the origin. The reaction is, therefore, first order in tropone with no induction period. These together with the fact that bibenzyl

Table 2. Rate constants

Temperature (K)	Rate constant $\times 10^3$ (s^{-1})
711.6	4.2±0.27
734.0	13.4±0.93
745.4	23.6±0.80
754.6	41.7±5.5

was not formed would strongly suggest that the decarbonylation takes place *via* a simple unimolecular splitting off of carbonyl group.

Kinetic Parameters. Listed in Table 2 are the values of rate constant calculated from the slope of the lines in Fig. 1. Error limits, estimated from uncertainties involved in measured quantities, are also indicated for each value of the rate constants. Arrhenius plots based on the values listed in the table are given in Fig. 2. Thus, rate constant can be expressed by the following equation:

$$\log k(s^{-1}) = (14.22\pm0.67) - (54100\pm2000)/4.575\,T$$

Thermodynamic properties of the transition complex can therefore be characterized by the following values: $\Delta S^{\ddagger}=2.8\pm3.0$ eu, $\Delta H^{\ddagger}=52.6\pm2$ kcal·mol^{-1}, and $\Delta G^{\ddagger}=50.6\pm2$ kcal·mol^{-1}.

Discussion

Mechanism of Decarbonylation. Illustrated in Fig. 3 are feasible pathways through which tropone may undergo unimolecular decarbonylation.

Of the three paths, Path A, proposed for the reaction of 2-azidotropone,[13] can be ruled out for the present case in view of strong C_1–C_2 linkage. Recent investigations on tropone by use of X-ray analysis,[14] gas phase electron diffraction,[15] NMR spectroscopy, [16,17d] and on the basis of theoretical calculations[17] reveal its structure, as being planar, with pronounced bond alternation. Dipole moment of 4.17—4.30 D reported

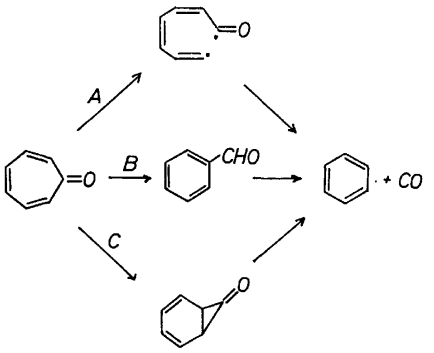

Fig. 3. Mechanism for the decarbonylation of tropone.

for tropone,[18] exhibits, along with the presence of carbonyl stretching band in lower frequency region,[19] π-stabilization to a considerable extent.[20] The stabilization energy for tropone measured from the heat of hydrogenation is higher than that for nonplanar cycloheptatriene[21,22] by 3 kcal mol^{-1}. All these structural evidences definitely indicate that the energy required for α-cleavage of tropone ring is no less than 78 kcal·mol^{-1}, the value usually assigned for D(CH_3CO-CH_3) in acetone.[23] The value of $E_a\approx54$ kcal·mol^{-1} observed in the present work is too low for the decarbonylation to take place *via* Path A. The value of $\Delta S^{\ddagger}\approx2.8$ eu observed is also incompatible with this path. Biradical formation would remove restrictions of internal motions, resulting in an increase of entropy by a considerable amount. The argument is quite similar to that given for the isomerization of cyclobutenes.[24] In this latter case, experimentally observed value of $\Delta S^{\ddagger}\approx-0.7$ eu was taken as an evidence against the biradical mechanism. Mention should also be made of the fact that bibenzyl was not detected in the present work.

Intermediary formation of benzaldehyde *via* α-cleavage concerted with hydrogen atom migration is assumed in Path B. The assumption is based on a somewhat superficial interpretation of the reactions of a similar type such as isomerizations of cycloheptatriene[2] and 2-chlorotropone.[12] This path is clearly ruled out on the following experimental grounds. According to our preliminary examinations, benzaldehyde was not detected in the pyrolyzates and benzene was not formed from benzaldehyde under conditions comparable with those in the present work.

Only Path C is now left for consideration. As will be seen later, it is concluded in our present discussion that Path C with slight modification is in accord with a bulk of the latest informations. Since norcaradienone assumed in this path bears an intimate relation with norcaradiene intermediate in the isomerization of cycloheptatriene, the mechanism *via* Path C will be discussed separately in the subsequent paragraph with special reference to that of the latter compound.

Norcaradiene Skeleton as Transient Structure. As has been mentioned earlier, cycloheptatriene isomerizes to the corresponding benzene derivatives at temperatures around 100 °C.[2] The values of kinetic parameters have been assigned as being $E_a\approx51$ kcal mol^{-1} and $A\approx10^{13.5}$ s^{-1}. The reaction, therefore, takes place

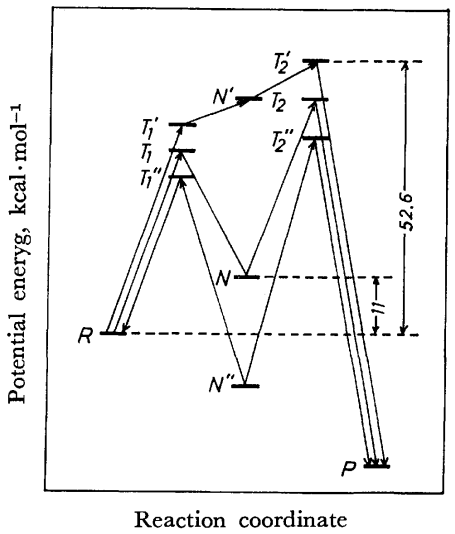

Fig. 4. Potential energy diagram for reactions involving norcaradiene skeleton.

Table 3. Symmetry of HOMO and LVMO of tropone

Orbital numbers	1	2	3	4	5	6	7	8
HOMO	−	+	+	−	−	+	+	−
LVMO	0	+	−	−	+	+	−	0

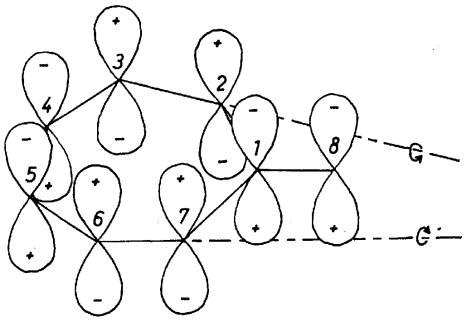

Fig. 5. Orbital symmetry and steric course for the decarbonylation of tropone.

at a rate comparable with that of tropone. Klump and Chesick discussed the reaction in terms of a metastable norcaradiene intermediate in equilibrium with cycloheptatriene.[2b] Energetics of the Klump-Chesick mechanism can best be expressed by the steps, R→T_1 →N→T_2→P, illustrated in Fig. 4. In this figure, R, P and N (also N′ and N″) represent energy levels of reactant, product and transient complex having norcaradiene skeleton, respectively. Those of the first and the second transition-states are also represented by T_1 and T_2 (also T_1', T_1'', T_2' and T_2''). Although mechanistic similarity does exist between the pyrolyses of cycloheptatriene and tropone as to the tendency toward the formation of norcaradiene skeletone, norcaradienone formed from tropone is believed to be far less stable than norcaradiene assumed in the Klump-Chesick mechanism.

Referred to below are some indirect evidences in support of the above statement. Valence isomerization between the cycloheptatrienes and norcaradienes has been extensively studied[25] and many norcaradiene derivatives were found to exist even at room temperatures.[3,26] Norcaradiene in equilibrium with cycloheptatriene has never been observed spectroscopically but the Diels-Alder reaction of cycloheptatriene with dienophiles such as maleic anhydride affords an adduct derived from norcaradiene as an only product.[27] Contrary to these, an isolation of norcaradienone has never been documented and there is no evidence for its existence. The Diels-Alder reaction of tropone gives rise not to an adduct derived from norcaradienone but to that obtained by direct addition to 2 and 5 positions of tropone nucleus.[28] Furthermore, higher reactivity found in cyclopropanone which undergoes ring opening quite readily[29] and the higher π-stabilization found in planar tropone than that in nonplanar cycloheptatriene[21,30] suggest that the process from tropone to norcaradienone is energetically less favorable than that from cycloheptatriene to norcaradiene. Thus, for the case of tropone, N in Fig. 4 would be raised to N′, and consequently T_1 to T_1' and T_2 to T_2'. The reaction now takes place through Path C comprizing the steps: R→T_1'→N′→T_2'→P. The level N′ no longer stands for an intermeidate in its usual terminology, but is more like a transient complex between two transition-states. The assumption of such norcaradienone-like complex does not conflict with the observed normal *A*-factor and moderate E_a value. Steric course of the proposed mechanism will be discussed in more detail on the light of the rule advanced by Woodward and Hoffmann.[10]

It should be mentioned that 7,7-dicyanonorcaradiene and 7-cyano-7-(trifluoromethyl)norcaradiene have been recognized in stable form.[3] In these compounds, electrophilic substituents on C_7 must have strong stabilization effect toward norcaradiene.[31] The net effect in this case is, therefore, to lower the intermediate level from N to N″, and hence the transition-state levels from T_1 and T_2 to T_1'' and T_2'', respectively. The isomerization would then take place in two ways: N″→T_1''→R and N″→T_2''→P. Results obtained by Giganek support this view.

Molecular Orbital Symmetry Theory. Molecular orbital symmetry theory provides a clear-cut account for stereochemical consequences observed in thermal as well as photochemical valence isomerizations of polyolefins.[10] The decarbonylation of tropone appears to be a newer addition to those for which this theory is obeyed. Listed in Table 3 are the reported symmetry factors of the highest occupied and the lowest vacant molecular orbitals of tropone.[32] For thermal reactions where HOMO determines the steric course, the theory predicts the overlap between orbitals of the C_2 and C_7 positions by disrotatory process as illustrated in Fig. 5. As the C_2–C_3 and C_6–C_7 bonds rotate in the directions indicated by curved arrows in Fig. 5, a partial bond is formed between the C_2 and C_7 positions, and carbonyl group is squeezed out from the plane of the ring. This can only take place at the expense of the weakening of the C_1–C_2 and C_1–C_7 bonds. The compensation described above as to the rigidity of the molecule as a whole is in con-

formity with the small value of $\Delta S^{\neq}$ 2.8 eu observed in the present study. The resulting structure is identical with the norcaradienone-like transient complex brought up earlier in connection with Path C.

In sharp contrast with thermally induced reactions, photolysis of tropones has been known to form $\Delta^{3,6}$-bicyclo[3.2.0]hepta-3,6-dien-1-one.[11] Since the steric course of photochemical reactions is determined by the symmetry of LVMO, the photolyzate of tropones is again in conformity with the theory. Thus, it appears that the molecular orbital symmetry theory can be extended to cover reactions of seven-membered conjugate system at elevated temperatures.

The Crystal and Molecular Structure of (+)-1-Bromo-2-hydroxy-2-phenylethyl *p*-Tolyl Sulfoxide: The Bromohydrin of (+)-*trans*-β-Styryl *p*-Tolyl Sulfoxide

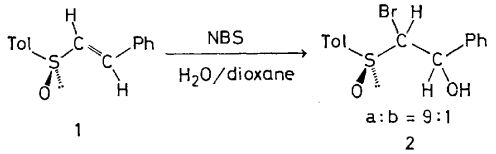
(Received February 2, 1976)

The crystal structure of (+)-1-bromo-2-hydroxy-2-phenylethyl *p*-tolyl sulfoxide, a major isomer formed by the electrophilic addition of BrOH to (+)-*trans*-β-styryl *p*-tolyl sulfoxide (**1**), has been determined by the X-ray diffraction method. The crystal is hexagonal; space group, $P6_2$; $a=15.61$, $c=10.82$ Å, and $Z=6$. The final R value is 0.079. A helical chain of the hydrogen bond between hydroxyl and sulfinyl groups (O···O, 2.63 Å) is formed around the threefold screw axis. The absolute configuration has been determined to be S_S, $S_{C(1)}$, $S_{C(2)}$ from the Mo Kα anomalous scattering of bromine and sulfur atoms. The bromine atom is *gauche* to the sulfinyl oxygen across the C(1)–S bond and *trans* to the hydroxyl oxygen across the C(1)–C(2) bond. Based on the established absolute configuration of the title compound, a mechanism which involves the preferential formation of an intermediary bromonium ion is proposed for the addition of BrOH to **1**.

The electrophilic addition of BrOH to (+)-*trans*-β-styryl *p*-tolyl sulfoxide (**1**) results in a dominant formation of a diastereomer, (+)-1-bromo-2-hydroxy-2-phenylethyl *p*-tolyl sulfoxide (**2a**) as shown in Scheme 1. The absolute configuration of **2a** was determined chemically.[1] We have recently reported the crystal structure and the absolute configuration of 1,2-dibromo-2-phenylethyl *p*-tolyl sulfoxide (**3**), a dominant isomer formed by the ionic bromination of **1**, by X-ray analysis.[2] The high selectivity of these additions is attributed to the preferential formation of a bridged bromonium ion by the electronic demand of the adjacent chiral sulfinyl group.



1 2

Scheme 1.

An X-ray diffraction study was undertaken to establish the absolute configuration and the molecular conformation of **2a** in order to elucidate such a specific reaction mechanism.

Experimental

The dominant isomer of **2** was recrystallized from hexane–ethanol solution. The crystals are colorless needles elongated along the c axis. They are unstable in air, and more unstable in a thin glass capillary. Therefore the intensity measurement was carried out without coating.

The cell dimensions were calibrated with copper powder lines superposed on Weissenberg photographs (Cu K, $\bar{\alpha}=1.5418$, $\beta=1.3920$ Å). The crystal data are: $C_{15}H_{15}BrSO_2$, MW=339.25; hexagonal, $a=15.61\pm0.01$, $c=10.82\pm0.01$ Å, $U=2281$ Å^3, $Z=6$, $D_x=1.48$, $D_m=1.50$ g cm^{-3}; $F(000)=1032$, μ(Mo Kα)=27.8 cm^{-1}; mp 149—151 °C; $[\alpha]_D^{26}$ +222.4° (c 0.526, MeOH). Laue symmetry and systematic absences ($l\neq3n$ for $00l$) indicated the possible space group $P6_2$ or $P6_4$. The former was proved to be correct by the analysis for the absolute configuration.

Intensity data were collected on a RIGAKU automatic diffractometer, using MoKα radiation monochromatized with a graphite monochromator. An ω-2θ scan technique was used to obtain the intensities with width of $\Delta\omega=1.0°+0.5°\tan\theta$ and a scanning speed of 2° min^{-1}. At both ends of the scan range for each reflection, 10 s background counts were taken. The intensities of three standard reflections, measured after every 50 reflections, decreased over the period of data collection. Their final intensities were 85% of the original values. The data were corrected for decomposition. Reflections in the range $2\theta<55°$ and $-13\leq l\leq7$ were measured, and 1043 of these had $F_o>3\sigma(F)$, which were considered as observed reflections. This set included the reflections with indices hkl and $hk\bar{l}$ which were treated as independent because of the anomalous scattering of Mo Kα radiation by bromine and sulfur atoms.

Structure Determination

The position of the bromine atom was found by inspection of a three-dimensional Patterson map. For a heavy atom alone, the R value was 0.43. Successive cycles of Fourier syntheses revealed the location of the remaining non-hydrogen atoms. The atomic parameters were refined by block-diagonal least-squares method, first with isotropic temperature factors to an R value of 0.17 and then with anisotropic temperature factors for all the non-hydrogen atoms to an R value of 0.10. A difference Fourier map showed positive density at the expected hydrogen atom positions except those of the methyl group. The coordinate of the hydroxyl-hydrogen atom H(O1) was estimated from this map. But the positions of other hydrogen-atoms, except those of the methyl group, were calculated with C–H distance of 1.08 Å. These parameters were included in the structure-factor calculations though they were not refined. The isotropic thermal parameters for hydrogen atoms were assumed to be 7.0 Å^2. Further cycles of refinement were carried out on two enantiomorphic structures taking the anomalous dispersion effect into consideration. The lowest R values for the two enantiomers were 0.079 and 0.089, respectively. The former corresponded to the space group $P6_2$ and the latter to $P6_4$. The difference of the R values is significant,[3] so that the true space group is assigned as $P6_2$ and the molecule has an absolute configuration illustrated in Fig. 1.

The weighting scheme used was: $w=0.3$ if $|F_o|<15$, $w=1.0$ if $15\leq|F_o|\leq60$ and $w=(60/|F_o|)^2$ if $|F_o|>60$. The atomic scattering factors were taken from "International Tables for X-ray Crystallography".[4] The

final atomic parameters and their estimated standard deviations are given in Table 1. The observed and calculated structure factors are listed in Table 2.[5]

Results and Discussion

Figure 2 shows the crystal structure viewed along the c axis. The methyl groups are arranged around the sixfold screw axis. A helical chain of the hydrogen bonds between hydroxyl and sulfinyl groups is formed around the threefold screw axis: thus the structure consists of infinite columns parallel to the c axis. The O···O hydrogen-bond distance is 2.63 Å. Intermolecular contacts between adjacent columns are of van der Waals' type; those less than 4 Å are shown in Table 3.

The bond distances and angles are shown in Fig. 3 with their estimated standard deviations. The C(1)–S–O(1), C(9)–S–O(1) and C(1)–S–C(9) angles are 104, 111, and 100°; the corresponding angles in 1,2-dibromo-2-phenylethyl *p*-tolyl sulfoxide (**3**) are 105, 107, and 100°, respectively.[2] The S–O(1) distance is 1.49 Å, which agrees well with those in other sulfoxides.[6,7] The S–C(1) and S–C(9) distances are 1.88 and 1.78 Å. They are different from each other, while in (+)-methyl *p*-tolyl sulfoxide the corresponding S–C lengths are 1.796 and 1.797 Å, respectively.[6] The longer distance of S–C(1) is attributed to the presence of the bromine atom. The corresponding length in **3** is 1.82 Å. The non-bonding intramolecular distances of S···Br is 3.09 Å in **2** and also 3.09 Å in **3**, respectively.

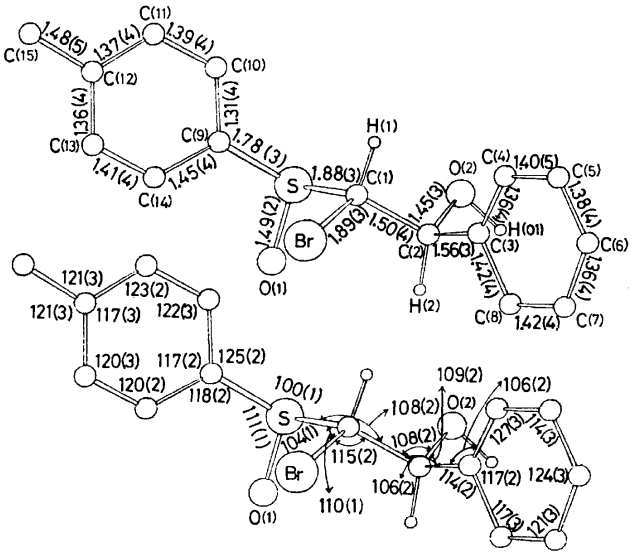

Fig. 3. Bond lengths (Å) and angles (°) with their estimated standard deviations.

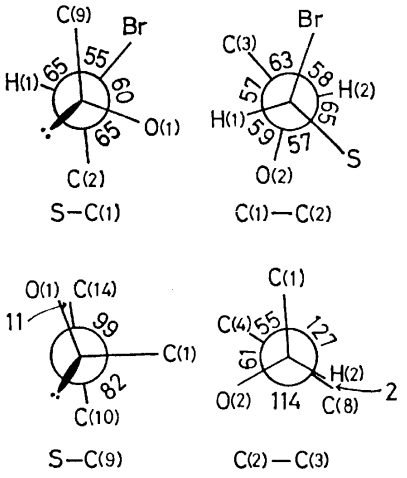

Fig. 4. Torsion angles in the molecule.

The length for C(1)–Br is 1.89 Å, which is slightly shorter than those of **3** (2.00 and 1.98 Å). The average values for C–C bonds in aromatic rings are 1.39 (phenyl) and 1.38 Å (tolyl), respectively. The length of C(12)–C(15) is 1.48 Å. The length of C(2)–O(2) is 1.45 Å, which is very similar to the corresponding values for methanol[8] and 1-hexadecanol.[9]

The least-squares planes are listed in Table 4. The dihedral angle between these planes is 70°.

The torsion angles of groups around the bonds, S–C(1), C(1)–C(2), S(1)–C(9), and C(2)–C(3) are shown in Fig. 4. The sulfinyl oxygen atom is *gauche* to Br across the S–C(1) bond. The torsion angle, O(1)–S–C(1)–Br is 60° and non-bonding distance O(1)···Br is 3.33Å; the corresponding values for **3** is 45° and 3.13 Å, respectively. The bromine atom is *trans* to the hydroxyl oxygen O(2) across the C(1)–C(2) bond. The non-bonding distances, Br···C(3), Br···C(9), S···O(2), and O(1)···C(14), are 3.20, 3.27, 2.97, and 3.02 Å, respectively.

The absolute configuration was unequivocally determined to be *S* at the sulfur atom, *S* at C(1), and *S* at C(2). Therefore the structure of the dominant isomer derived from the electrophilic addition of BrOH to **1** is (+)-(S_S, $S_{C(1)}$, $S_{C(2)}$)-1-bromo-2-hydroxy-2-phenylethyl *p*-tolyl sulfoxide (**2a**). The same assignment has been made earlier on the basis of chemical evidence.[1] Based on the assigned structure of (+)-(S_S, $S_{C(1)}$, $S_{C(2)}$)-**2a**, it can be concluded that the electrophilic addition of BrOH proceeds in the *trans* manner, giving a product in which the bromine atom is in the *gauche* position to the sulfinyl oxygen atom in the adjacent sulfinyl group. A similar result has been obtained for the ionic bromination of **1**. (+)-(S_S, $S_{C(1)}$, $S_{C(2)}$)-1,2-Dibromo-2-phenylethyl *p*-tolyl sulfoxide is formed as a dominant isomer.[2] The selectivity for these additions can be explained in terms of the preferential formation of intermediary bromonium ion (**4a**) rather than **4b**, as is shown in Scheme 2.

(Received January 31, 1976)

Benzaldehyde was obtained in good yields by the formylation of iodobenzene with carbon monoxide and hydrogen catalyzed by palladium(II) chloride in a pyridine solution. The effect of following variables on the rate of producing benzaldehyde was examined kinetically : initial catalyst and iodobenzene concentrations, partial pressure of carbon monoxide and hydrogen, and temperature. A probable reaction mechanism *via* formyl- and benzoyl-palladium(II) intermediates is discussed on the basis of this kinetic study.

The formylation of halobenzene with carbon monoxide and hydrogen has been recently reported to produce benzaldehyde in the presence of tertiary amine and a catalytic amount of dihalogenobis-(triphenylphosphine)palladium(II)[1] or palladium-black.[2] In both reactions, palladium(0) complex was suggested to be the active species. The formylation of halobenzene differs from the earlier hydroformylation of olefin in respect to the applicable substrate, though both reactions react with carbon monoxide and hydrogen to produce aldehyde. As an example of hydroformylation catalyzed by palladium-(II) chloride or metallic palladium, the production of propanal from ethylene has been known[3] but the yield was low and a considerable amount of ethane was simultaneously produced. In our previous paper,[4] methyl benzoate has been obtained from iodobenzene, carbon monoxide and methanol in the presence of such a tertiary amine as pyridine and a catalytic amount of palladium(II) chloride. In this reaction, the mechanism *via* methoxycarbonyl-palladium(II) intermediate was proposed on the basis of the kinetic study. The formylation is rather analogous to the methoxycarbonylation although hydrogen is placed of methanol, because both reactions demand the addition of amine capable of removing hydrogen halide generated during the reactions.

The formylation of iodobenzene according to Eq. 1, was examined kinetically in a pyridine solution using palladium(II) chloride as the catalyst. Benzaldehyde was obtained in good yields,

$$PhI + CO + H_2 \longrightarrow PhCHO + HI \qquad (1)$$

but the reaction mechanism of the formylation differed from that of methoxycarbonylation.

The purpose of this paper is to describe the results on the formylation of iodobenzene and to discuss its mechanism on the basis of the kinetic study.

Results

Preliminary Investigations. The formylations of some halobenzene were attempted under much the same conditions and the results are shown in Table 1. The maximum yield was obtained when iodobenzene was used as the substrate.

The reactivities of some palladium(II) halide were examined under the same conditions and the results are shown in Table 2. The yield increased to some extent in the order $PdCl_2 < PdBr_2 < PdI_2$. If the active species is palladium(0) complex, the difference of reactivities among palladium(II) halides is difficult to be explained.

In addition to benzaldehyde and pyridine hydroiodide salt, traces of benzene, biphenyl and chlorobenzene were detected in the reaction solutions; refer to the footnote of Table 1. But the sum of amounts of remaining iodobenzene and produced benzaldehyde accounted for over 96% of initial iodobenzene at each reaction time. Thus, the amounts of these by-products were neglected in this study.

The reaction proceeded rapidly in the early stage and then progressed linearly as the time went on; refer to Fig. 1 as an example. The equation $Y = At + B$, where Y and t represent respectively the produced benzaldehyde concentration ($mol \cdot l^{-1}$) and reaction time (min) while A ($mol \cdot l^{-1} \cdot min^{-1}$) and B ($mol \cdot l^{-1}$) are constants, can be applied as the empirical equation for expressing the relationship between time and the produced benzaldehyde concentration after 5—10 min.

The effect of stirring speed on the values of A and B in the empirical equation was examined and the

Reaction conditions were shown in the footnote of Fig. 1.

result is shown in Table 3. The value of A was independent of the stirring speeds and the value of B also seemed to be independent of the stirring speeds within an experimental error. Therefore, the reaction may be regarded not to be diffusion-controlled as far as it is carried out under milder conditions than those of Table 3. Henceforwared, the total volume was calculated as the sum of amounts of initial iodobenzene and pyridine.

Kinetic Results. The effects of following variables on the values of A and B in the empirical equation were examined and the results are written in order.

At first, the effect of initial palladium(II) chloride concentration was examined and the result is shown in Fig. 2. Both values of A and B were proportional to the palladium(II) chloride concentration, though the value of B was somewhat insufficient.

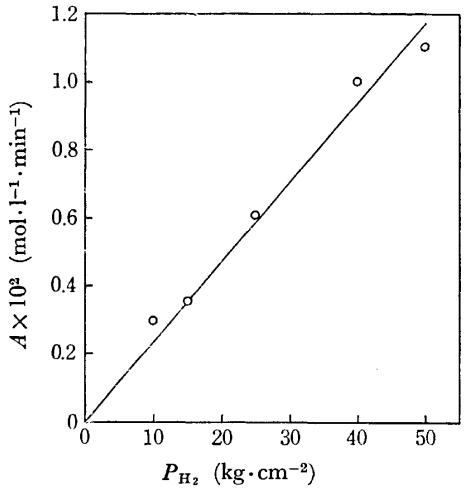

Fig. 3. Relation between P_{H_2} and A.
Reaction conditions were shown in the note of Table 5.

10	1.08	0.094

Next, the effect of partial pressure of carbon monoxide was examined and the result is shown in Table 4. The variation in the partial pressure of carbon monoxide did not affect both values of A and B, *i.e.*, the rate is independent of the partial pressure of carbon monoxide. In case of the methoxycarbonylation of iodobenzene the rate was dependent on the carbon monoxide pressure.[4] Thus, this result suggests that the mechanism of formylation is not analogous to that of methoxycarbonylation.

Next, the effect of partial pressure of hydrogen was examined and the result is shown in Fig. 3 and Table 5. The value of A was proportional to the partial pressure of hydrogen irrespective of the other partial pressure of carbon monoxide, as shown in Fig. 3. This result again shows that the rate is independent of the

partial pressure of carbon monoxide. On the other hand, the value of B hardly changed though the partial pressure of hydrogen changed, as seen in Table 5.

As the reaction proceeded linearly as the time went on except for the early stage, the rate is supposed to be independent of remaining iodobenzene concentration; refer to Fig. 1. The effect of initial iodobenzene concentration was examined and the result is shown in Table 6. The rate was remained constant by the change of initial iodobenzene concentration and this result also differed from that in case of the methoxycarbonylation of iodobenzene.[4)]

Finally, the effect of temperature was examined and the result is shown in Table 7. The rise in temperature caused the increase in the value of A while little affected the value of B.

Discussion

Reaction Mechanism. The following mechanism is assumed;

$$\underset{\mathbf{1}}{PdCl_2(C_5H_5N)_2} + H_2 \xrightarrow{k_2} \underset{\mathbf{2}}{HPdCl(C_5H_5N)_2} + HCl \quad (2)$$

$$\mathbf{2} + CO \xrightarrow{\text{fast}} \underset{\mathbf{3}}{HCOPdCl(C_5H_5N)_2} \quad (3)$$

$$\mathbf{3} + PhI \xrightarrow{\text{fast}} \underset{\mathbf{4}}{PdClI(C_5H_5N)_2} + PhCHO \quad (4)$$

$$\mathbf{4} + H_2 \xrightarrow{k_5} \mathbf{2} + HI \quad (5)$$

$$\mathbf{4} + H_2 \xrightarrow{k_6} \underset{\mathbf{5}}{HPdI(C_5H_5N)_2} + HCl \quad (6)$$

$$\mathbf{5} + C_5H_5N + CO \xrightarrow{\text{fast}} \underset{\mathbf{6}}{Pd(CO)(C_5H_5)_3} + HI \quad (7)$$

$$\mathbf{6} + PhI \xrightarrow{\text{fast}} \underset{\mathbf{7}}{PhCOPdI(C_5H_5N)_2} + C_5H_5N \quad (8)$$

$$\mathbf{7} + H_2 \xrightarrow{k_9} \mathbf{5} + PhCHO \quad (9)$$

$$HCl \text{ or } HI + C_5H_5N \longrightarrow C_5H_6Cl \text{ or } C_5H_6I \quad (10)$$

where k_2, k_5, k_6 and k_9 represent the rate constants of elementary processes (2), (5), (6) and (9), respectively. The elementary processes (3), (4), (7) and (8) are assumed to proceed rapidly, because the rate was independent of iodobenzene concentration and partial pressure of carbon monoxide. The catalytic cycle from (7) to (9) is the same one proposed by Schoenberg and Heck[1)] and Ito *et al.*[2)] The reaction (8) is well known[5,6)] in case of the analogous triphenylphosphine complexes. However, this catalytic cycle cannot explain the following results mentioned before: the difference of reactivities among palladium(II) halides, the production of chlorobenzene and the rapid reaction in the early stage. Thus, the other catalytic cycle from (3) to (5), which bears a resemblance to the mechanism of methoxycarbonylation of iodobenzene,[4)] is assumed to produce benzaldehyde before the catalytic cycle from (7) to (9) proceeds. The existence of complex **2** is known[7)] in case of triphenylphosphine being used as a ligand. On the other hand, the formylpalladium(II) complex **3** is unknown but is probably possible to form during the reaction, because acylpalladium(II) complex is well known[8)] to be formed by the carbonylation of alkylpalladium(II) complex. The catalytic cycle from (3) to (5) corresponds to the part of rapid reaction in the early stage and the other cycle from (7) to (9) corresponds to the most part of reaction which proceeds linearly as the time goes on. The reaction (8) may proceed essentially *via* phenylpalladium intermediate of short lifetime, because the analogous reaction (triphenylphosphine was used in place of pyridine) has been reported[5)] to proceed *via* five co-ordinated phenyl-palladium intermediate. Benzene and biphenyl detected as by-products are probably formed by the attack of hydrogen and iodobenzene on the phenyl-palladium intermediate, respectively. But the reaction (8) is here assumed to be one elementary process, since the amounts of benzene and biphenyl were little enough to be negligiable. Similarly, the reaction (4) too may not always proceed as one ele-

mentary process, because detected chlorobenzene is probably formed by the exchange of halides between the chloride in the intermediate **3** and the iodide in iodobenzene.

Rate Equation. From the reaction mechanism proposed above, the rate equation of producing benzaldehyde can be derived in the following way.

The material balance for palladium can be expressed as,

$$C_1 + C_4 + C_7 = [PdCl_2]_0 \tag{11}$$

where C_n represents the concentration of intermediate ***n*** and $[PdCl_2]_0$ the initial palladium(II) chloride concentration. The rates of decreasing concentration of intermediates **1** and **4** are respectively expressed as,

$$-\frac{dC_1}{dt} = k_2HPC_1 \tag{12}$$

$$-\frac{dC_4}{dt} = k_6HPC_4 - k_2HPC_1 \tag{13}$$

where H and P represent the Henry's constant and partial pressure of hydrogen. From Eqs. 12 and 13, C_1 and C_4 can be obtained as,

$$C_1 = [PdCl_2]_0 e^{-k_2HPt} \tag{14}$$

$$C_4 = \frac{k_2[PdCl_2]_0}{k_{2-6}}(e^{-k_6HPt} - e^{-k_2HPt}) \quad (k_{2-6} \equiv k_2 - k_6) \tag{15}$$

and C_7 can also be obtained from Eqs. 11, 14 and 15.

$$C_7 = [PdCl_2]_0\left(1 + \frac{k_6}{k_{2-6}}e^{-k_2HPt} - \frac{k_2}{k_{2-6}}e^{-k_6HPt}\right) \tag{16}$$

The rate equation of producing benzaldehyde can be given from Eqs. 14, 15 and 16 as,

$$\frac{d[PhCHO]}{dt} = k_2HPC_1 + k_5HPC_4 + k_9HPC_7$$
$$= [PdCl_2]_0HP\left(k_9 - \frac{k_6k_{2-9} - k_2k_{2-5}}{k_{2-6}}e^{-k_2HPt} + \frac{k_2k_{5-9}}{k_{2-6}}e^{-k_6HPt}\right) \tag{17}$$

$(k_{2-9}, k_{2-5}, k_{5-9} \equiv k_2 - k_9, k_2 - k_5, k_5 - k_9)$

where [PhCHO] represents the produced benzaldehyde concentration. Finally, the relationship between time and the produced benzaldehyde concentration is derived from Eq. 17 as follows.

$$[PhCHO] = k_9HP[PdCl_2]_0t + \frac{k_2k_{5-9} + k_6k_{2-9}}{k_2k_6}[PdCl_2]_0 + \frac{k_6k_{2-9} - k_2k_{2-5}}{k_2k_{2-6}}[PdCl_2]_0e^{-k_2HPt} - \frac{k_2k_{5-9}}{k_6k_{2-6}}[PdCl_2]_0e^{-k_6HPt} \tag{18}$$

Analysis of Kinetic Results. The kinetic results are compared with the derived rate equation (18).

Since $\exp(-k_2HPt)$ and $\exp(-k_6HPt)$ in Eq. 18 are quickly drawn close to zero as the time goes on, they are assumed to be zero after about 10 minutes. On this assumption, Eq. 18 can be rewritten as,

$$[PhCHO] = k_9HP[PdCl_2]_0t + \frac{k_2k_{5-9} + k_6k_{2-9}}{k_2k_6}[PdCl_2]_0 \tag{19}$$

and Eq. 19 has the same shape as the empirical equation $Y = At + B$, giving the following relationships.

$$A = k_9HP[PdCl_2]_0 \tag{20}$$

$$B = \frac{k_2k_{5-9} + k_6k_{2-9}}{k_2k_6}[PdCl_2]_0 \tag{21}$$

As seen in Eq. 20, the value of A must be of the first order with respect to the palladium(II) chloride concentration and the partial pressure of hydrogen, as shown in Figs. 2 and 3. On the other hand, as seen in Eq. 21, the value of B must be of the first order with respect to the palladium(II) chloride concentration, as shown in Fig. 2. Accordingly, the kinetic results are sufficiently consistent with the relationships of Eq. 19.

Determination of Rate Constants. The value of k_9H is determined as 1.37×10^{-2} kg^{-1}·cm^2·min^{-1} at 130 °C as the average between 1.35×10^{-2} from the gradient in Fig. 2 and 1.39×10^{-2} in Fig. 3. The value of k_9H at the other temperatures are determined according to Eq. 20 as follows; 2.08×10^{-2}, 6.70×10^{-3} and 3.45×10^{-3} kg^{-1}·cm^2·min^{-1} at 140, 115 and 100 °C, respectively. The temperature coefficient of k_9H is obtained as 14.4 kcal·mol^{-1} from the Arrhenius plot shown in Fig. 4.

The values of other rate constants cannot be determined, but the values of k_2H and k_6H can be estimated roughly in the following way. As the produced benzaldehyde concentration 0.093 mol·l^{-1} at 1 min was observed as seen in Fig. 1, the value of 0.093 mol·l^{-1}·min^{-1} can be regarded to be nearly equal to the initial rate at the palladium(II) chloride concentration 1.7×10^{-2} mol·l^{-1}, the partial pressure of hydrogen 50 kg·cm^{-2} and 130 °C. On the other hand, the initial rate equation can be given from Eq. 17 as,

$$\left\{\frac{d[PhCHO]}{dt}\right\}_0 = k_2HP[PdCl_2]_0 \tag{22}$$

and the value of k_2H is estimated as 0.1 kg^{-1}·cm^2·min^{-1} at 130 °C. Next, the following equation can be

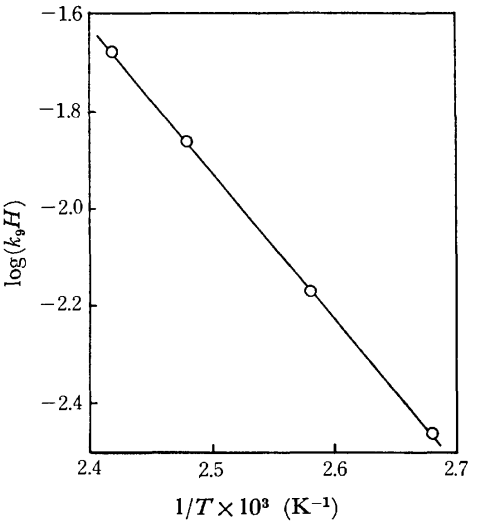

Fig. 4. Arrhenius plot of k_9H.
Reaction conditions were shown in the note of Table 7.

derived from Eq. 21 and the gradient of linear plot between palladium(II) chloride concentration and B in Fig. 2.

$$\left\{\frac{k_2k_{5-9}+k_6k_{2-9}}{k_2k_6}\right\} = 7.4 \quad (23)$$

By assuming that the value of k_5H is equal to that of k_2H because the reaction (5) has a resemblance to the reaction (2), the value of k_6H is estimated as 0.015 $kg^{-1}\cdot cm^2\cdot min^{-1}$ at 130 °C.

From the obtained values of k_2H and k_6H, the values of $\exp(-k_2HPt)$ and $\exp(-k_6HPt)$ can be regarded to be nearly equal to zero after about 10 min.

Calculated Relationship between Time and Benzaldehyde Concentration. Finally, the relationships between time and the produced benzaldehyde concentration which are calculated according to the derived rate equation (18), are compared with the observed ones. As an example, Fig. 1 shows that the calculated relationships are consistent with the observed ones including the part of rapid reaction in the early stage.

As discussed above, the proposed mechanism explains sufficiently the experimental results over the range of this study. Thus, the reaction mechanism is supposed to represent one of possible mechanisms.

Experimental

Materials. Palladium(II) chloride, palladium(II) bromide, palladium(II) iodide and biphenyl were commercially obtained and used without further purification. Iodobenzene, bromobenzene, chlorobenzene, benzaldehyde, benzene, pyridine and tetralin were distilled by means of ordinary methods. Hydrogen was commercial material and was over 99.9% pure. Carbon monoxide was prepared by decomposing formic acid in hot sulfuric acid, and was over 98% pure.

Procedure. Reactions were carried out in a glass-tube placed in a stainless-steel autoclave (*ca.* 200 cm^3) equipped with a Teflon stirrer and a Teflon sampling line. Palladium(II) chloride (0.2—1 mmol), iodobenzene(2—5 ml) pyridine (50—53 ml) and tetralin (5 ml) were placed in the autoclave, which was then purged with nitrogen three or four times. The autoclave was heated up to 100—140 °C within 60 min and then maintained over 20 min at the reaction temperature. Immediately after carbon monoxide and hydrogen mixture was added up to 20—100 $kg\cdot cm^{-2}$, the stirring (750 rpm) was started and this time was marked as zero time. The stirring was stopped from time to time and a sample (*ca.* 1 ml) was withdrawn through the sampling line into a trap chilled in a ice-bath within 30 s. To keep the pressure constant during the reaction, carbon monoxide and hydrogen mixture gas was supplied from the reservoir in which carbon monoxide and hydrogen were mixed beforhand in each fixed ratio.

Analysis. Products were identified by the comparison of their retention times in the gas chromatography with those of authentic samples. An Apiezon Grease L column (2 m, 3 mmϕ) with nitrogen carrier was used at 160 °C for the determination of the amounts of benzaldehyde and iodobenzene with tetralin as an internal standard.

(Received February 16, 1976)

Stereoselectivities in the Grignard, diazomethane and nitromethane reaction of methyl 3-*O*-benzoyl-4,6-*O*-benzylidene-α-D-*arabino*-hexopyranosid-2-ulose (**1**) were examined. In contrast to the Grignard reaction of **1** using methylmagnesium iodide to give a single 2-*C*-methyl derivative (**4**), the diazomethane reaction followed by reduction afforded another epimer (**6**). The nitromethan condensation product (**10**) of **1** was converted into the corresponding 2-*C*-acetaminomethyl derivative (**13**). The NMR spectrum of 2-*O*-acetate of **4** and comparison of the optical rotations of **4**, **6**, **10** and **13** in cuprammonium solution indicated that **4** and others have D-*gluco*- and D-*manno*-configuration, respectively. Discussions were made on the stereoselectivties of these reactions.

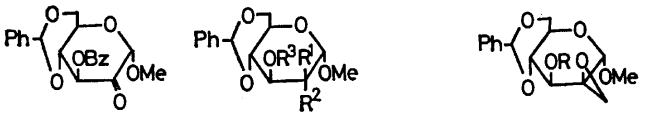
In a previous paper,[2] we reported that the Grignard and nitromethane reaction of methyl 2-*O*-benzoyl-4,6-*O*-benzylidene-α-D-*ribo*-hexopyranosid-3-ulose gave D-*allo*-type branched-chain sugars, while diazomethane reaction afforded a D-*gluco*-type product. In this paper, these reactions of the corresponding 2-ulose were carried out, and the complemental stereoselectivities of the Grignard and diazomethane reaction and a new evidence for the stereoselectivity of nitromethane reaction are described.

Results and Discussion

The starting material; methyl 3-*O*-benzoyl-4,6-*O*-benzylidene-α-D-*arabino*-hexopyranosid-2-ulose (**1**) was synthesized in 87% yield by the oxidation of methyl 3-*O*-benzoyl-4,6-*O*-benzylidene-α-D-glucopyranoside,[3] which was separated in 7% yield as a by-product in the selective synthesis of the corresponding 2-*O*-benzoate reported by Carey and Hodgson.[4] The structure of **1** was clearly supported by the presence of a sharp singlet of H_1 (δ 4.80) and a doublet of H_3 (δ 5.98, $J_{3,4}=10.0$) in the NMR spectrum.

Reaction of **1** with equimolar methyl magnesium iodide at room temperature gave the corresponding 2-*C*-methyl derivative (**2**) in 50% yield, which was then acetylated in the presence of acid catalyst to give 2-*O*-acetate (**3**) quantitatively. The chemical shift (δ 1.91) of methyl protons of the tertiary acetoxy group in **3** indicated that **3** has D-*gluco*-configuration.[5] Treatment of **2** in methanol with barium oxide gave the de-*O*-benzoylated product (**4**) in 37% yield.

On the other hand, reaction of **1** with diazomethane in benzene–ethanol–ether gave quantitatively the corresponding spiro-epoxide (**5**) which was characterized by the presence of an AB quartet of epoxy-methylene protons (δ 2.82 and 2.74, $J=4.0$) in the NMR spectrum. Reduction of **5** with lithium aluminium hydride gave the corresponding 2-*C*-methyl derivative (**6**) in 67% yield. The compound was determined to be 2-epimer of **4** from the physical constants and the optical rotation change in cuprammonium solution[6] (Table 1). Treatment of **5** with barium oxide in methanol gave the corresponding de-*O*-benzoylated product (**8**), and the ring-opening product; methyl 4,6-*O*-benzylidene-2-*C*-methoxymethyl-α-D-mannopyranoside (**7**). These results offer a new instance of the complemental stereoselectivity of the Grignard and diazomethane reactions.[2,7]



(**1**) (**2**) $R^1=CH_3$ $R^2=OH$ $R^3=Bz$ (**5**) R=Bz
(**3**) $R^1=CH_3$ $R^2=OAc$ $R^3=Bz$ (**8**) R=H
(**4**) $R^1=CH_3$ $R^2=OH$ $R^3=H$
(**6**) $R^1=OH$ $R^2=CH_3$ $R^3=H$
(**7**) $R^1=OH$ $R^2=CH_2OCH_3$ $R^3=H$
(**9**) $R^1=OH$ $R^2=CH_2NO_2$ $R^3=Bz$
(**10**) $R^1=OH$ $R^2=CH_2NO_2$ $R^3=H$
(**11**) $R^1=OH$ $R^2=CH_2NO_2$ $R^3=Ac$

(**13**) $R^1=OH$ $R^2=CH_2NHAc$ $R^3=H$

Reaction of **1** with nitromethane in tetrahydrofuran at room temperature gave the corresponding 2-*C*-nitromethyl derivative (**9**) and its de-*O*-benzoylated product (**10**) in 12% and 63% yield, respectively. Acid catalyzed acetylation of **10** gave only 3-*O*-acetate (**11**) in 80% yield. Catalytic hydrogenation of **10** gave the corresponding 2-*C*-aminomethyl derivative (**12**), which was then converted into 2-*C*-acetamidomethyl derivative (**13**) quantitatively. In order to determine the configuration of the nitromethane condensation product, optical rotations of **10** and **13** in cuprammonium solution were measured, together with **4** and **6**. The results shown in Table 1 clearly indicate that the epimeric correlation between the Grignard and nitromethane reaction products and also the same configuration of the nitromethane and diazomethane reaction products. From these results, the stereoselectivity of nucleophilic additions indicated that the Grignard reagent attacked the carbonyl group from the less hindered site, while diazomethane and nitromethane from the hindered site.

Excepting a few instances in which an additive attractive factor to magnesium atom is included in the substrate,[8] the same stereoselectivity between the

Table 1. Rotational change of compounds **4**, **6**, **10** and **13** in cuprammonium solution

Compound	$[\alpha]_D^{50\%\ MeOH}$		$[\alpha]_D^{Cupra\ A}$
4	+136°	⟶	+ 60°

10	+ 94°	⟶	+148°
13	+ 34°	⟶	+144°

Grignard reagent and simple catalytic reductions are generally accepted. As was pointed out in our previous paper,[2] the stereoselectivity of diazomethane reaction is mainly controlled by the attractive force between vicinal (or neighboring) axial-hydroxyl oxygens and diazomethylene cation of zwitterionic intermediate, and consequently, the Grignard and diazomethane reactions show sometimes complemental stereoselectivities.

Concerning the nitromethane condensation, it is known that the stereoselectivity is the same as the reduction or the Grignard reaction in the cases of methyl 4,6-*O*-benzylidene-2-substituted-α-D-*arabino*-hexopyranosid-3-uloses,[2] methyl 3,4-*O*-isopropylidene-β-L-*erythro*-pentopyranosid-2-ulose,[9] 1,2;5,6-di-*O*-isopropylidene-α-D-*ribo*-hexofuranos-3-ulose,[10] while, reversely in the case of methyl 6-deoxy 3,4-*O*-isopropylidene-α-L-*lyxo*-hexopyranosid-2-ulose.[11] Consequently, the last instance and the result obtained here imply the exceptional stereoselectivity of nitromethane condensation. However, it is known that nitromethane condensation gave the epimeric mixtures in various ratios depending upon the conditions used.[9,12] Moreover, similar phenomena in the addition of nucleophiles to enoses[13] and a furanos-3-ulose[14] are explained by isomerization of the kinetically-controlled product into thermodynamically-controlled product. A similar interpretation will be applied to the result of the nitromethane reaction.

In order to pursue the kinetically-controlled D-*gluco*-type product, the reaction was carried out at a lower temperature (−20 °C——78 °C) under monitoring with TLC. The starting material (R_f=0.46 with the solvent system; benzene/acetone=8/1) changed into a compound of R_f=0.18, and then gradually into **9** (R_f=0.35). However, the amount of the intermediate product (R_f=0.18) gradually diminished during the treatment of the reaction mixture at room temperature even after acidification, whereas that of **9** increased. Moreover, the intermediate product isolated with preparative TLC was always contaminated with the monohydrate of **1**. In one instance, a doublet of H_3 (δ 5.04, $J_{3,4}$=11.0) and a quartet of $C_{2'}$-methylene (δ 4.75 and 4.54, J=10.0) and a singlet of H_1 (δ 5.14) were observed in the NMR spectrum of such a product, in addition to the signals of the monohydrate. These chemical shifts are higher than that of **9** (H_3; δ 5.85; $J_{3,4}$=11.0, $C_{2'}$-methylene; δ 4.98 and 4.81, J=11.7, H_1; δ 5.20), and seems to be rational to assign to D-*gluco*-type product.

Experimental

All melting points were uncorrected. The solutions were evaporated under reduced pressure at a bath temperature not exceeding 50 °C. Optical rotations were measured in a 0.5-dm tube with a Carl Zeiss LEP-Al polarimeter. IR spectra were recorded with a Hitachi Model EPI-G2 spectrometer. NMR spectra were taken with JEOL 4H-100 spectrometer in deuteriochloroform containing TMS as an internal reference. Chemical shifts and coupling constants were recorded in δ and Hz units, and IR frequencies in cm^{-1}.

*Methyl 3-O-Benzoyl-4,6-O-benzylidene-α-D-arabino-hexopyranosid-2-ulose (**1**).* The starting material, methyl 3-*O*-benzoyl 4,6-*O*-benzylidene-α-D-glucopyranoside was obtained, from the mother liquor of the corresponding 2-*O*-benzoate prepared by the method of Carey and Hodgson,[4] in 7% yield which was recrystallized from acetone (mp 216—218 °C). The structure was confirmed by elemental analysis and the NMR spectrum of the corresponding 3-*O*-acetate (mp 154 °C, lit,[3] mp 153—154 °C); NMR: 1.9—2.8 (Ph, m), 5.82 (H_3; t, $J_{2,3}$=9.2), 5.48 (methine H; s), 5.11 (H_2; q; $J_{2,3}$=10.0), 4.96 (H_1; d, $J_{1,2}$=4.0), 4.31 ($H_{5,6e}$=4.0), 3.98 (H_5; sex, $J_{5,6a}$=10.0), 3.78 (H_4; t, $J_{4,5}$=9.2), 3.86 (H_{6a}; t, $J_{6a,6e}$=9.2), 3.42 (OMe), 1.96 (OAc).

A solution of the starting material (5.0 g, 12.9 mmol) in DMSO (50 ml) and acetic anhydride (30 ml) was kept at room temperature for 10 h, and then poured into ice-water. The resulting solution was neutralized with 2 M potassium carbonate, and then extracted with chloroform. Treatment of the chloroform extract in a usual manner gave a sirup, which was crystallized and recrystallized from acetone–water to give needles (4.5 g, 86.9%) of the monohydrate of **1**. Mp 136—137 °C; $[\alpha]_D^{17}$ +36.4° (*c* 0.75, $CHCl_3$); IR; 3530 and 3500 (OH), 1720 (ester).

Found: C, 63.08; H, 5.45%. Calcd for $C_{21}H_{20}O_7 \cdot H_2O$; C, 62.68; H, 5.51%.

Dehydration of the above hydrate at 100 °C/15 mmHg for 2 h gave again a sirupy **1**. $[\alpha]_D^{16}$ +35.0° (*c* 1.15, $CHCl_3$); IR: 1750 (C=O), 1720 (ester); NMR: 2.0—2.8 (Ph; m), 5.98 (H_3; d, $J_{3,4}$=10.0), 5.53 (methine H; s), 4.80 (H_1: s), 4.44 (H_{6e}; q, $J_{6a,6e}$=11.5), 4.26 (H_5: sex, $J_{5,6e}$=4.2), 4.05 (H_4; t, $J_{4,5}$=10.0), 3.83 (H_{6a};t,$J_{5,6a}$=11.5), 3.47 (OMe).

Found; C, 65.26; H. 5.35%. Calcd for $C_{21}H_{20}O_7$; C, 65.61; H, 5.24%.

*Methyl 3-O-Benzoyl-4,6-O-benzylidene-2-C-methyl-α-D-gluco-pyranoside (**2**).* To a solution of methylmagnesium iodide in ether (5 ml) prepared from magnesium turnings (60 mg, 2.47 mmol) and methyl iodide (5 ml) was added **1** (1 g, 2.6 mmol) in benzene (5 ml), and the reaction mixture was refluxed for 1.5 h, poured into cold ammonium chloride solution, and the resulting solution was extracted with methylene chloride. The extract was washed with water and evaporated to give a white powder which was crystallized from methanol–petroleum ether. Yield, 510 mg(49%). Mp 150—152 °C; $[\alpha]_D^{22}$ +17.6° (*c* 0.5, 50% MeOH); IR: 3610 (OH), 1750 (ester), 1595 (Ph); NMR: 8.2—7.2 (Ph; m), 5.67 (H_3; d, J=10.5), 5.51 (methine; s), 4.48 (H_1, s), 4.33 (H_{6e}; q, $J_{6e,5}$=4.0, $J_{6e,6a}$=10.0), 4.10—3.65 (H_4, H_5, H_{6a}; m), 3.46 (OMe), 2.74 (OH, broad s), 1.44 (*C*-Me; s).

Found; C, 66.18; H, 6.08%. Calcd for $C_{22}H_{24}O_7$: C, 65.99; H, 6.04%.

Acetylation of **2** with acetic anhydride in the presence of catalytic amount of *p*-toluenesulfonic acid gave the corresponding 2-*O*-acetate (**3**) in a quantitative yield, which was recrystallized from ethanol–hexane. Mp 163—165 °C; $[\alpha]_D^{22}$ +32.7° (*c* 0.5, acetone); IR: 1730 and 1720 (ester), 1600 (Ph); NMR: 8.2—7.2 (PH; m), 5.86 (H_3; d, $J_{3,4}$=10.0), 5.49 (methine; s), 5.46 (H_1; s), 4.30 (H_{6a}; q, $J_{6e,5}$=4.0, $J_{6a,6e}$=9.0), 4.15—3.65 (H_4, H_5, H_{6a}; m), 3.39 (OMe), 1.91 (OAc), 1.76 (*C*-Me; s).

Found: C, 65.29; H, 6.19%. Calcd for $C_{24}H_{26}O_8$: C, 65.15; H, 5.92%.

Methyl 4,6-O-Benzylidene-2-C-methyl-α-D-glucopyranoside (4). A suspension of **2** (400 mg, 1 mmol) and barium oxide (400 mg, 2.5 mmol) in methanol (20 ml) was refluxed for 30 min, filtered, and then evaporated. The residue was extracted with methylene chloride, and the extract was treated in a usual manner to give a sirup which was purified on a silica gel column (benzene/methanol/etheyl actate=5/1/1). The purified sirup (110 mg, 37.2%) crystallized slowly on standing. Mp 55—56 °C; $[\alpha]_D^{21}$ +92.2° (*c* 0.25, 50% MeOH); IR: 3450 (OH); NMR: 7.6—7.2 (Ph, m), 5.46 (methine, s), 4.36 (H_1; s), 4.22 (H_{6e}; q, $J_{6e,5}$=2.5, $J_{6e,6a}$=7.5), 3.95—3.3 (H_3, H_4, H_5, H_{6a}; m), 3.37 (OMe), 3.05 and 2.75 (2× OH; each broad s), 1.28 (*C*-Me, s).

Found: C, 60.54; H, 6.78%. Calcd for $C_{15}H_{20}O_6$; C, 60.80; H, 6.80%.

Methyl 2,2'-Anhydro-3-O-benzoyl-4,6-O-benzylidene-2-C-hydroxymethyl-α-D-mannopyranoside (5). To a suspension of **1** (200 mg, 0.52 mmol) in benzene (40 ml)–ethanol (6 ml) was added dropwise a solution of diazomethane (1 mmol) in ether (30 ml) at O °C. With proceeding the reaction, the mixture turned to be homogeneous. After standing the mixture at 0 °C for 3 h, the solution was evaporated, and the resulting sirup crystallized gradually. The crystals were recrystallized from ethanol to give colourless needles in a quantitative yield. Mp 144 °C; $[\alpha]_D^{23}$ +13.1° (*c* 1.0, acetone); IR: 1720 (ester), 1590 and 710 (Ph); NMR: 8.12—7.22 (Ph and PhCO; m), 6.01 (H_3; d, $J_{3,4}$=10.0), 4.34 (H_{6e}; q, $J_{6e,6a}$=8.8, J_{6e}=3.7), 4.23 (H_1, s), 4.10 (H_4; t, $J_{4,5}$= 8.2), *ca.* 4.08 (H_5, m), 3.88 (H_{6a}; q, $J_{6a,5}$=9.8), 3.41 (OMe), 2.82 and 2.74 (CH_2; ABq, J=4.0).

Found: C, 66.13; H, 5.62%. Calcd for $C_{22}H_{22}O_7$: C, 66.32; H, 5.57%.

Methyl 4,6-O-Benzylidene-2-C-methyl-α-D-mannopyranoside (6). To a solution of **5** (200 mg, 0.5 mmol) in ether (20 ml) was added lithium aluminium hydride (60 mg), and the mixture was stood at room temperature for 1 h. The excess hydride was carefully decomposed with water, and the water layer was extracted with ether. The combined ether extract was washed with water, dried, and evaporated to give a colorless needles which were recrystallized from ethanol–hexane. Yield, 100 mg (67.2%); mp 149—150 °C; $[\alpha]_D^{22}$ +39.1° (*c* 0.5, 50% MeOH); IR: 3450 and 3370 (OH), 1450 and 700 (Ph).

Found: 61.14; H, 6.78%. Calcd for $C_{15}H_{20}O_6$: C, 60.80; H, 6.80%.

Methyl 2,2'-Anhydro-4,6-O-benzylidene-2-C-hydroxymethyl- (8) and 4,6-O-benzylidene-2-C-methoxymethyl-α-D-mannopyranoside (7). A suspension of **5** (200 mg, 0.5 mmol) and barium oxide (200 mg, 1.25 mmol) in methanol (20 ml) was refluxed for 30 min, filtered, and then evaporated. A solution of the residue in methylene chloride was washed with water, dried, and evaporated to give a sirup which showed two spots on tlc (R_f=0.4 and 0.2; benzene/methanol/ethyl acetate= 5/1/1). The two products were separated on a silica gel column, to give **8** (R_f=0.4; 35 mg, 23.7%) and **7** R_f=0.2; 30 mg, 18.3%).

Compound **8**: mp 160—162 °C; $[\alpha]_D^{21}$ +77.4° (*c* 0.25, CH_2Cl_2); IR: 3300 (OH), 3000 (epoxy methylene); NMR: 7.5—7.2 (Ph; m), 5.52 (methine; s), 4.35—4.15 (H_{6e}, H_4; m), 4.19 (H_1; s) 3.77 (H_5; sex, $J_{6e,5}$=4.0, $J_{5,6a}$=$J_{5,4}$=10.0), 3.82 (H_3; d, $J_{3,4}$=9.5), 3.16 (H_{6a}; t, $J_{6a,6e}$=8.0), 3.36 (OMe), 3.13 and 2.70 (CH_2; ABq, J=5.0), 2.05 (OH).

Found; C, 61.09; H, 6.35%. Calcd for $C_{15}H_{18}O_6$: C, 61.21; H, 6.17%.

Compound **7**: mp 163—165 °C; $[\alpha]_D^{22}$ +50.6° (*c* 0.58, CH_2Cl_2); IR: 3470 (OH); NMR: 7.5—7.2 (Ph, m), 5.53 (methine, s), 4.55 (H_1; s), 4.3—4.2 (H_4), 3.9—3.75 (H_{6e}, H_{6a}, H_5, H_3; m), 3.70 and 3.51 (CH_2; ABq, J=11.0), 3.36 and 3.35 (2×OMe), 3.08 and 2.85 (2×OH).

Found: C, 58.69; H, 6.68%. Calcd for $C_{16}H_{22}O_7$; C, 58.88; H, 6.80%.

Methyl 3-O-Benzoyl-4,6-O-benzylidene-2-C-nitromethyl-α-D-mannopyranoside (9). To a solution of nitromethane (5 ml) in tetrahydrofuran (5 ml) were added successively sodium methoxide (Na; 0.07 mmol) and **1** (1 g, 2.6 mmol) with stirring, and the resulting solution was stirred for 6.5 h at room temperature, neutralized with acetic acid (70%), extracted with chloroform. The extract was washed with water, dried, and evaporated to give colorless prisms which were recrystallized from ethanol, and **9** was separated from the corresponding de-*O*-benzoylated compound (**10**) by fractional crystallization from ethanol. Yield, 140 mg (12.1%); mp 221—223 °C; $[\alpha]_D^{22}$ +90.0° (*c* 1.0, acetone); IR: 3450 (OH), 1750 (ester), 1545 (NO_2); NMR; 8.10—7.20 (Ph and PhCO; m), 5.85 (H_3; d, $J_{3,4}$=11.0), 5.49 (CH_2; s), 5.20 (H_1; S), 4.98 and 4.81 (CH_2; ABq, J=11.7), 4.35 (H_{6e}; q, $H_{6a,6e}$=10.0, $J_{6e,5}$=5.0), 4.02 (H_5; m), 3.82 (H_4; t, $J_{4,5}$=11.0), 3.60 (H_{6a}; t, $J_{6a,5}$=10.0), 3.52 (OMe), 3.16 (OH).

Found: C, 59.66; H, 5.25; N, 3.17%. Calcd for $C_{22}H_{23}NO_9$: C, 59.32; H, 5.21; N, 3.14%.

Methyl 4,6-O-Benzylidene-3-C-nitromethyl-α-D-mannopyranoside (10): Yield, 55.5 mg (62.5%); mp 244—245 °C; $[\alpha]_D^{22}$ +40.0° (*c* 1.0, acetone); IR: 3500 and 3400 (OH), 1560 (NO_2).

Found: C, 52.80; H, 5.60; N, 3.91%. Calcd for $C_{15}H_{19}NO_8$: C, 52.78; H, 5.61; N, 4.10%.

Methyl 3-O-Acetyl-4,6-O-benzylidene-2-C-nitromethyl-α-D-mannopyranoside (11). Acid Catalyzed acetylation of **10** (100 mg) at room temperature and recrystallization of the product from ethanol–hexane gave the 3-*O*-acetate in 80.1% (90 mg) yield. Mp 196—197 °C; $[\alpha]_D^{22}$ +22.8° (*c* 0.5, acetone); IR: 3400 (OH), 1708 (ester), 1542 (NO_2); NMR: 7.5—7.25 (Ph; m), 5.51 (methine, s), 5.35 (H_3; d, J= 10.0), 4.76 (H_1; s), 4.72 and 4.43 (CH_2; ABq, J=12.0), 4.4—3.8 (H_4, H_5, H_{6a}, H_{6e}; m), 3.43 (OMe), 2.10 (OAc), 1.63 (OH).

Found: C, 52.99; H, 5.47; N, 3.60%. Calcd for $C_{17}H_{21}NO_9$: C, 53.26; H, 5.52; N, 3.65%.

Methyl 2-C-Aminomethyl-4,6-O-benzylidene-α-D-mannopyranoside (12). Hydrogenation of **10** (500 mg) in ethanol in the presence of palladium-charcoal (10%), and cryrestallization of the product from ethanol–hexane gave prisms in 57% (260 mg) yield. Mp 170 °C; $[\alpha]_D^{22}$ +55.2° (*c* 1.0, acetone); IR: 3500 and 3600 (OH), 3290 (NH_2).

Found: C, 57.98; H, 6.87; N, 4.63%. Calcd for $C_{15}H_{21}NO_6$: C, 57.86; H, 6.80; N, 4.50%.

Methyl 2-C-Acetamidomethyl-4,6-O-benzylidene-α-D-mannopyranoside (13). Acetylation of **12** with acetic anhydride in ethanol and recrystallization of the product from ethanol–hexane gave the *N*-acetate in a quantitative yield. Mp 204—205 °C; $[\alpha]_D^{22}$ +34.0° (*c* 0.5, 50% MeOH); IR: 3540 (OH), 3300 (NH), 1635 and 1540 (amide).

Found: C, 58.31; H, 6.69; N, 3.79%. Calcd for $C_{17}H_{23}NO_7$: C, 57.78; H, 6.56; N, 3.96%.

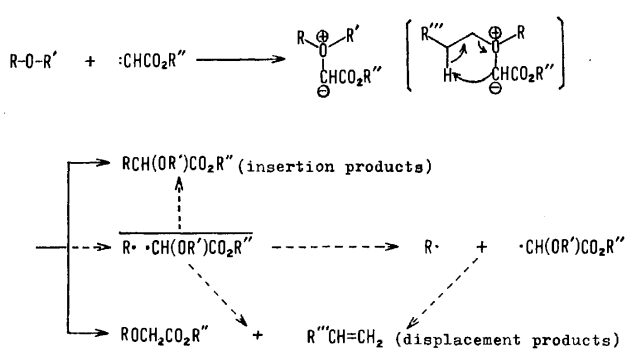
(Received February 26, 1976)

When methyl diazoacetate is allowed to react thermally with dibenzyl, benzyl phenyl and benzyl ethyl ethers, insertion into the benzylic carbon-oxygen bonds takes place *inter alia* to give $PhCH_2CH(OR)CO_2CH_3$(**3**, R=$PhCH_2$, Ph, and CH_3CH_2, respectively). Strongly polarized signals due to the insertion products **3** were observed in the ^1H and ^{13}C NMR spectra of the reacting mixture. Application of Kaptein's rules to the CIDNP signals demonstrates the formation of **3** by the cage recombination of radical pairs $\overline{PhCH_2\cdot\cdot CH(OR)CO_2CH_3}$ (**2**). Product analyses by VPC have also been performed and escape products toluene and $ROCH_2CO_2CH_3$ (**4**) inherent to the radical pairs were detected. In the reaction with benzyl ethyl ether, **4** (R=$PhCH_2$) without noticeable CIDNP is produced about six times more than **4** (R=CH_3CH_2). No methyl α-benzyloxybutyrate is formed. The results indicate that the ethyl group is more easily cleaved than the benzyl *via* a non-radical path. Formation of an ylide intermediate $(PhCH_2)R\overset{\oplus}{O}-\overset{\ominus}{C}HCO_2CH_3$ (**1**, R=CH_3CH_2) followed by the Hoffmann type β-elimination of ethylene is the most reasonable explanation. Homolysis of the same ylide **1** is considered to give the radical pair **2** (R=CH_3CH_2). A similar process appears to lead solely to radical pairs **2** (R=$PhCH_2$, Ph) in the case of ylides lacking β-hydrogen. The potentiality of this ylide mechanism in the reactions of ethers is discussed.

In contrast to nearly random insertion of methylene into various C–H bonds, the reaction of electrophilic alkoxycarbonylcarbene with ethers is characterized by two types of reactions, namely, the insertion reaction into the C–O bonds and the displacement reaction of one of the alkyl groups. There are several *a priori* mechanisms conceivable for these reactions. A widely quoted one is the electrophilic attack of the carbene at the lone pair of electrons to form an ylide intermediate which then undergoes the Stevens rearrangement and/or the Hoffmann type β-elimination of an olefin (Scheme 1). However, the experimental supports so far obtained for the mechanism are limited and not conclusive.[1)]

Recent mechanistic studies disclosed the mechanism of the Stevens rearrangement of ammonium and sulfonium ylides;[2)] it is not a simple ionic intramolecular process but a homolysis-recombination one. Accordingly radical pairs $\overline{R\cdot\ \cdot CH(OR')CO_2R''}$ might play an important role in the present case and the inserted and/or displaced products might be derived from recombination and/or disproportionation or hydrogen abstraction after diffusion (broken lines, Scheme 1).



Scheme 1.

In order to confirm these possibilities, we chose the CIDNP technique which is considered to provide direct verification of intermediacy of radical pairs for a particular product of interest. A minor preference was given to the ESR method by which we can prove the presence of radical species but can not obtain anything definite about the manifold reaction paths. Methyl diazoacetate was allowed to react with benzyl ethers in the heated NMR probe. Benzyl ethers were selected because of their simple NMR spectra and their high boiling points sufficient to generate the carbene thermally, in spite of the complexity of the reaction caused by the addition of the carbene to the aromatic ring. Standard product analyses by means of VPC were also made to determine the composition of the products.

Results

CIDNP Spectra. The 60 MHz proton NMR spectra obtained during the course of thermal decomposition of *ca.* 10 vol % solutions of methyl diazoacetate (MDA) in dibenzyl, benzyl phenyl, and benzyl ethyl ethers at 180 °C are shown in Figs. 1a, 1b, and 1c, respectively. A strong emissive signal (denoted by E) is seen in the δ 2.9—3.1 region in each ether solution. By comparison of the chemical shifts with those of authentic samples, these emission signals are assigned to the *C*-benzyl methylene protons (A_2 parts of approximately A_2X patterns) of insertion products, methyl α-benzyloxyhydrocinnamate (**3a**), α-phenoxyhydrocinnamate (**3b**), and α-ethoxyhydrocinnamate (**3c**). The large difference in intensity of the lower and higher field halves is due to the superposition of multiplet effect of E/A phase on net emission. The enhanced absorption singlet (denoted by A) at higher field is assigned to the methyl protons of toluene. In addition we see enhanced abosprtion at the shoulder on the high-field side of the benzylic methylene proton signals of the solvent (Fig. 1a) and the corresponding

Table 1. Product analyses of the reactions of methyl diazoacetate with dibenzyl, benzyl phenyl, and benzyl ethyl ethers by VPC

Types of products	Products	Yields (%) R=CH_2Ph	R=Ph	R=CH_2CH_3
Recombination	$PhCH_2CH(OR)CO_2CH_3$	6.9	2.7	9.4
	$RCH(OCH_2Ph)CO_2CH_3$	—	≪0.1	≪0.1
Escape	$PhCH_3$	2.8	0.6	2.1
	$ROCH_2CO_2CH_3$	3.1	0.2	0.9
Hoffmann-type	$PhCH_2OCH_2CO_2CH_3$	—	—	5.6
C-H insertion	$PhCH(OR)CH_2CO_2CH_3$	4.2	0.8	3.0
	$CH_3CH(OCH_2Ph)CH_2CO_2CH_3$	—	—	5.4
	$PhCH_2O(CH_2)_3CO_2CH_3$	—	—	1.6

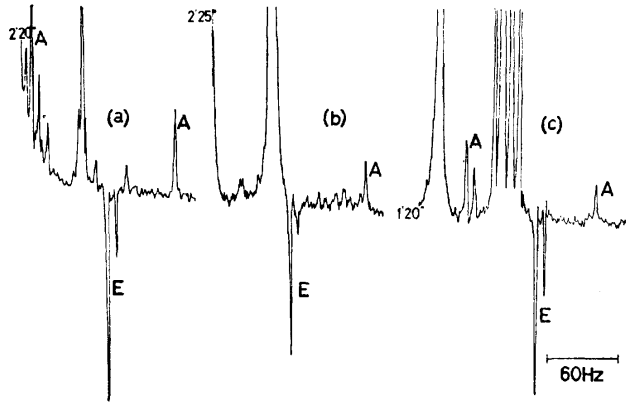


Fig. 1. The 60 MHz ^1H NMR spectra taken during thermal decomposition at 180 °C of *ca.* 10 vol% methyl diazoacetate in (a) dibenzyl ether, (b) benzyl ethyl ether, and (c) benzyl ethyl ether. The time when cw scanning of 600 Hz/200 s was started after insertion of the samples into the NMR probe is indicated.

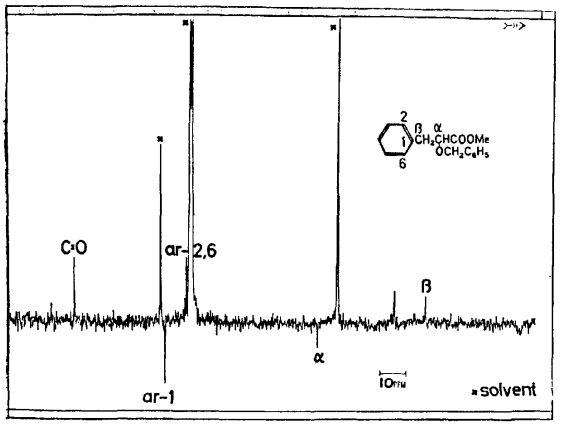

Fig. 2. The 20.1 MHz ^{13}C spectrum taken during the thermolysis at 170 °C of a 15 wt% solution of methyl diazoacetate in dibenzyl ether. The free induction decay signal was accumulated 1200 times on three portions of the batch solution.

enhanced absorption between the solvent signals (Fig. 1c). Their chemical shifts correspond to those of methine protons (X part of A_2X spins) of **3a** and **3c**. In the latter case, the lowest-field signal out of the triplet almost disappears as a result of the superposition of E/A multiplet effect. When the reactions are over,

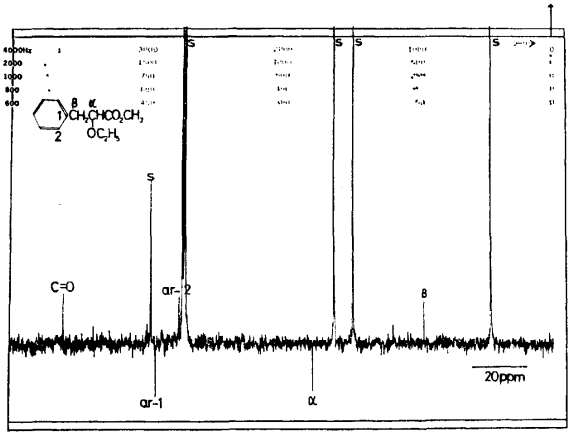

Fig. 3. The 20.1 MHz ^{13}C spectrum taken during the thermolysis at 170 °C of a 6 wt% solution of methyl diazoacetate in benzyl ethyl ether. The free induction decay signal was accumulated 2000 times on four portions of the batch solution. S denotes solvent signal.

all the polarized signals collapse and nothing can be seen except those of the solvents unless the H_1 level and sensitivity of a spectrometer are increased.

The pulse Fourier transform ^{13}C spectra (20.1 MHz) taken during the course of thermolysis of MDA in dibenzyl and benzyl ethyl ethers are reproduced in Figs. 2 and 3, respectively. The spectra are time-averaged for *ca.* 800 s from 500 s after the start of the reaction (see Experimental). The emission signals at 10.8 and 68.5 ppm (down field from the benzylic carbon signal of solvent dibenzyl ether) are assigned to the α and aromatic C-1 carbon atoms of **3a** (Fig. 2). The enhanced absorption signals at −33.2, 56.9, and, 99.1 ppm are found to be due to the β, aromatic C-2 (C-6), and carbonyl carbon atoms of **3a**. Relatively high intensity of polarized signals in spite of the low yield of **3a** (*vide infra*) as compared with those of solvent indicates a considerably large enhancement ($\sim 10^2$). The emission signals at 65.5 and 7.9 ppm (down field from the benzylic carbon signal of solvent benzyl ethyl ether) are due to aromatic C-1 and α-carbons of **3c** (Fig. 3). The enhanced absorption signals at 99.3, 56.8 and −33.1 ppm are assigned to the carbonyl, aromatic C-2 (C-6), and β-carbons, respectively, of **3c**.

Reaction Products. Table 1 shows the results of product analyses by VPC for the reaction of MDA in

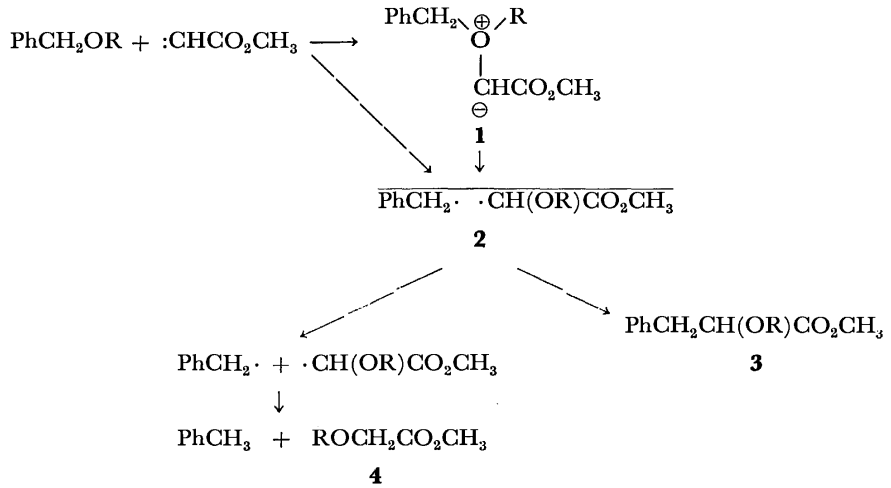


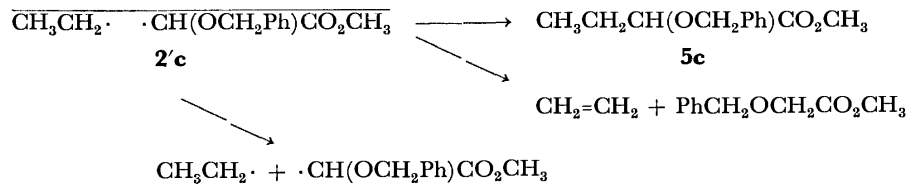
Scheme 2.

dibenzyl, benzyl phenyl, and benzyl ethyl ethers, respectively, at 170 °C for 1 h. The products are classified with respect to the type of reaction from which they were derived. All the possible C–H insertion products are formed in moderate yields.[3] The mass balance is not satisfactory since the main reaction of methoxycarbonylcarbene to give norcaradiene or cycloheptatriene derivatives *via* the addition to the aromatic rings is not taken into account. Peaks probably due to these products appear near or beyond the peaks due to the products analysed. Most values are accurate within 10%, some exceeding the limit because of the low yield and/or incomplete separation of the VPC peaks.

Discussion

All the spectral results are consistent with the formation of the singlet geminate radical pairs $\overline{PhCH_2\cdot\ \cdot CH(OR)CO_2CH_3}$ (**2**, **a**; R=$PhCH_2$, **b**; R=Ph, **c**; R=CH_3CH_2) followed by cage recombination to give the C–O insertion products **3**. The signs of net polarization (Γ_{ne}+ for absorption and−for emission) are given by $\Gamma_{ne}=\mu\varepsilon\Delta g A_i$ according to the first order treatment of Kaptein,[4] where μ, ε and A_i labels indicate the multiplicity of the precursor (−for singlet precursor), the type of the products (+for cage recombination) and the sign of hyperfine coupling of the nucleus i under consideration, respectively. Radicals $\cdot CH(OR)CO_2CH_3$ are assumed to have a *g*-value not far from 2.0036 of analgous radical $\cdot CH(OH)CO_2H$,[5] while the *g*-value of benzyl radical is 2.0025.[6] The methylene protons of insertion products **3**, for example, reside in the component of the pair which has a smaller *g*-value, their hyperfine coupling constant being negative (−16.3 gauss).[7] Their polarization is predicted to be emission when the insertion products are formed by the cage recombination (ε, +) of the singlet radical pair (μ, −). Similarly the polarization of the carbonyl carbons of **3** which are on the component with larger *g*-value of the radical pairs and possess negative hyperfine coupling constants[8] is considered to be an ehnanced absorption (Γ_{ne}=−−+−=+). The agreement between the theory and the observed signs of CIDNP is satisfactory (Table 2). There is no doubt about the intermediacy of radical pairs **2** for the formation of the insertion products.

The product distributions also support the above conclusion. Toluene and $ROCH_2CO_2CH_3$ (**4**) are formed in less than one fourth the amount of the insertion products **3** and are quite natural as escape products of radical pairs **2**. Their formation is difficult to justify by other routes. The observed enhanced absorption of the methyl protons of toluene is consistent with such a mode of formation (Table 2). Emission is expected for the methylene protons of $ROCH_2CO_2CH_3$ but can not be detected. The question is now where the radical pairs **2** come from.



Scheme 3.

Two alternatives are possible, namely, direct abstraction of an alkoxy group OR by the carbene or homolysis of the oxonium ylides **1** which in turn are formed by electrophilic attack of the carbene at the lone pair of electrons (Scheme 2). A clue to the proper selection can be found from Table 1.

Benzyl phenyl ether gives each type of products in fairly lower yields as compared with those of other ethers. The reduced reactivity corresponds to the lower nucleophilicity of the lone pair of electrons of the oxygen atom and to the higher reactivity at the aromatic rings of phenyl ethers. Actually the reactions of dichlorocarbene with phenoxides and anisoles at the ring give phenol aldehydes and tropone derivatives, respectively.[9] Products derived from insertion into the O–R bond (R≠CH_2Ph) are not detected.

The yields of insertion products **3a** and **3c** do not differ much in dibenzyl and benzyl ethyl ethers. However, methyl benzyloxyacetate is formed in the latter nearly twice as much as in the former (Table 1). Methyl benzyloxyacetate is produced in a greater amount as compared with methyl ethoxyacetate (**4c**) in benzyl ethyl ether even if the lower yield of the latter than that of toluene may partly be an artefact.[10] The results indicate that the ethyl group is more easily cleaved than benzyl. The apparent cleavage of the benzyl group is actually due to diffusion of the radical pairs **2** (*vide supra*). However, cage disproportionation of radical pair $\overline{CH_3CH_2\cdot \cdot CH(OCH_2Ph)CO_2CH_3}$ (**2'c**) and/or hydrogen abstraction by $\cdot CH(OCH_2Ph)CO_2CH_3$ after diffusion from **2'c** (Scheme 3) can not be the origin of cleavage of the ethyl group for the following reasons.

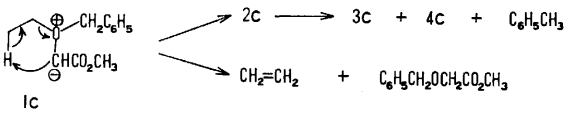
First of all, the cage recombination product methyl α-benzyloxybutyrate (**5c**) of the radical pair **2'c** is absent (*vide supra*). If **2'c** were formed, it could have recombined to give **5c** in a detectable amount as judged from the amount of the disproportionation and/or escape product, methyl benzyloxyacetate. The radical pair **2'c** is, therefore, considered not to be formed.

In order to find a rationale, let us have recourse to thermochemical data. From the standard heats of formation of radicals,[11] the dissociation energy of O–benzyl bond is estimated to be smaller by *ca.* 15 kcal/mol than that of the O–alkyl bond in benzyl alkyl ethers or benzyl dialkyl oxonium ions:

$$\begin{aligned} &D(PhCH_2\overset{\oplus}{O}R_2) - D(PhCH_2\overset{\oplus}{R}O\text{-}R) \\ &\approx D(PhCH_2\text{-}OR) - D(PhCH_2O\text{-}R) \\ &= \Delta H_f^\circ(PhCH_2\cdot) + \Delta H_f^\circ(RO\cdot) - \Delta H_f^\circ(PhCH_2O\cdot) \\ &\quad - \Delta H_f^\circ(R\cdot) \\ &\approx -15 \text{ kcal/mol} \end{aligned} \quad (1)$$

The cleavage of the O–benzyl bond to give **2c** is, therefore, considered to be easier than that of the O–alkyl bond to give **2'c**, whether they occur at the same time with the attack of the carbene at oxygen or in oxonium ylide **1c**.

Secondly no CIDNP of methyl benzyloxyacetate and ethylene expected to arise in the cage disproportionation of **2'c** is observed. Thus, formation of the ylide intermediate **1c** followed by the Hoffmann type β-elimination of ethylene by a non-radical path gives a reasonable explanation for the easy cleavage of the ethyl group. Homolysis of the same ylide is considered to give the radical pair **2c** (Scheme 4).



Scheme 4.

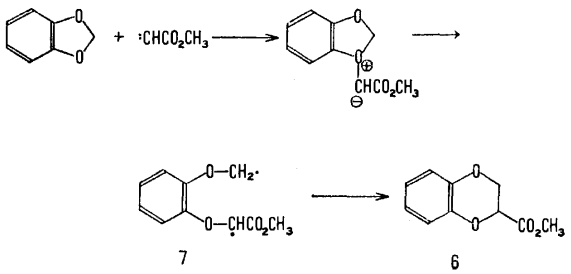
Similarly in dibenzyl and benzyl phenyl ethers the carbene attacks at oxygen to give ylide intermediates **1a** and **1b**. However, a possible path for their disappearance is restricted to the dissociation to the radical pairs **2a** and **2b**, respectively. Formation of methyl benzyloxyacetate in benzyl ethyl ether is only an additional pathway of dissipation of oxonium ylide which becomes available for **1c** because of the presence of hydrogen at β-carbon.

Path **1→3** is formally [1,2]sigmatropy to the anionic center. The process is forbidden as a concerted reaction with respect to orbital symmetry. Prior dissociation to radical pairs may be favored. The same rationale is widely used to explain the general radical nature of the Stevens rearrangement.[2] In contrast, path **1c** to methyl benzyloxyacetate *via* Hoffmann-type β-elimination of ethylene is formally [2,3]sigmatropy including anionic center. Six electrons are involved in a cyclic array of orbitals, the reaction being allowed as a concerted reaction. This may be the reason for the path being effectively competitive with path **1c→3c**.[12]

While chemical yields of the C–O insertion products are not necessarily high for the benzyl ethers, the insertion reaction is often of preparative value. The mechanistic information we obtained above together with the survey on the successful reaction types for insertion[1] reveal that there are three structural features governing the C–O insertion reaction.

Firstly it is small ring ethers which lead effectively to ring-enlarged products as a result of the C–O insertion of the carbene. Relief of the ring strain is considered to be responsible for the weak C–O bond. In contrast, displacement products and the corresponding olefins are almost exclusively formed in the case of acyclic ethers, especially when there are β-hydrogen

atoms available. In small ring ethers, the β-hydrogen atoms, if present, can not take part in conformation **1c** necessary for the displacement reaction. Lower steric demand for electrophiles of the oxygen atom in small ring ethers as compared to acyclic ethers should also be taken into account. There are many examples of higher reactivity or basicity of tetrahydrofuran when compared to diethyl ether.[13] Attempt to detect CIDNP for these high-yield insertion products of cyclic ethers has been unsuccessful. As an example the CH_2CH moiety of product **6**[14] appears in the δ 4.1—4.9 region as an approximate A_2X pattern, showing normal increase in its absorption signals during the course of formation in an NMR probe. The negative result does not necessarily rule out the homolysis-recombination mechanism of the intermediate oxonium ylide. Singlet 1,6-biradicals are formed instead of radical pairs. Exchange coupling between the unpaired electrons in **7** is estimated to be too large to allow the appearance of CIDNP.[15] On the other hand, internal recombination to give the C–O insertion product is expected to be efficient, resulting in a high yield of **6**.



7 6

Secondly, a high yield of C–O insertion is found in allyl ethers. The C–O insertion is accompanied by allyl inversion as shown in the following.[1c]

8

The transition state is aromatic with 6π electrons in a cyclic array of five atomic orbitals; the reaction is rationalized to be efficient.

Thirdly, phenyl ethers are disfavored with respect to reactivity to give insertion products. In addition to the enhanced reactivity at the aromatic ring and the β-elimination of the alkyl chain, if structurally possible, displacement of the methyl group takes place indicating the inertness of the C(aryl)–O bond towards carbene insertion.[16]

$$PhOCH_3 + :CHCO_2R \longrightarrow PhOCH_2CO_2R$$

Experimental

General Procedure for Measuring CIDNP Spectra. ^1H NMR spectra were measured on a Hitachi R-20B Spectrometer (60 MHz). Cw sweep of 200 or 400 s/600 Hz was employed. The pulse Fourier transform ^{13}C NMR spectra were obtained on a Varian CFT-20 spectrometer (20.1 MHz). The free induction decay signals, obtained by application of a short radio frequency pulse of 8 μs width, acquisition time of 1.023 s and 8K data points over the 4000 Hz spectral width, were accumulated a few thousand times on several portions of a batch solution (400—500 times for each portion). Pulse delay of 1 s was taken in the case of dibenzyl ether. As an internal lock, a capillary of dimethyl sulfoxide-d_6 was fixed concentrically at the center of a sample tube of 8 mm o.d. The reaction was started by introducing the sample tube containing *ca.* 5—15 wt or vol% solution of MDA in ethers to the NMR probe preheated at 170—180 °C. Under these conditions the half-life of MDA is less than 5 min. The assignment of the signals was made by comparison of their chemical shifts with those of the authentic samples under the experimental conditions.

VPC Analyses. VPC analyses were carried out on a Shimadzu GC-4A instrument equipped with an FID detector under nitrogen flow rate of 60 ml/min. A 3 m glass column of 4 mm i.d. packed with 10% polyethylene glycol 20 M on 60/80 mesh Uniport B and a 1.5 m glass column of the same diameter packed with 20% diethylene glycol stearate on 60/80 mesh Uniport B were used. The samples for VPC analyses were prepared separately from those for NMR study by heating the sample solutions in glass ampoules in an oil bath at 170 °C for a longer period (1 h) to ensure the completion of the reactions and to avoid the loss of low boiling materials. Molar ratios of dibenzyl, benzyl phenyl, and benzyl ethyl ethers to MDA were 12.9, 12.8, and 13.3, respectively. Identification of VPC components was carried out by comparison of the retention time with that of authentic samples. All the quantitative analyses were carried out by using an internal standard, bromobenzene in most cases. The C–H insertion product was not sufficiently separated from other components of unknown origin to determine the yield accurately, and the same detector response as for the corresponding C–O insertion product was assumed.

Starting Materials. Commercial dibenzyl and benzyl phenyl ethers were purified by distillation. Benzyl ethyl ether was prepared from benzyl chloride and ethanol by the standard method to give clear liquid; bp 183 °C (lit,[17] 189 °C). MDA was obtained by the same procedure as for the corresponding ethyl ester.[18]

Authentic Samples for Identification of Reaction Products. Methyl Benzyloxy-, Phenoxy- and Ethoxyacetates. Free acids were prepared according to literature[19-21] and esterified with methanol and sulphuric acid. Their boiling points are 112 °C/3 mmHg, 130 °C/5 mmHg (lit,[22] 245 °C) and 57—58 °C/29 mmHg (lit,[23] 148 °C/734 mmHg), respectively.

Most insertion products into the C–O or C–H bonds were prepared by the coupling of appropriate hydroxy and halogen compounds promoted by silver oxide.[24] The general procedure is as follows. To a water cooled mixture of 50 mmol of a hydroxy compound and 150 mmol of a halide was added portionwise 75 mmol of silver oxide under vigorous stirring. In some cases exothermic reactions took place. The mixture was gradually heated up to *ca.* 100 °C and maintained at the temperature for 6 h under stirring. Its color turned grey from black due to the formation of silver halide. With the aid of diethyl ether the solid was filtered off and the concentrated filtrate was chromatographed on silica gel with hexane–ether as an eluent. Further purification was performed by preparative TLC. 10—80% Yields were obtained based on hydroxy compounds. Reactants, bp's, NMR spectra, and the results of elemental analyses are summarized in Table 3.

Commercially unavailable reactants were prepared as follows. α-Hydroxyhydrocinnamic acid was prepared from phenylacetaldehyde[25] and esterified with methanol and

$CH_3CH(OCH_2Ph)CH_2CO_2CH_3$	$CH_3CH(OH)CH_2CO_2CH_3$	$PhCH_2Br$	106/4	1.21(d, 3H), 2.16—2.78(m, 2H), 3.59 (s, 3H), 3.91(m, 1H), 4.45(s, 2H), 7.21(s, 5H)	69.04	7.79		
$CH_3CH_2CH(OCH_2Ph)CO_2CH_3$	$CH_3CH_2CH(OH)CO_2CH_3$	$PhCH_2Br$	106/5	0.8—1.1(m, 3H), 1.4—2.1(m, 2H), 3.67(s, 3H), 3.77(t, 1H), 4.46(ABq, 2H, J=12 Hz), 7.24(s, 5H)	69.10	7.69		

sulphuric acid to give methyl α-hydroxyhydrocinnamate, an oil, bp 99 °C/3 mmHg. Methyl β-hydroxyhydrocinnamate was obtained by the same procedure as for the corresponding ethyl ester.[26] Bromination with phosphorous tribromide gave methyl β-bromohydrocinnamate, an oil, bp 115 °C/4 mmHg. Reduction of methyl acetoacetate with sodium borohydride gave methyl β-hydroxybutyrate, an oil, bp 82 °C/26 mmHg. Propionaldehyde cyanohydrin prepared according to the method of Letch and Linstead[27] was hydrolyzed with concd hydrochloric acid. Esterification of the resulting acid with methanol and sulphuric acid gave methyl α-hydroxyburyrate, an oil, bp 58 °C/18 mmHg.

Methyl α-Phenoxyhydrocinnamate. To a stirred suspension of 50 mmol sodium phenoxide in 70 ml of benzene was added dropwise a solution of 50 mmol of methyl α-bromohydrocinnamate (an oil obtained by esterification of the free acid,[28] bp 100 °C/2.5 mmHg) in benzene, and the mixture was refluxed for 4 h. The cooled mixture was treated as usual and purified by column chromatography on silica gel and preparative TLC to give an oil, bp 144 °C/3 mmHg. NMR(CCl_4, δ); 3.15(d, 2H), 3.57(s, 3H), 4.41(t, 1H), *ca.* 6.2—6.7 (m, 5H), 7.18(s, 5H). Anal. Found: C, 75.63; H, 6.60. Calcd for $C_{17}H_{18}O_3$; C, 75.53; H, 6.71%.

Methyl γ-Benzyloxybutyrate. γ-Benzyloxybutyric acid was prepared by a procedure similar to that of Reppe *et al.*.[29] Esterification with diazomethane gave a clear oil, bp 112 °C/5 mmHg. NMR(CCl_4, δ): *ca.* 1.6—2.6(m, 4H), 3.44 (t, 2H, J=6 Hz), 3.58(s, 3H), 4.42(s, 2H), 7.22(s, 5H). Treatment of the ester with ammonia in a methanol gave the corresponding amide, mp 81—82 °C (benzene-cyclohexane). Anal. Found: C, 68.52; H, 7.97; N, 7.39%. Calcd for $C_{11}H_{15}NO_2$: C, 68.37; H, 7.82; N, 7.25%.

3) The C–H insertion products do not show any CIDNP. This is in harmony with the widely accepted view that singlet carbenes insert into the C–H bonds in one step.[30] In the contrast, the insertion of triplet carbenes into the C–H bonds is considered to occur by abstraction-recombination mechanism[30] and CIDNP has been observed.[31]
